Small round viruses include Norwalk virus, calicivirus, Snow Mountain agent, and SRSV. These viruses are a major cause of shellfish-associated gastroenteritis.^{*} Caliciviruses are small, single-stranded RNA and have been responsible for a number of oyster-related gastroenteritis outbreaks in Louisiana.^[72] ^[77] Norwalk virus has been located both in and outside the shellfish alimentary tract and is poorly deputed using conditions favorable for *E. coli* deputation. Reverse transcription PCR (RT-PCR) assay can easily detect Norwalk virus in contaminated water, shellfish, and stool from infected people.^[233] ^[353] The virus may be excreted in the feces of food handlers and harvesters for 48 hours after recovery from the infection.^[43] Symptoms including nausea, vomiting, fever, abdominal cramps, and nonbloody diarrhea appear 24 to 48 hours after ingesting contaminated shellfish and resolve over 1 to 2 days. Antibodies to Norwalk virus have been measured in serum of patients with gastroenteritis, and electron microscopy or RT-PCR can detect virus in stool.^[233] Treatment is supportive, and complications are rare.

Vibrio Poisoning and Septicemia

Over the last few decades, naturally occurring bacteria are becoming a more important cause of shellfish illness, particularly the bacteria belonging to the family Vibrionaceae. *Vibrio* organisms can cause gastroenteric disease and soft tissue infections, which can lead to bacteremia and death, particularly in immunocompromised hosts, after the consumption of raw shellfish. Between 1988 and 1996, 422 infections from *Vibrio vulnificus* were reported to the CDC; 61% of patients with primary septicemia died.^[363]

Vibrio species are the most potentially virulent halophilic organisms that flourish in the marine environment. In general, they are not associated with fecal contamination, hence surveillance methods as mentioned above for bacteria and viruses do not correlate with the presence of *Vibrio*. *Vibrio* species proliferate in warmer water; infections seem to cluster during the summer months, which may be related to increased numbers of

people at the seashore.^[280] *Vibrio* species are mesophilic organisms and grow best at temperatures of 24° to 40° C (75.2° to 104° F), with essentially no growth below 8° to 10° C (46.4° to 50° F).^[57] *Vibrio* species can grow in brackish waters and require less sodium for maximal growth than do other more fastidious marine organisms, a factor that allows explosive reproduction in the 0.9% saline environment of the human body. *V. parahaemolyticus* has also been identified in freshwater habitats.^[20]

Gastrointestinal illness has been associated with *V. cholerae* O group 1, non-O1, *V. parahaemolyticus*, *V. fluvialis*, *V. mimicus*, *V. hollisae*, *V. furnissii*, *V. alginolyticus*, and *V. vulnificus*.^{*} Septicemia, with or without an obvious source, has been attributed to infections with *V. cholerae* non-O1, *V. parahaemolyticus*, *V. alginolyticus*, *V. vulnificus*, *V. hollisae*, and *V. metschnikovi*.[†]

Whenever a *Vibrio* species is suspected, the microbiology laboratory must be alerted to use an appropriate selective culture medium for stool cultures, such as thiosulfate-citrate-bile salts-sucrose (TCBS) agar or Monsur taurocholate-tellurite-gelatin agar.^{[262] [281]} Pathogenic *Vibrio* species generally grow on MacConkey agar. The stool specimen should be collected if possible within the first 24 hours of illness and before the administration of antibiotics; specimens should not be allowed to dry. The specimen may be transported in the semisolid transport medium of Cary and Blair; buffered glycerol-saline is not satisfactory because glycerol is toxic to vibrios. Tellurite-taurocholate-peptone broth is adequate. All *Vibrio* species grow in routine blood culture mediums and on nonselective mediums, such as blood agar.

Key characteristics that aid in the separation of *Vibrio* species from other medically significant bacteria (*Enterobacteriaceae*, *Pseudomonas*, *Aeromonas*, *Plesiomonas*) are the production of oxidase, fermentative metabolism, requirement of sodium chloride for growth, and susceptibility to the O/129 vibriostatic compound.^[204] Species that cannot be identified in the hospital microbiology laboratory may be referred to a state laboratory or the CDC. Multiple PCR methods are now used to detect various strains of *Vibrio* species in oyster tissue and water samples that are sensitive and reliable.^{[34] [256] [436]}

Vibrio Vulnificus.

Vibrio vulnificus is a free-living, motile halophilic gram-negative bacillus that causes septicemia, gastroenteritis, and wound infections that occur 12 hours to 7 days after the ingestion of contaminated raw or undercooked seafood, particularly raw oysters. Persons with compromised immune systems and liver disease are at a significantly high risk for fatal septicemia. *V. vulnificus* has a rapid onset and the highest mortality rate of any of the *Vibrio* species. *V. vulnificus* is naturally present in marine environments; it has a worldwide distribution and is found throughout the United States.^{[336] [363]}

The growth of *V. vulnificus* is favored in waters with an intermediate salinity of 5 to 25 ppt. The optimal temperature for growth (doubling time 15 minutes) for *V. vulnificus* is 35° C (95° F). Below 10° C (50° F), *V. vulnificus* enters a nonculturable state and is viable but ceases to replicate.^[305] The number of *V. vulnificus* found in the marine environment and in shellfish increases

*References [\[72\]](#) [\[77\]](#) [\[116\]](#) [\[233\]](#) [\[387\]](#) [\[393\]](#) .

†References [\[1\]](#) [\[45\]](#) [\[79\]](#) [\[163\]](#) [\[206\]](#) [\[227\]](#) [\[228\]](#) [\[236\]](#) [\[261\]](#) [\[363\]](#) .

and peaks during the summer months, as does the incidence of *V. vulnificus* infections.[\[288\]](#)

V. vulnificus may appear as one of two morphotypes; opaque and virulent, or translucent and less virulent. The opacity of the virulent morphotype is due to an acidic mucopolysaccharide capsule (opaque colony) that increases the resistance of the organism against bactericidal activity of human serum and phagocytosis and thus renders the organism more virulent. At extremely low frequency, some strains can shift between unencapsulated and capsulated serotypes.[\[469\]](#) The encapsulated isolates are sensitive to iron. The organism is unable to use transferrin-bound iron for growth. In patients with iron overload and transferrin saturation greater than 75%, free iron is available for use. Additionally, virulent isolates can use iron in hemoglobin and hemoglobin-haptoglobin complexes.[\[54\]](#) [\[56\]](#) [\[472\]](#) *V. vulnificus* can bind specifically to human intestinal cells and quickly induce cytotoxic effects.[\[235\]](#) In vivo studies show that 4 hours after inoculation in the duodenum, the organism is found in the systemic circulation via bacterial translocation.[\[191\]](#) The severity of *V. vulnificus* infections is related to both bacterial characteristics as described above and host factors. In patients with liver disease, chronic cirrhosis, and alcoholism, portal hypertension allows shunting of the organism around the liver. These patients also have reduced phagocytic acidity, chemotaxis, opsonization, and complement levels, thus promoting the virulence of *V. vulnificus*.[\[325\]](#) Persons with high serum iron levels (from chronic cirrhosis, hepatitis, thalassemia major, or hemochromatosis) are at increased risk for infection as described above.[\[56\]](#) [\[236\]](#) [\[441\]](#) Any individual with impaired immunity (e.g., malignancy, human immunodeficiency virus [HIV] infection, diabetes, long-term corticosteroids) is at greater risk for fulminant bacteremia.[\[398\]](#) Based on the prevalence of predisposing diseases in the general population, 3.8% of the general population is at risk of having *V. vulnificus* septicemia if they contact this organism.[\[104\]](#)

CLINICAL PRESENTATION.

V. vulnificus infection occurs as two clinical syndromes: primary septicemia and wound infection. The syndrome consists of flulike malaise, fever, vomiting, diarrhea, chills, hypotension, and early skin vesiculation that evolves into necrotizing dermatitis, with vasculitis and myositis (see [Chapter 60](#) for discussion of *Vibrio* wound infections). Primary septicemia occurs when *V. vulnificus* is acquired through the gastrointestinal tract. Blood cultures are positive for the organism in 97% of patients. Septic shock, disseminated intravascular coagulation, and death may occur.[\[441\]](#) The mortality of patients with primary septicemia is 56% and increases to 92% when septic shock occurs.[\[189\]](#)

Gastroenteritis was previously thought to exist as an isolated entity in 10% of cases. However, it is more likely that other enteric pathogens are the causal agent and *V.*

vulnificus illness has been erroneously attributed to the asymptotically carried organism.^[203]

V. vulnificus is also implicated in other infectious presentations, including meningitis, spontaneous bacterial peritonitis, corneal ulcers, epiglottitis, osteomyelitis, rhabdomyolysis, endocarditis, and infections of the testes and spleen.* *V. vulnificus* endometritis has been reported after an episode of intercourse in the water of Galveston Bay, Texas.^[418]

TREATMENT.

Early recognition of *V. vulnificus* infection is essential for effective treatment. Blood and wound cultures should precede immediate and aggressive antibiotic and supportive treatment. Current recommendations include doxycycline (100 mg IV q12h) and ceftazidime (2 g IV q8h) or ciprofloxacin 400 mg IV q12h).^[152] Other antibiotics that have been suggested include imipenem/cilastatin, trimethoprim/sulfamethoxazole, carbenicillin, tobramycin, gentamicin, and many third-generation cephalosporins. Supportive care includes crystalloid and pressor agents for hypotension.

Vibrio Parahaemolyticus.

Vibrio parahaemolyticus is a halophilic gram-negative rod that can cause gastroenteritis when consumed in raw or partially cooked seafood and has been reported in temperate, subtropical and tropical coastal regions.^{[32] [73] [75] [182] [271]} The organisms are found in marine and estuarine waters along the entire coastline of the United States. The concentration of *V. parahaemolyticus* in seawater increases with rising water temperature and corresponds with an increased incidence of clinical disease in warm summer months when the organism is commonly found in zooplankton.^[189] The optimal growth temperature of *V. parahaemolyticus* is 35° to 37° C (95° to 98.6° F). *V. parahaemolyticus* has also been isolated from colder waters. The largest reported outbreak in North America of culture confirmed *V. parahaemolyticus* infections occurred during July-August 1997 in the Pacific Northwest; 209 persons became ill and one person died after eating raw or undercooked oysters.^[73] *V. parahaemolyticus* has been recovered at frequencies up to 25% in frozen peeled shrimp.^[455]

Ingestion of raw or partially cooked *V. parahaemolyticus*-contaminated shrimp, oysters, crab, or fish is followed in 6 to 76 hours by explosive diarrhea, nausea, vomiting, headache, abdominal pain, fever, chills, and prostration. In immunocompetent persons, *V. parahaemolyticus* causes mild to moderate gastroenteritis with

*References ^[111] ^[130] ^[221] ^[276] ^[424] ^[434] ^[441] ^[456] .

a mean duration of illness of 3 days. Serious illness and death can occur in persons with underlying disease (preexisting liver disease, diabetes, iron overload states, or

compromised immune system).^[227] The stools may contain blood and classically demonstrate leukocytes on methylene blue staining. The syndrome generally resolves spontaneously in 24 to 72 hours but may be of a severity sufficient to cause significant fluid and electrolyte depletion. Stool cultures should be obtained before the initiation of antibiotic therapy. Panophthalmitis requiring enucleation occurred in a man who suffered a corneal laceration.^[399] A course of oral ciprofloxacin, trimethoprim/sulfamethoxazole, or tetracycline may shorten the course of severe gastroenteritis.

Vibrio Mimicus.

Vibrio mimicus is a motile, non-halophilic, gram-negative, oxidase-positive rod with a single flagellum. It can be distinguished from *V. cholerae* by its inability to ferment sucrose, inability to metabolize acetylmethyl carbonyl, sensitivity to polymyxin, and negative lipase test.^[102] Multiple toxins are produced by *V. mimicus*, including cholera-like toxin, enterotoxin, and hemolysin.^{[326] [367] [436]} *V. mimicus* causes a syndrome of gastroenteritis (diarrhea, nausea, vomiting, abdominal cramps, fever, and headache) following the ingestion of raw oysters, crawfish, crab, or shrimp. *V. mimicus* was identified by PCR in 11 individuals with gastroenteritis from eating raw turtle eggs.^[62] Nonfatal bacteremia resulting from *V. mimicus* has been reported.^[228] The median incubation period is 24 hours, with delayed diarrhea noted up to 3 days after ingestion of contaminated seafood. Isolates are sensitive to tetracycline, ciprofloxacin, and norfloxacin.^[280]

Vibrio Alginolyticus.

Vibrio alginolyticus can cause gastroenteritis in immunocompetent individuals and bacteremia in immunosuppressed patients.^{[261] [330]} More commonly, it is implicated in soft tissue infections (such as those caused by coral cuts or surfing scrapes), sinusitis, and otitis media and externa.^{[146] [261] [331] [425]}

Vibrio Cholerae.

In developing countries, cholera caused by toxigenic *V. cholerae* is a major public health problem. The last several cholera pandemics were caused by the consumption of fecal contaminated water.^[459] *V. cholerae* is commonly linked to ingestion of raw or inadequately cooked mollusks and crustaceans and is responsible for the third highest number of shellfish-related illnesses behind other noncholera *Vibrio* species and Norwalk virus.^{[213] [452]} Toxigenic O1 *V. cholerae* infections are associated with a secretory, profuse watery diarrhea, nausea, and vomiting. Since the stool is virtually isotonic, large amounts of fluid and electrolytes are lost, which leads to rapid dehydration, shock, acidosis, and renal failure. The treatment consists of aggressive fluid replacement, intravenous if available, combined with oral rehydration. In a recent outbreak in Italy, all strains were resistant to tetracycline but the patients responded to ciprofloxacin.^[264] Untreated, the disease remits in 3 to 8 days.

Nontoxigenic, non-O1 *V. cholerae* strains cause gastroenteritis and septicemia.^[200] Self-limited (24 to 48 hours) nausea, vomiting, abdominal cramping, and invasive

diarrhea with blood and fecal leukocytes are typical. Spontaneous non-01 *V. cholerae* bacteremia and peritonitis have been reported in patients with cirrhosis after eating raw oysters.^[255] ^[319] ^[338] Meningitis and death have also been associated with non-01 *V. cholerae*.^[79] ^[227]

Other Vibrios.

Vibrio metschnikovii has caused bacteremia in a patient with cholecystitis; the authors postulated that it may have been associated with long-term carriage after seafood ingestion.^[206] *Vibrio cincinnatiensis* has caused meningitis; a relationship to foreign travel, seawater exposure, or seafood ingestion has not been established.^[45] *Vibrio fluvialis*, previously designated as enteric group EF-6 or group F, is common in the marine environment. It causes diarrheal disease associated with vomiting, abdominal pain, dehydration, and fever.^[400] Fatal gastroenteritis has been reported.^[228] It can be mistaken easily in the microbiology laboratory for *Aeromonas hydrophila*, from which it can be distinguished by growth in 6% to 7% sodium chloride. *Vibrio hollisae* and *V. furnissii* have both been linked to gastroenteritis after seafood ingestion and *V. hollisae* has been associated with septicemia.^[1] ^[163]

PREVENTION.

Persons who are immunosuppressed or chronically ill, particularly with hepatic insufficiency, should not eat raw or partially cooked shellfish. All seafood should be cooked thoroughly, protected from cross-contamination after cooking, and eaten promptly or stored at temperatures above 60° C (140° F) or below 4° C (39.2° F) to prevent multiplication of *Vibrio* species.

The FDA has prepared a series of four booklets for subpopulations of persons with altered immunity who may be susceptible to *Vibrio* infections. One set of booklets on seafood safety for high-risk individuals is available to health professionals free of charge from: FDA, Seafood Brochures, HFI-40, 5600 Fishers Lane, Rockville, MD 20857.^[136]

Botulism

Botulism is a paralytic disease caused by the potent natural toxin of *Clostridium botulinum*. Seven toxins (A to G) have been identified, but only A, B, E, F, and G cause human illness.^[383] Seafood-related botulism can be caused by raw, parboiled, salt-cured, or fermented meats from marine mammals (seal, walrus, whale) or fish products (particularly salmon and salmon roe).^[185] Toxin type E spores are found in mud and sediment in northern coastal areas and inland

lakes, accounting for the prevalence of type E toxin in fish-borne botulism (although types A and B may also be involved). Improperly preserved (smoked, dried, or canned)

foods are at high risk for *C. botulinum* toxin proliferation. The technique of "hanging" meat for decomposition (flavor and texture improvement) supports growth of the nonproteolytic, psychotolerant forms of *C. botulinum*, which may grow at temperatures as low as 4° C (39.2° F).^[185]

In the last four decades in the United States, over 10% of outbreaks of food-borne botulism have been related to the consumption of fish. Using quantitative PCR analysis, the prevalence of *C. botulinum* type E gene was 10% to 40% in raw fish samples and 4% to 14% in fish roe samples in Finland.^[196] In 1991, 91 patients were hospitalized in Cairo with botulism intoxication associated with eating faseikh (uneviscerated salted mullet fish); *C. botulinum* type E was isolated.^[444]

C. botulinum spores germinate in an environment of appropriate pH (greater than 4.6), warm temperature (higher than 10° C [50° F]), sufficient moisture, and an anaerobic environment. The toxins are proteins of approximate molecular weight 150,000 daltons and are absorbed in the proximal gastrointestinal tract.

Clinical Presentation.

The toxin affects the presynaptic cholinergic neuromuscular junction, where it blocks the release of acetylcholine and causes flaccid paralysis.^[29] Signs and symptoms develop within 12 to 36 hours of ingestion and include nausea, vomiting, abdominal pain, and diarrhea, followed by dry mouth, dysphonia (hoarseness), difficulty swallowing, facial weakness, ptosis, nonreactive or sluggishly reactive pupils (third cranial nerve), mydriasis, blurred or double vision (sixth cranial nerve), descending symmetric muscular weakness leading to paralysis, and bulbar and respiratory paralysis. With adequate ventilatory support, mentation frequently remains normal. Death occurs in 10% to 50% of cases, depending on the availability of antitoxin.

If botulism is suspected, a careful food history should be obtained and the suspected food items collected. Laboratory confirmation of botulism is achieved when botulinum toxin or viable *C. botulinum* is detected in the food, toxin is demonstrated in the victim's serum or stool, or the organism is cultured from the stool. Toxin types are distinguished using type-specific antitoxin.^[29] To determine the clinical need for botulism antitoxin, a number of tests may be helpful. Electromyography should be performed using repetitive stimulation at 40 Hz or greater; a positive test shows diminished amplitude of the muscle action potential with a single supramaximal stimulus, and facilitation of action potentials using paired or repetitive stimuli.^[29] Cerebrospinal fluid may be examined for white blood cells and protein (to rule out infectious etiologies), and edrophonium (Tensilon) challenge test may be performed to rule out myasthenia gravis. Vital capacity should be monitored as a sensitive indicator of clinical deterioration.

Treatment.

Ventilatory support should be provided at the first sign of respiratory inadequacy. Cathartics are recommended to eliminate residual toxin in the gastrointestinal tract. Equine trivalent antitoxin A, B, E should be administered as soon as possible to any person with symptoms, before irreversible neural dysfunction.^[401] Each 8-ml vial of

trivalent antitoxin contains 7500 IU type A, 5500 IU type B, and 8500 IU type E antitoxin.^[29] A physician who seeks antitoxin should first contact the state health department. If this is unsatisfactory, the CDC may be telephoned at 404-329-2888 (24 hours). The trivalent antitoxin is administered as an initial dose of 16 ml (two vials) every 2 to 4 hours for 3 to 5 doses or longer if symptoms persist.^[29] Before administration the victim should be skin tested for hypersensitivity to horse serum. If horse serum test material is not available, 0.1 ml of a 1:10 dilution of antitoxin in saline may be used. The antitoxin should not be stored at a temperature greater than 37° C (98.6° F).

An adjunct to therapy may be administration of guanidine, which increases the release of acetylcholine from nerve endings. The dosage is 15 to 50 mg/kg/day orally in four divided doses.

Prevention.

Prophylaxis with antitoxin is not currently recommended, nor is general pentavalent (A to E) toxoid immunization.^[9] The best prevention is public health education with respect to food preparation and avoidance of improperly stored food products. Since the spores are frequently detected in fish intestines, it is important to clean fish properly and to avoid consumption of the viscera, even in salt-cured products. To eliminate spores in food, heat or irradiation may be used. Types A and B may survive boiling for several hours (particularly at the lower temperatures associated with higher altitude) and generally require pressure heating at 120° C (248° F) for 30 minutes; type E spores are killed at 80° C (176° F) after 30 minutes. Preformed toxin is inactivated after heating for 20 minutes at 80° C or 10 minutes at 90° C (194° F). Germination is inhibited by acidification, refrigeration, freezing, drying, or the addition of salt, sugar, or sodium nitrate; however, heating remains the most reliable technique.^[29]

PARASITES IN SEAFOOD

Most parasites of marine animals are of little public health concern to humans. However, there are 50 species of helminths worldwide from fishes, crabs, crayfishes, and bivalves that can cause human infections. With the increasing consumption of raw seafood such as sushi and sashimi, the number of documented

1314

human infections is increasing. The overall risk of human infection is small.

Fish Tapeworm

In the United States the consumption of raw fish (sushi) is increasingly popular, which has led to more frequent recognition of infestation with the fish tapeworm, *Diphyllobothrium latum*. Salmon appears to be a popular culprit.^{[97] [121] [195] [420]} Diphyllobothriasis is also reported from eating raw flesh of redlip mullet.^[86] The fish tapeworm has a complex life cycle, in which a gravid egg released into freshwater releases a ciliated coracidium, which is eaten by a crustacean intermediate host. The coracidium penetrates the intestinal wall of the crustacean and then develops into a proceroid larva. A fish eats the small crustacean, and the proceroid larva migrates through the intestinal wall of the fish into fish muscle, where it changes into a plerocercoid larva. It is this final larval stage that is ingested by a human and that subsequently attaches to the intestine, where it grows into a mature tapeworm.

Classic symptoms include subacute abdominal pain, nausea, vomiting, diarrhea, and weight loss. Proglottids may be passed in the stool. Chronic *D. latum* infestation may induce megaloblastic anemia, as the tapeworm splits the vitamin B₁₂-intrinsic factor complex and prevents absorption of the vitamin.^[161] The diagnosis can be made by examination of the stool for typical proglottids or operculate egg forms, which measure 60 to 75 μm in length. Proper identification of the eggs is important in the differentiation from the ova of trematodes endemic in Southeast Asia, such as *Paragonimus westermani*, which may be carried by refugees to the United States.^[114] For documented *D. latum* infestation, praziquantel 10 mg/kg in one dose for adults or children is the recommended treatment.^{[154] [303]} Magnesium sulfate as a purgative has been used to help expel the worm.^[420] Niclosamide can also be used for treatment.^[314] Because a worm may not be identifiable if expulsion is delayed or follows a purge, stool analysis should be repeated at 3 months to confirm successful therapy.

Fish tapeworm infection can be avoided by cooking fish until the parts for consumption reach a temperature of at least 56° C (133° F) for 5 minutes or freezing the fish to -18° C (0° F) for 24 hours or -10° C (14° F) for 72 hours.^[454]

Trematodes

Humans can acquire an intestinal infection from the trematode *Nanophyetus salmincola*, which infests salmonid fishes, such as steelhead trout or salmon.^[120] Canine infection with this fluke is a well-known phenomenon in the Pacific Northwest of the United States.

Humans ingest the flesh of fish infested with the metacercariae, which excyst in the host and attach to the upper small bowel. The worms release eggs that are detected in the stool approximately 1 week after ingestion of infected fish.

Symptoms of nanophyetiasis include diarrhea, peripheral blood eosinophilia, abdominal discomfort, bloating, nausea and vomiting, weight loss, and fatigue. Although symptoms may resolve spontaneously over a period of months, antihelminthic treatment is recommended. Praziquantel 25 mg/kg orally 3 times a day for 1 day is the first-line treatment.^[2] Other regimens have included bithionol 50 mg/kg orally for two doses, niclosamide 2 g orally for three doses, or mebendazole 100 mg orally bid for 3 days. A similar syndrome has been caused by intestinal infection with *Heterophyes heterophyes*, which was successfully treated with praziquantel.^[2]

Numerous other trematode infections are the cause of enormous morbidity worldwide as the liver and intestinal flukes cause distinct medical syndromes. For instance, in Southeast Asia, opisthorchosis caused by the liver fluke *Opisthorchis viverrini* is quite serious. The cercariae are ubiquitous in cyprinid fish.^[150] Clonorchiasis occurs when humans eat raw or undercooked freshwater fish harboring the metacercariae of *Clonorchis sinensis*.^[358]

Anisakiasis

Approximately 5000 restaurants serve sushi in the United States. Many of these do so without specific knowledge of the various parasites that can infest their fare. For instance, many serve raw salmon, squid, shrimp, and mackerel.

The first report of acute gastric anisakiasis caused by penetration of the *Anisakis* larvae through the gastric mucosa was by Van Thiel in 1960.^[433] It is a rare problem in the United States but increasingly noted in Japan, where raw fish is more commonly eaten.^[225] ^[394] In a Japanese series the fish consumed included predominantly mackerel; less common perpetrators included horse mackerel, bream, squid, sardines, and bonito.^[394] In the United States, anisakine nematodes are present in many commercial fish intended for raw or semiraw consumption, such as Pacific herring (thus "herring worm disease"), sablefish, Pacific cod (thus "codworm disease"), arrowtooth flounder, petrale sole, coho salmon, Pacific ocean perch, silvergray rockfish, yellowtail rockfish,

and bocaccio. [295] In rare cases the anisakine worm can be present in tuna or yellowtail. The preservation of marine mammals along the West Coast of the United States has been linked to greater worm burdens in fishes associated with these mammals, such as Pacific rockfish, red snapper, and salmon. [274]

Life and Habits.

Anisakine nematodes, members of the order Ascarida (suborder Ascaridae), are found in great numbers in the viscera and muscles of fish. [291]

1315

There are 30 genera in the family Anisakidae, including *Anisakis* and *Pseudoterranova* (or *Phocanema*). Adult worms infest the stomachs of marine mammals, burrowing in clusters into the mucosal surface. Eggs passed in the stool embryonate and hatch in seawater to produce second-stage larvae, which are ingested by crustaceans, which are in turn eaten by squid or fish. In these hosts the larvae migrate through the gut wall and encyst in the viscera or musculature. [348] The fish may then pass the parasite to other fish, to humans, or back to another marine mammal. The coiled *Anisakis* larva grows to approximately 2.5 to 3 cm in length and 0.5 to 1 mm in diameter. Thus fish are usually the intermediate (transport) host for larval anisakines.

The definitive host for *Phocanema decipiens* is the seal; the *Anisakis* larvae grow to maturity in the whale. Shellfish are not infested. Only four genera of anisakine nematodes have been implicated in human anisakiasis: *Anisakis*, *Phocanema*, *Porrocaecum*, and *Contraecum*. In the United States, all cases are related to the larval stages of *Anisakis simplex* and *Phocanema decipiens*. [274]

Clinical Aspects.

Symptoms from ingestion of *Anisakis* may begin within 1 hour of ingestion of raw fish and include severe epigastric pain, nausea, and vomiting. The presentation may mimic an acute abdomen. Asymptomatic gastroduodenal anisakiasis has also been a cause of acute urticaria and severe anaphylaxis in sensitized patients. [100] [139] [145] If the anisakine worms (such as *Phocanema*) do not implant and the infection is luminal without tissue penetration, the worms may be coughed up, vomited, or defecated, generally within 48 hours of the meal. [99] If the worm is felt in the oropharynx or proximal esophagus, the "tingling throat syndrome" is described. [274] An anisakine worm has been documented in the tonsil of a 6-year-old girl with recurrent tonsillitis. [39]

Intestinal anisakiasis is more often delayed in onset (up to 7 days after ingestion) and marked by abdominal pain, nausea, vomiting, diarrhea, fever, eosinophilia (particularly with gastric anisakiasis), and occult blood in the stool. [99] This may be easily confused with appendicitis, regional enteritis, gastric ulcer, colonic or other gastrointestinal carcinoma, or most commonly, other causes of small bowel inflammation with partial obstruction. [52] [210] [369] [402] In one study, 29% of patients with Crohn's disease had

detectable specific total immunoglobulin (IgG), IgM, and IgA antibodies against *A. simplex*.^[167]

Diagnosis and Treatment.

The definitive diagnosis of anisakiasis is usually made on the basis of morphologic characteristics of the whole worm when the creature is expelled by the patient or removed from the stomach after endoscopic examination.^[348] In gastrointestinal tract X-rays, threadlike gastric filling defects approximately 30 mm in length are typical, with a circular or ringlike shape.^[52] ^[394] Edema of the mucosa and pseudotumor formation are also seen. Ultrasound can be useful in identifying intestinal anisakiasis.^[197] If the worms have migrated to extragastric sites, the diagnosis can be difficult.

Early fiberoptic gastroscopy is recommended for patients in whom acute gastric anisakiasis is suspected and for those who have eaten raw fish within 6 to 12 hours before the onset of gastric symptoms. *Anisakis* is usually found in the greater curvature of the stomach, often associated with severe mucosal edema.^[212] Worms may penetrate the wall of the intestine.

The larvae of *Anisakis* can be visualized on endoscopy and removed with biopsy forceps. Fourth-stage larvae of *Anisakis simplex* and *Pseudoterranova (Phocanema) decipiens* are found in the intestine and stomach of humans.^[226] The larva is visible in the mucosa or buried within the submucosa, surrounded by an intense inflammatory granulomatous response.

When laparotomy is performed for presumed appendicitis, the diagnosis is based on identification of the worm in an inflamed segment of appendix, cecum, small intestine, mesentery, or omentum.^[63] ^[105] The only effective therapy for inflamed bowel is resection.

Antibodies to the ileal worm have been detected by radioallergosorbent test (RAST), ELISA, and immunofluorescent antibody assay, but these laboratory methods are not widely available.^[167] Physical removal by endoscopy or surgery is the treatment of choice. Mebendazole 200 mg po bid for 3 days is also recommended.^[154]

Prevention.

The larvae are extremely difficult to spot in fish flesh, since they are colorless and normally tightly coiled in a spiral of approximately 3 mm. Only cooked (above 60° C [140° F]) or previously frozen (to -20° C [-48° F] for 24 hours) fish should be eaten. Smoking (kippering), marinating, pickling, brining, and salting may not kill the worms.^[99] Candling is an inadequate method of surveillance, particularly in dark-fleshed fish infested with *Anisakis* larvae. Fish should be gutted as soon as possible after they are caught to limit the migration of worms from the viscera into the muscle.

The irradiation of fish to limit their infectivity is controversial because of potential generation of long-lived free radicals within the fish, as well as germination of spores of

Clostridium botulinum. ^[453] To date, this practice is not legal for seafood in the United States, although it is used in other countries.

Eustrongylides

Eustrongylides is a genus of roundworms that can invade fish in its larval form and thus be consumed by humans in their quest for sushi and sashimi. *Eustrongylides* may also parasitize bait minnows, which

1316

are swallowed whole by fishermen. The worms are released into the human gastrointestinal tract, where they attain lengths of 15 to 30 cm and penetrate the intestinal wall to enter the peritoneal cavity. Symptoms include unexplained abdominal pain, peritonitis, and fever in a live-bait fisherman. Surgical intervention may be required in pursuit of the acute abdomen, at which time the characteristically bright red worm is identified. ^[454]

OTHER SEAFOOD-RELATED POISONINGS

Poisoning by Environmental Contamination

In the process of concentrating fish proteins as a food source, a variety of protein-bound, non-water-soluble, or non-alcohol-soluble toxic compounds may be preserved. These include organic mercurials, hydrocarbons, dioxins, polychlorinated dibenzofurans, chlorinated pesticides, and heavy metals (e.g., antimony, arsenic, cadmium, chromium, cobalt, lead, phosphorus, mercury, nickel, zinc).^[23] ^[92] ^[396] The overall public health risk for environmental contamination is concerning; however, the true risk of exposure is unknown.

Higher concentrations of polychlorinated biphenyls (PCBs) and dioxin-like compounds are found in Inuit people in the Arctic because of their traditional diet, which includes large quantities of sea mammal fat.^[23] Data suggest that there is an elevated risk of multiple myeloma in groups with high consumption of dioxin-contaminated fish from the Baltic Sea, Alaska, and accidental exposure in Italy.^[355] Dioxin has been found in Dungeness crabs in Humboldt Bay, California.

In Taiwan, high levels of copper, zinc, and arsenic concentrations were found in oysters. The long-term exposure of metals from seafood consumption is potentially dangerous, although the real risk is unknown.^[179] Urine arsenic levels have been shown to increase 2 to 7 times after consumption of certain types of seafood (mackerel, herring, crab, and tuna).^[14] Consumption of fish rich in amines has been shown to increase the excretion of *N*-nitrosodimethylamine in the urine, demonstrating increased formation of carcinogenic *N*-nitrosamines.^[435]

Mercury is found in marine organisms in the form of methylmercury (MeHg) and is concentrated in the food chain. Increased fish consumption is associated with higher blood levels of mercury.^[265] MeHg is neurotoxic and crosses the placenta and blood-brain barrier; prenatal poisoning causes mental retardation and cerebral palsy. The risk from seafood is unclear. High blood and hair concentration of mercury have been found in fishermen of coastal villages, and adverse effects have been reported.^[292] ^[332] Controversy exists over the fetal risk from exposure to low-dose MeHg from maternal consumption of fish.^[22] A recent study on children exposed to MeHg from seafood in a Madeira fishing community did not show any mercury-associated deficits.^[289] A longitudinal cohort study of children showed no adverse outcome with either prenatal or postnatal MeHg exposure.^[101]

Spills of toxic chemicals and petroleum by-products will certainly continue to expand the list of carcinogens to which humans are becoming exposed through the marine

environment. Although radiation exposure is not known to induce production of new marine poisons, the ingestion of radioactive fish poses a potential radiation hazard. Divers are exposed to a variety of environmental contaminants while exploring polluted waters. These hazards include solvents, nuclear wastes, herbicides, chemical effluents, and sewage.

Red Seaweed

Seaweed is a common component in the diet of individuals living in the Pacific Islands and the Pacific Rim. It can be eaten raw or cooked. Most *Gracilaria* species are nontoxic and edible. A number of poisonings and deaths have been reported in Japan, Guam, and Hawaii. Ingestion of the red seaweeds *G. verrucosa* (ogonuri) and *G. chorda* (tsurushiramo) are associated with a toxic syndrome, including gastroenteritis and death.^[301] It is commonly referred to as Japanese "ogonuri poisoning."

In 1991 in Guam, 13 individuals became ill and 3 died after ingesting the red algae *Polycavernosa tsudae* (formerly *Gracilaria tsudae* or *edulis*).^[477] Symptoms consisted of diarrhea, abdominal cramping, vomiting, generalized numbness, perioral and extremity paresthesias, numbness of the fingertips, diaphoresis, jaw aching, muscle spasm, tremors, and hypotension. *G. lemanaeformis* may have been responsible for three illnesses in California in 1992.^[69] In Japan, two people became ill with nausea, vomiting, and hypotension and one died after ingestion of *G. verrucosa*. Prostaglandin E₂ is suggested as the toxic component of *G. verrucosa*, and polycavernosides, which are glycosidic macrolides, are the probable toxins in *G. tsudae*.^[301] ^[471]

An outbreak of acute gastroenteritis from the ingestion of the red alga *G. coronopifolia* occurred in Hawaii in 1994, in which seven individuals reported symptoms of diarrhea, nausea, vomiting, and a burning sensation in the mouth and throat.^[69] Aplysiatoxin and debromoaplysiatoxin have been isolated as the causative agents.^[293] These toxins probably are produced by blue-green algae that are found on the surface of *G. coronopifolia* and are known to cause contact dermatitis in swimmers in Hawaii. Aplysiatoxin and debromoaplysiatoxin experimentally cause edema and bleeding of the small intestine, leading to hemorrhagic shock and diarrhea in the large intestine.^[201]

Sea Turtle Poisoning (Chelonintoxication)

A variety of tropical Pacific, particularly Japanese, marine turtles are toxic when ingested ([Box 54-5](#)).^[385] The term chelonintoxication comes from the Order Chelonia. All portions of the turtle are toxic; the freshness of the meat is irrelevant. In Madagascar, 60 people became ill after eating sea turtle in 1994. The mortality rate was 7.7%.^[327] Lyngbyatoxin A has been isolated from the meat of a green turtle, *Chelonia mydas*, that was involved in a fatal intoxication.^[462] The source of the toxin was suspected to be a blue-green algae belonging to the genus *Lyngbya*. The sea turtle may feed on sea grass contaminated with this algae.

Symptoms develop from 1 to 48 hours after ingestion and include ulcerative glossitis and stomatitis, pharyngitis, diaphoresis, hypersalivation, nausea, vomiting, diarrhea, abdominal pain, vertigo, icterus, desquamative dermatitis, hepatosplenomegaly,

centrilobular hepatic necrosis with fatty degeneration, renal failure, somnolence, and hypotension. The mortality rate can be as high as 28% to 44%. Therapy is supportive and based on symptoms.

A variety of *Salmonella* serotypes have been isolated from pet turtles (*Pseudemys* [or *Chrysemys*] *scripta elegans*) imported into and from the United States.^{[107] [232] [266]} Pet-associated salmonellosis was a significant problem in the 1970s. In 1975, Canada banned the importation of turtles, and in the same year, the FDA prohibited the sale of small turtles in the United States. However, the popularity of iguanas and other reptiles is increasing; these reptiles can also transmit salmonella to humans. Reptile-associated salmonellosis causes febrile gastroenteritis, septicemia, and meningitis; one death has been reported due to myocarditis from *S. virchow* in a small child.^{[67] [107] [298]}

Liver Poisoning—Hypervitaminosis A

Hypervitaminosis A can occur with the ingestion of the livers of certain polar bears, seals, sea lions, whales, dolphins, walruses, husky dogs, and Pacific sharks. The vitamin A content of shark liver can attain 100,000 IU/g. A typical ingestion involves the administration of more than 1 million (and occasionally up to 3 to 8 million) IU of vitamin A (the recommended daily allowance is 4000 to 5000 IU). Symptoms of hypervitaminosis A include formication, headache, apathy, drowsiness, giddiness, irritability, photophobia, nausea, vomiting, diarrhea, polyarthralgia, seizures, desquamative dermatitis, ophthalmoplegia, and raised cerebrospinal fluid pressure with a pseudotumor cerebri-type presentation (acute or chronic, the latter with headache, lip fissuring, papilledema, decreased visual acuity, and tinnitus).^{[128] [279]} Elevated levels of serum glutamic oxaloacetic transaminase and serum vitamin A (markedly in excess of 70 mg%) may be measured. A normal serum β -carotene level excludes the possibility of a plant source (for example carrots or mangoes) for the vitamin.^[279] The syndrome is rarely fatal and resolves in 2 to 8 weeks.

AMEBIC INFECTIONS

Free-living, amphizoic amebas belonging to the genera *Naegleria*, *Acanthamoeba*, and *Balamuthia* can cause significant central nervous system (CNS) pathology in human beings. Approximately 350 cases of human infection have been reported to date.^{[269] [337]} These amebas are ubiquitous in nature; they are found in soil, lakes, ponds, swimming pools, hot springs, and warm water around the world. Human infection caused by amebas has significantly increased over the last 10 years.^[269]

Free-living amebas are responsible for three disease entities: (1) primary amebic meningoencephalitis (PAM) produced by *Naegleria fowleri*, (2) granulomatous amebic encephalitis (GAE) caused by *Acanthamoeba* species and *Balamuthia mandrillaris*, and (3) *Acanthamoeba* keratitis (AK), caused by *Acanthamoeba* species.

Primary Amebic Meningoencephalitis

PAM is a fulminant, rapidly progressive CNS infection produced by *N. fowleri*. It was first described in 1965 by Malcolm Fowler and Rodney Carter in four human cases of meningoencephalitis from *N. fowleri*.^[138] Worldwide, approximately 180 cases of PAM have been reported, with over 80 cases reported in the United States alone.* *N. fowleri* multiplies and grows between 40° and 45° C (104° and 113° F). In response to adverse environmental conditions, such as cold temperature, the ameba encysts and remains in the sediment in the bottom of lakes, rivers, and pools.

*References ^[66] ^[106] ^[240] ^[269] ^[337] ^[439] .

Infections occur in healthy children and adults who contact the ameba while swimming in polluted water in human-made lakes, ponds, and swimming pools, or the ameba may be inhaled from the dust and air.^[269] Infection is more common during summer months. The amebas enter the CNS through the nasal mucosa and olfactory neuroepithelium. The amebic trophozoites travel up the unmyelinated fila olfactoria of the olfactory nerves and through the cribriform plate to the subarachnoid space.^[208] They proliferate and penetrate into the CNS, causing edema and necrosis. The incubation period is from 1 to 15 days. Symptoms include severe headache, fever, nausea, vomiting, and stiff neck. Rapid neurologic deterioration accompanied by signs of fulminant meningitis with seizures, coma, and death follows within 2 to 3 days.

Diagnosis is made by the direct visualization of trophozoites in the cerebrospinal fluid

along with polymorphonuclear pleocytosis, elevated protein, and low glucose. *Naegleria* trophozoites typically measure 8 to 12 microns in diameter with indistinct cytoplasm, a round nucleus, and a perinucleolar halo.^[269] *N. fowleri* causes acute leptomeningitis and hemorrhagic necrosis of the orbitofrontal cortex, olfactory bulbs, and base of the brain with edema of the cerebral hemispheres and cerebellum. Computed tomography (CT) scan of the brain shows nonspecific cerebral edema.^[222]^[351] Early detection and treatment is essential, since this disease carries a very poor prognosis with a mortality rate of 98%. To date, there are six cases of successful treatment of PAM in individuals who were treated very early in the clinical course.^[55]^[320]^[359]^[442] Treatment includes high-dose intravenous and intrathecal amphotericin B alone or in combination with miconazole.^[153] Oral ketoconazole and rifampicin have been used in addition to amphotericin B.^[320]

PAM should be suspected in any previously healthy individual who has been exposed to fresh warm water within 7 days of onset of illness and who has clinical findings of bacterial meningitis with a basilar distribution of exudate by brain CT.^[66]

Granulomatous Amebic Encephalitis

Several species of *Acanthamoeba* and *B. mandrillaris* are pathogenic opportunistic amebas that cause GAE, mainly in victims who are immunocompromised, debilitated, diabetic, or alcoholic. GAE has been reported in patients with systemic lupus, acquired immunodeficiency syndrome (AIDS), and bone marrow transplantation.^[4]^[129]^[234]^[404] However, two recent cases of GAE caused by *B. mandrillaris* occurred in apparently immunocompetent individuals.^[337] Approximately 170 cases of GAE have been reported worldwide.^[269]

Acanthamoeba species are ubiquitous in nature; they have been found in ocean water, ponds, sewage, rivers, air-conditioner filters, cooling towers, eye wash stations, and dust. Some of the *Acanthamoeba* opportunistic species include *A. castellanii*, *A. hatchetti*, *A. culbertsoni*, *A. astronyxis*, *A. polyphaga*, *A. rhyodes*, and *A. mauritaniensis*.^[269] *B. mandrillaris* has not been isolated from the environment, although it probably exists in cyst form similar to *Acanthamoeba*. The trophozoites and cysts can enter through the lungs and ulcerations in the skin. The olfactory neuroepithelium may also act as a portal of entry.^[205]^[269] The incubation period is unknown but is probably weeks.

Both *Acanthamoeba* species and *B. mandrillaris* produce a chronic granulomatous encephalitis. The clinical presentation may mimic tuberculous meningitis or viral encephalitis. Symptoms include headache, fever, seizures, personality changes, cranial nerve palsies, hemiparesis, and coma. There may be ulcerations of the skin. The amebas cause hemorrhagic necrosis and foci of encephalomalacia in occipital, parietal, temporal, and frontal lobes. The lesions are multifocal and most numerous in the basal ganglia, midbrain, brainstem, and cerebral hemispheres.^[269] Angiitis can occur, and trophozoites are often found invading the vascular walls.^[335] The amebas multiply and can disseminate throughout the body; other organs involved (at the time of autopsy) include liver, lungs, kidneys, adrenals, pancreas, lymph nodes, and heart.^[4]^[404]

CT scans and magnetic resonance imaging (MRI) have shown multiple enhancing lesions in the cerebral hemispheres and cerebellum; however, the scans are nondiagnostic.^[222]^[335]^[351] Diagnosis is difficult, since amebas are rarely observed in the CSF. Examination of the CSF shows a moderate mononuclear pleocytosis, elevated protein, and low glucose. Definitive diagnosis is made by direct visualization of amebic trophozoites and cysts within brain tissue. Unfortunately, there is no effective treatment for GEA, and mortality is 100% in immunocompromised patients.^[269] Although pentamidine isethionate, propamidine, sulfadiazine, and ketoconazole are effective in vitro, these drugs do not appear to be useful because of the underlying immunosuppression of most of these patients.^[269] Based on tissue-culture studies, pentamidine isethionate appears to be the best choice for treatment of *B. mandrillaris* encephalitis.^[352] Only one case of widespread granulomatous skin lesions in an immunocompromised patient resulting from *A. rhysodes* was successfully treated with intravenous pentamidine isethionate for 4 weeks, topical chlorhexidine gluconate, and ketoconazole cream followed by oral itraconazole.^[377]

Acanthamoeba Keratitis

Acanthamoeba keratitis is caused by *Acanthamoeba* species; over 700 cases have been reported worldwide.^[269] *Acanthamoeba* enters the corneal stroma through minor trauma or abrasion, causing chronic inflammation of the cornea, which can impair vision and lead to vascularized corneal scarring, perforation, and loss of

1319

the eye. The use of soft contact lenses and homemade saline solutions are the greatest risks for AK. Symptoms include severe eye pain, photophobia, conjunctival inflammation, and blurred vision. Diagnosis is by identification of the trophozoites or cysts by corneal scrapings or biopsies. The treatment of choice for AK is 0.02% polyhexamethylene biguanide (PHMB) or propamidine 0.1% with topical polymyxin B, gramicidin, or neomycin.^[151]^[241] Penetrating keratoplasty and corneal grafting have been used.^[132] Contact lens wearers should use sterile solutions for lenses and should consider not wearing contacts while engaged in water sports.^[198]

Chapter 55 - Seafood Allergies

Susan L. Hefle
Robert K. Bush

True seafood allergies are immunoglobulin E (IgE)-mediated reactions. Although allergic reactions can occur to all classes of seafoods, accurate epidemiologic data are difficult to obtain. Crustacean allergies are one of the most common types of food allergy in the U.S. adult population^[62] ; codfish allergy is probably the most common form of food allergy in Scandinavian countries.^[2]

BIOLOGIC CLASSIFICATION

An understanding of the taxonomic relationships among different species of marine animals is important. Although many seafood species may be allergenic, most allergic patients are not sensitive to all species. The degree of allergic cross-reactivity among the different fish species varies widely among patients. Thus selective avoidance diets are possible. The biologic classification of the edible species of fishes is given in [Table 55-1](#). Most edible fishes belong to class Osteichthyes, although sharks are in a different class. The most common fishes consumed belong to only a few orders: Salmoniformes (salmons, trout, whitefishes, smelts, and pikes), Perciformes (basses, perches, dolphins, snappers, groupers, redfishes, mackerels, and tunas), Gadiformes (codfishes, pollocks, haddocks, and hakes), Pleuronectiformes (flounders, halibuts, and soles), Clupeiformes (herrings, sardines, anchovies, shad, menhadens, and alewives), Cypriniformes (carps and catfishes), and Scorpaeniformes (rockfishes). Many of the edible fish species belong to the orders Salmoniformes, Perciformes, and Gadiformes ([Table 55-2](#), [Table 55-3](#), [Table 55-4](#)).

The physician should be alert to the confusing common names of fishes. For instance, king mackerel may be sold as cero, silver cero, black salmon, cavalla, or kingfish. Kingfish can also mean king whiting, which itself is sold as ground mullet, whiting, gulf whiting, surf whiting, southern whiting, sand whiting, or silver whiting. Whiting may be a name used to describe hake. The identification of fish is often erroneous, particularly when performed by sport fishermen.

Crustacea are classified as arthropods with spiders, centipedes, and insects. At least 30 edible species of crustacea are consumed in the United States. The Mollusca include clams, mussels, oysters, cockles, snails, cuttlefish, limpets, abalone, and squid and octopus ([Table 55-5](#), [Table 55-6](#), [Table 55-7](#)).

CLINICAL MANIFESTATIONS

The symptoms of seafood allergy are the same as those caused by other allergenic foods. The symptoms are often related to the method of exposure, whether ingestion, inhalation, or physical contact. With ingestion, symptoms may occur first in the mouth and on the face, including localized or general pruritus, urticaria, laryngeal edema, and angioedema.^[84] Atopic dermatitis may be exacerbated by seafood allergies.^[92] Gastrointestinal (GI) symptoms such as nausea, vomiting, diarrhea, and cramps may occur as a result of ingestion. Some reports indicate severe asthma and bronchospasm as primary symptoms after consumption of certain mollusks^{[16] [26]} and fish.^[85] In some individuals, seafood can cause anaphylaxis. Symptoms of anaphylaxis may include these symptoms in addition to hypotension, electrocardiogram (ECG) changes, and cardiovascular collapse. Symptoms of food allergy usually occur within an hour after ingestion.^{[1] [14] [15] [23]} However, delayed reactions (3 to 24 hours after ingestion) have been noted with fish,^[85] cuttlefish,^[94] abalone,^[72] and limpets.^[80] With food-dependent exercise-induced anaphylaxis, persons in the resting state can eat food without difficulty. However, exercise within 2 to 4 hours after ingestion can bring on the symptoms of anaphylaxis. Shrimp, mollusks, and squid are among the implicated foods.^{[52] [76] [77]}

Occupational reactions can include dermatitis, urticaria, angioedema, rhinitis, conjunctivitis, asthma, and hypersensitivity pneumonitis. Employees in the fishing and seafood processing industries are at risk of developing occupational allergy. Although asthma is the most prominent symptom, anaphylaxis has been reported with occupational exposure.^[74] Physical contact with seafood can elicit allergic symptoms in sensitive individuals, and urticaria, contact dermatitis, angioedema, and asthma have been reported after contact with shellfish^{[22] [37] [96] [106] [108]} and fish.^{[8] [22] [30]} Most of these contact reactions occur as part of occupational exposure, but consumers can also be affected.^[84] Inhalation reactions are most often associated with occupational exposure, such as in cleaning and cooking seafood, but can also occur when seafood is cooked at home or in restaurants. Seafoods implicated in occupational asthma include oysters,^[83] clams,^[29] shrimp,^{[29] [63]} prawns,^[38] fish,^{[20] [32]} snow and king crabs,^{[17] [86]} lobsters,^{[63] [91]} sea squirts,^[53] abalone,^[19] powdered marine

TABLE 55-1 -- Taxonomic Relationships Among the Edible Fishes

TAXONOMIC CLASSIFICATION

CLASS	SUBCLASS OR ORDER	COMMON NAME
Chondrichthyes	Elasmobranchii	Sharks
Osteichthyes	Acipenseriformes	Sturgeons, paddlefishes
	Elopiformes	Tarpons, ten-pounders, bonefishes
	Anguilliformes	Common eels, morays
	Clupeiformes	Herrings, sardines, alewives, shad, menhaden, anchovies
	Salmoniformes	Trouts, salmons, whitefishes, graylings, discoses, pikes, lake herrings, pickerels, muskelunges, euchalons, capelins, smelts, saugers
	Gonorynchiformes	Milkfishes, awa
	Cypriniformes	Minnows, carps, suckers, catfishes
	Beloniformes	Sauries, needlefishes, flying fishes
	Mugiliformes	Mulletts, barracudas, silversides, threadfishes
	Lambridiformes	Opah, mariposas
	Tetradontiformes	Pufferfishes, boxfishes, trunkfishes
	Pleuronectiformes	Flounders, halibuts, soles, dabs, turbotts
	Perciformes, suborder Percodei	Basses, crappies, bluegills, sea basses, sunfishes, perches, bluefishes, jacks, pompanos, dolphins, snappers, groupers, scups, grunts, porgies, pomfrets, sheepsheads, snooks, robalos, bigeyes, catalugas, croakers, spots, redfishes, tautogs, butterfly fishes, wrasses, spadefishes, goatfishes, mojarras, rudderfishes, surffishes, weakfishes, roaches, drums, cichlids
	Perciformes, suborder Scombroidei	Mackerels, tunas, cutlassfishes, albacores, bonitos, kingfishes
	Perciformes, suborder Xiphoidei	Swordfishes, marlins, sailfishes, spearfishes
	Perciformes, suborder Ammodytoidei	Sand lances (sand eels)
	Perciformes, suborder Stromateoidei	Butterfishes

	Scorpaeniformes	Rockfishes, scorpionfishes, greenlings
	Gadiformes	Codfishes, ling cods, pollocks, haddocks, tomcods, hakes, codlings
	Percopsoidei	Trout-perches, sand rollers

TABLE 55-2 -- Taxonomic Relationships Among Salmoniformes

TAXONOMIC CLASSIFICATION			
SUBORDER	FAMILY	GENUS	COMMON NAME
Salmonoidei	Salmonidae	<i>Coregonus</i>	Whitefishes, ciscoes, bloaters, lake herrings
		<i>Onchorhynchus</i>	Pacific salmons
		<i>Salmo</i>	Trouts, Atlantic salmon
		<i>Salvelinus</i>	Chars, brook trout, Dolly Varden trout, lake trout
		<i>Thymallus</i>	Grayling
	Osmeridae	<i>Osmerus</i>	Smelts
		<i>Mallotus</i>	Capelins
		<i>Thaleichthys</i>	Euchalon
Esocoidei	Escidae	<i>Esox</i>	Pikes, saugers, pickerels, muskelunges

1329

TABLE 55-3 -- Taxonomic Relationships Among Perciformes

TAXONOMIC CLASSIFICATION		
SUBORDER	FAMILY	COMMON NAME
Percoidei	Centraranidae	Largemouth bass, black basses, breams, bluegill, sunfishes, crappie, Sacramento perch
	Percichthyidae	Striped bass, white bass, white perch, yellow bass
	Serranidae	Groupers, sea basses, jawfishes
	Percidae	Pikes, saugers, yellow perch, river perch
	Centropomidae	Snooks, robalos
	Priacanthidae	Cataluras, bigeyes
	Pomatomidae	Bluefish

	Coryphaenidae	Dolphin fish (mahi mahi)
	Carangidae	Jacks, pompanos, cavallas, moonfishes, scads, jack mackerel
	Bramidae	Pomfret
	Pomadasyidae	Grunts
	Lutjanidae	Snappers, mutton fish, raborubias
	Chaetodontidae	Butterflyfishes
	Ephippidae	Spadefishes
	Labridae	Wrasses, tautog
	Cichlidae	Cichlids
	Sciaenidae	Drums, redfish, croakers, weakfishes, kingfishes
	Mullidae	Goatfishes
	Sparidae	Porgies, scups, spots, sheepsheads
	Gerridae	Mojarras
	Kyphosidae	Rudderfishes, sea chubs
	Embiotocidae	Surffishes
Scombroidei	Scombridae	Mackerels, tunas, bonitos, Spanish mackerels, sierra, kingfish, cero, cavalla, petos
	Trichiuridae	Cutlassfishes
Xiphiodei	Xiphiidae	Swordfishes
	Istiophoridae	Marlins, sailfishes, spearfishes
Ammodytoidei	Ammodytidae	Sand lances (sand eels)
Stromateoidei	Stromateidae	Butterfishes

TABLE 55-4 -- Taxonomic Relationships Among Gadiformes

TAXONOMIC CLASSIFICATION			
SUBORDER	FAMILY	GENUS	COMMON NAME
Gadoidei	Merlucciidae	<i>Merluccius</i>	Pacific hake
	Gadidae	<i>Pollachius</i>	Pollock
		<i>Theragra</i>	Walleye pollock
		<i>Gadus</i>	Codfishes
		<i>Microgadus</i>	Tomcods
		<i>Lota</i>	Turbot

		<i>Melanogrammus</i>	Haddock
		<i>Urophycis</i>	Atlantic hake, red hake, Gulf hake

1330

TABLE 55-5 -- Taxonomic Relationships Among Edible Mollusks and Crustacea

TAXONOMIC CLASSIFICATION			
PHYLUM	CLASS	SUBCLASS	COMMON NAME
Mollusca	Gastropoda	Prosobranchi	Marine snails, abalone, periwinkles, whelks
		Pulmonata	Freshwater snails
	Bivalvia	Lamellibranchii	Mussels, cockles, oysters, scallops, clams
	Cephalopoda	Coleoidea	Squid, octopus
Arthropoda	Crustacea	Malacostraca	Shrimp, crabs, lobsters, crayfish

TABLE 55-6 -- Edible Bivalves and Cephalopods

GROUP	COMMON NAME	SCIENTIFIC NAME
Clams	Surf or bar clam	<i>Macra solidissima</i>
	Soft clam	<i>Mya arenaria</i>
	Hard clam or quahog	<i>Venus mercenaria</i>
	Atlantic razor clam	<i>Ensis directus</i>
	Pacific razor clam	<i>Siliqua patula</i>
	Stout razor clam	<i>Tagelus gibbus</i>
	Butter clam	<i>Saxidomus nuttali</i>
	Little neck clam	<i>Tapes staminea</i>
	Geoduck clam	<i>Panope generosa</i>
	Freshwater clam	<i>Coribula leana</i>
	Pismo clam	<i>Tivela stultorum</i>
	Short-necked clam	<i>Venerupis japonica</i>
	Jackknife clam	<i>Tagelus californianus</i>
Mussels	European or Atlantic mussel	<i>Mytilus edulis</i>
	Pacific mussel	<i>Mytilus californianus</i>

	South Asian green mussel	<i>Mytilus smaragdinus</i>
Cockles	Common cockle	<i>Cardium corbis</i>
	Red cockle	<i>Cardium echinatum</i>
	Spiny cockle	<i>Cardium aculateum</i>
Scallops	Common scallop	<i>Pecten gibbus borealis</i>
	Deep water scallop	<i>Placopecten megallanicus</i>
	Japanese scallop	<i>Pecten yessoensis</i>
Oysters	Pacific oyster	<i>Cassostrea gigas</i>
	Atlantic oyster	<i>Crassostrea virginica</i>
	Japanese oyster	<i>Crassostrea laperousei</i>
	Coon oyster	<i>Ostrea frons</i>
Squid	North American squid	<i>Loligo paeleii</i>
	North American squid	<i>Loligo opalescens</i>
	Japanese squid	<i>Ommastrephes sloani pacificus</i>
Octopus	Common octopus	<i>Octopus vulgaris</i>

TABLE 55-7 -- Edible Crustacea

GROUP	COMMON NAME	SCIENTIFIC NAME
Lobsters	Atlantic lobster	<i>Homarus vulgaris</i>
	European lobster	<i>Homarus gammarus</i>
	Northern lobster	<i>Homarus americanus</i>
	Spiny lobster	<i>Panulirus argus</i>
Crabs	Blue crab	<i>Callinectes sapidus</i>
	Deep sea blue crab	<i>Portunus pelagicus</i>
	Dungeness crab	<i>Cancer magister</i>
	Jonah crab	<i>Cancer borealis</i>
	King crab	<i>Paralithodes camtschatica</i>
	Snow crab	<i>Chionoectes bairdi</i>
	Tanner crab	<i>Chionoectes tanneri</i>
	Spider crab	<i>Talvia maticum</i>
	Stone crab	<i>Menippe mercenaria</i>
Prawns and shrimp	Common prawn	<i>Palaemon serratus</i>

	Deep water prawn	<i>Pandalus borealis</i>
	Pink Maine shrimp	<i>Pandalus borealis</i>
	Coon stripe shrimp	<i>Pandalus hypsinotus</i>
	Brown shrimp	<i>Panaeus aztecus</i>
	Pink shrimp	<i>Panaeus duorarum</i>

DIAGNOSIS

Medical History

The diagnosis of food allergy may be simple or extremely complex. With seafood it is particularly important to identify the offending food correctly to determine if cross-reaction patterns can be established. An estimate of the quantity of the food needed to elicit the reaction may help to distinguish intolerance from a true seafood allergy.

Skin Testing and Radioallergosorbent Test

The skin prick test is extremely useful, but commercial extracts are not available for all individual seafood species. Often, mixed extracts are used. Some risk exists for patients who have experienced severe anaphylactic reactions. As with other food allergen extracts, fish skin prick tests have superior sensitivity and negative predictive accuracy, but poor positive predictive value and specificity.^[9] Some commercial fish skin test extracts may contain relatively high levels of histamine,^[102] which could be a contributing factor; however, the person often fails to distinguish the species causing the allergy. Allergists generally recommend removing all edible fish from a person's diet, including both Osteichthyes (bony fish) and Chondrichthyes (shark), when the person has a history of allergic reaction to any fish or a positive skin test or radioallergosorbent test (RAST) to a fish extract. However, research using double-blind placebo-controlled fish (food) challenges^[9] (DBPCFCs) and other tests^[2] ^[28] in fish-allergic children has shown that they are not uniformly sensitive to all species. Hypersensitivity to one species does not automatically warrant dietary elimination of all fish. Fish challenges in children with negative skin tests were negative; therefore skin testing may be advisable first.^[9] Seafood extracts are available for skin prick testing and as reagents for CAP-RAST ([Box 55-1](#)). CAP-RAST is reserved for persons who have had severe reactions to skin testing.

Double-Blind Placebo-Controlled Food Challenges

The ultimate test to verify that a particular food causes a reaction is the DBPCFC.^[11] ^[12] This should not be performed in persons who have experienced life-threatening reactions and should be undertaken only under close physician supervision. Dried or freeze-dried foods are encapsulated in opaque, dye-free capsules, and appropriate identical placebo capsules are prepared. Although such testing is time-consuming and expensive, DBPCFC permits a precise diagnosis.

**Box 55-1. COMMERCIALY
AVAILABLE SEAFOOD EXTRACTS
FOR SKIN AND
RADIOALLERGOSORBENT TESTING**

SKIN TEST

Fish: anchovy, bass, catfish, codfish, flounder, haddock, halibut, herring, mackerel, perch, pickerel, salmon, sardine, smelt, snapper, sole, swordfish, trout, tuna, whitefish

Fish mixtures

1. Codfish, flounder, mackerel, tuna
2. Codfish, halibut, mackerel, perch, salmon, trout, tuna

Crustacea: crab, lobster, shrimp

Mollusks: clam, oyster, scallop

Shellfish mixtures

1. Clam, crab, oyster, scallop, shrimp
2. Clam, crab, lobster, oyster, shrimp, scallop

***RADIOALLERGOSORBENT TEST
(CAP-RAST)***

Fish: anchovy, cod, eel, hake, halibut, herring, jack mackerel, mackerel, chub mackerel, megrim (whiff), plaice, trout (rainbow), salmon, sardine, swordfish, tuna

Crustacea and mollusks: crab, lobster, shrimp (pink), lobster (spiny), mussel (blue), octopus, oyster, snail, squid

Elimination Diets

When a certain type of seafood is suspected of producing symptoms, it may be eliminated from the diet. After the initial complaints have resolved, the person then reintroduces the food to see if the reaction recurs. Elimination diets should only be used in persons who have not experienced life-threatening symptoms as a manifestation of seafood allergy.

Controversial Techniques

A number of clinical and laboratory tests are unreliable predictors of the presence of seafood allergy. These include pulse index, in vitro cytotoxic food tests, intracutaneous provocation, sublingual provocation, basophil degranulation, and sublingual neutralization.^[5]

Occupational Asthma

Although the measures described previously are useful in diagnosing cutaneous, GI, or systemic manifestations of food allergy, the diagnosis of occupational asthma requires a different approach. If the person notes the onset of asthma symptoms related to work exposure, then improves on weekends or while on vacation, occupational asthma should be suspected. Asthma is verified by

1332

appropriate pulmonary function tests, such as spirometry with and without bronchodilators. If the history is suggestive but not corroborated by physical examination or simple spirometry, performing provocation with inhaled methacholine or histamine may be necessary to document airway hyperreactivity. The diagnosis depends ultimately on the provocation of asthma by a bronchial inhalation challenge with the suspected allergen. Such evaluation should occur under close observation in a hospital setting.

TREATMENT

The treatment for seafood allergies is the same as for other allergic reactions. Avoidance should encompass both consumption and inhalation of cooking vapors from the appropriate species. To avoid unnecessary dietary restrictions, proper diagnosis is extremely important.

IDENTIFICATION AND CHARACTERIZATION OF SEAFOOD ALLERGENS

Fish

Of the seafood allergens that have been isolated and purified, the best characterized is the major allergen of codfish, *Gad c 1*, which belongs to a group of muscle tissue proteins known as parvalbumins.^[34] *Parvalbumins* are responsible for mediating the concentration of calcium in muscle. *Gad c 1* is an acidic protein with a molecular weight of 12,328 daltons, is composed of 113 amino acids and 1 glucose molecule, and has an isoelectric point of 4.75. It comprises three domains: AB, CD, and EF, consisting of three helices interspaced by one loop.^[35] Each of the loops of the CD and EF domains coordinates one Ca⁺² binding site; these sites correspond to IgE binding sites. It is stable to heat, extremes of pH, and mild proteolysis. The allergenicity of *Gad c 1* is decreased by acetylation or polymerization of the tyr-30 residue,^[6] modification of the arg-75 residue, or dechelation of the two calcium ions,^[33] but these methods cannot be used commercially.

Another codfish allergen was identified in an in vitro study with cod-allergic patient sera to have a molecular size of 41 kilodaltons (kD), in addition to six other bands at 13, 21, 27, 47, and 58 kD.^[39] The 41-kD allergen had an isoelectric point estimated at 5.8. The 13-kD band was a major allergen for all subjects in the study. The 13- and 41-kD bands were recognized by antiparvalbumin monoclonal antibodies specific for the first calcium binding site, as were the bands at 28 and 49 kD. No correlation exists between the amino acid composition of the 41-kD allergen and other cod allergens previously described in the literature.^[39] In another study investigating IgE binding in sera of fish-allergic patients, prerigor cod muscle was found to contain IgE binding bands of 12, 22, 30, 45, 60, 67, 104, and 130 kD.^[31] A major IgE binding band for all sera was at 12 kD; the 30- and 67-kD bands also possessed good IgE binding activity. The bands at 104 and 130 kD were thought to be aggregates of smaller bands. When the cod had been dead for several days, new IgE binding bands of 18, 41, and 80 kD appeared, and the relative content of IgE binding proteins was increased. The action of naturally occurring proteases could have opened up sections of the peptides and made them more accessible to IgE binding during this period. The codfish antiparvalbumin monoclonal antibody was also found to bind to all IgE binding bands identified in this study, indicating that all peptides shared similar structures.

Protamine sulfate, a sperm protein of salmon, herring, trout, and other species belonging to the families Salmonidae and Clupeidae, has been identified as an allergen in some persons with sensitivities to salmon, herring, and related fish.^[56] It is a low-molecular-weight protein widely used as a heparin antagonist. Surimi, a collection of

one or many different varieties of small fish that are minced and washed extensively, gave a single band at 63.5 kD that bound IgE from all sera of fish-allergic patients in one study.^[75] Although many fish-allergic patients are allergic to multiple fish species, monospecificity has been reported to tuna, cod, and swordfish. In these studies, subjects with multiple allergies to fish species showed IgE binding to 12- to 13-kD bands, whereas the monospecifically sensitive subjects showed IgE binding to unique bands at 40 kD in tuna and 25 kD in swordfish.^{[51] [55]}

Structurally related parvalbumins in divergent fish species may explain cross-reactivity to fish species in certain allergic individuals. Hansen et al^[43] noted that in adults with clinical sensitivity to cod, reactions were reported to mackerel, herring, and plaice, and in vitro results showed IgE binding to a single band in the 11- to 14-kD region of mackerel, herring, and plaice extracts. An IgE binding protein from salmon, *Sal s 1*, was identified by in vitro analyses and shown to be salmon parvalbumin.^[71] In one study, almost 50% of cod-allergic patients had clinical sensitivity to salmon.^[3] *Sal s 1* has two bands at 12 and 14 kD and therefore has at least two isotypic variants.^[71] While tuna-allergic individuals have been noted to have IgE binding to the 12-kD *Gad c 1* codfish allergen,^[13] one study noted that raw tuna extracts seemed to lack the IgE binding bands in the parvalbumin size range that were present in extracts of catfish, cod, and snapper.^[53] However, Park et al^[89] described IgE binding in sera from fish-allergic persons to tuna proteins at 12–13 kD. Sera from fish-allergic patients possessed IgE to bands at 12 to 13 kD in mackerel, pollock, and cod and showed unique binding to a band at 19 kD from saury and 37 kD from tuna. In one study, canned tuna did not present problems for five fish-allergic children^[10]; canning may decrease the allergenicity of cod. Amino acid sequencing has shown,

1333

however, that the 12 to 13-kD band from tuna does not have the same sequence as cod, which may explain why tuna does not cross-react extensively with other species.^{[9] [46] [90]}

Although many studies have shown skin prick test reactivity and in vitro reactivity between multiple species of fish, Glazzaz et al^[40] found that amounts of parvalbumin in different fish extracts did not affect skin prick tests in fish-allergic subjects. An important verification tool is the oral challenge (DBPCFC). Bernhisel-Broadbent et al^[9] found that in 11 subjects demonstrating in vitro allergy to fish, positive DBPCFC occurred only to one species in seven subjects, to two species in one subject, and to three in two others. Other studies using DBPCFC confirm this observation.^[51] Different species of fish have shared allergenic determinants, and some fish-allergic patients are sensitive to multiple species of fish. Aas^[1] found that of 61 fish-allergic children challenged with fish, 34 reacted to all species tested, and 27 could tolerate one or more types of fish. Other studies have found that subjects clinically react to multiple fish.^{[44] [51] [70]} Negative skin prick tests are an excellent predictor of lack of allergy. Skin prick testing is an important tool, but DBPCFC should follow to determine the species that fish-allergic patients can tolerate.

Crustacea

The crustacean family includes shrimp, prawns, crabs, lobsters, and crayfish^[107] and is a common reported cause of food hypersensitivity. Research indicates that crustacea share allergenic and antigenic determinants,^{[42] [61]} although some reactions are species specific.^{[59] [79]} Also, qualitative differences in the allergenic determinants of different shrimp extracts have been reported^[79]; therefore use of extracts from more than one species for skin testing and CAP-RAST is recommended. Presence of IgE to either unique or shared allergens may explain an individual's clinical sensitivity to one or more members of this taxonomic class.

Shrimp is the most thoroughly studied of the crustacea in regard to allergens. Hoffman et al^[47] were the first to characterize allergens from shrimp. Antigen I, isolated from raw shrimp, was an acidic, heat-labile protein composed of two noncovalently bound 21-kD polypeptide chains. Antigen II, isolated from cooked shrimp, was an acidic heat-stable 38-kD glycoprotein with an isoelectric point of 4.5 composed of 341 amino acid residues and 4% carbohydrate. Antigen II appeared to be a major allergen for the subjects in this study.

An allergenic transfer ribonucleic acid (tRNA) moiety from cooked prawns has been described.^[81] The researchers could not isolate a preparation completely devoid of protein, however, so the allergenicity may have been caused by RNA-associated proteins. Further work by this group^[82] yielded the description of two allergenic polypeptides from cooked shrimp; SA-I, at 8.2 kD, was not analyzed further. The second allergen, SA-II, at 34 kD, was composed of 301 amino acid residues and appeared similar to antigen I isolated by Hoffman and colleagues.

The major shrimp allergen of 36 kD, readily isolated from the boiling water and meat of cooked shrimp, is *tropomyosin*, a muscle protein.^[24] The allergen is composed of 312 amino acid residues and 2.4% carbohydrate. Monoclonal antibodies directed against the 36-kD shrimp allergen, *Pen a 1* reacted to a 36-kD protein in crayfish, crab, and lobster extracts.^[24] Antigen I, SA-II, and *Pen a 1* appear to be the same protein. A tropomyosin is the major allergen, identified as SA-II, of two additional shrimp species, *Par 1 1* (*Parapenaeus fissurus*)^[69] and *Met e 1* (*Metapenaeus ensis*).^{[64] [93]} Lin et al^[69] identified a 74-kD component in shrimp with IgE binding in 40% of subjects with allergy to shrimp and positive skin prick tests. Minor components of 41, 47, 50, and 86 kD bound to IgE in 10% to 20% of the sera. A monoclonal antibody made against *Par 1 1* also reacted to a 39 kD component in crab, and the two bands had similar amino acid compositions. *Par f 1*, at 39 kD, has an isoelectric point of 5.1 to 5.6.

Crab

Leung et al^[66] describe the identification of a crab allergen, *Cha t 1*, from the crab species *Charybdis feriatus* from a constructed complementary deoxyribonucleic acid (cDNA) library screened with crab-allergic sera. Recombinant *Cha t 1*, at 34 kD, was identified as a tropomyosin. Snow crab also causes allergic sensitization in occupational settings.^{[17] [45]} Heat-labile and stable allergens have been found in snow crab extract;

snow crab-specific IgE bound more to boiled crab than to raw crab.^[45] The most prominent bands were at 37 to 42 kD in crab cooking water and extracts of cooked crab meat. In contrast to findings by Leung et al,^[66] however, a 14-kD protein seemed to be the most prominent IgE binding protein, indicating that in cases of sensitization through the inhalation route, the responsible allergens might be different than those for the ingestion route.

Lobster

Leung et al^[67] screened a library made from *Panulirus stimpsoni*, the spiny lobster, with sera from crustacea-allergic subjects. A recombinant IgE binding protein was designated *Pan s 1*, at 34 kD. The researchers also found a similar protein in *Homarus americanus*, the American lobster, which was designated *Hom a 1*. *Hom a 1* possesses cross-reactive IgE epitopes in lobster and shrimp and has significant homology to *Pen a 1* and *Met e 1*, with the major shrimp allergen. Similar IgE binding sites are found in *Met e 1*, *Pan s 1*, and *Hom a 1*. Although the size of *Hom a 1* was not directly reported,

1334

the work described a 60-kD fusion protein, which would make *Hom a 1* approximately 34 kD in size. Wiley and Griffin^[101] demonstrated two IgE binding proteins of 35 to 37 and 97 kD in extracts of lobster in pooled sera from subjects with respiratory symptoms to Norwegian lobster (*Nephrops norvegicus*). In native form the allergens were greater than 800 kD in size and were recognized by more than 80% of the serum samples involved, making them major respiratory allergens.

Mollusks

The mollusks are a diverse group. Squid and octopus are cephalopods, whereas clam, cockles, scallops, mussels, and oysters are bivalves. Abalones, conches, limpets, snails, and whelks are gastropods.

Squid

Allergic reactions have been documented in sensitive subjects after ingestion of squid or inhalation of vapors from cooking squid.^[15] Almost all these victims also experienced symptoms after ingesting shrimp and demonstrated strong positive skin test reactions to boiled squid extracts and various commercial crustacea extracts. Immunoassay studies showed cross-reactivity between shrimp and squid allergens, although cross-reactivity was not demonstrated between squid and octopus or squid and other mollusks. Miyazawa et al^[78] have described the major squid allergen as a 38-kD heat-stable protein, designated *Tod p 1*. Cross-reactivity between *Tod p 1* and shrimp allergens was demonstrated by in vitro IgE binding studies and with monoclonal antibodies. The amino acid sequence of *Tod p 1* showed marked homology with tropomyosin from the blood fluke (a snail) and was identified as squid tropomyosin.

Oyster

Two allergens, *Cra g 1* and 2, were isolated from the oyster *Crassostrea gigas*.^[48] They are both 86-kD glycoproteins with a carbohydrate content of about 5% and have 35-kD subunits. The allergic reactivity of the two allergens was equivalent in oyster-allergic patients. Studies on molecular characteristics and amino acid composition suggested that they are oyster tropomyosin. The allergenicity is apparently heat-stable, as is that of *Pen a 1*, shrimp tropomyosin. Partial digestion with a peptidase gave a protein sequence different from that for IgE binding characteristics of *Pen a 1*. *Cra g 1* has 76% protein sequence homology with mussel tropomyosin, 74% with the gastropod tropomyosin *Haliotis rufescens*, and 58% with *Metapenaeus ensis* (shrimp) tropomyosin.^[50]

Limpet and Abalone

Limpet and abalone can cause moderate to severe anaphylactic reactions and occasionally fatalities.^{[14] [18] [73] [80]} Sensitive subjects usually have positive skin tests and RASTs to extracts of the offending shellfish. In one study, five patients were monospecifically allergic to limpet and presented with symptoms of severe asthma after ingestion; 43 other patients in the study were cross-reactive to several species of shellfish and showed a range of allergic symptoms after ingestion.^[18] Another study noted that all six limpet-allergic subjects developed severe bronchospasm as their primary symptom after ingestion.^[16] The major IgE binding proteins of grand keyhole limpet appear to have molecular weights of 38 and 80 kD.^[73] Another research group^[72] found a unique 49-kD major IgE binding protein (*Hal m 1*) and another component of 38 kD that bound IgE in abalone. Although most subjects in the study (38) had immediate reactions to abalone, 13 had delayed (up to 7 hours) reactions after ingestion. Only 17 of these sera were positive by RAST to abalone. The abalone-allergic subjects primarily had bronchial symptoms, and those reporting delayed reactions predominantly showed respiratory and cutaneous symptoms.

Snail

In a study of 10 subjects allergic to snails, eight experienced bronchial symptoms, and six reported no skin or GI symptoms. All subjects could ingest cephalopods and bivalves without adverse reaction.^[27] In another study, asthma symptoms were reported after ingestion of snails by 15% of the subjects, and six different IgE binding protein bands, with molecular weight of 12 to more than 66 kD, were found in boiled snail extract. Keyhole limpet hemocyanin did not provoke cross-reactive responses in these subjects. Specific IgE binding was exhibited to bands at 12, 15, 24, and 66 kD, but these peptides were not characterized further.^[4] Many reports of severe anaphylactic reactions to snails involve bronchial symptoms and previous sensitization to dust mites (see Seafood-Insect Cross-Reactions).

Horned Turban Mollusk

One study has reported the major allergen of the gastropod *Turbo cornutus*, a horned turban mollusk and popular food item in Japan. The major allergen, *Tur c 1*, was identified as a tropomyosin of 35 kD. However, *Tur c 1* has an IgE binding epitope in the c-terminal region that is dissimilar to those in *Cra g 1* (oyster) and *Pen a 1* (shrimp).^[50] *T. cornutus* also causes exercise-induced anaphylaxis.^[52]

Shellfish Cross-Reactions

Shrimp-sensitive patients often report clinical histories of allergic reactions to several species of crustacea.^[100] Clinical and in vitro evidence for cross-reactions has been shown between mollusks and crustacea.^[58] ^[59] ^[60] ^[100] Leung et al^[65] found that IgE from subjects who were anaphylactic to shrimp recognized proteins from other

1335

crustaceans and also mollusks; tropomyosin was determined to be the cross-reactive allergen. In a study of crustacea-sensitive subjects, specific IgE binding was observed to six crayfish components and four spiny lobster components.^[42] One study found clinical association between clam and mussel, but not among clam and mussel and crustacea.^[18] No association was found between in vitro IgE binding and clinical history for shellfish. Squid-allergic IgE is cross-reactive with other mollusks.^[15] Clinical association can occur within the same and different phyla, reflecting common allergenic epitopes.^[18] The presence of IgE to unique and shared class allergens may explain an individual's clinical sensitivity to one or more members of a class.

Seafood-Insect Cross-Reactions

Insects belong to the Arthropoda, as do the crustacea. Patients allergic to chironomids (nonbiting midges) also often demonstrate positive skin tests to crustacea. Chironomid extracts have been found to inhibit RAST with shrimp, and vice versa,^[36] although other researchers report low cross-reactivity.^[105] Allergic reactions were reported among aquarists and fish-food factory workers when exposed to chironomids.^[68] Symptoms reported most often were conjunctivitis, rhinitis, asthma, and urticaria, and other reports indicate atopic dermatitis on exposure to chironomids in pet foods.^[104] The invertebrate hemoglobin (erythrocrucorin) molecule might be involved in the reported cross-reactivity of caddis fly and mollusk allergy. It is a potent allergen for chironomid-allergic individuals, and serum from caddis-sensitive persons in one study reacted with a component of similar molecular weight in mollusk and bee venom extracts.^[57] Thus individuals exposed to caddis fly antigens could develop allergic reactions during their first exposure to shellfish or their first bee sting.

Tropomyosins may be the major cross-reactive allergens between insects and shellfish. Shared antigenic and allergenic determinants between shrimp *Pen a 1* and fruitfly extract have been found, with *Pen a 1* sharing 87% homology with fruit fly tropomyosin.^[25] In vitro IgE cross-reactivity has been found between boiled Atlantic shrimp and the

German cockroach,^[21] showing binding in both types of extracts between 30 and 43 kD. Leung et al^[65] found that IgE from shrimp-allergic subjects bound to a 38-kD band in grasshopper, cockroach, and fruit fly preparations.

Castillo et al^[18] found an unexpectedly high prevalence of cockroach sensitivity among limpet-allergic subjects sensitive to crustacea and cephalopods. Crustacea and cockroaches are arthropods, but limpets are cephalopods and are less closely related, so this observation is most likely not caused by cross-reactive IgE, but by concomitant allergies. In six individuals with anaphylactic reactions to limpet, five experienced severe systemic reactions during dust mite immunotherapy. Since the limpet filter-feeds on sea mites and other small animals, the limpets could be contaminated with mites and thus cause a reaction.^[16] However, no mite allergen was found in the limpet extracts used. No significant cross-reaction occurs between abalone and dust mites.^[72]

Cross-reactions may be serious between mites and snails because severe reactions to snail ingestion are common in persons allergic to dust mites.^{[26] [41] [98] [99]} The sensitizing agent may be the dust mite for most snail-allergic patients.^[97] Allergy to snails may have been induced in individuals receiving immunotherapy for treatment of dust mite allergy; IgE from the subjects was cross-reactive for snails. Large increases of in vitro IgE reactivity to shrimp and snail were observed in some patients, and two patients developed oral symptoms after eating shrimp. The IgE response to mite allergens did not increase. The average IgE response to snail increased, and two of 17 patients converted from negative to positive for snails.^[97] Mite-allergic patients had no IgE reactivity to tropomyosin, but shrimp-allergic patients possessed IgE against mite extract,^[103] and tropomyosin appeared to be a major allergen for this latter group.^[97] However, tropomyosin was not found to be the major cross-reactive allergen in snail-allergic subjects.

Chapter 56 - Submersion Incidents

Andrew B. Newman

A man who is not afraid of the sea will soon be drowned, he said, for he will be going out on a day he shouldn't. But we do be afraid of the sea, and we do only be drowned now and again.

John Millington Synge, *The Aran Islands*

Humans' ancestral home was the water, and we are often drawn back to the aquatic environment. Three fourths of our planet's surface is water, and the earliest records of human perception of life in and under the oceans indicate both fascination and fear. In eighteenth-century Europe, sudden death by drowning sparked the interest of humanitarians, who thought actions could be taken to restore life. The incidence of drowning on commercial waterways was probably high, since roads were nearly nonexistent and swimming as recreation was unknown among the general populace. Drowning became a significant public health issue.^[11] In response to this fashionable humanitarian cause, the Society for the Recovery of Persons Apparently Drowned was formed in 1774. Their activities included research, public education, and treatment of victims. The organization survives today as the Royal Humane Society.^[109] Techniques for resuscitating drowning victims developed after groups with a special interest in the problem of drowning were established. A 1796 work describes mouth-to-mouth ventilation and tactile endotracheal intubation.^[97]

During the 1990s, greater understanding of the pathophysiology and natural history of submersion incidents has allowed revised approaches to therapy, confirmed the importance of immediate care to eventual outcome, and permitted adoption of more

optimistic medical attitudes. [\[53\]](#) [\[167\]](#)

PREVENTION

Prevention is as important as any action that can be taken after drowning or near drowning. Anyone who will be on or near the water should have swimming, rescue, and lifesaving skills, including a working knowledge of cardiopulmonary resuscitation (CPR). Prevention of near drowning must focus on several areas ([Box 56-1](#)). Water sport participants need to maintain adequate health and training for their possible levels of performance. Water knowledge includes readiness for an accident and self-assessment of skills. Open water activities should always be done with partners and with plans for self-rescue. Careful attention to the location, weather, and environment before the initiation of aquatic activities can prevent harmful events.^[53]

Swimming pools should be completely enclosed by a 5-foot fence with self-closing and self-latching locks above the reach of small children. Lifesaving equipment should be close at hand. Every pool should be equipped with a life preserver and a long pole for rescue attempts.^[129]

Parents should always be present to supervise children when they are in the water. After swimming, children should be dressed in clothing to discourage unsupervised returns to the swimming area. Children in families that have a pool or anticipate water-oriented vacations should have early swimming lessons.^[92] People prone to syncope or seizures should always be with someone when in or near the water. In addition, even a little alcohol may prove fatal in the marine environment.

Everyone on a boat or raft should have a U.S. Coast Guard-approved life vest or life jacket that will support the person with the head above water, even if the person becomes unconscious. Travelers on water should be aware of lifeboat and raft availability. Courses on safe boating, rescue, and navigation are offered by the local Coast Guard.

Emergency medical services (EMS) systems in areas with lake, river, or ocean access should consider adopting a plan for a water rescue unit prepared to respond and deal immediately with accidents. These units include improved boat access and paramedics who are master divers.^[233]

Physicians may help in their local areas by increasing drowning awareness among their patients or by teaching community-based CPR or emergency care classes.^[132] Medical schools may be able to improve preventive care by increasing education on drowning during training. Physicians should provide drowning prevention instruction and materials to all their patients with children or who engage in water-related activities.^[168]

TERMINOLOGY

Thirty-five years ago in a classic monograph on drowning, David Green succinctly summarized the problem:

1341

drowning is the process by which air-breathing animals succumb on submersion in a liquid. In the evolutionary process, water-living species adapted to terrestrial life, lost their ability to breathe under water, and became susceptible to drowning.^[85] *Near drowning* is a term introduced by Modell^[146] to indicate submersion with at least temporary survival.

*Modified from Near drowning:
forty-seventh workshop of the Undersea
and Hyperbaric Medical Society,
Kensington, Md, 1997, the Undersea and
Hyperbaric Medical Society.*

Drowning syndromes comprise the continuum from minimal aspiration of water to overwhelming lung injury and death. Several terms are used to describe different points in the continuum.^[55] ^[127] *Delayed drowning* or *secondary drowning* occurs when a victim appears to have survived an episode but then subsequently dies from respiratory failure (adult respiratory distress syndrome, or ARDS) or infectious complications that often originate with pneumonia. Submersion incidents or near drowning may also be classified with modifiers about aspiration of water or other liquid. Postimmersion syndromes include illnesses that occur after an immersion episode.

The use of a more neutral term without the implication of time, prognosis, or retrospective analysis is necessary to avoid confusion and to simplify classification. A person who is adversely affected by being submersed in water has experienced a *submersion incident*. The term is descriptive, implies no particular prognosis, and can therefore be used in immediate care without the considerations of time or outcome.

A new classification is based on severity of disease, and with the following six

categories of illness focusing on the pulmonary findings on clinical examination:

Grade 1: normal examination with cough

Grade 2: rales in some fields

Grade 3: acute pulmonary edema

Grade 4: pulmonary edema with arterial hypotension

Grade 5: isolated respiratory arrest

Grade 6: cardiopulmonary arrest

In conjunction with this classification system, 1831 drowning cases were analyzed to show an increase in mortality from 0% with grade 1 to 93% with grade 6.

INCIDENCE

It is difficult to estimate accurately the total number of submersion incidents, since such accidents are not reportable. Two of the largest and most densely populated countries do not report statistics to the World Health Organization (WHO), and little has been written about the morbidity of persons after submersion.^[56] Retrospective studies are beginning to quantify the problem and suggest directions for prevention and management. Drowning is second only to motor vehicle accidents as the most common cause of accidental death. In states with seat belt laws, drowning has become the leading cause of accidental death in children.^[28]^[29]^[143] An estimated 140,000 deaths occur worldwide annually from drowning.^[138]^[187] Of an estimated 80,000 submersion incidents, 9000 deaths occur each year in the United States.^[40] These statistics probably underestimate the problem, since many incidents are unreported or classified in other categories, such as motor vehicle accidents, acute illnesses, and suicide.^[15] Drowning kills mainly the young; 64% of all victims are less than 30 years of age, and 26% are under age 5.^[73]^[171] The incidence of near drowning may be 500 to 600 times the rate of drowning.^[113] Submersion incidents increase in areas with abundant recreational waterways, although the home swimming pool or even the bathtub can be the site of a lethal event. Recent catastrophic natural disasters, such as floods and tsunamis, have drawn media attention to drowning as a cause of death.

RISK FACTORS

The problem of submersion incidents can often be related to risk factors ([Box 56-2](#)) or to certain behaviors or groups. This is particularly true of children.^[180] Understanding these factors can help in planning and instituting preventive measures and practices.

Age

Age appears to be an indicator of risk. Drowning is a young person's accident. The most important age

1342

group is toddlers, with children under 1 year of age having the highest drowning rate, followed by teenage males.^[107] In 1989, 1200 deaths occurred in the 10- to 19-year-old group.^[204] In a survey of 9420 primary school children in South Carolina, up to 10% of children under age 5 experienced a "serious threat" of near drowning.^[213] The highest risk of near drowning is in the age group of 15 to 24 years, and the lowest risk is in persons over age 65.^{[27] [28] [193] [199] [220]}

Box 56-2. FACTORS COMMON TO DROWNING INCIDENTS

Age: toddlers, teenage boys

Location: home swimming pools

Gender: males predominate in every age group

Race: black children most at risk

Drugs: particularly alcohol

Trauma: secondary to diving, falls, horseplay

Toddlers are at risk because of their inquisitive nature and because they are often unsupervised, especially at home. Children frequently drown while bathing with a younger sibling without an adult present.^[107] The high risk of a submersion incident among teenage boys reflects their mobility and adventuresome nature and the absence of adult supervision. The low risk of a serious submersion incident in the older age group reflects decreased exposure to water environments, increased experience, and mature judgment.

Gender

Males predominate among drowning victims. In all age groups, males account for more than half of cases, with a male-to-female ratio of 12:1 for boat-related drownings and 5:1 for non-boat-related drownings.^[10] For males the peak drowning incidence occurs at age 2 years, decreases until the age of 10, and then rises rapidly to a peak at age 18. The incidence in females peaks at age 1 year, then falls off and does not rise again.^{[10] [60]}

A study of aquatic activity participation in 3042 households suggests that males may be more at risk for drowning because of higher exposure rates to aquatic activities, higher alcohol consumption while at the waterfront, and more risk-taking behavior.^[103]

Location

Drowning, that is, death by asphyxia resulting from submersion, is not necessarily a recreational accident. Incidents and deaths occur not only in the backyard swimming pool and in the ocean, but also in the unsupervised bath and the cleaning bucket.^{*} In rural areas, having a home well increases by sevenfold the risk of a young child drowning. Water barrels, courtyard pools, and underground cisterns are also hazardous sites.^[26] A survey of deaths in California from drowning in 1993 showed that they resulted in \$5.2 million in hospital charges.^[61] The location of the submersion incident is often determined by the geography and social aspects of the community. In water-oriented areas such as Florida, California, and Australia, submersion incidents are common year-round and often occur in home swimming pools. The great majority of drowning deaths in children under age 4 years occur at home.^[199]

Domestic swimming pools are especially dangerous, particularly for young children. Approximately 300 children drowned in home swimming pools in the United States in 1981, and in 1983 about 2000 children were seen in emergency departments after submersion incidents.^[228] Two of three victims of swimming pool drownings were under 3 years of age. Whereas black children tend to drown in lakes, canals, and quarry sites, white children die more frequently in backyard swimming pools. Public or motel pools are implicated infrequently. Despite ordinances defining safe operation of home swimming pools, safety features may be faulty or ignored. Although all but 3% of home swimming pools in a Florida community were properly fenced and protected, 70% of the locks were found to be unfastened or nonfunctioning.^[199] In a study of 700 pool owners in Florida, more than 40% did not know how to perform CPR.^[129] In an Australian study of drowning incidents, only 1 of 66 swimming pool barriers was considered adequate, and in 76% of the incidents there was no fence.^[187] The risk of drowning is almost 4

times greater in unfenced pools.^[185] The level of water in the pool may be important in the etiology of some deaths. The average distance from the water to the poolside lip is 12 to 14 inches (30 to 35 cm). This distance provides a significant barrier to young children who have fallen into a pool; they may reach the side but be unable to pull themselves out of the water. Some recommend raising the level of water in swimming pools.^[199]

Illegal immigrants who attempt to enter countries by crossing canals or bodies of water at night to escape detection are also at extreme risk for drowning episodes.^[1]

Although the incidence of drownings tends to be greater in coastal communities oriented to large bodies of water and the aquatic environment in general, most surveys indicate that drownings in salt water are relatively rare. Notable exceptions to this are in cold water fishing communities, such as in Alaska, Nova Scotia, Maine, western New Zealand, and the North Sea, where the annual fatality rate may be as high as 415 drownings per 100,000 fisherman.^[165] ^[211] Submersion incidents that do not result in death or even in hospitalization may be common in these communities.^[187] In my

*References ^[108] ^[110] ^[114] ^[137] ^[182] ^[214] .

experience, this is particularly true in Australia and California. This may be a result, at least in part, of effective surveillance and rescue efforts at public beaches by lifeguards and surf lifesaving societies.^[138]

Race

Evidence shows that race is a factor in the increased risk of exposure to submersion incidents, particularly in children. The incidence of both drownings and near drownings appears to be greater in black children. The drowning rate of black male children has been estimated to be as much as 3 times that of white males.^[212] In the United States, unsupervised swimming or accidental falls into unattended canals or quarries accounted for a large percentage of deaths in black males.^[199] Such statistics probably reflect socioeconomic conditions in the affected communities.

Ability to Swim

The ability to swim does not appear to be consistently related to drowning rates unless gender differences are considered. White males have a higher incidence of drowning than white females but reportedly have better swimming ability. On the other hand, black females are reported to have the lowest swimming ability but a very low rate of drowning.^[212] In Florida, nonswimmers or beginners accounted for 73% of drownings in home swimming pools and 82% of incidents in canals, lakes, and ponds.^[199]

Parental example is an important determinant of whether children can swim. Children

whose parents can swim are most likely to be strong swimmers; those with parents who cannot swim are likely to be nonswimmers. Parents of white children are much more likely to be swimmers than are the parents of black children. ^[212]

Drugs

Alcohol is the chief drug implicated in submersion incidents; the danger of its use in the aquatic environment cannot be overemphasized. ^[20] ^[135] An Australian study reported that 64% of males who drowned had measurable levels of alcohol in blood samples taken after death, and 53% of those over age 26 had blood alcohol levels greater than 100 mg/dl. ^[187] Although it cannot be stated definitively that alcohol was the cause of these tragedies, the common association of intoxication with drowning argues strongly against the use of alcohol near the water. ^[51] Despite the sobering statistics, a Massachusetts survey revealed that 36% of men and 11% of women had consumed alcoholic beverages during their most recent aquatic activities. ^[2] ^[102] Loss of judgment from use of intoxicants most likely explains the frequent association with drowning incidents. In addition, alcohol increases heat loss, decreases laryngeal reflexes, and increases the incidence of vomiting—all factors that worsen the prognosis in submersion incidents. ^[56] Drugs such as phencyclidine (PCP), lysergic acid diethylamide (LSD), and marijuana alter the sensorium, increasing the risk of accidents in the water. Up to 30% of adult drownings occur because of boating accidents in which occupants demonstrated poor judgment: overcrowding, speeding, use of boats for purposes not intended, failure to wear life jackets, and reckless handling of the craft. The incidence of drug use in these episodes is not known, but it can be assumed that intoxicants play a role in many such accidents. ^[51] ^[187]

Underlying Disease or Injury

Underlying injury or illness can account for loss of life in the water. Hypoglycemia, myocardial infarction, cardiac arrhythmias, depression and suicide, and syncope predispose to drowning incidents. ^[30] ^[77] ^[196] ^[209] Persons with a history of seizures must be supervised at all times while on boats or swimming and should be encouraged to shower (not take a bath) in a nonglass cubicle in an unlocked bathroom. ^[47] ^[117] ^[174] A search for an underlying cause of the tragedy should be made, particularly in persons who are evaluated in the hospital after rescue.

Cervical spine injuries and head trauma should be suspected in all unwitnessed incidents, particularly in those involving surfers and in victims found near diving boards or rafts in shallow water. Possible damage to the cervical spine should be a consideration in both immediate on-scene and ED management.

Child Abuse

Attention has been drawn to the problem of submersion incidents as a manifestation of child abuse. All suspicious incidents must have a thorough social service and legal investigation consistent with the laws of each community. ^[86] ^[121] ^[126] Frequently, however, this does not occur. In a study of 95 drownings and near drownings in Seattle, only 28% of the cases had a social service evaluation, and only eight drownings were

reported to children's protective services.^[65] A study of children sustaining bathtub near drownings between 1982 and 1992 found that 67% had historical or physical findings compatible with a diagnosis of abuse or neglect.^[125] Child abuse should be considered in any bathtub child drowning unless epilepsy or a developmental problem is present.^[118] Children who have been previously abused are also much more likely to be purposeful drowning victims.^{[75] [210]}

Hypothermia (see [Chapter 6](#) and [Chapter 8](#))

Recent reports of victims surviving after submersion periods of as long as 30 minutes in very cold water have elicited medical and lay hypotheses regarding survival after prolonged submersion.^{[30] [57] [104]}

1344

Drowning may result directly from hypothermia.^{[36] [100]} Experiences with persons shipwrecked even in relatively warm water have shown that the body temperature of victims can be lowered to the point at which hypothermia threatens survival. Thermal conductivity of cold water is approximately 25 to 30 times that of air.^{[100] [126] [128]} Water at 33° C (91.4° F) is thermally neutral, the point at which heat loss equals heat production for a swimmer without clothes. Any water colder than this will lead to ongoing heat loss. Thus, in very cold water, hypothermia may ensue rapidly and lead to drowning. This is particularly true in children, who have less subcutaneous fat and relatively greater body surface area than adults.^[126] Cooling may occur by a combination of conductive heat loss directly into the water and circulatory cooling from chilled venous blood returning to the circulation. Survivors of a Canadian boating tragedy painted a vivid picture of the effects of hypothermia that resulted in the deaths of an instructor and 12 of his students: "Gradually we could feel the sensation going out of our limbs, and we heard some of the boys starting to get paranoid about being in the water ... Some started to talk nonsense and then, one by one, their voices faded away as they lost consciousness."^[227]

Death in submersion-associated hypothermia can be attributed to the basic mechanisms discussed next.

Immersion Syndrome.

Immersion syndrome is defined as cardiac arrest secondary to massive vagal stimulation.^{[78] [115] [126]}

Excessive Fatigue and Confusion.

The combination of hypothermia, exertion, panic, and confusion leads to poor judgment, which causes victims to endanger themselves further by swimming away from help, leaving an overturned canoe, or misjudging the distance to shore.

Direct Hypothermia.

At or below a core temperature of 28° C (82° F), ventricular fibrillation is a real risk^[93] ^[160] ^[219] (see [Chapter 6](#)). It has been estimated that at a water temperature of 0° C (32° F), the victim of submersion cannot survive for more than 1 hour; at a water temperature of 15° C (59° F), survival is not common after 6 hours.^[35] ^[76] However, several Canadian cases temper blind acceptance of any particular dogma. In one incident, a pilot and passenger ditched their plane into a lake on final approach to an island airport.^[142] Air temperature was 2.2° C (36° F) and water temperature 4° C (39.2° F). Both men were similarly clothed and in the water for 60 minutes before being rescued. The passenger, a 48-year-old man, weighed 101 kg, was 190 cm in height, and had a core temperature of 32° C (89.6° F) on admission to the hospital. He was alert, complained only of being cold, was actively rewarmed, and left the hospital the next day. The pilot, a previously healthy 38-year-old man, was of medium body habitus and had little subcutaneous fat. He was admitted to the same regional trauma unit in ventricular fibrillation with a core temperature of 29.1° C (84.2° F). Despite core rewarming and vigorous resuscitative measures over 4 hours, he could not be revived. In view of the identical environmental conditions, clothing worn, and time in the water, the authors concluded that skinfold thickness was the most important discriminating factor in the outcome.^[149]

A second case illustrates that preparation and protective clothing may lengthen survival time in cold water.^[141] A married couple, both experienced sailors, began to take on water in their boat about 11 km from shore in a Canadian lake.^[226] The boat sank after 40 minutes, during which time they were able to prepare for abandoning ship by lashing together life preservers and donning heavy parkas and special survival gear carried in the boat. The month was August, but a storm had developed with gale-force winds of 60 km/hr and high waves. Water temperature was estimated to be 18° C (64° F). Both persons spent over 18 hours in the water before rescue and helicopter transport to the regional trauma unit. Both were mildly hypothermic on admission; the husband's rectal temperature was 32° C (89.6° F), and the wife's was 36.4° C (97.5° F). Both were discharged the next day without complications, with survival attributed to survival preparedness and protective clothing.

In victims kept afloat by life preservers or other means, death may result directly from hypothermia. Although some people may appear to be dead after rescue, efforts to resuscitate and rewarm them may be rewarded with recovery. Still, the absolute effect of hypothermia on eventual survival after a submersion incident remains in doubt. In certain cases, hypothermia appears to be protective, as in the case of the Norwegian child who survived neurologically intact after being rescued from an ice-laden stream in which he had been submerged for 40 minutes.^[217] His temperature on admission to the hospital was 24° C (75° F), and after 1 hour of resuscitation, spontaneous circulation returned. He was discharged from the hospital 8 days later. Similar cases have involved submersion under ice with eventual survival.

Orlowski^[171] reviewed the world literature on prolonged submersion with good outcomes. He reported 17 victims, most of whom were younger than 19 years of age and male. He concluded that no one factor correlated well with outcome. These factors included water

temperature, core temperature, rewarming techniques, and duration of resuscitation. He further cautioned against assuming a good prognosis in victims submerged in very cold water, citing several cases of children who, despite hypothermia and appropriate

treatment, had poor outcomes.^[238] Some children may survive after long periods of submersion in very cold water because the "diving reflex" present in lower mammals may be operative.^{[37] [79] [141]} The mammalian diving reflex, especially impressive in seals, slows heart rate, shunts blood to the brain, and closes the airway. However, recent evidence suggests that the diving reflex present in seals is active in only 15% to 30% of human subjects. This response, with its potential for improved brain circulation, may be a significant factor in why some persons survive and others drown.^{[80] [91]} After a study of breath-holding and bradycardia in children and adults, one group concluded that the diving reflex in children is weak and may not contribute significantly to survival after cold water submersion.^[192]

Immersion in cold water may lead quickly to hypothermia because of surface heat loss and core cooling. In addition, swallowing or aspiration of cold water may contribute to rapid cooling.^{[91] [171]} Rapid onset of hypothermia during freshwater drowning may result from core cooling from pulmonary aspiration and rapid absorption of cold water. Significant cerebral cooling is therefore likely before cessation of circulation.^[38]

If the diving reflex is discounted, the most likely explanation for survival after prolonged submersion in cold water is that rapidly induced hypothermia reduces tissue oxygen demand and protects the brain. Catecholamine release may be blunted in victims who quickly become hypothermic in very cold water, lessening the propensity to ventricular fibrillation that accompanies warm water submersion incidents.^[171] Muscle movement is probably less in persons exposed suddenly to very cold water, further reducing oxygen demand.

In contradistinction to the possible protective effect of hypothermia in submerged victims, hypothermia can create serious problems for the victim struggling to survive in cold water. Specific patterns of heat loss can be demonstrated in subjects placed in water at temperatures as low as 4.5° C (40.1° F).^[35] In these studies, thermograms have graphically recorded heat loss from various parts of the body, demonstrating preferential loss from the head and neck (up to 50%), thoracic cage, and inguinal area. Movement of any kind increases heat loss.

Collis^[35] compared several options available to victims faced with the dilemma of cold water survival. He concluded that methods of survival that require much movement would be "suicidal" and, based on the observations of heat loss, devised preferred means of conserving body heat while immersed in cold water. These methods have been approved and adopted by the U.S. Coast Guard (Department of Transportation).

As summarized in [Figure 56-1](#) , treading water, swimming, and drown-proofing all

resulted in reduced survival time (less than 2 hours) at a water temperature

Figure 56-1 Survival times in cool (10° C [50° F]) water using various techniques in several situations. (Data from Collis ML: *Survival behaviour in cold water immersion*. In *Proceedings of the Cold Water Symposium, Toronto, 1976, Royal Life-Saving Society of Canada.*)

Figure 56-2 Heat escape lessening posture (HELP). (Courtesy Alan Steinman, MD.)

of 10° C (50° F). Survival time was estimated to double if victims assumed a position designed to protect areas of body heat loss. In this position, termed the *heat escape lessening posture* (HELP), the arms are folded across the chest and pressed to the sides, the knees are drawn up to the chest, and the legs are crossed at the ankles. In this position the victim attempts to keep still, maintaining the head out of water. To assume this position, the victim must be wearing a life jacket ([Figure 56-2](#)). When this position was tested on members of the swim team at the University of Pittsburgh, they reported it as fatiguing at best.

If two or more persons are in the water, the *huddle position* is recommended to lessen total body heat loss. Since children become hypothermic much more quickly than adults, they should be placed in the middle

1346

Figure 56-3 Huddle technique. (Courtesy Alan Steinman, MD.)

of the huddle. In this position, life jackets are tied behind the back to press together the groin and lower body regions ([Figure 56-3](#)).^[35]

Because hypothermia alters the therapeutic approach to victims of submersion incidents, core temperatures should be determined in all potentially hypothermic victims brought to the ED. Resuscitation efforts must persist until normal core temperature is approached.^{[176] [219]} No decision on survival should be made until the patient is nearly euthermic (see [Chapter 6](#) and [Chapter 8](#)).

Type of Water

Drowning may occur in almost any type of fluid, and victims of submersion may aspirate salt or fresh water, sewage, wash water, or tap water.^{[41] [155] [156] [225]} Most victims aspirate impurities or foreign materials, including algae, bacteria, sewage, chemicals, and sand.^[82] In animal experiments the osmolarity of water has been shown to cause biochemical changes in nonsurvivors. Although the difference between saltwater and freshwater submersion is not of immediate clinical importance, knowledge of the effect of aspiration of several kinds of fluids helps in the interpretation of laboratory and clinical findings.^[201]

Theoretically, the changes that occur after aspiration of salt water and fresh water should be different, and the biochemical abnormalities secondary to such aspiration should play a role in management. This has not proved to be the case. The amount of water aspirated, not the type, is of prime importance.^{[32] [153] [155] [156]}

Orlowski et al^[173] studied pulmonary injury and the ability to resuscitate dogs after "drowning" produced by instilling fluids of varied tonicity into the lungs. The six fluids used were sterile water and 0.225%, 0.45%, 0.9%, 2%, and 3% sodium chloride solutions. Each of these solutions was tested with and without additional chlorine. The dogs were anesthetized, intubated, and ventilated with room air; 20 ml/kg of each fluid was instilled into the endotracheal tube, which was then clamped for 5 minutes before resumption of ventilation with 100% oxygen and 10 cm of positive end-expiratory pressure (PEEP). Three control dogs were made anoxic for 5 minutes by occlusion of the endotracheal tubes, without fluid instillation.

When judged by the effect on pulmonary variables (A-a oxygen pressure difference, intrapulmonary shunt fraction, and P_{aO_2}/F_{IO_2} ratio), the 0.225% saline solution was less disruptive to lung function, particularly when compared with sterile water, with or without chlorine. Sterile water was found to be the most damaging to the lungs, whether chlorinated or not. No differences between solutions were seen in the ability to resuscitate dogs with cardiac arrest. The authors suggested that swimming pool water be salinated to 0.225% normal sodium chloride solution to reduce pulmonary injuries of persons who suffer submersion injuries. These studies clearly indicate that the cardiovascular changes that occur with drowning are really from anoxia and do not depend on tonicity of the aspirated fluid.^[175]

Freshwater Aspiration

Freshwater is hypotonic to plasma and passes readily out of the alveolus into the

circulation. Theoretically, if a sufficient volume is aspirated (more than 22 mg/kg), blood volume can increase and hemolysis can result. Hemolysis, along with hypoxia, can lead to hyperkalemia, high levels of circulating free hemoglobin, and lowered hematocrit value. Expansion of blood volume caused by fluid shifts from the alveoli to the intravascular compartment lowers the concentrations of serum sodium chloride, calcium, and magnesium.^{[155] [156]}

Hypokalemia has also been reported,^[69] but this may be caused by other factors, such as administration of epinephrine, glucose, and bicarbonate during resuscitation.^[34] Despite theoretic changes, few near drowning victims (survivors) have electrolyte abnormalities serious enough to warrant therapy. In survivors of a submersion injury, biochemical and blood volume changes are corrected quickly and should be considered transient.^{[149] [153] [201]} Management efforts in both freshwater and saltwater submersion should be directed primarily toward the effects of aspiration on the lungs.

Aspiration of fresh water induces pulmonary changes, the most important of which is the washout of surfactant.^[159] This leads to atelectasis, with consequent ventilation-perfusion imbalance and hypoxia.^{[151] [157]} In addition, direct destruction of alveolar cells may lead to accumulation of fluid within the lungs and decreased compliance. Thus the overwhelming insult in the initial management of submersion injury is hypoxia.

Seawater Aspiration

Seawater has an osmolarity three to four times that of blood. Aspiration of this hypertonic fluid results in a rapid shift of plasma fluid into the alveoli and interstitial spaces of the lung parenchyma, resulting in severe pulmonary edema.^{[32] [126] [151] [156]} Theoretically, loss of fluid from the circulation should produce a blood volume decrease and rise in serum electrolytes because of high concentrations of sodium, potassium, and magnesium in seawater. However, as with freshwater aspiration, electrolyte changes do not appear to be important in the early management of submersion casualties.^{[149] [171]}

Unusual exceptions to this rule occur. Near drownings from bodies of water with high electrolyte content, such as the Dead Sea, are characterized by significant changes in concentrations of serum electrolytes, particularly calcium and magnesium. Yagil et al^[236] confirmed these findings and a high mortality rate (50%) in eight treated patients. Experts still stress the importance of hypoxia and pulmonary injury caused by aspiration in the deaths of all victims of submersion.^{[148] [179]}

In a case of seawater aspiration, pulmonary edema results quickly, with outpouring of protein-rich fluid into the alveoli and interstitium, reduction of compliance, and direct parenchymal damage.^[159] Hypoxia and metabolic acidosis remain the immediate concerns.

Contaminants

Most water in which submersion incidents occur contains chemicals, contaminants, or particulates that may produce further pulmonary injury.^{[100] [151]} Calcium salts, frequently used near oil drilling equipment, may render near-drowned divers hypercalcemic.^[70] Although some maintain that pool water containing chlorine may be irritating to the tracheobronchial tree, animal studies indicate that the hypotonicity of the fluid, rather than the chlorine, causes the damage.^[173] Water contaminated with chemical wastes, cleaning solvents, detergents, or disinfectants may induce further fluid accumulation in the already edematous lung.^{[155] [214]} Inhalation of mud, sand, and other particulates may require bronchoscopy to cleanse the airway. Although uncommon in survivors, "sand bronchograms" have been described on chest films and computed tomography (CT) scans of surfers and others who aspirated radiopaque calcium carbonate sand.^{[19] [54]}

Persons submerged in fresh water may be exposed to microbes, such as *Aeromonas hydrophila*, that are resistant to common antibiotics.^{[132] [136] [139]} In patients who develop lung infection, culture and sensitivity testing is essential to identify the causative agents and to choose the appropriate antibiotic(s).^{[63] [64] [195]} Cerebral infection with *Pseudallescheria mycosis*, as well as disseminated aspergillosis, has also been reported as a complication of near drowning.^[202] [Table 56-1](#) provides an extensive list of possible pathogens.^{[24] [53]}

TABLE 56-1 -- Organisms Associated with Infection in Near Drowning Victims*

	TYPE OF WATER
BACTERIA	
<i>Klebsiella oxytoca</i>	FW
<i>Herellea</i> spp.	FW
<i>Neisseria meningitidis</i>	FW
<i>Pseudomonas aeruginosa</i>	FW
<i>Listeria monocytogenes</i>	FW
<i>Plesiomonas shigelloides</i>	FW
<i>Edwardsiella tarda</i>	FW
<i>Chromobacterium violaceum</i>	FW
<i>Aeromonas hydrophila</i>	SW, FW
<i>Escherichia coli</i>	SW, FW

<i>Pseudomonas putrefaciens</i>	SW
<i>Francisella philomiragia</i>	SW
<i>Vibrio parahaemolyticus</i>	SW
FUNGI	
<i>Pseudallescheria boydii</i>	FW
<i>Aspergillus fumigatus</i>	FW

Modified from Brown SD, Piantadosi CA: Near drowning: hospital management. In Near drowning: Forty-seventh workshop of the Undersea and Hyperbaric Medical Society, Kensington, Md, 1997, the Undersea and Hyperbaric Medical Society.

FW, Fresh water; SW, salt water.

*Organisms isolated from sputum or blood of clinically infected near drowning victims soon after admission. This list does not include organisms recovered from infected wounds.

CLASSIFICATION AND TYPES OF DROWNING

Death by submersion, or drowning, has historically been classified according to pathophysiology. Such classifications are usually made after the fact and are of little use in immediate management.

Wet vs. Dry Drowning

The term *wet drowning* refers to the great majority of patients who aspirate water; the lungs are wet, with pulmonary derangements resulting from the effect of the fluid. An estimated 85% to 90% of victims fall into this category.^{[100] [151] [179]} The remaining 10% to 15% do not aspirate to a significant degree and have "dry" lungs. Such *dry drowning* victims may develop laryngospasm in response to the cold water stimulus, mechanical irritation of swallowed water, or initial inhalation of fluid.^{[73] [146]} Although one might assume that victims who do not aspirate will respond better to resuscitation measures, no evidence supports this notion. The response to resuscitation depends more on rapid reversal of hypoxia than on the type of submersion injury.

1348

Acute and chronic responses of the lungs to various amounts and types of fluids may range from mild to severe, as discussed later. Persons with preexisting pulmonary disease are at greater risk for decompensation if they have a submersion incident.

Shallow Water Blackout

The phenomenon known as shallow water blackout predisposes to drowning in persons who hyperventilate before entering the water for an endurance underwater swim, a training method sometimes attempted by competitive swimmers. Hyperventilation substantially reduces arterial carbon dioxide pressure (P_{aCO_2}) without increasing oxygen storage. Vigorous underwater muscular activity may use the available stored oxygen, causing hypoxia before sufficient CO_2 accumulates in the blood to provide a stimulus to return to the surface to breathe. Without sufficient hypercapnia to stimulate breathing, consciousness can be lost because of hypoxia, and the victim may drown. Apparent shallow water blackout affected one author, who spent several days in his own intensive care unit.^[235] Another clinician warns against hyperventilation during training.^[99]

Immersion Syndrome and Diving Reflex

Immersion syndrome is sudden death after contact with very cold water, presumably a result of vagal stimulation^[78] and resultant cardiac arrest.^[115] The exact mechanism of this phenomenon is not understood, but in the past it has been attributed to the mammalian diving reflex, also present in seals and lower mammals. Investigation into the nature of this reflex was reported in the early 1960s. Cold water stimulation of cutaneous receptors appears to trigger shunting of blood to the brain and heart from the skin, gastrointestinal tract, and extremities. Bradycardia results from the reflex vagal response to increased central volume. This allows increased cerebral circulation with longer breath-holding times because of lower peripheral oxygen use. The diving reflex does not occur to the same extent in all people. Work in humans suggests that the diving reflex is part of the mechanism of survival in cold water for all near drownings and may be a significant factor for the 10% to 20% of victims who have a profound diving reflex response, helping them survive.² Studies indicate that less arterial desaturation occurs during nonexertional breath-holding in water than while not immersed and that the extent of the diving response may respond to training. Korean and Japanese pearl divers, as well as other trained breath-holding divers, exhibit more diving-related bradycardia than their nondiving counterparts.^{[6] [208] [222]} This probably prolongs breath-holding dive times.

Postimmersion Syndrome

"Postimmersion syndrome" is an unsatisfactory term referring to delayed development of ARDS, which is preceded by a relatively asymptomatic interval of several hours to several days.^[72] The term "secondary drowning" has been used to refer to delayed-onset pulmonary failure, but continued use of this term adds little to understanding submersion injury.

PATHOPHYSIOLOGY OF SUBMERSION

The effects of submersion on mammals were first reported in the scientific literature in the late 1800s. In his classic monograph, Greene noted that, "inundation of the upper airway, the bronchial tree and segments of the alveolar spaces blocks gas exchange in the lung and produces asphyxia. Thus drowning involves the rapid development of hypoxia, hypercapnia and acidosis with the associated sequence of hypertension, bradycardia, arrhythmias, hypotension, hyperpnea, apnea, and terminal gasping." Findings in animals were consistent with drowning episodes later observed in humans.^{[100] [133] [163]} The initial response in humans to submersion, particularly in cold water, includes a period of panic, accompanied by hyperventilation caused by stimulation of thermal receptors in the skin. Breath-holding may be attempted, but at some point in breath-holding, the breaking point is reached. This is the point at which no voluntary efforts will prevent respiration and is determined by both CO₂ and oxygen levels. Hyperventilation before diving or swimming may prolong this point, which is also responsible for blackout in swimmers attempting long underwater swims.^[127] Hyperventilation is usually uncontrollable by the victim and can result in aspiration of significant quantities of water. If the water is very cold, such aspiration probably hastens the onset of hypothermia and may explain the "protection" apparent in some cases of cold water immersion. Swallowing large amounts of water may lead to vomiting and subsequent aspiration of gastric contents.^{[126] [141]} This may present difficulties to initial rescuers; gastric distention may make ventilation more difficult, and regurgitation is a constant danger.

In most victims of submersion, violent struggling occurs before loss of consciousness; exercise-induced acidosis leads to greater hyperventilation and risk of aspiration of water ([Figure 56-4](#)).

The common denominator of submersion is hypoxia, caused by either laryngospasm or water aspiration. Once the victim is unconscious, all airway reflexes are abolished, and fluid is passively introduced into the airway. Cardiac arrest follows this sequence of events. Hypoxia and acidosis lead to derangements in many organ systems in victims of serious incidents.^[100]

*References ^{[80] [91] [101] [151] [171] [177] [191] [192] [223]} .

Figure 56-4 Progression of the drowning incident.

Pulmonary System

The target organ in submersion episodes is the lung ([Figure 56-5](#)). Once aspirated, water evokes vagally mediated pulmonary vasoconstriction and pulmonary hypertension.^{[33] [34]} Neurogenic pulmonary edema may also occur at this time.^[203] In cases of freshwater aspiration, fluid moves quickly across the alveolar-capillary membrane into the microcirculation, surfactant destruction or washout occurs, and high surface tensions in the lung lead to reduced compliance and atelectasis. Marked ventilation-perfusion mismatching occurs, with as much as 75% of blood flowing through hypoventilated lung tissue.^{[14] [100] [113] [159]} Seawater aspiration also leads to surfactant destruction and produces rapid exudation of protein-rich fluid into the alveoli and pulmonary interstitium, reduced compliance, and direct capillary damage.^[105] These changes usually lead quickly to serious hypoxia. In some cases of near drowning, this may not occur until hours later, when alveolitis, atelectasis, and shunting show clinical effects.

Even in survivors of near drowning, it may be days before normal ventilation-perfusion matching returns.^[127] Normal lung function depends on alveoli that expand easily with inspiration (low surface tension)

Figure 56-5 Pulmonary effects of water aspiration.

and recoil efficiently. These properties are facilitated by the presence of surfactant, a layer of fluid lining the alveolar walls. Fifty percent or more of this substance is dipalmitoyl phosphatidylcholine, a phospholipid; the rest is composed of other phospholipids and proteins. Surfactant is manufactured by alveolar epithelial type II cells, and its metabolism is under hormonal control as well as control through the interaction of β -adrenergic agonists, cyclic adenosine monophosphate, and prostaglandins.^[119] Alveolar aspiration of water appears to destroy or "dilute" pulmonary surfactant.^{[73] [74]} When the substance is absent or does not function properly, atelectasis occurs and stiff, noncompliant lungs result. The consequence in the nearly drowned patient is severe shunting and hypoxia.^[100]

An important development in the treatment of premature infants who are surfactant deficient has been instillation of exogenous surfactant through an endotracheal tube.^[71] The surfactant, which was first derived from bovine or human amniotic fluid, is now produced from artificial sources. Dramatic results have been reported, with pulmonary function and oxygenation improving within hours of treatment.^[145] Theoretically this therapy should benefit the injured lung in near drowning.^[9]

1350

Inhalation of particulate matter, contaminants, bacteria, or chemicals can produce irritation that results in more tracheobronchial fluid deposition or even alveolar destruction.^[153] ^[215] Despite the absence of direct evidence in humans, it is suspected that damage to the alveolar-capillary membrane may be produced by coagulation defects, platelet breakdown, microembolization, and other adverse effects initiated by fluid aspiration or hypoxia. Although alveolar and surfactant destruction has been emphasized in most studies, the initial pulmonary insult may be damage to the vascular endothelium rather than the alveolar cells.^[112]

Hypoxia in humans after submersion incidents is the result of fluid in the alveolar and interstitial spaces, loss of surfactant, proteinaceous material in the alveoli and tracheobronchial tree, damage to the alveolar-capillary membrane and vascular endothelium, and hypoxia-initiated central nervous system (CNS) reflex mechanisms.^[100] ^[126] ^[146] Acute respiratory failure follows, with reduced compliance and increased ventilation-perfusion mismatching, resulting in enhanced shunt.^[56] ^[100] The difference in oxygen tension between alveoli and arterial blood is increased with pulmonary failure after submersion. In normal subjects breathing 100% oxygen the difference is about 35 mm Hg; in human victims of submersion, differences as high as 600 mm Hg with 100% oxygen have been reported.^[100]

In cases of prolonged submersion or significant aspiration, pulmonary derangements occur rapidly. In lesser insults the onset of symptoms may be delayed for as long as 24 hours. This phenomenon probably represents delayed onset of the initial insult rather than severity of the injury or a different disease entity or syndrome.^[147] ^[189]

The type of water aspirated during a submersion incident may determine the extent of lung damage and degree of resultant hypoxia. In animal models, sterile water has produced the most profound changes in pulmonary function.^[84] ^[158] Isotonic sodium chloride solution (0.9%) has been shown to produce injury, but not as great as that produced by sterile water.^[173] The presence of chlorine in a concentration of 1 to 2 ppm apparently does not influence the degree of pulmonary injury or dysfunction.

Cardiovascular System

Cardiovascular derangements in cases of serious submersion injury are usually secondary to hypoxia, acidosis, or other indirect causes, rather than being caused by

actual fluid aspiration. In the past, death was thought to be caused by induction of ventricular fibrillation by electrolyte changes, but this is not the case. Cardiac dysrhythmias and depression of myocardial function are caused by acidosis and hypoxia resulting from pulmonary injury.^[89] ^[100]

Supraventricular tachycardias are common.^[56] Karch^[111] reported that the myocardia of rabbits subjected to aspiration of fresh and salt water demonstrated focal areas of eosinophilia and disruption of some myocardial elements. The lesions resembled those produced in hearts exposed to very high levels of catecholamines. Cardiac derangements seen in near drowning may result from increased catecholamines secondary to the stress of the incident.^[58] ^[111]

Management requires close observation of the cardiovascular system. A delicate balance often exists between pulmonary function and oxygenation vs. cardiac output and right-sided heart return. This has particular relevance when PEEP is used to improve oxygenation.

Central Nervous System

The end point of successful resuscitation of victims of submersion incidents once was restoration of adequate perfusion and pulmonary function. With development of more sophisticated monitoring capabilities, however, attention is now directed toward preserving CNS function and preventing further damage once vascular perfusion has been restored. "Cerebral resuscitation" is well studied, but most pharmacologic interventions are still experimental. The most important step in cerebral preservation is rapid institution of rescue measures and basic life support, without which later measures may be futile.

Insults to the CNS include hypoxia and trauma to the spine and spinal cord. A search for other causes of CNS dysfunction is mandatory in persons who remain comatose after submersion incidents. All patients should be investigated for expanding intracranial lesions secondary to trauma or for damage to the spinal cord, which may occur in surfing mishaps, in platform diving accidents, or during horseplay.

The initial insult to brain tissue is hypoxia and ischemia, but evidence suggests that tissue damage can continue after restoration of cerebral blood flow.^[40] ^[206] Dysfunction of the CNS occurs rapidly after the onset of hypoxia; flattening of the electroencephalogram takes place within 20 seconds of total cerebral ischemia. Continued CNS injury after resuscitation results from edema, elevated intracranial pressure (ICP), and increased cerebral vascular resistance, which compromise oxygenation.^[100] ^[206] Hyperpyrexia that accompanies drowning increases cerebral oxygen consumption and tissue insult.^[39] ^[40]

Methods to monitor ICP are often promoted as essential guides to the success of measures directed toward cerebral resuscitation, but this has not been demonstrated definitively. Attempts to prevent postresuscitation cerebral injury may play a prominent role in management of patients who remain comatose after serious submersion accidents.^[152] ^[154] ^[171] Magnetic resonance spectrography may help to provide treatment

indices and to help determine progress and outcome. A spectrographic

1351

prognosis index has been proposed based on ratios of metabolites.^[123] Loss of *N*-acetylaspartate and increases in glutamine/glutamate and lactate were worrisome. Generalized brain edema, indistinct lentiform nuclei margins, and basal ganglia hyperintensity were all predictors of poor outcome.

Renal System

Acute renal failure is not common in victims of submersion incidents. When it occurs, the most frequent cause is destruction of tubules secondary to hypoxia. Reduced blood flow secondary to shock and acidosis increases the incidence of renal failure.^{[100] [126]}

Metabolic Changes

Electrolyte changes in a survivor of a submersion incident do not appear to be either consistent or important in initial management. An unusual exception is near drowning in water with extremely high electrolyte concentrations, such as in the Dead Sea.^[236] Sodium concentrations are three times as high (1493 vs. 531 mmol/L) in the Dead Sea as in the Mediterranean Sea; chloride 6092 vs. 630 mmol/L; potassium 970 vs. 11 mmol/L; calcium 1709 vs. 48 mmol/L; and magnesium 6987 vs. 273 mmol/L.

Drowning in hot springs baths may also result in elevated levels of calcium from absorption of calcium in the spring water.^[134]

Elevations of potassium levels in victims who have aspirated fresh water have been ascribed to hemolysis. Few patients who survive aspirate sufficient water to pose any problem; aspiration of quantities that would cause serious electrolyte imbalance usually results in death.^{[36] [72]} This applies equally to the aspiration of fresh and salt water. Postmortem measurements of electrolytes in experimental animals have uncovered increases in serum sodium, chloride, calcium, and potassium, presumably a result of the high concentrations in seawater. Again, these problems are not seen consistently in survivors of submersion incidents.

Respiratory acidosis is the main immediate problem in patients.^{[100] [149] [171] [176]} In most patients, severe metabolic acidosis develops, in part because of pulmonary failure with resultant cellular anaerobic metabolism. Persistent acidosis depresses myocardial function and leads to lethal arrhythmias.

Hematologic Changes

Hemolysis has been described in both freshwater and saltwater aspiration, more often in the former, with levels of circulating free hemoglobin ranging from 8 to 500 mg/dl.^[155]

There is no consistent change in the level of hemoglobin or hematocrit after submersion in humans. Low values should initiate a search for underlying trauma with hemorrhage or a bleeding disorder. Disseminated intravascular coagulation has been described with submersion and aspiration.^[43] ^[100] Contributing to the genesis of this disorder are hypoxia, acidosis, sepsis, hemolysis, and low-perfusion states.

PREDICTING OUTCOME

It would be helpful to be able to predict the future course of victims, particularly those with severe injuries. Previous attempts to predict outcome were thwarted by lack of uniformity of terminology and of a standard classification of patients' conditions. Recent attempts have been more successful. The importance to eventual survival of rapid rescue and immediate CPR has been recognized by almost all authorities on the subject of near drowning.³ The extent of cerebral recovery can be related to age and gender, hypothermia, submersion time, initial resuscitation, and critical care with special measures of cerebral salvage.^{[44] [106] [170]}

Predicting the outcome of patients is based largely on initial and serial examinations of cerebral function. Orłowski^{[170] [171]} developed a "score" that, in conjunction with the Glasgow Coma Scale (GCS), permits a fairly accurate estimate of the likely outcome ([Box 56-3](#)). Unfavorable prognostic factors include young age and severe acidosis. With one or two adverse factors present, a 90% chance of recovery is indicated; three or more reduce the chances to less than 5%.

Prolonged attempts to resuscitate victims who have not been hypothermic and who did not initially have vital signs may result in more deaths or more survivors with persistent vegetative states.^[16] The importance of initial assessment to predicting outcome cannot be overemphasized. Victims who are alert on admission, are in sinus rhythm, and have reactive pupils should do well, whereas those who are in coma with absent brainstem reflexes, unreactive pupils in the ED, or a GCS score of less than 5, as well as those who have been submerged more than 10 minutes and had resuscitation durations of more than 25 minutes, have a less than 5% chance of recovery.^{[68] [80] [116] [124]}

Unconscious victims who have not regained normal spontaneous purposeful movements and brainstem functions, including pupillary light reflexes, oculovestibular reflexes, corneal reflex, and respiratory pattern, carry a grave prognosis. [\[22\]](#) [\[23\]](#) [\[31\]](#) [\[87\]](#)

MANAGEMENT

Immediate Care

The scene of the submersion incident is often characterized by general chaos. Modell^[151] notes that persons on the scene of the event rarely report seeing someone who was "flailing and screaming for help" while they "struggled to remain on the surface of the water." Instead, they found victims floating on the surface of the water or saw swimmers suddenly become motionless or dive under water and never surface. Attempts at rescue must consider the safety of rescuers so that multiple drownings do not occur. The Red Cross recommends that whenever possible, safety devices should be used to tow in the victim, or life preservers should be tossed to people in trouble before a human lifesaver actually enters the water in a boat or on a board to attempt a rescue. Well-intentioned but ill-advised heroic efforts can create additional victims and compound the tragedy.

Recovery of victims still submerged should be the responsibility of professional or volunteer workers trained specifically in water retrieval and rescue. Water rescue demands special equipment and expert personnel and may be carried out in extremely adverse circumstances, especially in winter weather^[169] ([Figure 56-6](#)). Australian studies indicate much higher levels of success in resuscitations closer to lifeguard stands.^[66] An EMS physician should be involved in consultation early during the incident, particularly when cold weather rescue and hypothermia are involved.

Until evidence shows that aggressive on-scene resuscitation does not help prevent loss of life, no effort

Figure 56-6 Cold water rescue; both victim and rescuer are dressed in wet suits.
(Courtesy Alan Steinman, MD.)

should be withheld. Prehospital care workers should be given definitive guidelines that insist on prompt application of life support to all victims of submersion unless hypothermia is not present and the duration of submersion has been long. Thus rescuers must begin resuscitative measures and present the patient to the in-hospital team, which can decide on therapy. This is especially true in the case of winter or cold water conditions. The decision to withhold or cease resuscitation attempts is rarely

made in the field, except in a remote wilderness area. Transport of the near-drowned victim from remote terrain has been made more expeditious with wider availability of helicopter evacuation.

Estimates of time under water are notoriously inaccurate when made by bystanders, parents, and even trained rescuers.^[154] The history can be crucial in this regard. In one case, rescuers delayed instituting life support to a victim of submersion in a river with a water temperature of 11.7° C (53° F).^[186] Later it was found that the initial radio message relayed from the first unit receiving the call did not include information that the woman was struggling as she floated down the river. The rescuers removing her from the water assumed she had been submerged for some time and did not begin CPR until a rhythm was detected on the electrocardiogram. The victim was hypothermic, responded almost immediately to resuscitative measures, and survived to leave the hospital.

Specific Therapy

Initial evaluation and resuscitation of any victim must include complete examination for obvious trauma, with appropriate stabilization and repeated examination. Thorough examination should minimize death from unrecognized trauma, such as ruptured spleen or fractured cervical spine. Appropriate intensive care monitoring should be part of the management routine.

The victims of submersion incidents may be classified into four groups: (1) the asymptomatic patient, (2) the symptomatic patient, (3) the patient in cardiopulmonary arrest, and (4) the obviously dead or still-submerged patient.

Asymptomatic Patient.

The patient who has experienced a period of submersion or a near drowning episode and who remains asymptomatic presents a particular dilemma. The history is of prime importance. A description of the incident, an estimate of submersion time, and the past medical history of the patient should be obtained. All patients with possible history of submersion who manifest shortness of breath (however slight) should be considered hypoxic; oxygen by simple face mask at 8 to 10 L/min should be given. It may be better to err on the safe side and administer oxygen to any patient seen in the field with a history of

submersion, regardless of the time submerged or the absence of symptoms.

It has been frequently recommended that all patients with a history of submersion be treated as if a lung insult had occurred and that admission to a hospital for a period of observation be mandatory.^{[141] [171] [195]} This recommendation is often made in the belief that in patients sustaining a near drowning episode with apparently successful resuscitation, an asymptomatic period sometimes precedes the onset of respiratory

failure, a condition termed secondary drowning. Close examination of the patients on whom this belief is based indicates that persons with significant pulmonary insults rarely fail to show signs or symptoms immediately after rescue and initial resuscitation.

In a survey of 52 swimmers who had submersion incidents on California beaches, 31 declined medical attention and left the beach.^[189] Telephone follow-up of 26 persons indicated that none had sought medical care subsequent to the incident and that all returned to a normal state of health. Of 21 persons evaluated in a hospital, respiratory distress was manifested within 4 hours. Despite its obvious limitations and uncontrolled nature, this report suggests guidelines for the emergency management of the asymptomatic or minimally symptomatic patient with a history of near drowning ([Table 56-2](#)).

Secondary drowning probably represents evolution of preexisting lung injury rather than sudden and unexpected

TABLE 56-2 -- On-Scene Management of the Asymptomatic Patient*

HISTORY	EXAMINATION	INTERVENTION
Time submerged	Appearance	Oxygen by face mask, 8–10 L/min
Description of incident	Vital signs	Intravenous line at "keep-open" rate
Complaints	Chest examination	Reexamine patient as needed
Past health	Electrocardiographic monitor	Transport patient

*Patients refusing treatment should have telephone number and address taken and arrangement for follow-up made.

TABLE 56-3 -- Field Approach to the Symptomatic Patient*

HISTORY	EXAMINATION	INTERVENTION
Description of incident	General appearance	Oxygen via mask (8–10 L/min) by demand valve
Time submerged, water temperature, water contamination, vomiting, type of rescue	Level of consciousness	Intravenous line at "keep-open" rate; consider intubation if patient is tachypneic or dyspneic with cyanosis or depressed mental status
Symptoms	Vital signs, electrocardiographic monitor	Transport patient

*Be prepared for vomiting. Take measures to prevent hypothermia and shivering. Treat cardiac arrhythmias as they arise, keeping in mind that hypoxia may be the underlying cause.

occurrence in a patient exposed to near drowning. Most injured patients can be identified through careful evaluation and a 4- to 6-hour observation period in the ED combined with a plan for careful follow-up. Asymptomatic survivors of a submersion incident should not be sent home from the site of the incident. All potential victims should be taken to a hospital for competent medical evaluation, or at least strongly encouraged to seek medical advice.^[189]

Symptomatic Patient.

Any victim who shows signs of distress (anxiety, tachypnea, dyspnea, syncope, persistent cough, or vital sign change) at the scene has had a significant submersion injury until serial observations in the hospital prove otherwise ([Table 56-3](#)). Two immediate problems will be hypoxia and acidosis. Correction involves respiratory manipulation. The airway must be kept patent, which can be a problem in persons who are vigorously vomiting. Emesis is frequent in submersion victims, especially in persons who have swallowed large amounts of seawater. If transport time is long, diarrhea caused by the laxative effect of swallowed seawater may add insult to injury.

SUPPLEMENTAL OXYGEN.

If the victim is breathing spontaneously, high flow rates should be provided by face mask (12 to 15 L/min via a nonrebreathing mask) or by demand valve, which gives 100% oxygen at the valve outlet. If available, pulse oximetry may be used to monitor

oxygen saturation. Persons in respiratory distress who breathe spontaneously might benefit from continuous positive airway pressure (CPAP) using a tight-fitting mask. No prehospital experience has yet been reported with the use of this modality.

Body temperature should not decrease. All wet clothing must be removed and the patient wiped dry. If the patient continues to shiver, carefully wrapped hot packs may be placed in the axillae and inguinal areas and near the scalp and neck (see [Chapter 6](#) and [Chapter 8](#)).

Attention to potential metabolic acidosis is given after establishment of a patent airway, oxygenation, and access to the intravascular space. Metabolic acidosis can exist even in relatively asymptomatic victims of submersion.^{[100] [171]} The first line of treatment is adequate ventilation and correction of hypoxia.^[169] Administration of sodium bicarbonate has been advocated in patients with adequate circulation who are tachypneic or dyspneic with cyanosis.^[144] Recommendations do not support this practice, particularly in the field environment. ^[149] Administration of bicarbonate should follow vigorous

attention to ventilation and oxygenation and generally awaits arterial blood gas (ABG) analysis.

For the most part, other drugs are administered in the hospital. Cardiac irritability usually responds to correction of hypoxia and acidosis. If significant ventricular irritability persists, judicious field use of lidocaine by multibolus technique is justified, using an initial dose of 1 mg/kg over 2 minutes and 0.5 mg/kg every 5 to 10 minutes, not to exceed a total dose of 225 mg.

PATIENT IN CARDIOPULMONARY ARREST.

Vigorous CPR can be initiated immediately, even with the victim in the water ([Box 56-4](#)). This is the most important survival factor in drownings.^[143] Mouth-to-mouth ventilation should be attempted during extrication, but this may be difficult, depending on the strength of the rescuer and demands of the environment ([Figure 56-7](#)). As soon as the shore, jetty, shallow water, surfboard, or boat is reached, mouth-to-mouth ventilation should begin in earnest.

Some suggest initiating closed-chest compressions in the water as soon as the victim is reached.^[140] Trials in which a recording manikin was ventilated and compressed, using a modified ventilator and posterior grasp position, demonstrated adequate chest compression and ventilation. However, these trials did not measure blood flow achieved when the patient was held in a nearly upright position. The likelihood of providing any circulation or keeping such a victim afloat is remote. Other factors that argue against this technique include frigid water and rescuer fatigue; dangers from wave, surge, and current; wet suit and scuba apparatus obstruction; and the delay to definitive out-of-water CPR.^[120] ^[122] No reports have been published regarding the successful use of this technique in an actual submersion incident.

**Box 56-4. FIELD INTERVENTION IN
VICTIMS IN CARDIOPULMONARY
ARREST***

***BEGIN VENTILATION AND
COMPRESSION***

Use mouth-to-mouth, mouth-to-mask (preferably with oxygen supplementation), or bag-valve-mask (preferably with balloon mask or two-rescuer) ventilation

Use supplemental oxygen

ENDOTRACHEAL INTUBATION

Positive end-expiratory pressure at 5 to 10 cm may be useful

Intravenous line at "keep-open" rate

***IF COPIOUS DRAINAGE FROM LUNGS
OR STOMACH***

Suction through endotracheal (ET) tube

Pass nasogastric tube

Apply abdominal thrusts between ventilations if ET tube in place and copious drainage persists

*Sodium bicarbonate ordered on advice of physician or according to protocol of the system. Treat dysrhythmias in standard fashion. If cervical injury is suspected, use collar and sandbags, etc.

Figure 56-7 Mouth-to-mouth ventilation in the water is difficult in the best of circumstances. (Courtesy Alan Steinman, MD.)

As soon as the victim is extracted from the water, he or she should be placed on a firm surface (float board, backboard, jetty, or boat deck) and appropriate resuscitation measures continued. Basic care given at the scene is thus far the most important treatment factor in determining survival.^[67] A trial of CPR with a pneumatic device appeared to produce better blood flow than did traditional CPR. Additional trials with this technique will suggest if it should become a new standard.^[91] If rescue is performed on a sloping beach, the victim should be placed parallel to the water's edge (neither

*References ^[67] ^[149] ^[171] ^[176] ^[180] ^[195] .

1355

head up nor head down), theoretically to prevent a decrease in forward blood flow during chest compressions in the head-up position or an increase in intracranial pressure in the head-down position.

An adequate airway provides access not only for positive-pressure ventilation but also for clearing of copious secretions. This can be achieved only by prompt insertion of an endotracheal tube, which should be placed after good initial ventilation. When only tank oxygen with a delivery hose, nasal cannula, or face mask is available, mouth-to-mouth or mouth-to-mask ventilation may be supplemented with oxygen by applying the nasal prongs to the rescuer (at 6 to 8 L/min). This increases the delivered oxygen concentration from 21% to 40%.^[101] CPR using a bag valve mask, laryngeal mask or combitube provides a safe format for mouth-to-mouth resuscitation and also prevent the possibility of AIDS transmission.^[48] ^[169] If a bag-valve-mask ventilator is used, it must have an oxygen reservoir to increase the percentage of oxygen delivered to the patient. This reservoir should be of the soft inflatable type with a capacity of at least 2.5 L.^[4] ^[25] It should be fitted with a balloon mask that provides a tight seal on the patient's face and reduces leak.^[224] Without this mask, bag-valve-mask devices are not the preferred method of applying positive-pressure ventilation in a field setting because of the difficulty in achieving a mask seal and because of operator fatigue, both of which inevitably reduce delivered volumes.^[4] ^[59] ^[90]

LUNG DRAINAGE.

Frequent airway clearing is necessary with most victims of submersion. Vomiting and copious drainage from the lungs and stomach can occur. The issue of lung drainage is historically and currently controversial. Draining the lungs is reasonable, since

submerged victims have been estimated to aspirate up to 2 L,^[176] as well as to accumulate pulmonary edema fluid. The concept of draining water from the lungs dates back to the seventeenth and eighteenth centuries. The Dutch method consisted of rolling the victim over a barrel; another method advised flinging the victim over the back of a horse, which was then made to trot.^[131] In 1975, Dr. Henry Heimlich introduced an abdominal compression maneuver (Heimlich maneuver), advocated for victims of food choking.^[94] In the initial and subsequent reports, he suggested its use in the victims of drowning.^{[95] [96]}

Evidence for the effectiveness of the maneuver in drowning is anecdotal at best. Abdominal compression in victims of submersion may predispose to induced emesis of large amounts of swallowed water, thus exposing the patient to further aspiration, this time of gastric contents.^[172]

Although one study demonstrated greater survival rates in animals subjected to drainage techniques,^[159] the dogs used apparently did not require closed-chest CPR. It was concluded that drainage techniques were useful only in victims of seawater aspiration. Studies at the University of Pittsburgh demonstrated no difference in canine survival in groups treated without drainage, with the Heimlich maneuver, or with Trendelenburg positioning.^[234] As far back as 1962, efforts to drain water from the lungs were condemned as "of no practical use" and "a waste of valuable time" in applying mouth-to-mouth ventilation.^[200] The same investigators showed in cadavers that only small amounts of the 1 L of 1% saline solution instilled into the lungs could still be recovered by prone positioning, "jackknifing," or thoracic compression. A delivered volume of up to 2 L of air could still be accomplished with higher ventilating pressures.

No human studies of lung drainage in submersion have been reported, and descriptions of drainage procedures refer to *gastric* drainage.^[206] The technique in these cases was to place the patient on the side and compress the abdomen, or to place the patient in a prone position, grasp him or her about the abdomen, and lift ("breaking" the victim, in older lay language). Whether these maneuvers led to drainage of water from the stomach or lungs is not clear.

Gastric drainage may be required in persons who have swallowed large amounts of water, since gastric distention may interfere with ventilation. If gastric distention is a problem, abdominal compression with adequate suction available (or gravity drainage) may suffice. Abdominal compression accomplishes drainage without the need to interrupt cardiac compressions or ventilation for as long a time as other methods. Whatever the method, it must be performed quickly so that basic life support can continue. A nasogastric tube is preferred to all other methods. Most clinicians, the American Heart Association, and the Institute of Medicine advise against the Heimlich maneuver except when the airway is obviously blocked with foreign material.^{[4] [190] [197]} None of the methods suggested for gastric drainage should precede initial attempts at ventilation.

ENDOTRACHEAL INTUBATION AND POSITIVE END-EXPIRATORY PRESSURE.

Endotracheal intubation controls the airway by reducing dead space, providing

protection against aspiration, and facilitating pulmonary toilet. In apneic submersion patients requiring positive-pressure ventilation, PEEP has been demonstrated to be useful.^{[113] [180] [199] [205] [229]} Although there is no decrease or is even an increase in total lung water, PEEP acts in several ways to improve ventilation patterns in the noncompliant lung: (1) by shifting interstitial pulmonary water into capillaries; (2) by increasing lung volume through prevention of expiratory air space collapse; (3) by increasing the diameter of large and small airways to improve ventilation distribution; and (4) by decreasing alveolar-capillary blood flow and providing better alveolar ventilation, with improved ventilation-perfusion ratio and PaO₂ .

1356

The use of PEEP in the field situation is possible with a small apparatus adaptable to manual self-inflating bag ventilation devices.^[130] Experience with field PEEP is limited, and clinicians must be thoroughly familiar with its drawbacks. These include reduced venous return to the right side of the heart, increased fluid retention in an already stressed lung, increased pulmonary artery pressure, decreased cardiac output, and, at high levels, increased ICP.^{[7] [46] [161] [216]} High-frequency jet ventilation in the intensive care unit may prevent further pulmonary barotrauma to an injured lung.^[218]

DRUGS.

In the past, standard drug therapy in CPR emphasized prompt attention to sodium bicarbonate administration. Severe metabolic acidosis may exist in a submersion victim because of circulatory arrest and preceding muscular activity in the struggle for survival.^[157] Administration of bicarbonate has potential disadvantages, including increased sodium concentration with resultant fluid load, which may not be beneficial to patients whose cardiovascular reserve is already limited.^{[221] [232]} Other problems include impairment of oxygen delivery to the tissues, paradoxical increase in lactate production, and increase in CO₂ production, which can worsen already profound metabolic and respiratory acidosis.^{[113] [221] [232]} The possible inappropriateness of bicarbonate administration in cardiac arrest has led to reconsideration of this practice.^{[4] [17]} The decision to administer bicarbonate should be made by the in-hospital team after more data are available on which to base a decision. The most likely problems leading to acid-base imbalance are hypoxia and respiratory acidosis, which require effective ventilation before consideration of sodium bicarbonate.

OBVIOUSLY DEAD OR STILL-SUBMERGED PATIENT.

"Obviously dead" refers to any patient who has a normal temperature and demonstrates asystole, absent respirations, postmortem lividity, or rigor mortis. If rescue operations have been in progress for more than 30 minutes, victims who are retrieved from warm water during summer months or in warm southern waters may be considered dead on the scene. Because cold water submersion for more than 40 minutes has been associated with neurologic survival,^[217] rescue crews must institute life support measures in all persons who are not obviously dead, who may be hypothermic, and

whose histories suggest recent signs of life.

When persons are obviously dead or still submerged, the rescue team must comfort the family and friends and participate in body recovery. Once retrieved, the victim should be covered immediately and treated with proper dignity. Family members and friends should be escorted from the scene, if possible, before recovery. Most drownings are medical examiner

TABLE 56-4 -- Classification of Near Drowning Victims*

CATEGORY	DESCRIPTION
A	Awake—fully oriented
B	Blunted—arousable; purposeful response to pain
C	Comatose—not arousable; abnormal response to pain
C ₁	Flexor response to pain
C ₂	Extensor response to pain
C ₃	Flaccid
C ₄	Arrested

*Assessment is made in emergency department within 1 hour of rescue.

cases, since the possibility of foul play must be investigated.

In-Hospital Management.

Once the victim reaches the hospital, a brief but pertinent description of the event, an estimate of time submerged, and the extent of field intervention will provide team members with important information bearing on further treatment, as well as offer some basis for expectation of outcome.

CLASSIFICATION OF PATIENTS.

Patients may be classified on admission in a manner similar to that used in the field setting: asymptomatic, symptomatic, in cardiac arrest, or obviously dead ([Table 56-4](#)). In 1980, Modell and Conn^[152] suggested an ABC classification of patients based on presenting neurologic examination. This system has undergone revision, with the time of initial examination being changed to the ED after initial resuscitation, and usually within 1 hour of rescue. More aggressive resuscitation led to the introduction of a fourth subgroup under "C." Under this system, patients were "A"—alert, "B"—blunted in consciousness, or "C"—comatose. The comatose patients were further categorized

according to their abnormal neurologic responses: C₁ —flexor response; C₂ —extensor response; or C₃ —flaccid. A C₄ category was added to include patients in whom vigorous CPR was being applied that might result in a change in condition and therefore prognosis.^[38]

In their series on children, Conn et al^{[39] [40]} reported that all patients in category A survived and were normal and that all but one patient survived in category B. The patients in coma were most likely to benefit from therapy while being most at risk. The C group showed various responses, with increasingly poor outcomes. Similar studies in adults have not yet been reported.

Graf et al^[81] studied 194 submersion victims and found that four variables could predict unfavorable outcome: comatose state, lack of pupillary light reflex, male gender, and initial blood glucose level greater

§Use measured values.

than 200 mg/dl on presentation. Some studies suggest the use of the pediatric risk of mortality (PRISM) score to predict outcome. Victims with PRISM scores greater than 20 died or survived with severe neurologic deficits.^{[66] [87]} ([Table 56-5](#).)

ASYMPTOMATIC PATIENTS.

Victims may arrive in the ED with little or no evidence of submersion injury ([Box 56-5](#)). It is widely believed that respiratory complications develop in some victims of submersion incidents 12 to 72 hours after the event.^[176]^[178] This has led many to recommend that even asymptomatic patients be admitted for observation for this period. Almost all these patients had a history of severe insult (cardiopulmonary arrest requiring resuscitation) or had shown some abnormalities on arrival at the ED. Victims with minor symptoms who decline on-scene medical help probably do not deteriorate.^[189] Most acute care clinicians, faced with a reliable history of submersion, elect to perform a physical examination, obtain ABG measurements, and acquire a chest x-ray study on even asymptomatic or minimally symptomatic victims of a

1358

near drowning.^[122]^[149]^[171]^[180] Persons who show abnormalities or who deteriorate within 4 hours of admission to the ED should be admitted for observation and further management.^[171]

Box 56-5. IN-HOSPITAL MANAGEMENT OF ASYMPTOMATIC VICTIMS OF SUBMERSION INCIDENTS

CHECK AIRWAY

Supplemental oxygen: nonrebreathing mask at 12 to 15 L/min or via demand valve pending oximetry or arterial blood gas determinations

Obtain history and estimate severity of incident, look for possible underlying causes, e.g., cerebrovascular accident, epilepsy, drugs, myocardial infarction, arrhythmia

TAKE VITAL SIGNS AND EXAMINE PATIENT

Draw and hold blood samples for complete blood count, electrolytes, blood urea nitrogen, platelets,

**TAKE VITAL SIGNS AND EXAMINE
PATIENT**

Draw and hold blood samples for complete blood count, electrolytes, blood urea nitrogen, platelets, prothrombin time, partial thromboplastin time; send if indicated

Arterial blood gases; consider pulse oximetry; consider blood alcohol level and toxicology screen

Urinalysis

Chest radiograph

DISPOSITION

Observe all patients for 4 to 6 hours; discharge home if completely asymptomatic and adequate telephone or medical follow-up can be guaranteed

Supportive therapy.

The patient who remains asymptomatic may need attention because of the psychologic trauma of the near tragedy. This is frequently important when others have been involved in the incident, particularly when fatalities resulted. Survivors frequently suffer from posttraumatic stress syndrome with depression and disturbances of sleep and concentration.^[49]

Radiographic studies.

Radiographic examination of the chest is performed on all persons with a history of submersion. The findings vary widely with the severity of the incident and other factors. The usual pattern seen in persons with a significant insult is similar to that of noncardiogenic pulmonary edema. In mild cases, fine alveolar infiltrates are found, predominantly in the periphery. Persons who become symptomatic often demonstrate changes consistent with diffuse or localized intraalveolar or interstitial infiltrates, segmental atelectasis, or "shock lung." Air bronchograms are frequently seen in severely affected patients, and the lungs may appear opaque. An initial normal chest radiograph does not rule out a significant pulmonary insult. Depending on the duration of submersion, findings are usually seen within several hours of the incident, but changes have been delayed for as long as 24 hours after the patient became

Box 56-6. IN-HOSPITAL APPROACH TO SYMPTOMATIC VICTIMS OF SUBMERSION INCIDENTS

CHECK AIRWAY

Supplemental oxygen: nonrebreathing mask at 12 to 15 L/min or via demand valve

CONSIDER ENDOTRACHEAL INTUBATION

For comatose patients

For patients unable to maintain a PaO₂ above 90 mm Hg on high-flow oxygen (nonrebreathing mask at 12 to 15 L/min), or unable to maintain a PaCO₂ below 45 mm Hg

CHECK VITAL SIGNS

Start intravenous line: draw blood for complete blood count, electrolytes, blood urea nitrogen, platelets, prothrombin time, partial thromboplastin time

Arterial blood gas studies

Urinalysis

Administer bicarbonate according to blood gas results if acidosis is severe and cannot otherwise be corrected

Chest radiograph

Administer bicarbonate according to blood gas results if acidosis is severe and cannot otherwise be corrected

Chest radiograph

Cervical spine radiograph if any doubt about circumstances of incident

Nasogastric tube

Indwelling urinary catheter if necessary

DISPOSITION

Admit all patients with abnormal vital signs, abnormal radiologic signs, or abnormal findings on blood gas measurements

Completely asymptomatic patients with no findings may be discharged after 4 to 6 hours observation if adequate telephone or other medical follow-up can be guaranteed

Spinal injury should be suspected in victims who have been platform diving or surfing or who may have fallen from a height into the water. A full radiographic series of all seven cervical vertebrae is standard before neck manipulation.

SYMPTOMATIC PATIENTS.

Patients complain of combinations of coughing, sore throat, burning in the chest, and dyspnea ([Box 56-6](#)). Patients who are dyspneic are almost always hypoxic and if severely affected (with cyanosis) are likely to be acidotic. Intervention must be aggressive and planned. Initial ABG and serum chemistry measurements should be performed. A chest radiograph may be taken by portable machine unless the patient receives priority in the main radiology department.

ABG determinations or pulse oximetry can be carried out rapidly in most EDs and usually guide therapy. Oxygen is administered by demand valve (100%) or through a nonrebreathing mask at a rate of 12 to 15 L/min. This will suffice if the PaO₂ can be maintained at or above 90 mm Hg at an F_{IO₂} of 0.50 or less.^[73] Maintaining positive

pressure in the airway during expiration can be valuable. This is particularly indicated if the $\text{PaO}_2/\text{FiO}_2$ ratio is 300 or less.^[171] In some patients who are able to hold a mask, CPAP can be provided via the tight-fitting mask, and intubation may be avoided.^{[83] [216]} Although experience with this method is growing, patients must be carefully chosen. In selected cases in the intensive care unit, use of mask CPAP has delayed or eliminated the need for intubation.^[83] When provided by experienced personnel, it is an acceptable adjunct to ED therapy. Inability to maintain a PaO_2 of 55 mm Hg on an FiO_2 of 0.50 is one criterion for use of this method.^[151] In addition, the patient must be able to respond to verbal commands and control his or her airway and must be nonhypercarbic (PaCO_2 less than 45 mm Hg).^[216] Pressures used within the system, as well as the FiO_2 , vary according to the clinical and ABG response. Pressures may range from 0 to 4 cm H_2O on inspiration and 4 to 14 cm H_2O on expiration. Experience with this method is insufficient for it to be recommended definitively in the prehospital environment.

Irritation of the tracheobronchial tree by inhaled water and particles may evoke cough and bronchospasm. Bronchospasm may worsen hypoxia; aggressive management is essential in symptomatic patients. Aerosolized albuterol is the drug of choice for initial treatment of bronchospasm in the ED. It is a relatively selective β_2 -adrenergic agonist, rapid acting, and with minimal side effects.^{[13] [194]} It is administered to spontaneously breathing patients via a nebulizer fitted with mouthpiece or face mask. The average dose for a single treatment is 1.25 to 2.5 mg (0.25 to 0.50 ml) diluted in 2 to 5 ml or more of sterile normal saline or sterile water. With severe bronchospasm the first dose may be increased to 5 mg, or the initial lower dose may be repeated if necessary. Albuterol may be administered to intubated patients using a nebulizer attached to a T-piece hooked to the endotracheal (ET) tube. Ipratropium (Atrovent) nebulizer solution may be combined with β -agonists to try to decrease mucus and spasm. Aminophylline, in an intravenous (IV) loading dose of 5.6 mg/kg over 20 to 30 minutes, may be added if bronchospasm is not relieved.^{[166] [194]} This is useful predominantly for persons who are already taking the medicine and in whom subtherapeutic blood levels are determined.

The decision to perform ET intubation is made on the basis of ABG determinations and the following: (1) comatose patient unable to handle secretions; (2) comatose patient who requires a nasogastric tube; or (3) patient with a PaO_2 of 90 mm Hg or less on high-flow oxygen by nonrebreathing mask at 12 to 15 L/min or with a PaCO_2 greater than 45 mm Hg.^[96] A trial of nasal CPAP (continuous positive airway pressure) may help avert intubation.^[50] CPAP delivers positive pressure to the airways by a pressurized face mask from a ventilator circuit.

**Box 56-7. PROGNOSTIC SIGNS IN
SUBMERGED VICTIMS**

GOOD

Alert on admission

Hypothermic

Older child or adult

Brief submersion time

On-scene basic or advanced life support (probably most important)

Good response to initial resuscitation measures

POOR

Age less than 3 years

Fixed, dilated pupils in emergency department

Submerged longer than 5 minutes

No resuscitation attempts for more than 10 minutes

Preexisting chronic disease

Arterial pH 7.10 or less

Coma on admission to emergency department

An IV line should be placed, as well as an external cardiac monitor, indwelling urinary catheter (as needed), and nasogastric tube.

Comatose Patients or Patients in Cardiac Arrest

PROGNOSTIC SIGNS.

Guidelines on predicting outcomes offer a uniform approach to management, allow for realistic expectations based on measurable data, and propose common terminology and nomenclature.^{[38] [171]} Despite advances, resuscitating patients who face serious CNS deficits may carry a poor prognosis. In some pediatric studies, 21% of children who survived had severe encephalopathy.^[183] Others report that the outlook, particularly in children, is good, with morbidity ranging from 3.5% to 5%.^{[39] [154] [181] [231]}

In the absence of profound hypothermia, the neurologic status of a victim on admission to the ED is crucial in determining the patient's course. Persons who are alert when admitted should seldom die.^{[3] [44] [106] [154] [170]} Prognostic indicators, particularly in pediatric patients, have included the Glasgow Coma Scale^[44] and the presence of spontaneous respirations.^{[52] [81] [106] [123]} The duration of submersion, because of its unreliability, is not a helpful gauge of the outcome of resuscitation attempts. Full recovery of some patients with initial fixed and dilated pupils tempers the tacit acceptance of all factors historically outlined as prognostic signs. However, good and poor signs can significantly affect the chances of recovery ([Box 56-7](#)).

1360

For ED personnel, initiation and continuation of resuscitation begun in the field should be automatic, except in the most unusual circumstances. Termination of efforts is entertained only after standard methods have been used.

HOSPITAL MANAGEMENT.

The airway is reevaluated ([Box 56-8](#)). If the patient does not already have an ET tube in place and is comatose without gag or cough reflexes, a nasotracheal or ET tube should be inserted after initial hyperventilation with 100% oxygen via bag-valve device. ABGs should be measured immediately. Cervical spine precautions should be observed.

If the patient is not breathing spontaneously, 100% oxygen should be administered by volume ventilator. The object in these patients is to increase the functional residual capacity and to reduce ventilation-perfusion mismatching. PEEP may be necessary, beginning at 5 cm H₂O to increase the ratio of PaO₂/F_IO₂ to 300 or greater.^[171]

Respiratory acidosis is managed with appropriate airway measures, including intubation, pulmonary toilet, and PEEP. Metabolic acidosis is often severe. Despite recent reluctance to administer bicarbonate during states of cardiac arrest,^{[4] [221]} most clinicians advise administration of sodium bicarbonate if the pH is less than 7.25 and not improving with vigorous respiratory management.^[151] One formula for calculating the

dose of bicarbonate is: sodium bicarbonate (mEq) = patient weight (kg) × base deficit × 0.2.^[149] One-half the calculated dose is given initially and the effect on ABGs observed.

**Box 56-8. IN-HOSPITAL MANAGEMENT
OF PATIENTS IN COMA OR CARDIAC
ARREST***

AIRWAY CONTROL

Endotracheal tube; nasotracheal preferred

Supplemental oxygen or mechanical ventilation with intermittent mandatory ventilation (IMV), continuous positive airway pressure, or IMV with positive end-expiratory pressure

Bicarbonate therapy guided by arterial blood gas values

Treatment of cardiac arrhythmias according to protocol

DIAGNOSTIC

Arterial blood gases

Blood for complete blood count, electrolytes, coagulation baseline

Urinalysis

Chest x-ray examination

Cervical spine films (if indicated)

Electrocardiographic monitoring

Computed tomography or magnetic resonance imaging suggested in patients who remain comatose

Electrocardiographic monitoring

Computed tomography or magnetic resonance imaging suggested in patients who remain comatose

No antibiotics

No steroids

FURTHER INTENSIVE CARE MEASURES

Arterial line

Swan-Ganz catheterization when fluid status in doubt

Diuretics

H₂ antagonists

Paralysis (pancuronium, 0.1 mg/kg IV prn)

Maintain blood pressure: fluids if needed and vasopressors: dopamine, 1–20 µg/kg/min; dobutamine, 2–15 µg/kg/min

*Routine hypothermia is not recommended. Barbiturates after cardiac arrest are not proven effective. Intracranial pressure monitoring may be considered.

Hypoglycemia may be present as a result of marked fatigue and alcohol ingestion.^[56] After initial resuscitation, treatment is directed toward correcting derangements in specific organ systems, including pulmonary, cardiovascular, and central nervous systems.

PULMONARY SYSTEM.

The major insult to the lung follows reduction of surfactant and accumulation of intrapulmonary and interstitial fluid.^{[73] [74] [100] [126]} The treatment of pulmonary failure caused either by salt or fresh water is mechanical ventilation with or without some form of CPAP. The aim is to maintain a balance between adequate oxygenation, cardiac output, and reduction in intrapulmonary shunting. Continuous mechanical ventilation is appropriate for apneic patients or those who are spontaneously breathing but are

unable to maintain a PaO_2 of at least 90 mm Hg while wearing a face mask delivering an FIO_2 of 0.50. Patients with a $\text{PaO}_2/\text{FIO}_2$ ratio less than 300 need positive airway pressure in addition to oxygen.^[171] In comatose patients this requires endotracheal intubation.

The most desirable form of ventilation in severely affected patients is intermittent mandatory ventilation, in which spontaneous breaths between mechanical inflations improve venous return and ensure adequate cardiac output. Most consultants recommend maintaining the PaCO_2 at 40 mm Hg and the pH above 7.35^[100] unless hyperventilation is undertaken for control of intracranial hypertension. The airway pressures required to provide a PaO_2 of at least 60 mm Hg with an FIO_2 of 0.45 vary according to the severity of the pulmonary insult and individual factors in different patients.^{[45] [126]}

In intubated patients whose ventilation is being controlled, PEEP may be used and should be maintained at a level that will ensure a balance between cardiac output and a reduction of shunt. After an adequate level of oxygenation is achieved, PEEP or CPAP should be maintained for at least 24 hours to foster the regeneration of surfactant.^{[126] [176]} Airway pressures with PEEP must be carefully monitored in postsubmersion patients, since increasing intrathoracic pressure leads to elevations in ICP.

1361

Care must be exercised in removing patients from ventilatory support. Some respond dramatically to controlled ventilation, but 2 to 4 days may be required to replenish surfactant and resolve the problem of atelectasis. Premature removal from the ventilator may be followed by deterioration in pulmonary status, which could require reintubation and reintroduction of mechanical ventilation.^[126] Generally, when a PaO_2 of 60 mm Hg or above can be supported with an FIO_2 of 0.40 or less in the absence of PEEP, the patient can be removed from the ventilator.

The use of steroids to prevent deterioration of lung function after submersion injury has few advocates.^{[100] [149] [171]} No evidence shows a benefit in pulmonary failure, and good data suggest the progression of chemical aspiration to bacterial pneumonitis.^{[151] [153]} Intratracheal instillation of surfactant may help patients not responding to maximal medical therapy. Experimental studies are now investigating the use of butyl alcohol vapor or surfactant as an adjuvant to traditional respiratory support.^{[23] [230]}

Prophylactic antibiotics are not recommended. Daily Gram's stain of sputum and frequent blood, urine, and sputum cultures may be required in the long-term management of these patients.

CARDIOVASCULAR SYSTEM.

Cardiac dysrhythmias and arrest during the course of resuscitation often are corrected by improvements in oxygenation and acid-base status. An arterial pressure cannula is

helpful to monitor cardiovascular status and ABGs.

The use of Swan-Ganz catheters is advisable in patients who develop hemodynamic instability or who require high levels of CPAP or PEEP to maintain oxygenation.^[149] When shock is evident, pulmonary artery wedge pressures and cardiac output determinations allow a more rational approach to fluid administration. The Swan-Ganz catheter allows measurement of mixed venous oxygen saturation and can provide some information on oxygen transport and cardiac output. Pressor agents, such as dopamine and dobutamine, may be required if arterial hypotension and reduced cardiac output persist after adequate hydration is ensured. In most animal studies, cardiac output is best supported by fluids rather than inotropic agents.^[56] The cause of most cases of postsubmersion pulmonary edema is altered permeability rather than pump failure. However, dopamine (2 to 20 µg/kg/min) and dobutamine (2 to 15 µg/kg/min) have been effective in some patients.^[98] Sepsis and shock are constant threats.

RENAL AND METABOLIC FUNCTION.

In victims of significant submersion injury, renal blood flow may decrease as a result of hypovolemia or hypotension. This can be detected by close attention to urine output. Renal failure is usually caused by hypoxia and acidosis with tubular damage.^[82] ^[111] Deposition of hemoglobin in the tubules from hemolysis of red blood cells is rarely a cause of renal failure. Maintenance of adequate circulating blood volume and restoration of renal perfusion are the best insurance against renal damage. An indwelling urinary catheter should be placed and urine production monitored and maintained at a minimum of 50 ml/hr. Mannitol in a dose of 0.25 g/kg intravenously has been used to maintain adequate urine flow and prevent obstruction of the tubules. This is given only after adequate intravascular volume is obtained.

CEREBRAL RESUSCITATION.

Until recently, therapeutic measures were exclusively directed toward stabilizing the cardiovascular and pulmonary systems. Patients who were restored to adequate levels of cardiopulmonary function often died later from brain failure. Although some measures to protect the brain from postischemic insults are still experimental, the outlook for patients with severe initial defects is improving.^[38] ^[39] ^[40] ^[45] ^[152] Measures directed toward cerebral salvage began with observations of the effect of hypothermia on brain metabolism. The initial enthusiasm and expectations for barbiturate cerebral resuscitation after cardiac arrest have not been justified in international multicenter studies.^[21] ^[162] ^[237]

The most important approach to CNS resuscitation in postsubmersion patients is provision of an adequate airway and attention to ventilation and oxygenation. Patients who respond promptly to such measures are unlikely to require methods of cerebral preservation, probably because the cerebral insult has not been severe. Patients who remain comatose and who may have head trauma should be examined with computed tomography (CT) or magnetic resonance imaging (MRI) as soon as practical. Scanning may reveal intracranial or intracerebral hemorrhage and provides an early picture of the

extent of cerebral edema.

When the victim does not respond immediately to vigorous resuscitation measures, one practical protocol for management requires control of several elements, including ventilation, hydration, temperature, brain metabolism and edema, and muscular activity.^[38] ^[40] ^[152]

VENTILATION.

Hyperventilation is maintained to achieve a P_{aCO_2} of about 30 mm Hg to balance cerebral vasoconstriction with cerebral blood flow. PEEP is used to maintain a high P_{aO_2} (150 mm Hg), since it is thought that this facilitates cerebral oxygen transport.

HYDRATION.

Diuresis is promoted with a loop diuretic (furosemide, 0.5 to 1 mg/kg). Fluid restriction is guided by laboratory and clinical measurements such as blood pressure, pulmonary wedge pressure, and occasionally blood volume measurements.

1362

TEMPERATURE.

Normothermia should be maintained and hyperpyrexia prevented with the use of cooling mattresses if necessary. The routine use of induced hypothermia is not recommended, particularly because hypothermia can induce neutropenia and lead to sepsis.^[18] ^[179] ^[180] In the case of ICP uncontrolled by other measures, some clinicians advise reduction of core temperature to 30° C (86° F) while paralyzing the patient to combat shivering.^[40] Revisions of this opinion urge caution, since the effect on outcome is uncertain.^[149] ^[150]

CEREBRAL METABOLISM AND EDEMA.

Control of cerebral metabolism and reduction of edema are difficult and controversial areas of management. Patients who remain comatose and do not respond to adequate fluid balance and hyperventilation should have the management of presumed ICP elevation guided by clinical examination and direct monitoring using an epidural transducer, ventricular catheter, or subarachnoid bolt.

The use of barbiturates for cerebral protection after cardiac arrest has not been encouraging, but the ability of these drugs in certain circumstances to reduce ICP by cerebral vasoconstriction can be helpful to patients with an ICP above 20 cm H₂ O.^[150] A direct "protective" effect of barbiturates on nerve tissue has not been demonstrated. Difficulties with instituting barbiturate therapy and maintaining patients on the regimen include hypotension and inability to evaluate the patient clinically. Conn et al^[39] ^[40] used

phenobarbital for a minimum of 4 days in children (50 mg/kg on day 1 in three divided doses, then half that dose subsequently), with daily determinations of barbiturate levels. Reports of equivocal results in children treated with barbiturates and hypothermia indicate that these measures should not be used routinely.^[18] ^[171]

If barbiturates are used, the patient should be placed in an intensive care unit with staff fully skilled in the use of these agents. When pentobarbital is used, a constant infusion technique is guided by monitoring arterial pressure, ICP, and cardiac output. If blood pressure falls, the infusion rate should be decreased or an inotropic agent (dopamine, dobutamine) used to support myocardial function.^[98] ^[100] Whenever barbiturate therapy is considered, mass intracranial lesions should first be ruled out by CT or MRI because any clinical signs caused by these lesions might be masked by the barbiturate. Sudden increases in ICP can be managed by hyperventilation and the use of mannitol (0.5 to 1 g/kg IV bolus). No comparative studies have demonstrated the success of therapy directed at reducing ICP and maintaining cerebral perfusion pressure.

Because postischemic brain insult was associated with high intraneuronal calcium ion concentration, calcium channel blocking agents were used to ameliorate the effects of ischemia on the CNS.^[162] ^[207] The use of these agents remains under investigation.

Some clinicians have used corticosteroids because steroid use improved the CNS function of patients with primary or secondary brain tumors,^[12] apparently by reducing cerebral reaction and swelling around the mass lesions.^[11] In an attempt to duplicate this beneficial effect in patients with acute intracranial hemorrhage, large doses of corticosteroids were administered to patients with head injury. No benefit was seen,^[42] and most clinicians no longer recommend corticosteroids for the reduction of ICP and for cerebral protection after ischemic brain insults.^[38] ^[149] Steroids in high doses appear to be beneficial in selected cases of spinal cord injury.

MUSCULAR ACTIVITY.

Complete muscular paralysis is advocated by Conn et al^[40] to facilitate control of ventilation and to prevent ICP increase induced by muscle rigidity and restlessness. Muscle paralysis is achieved with pancuronium (0.1 mg/kg intravenously) hourly or as needed.

GENERAL MEASURES.

Other measures for patient support during intensive postsubmersion therapy include placement of a nasogastric tube and selective administration of antacids or a histamine-2 antagonist, such as cimetidine, to prevent gastric hemorrhage.^[171] ^[184]

Chapter 57 - Diving Medicine

Kenneth W. Kizer

More than 70% of Earth's surface is covered by water, but less than 5% of this underwater wilderness has ever been seen by man. Only recently has this last frontier of the planet begun to be explored in a systematic way. Much of this exploration has been possible because of the development of scuba diving.

Scuba diving is an exhilarating and generally safe activity for persons who are healthy, well trained, well conditioned, well equipped and "water wise." It can, however, be a demanding and even dangerous sport because of intrinsic hazards of the underwater environment.

The hazards of scuba diving include the generic problems found in other aquatic activities, such as near drowning, hypothermia, immersion-related skin disorders, water-borne infectious diseases, and hazardous marine life, as well as several relatively unique problems related to the increased atmospheric pressure found under water and the effects of various breathing gases at elevated pressure.

Currently there are many millions of recreational scuba divers around the world, and hundreds of thousands of new divers are certified each year. Scuba diving is conducted in lakes, rivers, quarries, oceans, and almost every other imaginable aquatic setting. Despite the extent of diving activity, scuba-diving fatalities and serious injuries are relatively infrequent. In 1997 the 270 recompression chambers worldwide reporting to the Divers Alert Network reported a total of 972 diving injury cases and 82 fatalities from recreational scuba diving that year.^[36] The total number of injuries was roughly similar to other recent years, whereas the number of fatalities was down from 104 in 1995 (but up from 67 in 1991) and less than the 10-year average of 89 deaths per year. Notwithstanding this apparent downward trend in fatalities, concern about the safety of diving continues because of the changing character of the sport-diving population and what is considered to be recreational diving.

In the past 40 years the nature of the scuba-diving population has substantially changed. Scuba divers of the 1950s and 1960s were generally "water

people"—well-trained, vigorous athletes experienced in breath-hold diving and competitive swimming. To don a scuba tank and regulator was a natural extension of familiar activity. These early scuba divers seldom encountered problems that required the attention of the general medical community. However, as scuba diving equipment became more available, adventure-minded persons from all walks of life became attracted to the sport. The popularization of scuba diving in recent years has attracted participants who may be poorly conditioned, have little or no experience in aquatic or other sports, are of advanced age, or have significant underlying medical conditions. Because of the arduous and unforgiving nature of the aquatic environment, such persons may be at increased risk of a diving-related injury or illness. Certain medical conditions are an absolute contraindication to diving.

In the last decade recreational divers have increasingly sought more technically complicated diving in efforts to increase the amount of time they can spend underwater or the depth to which they can dive. Although these diving techniques have been long used in commercial and military diving under controlled conditions, there are significant concerns about the safety of "technical" diving in the much less controlled recreational diving setting.

All primary care physicians should be prepared to answer basic questions about fitness for diving and to initially manage diving-related medical emergencies. Likewise, every emergency medical treatment facility should be prepared to evaluate, provide urgent care and, if needed, arrange transport to a hyperbaric treatment facility (recompression chamber) if a diver is suspected to have decompression sickness or arterial gas embolism.

This chapter focuses primarily on the pressure-related diving syndromes collectively known as *dysbarism*; other conditions relevant to diving are discussed in other chapters (e.g., immersion hypothermia in [Chapter 8](#) , hazardous marine life in [Chapter 60](#) [Chapter 61](#) [Chapter 62](#) , and near-drowning in [Chapter 56](#)).

HISTORICAL PERSPECTIVE

Human beings did not evolve for an aquatic existence and are not well adapted for function in the aquatic environment. Nonetheless, they have been breath-hold diving to gather food and other natural resources from the oceans for thousands of years. There is archaeological evidence that Neanderthal man breath-hold dived 40,000 years ago. The Ama of Japan and Hae-Nyu of Korea have been breath-hold diving to collect edible mollusks and seaweed for about 6000 years. The Indians of southern Patagonia engaged in similar diving

1367

practices, and fires along the shores of the Straits of Magellan built to warm these native American divers are believed to be the source of the name "Tierra del Fuego" (Land of Fire) given to the area by Ferdinand Magellan.

Written records of diving for salvage and military purposes date back to around 500 BC, when the Greek historian Herodotus recorded the feats of Scyllis as he dived in the Mediterranean Sea for the Persian king Xerxes during the 50-year war between Greece and Persia. Other colorful accounts of military and salvage divers dot the history of Roman and other early cultures. However, human underwater exploits remained limited to breath-hold diving until about 300 years ago, when a series of technologic developments began to expand human underwater activity. These developments principally involved the use of different types of external air supply to prolong submergence.

In the seventeenth century, primitive bells containing air were carried from the surface, allowing Swedish divers to stay underwater longer than a single breath and to salvage cannons from Stockholm's harbor.^[97] In 1690 Sir Edmund Halley devised a leather tube to carry surface air to barrels, which resupplied air to manned bells at a depth of 60 feet. These barrels were submerged, and the air they contained was compressed.^[34]

The first practical diving suit was fabricated by Augustus Siebe in 1837.^[2] ^[34] ^[97] Atmospheric air was supplied to the diver as compressed air from a manually powered pump on the surface. By 1841 French engineers had developed the technique of using compressed air to keep water and mud out of caissons sunk to the bottom of riverbeds for bridge footings and tunnels. Soon thereafter it was noted that people working in a compressed-air environment sometimes suffered joint pains, paralysis, and other medical problems soon after leaving the caisson. This poorly understood condition was called "caisson's disease" and was the first recognition of what is now known as

decompression sickness. ^[98]

Underwater diving remained an esoteric activity having limited commercial and military utility until the 1930s. By that time, and increasingly during World War II, the military importance of submarines and other undersea activities became evident to navies throughout the world. With the development of submarine forces came the need to train men to escape from submarines that became disabled at depth (an all too frequent occurrence in the early days of submarines). Given the shallow operational depths of these early boats, it was usually possible to escape by simply exiting the vessel and ascending to the surface. It was noted early that failure to exhale while ascending through the water led to pulmonary over-pressurization accidents and a new and dramatic syndrome that we now know to be *arterial gas embolism*.

In 1865 the French engineers Rouquayrol and Denayrouse developed a device that could supply air on demand at ambient pressures different from the 1 atm of pressure found at sea level. These inventors were able to supply air on demand at appropriate breathing pressure to persons underwater with a "demand regulator," as it subsequently became known. This device originally required a surface air supply connection.^[2] The demand valve regulator was later modified to supply auxiliary oxygen for pilots operating at high altitude. In 1943, while working with the French resistance against Nazi Germany, Jacques-Yves Cousteau and Emile Gagnon combined a demand valve regulator with a compressed air tank, giving rise to what they called "self-contained underwater breathing apparatus," or *scuba*.

The potential military usefulness of scuba was immediately recognized and led to a considerable amount of investigation during World War II. As initially configured, scuba was used in an open-circuit mode in which exhaled air was just vented into the water. This was wasteful of the compressed air supply and had other disadvantages for military uses. Further work led to refinement of rebreather scuba devices (both closed and semiclosed circuit systems), such as Lambertsen's amphibious respiratory unit.^[8] These rebreather systems conserved the breathing gas by using a carbon dioxide scrubber and recirculating all or part of each exhalation (see rebreather section below). These specialized scuba systems were useful for military purposes because they allowed longer submergence times and could be used in clandestine operations or when disarming pressure-sensitive explosive devices. However, they had a greater risk of mishap, so rebreather systems were not widely used.

After World War II the development and marketing of open-circuit scuba equipment to the general public made the underwater world accessible to growing numbers of people. In the last four decades, scuba diving has opened the underwater world to millions of divers and hundreds of millions of cinema observers. Scuba is now used as a basic tool with myriad commercial, military, scientific, and recreational applications (Box 57-1 (Box Not Available)).^[5] The growth of sport diving has been especially noteworthy. For example, since scuba was first introduced into the United States in 1951, it is estimated that over 7 million Americans have been certified as recreational or sport divers.

TYPES OF DIVING AND DIVING EQUIPMENT

There are five general types of diving, each using different equipment and having different logistical support needs. From the least to the most sophisticated equipment used, the types of diving are breath-hold or free diving, scuba diving, surface-supplied or tethered diving, saturation diving, and one atmosphere diving.

1368

Box 57-1. TYPES OF COMMERCIAL DIVING

(Not Available)

Modified from Kizer KW: Medical aspects of scuba diving. In Noble J, editor: Textbook of general medicine and primary care, Boston, 1987, Little, Brown.

Breath-Hold or Free Diving

Breath-hold diving—also known as *free diving*, *skin diving*, or *snorkeling*—is the simplest and oldest form of underwater diving. It uses no external supply of air, so submergence time is limited to the length of time the diver can hold his or her breath. Generally, the breath-hold diver uses a face mask to facilitate underwater vision, fins for propulsion, a snorkel to breathe air while swimming face down on the water's surface, some sort of attire for thermal protection (e.g., a neoprene wet suit), and sometimes lead weights to counterbalance the positive buoyancy of a wet suit or one's innate positive buoyancy.

Scuba Diving

Scuba diving uses a tank fitted with a pressure regulator that supplies compressed air to

the diver at a pressure equal to ambient water pressure. In sport diving, the diver's scuba tank usually contains either 72 or 90 cubic feet of filtered, oil-free compressed air pressurized to about 2200 or 3300 pounds per square inch gauge (PSIG). The regulator employs two stages. The first stage is attached to the tank and makes an initial reduction in pressure to the lower-pressure second stage, which is attached to the diver's mouthpiece and from which the diver actually breathes.

Like the snorkeler, the scuba diver wears a face mask covering the eyes and nose to allow underwater vision, fins for propulsion, snorkel for surface swimming, weight belt, buoyancy-compensating vest to adjust buoyancy under water and for flotation in case of an emergency, diving watch and depth gauge (or a diving computer) to track time and depth underwater, compass, and tank pressure gauge to monitor air consumption. Because of the higher thermal conductivity of water, divers typically wear neoprene wet suits in all but warm tropical waters. These suits maintain a layer of water warmed by body heat between the skin and suit. A nonpermeable "dry suit" and warm undergarments are usually worn when diving in colder water (e.g., colder than 10° C [50° F]).

In addition to the preceding basic equipment, additional equipment may be needed for safety, navigation, communication, or other special purposes (e.g., camera, spear gun, or game bags). All of these objects increase the diver's resistance to movement underwater and decrease efficiency of movement.

Although recreational scuba diving is mostly done using compressed air in an open-circuit mode, special types of scuba gear may be used for mixed-gas diving (see below) or to achieve semiclosed or closed-circuit diving.

Surface-Supplied or Tethered Diving

Surface-supplied or tethered diving includes several different diving technologies, all of which share the common characteristic of the diver's breathing gas (compressed air or mixed gas) being supplied to the diver by hoses from a surface supply or from a diving bell at a pressure equal to water pressure.

The best known form of surface-supplied diving is classic *hardhat diving*, which is sometimes called *mud diving* because it is often done in harbors (which typically have very muddy bottoms). In this type of diving, the diver wears a large bronze helmet with face plates, a canvas suit, weight belt and weighted shoes, and other gear. The gear alone weighs 192 pounds for the typical helmet diver. Surface-supplied diving is most often used for commercial or military purposes. It is frequently performed in very arduous environments having zero visibility (i.e., the diver operates in total darkness, often against a current or surge, performing tasks primarily by feel).

The diving techniques of surface-supplied diving are quite different than those of scuba and they are not further discussed here; however, the unique physiologic and medical problems of surface-supplied

divers are identical to those encountered in scuba diving.

Saturation Diving

Once under water, the diver begins to absorb increased amounts of nitrogen or other inert gas, depending on the breathing medium, until a new equilibrium is established according to the pressure of the depth of submergence. In certain deep-diving scenarios, the time needed to off-gas, or "decompress," this inert gas on returning to normal atmospheric pressure may be much greater than the time spent at depth.

In the late 1950s, experiments by U.S. Navy diving medical officers George Bond and Robert Workman coincided with those of Jacques-Yves Cousteau and Edward Link in the commercial sector, all of whom were working on ways to stay under water at great depths long enough to perform useful work.^[2] The need for prolonged decompression after deep diving led to the development of saturation diving.

The basic concept of saturation diving is that after approximately 24 hours at any given depth, the diver's tissues have established equilibrium with the gases in the breathing mixture. From that point, the decompression obligation remains the same no matter how long the diver remains at that depth. If the diver can be kept "at pressure" for a prolonged period, the decompression is the same as if he or she were there for only a short time.

Modern saturation complexes allow divers to live for days in large chambers at the pressure of a given work site and to be transported to the underwater site by locking into a personal transfer capsule (PTC) or sealed diving bell. When depth is reached, the water pressure equals the gas pressure within the capsule and divers may exit the PTC into the water while breathing gas supplied by umbilical hoses. To maintain the diver's thermal balance in the very cold water found at great depths, heated water is circulated in special hot-water suits.

Another application of saturation diving, used primarily for scientific purposes, is characterized by the use of underwater habitats (i.e., steel chambers situated at a given depth of water and pressurized with a compressed gas atmosphere at the same pressure as the surrounding water). Divers may live for days or weeks in the habitat, leaving the chamber with scuba equipment to perform studies or observe marine life in its natural state. In this specialized type of diving, rigorous precautions are taken to avoid inadvertent surfacing, thermal stress, and skin and ear infections during prolonged stays in the continuously moist environment of the habitat. Prolonged saturation decompression schedules, often taking several days, are required to return

Figure 57-1 JIM diving suit. The diver remains at sea level pressure inside the suit and can work for prolonged periods of time at extreme depths underwater.

divers safely to sea level pressure on completion of the underwater mission.

One-Atmosphere Diving

In recent years it has become clear that humans cannot reliably or safely function at the greatly elevated pressure of deep water, and this has become the limiting factor in human exploration of the ocean depths. This has led to numerous developments in one-atmosphere diving systems. Leonardo de Vinci drafted schematic drawings that look similar to modern one-atmosphere diving systems, but these systems had to await late twentieth century advances in metallurgy, engineering, and communications.

One-atmosphere absolute (ATA) diving systems are, in essence, small submarines with various types of propulsion systems and manipulators that allow the operator to work at great depth. The interior of the unit is maintained with environmental control systems to retain safe physiologic parameters. These systems range from one-person ATA suits in which a diver can "walk" ([Figure 57-1](#)) to submersibles that accommodate two or more occupants.

1370

Mixed-Gas Diving

Diving can be done using either compressed air or "mixed gas." Compressed air is most commonly used, especially with scuba, but there are a number of settings where mixed gas is needed or preferred.

Mixed-gas diving refers to diving using a breathing medium other than compressed air (i.e., a gas mixture in which the concentrations of nitrogen and oxygen have been changed or in which a different inert gas [e.g., helium] is substituted for nitrogen). Mixed-gas diving can be used in surface-supplied, saturation, or scuba diving modes, although historically it has been used most often in surface-supplied or saturation diving operations.

Mixed-gas diving has been used for many decades, but because of the greater logistical support it requires and its greater expense and hazards it has been used primarily in commercial and military diving operations. That has changed in the past decade as

"technical" sport divers have sought to go deeper and stay down longer.

Enriched Air Nitrox.

Nitrox is a breathing-gas mixture containing oxygen and nitrogen in concentrations different from those found in air. More than a dozen different such mixtures have been used by recreational divers, all of which are lumped under the heading "nitrox," but the two most commonly used mixtures are the ones labeled by the National Oceanographic and Atmospheric Administration (NOAA) as Nitrox I (a gas mixture containing 32% oxygen and 68% nitrogen) and Nitrox II (a gas mixture containing 36% oxygen and 64% nitrogen). Each nitrox mixture, or blend, requires its own set of decompression tables and has its own bottom time limits. Only Nitrox I is approved for recreational diving use, and subsequent reference to enriched air nitrox in this chapter is to this mixture.

Of note, the term "nitrox" historically was used to refer to gas mixtures having less than 21% oxygen. These mixtures were used in diving habitats or other saturation diving situations in which one wanted to avoid, or at least lessen, the risk of oxygen toxicity. Technically, if the oxygen percentage is adjusted to greater than 21%, the mixture is called "enriched air nitrox" (EAN), or "oxygen enriched air" (OEA), although "EAN" and "nitrox" are used interchangeably in common diver's parlance.

Beginning in the 1980s an increasing number of recreational divers began using EAN to reduce decompression risk or to extend bottom time (compared with what was possible using compressed air) without incurring additional decompression risk. Although many thousands of recreational EAN divers have been certified over the past decade, its use continues to be closely observed because of safety concerns.

EAN diving enthusiasts typically claim that nitrox is safer than compressed air because it has less risk of decompression sickness (compared with compressed air) for equivalent bottom times. In particular, at depths between 50 and 130 feet of sea water (fsw), EAN allows up to twice the bottom time without required decompression when compared with compressed air. However, this rationale does not constitute a complete analysis of the situation.

Although diving with nitrox may lessen the risk of decompression sickness compared with diving with compressed air, it does not eliminate the risk, and EAN presents additional risks of its own. The main concern is with central nervous system (CNS) oxygen toxicity, which usually manifests suddenly (with few, if any, prodromal symptoms) by loss of consciousness and onset of convulsions. Because of the risk of CNS oxygen toxicity, EAN should not be used below 130 fsw.

A diver can still suffer decompression sickness diving with EAN if he or she stays down too long, surfaces too fast, bypasses a required decompression stop, or uses the wrong nitrox decompression table for the particular breathing medium. Further, although nitrox may increase a diver's allowable no-decompression bottom time, this is usually irrelevant because a diver's bottom time is as much a function of gas supply as the decompression limit. The average scuba diver would exhaust his gas supply long before

reaching the no-decompression limit.

Overall, nitrox diving for recreational purposes is still in its infancy. Clearly, it has advantages and disadvantages ([Box 57-2](#)), with the advantages being most likely realized in a setting that ensures strict discipline and adherence to safety.

Heliox.

Other than nitrox, the most commonly used mixed gas is heliox, or oxy-helium, a mixture of helium and oxygen. Helium is used as the inert gas, replacing nitrogen and part of the oxygen. Use of heliox eliminates nitrogen narcosis and allows the oxygen level to be controlled to reduce the risk of oxygen toxicity. As with nitrox, *heliox* is a generic term that applies to a number of different gaseous blends or mixtures of helium and oxygen.

Because it causes negligible, if any, narcosis and is easier to breathe at greater depths (because of its lesser density), heliox is the preferred gas used in commercial diving at depths over 130 fsw. The major problems with helium are its expense, which precludes its widespread use in recreational diving, and hindrance of speech. In commercial and military settings, helium speech unscramblers are typically used.

Tri-Mix.

Tri-mix is another generic term, in this instance referring to any mixture of helium, nitrogen, and

oxygen. This breathing medium was developed by the military for diving operations at depths greater than those possible with air. Helium replaces some of both the nitrogen and oxygen in an effort to eliminate or minimize nitrogen narcosis and to prevent CNS oxygen toxicity. The precise concentrations of helium, nitrogen, and oxygen used in tri-mix vary according to the specific depth profile of the dive. Obviously, in deep diving operations, the percentage of both nitrogen and oxygen will be much less than in air, which means that a "travel" gas mixture is needed for breathing in the shallower depths that must be traversed to get to the depth at which the tri-mix will be used. Currently, the U.S. Navy specifies the use of tri-mix for diving at depths greater than 190 fsw, and tri-mix is typically used in extreme-depth (e.g., greater than 600 fsw) commercial diving.

Box 57-2. ADVANTAGES AND DISADVANTAGES OF ENRICHED OXYGEN NITROX DIVING COMPARED WITH COMPRESSED AIR AT DEPTHS BETWEEN 50 AND 130 FSW

ADVANTAGES

- Decreased risk of decompression sickness
- Decreased occurrence of nitrogen narcosis
- Reduced residual nitrogen time
- Shorter surface interval times
- Reduced decompression times if maximum bottom time limits are exceeded
- Reduced surface intervals between diving and flying

DISADVANTAGES

- Requires special training
- Requires equipment dedicated for use with nitrox only
- Increased oxidation of scuba cylinders
- Possible increased rate of deterioration of equipment
- Increased fire hazards
- Inability to use air-based dive computers
- Potential for nitrox mixing and filling problems
- Risk of CNS oxygen toxicity

A spin-off of tri-mix that has begun to be used in recreational diving is oxygen-enriched tri-mix, or *helitrox*. A tri-mix blend commonly used in this setting is 26% oxygen, 17% helium, and 57% nitrogen (TX 26/17). Helitrox advocates promote its use for diving to depths of up to 150 fsw, using either helitrox to decompress or switching to pure oxygen at the 20-fsw decompression stop.

A number of untimely deaths of sport divers have been associated with the use of

tri-mix, and its use in recreational diving remains controversial. However, its use is expected to grow in the years ahead, as has occurred with nitrox.

Rebreather Diving

Although most people connect the first self-contained underwater diving with scuba, it was actually first done with the assistance of a rebreather in the 1880s. Rebreathing devices for diving were perfected over the years, but with the advent of scuba in the 1940s, rebreathers were relegated to use in only a few special commercial and military situations. Beginning in the 1990s, however, rebreathers have started to be used increasingly in recreational diving (especially for underwater photography and cave diving).

Conceptually, rebreathers are devices that capture and recirculate a diver's exhaled breath, removing the carbon dioxide added by the body's metabolism and replacing the oxygen extracted by the body before giving the air back to the diver to once again breathe. As a diving technology, rebreathers are much more efficient than open-circuit scuba, and they allow one to dive to greater depths and stay underwater longer than is possible with conventional open-circuit scuba. They are also very useful when exhaled bubbles may be problematic (e.g., when studying or photographing marine life or when disarming a mine). However, they can be quite hazardous if not maintained and operated properly.

All rebreathers have certain elements in common, and all fall into one of four general categories of devices^[6] :

1. Closed-circuit oxygen rebreather
2. Closed-circuit mixed-gas rebreather
3. Semiclosed-circuit rebreather using premixed gas
4. Semiclosed-circuit rebreather that mixes the breathing gas on board.

There are many different rebreather designs available, and new systems continue to be developed. Therefore a diver must be individually trained on the use of each rebreather.

SPECIAL DIVING SITUATIONS

Diving in general, and scuba diving in particular, has become a tool that allows humans to engage in a wide array of underwater activities (see Box 57-1 (Box Not Available)). There are a number of special diving situations.

Under-Ice and Cold-Water Diving

Diving under the ice in extremely cold environments is done for exploration, search and rescue, salvage, inspections, research, and other work. This takes place in lakes, rivers, and polar regions. Besides meticulous preparation and provision of thermal protection for the diver under ice, extremely low temperature, wind, and snow above water at the dive site necessitate careful planning for topside shelter. For diving in such cold water, dry suits or hot-water suits are used. Dry suits are made of closed-cell foam neoprene, rubber, or rubberized

1372

canvas and fit loosely on the body, with seals at the wrists, ankles, and neck to keep the diver and insulating underwear dry and to allow admission of air to maintain equal suit volume during the dive. Free-flooding hot-water suits are loosely fitted, closed-cell foam neoprene suits with hoses inside to allow warm water to flow continuously over the diver's body and exit at the wrist and neck.^[109] In this specialized type of diving, other considerations are provision of breathing regulators that are not likely to freeze, planning for immediate rescue and rapid rewarming of an individual who might fall into the frigid water without adequate protection, maintenance of adequate nutrition and hydration, and total prohibition of alcoholic beverages or mind-altering drugs at the dive operation because these activities permit little margin for error.

Cave and Cavern Diving

The advent of scuba has allowed exploration of many underwater caverns and cave systems, leading to important archaeologic and geologic discoveries. However, cave diving is the most dangerous form of diving.^[54]

To trained, experienced, and properly equipped cave divers, the number of cave-diving fatalities (over 300 in Florida alone since 1960) is distressing, although generally explainable. Most fatalities have involved inexperienced recreational scuba divers who were never formally trained in cave diving. Most often, the divers became lost and ran

out of air while in a cave. The National Association of Cave Divers (NACD) and the National Speleological Society-Cave Diving Section (NSS-CDS) are the recognized training organizations for cave diving.

Because cave divers are separated from the outside world and cannot simply surface in case of an emergency, specific equipment and procedures are required. These include double tanks, meticulous planning of air consumption, backup lights, and guide cables to avoid becoming lost. No one should attempt cave diving without completing formal training approved by either the NACD or the NSS-CDS.

River Diving

Diving in rivers is often done by public safety personnel in search of evidence or to retrieve bodies (usually drowning victims). Because of the typically poor visibility, strong currents, and potential for entanglement in debris, this type of diving should be done only by persons who have been trained in the special techniques of river diving and who have proper surface support.

Miscellaneous Other Settings

Diving is undertaken for a variety of special purposes in settings that pose unique hazards. Examples of these settings include nuclear power plants, harbors with toxic chemical or infectious disease contamination, water treatment facilities, and dams generating electric power. Each of these settings requires special diving techniques, health monitoring, and safety precautions.

DYSBARISM

Divers encounter many adverse environmental conditions underwater. These include cold, changes in light transmission and sound conduction, lack of air to breathe, increased density of the surrounding environment, and increased atmospheric pressure. Not surprisingly, diverse medical problems are related to diving ([Box 57-3](#)).

Of the various environmental factors affecting divers, pressure is by far the most important because it contributes either directly or indirectly to the majority of serious diving-related medical problems.

1373

Therefore understanding the basic physics and physiologic effects of pressure is essential to treating the pressure-related maladies that fall under the general term *dysbarism*.

Definitions and Terminology

Dysbarism is a term that encompasses all the pathologic conditions caused by altered environmental pressure. These disorders primarily affect divers and persons who work in compressed-air environments, who are also exposed to increased atmospheric pressure; however, some of the conditions may also occur in aviators, astronauts, and certain types of industrial workers as a result of abrupt exposure to the reduced pressure found at actual or simulated high altitude.

Dysbarism most often develops acutely because of problems caused by the mechanical effects of pressure on closed air spaces (*barotrauma*) or problems caused by breathing gases at elevated partial pressure (such as *nitrogen narcosis* or *decompression sickness*). Less often, clinical effects are delayed for months or years, as in the case of dysbaric osteonecrosis; the pathophysiology of these conditions is less well understood.

Pressure is defined as force per unit area. *Atmospheric pressure* is the pressure exerted by the air above the earth's surface. Atmospheric pressure varies with altitude. At sea level, atmospheric pressure is 760 millimeters of mercury (mm Hg) or 14.7 pounds per square inch (PSI). The barometric pressure at sea level is generally referred to as 1 atmosphere (atm). *Absolute pressure* is the total barometric pressure at any point. With pressure gauges calibrated to read zero at sea level, gauge pressure is the amount of pressure greater than atmospheric pressure. In general, gauge pressure is 1 atm less than absolute atmospheric pressure. It is always important to specify whether pressure is expressed in terms of gauge or absolute pressure. Except in situations requiring laboratory precision, the following units are commonly used to express water pressure:

- Feet of seawater (fsw)
- Feet of fresh water (ffw)
- Atmospheres absolute (ATA)

- Pounds per square inch gauge (psig)
- Pounds per square inch absolute (psia)

As a diver descends under water, absolute pressure increases much faster than in air. Each foot of seawater exerts a force of 0.445 psig. Therefore if the 14.7 psi pressure of 1 atm is divided by 0.445 psi per foot of seawater, at 33 fsw the absolute pressure will have doubled. In the ocean, each 33 feet of depth adds one additional atmosphere of pressure. The gauge pressure at 33 fsw is 14.7 psig (in excess of atmospheric pressure), and the absolute pressure is 29.4 psia.

Because of the weight of solutes in seawater, it is slightly heavier than fresh water. In fresh water, 34 feet equals one additional atmosphere of pressure.

Pressure change with increasing depth is linear, although the greatest relative change in pressure per unit of depth change occurs nearest the surface. [Table 57-1](#) lists commonly used units of pressure measurement in seawater.

When a diver submerges, the force of the tremendous weight of the water above is exerted over the entire body. Except for air-containing spaces such as the lungs, paranasal sinuses, intestines, and middle ears, the body behaves as a liquid. The law that describes the behavior of pressure in liquids is named for the seventeenth century scientist Blaise Pascal. Pascal's law states that a pressure applied to any part of a fluid is transmitted equally throughout the fluid. Thus when a diver reaches 33 fsw, the pressure on the surface of the skin and throughout the body tissues is 29.4 psia or 1520 mm Hg ([Figure 57-2](#)). The diver's body is generally unaware of this pressure, except in the air-containing spaces of the body. The gases in these spaces obey Boyle's law ([Figure 57-3](#)), which states that the pressure of a given quantity of gas for which temperature remains unchanged varies inversely with its volume. Thus air in the middle ear, paranasal sinuses, lungs, and gastrointestinal tract is reduced in volume during compression or descent under water. Inability to maintain gas pressure in these body spaces equal to the surrounding water pressure leads to various untoward mechanical effects, which are discussed later.

Because of the weight of the water exerting pressure over the chest wall, humans can breathe surface air through a snorkel or tube connected to the surface for only a short distance underwater, typically only to a depth of 1 to 2 feet. Attempts to breathe at greater depths through the tube are not only impossible but

TABLE 57-1 -- Commonly Used Units of Pressure in the Underwater Environment

DEPTH (fsw)	PSIG	PSIA	ATA	mm Hg (ABSOLUTE)
Sea level	0.0	14.7	1	760
33	14.7	29.4	2	1520
66	29.4	44.1	3	2280
99	44.1	58.8	4	3040
132	58.8	73.5	5	3800

165	73.5	88.2	6	4560
198	88.2	102.9	7	5320
231	102.9	117.6	8	6080
264	117.6	132.3	9	6840
297	132.2	147.0	10	7600

1374

Figure 57-2 Pascal's law. Pressure applied to any part of a fluid is transmitted equally throughout the fluid.

dangerous, because the respiratory effort greatly augments the already physiologic negative-pressure breathing. In other words, when the respiratory muscles are relaxed at sea level, alveolar pressure is equal to surrounding air pressure. At a depth of 1 foot, the total water pressure on the chest wall is nearly 200 pounds. Because of the loss of normal chest expansion and the pressurization of intraalveolar air, the diver has to use forceful negative-pressure breathing to draw surface air into the lungs through the tube. Even at a depth of 1 foot, the great respiratory effort required is rapidly fatiguing, and respiration becomes impossible at further depths of only a few inches. Forced negative-pressure breathing can ultimately result in pulmonary capillary damage, with intraalveolar edema or hemorrhage. Symptoms include dyspnea and hemoptysis. Should this occur, there is no specific treatment; therapy is purely supportive.

1375

Figure 57-3 Boyle's law. The volume of a given quantity of gas at constant

temperature varies inversely with pressure: $P_1 V_1 = P_2 V_2$.

BAROTRAUMA

Gas pressure in the various air-filled spaces of the body is normally in equilibrium with the environment. However, if anything obstructs the passageways of gas exchange for these spaces and a change in ambient pressure occurs, a pressure disequilibrium develops. The tissue damage resulting from such pressure imbalance is known as *barotrauma*.

Overall, barotrauma is the most common medical problem in scuba diving, potentially involving any structure or combination of structures that leads to entrapment of gas in a closed space. This may include skin trapped under a fold in a dry suit, the portion of the face under a face mask, ears, paranasal sinuses, lungs, and gastrointestinal tract.

Specific Types of Barotrauma

Mask Squeeze.

For humans to see underwater, an airspace must be present between the eye and water. In scuba diving, this is created by use of a face mask consisting of tempered safety glass in a soft malleable mask that seals across the forehead, on the sides of the face, and under the nose to allow nasal exhalations to maintain air pressure inside the mask equal to water pressure during descent. If inexperience or inattention causes the diver to forget to maintain this balance, negative pressure in the mask can rupture capillaries, causing skin ecchymoses and conjunctival hemorrhage. This condition is known as *mask squeeze* (see [Figure 22-19](#)). Such a pressure imbalance could be especially dangerous after keratotomy because of the slow healing rate of corneal incisions.^[30]

1376

Ear Canal Squeeze.

A tight-fitting wet-suit hood can trap air in the external auditory canal and potentially lead to a painful *external ear squeeze* during descent as the volume of air is reduced according to Boyle's law. This problem can be prevented by remembering to break the seal to allow water to fill the external ear canal before descent. External ear squeeze also can occur if the canal is blocked by cerumen, exostoses, or ear plugs (which should never be worn when diving).

Symptoms and signs of ear canal squeeze include pain, swelling, erythema, petechiae, or hemorrhagic blebs of the ear canal wall. In very severe (and very rare) cases, the tympanic membrane can rupture from the negative pressure in the ear canal. If this occurs, further diving is contraindicated until the membrane has healed (as discussed below).

Barotitis Media or Middle Ear Squeeze.

Referred to in diver parlance as ear *squeeze*, barotitis media is the most common medical problem in scuba diving, probably affecting more than 40% of divers.^[53] The problem is a direct application of Boyle's law ([Figure 57-4](#)), potentially compounded by the structure of the eustachian tube.

As previously noted, Boyle's law describes the inverse relationship of pressure and volume in an enclosed airspace. It also explains why the greatest relative

Figure 57-4 Middle ear barotrauma. Symptoms include fullness and pain caused by stretching of the tympanic membrane.

volume change for a given depth change occurs near the surface, which is why the greatest risk of middle ear squeeze occurs near the surface.

Because each foot of seawater exerts a pressure of about 23 mm Hg, a diver who descends 2.5 feet and does not equalize the pressure in his or her middle ear will develop a relative vacuum in the middle ear because of the contraction of air volume in the ear. Typically the diver notices slight pain at a 60-mm Hg pressure differential between air in the middle ear and ambient water pressure. This pressure differential causes the tympanic membrane to stretch and bulge inward, causing increasing discomfort and eventually severe pain. At a depth of 4 feet, a 90-mm Hg pressure differential is generated, and the unsupported, flutter-valve medial third of the eustachian tube collapses and becomes obstructed. At this point, attempts to autoinflate the middle ear by Valsalva or Frenzel maneuvers may be unsuccessful. The diver must ascend to equalize middle ear pressure with ambient environmental pressure.

The Valsalva maneuver involves blowing with an open glottis against closed lips and nostrils to increase pressure in the nasopharynx to inflate the middle ear through the eustachian tube. This may force open a collapsed eustachian tube. The Frenzel maneuver is performed by swallowing with a closed glottis while the lips are closed and

the nostrils are pinched.

If a diver does not heed the symptoms of barotitis media and allows the pressure differential to reach 100 to 400 mm Hg (i.e., at depths of 4.3 to 17.4 feet), the pressure imbalance may be unsatisfactorily resolved by rupture of the tympanic membrane.^[50] In such a case, the problem for the diver may be compounded by entry of cold water into the middle ear. This may cause severe vertigo. Before this event, serum may have been drawn into the middle ear by the relative vacuum, causing serous otitis media.

Prevention is the key in dealing with barotitis media. Divers who understand the sequence just described generally take steps to inflate the middle ear immediately on submerging and thereby avoid the entire sequence as they descend in the water. If middle ear pressure is kept equal to or greater than water pressure, no problem should occur. However, if the diver forgets to inflate the middle ear or suffers from eustachian-tube dysfunction (caused by mucosal congestion secondary to upper respiratory infection, allergies, smoking, mucosal polyps, excessively vigorous autoinflation maneuvers, or previous maxillofacial trauma), middle ear barotrauma may occur. This most often happens just after the diver leaves the surface, with the diver complaining of ear fullness or pain. Generally, the pain rapidly becomes so severe that the diver either corrects the problem or aborts the dive.

1377

The otoscopic appearance of the tympanic membrane in cases of barotitis media varies with the severity of the injury. A commonly used grading scheme is the Teed classification, which grades the severity according to the amount of hemorrhage in the tympanic membrane.^[45] Grade 0 is for symptoms only (i.e., pain without any physical stigmata); grade 1 is for erythema over the malleus; grade 2 is for erythema of the malleus plus mild or spotty hemorrhage within the tympanic membrane; grade 3 is for gross hemorrhage throughout the tympanic membrane; grade 4 is for free blood in the middle ear; and grade 5 is for free blood in the middle ear plus perforation of the tympanic membrane. Each higher grade tends to be more painful than the preceding one, except for grade 5, which may be relatively painless. With grade 5, the cessation of pain corresponds with the membrane tearing, which immediately equalizes the pressure in the middle ear with the external environment. Use of this grading scheme facilitates communication when describing these injuries.

In addition to having an abnormal-appearing tympanic membrane, persons with barotitis media occasionally have a small amount of bloody drainage around the nose or mouth and mild conductive hearing loss.

Middle ear squeeze should be treated with decongestants and analgesics. Antihistamines may be used if the eustachian-tube dysfunction has an allergic component. Divers should abstain from diving until the condition has resolved. Combining an oral decongestant with a long-acting topical nasal spray (such as 0.5% oxymetazoline or phenylephrine) for the first few days is usually most effective.

Repeated gentle autoinflation of the middle ear by use of the Frenzel maneuver also can help to displace any collection of middle ear fluid through the eustachian tube. Antibiotics (such as amoxicillin-clavulanic acid) should be used when there is a tympanic membrane rupture or preexisting infection. If the tympanic membrane has ruptured, no diving should be done until it is fully healed or a surgical repair is successful, and until eustachian-tube function allows easy autoinflation.

Most cases of barotitis media resolve without complication in 3 to 7 days, although occasionally it takes longer. The condition can be prevented if a diver refrains from diving when unable to easily equalize pressure in the ears and heeds the warning symptoms of ear pain.

Barosinusitis.

Barosinusitis, or *sinus squeeze*, results from essentially the same mechanism as barotitis media but is less common ([Figure 57-5](#)). If there is inability to maintain the air pressure in any paranasal sinus during descent, a relative vacuum develops in the sinus cavity. This initially produces intense pain, then damage to the sinus wall mucosa, with bleeding into the sinus. Less commonly, a reverse sinus squeeze can occur on ascent in the water. In this condition, pain is produced by relatively high air pressure in the sinus. This usually occurs in the setting of a diver who has an upper respiratory infection or severe allergies and who has taken a decongestant some time before diving but in whom the vasoconstricting effect wears off while at depth.

Prevention of barosinusitis requires avoidance of diving with an upper respiratory infection or while allergic rhinitis is causing edema of the mucosa about the sinus orifices, and when sinusitis, nasal polyps, or any other condition is present that impairs free flow of air from sinus cavity to nose. Treatment involves use of systemic (e.g., pseudoephedrine) and topical (e.g., phenylephrine or oxymetazoline) vasoconstrictors, analgesics, abstinence from diving until resolved, and antihistamines if needed. Antibiotics may be needed in the event of a severe squeeze with bleeding into the sinus cavity or in cases of frontal sinusitis.

Barodontalgia.

One of the most infrequent yet dramatic types of barotrauma is *barodontalgia*, or *tooth squeeze*; this is sometimes called *aerodontalgia*. This painful condition is caused by entrapped gas in the interior of a tooth or in the structures surrounding a

Figure 57-5 Frontal sinus barotrauma 3 days earlier. Note the persistent air-fluid level.

tooth. The confined gas develops either positive or negative pressure relative to ambient pressure, which exerts force on the surrounding sensitive dental structures and causes pain.

Barodontalgia may be caused by an array of dental conditions, including caries, defective restorations, oral tissue lacerations, recent extractions, periodontal abscesses, pulpal or apical lesions or cysts, and endodontal (root canal) therapy. If a pocket of trapped air remains at sea level pressure while ambient pressure increases during descent, the tooth can implode or the cavity can fill with blood. Conversely, air that is forced into a tooth during descent can expand during ascent, causing the tooth to explode. To prevent barodontalgia, a diver should wait at least 24 hours after dental treatment (including fillings) before diving.

Other causes of tooth pain associated with pressure changes are less well understood. Pulpitis or other dental infections can produce pain during a dive. Of course, upper tooth pain associated with pressure changes should raise a question about a pathologic condition in the maxillary sinus.

Labyrinthine Window Rupture.

A serious but relatively unusual form of aural barotrauma is *inner ear barotrauma* causing *labyrinthine window rupture*. This is the most serious form of aural barotrauma because of possible injury to the cochleovestibular system that may lead to permanent deafness or vestibular dysfunction. ^[43] ^[49]

Inner ear barotrauma results from rapid development of markedly different pressures between the middle and inner ear, such as may occur from an overly forceful Valsalva maneuver or an exceptionally rapid descent, during which middle ear pressure is not adequately equalized. The pressure disequilibrium may cause several types of injury to the cochleovestibular apparatus, including hemorrhage within the inner ear; rupture of Reissner's membrane, leading to mixing of endolymph and perilymph; fistulation of the oval or round window, with development of a perilymph leak; or a mixed injury involving any or all of these things. ^[95]

The classic triad of symptoms indicating inner ear barotrauma is roaring tinnitus, vertigo, and hearing loss. In addition, a feeling of fullness or "blockage" of the affected ear, nausea, vomiting, nystagmus, pallor, diaphoresis, disorientation, or ataxia may be present in varying degree.

Symptoms of inner ear barotrauma may develop immediately after the injury or may be delayed for hours, depending on the specific damage and the diver's activities during and after the dive. Vigorous isometric exercise after a dive may complete an incipient or

partial membrane rupture. Findings on physical examination may be normal or may reveal signs of middle ear barotrauma or vestibular dysfunction. Audiometry may demonstrate mild to severe sensorineural hearing loss.

Hemorrhage within the inner ear is usually associated with findings of middle ear barotrauma, absent or transient vestibular symptoms, and diffuse mild to severe sensorineural hearing loss. Patients should be treated with bed rest (with the head elevated to 30 degrees), avoidance of any strenuous activity, and symptomatic measures as needed. There is a good prognosis for full recovery of hearing in 3 to 12 weeks. Patients with a tear in Reissner's membrane have manifestations similar to those with inner-ear hemorrhage, although there will be persistent localized sensorineural hearing loss commensurate with the area of membrane tear. The management is the same.

A patient with a perilymph fistula usually has high-frequency sensorineural hearing loss or marked cochleovestibular dysfunction and little evidence of middle ear barotrauma. Initially, he or she should be treated with bed rest, avoidance of strain, and symptomatic measures, although some authorities advocate immediate tympanotomy if severe symptoms are present. In all cases, however, deterioration of hearing, worsening of vestibular symptoms, or persistence of significant vestibular symptoms after a few days heralds the need for detailed otolaryngologic evaluation and probable surgical exploration and repair.

A diagnostic dilemma exists whenever a diver complains of vertigo, tinnitus, and hearing loss associated with a dive. These symptoms are classic for labyrinthine rupture, in which case recompression is contraindicated because of the potential for further barotrauma to worsen the injury. Conversely, these symptoms may indicate a diagnosis of inner ear decompression sickness, which requires expeditious treatment in a hyperbaric chamber. In such cases the most important differential feature for diagnostic use on a dive boat or other diving site is a careful history as to time of onset and dive activities preceding the onset of symptoms. If symptom onset was during descent and ear clearing was difficult or impossible, requiring forcible Valsalva maneuvers, perilymph fistula is more likely. If the onset was during or after a decompression dive, decompression sickness must be assumed and chamber treatment sought. In some cases, however, it simply is not possible to rule out decompression sickness, or rarely, air embolism, and a "trial of pressure" in the recompression chamber may be necessary.

Alternobaric Vertigo.

An unusual type of aural barotrauma is *alternobaric vertigo* (ABV). This usually occurs with ascent and is caused by sudden development of unequal middle ear pressure, which causes asymmetric vestibular stimulation and resultant pronounced vertigo.^[83] Although usually only transient and requiring no treatment, ABV may precipitate a panic response

leading to near drowning, pulmonary barotrauma and resultant air embolism, or other serious injury. Rarely, alternobaric vertigo lasts for several hours or days, in which case it should be treated symptomatically after excluding inner ear barotrauma.

Suit Squeeze.

If an area of the diver's skin becomes trapped under a fold or wrinkle of a dry suit, causing a closed airspace, the pressure-induced contraction of air under the fold, and resulting partial vacuum, can cause transudation of blood through the skin. This is unusual and generally benign, although the resultant skin ecchymosis may have a dramatic appearance. *Suit squeeze* requires no treatment and resolves in a few days to a couple of weeks.

Lung Squeeze.

Lung squeeze is a very unusual form of barotrauma that has been observed with breath-hold diving. Persons having this syndrome complain of shortness of breath and dyspnea after surfacing from a deep (greater than 100 FSW) breath-hold dive. The diver may cough up frothy blood, and a chest radiograph may show pulmonary edema. The condition is treated with supplemental oxygen and respiratory support as needed. Symptoms typically resolve within a few days.

The classic understanding of lung squeeze is that it occurs when a diver descends to a depth at which total lung volume (TLV) is reduced to less than residual volume (RV), at which point transpulmonic pressure exceeds intraalveolar pressure, causing transudation of fluid or frank blood (from rupture of pulmonary capillaries) and the overt manifestations of pulmonary edema and hypoxemia.

According to this scenario, a breath-hold diver with a TLV of 6000 ml and an RV of 1200 ml could dive to only $6000/1200$ or 5 ATA (equal to 132 FSW) before lung squeeze would occur. However, breath-hold divers have dived much deeper without apparent problem.

In 1968 Schaefer and associates^[104] reported that breath-hold divers pool their blood centrally, accumulating a central volume increase of as much as 1047 ml at 90 FSW. If it is assumed that this adjustment in pulmonary blood volume reduces the RV, then theoretically it should be possible for the diver with a TLV of 6000 ml to breath-hold to $6000/(1200 \text{ to } 1047)$ or almost 40 ATA. Although Gianluca Grenoni's 1997 world record breath-hold dive to 395 FSW seems to support the beneficial effect of central pooling of blood, cases of lung squeeze continue to occur at much shallower depths. The exact pathophysiology of this condition remains unclear. Fortunately, it occurs very infrequently.

Underwater Blast Injury.

Barotrauma can be caused by underwater explosions. Shock waves from a blast are propagated farther in the dense medium of water than in air.^[24] Underwater explosions may result from ordnance or ignition of explosive gases during cutting or welding operations.

Underwater blasts can cause serious injuries to divers. Air-containing body cavities such as the lungs, intestines, ears, and sinuses are most vulnerable. Pneumothorax, pneumomediastinum, and air embolism may result from laceration of the lung and pleura.^[62] There may be intestinal perforation, subserosal hemorrhage, and subsequent peritonitis. The occurrence of air embolism at depth, which worsens with decompression, requires treatment by recompression, if possible. Otherwise, management of underwater blast injuries is no different than for terrestrial blast injury.

Gastrointestinal Barotrauma.

Because the intestines are pliable, contraction of intraluminal bowel gas during descent does not cause barotrauma. In unusual situations, however, expanding gas can become trapped in the gastrointestinal tract during ascent and cause gastrointestinal barotrauma, which is also known as *aerogastralgia*, or gas in the gut.^{[26] [82]} This infrequent condition has been noted most often in novice divers, who are more prone to aerophagia; in divers who repeatedly perform the Valsalva maneuver in the head-down position, which may force air into the stomach, or who chew gum while diving; and in divers who consume large quantities of carbonated beverages or legumes shortly before diving.

Divers with gastrointestinal barotrauma typically complain of abdominal fullness, colicky abdominal pain, belching, and flatulence. Rarely, syncope has been reported and is presumed to result from a combination of decreased venous return and vagal reflexes. Most often the physical examination of divers having symptoms of gastrointestinal barotrauma is normal because the condition typically resolves by the time medical care is obtained. However, abdominal distention, tympany, and abdominal tenderness may be seen. In extreme cases there may even be signs of cardiovascular compromise as a result of obstruction of venous return.^[44]

Gastrointestinal barotrauma is most often self-remedied by elimination of the excess gas. Recompression may be necessary in severe cases, but this is exceedingly rare.

Pulmonary Barotrauma of Ascent (Pulmonary OverPressurization Syndrome).

The most serious type of barotrauma is pulmonary barotrauma of ascent, which results from expansion of gas trapped in the lungs. If a diver does not allow the expanding gas to escape, it ruptures alveoli, producing a spectrum of injuries collectively referred to as *pulmonary overpressurization syndrome* (POPS), or burst lung. Basically, POPS is a

dramatic clinical demonstration of Boyle's law.

1380

Divers suffering pulmonary overpressurization typically give a history of rapid and uncontrolled ascent to the surface before the onset of symptoms (e.g., as a result of running out of air, panic, or sudden development of uncontrolled positive buoyancy, such as a dropped weight belt or inadvertent inflation of the buoyancy compensator). However, localized overinflation of the lung from focally increased elastic recoil may also occur in divers who ascend at a proper rate.^[25]

It is important to remember that the purpose of all diving regulators is to keep intrapulmonic pressure equal to surrounding water pressure, thus avoiding negative-pressure breathing. As long as these pressures are equal, the diver is relatively unaware of the surrounding crushing water pressure and no problems occur. In this regard, three additional factors have clinical importance:

1. There is significant change in barometric pressure in shallow water. Boyle's law dictates greater volume changes for a given change in depth near the surface than at greater depths. Thus shallow depths are the most dangerous for breath-holding ascents.
2. A pressure differential of only 80 mm Hg (alveolar air) above ambient water pressure on the chest wall, or about 3 to 4 feet of depth, is adequate to force air bubbles across the alveolar-capillary membrane.
3. Fatal pulmonary overpressure accidents have occurred from breath-holding during ascent from a depth as shallow as 4 feet of water.

If a given intrapulmonary gas volume is trapped by forcible breath-holding or a closed glottis, or even in a small portion of the lung by bronchospasm during ascent, intrapulmonary volume increases (according to Boyle's law) until the elastic limit of the chest wall is reached. After that, intrapulmonary pressure rises until, at a positive differential pressure of about 80 mm Hg, air is forced across the pulmonary capillary membrane. This air usually enters either the pulmonary interstitial spaces or the pulmonary capillaries.

The diagnosis of POPS is based on the development of characteristic symptoms after diving. The actual clinical manifestations may take several forms, including pneumomediastinum, subcutaneous emphysema, pneumopericardium, pneumothorax, pneumoperitoneum, and pulmonary interstitial emphysema. Diffuse alveolar hemorrhage has been described as a rare manifestation of pulmonary barotrauma.^[3] Systemic arterial gas embolism resulting from gas leaking into ruptured pulmonary veins is the most feared complication of POPS.

The specific clinical manifestations of POPS depend on the location and amount of air that escapes into an extraalveolar location.

Mediastinal Emphysema.

Mediastinal emphysema is the most common form of POPS, resulting from pulmonary interstitial air dissecting along bronchi to the mediastinum. In these cases the diver usually has gradually increasing hoarseness, neck fullness, and substernal chest pain several hours after diving. Subcutaneous emphysema may be present. In severe cases, the diver may complain of marked chest pain, dyspnea, and dysphagia. Syncope may occur. Radiographs may show extraalveolar air in the neck, mediastinum, or both, although radiographs are rarely necessary to make the diagnosis.

Treatment of mediastinal emphysema and most other forms of POPS is conservative, consisting of rest, avoidance of further pressure exposure (including flying in commercial aircraft), and observation. Supplemental oxygen administration may be useful in severe cases. Recompression is indicated only in extraordinarily severe cases because it carries a risk of causing further barotrauma and worsening the situation.

Pneumothorax.

Pneumothorax is an infrequent manifestation of diving-related pulmonary overpressurization because it requires that air be vented through the visceral pleura, a path generally having greater resistance than air tracking through the interstitium. Despite being infrequent, pneumothorax must be considered and excluded whenever POPS is suspected.

In cases of diving-related pneumothorax, the diver usually complains of pleuritic chest pain, breathlessness, and dyspnea, just as in cases of pneumothorax from any other cause. Radiographs may confirm the diagnosis. It is treated in the standard fashion with tube thoracostomy in all but trivial cases.

A diver with an untreated pneumothorax should not be recompressed except in dire circumstances, and then only if tube thoracostomy will be completed before decompression begins. Because the intrapleural gas of a pneumothorax cannot be vented to the environment, it may convert to a lethal tension pneumothorax during depressurization from hyperbaric treatment.

ARTERIAL GAS EMBOLISM

Arterial gas embolism (AGE), also known as *dysbaric air embolism* and *cerebral air embolism*, is the most feared complication of POPS. AGE is one of the most dramatic and serious injuries associated with compressed-air diving and is a major cause of death and disability among sport divers.^[72]

AGE results from air bubbles entering the pulmonary venous circulation from ruptured alveolae. When air is introduced into the pulmonary capillary blood, gas bubbles are showered into the left atrium, to the left ventricle, and subsequently into the aorta, where bubbles may enter

1381

the coronary arteries and produce myocardial infarction or cardiac arrest secondary to vessel occlusion.^[19] Gas embolization to the coronary arteries also may induce arrhythmias, which may be exacerbated by or independently generated by cerebral air embolism.^{[48] [68]}

Most of the bubbles entering the aorta pass into the systemic circulation, lodging in small arteries and occluding the more distal circulation. Bubbles most often travel up the carotid arteries to embolize the brain. They may also embolize the vertebral arteries, causing sudden cardiopulmonary arrest from brainstem ischemia.

Depending on the site or sites of circulatory occlusion, AGE produces myriad and often disastrous consequences. The neurologic pattern may be confusing as showers of bubbles randomly embolize the brain's circulation, producing ischemia and infarction of diverse brain regions. Combined carotid and vertebral artery embolization may produce severe, diffuse brain injury ([Figure 57-6](#)).^[72]

Figure 57-6 A to D, Cross sections of the brain of a 31-year-old male sport diver who suffered an arterial gas embolism, dying 4 days after the accident and extended hyperbaric oxygen treatment. Bubble-induced infarcts are found throughout the brain in the distribution of both the carotid

and vertebral arteries. (Kenneth W. Kizer, MD.)

TABLE 57-2 -- Pulmonary Overpressure Accident: Typical Symptoms and Signs

CONDITION	SYMPTOMS	SIGNS
Arterial gas embolism	Seizure (focal or general), unconsciousness, confusion, headache, visual disturbances, bloody sputum	Hemiplegia, monoplegia, altered level of consciousness, blindness, visual motor deficit, focal motor or sensory loss
Mediastinal-subcutaneous emphysema	Substernal pain, "brassy voice," neck swelling, dyspnea, bloody sputum	Subcutaneous crepitus, gas patterns on radiograph of mediastinum and neck
Pneumothorax	Chest pain, dyspnea, bloody sputum	Loss of breath sounds, hyperresonant chest percussion, tracheal shift

Arterial gas embolism typically develops immediately after the diver surfaces, at which time the high intrapulmonary pressure resulting from lung overpressurization is relieved, allowing bubble-laden pulmonary venous blood to return to the heart and pass into the systemic circulation. It is axiomatic that symptoms of AGE develop within 10 minutes of surfacing from a dive, although most often they are clearly evident within the first 2 minutes. Sudden loss of consciousness on surfacing from a dive should be considered to represent air embolism until proven otherwise.

In a pulmonary overpressure accident, as soon as normal breathing resumes at the surface of the water, the pressure differential that drives air bubbles into the pulmonary capillaries is equalized. From this point on, usually no further intraarterial air is introduced.

Clinical Manifestations of Arterial Gas Embolism

Clinical manifestations of cerebral air embolism are sudden, dramatic, and often life threatening. Many diver deaths officially listed as drowning probably have been cases of cerebral air embolism. Unfortunately, the accident investigation and postmortem evaluation of many diving-accident victims are insufficient to establish the precise cause of death. Autopsies of diving-accident victims should be performed according to special procedures.^[33]

Neurologic manifestations of AGE are typical of an acute stroke, although hemiplegia and other purely unilateral brain syndromes are infrequent. Loss of consciousness, monoplegia or asymmetric multiplegia, focal paralysis, paresthesias or other sensory disturbances, convulsions, aphasia, confusion, blindness or visual field defects, vertigo, dizziness, or headache are most often observed ([Table 57-2](#)).^{[38] [48] [72] [88] [93]}

The physical findings of AGE are extremely variable and depend on the specific site or sites of vascular occlusion. Neurologic findings generally dominate the clinical picture because of the frequency of cerebral involvement. All patients with suspected AGE should be carefully examined for neurologic deficits. Specific manifestations of POPS (such as subcutaneous or mediastinal

emphysema) may or may not be present but should always be carefully sought.

Rarely, air bubbles may be visualized in the retinal arteries, or sharply circumscribed areas of glossal pallor (Liebermeister's sign) may be noted, but these findings cannot be relied on to make the diagnosis. The diagnosis of dysbaric air embolism is clinical and based on the diving history and symptoms.

Treatment of Arterial Gas Embolism

All cases of suspected AGE must be referred for recompression treatment (hyperbaric oxygen therapy) as rapidly as possible. This is the primary and essential treatment for the condition.^[42]

Before recompression, whether in the field, emergency department, or clinic, or during transport to a recompression chamber, the affected diver should be given supplemental oxygen at a high flow rate (e.g., 6 to 8 L/min by mask) with other necessary supportive measures as indicated by the specific clinical condition.

Historically, much attention was directed toward keeping the AGE patient in the Trendelenburg position in the field. This was based on anecdotal reports and limited experimental data.^[75] The rationale for keeping the patient with AGE head down was the belief that the weight of the column of blood would force bubbles through the cerebral capillary bed, that the buoyancy of the bubbles would keep them in the aorta or heart, and that the weight of the spinal fluid might compress bubbles in the cord. These benefits were never well demonstrated or experimentally confirmed, and a relatively recent study showed that the Trendelenburg position did not keep bubbles from being distributed to the systemic circulation.^[16] Likewise, it is more difficult to oxygenate persons in a head-down position, and if one is maintained in this position for longer than 30 to 60 minutes, it may cause or worsen cerebral edema. Therefore, in contrast to former recommendations, it is now recommended that AGE patients be maintained in the supine position, both in the field and during transport to an emergency medical treatment facility or recompression chamber.

Because the AGE event so often occurs while the victim is in the water, he or she frequently suffers concomitant near drowning. Thus the rescuer must be prepared to provide cardiopulmonary resuscitation (CPR) and to protect the airway from aspiration

of gastric contents secondary to vomiting.

While life support measures are being instituted, a member of the diving or rescue team should telephone the nearest civilian or military recompression chamber and contact an air ambulance if air evacuation is required. Aircraft selection is crucial because the stricken diver should not be exposed to a significantly lower atmospheric pressure in the aircraft. Ideally, the diver should be transported by aircraft pressurized to sea level so that existing intraarterial bubbles do not expand further. In the case of helicopter evacuation or in the event that an unpressurized aircraft is required, the flight altitude must be maintained as low as possible, not to exceed 1000 feet above sea level, if possible.

An intravenous infusion of isotonic solution should be started, and urine output maintained at 1 to 2 ml/kg/hr.^[29] It is important to maintain adequate intravascular volume because inert gas cannot be effectively eliminated from tissues or from intravascular bubbles at the arteriolar-capillary level unless adequate capillary perfusion is maintained.

The AGE-affected diver should be transported to the recompression chamber as quickly as possible. Delay prolongs cerebral ischemia and cellular hypoxia, resulting in significant cerebral edema, which typically leads to a more difficult course of therapy. Conversely, transport should still be undertaken even if delay is unavoidable. Remarkable improvement has been seen in cases in which treatment was delayed for more than 24 hours after the onset of neurologic manifestations.^[69]

If the AGE-stricken diver is first seen at a hospital emergency department or clinic, and if transport to a hyperbaric treatment facility will not be delayed, baseline laboratory, radiographic, and other diagnostic tests (such as electrocardiography) should be obtained before the patient is sent to the chamber. Computed tomography (CT) or magnetic resonance imaging (MRI) of the brain should be deferred until after initial hyperbaric treatment unless intracranial hemorrhage, carotid artery dissection,^[91] or other nondiving injury is strongly suspected.

Hyperbaric treatment consists of rapidly increasing ambient pressure (recompression) to reduce intravascular bubble volume and to restore tissue perfusion, using oxygen-enriched breathing mixtures to enhance bubble resolution and to supply oxygen to hypoxic nervous tissue, and then providing slow decompression to avoid the reformation of bubbles.^{[15] [29] [32]} Additional details about the hyperbaric regimens used for treating AGE are provided in [Chapter 59](#). Ideally, these patients should be treated in multiplace hyperbaric chambers ([Figure 57-7](#)) capable of being pressurized to 6 ATA and in which both air and oxygen can be administered to the patient. There is growing evidence that recompression to 2.8 ATA on 100% oxygen may be more effective treatment than initial pressurization to 6 ATA for sports divers because of the typical several-hour delay in getting to a chamber and, thus, less need for the higher pressure to resolubilize bubbles (and perhaps a greater immediate need for tissue oxygenation).^{[24] [39] [71] [72] [78] [79]}

Although the majority of victims with AGE have neurologic deficits when examined, the

initial manifestations may spontaneously resolve by the time the victim is seen by medical personnel. Occasionally a person has symptoms but no reproducible neurologic

1383

Figure 57-7 An example of a large modern hyperbaric chamber. Preferably, a hyperbaric chamber for treating decompression sickness or arterial gas embolism should have a pressure capability of at least 6 ATA (165 fsw) and should have space for an attendant to provide ongoing "hands-on" care and repeated neurologic examinations. It must have provisions for supplying 100% oxygen and other gases for treatment of the stricken diver.

deficits on physical examination.^[72] ^[77] Nonetheless, all patients must be referred for diving medicine consultation and hyperbaric treatment if the history is suggestive of AGE because neurologic impairment is impossible to exclude in the acute care setting, and waiting to complete definitive diagnostic studies may allow subtle neurologic injuries to become irreversible.^[93]

Prevention of Pulmonary Overpressure Accidents

In view of the potentially catastrophic consequences of POPS, one of the key goals of scuba-diving training is to prevent pulmonary overpressure accidents. Divers must be warned of the potentially great intrathoracic volume changes that can occur at shallow depths and trained to keep an open airway during ascent, particularly through the last 10 feet to the surface. If equipment malfunction or depletion of air supply at depth makes this impossible, the diver must make every attempt to exhale continuously during an "emergency swimming ascent." This is an attempt to vent the increasing volume of air in the lungs. With a satisfactory air supply the diver should simply breathe normally on ascent to the surface, taking care to ascend slowly near the surface.

INDIRECT EFFECTS OF PRESSURE

Several diving-related problems may develop as a result of breathing gases at higher than normal atmospheric pressure. Chief among these are nitrogen narcosis, oxygen toxicity, and decompression sickness.

Dalton's Law of Partial Pressures

Dalton's law of partial pressures states that the total pressure exerted by a mixture of gases is the sum of the pressures that would be exerted by each of the gases if it alone occupied the total volume. The partial pressure of a gas in a mixture is the pressure exerted by that gas alone. The symbols for partial pressure of oxygen, nitrogen, carbon dioxide, and water vapor are P_{O_2} , P_{N_2} , P_{CO_2} , and P_{H_2O} , respectively. Dalton's law states that in an air mixture the total pressure (PT) = $P_{N_2} + P_{O_2} + P_{H_2O} + P_{other}$. The partial pressure of each gas in the mixture is found by multiplying the percentage of that gas present by the total pressure. In [Figure 57-8](#), a mixture of air, nitrogen is assumed to be present in a proportion of 78%, oxygen at 21%, carbon dioxide at 0.03%, and the balance composed of water vapor and other trace gases.

The partial pressures of inspired gases in a gas mixture, not their percentages, are of prime importance in

1384

diving. For example, it has been shown that in hyperbaric chamber treatment of decompression sickness, 100% oxygen can be safely used at depths to 60 fsw (2.8 ATA) for 20-minute periods with the subject at rest in the dry chamber. On the other hand, with 21% oxygen in a helium-oxygen mixture at 600 fsw (20 ATA), the diver would breathe $(0.21) \times (20 \text{ ATA})$, or 4.2 ATA of oxygen, which would rapidly produce CNS oxygen poisoning. This type of problem is avoided in deep diving by reducing the oxygen percentage in the gas mixture to between 0.35 and 0.50 ATA, so that the P_{O_2} will be between 266 and 380 mm Hg.

The scuba diver who uses open-circuit compressed air is subject to the effects of the component gases in the air according to their partial pressures. Thus, even though the gas mixture is simply air with normal percentages of oxygen and nitrogen, the increases in partial

Figure 57-8 Dalton's law of partial pressures. The total pressure exerted by a mixture of gases is the sum of the pressures that would be expected by each of the gases if it alone were present and occupied the total volume.

pressures of these gases and those of the trace contaminants at sea level create numerous potential breathing medium-related problems. Most notable among these for scuba divers is the problem of nitrogen narcosis.

Nitrogen Narcosis

Nitrogen narcosis, also known as *rapture of the deep*, *inert gas narcosis*, or the *narcs*, is development of increasing intoxication as the partial pressure of nitrogen in inspired compressed air increases at depth. Nitrogen narcosis is important to divers because it causes anesthetic-like euphoria, overconfidence, and deterioration in judgment and cognition, all of which can lead to serious errors in diving techniques, accidents, and drowning. Many divers have died as a consequence of nitrogen narcosis.

During the 1930s Behnke and associates^{[9] [9]} first suggested that the mood changes described by divers breathing compressed air at 200 fsw were caused by high inspired P_{N_2} . Much has been learned since that time, and a complete compilation of data on inert gas narcosis has been provided by Bennett.^{[11] [12] [13]} The subject was more recently reviewed by Hamilton and Kizer.^[56]

Theories to explain the mechanism by which nitrogen causes its intoxicating effects center on the effects of gaseous anesthetics in general. According to currently accepted theory, an alteration in electrical properties of cellular membranes is effected by absorption of gas molecules into their lipid component. Supporting this theory is the observation that the greater the lipid solubility of a given gas, the greater its narcotic potency. Thus higher partial pressures of pure nitrogen are required to produce an anesthetic effect than can be achieved by a much lower partial pressure of nitrous oxide, which is much more soluble in lipid than is nitrogen. Helium's lack of narcotic effect is in accord with its low lipid solubility. Indeed, substitution of helium for nitrogen as the inert gas in the diver's breathing gas prevents nitrogen narcosis and is the main reason helium-oxygen mixtures are used for deep diving.

Typically, a scuba diver breathing compressed air develops symptoms of nitrogen narcosis at depths between 70 and 100 fsw. These symptoms include light-headedness, loss of fine sensory discrimination, giddiness, and euphoria. Symptoms progressively worsen at deeper depths. At depths over 150 fsw, a diver becomes severely intoxicated,

manifesting increasingly poor judgment and impaired reasoning, overconfidence, and slowed reflexes. At depths of 250 to 300 fsw, auditory and visual hallucinations may occur, along with feelings of impending blackout. Most divers will lose consciousness when they reach a depth of 400 fsw.

Of note, individual and diurnal variability occur in the depth of onset and severity of symptoms in nitrogen narcosis. Also, some degree of acclimatization allows

1385

experienced divers to work more safely at greater depths than can inexperienced divers. Nonetheless, nitrogen narcosis is a major problem for all compressed-air divers at depths greater than 100 fsw. This is one of the factors that led to the general recommendation that sport divers not dive deeper than 100 fsw.

Treatment of nitrogen narcosis requires ascent to a shallower depth (usually less than 70 to 100 fsw), where symptoms promptly clear. Of course, the condition is prevented by avoiding deep dives. In commercial diving, where there may be good reasons to dive deeper than 100 fsw, the problem is prevented by using heliox.

Oxygen Toxicity

Although oxygen is essential for most life-forms on Earth, it becomes a poison at elevated partial pressures, so *oxygen toxicity* is another indirect effect of pressure that divers need to understand. Oxygen toxicity in divers can affect either the central nervous or the pulmonary system.

High inspired P_{O_2} can occur in diving in two ways. Breathing 100% oxygen in underwater or hyperbaric chambers is one. The second results from Dalton's law of partial pressures. If a normal 21% oxygen-gas mixture is breathed at 300 fsw (10 ATA), an inspired P_{O_2} of 2.1 ATA is generated, equivalent to breathing 100% oxygen at 36 fsw. Again, it is the partial pressure of a gas that determines its biologic effects.

Pulmonary Oxygen Toxicity.

Retrolental fibroplasia in premature infants and pulmonary oxygen toxicity in adults are well-known problems associated with the use of therapeutic oxygen. Pulmonary oxygen toxicity is induced by breathing an above normal, but relatively low P_{O_2} for prolonged periods. The limit for indefinite exposure without demonstrable lung damage is generally considered to be a P_{O_2} of about 0.5 ATA. On a time-dose curve, it is generally considered safe to breathe 100% oxygen at 1 ATA for up to about 20 hours, or at 2 ATA for up to 6 hours. This time can be lengthened significantly by using intermittent exposures, such as interspersing a 5-minute air break between every 20 minutes of oxygen breathing.^[58] At 2.8 to 3 ATA (60 to 66 fsw), at which 100% oxygen is used to treat decompression sickness and gas gangrene, pulmonary oxygen toxicity is rarely a

problem because CNS manifestations usually intervene before sufficient time elapses to induce pulmonary damage. This subject has been thoroughly reviewed by Clark and Lambertsen.^[22] Use of hyperbaric oxygen according to U.S. Navy Treatment Table 6 (as is used in treating decompression sickness; see [Chapter 59](#)) does not produce clinical manifestations of pulmonary oxygen toxicity. However, animal studies with more extreme oxygen exposures have shown a pathologic sequence of alveolar capillary endothelial damage, with increased permeability leading to pulmonary edema and hemorrhage. While species variation in susceptibility occurs, interruption of exposure usually results in reversal of these pathologic changes.^[19]

The most common clinical manifestation of pulmonary oxygen toxicity is substernal discomfort on inhalation. If exposure continues, this can progress to severe burning substernal pain and persistent coughing. Reduction of inspired oxygen partial pressure to 0.21 to 0.5 ATA usually results in prompt relief. Severe cases of pulmonary oxygen toxicity may require endotracheal intubation and positive end-expiratory pressure (PEEP) ventilation to achieve adequate arterial oxygenation at the required lower partial pressures of inspired oxygen.

Central Nervous System Oxygen Toxicity.

During the 1880s the French physiologist Paul Bert described convulsions in animals breathing 100% oxygen at elevated chamber pressures. The same phenomena were observed in humans in the 1930s by Behnke and others. Donald's classic observations on divers were published in 1947 and provide much of the current knowledge on predisposing factors and clinical manifestations of CNS oxygen toxicity.^{[40] [41]}

In brief, Donald found that, at a given duration and pressure of oxygen, a diver in the water was more susceptible to oxygen-induced seizures than was the same diver in a warm, dry hyperbaric chamber. Based on this observation, a limit of 25 fsw was imposed for military special operations dives using 100% oxygen.

Most people can tolerate breathing 100% oxygen for 30 minutes at rest at 2.8 ATA in a dry chamber, although some manifest toxicity even at this exposure. Common symptoms and signs of CNS poisoning are shown in [Box 57-4](#). Unfortunately, some persons may have no warning symptoms, and the first manifestation of CNS oxygen toxicity may be a generalized convulsion.

1386

Treatment for CNS oxygen toxicity in a hyperbaric chamber involves removal of the oxygen mask, maintenance of the airway, and keeping the patient from injuring himself or herself. Of note, chamber pressure should be kept constant until the seizure activity ceases to prevent a possible pulmonary overpressure accident.

After a postictal period, the patient who has had an oxygen-induced seizure recovers without sequelae. Although anticonvulsant drugs theoretically should suppress oxygen-induced seizures, none has been tested to determine efficacy or therapeutic dosage.

Anticonvulsant therapy is not usually considered necessary for persons who have had oxygen-induced seizures because termination of oxygen breathing routinely stops the seizure and recurrent seizures are exceedingly rare. Removing oxygen at the first sign of CNS toxicity (e.g., when feelings of apprehension are noted or when sweating, nausea, or twitching are observed) has to date prevented any documented permanent CNS damage after an oxygen-induced seizure. Importantly, there is no reason for a person who has had an oxygen-induced seizure not to receive normobaric 100%

oxygen if it is medically indicated.

Contaminated Breathing Gas

As breathing-gas cylinders are pressurized or filled, the sea level partial pressure of each gaseous component is multiplied. Thus any contaminant in the air source can potentially become dangerous to the diver at the elevated pressure found underwater. Compressor motors must be free of oil that could be pumped into tanks; otherwise, the oil mist in the air may cause the diver to suffer lipid pneumonitis. ^[73]

Compressed air inlets should always be situated so that they avoid engine exhaust from the compressor, parking lots, or other combustion sources that produce carbon monoxide. Because carbon monoxide is colorless, odorless, and tasteless, the diver cannot detect it unless it is accompanied by other contaminants. The first warning of carbon monoxide poisoning may be headache, nausea, or dizziness during the dive. Examination at the surface may show lethargy, mental dullness, and nonspecific neurologic deficits, which may be confused with those accompanying decompression sickness or air embolism. The cherry-red skin color often mentioned in standard medical texts is actually rarely observed in carbon monoxide poisoning. Fortunately, the treatment of choice for serious acute carbon monoxide poisoning, decompression sickness, and air embolism is hyperbaric oxygen.

Another potential breathing-gas problem involves carbon dioxide. Alveolar partial pressure of carbon dioxide (P_{aCO_2}) reflects arterial P_{CO_2} ; thus even as ambient pressure increases at depth, P_{aCO_2} remains constant at about 40 mm Hg unless environmental or physiologic changes occur. Hypercapnia can occur because of increased P_{CO_2} in the breathing gas or decreased pulmonary ventilation. Unless there is regulator malfunction or contaminated breathing gas, hypercapnia is exceptionally rare in open-circuit scuba diving. Hypercapnia can occur in helmet or chamber diving if these closed spaces are inadequately ventilated or the breathing gas becomes contaminated by carbon dioxide, and in closed-circuit scuba diving if there is failure of the CO_2 -absorbent (scrubbing) material.

At sea level, a concentration of 5% to 6% inspired CO_2 leads to dyspnea, increased respiratory rate, and mental confusion. At 10% inspired CO_2 , pulse rate and blood pressure may fall to the point that unconsciousness occurs. With prolonged exposure to 12% to 14% inspired CO_2 , such that P_{aCO_2} exceeds 150 mm Hg, central respiratory and cardiac depression can be fatal. Because elevated P_{aCO_2} causes vasodilation, hypercapnia potentially increases susceptibility to nitrogen narcosis, oxygen toxicity, and possibly decompression sickness.

Hyperventilation

Hypocapnia can result from *hyperventilation* during or before diving. The well-known symptoms of hyperventilation—dizziness and paresthesia—have been postulated to cause unconsciousness among divers, but whether this actually occurs is unclear. In

contrast, unconsciousness associated with hyperventilation before a breath-hold dive is caused by hypoxia, rather than hypocapnia.

In what is commonly described as *shallow water blackout*, a diver hyperventilates before a dive, lowering alveolar P_{CO_2} to 20 to 30 mm Hg. However, because hemoglobin is nearly saturated with oxygen during normal respiration, there is little gain in arterial P_{O_2} . In an underwater swim, even in a shallow swimming pool, exercise-induced hypoxia sufficient to cause unconsciousness may occur before arterial P_{CO_2} reaccumulates to provide sufficient stimulus to breathe.^[7]

In a deep breath-hold dive the problem is compounded. In addition to the initial depression of arterial P_{CO_2} secondary to hyperventilation, elevations in alveolar and arterial P_{O_2} occur. During the dive these serve to suppress the respiratory response to hypercarbia. During descent in the water, P_{aCO_2} increases from the increased pressure, but after oxygen consumption at depth, depressurization on return to the surface causes a dramatic drop in alveolar and arterial P_{CO_2} . Even if P_{aCO_2} rises to the stimulatory breakpoint during ascent, hypoxemia may cause unconsciousness and near drowning. An expansion of Edmonds' *Commonest Causes of Unconsciousness in Divers* is presented in [Box 57-5](#).^[44]

DECOMPRESSION SICKNESS

In the mid-nineteenth century, tunnel and bridge workers who labored in caissons pressurized with compressed air were sometimes observed to suffer joint pains, paralysis, and various other medical problems after decompression. The condition was not understood and became dubbed as *caisson disease* or *compressed air illness*.^[98] Of course, these early high-pressure workers were experiencing the same symptoms that were later observed in divers and aviators and that we now know to be decompression sickness (DCS).

For many decades caisson disease remained a medical curiosity, but because of its occurrence in increasingly important areas of activity in the twentieth century, considerable research has been directed toward its causes and treatment in the past several decades.

Today, we know that DCS is caused by the formation of bubbles of inert gas (such as nitrogen) within the intravascular and extravascular spaces after a reduction in ambient pressure. This may occur during or after decompression from being underwater or in a caisson or hyperbaric chamber in which pressures are greater than at sea level, or in aviators, astronauts, or hypobaric (high-altitude) chamber workers who travel rapidly from sea level to pressures less than 0.5 ATA. Although DCS is a major concern in commercial divers who breathe heliox, this discussion concentrates on compressed-air diving situations likely to be encountered by recreational scuba divers.

Etiology of Decompression Sickness

To understand the etiology of DCS, one must understand the temporal uptake and elimination of inert gases supplied in the diver's breathing medium. Clearly, if it were possible for a diver to breathe 100% oxygen while underwater, there would be no problems with decompression sickness because oxygen is rapidly metabolized by the body and for all practical purposes does not contribute to bubble formation on ascent from depth. Unfortunately, pure oxygen breathing at increased atmospheric pressure causes CNS toxicity and thus cannot be used in sport diving. The requirement to have an inert gas diluent (nitrogen) in the diver's breathing medium is the crux of the problem in DCS.

As alveolar air pressure increases at depth, partial pressures of inspired gases increase. At 99 FSW (4 ATA), the absolute pressure is 3040 mm Hg (see [Table 57-1](#)). Seventy-nine percent of this pressure is nitrogen (2400 mm Hg, as compared with 600 mm Hg P_{N_2} at sea level). Accounting for water vapor and carbon dioxide, this results in an alveolar partial pressure of nitrogen ($P_{a_{N_2}}$) of about 2360 mm Hg. This $P_{a_{N_2}}$ is

rapidly reflected across the alveolar-capillary membrane to the arterial blood, where (according to Henry's law) nitrogen becomes physically dissolved in the blood. Henry's law states that the amount of gas dissolved in a liquid at any given temperature is a function of the partial pressure of the gas in contact with the liquid and the solubility coefficient of the gas in that particular liquid. As nitrogen-laden blood is presented to tissues at the capillary level, a complex set of variables dictated by perfusion, diffusion, and inert gas solubility results in a family of nitrogen uptake curves similar to the pharmacokinetic drug uptake curves commonly displayed for medications. Thus tissue nitrogen saturations on any given dive are a function of depth (i.e., pressure) and time.

Clinical Manifestations of Decompression Sickness

DCS is a multisystem disorder caused by a rapid decrease in ambient atmospheric pressure such that inert gas (e.g., nitrogen) comes out of solution, causing the formation of bubbles in tissue and venous blood. Conceptually, DCS is the same illness whether it occurs in high-altitude aviators or deep-sea divers, although there are some differences in the symptoms of the disease depending on whether it is caused by hyperbaric or hypobaric exposure.

The physiologic sequelae of bubble formation in tissue and venous blood are myriad. These effects include cellular distention and rupture; mechanical stretching of tendons or ligaments, producing pain; and intravascular or intralymphatic occlusion, resulting in congestive ischemia and infarction or lymphedema.

1388

Intravascular bubbles also cause multiple biophysical effects at the blood-bubble surface interface because bubbles are viewed by the immune system as foreign matter and incite an inflammatory reaction. The key step in the process is activation of Hageman factor, which in turn activates the intrinsic clotting, kinin, and complement systems, producing platelet activation, cellular clumping, lipid embolization, increased vascular permeability, interstitial edema, and microvascular sludging. The overall effect is decreased tissue perfusion and ischemia.

As with arterial gas embolism, the diagnosis of DCS is a clinical diagnosis based on the history of diving with compressed air and subsequent development of characteristic symptoms and signs. The majority of patients with DCS become symptomatic in the first hour after surfacing from a dive, with most of the rest noticing symptoms within 6 hours after diving. A very few DCS patients (1% to 2%) may not note their symptoms until 24 to 48 hours after diving.

The clinical manifestations of DCS are protean ([Table 57-3](#)), with the neurologic and musculoskeletal systems being most often affected. Symptoms of DCS are often categorized into *types I* and *II*, with type I referring to the mild forms of DCS (cutaneous, lymphatic, and musculoskeletal) and type II including the neurologic and other serious forms. In addition, some investigators in recent years have advocated for use of the

term *type III decompression sickness*

TABLE 57-3 -- Common Symptoms and Signs of Decompression Sickness

CONDITION	SYMPTOMS	SIGNS
Musculoskeletal decompression sickness, limb bends	Severe joint pain, single or multiple joints involved, paresthesia or dysesthesia about joint, lymphedema (uncommon)	Tenderness, which may be temporarily relieved by local pressure with blood pressure cuff; pain worsened by movement of joint
Neurologic decompression sickness		
Spinal cord	Back pain, girdling abdominal pain, extremity heaviness or weakness, paralysis, paresthesia of extremities, fecal incontinence, urine retention	Hyperesthesia or hypoesthesia, paresis, anal sphincter weakness, loss of bulbocavernosus reflex, urinary bladder distention
Brain	Visual loss, scotomata, headache, dysphasia, confusion	Visual field deficit, spotty motor or sensory deficits, disorientation or mental dullness
Fatigue	Profound generalized heaviness or fatigue	May precede signs of other forms
Cutaneous manifestations	Intense pruritus	No visible signs, mottling, local or generalized hyperemia or marbled skin (cutis marmorata)
Chokes	Dyspnea, substernal pain that is worsened on deep inhalation, nonproductive cough	Cyanosis, tachypnea, tachycardia
Vasomotor decompression sickness (decompression shock)	Weakness, sweating, unconsciousness	Hypotension, tachycardia, pallor, mottling, hemoconcentration, decreased urine output

to refer to combined AGE and DCS with neurologic symptoms.^[92] Other numerical classification schemes have also been espoused.

Although the categorization of DCS as types I and II is firmly entrenched in the literature, its use is not advocated. It is clinically more meaningful to refer to the body systems affected when discussing patients with DCS, especially in light of the growing

awareness that all DCS must be considered serious and treated vigorously.

Musculoskeletal Decompression Sickness.

Musculoskeletal DCS, or *the bends*, is periarticular joint pain associated with DCS. It is the most common symptom of DCS, occurring in about 70% of patients. This form of DCS is often referred to as *limb bends*, *joint bends*, or *pain-only bends*.

The term *bends* originated at the beginning of the twentieth century when caisson workers on the Brooklyn Bridge who were suffering from DCS of the hips were noted to walk stiffly, bending forward at the hips.^[98] Co-workers would describe the stricken men as walking as if they were trying to do the "Grecian bend," a forward bending, stiff-at-the-hips way that stylish women of the day would walk because of their tight corsets. Over time the term became shortened to just "bends."

The shoulders and elbows are the joints most often affected by DCS in scuba divers, but any joint may be

1389

involved. Conversely, the hips and knees are most commonly affected in saturation divers, caisson workers, and aviators. The reason for the different anatomic predilection is not known.

The pain of joint bends is usually described as "boring" or a dull ache deep within the joint, although it may also be characterized as sharp or throbbing. It is sometimes described as "tearing" or feeling like tendinitis or bursitis. It may radiate to surrounding areas. Movement of the joint worsens the pain, so the joint is usually held immobile. An area of vague numbness or dysesthesia may surround the affected joint, but this typically does not conform to any anatomic distribution and should not be confused with neurologic involvement. There also may be erythema around the joint, and it may be mildly swollen. The joint may also be tender to touch.

Sometimes divers will complain of having a "niggle" after a dive. This is mild pain in a single joint that improves 10 to 15 minutes after the onset of pain and then disappears without treatment. Whether niggles should be treated with recompression is controversial, but the safest approach is to treat them with at least a U.S. Navy Treatment Table 5.

The differential diagnosis between limb bends and trauma may be aided by inflation of a sphygmomanometer cuff placed around the joint to 150 to 250 mm Hg.^[102] By reducing the gas volume in tendons and ligaments, this may immediately relieve the pain directly under the cuff if the pain is caused by DCS. This relief suggests that the mechanism of pain is gas expansion (i.e., bubbles) in tendons and ligaments that stretches nerve endings. The pain of limb bends recurs when the cuff is deflated. The test is helpful when it is positive. Failure to respond to the application of local pressure, however,

should not be used to rule out the presence of DCS; this must be done with a "test of pressure" in a hyperbaric chamber. Importantly, most often there may be neither abnormal physical signs (other than splinting or stiffness from pain) nor abnormal radiographic findings.

Limb bends pain itself is not immediately threatening to life or function but indicates that bubbling may be occurring in venous blood. Often, patients who begin with musculoskeletal DCS and are not treated progress to more serious forms of DCS. Likewise, as discussed later, untreated DCS may lead to osteonecrosis of the major joints.

Fatigue.

Profound fatigue that is out of proportion to the activity performed underwater, or otherwise while under pressure, may be an early manifestation of DCS. Although its etiology is unknown, a feeling of severe fatigue after diving demands careful evaluation for other manifestations of DCS and may in and of itself justify a "test of pressure."

Skin Bends or Cutaneous Decompression Sickness.

DCS may present a variety of cutaneous manifestations, including scarlatiniform, erysipeloid, or mottled rashes, pruritus, and formication. Occasionally, localized swelling or peau d'orange may result from lymphatic obstruction, and rarely, an entire limb may become edematous.

Skin manifestations are relatively uncommon, and in and of themselves are usually not serious. However, mottling or marbling of the skin (cutis marmorata) is often a harbinger of more severe DCS. The exact physiologic basis of the mottled skin lesion is unknown. Skin bends should be easily distinguished from cutaneous barotrauma, "wet suit dermatitis,"^[76] ^[103] marine envenomation, or other skin rashes often seen in divers.

Itches, or the creeps, is a type of skin bends seen during decompression in hyperbaric chamber workers when the skin is exposed to the high partial pressure of nitrogen in compressed air. This is a highly pruritic skin reaction most intensely felt on body parts exposed to the compressed air. The sensation is often described as feeling like ants crawling over one's body.

In hyperbaric chambers, inert gas from the external environment is absorbed directly into skin, and itches represents bubble formation in the skin during decompression. The concentrations of dissolved gases in ocean water are essentially constant at all depths, so the skin is not exposed to elevated partial pressures of inert gases under water.

Chokes or Pulmonary Decompression Sickness.

The *chokes* is an unusual but very serious form of DCS characterized by burning substernal pain (especially on inhalation), cyanosis, dyspnea, and nonproductive cough. Animal studies have demonstrated gas bubbles or foam in the pulmonary arteries, right

atrium, and right ventricle after unsafe decompression. Chokes probably represents massive pulmonary gas embolism with mechanical obstruction of the pulmonary vascular bed by bubbles. Typically, symptoms of pulmonary venous air embolization begin when 10% or more of the pulmonary vascular bed is obstructed. Patients with chokes can progress rapidly to profound shock and/or neurologic DCS. The specific clinical and radiologic manifestations of the chokes are similar to those seen with venous gas embolism (VGE) from other causes.^[74]

Symptoms of VGE include air hunger, dyspnea, cough, and chest pain. Findings may include pallor, diaphoresis, tachypnea, tachycardia, hypotension, cyanosis, expiratory wheezing, neurologic signs, and a "mill wheel" heart murmur. Victims may also exhibit increased central venous or pulmonary artery pressure, electrocardiographic changes of ischemia or cor pulmonale, decreased end-tidal carbon dioxide fraction, and precordial Doppler sounds of circulating gas bubbles.

1390

Rarely, air may be visualized in the main pulmonary artery on chest radiographs; this is pathognomonic for pulmonary air embolism.^[62] ^[74]

Neurologic Decompression Sickness.

Neurologic impairment may occur as the sole manifestation of DCS or as part of a larger dysbaric syndrome. Neurologic DCS is manifested by a myriad of symptoms and signs because of the random nature by which DCS affects the nervous system. Although any level of the CNS may be affected, the most commonly involved site in divers is the spinal cord, specifically in the lower thoracic and lumbar regions. The peripheral nervous system also may be involved.^[64]

Based on military experience, neurologic DCS was believed to occur in only 10% to 20% of DCS cases,^[100] but neurologic manifestations of DCS have been found in 50% to 60% of scuba-diving casualties treated in Hawaii^[47] ^[65] and have been reported in similarly high frequencies in other populations of sport divers.^[29] ^[38]

Classically, dysbaric spinal cord injury occurs in the lower thoracic, lumbar, and sacral portions of the cord, producing low back pain, subjective "heaviness" in the legs, paraplegia or paraparesis, lower extremity paresthesia or dysesthesia, and possible bladder or anal sphincter dysfunction. General malaise or fatigue is often noted as well. Involvement of the cervical and thoracic cord may cause chest or abdominal pain and weakness or sensory disturbances in the upper extremities. Absence of the bulbocavernosus reflex, elicited by gently squeezing and pulling the glans penis to seek reflex contraction of the anal sphincter, often foretells a poor prognosis, as does absence of the superficial anal reflex, which can be elicited in the male or female by stroking the perianal region.

The mechanism of spinal cord DCS is multifactorial, involving autochthonous inert gas

bubble formation in the cord^[52] ^[96] and in the epivertebral venous system (Batson's plexus), with resulting congestive infarction of the spinal cord,^[55] and other mechanisms that are not well understood.^[59] ^[96]

DCS of the brain produces a variety of symptoms, most of which are indistinguishable from AGE. These include dizziness, vertigo, altered mentation or level of consciousness, generalized weakness, and visual deficits (e.g., diplopia, scotoma, visual field defects and blindness). Involvement of the cerebellum or inner ear may produce ataxia and loss of balance.

Inner Ear or Vestibular Decompression Sickness.

The *staggers* is another classic DCS syndrome. In this case, the inner ear is primarily affected, and the name derives from the unsteady gait that results from the vestibular damage. Other manifestations include dizziness, vertigo, nystagmus, tinnitus, nausea, and vomiting. It is most often seen in saturation divers when there is a rapid ascent on heliox, or when switching gases on ascent during very deep dives.

Vasomotor Decompression Sickness.

Vasomotor DCS, or *decompression shock*, is a rare, life-threatening form of DCS. The pathogenesis of this shock syndrome is not completely understood, but it is believed to be caused by a rapid shift of fluid from intravascular to extravascular spaces secondary to diffuse bubble embolization, ischemia, and hypoxia.^[21] Hypotension may also result from massive venous air embolization of the lungs.

Despite vigorous intravenous fluid replacement, the hypotension of decompression shock may not respond until recompression is undertaken. Unfortunately, the condition is highly lethal, and many patients do not survive to undergo recompression unless a hyperbaric chamber is immediately available.

Long-Term Sequelae of Decompression Sickness

Although DCS is the most overt manifestation of inadequate decompression after diving, it has now been clearly established that there may be long-term sequelae of diving related to inadequate decompression, even if the diver never manifests overt DCS. The best characterized of these problems is dysbaric osteonecrosis.

Dysbaric Osteonecrosis.

Dysbaric osteonecrosis (DON) is a form of avascular or aseptic necrosis of bone associated with pressure changes. The major joints (i.e., shoulders, elbows, hips, and knees) are most often affected, although any bone can be involved.^[20] ^[46] ^[87]

DON was first recognized in compressed-air workers in the early 1900s.^[94] Since then its incidence in professional divers has been found to range from less than 1% to over 80%, depending on the age of the diver and the type of diving done. Its occurrence

correlates well with deep diving, decompression diving, the occurrence of DCS, and missed decompression.^{[35] [46] [63] [87] [107]} Most diving medicine experts consider DON a long-term sequel to inadequate decompression. Interestingly, fossil evidence of avascular necrosis has been found in some species of marine mosasaurs of the Cretaceous period, suggesting that at least some of these extinct giant marine lizards dived deeply.^[101]

Dysbaric Retinopathy.

Infrequently, DCS affects the eyes, producing a wide array of acute ophthalmic effects, including homonymous hemianopsia, cortical blindness, central retinal artery occlusion, retinal hemorrhage, nystagmus, convergence insufficiency, and optic neuropathy.^{[17] [18]} Some long-term ophthalmic findings in divers also have been observed.

A retinal fluorescein angiography survey of asymptomatic divers found a higher incidence of retinal pigment epithelium than in nondivers and various capillary

changes at the fovea.^[99] The significance of these abnormalities is unclear because none of the divers had visual loss. Similarly, the cause of such changes is unclear, although they are postulated to be the result of small bubble microembolization.

Diagnosis of Decompression Sickness

A variety of laboratory abnormalities may be demonstrated in DCS, but most have little or no usefulness in the immediate management of patients. Two tests that may be useful, however, are measurement of the urine specific gravity and hematocrit because intravascular volume depletion and hemoconcentration are common in serious DCS because of increased vascular permeability caused by endothelial damage and release of kinins. The results of these tests can help guide replacement fluid therapy. Hematocrit percentages are commonly in the high 50s or 60s in serious DCS.

As with laboratory tests, radiographic evaluation of patients with suspected DCS may yield various findings, but the radiographs are rarely useful in acute management of the patient. Bone radiographs of patients with acute joint bends do not show abnormalities. Months to years later, they may demonstrate findings of DON. Noncardiogenic pulmonary edema may be seen on chest radiographs of persons with pulmonary or vasomotor DCS.

Both CT and MRI have been used to evaluate neurologic DCS injury, although conventional CT suffers from poor sensitivity of early lesions and its inability to image spinal cord lesions.^{[60] [67]} Limited clinical data support the feasibility and efficacy of MRI of these conditions,^{[80] [108]} especially when intracranial injury is suspected, although the exigency of obtaining recompression treatment makes these modalities useful primarily

in the postrecompression evaluation of residual deficits.

Treatment of Decompression Sickness

All persons with suspected DCS must be referred to a hyperbaric treatment facility as quickly as possible because recompression is the primary and essential treatment for this condition. The physician must have a high index of suspicion when diagnosing DCS, because the often diverse manifestations of DCS may present a very confusing clinical picture. The history of the dive profile is helpful if the diver knowingly violated decompression procedures, but DCS may occur on dives that should be safe according to current decompression schedules.^[1] Likewise, the reported depth and time of the dive are often not accurate.

Management of DCS must be commenced as soon as the condition is suspected.^[29] Sport divers are usually far from a recompression chamber when their symptoms develop, so treatment is often initiated in the field or at an outpatient acute care facility. One hundred percent oxygen should be administered by a tight oronasal mask to provide a favorable gradient for nitrogen washout. Of equal importance is maintenance of intravascular volume to ensure capillary perfusion for elimination of microvascular inert gas bubbles and for tissue oxygenation. An intravenous infusion of isotonic solution should be started and run at a flow rate sufficient to maintain urine output at 1 to 2 ml/kg/hr. With spinal cord involvement, an indwelling urinary catheter may be needed because of sacral nerve root dysfunction. Intractable vomiting or vertigo should be treated with appropriate parenteral agents. Diazepam has been quite effective in providing relief from the vertigo associated with labyrinthine DCS when other agents have failed. Oral aspirin (5 to 10 grains) also may be useful for its antiplatelet activity. Of course, advanced life support measures should be undertaken appropriate to the patient's clinical condition.

While these measures are undertaken, someone should arrange for emergency transportation to the nearest recompression chamber. Because of the large number and frequently changing status of recompression chambers, no list is provided here. Instead, refer to the national Divers Alert Network (DAN) at Duke University ([Figure 57-9](#)). Help with the treatment of dive-related incidents may be obtained 24 hours a day by calling 919-684-8111 and requesting DAN. This telephone number should be readily available to all divers and medical facilities. DAN's diving medicine experts provide help with diagnosis and immediate care of the patient and provide information about the location of the nearest hyperbaric chamber.

Before a patient is transferred to the hyperbaric treatment facility, it is imperative to contact the chamber to determine its availability. The chamber may be out of service or tied up with the treatment of another patient. The physician should never send a patient without first discussing the transfer with the hyperbaric treatment personnel.

1392

If airborne evacuation is required, it is critical to obtain an aircraft that can maintain sea level cabin pressurization during flight. Examples of such aircraft are the military C9 and C-130 Hercules, Learjet, and Cessna Citation. In the case of helicopters (which cannot be pressurized), the crew must maintain the lowest possible flight altitude, and preferably never greater than 1000 feet above the starting elevation. This is always problematic in evacuations from mountain lakes. All resuscitative measures must be maintained in flight.

At the recompression chamber, one of several standard hyperbaric treatment protocols is followed. In a multi-lock compressed air chamber, the patient and an attendant can be pressurized with compressed air and the patient given 100% oxygen by mask.

As with AGE, hyperbaric treatment of decompression sickness has undergone significant evolution during the past two decades and is discussed in more detail in [Chapter 59](#). It is most often successful, but the likelihood of success is difficult to predict for any given diver. In general, the sooner after the onset of symptoms that treatment begins, the better the outcome.^[4] In one series of 92 sport scuba divers treated after a significant delay between the offending dive and the start of recompression treatment, 85% had good results when standard U.S. Navy treatment tables were followed.^[29] Similar results were achieved in another series of 50 patients.^[70] Such treatment is usually given according to U.S. Navy Tables 5 and 6 ([Figure 57-10](#)). Any patient with neurologic or pulmonary DCS requires treatment with at least the protocol in Table 6 ([Figure 57-10, B](#)), with extension of the hyperbaric oxygen periods depending on how the patient responds.

Monoplace hyperbaric chambers are used to treat decompression sickness and air embolism,^{[57] [71]} but the "conventional wisdom" is to use a multiplace chamber whenever possible because of the free access to the patient possible in these larger chambers and the flexibility in treatment schedules, if needed.

U.S. Navy Treatment Table 7 is an option for serious DCS cases; however, this treatment table should be reserved for patients with major deficits because of its length and commitment of resources. The diver and attendant are held at 2.8 ATA for at least 12 hours, and longer if needed, with the patient breathing oxygen in 30-minute periods as tolerated. A final, slow, 32-hour decompression follows, regardless of the time spent

at 2.8 ATA. Details of Table 7 are found in the U.S. Navy Diving Manual.^[37]

Another potentially useful recommendation for dealing with the recurrence of neurologic symptoms and signs after apparently successful chamber treatment of neurologic DCS has been advanced by Edmonds.^[44] Frequent postrecompression recurrence of neurologic manifestations led him to institute multiple 30-minute sea level oxygen-breathing periods with 30-minute air breaks for 6 to 8 hours during posttreatment hospital observation, rechecking vital capacity frequently to detect and prevent pulmonary oxygen toxicity.

Although experimental proof of their efficacy is lacking, high-dose parenteral corticosteroids have been widely recommended and used in the past as an adjunct to recompression treatment of both neurologic DCS and AGE. Rapid-acting hydrocortisone hemisuccinate (1000 mg) or methylprednisolone sodium succinate (125 mg) followed by dexamethasone, 4 to 6 mg every 6 hours, with continuation of the dexamethasone for 72 hours, has been the standard regimen.

The use of steroids became prevalent based on the belief that they were beneficial in the treatment of cerebral edema, shock, and other conditions pertinent to DCS, although their benefit in many of these conditions is uncertain. Anecdotal data suggesting that steroids were beneficial in combination with hyperbaric oxygen treatment have been reported,^{[29] [66] [77]} but there have been no published clinical series or controlled trials demonstrating their efficacy. In contrast, controlled studies of high-dose parenteral dexamethasone and methylprednisolone in DCS-affected dogs showed that the use of glucocorticoids as an adjunct to conventional hyperbaric oxygen therapy produced no benefit, and even suggested that the steroid-treated animals did less well.^[51] Thus the benefit and role of steroids in the treatment of DCS continue to be a matter of controversy. Similarly, the value of intravenous lidocaine is speculative.^[23]

Because the outcome of recompression treatment is influenced by the time interval from onset of symptoms to the initiation of treatment, every emergency department and every diver should know the location of the nearest recompression chamber. Spinal cord decompression sickness treated after a few hours delay may result in residual deficits ranging from mild weakness or sensory changes to permanent paraplegia or worse. On the other hand, dramatic improvements have been witnessed even in persons arriving at a chamber many days after the insult.

Prevention of Decompression Sickness

Ever since DCS was first recognized, efforts have been directed at preventing its occurrence. Such efforts have utilized all manner of intervention, but to date the only effective way to prevent DCS is to limit the time a diver spends at increased pressure (i.e., depth) and/or to ensure that decompression from increased pressure is slow enough, or staged, so that the body's burden of excess inert gas is eliminated without forming bubbles. Such depth/time ascent schedules have given rise to a variety of decompression tables.

Decompression Tables.

Navies and commercial diving companies around the world have developed various

1393

Figure 57-10 Examples of U.S. Navy decompression tables. Dark shading represents oxygen breathing; light shading represents air breathing. **A**, USN Treatment Table 5, oxygen treatment of type-1 decompression sickness. **B**, USN Treatment Table 6, oxygen treatment of type-2 decompression sickness. (Modified from *Department of the Navy: U.S. Navy diving manual, vol 2, rev 2, Flagstaff, Ariz, 1988, Best Publishing Company.*)

1394

decompression schedules based on calculations and actual testing (animal and human) that allow divers to avoid exceeding safe rates of decompression after specified depth-time dive profiles. These listings of "safe" depth-time diving profiles are generally referred to as *decompression tables*. Many different sets of decompression tables exist, with the U.S. Navy Standard Air Decompression Tables being the most widely used.^[37] Decompression tables continue to be the subject of considerable scientific controversy, however, resulting in periodic revision and continual search for improved safety.

Over the years, the U.S. Navy Standard Decompression Tables have been the ones most often used in recreational diving. Various rearrangements or modifications of these tables have been promulgated by sport diving groups in recent years in efforts to improve the safety of recreational diving, which is qualitatively different from military diving (for which the Navy decompression tables were developed). In general, these sport-diving modifications have involved applying various safety factors to the standard Navy protocols.

Recent "multilevel" dive tables also have been developed to address the depth fluctuations that typically occur in sport diving because the diver ranges from shallow to deep repetitively during the course of a dive. These multilevel tables give the diver decompression "credit" for the time spent at shallower depths, as opposed to the Standard U.S. Navy tables, which require the diver to use the maximum depth of the dive to select no-decompression limits or decompression schedules and repetitive-dive

group designations. The reason for doing this has been the belief that the U.S. Navy tables are too restrictive and excessively limit the diver's time underwater. Multilevel tables allow a diver to spend more time underwater, although there continues to be concern that they provide less safety margin.

Dive Computers.

Automatic decompression meters that measure and record time and pressure underwater give the diver an indication of decompression status.^[105] These "dive computers" track the exact dive profile and then calculate a decompression requirement according to the actual dive profile. The devices have used different physiologic and decompression models and technologies. Early automated decompression meters presented problems because their use was associated with an unacceptable rate of DCS. More recent technologic innovations, however, have overcome many of the earlier difficulties. The most recent generation of dive computers is considerably more advanced than the initial devices.^{[61] [81]} The sport scuba diver now has access to a variety of devices that offer the convenience of automatic and accurate depth-time recording, together with accurately computed multilevel decompression schedules.

Currently available dive computers typically use microprocessors with decompression tables stored in memory. The microprocessor in the dive computer quickly reads a pressure transducer (which converts pressure into electrical impulses) and applies nitrogen uptake and elimination algorithms to this information every few seconds. The computer tracks a diver's exact profile and calculates decompression requirements accordingly.

Use of dive computers has become the norm, although concerns about their safety remain. Clearly, these computers are accurate depth-time recorders and are convenient because they obviate the clerical aspect of diving (i.e., the need to write down the depth and time of all dives, consult the decompression tables, calculate and record residual nitrogen time and surface intervals, and so on). Dive computers also offer advantages for some types of diving over use of the standard U.S. Navy decompression tables. They are especially useful in multilevel diving because they give bottom-time credit for time spent underwater at depths shallower than the deepest depth attained. However, it must be remembered that dive computers calculate decompression status based on models designed to simulate nitrogen uptake and release in a diver's body. These models may not accurately predict gas flow into and out of a given diver's tissues. Human physiology is not always as predictable as the computer model, and many factors can influence the actual rate of inert gas uptake and elimination. Also, most computers have no built-in safety margin to compensate for the difference between predicted and actual gas uptake and elimination, in contrast to decompression tables, which usually contain an inherent safety margin and require "rounding up" intermediate depths and times, providing a further safety factor.

Because of the multiple-tissue compartment modeling that dive computers use, another concern with their use is that they integrate the entire depth-time profile, so that in cases of repetitive diving (multiple dives per day, or multiple successive days of diving), dive computers would be more liberal than the Navy tables, allowing more time under water

and potentially allowing a gradual unsafe accumulation of nitrogen in slow tissues. In such settings the risk of developing DCS may be greater.

Other notable concerns associated with the use of dive computers are their allowance of multiple reverse-profile dives (shallow, then deep dives—an inherently risky way to dive), risk of equipment failure (such as battery failure or flooding of the battery compartment), loss of information by inadvertently turning off the computer, or failure to turn on the computer at the beginning of a dive. In the last three scenarios, the safety

1395

of the dives done after the one in which the problem occurred would be jeopardized.

Despite the widespread use of dive computers in recent years, it is not possible, at this time, to say whether they are more or less safe than the U.S. Navy Standard Decompression Tables when the tables are actually followed. The fact that substantial numbers of divers treated for DCS in recent years (more than half of diving casualties treated at some recompression chambers) were using dive computers underscores that they do not inherently protect a diver from getting the bends.^{[39] [85] [86]} Based on experience, dive computers appear to be relatively safe when used as directed.

SAFE SCUBA DIVING

Sport scuba divers are fortunate that the most colorful marine life and abundant natural light exist at shallow depths. This obviates the need to dive deep. Indeed, 100 fsw should be considered a deep dive for sport diving and, for all intents and purposes, the maximum depth for recreational diving.

Recreational diving is usually done hours to days away from the nearest recompression chamber, so the occurrence of DCS or AGE usually necessitates a major effort to evacuate an afflicted diver to the chamber. This often requires the use of special aircraft. Unfortunately, the delay between symptom onset and treatment may cause the damage to be poorly responsive to hyperbaric treatment. Therefore divers should do their best to avoid developing AGE or DCS.

The need to take a conservative approach to depth and time is even clearer when one considers that individual variability in DCS susceptibility, workload during the dive, water temperature, and ill-advised post-dive exercise or altitude exposure may confound any set of decompression tables or dive computers. Indeed, the potentially devastating consequences of DCS, even with the most vigorous hyperbaric treatment, mandate that divers always dive with the prevention of this disease foremost in their minds.

The following safe diving recommendations should be adhered to by recreational or sport divers:

- Dive within the limits of "no-decompression" ("no-D") tables. When a decompression computer is used, do not approach the limits of no-decompression diving.
- When using the decompression tables, always use the next greater depth to determine the "no-D" limits, then "jump" tables. For example, a 37-minute dive with maximum depth of 68 feet is considered a 70-foot dive and the "no-decompression limit" should be determined for the next jump, or in this case, that of an 80-foot dive for 40 minutes. Ascent toward the surface at a rate no faster than 1 foot per second should begin at the end of the prescribed limit (40 minutes in this example), regardless of how much time was actually spent at shallower depths. This "penalty" for dive time spent at shallower depth is an important safety factor.
- After any dive deeper than 60 fsw, and at the conclusion of all repetitive dives, make at least a 3- to 5-minute safety stop at 10 to 15 fsw.
- When using the decompression tables, use the surface-to-surface time or "total time of dive" in selecting the repetitive group designation.
- Carefully plan any repetitive dive so that it will be shallower than the previous dive and so that you stay well within "no-decompression" limits.

- Remember that any device or table that allows prolonged time at shallow depths after a deeper excursion also allows continued uptake of inert gas.
- Maintain hydration during diving days to ensure normal capillary perfusion for inert gas exchange. Remember that immersion diuresis and topside sweat loss in tropical regions can result in significant dehydration, which is often not overtly apparent. Keep the urine "clear and copious" on diving days.
- Do not engage in heavy exercise, such as jogging or wind surfing, for at least 6 hours after a dive.
- Do not fly, even in the pressurized cabin of commercial airlines, for at least 12 hours after "no-decompression" diving. If decompression stops were required, wait at least 24 hours before flying. If aircraft cabin altitude (e.g., an unpressurized airplane) will exceed 8000 feet, wait 24 hours before flying after any compressed gas dive.

Diving in mountain lakes requires significant adjustments in decompression tables to account for the decreased atmospheric pressure at the surface of the lake. Dive computers must be calibrated for altitude. Boni and associates^[14] pointed out that for the same depth and the same bottom time of a dive, surfacing at a lower ambient air pressure than sea level necessitates longer decompression times. Several decompression tables for altitude diving have been calculated and tested in the field.^[10]^[27]^[90] The U.S. Navy Standard Decompression Tables can be used up to an altitude of 2300 feet.

Even when these safe diving practices are followed, unexplained DCS cases sometimes occur.^[1] Two mechanisms are postulated to account for these cases. After an otherwise safe dive, one well within the specified decompression procedure, elevated inert gas tensions exist in tissues and venous blood, which carry gas to the lungs for elimination. If all else is normal and conservative depths and times have been followed, the inert gas remains in solution or, at worst, "silent" or asymptomatic volumes of venous gas emboli are returned to the lungs. If a physiologically patent foramen

ovale (PFO) allows intermittent retrograde flow from the right to the left atrium, bubbles can become arterial gas emboli. The potential for this type of paradoxical gas embolism to occur has been demonstrated in recent years for both PFO and other types of intracardiac shunts.^[28]^[89]^[106] Whether the presence of a PFO should disqualify someone from diving is currently unclear because conflicting data have been found as to the association of a PFO and the occurrence of neurologic DCS.^[28]^[89]^[106]^[111]^[112]^[113]

Another plausible explanation for DCS occurring after safe diving postulates that focal pulmonary barotrauma, or inadvertent breath-holding during decompression, produces local air trapping during ascent and releases "microbubbles" into the systemic circulation. These microscopic "seed" bubbles in arterialized blood then pass through the capillary bed to become bubble nuclei in venous blood, precipitating overt bubble

formation and the classic manifestations of DCS.

DIVE ACCIDENT INVESTIGATION

When investigating a dive accident, whether for treatment purposes or as part of a forensic evaluation in the case of a fatal accident, the investigator begins by taking a detailed dive-accident history. A number of specific details must be determined about the patient's diving activities, the time of symptom onset, and the nature and progression of the symptoms, in addition to past medical history and other information that should be obtained on any patient. The diving-related history should specifically solicit information in the following areas^[70] :

1. *The type of dive and equipment used.* Inquire specifically as to whether a decompression computer, diving watch, and depth gauge were used. Was compressed air or mixed gas used, and what was the source of the gas? Was a rebreather used?
2. *The number, depth, bottom or total dive time, and surface interval or intervals between dives for all dives in the 72 hours preceding symptom onset.* This information will be needed by the diving medicine consultant because it allows calculation of any omitted decompression and thus helps decide the likelihood of the patient having DCS or other problems. Unfortunately, the diver's interpretation of whether required decompression was omitted cannot be the sole source of data; this is notoriously unreliable. If a decompression computer was used, it should be checked for information about the need for recompression and whether it was worn on all dives.
3. *Whether in-water decompression was taken and if so, how much.* This is relevant to the likelihood of the diver having DCS. If a decompression computer was used, the diver should be asked whether the specified decompression profile was followed.
4. *Whether in-water recompression with compressed air was attempted after the onset of symptoms.* For all practical purposes, this should never be done because it almost always leaves the diver in a worse condition and is fraught with other hazards. (Of note, special protocols for in-water recompression treatment using 100% oxygen have been developed for emergency situations in exceptionally remote places.)
5. *The site of diving (e.g., ocean, lake, or quarry) and the environmental conditions (such as water temperature or presence of current or surge) associated with the dive.* These factors enter into the differential diagnosis and may raise the possibility of the symptoms being caused by something other than a bubble-related problem. For example, DCS is more common after diving in cold water, other things being equal, or motion sickness may develop in a diver swimming back to shore on a choppy sea even if there was no problem with seasickness before or during the dive.
6. *Primary diving activity (such as spearfishing, underwater photography, or shell*

collecting). Like knowledge of environmental conditions, this helps in the differential diagnosis. For example, DCS is more likely after an arduous dive such as may occur with spearfishing than a dive to take photographs.

7. *Presence of predisposing factors for DCS.* A number of factors have been associated with an increased risk of DCS, including dehydration, vigorous exercise under water, advanced age, obesity, poor physical conditioning, local physical injury, and multiple repetitive dives in unacclimatized individuals.
 8. *Whether the dive was complicated by running out of air, an untoward marine animal encounter, trauma, or other unexpected event.* For example, low back pain suggestive of DCS may be caused by a muscle strain from lifting the scuba tank or climbing into the dive boat, and tingling or numbness in an extremity may be caused by jellyfish envenomation.
 9. *Whether the patient flew in an airplane, went jogging, or engaged in any other particular activity after diving but before the onset of symptoms.* If so, the effect of the activity on the symptoms should be ascertained. Some activities (such as flying in an unpressurized aircraft or vigorously exercising immediately after diving) may precipitate DCS in someone who might otherwise not be affected, or trivial dysbaric symptoms may become severe after similar activities.
-

1397

10. *Time of symptom onset.* Symptoms that began soon after getting in the water (e.g., nausea from motion sickness), even if they worsen afterward, are not likely to be from DCS.

In fatal diving accidents, information gathered from the diving accident history should be supplemented with an appropriate diving accident autopsy, thorough evaluation of the diving equipment used, and detailed environmental history.^[33] Environmental factors, such as weather, currents, wave action, visibility, water temperature, potential for entanglement, and dangerous marine life, must be also be considered. The diving equipment should be carefully studied for proper function and amount of compressed air in the tanks, and the air should be analyzed for contaminants. The diver's medical and psychologic histories should be sought because they may contain clues to a coincidental medical event that led to the diver's death but was unrelated to the dive. Aside from the obvious psychosocial risk factors such as alcoholism, drug abuse, or propensity to panic, the use of a scuba dive for suicide or homicide must be considered.

Unique aspects of the diving-victim autopsy should include a careful search for subcutaneous emphysema or other physical signs of POPS and a search for signs of marine envenomation. For example, before the surface of the body is washed, it should be examined for evidence of nematocysts from coelenterate stings. In addition, in contrast to the thoracic incision being made first, the calvarium should be opened before other incisions to prevent accidental introduction of air into the intracranial circulation. A finding of gas bubbles in intracranial vessels may result from AGE or DCS. Postmortem introduction of gas into the cerebral veins can be avoided if the calvarium is opened under water.^[33] Likewise, the initial thoracic incision must be made with care to determine whether pneumothorax is present. A careful search should be made for gas bubbles in the major blood vessels and the heart. The middle ear should be examined

for the presence of blood, and the tympanic membrane and paranasal sinuses should be examined for evidence of barotrauma.

Meticulous investigation of dive accidents is important to find equipment, procedural, or medical causes that could be useful in improving the safety of diving and to gather information for legal procedures that often follow diving accidents.

MEDICAL FITNESS FOR DIVING

General Considerations

Persons who want to take up scuba diving should first be cleared medically. The diving examination should focus on the pulmonary, otolaryngologic, cardiac, neurologic, and integumentary systems, as well as the person's psychological stability.

Many medical conditions are contraindications for diving because of the changes in pressure that occur with excursions underwater; the physical and sometimes psychological stress of diving; the potential for nitrogen narcosis, altered sensory stimulation, and other factors to interact with pharmaceuticals; and the inherent nature of being underwater. In general, these can be divided into five categories. Persons falling into any of these categories are at increased risk for a diving-related problem:

1. Persons who are unable to equalize pressure in one or more of the body's air spaces are at increased risk for barotrauma.
2. Persons who have a medical or psychiatric condition that may become manifest underwater or at a remote diving site and endanger the diver's life because of the condition itself, because it occurs in the water, or because inadequate medical help is available.
3. Persons who have impaired tissue perfusion or diffusion of inert gases and thus have an increased risk of DCS.
4. Persons who are in poor physical condition and thus at increased risk of DCS or exertion-related medical problems. The factors compromising physical condition may be physiologic or pharmacologic.
5. Women who are pregnant, because the fetus may be at increased risk of dysbaric injury.

Disqualifying Conditions

In accordance with the likelihood of causing a diving problem and the potential seriousness of the problem, conditions falling into one of the preceding five categories may be absolutely, relatively, or temporarily disqualifying for scuba diving.

Absolutely Disqualifying Conditions.

Based on the opinion of a multispecialty panel of diving medicine experts,^[30] ^[31] the following conditions are considered to be absolute, or near absolute, disqualifications for

diving:

1. *History of epilepsy or other seizure disorder.* Seizures occurring underwater essentially always result in a catastrophic outcome. After head injury, diving should not be allowed during that period of time when the patient is at increased risk of seizures.
 2. *Insulin-dependent diabetes mellitus.* The risk of a hypoglycemic reaction underwater is increased by the possible need for sudden bursts of energy expenditure in emergencies. Underwater incapacitation due to hypoglycemia not only endangers the life of the individual but may also risk the lives of other persons during rescue attempts. Sport diving sometimes may be possible
-

1398

for persons with diabetes that can be controlled by diet and exercise or, in special situations, diabetics who are well controlled on insulin, used to vigorous physical exercise, knowledgeable about their condition, and dive with prepared buddies.

3. *Symptomatic coronary artery disease.* In addition to the need for cardiac reserve in an in-water emergency, carrying tanks, donning equipment, and swimming against current entail significant physical stresses. A history of myocardial infarction is considered a disqualification for sport diving, except in cases of exceptional rehabilitation after revascularization or comparable procedures.
4. *Sickle-cell disease or trait.* The chances that a sport diver will breathe a hypoxic gas mixture are remote, but it is possible. Other concerns are heavy exertion in cold water or local compromise of microvascular blood flow by bubble evolution during decompression, which could lead to sickling and a vicious cycle of hypoxia with further sickling.
5. *Unexplained syncope.*
6. *Inability to equalize pressure in the middle ear by autoinflation.* Of note, this may be caused by a correctable problem, such as polyps, allergic rhinitis, nasal septal deviation, or coryza, in which case the diver can be reevaluated after successful treatment.
7. *Bullous lung disease.* Air-containing pulmonary blebs or cysts can trap air and lead to local pulmonary overpressure accidents during decompression. If a ball-valve or flutter-valve effect allows such a bleb or cyst to equalize with the elevated breathing pressure during compression or descent, but blocks the escape of air during decompression, rupture could cause POPS and air embolism.
8. *Significant pulmonary obstructive disease.*
9. *Substance abuse.*
10. *Reactive airway disease (asthma).* Because of the risk of local air trapping and pulmonary overpressure accidents, persons having asthma should not dive. Although scuba air is generally free of pollens, other stresses in diving (such as cold, heavy exertion, or psychologic stress) could precipitate bronchospasm at depth, with resultant local air trapping during ascent. If there is any suggestion of bronchospastic tendencies, pulmonary function studies should be performed. Even minimal air trapping at sea level takes on great significance at depth.
11. *Spontaneous pneumothorax.* Even without the pressure variations of diving, a history of previous spontaneous pneumothorax carries a significant incidence of

recurrence, and the candidate must be advised against compressed-gas diving. A pneumothorax that occurs while the diver is still at pressure underwater or in a recompression chamber can become a life-threatening tension pneumothorax as the pleural cavity air expands (Boyle's law) during ascent. Persons who have had traumatic or surgical pneumothorax may be cleared for diving, depending on the specific circumstances.

12. *Perforation of the tympanic membrane.* Until the eardrum is fully healed or successfully repaired and eustachian tube function is good, diving is contraindicated.

Possibly Disqualifying Conditions.

The following disorders require special consideration; whether they are disqualifying for diving is controversial among diving physicians.

1. *Migraine and other vascular headaches.* Scintillating scotomas and other neurologic symptoms associated with migraines may be confused with DCS. A migraine after diving could be misinterpreted, causing unnecessary recompression treatment. Because commercial diving generally requires constant readiness to dive, migraine is often viewed as disqualifying for commercial diving.
 2. *Middle ear surgery with placement of a prosthesis in the conduction chain.* The risk of displacement during pressure change and ear clearing is the determining factor in these cases.
 3. *History of overpressure accident in previous diving.* The circumstances of the offending dive weigh heavily in these cases. For instance, if a diver suffers a "physiologically undeserved" or unexplained episode of POPS (i.e., the diver breathes normally to the surface, yet suffers an air embolism), risk of recurrence would be of greater concern. On the other hand, a diver who suffers a pulmonary overpressure accident that is considered "physiologically deserved" (e.g., rapid ascent after inadvertent inflation of a buoyancy compensator) could be considered for a return to diving after full neurologic recovery and with the determination of normal pulmonary function. However, some argue that even this diver is at greater risk because of potential pulmonary scarring and the inability to detect small airway air trapping.
 4. *Hypertension.* The suitability of a hypertensive person for diving is based largely on the therapy required for blood pressure control. Diving has little effect on blood pressure, and when a regimen of weight control, diet, and mild diuretics is successful, diving usually can be allowed. If more potent antihypertensive agents are needed, diving may be contraindicated.
-

5. *Decreased visual acuity.* In sport diving, corrective lenses can be mounted in scuba face masks or contact lenses can be worn, so this is no longer as much a concern as in the early days of scuba diving. Soft contact lenses are preferable for diving.

Temporarily Disqualifying Conditions.

The following disorders are temporary disqualifications for diving:

1. *Coryza or bronchitis*. These conditions may cause inability to equalize pressure in the ears, sinuses, or lungs because of mucosal edema, mucus plugs, or bronchospasm.
2. *Pregnancy*. At present, there is near consensus that a woman who is or may be pregnant should suspend compressed-air diving until after delivery. Animal studies have produced conflicting results in different species and laboratories, but the possibility of bubble formation in fetal or placental tissues is a concern, even on a dive that is safe for the mother.
3. *Abdominal hernias*. These present a potential risk of trapping expanding gas in a herniated loop of bowel during ascent. In general, diving should be suspended until surgical repair is completed.
4. *Poor physical fitness*. Sport scuba diving is deceptively easy until an emergency occurs that requires swimming against a current, rescue of a buddy diver, or other vigorous activity. The diver should be capable of performing strenuous activity before entering the water. Regular swimming or other exercise programs to ensure cardiovascular fitness are encouraged.

Selection and Training of Disabled Divers

In recent years, many persons with limb amputations or other serious orthopedic impairment, spinal cord injury, cerebral palsy, or similar physical condition have sought to participate in scuba diving. Some of these persons were accomplished athletes or divers before an accident changed their physical status. For others, scuba diving is a completely new experience, being offered as part of a rehabilitation program. Whatever the case, it is clear that persons having "disabilities" can enjoy diving as much as anyone else if they are properly trained, understand their condition and the limitations it causes them, and make appropriate adjustments, when necessary, for their condition.^[36]

Indeed, when done in this context, scuba diving can open exciting new vistas for some disabled persons. Williamson and co-workers^[119] demonstrated significant improvement in self-concept and body image among a group of young people with disabilities ranging from post-head injury brain damage, congenital deafness, blindness, and spinal cord dysfunction to major limb amputations. They were examined according to standard diving medicine practice regarding pulmonary and ear, nose, and throat status and detailed psychological testing. Motivation proved to be an important predictor of success. The subjects were given extensive scuba-diving training with at least one-on-one instructor attention.

In any of these situations, the diver and his or her buddy need to fully understand the concerns attendant to his or her condition (e.g., autonomic dysreflexia, skin breakdown, personal hygiene, and a possible increased risk of DCS) and the wisdom of taking a conservative no-decompression approach to diving.

FLYING AFTER DIVING

Because diving is often done at remote destinations, the question of when it is safe to fly after diving often comes up. Flying too soon after diving can seriously jeopardize decompression safety, leading to development of DCS during or after the flight because of the reduced atmospheric pressure present in most commercial aircraft.

The normal commercial aircraft cabin pressure is equivalent to an altitude exposure of 5000 to 8000 feet, which is sufficient pressure reduction to cause dissolved nitrogen to come out of solution and form intravascular bubbles. (Depending on the age and maintenance of the aircraft, the internal cabin pressure may be equivalent to an even higher altitude.) The Divers Alert Network reports that 5% to 7% of divers with DCS contacting them in recent years reported flying before the onset of their symptoms. (The actual significance of these statistics is uncertain because the total number of divers who flew after diving is unknown, but the total is estimated to be very large compared with the number who developed DCS.)

With the continued growth of the dive-travel vacation industry, the issue of when it is safe to fly after diving has become even more important. Unfortunately, not enough experimental or detailed experiential data on the subject are available to precisely quantitate the risks, or to establish precise surface intervals for various types of diving profiles. However, this matter has been the subject of a number of workshops sponsored by the Undersea and Hyperbaric Medical Society and other concerned groups.

At present the generally accepted guidelines for flying after recreational diving are as follows:

1. Observe a minimum surface interval of 12 hours between the last dive and flying in a commercial jet.
 2. Divers who make daily, multiple dives for several days, or who make dives that require decompression stops should exercise special caution and wait for an extended surface interval beyond 12 hours before flying in a commercial airliner. (Exactly what this extended surface interval should be is less well quantified, but many authorities
-

suggest at least 24 hours.) The longer the interval between diving and flying, the

less the likelihood of DCS.

Having noted the above, it is important to emphasize that no rule about flying after diving can be guaranteed to prevent DCS. These are guidelines that represent the best estimate of a safe surface interval for the majority of sport scuba divers.

Chapter 58 - Emergency Oxygen Administration

Kimberley P. Walker

Emergency medical oxygen (O₂) administration is a critical part of emergency medical care of the ill and injured. Every provider of emergency medical care must be familiar with O₂, its therapeutic value, indications, and hazards. Equipment and techniques associated with its administration must also be well understood. O₂ is a colorless, odorless, and tasteless gas that is necessary for cellular metabolism. It makes up 21% of Earth's atmosphere, and although it is not flammable by itself, it is necessary to support combustion. O₂ utilized for respiration is diatomic and is obtained commercially by fractional distillation of air.^[4] ^[5] In the case of an ill or injured person suffering from hypoxia or anoxia, supplemental O₂ is used regularly as first aid (before emergency medical service personnel arrive), prehospital, or in-hospital emergency medical treatment.

THERAPEUTIC VALUE OF SUPPLEMENTAL OXYGEN

The therapeutic value of supplemental O₂ is to treat hypoxia and anoxia by increasing the amount of dissolved O₂ in the plasma and bound to hemoglobin, thereby increasing cellular perfusion by oxygenated blood. In addition, O₂ is a mild vasoconstrictor and may in certain circumstances help to limit edema generation.

INDICATIONS

Indications for the use of supplemental O₂ include (but are not limited to) the following^[2]
^[6] :

- Shock, hypoxia
- Hypoxemia
- Trauma
- Medical emergencies (asthma, anaphylaxis, acute myocardial infarction, cerebrovascular accident)
- Decompression illness (DCI), including both decompression sickness (DCS) and arterial gas embolism (AGE)
- Acute mountain sickness (AMS)
- High altitude pulmonary edema (HAPE)
- High altitude cerebral edema (HACE)
- Carbon monoxide (CO) poisoning
- Respiratory or cardiopulmonary arrest

CONTRAINDICATIONS

In an acutely hypoxic patient there is no contraindication to the administration of high concentrations of supplemental O₂ for a limited time. O₂ should not be withheld out of fear of suppressing respiration when hypoxia is suspected.^[10] However, a person with a history of chronic obstructive pulmonary disease (COPD) who is not acutely hypoxic or in need of emergency prehospital care and transport to an emergency department should not be administered more than his or her prescribed flow rate of supplemental O₂.

Pulmonary Oxygen Toxicity

In situations in which high concentrations of supplemental O₂ administration may be carried out for many hours, there exists a concern for possible pulmonary O₂ toxicity. Prolonged exposure to high concentrations of O₂ is associated with intratracheal and bronchial irritation, with substernal or retrosternal burning, chest tightness, cough, and dyspnea. Continued exposure may result in adult respiratory distress syndrome (ARDS). Early pulmonary changes associated with pulmonary O₂ toxicity are reversible with cessation of O₂ therapy.^[12]

At a fraction of inspired oxygen (F_{IO₂}) of 0.5 to 1.0 (constant with no air breaks) and at normobaric or hypobaric ambient pressure, signs and symptoms of pulmonary O₂ toxicity may begin to appear in approximately 10 to 18 hours. Avoidance of the onset of symptoms may be accomplished by the use of periodic "air breaks," during which the patient breathes air for 5 to 10 minutes.^{[7] [12]}

Central Nervous System Oxygen Toxicity

Central nervous system (CNS) O₂ toxicity is of concern when a person is exposed to O₂ at ambient pressures greater than one atmosphere (sea level) and where F_{IO₂} exceeds 1.0, such as while scuba diving or in a hyperbaric O₂ chamber. It is not of concern to persons at normobaric or hypobaric ambient pressure. Signs and symptoms may appear at F_{IO₂} of greater than 1.6 and include (but are not limited to) sweating, bradycardia, mood changes, visual field constriction, twitching, syncope, and seizures. During hyperbaric O₂ therapy the likelihood of CNS O₂ toxicity is reduced by the use of periodic air breaks.^[12]

EQUIPMENT

Cylinders

Medical O₂ cylinders or tanks are made of aluminum or steel and come in a variety of sizes ([Table 58-1](#)). In the United States, any pressure vessel that is transported on public roads is subject to U.S. Department of Transportation (US DOT) regulations. The US DOT requires that cylinders be visually and hydrostatically tested every 5 years and either be destroyed if they fail or be stamped and labeled appropriately if they pass.^[15] Gas suppliers will not fill cylinders that have not been appropriately tested and stamped. The working pressure of steel medical O₂ cylinders is 2015 psi. The working pressure of aluminum O₂ cylinders is either 2015 psi or 2216 psi, depending on the type.

Valves

Valves for medical O₂ cylinders sold in the United States are designed to accept only medical O₂ regulators to avoid the possibility of using a medical O₂ regulator with an incompatible gas such as acetylene. The two types of valves available in the United States are the CGA-870 and the CGA-540. The CGA-870 is also known as the *pin-index valve* and is used on smaller portable cylinders (e.g., D, E). The CGA-540 is used primarily on larger, nonportable cylinders, such as those mounted in ambulances (e.g., H, M).

There a number of other valve types manufactured and used with medical O₂ throughout the world. For example, there are adapters available to make a U.S. pin-index regulator fit on an Australian bull-nose valve, but it must be noted that the use of adapters is discouraged by the U.S. Compressed Gas Association (CGA).

Regulators

The device that mounts directly to the cylinder is the regulator. Its function is to regulate the flow rate of the O₂ by reducing the pressure of the O₂ from either

TABLE 58-1 -- Common Portable Medical Oxygen Cylinder Specifications

CYLINDER SIZE	ALLOY	WORKING PRESSURE (lbs/sq inch or psi)	VOLUME (L, cu ft)	LENGTH (in, cm)	DIAMETER (in, cm)	WEIGHT (lb, kg)
M9	Aluminum	2015	246.3, 8.7	10.9, 27.7	4.4, 11.1	3.9, 1.8
D	Aluminum	2015	424.71, 15	16.5, 41.9	4.4, 11.1	5.5, 2.5
D*	Steel	2015	410.4, 14.5	16.75, 42.5	4.4, 11.1	7.5, 3.4
Jumbo D	Aluminum	2216	648.3, 22.9	17, 43.2	5.3, 13.3	9.0, 4.1
E	Aluminum	2015	679.4, 24	25.6, 65.0	4.4, 11.1	8.0, 3.6
E*	Steel	2015	682.0, 24.1	25.75, 65.4	4.4, 11.1	10.5, 4.8

NOTE: Aluminum cylinder specifications provided by Luxfer Inc.

*Steel cylinder specifications provided by Pressed Steel Tank Co.

2015 psi or 2216 psi to a usable flow rate. Regulators primarily have three types: constant flow only, demand/flow restricted oxygen-powered ventilator (FROPV) only, or multifunction, which has both constant flow and demand/FROPV capability.

The regulator mounts to the cylinder with a matching-type valve. A pressure gauge allows the user to monitor the amount of O₂ in the cylinder. Other features may include a diameter index safety system (DISS) fitting for an FROPV, a constant flow controller device (either knob or gauge), or both, as in the case of the multifunction regulator.

Devices for Ventilation of Nonbreathing Patients

All of the following devices keep direct patient contact at a minimum to reduce the risk of disease transmission. Other body substance isolation equipment (e.g., gloves, goggles) and practices should be observed as well.

In addition, when used on a nonintubated patient, all of the devices discussed below depend on adequate mask seal to be able to deliver adequate ventilations and ensure adequate respiration. The single most common cause of inadequate ventilation and respiration is poor mask seal.

FROPV/Positive Pressure Demand Valve.

Older style positive pressure demand valves (PPDVs) such as the LSP 063-05 or Elder CPR Demand valve (both manufactured by Life Support Products/Allied Health Care) function both in positive pressure mode (pushing the button to ventilate a nonbreathing patient) and in demand mode.

When used in demand mode, the recipient simply holds the mask to his or her face. When he or she inhales, negative pressure in the mask and demand valve opens the valve, and gas flows. The flow of gas stops when the person stops inhaling or exhales, similar to other demand regulators such as scuba and aviation regulators.

1404

There has been a misconception that a PPDV will easily cause pulmonary overpressurization injury, and thus they have fallen out of favor with some health care providers. In fact, in positive pressure mode, all PPDVs manufactured in the United States are required to have an overpressure relief valve that stops the flow of gas at a pressure of 55 to 65 cm H₂O (a little more than half the pressure required to overpressurize a human lung). This was done to avoid pulmonary overpressurization injury. The most recent model introduced in 1993, the MTV-100 FROPV (LSP/Allied) has two overpressure relief valves, the first set at 60 cm H₂O and the second at 65 to 80 cm H₂O.^[10]

With respect to the positive pressure mode, earlier PPDVs were originally designed to meet the Emergency Cardiac Care Committee (ECC) cardiopulmonary resuscitation (CPR) guidelines before 1986, which called for "four quick initial breaths and then two quick breaths after every 15 compressions."^[10] This faster rate of ventilation was equivalent to 160 L/min (liters per minute).

In 1986 CPR standards were changed to "two slow breaths, each one and one-half seconds in duration."^[10] The standard changed again in 1992 to the current one of "two slow, full breaths, with a duration of 1 ½ to 2 seconds each" (equivalent to 40 L/min).^[10] This was changed to reduce the possibility of gastric insufflation, regurgitation, and aspiration of gastric contents. To meet this guideline of a 1 ½- to 2-second breath, the manufacturers of PPDVs added a restricting orifice that limited the flow rate to 40 L/min. Unfortunately, this created increased breathing resistance to the demand feature.

In 1993 a new style PPDV, called a *flow restricted oxygen-powered ventilator* (FROPV) (MTV-100, manufactured by LSP/Allied) was introduced. Its specifications include a flow rate of 40 L/min while being used in positive pressure mode and 115 L/min in demand mode, eliminating the difficulties of the earlier models.

The mask adapter is a standard 15-mm fitting that fits a variety of masks and can also be used directly with an endotracheal tube. The disadvantages of the FROPV are that a supply of O₂ is required for its use and that in intubated patients the health care provider

will not be able to "feel" decreased lung compliance.

Bag-Valve-Mask.

The bag-valve mask (BVM) consists of a mask, bag, and valves that control or direct the flow of air and O₂. Like the FROPV, the mask can be changed to different styles to accommodate different faces or can be used directly with an endotracheal tube. The volume of the bag is 1000 to 1200 ml, depending on the manufacturer. Some have an outlet and reservoir for use with supplemental O₂.

An advantage to the BVM is that although it works best with supplemental O₂, it will function on room air if the O₂ supply is depleted. In addition, in intubated patients, some health care providers are able to "feel" decreased lung compliance.

The primary disadvantage is that it requires training and practice to effectively use a BVM, and even with much practice, many find it is difficult to maintain adequate mask seal and ventilate sufficient volumes when only one rescuer is available to use it. Even with proper training, few individuals can maintain adequate mask seal and a patent airway with one hand while squeezing the bag fully to achieve the 800 to 1200 ml standard volume. The US DOT National Standard Curricula for First Responder to Paramedic recommend the BVM be used first with two rescuers (one maintaining mask seal and patency of the airway, the other squeezing the bag). The NSC recommends that a BVM with one rescuer be the last choice (after all other devices and techniques) in ventilating a patient.^[15] In addition, there is no over-pressurization relief valve. This is rarely a concern in unintubated patients because of the aforementioned difficulties in achieving even minimally acceptable ventilatory volumes, but it is of concern in intubated patients.

Resuscitation Mask

The pocket-type resuscitation mask consists of a clear, flexible plastic mask designed to fit over the mouth and nose of the victim while the health care provider ventilates by exhaling through the "chimney." There is usually a one-way valve that directs the rescuer's breath into the victim while at the same time directing the exhaled breath of the victim away from the rescuer. It is a relatively simple device that requires minimal training, is lightweight, and is more likely to be available when equipment is at a minimum. It is available both with and without an outlet for supplemental O₂.

The pocket-type mask is most effective when used with supplemental O₂. It will also function on room air and does not have an overpressurization relief valve.

Constant Flow Devices for Adequately Breathing Patients.

The nonrebreather mask is the first choice when considering constant flow supplemental O₂ in an acute medical emergency. It consists of a mask, reservoir bag,

and two or three one-way valves, one separating the reservoir from the mask and the other one or two on the sides of the mask. Oxygen flows into the reservoir bag so that when the patient inhales, he or she inhales O_2 from the reservoir. The one-way valves on the sides of the mask keep air from coming into the mask and diluting the O_2 . When the patient exhales, expired air goes out of the mask through the one or two valves on the face and is prevented from entering the reservoir.

*Specifications from Allied Healthcare, Inc./Life Support Products.

1405

The efficiency of this mask depends on the mask fit and seal and proper functioning of the valves. Under ideal conditions this mask (when fitted with all three valves) may deliver an F_{IO_2} of up to 0.95. Field studies show it may deliver F_{IO_2} as low as 0.60, but it is still the most effective constant flow device available (except for O_2 rebreathers).^[14]

To use the mask, it is attached to the O_2 supply at a flow rate of 10 to 15 L/min. The reservoir bag must be inflated or "primed" before placing it on the patient. This can be accomplished by placing a thumb or fingers on the valve between the reservoir and mask while the reservoir inflates. Care must be taken to not allow the O_2 supply to be depleted while the mask is on the patient. Because of the one-way valves, if there is no O_2 supply, suffocation may result. The mask is available with either two one-way valves on the sides or with only one (labeled as "with safety outlet"). If the mask has only one valve on the side of the mask, it will deliver reduced F_{IO_2} .

The advantage of the nonrebreather mask is that it provides the highest F_{IO_2} of the constant flow devices. However, it also wastes O_2 and may not deliver a high F_{IO_2} under less than ideal conditions. Care must be taken to monitor the patient and O_2 supply closely to avoid allowing the tank to empty while the mask is still on the patient's face.

The only other recommended constant flow device for prehospital emergency O_2 administration is the nasal cannula.^[15] This is recommended when the patient will absolutely not tolerate any kind of mask, such as a person with a long history of COPD. In this case it is believed that some supplemental O_2 is better than none. It must be understood that a nasal cannula is capable of only delivering F_{IO_2} of 0.24 to 0.29.^[14] In wilderness medicine, the nasal cannula should rarely warrant consideration.

Flow rates for a nasal cannula are limited to 1 to 6 L/min. To use the nasal cannula, place the prongs in the patient's nares and loop the tubing over the top of the ears to hold it in place. Adjust the tightness at the neck to a comfortable level. Flow rates exceeding 6 L/min are extremely uncomfortable for the patient and may result in drying of the nasal mucosa.

Other constant flow masks, such as the partial rebreather mask, the simple face mask,

and the venturi mask, are not recommended for use in prehospital emergency medicine because of low levels of delivered F_{IO_2} . [14] [15]

Oxygen Rebreathers

One of the problems with long transports commonly seen in the case of wilderness or remote emergency medical care is that all of the previously discussed O_2 delivery devices waste O_2 and require multiple portable or large nonportable cylinders if the transport time exceeds 1 hour. Breathing room air, a person inhales 21% O_2 and exhales 16% O_2 . If a person inhales (under ideal conditions) 100% O_2 , the exhaled gas will contain 95% O_2 and 5% CO_2 . The theory of the design of a rebreather is to remove CO_2 from the exhaled gas, supplement for the 5% O_2 that was metabolized, and reuse the exhaled O_2 .

There are several manufacturers of rebreathers for emergency medical O_2 administration and they all have the same basic components. There is a mask, a breathing circuit (similar to anesthesia equipment), and a canister with an absorbent chemical, usually soda lime or Sodasorb.*

The soda lime chemically removes CO_2 from the exhaled gas, allowing for the O_2 to be rebreathed.† Supplemental O_2 is added at flow rates of less than 2 Lpm to replace the metabolized O_2 , and thus the cylinder that can last 45 minutes with a nonrebreather mask or a little more than 1 hour on demand now lasts more than 6 hours, and the patient (with proper technique) will still receive F_{IO_2} of 0.85 to 0.99. In a situation in which equipment is limited because of size and weight, this device may prove invaluable.

Different manufacturers recommend beginning the patient on O_2 during assembly, setting up the unit, flushing the system of air, applying it to the patient, and considering air breaks to minimize the risk of pulmonary oxygen toxicity.

Thermal considerations are important because of the chemical reaction that takes place with the soda lime. The reaction produces heat and water, so it provides warmed and humidified O_2 . In cold climates, this is an advantage, but in hot climates it may be a disadvantage. If one is in a hot climate, it is recommended to pass the breathing circuit hoses through cold or ice water to cool the gas. Rebreather set-ups are typically lightweight and allow high F_{IO_2} (>0.80) at constant flow rates of less than 2 L/min, thereby extending the life of the cylinder.

Disadvantages are the training requirement and that the breathing circuit and absorbent canister containing the soda lime are typically "single-patient use." Like other O_2 delivery devices, the rebreather also depends on an adequate mask seal to function effectively. Poor mask seal results in dilution of inhaled gas with air and lower F_{IO_2} . There may also

be an increase in breathing resistance when compared with a constant-flow mask.

The most common types of resuscitators available on the market today are the American DAN REMO₂ system, two German systems (the Wenoll and the Circulox), and an Australian system (OXI-Saver Resuscitator).^[11]^[13]

CONCERNS INVOLVING VENTILATING OR ASSISTING VENTILATIONS IN NONBREATHING OR INADEQUATELY BREATHING PATIENTS

Concerns for ventilating nonbreathing patients include rate (breaths per minute), volume, flow rate or speed, pressure, and oxygenation. The rate of ventilations per minute is 12 per minute for an adult (over 8 years old) and 20 per minute for children and infants.^[10]

The recommended volume for ventilations for an adult is 800 to 1200 ml. If a ventilation device or technique does not have an over-pressure relief valve and greater volumes are administered, pulmonary barotrauma (pulmonary overpressurization injury) may result. Ventilatory volumes less than 800 ml may not be sufficient to inflate the alveoli, and thus gas exchange will be inadequate. Each ventilation should be at least 1 ½ to 2 seconds in duration (equivalent to 40 L/min). Faster ventilation rates or speeds force open the esophagus and then force air into the stomach rather than the lungs. Increased gastric insufflation greatly increases the risk of regurgitation and aspiration of gastric contents.^[10]

It has been demonstrated that a differential pressure of as little as 90 to 110 cm H₂O has been sufficient to rupture alveolar septa and to allow gas to escape into interstitial spaces.^{[1] [2] [3]} Care must be taken to not exceed these pressures when ventilating a patient. Humans can easily generate pressures exceeding 120 cmH₂O by exhaling forcefully, and thus according to ECC CPR guidelines, one should "blow until the chest rises" to accommodate various sizes of patients. The only device for ventilating adult patients that has an overpressure relief valve is the PPDV/FROPV.

The primary goal of ventilation is oxygenation of the patient. With mouth-to-mouth or mouth-to-mask breathing without supplemental O₂, F_{IO₂} will be the same as exhaled gas, which is 0.16, or 16% O₂. Adding O₂ at a flow rate of 15 L/min may increase the F_{IO₂} with a pocket mask to up to 50%. A BVM on room air is 0.21, and with O₂ at 15 L/min up to 0.9, depending on the equipment and the skill of the ventilator. A FROPV delivers close to 1.0, or 100% O₂.^{[2] [10]}

Both the volume and oxygenation achieved by ventilations depend on the quality of the mask seal and patency of the airway. The single most common cause of inadequate ventilation in a nonintubated patient is poor mask seal. Great care must be taken to ensure that the airway is fully patent and that there is a good mask seal with each ventilation. If the patient is not intubated, an oropharyngeal, nasopharyngeal, or a combination airway should be used if available.

Because a FROPV delivers the highest F_{IO_2} , is the only device that is limited to 40 L/min flow rate (1 ½ to 2 seconds in duration) and has an overpressure relief valve, it may be the best choice for ventilating a person in respiratory arrest, whether or not they are intubated. A BVM unit used by rescuers (one to maintain the mask seal, and the other to squeeze the bag) is the best alternative. This method of ventilation is the first choice for ventilating a person in respiratory arrest, according to the US DOT National Standard Curricula for EMTs (1994), First Responders (1995), and Paramedics (1998). [\[9\]](#) [\[15\]](#) According to these same curricula, the following is the order of preference in ventilating a person in respiratory arrest:

1. BVM unit with two rescuers and supplemental O_2
2. Pocket mask with supplemental O_2
3. FROPV
4. BVM unit with one rescuer and supplemental O_2
5. Last choice, and not an option for the professional rescuer, is mouth-to-mouth breathing, because of the risk of disease transmission

HAZARDS

Oxygen alone or in a vacuum is not flammable. However, in the presence of flammable substances, combustion can be very vigorous. It is imperative to use O₂ only in open, well-ventilated areas and not in the presence of burning materials. Care must be taken when handling O₂ equipment to avoid allowing contaminants such as petroleum products to come into contact with the regulator, particularly in or around the orifices on the cylinder or regulator through which O₂ flows. Cylinders should not be exposed to temperatures above 52° C (125° F).

LEGAL ISSUES

The United States Food and Drug Administration (FDA) regulations regarding O₂ administration equipment state that to qualify as "emergency medical oxygen administration equipment" the device must "be capable of administering a flow rate of at least 6 L/min for a period of at least 15 minutes."¹ Equipment not meeting this minimum standard may not be sold in the United States as emergency medical O₂ administration equipment.

To fill a medical O₂ cylinder, the FDA states, "For emergency use only when administered by properly trained personnel for O₂ deficiency and resuscitation. For all other medical applications, Caution: Federal law prohibits dispensing without prescription."¹

Chapter 59 - Principles of Hyperbaric Oxygen Therapy

Claude A. Piantadosi

Hyperbaric oxygen therapy (HBOT) is defined as the inhalation of oxygen at a partial pressure greater than the normal barometric pressure at sea level of 760 mm Hg (one atmosphere absolute [atm]). HBOT is used as a treatment in which a patient breathes pure oxygen inside a pressurized chamber to help resolve certain difficult or refractory medical problems. Most treatments are performed at 2 to 3 atm; these pressures are equivalent to 33 to 66 feet of seawater (FSW).

HBOT may be used as either a primary therapeutic modality (e.g., for decompression sickness [DCS]) or as an adjunctive modality (e.g., for clostridial myonecrosis). The therapeutic effects of hyperbaric oxygen (HBO) are related to specific physical, physiologic, and biochemical effects of high partial pressures of oxygen (P_{O_2}) in the blood and tissues of the body. The conditions for which HBOT has a sound scientific rationale and demonstrated clinical efficacy are relatively few but encompass a heterogeneous body of disorders, indicating that its pharmacologic effects are not mediated by a single mechanism of action. Currently, HBOT is widely recommended for only 13 medical conditions ([Table 59-1](#)); these constitute the indications approved by the Undersea and Hyperbaric Medical Society.^[3]

BIOLOGIC EFFECTS OF HYPERBARIC OXYGEN

The biologic effects of HBO are related to changes in physicochemical processes in the body by molecular oxygen. These processes include gas diffusion, convective transport of oxygen and inert gases, and chemical reactions involving oxygen, including generation of reactive oxygen species. The physiologic effects of HBO are related primarily to the first two of these processes, diffusion and convection, which allows substantial increases in the P_{O_2} of arterial blood and in certain body tissues under hyperbaric conditions. Diffusion is also necessary to facilitate movement of bubbles of inert gas (such as nitrogen) in the blood and tissues in the resolution after decompression from a higher-pressured to a lower-pressured environment. The third process, the chemical activity of oxygen, determines the effects of HBO on normal metabolic events, as well as the manifestations of oxygen toxicity.

Transport of oxygen from the ambient environment to the tissues depends on a gradient of partial pressures between the air spaces of the lung and the cells of the body. This gradient, known as the oxygen cascade, normally begins during air breathing at sea level with inspired P_{O_2} of about 150 mm Hg. From the lungs, oxygen diffuses into the pulmonary capillaries, where it is carried in arterial blood out to the tissues. Hyperbaric oxygen produces profound effects on gas exchange by the lungs, oxygen transport to tissues, and P_{O_2} in the tissues.

Gas Exchange by the Lungs

Normal oxygen exchange begins in the alveoli of the lungs after inspired gas is warmed to body temperature, humidified and diluted with carbon dioxide (CO_2) leaving the body through ventilation. These factors are taken into account by subtracting the partial pressures of water vapor (47 mm Hg) and CO_2 (P_{ACO_2} , normally 40 mm Hg) from total gas pressure in the alveoli. These relationships are described by the alveolar air equation:

$$P_{AO_2} = F_{IO_2} (P_B - P_{H_2O}) - P_{ACO_2} \times [F_{IO_2} + (1 - F_{IO_2})/R]$$

where P_{AO_2} is the partial pressure of oxygen in the alveoli; P_B and P_{H_2O} are the barometric and water vapor pressure, respectively; F_{IO_2} is the fractional concentration of oxygen in inspired air; and R is the respiratory quotient (usually 0.8). During air breathing at F_{IO_2} of 0.21 and assuming R value of 0.8, the equation can be simplified to:

$$P_{AO_2} = 0.21 (P_b - 47) - 1.25(P_{ACO_2})$$

where P_{ACO_2} has been replaced by the arterial P_{CO_2} (P_{aCO_2}). Therefore P_{O_2} in the ideal alveolus at sea level is $0.21(760 - 47) - 1.25(40)$ or $(150 - 50)$ or 100 mm Hg. Alveolar P_{O_2} is slightly higher than the value in arterial blood because of the presence of small shunts and regions of ventilation-perfusion mismatch. Areas of shunt, where ventilation is zero but blood flows from right to left or left to left circulations, occur normally in the thebesian veins of the heart and the bronchial circulation. This shunt amounts to 2% to 5% of cardiac output and produces arterial P_{O_2} in normal adults of approximately 90 mm Hg. The difference between the ideal alveolar and the actual arterial P_{O_2} is called the alveolar to arterial oxygen difference ($AaDO_2$). This difference widens to about 100 mm Hg during 100% oxygen breathing; however, the ratio of P_{aO_2} to P_{AO_2} (a/A ratio) remains constant over this range of partial pressures because it is the slope of the

TABLE 59-1 -- Approved Indications for Hyperbaric Oxygen Therapy

INDICATION	RECOMMENDED PROTOCOL	NUMBER OF TREATMENTS*
Arterial gas embolism	U.S. Navy Table 6 or Table 6A	1–10
Carbon monoxide poisoning	2.4–3 atm for 90–120 min	1–5
Clostridial myonecrosis	2.4–3 atm for 90 min	3–10
Compromised skin grafts	2–2.5 atm for 90–120 min	10–40
Crush injuries	2–2.5 atm for 90–120 min	3–12
Decompression sickness	U.S. Navy Table 5 or Table 6	1–10
Delayed radiation injury	2–2.5 atm for 120–140 min	30–60
Exceptional blood loss	2.5–3 atm for 120–240 min	—
Intracranial abscess	2–2.5 atm for 60–90 min	10–20
Necrotizing infections	2–2.5 atm for 90–120 min	3–30
Problem wounds	2–2.5 atm for 90–120 min	10–30
Refractory osteomyelitis	2–2.5 atm for 90–120 min	20–40
Thermal burns	2–2.5 atm for 90–120 min	20–50

*The higher numbers are limits for utilization recommended by the Undersea and Hyperbaric Medical Society.

line describing the relationship between arterial and alveolar P_{O_2} .

The arterial P_{O_2} that can be achieved during exposure to HBO has been studied in healthy individuals and patients and found to be predictable from the a/A ratio measured at 1 atm. With the help of the following equation, P_{aO_2} can be predicted for a patient breathing hyperbaric oxygen:

$$P_{aO_2} \text{ (predicted)} = (P_{aO_2}/P_{AO_2})[(760 \text{ atm} - 47) - P_{aCO_2}]$$

where the atm is the ambient pressure in atmospheres. In general, P_{aO_2} values of greater than 1000 mm Hg are needed to produce therapeutic effects during HBOT.

Hyperbaric oxygen has significant effects on ventilation and CO_2 excretion. HBO affects ventilation by reducing carotid chemoreceptor activity. It also increases the density of the breathing gas in direct proportion to the ambient pressure and increases the CO_2 content of the tissues. The latter effect is due to "arterialization" of venous blood under hyperbaric conditions (see below), which prevents CO_2 from binding to hemoglobin as the carbamino compound. This additional load of oxygen causes the P_{CO_2} of venous blood to increase by about 5 mm Hg and produces mild respiratory acidosis. The net effect of these responses is a small increase in resting ventilation during HBO. This increase in ventilation allows a normal P_{aCO_2} to be maintained. However, P_{aCO_2} may rise rapidly with exertion under hyperbaric conditions.

Oxygen Transport to Tissues and the Effects of HBO

Oxygen is transported in the blood by two physical processes. Most oxygen is chemically bound to the hemoglobin molecule and thereby transported by red blood cells. Hemoglobin accounts for more than 98% of the oxygen content of normal blood. The remaining oxygen is carried in plasma in physically dissolved form. The oxygen transport system is described by the Fick equation:

$$V_{O_2} = Q(C_{aO_2} - C_{vO_2})$$

where V_{O_2} is the oxygen consumption rate of the body (ml/min), Q is cardiac output (L/min) and C_{aO_2} and C_{vO_2} are the arterial and mixed venous oxygen content values (ml/dl), respectively. Oxygen delivery is the product of Q and C_{aO_2} . The basal oxygen consumption rate is approximately 250 ml/min. Oxygen extraction, the difference between arterial and venous oxygen content (AV_{DO_2}), is approximately 5 ml/dl.

The oxygen content of blood is the sum of oxygen carried by hemoglobin and oxygen dissolved in the blood plasma. The oxygen content of hemoglobin is determined by multiplying hemoglobin concentration by the oxygen saturation and the oxygen carrying capacity of the molecule. Each gram of hemoglobin can carry 1.34 ml of oxygen when fully saturated. At a normal concentration of 15 g/dl, hemoglobin carries 20 ml/dl of oxygen. The oxygen content of blood plasma is determined by the solubility of O_2 in

plasma at 37° C, which is (0.0031 ml/mm Hg) times the P_{O_2} , which at 100 mm Hg results in oxygen in solution of only 0.31 ml/dl. Once hemoglobin has combined fully with oxygen, increases in P_{O_2} can only increase the oxygen content of blood by increasing the amount of oxygen in solution. At P_{O_2} values above 100 mm Hg, the oxygen content increases in direct proportion to P_{O_2} in the blood ([Figure 59-1](#)).

During hyperbaric oxygen therapy, P_{O_2} will increase approximately 700 mm Hg and Ca_{O_2} will increase approximately 2.1 ml/dl for every atmosphere of pressure for patients with normal pulmonary gas exchange. At

1410

Figure 59-1 Effects of hyperbaric oxygen on the oxygen content of arterial blood. The blood oxygen content (Ca_{O_2}) under normal conditions is approximately 20 ml/dl and is carried almost exclusively by hemoglobin. The normal oxygen extraction (AV difference) is approximately 5 ml/dl or about one quarter of the total Ca_{O_2} . During HBOT, dissolved O_2 in plasma can be increased to provide the entire AV difference without unloading O_2 from hemoglobin.

the partial pressures of oxygen used for clinical HBO treatments (2 to 3 atm), the amount of oxygen in physical solution in the blood approaches or exceeds the 5 ml/dl needed to meet the oxygen requirement of the body at a normal cardiac output. Hence, the heart can deliver enough oxygen in plasma under hyperbaric conditions to avoid any unloading of oxygen from hemoglobin.

Tissue Effects of HBO and Assessment of Tissue Oxygenation

In the systemic capillaries, oxygen is released by hemoglobin into the plasma, where it diffuses down a concentration gradient into cells to be consumed in mitochondria by an irreversible, enzymatic reaction. The enzyme cytochrome c oxidase is the final member of the respiratory chain that reduces oxygen to water. This reaction accounts for more than 90% of oxygen consumed by the body. Although mitochondria can respire at very low values of P_{O_2} , if oxygen concentration falls too low, the rate of respiration becomes limited by oxygen availability, the cell becomes hypoxic, and production of high-energy metabolites (e.g., adenosine triphosphate [ATP]) is compromised. Normally, tissue oxygenation can be regulated only by changes in blood flow or changes in oxygen extraction. Changes in local oxygen demand (metabolic rate) are met by these two processes singly or in combination.

Hyperbaric oxygen has at least two obvious advantages for maintaining oxygen availability in tissues. First, as noted above, convective delivery of oxygen to systemic capillaries is greater than normal at any cardiac output owing to the increase in arterial

oxygen content. Second, large increases in C_{aO_2} result in a higher P_{O_2} at both the arterial and venous ends of the capillaries for any oxygen consumption rate. The resulting increase in tissue oxygen concentration has important physiologic and biochemical effects in both normal and diseased tissue.

Oxygen directly alters organ blood flow by adjusting vessel caliber. Remarkable decreases in tissue blood flow have been observed when arterial P_{O_2} rises to above 500 mm Hg. Oxygen-induced vasoconstriction occurs in both the arterial and venous sides of the circulation; its mechanisms are complex and not yet understood completely. In humans, decreases in cerebral, retinal, and renal blood flow have been demonstrated during HBOT. Even in the presence of vasoconstriction, however, HBO readily oxygenates both normal and diseased tissues, provided that blood flow through major arteries has been preserved. HBO can produce tissue P_{O_2} values in the range of several hundred mm Hg as measured by indwelling P_{O_2} electrodes or transcutaneous oxygen measurements.

HYPERBARIC CHAMBERS AND PROCEDURES

Hyperbaric oxygen treatments can be conducted in either a multiplace or a monoplace chamber facility. Each type of chamber has specific advantages and disadvantages. In general, either device is suitable for the routine treatment of stable patients. Critically ill patients, however, are more easily and safely managed in multiplace chambers, where nurses and other medical personnel can attend the patients immediately. In recent years, portable monoplace recompression chambers

1411

Figure 59-2 Multiplace hyperbaric chamber. Multiplace chambers allow more than one patient at a time to receive hyperbaric oxygen. Attendants may accompany the patients during treatments. (Courtesy Duke University Photography. Photo by Les Todd.)

with limited capabilities have been developed for remote diving sites and high-altitude expeditions to relatively inaccessible regions of the world.

Multiplace Chambers^[7]

Multiplace hyperbaric chambers hold two or more people, including patients, nurses, respiratory therapists, and other attendants (often known as tenders). The chamber is pressurized to the treatment depth with air, and the patient breathes 100% oxygen by mask or head tent or through an endotracheal tube. Large chambers are capable of treating a dozen or more patients at the same time ([Figure 59-2](#)).

Monoplace Chambers^[10]

Monoplace chambers accommodate a single patient and are generally pressurized with pure oxygen that the patient breathes directly ([Figure 59-3](#)). Air breaks are given by mask or with a scuba regulator. Alternatively, the monoplace chamber may be

pressurized with air and the patient supplied with oxygen from a mask, regulator, or other built-in breathing system (BIBS). The monoplace chamber must be decompressed for attendants to have direct access to the patient.

Figure 59-3 Monoplace hyperbaric chamber. Monoplace chambers hold a single patient, usually in an environment of pure oxygen. Attendants remain outside the chamber during treatment.

Portable Recompression Chambers

Portable recompression chambers can be either rigid or collapsible. Rigid chambers tend to have greater versatility but are more cumbersome to transport than collapsible chambers. Portable chambers usually rely on compression with ambient air, and for collapsible chambers, internal pressure and inspired P_{O_2} can only be increased by a few tenths of an atmosphere. Collapsible systems, for example, the Gamow bag or the Certec chamber, are most often used on high-altitude expeditions for temporary treatment of serious high altitude-related illness when descent is not feasible or is delayed unavoidably. The extent to which simulated descent can be achieved in a collapsible chamber depends on the altitude at which it is used. For instance, the Gamow bag has a nonadjustable pressure "pop-off" valve at 2 psi (0.13 atm). The Certec chamber can operate at a slightly higher pressure (0.22 atm). The beneficial effects of these small increases in pressure on altitude sickness are transient. Furthermore, some patients, such as those with high-altitude pulmonary edema, may not tolerate lying down inside a small tube. If available, administration of supplemental oxygen while awaiting descent is logistically easier and preferred to recompression in a collapsible chamber for treatment of serious altitude illness (see [Chapter 1](#)).

Portable, or "fly-away," systems also have been used to treat decompression illness in divers. Use of these systems is expensive and requires a considerable degree of technical expertise and logistic support. These systems are available primarily in the U.S. Navy and to commercial diving contractors. Therefore routine emergency treatment for all forms of decompression illness at sites of remote diving operations is administration of high-flow supplemental oxygen by mask (or endotracheal tube) until the victim can undergo recompression in a fully-equipped facility. Treatment of decompression

illness by recompressing in the water is not recommended.

Patient Care Procedures and Monitoring^[7] [10]

Proper control of chamber atmosphere is essential for comfort, safety, and therapeutic efficacy during HBO administration. The most important variables affecting hyperbaric environments are the temperature, humidity, and concentrations of oxygen, CO₂, and contaminant gases.

The ideal inspired oxygen concentration is 100%; however, 98% O₂ or above is an attainable practical goal. The recommended maximum ambient CO₂ concentration is 3.18 mm Hg, which is 0.5% surface equivalent concentration. This recommendation is designed to avoid stimulation of ventilation and to minimize the risk of central nervous system (CNS) O₂ toxicity. The concentrations of contaminant gases, such as carbon monoxide, methane, and other hydrocarbons, in the gas supply should be monitored periodically and kept below accepted air purity standards. The relative humidity recommended for oxygen-enriched breathing gases is 50% to 70% for patient comfort and fire safety considerations.

A variety of standard patient monitoring and support devices can be used in hyperbaric environments with appropriate safety precautions. Available monitoring devices include electrocardiogram (including defibrillator), electroencephalogram, vascular pressure monitors, and evoked potential recorders. Support devices, including intravenous (IV) infusion pumps (using flexible IV bags) and mechanical ventilators, can be adapted successfully for chamber use. It has long been standard practice to minimize the number of electrical and electronic devices inside the chamber by plumbing electrical connections, including patient monitoring cables, through the chamber wall. This practice has proven to be an effective fire prevention method in hyperbaric chambers.

Hyperbaric Chamber Safety

Hyperbaric chambers are quite safe, and catastrophic failures are extremely rare. The most serious safety concern in hyperbaric environments is the risk of fire. Fires in oxygen-rich environments are far more dangerous than those occurring in normal atmospheres because of the ability of O₂ to support combustion. At ambient O₂ concentrations above 25% by volume, electrical sparks or chemical ignition can lead to explosive combustion and ultrarapid incineration of any flammable materials in the chamber. Of the more than two dozen chamber fires reported over the past 40 years, approximately half were caused by ignition sources, such as cigarette lighters and hand warmers, brought into the chamber by patients. Stringent precautions to avoid sources of combustion and flammable materials in the chamber should be taken at all times.

INDICATIONS FOR HYPERBARIC OXYGEN THERAPY

Reference to the therapeutic use of hyperbaric pressure can be found in the medical literature as early as the mid-seventeenth century, but until the 1920s, the treatment was largely restricted to caisson disease (decompression sickness, or DCS). In the 1920s, Cunningham advocated hyperbaric air to treat a variety of ailments for which HBOT had no scientific rationale. When the American Medical Association condemned this practice in 1928, the treatment fell out of favor until after World War II. The use of HBOT reemerged in the 1950s and 1960s after scientific reports supported its potential efficacy as a treatment for decompression illness, carbon monoxide poisoning, and gas gangrene. In 1976 the Undersea and Hyperbaric Medical Society established a multidisciplinary committee to review research and clinical data and provide recommendations about the safety and efficacy of HBOT. From the work of this committee has come a list of 13 indications currently accepted in the United States for the clinical application of HBO ([Table 59-1](#)).^[3] The rationale and approach to treatment of the most common conditions are briefly summarized below.

Decompression Sickness

The earliest therapeutic use of hyperbaric chambers was to recompress divers with DCS, also known as the bends. When divers suffering from mild to moderate cases of bends were recompressed promptly on air, complete relief of symptoms usually could be obtained. More severe types of DCS, such as those involving significant neurologic injury, responded less well to air recompression. The development of oxygen recompression tables, however, has substantially improved the clinical outcome for all types of DCS.^[6]

DCS arises from ascending too rapidly from underwater diving, flying after diving, or ascent in an unpressurized aircraft. It is also encountered after an exposure to increased pressure in a hyperbaric chamber or on exposure to decreased pressure in a hypobaric chamber. During decompression, bubbles of inert gas (nitrogen) form when the rate of ascent exceeds the rate at which diffusion and perfusion reduce the inert gas partial pressure in tissues. Inert gas bubbles may be formed in sufficient quantities to interfere with organ function by occluding blood flow or disrupting tissue, or they may produce biochemical events that damage tissue.^[2] The latter events include platelet aggregation, activation of coagulation, complement activation, leukocyte adhesion, endothelial damage, and capillary leakage.

The clinical manifestations produced by DCS vary by type and severity (see [Chapter 57](#)). Historically, they have been categorized into two types. Type I DCS involves pain only, usually in one or more joints ("limb bends"), whereas type II DCS involves more

severe

1413

symptoms, usually involving the nervous system or the cardiorespiratory system. The latter condition is known as "chokes." In severe cases, shock and death may occur. Other systems, however, may be involved, including the audiovestibular, skin, and lymphatic systems. Extreme fatigue after diving can also be a manifestation of serious DCS.

Two main points in differential diagnosis must be considered in evaluating a person for treatment of possible DCS. For limb pain the possibility of unrecognized trauma or strain injury is an important diagnostic consideration; however, in practice this distinction can be difficult. Under such circumstances, a trial of pressure in the chamber can be helpful. For patients with more serious DCS, distinguishing between DCS and arterial gas embolism (AGE) can be difficult, and the two conditions may coexist. This distinction, however, may not be as clinically useful as once believed because the same recompression tables may be appropriate for both conditions.

Treatment of DCS is based on the twin principles of reducing bubble size with recompression and hastening inert gas elimination with oxygen ([Figure 59-4](#)). The most widely used oxygen recompression tables for treatment of DCS are U.S. Navy Table 5 and Table 6.^[9] These tables require compression to 60 FSW (2.8 atm) and intermittent O₂ breathing for varying periods of time ([Figure 59-5](#)). Table 5 is used for mild DCS that responds

Figure 59-4 Effects of recompression therapy on gas bubble size. The relative bubble volume and diameter are plotted as a function of recompression depth (pressure in atm). The greatest effect occurs on bubble volume during the initial 2- to 3-atm pressure change. As the volume of the bubble decreases, the partial pressure of nitrogen (P_{N_2}) rises inside it. This allows N_2 to diffuse more rapidly down its concentration gradient into the tissue, where the P_{N_2} is lower. The addition of O₂ breathing lowers P_{N_2} in the tissue, thereby increasing the gradient for N_2 elimination.

Figure 59-5 U.S. Navy oxygen recompression tables for treatment of DCS.

Oxygen breathing periods are indicated in green; air breaks are shown in blue. The rate of compression to 60 FSW is 25 feet/min (2.4 min). US Navy Table 5 requires 135 minutes and Table 6 requires 285 minutes, excluding time of compression. U.S. Navy Table 6 may be extended up to two O₂ cycles at 60 FSW and two O₂ cycles at 30 FSW.

1414

promptly to recompression. Table 6 is designed for more refractory symptoms and is also suitable for treatment of AGE. When the volume of intravascular gas after AGE is sufficient to cause major neurologic deficits, however, some practitioners prefer U.S. Navy Table 6A with compression to 165 FSW using air or a 50% N₂/O₂ (nitrox) mixture. Longer oxygen treatment tables with extended decompression profiles are available for more severe and refractory cases of DCS involving the CNS.

The results of recompression therapy depend on severity of illness and delay to treatment. Three quarters of patients with DCS have pain only, and with prompt recompression, they obtain complete relief of symptoms after a single treatment. Patients with more severe DCS, particularly that involving the spinal cord or a prolonged delay between symptom onset and recompression, are more likely to have incomplete resolution of signs and symptoms. Such victims may require prolonged or repetitive treatments. Some patients with spinal cord DCS continue to show benefit from repetitive daily recompression tables for several days. In general, treatments are continued until the patient shows no further improvement during the treatment period. Alternatively, some multiplace facilities have the capacity to perform prolonged "saturation" treatments during which the patient remains at pressure for several days. During such treatments the patient continues to receive intermittent periods of O₂ breathing. Saturation treatments are expensive and logistically difficult for both the patient and medical personnel. However, they occasionally result in rapid, dramatic clinical responses in victims with serious neurologic injuries.

Adjunctive treatment for serious DCS is relatively limited. Immediate management includes high-flow supplemental oxygen (e.g., by face mask). Relief of symptoms of milder forms of DCS with oxygen alone is not uncommon; however, surface O₂ is not a substitute for recompression therapy. Aggressive oral or IV hydration is important in the first 24 to 48 hours. IV lidocaine, 2 mg/kg bolus followed by 1 to 2 mg/hr for 12 to 24 hours, has been recommended for treatment of spinal cord DCS. Lidocaine is relatively safe and easy to administer, but its benefit has not been proven in a controlled trial. The use of large doses of corticosteroids is also unproven and has produced variable results in experimental animal models of DCS. Therefore routine use of corticosteroids is not

recommended for treatment of serious DCS.

The probability of complete relief of symptoms and return of function after treatment in patients with neurologic DCS is difficult to predict. In general, immediate improvement is expected during the first recompression table unless the delay to treatment has been many hours. Some patients will suffer relapse of symptoms during decompression from the treatment table or between repetitive treatments; however, such recurrences generally respond to additional recompression treatments. A small number of patients are left with long-term neurologic deficits, including leg weakness, sensory changes, and bowel or bladder dysfunction. These deficits may either be permanent or improve gradually over 6 to 12 months.

Arterial Gas Embolism

Another mechanism by which gas may be introduced into the vasculature is rupture of a gas-containing space (e.g., the air spaces of the lungs) into a blood vessel (see [Chapter 57](#)). In compressed gas divers this can be caused by rapid ascent from depth, and in aviators, by explosive aircraft decompression. In compressed gas diving, gas embolism may occur with ascent from less than 1 m of water in the presence of breath-holding or an obstructive airway lesion. The rapid expansion of gas may cause pulmonary overdistension and disruption of the alveolar capillary membrane, allowing gas to enter the pulmonary veins and traverse the left heart to the systemic circulation.

AGE may occur under circumstances in which the rate and magnitude of ascent are insufficient to release enough gas to bubble out of physical solution to cause DCS. AGE, however, may coexist with DCS in divers undergoing rapid uncontrolled ascents, such as in the condition sometimes known as "blow-up." Under this circumstance the amount of gas released into the circulation can be massive, resulting in loss of consciousness, seizures, focal neurologic deficits, cardiac ischemia, and arrhythmias. AGE is a true medical emergency and requires immediate recompression to obtain clinical recovery. Delays to recompression of more than 1 to 2 hours are associated with a poor clinical outcome, including permanent neurologic impairment and death.

The treatment of AGE is similar to that of DCS. Recompression on U.S. Navy Table 6, Table 6A, or equivalent tables is usually recommended. Deeper recompression tables with nitrox treatment gases are preferred by some authors but have not been shown to provide better treatment outcomes than shallower treatment tables.

The Divers Alert Network (DAN) offers a free consultative service in triage and treatment of diving accidents worldwide. In the United States this service is available 24 hours a day, 7 days a week by calling (919) 684-8111 and asking for the on-call DAN team member.

Carbon Monoxide Poisoning^[8]

Exposure to carbon monoxide (CO) gas is the most frequent cause of accidental poisoning in the United States and accounts for approximately 1000 deaths per year.

CO is a toxic by-product of incomplete combustion of

1415

hydrocarbons, and CO exposure occurs primarily from inhalation of fumes from faulty gas furnaces, smoke from fires, and exhaust from internal combustion engines. CO poisoning has been reported in recreational boaters and campers who use internal combustion engines and fossil fuel heaters in enclosed spaces.

Tissue damage caused by CO has been viewed primarily as a hypoxic stress (CO hypoxia) caused by the formation of carboxyhemoglobin (COHb). CO binds to hemoglobin with an affinity of more than 200 times that of oxygen. This tight binding of CO to hemoglobin prevents hemoglobin from binding oxygen and increases the affinity of oxygen for remaining unoccupied heme sites. The result of this interaction is to shift the oxygen dissociation curve (ODC) to the left, leading to greater difficulty unloading oxygen to the tissues at any P_{O_2} . The decrease in O_2 content and leftward shift of the ODC produced by COHb leads to tissue hypoxia and its untoward consequences. These consequences are most pronounced in organs that require a continuous supply of oxygen, such as the brain and heart. In addition, tissue hypoxia facilitates movement of CO into cells, where it has deleterious effects. These include binding to critical heme proteins (e.g., myoglobin, cytochrome oxidase), generation of oxidative stress, and interference with normal cell signaling processes.

Standard treatment for CO poisoning is administration of high concentrations of inspired oxygen. Oxygen hastens dissociation of CO from hemoglobin and its removal from tissue stores. This process is greatly accelerated by HBO ([Figure 59-6](#)). In addition, HBO but not normobaric oxygen can ameliorate certain pathologic processes in the CNS associated with CO poisoning, such as delayed neurologic syndrome. The delayed syndrome occurs in 10% to 30% of persons with severe CO poisoning and is characterized by deterioration in

Figure 59-6 The effects of oxygen on the dissociation of CO from carboxyhemoglobin (COHb). Oxygen breathing at 1.0 atm decreases the half-life of COHb to 60 minutes from approximately 300 minutes in air. HBO at 2.5 atm reduces the half-life to 30 minutes, allowing most of the COHb to be removed from the body within 90 minutes.

cognitive and/or motor function, beginning a few days to several weeks after the initial event.

HBOT is usually recommended for victims of poisoning with COHb levels of 25% and greater, loss of consciousness, or any evidence of cardiac or neuropsychiatric

disturbances regardless of COHb level. The COHb level serves primarily as an indicator of significant poisoning, but it correlates poorly with the extent of neurologic impairment.

Patients who receive HBOT within 2 to 6 hours of CO poisoning usually show return of normal cognitive function after a single 90-minute treatment at 2.4 to 3 atm. These victims also have a reduced risk of developing the delayed neurologic syndrome after a single HBOT treatment. The response to HBOT is less certain and recovery is less predictable when treatment is delayed more than 6 hours or when CO exposure has been particularly long or intense. Dramatic clinical responses should not be expected when treating comatose or severely poisoned patients after delays of more than 6 to 12 hours, although anecdotal reports have indicated significant cognitive improvement of severely poisoned patients who receive HBOT after delays of 24 hours or more.

Clostridial and Other Necrotizing Soft Tissue Infections ^[3]

Necrotizing soft tissue infections are acute, invasive, and potentially fatal bacterial infections of the subcutaneous tissues, fascia, and muscle. They are usually distinguished on the basis of microbiologic etiology and anatomic location and often involve anaerobic bacteria (e.g., clostridial myonecrosis, myositis). Common organisms include *Clostridium perfringens* (gas gangrene), group B streptococci, and *Escherichia coli*. Very often, infections of soft tissue occur that involve one or more aerobic and anaerobic bacteria. Such mixed infections appear in a variety of clinical settings, particularly after trauma, in surgical wounds, or in the vicinity of a foreign body. The patient is often compromised in some way, for example, with diabetes, malignancy, or vasculopathy.

HBOT for gas gangrene or other necrotizing soft tissue infections is adjunctive to surgical debridement and antibiotics. However, it is effective in blocking α -toxin production by clostridial species and inhibiting the growth of anaerobic bacteria. HBO may be limb saving and tissue sparing when used early in the course of these infections. In general, three treatments at 2.5 to 3 atm are recommended in the first 24 hours, and 5 to 10 total treatments over 3 to 5 days for maximum benefit.

Selected Problem Wounds

The adjunctive use of HBO in the treatment of wounds that fail to respond to routine medical and surgical

treatment has had substantial success, particularly in tissues with compromised blood flow and oxygen supply.^[3] Such wounds are usually hypoxic and have tissue oxygen tensions of only a few mm Hg. This hypoxia interferes with collagen deposition, angiogenesis, and immune function necessary for proper wound healing. Restoration of tissue P_{O_2} into the normal range with HBO accelerates healing in these problem wounds. HBOT has been particularly useful in treating diabetic ulcers, where controlled

trials have shown more rapid and complete healing when adjunctive HBOT is used. In general, however, these wounds are slow to heal and may require 40 to 60 treatments.

One type of wound of special interest is that caused by the bite of the brown recluse spider (*Loxosceles reclusa*). This spider releases a venom that can cause severe dermatonecrosis and a painful ulcer that enlarges progressively over 7 to 14 days. These ulcers have been reported to respond to HBOT at 2 to 3 atm when administered early in the course of the injury. A strong scientific rationale for HBOT is lacking for treatment of brown recluse spider bites in normal individuals.^[5] In addition, clinical reporting on HBOT for spider bites is anecdotal and uncontrolled.

Delayed or Late Radiation Injury of Soft Tissue and Bone^[4]

Delayed radiation injury is a long-term complication of radiation therapy, usually involving soft tissues and bone. It generally develops after a latent period of 6 or more months and is characterized by obliterative endarteritis, fibrosis, and tissue hypoxia. HBOT has been utilized prophylactically before oral surgery in a radiated tissue field and to treat delayed radiation tissue injury. In patients who have received radiation doses of 4500 Gy or greater, HBOT has been shown to be cost effective when used before oral surgery to prevent soft tissue breakdown and osteoradionecrosis of the mandible. It is also effective in combination with surgery for treatment of established osteoradionecrosis. HBOT also has been used successfully to treat soft tissue radionecrosis of the head and neck, larynx, chest wall, pelvis, bladder, and bowel. HBO enhances neovascularization in irradiated tissues, thereby improving tissue oxygen tension and tissue viability.

OXYGEN TOXICITY

Clinical applications of HBOT are limited primarily by the toxic effects of oxygen.^[1] Oxygen toxicity is related to the inspired oxygen concentration and duration of exposure. If exposure is sufficiently intense, molecular O_2 is eventually toxic to all living cells. Some tissues (e.g., lungs, premature retina) are susceptible to oxygen toxicity at partial pressures of O_2 in the normobaric range, whereas others (e.g., brain) require exposure to oxygen under hyperbaric conditions. Despite its potential for toxicity, oxygen is the most widely used therapeutic gas, and its safe use at high partial pressures, including those in the hyperbaric range, requires familiarity with its toxicity.

Mechanisms of Oxygen Toxicity

The susceptibility of any tissue to oxygen toxicity depends on its oxygen supply, metabolic activities, biochemical makeup, and antioxidant defenses. Each tissue therefore has a unique dose-response curve that describes the relationship between O_2 concentration and the duration of exposure necessary to produce toxicity. In general, these relationships can be described by a family of rectangular hyperbolas. Examples of such curves for pulmonary and CNS oxygen toxicity are illustrated in [Figure 59-7](#). The limit, or asymptote of the curve, for the lung occurs at approximately 0.5 atm, whereas that for the brain is reached at approximately 1.4 atm.

Tissue injury from oxygen is mediated by reactive oxygen species (ROS) generated by elevated P_{O_2} . These ROS include superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), and hydroxyl radical ($OH\cdot$). ROS are produced by both intracellular and extracellular chemical reactions involving single electron transfers to molecular oxygen or its metabolites. The sites and reactions that produce ROS in the cell involve many intracellular structures, including mitochondria, peroxisomes, endoplasmic reticulum, and nuclear and plasma membranes. These reactions usually depend on oxygen concentration; they proceed more rapidly as P_{O_2} is raised. As P_{O_2} increases, ROS production may overwhelm endogenous antioxidant defenses, resulting in lipid peroxidation, protein oxidation, sulfhydryl depletion, and

Figure 59-7 Hyperbolic relationship between oxygen concentration and time in tissue oxygen toxicity. Typical pressure-time curves for the CNS and lung are shown for comparison. The

threshold for CNS toxicity is approximately 1.4 atm and for pulmonary toxicity is approximately 0.5 atm.

1417

oxidation of nucleic acids. In addition, many extracellular sources of ROS and cellular inflammatory responses amplify oxygen toxicity. Most notably, the oxidative damage produced by inflammatory cells, such as neutrophils and macrophages, contributes to later phases of pulmonary oxygen toxicity.

Certain physiologic factors can amplify O₂ toxicity, particularly for manifestations involving the CNS. In diving, these factors include immersion, exercise, and elevated P_{CO₂}. In clinical settings, fever, thyrotoxicosis, adrenal stress, hypercapnia, and acute cerebral injury can exacerbate CNS O₂ toxicity. In addition, certain drugs are associated with an increased risk of CNS O₂ toxicity. These include catecholamines, such as dopamine and norepinephrine.

Clinical Manifestations of Oxygen Toxicity

The clinical manifestations of oxygen toxicity are diverse and difficult to predict. Signs and symptoms of O₂ toxicity related to the lungs, CNS, and eye are well described (see below). Hemolysis has been reported rarely, primarily in vitamin E-deficient patients. In addition, experimental studies of hyperoxia have reported evidence of cellular toxicity to cardiac, renal, and hepatic tissues. In clinical practice, however, HBO causes toxicity primarily to the lungs and CNS.

Pulmonary Oxygen Toxicity.

Clinical symptoms of pulmonary oxygen toxicity usually begin after 12 to 18 hours of continuous exposure to O₂ at 1 atm and within 3 to 6 hours of exposure to 2 atm. The initial symptoms are mild substernal irritation and dry cough that become more intense with continued exposure. The substernal irritation becomes painful and exacerbated by inspiration. Changes in mechanical airway function occur relatively early; these are characterized primarily by airflow obstruction. These airway changes are followed by parenchymal injury, leading to progressive impairment of pulmonary gas exchange. This is characterized by increased shunt fraction, ventilation-perfusion mismatch, and lung edema, which cause progressive hypoxemia.

CNS Oxygen Toxicity.

The symptoms of CNS O₂ toxicity are nonspecific and unpredictable. They only occur during O₂ exposures of 1.4 atm or greater and may include irritability, tinnitus, dizziness, tunnel vision, nausea, vomiting, and seizures. Oxygen seizures may occur without warning and are not distinguishable from other types of grand mal seizures. Oxygen seizures are self-limited and usually respond immediately to discontinuing oxygen. They

have not been associated with long-term neurologic sequelae. Because O₂ seizures are rare and self-limited, anticonvulsants are not generally recommended for prevention of seizures during HBOT.

OXYGEN TOLERANCE

Although high concentrations of oxygen produce conditions that can damage cells, most cells and tissues contain adequate antioxidant defenses to deal with the short-term effects of HBOT.^[1] These defenses, including antioxidant enzymes such as catalase and superoxide dismutase and low-molecular-weight scavengers such as glutathione and vitamin E, limit the damaging effects of ROS production at elevated P_{O_2} . Although most HBOT treatment tables and schedules are designed to avoid O_2 toxicity, it is also possible to improve O_2 tolerance, thereby decreasing the risk of toxicity. For instance, vitamin E supplements have been used for many years in Europe as an adjunctive therapy to lessen free radical damage during HBOT. In the typical clinical setting, however, there is significant variability in O_2 tolerance among individuals, and for any individual, variability in tolerance to repetitive exposures to the same HBO profile. The most useful proven way to extend O_2 tolerance is to introduce brief periods of air breathing (air breaks) during hyperbaric oxygen treatments. This is usually accomplished by interspersing 5-minute air breaks between each 20- to 30-minute O_2 breathing period for treatment pressures in excess of 2 atm and durations in excess of 2 hours.

Chapter 60 - Injuries from Nonvenomous Aquatic Animals

Paul S. Auerbach
Bruce W. Halstead

The expanses of ocean and freshwater that cover the earth are the greatest wilderness. Seventy-one percent of the earth's surface is composed of ocean, the volume of which exceeds 325 million cubic miles. Within the undersea realm exists four fifths of all living organisms.

The opportunity for direct encounters with aquatic organisms is constantly increasing because of recreational, industrial, scientific, and military oceanic and riverine activities. The underwater recovery of historical artifacts and treasures will accelerate in the new millennium. As fishermen harvest their catches, they handle animals that bite and sting in self-defense.

Nearly 80% of the world's population resides in coastal regions. It is estimated that 127 million U.S. citizens will live along the coasts by the year 2010. A significant proportion of this population will be directly involved as entrants into the aquatic world. Millions of sport scuba enthusiasts will venture into the undersea realm in the next decade. Therefore it is imperative that clinicians be familiar with hazards unique to the aquatic environment.

Although noxious marine organisms are concentrated predominantly in warm temperate and tropical seas, particularly in the Indo-Pacific region, hazardous animals may be found as far north as 50° latitude. Increasing numbers of saltwater aquaria in private homes and public settings, intercontinental seafood shipping, and accessibility of air travel for sport divers create additional risks.

Like the rainforest, the ocean depths have the potential to reveal virtually limitless active pharmaceutical agents. For example, genetically engineered reproduction of the adhesive protein of the marine mussel *Mytilus edulis* has created a tissue adhesive agent that may one day prove superior to cyanoacrylic compounds. Toxins isolated from

ascidians (tunicates or sea squirts) include cyclic peptides, some of which (esteinascidin 743, aplidine) have undergone evaluation for cancer chemotherapy; others (e.g., thiocoralina and kahalide F) may follow. Investigative techniques continue to improve. In pursuit of anatomic information that can elucidate the biology and ecology of fish, evolution, cellular physiology, and aquatic models of human disease, nuclear radiologists have performed in vivo nuclear magnetic resonance imaging (MRI) and spectroscopy of anesthetized (tricaine methsulfonate [MS222]) aquatic organisms.^[14]

Despite the wondrous nature of the deep, jeopardy exists. The ubiquity of hazardous creatures and their propensity to appear at inopportune times make it imperative to be aware of them, to respect their territorial rights, and to avoid needless unpleasant contact with them.

DIVISIONS AND DEFINITIONS

Dangerous aquatic animals are divided into four groups: (1) those that bite, rip, puncture, or shock without envenomation; (2) those that sting (envenom), discussed in [Chapter 61](#) and [Chapter 62](#) ; (3) those that are poisonous on ingestion (see [Chapter 54](#)); and (4) those that induce allergies (see [Chapter 55](#)). Aquatic skin disorders are discussed in [Chapter 63](#) .

IN DEFENSE OF THE FISH

A word must be written in defense of the fish. As in all nature (except for humans), indiscriminate aggression is rarely involved when injuries are inflicted by aquatic animals. Most injuries result from gestures of warning or self-defense; with the exception of some sharks, few aquatic creatures attack humans without provocation. Attacks are made in defense of young, in territorial dispute, or to procure food. It is hoped that better understanding will foster caution when dealing with potentially injurious aquatic creatures.

GENERAL PRINCIPLES OF FIRST AID

The physician must adhere to fundamental principles of medical rescue. Although many injuries and envenomations have unique clinical presentations, the cornerstone of therapy is immediate attention to the airway, respiration, and circulation. Along with specific interventions directed against a particular venom or poison, the rescuer must simultaneously be certain that the victim maintains a patent airway, breathes spontaneously or with assistance, and is supported by an adequate blood pressure. Because marine attacks and envenomations may affect a scuba diver, the rescuer should anticipate near drowning (see [Chapter 56](#)), immersion hypothermia (see [Chapter 8](#)), and decompression sickness or arterial air embolism (see [Chapter 57](#)). Any victim rescued from the ocean should be thoroughly

1419

examined for external signs of a bite, puncture, or sting.

WOUND MANAGEMENT

Whether the injury is a bite, abrasion, or puncture, meticulous attention to basic wound management is necessary to minimize posttraumatic infection.

Wound Irrigation

All wounds acquired in the natural aquatic environment should be vigorously irrigated with sterile diluent, preferably a normal saline (0.9% sodium chloride) solution. Seawater is not a favorable irrigant because it carries a hypothetical infection risk. Sterile water or hypotonic saline is acceptable. Tap water (preferably disinfected) appears to be a suitable irrigant and should be used when the alternative is delay to irrigation.^[3] Irrigation should be performed before and after debridement to maximize the benefits. A 19-gauge needle or 18-gauge plastic intravenous (IV) catheter attached to a syringe that delivers a pressure of 10 to 20 psi will dislodge most bacteria without forcing irrigation fluid into tissue along the wound edges or deeper along dissecting tissue planes. Convenient ring-handle syringes with blunt irrigation tips and IV tubing that connects to standard IV bags are available. At least 100 to 250 ml of irrigant should be flushed through each wound. If a laceration is from a stingray, proteinaceous (and possibly) heat-labile venom may be present in the wound. In such a case the irrigant should be warmed to 45° C (113° F).^[6]

An antiseptic may be added to the irrigant if the wound appears to be highly contaminated. Povidoneiodine solution in a concentration of 1% to 5% may be used with a contact time of 1 to 5 minutes.^[63] ^[90] When antiseptic irrigation is completed, the wound should be thoroughly irrigated with normal saline or tap water to minimize tissue toxicity. Antiseptics that are particularly harmful to tissues include full-strength hydrogen peroxide, povidone-iodine scrub solution, hexachlorophene detergent, and silver nitrate.

Scrubbing should be used to remove debris that cannot be irrigated from the wound. Sharp surgical debridement is preferable to sponge scrubbing, which may increase infection rates, particularly when applied with harsh antiseptic solutions. Poloxamer 188 (Pluronic F-68) is a nontoxic nonionic surfactant skin wound cleanser that may be used to irrigate or scrub wounds. It does not offer any significant advantage over traditional sterile saline irrigation.

Wound Debridement

Debridement is more effective than irrigation at removing bacteria and debris. Crushed or devitalized tissue should be removed with sharp dissection to provide clean wound edges and encourage brisk healing with minimal infection risk. The limitations are those

imposed by anatomy, specifically skin tautness or the presence of vital structures. Anesthesia of wound edges may be attained by regional nerve block or local infiltration with lidocaine, which do not damage local tissue defenses. A topical anesthetic mixture of tetracaine, epinephrine, and cocaine may be less desirable because of the vasoconstrictive effect of epinephrine and theoretical infection-potentiating effects. Definitive wound exploration, debridement, and repair should be undertaken in the most appropriate sterile environment. It is inappropriate to explore complex wounds in the emergency department. Whenever necessary, operating loupes should be used to inspect the wound for residual foreign material, such as sand, seaweed, teeth, spine fragments, or integumentary sheath shards. Standard radiographs, static soft tissue techniques, MRI, or fluoroscopy may be used preoperatively or perioperatively to localize spines or teeth.

Wound Closure

The decision to close a wound weighs the cosmetic result against the risk of infection. The incidence of infection is high in wounds acquired in natural bodies of water because such wounds may be contaminated with venom, potentially virulent microorganisms, or both; because early adequate irrigation and debridement are often unavailable; and because definitive care is often delayed. Tight wound closure restricts drainage and promotes bacterial proliferation. Wounds at high risk in this regard include those on the hands, wrists, or feet; punctures and crush injuries; wounds into areas of fat with poor vascularity; and wounds to victims who are immunosuppressed. Whenever possible, the use of sutures to close dead space in contaminated wounds should be avoided because the absorbable sutures act as foreign bodies.

Prophylaxis against Tetanus

Any wound that disrupts the skin can become contaminated with *Clostridium tetani*. Anaerobic bacteria, predominantly of the genus *Clostridium*, have been isolated in shark tissue and as part of the oral flora of alligators and crocodiles. Proper immunization with tetanus toxoid virtually eliminates the risk of disease. However, although it was previously accepted that the protective level of toxin-neutralizing antibody is 0.01 antitoxin unit/ml, it appears that clinical tetanus can develop despite an antibody level many times that amount. Therefore it is imperative to provide an early and adequate booster injection. If the victim is over 50 years of age, is from an underdeveloped country, or cannot provide a definite history of tetanus immunization, it is more likely that circulating toxin-neutralizing antibody will be suboptimal. Prophylaxis should be provided according to the scheme in [Table 18-3](#).

BACTERIOLOGY OF THE AQUATIC ENVIRONMENT

Wounds acquired in the aquatic environment are soaked in natural source water and sometimes contaminated with sediment. Penetration of the skin by the spines or teeth of animals, the razor edges of coral or shellfish, or the blades of a boat propeller may inoculate pathogenic organisms into a wound. Sports activities, such as surfing, snorkeling, and diving, lead to ubiquitous abrasions and minor lacerations that heal slowly and with marked soft tissue inflammation. Wounds acquired in the aquatic environment tend to become infected and may be refractory to standard antimicrobial therapy. Not infrequently, indolent or extensive soft tissue infections develop in the normal or immunocompromised host.^{[10] [68]} A clinician faced with a serious infection after an aquatic injury frequently needs to administer antibiotics to a patient before definitive laboratory identification of pathogenic organisms.

Marine Bacteriology

Marine Environment.

Ocean water provides a saline milieu for microbes. The salt dissolved in ocean water (3.2% to 3.5%) is 78% sodium chloride (sodium 10.752 g/kg; chlorine 19.345 g/kg). Other constituents include sulfate (2.791 g/kg), magnesium (1.295 g/kg), potassium (0.39 g/kg), bicarbonate (0.145 g/kg), bromine (0.066 g/kg), boric acid (0.027 g/kg), strontium (0.013 g/kg), and fluorine (0.0013 g/kg). The temperature of the surface waters varies with latitude, currents, and season. Tropical waters are warmer and maintain a more constant temperature than temperate and subtropical waters, which are subject to substantial meteorologic variation. Shallow and turbulent coastal waters are generally richer in nutrients than the open ocean, which is reflected in the diversity of life that can be identified in the intertidal zone. Although the greatest number and diversity of bacteria are found near the ocean surface, diverse bacteria and fungi are found in marine silts, sediments, and sand. In ocean waters having marked differences in density, the greatest concentration of bacteria is noted at the thermocline, where changes in both temperature and salinity are usually found.^[73] This effect is lost in active coastal waters, where the constant admixture creates an even distribution of sediments, microbes, salinity, and temperature. Microbes are most abundant in areas that have the greatest numbers of higher life-forms. Marine bacteria are generally halophilic, heterotrophic, motile, and gram-negative rod forms. Growth requirements vary from species to species with respect to use of organic carbon and nitrogen sources, requirements for various amino acids, vitamins and cofactors, sodium, potassium, magnesium, phosphate, sulphate, chloride, and calcium. Most marine

bacteria are facultative anaerobes, which can thrive in oxygen-rich environments. Few are obligatory aerobes or anaerobes. Some marine bacteria are highly proteolytic, and the proportion of proteolytic bacteria seems to be greater in the oceans than on land or in freshwater habitats.^[73]

Diversity of Organisms.

Unique conditions of nutrient and inorganic mineral supply, temperature, and pressure have allowed the evolution of unique, highly adapted marine microbes.^[99]^[100] In addition, numerous other bacteria, microalgae, protozoa, fungi, yeasts, and viruses have been identified in or cultured from seawater, marine sediments, marine life, and marine-acquired or marine-contaminated infected wounds or body fluids of septic victims. In their natural environment the bacteria presumably serve to scavenge and transform organic matter in the intricate cycles of the food and growth chains. Some of these bacteria are listed in [Box 60-1](#) . Enteric pathogenic bacteria have been isolated from sharks.^[32] A shark attack victim in South Africa who sustained serious injuries to his lower

extremities was reported to have developed a fulminant infection attributed to *Bacillus cereus* shown to be sensitive to fluoroquinolones, amikacin, clindamycin, vancomycin, and tetracyclines and resistant to penicillin and cephalosporins (including third generation). In another report, one shark (presumed bronze whaler) attack victim in Australia grew both *Vibrio parahaemolyticus* and *Aeromonas caviae* from his wounds, whereas another grew *Vibrio alginolyticus* and *Aeromonas hydrophila* from his wound.^[74]

For practical purposes, most marine isolates are heterotrophic (require exogenous carbon and nitrogen-containing organic supplements) and motile gram-negative rods. Previous opinions that enteric pathogens (associated with the intestines of warm-blooded animals) deposited into marine environments ultimately succumbed to sedimentation, predation, parasitism, sunlight, temperature, osmotic stress, toxic chemicals, or high salt concentration may be untrue.^[31] Pathogens may accumulate in surface water in association with lipoidal particulates, from which they are rapidly dispersed toward shore by wave and wind activity. In addition, dredging, storms, upwellings, and other benthic disturbances may churn enteric organisms into the path of wastewater nutrients.

Wound Infections Caused by *Vibrio* Species.

Vibrio organisms can cause gastroenteric disease (gastroenteric *Vibrio* infections are discussed in [Chapter 54](#)) and soft tissue infections, particularly in immunocompromised hosts. Extraintestinal infections may be associated with bacteremia and death. *Vibrio* species are the most potentially virulent halophilic organisms that flourish in the marine environment. The teeth of a great white shark have been swabbed and yielded *V. alginolyticus*, *V. fluvialis*, and *V. parahaemolyticus*.^[16] Mako shark tooth culture has yielded *V. damsela*, *V. furnissii*, and *V. splendidus* I.^[4] *V. parahaemolyticus* has also been identified in freshwater habitats.^[7] Water that is brackish (salinity of 15 to 25 parts per

thousand) allows the growth of *Vibrio* species if appropriate nutrients are present; *V. vulnificus* infection has been documented after exposure to waters with salinities of 2 and 4 ppt. The optimal season for disease appears to be summer, when water temperatures encourage bacterial proliferation. In most studies reported, infections seem to cluster during the summer months; this may be related to increased numbers of people at the seashore. This has been corroborated to some degree by the observation that *V. parahaemolyticus* cultured from marine mammals was recovered only in the warmer months of the year in the Northeast or in animals from subtropical regions. Sharks appear to develop some immunity to autochthonous *Vibrio* species, as suggested by the detection of a binding protein similar to the immunoglobulin M (IgM) subclass of immunoglobulin. Allochthonous (for the shark) *Vibrio* species, such as *V. carchariae*, may be the agents of elasmobranch disease when the animal is under stress.

Vibrio species are halophilic, gram-negative rods that are facultative anaerobes capable of using D-glucose as their sole or principal source of carbon and energy.^[22] They are part of the normal flora of coastal waters not only in the United States but also in many exotic locations frequented by recreational and industrial divers and seafarers. *Vibrios* are mesophilic organisms and grow best at temperatures of 24° to 40° C (75.2° to 104° F), with essentially no growth below 8° to 10° C (46.4° to 50° F). Other marine bacteria are facultative psychrophiles, barophiles, or both. *Vibrio* species seem to require less sodium for maximal growth than do other more fastidious marine organisms, a factor that allows explosive reproduction in the 0.9% saline environment of the human body. At least 11 of the 34 recognized *Vibrio* species have been associated with human disease.^[22] Wound infections have been documented to yield *V. cholerae* 0 group 1 and non-01, *V. parahaemolyticus*, *V. vulnificus*, *V. alginolyticus*, and *V. damsela*. Septicemia, with or without an obvious source, has been attributed to infections with *V. cholerae* non-01, *V. parahaemolyticus*, *V. alginolyticus*, *V. vulnificus*, and *V. metschnikovii*.

VIBRIO PARAHAEMOLYTICUS.

Vibrio parahaemolyticus is a halophilic gram-negative rod. The organisms are found in waters along the entire coastline of the United States. Generally the incidence of clinical disease is greatest in the warm summer months when the organism is commonly found in zooplankton. *V. parahaemolyticus* adsorbs onto chitin and to minute crustacean copepods that feed on sediment. It has been postulated that unusual warm coastal currents (such as El Niño) may contribute to increased proliferation of *Vibrio* species. The optimal growth temperature of *V. parahaemolyticus* is 35° to 37° C (95° to 98.6° F); under ideal conditions the generation time has been estimated at less than 10 minutes, with explosive population growth from 10 to 10⁶ organisms in 3 to 4 hours.

Extraintestinal wound infections are most common in persons who suffer chronic liver disease or immunosuppression. Although over 95% of *V. parahaemolyticus* strains associated with human illness are positive, the relationship to pathogenicity of the Kanagawa reaction (production of a cell-free hemolysin on high salt-mannitol [Wagatsuma] agar), caused by a heat-stable direct hemolysin, is not yet clear. Furthermore, most marine strains are not Kanagawa positive. Some primary soft tissue

infections previously attributed to *V. parahaemolyticus* may theoretically be attributed to misidentified *V. vulnificus*. Panophthalmitis requiring enucleation occurred in a man who suffered a corneal laceration.

VIBRIO VULNIFICUS.

Vibrio vulnificus (formerly known as a "lactose [fermenting]-positive" vibrio) is a halophilic gram-negative bacillus. *V. vulnificus* ("wounding") is found in virtually all U.S. coastal waters and has been reported to cause infection worldwide.^[9] It prefers salinity of 0.7% to 1.6%; although it prefers a habitat of warm (at least 20° C [68° F]) seawater, it can be found in much colder water. It does not appear to be associated with fecal contamination of seawater. It has been shown to exist in Chesapeake Bay with bacterial counts comparable with those reported from the Gulf of Mexico.^[97]

The organism may or may not have an acidic polysaccharide capsule (opaque colony), which confers protection against bactericidal activity of human serum and phagocytosis and thus renders the organism more virulent in animals. At extremely low frequency, some strains can shift between unencapsulated (avirulent; translucent colony) and capsulated (virulent) serotypes. The encapsulated isolates show exquisite (positive) sensitivity to iron. Virulent isolates can use 100% but not 30% saturated (normal for humans) transferrin as an iron source, as well as iron in hemoglobin and hemoglobin-haptoglobin complexes. *V. vulnificus* exhibits enhanced growth and virulence in the presence of increased serum iron concentration and/or saturated transferrin-binding sites.^[4] *V. vulnificus* is classified in two biotypes: biotype 1 (pathogenic for humans) and biotype 2 (pathogenic for fish).^[22]

Infection evolves rapidly after the initiation of symptoms and has been noted most frequently in men over 40 years of age with preexisting hepatic dysfunction, leukopenia, or impaired immunity (malignancy, human immunodeficiency virus [HIV] infection, diabetes, long-term corticosteroids), although it has been reported in young, previously healthy individuals. Preexisting liver disease is a predictor of death, with 50% of such individuals succumbing to the illness in one series.^[36] Persons with high serum iron levels (from chronic cirrhosis, hepatitis, thalassemia major, hemochromatosis, multiple transfusions [such as are given for aplastic anemia]) or achlorhydria (low gastric acid; may be iatrogenically induced with H₂ blockers) may be at greater risk for fulminant bacteremia.^[4] ^[81] ^[88] This has been attributed in part to the protective effect of gastric acid, the iron requirement of the organism, and the effects of liver disease (decreased polymorphonuclear leukocyte and macrophage activity, flawed opsonization, shunting of portal blood around the liver). *V. vulnificus* produces a siderophore ("vulnibactin") and a protease that may enhance pathogenicity.^[4]

The syndrome consists of flulike malaise, fever, vomiting, diarrhea, chills, hypotension, and early skin vesiculation that evolves into necrotizing dermatitis and fasciitis, with vasculitis and myositis ([Figure 60-1](#) and [Figure 60-2](#)).^[98] Hematogenous seeding of

vibrios to secondary cutaneous lesions is probable. Primary wound

Figure 60-1 Ecthyma gangrenosum associated with *Vibrio vulnificus* sepsis. (Courtesy Edward J. Bottone, MD., Dept. of Microbiology, Mt. Sinai Hospital, N.Y.)

Figure 60-2 Torso of a victim with *Vibrio vulnificus* sepsis.

infections (approximately 30% of cases) rapidly show marked edema, with erythema, vesicles, and hemorrhagic or contused-appearing bullae, progressing to necrosis. This may require radical surgical debridement or amputation. Up to 25% of these victims may have sepsis. When this *Vibrio* species is recovered from the blood of a victim with sepsis attributable to a wound infection, the case fatality rate may exceed 30%.^[36] Extracellular elastin-lysing proteases elaborated by the organism, as well as a potent collagenase, probably contribute to the rapid invasion of healthy tissue. *V. vulnificus* also produces a cytotoxin-hemolysin and phospholipases. Cytolysin produced by most pathogenic strains of *V. vulnificus* is extremely toxic to mice when injected IV and results in severe perivascular edema and neutrophil infiltration in lung tissues.^[64] The precise roles of these and other factors (pili, mucinase, chondroitinase, hyaluronidase) in the in vivo pathogenicity of the organism have yet to be determined. Bleeding complications (which may include gastrointestinal hemorrhage and disseminated intravascular coagulation) are common and may be attributed in part to thrombocytopenia. Gastroenteritis is more common (15% to 20%) with the septicemic presentation than with primary wound infection and may exist as an isolated entity (approximately 10% of cases), although it

is debated that illness has been erroneously attributed to the asymptotically carried organism. *Vibrio vulnificus* endometritis has been reported after an episode of intercourse in the water of Galveston Bay, Texas. Other presentations of *Vibrio vulnificus* infections have included meningitis, spontaneous bacterial peritonitis, corneal ulcers, epiglottitis, and infections of the testes, spleen, and heart valves.

The explosive nature of the syndrome can lead to gram-negative sepsis and death, reportedly in up to 50% of cases. The mortality rate may be as high as 90% in victims who become hypotensive within 12 hours of initial examination by a physician. Appropriate antibiotics should be administered as soon as the infection is suspected (see below). In one report, *V. vulnificus* sepsis was treated with antibiotic therapy, debridement of necrotic tissues, and direct hemoperfusion using polymyxin B

immobilized fiber, which serves as an artificial reticuloendothelial system and removes endotoxin from the circulating blood.^[75] For wound infections from all *Vibrio* species, the organism may only be recovered from blood specimens in less than 20% of victims.^[36] In an immunocompetent victim who acquired a *V. vulnificus* hand infection from peeling shrimps, treatment with oral ciprofloxacin was successful. In a series of seven patients treated for primary skin and soft tissue infections secondary to *V. vulnificus*, prompt operative exploration and debridement were correlated with a decrease in the intensive care unit and hospital length of stay, particularly if the surgery occurred within 72 hours from the time of infection.^[35] The authors noted that all patients had necrosis of underlying subcutaneous tissue, while some did not demonstrate skin necrosis.

VIBRIO MIMICUS.

Vibrio mimicus is a motile, nonhalophilic, gram-negative, oxidase-positive rod with a single flagellum. It can be distinguished from *V. cholerae* by its inability to ferment sucrose, inability to metabolize acetylmethyl carbonyl, sensitivity to polymyxin, and negative lipase test. An ear infection may follow exposure to ocean water. Isolates are sensitive to tetracycline. Physicians who collect stool samples for culture to identify suspected *V. mimicus* must alert the laboratory to use appropriate culture media (thiosulfate-citrate-bile salts-sucrose [TCBS] agar).

VIBRIO ALGINOLYTICUS.

Vibrio alginolyticus, found in seawater, has been implicated in soft tissue infections (such as those caused by coral cuts or surfing scrapes), sinusitis, and otitis, particularly after previous ear infections or a tympanic membrane perforation. Although bacteremia has been reported in immunosuppressed patients and patients with burns, *V. alginolyticus* does not generally carry the virulent potential of *V. vulnificus*. Typical symptoms include cellulitis, with seropurulent exudate.

VIBRIO DAMSELA.

Vibrio damsela, formerly enteric group EF-5 and so named because it is pathogenic for the damselfish, causes wound infections similar to those attributed to other vibrios. Rapidly progressive infection leading to muscle necrosis or to sepsis and death may transpire in an immunosuppressed victim. This may be related to an extracellular cytolytic or other unidentified enzymes. It has been proposed that *V. damsela* be placed into the new genus *Listonella*.

VIBRIO CHOLERAЕ.

A case of necrotizing fasciitis and septic shock caused by *V. cholerae* non-O1 (not agglutinated in cholera polyvalent O1 antiserum) acquired in San Diego, California, has been described.^[92] The victim suffered from preexisting diabetes mellitus complicated by chronic plantar ulceration of the affected limb.

Growth in Culture.

Although plating on standard clinical laboratory media may detect only 0.1% to 1% of the total number of microorganisms found in seawater or marine sediment, most marine bacteria that are pathogenic to humans can be readily recovered on standard media. Although pathogenic *Vibrio* species can grow on conventional blood agar media, other marine bacteria may require saline-supplemented media and incubation at 25° C (77° F) instead of the standard 35° to 37° C (95° to 98.6° F). In culture, marine bacteria may grow at a slower rate than terrestrial bacteria, which delays identification. Pleomorphism in culture may be attributed to adaptation to small concentrations of nutrients in seawater. Most organisms require sodium, potassium, magnesium, phosphate, and sulfate for growth; a few require calcium or chloride.

TCBS agar is selective and recommended for the detection of marine *Vibrio* organisms, although cellobiose-polymyxin B-colistin (CPC) agar may be as good or better.^[42] ^[50] An alternative is Monsur taurocholate-tellurite-gelatin agar. A large clinical laboratory near the ocean might consider the use of TCBS or CPC agar routinely. Pathogenic vibrios generally grow on MacConkey agar. All species except *V. cholerae* and *V. mimicus* require sodium chloride for growth. Enrichment broth (alkaline peptone water with 1% NaCl) is recommended for isolation of vibrios from convalescent and treated patients. Another enrichment broth that may be more effective is 5% peptone, 1% NaCl, and 0.08% cellobiose (PNC) at pH 8.0.^[38] All *Vibrio* species grow in routine blood culture mediums and on nonselective mediums, such as blood agar. A recent comparison of strategies for the detection and recovery of *V. vulnificus* from marine samples of the western Mediterranean coast determined that the best strategy consisted of the combination of culture-based methods (3-hour enrichment in alkaline-saline peptone water at 40° C [104° F], followed by culture on CPC agar) and deoxyribonucleic acid (DNA)-based procedures (specific polymerase

chain reaction [PCR] amplification of the presumptive colonies with primers Dvu 9V and Dvu 45R).^[4]

Key characteristics that aid in the separation of *Vibrio* species from other medically significant bacteria (Enterobacteriaceae, *Pseudomonas*, *Aeromonas*, *Plesiomonas*) are the production of oxidase, fermentative metabolism, requirement of sodium chloride for growth, and susceptibility to the O/129 vibriostatic compound. *Vibrio vulnificus* can be cultured from the blood, wounds (bullae), and stool. The laboratory must be cautioned to use selective culture media with a high salt content (3% NaCl) for prompt identification. Suggestive features include positive fermentation of glucose, positive oxidase test, positive indole test, positive reaction for both lysine and ornithine decarboxylase, positive o-nitrophenyl-β-d-galactopyranoside, and inability to ferment sucrose. A useful identification scheme for pathogenic *Vibrio* species is found in the chapter on *Vibrio* in the most recent edition of the American Society for Microbiology's *Manual of Clinical*

Microbiology.

Because growth of *V. vulnificus* in culture generally requires 48 hours, current research is directed at a more rapid diagnostic test. Direct identification of *V. vulnificus* in clinical specimens by nested PCR has been accomplished utilizing serum specimens and bulla aspirates from septicemic patients.^[49] A nested PCR method for rapid and sensitive detection of *V. vulnificus* in fish, sediments, and water has been developed.^[5]

Mycobacteria must be cultured in media such as Middlebrook 7H10 or 7H11 agar or Lowenstein-Jensen medium; fungi require a medium such as Sabouraud dextrose or brain-heart infusion/Sabhi agar. Antibiotic susceptibility testing can be performed using established procedures, except for the addition of NaCl 2.3% to the Mueller-Hinton broth or agar used for disk diffusion. Certain commercial test kits may not accurately identify marine organisms. In the setting of wound infection or sepsis, the clinician should alert the laboratory that a marine-acquired organism may be present. If a laboratory does not have the time or resources to perform a complete identification, the bacteria may be sent to a reference laboratory. Marine bacteria are kept in the American Type Culture Collection. Because of the diversity of species, complete agreement has not yet been reached on comprehensive taxonomic criteria for identification.

Antibiotic Therapy.

The objectives for the management of infections from marine microorganisms are to recognize the clinical condition, culture the organism, and provide antimicrobial therapy. Management of marine-acquired infections should include therapy against *Vibrio* species. Third-generation cephalosporins (cefoperazone, cefotaxime, or ceftazidime) provide variable coverage in vitro; first- and second-generation products (cefazolin, cephalothin, cephapirin, cefamandole, cefonicid, ceforanide, or cefoxitin) appear to be less effective in vitro. The organism has been reported in some cases to be resistant in vitro to third-generation cephalosporins, mezlocillin, aztreonam, and piperacillin.^[66] A combination of cefotaxime and minocycline seems to be synergistic and extremely effective against *V. vulnificus* in vitro.^[23] Oral cultures taken from two captive moray eels at the John G. Shedd Aquarium in Chicago, Illinois, demonstrated *V. fluvialis*, *V. damsela*, *V. vulnificus*, and *Pseudomonas putrefaciens* sensitive to cefuroxime, ciprofloxacin, tetracycline, and trimethoprim/sulfamethoxazole.^[30] Imipenem/cilastatin is efficacious against gram-negative marine bacteria, as are trimethoprim/sulfamethoxazole and tetracycline. Gentamicin, tobramycin, and chloramphenicol have tested favorably against *P. putrefaciens* and *Vibrio* strains. Nonfermentative bacteria (such as *Alteromonas*, *Pseudomonas*, and *Deleya* species) appear to be sensitive to most antibiotics. In a mouse model, combination therapy with minocycline and cefotaxime was more effective than either drug alone.^[24]

Quantitative wound culture has no advantage before the appearance of a wound infection. Pending a prospective evaluation of prophylactic antibiotics in the management of marine wounds, the following recommendations are based on the indolent nature and malignant potential of soft tissue infections caused by *Vibrio* species:

1. Minor abrasions or lacerations (such as coral cuts or superficial sea urchin puncture wounds) do not require prophylactic antibiotics in the normal host. Persons who are chronically ill (as with diabetes, hemophilia, or thalassemia) or immunologically impaired (as with leukemia or acquired immunodeficiency syndrome [AIDS], or undergoing chemotherapy or prolonged corticosteroid therapy), or who suffer from serious liver disease (such as hepatitis, cirrhosis, or hemochromatosis), particularly those with elevated serum iron levels, should be placed immediately after the injury on a regimen of oral ciprofloxacin, trimethoprim/sulfamethoxazole, or tetracycline because these persons appear to have an increased risk of serious wound infection and bacteremia. Preliminary experience suggests that cefuroxime may be a useful alternative. Penicillin, ampicillin, and erythromycin are not acceptable alternatives.^[58] ^[60] Norfloxacin may be less efficacious against certain vibrios.^[59] ^[70] Other quinolones (ofloxacin, enoxacin, pefloxacin, fleroxacin, lomefloxacin) have not been extensively tested against *Vibrio*; they may be useful alternatives, but this awaits definitive evaluation. The appearance of an infection indicates the need for prompt debridement and antibiotic therapy. If an infection develops, antibiotic coverage should be chosen that will
-

1425

also be efficacious against *Staphylococcus* and *Streptococcus* because these are still the most common perpetrators of infection. In general, the fluoroquinolones, which are particularly effective for treating gram-negative bacillary infections, may become less and less useful against resistant staphylococci.^[87] If *Staphylococcus* is a β -lactamase-producing strain, a semisynthetic penicillin (nafcillin or oxacillin) should be chosen, with a cephalosporin such as cefazolin or cephalothin used if there is a history of delayed-type penicillin allergy. Vancomycin is recommended in the event of methicillin resistance.^[51]

2. Serious injuries from an infection perspective include large lacerations, serious burns, deep puncture wounds, or a retained foreign body. Examples are shark or barracuda bites, stingray spine wounds, deep sea urchin punctures, scorpaenid spine envenomations that enter a joint space, and full-thickness coral cuts. If the victim requires hospitalization and surgery for standard wound management, recommended antibiotics include gentamicin, tobramycin, amikacin, ciprofloxacin, and trimethoprim/sulfamethoxazole. Cefoperazone and cefotaxime may or may not be effective. There is a recommendation in the literature advocating the use of ceftazidime (in combination with tetracycline).^[44] Chloramphenicol is an alternative agent less commonly used because of hematologic side effects. Imipenem/cilastatin is an extremely powerful antibiotic that should be used in a circumstance of sepsis or treatment failure. Patients who simultaneously receive imipenem or ciprofloxacin and theophylline may have an increased tendency to seizures.^[77]
If the victim is managed as an outpatient, the drugs of choice to cover *Vibrio* are ciprofloxacin, trimethoprim/sulfamethoxazole, or tetracycline. Cefuroxime is an alternative. It is a clinical decision whether oral therapy should be preceded by a single intravenous or intramuscular loading dose of a similar or different antibiotic,

- commonly an aminoglycoside.
3. Infected wounds should be cultured for aerobes and anaerobes. Pending culture and sensitivity results, the patient should be managed with antibiotics as described previously. In a person who has been wounded in a marine environment and has rapidly progressive cellulitis or myositis, *Vibrio parahaemolyticus* or *V. vulnificus* infection should be suspected, particularly in the presence of chronic liver disease. If a wound infection is minor and has the appearance of a classic erysipeloid reaction (*Erysipelothrix rhusiopathiae*), penicillin, cephalixin, or ciprofloxacin should be administered (see [Chapter 63](#)).

Freshwater Bacteriology

Diversity of Organisms.

Although it has not been as extensively studied as the marine environment, the natural freshwater environment of ponds, lakes, streams, rivers, lagoons, harbors, estuaries, and artificial bodies of water is probably as hazardous as the ocean from a microbiologic standpoint. Waterskiing accidents, propeller wounds, fishhook punctures, lacerations from broken glass and sharp rocks, fish fin or catfish stings, and crush injuries during white-water expeditions are commonplace. A large number of bacteria have been identified in water, sediments, animals, and wounds. In fringe areas of the ocean that carry brackish water (NaCl content below 3%), marine bacteria, salt-tolerant freshwater bacteria, and brackish-specific bacteria, such as *Agrobacterium sanguineum*, are noted. The combined effects of human and animal traffic and waste disposal increase the risk for coliform contamination. In Great Britain, antibiotic-resistant *Escherichia coli* have been documented in rivers and coastal waters.^[80] Coxsackievirus A16 has been isolated from children stricken ill after bathing in contaminated lake water.^[26] Of particular note is the presence of virulent species, such as *Chromobacterium violaceum*, *Vibrio parahaemolyticus*, and *Aeromonas hydrophila*, associated with serious and indolent wound infections.^[56] ^[91] The last can be cultured from natural bodies of water, as well as from the mouths of domesticated aquarium fish, such as the piranha.^[72] Biologic control agents, such as guppy fish bred in wells to control mosquito proliferation, can carry bacterial pathogens, such as *Pseudomonas*.^[21]

One investigation sampled water, inanimate objects, and animals from freshwater environments in California, Tennessee, and Florida.^[7] Bacteria isolated were predominantly gram-negative and included *Aeromonas hydrophila*, *Flavobacterium breve*, *Pseudomonas* species, *Vibrio parahaemolyticus*, *Serratia* species, *Enterobacter* species, *Plesiomonas shigelloides*, *Bacillus* species, *Acinetobacter calcoaceticus*, and *Alcaligenes denitrificans*.

Wound Infections Caused by *Aeromonas* Species.

Aeromonas hydrophila ("gas producing and water loving") is a gram-negative, facultatively anaerobic, polarly flagellated, non-spore-forming, and motile rod member of the family Vibrionaceae that commonly inhabits soil, freshwater streams, and lakes.^[2] ^[9] *Aeromonas* species are widely distributed and found at wide ranges of temperature and pH. Three species (*A. hydrophila*, *A. sobria*, and *A. caviae*) have been associated with

human disease; there are seven or more distinct genotypes. *A. hydrophila* is pathogenic to amphibians, reptiles, and fish. Soft tissue and gastroenteric human infections occur predominantly during the period from May to November. Virulence factors elaborated by *Aeromonas* species include hemolysin, cytotoxin, enterotoxin, cholera toxin-like factor, and hemagglutinins.^[15] ^[89]

1426

A wound, particularly of the puncture variety, immersed in contaminated water may become cellulitic within 24 hours, with erythema, edema, and a purulent discharge.^[96] The lower extremity is most frequently involved. This usually occurs from stepping on a foreign object or being punctured underwater. The appearance may be indistinguishable from a typical streptococcal cellulitis, with localized pain, lymphangitis, fever, and chills. Untreated or managed with antibiotics to which the organism is not susceptible, this may rarely progress to a severe gas-forming soft tissue reaction, bulla formation, necrotizing myositis, or osteomyelitis. Appearance similar to ecthyma gangrenosum caused by *Pseudomonas aeruginosa* has been reported in *Aeromonas* septicemia.

Fever, hypotension, jaundice, and chills are common manifestations of septicemia.^[43] Additional clinical manifestations include abdominal pain or tenderness, altered consciousness, acute renal failure, and coagulopathy. In a manner analogous to the pathogenicity of virulent *Vibrio* species, the chronically ill or immunocompromised host (chronic liver disease, neoplasm, diabetes, uremia, corticosteroid therapy, extensive burns, etc.) is probably at greater risk of a severe infection and/or complication, such as meningitis, endocarditis, or septicemia. Freshwater aspiration may result in *Aeromonas hydrophila* pneumonitis and bacteremia. Infection has followed the bite of an alligator. A 15-year-old boy suffered *A. hydrophila* wound infection after a bite from his pet piranha. For unknown reasons there is a marked preponderance of male victims. This may represent the phenotypic variation of critical bacterial adhesins. Corneal ulcer caused by *A. sobria* was reported after abrasion by a freshwater reed.^[19]

In the microbiology laboratory, *Aeromonas* species may be identified on the basis of positive oxidase reaction, no growth on TCBS agar, growth on MacConkey agar, and resistance to the vibriostatic compound O/129.^[43]

Gram's stain of the purulent discharge may demonstrate gram-negative bacilli, singly, paired, or in short chains. Given the appropriate clinical setting (after a wound acquired in the freshwater environment), this should not be casually attributed to contamination.^[41] *Aeromonas hydrophila* is generally sensitive to chloramphenicol, aztreonam, gentamicin, amikacin, tobramycin, trimethoprim/sulfamethoxazole, cefotaxime, cefuroxime, moxalactam, imipenem, ceftazidime, ciprofloxacin, and norfloxacin. In one case, culture of a severe wound infection demonstrated the presence of two species, *Aeromonas hydrophila* and *A. sobria*. Notably, the latter was resistant to tetracycline in vitro. Initial therapy for a severe infection that includes an aminoglycoside provides coverage against concomitant *Pseudomonas* or *Serratia* infection. As has been demonstrated with *Vibrio* species, the first-generation cephalosporins, penicillin, ampicillin, and ampicillin/sulbactam are not efficacious, perhaps because of the

production of a β -lactamase by the organism. *Aeromonas* species are capable of producing chromosomally encoded β -lactamases induced by β -lactam antibiotics. This leads to resistance to penicillins, cephalosporins, and monobactams. The β -lactamase inhibitors, such as clavulanate, are not effective against these β -lactamases, so that amoxicillin-clavulanate may not kill *Aeromonas*.^[65] Because of the microbiologic similarity of *Aeromonas* on biochemical testing to members of the Enterobacteriaceae family, such as *Escherichia coli* or *Serratia* species, it is important to alert the laboratory to the clinical setting.

Initial therapy of a severe soft tissue infection related to *Aeromonas* should include aggressive wound debridement to mitigate the potentially invasive nature of the organism. In one case of severe cellulitis unresponsive to debridement, fasciotomy, and antibiotic therapy, treatment with hyperbaric oxygen was felt to contribute to successful infection control.^[53]

Curiously, medicinal leeches can harbor *Aeromonas* in their gut flora; soft tissue infections related to this phenomenon have been reported. The genus *Plesiomonas* also belongs to the family Vibrionaceae; it has been definitively linked with aquarium-associated infection complicated by watery diarrhea and fever.

Infections Caused by a Fish Pathogen, *Streptococcus iniae*.

Streptococcus iniae is a pathogen of fish, noted to cause subcutaneous abscesses in Amazon freshwater dolphins (*Inia geoffrensis*) kept in captivity.^[94] Epizootic fatal meningoencephalitis in fish species caused by streptococci has been observed in outbreaks affecting tilapia, yellowtail, rainbow trout, and coho salmon. Persons who handle these fish are at risk for bacteremic illness, which can be manifest as cellulitis or sepsis. Endocarditis, meningitis, and arthritis have been noted to accompany *S. iniae* infection.

The tilapia (*Oreochromis* species) is also known as St. Peter's fish or Hawaiian sunfish. The surface of this commonly aquacultured fish may be colonized with *S. iniae*. Persons of Asian descent have been identified as prone to infection, probably because they often prepare this fish with the intent to dine. Typically, the victim recalls puncturing the skin of the hand with a fin, bone, or implement of preparation. Cellulitis with lymphangitis and fever is common, without skin necrosis or bulla formation.^[94]

In culture, *S. iniae* shows β -hemolysis. However, it may appear to be a-hemolytic because the narrow zone of β -hemolysis is ringed by more prominent zone of a-hemolysis. Therefore it may be misidentified as a viridans streptococcus and therefore considered a contaminant. A reasonable approach to antibiotic therapy includes penicillin, cefazolin, ceftriaxone, erythromycin, clindamycin, or trimethoprim/sulfamethoxazole. In one series, ciprofloxacin showed slightly less efficacy in vitro.

A General Approach to Antibiotic Therapy.

Management of freshwater-acquired infections should include therapy against *Aeromonas* species. First-generation cephalosporins provide inadequate coverage against growth of freshwater bacteria. Third-generation cephalosporins provide excellent coverage, whereas second-generation products are less effective. Ceftriaxone may not be efficacious against *Aeromonas* species. Ciprofloxacin, imipenem, ceftazidime, gentamicin, and trimethoprim/sulfamethoxazole are superb antibiotics against gram-negative microorganisms. Trimethoprim alone may be inefficacious, as is ampicillin.

Whether to begin antimicrobial therapy before establishment of a wound infection is controversial. Pending a prospective evaluation of prophylactic antibiotics in freshwater-acquired wounds, the following recommendations are based on the potentially serious nature of soft tissue infections caused by *Aeromonas* species:

1. Minor abrasions or lacerations do not require the administration of prophylactic antibiotics in the normal host. Persons who have chronic illness, immunologic impairment, or serious liver disease, particularly those with elevated serum iron levels, should be placed immediately on a regimen of oral ciprofloxacin or norfloxacin (first choice), trimethoprim/sulfamethoxazole (second choice), or doxycycline/tetracycline (third choice—use only in the setting of allergy to the first two choices, since resistance to *Aeromonas* species has been observed) because these persons appear to have an increased risk of serious wound infection and bacteremia. Penicillin, ampicillin, erythromycin, and trimethoprim do not appear to be acceptable alternatives. The appearance of an infection indicates the need for prompt debridement and antibiotic therapy. If an infection develops, antibiotic coverage that will also be efficacious against *Staphylococcus* and *Streptococcus* should be chosen, since these are still probably the most common perpetrators of infection.
2. If the victim requires surgery and hospitalization for wound management, recommended antibiotics include ciprofloxacin, gentamicin, or trimethoprim/sulfamethoxazole. Imipenem/cilastatin is an extremely powerful antibiotic that should be used in a circumstance of sepsis or treatment failure. If the victim is to be managed as an outpatient, the oral drug of choice is trimethoprim/sulfamethoxazole, or tetracycline or doxycycline. It is a clinical decision whether oral therapy should be preceded by a single intravenous or intramuscular loading dose of a similar or different antibiotic, commonly an aminoglycoside.
3. Infected wounds should be cultured. Pending culture and sensitivity results, the patient should be managed with antibiotics as outlined previously. If fever or rapidly progressive cellulitis characterized by bullae and large areas of necrosis develops, *Aeromonas hydrophila* infection should be suspected. Less rapidly progressive *Aeromonas* infections may have the appearance of streptococcal

cellulitis.^[42]

SHARKS

Myth and folklore surround sharks, the most highly feared of all sea creatures. These occasionally savage animals are the subjects of many behavioral investigations, but until more reproducible data are available, a degree of mystery will remain. Shark attacks on humans have always held enormous fascination for scientists, adventurers, and clinicians. H. David Baldrige prepared a special technical report, *Shark Attack Against Man*, for the U.S. Navy Bureau of Medicine and Surgery in 1973. The International Shark Attack File, initiated by Perry W. Gilbert and Leonard P. Schultz in 1958 for the American Institute of Biological Sciences and the Office of Naval Research and formerly maintained at the Mote Marine Laboratory in Sarasota, Florida, is now housed at the University of Florida at Gainesville, where it is maintained by the International Elasmobranch Society and the Florida Museum of Natural History.^[17] It remains an authoritative collection of analyzed data, containing a series of approximately 3000 individual investigations from the mid-1500s to the present. Mote Marine Laboratory (www.mote.org) is an independent, nonprofit marine research institution that operates The Center for Shark Research, focused on behavioral and medicine-related research. The Shark Research Institute (www.njscuba.com) publishes that it maintains a database that "contains more than 2,000 incidents involving divers, surfers, swimmers and fisherman," with a "network of investigators throughout the world that actively investigates attacks." Other records of shark attacks are maintained by the California Department of Fish and Game and the Waikiki Aquarium in Honolulu, Hawaii.

Although dreaded, sharks are among the most graceful and magnificent denizens of the deep. Sharks may be found in oceans, tropical rivers, and lakes. The bull shark *Carcharhinus leucas* is a frequent river inhabitant. Sharks range in size from 10 to 15 cm (*Squaliolus laticaudus*) to over 15 m and more than 18,144 kg (the whale shark *Rhincodon typus*, fortunately a plankton feeder).

The world's shark population is in danger from overfishing. Each year, more than 100 million animals, or 10 million sharks for each human shark-related fatality, are mutilated or slaughtered. This occurs in large part for the heinous practice of finning, in which a shark is captured, its fins are sliced off, and then it is returned

to the water.^[52] The fins are sold for the extraction of putative aphrodisiacs or to make shark-fin soup, which is extremely popular in Asia. Shark flesh is a major food source (commonly the "fish" in "fish and chips"), particularly since, to date, sharks do not appear to carry ciguatera toxin except in the liver. Innumerable animals are ground into

fertilizer. Although at least 7150 tons of sharks were harvested commercially in U.S. coastal waters in 1989, more than 90% of captured sharks were discarded. In addition, vast numbers of sharks are caught in fishing nets as "by-catch" and meet an untimely end. This activity may double the estimated shark kill figures. (The National Marine Fisheries Service estimates that 20 million metric tons of marine wildlife are killed and thrown back into the sea as by-catch.) In Tahiti and other Polynesian locations, sharks are mercilessly killed to acquire their teeth for jewelry manufacture. In 1991 the South African government declared the great white shark a protected species within 200 miles of its coast. The U.S. government has lowered allowable fishing quotas in Atlantic waters. Great white sharks are protected off Australia, the southern coastline of Africa, the Maldives, and parts of the United States. Still, the populations of these and other shark species are declining, and unless there are further interventions, extinctions are likely.

Life and Habits

Sharks have inhabited the oceans for at least 400 million years. They appeared on the planet during the Devonian period, approximately 200 million years before the dinosaurs. Ancestral sharks may have been enormous; *Carcharodon megalodon* probably grew to a length of more than 15 m, with teeth longer than 3.2 cm. This was a predator of astronomic proportions.

Some 32 of the currently known 375 (approximate) species of sharks have been implicated in the 100 to 150 shark attacks upon humans that are estimated to occur annually worldwide, and another 35 to 40 species are considered potentially dangerous. U.S. coastal waters may be the setting for nearly one quarter of the attacks. Between 6 and 10 deaths from shark attacks are reported worldwide each year. The most frequently implicated offenders are the larger animals, such as the great white ([Figure 60-3](#)), bull, tiger (*Galeocerdo cuvieri*), and oceanic whitetip sharks. Sporadic attackers include the gray reef, blue ([Figure 60-4](#)), shortfin mako, dusky, hammerhead ([Figure 60-5](#)), lemon, Ganges River, Galápagos, spinner, sand, nurse, blacktip, blacknose, blue, bronze whaler, and ragged tooth sharks.^[61] Tiger sharks were identified in a cluster of attacks around the Hawaiian Islands in the winter of 1993.

Sharks are carnivorous; many are apex predators. Their danger to humans results from the combination of size, aggression, and dentition. Some sharks, such as the giant whale shark (the largest fish at 50 feet in

Figure 60-3 Great white shark (*Carcharodon carcharias*). The most dangerous of sharks, this animal has been implicated in many attacks on humans. (Photo by Howard Hall.)

Figure 60-4 Blue shark, considered a dangerous species. (Photo by Marty Snyderman.)

length and more than 40,000 pounds), eat plankton and use their teeth as filters (Figure 60-6 (Figure Not Available)). Even small sharks can be powerful and destructive. The white shark is responsible for more attacks than any other species, particularly in the waters of southern Australia, the east coast of South Africa, the middle Atlantic coast of North America, and the American Pacific coast north of Point Conception, California. Attacks by great white sharks off the coast of northern California have led to the designation of a "red (or bloody) triangle" bordered on the north by Point Reyes and Tomales Bay through the Farallon Islands to the west and down south to Año Nuevo and Point Sur facing the Monterey Bay. This is a

1429

Figure 60-5 Hammerhead sharks, schooling off Cocos Island. The positioning of the eyes is reputed to increase the peripheral vision of these apex predators. (Photo by Howard Hall.)

breeding area for elephant seals (*Mirounga angustirostris*) ([Figure 60-7](#)), which yield 200-pound pups, perfect food for the immense predators.

The tiger (*Galeocerdo cuvieri*) (up to 18 feet and 2000 pounds) and bull (*Carcharinus leucas*) sharks are the next most dangerous with regard to attacks on humans. The great hammerhead (*Sphyrna mokarran*) (see [Figure 60-5](#)) has a reputation as a man-eater in equatorial waters. Scattered over its entire undersurface, the hammerhead has ampullae sensitive to electromagnetic fields, which in combination with its highly developed sense of smell may make it a superior predator.

In an analysis of California attacks, Miller and Collier^[57] attributed unprovoked attacks north of San Miguel Island to white sharks, while those south of this area involved members of the families Carcharhinidae (requiem sharks), Sphyrnidae (hammerheads), and possibly Squatinidae (angel sharks).

Sharks are members of the class Chondrichthyes, or

Figure 60-7 The elephant seal, shown here swimming through a kelp bed, is a favorite food for the great white shark. (Photo by Howard Hall.)

cartilaginous fish, which also includes skates, rays, and chimaeras, comprising approximately 780 species.^[20] Unlike many bony fish, sharks are not buoyant because they do not possess swim bladders for flotation. In certain species, a large liver contributes to buoyancy. Thus sharks must stay in constant motion to keep from sinking and to drive water past the gills. Only a few bottom-dwelling species rest. Although sharks are not highly intelligent, they are endowed with remarkable sensory systems. Their color vision is poor but well compensated for by the acute perception of motion; the eye musculature is adapted for fixation with any body motion. The *tapetum lucidum* (responsible for the eye shine seen at night) is a series of reflecting plates containing silver guanine crystals in the choroidal layer behind the retina, which reflects light from a photoreceptor back along the same optical path to increase the sensitivity of the eye. This is present in sharks that are active in low-light environments.^[84] The eyes are protected by upper and lower eyelids and the nictitating membrane (except for the great white shark, which does not have the membrane; it rotates its eyes in the sockets to avoid injury). Keen olfactory and gustatory chemoreceptors permit taste and the recognition of blood, urine, or peritoneal fluid in the water (in some cases, 1 part blood in 100 million parts of water). Sharks are most sensitive to chemicals that are similar to those produced by normal prey, such as amino acids, amines, and small fatty acids.^[61] Up to two thirds of the shark brain can be devoted to smell. The nostrils are the openings of the olfactory organs and do not

1430

take part in breathing, which is accomplished by oxygen extraction from the water through a series of five to seven gill slits. Additionally, sharks possess skin chemoreceptors that detect chemical irritants. The lateral line system extending from the back along the side to the tail responds to sonic vibrations or pulsed low-frequency (20 to 60 cycles/sec) sound waves.^[20] The lateral line organs are small holes along the sides of the shark's body that register motion in the water. These systems allow the shark to locate struggling fish, swimmers, or divers. Perhaps the most important series of telereceptors is located about the head, within the jelly-filled ampullae of Lorenzini, which are extremely sensitive to electrical voltage gradients (generated by the muscle contractions of fish; down to a $1/10^9$ volt per cm). Continuing research is directed at delineating the piscine ability to recognize electric fields. For instance, the common smooth dogfish (*Mustelus canis*) can detect an electrical voltage gradient of 5/1000 of a microvolt. Sharks also have extremely sensitive hearing, which may detect prey underwater from a distance of 914 m (3000 feet).

Research has in the past focused on isolation of antineoplastic agents from shark cartilage, organs, and body fluids.^[48] ^[67] For instance, sphyrnastatins have been isolated

from the hammerhead shark *Sphyrna lewini*.^[67] "Squalamine," produced by the spiny dogfish, is a broad-based antibiotic with antibacterial and antifungal properties. Shark cartilage (which does not appear to have significant antineoplastic activity) is used in the creation of artificial skin for humans, and shark blood and liver oil are being investigated for hematologic and immunologic properties. The latter is used in preparations to shrink hemorrhoids.

Shark Feeding and Attack

As previously noted, sharks are well equipped in the sensory aspects of feeding. They seem particularly able to avoid detection by potential prey, by virtue of coloration and a stealthy approach. Sharks feed in two basic patterns: (1) normal or subdued, with slow, purposeful group movements; and (2) frenzied or mob, as the result of an inciting event. The latter is precipitated by the sudden presentation of commotion or food/blood in the water. Frenzied behavior is enhanced by the proximity of other sharks in large numbers. In a frenzy, sharks become fearless and savage, snapping at anything and everything, including each other. After a shark decides to attack, it "postures," swimming erratically with elevated snout, arched back, pectoral fin depression, stiff lateral bending of the body, and rapid tail motion, in contrast to its normal sinuous and graceful swimming style.^[40] In bursts of speed a shark can use its powerful caudal fin muscles and attain speeds in the water of 20 to 40 miles (32 to 64 km) per hour. As the Carchariniform shark prepares to strike, it rapidly opens and closes its jaws (up to three times each second), depresses the pectoral fins in a braking action, and elevates the head. During a bite, the shark shakes its head and forebody in an effort to tear flesh from the victim. The shark may bite and spit to mortally wound the victim before eating it. Sharks swallow food whole without chewing it. Analysis of human remains recovered from a tiger shark indicate that the human victim was dismembered and then swallowed and digested.^[39] It is difficult to postulate hunger as the sole attack motive, since more than 70% of victims are bitten only once or twice. Hit-and-run attacks are most common. Usually the lower teeth are used first in feeding; solitary upper tooth slashes might indicate attacks unrelated to feeding. Up to 60% of wounds involve only the upper teeth. At the moment of the strike the shark rolls its eyes back in the socket and uses the ampullae of Lorenzini to home in on the victim.

Sharks are selective feeders with clear dietary preferences. They commonly attack young, old, injured, or sick prey. Sea turtles, squid, penguins, seals, and stingrays are consumed in preference to humans. Sharks often eat other sharks. The great white shark cruises along the bottom of the ocean preparing to launch an attack on an unsuspecting surface animal. It can strike with enough force to lift the animal out of the water and breach itself, tearing a 50-pound chunk of flesh from its victim or even decapitating the animal ([Figure 60-8](#)). The cookiecutter (or cigar) shark *Mirounga angustirostris* or *Isistius brasiliensis* ([Figure 60-9](#)) creates a circular craterlike wound approximately 5 to 6 cm in diameter when it attacks its pinniped prey. Sharks have short intestines, seem to be able to selectively digest ingested foodstuffs, and may be able to keep portions of what they ingest intact for prolonged periods of time, perhaps as a method to regulate nourishment.

It is difficult to generalize about shark attacks on humans. Current explanations suggest

that frightened

Figure 60-8 The great white shark advances its upper jaw in the act of biting to feed. (Photo by Pete Romano, Images Unlimited, Inc.)

1431

persons are more likely to be targets of aggression. This has been demonstrated in the case of the gray reef shark, *Carcharhinus amblyrhynchos*. Aggression may be aggravated by purely anomalous behavior, the violation of courtship patterns, or territorial invasion. More docile behavior tends to be the rule with other reef sharks, such as the silvertip (*Carcharhinus albimarginatus*), blackfin (*C. melanopterus*), or whitetip (*Triaenodon obesus*) ([Figure 60-10](#)). The legs and buttocks are most commonly bitten ([Figure 60-11](#)), perhaps an indication of dangling legs or buttocks displayed by an abalone diver facing a rock or ledge. Since sharks do not chew

Figure 60-9 The cookie cutter shark (*Isistius brasiliensis*) cuts pieces of flesh off its prey with its unusual tooth configuration. (Photo by Norbert Wu.)

Figure 60-10 Whitetip reef shark. This species tends to be fairly docile.

their food, their method of biting and rolling or thrashing allows flesh to be stripped from the victim. Teeth may be embedded in prey ([Figure 60-12](#)), but fractured bones are surprisingly rare.^[39] A large shark can attack and sink a boat but may wait to return and consume the human boaters.

The great white shark (*Carcharodon carcharias*) is a man-attacker but probably not a man-eater. This statement reflects the observation that this highly feared animal (which has been observed at a length of 19.5 feet and an estimated weight of 4500 pounds; it is claimed, but not proven, that it can attain a length of 25 feet and a weight of 5500 pounds) usually releases its victim following a single "inquisitory" bite, after it recognizes that a mouthful of neoprene, fiberglass, or lead weights is not normal dietary fare. This

is small consolation to the unfortunate victim, who may have an entire

Figure 60-11 Shark bite of the buttocks. (Courtesy T. Hattori, MD.)

Figure 60-12 The presence of a shark tooth in the arm is revealed by x-ray examination.

1432

Figure 60-13 Victim of great white shark attack. **A**, Damaged surfboard ridden by the victim. **B**, Massive thoracic injury after a single bite. It was estimated that the shark was 20 feet long. (Courtesy P. Crossman, Coroner's Division, Salinas, Calif.)

hemithorax or limb removed ([Figure 60-13](#)). The great white shark has only recently been closely observed in the wild and is thus the subject of much speculation about predation strategies. ^[55] The feared trait of the great white sharks is that they initiate contact with humans. ^[28] Their unpredictable nature ranges from a seemingly docile approach to a research boat to a powerful attack on a surface sea lion. Adults feed largely on pinnipeds; the bite-and-spit behavior is considered a means of avoiding injury from struggling prey ([Figure 60-14](#)). One theory is that a shark that largely consumes a human victim does so because the victim was solitary in the water. ^[29] Breath-hold diver behavior and the similarity of the silhouette of a contemporary surfboard to that of a surface seal may be responsible for attacks on humans. Most attacks on humans occur at the water's surface. One fatal attack in 1989 with two victims was on sea kayakers off the coast of southern California. At the time of this writing, there have been (since 1876) approximately 250 documented attacks by great white sharks upon humans, with approximately 65 fatalities.

Shark attacks have occurred from the upper Adriatic Sea to southern New Zealand, with most between latitudes 46° N and 47° S. The odds of being attacked by a shark along the North American coastline are approximately 1 in 5 million. The danger is greater during the summer months (more persons in the water), in recreational areas, during late afternoon and nighttime feeding, and in murky, warm (20° C [68° F]) water. White

sharks frequently venture into colder water, and attacks

Figure 60-14 Giant sunfish (*Mola mola*). Note the shark bites on the posterior end of the fish. (Photo by Paul S. Auerbach, MD.)

have occurred in waters as cold as 10° C [50° F]). The frequency of shark attacks off the northern California coastline appears to be increasing, particularly with respect to the great white shark. Contrary to the findings of worldwide shark attack analysis, attacks in northern California occur more frequently in clearer water at temperatures of less than 16° C [60° F)].^[57] Shark attacks in Hawaiian waters are relatively rare, with the exception of recent events.^[93]

Although most attacks occur within 100 feet of shore, it is believed that the danger is greater further out, in deep channels or drop-offs. Because of their ability

1433

Figure 60-15 **A**, Silhouette of diver on surfboard to demonstrate similarity in shadow and contour to a sea lion at the surface. **B**, A great white shark passes underneath a dummy on a surfboard before making an attack. **C**, The shark begins to elevate its head from the water. **D**, With jaws wide, the shark attacks the dummy. **E**, With great commotion, the dummy and surfboard are dragged beneath the surface. to detect contrasts, sharks have a predilection to attack bright, contrasting, or reflective objects. Movement is an added attraction to sharks, which have been known to bite surfboards, boats, and buoys. Recent shark attacks in northern California coastal waters involved swimmers on surfboards (black on white) who entered migratory elephant seal (shark food) habitats ([Figure 60-15](#)).

Most victims are attacked by single sharks, violently and without warning. In the majority of attacks the victim does not see the shark before the attack. The first contact may be a bumping, which is an attempt by the shark to wound the victim before the definitive strike. Severe skin abrasions from the shark skin (shagreen) placoid scales (denticles) are produced in this manner. These microscopic appendages have the same origin as

teeth, with a pulp cavity, dentine, and vitreodentine ("enamel") covering.

Clinical Aspects

The jaws of the major carnivorous sharks are crescent-shaped and contain up to five or six rows or series of razor-sharp ripsaw triangular teeth, which are replaced every few weeks by advancing inner rows (Figure 60-16 (Figure Not Available)). Each species has distinctively shaped teeth.^[84] However, a study of the teeth of the great white shark revealed no consistent pattern of size or arrangement of the marginal serrations that was sufficiently characteristic within an individual shark to serve as a reliable index of identification of a tooth as originating from that particular shark. However, the serrations are sufficiently distinctive to enable the potential identification of an individual tooth as having been the cause of a particular bite mark.^[62] Although normal tooth replacement takes 7 to 10 days, in some species a lost tooth can be replaced within 24 hours. Amazingly, some sharks produce up to 25,000 teeth in a lifetime. The upper jaws generally have larger cutting teeth, whereas the sharp lower teeth are designed to fasten onto and hold prey during capture.^[33] The teeth are cartilaginous, strengthened by the deposition of calcium phosphate crystals (apatite) in a protein matrix, all covered by an enameloid substance. They are considered to be as hard as granite and as strong as steel. In a great white shark, the largest serrated triangular teeth can grow to 2.5 inches. There are 26 upper and 24 lower teeth exposed in the front row. The height of the enamel of the largest tooth in the upper jaw is proportional to the animal's length, so a body length of up to 25 feet may be possible. The upper jaw is advanced forward and protruded to allow its participation in the biting action (Figure 60-17 (Figure Not Available)). The biting force of some sharks is estimated at 18 tons per square inch. Severe shark bites result acutely in massive tissue loss, hemorrhage, shock, and death. Even a smaller animal, such as a lemon shark, can

Figure 60-16 (Figure Not Available) Teeth of bull shark (*Carcharhinus leucas*). (Photo by Norbert Wu.)

bite with bone-crushing force.^[34] The potential for destruction is unparalleled in the animal kingdom.

The human leg (or legs) is most frequently bitten, followed by the hands and arms, as the victim attempts to fend off the shark. Proximal femoral artery disruption carries a poor prognosis because of the torrential hemorrhage ([Figure 60-18](#)). Although fractures are not common, broken ribs often accompany intrathoracic, intraperitoneal, and retroperitoneal injuries. Because the victim is generally far from medical assistance, blood loss may be profound. The wounds have historically been fatal in 15% to 25% of attacks, with major causes of death listed as hemorrhage and drowning. Rapid response and prehospital care seem to be somewhat improving this statistic.

1435

Treatment

In most cases the immediate threat to life is hypovolemic shock. Thus it is occasionally necessary to compress wounds or manually to constrict arterial bleeding while the victim is in the water. As soon as the victim is out of the water, all means available must be used to ligate large, disrupted arteries or to apply compression dressings. If possible, the injudicious use of pressure points or tourniquets should be avoided. If intravascular volume must be replaced in large quantities, at least two large-bore IV lines should be inserted into the uninvolved extremities to deliver crystalloid (lactated Ringer's solution, normal saline, or hypertonic saline), colloid, or blood products.^[63]^[85] Central venous cannulation should be reserved for the emergency department.

The victim should be kept well oxygenated and warm while being transported to a facility equipped to handle major trauma. Blood losses should be replaced with whole blood or packed red blood cells and fresh-frozen plasma.^[86] The precise ratio of crystalloid to blood products and proper mean arterial blood pressure endpoint of primary resuscitation in the presence of a major vascular injury are the subjects of ongoing investigations.^[82] The victim should be thoroughly examined for evidence of cervical, intrathoracic, and intraabdominal injuries. Because *Clostridium* can be cultured from ocean water, tetanus toxoid 0.5 ml intramuscularly (IM) and tetanus immune globulin (Hyper-Tet, Cutter) 250 to 500 units IM must be given. The administration of prophylactic antibiotics is more controversial. The victim of a shark bite should be treated with an IV third-generation cephalosporin, trimethoprim/sulfamethoxazole, an aminoglycoside, ciprofloxacin, or some reasonable combination

Figure 60-19 Operative repair of shark bite wound shown in [Figure 60-11](#) . **A**, Debridement and exploration of the wound in the operating room. **B**, Proper closure technique with tension-releasing sutures. (Courtesy T. Hattori, MD.)

of these agents. Imipenem/cilastatin should be reserved for established wound infections or early indications of septicemia, particularly in the setting of immunosuppression. The rationale for prophylactic antibiotics is that shark wounds are prone to heavy contamination with seawater, sand, plant debris, shark teeth, and shark

mouth flora. After a clinical infection is recognized, wounds should be cultured for aerobes and anaerobes by insertion of sterile swabs deeply into available lesions.

Proper operative intervention is mandatory. It is inappropriate to attempt emergency department exploration of what often prove to be extensive and complicated wounds. In the operating room, devitalized tissue should be widely debrided and the wound irrigated copiously to remove all foreign material ([Figure 60-19](#)). An x-ray may reveal one or more shark teeth in the wound (see [Figure 60-12](#)). Unless it is absolutely necessary to achieve tight closure, the wound should be closed loosely around multiple drains (preferably closed systems) or packed open to await delayed primary closure. Although there is debate about whether to use internal or external fixation of grossly open and contaminated fractures, it seems logical to recommend surgical stabilization to facilitate vascular and soft tissue repair. In the pediatric population, damage to the physis and future limb length discrepancy should be anticipated. ^[34]

The abrasion associated with a shark "bumping" should be managed like a second-degree burn, with daily debridement and application of antiseptic ointment.

A reasonable "shark pack" should be available in emergency facilities and rescue vehicles near shark-infested waters. This must be portable and should include

1436

items necessary to control hemorrhage and initiate IV therapy.

Prevention

Every precaution should be taken to avoid shark attack, beginning with an intimate knowledge of the local waters. The following is precautionary advice and a list of alternatives for action in the event of a confrontation:

1. Avoid shark-infested water, particularly at dusk and at night. Do not swim through schools of bait fish. Do not enter posted waters. Do not wander too far from shore. Surfers are generally at greater risk than divers. Do not disguise yourself as a pinniped (seal). Do not swim with animals (such as dogs or horses) in shark waters. Shark behavior can be unpredictable, so it is best not to remain in the water with sharks, particularly if you are fearful. Although some persons believe that sharks can be domesticated, there is no such thing as a friendly shark. Photograph hazardous sharks from within the confines of a protective cage ([Figure 60-20](#)), rather than from an unprotected position.
2. Swimmers should remain in groups. Isolation creates a primary target and eliminates companion surveillance. When diving, maintain constant vigilance.
3. Turbid water, drop-offs, deep channels, breeding inlets, and sanitation waste outlets are areas frequented by larger sharks and should be avoided. However, it appears that sharks attack at least half the time in clear water. Humans are most often attacked in shallow water or beyond the breakers.

4. Blood and other body fluids (including peritoneal fluid) attract sharks. No person should be in shark waters with an open wound. Women have historically been advised to avoid diving during menstruation, although there are no data to support attraction of sharks to the discharge of menstruation.
 5. Brightly colored swimwear or diving equipment and shiny snorkeling gear attract certain sharks. Bright (international) orange appears to be particularly attractive to sharks. Flat black is probably the least attractive color. There is scant evidence that sharks are more attracted to light-skinned bathers.
 6. Captured fish must be tethered at a distance from any divers. There is no greater chemical attractant for a shark than fish blood. Divers who harvest abalone should be aware that the banging and prying noise of an "abalone iron" may attract sharks.
 7. The presence of porpoises in the water does not preclude the presence of sharks. Be alert for the presence of a shark whenever schools of fish behave in an erratic manner.
 8. Do not tease or corner a shark. This is particularly true with captive animals. Do not pull on a shark's tail. Do not chase after a shark. If a shark begins to act in an erratic manner, do not photograph it at close range using a strobe flash apparatus.
 9. If a shark appears in shallow water, swimmers should leave the water with slow, purposeful movements, facing the shark if possible and avoiding erratic behavior that could be interpreted as distress. If a shark approaches in deep water, the diver should remain submerged, rather than wildly surface to escape. The diver should move to defensive terrain with posterior protection to fend off, as best as possible, a frontal attack. It is inadvisable to trap a shark so that it must attack to obtain freedom. Fighting sharks is difficult; they are best repulsed with blunt blows to the snout, eyes, or gills. If possible, the bare hand should not be used, to avoid severe abrasions or lacerations. A stream of air bubbles from a scuba regulator directed into the face of a shark may be sufficient deterrent. Although spears, knives, shotgun shell- or 30.06-loaded powerheads ("bang sticks" [[Figure 60-21](#)]), strychnine-filled spears, and carbon dioxide darts can kill small sharks, they can worsen the situation if they are misapplied or their application promotes frenzy in a school of sharks.
Do not splash on the surface or create a commotion in a manner that might cause a shark to interpret your behavior as that of a struggling fish. Surface chop and perhaps the sounds created by helicopter rotor wash attract sharks. During a helicopter rescue, exit the water as soon as possible.
-

10. Shark defense techniques and repellents are constantly evolving. In response to shark attacks on downed airmen and sailors during World War II, copper acetate blended with a water-soluble wax and nigrosine dye was packaged as a slowly dissolving waxy cake for deployment as "Shark Chaser" by the Office of Naval Research of the U.S. Navy.^[11] It was theorized that the acetate resembled the decaying carcasses of sharks and sharks would thus be repelled. Unfortunately, while a morale booster, this was and is not a reliable deterrent. Its use was discontinued by the Navy in 1976. Limited progress has been made since that time. Recreational beaches in Australia and South Africa are protected with

extensive gill net systems ("meshing") to trap overly curious animals. These work to a certain degree but are not foolproof. Electric shark barriers ("cable device") using 0.8-msec pulses 15 times per second to create a field of 4 volts per meter seem to generate a fright response in sharks longer than 1.2 m and are being investigated.^[18] ^[79] Their benefits include repulsion rather than shark capture or destruction. However, some sharks respond weakly to these stimuli. Abalone divers in South Australia work from one-person, self-propelled shark cages.

Figure 60-20 Caged divers view an inquisitive great white shark. (Photo by Carl Roessler.)

Experimental devices for individuals include chain-mesh diving suits, inflatable dull-colored plastic protective bags (yellow is easy for aircraft to spot, but most attractive to sharks), acoustic and hand-held electrical field transmitters, surfactants and other chemical repellents (such as firefly and the Red Sea and western Indian Ocean Moses sole [flatfish; *Pardachirus marmoratus*] glandular extract [pardaxin]).^[25] Pardaxin is an excitatory polypeptide neurotoxin that forms voltage-gated pores and triggers neurotransmitter release.^[47] The ichthyotoxic secretion from the fish, which appears as a

Figure 60-21 Diver carrying a "bang stick" in the presence of a blue shark. (Photo by Howard Hall.)

milky substance from a series of glands located along the dorsal and anal fins, also contains shark repellent lipophilic constituents that appear to be steroid monoglycosides.^[69] ^[83] It appears that in sharks, the gills and/or pharyngeal cavity are the target organ(s) for the repellent action. However, it has been estimated that about 24 kg of any effective drug would have to be contained in the volume of water through which a slowly approaching shark might swim as it attacked a human in the ocean.^[11] For the exudate from the Moses sole, concentrations of 10 to 25 g/m³ are needed to elicit an immediate indication of repellency. For more common synthetic detergents (sodium dodecyl sulfate), the concentration needed is 800 g/m³. These findings show that a chemical carried in a life jacket cannot be reliably useful against sharks, since it would have to be instantaneously effective at a concentration of no greater than 100 parts per billion. There is no question that shark avoidance is the most reliable maneuver.

The SharkPOD ([Figure 60-22](#)) is a personal device marketed to recreational, commercial, and scientific divers with an output of 90 volts of 75 minutes duration on a rechargeable battery that has been evaluated in both startle (turn the device on when the shark is within 1-m distance) and exclusion (turn on when the shark is out of range

of the electrical field) tests on a variety of shark species, including the great white shark. The effective electrical field created by the device is approximately 7 feet in diameter. Observations have included that sharks already in the process of feeding may not be repelled by the device, so the current

Figure 60-22 SharkPOD shark repellent device.

1438

thought is that the device should be turned on at the beginning of a dive to create a situation of "exclusion." A wand-type unit is currently being evaluated.

BARRACUDA

To many divers, the barracuda appears more sinister than the shark, and it is more highly feared. Barracuda are distributed from Brazil north to Florida, and in the Indo-Pacific from the Red Sea to the Hawaiian Islands. Of the 22 species of barracuda, only the great barracuda (*Sphyraena barracuda*) has been implicated in human attacks.

Life and Habits

The great barracuda is encountered in all tropical seas and can grow to 2.5 m and 50 kg but is rarely sighted at a length greater than 1.5 m ([Figure 60-23](#)). A solitary swimmer, the fish is extremely swift and swims in a disconcerting darting fashion. The barracuda possesses an elongated narrow mouth filled with large knifelike teeth, similar in appearance to those of canines ([Figure 60-24](#)). Smaller fish may be found in large schools.

Although great barracuda seldom attack divers, they do so rapidly and fiercely, often out of confusion in murky waters. More commonly the fish charges through or leaps from shallow water to bite the dangling legs of a boater, particularly if a shiny anklet (which resembles a fishing lure) is worn. Persons have been bitten on the scalp while wearing a barrette or on the face when trying to feed a barracuda by holding a dead fish bait in their mouths. Considering the great frequency with which barracuda are encountered and the low number of reported attacks, they do not pose nearly the hazard of sharks.

Clinical Aspects

Barracuda jaws contain two nearly parallel rows of teeth, which produce straight or V-shaped lacerations, in contradistinction to the crescent-shaped bite of the shark. Except for this difference and the magnitude of injury, the surgical problems generated by the barracuda do not differ from those of the shark. The clinician encounters tissue loss, moderate hemorrhage, and wound infections.

Treatment

Barracuda bites are treated identically to shark bites. If a barracuda is captured, it should not be eaten in ciguatera toxin-endemic regions.

Prevention

Barracuda are attracted to turbid waters, underwater commotion, irregular motion,

surface splashing, shiny objects, and tethered fish. These should all be avoided. It

Figure 60-23 Great barracuda (*Sphyraena barracuda*). (Photo by Paul S. Auerbach, MD.)

Figure 60-24 Jaws of the great barracuda, with canine-configured teeth next to the author's hand.

is unwise to dangle a body part adorned with reflective jewelry before the jaws of a barracuda.

MORAY EELS

Life and Habits

Moray eels are found in tropical, subtropical, and some temperate waters. In the family Muraenidae, some individuals of the larger species may attain lengths of 3.5 m and diameters of more than 35 cm. Morays are muscular, powerful, and savage bottom dwellers, residing in holes or crevices or under rock and coral. They have a snakelike appearance and rarely have scales or pectoral fins. The distinguishing feature of the morays is the small, round gill opening. The skin of the moray eel is leathery and mucus coated, not easily lacerated with a knife. Fortunately, the eel usually evades confrontation unless cornered or provoked. Bites occur when a diver intentionally probes into a coral bed or cave, or a fisherman reaches into a net and offers a

1439

Figure 60-25 Moray eel, demonstrating the sharp teeth and biting potential. (Photo by Paul S. Auerbach, MD.)

Figure 60-26 Diver alongside a giant grouper. (Courtesy Bruce Halstead, MD.)

hand to a feeding eel. Aquarium-housed morays may strike when handled improperly. Most moray eels are easily intimidated and avoid confrontation unless cornered. An aggressive eel may strike out in competition for prey, particularly lobster. Elderly, vision-impaired eels may attack without specific provocation, especially at night. In U.S. coastal waters, the most prevalent species are the California, green, and spotted morays.

Clinical Aspects

Morays are forceful and vicious biters that can inflict severe puncture wounds with their narrow and viselike jaws, which are equipped with long, sharp, retrorse, and fanglike teeth ([Figure 60-25](#)). Molar-type teeth are present in some species. A moray eel has the tenacity of a bulldog and will hold on to a victim, rather than strike and release. Multiple small puncture wounds are common after the bite of smaller eels, with the hand most commonly involved. If the eel is ripped forcefully from the victim, the resulting lacerations may be extensive.

Treatment

Moray bites are treated in a manner analogous to that of shark bites. If the eel remains attached to the victim, the jaws may need to be broken or the animal decapitated to effect release. The primary wound should be irrigated copiously and explored to locate any retained teeth. The risk of infection is high, particularly in bites to the hand. The puncture wounds should be left unsutured to allow drainage and the victim given appropriate prophylactic antibiotics. If the wound is extensive and more linear in configuration (resembling a dog bite), the wound edges may be debrided and loosely approximated with nonabsorbable sutures or staples, and antibiotics may be administered. In all cases, it is prudent to inspect the wound at 24 and 48 hours to detect the onset of infection.

Prevention

It is unwise for a snorkeler or diver to place a hand underneath unexplored coral or rock unless it has been probed or otherwise disturbed specifically in search of an eel. All fishing nets should be handled carefully. A dive guide who feeds moray eels by holding a loaf of bread or bait fish in his mouth is offering his nose and mouth as a meal for an unpredictable eel.

GIANT GROUPERS

Some of the larger species of sea bass or grouper (family Serranidae) may grow to exceed 3.6 m and 227 kg ([Figure 60-26](#)). Distributed in both tropical and temperate seas, they are curious, pugnacious, and voracious feeders. Although not aggressive like a shark, a giant grouper should be respected for its fearlessness, bulk, and cavernous mouth. Groupers can be found frequenting shipwrecks; swimming in caves, caverns, and holes; and lurking behind large rocks and coral outcroppings. They are territorial and may become aggressive while protecting their domain. Bite wounds may be ragged with extensive maceration and are treated the same as shark bites. Large groupers should not be eaten in ciguatera toxin-endemic regions. It is always wise to visually survey an underwater cave before entering or exiting. The diver should not block the exit if a grouper is attempting to escape and should not carry speared fish. Many scare tactics used against sharks are of no avail with groupers.

1440

Figure 60-27 Sea lion and pup. Parents of both genders aggressively protect their young.
(Photo by Paul S. Auerbach, MD.)

SEA LIONS

Sea lions (family Otariidae) and seals (family Phocidae) are mild-mannered mammals except during the mating season, when the males may become aggressive, and the breeding season, when both genders attack in defense of their newborn pups ([Figure 60-27](#)). Divers have been seriously bitten and therefore should avoid ill-tempered and abnormally aggressive animals. There is nothing unique about the clinical aspects of these injuries, except for the posttraumatic infections. The bites are treated the same as shark bites.

"Seal finger" (speck finger, blubber finger) follows a bite wound from a seal or from contact of even a minor skin wound with a seal's mouth or pelt. The affliction is characterized by swelling of the digit, with or without articular involvement. There may be lymphadenopathy and involvement of adjacent joints. No particular organism has been consistently cultured from these injuries, but there has been suggestion that in addition to *Staphylococcus* and *Streptococcus*, *Erysipelothrix rhusiopathiae* may an inciting pathogen (see [Chapter 63](#)).

CROCODILES AND ALLIGATORS

Crocodiles (genus *Crocodylus*) and alligators (genus *Alligator*) are long-bodied loricates with reputations as ferocious aquatic reptiles. Considered to be less sluggish than alligators, crocodiles (*C. niloticus* in the Nile and

Figure 60-28 The jaws of a saltwater crocodile. (Courtesy Allan P. Mekisic.)

the larger estuarine *C. porosus* of eastern Asia and the Pacific islands) may attack and severely injure a human. *C. porosus*, which ranges over an extensive geographic area, including India, Sri Lanka, southern China, the Malay Archipelago, Palau, the Solomon Islands, and northern Australia, has been claimed to be a prolific man-eater. Estimates of human fatalities may be exaggerated based on isolated reports of atrocities committed by this beast. An adult crocodile devours prey much larger in size than a human. According to one report, the stomach of an Australian estuarine crocodile contained the remains of an aborigine and a 4-gallon drum containing two blankets. At a length greater than 20 feet and a weight exceeding 2500 pounds, the crocodile can travel in water at a speed of 20 mph and can charge a short distance over land at 15 to 30 mph. The enormous jaws and canine teeth ([Figure 60-28](#)) can bite with sufficient force to sever an outboard boat propeller. However, the teeth are not well suited for tearing apart or chewing, so most prey is allowed to rot, which makes them easier to swallow. Most crocodiles are content to eat fish, turtles, kangaroos, and wild pigs. However, excursions into freshwater rivers and onto land have introduced them to cows, horses, and humans. A crocodile attacks by grasping the victim in its powerful jaws and dragging it underwater, where it drowns and dismembers the victim with a constant twirling motion ("death rolls"). In a series of 16 crocodile attacks reported from the Northern Territory of Australia, four fatalities involved transection of the torso or decapitation.^[56] Most attacks (fatal and nonfatal) were on persons swimming or wading in shallow water. In riverine areas of Tanzania, crocodiles are a considerable health hazard. In the Korogwe District from 1990 to 1994, 51 human and 49 crocodile deaths were reported. The attacks are attributed to increased waste products in the water, which reduces the crocodiles' primary food supply.

Figure 60-29 Needlefish beak, capable of causing a penetrating injury.

In addition, "tamed" crocodiles are not hunted for fear of reprisal by witchcraft and because of local superstitions.^[76] The American alligator *Alligator mississippiensis* most commonly attacks in the water but will also attack on land. These attacks seem to be motivated by feeding.

Crocodile bites produce large crush injuries and lacerations. Surgical wound management is similar to that for dog bites. The bacteriologic considerations have not been extensively studied but should be assumed to be the same as for other animals that reside in the aquatic environment. Wound infections should be anticipated in the largely contaminated extensive crush injuries. Prophylactic antibiotics to cover *Aeromonas hydrophila*, *Pseudomonas*, and *Vibrio* should be administered. Coverage against anaerobes, such as *Bacteroides*, is prudent. Antitetanus primary or booster immunization is mandatory.

NEEDLEFISH

Marine needlefish (family Belonidae) are slender, tubular, silver, and lightning-quick surface swimmers found in tropical seas. They resemble, but are not related to, the freshwater gar and may attain streamlined lengths of up to 2 m. Possessed of an elongated pointed snout, which comprises one quarter the length of the fish and contains small pointed teeth, the fish moves rapidly, often leaping out of the water in fear or when attracted to lights or windsurfers ([Figure 60-29](#)). The needlefish, or garfish, is an occupational hazard for persons who fish from small canoes at night in tropical Indo-Pacific ocean waters.^[13] On occasion they have flown into people, spearing them in the chest, abdomen, extremities, head, and neck. In one reported case a fish caused brain injury with an internal carotid-cavernous sinus fistula after orbitocranial perforation.^[54] In another case, the calcified elongated jaws of a needlefish embedded in a woman's neck were retained for over a month before removal.^[95] In another, penetration of the knee by *Tylosurus crocodilus* occurred in an ocean surface swimmer in New Caldedonia.^[45] Exsanguination from a neck wound has been anecdotally reported from Papua New Guinea. A chest wound can be accompanied by a pneumothorax. Death may occur from chest or abdominal penetration. Treatment is according to the nature of the injury. All wounds should be debrided and irrigated, followed by a search for foreign material. Radiographs appropriate to identify foreign bodies should be obtained. A small superficial wound may cause the physician to underestimate an internal injury. The major risk is wound infection. Injury prevention is difficult, although it has been suggested that canoes be positioned in a circle to allow spearing of fish in a central pool of light. Other species of flying fish pose less risk, since they have blunt heads.

Many other fish leap from the water, but injuries are extremely uncommon. A single case of a wahoo (150 cm; 22.5 kg), family Scombridae, leaping from the water and biting a victim on the upper extremity has been reported.^[37] The razor-sharp teeth generated extensor tendon lacerations on the dorsal hand and forearm that required surgical repair. A careless fisherman can easily be cut by a wahoo when extracting a fishing lure. As previously described, barracuda exit the water in pursuit of shiny metallic objects that resemble fishing lures. Bluefish (*Pomatomus saltatrix*) school and feed in a frenzy, but most bites occur as the fish are handled out of the water; in-water attacks on humans are theoretic.^[46] The fish has sharp, conical canine teeth in both the upper and lower jaws and can grow to 1.2 m and over 12 kg.

The sailfish sports an elongated bill. Although not considered a predator, a sailfish has on at least a few occasions driven its bill into a human victim ([Figure 60-30](#)), in one case causing a colon perforation in a snorkeler.

KILLER WHALES

The killer whale, *Orcinus orca*, is probably not the ferocious killer it is reputed to be. The largest of the living mammalian dolphins, these magnificent animals (Figure 60-31 (Figure Not Available)) grow to 33 feet and 10 tons and are found in all oceans. They usually travel in pods of up to 40 individuals. Swift and enormously powerful creatures, they feed on squid, fish, birds, seals, walruses, and other whales. Their powerful jaws are equipped with cone-shaped teeth directed back into the throat, designed to

1442

Figure 60-30 Sailfish bill lodged in the posterior knee. **A**, Lateral view. **B**, Anterior view.

Figure 60-31 (Figure Not Available) Distinctive markings of a killer whale near the San Juan Islands, Washington State. (Photo by Norbert Wu.)

grasp and hold food. The killer whale can generate enough crushing power to bite a seal or porpoise in two with a single snap.

In captivity, killer whales are playful creatures and seem intelligent, without the primal behavior of sharks. Nonetheless, although killer whales are believed not to prey on humans, they should be regarded with respect and at a distance in their natural habitat. Mistaken for a sea lion, a human would be a nice snack for a killer whale.

Other whale species, such as the finback, have rammed boats, theoretically in defense of their young. Territorial behavior should be anticipated and respected.

GIANT CLAMS

Although many adventure stories describe divers being caught in the clamp of a giant clam (family Tridacnidae), there are no verifiable reports of such a calamity resulting in a major injury. *Tridacna gigas* can attain a length of 1 m ([Figure 60-32](#)) and weigh as much as 300 kg. The hazard to divers is hypothetical.

GIANT SQUID

The giant decapod (10 arms) squid (Figure 60-33 (Figure Not Available)), possibly *Architeuthis*, grows to a length in excess of 20 m and weight of 38,000 kg, with long (10 m) menacing tentacles, eyes of nearly 35 cm (Figure 60-34 (Figure Not Available)), and a razor-sharp beak that it uses to eat prey. The tentacles are armed with chitinous serrated rings equipped with teeth on each of the suckers (Figure 60-35 (Figure Not Available)). Sperm whales have been examined with sucker wounds of diameter 46 cm, which would extrapolate to a monstrous squid measuring at least 60 m in length. The battles between sperm whales and giant squid are legendary, but humans are unlikely to encounter this awesome animal, which is found at depths far beyond the range of a sport scuba diver.^[27] With increased deep sea exploration by small submersibles, we may learn more about this fascinating creature. It is possible that a hungry giant squid

1443

1444

might ingest a human, but this has not yet been observed.

GIANT OCTOPUS

The Pacific giant octopus *Octopus dofleini* is a predator that has been captured at 272 kg with an arm span of over 30 feet. It ranges off the western North American coast from northern California to Alaska and off eastern Asia southward to Japan. The cephalopod is armed with suckers on eight arms and a parrotlike chitinous mouth located centrally underneath the head. Although it exhibits curiosity, it does not exhibit aggression directed against humans. However, it possesses the strength and agility to easily overwhelm a human. Anecdotes from the South Pacific tell of native breath-hold divers being subdued and drowned by angered captive octopuses.

GIANT MANTA RAY

The giant manta ray *Manta birostris* can have a wing span of more than 6 m and a weight of 1600 kg ([Figure 60-36](#)). The caudal appendage carries a vestigial stinger that poses no threat to humans. However, the coarse dermal denticles can create severe abrasions, which generally occur when divers attempt to ride these gentle and accommodating creatures.

MANTIS SHRIMP

The mantis shrimp (e.g., *Gonodactylus bredini*, *Hemisquilla ensigera californiensis*) is not a true shrimp but resembles a large flattened shrimp or miniature lobster (up to 36 cm) and is equipped with a pair of legs that serve as specialized jackknife claws (Figure 60-37 (Figure Not Available)). The tail carries numerous sharp spines that may project beyond the edge of the sturdy tail fin. Lacerations may be

Figure 60-36 Giant manta ray. The sting on the caudal appendage is vestigial, but the "wings" can slap and abrade the unwary individual. (Photo by Paul S. Auerbach, MD.)

induced by either the front raptorial (prey-acquiring) claws or the tail, particularly when the shrimp attacks an unwary victim. It has been claimed that an attacking mantis shrimp struck with enough force to crack a diver's face mask. In the Caribbean, the stomatopod ("foot-mouth") mantis shrimp is known as "thumb splitter." *Odontodactylus scyllarus* from the Indo-Pacific can be afflicted with a disease that digests areas of its dorsal cuticle and eventually is lethal. This may explain one anecdotal report of a human finger wound (which led to amputation) characterized by cartilage destruction and from which no pathogenic organism could be cultured. The mantis shrimp is a superb predator, in part because it has the most highly developed eyes of any crustacean.

PIRANHA

South American characins include the piranha *Serrasalmus natterei*, equipped with a formidable set of razor-sharp teeth. These small fish (Figure 60-38 (Figure Not Available)) attack

Figure 60-37 (Figure Not Available) Mantis shrimp, ready to strike with its claws. (Photo by Norbert Wu.)

Figure 60-38 (Figure Not Available) Piranha. (Photo by Norbert Wu.)

1445

in schools of several hundred and can theoretically reduce a human to a shiny skeleton in short order. They are attracted by blood or commotion.

TRIGGERFISH

The triggerfish are usually shy and unimposing, but during mating season the females of at least two species (*Pseudobalistes fuscus* and the "giant" *Balistoides viridescens*) can become extremely territorial in guarding a nest and thus aggressive, inflicting painful bites. The former can grow to 55 cm and the latter to 75 cm. The strong jaws each carry eight long, protruding, and chisel-like teeth ([Figure 60-39](#)) in an outer row, backed by an inner row of six teeth.^[71] Usually the fish "bites and runs," but the orange-striped triggerfish *Balistoides undulatus* has been reported to bite and not release. It is common to have to strike the fish in some manner to get it to release. In the Gilbert Islands a release technique is to bite the fish on the top of the head.

STONY CORALS

Life and Habits

The anthozoan Madreporariae, or true (stony) corals, exist in colonies that possess calcareous outer skeletons (the origin of calcium carbonate, or limestone) with pointed horns, razor-sharp edges, or both ([Figure 60-40](#)). There are nearly 1000 species of corals. Corals live in waters at temperatures of 20° C (68° F) or higher, generally at depths of up to 20 fathoms. A "coral head" is actually a colony of individual polyps. Rare species have been noted at depths of more than 6000 fathoms. Certain coral species, such as *Plexaura homomalla*, are under investigation as sources of prostaglandins and other pharmaceutical precursors to treat conditions as diverse as asthma, leukemia, and infections. Pieces of coral have been evaluated for use as bone grafts.

Figure 60-39 Triggerfish. (Photo by John Randall.)

Coral reefs are under pressure worldwide from climatic changes (e.g., El Niño), chemical poisons (e.g., cyanide used for fishing), natural predators (e.g., crown-of-thorns sea star), and mechanical destruction (e.g., ship anchors and explosives).

Clinical Aspects

Snorkelers and divers, particularly photographers and spear fishermen, frequently handle or brush against these living reefs, resulting in superficial cuts and abrasions on the extremities ([Figure 60-41](#)). Coral cuts are probably the most common injuries sustained underwater. The initial reaction to a coral cut is stinging pain, erythema, and pruritus, most commonly on the forearms, elbows, and knees. Divers without gloves frequently receive cuts to the hands. A break in the skin may be surrounded within minutes by an erythematous wheal, which fades over 1 to 2 hours. The red, raised welts and local pruritus are called coral poisoning. Low-grade fever may be present and does not necessarily indicate an infection. With or without prompt

Figure 60-40 Coral garden. (Photo by Paul S. Auerbach, MD.)

Figure 60-41 Abrasions of the leg from bumping against sharp coral. (Photo by Paul S. Auerbach, MD.)

1446

treatment, the wound may progress to cellulitis with ulceration and tissue sloughing. These wounds heal slowly (3 to 6 weeks) and result in prolonged morbidity. In an extreme case the victim develops cellulitis with lymphangitis, reactive bursitis, local ulceration, and wound necrosis.

Treatment

Coral cuts should be promptly and vigorously scrubbed with soap and water, then irrigated copiously with a forceful stream of freshwater or normal saline to remove all foreign particles. Using hydrogen peroxide to bubble out "coral dust" is occasionally helpful. Any fragments that remain can become embedded and increase the risk for an indolent infection or foreign body granuloma. If stinging is a major symptom, there may be an element of envenomation by nematocysts (see [Chapter 61](#)). A brief rinse with diluted acetic acid (vinegar), papain solution, or isopropyl alcohol 20% may diminish the discomfort (after the initial pain from contact with the open wound). If a coral-induced laceration is severe, it should be closed with adhesive strips rather than sutures if possible; preferably it should be debrided for 3 to 4 consecutive days and closed in a delayed fashion.

A number of approaches can be taken with regard to subsequent wound care. One method is to apply twice-daily sterile wet-to-dry dressings, using saline or a dilute antiseptic (povidone iodine 1% to 5%) solution. Alternatively, a nontoxic topical antiseptic or antibiotic ointment (mupirocin, bacitracin, or polymyxin B-bacitracin-neomycin) may be used sparingly and covered with a nonadherent dressing (e.g., Telfa). Secondary infections are dealt with as they arise. A final approach is to apply a full-strength antiseptic solution, followed by a powdered topical antibiotic, such as tetracycline. An "alternative medicine" technique that has been reported to me to be effective is to apply Tibet Red Flower Seed Oil (brand "Dragon" is authentic) 4 times a day, noting that the application will cause burning pain for a short period of time. No method has been supported by any prospective trial.

Despite the best efforts at primary irrigation and decontamination, the wound may heal

slowly, with moderate to severe soft tissue inflammation and ulcer formation ([Figure 60-42](#)). All devitalized tissue should be debrided regularly using sharp dissection. This should be continued until a bed of healthy granulation tissue is formed. Wounds that appear infected should be cultured and treated with antibiotics as previously discussed.

The victim who demonstrates malaise, nausea, and low-grade fever may have a systemic form of coral poisoning or be manifesting early signs of a wound infection. It is prudent at this point to search for a localized infection, procure wound cultures or biopsy specimens as indicated, and initiate antibiotics pending confirmation

Figure 60-42 Poorly healing wound following coral cut. (Photo by Paul S. Auerbach, MD.)

of organisms. If the victim is started on an antibiotic and does not improve, a supplemental trial of a systemic glucocorticoid (prednisone 80 mg tapered over 2 weeks) is not unreasonable. In the absence of an overt infection, the natural course of the wound is to improve spontaneously over a 4- to 12-week period.

Prevention

Divers exploring near coral reefs must take every care to avoid coral cuts. Protective clothing and gloves should be impenetrable. Snorkelers and underwater photographers in shallow water should wear adequate hand, elbow, and knee protection.

SHOCKING MARINE AND FRESHWATER ANIMALS

Only two groups of electric fish are marine; the remainder are freshwater animals. They rarely pose a health hazard but rather are curious creatures surrounded by superstition and folklore. The marine electric fish include the stargazers (*Astroscopus*) (Figure 60-43 (Figure Not Available)) and the electric rays (*Torpedo*). The electric eel is a freshwater Amazonian animal.

Electric rays are found in temperate and tropical oceans. Of the class Chondrichthyes, they are round bodied, with short tails and thick bodies (compared with stingrays). In California, *Torpedo californica* (Figure 60-44 (Figure Not Available)) attains a length of 4 feet and weight of 80 to 90 pounds. It swims slowly and sluggishly and is usually

1447

found partially buried in bottom mud and sand. Well camouflaged, its dorsal surface is multicolored and the ventral surface creamy white. The externally visible electric organs are located on each side of the anterior part of the disk between the anterior extension of the pectoral fin and the head, extending from above the level of the eye backward past the gill region onto the ventral surface. The electric organs are composed of a honeycomb network of modified muscles organized into columnar prismlike structures and connective tissue, which generate an electrical charge by neuromuscular activity. The muscle cells ("electroplaques") are stacked 500 to 1000 deep, creating up to 500 cm² of surface area. The electroplaques depolarize in series and in parallel simultaneously, producing amperage sufficient to stun prey. Species in the tropical eastern Pacific include the lesser ray, *Narcine entemedor*, and the bulls-eye ray *Diplobatis ommata*.

Generally the ventral surface of the ray is negative and the dorsal side is positive. An electrical discharge is reflexively produced on contact, often in a series exhaustive for the fish. This necessitates a period of recharging. Electricity is delivered in doses of 8 to 220 volts. The Atlantic *Torpedo nobiliana* produces 180 to 220 volts. Although the shock is of low amperage, it is sufficient to stun a grown man and might induce drowning. Recovery from the shock has been reported anecdotally to usually be uneventful. An

electric ray should not be handled. The energy generated by skates is considerably less, measured in millivolts to 1 to 2 volts.

Chapter 61 - Envenomation by Aquatic Invertebrates

Paul S. Auerbach

This chapter discusses envenomation by aquatic invertebrate life-forms. [Chapter 62](#) discusses envenomation by aquatic vertebrate life-forms.

See [Chapter 60](#) for a discussion of infections associated with aquatic wounds and the relevant antimicrobial therapy. Standard wound care measures, such as antitetanus immunization, should be undertaken whenever there is penetration of the skin.

The science of poisons, biotoxicology, is divided into plant poisons, or phytotoxicology, and animal poisons, or zootoxicology. "Toxinology" connotes the science of toxic substances produced by or accumulated in living organisms, their properties, and their biologic significance for the organisms involved.^[77] Animals in which a definite venom apparatus is present are sometimes called phanerotoxic, whereas animals whose body tissues are toxic are termed cryptotoxic.^[97] Naturally occurring aquatic zootoxins may be designated as oral toxins (which are poisonous to eat and include bacterial poisons and products of decomposition), parenteral toxins (venom produced in specialized glands and injected mechanically [by spine, needle, fang, fin, or dart]), and crinotoxins (venom produced in specialized glands and administered as slime, mucous, and gastric secretion). Within these three subdivisions, further classifications are by phylogeny, chemical structure, and clinical syndrome.

Although all venoms are poisons, not all poisons are venoms. According to the theory that offensive venoms are generally oral (mouth and fang) and defensive venoms are aboral (tail and sting) or dermal (barb and secretion), the majority of marine venoms are defensive. In the evolutionary scheme, it appears that venomous fish seek specific self-defense, whereas poisonous fish are noxious in a nonspecific manner.^[4] A brief comparison of the features of venoms and poisons shows that poisons produced in skin, muscle, blood, or organs are generally heat stable (46° to 49° C [115° to 120° F]), gastric acid stable, and carry seasonal toxicity. They are not "released" and may lack a well-defined biologic function. Venoms are more commonly heat labile, gastric acid labile, and nonseasonal in toxicity. They can be released in varying amounts and have

evolved for conquest and defense.

In snakes, the latency, toxicity, and duration of a venom effect are related to the route of envenomation. Intravascular injection is significantly more lethal than intraperitoneal or transcutaneous injection, as determined by the measured lethal dose of 50% survival of the group (LD_{50}). This principle is not commonly applied to marine venoms because few encounters involve direct intravascular invasion.

Most venoms are high-molecular-weight amalgams of vasoactive amines, proteolytic enzymes, and other biogenic compounds. These substances denature membranes, catabolize cyclic 3',5'-adenosine monophosphate, degranulate mast cells, provoke histamine release, initiate arachidonate metabolism, accelerate coagulopathy, interfere with cellular transport mechanisms, disrupt metabolic pathways, impede neuronal transmission, and evoke anaphylaxis and shock. Frustratingly, although many marine venoms are composed of protein and polypeptide subunits, they lack sufficient immunogenicity to allow development of antitoxins or antivenoms. Poisons represent metabolic by-products and are usually of smaller molecular weight.

Taxonomy of marine animals can sometimes be confusing. The hierarchical distinctions are made in descending order: kingdom, phylum, class, order, family, genus, and species.

ANAPHYLAXIS

An envenomation or administration of antivenom can elicit an allergic reaction. In the previously sensitized individual, the antigen (venom, aquatic protein, or animal serum) complexes with immunoglobulin E (IgE) and perhaps with IgG homocytotoxic antibodies or activated complement cleavage products attached to the membranes of mast cells and basophils. This induces membrane permeability, which allows degranulation or membrane production of histamine, serotonin, kinins, prostaglandins, platelet-activating factor, eosinophil and neutrophil chemotactic factors, leukotrienes, and other bioactive chemical mediators.^[6]

The signs and symptoms of anaphylaxis may occur within minutes of exposure and include hypotension, bronchospasm, tongue and lip swelling, laryngeal edema, pulmonary edema, seizures, cardiac arrhythmia, pruritus, urticaria, angioedema, rhinitis, conjunctivitis, nausea, vomiting, diarrhea, abdominal pain, gastrointestinal bleeding, and syncope. Most severe allergic reactions occur within 15 to 30 minutes of envenomation, and nearly all occur within 6 hours. Fatalities are related to airway obstruction or hypotension. Acute elevated pulmonary vascular resistance may contribute to hypotension that results from generalized arterial vasodilation.^{[7] [9]}

1451

Treatment

Decisive treatment should be instituted at the first indication of hypersensitivity. Specific treatment recommendations for anaphylaxis are found in [Box 46-3](#).

ANTIVENOM ADMINISTRATION

A number of marine envenomations, such as those by the box-jellyfish and certain sea snakes, may require the administration of specific antivenom. Marine antivenoms are raised in sheep and horses and therefore are antigenic in humans, inducing both immediate and delayed hypersensitivity. Most authorities recommend that a skin test be performed for sensitivity to horse serum, if the clinical situation permits, after a sea snake envenomation. (There is rarely time for a skin test with a *Chironex* envenomation, which requires immediate intervention.) This should be done only after deciding to administer antivenom and not to determine whether antivenom is necessary. The purpose of sensitivity testing is to allow adequate prophylaxis against anaphylaxis. The skin test is performed with an intradermal injection into the upper extremity of 0.02 ml of a 1:10 dilution of horse serum test material in saline, with 0.02 ml saline in the opposite extremity as a control. Erythema and pseudopodia are present in 15 to 30 minutes in a positive response. Because antivenom contains many times the protein content of horse serum used for skin testing, the use of antivenom for skin testing may increase the risk of anaphylactic reaction. If the skin test is positive, the antivenom intended for intravenous (IV) infusion should be diluted in sterile water to a 1:100 concentration for administration. Successive vials should be less dilute if the allergic reaction is minimal (controlled by antihistamines and epinephrine). A negative skin test does not preclude the possibility of an anaphylactic response to antivenom administration.

The rationale for administering antivenom is to provide early and adequate neutralization of the toxin at the tissue site of entry before it gains systemic dominance. Except for stonefish antivenom, the product should preferentially be administered intravenously, taking care to provide adequate doses for children and the elderly, who have a decreased volume of distribution and increased sensitivity to venom effects. The antivenom intended for IV administration should always be diluted with normal saline, Ringer's lactate, or dextrose 5% in water.

Marine antivenoms are produced and distributed in the Indo-Pacific regions. They include the following:

1. *Chironex fleckeri* (box-jellyfish) antivenom, from Commonwealth Serum Laboratories (CSL), Melbourne, Australia. A hyperimmune sheep globulin preparation, this may be used to neutralize the stings of *Chironex fleckeri* and *Chiropsalmus quadrigatus*.
2. *Enhydrina schistosa* (beaked sea snake) sea snake antivenom, from CSL. A hyperimmune horse globulin preparation, this may be used to neutralize the bites of most sea snakes. It is prepared by immunizing horses with venom from *E. schistosa* and the Australian tiger snake *Notechis scutatus*.
3. *Notechis scutatus* (tiger snake) antivenom, from CSL. This is the antivenom of

second choice against the bites of most sea snakes.

4. *Enhydrina schistosa* (beaked sea snake) monovalent antivenom, from the Haffkine Institute in Bombay, India. This may be used to neutralize the bites of most sea snakes; it is most effective against the bite of *E. schistosa*.
5. *Synanceja trachynis* (stonefish) antivenom, from CSL. A hyperimmune horse globulin preparation, this may be used to neutralize the stings of stonefish and more virulent scorpionfish species.

A person who is known to be sensitive to horse or sheep serum, has a positive skin test, or develops signs of an allergic reaction or anaphylaxis during antivenom therapy requires aggressive medical management. A recipient of antivenom should be pretreated with 50 to 100 mg of IV diphenhydramine (1 mg/kg in children). After this, the initial dose of antivenom is administered at a rate no faster than one vial each 5 minutes. If no allergic manifestation ensues, the antivenom can be administered at a more rapid rate. If signs of anaphylaxis develop, usually heralded by an urticarial eruption or pruritus, 0.1 to 0.2 ml aliquots of antivenom should be alternated with 3 to 10 ml (0.03 to 0.1 mg) IV doses of aqueous epinephrine 1:100,000 (infused over 5 to 10 minutes). Alternatively, an epinephrine drip may be prepared as previously described in the discussion on anaphylaxis. The victim should be managed in an intensive care unit, with electrocardiographic and blood pressure monitoring. The dose of epinephrine should not exceed that which elevates the pulse rate above 150 beats/min. The administration of IV epinephrine may cause transient hypokalemia as potassium is driven intracellularly; cessation of the epinephrine infusion may create a transient hyperkalemia as the potassium regains entry into the extracellular space. If a victim is highly allergic to antivenom, serious consideration should be given to supportive therapy (including hemodialysis) without antivenom administration.

In one series, stonefish antivenom was administered to 24 victims in a dose of one or two ampules by the intramuscular (IM) route, without any "immediate reactions" reported.^[112] In this same report, six victims received box-jellyfish antivenom by the IV route without immediate or delayed reactions.

Serum Sickness

The formation of IgG antibodies in response to antigens present in antivenom (heterologous serum) results in

the deposition of immune complexes in many tissue sites, notably in the walls of blood vessels. These complexes induce vascular permeability, activate the complement cascade and chemotactic factors, degranulate mast cells, and trigger the release of proteolytic enzymes. Decreased levels of C_3 and C_4 are accompanied by increased C_{3a} / C_{3a} des-arginine, a split product C_3 .^{[45] [64]} Although immune complexes can be measured by various tests (Raji-cell IgG assay and C_{1q} -binding assay), levels of immune complexes may not correlate with the clinical presentation.^{[45] [82]} Dermal biopsy

of lesional skin may reveal leukocytoclastic vasculitis.

Symptoms are generally present within 8 to 24 days and include fever, arthralgias, malaise, urticaria, lymphadenopathy, urticarial and morbilliform skin rashes, peripheral neuritis, and swollen joints. It is not uncommon for the primary urticarial lesion to be noted at the injection site. Serum sickness is managed with the administration of corticosteroids. An initial loading dose of prednisone (40 to 60 mg for adults; 2 to 5 mg/kg, not to exceed 50 mg, for children) should be administered and maintained daily until symptoms markedly resolve. The corticosteroid should be tapered over a 2- to 3-week course to avoid induction of adrenal insufficiency. Aspirin or other nonsteroidal antiinflammatory agents are rarely helpful and may be contraindicated because of circulating immune complex-induced platelet dysfunction.

STINGING ANIMALS

The stinging animals constitute a large collection of marine organisms containing invertebrates and vertebrates (see [Chapter 62](#)), ranging from primitive to extremely sophisticated organisms. Aggregated, stinging animals pose the most frequent hazards for swimmers and divers.

INVERTEBRATES

Sponges

Life and Habits.

There are approximately 5000 species of sponges (phylum Porifera; predominately class Desmospongiae), which are supported by horny, but elastic, internal collagenous skeletons of "spongin," some forms of which we use as bath sponges. Sponges are without digestive, excretory, respiratory, endocrine, circulatory, and nervous systems. Embedded in the connective tissue matrices and skeletons are spicules of silicon dioxide (silica) or calcium carbonate ("calcite"), by which some sponges can be definitively identified. In general, sponges are stationary acellular animals that attach to the sea floor or coral beds and may be colonized by other sponges, hydrozoans, mollusks, coelenterates, annelids, crustaceans, echinoderms, fish, and algae. These secondary coelenterate inhabitants are responsible for the dermatitis and local necrotic skin reaction

Figure 61-1 (Figure Not Available) Pacific fire sponge. (Photo by Norbert Wu.)

termed sponge diver's disease (maladie des plongeurs).^[107] In recognition of a medicinal property, the ancient Greeks burnt sea sponges and inhaled the vapors in prophylaxis against goiter.^[31] Sponges harbor various biodynamic substances, with possible antineoplastic, antibacterial, growth-stimulating, antihypertensive, neuropharmacologic, psychopharmacologic, and antifungal properties. A number of sponges produce crinotoxins that may be direct dermal irritants, such as subcritine, halitoxin (*Haliclona* species), p-hydroxybenzaldehyde, and okadaic acid. These may be present in surface or internal secretions. Murine monoclonal antibodies against okadaic acid intended for use in an assay system for the detection of diarrhetic shellfish poisoning have been prepared from the sponge *Halichondria okada*.^[119]

Clinical Aspects.

Two general syndromes, with variations, are induced by contact with sponges. The first is a pruritic dermatitis similar to plant-induced allergic dermatitis, although the dermatopathic agent has not been identified. Rarely, erythema multiforme or an anaphylactoid reaction may be present. A typical offender is the friable Hawaiian (Figure 61-1 (Figure Not Available)) or West Indian fire sponge (*Tedania ignis*), a brilliant yellow-vermilion-orange ([Figure 61-2](#)) or reddish-brown organism with a crumb-of-bread appearance found off the Hawaiian Islands and the Florida Keys.^{[100] [105]} This sponge grows in thick branches, which are easily broken off, extending from a

larger base. Other culprits include *Fibula* (or *Neofibularia*) *nolitangere*, the "poison bun sponge" ([Figure 61-3](#)) (and the related sponge *N. mordens*), and *Microciona prolifera*, the red moss sponge (found in the northeastern United States). ^[61] *F. nolitangere* is found in deeper water and grows in clusters, with holes (oscula) large enough to admit a diver's finger. It is brown ([Figure 61-4](#)) and breadly in texture, so it may crumble in the hands.

Within a few hours, but sometimes within 10 to 20 minutes after skin contact, the reactions are characterized

1453

Figure 61-2 Atlantic fire sponge. (Photo by Dee Scarr.)

by itching and burning, which may progress to local joint swelling, soft tissue edema, vesiculation, and stiffness, particularly if small pieces of broken sponge are retained in the skin near the interphalangeal or metacarpophalangeal joint. Most victims of sponge-induced dermatitis have hand involvement, since they handle sponges without proper gloves. In addition, abraded skin, such as that which has been scraped on stony coral, may allow more rapid or greater absorption of toxin(s). ^[97] When the sponge is penetrated, torn, or crumbled, the skin is exposed to the toxic substances. Untreated, mild reactions subside within 3 to 7 days. ^[50] When large skin areas are involved, the victim may complain of fever, chills, malaise, dizziness, nausea, muscle cramps, and formication. Bullae induced by contact with *Microciona prolifera* may become purulent. Systemic erythema multiforme or an anaphylactoid reaction may develop a week to 14 days after a severe exposure. ^[133] The skin may become mottled or purpuric,

occasionally after a delay of up to 10 days.^[105]

The second syndrome is an irritant dermatitis and follows the penetration of small spicules of silica or calcium carbonate into the skin. Most sponges have spicules; toxic sponges may possess crinotoxins that enter microtraumatic lesions caused by the spicules.

In severe cases, surface desquamation of the skin may follow in 10 days to 2 months. No medical intervention can retard this process. Recurrent eczema and persistent arthralgias are rare complications.

Treatment.

Because distinguishing clinically between the allergic and spicule-induced reactions is usually impossible, it is reasonable to treat for both. The skin should be gently dried. Spicules should be removed, if possible, using adhesive tape, a thin layer of rubber cement, or a facial peel. As soon as possible, dilute (5%) acetic acid (vinegar) soaks for 10 to 30 minutes 3 or 4 times a day should be applied to all affected areas.^{[105] [108] [132]} Isopropyl alcohol 40% to 70% is a reasonable second choice. Although topical steroid preparations may help relieve the secondary inflammation, they are of no value as an initial decontaminant. If they precede the vinegar soak, they may worsen the primary reaction. Delayed primary therapy or inadequate decontamination can result in the persistence of bullae, which may become purulent and require months to heal.

Erythema multiforme may require the administration of a systemic glucocorticoid, beginning with a moderately high dose (prednisone 60 to 100 mg) tapered over 2 to 3 weeks. Anecdotal remedies for the management of sponge envenomation that have been suggested without demonstration of efficacy include antiseptic dressings, broad-spectrum antibiotics, methdilazine, pyribenzamine, phenobarbital, diphenhydramine, promethazine, and topical carbollic oil or zinc oxide cream.^[105]

After the initial decontamination, a mild emollient cream or steroid preparation may be applied to the skin. If the allergic component is severe, particularly if there is weeping, crusting, and vesiculation, a systemic glucocorticoid (prednisone 60 to 100 mg, tapered over 2

weeks) may be beneficial. Severe itching may be controlled with an antihistamine.

Because *Clostridium tetani* has been cultured from sea sponges, they should not be used to pack wounds. Proper antitetanus immunization should be part of sponge dermatitis therapy. Frequent follow-up wound checks are important because significant infections sometimes develop.^[62] Infected wounds should be cultured and managed with antibiotics (see [Chapter 60](#)). If sponge poisoning induces an anaphylactoid reaction, standard resuscitation using epinephrine, bronchodilators, corticosteroids, and

antihistamines should be undertaken.^[133]

As mentioned previously, sponge diver's disease is not caused by any toxin produced by the sponge, but rather is a stinging syndrome related to contact with the tentacles of the small coelenterate anemone *Sagartia rosea* (family Sagartiidae) or anemones from the genus *Actinia* (family Actiniidae) that attach to the base of the sponge. Treatment should include that for coelenterate envenomation.

Prevention.

All divers and net handlers should wear proper gloves. Sponges should not be broken, crumbled, or crushed with bare hands. If the victim brings a specimen, the physician should take care to document its appearance. Dried sponges may remain toxic.

Coelenterates (Cnidaria)

Coelenterates are an enormous group, comprising approximately 10,000 species, at least 100 of which are dangerous to humans. Coelenterates that possess the venom-charged stinging organoids commonly called nematocysts are known as cnidaria (nettle); those without nematocysts are acnidaria. For practical purposes the cnidaria can be divided into three main groups: (1) hydrozoans, such as the Portuguese man-of-war; (2) scyphozoans, such as true jellyfish; and (3) anthozoans, such as soft corals (alcyonarians), stony corals, and anemones. Gorgonians (order Gorgonacea, class Anthozoa, subclass Alcyonaria) secrete mucinous exudates having toxic effects in experimental animals that can be characterized as hemolytic, proteolytic, cholinergic, histaminergic, serotonergic, and adrenergic.^[43] Fenner divides jellyfish into three main classes: scyphozoans (true jellyfish), with tentacles arising at regular intervals around the bell; cubozoans (e.g., "box" jellyfish), with tentacles arising only from the corners—these may be further divided into carybdeids (e.g., Irukandji), with only one tentacle (except in rare cases) arising from each lower corner of the bell, and chirodropids, which have more than one tentacle in each corner of the bell; and other jellyfish, such as the hydrozoans (e.g., *Physalia* species).

Morphology, Venom, and Venom Apparatus.

Coelenterates ("hollow gut") are predators that feed on

Figure 61-5 Nematocyst before discharge.

other fish, crustaceans, and mollusks. They are radially symmetric animals of simple structure (95% water) and exist in two predominant life-forms, either as sedentary, asexual polyps (hydroids) or as free-swimming and sexual medusae.^[57] They are the lowest form of life organized into different layers.^[97] Generally, the polyps are saclike creatures attached to the substrate at the caudal (aboral) end, with a single orifice or mouth at the upper end surrounded by stinging tentacles (dactylozooids). This form predominates in the hydrozoans and anthozoans. The medusa is a bell-shaped creature, with a floating gelatinous umbrella from which hang an elongated tubular mouth and marginal nematocyst-bearing tentacles. This form predominates in the scyphozoans and is also found in the hydrozoans.

Cnidocytes are living cells that encapsulate the nonliving intracytoplasmic stinging organoids called cnidae (which include nematocysts, spirocysts, and ptychocysts). The cnidocytes are located on the outer epithelial surfaces of the tentacles or near the mouth and are triggered by contact with the victim's body surface. The nematocyst is contained within an outer capsule called the cnidoblast, to which is attached a single pointed "trigger," or cnidocil. The nematocyst (3 to 10 μm in diameter) is filled with fluid and contains a hollow, sharply pointed, coiled or folded "thread" tubule (nema) ([Figure 61-5](#)). This tubule may attain lengths of 200 to 850 μm and is sufficiently hardy to penetrate a surgical glove. In the undischarged state, the toxin is located in the folds and invaginations of the tubule's membrane. The tubule is lined with hollow barbs, which help it penetrate and anchor into the victim. In the undischarged state, the barbs occupy the lumen of the twisted and folded tubule. When the cnidocil is stimulated, either by physical contact or by a chemoreceptor mechanism, it causes the opening of a trapdoor (operculum) in the cnidoblast, and the venom-bearing tubule is everted ([Figure 61-6](#)) within 3 microseconds. This exocytosis has been hypothesized to occur because

1455

Figure 61-6 Nematocyst after discharge.

Figure 61-7 Helical arrangement of barbs on the tubule of a nematocyst. (Photo by Amit Lotan.)

of osmotic swelling of the capsular matrix caused by influx of water (leading to a hydrostatic pressure of up to 150 atm), release of intrinsic tensile forces (up to 375 MPa on the inner capsule wall), or deformation of the wall-induced internal pressure. The sharp tip of the thread tube enters the victim's skin and envenomation occurs as toxin is translocated by hydrostatic forces from the surface of the everted and extended tubule through the now helically arranged ([Figure 61-7](#)) and extended hollow barbs.^[66] ^[67] It has been estimated that the velocity of ejection attains 2 m/sec, which corresponds to an acceleration of 40,000 g, with an estimated skin striking force of 2 to 5 psi.^[32] ^[95] A human encounter with a large Portuguese man-of-war could conceivably trigger the release of several million stinging cells. The thread penetrates the epidermis and upper dermis, where the venom diffuses into the general circulation. The agitated victim moves about and assists the venom's distribution by the muscle-pump mechanism. Based on mouse studies, it appears that the rapid death of a victim is related to discharge of venom directly into capillaries, as opposed to that which must diffuse into the bloodstream from the dermis.

In the case of the Indo-Pacific box-jellyfish *Chironex fleckeri*, which may carry up to 59 tentacles bearing millions of nematocysts, it is the cigar-shaped microbasic p-mastigophores that are most important in human envenomation ([Figure 61-8](#)). The capsule of the structure holds a hollow coiled tube and granular matrix. The thread tube has a thick butt end that is attached to the operculum. The tube contains three rows of helically arranged spines. When the nematocyst fires into the human victim, the tube everts through the opercular end of the nematocyst, with the butt anchoring first to keep the nematocyst adherent to the victim. The thread then everts through the hollow butt and uncoils, presenting the spines and accompanying toxins to the living tissue. Although the major toxic fractions appear to be present in the nematocysts, there appears to be toxic material present in tentacles denuded of such organelles.^[14] The largest nematocysts of *C. fleckeri* can penetrate human skin to a depth of 0.9 mm.^[77]

Coelenterate venoms are viscous mixtures of proteins, carbohydrates, and other nonproteinaceous components. To date, they have been difficult to fractionate. Although they are heat labile *in vitro*, this does not seem to apply in the clinical setting. The primary difficulties encountered in jellyfish venom purification are the lack of stability and the tendency of active toxins to adhere to each other and to support matrices.^[86] Cytolytic toxins have been characterized from *Physalia physalis*, *Rhizostoma pulmo*, *Chironex fleckeri*, and *Carybdea marsupialis*.^[96] Many jellyfish and marine animal venoms generate autonomic neurotoxicity.^[25] This may be a result of their ability to affect ion transport (sodium and calcium in particular), induce channels or pores in nerve and muscle cell membranes, alter membrane configurations, and release mediators of inflammation. Coelenterate venoms can target the myocardium, Purkinje fibers, atrioventricular (AV) node, and aortic ring, as well as injure the hepatic P-450 enzyme family.

Clinical Aspects.

For clinical purposes, a considerable phylogenetic relationship exists among all stinging species, so that the clinical features of the coelenterate syndrome are fairly constant, with a spectrum of severity. This is related to the season and species (venom potency

and configuration of the nematocyst), the number of nematocysts triggered and the size of the animal

1456

(venom inoculum), the size and age of the victim (the very young and old and the smaller person tend to be more severely affected), the location and surface area of the sting, and the health of the victim. The wise clinician suspects a coelenterate envenomation in all unexplained cases of collapse in the surf, diving accidents, and near drownings. Any victim in distress pulled from marine waters should be carefully examined for one or more cutaneous lesions that may provide the clue to a coelenterate envenomation.

Mild envenomation may result only in an annoying dermatitis, whereas severe envenomation can progress rapidly to involve virtually every organ system, resulting in significant morbidity and mortality. Clinical envenomation is described here by severity, with the understanding that there is a fair amount of overlap.

MILD ENVENOMATION.

The stings caused by the hydroids and hydroid corals, along with lesser envenomations by *Physalia*, *Velella velella*, *Drymonema dalmatinum* (stinging cauliflower), *Olindias sambaquiensis* (endemic to Blanca Bay area south of Buenos Aires province), scyphozoans, and anemones, result predominantly in skin irritation.^[63] There is usually an immediate pricking or stinging sensation, accompanied by pruritus, paresthesias, burning, throbbing, and radiation of the pain centrally from the extremities to the groin, abdomen, and axillae. The area involved by the nematocysts becomes red-brown-purple, often in a linear whiplike fashion, corresponding to tentacle prints. Other features are blistering, local edema, angioedema, and wheal formation, as well as violaceous petechial hemorrhages. The papular inflammatory skin rash is strictly confined to the areas of contact and may persist for up to 10 days. Areas of body hair appear to be somewhat more protected from contact than hairless areas. If the envenomation is slightly more severe, the aforementioned symptoms, which are evident in the first few hours, can progress over a course of days to local necrosis, skin ulceration, and secondary infection. This is particularly true of certain anemone (*Sagartia*, *Actinia*, *Anemonia*, *Actinodendron*, and *Triactis*) stings. A painless "jellyfish sting," in which there is a pattern of hyperpigmented linear streaks, might represent the

occurrence of phytophotodermatitis (e.g., from citrus juice spilled on skin and later exposed to light).^[13]

1457

Untreated, the minor to moderate skin disorder resolves over 1 to 2 weeks, with occasional residual hyperpigmentation for 1 to 2 months. Rubbing can cause lichenification. Local hyperhidrosis, fat atrophy, and contracture may occur.^[18] Facial swelling with sterile abscess formation has been reported.^[114] Permanent scarring or keloids may result. Persistent papules or plaques at the sites of contact may demonstrate a predominantly mononuclear cell inflammatory infiltrate, which may represent a delayed hypersensitivity response to an antigenic component of the coelenterate nematocyst or venom. This may be accompanied by localized arthritis and joint effusion. It has been suggested that sensitization may occur without a definite history of a previous sting, since coelenterates may release antigenic and allergenic venom components into the water. Granuloma annulare, which is usually both a sporadic and a familial inflammatory dermatosis, has been associated with a *Physalia utriculus* envenomation.^[70] Gangrene has been observed.

MODERATE AND SEVERE ENVENOMATION.

The prime offenders in this group are the anemones, *Physalia* species, and scyphozoans. The skin manifestations are similar or intensified (as with *Chironex*) and are compounded by the onset of systemic symptoms, which may appear immediately or be delayed by several hours:

1. Neurologic: malaise, headache, aphonia, diminished touch and temperature sensation, vertigo, ataxia, spastic or flaccid paralysis, mononeuritis multiplex, Guillain-Barré syndrome, parasympathetic dysautonomia, plexopathy, radial-ulnar median nerve palsies, brainstem infarction (not a confirmed relationship), delirium, loss of consciousness, convulsions, coma, and death^{[27] [37] [78] [89]}
2. Cardiovascular: anaphylaxis, hemolysis, hypotension, small artery spasm, bradyarrhythmias (including electromechanical dissociation and asystole), tachyarrhythmias, vascular spasm, deep venous thrombosis, congestive heart failure, and ventricular fibrillation
3. Respiratory: rhinitis, bronchospasm, laryngeal edema, dyspnea, cyanosis, pulmonary edema, and respiratory failure
4. Musculoskeletal or rheumatologic: abdominal rigidity, diffuse myalgia and muscle cramps, muscle spasm, fat atrophy, arthralgias, reactive arthritis (sero-negative symmetric synovitis with pitting edema),^[122] and thoracolumbar pain
5. Gastrointestinal: nausea, vomiting, diarrhea, dysphagia, hypersalivation, and thirst
6. Ocular: conjunctivitis, chemosis, corneal ulcers, corneal epithelial edema, keratitis, iridocyclitis, elevated intraocular pressure, synechiae, iris depigmentation, chronic unilateral glaucoma, and lacrimation^{[46] [47]}

7. Other: acute renal failure, lymphadenopathy, chills, fever, and nightmares

The extreme example of envenomation occurs with *Chironex fleckeri*, the dreaded box-jellyfish. *Physalia* and anemone stings, although extremely painful, are rarely fatal. Death after *Physalia* stings has been attributed to primary respiratory failure or cardiac arrhythmia, which may have reflected an element of anaphylaxis.^{[21] [109]} Confirmed deaths after coelenterate envenomation have been attributed to *Chironex fleckeri*, *Chiropsalmus quadrigatus*, and *Chiropsalmus quadrumanus*.^[77] *Stomolophus nomurai* (the sand jellyfish) has caused at least eight deaths in the South China Sea.^[33] Although there have been other deaths, the animals have not been definitively identified.

Clinical reports and studies on the serologic response to jellyfish envenomation suggest that allergic reactions may play a significant pathophysiologic role in humans. When crude or partially purified nematocyst venom and an antigen are used in an enzyme-linked immunosorbent assay (ELISA), both IgG and IgE can be detected.^{[44] [98]} Elevated specific anti-jellyfish IgG and IgE may persist for several years, recurrence of the clinical cutaneous reaction to jellyfish stings may occur within a few weeks without additional contact with the tentacles, and serologic cross-reactivity between the sea nettle (*Chrysaora quinquecirrha*) and *Physalia physalis* occurs. In a case of significant envenomation by the moon jellyfish *Aurelia aurita*, the victim developed significant cross-reacting antibodies to *Chrysaora quinquecirrha* antigens.^[20]

Persons with extracutaneous or anaphylactoid responses to a coelenterate sting have been noted to have higher specific IgG and IgE antibody levels.^[98] However, elevated persistent specific anti-jellyfish serum IgG concentrations are not protective against the cutaneous pain resulting from a natural sting.^[23] A false-positive ELISA serologic test to venom may occur, as demonstrated by negative skin testing.

A person recently stung by *Physalia physalis* may have recurrent cutaneous eruptions for 2 to 3 weeks after the initial episode, without repeated exposure to the animal. This may take the form of lichenification, hyperhidrosis, angioedema, vesicles, large bullae, nodules that resemble erythema nodosum, granuloma annulare, or a more classic linear urticarial eruption.^{[5] [22] [71]} Recurrent eruptions have also followed a solitary envenomation by the cnidarian *Stomolophus meleagris*.^[17] In a histologic study of delayed reaction to a Mediterranean Sea coelenterate, skin biopsy demonstrated grouping of human leukocyte antigen-DR-positive cells with Langerhans' cells and helper/inducer T lymphocytes, which indicates the possibility of a type IV immunoreaction.^[90]

Venom-specific IgG antibodies appear to persist for longer periods than IgM antibodies. The binding of brown recluse spider venom and purified cholera toxin

to anti-*Chrysaora* and anti-*Physalia* monoclonal antibodies indicates that there may be a common or cross-reacting antigenic site or sites between these toxic substances and

certain coelenterate venoms.^[85]

Acute regional vascular insufficiency of the upper extremity has been reported after jellyfish envenomation. It can be manifested by acral ischemia, signs and symptoms of compartment syndrome, and massive edema.^[129]

Treatment.

Therapy is directed at stabilizing major systemic decompensation, opposing the venom's multiple effects, and alleviating pain.

SYSTEMIC ENVENOMATION.

Generally, only severe *Physalia* or Cubomedusae stings result in rapid decompensation. In both cases, supportive care is based on the signs and symptoms. Hypotension should be managed with the prompt IV administration of crystalloid, such as lactated Ringer's solution. This must be done in concert with detoxification of any nematocysts (particularly those of *Chironex* or *Chiropsalmus*) that are still attached to the victim, to limit the perpetuation of envenomation. Hypotension is usually limited to very young or elderly victims who suffer severe and multiple stings, the effects of which are worsened by fluid depletion that accompanies protracted vomiting. Hypertension is an occasional side effect of a cubomedusan envenomation, such as that of *Carukia barnesii*.

Excessive catecholamine stimulation is one putative cause, which has prompted clinical intervention with phentolamine, an α -adrenergic blocking agent (5 mg intravenously as an initial dose, followed by an infusion of up to 10 mg/hr). Bronchospasm may be managed as an allergic component. If the victim is in respiratory distress with wheezing, shortness of breath, or heart failure, arterial blood gas measurement may be used to guide supplemental oxygen administration by face mask. Seizures are generally self-limited but should be treated with IV diazepam for 24 to 48 hours, after which time they rarely recur.

Any victim with a systemic component should be observed for a period of at least 6 to 8 hours because rebound phenomena after successful treatment are not uncommon. All elderly victims should undergo electrocardiography and be observed on a cardiac monitor, with frequent checks for arrhythmias. Urinalysis demonstrates the presence or absence of hemoglobinuria, indicating hemolysis after the putative attachment of *Physalia* venom to red blood cell membrane glycoprotein sites.^[49] If this is the case, the urine should be alkalized with bicarbonate to prevent the precipitation of pigment in the renal tubules, while a moderate diuresis (30 to 50 ml/hr) is maintained with a loop diuretic (such as furosemide or bumetanide) or mannitol (0.25 g/kg intravenously every 8 to 12 hours). In rare instances of acute progressive renal failure, peritoneal dialysis or hemodialysis may be necessary.

If there are signs of distal ischemia or an impending compartment syndrome, standard diagnostic and therapeutic measures apply. These include Doppler ultrasound, angiography, or both for diagnosis, regional thrombolysis for acutely occluded blood vessels, measurement of intracompartmental tissue pressures to guide fasciotomy, and so forth. Reversible regional sympathetic blockade may be efficacious if vasospasm is a

dominant clinical feature. However, the vasospasm associated with a jellyfish envenomation may be severe, prolonged, and refractory to regional sympathectomy and intraarterial reserpine or pentoxifylline.^[1]

A small child may pick up tentacle fragments on the beach and place them into his or her mouth, resulting in rapid intraoral swelling and potential airway obstruction, particularly in the presence of exceptional hypersensitivity. In such cases an endotracheal tube should be placed before edema precludes visualization of the vocal cords. In no case should any liquid be placed in the mouth if the airway is not protected. In 1999, a lifeguard in Cairns, Australia, drank from a container containing 4-day-old *Chironex fleckeri* tentacles. He fortunately suffered only a sore throat and transient shortness of breath.

Chironex fleckeri, the box-jellyfish, produces the only coelenterate venom for which a specific antidote exists. To date, the venoms of *Physalia* and *Chrysaora* species have not been sufficiently purified as antigens to permit the production of an antitoxin. Antivenom administration may be lifesaving and should accompany the first-aid protocol previously described.

PAIN CONTROL.

Often the pain can be controlled by treating the dermatitis. However, if pain is excruciating and there is no contraindication (such as head injury, altered mental status, respiratory depression, allergy, or profound hypotension), the administration of a narcotic (morphine sulfate, 2 to 10 mg intravenously; nalbuphine, 2 to 10 mg intravenously; or intramuscularly; meperidine, 50 to 100 mg, with hydroxyzine, 25 to 50 mg intramuscularly; or meperidine, 15 to 30 mg, with promethazine, 12.5 to 25 mg, or prochlorperazine, 2.5 mg intravenously) is often indicated. Severe muscle spasm may respond to 10% calcium gluconate (5 to 10 ml IV slow push), diazepam (5 to 10 mg intravenously), or methocarbamol (1 g, no faster than 100 mg/min through a widely patent IV line).

TREATMENT OF DERMATITIS.

If a person is stung by a coelenterate, the following steps should be taken:

1. Immediately rinse the wound with seawater, not with freshwater. Do not rub the wound with a towel or clothing to remove adherent tentacles. Nonforceful freshwater rinsing or a rubbing variety
-

of abrasion (the latter in the absence of simultaneous application of a decontaminant such as papain or vinegar) is felt to stimulate any nematocysts that have not already fired. Surf life savers (lifeguards) in the United States and Hawaii have reported that a freshwater hot shower applied with a forceful stream may

decrease the pain of an envenomation. If this is successful, one theoretic explanation is that the mechanical effect of the water stream (that dislodges tentacle fragments and/or stinging cells) supercedes the deleterious (sting-stimulating) effect of the hypotonic water. Remove any gross tentacles with forceps or a well-gloved hand. In an emergency, the keratinized palm of the hand is relatively protected, but take care not to become envenomed.

Commercial (chemical) cold or ice packs applied over a thin dry cloth or plastic membrane have been shown to be effective when applied to mild or moderate *Physalia utriculus* ("bluebottle"—see below) stings.^[32] Whether the melt-water from ice applied directly to the skin can stimulate the discharge of nematocysts has not been determined. Applications of hot packs or gentle rinses with hot water are not recommended because they may worsen the pain of the envenomation.

2. Acetic acid 5% (vinegar) is the treatment of choice to inactivate *Chironex fleckeri* toxin. Vinegar will not alleviate the pain from a *Chironex* sting but interrupts the envenomation. It may not be extremely effective against *Chrysaora* or *Cyanea*. The detoxicant should be applied continuously for at least 30 minutes or until the pain is relieved. A sting from the Australian *Physalia physalis*, a relatively recently differentiated species, should not be doused with vinegar, since this may cause discharge of up to 30% of nematocysts.^[36]

For a sting from *Chironex fleckeri*, if the pressure-immobilization technique for venom sequestration is going to be used, the bandage should be applied as soon as possible (see below). If vinegar is immediately available, a liberal dousing should occur and at least 30 seconds should pass before removing the tentacles. After the tentacles are removed, proceed at once with pressure-immobilization. If vinegar is not available, remove the tentacles before applying pressure-immobilization.^[34] A venolymphatic occlusive tourniquet should be considered only if a topical detoxicant and pressure-immobilization is unavailable, the victim suffers from a severe systemic reaction, and transport to definitive care is delayed.

For stings from other species, there are substances that may be more specific and therefore more effective. Depending on the species, these include isopropyl alcohol (40% to 70%), dilute ammonium hydroxide, sodium bicarbonate (particularly for stings of the sea nettle *Chrysaora quinquecirrha*), olive oil, sugar, urine, and papain (papaya latex [juice] or unseasoned meat tenderizer powdered or in solution). The last is supposed to work by cleaving active polypeptides into nontoxic amino acids. Ammonia has been noted to be relatively ineffective for stings of *Carybdea marsupialis* in the Adriatic Sea.^[88]

Perfume, aftershave lotion, and high-proof liquor are not particularly efficacious and may be detrimental. Other substances mentioned to be effective at one time or another, but which are to be condemned on the basis of inefficacy and toxicity, are organic solvents such as formalin, ether, and gasoline.

There is recent evidence that alcohol may stimulate the discharge of nematocysts in vitro; the clinical significance is as yet undetermined. The rescuer must remember that pain relief may not equate with nematocyst inhibition.^[77]

A commercial aqueous solution of aluminum sulfate 20% and 11% anionic surfactant in aqueous solution (Stingose) has sometimes been mentioned as effective on the basis that the aluminum ion interacts with proteins and long-chain polysaccharide components to denature and inactivate venom. Prior treatment with topical alcohol or methylated spirits reduces the effectiveness of aluminum

sulfate solution. This product seems to have fallen out of favor with clinician jellyfish experts in Australia.

3. No systemic drugs (other than antivenom for a *Chironex* envenomation) are of verifiable use. Ephedrine, atropine, calcium, methysergide, and hydrocortisone have all been touted at one time or another, but no proof exists that they help. Antihistamines may be useful if there is a significant allergic component. The administration of epinephrine is appropriate only in the setting of anaphylaxis.
 4. Immersing the area in hot water is generally not recommended; the hypotonic solution causes nematocysts to discharge.
 5. Once the wound has been soaked with a decontaminant (e.g., vinegar), remaining (and often "invisible") nematocysts must be removed. The easiest way to do this is to apply shaving cream or a paste of baking soda, flour, or talc and to shave the area with a razor or similar tool. If sophisticated facilities are not available, the nematocysts should be removed by making a sand or mud paste with seawater and using this to help scrape the victim's skin with a sharp-edged shell or piece of wood. The rescuer must take care not to become envenomed; bare hands must be rinsed frequently.
-

1460

If a scrub brush or pad has been used to treat the envenomation, this step may not result in as much, if any, clinical improvement.

6. A topical anesthetic ointment (lidocaine, 2.5%) or spray (benzocaine, 14%), antihistaminic cream (diphenhydramine or tripeleminamine), or mild steroid lotion (hydrocortisone, 1%) may be soothing. These are used after the toxin is inactivated. Paradoxical reactions to benzocaine are rarely noted.
7. Victims should receive standard antitetanus prophylaxis.
8. Prophylactic antibiotics are not automatically indicated. Each wound should be checked at 3 and 7 days after injury for infection. Any ulcerating lesion should be cleaned 3 times a day and covered with a thin layer of nonsensitizing antiseptic ointment, such as mupirocin. A jellyfish sting to the cornea may cause a foreign body sensation, photophobia, and decreased or hazy vision. Ophthalmologic examination reveals hyperemic sclera, chemosis, and irregularity of the corneal epithelium with stromal edema. Depending on the extent of the wound, the anterior chamber may demonstrate the inflammatory response of iridocyclitis (flare with or without cells).^[131] The victim should be referred to an ophthalmologist, who may prescribe steroid-containing eye medications, such as prednisolone acetate 1% with hyoscine 0.25%. Applying a traditional skin detoxicant directly to the cornea is not recommended, since it is likely to worsen the tissue injury.

DELAYED REACTION.

A delayed reaction, similar in appearance to erythema nodosum, may be noted in areas of skin contact, and be accompanied by fever, weakness, arthralgias, painful joint swelling, and effusions. This may recur multiple times over the course of 1 to 2 months. The treatment is a 10- to 14-day taper of prednisone, starting with 50 to 100 mg. Prednisone administration may need to be prolonged or repeated with each flare of the

reaction.

PERSISTENT HYPERPIGMENTATION.

Postinflammatory hyperpigmentation is common after the stings of many jellyfish and other lesser coelenterates. A solution of 1.8% hydroquinone in a glycol and alcohol base (70% ethyl alcohol and propylene glycol mixed at a 3:2 ratio) twice a day as a topical agent for 3 to 5 weeks has been used successfully to treat hyperpigmentation after a *Pelagia noctiluca* sting.

PERSISTENT CUTANEOUS HYPERSENSITIVITY.

Persistent local dermal hypersensitivity may occur after a jellyfish sting, such as that from the Hawaiian box-jellyfish *Carybdea alata*.^[116] This is characterized by erythematous papulonodular lesions in the pattern of the original sting, which may persist for months. Treatment, which may be unsatisfactory, consists of topical and intralesional steroids.

Prevention.

A protocol has been developed to establish the effectiveness of topical agents to block firing of nematocysts.^[29] Current research is directed at a combination jellyfish sting inhibitor-sunscreen lotion that may prevent discharge of more than 90% of nematocysts that contact protected skin. Failed topical barriers include petrolatum, mineral oil, silicone ointment, cocoa butter, and mechanic's grease.

If jellyfish are sighted, they should be given a wide berth because the tentacles may trail great distances from the body. All swimmers and divers in hazardous areas should be on constant alert. Persons should not dive headfirst into jellyfish-infested waters; it is far safer to walk in. Bathers should wear protective clothing in infested areas. This includes "stinger suits" or a double thickness of panty hose. If "stinger enclosures" are present, bathers should stay within the netted barriers.

Divers concerned about jellyfish tentacles dangling from the surface or congregations of creatures at the surface should remain deeper than 20 feet and should always check snorkel and regulator mouthpieces for tentacle fragments before entering the water in endemic areas. In areas inhabited by anemones and hydroid corals, protective gloves should be worn when handling specimens. Beached dead jellyfish or tentacle fragments washed up after a storm can still inflict serious stings. Any person stung by a jellyfish should leave or be assisted from the water because of the risk of drowning.

The International Consortium for Jellyfish Stings was formed to gather reports and encourage prospective investigations. At the time of this writing, a marine sting or bite report form can be obtained from Joseph W. Burnett, M.D., Department of Dermatology, 6th Floor, University of Maryland Hospital, 405 West Redwood Street, Baltimore, MD 21201-1703.

Hydrozoa.

The hydrozoans range in configuration from the feather hydroids and sedentary *Millepora* hydroid coral to the free-floating siphonophore *Physalia* (Portuguese man-of-war). These are perfect examples of the class Hydrozoa.

HYDROIDS.

Hydroids are the most numerous of the hydrozoans. The feather hydroids of the order Leptomedusae, typified by *Lytocarpus philippinus* ("fire weed" or "fire fern"), are featherlike or plumelike ([Figure 61-9](#)) animals that sting the victim who brushes against or handles them. ^[93] After a storm the branches may be fragmented and dispersed through the water, so that merely diving or swimming in the vicinity

1461

Figure 61-9 Coelenterate hydroid. (Photo by Paul Auerbach, MD.)

Figure 61-10 (Figure Not Available) Hydroid sting on the arm of a diver. (Photo by Neville Coleman.)

causes itching and burning and may induce visible skin irritation.

Clinical aspects.

Contact with the nematocysts of a feather hydroid induces a mild reaction, which consists of instantaneous burning, itching, and urticaria. If the exposure is brief, the skin rash may not be noticeable or it may consist of a faint erythematous and miliary irritation (Figure 61-10 (Figure Not Available)). A second variety of envenomation consists of a delayed papular, hemorrhagic, or zosteriform reaction ([Figure 61-11](#)) with onset 4 to 12 hours after contact. Rarely, erythema multiforme or a desquamative eruption may develop. In turbulent waters or in a strong current, fragments may be washed into a diver's mask or regulator mouthpiece; this will be evident as a burning sensation in the conjunctivae or oral mucous membranes. Systemic manifestations (such as abdominal pain, nausea, vomiting, diarrhea, muscle cramps, and fever) are rarely reported and are associated with large areas of surface involvement. Allergic sensitization and subsequent anaphylaxis have been proposed.

Figure 61-11 Fernlike hydroid "print" on the knee of a diver. (Photo by Paul Auerbach, MD.)

Treatment.

The skin should be rinsed with seawater and gently dried without abrasive activity. Application of freshwater and brisk rubbing are strictly prohibited because they encourage any nematocysts remaining on the skin to discharge and thus worsen the envenomation. Acetic acid 5% (vinegar) or isopropyl alcohol 40% to 70% has been traditionally recommended for application to the skin for 15 to 30 minutes to relieve the cutaneous reaction. In an in vitro evaluation, vinegar and urine caused discharge of a few nematocysts in 10% to 15% of defensive tentacle polyps; methylated spirits were found to cause gross discharge of microbasic mastigophores in all defensive polyps.^[93] Freshwater did not cause discharge. On the basis of this study the authors recommended that freshwater irrigation and the application of ice be used to treat acute stings. However, the clinical correlation remains to be described.

Alternative topical agents are discussed in the larger discussion on therapy for coelenterate stings. After pain relief is achieved, a mild steroid cream (hydrocortisone 1%) or moisturizing lotion may be applied.

FIRE CORAL.

The stony, hydroid, and coral-like *Millepora* species (for example, *M. alcicornis*), or fire corals, are not true corals. They are widely distributed in shallow tropical waters. Sessile creatures, they are found attached to the bottom in depths of up to 1000 m (3281 feet). They are often mistaken for seaweed because they attach to pilings, rocks, shells, or coral. Although smaller segments resemble Christmas trees or bushes 3 to 4 inches in height, they may attain heights of 2 m. The color ranges from white to yellow-green, with pale yellow ([Figure 61-12](#)) most common. Rare purple fire corals exist. Fire coral is structured on a razor-sharp lime carbonate exoskeleton, which is an important component in the development of coral reefs. The outcroppings assume upright, clavate, bladelike, honeycomb, or branching calcareous growth structures that form encrustations over coral and objects such as sunken vessels.

Figure 61-12 Fire coral. (Photo by Paul Auerbach, MD.)

Figure 61-13 Fire coral sting of the author. (Photo by Kenneth Kizer, MD.)

From numerous minute surface gastropores protrude tiny nematocyst-bearing tentacles, wherein lies the stinging apparatus. *M. alcicornis* probably accounts for more coelenterate envenomations than any other species. Unprotected and unwary recreational scuba enthusiasts handle, kneel, or lean on this marine stinger.

Clinical aspects.

Immediately after contact with fire coral, the victim suffers burning or stinging pain, rarely with central radiation. Intense and painful pruritus follows within seconds, which frequently induces the victim to rub the affected area vigorously, worsening the envenomation. Over the course of 5 to 30 minutes, urticarial wheals develop, marked by redness, warmth, and pruritus ([Figure 61-13](#)). The wheals become moderately edematous and reach a maximum size in 30 to 60 minutes. Untreated, they flatten over 14 to 24 hours and resolve entirely over 3 to 7 days, occasionally leaving an area of hyperpigmentation ([Figure 61-14](#)) that

Figure 61-14 Hyperpigmentation of forearm depicted in [Figure 61-13](#) following a fire coral sting. (Photo by Kenneth Kizer, MD.)

may require 4 to 8 weeks to disappear. The pain generally resolves without treatment in 30 to 90 minutes. In the case of multiple stings, regional lymph nodes may become inflamed and painful. This does not necessarily indicate a secondary infection. Long thoracic mononeuritis with serratus anterior muscle paralysis has been described after *Millepora* sting, confirmed by demonstrated presence of immune-specific IgG.^[79]

Treatment.

The skin should be rinsed liberally with seawater and then immediately soaked with

acetic acid 5% (vinegar) or isopropyl alcohol 40% to 70% until pain is relieved. Alternative topical agents are discussed in the larger coelenterate treatment section. Residual dermatitis is generally not very severe and can be managed in a fashion similar to that after a feather hydroid sting. If the rash becomes eczematous and indolent, it may respond to a course of systemic corticosteroids (prednisone 60 to 100 mg, tapered over 2 weeks). Divers should avoid touching with bare skin anything resembling coral. For instance, the underwater statue of Jesus at John Pennycamp Park in Key Largo, Florida, is encrusted with fire coral, so posing divers have been envenomed.

PHYSALIA (MAN-OF-WAR).

The Atlantic Portuguese man-of-war (*Physalia physalis*) of the phylum Coelenterata, order Siphonophora, is a pelagic (open sea) polymorphic colonial siphonophore that inhabits the surface of the ocean. It is constructed of a blue or pink-violet and iridescent floating sail (pneumatophore), nitrogen and carbon monoxide filled and up to 30 cm in length, from which are suspended multiple nematocyst-bearing tentacles, which may measure up to 30 m (98 feet) in length (Figure 61-15 (Figure Not Available)). It has recently been reported that an Australian version of *Physalia physalis* is present in north Australian waters.^[36] This jellyfish

1463

Figure 61-15 (Figure Not Available) Atlantic Portuguese man-of-war. (Photo by Norbert Wu.)

is characterized by float lengths of up to 15 cm, up to five thick dark blue "main" tentacles, and up to 10 other long, thin, and pale-colored tentacles. The smaller Pacific bluebottle (*Physalia utriculus*) usually has a single fishing tentacle, which attains lengths of up to 15 m. In some species the sail can be deflated to allow the animal to submerge in rough weather.

The physaliae depend on the winds, currents, and tides for movement, traveling as individuals or in floating colonies that resemble flotillas. They are widely distributed but seem to abound in tropical waters and in the semitropical Atlantic Ocean, particularly off the coast of Florida and in the Gulf of Mexico. Envenoming has been reported as far south as the coast of Brazil.^[29] Their arrival at surf's edge can transform a halcyon vacation into a stinging nightmare. Unfortunately, peak appearance time for both the man-of-war and sea nettle is July through September, which is prime beach season.

As with icebergs, the scene above water conceals much of the story. Because the tentacles are nearly transparent, they pose a hazard to the unwary. As the animal moves in the ocean, the tentacles rhythmically contract, sampling the water for potential prey. If the tentacle strikes a foreign object, the nematocysts are stimulated and discharge their contents into the victim. Each tentacle in a larger specimen may carry more than 750,000 nematocysts. To increase the intensity of the "attack," the remainder of the tentacle shortens in such a way as to create loops and folds, presenting a greater

surface

Figure 61-16 Tentacles of the Atlantic Portuguese man-of-war. Nematocysts may number in the hundreds of thousands on tentacles coiled into "stinging batteries." (Courtesy Larry Madin, Woods Hole Oceanographic Institution.)

Figure 61-17 Pacific man-of-war washed ashore may retain their stinging potency for weeks. (Courtesy John Williamson, MD.)

area and number of nematocysts for offensive action in what are called "stinging batteries" ([Figure 61-16](#)).

Detached moistened tentacles, often found by the thousands fragmented on the beach, carry live nematocysts capable of discharging for months. Air-dried nematocysts may retain considerable potency, even after weeks ([Figure 61-17](#)). The loggerhead turtle (*Caretta caretta*) ([Figure 61-18](#)) feeds on *Physalia*. Like the clown-fish with the sea anemone, the brightly colored fish *Nomeus gronovii* has a unique symbiotic relationship with the man-of-war, living freely among the tentacles. Two species of nudibranch (sea slug), *Glaucus atlanticus* and *G. glaucilla*, eat the tentacles and nematocysts of *P. physalis*. The nematocysts are not digested and ultimately reside in the dorsal papillae of the nudibranchs, where they may sting on contact. Other nudibranchs are also able to ingest hydroids and store their stinging cells in the cerata, or flesh appendages. Dermatitis can also result from contact with water containing venom that has already been released from stimulated nematocysts.

1464

The Mediterranean octopus *Tremoctopus violaceus* stores intact dactylozoid

segments in its suckers for later use.^[22]

GONIONEMUS SPECIES.

These small hydrozoans are distributed worldwide but have only been reported as causing severe envenomation in the Sea of Japan near Vladivostock, Russia, and the northwest shores of Honshu Island, Japan.^[33] It is a small creature of 5 to 15 mm in diameter across the bell, with a symmetric, right-angled cross visible in the transparent part.

When the reaction is painful, the victim suffers muscle, joint, chest, and pelvic pain for up to 3 days. There may be muscle fasciculations. In a respiratory presentation, the victims suffer rhinitis, tearing, hoarseness, cough, and shortness of breath. In addition, there may be a combination of symptoms, with or without sore throat, tachycardia, vomiting, and mild hypertension. Psychiatric depression and hallucinations may occur.^[33]

It has been noted that envenomation may occur beneath a bathing suit. In addition, a similar syndrome was reported after ingestion of raw seaweed, to which was presumably attached the jellyfish.^[33]

Seabather's Eruption.

Seabather's eruption, commonly termed "sea lice" ("pika-pika" around the Belize barrier reef; "sea poisoning," "sea critters," and "ocean itch" are other names), refers to a dermatitis that results from contact with ocean water.^[57] It has become a seasonal problem afflicting oceangoers in south Florida and across the Caribbean. It predominantly involves covered areas of the body and is commonly caused by pinhead-sized (0.5 mm) greenish-brown to black larvae of the thimble jellyfish *Linuche unguiculata* ([Figure 61-19](#)), which breeds in Caribbean waters throughout the summer with a peak in May.^[118] *L. unguiculata* exists in three other forms during its life cycle: schyphistomae (polyp), ephyra (first swimming stage), and adult medusa. It is likely that the

Figure 61-19 Mature *Linuche unguiculata*, the causative agents of seabather's eruption. The planula or larvae of these coelenterates were collected from plankton tows and grown to maturity at the University of Miami Marine school. Slightly smaller than their brethren found in the open ocean, these specimens are approximately 2 cm in diameter when open and 1 cm when contracted. (Courtesy David Taplin and Terri L. Meinking.)

Figure 61-20 Seabather's eruption. (From Wong DE et al: *J Am Acad Dermatol* 30:399, 1994.)

adult and ephyra *L. unguiculata* can also initiate the eruption.^[91] Another culprit off Long Island, New York, has been the planula larval form (visible at 2 to 3 mm) of the sea anemone *Edwardsiella lineata*, which carries hundreds of nematocysts.^[38]^[39] Given the number of coelenterates that inhabit the oceans of the world and the cross-reactivity of antigens, it is likely that etiologic organisms are numerous.

A swimmer who encounters the stinging forms usually complains of cutaneous discomfort soon after contact, often while in the water or soon after exiting. Application of fresh water may intensify the sting. The eruption occurs a few minutes to 12 hours after bathing and consists of erythematous and intensely pruritic wheals, vesicles, or papules that persist for 2 to 14 days and then involute spontaneously. When a bathing suit has been worn by a woman, the areas commonly involved include the buttocks, genital region, and breasts ([Figure 61-20](#)). A person at the water's surface (commonly

1465

Figure 61-21 Seabather's eruption on the neck of a diver in Cozumel, Mexico. (Photo by Paul Auerbach, MD.)

a person who surfaces after a dive) may suffer stings to the exposed neck ([Figure 61-21](#)), particularly if there has been recent motorboat activity in the vicinity, which may disturb and fragment the causative jellyfish. Nematocysts adherent to scalp hair may sting the neck as the hair hangs down. Coalescence indicates a large inoculum. Individual lesions resemble insect bites. Surfers develop lesions on areas that contact the surfboard (chest and anterior abdomen). The rash may also be seen under bathing caps and swim fins or along the edge of the cuffs of wet suits, T-shirts, or "stinger suits" ([Figure 61-22](#)).^[118] In children with extensive eruptions, fever is common. Other symptoms can include headache, chills, fatigue and malaise, vomiting, conjunctivitis, and urethritis. Itching is often pronounced at night and awakens the victim from sleep. Burnett and Burnett^[12] reported blurred vision and left arm weakness in a teenager stung by adult *Linuche*. Persons who note a stinging sensation during the primary contact while still in the water may have a higher incidence of previous sensitization to the

antigen or antigens. Persons who wear clothing that has been contaminated with the larvae may suffer recurrent reactions. Prior sensitization may precede prolonged (up to 6 weeks) reactions (rash and pruritus).

Elevated IgG levels specific for *Linuche unguiculata* can be measured by ELISA in the sera of victims who have suffered from seabather's eruption. The extent of the cutaneous eruption or sting severity appears to correlate with the antibody titer.^[24] In an evaluation of

Figure 61-22 Seabather's eruption in an area under the weight belt. (Courtesy Doug Wong, MD.)

southeast Florida victims envenomed by *L. unguiculata*, histopathologic examination of inflammatory papules demonstrated superficial and deep perivascular and intersitial infiltrate consisting of lymphocytes, neutrophils, and eosinophils.^[130]

Field management is identical to that for any coelenterate sting (see above), with the empirical observation that topical papain may be more effective as an initial decontaminant than vinegar, isopropyl alcohol, or other substances. This may be more effective if applied with a mildly abrasive scrub pad. On the basis of anecdotal reports, this approach appears to be effective field therapy for seabather's eruption. Whether the pain relief is due to nematocyst inactivation or counterirritation is not yet known. Substances that are believed to be ineffective include hydrogen peroxide, garlic, antifungal spray, anti-head lice medication, petroleum distillates, fingernail polish, and citrus juice.

The skin eruption is self-limited and usually remits within 10 days. However, in a severe envenomation, the rash may persist for up to 4 weeks and leave atrophic scars.^[69] Further treatment is palliative and consists of calamine lotion with 1% menthol. Because the lesions rarely extend into the dermis, a potent topical corticosteroid may be helpful in mild cases, but benefit is not invariably attained. In a more severe case, an oral or parenteral antihistamine or systemic corticosteroid may be used. A thorough soap and water scrub (not a casual rinse) on leaving the water provides partial prophylaxis. Avoidance logically includes advice to ocean bathe in abbreviated swimwear (which may expose a person to other stings), to maintain tightly occlusive cuffs on dive skins and wet suits, to change swimwear as soon as possible after leaving the water, and to use caution during high season for *L. unguiculata* (April to July off south Florida) or *E. lineata* (August to November off Long Island) and when there are strong onshore winds. Swimwear worn and suspected to be contaminated with nematocysts should be washed in detergent and freshwater and dried before wearing.^[100]

As mentioned previously, current research is directed at a specific topical jellyfish sting

inhibitor. The

1466

first such product to be commercialized is Safe Sea ("jellyfish safe sun block") by Nidaria Technology Ltd, Jordan Valley, Israel. DermaShield (Benchmark Enterprises, Salt Lake City, Utah) is a barrier topical formulation that contains lanolin, aloe vera, and vitamin E. According to the manufacturer, this chemically inert (1-vinyl-2-pyrrolidione) protectant is hydrophobic (dimethicone and stearic acid) and does not wash off but is shed as the epithelium sloughs naturally. It has been reported anecdotally by ocean bathers to protect against the agents of seabather's eruption. To my knowledge, no prospective evaluation of the use of DermaShield to protect against any coelenterate stings has been published. Smerbeck et al were assigned a U.S. Patent in 1999 for a method and composition containing polymeric quaternary ammonium salts for protecting the skin from jellyfish stings.

True sea lice (see [Chapter 63](#)) are parasites on marine creatures and do not cause this disorder.

Scyphozoa.

This group of animals comprises the larger medusae or jellyfish, including the deadly box-jellyfish and sea wasps (e.g., *Chironex*, *Cyanea*, and *Chiropsalmus*). These creatures are armed with some of the most potent venoms in existence. Jellyfish are mostly free-swimming pelagic creatures; however, some can be found at depths of more than 2000 fathoms. They may be transparent or multicolored and range in size from a few millimeters to more than 2 m (6 ½ feet) in width across the bell, with tentacles up to 40 m (131 feet) in length. Like physaliae, the scyphozoans depend on the wind, currents, and tides for transport and are widely distributed. Some vertical motion may be produced by rhythmic contractions of the gelatinous bell, from which originate the feeding tentacles.

Some jellyfish contain less than 5% solid organic matter. Regardless, they can withstand remarkable temperature and salinity variations, although they do not fare well with violent activity and thus may descend to the depths during stormy surface weather. Some scyphozoans avoid sunlight; others follow an opposite pattern. Certain jellyfish have adapted to local nutrient (largely algal) supply and lost their ability to sting humans (Figure 61-23 (Figure Not Available)).

In the eastern coastal waters of the North American continent, the creatures appear to grow larger as they progress north ([Figure 61-24](#)), so that true giant jellyfish, typified by *Cyanea capillata* (lion's mane), are found in arctic waters (Figure 61-25 (Figure Not Available)). Tentacles (which may number up to 1200) of larger specimens may exceed 30 m (100 feet) in length.^[22] *Pelagia* species (purple-striped or "mauve"-pink stingers) are commonly found in large numbers off the California coast and appear in the Mediterranean Sea in abundance every 10 to 12 years.^[92] *P. noctiluca* ([Figure 61-26](#))

phosphoresces at

Figure 61-23 (Figure Not Available) The author snorkels in "Jellyfish Lake" in Palau. The jellyfish have evolved to subsist on algae and thus no longer pose a stinging hazard to humans. (Photo by Avi Klapfer.)

Figure 61-24 Lion's mane jellyfish (*Cyanea capillata*). (Photo by Carl Roessler.)

night, hence its name.^[77] *Olindias sambaquiensis* is a jellyfish that stings bathers in South American coastal waters. *Rhopilema nomadica* is a tropical jellyfish that has invaded the eastern Mediterranean.^{[34] [65] [66]} As a further example, stings from *Stomolophus nomurai* in the Bohai waters of China produce severe pulmonary edema, coma, convulsions, psychoses, and death. Australian jellyfish include the blubber jellyfish (*Catostylus* species), hair jellyfish (*Cyanea* species), little mauve stinger (*Pelagia noctiluca*), and the cuboid-shaped jellyfish (*Chironex fleckeri* and *Chiropsalmus quadrigatus*). A

1467

Figure 61-25 (Figure Not Available) Lion's mane jellyfish (*Cyanea capillata*) can reach 3 m (10 feet) in diameter in Arctic waters. (Photo by Norbert Wu.)

Figure 61-26 Mauve stinger (*Pelagia noctiluca*). (Courtesy Larry Madin, Woods Hole Oceanographic Institution.)

number of cubomedusan ("box-shaped jellyfish") scyphozoans of highly toxic nature inhabit Indo-Pacific and, less frequently, Caribbean waters. These include *Carybdea rastoni* (jimble) and *C. marsupialis* (sea wasp), *Chiropsalmus quadrumanus* (box-jellyfish or sea wasp), *C. quadrigatus* (sea wasp), and *Chironex fleckeri* (box-jellyfish). The

Figure 61-27 Box-jellyfish (*Chironex fleckeri*), swimming just beneath the surface of the water. (Courtesy John Williamson, MD.)

"carybdeids" of order Carybdeidea have four tentacles only, whereas the "chirodropids" of order Chirodropidea may have up to 60 tentacles. All are frequently called "box-jellyfish."

CHIRONEX (BOX-JELLYFISH).

The dreaded chirodropid box-jellyfish (*Chironex fleckeri* Southcott), often misnamed the "sea wasp," is the most venomous sea creature and can induce death in less than 60 seconds with its potent sting. Like all other scyphozoans, it is a carnivore, adapted to deal rapidly with prey. It is a member of the group of Cubomedusae jellyfish and ranges in size from 2 to 30 cm across the bell. Although these creatures seem to prefer quiet, protected, and shallow areas, chiefly in the waters off northern Queensland, Australia, they can be found in the open ocean. A seasonal alternation of polypoid and medusoid generations from winter to summer, respectively, appears to account for the shift in preferred habitat from tidal estuaries to the open eulittoral zone.^[52] The "stinger season" in the Northern Territory of Australia is from October 1 to May 31.^[28] Its presence precludes swimming and bathing in littoral and estuarine waters of Indonesia, Malaysia, and Northern Australia during this season, which coincides with the hottest tropical months in the southern hemisphere.^[87] *Chironex* are fragile and photosensitive and thus are found submerged in bright sunlight ([Figure 61-27](#)), seeking the surface in the early morning, afternoon, and evening. They are swift and graceful travelers, capable of sailing along at a steady 2 knots.

An adult *Chironex* carries up to 15 broad tentacles ([Figure 61-28](#)) in each corner of its bell (up to 60 tentacles total, each with a length of up to 3 m [10 feet]) and has enough venom (in excess of 10 ml) to kill three adults.^[110] Two fractions have been isolated from the venom: a "lethal" fraction of molecular weight 150,000, and a lethal-hemolytic-dermatonecrotic fraction of molecular weight 79,000. At least 72 fatalities have been verified in Australian and Southeast Asian waters, with greater numbers probably lacking official documentation. Thus the box-jellyfish is a much greater true hazard than the more fearsome shark. Other jellyfish, such as *Carybdea rastoni* and *Pelagia noctiluca*, infrequently cause severe prolonged reactions and have rarely been reported to lead to death but are capable of causing dramatic immediate reactions. Sudden death in a child has followed envenomation by *Chiropsalmus quadrumanus* in the Gulf of Mexico at Crystal Beach, Texas.^[10] Death was attributed to

acute arrhythmia after a catecholamine surge, followed by cardiogenic shock and pulmonary edema.

Clinical aspects.

The extreme example of envenomation occurs with the chirodropid *Chironex* ("the assassin's hand") *fleckeri* (after Dr. Hugo Flecker).^[87] Death is attributed to hypotension, profound muscle spasm, muscular and respiratory paralysis, and subsequent cardiac arrest. The overall mortality after box-jellyfish stings may approach 15% to 20% in selected locales. Most

Figure 61-28 Close-up of the tentacle mass of an adult box-jellyfish (*Chironex fleckeri*). (Courtesy Bob Hartwick.)

commonly, bathers are stung, frequently aboriginal children in shallow and remote coastal waters who do not recognize the small, semitransparent, and submerged creature, which may approach as a member of a small armada. Most stings are minor; severe reactions or death follows skin contact with tentacles longer than 6 or 7 m (20 to 23 feet), although 10 cm of tentacle is capable of delivering a lethal dose of venom.^[87]^[111] The sting is immediately excruciatingly painful, and the victim usually struggles purposefully for only a minute or two before collapse. The toxic skin reaction may be intense, with rapid formation of wheals, vesicles, and a darkened reddish brown or purple whiplike flare pattern with stripes 8 to 10 mm in width ([Figure 61-29](#)). With major stings, skin blistering occurs within 6 hours, with superficial necrosis in 12 to 18 hours ([Figure 61-30](#)). The skin defect(s) that result from a severe envenomation can be profound ([Figure 61-31](#)). On occasion a pathognomonic "frosted" appearance with a transverse cross-hatched pattern may be present ([Figure 61-32](#)). More severe reactions and increased mortality in women and small children have been attributed to greater hairless body surface area and smaller body mass.

Figure 61-29 Intense necrosis (here at 48 hours) is typical of a severe box-jellyfish (*Chironex fleckeri*) sting. **A**, Involvement of nearly an entire limb. **B**, Skin darkening can be rapid with

cellular death. (A and B courtesy John Williamson, M.D.)

Figure 61-31 Skin destruction 3 weeks after an untreated box-jellyfish (*Chironex fleckeri*) envenomation. (Courtesy John Williamson, MD.)

Treatment. In the case of a known or suspected box-jellyfish envenomation, the victim must be assessed rapidly for adequacy of breathing and supported with an airway and artificial ventilation if necessary. The victim should be moved as little as possible. It is essential to immediately and liberally flood the skin surrounding any adherent tentacles with acetic acid 5% (vinegar) before any attempt is made to remove them; this paralyzes the nematocysts and avoids worsening the envenomation ([Figure 61-33](#)). Significant pain relief should not be expected from this maneuver. Although most nematocysts cannot penetrate the thickened skin of the human palm, the rescuer should pay particular attention to his or her own skin protection. If acetic acid is not available, aluminum sulfate surfactant (Stingose) may be used in substitution, although its efficacy has not been well demonstrated for a *Chironex* envenomation. A number of experts recommend that isopropyl alcohol not be used as a topical decontaminant for a box-jellyfish envenomation, based on in vitro observations of inefficacy

Figure 61-32 Frosted cross-hatched pattern pathognomonic for a box-jellyfish envenomation. **A**, The victim of this sting expired rapidly. **B**, The enhanced "frosted" appearance is a result of application of a spray of aluminum sulphate. (A and B courtesy John Williamson, MD.)

and nematocyst discharge after application of this detoxicant.^{[53] [111]}

The pressure-immobilization bandaging technique (see [Figure 39-2](#)) can be used to prevent the absorption of *Chironex* venom and is applied after vinegar has been used to inactivate the nematocysts.^{[110] [126]} Pressure-immobilization is applied by taking a cloth or gauze pad of approximate dimensions 6 to 8 cm by 6 to 8 cm by 2 to 3 cm (thickness) and placing it directly over the bite. The pad is then held firmly in place by a circumferential bandage 15 to 18 cm wide applied at lymphatic-venous occlusive pressure (40 to 70 mm Hg for the upper extremity; 55 to 70 mm Hg for the lower extremity).^[127] If the pad is not available, the wrap is applied without it. The arterial circulation should not be occluded, as determined by the detection of arterial pulsations and proper capillary refill. One hypothesis holds that the pressure-immobilization technique devascularizes the area immediately below the pad and prevents the distribution of venom into the general circulation.^[5] After the wrap is applied, the limb should be splinted to prevent motion. The bandage should be released after the victim has been brought to proper medical attention and the rescuer is prepared to provide systemic support. It should be noted that pressure-immobilization is not uniformly recommended throughout

1470

Figure 61-33 Surf lifesavers pour vinegar on the leg of a simulated box-jellyfish envenomation. Note how they restrain the victim's arms to prevent him from handling the harmful tentacles. (Courtesy John Williamson, MD.)

Australia, since some have questioned its efficacy and have noted the fact that large affected skin surfaces cannot be effectively bandaged.

In the absence of the ability to apply a pressure-immobilization bandage, a rescuer might apply a constriction bandage proximal to the site of an extremity sting, to impede lymphatic and superficial venous return. Such a bandage should be loosened for 90 seconds every 10 minutes and should be completely removed after 1 hour. In no case should an arterial tourniquet be applied. Use of a proximal constriction band has not been proven to be helpful.

Chironex antivenom should be administered intravenously as soon as possible. The intramuscular route is less preferred. The antivenom is supplied in ampoules of 20,000 units by CSL ([Figure 61-34](#)). The initial dose is one ampoule (diluted 1:5 to 1:10 in isotonic crystalloid; dilution with water is not recommended) administered intravenously over 5 minutes, or three ampoules intramuscularly. This has been administered

successfully over the years by members of the Queensland Surf Life-Saving Association and the Queensland Ambulance Transport Brigade. Although the antivenom

Figure 61-34 Box-jellyfish antivenom. (Courtesy John Williamson, MD.)

is prepared by hyperimmunizing sheep and adverse reactions reported to date have been rare and mild, the prudent physician is always prepared to treat anaphylaxis or serum sickness.^[28] It cannot be overemphasized that the timely administration of antivenom can be lifesaving.^[125] In addition to its lifesaving properties, the early administration of antivenom may markedly reduce pain and decrease subsequent skin scarring.^[128] Antivenom administration may be repeated once or twice every 2 to 4 hours until there is no further worsening of the skin discoloration, pain, or systemic effects. A large sting in an adult may require the initial administration of up to three ampoules IV. The antivenom may also be used to neutralize the effects of a *Chiropsalmus* envenomation.^[110] The antivenom should be stored in a refrigerator at 2° to 10° C (35.6° to 50° F) and must not be frozen.^[22] The concomitant administration of a glucocorticoid (such as hydrocortisone 200 mg intravenously) is often recommended for its antiinflammatory activity but is no substitute for the administration of antivenom.

Even with successful treatment, skin irritation may persist for months, marked by discolored striae, intermittent

1471

desquamation, and pruritus. Burnett and Calton^[16] discovered that verapamil can prolong the life of mice challenged with box-jellyfish, sea nettle, or Portuguese man-of-war venom. It was considered to be inactive or deleterious in anaesthetized laboratory pigs envenomed with box-jellyfish venom.^[117] To date, extrapolation of these data to the human condition is as yet untested. Although there is logic to using verapamil from a theoretic pharmacologic perspective (venom affects calcium influx through voltage-dependent channels), the suitability of using verapamil as an adjunct to therapy in humans has been questioned because of the perceived problem of administering a hypotensive agent during an episode of cardiac decompensation.^[55] Further information and opinions about the use of verapamil will undoubtedly be forthcoming.

IRUKANDJI.

Carukia barnesii, the carybdeid jellyfish known as "Irukandji," is a small (1 to 2.5 cm across the bell) translucent jellyfish with four thin nematocyst-covered tentacles (2.5 to 4.5 cm in length at rest, and up to 65 cm extended) found off the coast of northern Australia in both inshore and open waters.^[8] ^[106] Most stings occur near shore and during the afternoon.^[3] ^[87] Because the jellyfish tend to aggregate, victims often present in clusters. After causing a severe immediate skin reaction characterized by pain and erythema without wheal formation, the venom may induce muscle pain and spasm, back pain, abdominal pain, parasympathetic dysautonomia, respiratory difficulty, headache, nausea, and vomiting, which progress to profound weakness and collapse.^[40] Localized piloerection and sweating have been reported. Generally the discomfort remits in 6 to 24 hours; however, it occasionally recurs. The "Irukandji syndrome" presupposes massive catecholamine release, with abdominal and chest pain, vomiting, diaphoresis, hypertension (diastolic blood pressure to 140 mm Hg), tachycardia, severe pulmonary edema, and hypokinetic heart failure.^[35] ^[72] This resembles what might be seen with a pheochromocytoma. Papilledema and coma in a child have been described. Although the systemic syndrome can be quite distinctive, there can be minimal cutaneous signs of envenomation.^[50] To date, death has not been reported. It is interesting to note that many Irukandji-like stings occur inside "stinger enclosures" (bathing nets) designed to exclude *Chironex fleckeri*. Other carybdeid medusae that envenom with lesser severity include the jimble (*Carybdea rastoni*) and fire jelly (*Tamoya haplonema*). The morbakka is a stinging creature that resembles the Irukandji but is larger. The bell, which measures up to 16 by 12 cm, is covered with clumps of nematocysts and may be as dangerous to handle as the meter-long tentacles. This animal may have been previously misidentified as *Tamoya*.

CHRYSAORA (SEA NETTLE).

Sea nettles (such as *Chrysaora quinquecirrha* and *Cyanea capillata*) are considerably less lethal animals and can be found in both temperate and tropical waters, particularly in Chesapeake Bay, where they are found in seasonal "plague" proportions.^[77] Not as dangerous as the Indo-Pacific box-jellyfish, they are still capable of inducing a moderately severe sting. *Chrysaora quinquecirrha* and similar species carry a proteinaceous venom that contains at least seven enzymes, with at least one antigenic and thermolabile component that is cardiotoxic, neurotoxic, and dermatonecrotic. The venom also contains histamine, histamine releasers, prostaglandins, serotonin, and kininlike factors; the last mentioned have also been found in venoms of *Chironex fleckeri* and *Physalia physalis*.^[14] Large intradermal injections of crude sea nettle venom in normal saline produced immunosuppression (T cells) for several days, which was homologous against the same coelenterate antigen and heterologous against antigens contained within vaccinia and herpes simplex viruses and tetanus bacillus.^[120]

Clinical aspects.

The clinical presentation of a sea nettle envenomation is similar to that of *Physalia* species, with perhaps a greater incidence of systemic complications. Death is exceedingly rare. Elevated levels of serum anti-sea nettle venom IgM, IgG, and IgE may persist for years in victims who suffer exaggerated reactions to *Chrysaora quinquecirrha*

stings. These antibodies cross-react with *Physalia* venom and have been postulated to be of value in identifying victims at risk for a severe reaction.^[15] Currently this technique is not widely available or frequently used, and its reliability and reproducibility require further verification.

The reaction after a sting by the blubber jellyfish (*Catostylus* species) is relatively mild, with the formation of wheals, erythema, and pruritus limited to the areas of contact. Systemic effects are exceedingly rare. *Cyanea* species carry long thin tentacles that induce a similar effect, with occasional muscle aching, nausea, and drowsiness, particularly in small children. *Pelagia* species also induce wheals, which are more circinate or irregularly shaped and may not follow a linear pattern. The venom is sufficiently toxic to cause severe generalized allergy, with bronchospasm and pruritus.

Treatment.

Treatment for a sea nettle envenomation is similar to that for the sting of *Physalia* species. Baking soda may be the most effective commonly available initial detoxicant.^[35] Monoclonal antibodies to jellyfish venoms have been developed that demonstrate cross-reactivity among venoms of a variety of coelenterates, which may allow the development of a single protective antivenom or vaccine.

Anthozoa.

The class Anthozoa includes the sea anemones, stony (true) corals (Zooantharia), and the

soft corals (Alcyonaria). The anemones are considered here because they envenom.

ACTINARIA (ANEMONES).

Actinarians (sea anemones) are abundant (1000 species) multicolored animals with sessile habits and a flowerlike appearance. They are composed of stalked, fingerlike projections capable of stinging and paralyzing passing fish. Their sizes range from a few millimeters to more than 0.5 m; they are found at depths of up to 2900 fathoms. The insides of some anemones can be eaten after they are dried.

Anemones can be colorful creatures and found in tidal pools, where the unwary brush up against them or inquisitively touch them. Other anemones burrow into bottom mud or sand. Like other coelenterates, they possess tentacles loaded with one of two variations of the nematocyst, either the sporocyst or the basitrichous isorhiza (basitrich). These wreak havoc once stimulated by an unfortunate victim. Some sporocysts are adhesive and act to hold and to envenom the prey. When an exposed anemone wishes to present a greater number of nematocysts to the victim, it inflates the tentacles by filling them

with water. Many anemones also secrete mucous, which covers the anemone's body and may contain cytolytic and hemolytic protein toxins. These may serve to repel potential predators.

Although a number of sea animals, such as clownfish (anemonefish) of the genera *Amphiprion* and *Premnas*, live in symbiosis with certain anemones (*Heteractis* spp., *Stichodactyla* spp., *Macrodactyla doreensis*, *Entacmaea quadricolor*, and *Cryptodendrum adhaesivum*), humans are not so fortunate and are frequently stung when attempting to handle these not so delicate "flowers." The clownfish have evolved resistance to the anemone's sting by repeated contact and development of a mucous coat ([Figure 61-35](#)), and perhaps by immunity.^[75]

Sea anemones contain biologically active substances, including neurotoxins (sodium channel interaction), cardiotoxins, hemolysins (for erythrocytes and platelets), and proteinase inhibitors.^[76] ^[102] A cytolytic toxin has been isolated from the Indo-Pacific sea anemone *Stoichactis kenti*.^[11] The anemone *Actinia equina* elaborates cytolytic polypeptide toxins known as equinatoxins, which may induce hemolysis and cardiorespiratory arrest in animals, attributed by some to coronary vasospasm.^[68] Tenebrosin-C from the anemone *Actinia tenebrosa* is a positive inotrope that can be inhibited by the cyclooxygenase blockers indomethacin and aspirin, a lipooxygenase blocker and leukotriene antagonist, and mepacrine (a phospholipase A₂ inhibitor).^[41] Potassium channel toxins have been isolated from the sea anemones *Bundosoma granulifera* and *Stichodactyla helianthus*.^[54] Cytolytic toxins elaborated by anemones include "cytolysins," which are thought to

Figure 61-35 Clownfish in peaceful coexistence with a sea anemone. (Photo by Kenneth Kizer, MD.)

exert their effect by damaging membranes via pore or channel formation.

Clinical aspects.

Most victims are stung when they handle or accidentally brush against an anemone in shallow water. Nudists may acquire genital injuries; small children may accidentally or intentionally ingest tentacles. The dermatitis caused by contact with an anemone is similar in all regards to that from fire coral or a small man-of-war; it is often likened to a bee sting. The variation in skin reaction is related to the specific toxicity of the venom, so that although *Actinia* species produce painful urticarial lesions, *Anemonia* species induce paresthesias, edema, and erythema.^[64] Most commonly the initial skin lesion is centrally pale with a halo of erythema and petechial hemorrhage. This is soon followed by edema and diffuse ecchymosis. If the envenomation is severe, intense local hemorrhage, vesiculation, necrosis, skin ulceration, and secondary infection may occur, particularly after the stings of certain species (*Sagartia*, *Actinia*, *Anemonia*,

Actinodendron, and *Triactis*). In Floridian waters, the turtle grass anemone *Viatrix globulifera*, translucent-white and less than 1 inch in diameter, is very hazardous, particularly for fishermen wading on grass flats. The Hell's fire sea anemone (*Actinodendron plumosum*) is aptly named. Systemic reactions are less likely after the sting of an anemone than after that of a man-of-war; reactions include fever, chills, somnolence, malaise, weakness, nausea, vomiting, and syncope. Fulminant fatal hepatic failure 3 days after a sea anemone sting of approximately 3 cm diameter upon the scapula and complicated by coma, severe coagulopathy, and renal failure has been attributed to *Condylactis* (Figure 61-36 (Figure Not Available) ; commonly found in reefs and lagoons of south Florida, the Bahamas, and the Caribbean) on the basis of a positive serum test of IgG by ELISA at a dilution of 1:450.^[42]

In most cases, mild envenomations resolve within 48 hours. More severe reactions, characterized by discoloration and vesicle formation, may become indolent, with eschar leading to residual hyperpigmentation, hypopigmentation, or keloid formation.

1473

Figure 61-36 (Figure Not Available) Giant anemone (*Condylactis gigantea*). (Photo by Norbert Wu.)

Sponge fisherman's (diver's) disease is caused by contact with an anemone (*Sagartia* or *Actinia*) that attaches itself symbiotically to the base of a sponge. A few minutes after contact with the sponge, the victim's skin begins to itch and burn, with development of erythema and small vesicles. As described previously, this transforms to a darkened purple appearance, with frequent systemic components (headache, nausea, vomiting, fever, chills, and muscle spasm).

Treatment.

Treatment for an anemone envenomation is similar to that for the sting of *Physalia* species. The dermatitis is frequently more severe and may require prolonged wound care consisting of debridement and antibiotic therapy for secondary infection. The healing process is generally slower after an anemone sting than after a man-of-war envenomation.

Echinodermata

The phylum Echinodermata ("spiny skin") has five classes: sea lilies, brittle stars, starfish, sea urchins, and sea cucumbers. Only the last three are of human medical interest, although some brittle stars carry toxins capable of causing paralysis and death in small animals.

Starfish

LIFE AND HABITS.

Starfish are simple, free-living, and stellate echinoderms covered with thorny spines of calcium carbonate crystals held erect by muscle tissue. The creatures move upon the ocean floor by means of tube feet located under the arms (rays). They eat other echinoderms, mollusks, coral, worms, and poisonous shellfish. Starfish proliferation and destruction of coral beds within the Great Barrier Reef off the coast of Australia is a conservation issue of international concern. The starfish everts its membranous stomach through its mouth and secretes digestive enzymes that destroy coral polyps. Only the stark white coral skeleton remains. The

Figure 61-37 Crown-of-thorns starfish (*Acanthaster planci*). (Photo by Paul Auerbach, MD.)

Figure 61-38 Spines of the crown-of-thorns starfish (*Acanthaster planci*). (Photo by Paul Auerbach, MD.)

crown-of-thorns starfish (*Acanthaster planci*) is found in the coral reef communities of the Great Barrier Reef, throughout the Pacific and Indian Oceans, in the Red Sea, and in the Gulf of California.

VENOM AND VENOM APPARATUS.

Glandular tissue interspersed in or underneath the epidermis (integument) produces a slimy venomous substance. The carnivorous *Acanthaster planci* is a particularly venomous species normally 25 to 35 cm in diameter, which attains sizes of up to 70 cm in diameter, with 7 to 23 arms ([Figure 61-37](#)). The sharp, rigid, and venomous aboral spines of this animal may grow to 4 to 6 cm ([Figure 61-38](#)). Potentially toxic saponins and histamine-like compounds have been isolated from the spine surfaces; crude venom extracts demonstrate hemolytic, capillary

permeability increasing, myotoxic (phospholipase A₂), myonecrotic, and anticoagulant effects. *A. planci* lethal factor is a potent hepatotoxin in laboratory animals.^[103] "Plancinin" is an anticoagulant purified from the crown-of-thorns starfish. This peptide shows activity in mice that suggests a longer duration of action than heparin.^[60] Severe systemic hypotension, thrombocytopenia, and leukopenia were induced by *A. planci* venom in dogs.^[104] Indomethacin, a cyclooxygenase inhibitor, suppressed the hypotension. *A. planci* venom caused smooth (uterine) muscle contraction in rats, which was blocked by inhibitors of prostaglandin synthesis but not by atropine.^[59]

Other starfish that might envenom humans are those of genus *Echinaster*. The slime (cushion) star *Pteraster tessalatus*, which inhabits Pacific coastal waters from Puget Sound to Alaska, generates the unique defense of copious gelatinous or rubbery, poisonous mucus to repel natural enemies. No human injuries have been reported to date.

CLINICAL ASPECTS.

The ice pick-like spine of *Acanthaster planci* can penetrate the hardest of diving gloves. Most spines are composed of porous crystalline magnesium calcite, articulated at the base and extremely sharp, with three raised cutting edges at the tips. As the spine enters the skin, it carries venom into the wound, with immediate pain, copious bleeding, and mild edema. The pain is generally moderate and self-limited, with remission over a period of ½ to 3 hours. The wound may become dusky or discolored. Multiple puncture wounds may result in acute systemic reactions, including paresthesias, nausea, vomiting, lymphadenopathy, and muscular paralysis. If a spine fragment is retained, a granulomatous lesion may develop akin to that from a sea urchin puncture wound. If the victim has been previously sensitized, he or she may suffer a prolonged reaction lasting for weeks and consisting of local edema and pruritus. Contact with other less injurious starfish may induce a pruritic papulourticarial eruption (irritant contact dermatitis).

TREATMENT.

Immersion therapy may provide some relief from the pain. The wound should immediately be immersed into non-scalding hot water to tolerance (45° C [113° F]) for 30 to 90 minutes or until there is significant pain relief. The pain is rarely severe enough to require local anesthetic infiltration. The puncture wound should be irrigated and explored to remove all foreign material. Because of the stout nature of the spines, it is rare to retain a fragment. However, if any question of a foreign body exists, a soft tissue radiograph often identifies the fractured spine. Not infrequently the victim suffers an indolent contact dermatitis from handling a starfish, such as *Solaster papposus*, the sun (Figure 61-39 (Figure Not Available)) or rose star. The dermatitis may be managed in standard fashion with topical solutions, such as calamine with 0.5% menthol, or a corticosteroid preparation. Systemic therapy is supportive. Granulomas from retained spine fragments may require excision. Starfish that have ingested poisonous shellfish

are themselves toxic on ingestion.

Sea Urchins

LIFE AND HABITS.

Sea urchins are free-living echinoderms that have an egg-shaped, globular, or flattened body. A hard skeleton (test) comprised of fused calcareous plates surrounds the viscera and is covered by regularly arranged spines and triple-jawed (pincerlike) pedicellariae, the latter of which (globiferous, or glandular) are sometimes used for defense. Urchins are nocturnal and omnivorous (mostly in pursuit of algae) eaters yet are shy, nonaggressive, and slow-moving animals found on rocky bottoms or burrowed in sand and crevices ([Figure 61-40](#)). Their bathymetric range extends from the intertidal zone to great depths. The raw or cooked gonads of several species are eaten as great delicacies by humans.

Figure 61-39 (Figure Not Available) Sun starfish (*Solaster*). (Photo by Norbert Wu.)

Figure 61-40 Needlelike spines of sea urchins in their natural habitat. (Photo by Kenneth Kizer, MD.)

1475

VENOM AND VENOM APPARATUS.

The venom apparatuses of sea urchins consist of the hollow, venom-filled spines and the triple-jawed globiferous pedicellariae. Venom may also be released from within a thin integumentary sheath on the external surface of the spines of certain urchins.

Figure 61-41 Nontoxic "pencil" urchin with blunt, rounded tips. (Photo by Paul Auerbach, MD.)

Figure 61-42 Three examples of sharp-spined (venomous) sea urchins. (Photos by Paul Auerbach, MD.)

The spines of sea urchins, formed by the calcification of a cylindrical projection of subepidermal connective tissue, may either be non-venom-bearing, with solid blunt and rounded tips ([Figure 61-41](#)), or venom-bearing (such as families Echinothuriidae and Diadematidae), with hollow, long, slender, and sharp needles ([Figure 61-42](#)). These are extremely dangerous to handle; the spines, which are attached to the shell with a modified ball-and-socket joint, are brittle and break off easily in the flesh, lodging deeply and making removal difficult. They are keen enough to penetrate rubber gloves and fins. *Diadema setosum* (black sea urchin) spines may exceed 1 foot in length. *Echinothrix* species also carry lengthy spines. The purple sea urchin *Strongylocentrotus purpuratus* ([Figure 62-43](#)) of California has much shorter spines. The genera *Asthenosoma* and *Aerosoma* have special venom organs (sacs) on the sharp tips of the aboral spines, which introduce the potent venom.

Pedicellariae are small, delicate seizing organs attached to the stalks scattered among the spines. These are considered to be modified spines with flexible heads.^[97] Globiferous pedicellariae are typified by those found in *Toxopneustes pileolus* (flower urchin) ([Figure 61-44](#))

1476

Figure 61-43 Purple sea urchins. (Photo by Howard Hall.)

Figure 61-44 Flower urchin (*Toxopneustes pileolus*). (Photo by Ken Kizer, MD.)

and *Tripneustes* species and have globe-shaped heads which contain the venom organs ([Figure 61-45](#)). The terminal head, with its calcareous pincer jaws (2 to 4;

usually 3), is attached by the stalk to the shell plates of the sea urchin. The outer surface of each opened "jaw" is covered by a large venom gland, which is triggered to contract with the jaw on contact. When the sea urchin is at rest in the water, the jaws are extended, slowly moving about ([Figure 61-46](#)). Anything that touches them is seized. As long as the object is moving, the pedicellariae continue to bite and envenom. Once a pedicellaria attaches to a victim, it will be torn from the shell rather than let go. Detached

Figure 61-45 Globiferous pedicellaria of a sea urchin, used to hold and envenom prey.

Figure 61-46 Close-up of opened flower urchin (*Toxopneustes pileolus*) pedicellariae seeking prey. (Photo by Ken Kizer, MD.)

pedicellariae may remain active for several hours. The *Toxopneustes* sea urchin also has solid spines, but these are nonvenomous.

The venom of sea urchins contains various toxic fractions, including steroid glycosides, hemolysins, proteases, serotonin, and cholinergic substances. The Pacific *Tripneustes* urchin carries a neurotoxin with a predilection for facial and cranial nerves. A toxic substance from the sea urchin *Toxopneustes pileolus* induces histamine release from rat peritoneal mast cells.^[115] Contractin A from the pedicellariae of the same species causes contraction of isolated guinea pig tracheal smooth muscle.^[81]

1477

Figure 61-47 Thigh of the author demonstrating multiple sea urchin punctures from black

sea urchins (*Diadema*). Within 24 hours, the black markings were absent, indicative of spine dye without residual spines. (Photo by Ken Kizer, MD.)

CLINICAL ASPECTS.

Most victims are envenomed when they step on, handle, or brush up against a sea urchin. Because the creatures tend to be nocturnal, divers are most commonly injured in dark waters during night diving activities, particularly in small caves or in shallow turbulent waters. Young inquisitive children who explore tidepools frequently handle urchins incorrectly and may be injured. If a diver moves his or her hand slowly toward a spiny (venomous) sea urchin, the spines may align to offer the greatest defense.

Venomous spines inflict immediate and intensely painful stings. The pain is initially characterized by burning, which rapidly evolves into severe local muscle aching with visible erythema and swelling of the skin surrounding the puncture site or sites. Frequently a spine breaks off and lodges in the victim. Some sea urchin spines (such as those of *Diadema setosum* or *Strongylocentrotus purpuratus*) contain purplish dye, which may give a false impression of spines left in the skin ([Figure 61-47](#)). Soft tissue density x-ray techniques or magnetic resonance imaging may reveal a radiopaque foreign body. If a spine enters a joint, it may rapidly induce severe synovitis. If multiple spines have penetrated the skin, particularly if they are deeply embedded, systemic symptoms may rapidly develop, including nausea, vomiting, paresthesias, numbness and muscular paralysis, abdominal pain, syncope, hypotension, and respiratory distress. The presence of a frank neuropathy may indicate that the spine has lodged in contact with a peripheral nerve. The pain from multiple stings may be sufficient to cause delirium. Secondary infections and indolent ulceration are common. A delayed hypersensitivity-type reaction ("flare-up") at the site of the puncture(s) has been described, in which the victim demonstrates erythema and pruritus in a delayed fashion (7 to 10 days) after primary resolution from the initial envenomation.^[3] The sensitizing antigen in such cases has yet to be identified.

Two separate unusual cases were reported in 1993 to me by neurologists. In each case the victim sustained multiple punctures from one or several black sea urchins in Hawaiian waters. The immediate clinical reaction was typical, but it was followed in 6 to 10 days by severe bulbar polyneuritis with respiratory insufficiency. In one case the victim was hyporeflexic and appeared to suffer a Guillain-Barré variation with elevated protein levels in cerebrospinal fluid; in the other, the victim manifested meningoencephalitis documented by magnetic resonance imaging. The relationship to the urchin stings suggests an autoimmune phenomenon.

A spine that enters a finger in proximity to the nail apparatus may cause a subungual or periungual granulomatous nodular lesion. Excision may cause permanent nail plate dystrophy.

The stings of pedicellariae are often of greater magnitude, causing immediate intense radiating pain, local edema and hemorrhage, malaise, weakness, paresthesias, hypesthesia, arthralgias, aphonia, dizziness, syncope, generalized muscular paralysis, respiratory distress, hypotension, and, rarely, death. In some cases the pain may

disappear within the first hour, whereas the localized muscular weakness or paralysis persists for up to 6 hours.

TREATMENT.

The envenomed body part should immediately be immersed in nonscalding hot water (upper limit 45° C [113° F]) to tolerance for 30 to 90 minutes in an attempt to relieve pain. Any pedicellariae still attached to the skin must be removed or envenomation will continue. This may be accomplished by applying shaving foam and gently scraping with a razor. Embedded spines should be removed with care because they easily fracture. Black or purplish discoloration surrounding the wound after spine removal is often merely spine dye and therefore may be of no consequence. Although some thin venomous spines may be absorbed within 24 hours to 3 weeks, it is best to remove those that are easily reached. All thick spines (calcium carbonate, magnesium carbonate, and silica) should be removed because of the risk of infection, foreign body encasement granuloma, or dermoid inclusion cyst. External percussion to achieve fragmentation may prove disastrous if a chronic inflammatory process is initiated in sensitive tissue of the hand or foot. If the spines have acutely entered joints or are closely aligned to neurovascular structures, the surgeon should take

1478

advantage of an operating microscope in an appropriate setting to remove all spine fragments. The extraction should be performed as soon as possible after the injury. If the spine has entered an interphalangeal joint, the finger should be splinted until the spine is removed to limit fragmentation and further penetration. This also may control the fusiform finger swelling ([Figure 61-48](#)) commonly noted after a puncture in the vicinity of the middle or proximal interphalangeal joint. It is inappropriate to rummage about in a hand wound in the emergency department, virtually looking for a needle in a haystack. If the presence of a spine is in question, soft tissue density radiographic techniques for a radiopaque foreign body may be diagnostic. Magnetic resonance imaging ([Figure 61-49](#)) may be quite useful to locate spine fragments. Although the calcium carbonate is relatively inert, it is accompanied by slime,

Figure 61-48 Finger swelling from sea urchin puncture. A single spine entered the palm over the mid third metacarpal bone. Swelling was severe in the second and third digits. (Photo by Paul Auerbach, MD.)

Figure 61-49 Magnetic resonance imaging of the hand of a victim of multiple sea urchin spine punctures, demonstrating the presence of spine fragments in the soft tissues. (Photo by Paul Auerbach, MD.)

bacteria, and organic epidermal debris. Therefore secondary infections are common ([Figure 61-50](#)) and deep puncture wounds are an indication for prophylactic antibiotics.

Some sea urchin spines are phagocytosed in the soft tissues and ultimately dissolve. The granulomas caused by retained sea urchin spine fragments have sarcoidal histologic features and generally appear as flesh- or dye-colored surface or subcuticular nodules 2 to 12 months after the initial injury ([Figure 61-51](#)).^[95] In thin-skinned areas these nodules are erythematous and rubbery, painless, and infrequently umbilicated. In thicker-skinned areas (palms, soles, and knees) that are frequently abraded, they have a keratinized appearance. Although necrosis and microabscess formation may be evident microscopically, suppuration is unusual. Rarely, the destructive nature of the inflammatory

Figure 61-50 Infection after sea urchin puncture. The rapid onset, gas-containing hemorrhagic blister, and severe cellulitis with sepsis are common features of infection with *Vibrio* species. (Photo by Paul Auerbach, MD.)

Figure 61-51 Subcuticular nodule after sea urchin puncture. (Photo by Paul Auerbach, MD.)

process may be severe enough to necessitate amputation of a digit. If a spine cannot be removed and becomes a nidus for cyst or granuloma formation, the lesion may be removed surgically. Intralesional injection with a corticosteroid (triamcinolone hexacetonide 5 mg/ml) is less efficacious but may be successful. Systemic antiinflammatory drugs may be minimally helpful but are not substitutes for removal of

the spine. A diffuse delayed reaction, consisting of cyanotic induration, fusiform swelling in the digits, and focal phalangeal bony erosion, may be treated with a systemic corticosteroid and antibiotics.

Sea Cucumbers

LIFE AND HABITS.

Sea cucumbers are free-living worm- or sausage-shaped bottom feeders of diverse external patterns ([Figure 61-52](#)) and coloration that are essentially scavengers. They are cosmopolitan in distribution, found in both shallow and deep waters. Cucumbers are harvested as a food (trepang, bêche-de-mer) in the South Pacific.

VENOM AND VENOM APPARATUS.

Cucumbers produce in their body walls a visceral cantharidin-like liquid toxin ("holothurin"). Holothurin is concentrated in the tentacular organs of Cuvier, which can be projected and extended anally when the animal mounts a defense ([Figure 61-53](#)). Toxic genera include *Actinopyga*, *Stichopus*, and *Holothuria*. Some cucumbers dine on nematocysts and thus can secrete coelenterate venom as well.

CLINICAL ASPECTS.

Holothurin may induce contact dermatitis when the tentacular organs directly contact the skin. Generally the substance is diluted in the surrounding ocean water and the reaction is minimal. However, persons who dissect sea cucumbers topside

Figure 61-52 Sea cucumber. (Photo by Paul Auerbach, MD.)

in the preparation of food products may inadvertently handle the toxin and develop a papular skin irritation. The major risk underwater is to the corneas and conjunctivae, which may become intensely inflamed if directly contacted by tentacular fragments or high concentrations of the toxin. This may occur if the mask is cleared in the immediate vicinity of recent sea cucumber manipulation. A severe reaction may lead to blindness. Holothurin is a potent cardiac glycoside and may cause severe illness or death on ingestion.

TREATMENT.

The management of holothurin-induced contact dermatitis is similar to that for starfish dermatitis. A topical or systemic corticosteroid may be necessary to manage a severe

reaction. Because cucumbers that dine on nematocysts may secrete coelenterate venom, the initial skin detoxification should include topical application of 5% acetic acid (vinegar), papain, or 40% to 70% isopropyl alcohol. If an eye is involved, it should be anesthetized with 1 or 2 drops of proparacaine 0.5% and then irrigated with 100 to 250 ml of normal saline to remove any residual foreign matter. The cornea should then be stained with fluorescein to identify corneal defects. A proper slit-lamp examination is optimal to determine whether inflammation extends into the anterior chamber or involves the iris. If there is no sign of infection, a moderate approach to the inflammatory keratitis includes regular instillation of cycloplegic, mydriatic, and corticosteroid ophthalmic solutions. Prompt referral to an ophthalmologist is essential.

Annelid Worms

LIFE AND HABITS.

There are 6200 species of segmented marine worms (phylum Annelida, class Polychaeta), either free moving or sedentary. Some members of the former group are considered toxic and may attain 1

Figure 61-53 Extruded tentacular organs of Cuvier from within a sea cucumber. (Photo by Paul Auerbach, MD.)

1480

foot in length. The worms are predominantly carnivorous and exist in the tidal zone to depths of 5000 m (16,405 feet), mostly as bottom feeders. Each segment of the worm possesses paddlelike appendages (parapodia) for locomotion. From these project numerous silky or bristlelike setae, which are capable of puncturing the victim ([Figure 61-54](#)).

The chitinous urticating bristles are arranged in soft rows about the body. When a worm is stimulated, its body contracts and the bristles are erected. There are no associated venom-producing cells. Easily detached, the bristles penetrate skin like cactus spines and are difficult to remove. The ubiquitous bottom-dwelling bristleworm *Hermodice carunculata* is frequently handled in Floridian and Caribbean waters by snorkelers and divers. This worm can attain a length of 1 foot and a width of 1 inch. It is found on coral, under rocks, and moving among sponges. The body is green or reddish with tufts of white bristles. *Chloeia flava* is found along the Malayan coast, *Chloeia viridus* in the West Indies, Gulf of California, and Gulf of Mexico south to Panama, and *Euythoe complanata* in Australia and other tropical seas. Other worms, such as *Chloeia euglochis ehlers*, are free swimming. Some marine worms possess strong chitinous

jaws with pharyngeal teeth and can inflict painful bites.

CLINICAL ASPECTS.

The bite or sting of an annelid worm may induce intense inflammation typified by a burning sensation with a raised, erythematous, and urticarial rash, most frequently on the hands and fingers ([Figure 61-55](#)). Edema and papules ensue, with rare necrosis. The setae are easily fractured into the skin and are generally not visible on external inspection, although the victim may report a sensation of pricking or abrasion. Untreated, the pain is generally self-limited over the course of a few hours, but the inflammatory component of erythema and urticaria may last for 2 to 3 days, with total resolution of the skin discoloration over 7 to 10 days. With multiple stings, marked

Figure 61-54 The chitinous spines of a bristleworm are easily dislodged into the skin of an unwary diver. (Photo by Paul Auerbach, MD.)

local soft tissue edema and pruritus may develop. Secondary infections and cellulitis may occur if the eczematous component is severe.

TREATMENT.

All large visible bristles should be removed with forceps. The skin should be dried (without scraping, to avoid breaking or embedding the spines further into the skin) so that a layer of adhesive tape may be applied to remove the remaining smaller spines, which are too tiny for individual extraction. Application of tape may force spines into the tissue, causing pain. Alternatively, a facial "peel" or thin layer of rubber cement may be applied and removed. After this maneuver, acetic acid 5% (vinegar), isopropyl alcohol 40% to 70%, dilute ammonia, or a paste or solution of unseasoned meat tenderizer (papain) or application of a papain scrub brush may provide some pain relief. If the inflammatory reaction becomes severe, the victim may benefit from the administration of a topical or systemic corticosteroid.

Mollusks

The phylum Mollusca (45,000 species) encompasses a group of unsegmented, soft-bodied invertebrates, many of which secrete calcareous shells. Generally a muscular foot is present with various modifications. There are five main classes, of which three predominate in their hazard to humans: the pelecypods (such as scallops, oysters, clams, and mussels), the gastropods (such as snails and slugs), and the cephalopods (such as squids, octopuses, and cuttlefish). Mollusks are often implicated as the transvectors in poisonous ingestions.

Cone Snails ("Cone Shells")

LIFE AND HABITS.

There are approximately 300 species of these circumtropical, beautiful, yet potentially lethal, univalve and cone-shaped shelled mollusks of the class Gastropoda, family Conidae, genus *Conus* (Figure 61-56 (Figure Not Available)).

Figure 61-55 Skin rash caused by a bristleworm. (Photo by Paul Auerbach, MD.)

1481

Most of these carnivores carry a highly developed venom apparatus, and at least 18 species have been implicated in human envenomations, with occasional fatalities (approximately 16 to 30 have been recorded).^[48] These include *Conus aulicus* (court), *C. geographus* (geographer), *C. gloria-maris* (glory of the sea), *C. omaria* (marbled), *C. striatus* (striated), *C. textile* (textile), and *C. tulipa* (tulip).

Most harmful cone snails ("cones") are creatures of shallow Indo-Pacific waters; the variance in feeding habits and venom production accounts for the varying toxicity. Atlantic species, such as *C. ermineus* (turtle) are less toxic. *Conus regious* (crown or queen) and *C. spurius* (Chinese alphabet) are found in Florida waters. Apparently, cones that feed on fish or mollusks are the most dangerous. Less toxic stings are attributed to cones that feed on marine worms. Predominantly nocturnal creatures, cones burrow in the sand and coral during the daytime, emerging at night to feed.

Figure 61-56 (Figure Not Available) Cone snail found in the Red Sea. (Photo by Norbert Wu.)

Figure 61-57 Venom apparatus of the cone snail.

VENOM AND VENOM APPARATUS.

Cone snails are predators that feed by injecting rapid-acting venom by means of a detachable, dartlike radular tooth ("radula"). To do this, the head of the animal must extend out of the shell. The venom apparatus is composed of a set of minute,

harpoonlike, chitinous, and hollow radular teeth associated with a venom bulb, long convoluted duct, and radular sheath ([Figure 61-57](#)).^[77] The barbed teeth, which may attain a length of 1 cm, are housed within the radular sheath. The act of envenomation is performed by the release of a radular tooth from the sheath into the pharynx, where it is "charged" with venom from the venom duct and then transferred to the extensible proboscis. This appendage, which may extend in some species as far back as the spire of the shell, grasps the venom-impregnated and barbed tooth and thrusts it into the flesh of the victim. The venom is composed of biologically active peptides (to date, more than 100 "conotoxins" have been identified) of 13 to 35 amino acids in length.^[84] Smaller peptides are probably strategic from an evolutionary perspective because of the speed of diffusion through a poisoned fish. The venom targets are neuromuscular transmission and ion channels.^[48] At the same site as tetrodotoxin and saxitoxin, μ -conotoxins bind and modify muscle sodium channels.^[51] ^[81] Voltage-dependent calcium uptake at the presynaptic cleft and cholinergic transmission in avian and mammalian neuromuscular junctions are inhibited by γ -conotoxins like that from *Conus geographus*.^[30] These γ -conotoxins bind to neuronal (N-type) rather than the cardiac (L-type) calcium channels, which prevents the calcium influx necessary for neurotransmitter release. Ziconatide is a conotoxin under investigation at the time of this writing as a potent analgesic intended for human application directly to the spinal cord and to prevent cell death in the brain after head trauma and ischemic events. The α -conotoxins

1482

block the nicotinic acetylcholine receptor.^[48] ^[81] A sleeper peptide in *C. geographus* venom causes test animals to enter a deep sleeplike state. ^[48] If the observation that certain conotoxins target *N*-methyl-D-aspartate (NMDA) receptors can be translated into an effective drug, this may lead to another approach to the treatment of epilepsy. Serotonin is present in venom from the cone snail *C. imperialis*, which is a worm feeder.^[74] In the act of envenomation, milky venom from the venom duct is transformed into a clear product, which may indicate conversion from an ineffective to effective toxin.

CLINICAL ASPECTS.

Most stings occur on the fingers and hand, as the unknowledgeable fossicker incorrectly handles a hazardous specimen. Mild stings are puncture wounds that resemble bee or wasp stings, with associated burning or sharp stinging sensation. The initial pain is followed by localized ischemia, cyanosis, and numbness in the area surrounding the wound. Numbness may occur without preceding pain, or in a rare case, the envenomation may be without any specific dermal sensation. More serious envenomations induce paresthesias at the wound site, which rapidly encompass the limb and then become perioral before generalized. Partial paralysis transitions to generalized muscular paralysis causing diaphragmatic dysfunction and respiratory failure; bronchospastic respiratory distress is not commonly seen. Coma has been observed, and death is attributed to diaphragmatic paralysis or cardiac failure. Other symptoms include dysphagia, syncope, weakness, failing coordination, areflexia, aphonia, dysarthria, diplopia, ptosis, absent gag reflex, blurred vision, and pruritus. The bite of *C. geographus* may be rapidly toxic, with progression to cerebral edema, coma,

respiratory arrest, and cardiac failure within a few hours, perhaps even 1 hour. Although mild stings may cause symptoms of nausea, blurred vision, malaise, and weakness for only a few hours, a severe envenomation may induce symptoms that require 2 to 3 weeks to achieve total resolution. *C. textile* and *C. marmoreus* have been reported to kill humans. A fatality has been attributed to *C. gloria-maris*, but this has not yet been confirmed.^[77]

TREATMENT.

No antivenom is available for a cone shell envenomation. Numerous therapies have been recommended, including the pressure-immobilization technique, application of a proximal lymphatic-venous occlusive bandage, incision and suction, soaking in non-scalding hot water to tolerance (upper limit 45° C [113° F]) until pain is relieved, injection of a local anesthetic (lidocaine 1% to 2% without epinephrine), and local excision. The pressure-immobilization technique makes sense and should be applied.

Cardiovascular and respiratory support are the usual priorities after a severe envenomation. The wound should be inspected for the presence of a foreign body (radula). Edrophonium (10 mg intravenously in an adult) has been suggested as empirical therapy for paralysis. A rational approach would be to administer an edrophonium (Tensilon) test to determine effectiveness. The clinician should choose a weak muscle group for which strength can be objectively measured, then inject edrophonium 2 mg IV. If there is improvement, this is followed by edrophonium 8 mg IV. Adverse reactions to edrophonium (anticholinesterase inhibitor) include salivation, nausea, diarrhea, and muscle fasciculations. These can be ameliorated with atropine 0.6 mg IV.

Cone shells should be handled only when wearing proper gloves; if the proboscis protrudes, the cone should be dropped. If the animal must be carried, it should always be lifted by the large posterior end of the shell, although this does not afford complete protection. A collector should never carry a live cone inside a wet suit, clothing pocket, or buoyancy compensator pocket.

Octopuses

LIFE AND HABITS.

Octopuses and cuttlefish are cephalopods that are usually harmless and retiring. On occasion, they are noted to manifest "curiosity" or "play behavior," by navigating mazes or manipulating objects without intent to feed or create a habitat. True octopuses are inhabitants of warmer waters and have little tolerance for extremes in salinity. They prefer rocky bottoms and rock pools in the intertidal zones. The entertainment media have created the image of a giant creature that envelops its victim in a maze of tentacles and suction cups. The truth is that most dangerous (envenoming) creatures are smaller than 10 to 20 cm and do not squeeze their victims at all. However, there are reports in the South Pacific of breath-hold spearfishermen drowned while hunting octopuses. The method used to kill the animals was to allow an octopus to cling to a

diver, who would bite the animal between the eyes as the combatants surfaced. Apparently, the octopuses were large enough (4-m [13-foot] tentacle span) to resist the technique.

Octopus bites are rare but can result in severe envenomations. Fatalities have been reported from the bites of the Australian blue-ringed (or "spotted") octopuses, *Octopus (Hapalochlaena) maculosus* and *O. (H.) lunulata*. These small creatures, which rarely exceed 20 cm in length with tentacles extended, are found throughout the Indo-Pacific (Australia, New Zealand, New Guinea, Japan) in rock pools, under discarded objects and shells, and in shallow waters, posing a threat to curious children, tidepoolers, fossickers, and unwary divers.^[113] Divers rarely spot them in water deeper than

1483

Figure 61-58 (Figure Not Available) Blue-spotted octopus. (Photo by Norbert Wu.)

3 m. In Australian waters, *H. maculosa*, the southern species, is smaller and yellow. *H. lunulata* is found in the north; larger, darker, and predominantly brownish, it favors the warmer tropical water. When either animal is at rest, it is covered with dark brown to yellow-ochre bands over the body and arms, with superimposed blue patches or rings.^[110] When the animal is excited or angered, the entire body darkens and the blue circles or stripes glow iridescent peacock blue, a trait shared by other animals, such as the peacock flounder (*Bothus lunatus*). The colorful appearance is attractive to small children, who can easily handle the 25- to 90-g animal (Figure 61-58 (Figure Not Available)). The smallish *Octopus joubini* of the Caribbean, which lives in small shells and empty containers, such as submerged bottles, is dangerous to a lesser degree; envenomation causes pain followed by numbness, fever, and nausea. The large common octopus *O. vulgaris* is nontoxic. Many octopuses can release inky fluid into the water, which is used to confuse attackers; this mechanism is not present in the blue-ringed octopus. The chameleon-like changing of colors to match the surroundings is accomplished with pigment cells (chromatophores).

VENOM AND VENOM APPARATUS.

The venom apparatus of the octopus consists of the anterior and posterior salivary glands, salivary ducts, buccal mass, and beak. The mouth is located ventrally and centrally at the base of the tentacles and is surrounded by a circular lip fringed with fingerlike papillae, leading into a muscular pharyngeal cavity. This anatomic complex (buccal mass), concealed by the tentacles, is fronted by two parrotlike, powerful, and chitinous jaws (the "beak"), which bite and tear with great force at food held by the suckers. The salivary glands, particularly the posterior, secrete maculotoxin (or cephalotoxin) via the salivary ducts into the pharynx. This venom, normally released into the water to subdue crabs, may be injected into the victim with great force through the dermis down to the muscle fascia.^[113] Only the venom of *H. maculosa* has been extensively studied. The toxin, maculotoxin (molecular weight less than 5000), contains at least one fraction identical to tetrodotoxin (C₁₁ H₁₇ O₈ N₃) of molecular weight 319.3,

which blocks peripheral nerve conduction by interfering with sodium conductance in excitable membranes.^[101] This paralytic agent rapidly produces neuromuscular blockade, notably of the phrenic nerve supply to the diaphragm, without any apparent direct cardiotoxicity. It has been estimated that enough venom (25 g) may be present in one adult octopus to paralyze 750 kg of rabbits or 10 adult victims.^{[110] [113]} An adult blue-ringed octopus can inject a second fatal dose of toxin after a 1-hour interval. The venom is active on ingestion or by parenteral administration, the latter being much more effective. Other components of the venom, which include hyaluronidase, histamine, 5-hydroxytryptamine, tyramine, serotonin, and "hapalotoxin" (still not confirmed as being present), are not thought to be major contributors to the clinical effects of an octopus bite.¹⁵⁹ Because most venoms and toxins with molecular weights less than 30,000 are poor antigens, octopus venom elicits no good antivenom.^[113]

CLINICAL ASPECTS.

Most victims are bitten on the hand or arm, as they handle the creature or "give it a ride." No blue-ringed octopus bites have yet been reported from an animal in the water.^[124] An octopus bite usually consists of two small puncture wounds produced by the chitinous jaws. The bite goes unnoticed or causes only a small amount of discomfort, described as a minor ache, slight stinging, or a pulsating sensation. Occasionally the site is initially numb, followed in 5 to 10 minutes by discomfort that may spread to involve the entire limb, persisting for up to 6 hours. Local urticarial reactions occur variably, and profuse bleeding at the site is attributed to a local anticoagulant effect or may rarely be a harbinger of coagulation abnormalities. Within 30 minutes, considerable erythema, swelling, tenderness, heat, and pruritus develop. By far the most common local tissue reaction is absence of symptoms, a small spot of blood, or a tiny blanched area.^[123] More serious symptoms are related predominantly to the neurotoxic properties of the venom. Within 10 to 15 minutes of the bite, the victim notices oral and facial numbness, rapidly followed by systemic progression.^[124] Voluntary and involuntary muscles are involved, and the illness may rapidly progress to total flaccid paralysis and respiratory failure. Other symptoms include perioral and intraoral anesthesia (classically, numbness of the lips and tongue), diplopia, blurred vision, aphonia, dysphagia, ataxia, myoclonus, weakness, a sense of detachment, nausea, vomiting, peripheral neuropathy, flaccid muscular paralysis, and respiratory failure, which may lead to death. Ataxia of cerebellar configuration may occur after an envenomation that does not

Figure 61-59 Algorithmic approach to marine envenomation. *A gaping

laceration, particularly of the lower extremity, with cyanotic edges suggests a stingray wound. Multiple punctures in an erratic pattern with or without purple discoloration or retained fragments are typical of a sea urchin sting. One to eight (usually two) fang marks are usually present after a sea snake bite. A single ischemic puncture wound with an erythematous halo and rapid swelling suggests scorpionfish envenomation. Blisters often accompany a lionfish sting. Painless punctures with paralysis suggest the bite of a blue-ringed octopus; the site of a cone shell sting is punctate, painful, and ischemic in appearance. †Wheal and flare reactions are nonspecific. Rapid (within 24 hours) onset of skin necrosis suggests an anemone sting. "Tentacle prints" with cross-hatching or a frosted appearance are pathognomonic for box-jellyfish (*Chironex fleckeri*) envenomation. Ocular or intraoral lesions may be caused by fragmented hydroids or coelenterate tentacles. An allergic reaction must be treated promptly. ‡Sea snake venom causes weakness, respiratory paralysis, myoglobinuria, myalgias, blurred vision, vomiting, and dysphagia. The blue-ringed octopus injects tetrodotoxin, which causes rapid neuromuscular paralysis. §If *immediately* available (which is rarely the case), local suction can be applied without incision using a plunger device, such as The Extractor (Sawyer Products, Safety Harbor, Fla.). As soon as possible, venom should be sequestered locally with a proximal venous-lymphatic occlusive band of constriction or (preferably) the pressure immobilization technique, in which a cloth pad is compressed directly over the wound by an elastic wrap that should encompass the entire extremity at a pressure of 9.33 kPa (70 mm Hg) or less. Incision and suction are not recommended. ¶Early ventilatory support has the greatest influence on outcome. The minimal initial dose of sea snake antivenin is one to three vials; up to ten vials may be required. ?The wounds range from large lacerations (stingrays) to minute punctures (stonefish). Persistent pain after immersion in hot water suggests a stonefish sting or a retained fragment of spine. The puncture site can be identified by forcefully injecting 1% to 2% lidocaine or another local anesthetic agent without epinephrine near the wound and observing the egress of fluid. Do not attempt to crush the spines of sea urchins if they are present in the wound. Spine dye from already-extracted sea urchin spines will disappear (be absorbed) in 24 to 36 hours. **The initial dose of stonefish antivenin is one vial per two puncture wounds. ††The antibiotics chosen should cover *Staphylococcus*, *Streptococcus*, and microbes of marine origin, such as *Vibrio*. ‡‡Acetic acid 5% (vinegar) is a good all-purpose decontaminant and is mandated for the sting from a box-jellyfish. Alternatives, depending on the geographic region and indigenous jellyfish species, include isopropyl alcohol, bicarbonate (baking soda), ammonia, papain, and preparations containing these agents. §§The initial dose of box-jellyfish antivenin is one ampule intravenously or three ampules intramuscularly. ¶¶If inflammation is severe, steroids should be given systematically (beginning with at least 60 to 100 mg of prednisone or its equivalent) and the dose tapered over a period of 10 to 14 days. ***An alternative is to apply and remove commercial facial peel materials. ??An alternative is to apply and remove commercial facial peel materials followed by topical soaks of 30 ml of 5% acetic acid (vinegar) diluted in 1 L of water for 15 to 30 minutes several times a day until the lesions begin to resolve. Anticipate surface desquamation in 3 to 6 weeks.

progress to frank paralysis. The victim may collapse from weakness and remain awake, so long as oxygenation can be maintained. When breathing is disturbed, respiratory assistance may allow the victim to remain mentally alert, although paralyzed. Cardiac arrest is probably a complication of the anoxic episode.^[121] Although tetrodotoxin is a potent vascular smooth muscle depressant, it does not appear to often produce significant hypotension in humans. However, hypotensive crisis has been mentioned in the literature as a complicating factor.

TREATMENT.

First aid at the scene might include the pressure-immobilization technique described in the section on treatment of box-jellyfish envenomation, although this is as yet unproven for management of octopus bites. A monoclonal rabbit serum antibody IgG has been effective against tetrodotoxin injected into mice.^{[73] [94]} This raises the possibility of the practical use of passive immunotherapy in the event of tetrodotoxin poisoning.

Treatment is based on the symptoms and is supportive. Prompt mechanical respiratory assistance has by far the greatest influence on the outcome. Respiratory demise should be anticipated early, and the rescuer should be prepared to provide artificial ventilation, including endotracheal intubation and the application of a mechanical ventilator. The duration of intense clinical venom effect is 4 to 10 hours, after which the victim who has not suffered an episode of significant hypoxia shows rapid signs of improvement.

1485

If no period of hypoxia occurs, mentation may remain normal. Complete recovery may require 2 to 4 days. Residua are uncommon and related to anoxia rather than venom effects.

Management of the bite wound is controversial. Some clinicians recommend wide circular excision of the bite wound down to the deep fascia, with primary closure or an immediate full-thickness free skin graft, whereas others advocate observation and a nonsurgical approach. Because the local tissue reaction is not a significant cause of morbidity, excision is recommended, presumably to remove any sequestered venom. Kinetic studies of radiolabeled venom absorption are necessary to track the movement of octopus bite-introduced tetrodotoxin. As previously mentioned, there is no antivenom. Granuloma annulare of the hand developing over a 2-week period after an octopus (presumed to be *Octopus vulgaris* of the Florida Gulf Coast) bite of the hand has been reported.^[40] On biopsy, histologic sections demonstrated superficial and deep dermal foci of altered dermis surrounded by histiocytes, lymphocytes, and fibroblasts. Intralesional triamcinolone acetonide injections were temporarily successful in treating the primary lesion.

PREVENTION.

All octopuses, particularly those less than 20 cm in length (including *Octopus joubini* of the Caribbean), should be handled with gloves. Divers need to be familiar with the lethal creatures in their domain. Giving an octopus a ride on the back, shoulder, or arm is not recommended.

SUMMARY

A summary algorithmic approach to marine envenomation can be followed when the causative agent cannot be positively identified ([Figure 61-59](#)). Once the physician has made a commitment to a course of treatment based on a presumption of what creature has caused the injury, the subtleties of therapy can be utilized.

Chapter 62 - Envenomation by Aquatic Vertebrates

Paul S. Auerbach

See [Chapter 60](#) for a discussion of infections associated with aquatic wounds and the relevant antimicrobial therapy.

STINGRAYS

The stingrays are the most commonly incriminated group of fish involved in human envenomations. They have been recognized as venomous since ancient times, known as "demons of the deep" and "devil fish." Aristotle (384–322 BC) made reference to their stinging ability.

Stingrays are members of the class Chondrichthyes (cartilaginous fish), subclass Elasmobranchii (plates and gills; with sharks and chimaeras), order Rajiformes (which contains stingrays [Dasyatidae], guitarfish [Rhinobatidae], skates [Rajidae], electric rays [Torpedinidae], eagle rays [Myliobatidae], mantas [Mobulidae], and freshwater rays [Potamotrygonidae]). There are 22 species of stingrays found in U.S. coastal waters, 14 in the Atlantic and 8 in the Pacific. The family Dasyatidae includes most of the species that cause human envenomation. Skates are harmless. It is likely that at least 2000 stingray injuries take place each year in the United States. On the west coast of the United States, the round stingray (*Urolophus halleri*) is a frequent stinger; along the southeastern coast, it is the southern stingray (*Dasyatis americana*). Most attacks occur during the summer and autumn months, as vacationers venture into the surf that may be laden with congregating (for spawning purposes) rays. Freshwater species do not inhabit U.S. waters. They are found in South America, Africa, and Southeast Asia.

Life and Habits

Stingrays are usually found in tropical, subtropical, and warm temperate oceans, generally in shallow (intertidal) water areas, such as sheltered bays, shoal lagoons, river mouths, and sandy areas between patch reefs.^[35] Rays can enter brackish and fresh waters, as well. Although rays are generally found above moderate depths, at least one deep-sea species has been discovered.

Rays are small (several inches) to large (up to 12 feet by 6 feet) creatures observed lying on top of the sand and mud or partially submerged, with only the eyes, spiracles, and part of the tail exposed ([Figure 62-1](#)). Their flattened bodies are round-, diamond-, or kite-shaped, with wide pectoral fins that look like wings ([Figure 61-2](#)). Rays are nonaggressive scavengers and bottom feeders that burrow into the sand or mud to feed on worms, mollusks, and crustaceans. The mouth and gill plates are located on the ventral surface of the animal ([Figure 62-3](#)).

Venom and Venom Apparatus

The venom organ of stingrays consists of one to four venomous stings on the dorsum of an elongate, whiplike caudal appendage. There are four different anatomic types of

stingray venom organs, based on their adaptability as a defense organ ([Figure 61-4](#)). Thus the stinging ability of rays may be divided into four categories: the gymnurid type (butterfly rays, or Gymnuridae), with a poorly developed sting of up to 2.5 cm placed at the base of a short tail; the myliobatid type (eagle and bat rays, or Myliobatidae), with a sting of up to 12 cm placed at the base of a cylindrical caudal appendage that terminates in a long whiplike tail; the dasyatid type (stingrays and whiprays, or Dasyatidae), with a sting of up to 37 cm placed at the base or further out on the caudal appendage that terminates in a long whiplike tail; and the urolophid type (round stingrays, or Urolophidae), with a sting of up to 4 cm located at the base of a short, muscular, well-developed caudal appendage. The efficiency of the apparatus is related to the length and musculature of the tail and to the location and length of the sting. Eagle rays and some mantas (Atlantic *Mobular mobular* and Pacific *Mobula japonica*) have a stinging apparatus, but it is less of a threat because the spine is located at the base of the tail and is not well adapted as a striking organ. Although the manta may grow to a width of 6 m (20 feet) and weight of 3000 pounds, it dines on small fish, crustaceans, and microorganisms ([Figure 62-5](#)). Many divers have "hitched" a ride on the wings of a manta; there are no reports of envenomation. However, manta skin is rough and can abrade unprotected human skin. A stingray "hickey" is a mouth-bite, created by powerful grinding plates, that produces superficial erosions and ecchymosis in an oral pattern. Persons who hand feed stingrays may incur this type of injury.^[15] The suction force generated by a stingray is sufficient to pull in a large amount of soft tissue, say, from a thigh. This may result in a large and painful contusion and/or hematoma.

In all cases, the venom apparatus of stingrays consists of a bilaterally retroserrate spine or spines and the enveloping integumentary sheath or sheaths. The elongate and tapered vasodentine spine is firmly attached

1489

Figure 62-1 Stingray nestled in the sand. Only the eyes and spiracles are visible.
(Photo by Paul Auerbach, MD.)

Figure 62-2 Diver cavorting with a large stingray. (Photo by Howard Hall.)

to the dorsum of the tail (whip) by dense collagenous tissue and is edged on either side by a series of sharp retrorse teeth. Along either edge on the underside of the spine are the two ventrolateral glandular grooves, which house the soft venom glands. The entire spine is encased by the integumentary sheath, which also contains some glandular cells. The sting is often covered with a film of venom and mucus. The spine is replaced if detached.

The venom contains various toxic fractions, including serotonin, 5'-nucleotidase, and phosphodiesterase. Russell^[43] investigated the pharmacologic properties of stingray venoms. In animal studies he demonstrated

Figure 62-3 Ventral surface of a stingray, demonstrating mouth and gill plates. (Photo by Paul Auerbach, MD.)

Figure 62-4 Four anatomic types of stingray venom organs.

Figure 62-5 Manta ray. (Photo by Paul Auerbach, MD.)

significant venom-induced peripheral vasoconstriction, bradycardia, atrioventricular block, ischemic ST-T wave abnormalities, asystole, central respiratory depression, seizure activity, ataxia, coma, and death. The venom did not appear to be a paralytic neuromuscular agent. Research on stingray venom from the 1950s observed that heating the venom to a temperature above 50° C (122° F) diminished some biologic effects.

Clinical Aspects

Stingray "attacks" are purely defensive gestures that occur when an unwary human handles, corners, or steps on a camouflaged creature while wading in shallow waters. The tail of the ray reflexively whips upward and accurately thrusts the caudal spine or spines into the victim, producing a puncture wound or jagged laceration ([Figure 62-6](#)). The integumentary sheath covering the spine is ruptured and venom is released into the wound, along with mucus, pieces of the sheath, and fragments of the spine. On occasion the entire spine tip is broken off and remains in the wound ([Figure 62-7](#)).^[44] "Domesticated stingrays," such as those that congregate at "Stingray City" in the waters of Grand Cayman Island, are habituated to the presence of humans and apparently pose less hazard.

Thus a stingray wound is both a traumatic injury and an envenomation. The former involves the physical damage caused by the sting itself. Because of the retrorse serrated teeth and powerful strikes, significant lacerations can result. Secondary bacterial infection is common. Osteomyelitis may occur if the bone is penetrated. Most injuries occur when the victim steps on a ray; another common cause is handling a ray during its extraction from a fishing net or hook. The lower extremities, particularly the ankle and foot, are involved most often, followed by the upper extremities, abdomen, and thorax. In a rare case, the heart was directly injured.^[42] Fatalities have occurred after abdominal or

Figure 62-6 The stingray lashes its tail upward into the leg and generates a deep puncture wound.

Figure 62-7 Stingray spine tip broken off into the heel of a victim. (Photo by Robert D. Hayes.)

thoracic (cardiac) penetration, and from exsanguination from the femoral artery. Another death has been attributed to tetanus complicating a leg wound. A spine partially or totally denuded of its sheath and venom glands may not cause an envenomation. ^[16]

1491

The envenomation classically causes immediate local intense pain, edema, and variable bleeding. The pain may radiate centrally, peaks at 30 to 60 minutes, and may last for up to 48 hours. The wound is initially dusky or cyanotic and rapidly progresses to erythema and hemorrhagic discoloration, with rapid fat and muscle hemorrhage and necrosis.^[6] If discoloration around the wound edge is not immediately apparent, within 2 hours it often extends several centimeters from the wound. Minor stings may simulate bacterial cellulitis. Systemic manifestations include weakness, nausea, vomiting, diarrhea, diaphoresis, vertigo, tachycardia, headache, syncope, seizures, inguinal or axillary pain, muscle cramps, fasciculations, generalized edema (with truncal wounds), paralysis, hypotension, arrhythmias, and death.^[23] ^[26] The paralysis may represent spastic muscle contractures induced by pain, which are a tremendous hazard for a diver or swimmer.

Treatment

The success of therapy is largely related to the rapidity with which it is undertaken. Treatment is directed at combating the effects of the venom, alleviating pain, and preventing infection. If hot water for immersion and irrigation (see below) is not immediately available, the wound should be irrigated immediately with nonheated water or saline. If sterile saline or water is not available, tap water may be used. This removes some venom and mucus and may provide minimal pain relief.

As soon as possible, the wound should be soaked in nonscalding hot water to tolerance (upper limit 45° C [113° F]) for 30 to 90 minutes. This might attenuate some of the thermolabile components of the protein venom (although this has never been proven in vivo) and/or interrupt nerve impulse transmission, and, in some envenomations, relieves pain. There is no indication for the addition of ammonia, magnesium sulfate, potassium permanganate, or formalin to the soaking solution. Under these circumstances they are toxic to tissue and may obscure visualization of the wound. During the hot water soak (or at any time, if soaking is not an option), the wound should be explored and debrided of any readily visible pieces of the sting or its integumentary sheath, which would continue to envenom the victim. Cryotherapy is disastrous, and no data yet support the use of antihistamines or steroids. One local remedy, application of half a bulb of onion

directly to the wound, has been reported to decrease the pain and perhaps inhibit infection after a sting from the blue-spotted stingray *Dasyatis kuhlii* ([Figure 62-8](#)).^[48] The author noted that this approach is used in the Northern Territory of Australia for other fish spine stings, and that the medicinal use of the Liliaceae plant family has been recorded in many cultures. No other folk remedy, such as the application of macerated cockroaches, cactus juice,

Figure 62-8 Blue-spotted stingray. (Photo by Paul Auerbach, MD.)

"mile-a-minute" leaves, fresh human urine, or tobacco juice, has been proven effective.^[37]

Local suction, if applied in the first 15 to 30 minutes, has been suggested by some clinicians to be of potential value (this is controversial), as may a proximal constriction band (also controversial) that occludes only superficial venous and lymphatic return. This should be released for 90 seconds every 10 minutes to prevent ischemia.

Pain control should be initiated during the first debridement or soaking period. Narcotics may be necessary. Local infiltration of the wound with 1% to 2% lidocaine (Xylocaine) or bupivacaine 0.25% (not to exceed 3 to 4 mg/kg total dose in adults; not approved in children under the age of 12 years) without epinephrine may be useful. A regional nerve block may be necessary.

After the soaking procedure, the wound should be prepared in a sterile fashion, reexplored, and thoroughly debrided. Wounds should be packed open for delayed primary closure or sutured loosely around adequate drainage in preference to tight closure, which might increase likelihood of wound infection. Another approach that has been mentioned is wound excision followed by packing with an alginate-based wick dressing.^[17] ^[37] Prophylactic antibiotics are recommended because of the high incidence of ulceration, necrosis, and secondary infection. Necrotizing fasciitis caused by *Vibrio alginolyticus* has followed stingray injury in a victim with preexisting hepatic cirrhosis.^[25] If the abdominal cavity is penetrated, the victim should receive cefoxitin or clindamycin-gentamicin intravenously in addition to any antibiotic(s) chosen to cover marine microbes.

If the treatment plan is to treat and release, the victim should be observed for at least 3 to 4 hours for systemic side effects.

Wounds that are not properly debrided or explored and cleansed of foreign material may fester for weeks

or months. Such wounds may appear infected, when what really exists is a chronic draining ulcer initiated by persistent retained organic matter. Within the first few weeks after an envenomation, a foreign body can sometimes be observed by soft tissue radiograph, ultrasound, or magnetic resonance imaging. After a few weeks, exploration may reveal erosion of adjacent soft tissue structures and the formation of an epidermal inclusion cyst or other related foreign body reaction.^[7] As with other marine-acquired wounds, indolent infection should prompt a search for unusual microorganisms. A case of invasive fusariosis (*Fusarium solani*) after stingray envenomation responsive to sequential debridement and ketoconazole (the latter of indeterminate effect) has been reported.^[24] Necrotizing fasciitis due to *Photobacterium damsela* (formerly *Vibrio damsela*) followed a leg laceration caused by a stingray. Notably, the patient had the wound sutured primarily and was not prescribed an antibiotic at the time of the repair.^[5A]

Prevention

A stingray spine can penetrate a wet suit, leather or rubber boot, and even the side of a wooden boat; therefore a wet suit or pair of sneakers is not adequate protection. Persons walking through shallow waters known to be frequented by stingrays should shuffle along and create enough disturbance to frighten off any nearby animals.

SCORPIONFISH

Scorpionfish are members of the family Scorpaenidae and follow stingrays as perpetrators of piscine stings. Distributed in tropical and less commonly in temperate oceans, several hundred species are divided into three groups typified by different genera on the basis of venom organ structure: (1) *Pterois* (zebrafish, lionfish, and butterfly cod), (2) *Scorpaena* (scorpionfish, bullrout, and sculpin), and (3) *Synanceja* (stonefish). All have a bony plate (stay), which extends across the cheek from the eye to the gill cover. Each group contains a number of different genera and species; at least 80 species of the family Scorpaenidae have been implicated in human injuries or studied anatomically, biochemically, or physiopharmacologically.

Other venomous fish that sting in a manner similar to scorpionfish include the Atlantic toadfish (family Batrachoididae and genus *Thalassophyrne*), with two venomous dorsal fin spines, and the Pacific ratfish (*Hydrolagus colliei*) ([Figure 62-9](#)) and European ratfish (*Chimaera monstrosa*), both with a single dorsal venomous spine. Toadfish hide in crevices and burrows, under rocks and debris, or in seaweed, sand, or mud. They may change coloration rapidly and remain superbly camouflaged. Rabbitfish (family Siganidae) and leatherjacks (leatherbacks or leatherjackets, family

Figure 62-9 Ratfish (*Hydrolagus colliei*). (Photo by Howard Hall.)

Carangidae) carry venomous spines or fins and pose additional risks. Stargazers (family Uranoscopidae) have spines but do not appear to be venomous.

Life and Habits

Zebrafish (lionfish, firefish, or turkeyfish) are beautiful, graceful, and ornate coral reef fish generally found as single or paired free swimmers or hovering in shallow water ([Figure 62-10](#)). They are increasingly popular as aquarium pets and are imported illegally as part of the "underground zoo."

Scorpionfish proper (*Scorpaena*) dwell on the bottom in shallow water, bays, coral reefs, and along rocky coastlines, to a depth of 50 fathoms. Their shape and coloration provide excellent camouflage, allowing them to blend in with the ambient debris, rocks,

and seaweed ([Figure 62-11](#)). They can be captured by hook and line and serve as important food fish in many areas. The protective coloration and concealment in bottom structures make scorpionfish difficult to visualize. Some species bury themselves in the sand, and most dangerous types lie motionless on the bottom. In many regions, scorpionfish are valuable as food fish. In the United States, they are found in greatest concentration around the Florida Keys and in the Gulf of Mexico, off the coast of southern California, and in Hawaii.

Stonefish live in shallow waters, often in tide pools and among reefs ([Figure 62-12](#)). They frequently pose motionless and absolutely fearless under rocks, in coral crevices or holes, or buried in the sand or mud. They are so sedentary that algae frequently take root on their skin ([Figure 62-13](#)). They are usually 15 to 20 cm in length. Stonefish are not indigenous to North American coastal waters.

Venom and Venom Apparatus

The venom organs are the 12 or 13 (of 18) dorsal ([Figure 62-14](#)), 2 pelvic, and 3 anal spines, with associated venom glands. Although they are frequently large,

1493

Figure 62-10 Three examples of lionfish. **A**, Juvenile lionfish from Sulawesi, Indonesia. **B**, Adult lionfish. **C**, Lionfish from the Red Sea. (Photos by Paul Auerbach, MD.)

Figure 62-11 Scorpionfish assuming the coloration of its surroundings. (Photo by Paul Auerbach, MD.)

plumelike, and ornate, the pectoral spines are not associated with venom glands. Each spine is covered with an integumentary sheath, under which venom filters along grooves in the anterolateral region of the spine from the paired glands situated at the base or in the midportion of the spine. It is estimated that the two

Figure 62-12 The deadly stonefish (*Synanceja horrida*). (Photo by Paul Auerbach, MD.)

venom glands of a dorsal stonefish spine carry 5 to 10 mg of venom, closely associated with antigenic proteins of high molecular weight (between 50,000 and 800,000).^[11] Scorpionfish venom contains multiple toxic fractions and, in the case of stonefish venom, has been likened in potency to cobra venom. The major toxic component

1494

Figure 62-13 Some stonefish are so sedentary that algae grow on their skin. (Photo by Paul Auerbach, MD.)

Figure 62-14 Scorpionfish spines. (Photo by Kenneth Kizer, MD.)

of *Synanceja* venom (stonustoxin) is a protein of molecular weight 148,000 (comprised of alpha and beta subunits of molecular weight 71,000 and 79,000, respectively) that is both antigenic and heat labile. The principal action of stonefish venom appears to be direct muscle toxicity, resulting in paralysis of cardiac, involuntary, and skeletal muscles.^[21] In one analysis of biologic activity, stonefish (*Synanceja horrida*) venom exhibited edema-inducing, hemolytic, hyaluronidase, thrombinlike, alkaline phosphomonoesterase, 5'-nucleotidase, acetylcholinesterase, phosphodiesterase, arginine esterase, and arginine amidase activities.^[27] In a recent evaluation, chromatographic analysis with electrochemical detection showed the presence of substances co-migrating with norepinephrine, dopamine, and tryptophan. Serotonin was not detected.^[20] Crude venom of the stonefish *Synanceja verrucosa* possesses numerous enzymatic properties, including hyaluronidase, 8 esterases, and 10 aminopeptidases.^[19] Stonefish venom causes pulmonary edema in laboratory animals, which may reflect a general vascular permeability.^[27] ^[30] It also causes species-restricted (nonhuman) hemolysis and platelet aggregation.^[28] Profound endothelial relaxation may

contribute directly to hypotension.^[33] The neuromuscular toxicity appears to be a consequence of the venom's dose-dependent presynaptic and postsynaptic actions at the myoneural junction, which include release and depletion of neurotransmitter from the nerve terminal, followed by irreversible depolarization of muscle cells and microscopically observable muscle and nerve damage.^[31] The nondialyzable opalescent venom retains full potency for at least 24 to 48 hours after the death of a scorpionfish.^[29]

Pterois species carry long, slender spines with small venom glands covered by a thin integumentary sheath. An extract of lionfish spine tissue contains acetylcholine and a toxin that affects neuromuscular transmission.^[12] *Scorpaena* species carry longer heavy spines with moderate-sized venom glands covered by a thicker integumentary sheath. *Synanceja* species carry short, thick spines with large, well-developed venom glands covered by an extremely thick integumentary sheath ([Figure 62-15](#) and [Figure 62-16](#)). However, the skin over the venom gland is loosely attached, so when a human treads on the fish, the skin is pushed down the spine and the venom gland is compressed by the crumpled sheath. The pressure forces the venom gland to empty up the paired narrow ducts so that venom and glandular tissue spurt into the wound.^[22]

When any of these fish is removed from the water, handled, stepped on, or otherwise threatened, it reflexively erects the spinous dorsal fin and flares out the armed gill covers and pectoral and anal fins. If provoked while still in the water, it actually attacks. The venom is injected by a direct puncture wound through the skin, which tears the sheath and may fracture the spine, in a manner analogous to that of a stingray envenomation.

Clinical Aspects

Native residents of the Indo-Pacific islands have great fear of a sting from the dreaded venomous stonefish, such as the Tahitian "nohu" ("nofu" or "no'u") or the Australian "warty ghouel." The presentation of the injury is similar to that of the stingray envenomation, in that the unwary diver or fisherman steps on or handles the fish. In the United States, marine aquarists and beneficiaries of illegal importation of tropical animals are increasingly envenomed as they unknowledgeably

1495

glands.

Figure 62-15 Lionfish, scorpionfish, and stonefish spines with associated venom

Figure 62-16 Spines of the venomous stonefish, demonstrating venom glands. (Courtesy John Williamson, MD.)

handle *Pterois volitans*, *P. radiata*, or *Scorpaena guttata*. In Indo-Pacific waters, envenomations of the foot and lower extremity are more commonly caused by the stonefish, such as *Synanceja horrida*, *S. trachynis*, or *S. verrucosa*. Scorpionfish stings vary according to the species, with a progression in severity from the lionfish (mild) through the scorpionfish (moderate to severe) to the stonefish (severe to life threatening).

The severity of the envenomation depends on the number and type of stings, species, amount of venom released, and age and underlying health of the victim. Pain is immediate and intense, with radiation centrally. Untreated, the pain peaks at 60 to 90 minutes and persists for 6 to 12 hours. With a stonefish envenomation, the pain may be severe enough to cause delirium and may persist at high levels for days. The wound and surrounding area are initially ischemic and then cyanotic, with more broadly surrounding areas of erythema, edema, and warmth. Vesicles may form ([Figure 62-17](#)). Human

Figure 62-17 Vesiculation of the hand 48 hours after the sting of a lionfish. (Photo by Howard McKinney.)

(hand) vesicle fluid after the sting of the lionfish *Pterois volitans* was analyzed for mediators of inflammation and demonstrated an appreciable quantity of prostaglandin F_{2a} ; thromboxane B_2 , prostaglandin E_2 , and 6-keto-prostaglandin F_{1a} were present in negligible quantities. Whether or not residual venom is present in blister fluid is a matter of conjecture. Rapid tissue sloughing and close surrounding areas of cellulitis, with anesthesia adjacent to peripheral hypesthesia, may be present within 48 hours. Necrotic ulceration is rare, but may occur, after a lionfish envenomation. ^[41] Severe local tissue reaction is more common after the sting of a scorpionfish or stonefish. Systemic effects include anxiety, headache, tremors, maculopapular skin rash, nausea, vomiting, diarrhea, abdominal pain, diaphoresis, pallor, restlessness, delirium, seizures, limb paralysis, peripheral neuritis or neuropathy, lymphangitis, arthritis, fever, hypertension, respiratory distress, bradycardia, tachycardia, atrioventricular block, ventricular

fibrillation, congestive heart failure, pericarditis, hypotension, syncope, and death. Pulmonary edema is a bona fide sequela.^[32] Death in humans, which is extremely rare, usually occurs within the first 6 to 8 hours. The wound is indolent and may require months to heal, only to leave a cutaneous granuloma or marked tissue defect, particularly after a secondary infection or deep abscess. Mild pain may persist for days to weeks. After successful therapy, paresthesias or numbness in the affected extremity may persist for a few weeks.

Treatment

As soon as possible, the wound or wounds should be immersed in nonscalding hot (upper limit 45° C [113° F]) water to tolerance. This may inactivate at least one of the thermolabile components of the protein venom that might otherwise induce a severe systemic reaction. Platelet aggregation in blister fluid is inhibited by heat treatment, which suggests that the venom or some other active component is neutralized. The soak should be maintained for a minimum of 30 minutes and may continue for up to 90 minutes. Recurrent pain that develops after an interval of 1 to 2 hours may respond to a repeat hot water treatment. As soon as is practical, all obvious pieces of spine and sheath fragments should be gently removed from the wound. Vigorous irrigation should be performed with warmed sterile saline to remove any integument or slime. If pain is severe or inadequately controlled (in terms of degree or rapidity or relief) by hot water immersion, local tissue infiltration with 1% to 2% lidocaine without epinephrine or regional nerve block with an anesthetic such as 0.25% bupivacaine may be necessary. After injection with a local or regional anesthetic, the hot water immersion should be discontinued or closely observed to avoid inadvertent creation of a burn wound in the now insensate body part. Infiltration with emetine, hydrochloride, potassium permanganate, or Congo red has been largely abandoned, despite reports of favorable experiences with acidic emetine. The biochemical bases for the success of folk remedies, such as the application of meat tenderizer, mangrove sap, or green papaya (papain), have yet to be confirmed. The effectiveness of alternative remedies may be related to the protein behavior of the venom, which is inactivated by heat, extremes of pH (it is partially inactivated at pH of greater than 8.6 and completely at a pH of less than 4), hydrogen peroxide, iodine, and potassium permanganate (which is, unfortunately, tissue toxic). Until further notice, no data are available to support the topical administration of empirical remedies, such as mineral spirits, organic dye, ground liver, or formalin. Cryotherapy is absolutely contraindicated, to avoid an iatrogenous cold-induced injury.

Although the spine rarely breaks off into the skin, the wound should be explored to remove any spine fragments, which will otherwise continue to envenom and act as foreign bodies, perpetuating an infection risk and poorly healing wound. If the spine has penetrated deeply into the sole of the foot, surgical exploration should be performed in the operating room with magnification. Vigorous warmed saline irrigation should be performed. Wide excision and debridement are unnecessary. Because of the nature of the puncture wound, tight suture or surgical tape closure should not be undertaken;

rather, the wound should be allowed to heal open with provision for adequate drainage. If the puncture wound is high risk (deep, into the hand or foot or both), a prophylactic antibiotic(s) should be administered. It is probably wise to remove blister fluid using aseptic technique.

A stonefish antivenom is manufactured by the Commonwealth Serum Laboratories (CSL), Melbourne, Australia ([Figure 62-18](#)). In cases of severe systemic reactions from stings of *Synanceja* species, and rarely from other scorpionfish, it is administered intramuscularly. The antivenom is supplied in ampoules containing 2 ml (2000 units) of hyperimmune Fab₂ horse serum active against *Synanceja trachynis*, with 1 ml capable of neutralizing 10 mg of dried venom.^[13] After skin testing to

Figure 62-18 Stonefish antivenom. (Courtesy John Williamson, MD.)

1497

estimate the risk for an anaphylactic reaction to equine sera, the antivenom should be given intramuscularly, since this is the only currently recommended route for this particular antivenom. However, review of the literature failed to identify any adverse effect attributable to intravenous (IV) administration other than the risk of anaphylaxis. As a rough estimate, one ampoule should neutralize one or two significant stings (punctures). For one or two puncture wounds, administer 1 ampoule; for three or four puncture wounds, 2 ampoules; for more than four puncture wounds, administer 3 ampoules. One or more additional ampoules may be necessary if there is recurrent severe pain. General guidelines for administration of antivenom have been previously discussed. When not in use, the antivenom should be protected from light and stored at 0° to 5° C (32° to 41° F), never frozen. Unused portions should be discarded.

Prevention

The most effective way to prevent envenomation is to avoid handling a scorpionfish. A diver should make a careful inspection before setting down on the bottom. Amateur aquarists should be exceedingly cautious when handling exotic tropical fish. Seemingly dead fish may yield an unpleasant surprise for the unwary.

CATFISH

Life and Habits

Approximately 1000 species of catfish inhabit both fresh and salt waters; many of these are capable of inflicting serious stings. Marine animals include *Plotosus lineatus* (oriental catfish), which lurks in tall seaweed and can inflict extremely painful stings, the larger sailcat (*Bagre marinus*), and the common sea catfish (*Galeichthys felis*), which hovers along the sandy bottom. The coral catfish (*Plotatus lineatus*) has also been reported to sting humans.^[45] Ocean catfish, particularly juveniles, "swarm" and feed along the bottom (Figure 62-19 (Figure Not Available)). Freshwater catfish of North America include the brown bullhead (*Noturus nebulosus*); Carolina madtom (*N. furiosus*); and channel (*N. punctatus*), blue (*N. furcatus*), and white (*N. catus*) catfish.

The catfish derives its name from the well-developed sensory barbels ("whiskers") surrounding the mouth. Catfish possess a slimy skin without any true scales. Marine catfish, unlike freshwater catfish, frequently travel in large schools. Most freshwater catfish are bottom feeders noted for their junkyard diet. They are poor swimmers and not very evasive.

The South American astroblepins have flattened suctorial lips that allow them to scale cliffs. Tiny South American (Amazonian) catfish of the genus *Vandellia* are known as "urethra fish" in English, "candirú" by Brazilians, and "canero" by Spanish speakers.^[8] Approximately an inch long, they carry short spines on their gill covers ([Figure 62-20](#)). The fish is putatively attracted to urine (water motion, warmth) and can swim up the human urethra or other urogenital apertures, where it extends the gill covers and thus becomes embedded, preventing removal by pulling on the fish's tail. Within the urethra, it causes extreme pain and inflammation. Since the animal normally seeks the outflow stream from a larger fish's gills, perhaps it is not urinophilic, but merely swimming upstream. Natives wear pudendal shields when urinating in natural bodies of water. A tight-fitting bathing suit is certainly prudent.

Figure 62-19 (Figure Not Available) Juvenile ocean catfish. (Photo by Norbert Wu.)

Figure 62-20 Amazonian catfish (candirú), which can enter the human urethra.

1498

At best, extraction is painful. Amputation of the penis by natives has been described in the older literature. Ingestion of the green fruit of the jagua tree or buitach apple (*Genipa americana* L.) as a concoction (tea) apparently works to dispel the urethra-lodged candirú by the action of a large quantity of citric acid (megadose vitamin C), which softens calcium spines.

Venom and Venom Apparatus

The venom apparatus of the catfish consists of the single dorsal and two pectoral fin spines ("stings") and the axillary venom glands. Both the dorsal and pectoral spines are exquisitely sharp and can be locked into an extended position by the fish when it is handled or becomes excited. The spines are enveloped by glandular tissue within an integumentary sheath; some spines have sharp retrorse teeth. Scattered reports note envenomation in persons who handled only the tail of the fish, such as the Arabian Gulf catfish (*Arius thalassinus*), which suggests the presence of a toxic skin secretion (crinotoxin). Other observers note that toxin released from epidermal skin cells can cause throbbing pain, tissue necrosis, and perhaps muscle fasciculations.^[18] Oriental catfish toxin, which is poorly antigenic, contains vasoconstrictive, hemolytic, edema-forming, dermatonecrotic, and other biogenic fractions.^[46] It behaves in vivo much like a milder version of stingray venom. In contrast, the crinotoxin of the Arabian Gulf catfish contracts smooth muscle and stimulates the release of prostaglandins; pretreatment with atropine and indomethacin attenuates the response.^{[1] [45]} Furthermore, wound healing responses are accelerated by repeated local application of preparations from the epidermal secretions of another Arabian gulf catfish (*Arius bilineatus* Valenciennes).^[2]

Clinical Aspects

Most stings are incurred when a fish is handled, which creates an injury out of proportion to the mechanical laceration. When the spine penetrates the skin, the integumentary sheath is damaged and the venom gland exposed. Catfish stings are described as instantaneously stinging, throbbing, or scalding, with central radiation up the affected limb. Normally the pain subsides within 30 to 60 minutes, but in severe cases it can last for up to 48 hours. The area around the wound quickly appears ischemic, with central pallor that gradually becomes cyanotic before the onset of erythema and edema. Swelling can be severe and secondary infections are frequent; gangrenous complications have been reported. Common side effects include local muscle spasm, diaphoresis, and fasciculations. Bleeding from the puncture wounds may

be more severe than expected. Less common sequelae are peripheral neuropathy, lymphedema, adenopathy, lymphangitis, weakness, syncope, hypotension, and respiratory distress. Death is extremely rare. The sting of the marine catfish is usually more severe than that of its freshwater counterparts and may have a propensity to more local hemorrhage.^[36] Infection risk (see [Chapter 60](#)) is similar to that for any aquatic-acquired wound, in that *Vibrio* and *Aeromonas* species may be pathogens and the infection may be polymicrobial.^[39] Other organisms that have been reported to be associated with marine or freshwater catfish-related injuries include *Edwardsiella tarda*, *Citrobacter freundii*, *Fusobacterium mortiferum*, *Morganella morganii*, *Providencia rettgeri*, *Enterococcus faecalis*, *Pseudomonas aeruginosa*, *Mycobacterium terrae*, and *Enterobacter cloacae*.^[39] *E. tarda* is a gram-negative bacillus of the family Enterobacteriaceae that is mainly associated with aquatic environments and the animals that inhabit them, particularly catfish and other coldblooded animals.^[3] ^[5] It may be a pathogen for eels and catfish. If *E. tarda* infection is determined, it is sensitive in vitro to ampicillin, aminoglycosides, β -lactamase stable cephalosporins, quinolones, tetracycline, and trimethoprim/sulfamethoxazole.^[5]

Treatment

There are no specific antidotes. As with stingray and scorpionfish envenomations, the success of therapy is related to the rapidity with which it is undertaken. With catfish envenomations, in contrast to those of stingrays, constriction bandages have not been shown to be of value. The wound should be immediately immersed in non-scalding hot water to tolerance (upper limit 45° C [113° F]) for 30 to 90 minutes or until there is significant pain relief. This may inactivate heat-labile components of the venom and perhaps helps to reverse local toxin-induced vasospasm. There is no evidence that adding mineral salts, solvents, antiseptics, or other chemicals to the water is of additional benefit. Cryotherapy is inefficacious. A popular and unstudied local (U.S. rural) remedy is to rub the sting with skin mucus (slime) from the catfish. If the hot water soak is not sufficient to control pain, local infiltration of the wound with buffered (alkalinized) bupivacaine or lidocaine without epinephrine or a regional nerve block may be necessary. It has been theorized that the pH alteration offered by the alkalinized local anesthetic may neutralize venom.^[34] The wound should be explored surgically to remove all spine and sheath fragments. Standard radiographs or soft tissue exposures may locate a radiopaque foreign body ([Figure 62-21](#)). The wound should be left unsutured to heal, to allow adequate drainage and minimize the risk of infection. All wounds must be carefully observed for infection until healed. If the puncture wound is high risk (deep, into the hand or foot or both), a prophylactic antibiotic(s) should be administered.

Figure 62-21 Catfish spine lodged in the foot. **A**, Radiograph demonstrating the

presence of a foreign body. **B**, The spine removed. (**A** and **B** by Paul Auerbach, MD.)

Figure 62-22 Lesser weeverfish.

Prevention

Catfish should be handled without grabbing the dorsal or pectoral fins, preferably by using a mechanical instrument or gaff. If possible, *Plotosus lineatus* should not be handled at all.

WEEVERFISH

Life and Habits

The weeverfish (*Echiichthys* species, formerly named *Trachinus*) ([Figure 62-22](#)) is the most venomous fish of the temperate zone. It is found in the Black Sea, Mediterranean Sea, eastern Atlantic Ocean, North Sea, and European coastal areas. Common names for the weeverfish include the adderpike, sea dragon, sea cat, and stang. Weeverfish are small (10 to 53 cm) marine creatures that inhabit flat sandy or muddy bays, usually burying themselves in the soft bottom with only the head partially exposed. They lead sedentary lives but when provoked can strike out with unerring accuracy. Weevers are terrors to fishermen working in shallow sandy areas.

Venom and Venom Apparatus

The venom apparatus consists of four to eight elongate and needle-sharp dorsal (up to 4.5 cm in length) and two opercular and daggerlike dentinal spines, associated holocrine glandular tissue, and the thin enveloping stratified squamous epithelium integumentary sheath. When excited, the fish extends the dorsal fin and expands the operculum, projecting the opercular spine out at a 35- to 40-degree angle from the

1500

longitudinal axis of the body. Weeverfish survive for hours out of the water, and the toxin remains potent for hours in dead animals, particularly when they are well refrigerated. Although incompletely characterized, the unstable (heat-labile) protein venom (ichthyocanthotoxin) contains several peptides, at least one protein of high molecular weight (324,000), and possibly 5-hydroxytryptamine, epinephrine, norepinephrine, histamine, and mucopolysaccharide components. To date, serotonin has not been identified in weeverfish venom. The greater weeverfish (*Echiichthys draco*) releases a protein venom, dracotoxin, which has membrane depolarizing and hemolytic activities. It appears to be a single polypeptide of molecular weight 105,000.^[10] Other weeverfish of significance include *E. draco*, *E. vipera*, *E. radiatus*, and *E. lineatus*.

Clinical Aspects

Weeverfish stings usually afflict professional fishermen or vacationers who wade or swim along sandy coastal areas. The thrust of the spine is sufficient to penetrate a leather boot and creates a substantial puncture wound. The integumentary sheath is

torn, and venom is injected into the wound. The onset of pain is instantaneous, described as intensely burning or crushing, and spreads rapidly to involve the entire limb. The pain usually peaks at 30 minutes and subsides within 24 hours but can last for days. Its intensity can induce irrational behavior and syncope; even narcotics are poorly effective. The puncture wound bleeds little and often appears pale and edematous initially. The sting of *E. vipera* may bleed freely. Over the course of 6 to 12 hours the wound becomes erythematous, ecchymotic, and warm. The edema may increase for 7 to 10 days, causing the entire limb to become markedly swollen. Secondary bacterial infections are common, and gangrene has been reported. The indolent wound may require months to heal, depending on the nature of the sting and underlying health of the victim. Raynaud's phenomenon in an envenomed digit occurring a few weeks after a weeverfish sting has been reported.^[9] Persistent edema has been noted to last for more than 1 year.

Systemic symptoms associated with weeverfish envenomation include headache, delirium, aphonia, fever, chills, dyspnea, diaphoresis, cyanosis, nausea, vomiting, seizures, syncope, hypotension, and cardiac arrhythmias. Deaths have been reported but remain to be confirmed.

Treatment

The wound should immediately be immersed in non-scalding hot water to tolerance (upper limit 45° C [113° F]) for 30 to 90 minutes, or until there is significant pain relief. This may inactivate heat-labile components of the venom and perhaps helps reverse local vasospasm that might contribute to local sequestration of venom and the inhibition of free bleeding. The addition of mineral salts, ammonia, vinegar, urine, or other substances to the water is of no proven value. Immersion in hot water is often a less successful therapy for a weeverfish sting than for that of a scorpionfish. When the heat inactivation method is inadequate to control pain, it is necessary to infiltrate the wound with a local anesthetic (1% to 2% lidocaine without epinephrine) or perform a regional nerve block. The liberal use of narcotics is often required. Cryotherapy is contraindicated.

Rarely, a spine breaks off into the skin. The wound should be gently explored, all fragments of sheath removed, and vigorous warmed saline irrigation performed. Wide excision and debridement are unnecessary. Because of the nature of the puncture wound, tight suture or surgical tape closure should not be undertaken; rather, the wound should be allowed to heal open with provision for adequate drainage. If the puncture wound is high risk (deep, into the hand or foot or both), a prophylactic antibiotic(s) should be administered. No commercial antivenom is currently available. An effective experimental antivenom was created at the Institute of Immunology in Zagreb, Yugoslavia, but is no longer available.

Prevention

Weeverfish hide in bottom sand and mud; thus persons must shuffle along with adequate footwear. These fish are easily provoked and should be avoided by scuba divers. They should never be handled alive and must be treated with extreme caution

even when dead. Weeverfish survive for hours out of the water, and careless handling of a seemingly dead fish may result in an envenomation.

VENOMOUS (HORNED) SHARKS

Life and Habits

Horned sharks are species that possess dorsal fin spines. In the United States the group is essentially limited to the spiny dogfish (*Squalus acanthias*) (Figure 62-23 (Figure Not Available)). These and similar animals are distributed throughout sub-Arctic, temperate, tropical, and sub-Antarctic seas. The Port Jackson shark *Heterodontus portusjacksoni* is particularly dangerous.

The fish are sluggish and prefer cooler water and shallow protected bays. They are erratic in their migration and may be found singly or in schools. Voracious feeders, they eat other fish, coelenterates, mollusks, crustaceans, and worms.

The venom apparatus consists of a spine anterior to each of two dorsal fins and the associated venom glands.

1501

Figure 62-23 (Figure Not Available) Spiny dogfish (*Squalus acanthias*). (Photo by Norbert Wu.)

Figure 62-24 Surgeonfish "blades." (Photo by Paul Auerbach, MD.)

Clinical Aspects

As with other vertebrate stings, there is immediate intense stabbing pain that may last for hours and is accompanied by erythema and edema. Although systemic side effects are rare, fatalities are possible.

Treatment

Treatment is the same as for stingray envenomation.

SURGEONFISH

Life and Habits

The surgeonfish (doctorfish, or "tang") is a tropical reef fish of the family Acanthuridae that carries one or more retractable jackknifelike epidermal appendages ("blades") on either side of the tail ([Figure 62-24](#)). When the fish is threatened, the blade may be extended out at a forward angle, where it serves to inflict a laceration ([Figure 62-25](#)). There does not appear to be any associated envenomation.

Figure 62-25 "Blade" mechanism of the surgeonfish.

Clinical Aspects

A victim cut by a surgeonfish notes a laceration or deep puncture wound that is immediately painful; it usually bleeds freely. The pain is moderate to severe and of a burning nature. Systemic reactions are infrequent and consist of nausea, local muscle aching, and apprehension.

Treatment

The wound should be irrigated and then soaked in nonscalding hot water to tolerance (upper limit 45° C [113° F]) for 30 to 90 minutes or until pain is relieved, although this may be of variable efficacy. It should be scrubbed vigorously to remove all foreign material and watched closely for the development of a secondary infection. Unless absolutely necessary for hemostasis, sutures should not be used to close the wound.

PLATYPUS

Venom and Venom Apparatus

The platypus *Ornithorhynchus anatinus* is a furry venomous mammal that inhabits riverine systems of eastern Australia between northern Queensland and southern Tasmania.^[14] These strange, fat animals have bills

1502

like a duck, webbed feet, a paddlelike tail, and claws on the feet. The male animal has an erectile keratinous spur on each hind limb linked via a distensible duct to a venom gland. The spur attains a length of 15 mm in mature animals. There is a duct on each side that connects the spur to a venom gland situated under the thigh muscles. The venom appears to have components that mediate a type I hypersensitivity reaction with mast cell degranulation, which is consistent with the clinical presentation of soft tissue edema. Other venom fractions include a natriuretic peptide, proteases, and hyaluronidase. Venom-induced local edema in laboratory rats is attenuated by ketanserin and, to a lesser degree, by cimetidine, which may indicate a role of 5-hydroxytryptamine and histamine.

Clinical Aspects

Normally, the platypus is a shy creature. However, when provoked, it grasps its opponent with the hind legs and thrusts a spur or spurs into the victim. From 2 to 4 ml of venom may be released. When a human is envenomed, symptoms include immediate severe pain, tissue edema, and prolonged local sensitivity to painful stimuli. Movement, even remote (such as coughing), worsens the pain. The pain and hyperesthesia may generalize for several days before the pain recedes back to the envenomed limb. The pain may last for weeks, and in a severe case, muscle mass may be lost.

Treatment

Therapy is supportive and includes pain medication, wound care, and physical therapy after the acute episode. Hot water immersion does not appear to be of benefit acutely. Short-term corticosteroid therapy has been suggested to diminish pain and mitigate swelling, but there is no proof that antiinflammatory agents are definitively useful.

SEA SNAKES

Life and Habits

Sea snakes ([Figure 62-26](#)) of the family Hydrophiidae (subfamilies Hydrophiinae [genera *Hydrelaps*, *Kerilia*, *Thalassophina*, *Enhydrina*, *Acalytophis*, *Thalassophis*, *Kolpophis*, *Lapemis*, *Astrotia*, *Pelamis*, and *Microcephalophis*] and Laticaudinae [genera *Laticauda*, *Aipysurus*, and *Emydocephalus*]) are probably the most abundant reptiles on earth. There are at least 52 species, all venomous. Species implicated in serious envenomations or human fatalities include *Astrotia stokesii*, *Enhydrina schistosa*, *Hydrophis ornatus*, *Hydrophis cyanocinctus*, *Lapemis hardwickii*, *Pelamis platurus*, and *Thalassophina viperina*.

The snakes are distributed in the tropical and warm temperate Pacific and Indian Oceans, with the highest number of envenomations occurring along the coast of Southeast Asia, in the Persian Gulf, and in the Malay Archipelago. No sea snakes live in the Atlantic Ocean or

Figure 62-26 Olive sea snake. (Photo by Michele Hall.)

Figure 62-27 Sea snake in the Coral Sea. (Photo by Carl Roessler.)

in the Caribbean Sea. Hawaii is the only U.S. state that has sea snakes (predominantly *Pelamis platurus*). The Pacific snakes usually inhabit sheltered coastal or coral reef waters and congregate about river mouths, and only on rare occasion venture into the open ocean. *Pelamis platurus*, the most widely distributed sea snake, is pelagic and may be found in the Pacific coastal waters of Central and South America (see [Figure 39-13](#)). It does not migrate to the Caribbean because of the freshwater barrier of Gatun

Lake in the center of the Panama Canal.

Although sea snakes have the general appearance of land snakes, true sea snakes and sea kraits have valve-like nostril flaps and rudimentary ventral plates, without gills, limbs, ear openings, sternum, or urinary bladder. Most species of sea snakes are 0.9 to 1.2 m (3 to 4 feet) long, but some attain lengths of up to 2.7 m (9 feet). They are sinuous scaled creatures whose bodies are compressed posteriorly into a flat, paddle-shaped tail designed for marine locomotion ([Figure 62-27](#)). They swim

1503

in an undulating fashion and can move backward or forward in the water with equal speed. On land, however, they are awkward and do not survive readily. They may be brightly colored, as is the yellow-bellied sea snake, *Pelamis platurus*. With a single lung the sea snake is capable of diving to 100 m (328 feet) and remaining submerged for 2 hours. The sea snake can be distinguished from a sea eel by the presence of scales and the absence of gills and fins.

Sea snakes use an air retention mechanism in the lung to control buoyancy. Their food, small fish swallowed whole, is captured underwater, usually around bottom rocks and coral. In general, sea snakes are docile creatures and flee when approached. However, when cornered or handled, they may become aggressive and strike out. During the reproductive season, some males adopt more irritable attitudes. The banded sea snake (sea krait) *Laticauda semifasciata* is served as a food (raw, smoked, or cooked) in certain Asian countries, notably Japan and the Philippines.

Venom and Venom Apparatus

The well-developed venom apparatus consists of two to four hollow maxillary fangs and a pair of associated venom glands. Fortunately, because the fangs are short and easily dislodged from their sockets, most bites (approximately 80%) do not result in significant systemic envenomation. Most fangs, except for those of *Astrotia stokesii* and *Aipysurus laevii*, are not long enough to penetrate a wet suit. The venom yield of sea snakes varies with species and is largely related to the size of the venom glands.

The protein venom is highly toxic and includes stable peripheral neurotoxins more potent than those of terrestrial snakes. Neuromuscular transmission is blocked predominantly at the postsynaptic membrane and caused by attachment of toxin to the a subunit of the acetylcholine receptor. Presynaptic toxin in sea snake venom has been less well studied but appears to be related to inhibition of transmitter release by blocking resynthesis of acetylcholine from choline. It seems probable that the action of *Laticauda semifasciata* venom on excitable membranes is to alter ionic permeability, particularly that of sodium and chloride, without effect on Na⁺ , K⁺ -dependent adenosine triphosphatase activity. Calcium transport abnormalities are currently under investigation. Among other fractions of the venom are phospholipases, nerve growth factors, capillary permeability factor, anticomplement-active factor, enzymes (including

acetylcholinesterase, hyaluronidase, leucine aminopeptidase, 5'-nucleotidase, phosphomonoesterase, phosphodiesterase), and hemolytic and myotoxic compounds, which result in skeletal muscle necrosis, intravascular hemolysis, and renal tubular damage. Myonecrosis is related to phospholipase A, which may inhibit calcium uptake into the sarcoplasmic reticulum. Neurotoxins are thought to exert

Figure 62-28 Beaked sea snake (*Enhydrina schistosa*). A common sea snake of Southeast Asia, the average length is about 1 m (3 feet). This creature inflicts a high proportion of the sea snake bites recorded in Asian coastal waters. (Photo by Sherman Minton, MD.)

their toxicity by binding in a nondepolarizing fashion to the nicotinic acetylcholine receptor and blocking neuromuscular transmission.^[40]

The venoms of sea snakes are similar, as is reflected in positive reactions during immunodiffusion, immunoelectrophoresis, cross-neutralization by antivenom against heterologous venoms, and amino acid composition and sequences of neurotoxins. This is a reflection of phylogenetic relationships and is a logistic aid in the preparation of effective antivenom.

Although large venom yields have been obtained from *Astrotia stokesii*, *Enhydrina schistosa* is considered the most dangerous sea snake ([Figure 62-28](#)). *E. schistosa* is the most widely distributed sea snake in the Arabian sea. *Aipysurus duboisii* and *Acalyptophis peronii* from the Coral Sea have recently be shown to carry venoms of high human lethality potential. In an evaluation of poisonous land and sea snakes representative of those encountered in Saudi Arabia, sea snakes were noted to have an average lethal dose in dogs of 0.05 mg/kg, in comparison with the average lethal dose of vipers (1.13 mg/kg) and elapids (0.69 mg/kg).^[47] Deaths were attributed to respiratory paralysis and failure.

Clinical Aspects

Bites are usually the result of accidental handling of snakes snared in the nets of fishermen, or of accidentally stepping on a snake while wading. Most sea snake poisonings occur in remote fishing villages and in boats engaged in fishing. Nearly all bites involve the extremities.

The diagnosis of sea snake bite is based on the following:

1. Location. A person must have been in the water or handling a fishing net containing a sea snake to have been bitten. Some snakes may foray briefly onto land, particularly in areas of heavy mangrove growth, but it is quite unusual for a bite to occur out of the water. Because snakes may inhabit sheltered coastal waters and frequently congregate near river mouths, a bite can occur in an

2. Absence of pain. Initially, a sea snake bite does not cause great pain and may resemble no more than a pinprick.
3. Fang marks. These are multiple pinhead-sized, hypodermic-like puncture wounds, usually 1 to 4, but potentially up to 20. If the skin is not broken, envenomation cannot occur. In some cases, particularly with a superficial injury through the arm or leg of a neoprene wet suit, the fang marks may be difficult to visualize because of the lack of a localized reaction.
4. Identification of the snake. Snakes should be captured or killed carefully with a nonmacerating blow behind the head and retained for identification by an expert.
5. Development of characteristic symptoms. These include painful muscle movement, lower extremity paralysis, arthralgias, trismus, blurred vision, dysphagia, drowsiness, vomiting, and ptosis. Neurotoxic symptoms are rapid in onset and usually appear within 2 to 3 hours. If symptoms do not develop within 6 to 8 hours, there has been no envenomation.

Envenomation by sea snakes characteristically shows an evolution of symptoms over a period of hours, with the latent period being a function of venom volume and victim sensitivity. The onset of symptoms can be as rapid as 5 minutes or as long as 8 hours. There is no appreciable local reaction to a sea snake bite other than the initial pricking sensation. The first complaint may be euphoria, malaise, or anxiety. Over 30 to 60 minutes, classic muscle aching and stiffness (particularly of the bitten extremity and neck muscles) develop, along with a "thick tongue" and sialorrhea, indicative of speech and swallowing dysfunction. Within 3 to 6 hours, moderate to severe pain is noted with passive movements of the neck, trunk, and limbs. Ascending flaccid or spastic paralysis follows shortly, beginning in the lower extremities, and deep tendon reflexes diminish and may disappear after an initial period of spastic hyperreactivity. Nausea, vomiting, myoclonus, muscle spasm, ophthalmoplegia, ptosis, dilated and poorly reactive pupils, facial paralysis, trismus, and pulmonary aspiration of gastric contents are frequent complications. Occasionally, bilateral painless swelling of the parotid glands develops.

Severe envenomations are marked by progressively intense symptoms within the first 2 hours of symptoms. Victims become cool and cyanotic, begin to lose vision, and may lapse into coma. Failing vision is reported to be a preterminal symptom. If peripheral paralysis predominates, the victim may remain conscious if hypoxia is avoided. Leukocytosis may exceed 20,000 white blood cells per milliliter; elevated plasma creatine kinase is variable. Elevated glutamic oxaloacetic transaminase reflects hepatic injury. Pathognomonic myoglobinuria becomes evident about 3 to 6 hours after the bite and may be accompanied by albuminuria and hemoglobinuria. Cerebrospinal fluid is normal. Respiratory distress and bulbar paralysis, pulmonary aspiration related hypoxia, electrolyte disturbances (predominantly hyperkalemia), and acute renal failure (attributed in part to myonecrosis and pigment load) all contribute to the ultimate demise, which can occur hours to days after the untreated bite. Preterminal hypertension may occur. The mortality is 25% in victims who do not receive antivenom

and 3% overall.

It is interesting to note the effects of sea snake (*Aipysurus laevis*) venom on prey fish.^[49]

The prey are subdued in six stages, which correlate roughly to certain aspects of a human envenomation: stage 1, increased ventilatory rate; stage 2, loss of mouth control, fin control, coordination, and buoyancy; stage 3, depressed ventilation, weakness, ineffective swimming; stage 4, apnea; stage 5, near paralysis, body color darkening; and stage 6, death.

Treatment

If possible, the offending snake should be captured for identification, taking care not to increase the number of victims. The therapy for bites by snakes of the family Hydrophiidae is similar to that for terrestrial snakes of the family Elapidae. The affected limb should be immobilized and maintained in a dependent position while the victim is kept as quiet as possible. The pressure-immobilization technique (see above) for venom sequestration should be applied. If the bite is on a digit where a compression bandage cannot be applied, a loose constriction bandage that constricts only the superficial venous and lymphatic flow may be applied proximal to the wound. This should be released for 90 seconds every 10 minutes and should be completely removed after 4 to 6 hours. If the bite is older than 30 minutes, neither technique may be very effective.

There is little clinical enthusiasm for the perpetuation of incision and suction therapy, which has just about been universally relegated to therapeutic history.

The victim must be kept warm and as still as possible. As with terrestrial snakebite, cryotherapy (immersion into ice water) is inefficacious and potentially harmful.

With any evidence of envenomation, sea snake antivenom (an equine pepsin-digested immunoglobulin from CSL) prepared against the venom of *Enhydrina schistosa* and the Australian tiger snake *Notechis scutatus* should be administered IV after appropriate skin testing for equine serum hypersensitivity. If this is not available, tiger snake (*Notechis scutatus*) antivenom should be used. As a last resort, CSL polyvalent snake antivenom can be used. Sea snake antivenom is specific and absolutely indicated in cases of envenomation. Supportive measures, although critical in management,

are no substitute. The administration of antivenom should begin as soon as possible and is most effective if initiated within 8 hours of the bite. The minimum effective adult dosage is one ampoule (1000 units), which neutralizes 10 mg of *E. schistosa* venom. The victim may require 3000 to 10,000 units (3 to 10 ampoules), depending on the severity of the envenomation. The proper administration of antivenom is clearly described on the antivenom package insert.

Sea snake envenomation may induce severe physiologic derangements that require

intensive medical management. Urine output and measured renal function should be closely monitored because hemolysis and rhabdomyolysis release hemoglobin and myoglobin pigments into the circulation, which precipitates acute renal failure. If hemoglobinuria or myoglobinuria is detected, the urine should be alkalinized with sodium bicarbonate and diuresis promoted with a loop diuretic (furosemide or bumetanide) or mannitol, as previously described for management of *Physalia* venom induced nephropathy. Acute renal failure may necessitate a period of peritoneal dialysis or hemodialysis. Hemodialysis offers an alternative therapy that may be successful if antivenom is not available.

Respiratory failure should be anticipated as paralysis overwhelms the victim. Endotracheal intubation and mechanical ventilation may be required until antivenom adequately neutralizes the venom effects. Serum electrolytes should be measured regularly to guide the administration of fluids and electrolyte supplements. Hyperkalemia related to rhabdomyolysis and renal dysfunction must be promptly recognized and treated.

As previously mentioned, symptoms usually occur within 2 to 3 hours after envenomation. If there is no early evidence of envenomation, the victim should be observed for 8 hours before discharge from the hospital.

SUMMARY

A summary algorithmic approach to marine envenomation can be followed when the causative agent cannot be positively identified (see [Figure 61-59](#)).^[4] Once the physician has made a commitment to a course of treatment based on a presumption of what creature has caused the injury, the subtleties of therapy can be utilized.

Chapter 63 - Aquatic Skin Disorders

Vicki Mazzorana

Dermatitis acquired from the aquatic environment can be related to exposure to diving equipment, chemicals, or animal or plant irritants. Hypersensitivity reactions to water have been documented. Bacteria, algae, and parasites can be the etiologic agents of a variety of aquatic infections. Wounds resulting from stings, bites, punctures, and suction may result from inadvertent contact with marine life.

CONTACT DERMATITIS

Diving Equipment

Diving Wet Suits.

An allergic reaction to wet suits may reflect sensitivity to either the rubber or thiourea compounds within the suit.^{[1] [66] [69]} N/N-diethylurea is a chemical compound used within the wet suit to bond the nylon lining to the rubber. It can cause contact dermatitis of the neck, trunk, and extremities in sensitive individuals.^{[1] [22] [66] [123]} The rash varies from generalized redness to severe, itchy papulovesicles. Wearing a tight diving suit may produce irritant skin lesions at the pressure points. Antihistamine use is recommended to provide symptomatic relief from the pruritus. Systemic corticosteroids may be necessary in the treatment of severe reactions. The rash should be observed because secondary cellulitis may occur.

Diving Masks, Goggles, and Mouthpieces.

The facial condition termed *mask burn* has been described as a reddish imprint of the mask on the face and was initially thought to be a requisite annoyance of snorkeling and scuba diving.^{[1] [4] [66]} More severe reactions, consisting of painful, disabling eruptions characterized by vesiculation, weeping, and crusting, have been described. Mouthpieces attached to regulators and snorkels may cause minor oral irritation described as a mild burning sensation. Persons who become sensitized to the constituents of the mouthpiece may suffer severe intraoral ulceration and inflammation accompanied by vesiculation of the oral mucosa, gingiva, and tongue.^[4] Neoprene swim goggles can cause raccoonlike periorbital contact dermatitis in sensitive individuals.^{[6] [80]} Chemical constituents in the equipment may be the causative agents.

Rubber mouthpieces and masks contain antioxidants similar to those that cause contact dermatitis in surgeons who are allergic to rubber gloves. Mercaptobenzothiazol, tetraethylthiuram, and isopropyl paraphenylene diamine have been implicated in such reactions.^[69] N-isopropyl-N-phenyl-paraphenylenediamine, a rubber antioxidant used in scuba masks, can cause facial dermatitis.^{[153] [240]} Use of diving equipment can result in both irritant and allergic reactions.^{[65] [68]} Acute facial dermatitis may be treated with the application of cool compresses containing Burow's solution and the administration of oral systemic corticosteroids, such as prednisone, beginning with a supraphysiologic dose and tapered over 7 to 10 days. For serious intraoral reactions, rinsing twice daily with a mouthwash consisting of equal parts antihistamine, such as diphenhydramine elixir, and milk of magnesia may be efficacious.^[69] Individual sores may be coated twice daily and again at bedtime with triamcinolone acetonide (0.1%) dental paste (Kenalog in

Orabase) for 5 to 7 days. The problem may be avoided at the outset by using silicone rubber hypoallergenic masks and mouthpieces.

Rubber Swim Gear.

Nose clips, ear plugs, and swim fins produce allergic contact dermatitides in some individuals.^[69] Nonallergenic equipment is available. Mercaptobenzothiazole, which is a constituent of some bathing caps, also can cause contact dermatitis.^[69] Silicone swim caps are available for persons who are allergic to standard bathing caps.

Chemical Irritants

Sulfur Springs.

Contact dermatitis has not been noted to occur in persons who bathe in hot springs. Skin lesions consisting of numerous pea-sized areas of raised erythema have been attributed to bathing in green sulfur springs.^[230] The lesions develop within 24 hours after bathing and are distributed over the trunk and limbs. No microorganisms that could cause the rash have been found in the water or the lesions. The most important characteristics of green sulfur springs that may account for the irritant reaction are the water's high soluble chloride and sulfur content and its extreme acidity.

Chlorinated Water.

Chlorinated pool or spa water rarely causes irritant dermatitis or an allergic reaction. It may produce contact urticaria. Nitrogen trichloride, which is produced when chlorine is added to water containing ammonia, has a pungent odor and may cause eye and nose irritation.^[67] ^[176]

Bromine.

Bromine-based disinfectants are used in swimming pools and spas. They are more effective than chlorine-based disinfectants against pseudomonads at

high temperatures.^[72] Bromine rash is described as a pruritic, generalized, eczematous irritant contact dermatitis arising within 24 hours of exposure to a spa or pool recently disinfected with 1 bromo-3-chloro-5, 5-dimethylhydantoin (Halobrome).^[199] The rash resolves spontaneously once spa use is discontinued. Treatment is symptomatic.

Algaecides.

Copper solutions or quaternary ammonium compounds may be used to combat algae

growth in pools and spas. Copper algacide solutions used to treat pool and spa water can cause greenish discoloration of the scalp hair in blondes. ^[138] Wetting the hair with fresh water before immersion in pool or spa water decreases the incidence and severity of hair discoloration. Shampooing decreases the green tint, and immersing the hair in 3% peroxide solution removes the green in a couple of hours.

Animal or Plant Irritants

Sea Cucumbers.

Sea cucumbers (see [Chapter 61](#)) are invertebrates that extrude sticky, white tenacular organs used to entangle prey. Humans who come into contact with these moplike strands suffer dermatitis. Cutaneous erythema, pain, and pruritus may occur. The skin manifestations are self-limited. Prompt washing with soap and water appears to remove any toxins. ^[154]

Ichthyocrinotoxic Fish.

A number of fish possess glands that secrete skin toxins (crinotoxins) but do not have venomous defense organs, such as spines. These fish include soapfish, trunkfish, gobies, sole, toadfish, clingfish, and pufferfish.^[90] The toxins can be extremely powerful, but resulting dermatitides are poorly documented. The soapfish (family Grammistidae), *Rypticus saponaceus* ([Figure 63-1](#)), receives its name from the soapy mucus it releases when handled or disturbed. Fisherman in the Caribbean know that holding a soapfish in a restricted volume of seawater with other fish results in death of the other fish.^[95] Human contact results in dermatitis. The skin irritant is called *grammistin*; similar substances have been isolated from boxfish and sea bass species.^{[29] [95] [187]}

Cool compresses of Burow's solution, aluminum sulfate and calcium acetate (Domeboro), or colloidal oatmeal alleviate the burning and itching caused by soapfish

Figure 63-1 Soapfish (*Rypticus saponaceus*). Skin contact with soapy mucus causes dermatitis. (Photo by Carl Roessler.)

dermatitis. In severe cases topical corticosteroids are beneficial. Systemic corticosteroids are rarely required. Wearing protective clothing and gloves when handling fish prevents these dermatitides. Washing protective wear with soap and water after use is required to remove toxins.

Sea Moss Dermatitis and Dogger Bank Itch.

Dogger Bank itch is an eczematous dermatitis caused by a plant (*Fragilaria striatula*) and bryozoarian animals referred to as *sea chervils* (*Alcyonidium hirsutum* and *Alcyonidium gelatinosum*).^[154] This irritant contact dermatitis is most common among

fishermen of the North Sea. These fishermen contact sea mosses or sea mats that are drawn up within fishnets. The irritation first appears on the palms and forearms and often disappears when the fisherman goes ashore.^[171] Recurrent exposure causes subsequent attacks to be more severe. The cutaneous reaction initially consists of erythema but may progress to vesiculated, edematous eruptions of the hands, arms, legs, and face. It is controversial as to whether or not this is an allergic reaction or an irritant dermatitis. Reactions to patch tests performed with an extract from the causative source and lack of reaction in controls support an allergic etiology.

Treatment is symptomatic. Application of dilute (26%) isopropyl alcohol in calamine lotion may provide relief. Severe reactions may require the use of oral antihistamines and corticosteroids or topical fluorinated corticosteroids. Wearing proper protective clothing may prevent this self-limited disorder.

Red Tide Dermatitis.

A "red tide" occurs when large numbers of unicellular microscopic free-swimming dinoflagellate organisms are present in the water. A variety of plant life proliferations, such as *Ptychodiscus breve*, have been implicated as causative agents of red tides. These unicellular algae reproduce at an alarming rate when conditions are favorable. They secrete toxins that can cause dermatitis, conjunctivitis, and respiratory symptoms in humans (see [Chapter 54](#)). Swimming during a red tide may result in an acute urticarial papular eruption. Massive blooms of toxic phytoplankton are toxic to fish. Avoidance of affected areas, especially during windy conditions, is the best prevention. Symptomatic treatment is provided after the victim has exited the water.

Ciguatera Dermatitis.

Blooms of toxic dinoflagellates, such as *Gambierdiscus toxicus*, synthesize toxins that become incorporated into the food chain.^[262] Ciguatera toxins are extremely harmful to humans (see [Chapter 54](#)). The dermatologic manifestations include an intense generalized pruritus associated with a diffuse maculopapular eruption leading to blisters and desquamation. Other manifestations include hair and nail loss, intense diaphoresis leading to dehydration,

cyanosis, and urticarial reactions. Symptom severity depends on factors such as geographic location.^[262]

Seaweed Dermatitis Caused by Algae.

Seaweed dermatitis is almost always secondary to irritation resulting from contact with algae, of which more than 25,000 species are known. Algae are loosely defined as chlorophyll-bearing or colorless organisms that are thallose (without true roots, stems, or leaves). They vary in size, shape, and color. Some are equipped with flagella and

propel themselves through the water.^[235] Algae range from microscopic diatoms (1 µm in length) to kelp plants (100 m in length). Algae are found in all marine environments and are extremely adaptive to temperature and depth variation. For instance, one form of blue-green algae thrives at hot spring temperatures of 71° C (160° F); others dwell in frigid Arctic water. Although sunlight can penetrate only to a depth of 900 feet in the ocean, some blue-green algae exist at depths up to 12,000 feet.

MICROCOLEUS LYNGBYACEUS.

Microcoleus lyngbyaceus, formerly known as *Lyngbya majuscula* Gomont, is a blue-green saltwater alga that has strains of varying toxicity, often within geographic proximity. The "stinging seaweed" is dark green or olive, drab, and finely filamentous, occurring in abundance at depths of up to 100 feet.^[212] ^[213] ^[218] It grows in hairlike masses or mats throughout the Pacific and Indian Oceans and Caribbean Sea, although large epidemics have been reported in Hawaii and Okinawa, Japan.^[111] Outbreaks of *Microcoleus* organism-induced dermatitis occur between March and September in Florida and between June and September in Hawaii. In Hawaii the largest reported series involved windward beaches.^[84] The assumption is that strong currents and winds dislodge the alga from its normal habitat, fragment it, and blow the fragments into the surf line.^[111] The alga produces a dermatonecrotic and potent inflammatory agent called *debromoaplysiatoxin*, as well as an indole alkaloid dermatitis-producing toxin called *lyngbyatoxin A*.^[37] ^[168] ^[218] An indole stain identifies the presence of lyngbyatoxin A; a radioimmunoassay is under development.^[111] *Vibrio alginolyticus* and *Vibrio parahaemolyticus* have been cultured from marine specimens of *M. lyngbyaceus* collected from the beaches of Hawaii. Typically the affected individual swam in turbid water infested with plant life and did not remove his or her bathing suit after leaving the water. Within minutes to hours a pruritic, burning, moist, and erythematous rash develops in a bathing suit distribution, followed by bullous escharotic desquamation in the genital, perineal, and perianal regions.^[213] Lymphadenopathy, pustular folliculitis, and local infections occur in some individuals. It may be difficult to differentiate this reaction from sea bather's eruption (which is attributed to thimble jellyfish or larval anemone organisms). There also are occasional outbreaks of similar skin reactions after exposure to freshwater blue-green algae.^[43] ^[99] Oral and ocular mucous membrane lesions, facial rash, conjunctivitis, and perhaps interstitial pulmonary edema have been attributed to *M. lyngbyaceus*.^[111] ^[212]

Treatment of dermatitis caused by *M. lyngbyaceus* consists of copious irrigation with soapy water, followed by isopropyl alcohol rinses and application of topical steroids. Severe cases may require oral administration of a systemic corticosteroid, such as prednisone, tapered over 2 weeks. Treatment of seaweed dermatitis is preventive. Prevention is accomplished by showering with soapy water and removing all swimwear immediately upon leaving the water. Avoid swimming in areas laden with seaweed.

SARGASSUM NATANS.

Sargassum species algae collect as seaweed masses in great numbers off the southeastern coast of Florida. Breezes blow the algae toward the coast in the winter. The algae are generally considered to be harmless to man. After *Sargassum* species

seaweed was placed in the swimwear of two children at play, they both developed an erythematous skin eruption with urticarial lesions. The rash disappeared within 4 hours.^[33]

Blue-Green Algae of Freshwater.

In freshwater environments, warm weather can cause rapid growth of blue-green algae (group Cyanophyta) in a "bloom."^[222] During conditions of a bloom, toxins are concentrated and become a significant hazard.^{[54] [58]} Species such as *Microcystis aeruginosa*, *Aphanizomenon flos-aquae*, *Nodularia spumigena*, *Nostoc* species, *Oscillatoria agardhii*, *Anabaena spiroides*, and *Anabaena flos-aquae* have been implicated in the acute poisoning and death of wild and domestic animals.^{[169] [198]} In most species of toxic cyanobacteria, the toxins are cyclic heptapeptides called *microcystins* or *cyanoginosins*.^{[215] [226]} More than 40 microcystins have been isolated from blue-green algae.^[215] The toxins are of multiple configurations and include alkaloids, polypeptides, and lipopolysaccharides (endotoxins).^[222] The rapid-acting "death factors" resemble saxitoxin and tetrodotoxin. Animals may collapse quickly and appear to suffer neuromuscular paralysis, with features of staggering muscle fasciculations, gasping, and convulsions.^[93] A different dominant symptom complex includes gastrointestinal hemorrhage and hepatic failure. Although ingestion of contaminated water may cause considerable animal mortality, human exposures to date have resulted primarily in local effects, including allergic reactions, conjunctivitis, ear infection, facial swelling, lip swelling, papulovesicular dermatitis, and gastroenteritis.^{[26] [143]} Therapy is supportive in both animals and humans because all afflictions appear to be self-limited. Cyclosporin A has been shown to inhibit the fatal effects of microcystins administered to mice.

HYPERSENSITIVITY REACTIONS

1510

Aquagenic Urticaria

Aquagenic urticaria is a rare condition that occurs when skin contacts water at any temperature, resulting in an urticarial rash at the site of exposure ([Figure 63-2](#)). ^[178] ^[180] ^[206] The appearance of the urticarial rash is usually preceded by itching. The rash is characterized by pruritic, punctate, and perifollicular wheals 1 to 2 mm in diameter that develop as soon as 10 minutes after contact with water and persist for up to 60 minutes. The rash is usually confined to the neck, upper trunk, and arms. The face, hands, legs, and feet are spared.^[178] An episode is usually followed by a refractory period lasting several hours. No systemic complications have been reported. This entity usually occurs in postpubescent individuals, and it is reported more frequently in women than in men.^[150] There may be a family history of atopy.^[24] The coexistence of other forms of physical urticaria has been demonstrated in some patients. ^[48] ^[156]

The pathogenesis of this phenomenon has been studied but is not completely understood. Histamine involvement is supported by the finding of elevated local histamine levels and suppression of the rash by various antihistamines.^[46] ^[48] ^[209] ^[254] Dermographism typically is not present, and serum IgE levels usually are normal. ^[209] In some cases prophylaxis with antihistamines fails to prevent the urticarial response to contact with water, suggesting a mechanism in the development of aquagenic urticaria unrelated to the release of

Figure 63-2 Aquagenic urticaria. Pruritic, punctate, and perifollicular wheals characteristic of the rash of aquagenic urticaria. (Courtesy Edgar Maeyens, MD.)

histamine. Some have suggested that water may react with a component of sebum on the stratum corneum, forming a toxic substance that diffuses through the skin and may either directly cause urticaria or stimulate mast cells to release histamine, resulting in

urticaria.^[46] ^[206] Another theory is that there is a change in the osmotic pressure in the skin around hair follicles, allowing for passive permeation of water through the skin.^[254] In some victims there is a significant increase in acetylcholinesterase activities, suggesting that the pathogenesis of aquagenic urticaria may be related to the release of acetylcholine in the nerve fibers of sebaceous glands.^[209] The ability of anticholinergics to suppress the hypersensitivity reaction in some individuals suggests that aquagenic urticaria is acetylcholine mediated.^[162] Aquagenic urticaria must be differentiated from other forms of physical urticaria, which can be induced by pressure, exercise, cold, or stress.^[156] Clinically the morphology and distribution of the rash are similar to those of cholinergic urticaria. Aquagenic urticaria can be differentiated from cholinergic urticaria by pretreating the skin with topical atropine, which does not prevent wheal formation in aquagenic urticaria but prevents the rash of cholinergic urticaria.^[209] Aquagenic urticaria also must be differentiated from aquagenic pruritus, in which exposure of skin to water elicits intense pruritus without cutaneous lesions.^[87] Before the diagnosis of aquagenic urticaria can be made, other physical urticarias must be ruled out and the patient must respond to a water provocation test.^[156]

Aquagenic urticarial reactions can be inhibited by applying petroleum ointment to the skin before water exposure.^[209] There may be a role for prophylaxis with antihistamines and anticholinergics. Exposure to ultraviolet (UV) light (psoralen plus UVA [PUVA] and UVB) may be considered as an alternative treatment if others fail.^[122] ^[155] ^[180] PUVA and UVB radiation may cause immunosuppression or inhibit mast cell response to the application of water. UV light treatment may thicken the epidermis, inhibiting the penetration of water. There is a case report in which a patient with aquagenic urticaria responded well to treatment with the anabolic steroid, stanozolol. At a dose of 10 mg/day, symptoms of aquagenic urticaria were controlled.^[63]

Aquagenic Pruritus

Transient itching of the skin after exposure to water is not unusual. Common etiologies of nonspecific water-mediated itching include eczema, xerosis, cold urticaria, heat urticaria, vibratory urticaria, cholinergic urticaria, symptomatic dermatographism, polycythemia rubra vera, aquagenic urticaria, aquagenic pruritus of the elderly, and aquagenic pruritus.^[224] Aquagenic pruritus, in which contact with water at any temperature consistently induces intense, disabling itching without

any visible cutaneous changes, is uncommon.^[52] ^[70] ^[87] The condition is characterized by generalized skin discomfort provoked by contact with water. It is a distinct clinical entity with clearly described diagnostic criteria. Criteria for the diagnosis of aquagenic pruritus include: (1) severe pruritus, prickling, stinging, or burning that consistently develops after skin contact with water, regardless of water temperature or salinity; (2) lack of visible cutaneous lesions; (3) reaction within minutes of exposure and lasting between 10 minutes and 2 hours; (4) lack of a concurrent skin disease, internal disorder, or medication use to account for the reaction; and (5) exclusion of all other physical urticarias, symptomatic dermatographism, and polycythemia rubra vera.^[52] ^[224] ^[225]

Symptoms may occur only in areas exposed to water. Typically the head, palms, soles, and mucosa are spared.^[225] The disabling nature of this intense, unrelenting skin discomfort may account for the mood changes demonstrated by more than half of patients.

Aquagenic pruritus is slightly more prevalent in males, can occur at any age, and may have a familial component.^{[52] [147] [190]} Aquagenic pruritus has been associated with haematoproliferative conditions, including polycythemia rubra vera, myelodysplasia, and hypereosinophilic disorders. Recently an association between histiocytic disorders, such as juvenile xanthogranuloma, and aquagenic pruritus has been established.^[91]

The pathogenesis of aquagenic pruritus is poorly understood, but it has been demonstrated that water, not other liquids, elicits the symptom complex. Increased mast cell degranulation (with an increase in circulating histamine), release of acetylcholine, and increased cutaneous fibrinolytic activity have all been implicated as potential etiologies for the hypersensitivity component of aquagenic pruritus.^{[70] [87] [148]} Topical application of capsaicin, the spicy component within the hot pepper plant, induces release of neuropeptides, including substance P, and reversibly suppresses the axon reflex in the skin.^{[96] [147]} This finding suggests that neuropeptides could play a significant role in the pathophysiology of pruritus.

Treatment for aquagenic pruritus has been disappointing. Preventive alkalinization of water and application of petroleum ointment have had limited success. Administration of antihistamines, anticholinergics, aspirin, iron, serotonin antagonists, propranolol, recombinant interferon-alpha, and triamcinolone is under investigation and has produced inconclusive results.^{[86] [96] [164] [190]} The use of UV radiation and psoralen photochemotherapy has had promising results. It is postulated that UV irradiation is effective because it may reduce end-organ responsiveness by producing ultrastructural changes within nerves or by raising sensory nerve thresholds.^{[96] [164] [217]} It may stabilize mast cells at nerve endings, inhibiting the release of histamine. Complete avoidance of water exposure is the only guaranteed effective therapy for aquagenic pruritus.

INFECTIOUS DERMATITIS

Freshwater Bacteria

Pseudomonas Aeruginosa.

Numerous cases of "hot tub" or "whirlpool" dermatitis have been described.^{[39] [202] [253]} Eruptions occur after the use of heated recreational water sources, such as whirlpools, hot tubs, swimming pools, and water slides.* Family bathtubs, contaminated bath toys, loofah sponges, moisturizing creams, and diving suits have been implicated in cases of pseudomonal folliculitis.^{[25] [71] [75] [105] [163]}

Pseudomonas aeruginosa is the most common microbe causing skin disorders in occupational saturation divers and can occur after recreational use of diving suits.^{[2] [136] [201]} *P. aeruginosa* (predominantly serotype 0–11) is a ubiquitous, motile, nonfermentative, obligate aerobic, gram-negative bacillus.^{[105] [163]} It is a fastidious organism, surviving in extremes of temperature, under hostile conditions, and with minimal nutritional support. It infects humans, other vertebrates, animals, and plants. Extracellular toxins and enzymes produced by *P. aeruginosa* contribute to its virulence and are responsible for cutaneous manifestations, including necrotizing subcutaneous nodules, cellulitis, ecthyma gangrenosum, and hemorrhage. *P. aeruginosa* infects healthy, moistened skin. No unusual host factors have been identified. The high water temperature, hydration of the skin, high concentration of organisms, and chemical irritants in the water all contribute to this dermatitis. In several outbreaks deficiencies in disinfection have been noted.

The follicular rash appears within 48 hours of exposure and resolves within 7 days without treatment. Biopsy specimens demonstrate folliculitis. There is minimal change in the epidermis, but there are perforations in the follicular epithelium, with inflammatory infiltrates. The eruption is most pronounced in areas covered by bathing garments, and the head and neck are spared unless they are submerged. Other symptoms include external otitis; conjunctivitis; tender breasts; enlarged, tender lymph nodes; fever; and malaise.^{[105] [203]} Serious infections arise in immunosuppressed and debilitated individuals. The erythematous, maculopapular, and vesiculopustular eruption usually is accompanied by pruritus.

The eruption is self-limited (7 to 14 days), and thus treatment can be conservative. Papules or abscesses can reappear for up to several months without reexposure. Skin lesions heal without scarring but can cause postinflammatory hyperpigmentation that clears with time. The pruritus may be managed with drying lotions, such as calamine, or with oral antihistamines. "Whirlpool" folliculitis is usually self-limited, and treatment is not

required. Local infections may be treated with applications

*References [\[57\]](#) [\[89\]](#) [\[106\]](#) [\[112\]](#) [\[160\]](#) [\[183\]](#) [\[202\]](#) [\[203\]](#) [\[208\]](#) [\[221\]](#) [\[234\]](#) [\[266\]](#) .

1512

of antimicrobial ointments, such as polymyxin B or gentamicin, until resolved. Rapid progression to severe systemic disease, manifested by hemorrhagic bullae, pneumonia, or septicemia, suggests immunosuppression.[\[57\]](#) [\[79\]](#) [\[195\]](#) [\[220\]](#) *P. aeruginosa* is resistant to many antibiotics. Systemic infection may be treated with an aminoglycoside or ciprofloxacin. Prevention of *P. aeruginosa* infection requires either use of adequate disinfectant or avoidance of recreational closed-water systems, and reservoirs and vehicles of transmission should be disinfected. Showering does not appear to prevent the disorder.[\[203\]](#)

Other infections that have been acquired in closed-cycle recreational water systems include eczema herpeticum and molluscum contagiosum. Whether diminished host resistance resulting from skin hyperhydration or an unusual presentation of pathogens causes viral afflictions after water exposure remains to be determined.

Aeromonas Hydrophilia.

Aeromonas hydrophilia is a gram-negative, facultatively anaerobic, polarly flagellated, non-spore-forming, motile rod member of the family Vibrionaceae that commonly inhabits soil, freshwater streams, and lakes.^{*} *Aeromonas* species are widely distributed and found at wide ranges of temperature and pH.[\[98\]](#) [\[249\]](#) Three species (*Aeromonas hydrophila*, *Aeromonas sobia*, and *Aeromonas caviae*) have been associated with human disease.

Although *A. hydrophilia* may produce soft tissue infections or cellulitis in normal hosts, serious infections are more commonly noted in immunocompromised persons.[\[157\]](#) [\[216\]](#) [\[257\]](#) [\[263\]](#) *A. hydrophila* may cause gastroenteritis, endocarditis, peritonitis, meningitis, and septicemia. Soft tissue and gastroenteric human infections occur predominantly between May and November.[\[113\]](#) [\[249\]](#) [\[258\]](#) A wound (frequently of the lower extremity) immersed in contaminated water may become cellulitic within 24 hours, with erythema, edema, and a purulent discharge.[\[257\]](#) [\[260\]](#) The wound is usually sustained when the individual steps on a foreign object or suffers a laceration or puncture wound while in water.[\[126\]](#) [\[205\]](#) The symptoms may be indistinguishable from those of streptococcal cellulitis, with localized pain, lymphangitis, fever, and chills. If managed with inappropriate antibiotics or if untreated, this infection may progress to a severe gasforming soft tissue reaction, bullae formation, necrotizing myositis, or osteomyelitis.[†] The appearance of aeromonad septicemia is reportedly similar to that of ecthyma gangrenosum caused by *P. aeruginosa*.[\[263\]](#) In a manner analogous to the pathogenicity of virulent *Vibrio* species, the chronically ill or immunocompromised host probably is at greater risk for severe complications, such as meningitis, endocarditis, or septicemia.^{*} In the individual who has aspirated freshwater, *A. hydrophila* can cause pneumonitis and bacteremia.[\[189\]](#) Infections also have occurred after individuals have been bitten by an

alligator or a pet piranha.^{[191] [197]} For unknown reasons there is a marked preponderance of male patients,^[11] which may reflect the phenotypic variation of critical bacterial adhesions.

A Gram's stain of the purulent discharge may demonstrate gram-negative bacilli. Given the appropriate clinical setting (after a wound has been acquired in the freshwater environment), this finding should not be casually attributed to contamination.^[126] *A. hydrophila* generally is sensitive to tetracycline, chloramphenicol, gentamicin, tobramycin, trimethoprim/sulfamethoxazole, cefotaxime, moxalactam, imipenem, ceftazidime, and ciprofloxacin.^{[10] [60] [125] [177]} However, it is typically resistant to penicillin. In one case, culture of a severe wound infection demonstrated the presence of two species—*A. hydrophila* and *A. sobia*.^[121] Notably the latter species was resistant to tetracycline in vitro. Initial therapy for a severe infection should include an aminoglycoside to provide coverage against concomitant *Pseudomonas* or *Serratia* species infection.^[92] As has been demonstrated with *Vibrio* species, the first-generation cephalosporins, penicillin, and ampicillin are not effective against *A. hydrophila*, perhaps because of the production of a β -lactamase by the organism.^{[10] [32] [60] [62] [177]} Because of the microbiologic similarity of *Aeromonas* species on biochemical testing to members of the Enterobacteriaceae family, such as *Escherichia coli* and *Serratia* species, it is important to alert the laboratory to the clinical setting. A case of *A. hydrophila* cellulitis that did not respond to antimicrobials and surgical debridement responded successfully to adjunct hyperbaric oxygen therapy.^{[44] [157]} High oxygen concentrations may suppress virulence factors and inhibit or kill anaerobic organisms.^[44]

In addition to antibiotic therapy, initial treatment of a severe soft tissue infection related to *Aeromonas* organisms should include aggressive wound debridement and adequate drainage to mitigate the potentially invasive nature of the organism. Medicinal leeches can harbor *Aeromonas* species in their gut flora; soft tissue infections related to leech attachment have been reported.^[251] The genus *Plesiomonas* also belongs to the family Vibrionaceae; it has been definitively linked with aquarium-associated infection complicated by watery diarrhea and fever.^[237]

Chromobacterium Violaceum.

Chromobacterium violaceum is a mesophilic (prefers a temperature of 20° C to 37° C [68° F to 98° F]), saprophytic, facultatively anaerobic, and gram-negative rod. It is motile, with both polar and lateral flagella. This bacterium produces a violet pigment (violacein) with oxidative and fermentative

*References ^{[76] [92] [121] [125] [197] [250]} .
†References ^{[49] [76] [125] [140] [216] [257]} .

glucose use. It is an abundant inhabitant of tropical and subtropical freshwater rivers and soil, especially in the southeastern United States, and is generally considered nonpathogenic.^{[109] [166]} The infection usually presents after the organism enters an

individual's body through a minor skin injury or after the individual ingests contaminated water.^{[114] [166] [172] [186] [223]} Sepsis is sometimes a feature of this infection. Bacteremia leads to diffuse pustular dermatitis, with *C. violaceum* cultured from both blood and skin pustules.^[223] Other skin manifestations include vesicles, ecchymotic maculae, a maculopapular rash, ulcers, subcutaneous nodules, cellulitis, lymphangitis, and digital gangrene.^[151] Additional manifestations are secondary to systemic disease and include suppurative lymphadenitis; osteomyelitis; urinary tract infection; sinusitis; orbital cellulitis; lung, kidney, and liver abscesses; and meningitis.^{[151] [166] [223] [239] [247]} Persons with chronic granulomatous disease, which is characterized by the inability of granulocytes and monocytes to convert oxygen into hydrogen peroxide and other oxygen metabolites necessary for microbicidal activity, are at particular risk for severe infection.^{[82] [116] [151]} Fortunately, *C. violaceum* infection, which is potentially fatal and associated with a high mortality rate, is rare. Of 34 reported cases, 65% were fatal.^[186] The interval between the onset of the illness and death ranged from 7 to 15 months. Although most patients with *C. violaceum* infection are not immunocompromised, the presence of immunodeficiency, such as that caused by chronic granulomatous disease, can be a predisposition to infection.

Treatment consists of antibiotics and prompt surgical drainage of purulent collections. The organism is generally sensitive to imipenem, carbenicillin, ciprofloxacin, chloramphenicol, tetracycline, gentamicin, kanamycin, tobramycin, and trimethoprim/sulfamethoxazole. Resistance to cephalosporins, penicillins, and aztreonam has been reported.^{[166] [223] [228]} Southeastern physicians should be highly suspicious when caring for a septic patient with a history of exposure to stagnant water and typical skin lesions, organ abscesses, or both.

Marine Bacteria

Mycobacterium Marinum.

Cutaneous granulomas, referred to as *swimming pool granulomas* or *fish tank granulomas*, caused by *Mycobacterium marinum* were first described in 1954 by Linell and Norden.^{[5] [142]} The lesions resembled tuberculosis verrucosa cutis ([Figure 63-3](#)). *M. marinum* is a so-called atypical (anonymous or unclassified) bacterium. Typical mycobacteria are animal pathogens that cannot multiply outside the animal host, whereas atypical mycobacteria are free-living soil and water saprophytes, rarely pathogens. *M. marinum* is an acid-fast and rod-shaped bacillus, a Runyon group 1 photochromogen that produces yellow-orange pigment after light exposure. It grows optimally at 31° C to 33° C (88° F to 91° F). Therefore human infections

Figure 63-3 *Mycobacterium marinum*. Cutaneous granulomas on the forearm of a patient with *Mycobacterium marinum*. (Courtesy Edgar Maeyens, MD.)

are limited to cooler acral skin and rarely involve deeper, warmer lymphatic or lymph node structures. Swimming pool chlorination provides little protection because the

organism is relatively resistant to chlorine. *M. marinum* is an opportunistic pathogen found in aquatic (freshwater and saltwater) environments. [27] [81] [85] [193] This lesion tends to be associated with trauma or exposure to fresh water, salt water, or marine life. [5] [31] [135] Fish may develop disseminated granulomatous disease. Human infection is typically limited to cutaneous granulomatous lesions, although deeper infections, including bursitis, tenosynovitis, septic arthritis, and osteomyelitis, may result. * *M. marinum* may be rapidly invasive, leading to sepsis in both healthy and immunocompromised individuals. [64] [108] Infections may occur after exposure to fresh, salt, or brackish water and are reported by commercial fish handlers, aquarium tenders, pool cleaners, and dolphin trainers. † *M. marinum* invades tissues through a preexisting skin lesion. Three types of lesions may occur: ascending lymphatic sporotrichin lesions, a solitary granulomatous verrucous papule or nodule that may ulcerate and express purulent drainage, and rare cutaneous disseminated lesions. [81] [185] In one variety of penetration, 7 to 10 days after the individual sustains a puncture wound or laceration, particularly of a cooler distal extremity, a localized area of cellulitis develops. In the absence of appropriate treatment, this area of cellulitis may progress to localized arthritis, bony erosion, formation of subcutaneous nodules, and superficial desquamation. [12] [104] [133] [261] Aspiration of a joint effusion may reveal the acid-fast bacilli. Alternatively, within 3 to 4 weeks of the primary inoculation, a red papule develops and slowly grows, becoming a hard purple nodule. This nodule often is scaly, ulcerated, and verrucous with a violaceous base, resembling tuberculosis verrucosa cutis. [65] [132] [146] [204] [211] The lesion may enlarge to 6 cm in diameter, although a diameter of 1 to 2 cm is more common. New lesions may develop in a pattern that resembles sporotrichosis, with dermal granulomas in a

*References [5] [15] [41] [94] [137] [207] [219] .

†References [31] [45] [51] [73] [117] [135] [137] [219] .

linear distribution along the superficial lymphatics. The granuloma may become secondarily infected, resulting in cellulitis or lymphangitis. The differential diagnosis should include sporotrichosis, cutaneous leishmaniasis, psoriasis, verrucous lichen planus, verruca vulgaris, iodine and bromine granulomas, sarcoidosis, paratuberculosis, syphilis, gout, other cutaneous mycobacteriosis, and chronic pyogenic infections. [115]

The diagnosis of *M. marinum* is frequently overlooked, resulting in significant delays in treatment, because there is no characteristic skin lesion. The diagnosis is confirmed by a skin biopsy or wound culture. The diagnosis of *M. marinum* granuloma is confirmed bacteriologically by isolation of the organism from a homogenized skin biopsy (minimum 4-mm punch) specimen on standard mycobacterial culture medium (Lowenstein-Jensen) at 31° C to 33° C (88° F to 91° F), rather than the standard 37° C (98° F). [5] [78] [115] [135] [259] Acid-fast bacilli are visualized directly in only 10% to 13% of biopsies, and approximately 50% of cultures are positive. [59] Cutaneous intradermal skin tests show cross reactivity between *M. marinum* and *M. tuberculosis*. Risk factors for the development of atypical cutaneous mycobacterial infection include immunosuppression secondary to lymphoma, leukemia, human immunodeficiency virus infection, and medical therapy.

The literature does not reflect consensus on treatment. Conservative therapy, aggressive surgical excision, and multiple antibiotic therapies have been described.[‡] Because most lesions are self-limiting and heal spontaneously within a few months to 3 years, generally leaving some scarring and residual pigmentation, some advocate conservative therapy. Small lesions often are easily excised but may be complicated by local recurrences. Although there have been few reports of prompt diagnosis and successful treatment with antibiotics before surgical biopsy, the astute physician may recognize the initial presentation before surgical intervention.^[12] The optimum treatment of cutaneous *M. marinum* infection, which may ultimately resolve spontaneously, is equally unclear. *M. marinum* is susceptible to many antibiotics. Those used previously with inconsistent results include amoxicillin/clavulanate, azithromycin, amikacin, kanamycin, clarithromycin, minocycline, tetracycline, levofloxacin, trimethoprim/sulfamethoxazole, and tuberculostatic drugs, such as streptomycin, isoniazid, ethambutol, and rifampin.[†] Because clinical evidence regarding the most efficacious treatment of *M. marinum* is lacking, the current recommendation is to treat the patient empirically with one of the aforementioned antibiotics until sensitivities are obtained.^[31] Drug sensitivities of the isolated organisms should be determined.[‡] Susceptibility testing of *M. marinum* is usually delayed for several weeks after treatment has begun and therefore does not have a role in directing initial treatment.^[137] Recent reports favor the use of trimethoprim/sulfamethoxazole or ethambutol plus rifampin as first-line therapy.^{[53] [135] [137]} Trimethoprim/sulfamethoxazole is safe, efficacious, and inexpensive.^[135] Subsequent treatment should be based on the sensitivity and clinical response. All studies agree that antibiotic treatment should be long term, with the duration of treatment varying from months to years.^{[53] [81]} Although the organism is sensitive to heat, heat therapy is no longer recommended. Intralesional steroids are contraindicated.^[56]

Vibrio Vulnificus.

The genus *Vibrio* is classified in the family Vibrionaceae, along with the genera *Photobacterium*, *Aeromonas*, and *Plesiomonas*.^[9] *Vibrio vulnificus* is a part of normal marine flora but is recognized as a virulent pathogen in the United States and other parts of the world (see [Chapter 54](#)). Two distinct clinical syndromes result from infection. Ingestion of raw or undercooked shellfish contaminated with *V. vulnificus* may result in fatal septicemia. *V. vulnificus* contamination of minor wounds can result in virulent, necrotizing cellulitis with bullous skin lesions that require surgical debridement.^[182] The lesions may be attributed to proteolytic, collagenolytic, and elastase activity. The organism has been isolated in warm (20° C [68° F] or warmer) coastal water and in water with salinity of 0.7% to 1.6%.^{[173] [182]} It has been found in brackish inland waters. Inoculation results from contamination of minor skin wounds, lacerations, and punctures by contaminated objects or from skin trauma suffered while exposed to contaminated water. Victims frequently report that they had been handling shellfish or fish in a marine environment when they obtained a small wound. The wound rapidly progresses to an edematous, erythematous or ecchymotic, cellulitic, and painful infection.^[20] What begins as an erythematous lesion may develop into hemorrhagic bullae or vesicles with distal satellite lesions. Lesions may advance rapidly to necrotizing vasculitis or myositis, with acute sepsis.^[127] Hematogenous seeding is

thought to be responsible for "hallmark" lesions.^[20]

Because of the severity and rapid progression of *V. vulnificus* wound infection, prompt diagnosis and antimicrobial treatment, along with early surgical debridement, are mandated.^[182] Antimicrobial therapy may include doxycycline, ciprofloxacin, chloramphenicol, gentamicin, imipenem/cilastatin, third-generation cephalosporins, amikacin, tobramycin, aztreonam, and trimethoprim/sulfamethoxazole. Multiple antimicrobials may be required. Despite prompt diagnosis and

treatment, the mortality rate remains high, especially in persons who are medically or immunologically compromised.

Erysipelothrix Rhusiopathiae.

Erysipeloid is an acute infection of traumatized skin caused by the slender gram-positive bacillus (rod) *Erysipelothrix rhusiopathiae* (formerly *Erysipelothrix insidiosa*) ([Figure 63-4](#)). The infection occurs in fishermen, butchers, and others who handle raw fish, poultry, or meat products. Also called *speck finger*, *fish handler's disease*, *blubber finger*, and less commonly *erysipeloid of Rosenbach*, the condition is noted most often in coastal regions where workers handle crabs and live fish.^[77] ^[88] ^[196] The bacillus is facultatively aerobic and nonmotile and has no spores or capsules. It is hardy enough to survive saltwater or freshwater exposure, drying, salting, pickling, and smoking and survives 12 days in direct sunlight, 4 months in putrefied flesh, and 9 months in a buried carcass.^[88]

Erysipelothrix organisms enter the skin through a puncture wound or abrasion, usually on the finger or hand. Between 1 and 7 days later, a hallmark lesion develops. The puncture wound takes on the appearance of a minor purple-red skin irritation or infected paronychia, with edema and a small amount of purulent discharge. This lesion is surrounded by an area of relative central fading or noninvolvement ("clearing"), which in turn is surrounded by a classical, centripetally advancing, raised, well-demarcated, and marginated erythematous or violaceous ring. Usually the lesion, which is located on the finger or hand, is warm and tender, with characteristic progression up the dorsal edge of the finger into the web space and descent along the adjoining finger ([Figure 63-5](#)).^[256] The lesion is painful and often pruritic, and regional lymph nodes may be inflamed. Pitting and suppuration are absent.^[88] The infection seldom affects the palm. Although the infection is generally limited to the hand, it may spread to the wrist or forearm.^[130] Low-grade fever and malaise are not uncommon. In the diffuse cutaneous form the local lesion enlarges, and dissemination results in multiple satellite lesions distant from the original site, occasionally

Figure 63-4 *Erysipelothrix rhusiopathiae*. (Courtesy Edgar Maeyens, MD.)

with vesiculation or formation of large bullae.^[55] Bacteremia, severe generalized cutaneous infections, systemic infections, and endocarditis are rare.^{[65] [88]}

E. rhusiopathiae may be cultured from the erysipeloid lesion by excising a punch biopsy or by injecting sterile (not bacteriostatic) saline into the edge of the lesion and then reaspirating without withdrawing the needle.^[256] For transport, the specimen should be immediately placed into an infusion broth containing 1% glucose. The microbiology laboratory should be alerted to the possible presence of *E. rhusiopathiae* because it is closely related bacteriologically to *Listeria monocytogenes* and *Corynebacterium* species and may be easily confused with streptococci or diphtheroids.^[88] Without treatment, erysipeloid usually is self-limited and runs its course within 3 weeks. For isolated skin involvement, penicillin VK or cephalexin (250 to 500 mg by mouth four times daily) or ciprofloxacin (500 to 750 mg by mouth twice daily) is rapidly effective.^[14] Erythromycin is no longer recommended. *E. rhusiopathiae* is resistant to aminoglycoside antibiotics.^[210] If arthritis, septicemia, or endocarditis is present, aqueous penicillin G should be administered in a dose of 2 to 4 million units intravenously every 4 hours for 4 to 6 weeks.

Shewanella Putrefaciens.

Shewanella putrefaciens, formerly known as *Pseudomonas putrefaciens*, is a ubiquitous bacterium isolated from sea water, soil, fish, and oily foodstuffs. It is a rare human pathogen that has been associated with lower limb ulceration, otitis media in divers, peritonitis, and bacteremia. Direct contact with sea water and inoculation of a preexisting wound are potential mechanisms of infection. Infection manifests as cellulitic ulcerations. Complications include phlegmon formation and sepsis. *S. putrefaciens* has been documented to produce the extracellular enzymes lecithinase, lipase, and DNase. These enzymes may cause the necrosis of the skin and subcutaneous tissue. Ciprofloxacin has been successfully used to treat this infection.^[179]

Algae

Human and animal infections have been caused by achlorophyllic mutants of the green alga *Chlorella*

Figure 63-5 Typical appearance of *Erysipelothrix rhusiopathiae* skin infection.

pyrenoidosa. The genus *Protheca* consists of nonpigmented algae from the family Chlorellaceae. Three species of *Protheca* are recognized: *Protheca stagnora*, *Protheca wickerhamii*, and *Protheca zopfii*. Only *P. zopfii* and *P. wickerhamii* are demonstrated pathogens in humans.^{[28] [47] [131] [252]} These organisms are ubiquitous and have been isolated in fresh and marine water, streams, lakes, sewage treatment systems, the slime flux of trees, and animal feces.^{*} Prothecae are unicellular, aerobic, and achlorophyllic spherical organisms with hyaline sporangia that reproduce asexually. They are unable to produce energy from photosynthesis and therefore exist as saprophytes.^[28] They are distinct from fungi and bacteria in size, morphology, and method of reproduction. They resemble *Chlorella* organisms and probably represent a mutation of this genus.^{[28] [232]} Protothecosis can present after recreational exposure in swampy areas or after aquarium management.^[28] It results from contamination of preexisting wounds with dirty water and soil or exposure of skin to contaminated water. Percutaneous inoculation with contaminated water after trauma is the most common mechanism of infection.^{[232] [252]}

Clinical manifestations include chronic subcutaneous or cutaneous lesions, olecranon bursitis, and rarely systemic infection involving several internal organs.^{[28] [165] [167] [233] [252]} Although widespread visceral disease has been noted in animals, infections in humans have been limited to the skin, subcutaneous tissue, and regional lymphatics. Most victims cannot identify the portal of entry. Protothecosis has been reported in humans worldwide.

Protothecosis takes two forms: a papular or eczematoid dermatitis in immunosuppressed individuals or a localized infection of the olecranon bursa in individuals with a healthy immune system.^{[170] [233] [252]} Infections are nontransmissible, exogenous, and occasionally associated with an episode of trauma or contact with contaminated water. In cases associated with a traumatic episode the initial lesion is a nodule or tender red papule, which enlarges, becomes pustular, and ulcerates. A purulent, malodorous, and blood-tinged discharge may be present. Satellite lesions usually develop and frequently become confluent. The lesions may become verrucous and resemble chromomycosis. Regional lymph nodes may develop metastatic granulomas. The lesions develop centrifugally and occasionally disseminate. In the olecranon bursitis form the infection develops several weeks after an elbow injury and is localized to the bursa and overlying sinus tracts.^[170] The diagnosis is made based on histologic sections and culture. The organisms are spherical, basophilic, and gram positive; they vary in diameter from 3 to 15 μm (*P. wickerhamii*) or 7 to 30 μm (*P. zopfii*) and stain well with Grocott-Gomori methenamine silver nitrate, colloidal iron for acid mucopolysaccharides, and periodic acid-Schiff. Larger organisms have thick walls and characteristic internal septation. *Protheca* organisms grow on Sabouraud agar, blood agar, or brain-heart infusion agar at an optimum temperature of 30° C to 32° C (86° F to 90° F). The colonies are cream colored, yeastlike, and microaerophilic and reproduce in 1 to 2 days.^{[17] [124]} Antisera for identification of species of *Protheca* can be used on fresh

or formalin-fixed tissues. [229]

Protothecosis and chlorellosis are chronic and progressive diseases. At least one case of chlorellosis has occurred, with the report of a granulomatous reaction of the human foot.[118] Effective therapy has not been established. Localized lesions can be excised, which may be curative. [159] [181] Topical medications are unsatisfactory. Algaecidal agents, including ketoconazole, itraconazole, fluconazole, miconazole, fluorocytosine, and tetracycline, may inhibit or kill the organisms in optimal conditions. There is early indication that parenteral therapy with amphotericin B combined with oral tetracycline may be effective. †

Parasites

Schistosomiasis.

There are three types of cutaneous manifestations of schistosomiasis, reflecting the trematode lifecycle.[61] "Swimmer's itch" presents when humans become abnormal, accidental hosts for nonhuman schistosomes. [61] [107] [248] This condition frequently is caused by avian, rodent, or ungulate schistosomes (of the genera *Trichobilharzia*, *Ornithobilharzia*, *Gigantobilharzia*, *Orientobilharzia*, *Austrotilharzia*, and *Bilharziella*). [8] [103] [152] [200] It is a reaction to penetration of the cercariae through the skin. The cercariae are immature, usually microscopic, larval forms of the parasitic flatworms. The condition's geographic distribution is worldwide, occurring in Arctic, temperate, and tropical zones and in fresh and salt water.[144] Although serious infestation is uncommon in North America, cercarial dermatitis is a vexing problem in certain U.S. locations and has been documented in Massachusetts, Rhode Island, Connecticut, New York, Florida, Louisiana, California, Texas, Oregon, Washington, North Dakota, Nebraska, Iowa, Wisconsin, Minnesota, Michigan, and Ohio. [13] Most commonly, snails and birds that inhabit the lakes of Wisconsin, Michigan, Manitoba (Canada) and neighboring North Central states are the intermediate hosts for these trematodes.[161] Any body of water that is infested with either the definitive or the intermediate host of the schistosome is a potential source of infection. Cercarial dermatitis has been noted in an aquarist who kept an aquarium containing watersnails.[16] Various synonyms, including *Pearl Harbor itch*, *sawah itch*, *el Caribe*, *Koganbyo*, *lakeside disease*, *clam digger's itch*, *swimmer's itch*, *collector's itch*, and *sea bather's eruption*, are used interchangeably with

*References [129] [167] [170] [233] [236] [238] [252] .

†References [28] [129] [158] [159] [165] [167] [184] [232] [233] [238] [245] [252] [246] .

the term *cercarial dermatitis*. However, there is a clear distinction between swimmer's itch and sea bather's eruption (see [Chapter 61](#)), limiting the former to eruptions caused by cercariae and the latter to dermatitis caused by larvae of cnidaria.[16] Abundant submerged vegetation, seaweed in the surf, strong shoreward winds, and high temperatures favor human exposure to schistosomes.[13]

Cercarial dermatitis results when humans become interlopers in the complex life cycle of the schistosome. Adult schistosomes are blood parasites that live in birds and mammals. Schistosome eggs are excreted in animal feces. Swimming miracidia hatch from these eggs and then infest certain species of snails, which serve as intermediate hosts. After incubation in a snail and passage through two sporocyst stages, approximately 200,000 fork-tailed cercariae (infective larvae) are released into the water.^[13] The parasites then enter a specific warm-blooded host and mature in the vascular system, unless humans accidentally intrude into the life cycle at the cercariae stage. When the adult worms produce eggs, the cycle restarts. The severity of the dermatitis and the time of onset depend on the number of cercariae involved and whether the victim has been previously exposed.^[61] Although the cercariae may penetrate the skin while the host is still in the water, penetration usually occurs when the film of water on the skin evaporates. The cercariae penetrate the epidermis but cannot travel beyond the papillary dermis. Histologic examination reveals intraepithelial burrows and abscesses surrounded by an infiltrate of eosinophils, polymorphonuclear leukocytes, and lymphocytes.^[264] The cercariae are walled off and destroyed within 10 to 20 hours of entering the epithelial layers of the skin, where they initiate the destructive inflammatory reaction.^[13] Cercariae are not evident in serial histologic sections if the biopsy is taken more than 24 hours after penetration.^[30]

Swimmer's itch triggers an immune response in the human, an unnatural host. This sensitization phenomenon is suggested by the more severe reactions in individuals who have been previously exposed. The victim initially experiences a prickling sensation. Itching occurs 4 to 60 minutes after the cercariae penetrate the skin and is accompanied by erythema and mild edema. The initial urticarial reaction subsides within 60 minutes, leaving red macules that become papular and more pruritic over the next 10 to 15 hours. Discrete and highly pruritic papules 3 to 5 mm in diameter that are surrounded by a zone of erythema are typical of this disorder. Vesicles, which may become pustules, frequently form within 48 hours. These lesions may persist for 7 to 14 days.^[103] The eruption occurs primarily on exposed body areas. Excoriation leads to pustulation, crusting, and secondary infection. The inflammatory response peaks within 3 days and subsides slowly over 1 to 2 weeks. In mild cases application of isopropyl alcohol or equal parts of isopropyl alcohol and calamine lotion controls the itching. Severe cases may require systemic corticosteroids (prednisone, 20 to 60 mg, tapered over 2 weeks). Secondary bacterial infections, which are most often caused by *Staphylococcus aureus* or *Streptococcus* species, may be managed with topical antiseptic ointments (mupirocin or bacitracin) or systemic antibiotics (such as erythromycin sustained release, 333 mg three times daily for 8 to 10 days). Cercarial dermatitis is diagnosed based on a detailed history and the clinical presentation. The cercariae are not evident on biopsy specimens because they are destroyed before medical attention can be obtained.

The avoidance of areas where there is submerged and dense vegetation allowing snails to flourish decreases the incidence of human infestation. Recently the study of lakes' limnologic characteristics has demonstrated a potential association between water temperature, lake depth, and algae levels and the risk of cercarial dermatitis.^[141] The identification of potential risk factors for the disease may result in better preventive recommendations for recreational bathers.^[40] ^[141] Briskly rubbing with a rough, dry towel immediately after leaving the water removes water droplets that harbor the cercariae

and may provide some protection against the condition. Washing the skin with rubbing alcohol or soapy water after bathing is not effective.^[13] Previously, copper sulfate was used as a molluscicide in cercariae-infested lakes, but this substance is now recognized as an environmental hazard.^[13] Niclosamide does not contain heavy metals and is applied as a molluscicide in 5% granular form to areas exposed during bathing.^[175] Preliminary experiments indicate that niclosamide applied to the skin prevents penetration of cercariae.^[13] Treatment is symptomatic. Antipruritic medications and antihistamines provide some relief.

Dermatitis schistosomia is a similar reaction resulting from human schistosome cercarial skin penetration. When human blood flukes penetrate the skin during the invasive stage of visceral schistosomiasis, an eruption that mimics the purely cutaneous syndrome occurs.^[61] Both the nonhuman and human schistosomes produce skin manifestations consisting of pruritic, erythematous macules and papules. The human blood flukes *Schistosoma mansoni*, *Schistosoma japonicum*, and *Schistosoma haematobium* cause local skin reactions and serious systemic disorders referred to as *visceral schistosomiasis* or *bilharziasis*.

Bilharziasis or schistosomiasis is a cutaneous manifestation caused by either the presence and migration of human schistosomes or the production and release of eggs. It is a hypersensitivity, immune complex-mediated response. An urticarial eruption is present and is associated with eosinophilia and frequently headache, fever, cough, and diarrhea.^[61] ^[248]

Bilharziasis cutanea tarda is a rare disorder that occurs when ova are ectopically deposited within the

dermis. It most frequently is caused by *S. haematobium* and affects the genital area.^[61] ^[248] Eggs reach this site by direct spread of adult flukes or eggs through anastomoses between the superficial veins and pelvic venous plexuses. Clinically, erythematous papules are observed. These papules may become erosive, nodular, vegetative, hypertrophic, or fistulous. Biopsy specimens demonstrate eggs surrounded by granulomatous infiltrates.

WOUNDS

Cutaneous Larva Migrans

Cutaneous larva migrans ("creeping eruption") is a cutaneous eruption caused by the larvae of various nematode parasites for which humans are an abnormal final host. *Ancylostoma braziliensis*, a hookworm of wild and domestic cats and dogs, is the most common helminthic infection affecting humans in the Western Hemisphere.^[101] Other less commonly reported species that can cause this condition are *Ancylostoma caninum*, *Gnathostoma spinigerum*, *Uncinaria stenocephala*, and *Bunostomum phlebotomum*.^[192] A transient creeping eruption also results from infestation with the larvae of the human hookworms *Ancylostoma duodenale* and *Necator americanus*. Humans can become accidental hosts when they contact soil that has been contaminated with the feces of parasitically infected animals. Eggs are eliminated in the feces, and the ova that are deposited in the soil hatch into larvae, which can penetrate human skin. Soil in sandy, warm, and shady areas is most favorable for larvae. Persons commonly affected include ocean bathers, children, gardeners, farmers, and those who work under buildings. Athletes also have been affected.^[19]

In humans the larvae penetrate the skin but not the dermis. Erythematous papules and petechiae develop at the site of the infection. The larvae migrate between the dermis and the epidermis, producing superficial linear serpiginous tunnels called *lava currents*. The feet and buttocks are involved most commonly. Some larvae remain quiescent for a few weeks or months, and then migration is manifested by a wandering, thin, linear, raised, and tunnel-like lesion 2 to 3 mm in width. Older lesions become dry and crusted. Nonspecific symptoms include pruritus, urticaria, and a maculopapular exanthem. A case of cutaneous larva migrans complicated by a systemic inflammatory disorder (erythema multiforme) has been documented.^[244] The larvae move between a few millimeters and a few centimeters each day. Larva migrans may be associated with eosinophilia (in 10% to 35% of cases) and Löffler's syndrome.

Larva currens is a special form of cutaneous larva migrans caused by *Strongyloides stercoralis*. Usually the eruption is associated with intestinal strongyloidiasis and begins in the perianal skin. It may involve the buttocks, thighs, back, and shoulders, but the genitalia are spared. Pruritus is intense, and the lesions spread rapidly, covering between 5 and 10 cm each hour. The larvae leave the skin, enter the bloodstream, and later settle in the intestinal mucosa, and the rash fades.

Treatment of cutaneous larva migrans includes cryotherapy and other physical modalities (application of liquid nitrogen and carbon dioxide with ethyl chloride), topical thiabendazole, and systemic administration of oral thiabendazole (25 to 50 mg/kg) for 2

to 4 days, albendazole (400 mg daily) for 7 days, or ivermectin (12 mg) as a single dose.³ Oral albendazole is an effective treatment, reducing the number of side effects, recurrences, and failures.^{[120] [174]} Secondary infection sometimes occurs and may require incision and drainage of pustules or furuncles and the use of topical and systemic antibiotics.

In endemic areas, precautions include (1) not sitting or lying on damp soil or sand, especially during rainy seasons; (2) not walking barefoot or using water shoes with fenestrated fabric^[231]; (3) draping the ground with impenetrable material before crawling in the dirt; and (4) covering sandboxes with a tarpaulin to prevent contamination by prowling cats.

Leeches

Leeches are members of the phylum Annelida, class Hirudinea. These segmented worms are found in freshwater and marine environments. Their biting jaws allow them to attach to the unsuspecting victim's skin. The freshwater leech may attach without causing significant pain, whereas the marine leech may produce a significant sting upon attachment, perhaps even drawing blood.^[154] Upon attachment of the leech, anticoagulants (hirudin and fibrinase) are released into local tissues, which causes moderate painless bleeding at the site after leech removal. A substance that has local analgesic qualities also may be released.^[83] The release of such a substance could account for the absence of significant pain during freshwater leech attachment. Leeches feed on their host until they become so engorged that they fall off.

Leeches are still used for medicinal and therapeutic purposes throughout the world.^{[97] [214]} The hyaluronidase, collagenase, and aspartase released may play a role in degrading connective tissue and increasing capillary permeability.^[214] Future benefits of therapeutic leech attachment may include the prevention of hypertrophic scar formation and venous congestion in skin transplant recipients.^[97] Symptoms and signs of leech attachment include local pain, redness, swelling, pruritus, and evidence of puncture wounds (caused by the leech's fangs).^[154] The wounds may bleed for a prolonged

*References ^[21] ^[38] ^[149] ^[192] ^[194] ^[243] .

time, heal slowly in unsensitized individuals, and become secondarily infected. Previous sensitization to leeches may lead to a more severe reaction. Leech bites can cause serious systemic allergic reactions, including anaphylaxis.^[100] The wound may become necrotic, urticarial, or bullous.

Leeches must be carefully removed from the skin. If a leech is ripped from the skin, its fangs may break off and remain embedded, which induces phagedena. Leech removal is facilitated by the application of a few drops of alcohol, vinegar, or brine. An alternative removal method involves the application of a lit match at the site of attachment.^[65] After the leech has been removed, the site is carefully inspected to ensure that the fangs are

absent. Hemostasis can be achieved by applying direct pressure and using a styptic pencil, oxidized regenerated cellulose absorbable hemostat, or topical thrombin solution. The wound should be cleansed thoroughly with an antiseptic agent several times daily to prevent infection. To prevent leech bites, avoid wading through waters infested with leeches. Individuals who must enter these waters should wear protective clothing and cover all exposed skin.

Parasitic Sea Lice (Cymothoidism)

Sea lice (cymothoids) are small marine crustaceans of the order Isopoda, suborder Cymothoidra. Water skiers, skin divers, and swimmers who frequent coastal and estuarine waters of temperate and tropical seas may encounter these free-swimming crustaceans.^[18] Sea lice may live as parasites on invertebrates and fish. Sea lice bites are commonly reported along the coast of southern California. Cymothoids are usually buried in sandy bottoms below water level, but they attack any creature that encroaches upon their space.^[69] They typically attack marine animals but may injure humans. They are equipped with a biting apparatus that readily allows them to attach to fish or to human skin.^[18] The bite is rapid and sharp, causing punctate hemorrhagic wounds referred to as *sea lice dermatitis* (cymothoidism). The wounds should be cleansed initially with hydrogen peroxide or a brisk soap and water scrub. A topical antiseptic ointment (neomycin or bacitracin) should be applied, and the wound should be inspected daily for secondary infection. The injury resolves over 5 to 7 days with appropriate care.

Crab Larvae

An unusual sensation and irritation described as "pine needles sticking in the skin" is reported when crab larvae contact exposed skin.^[34] This sensation resolves upon removal of the larvae. The larvae, found floating on the water's surface, are described as "floating sand particles or small, gray seeds." These larvae have small, translucent gray bodies with no glandular structures. Calcified spines induce traumatic injury upon contact with skin.^[69] Contact does not produce urticaria or any other form of dermatitis.

Other

For a discussion of the wounds inflicted by bristle-worms, sponges, and coelenterates, see [Chapter 61](#) .

DIVING-RELATED LESIONS

Diver's Hand

Diver's hand affects most long-term occupational saturation divers at one time or another. The condition is described as extensive peeling and scaling of the upper skin layers covering the palms of the hands and occasionally the soles of the feet.^[3] Victims complain that their skin peels off in large flakes, and they suffer palmar fissures. The peeling starts at the fingers and continues proximally. There are no vesicles, papulae, or hyperkeratosis. Secondary infection rarely occurs. The dermatitis continues for 1 to 2 weeks, but the skin remains sore and thin with fissures for 2 to 4 weeks. Victims complain of increased sensitivity to nonspecific toxic agents. Diver's hand may occur in divers without any previous skin problems. Skin biopsies reveal the formation of horizontal clefts in the upper two thirds of the stratum corneum. The absence of inflammatory components and infectious organisms might indicate that physical or chemical factors are of etiologic relevance. Diver's hand is theorized to develop in all phases of saturation (compression, bottom time, and decompression), as well as after the end of saturation. Divers without diver's hand may have several other skin symptoms, including *P. aeruginosa* infection and otitis externa, during a saturation period.^[2] ^[3] There is no effective protection or treatment available.

Mask Squeeze

Divers can experience bilateral subconjunctival hemorrhages and may sustain pressure marks in the shape of the diving mask if they are unable to equalize pressure within the mask as they descend (see [Figure 22-19](#)).

Nitrogen Rash

If scuba divers linger longer than the recommended time at depth, oversaturation of nitrogen under pressure in the subcutaneous tissue can rarely cause transient dermatitis. Nitrogen rash is manifested by pruritic, tender, and erythematous lesions involving primarily the flanks and elbows.^[154] Diving should be discontinued until all symptoms and signs resolve.

Decompression Rash

If a diver surfaces too rapidly after being at depth, decompression sickness (see [Chapter 57](#)) may result. Cutaneous

manifestations of decompression sickness include pruritus, erythema, mottling, and pallor.^[154] Recompression therapy is mandated.

AQUATIC SPORTS-RELATED DERMATOSES

Otitis Externa

Infection of the external ear canal is the most common of all aquatic dermatoses ([Figure 63-6](#)). It causes extreme discomfort and interferes with participation in aquatic activities. The duration of exposure to water is directly related to the incidence of otitis externa. Otitis externa is referred to as *swimmer's ear* because swimmers and scuba and deep-sea divers frequently are afflicted with this problem. As described by Strauss, the adult ear canal is a cul-de-sac lined with stratified squamous epithelium approximately 5 mm in diameter and 25 mm in length. The outer third of the ear has a physiologic barrier to infection, consisting of an acidic waxy mantle with sloughed epithelial cells. However, this barrier is not present to the same degree on the thinner and more delicate epithelium of the inner two thirds of the ear.^[227]

The pathophysiology of otitis externa involves the interaction of moisture retention, moderate to high temperatures, and infection. Other factors that predispose a diver to the development of otitis externa include canal occlusion (e.g., exostoses, cerumen plugs, entrapped particles of sand, earplugs), trauma related to mechanical attempts to clean the ear canal, intrinsic dermatoses (e.g., allergic conditions, eczema, psoriasis, contact and seborrheic dermatitis, neurodermatitis), cerumen degradation, and pH variation (normal pH is 4 to 5). The initial symptoms of otitis externa include itching of the ear canal, pain, pressure or fullness within the ear, and diminished hearing. As the inflammatory process within the ear canal progresses, the pain becomes more intense. Pain is noted upon applying pressure to the external auditory meatus or the tragus and upon pulling the ear lobe. A severe infection may develop into otitis media, canal occlusion, cervical lymphadenopathy, headache, nausea, fever, toxemia, and cellulitis with associated purulent discharge. Infection can spread to the periauricular soft tissues, parotid gland, and temporomandibular joint. A secondary periauricular irritant contact dermatitis may occur when suppuration in the ear canal discharges toward the surrounding skin. The usual bacterial pathogens responsible for otitis externa are *P. aeruginosa* and *S. aureus*.^{[102] [265]} Otitis externa is polymicrobial, so other isolates include *Acinetobacter calcoaceticus*, *Proteus mirabilis*, *Enterococcus faecalis*, *Bacteroides fragilis*, and *Peptostreptococcus magnus*.^{[42] [102] [265]} Otitis externa does not appear to be associated with bacterial indicators of recreational water quality, such as fecal coliform bacteria, enterococci, or *Pseudomonas* organisms.^[35] A recent

Figure 63-6 Malignant otitis externa. (Courtesy Edgar Maeyens, MD.)

study showed that even when current water standards for recreational aquatic activities are met, swimming can increase an individual's risk of otitis externa because of exposure to *P. aeruginosa*.^[242]

Treatment is directed at changing the environment within the ear canal. The goals of topical therapy are reacidification and desiccation of the ear canal and are accomplished by the topical administration of a mixture of alcohol and acetic acid (vinegar) or Burow's solution (aluminum sulfate and calcium acetate [Domeboro]). Mild otitis externa characterized by slight pain and itching can be treated with eardrops alone. An excellent topical preparation is nonaqueous acetic acid with or without hydrocortisone 1% (VoSol otic). If suppuration occurs, antibiotic eardrops, such as hydrocortisone 1%, polymixin B, and neomycin (Cortisporin otic) or ofloxacin otic, are indicated.^[119] Products not currently recommended include benzocaine, antipyrine, camphor, ichthammol, and thymol.^[227] If the ear canal is so swollen that drops cannot be instilled, a gauze wick should be placed and continually soaked with the topical agent for 24 to 72 hours. Systemic antibiotics, such as oral trimethoprim/sulfamethoxazole or amoxicillin/clavulanate, are indicated if cellulitis, adenopathy, profuse purulent discharge, or fever is present. Intravenous antibiotics are indicated when the infection worsens or does not resolve rapidly. In patients who do not respond to the standard antimicrobial management, a course of antibiotics that cover anaerobic bacteria is warranted.^[42] Fortunately, otitis externa rarely progresses to the life-threatening condition of malignant otitis externa. When the condition does not respond to other treatment measures, some suggest that hyperbaric oxygen can be effective. Analgesics are required for pain control. Systemic steroids should be avoided unless an underlying dermatosis exists because they may interfere with the host's response to infection. Oily suspensions or moisturizers must be avoided.

To prevent otitis externa, the individual must take prophylactic measures intended to inhibit moisture accumulation within the external ear canal. Head shaking, tilting, and fanning; use of a blow dryer; and use of desiccating and acidifying agents all prevent moisture accumulation and decrease the incidence of otitis externa. Cotton-tipped applicators should not be used to extract moisture or remove cerumen because they may damage the ear lining or press cerumen deeper into the canal. Cerumen softening products are not useful because they only soften hardened or impacted cerumen without removing it. If warranted, a trained professional may remove cerumen with irrigation or curettage. Earplugs should not be used because they produce ischemia of the ear canal lining. Oily substances, such as petroleum jelly, should not be used to form a water-tight seal because they will act as a moisture trap for debris, increasing the

incidence of otitis externa.

Chapter 64 - Survival at Sea

Michael E. Jacobs

It is difficult for us to grasp the idea that parts of our planet remain in an almost primordial state of wildness and isolation. There are only a few places left on earth where merely getting across them is an achievement: Antarctica ... the Sahara ... the Southern Ocean ... the wilderness of ice or sand or water or terrible places where nature retains power over humans to terrify and diminish.

Derek Lundy, *Godforsaken Sea*

The greatest wilderness on earth is the sea. It covers two thirds of the planet and, with the exception of the sun, has the greatest influence on global weather patterns. Although it may take hours to days to succumb in other environments, death at sea can happen in less than a minute. Compared with desert heat, high-altitude hypoxia, and polar subzero temperatures, water is the most hostile and life-threatening natural environment for inadequately equipped survivors.

The 1979 Fastnet Race distinguished itself as the worst disaster in the 100-year history of ocean yacht racing. When a killer storm approached the Irish Sea between southwest England and southern Ireland, it exploded without warning in the midst of the Fastnet racing fleet. Suddenly, 2700 men and women in 303 ocean sailing yachts unwittingly became participants in a study of survival at sea. With winds up to 55 knots and seas to 50 feet, waves knocked down one third of the fleet and completely capsized one fourth. Despite a massive response of personnel and equipment, 15 sailors drowned, 24 crews abandoned ship (five eventually sank), and 136 people were rescued from disabled yachts. The inquiry noted, "The common link between all 15 deaths was the violence of the sea, an unremitting danger faced by all who sail."

Mastering seamanship and survival skills requires training and experience. The ultimate challenge for every mariner is to confront and handle the fears that render a person helpless in a survival situation. Survival therefore depends on both a philosophic and a psychologic orientation, as well as skills and knowledge of equipment. This chapter

discusses some of the basics for survival at sea.

EMERGENCIES AT SEA

The Decision to Abandon Ship

The only time a crew should abandon ship is when the vessel is about to sink. Sinking is generally caused by flooding, fire, or collision. "Always step *up* to the life raft" means that it is usually unnecessary to abandon the vessel before the decks are awash. Leaving a ship prematurely often places the crew at greater risk than remaining with the disabled craft. Many flooded boats fill with water and then remain partially submerged on the sea surface because of the positive flotation integral to the hull's design and structure.

With rare exception, a floating disabled yacht is a much safer place than a life raft. The vessel is always the number-one life boat. The boat provides a more visible rescue platform from both the air and the sea compared with a small life raft. The vessel is more likely to withstand wind and waves because it is stronger than most life rafts. The equipment and provisions necessary for communication and survival are generally more extensive aboard the well-stocked mother ship than those found in the life raft. Conditions will be much worse in a life raft.

Flooding

Before abandoning ship, a quick assessment of the damage should be made. Time is the limiting factor. The crew's level of training, experience, and expertise will be decisive to prevent loss of the ship. Having the proper tools and repair materials to respond quickly and efficiently is equally important. [Box 64-1](#) lists the recommended contents of a damage control kit suitable for an offshore sail or power boat.

Flooding is the most common disaster at sea. It can result from material failure, system failure, accidents, and hull and rigging damage caused by extremely violent weather ([Box 64-2](#)).

Early detection of flooding is the critical first step to mounting an effective response. Frequent and regular visual inspections should be made of the bilge, engine room, galley, and head while underway. A backup bilge alarm is useful between inspections, and automatic bilge pumps are essential for unattended boats.

If flooding occurs, the following actions are recommended:

1. Alert the crew and put on life jackets.

2. Turn on the electric bilge pumps and start the engine to run the engine-driven pumps.
3. Send out a distress message.

The captain should try to transmit a distress call before the electric system short-circuits from water rising in the cabin. The call can always be canceled should the vessel be saved.

1526

Box 64-1. DAMAGE CONTROL KIT

Assorted hose clamps

Extra through-hull conical wooden plugs

3-M 5200 or equivalent sealant/glue (cartridge and gun)

Collision mat with 15-foot lines in corners

Water-activated fiberglass repair fabric ("Syntho-Glass")

Hacksaw with spare blades

Bolt and rigging cutters

Drifts matching size of clevis pins

Duct tape

Two 12- to 16-inch plywood squares for hole patches

Self-tapping screws (1 to 2 inches)

Hammer and large screwdriver

Shoring materials and wood wedges

Portable VHF emergency ship antenna

Hammer and large screwdriver

Shoring materials and wood wedges

Portable VHF emergency ship antenna

Emergency single-sideband (SSB)
coaxial antenna

Vise-grip pliers

Hand drill and bits

Extra canvas buckets

Extra dry chemical fire extinguishers

Box 64-2. SOURCES OF FLOODING

1. Failure of through-hull fittings involving the following systems: head, galley, wash basins, shower sump, bilge pumps, centerboard pins and cables, engine exhaust, engine cooling, deck and cockpit drains, bait box, drain plugs (for small boats), knot meter sensor, depth sounder sensor, propeller shaft stuffing box, shaft struts shaft log, rudder post
2. Failure of hose connections, clamps, pipes, and fittings
3. Open hatches, portholes, and ventilators
4. Siphoning of sea water back into the boat because of poor system design or failure of a check valve
5. Collision with large floating or submerged objects
6. Structural failure in hull, deck, or rigging
7. Punctured hull from overboard broken spars (e.g., dismasting)
8. Ruptured on-board water tanks (a boat will not sink from leaking internal water tanks)

The next three tasks are to (1) locate the source of flooding, (2) stop or reduce the

inflow, and (3) repair the damage. The volume of water coming in depends on the size of the opening and its depth below waterline. A typical ½-inch-diameter open seacock located 2 feet below waterline will admit 62 gallons per minute (gpm), and the same opening 4 feet down will allow 87 gpm. A 1-inch hole 2 feet below the waterline will bring water on board at the rate of almost 300 gpm and a 6-inch hole at 1000 gpm.

A boat equipped with the largest manual double-action twin-diaphragm bilge pump can only pump a maximum of 42 gpm. It is important to locate and stop the leak rather than fight a losing battle trying to bail a boat with hand-operated pumps. A bucket has a capacity of 3 gallons and weighs about 20 pounds. A bucket brigade may be effective for a limited time until the source is located.

As the water rises, it becomes more difficult to locate the leak. The rate of flooding slows as water rises above the hole and the pressure gradient is reduced. Inflow of water steadily decreases as the depth of water in the boat increases. The inherent buoyancy of the boat as it settles in the water may help attain a point of zero net flooding. Therefore the ship is not abandoned at the first sign of flooding. Many small wood and fiberglass boats float when fully flooded, or the rate slows sufficiently to allow pumps to handle the volume. Most small boats under 20 feet constructed in the United States after July 1972 are required to have sufficient built-in flotation to remain afloat when swamped. Every effort should be made to plug the hole and keep the pumps working, even if this is only partially effective, until help arrives or the leak is sealed. A diagram showing the location of all through-hull fittings with the routes of connecting hoses should be readily available. A tapered wood plug sized to fit a leaking through-hull fitting can serve indefinitely as an adequate seal. Any soft pliable material, such as blanket, towel, cushion, clothing, or foam pad, can be used as a plug to slow water rushing through a jagged break in the hull. It should be backed with a board or other firm solid material and shored in place with a stick or pole. Heeling the boat away from the area of damage to raise the hole will decrease water pressure and flow, and reducing forward speed decreases water coming in from the bow.

Flooding after a capsize is usually the result of massive structural damage breaching the watertight integrity of the hull. Broken spars (mast or boom) that are overboard must be cut away before they puncture the hull. Large holes in the hull can be overlaid with a collision mat placed outside the hull to supplement the interior patch. The mat is a piece of heavy canvas with grommets and lines that enable it to be positioned and secured on the outside surface. It is held in place by the water pressure and lines. These mats can be purchased or improvised by using a small sail or awning material. An umbrella-like device called a "Subrella" can be pushed through the damaged area from the inside and then opened on the outside of the hull by pulling it sharply back. The water pressure automatically spreads the patch over the hole to form an effective seal and holds it in place.

If on scene the Coast Guard can supply a portable gasoline-powered dewatering pump. If the pump is dropped into the sea from an aircraft, a retrieving line will be lowered to crew on deck. The pump is simple

to operate and comes in a waterproof barrel with hoses, gasoline, and operating instructions. It usually takes two people to lift the barrel from the sea onto the deck. A standard dewatering pump can pump 140 gpm.

Some oceangoing recreational boats are built with watertight compartments to confine flooding to a limited area. The crew must know the locations of watertight doors and how to operate them.

Finally, if the circumstances permit, the captain might consider intentionally running the boat onto shore, where it can be repaired and salvaged later.

Fire

Approximately 7500 pleasure boat fires and explosions occur annually, with at least 10% of the boats declared total losses. More than half the fire-related injuries occur on small, open motor boats. Extrapolating from the U.S. Coast Guard's recreational casualty statistics, 2700 serious injuries occur annually, with 3 to 13 fatalities.

Common causes of onboard fires include fuel leakage in the engine compartment, faulty electric wiring, leaking hydrogen battery gas, faulty or careless use of galley stoves and their fuels, improper stowage of paints and solvents, careless smokers, and lightning. [Box 64-3](#) lists ways to prevent fires.

The explosive potential of fuels depends in part on their vapors and where they accumulate in the enclosed, unventilated spaces in a boat. Hazardous liquids are classified according to their *flash points*, the lowest temperature at which a liquid releases enough vapor to sustain burning. Flammable liquids, such as gasoline, turpentine, lacquer thinner, and acetone, have flash points below 38° C (100.4° F), which means they release enough vapor at common ambient temperatures to form burnable and explosive mixtures. Combustible liquids, such as diesel oil, kerosene, and hydraulic fluid, have flash points above 38° C.

Most boat fires start in the engine compartment. The best protection and first priority is to install a properly sized automatic discharging extinguisher system. Some new products are designed to monitor the compartment and sound an alarm if they detect an open flame. They work by sensing ultraviolet radiation. Others incorporate a high temperature sensor that activates when the temperature exceeds 66° C (150.8° F).

Fuel leakage in the engine compartment and bilge is a common cause of boat fires. Gasoline ignites when it spills onto hot engine parts or from the heat within the enclosed space. A teaspoon of gasoline can vaporize and cause an explosion; a cup of gasoline has the explosive potential of several sticks of dynamite. Vaporized gasoline is heavier than air and accumulates in the lowest part of an enclosed compartment. Diesel fuel is much less explosive and dangerous. Other fuels, such as charcoal, can spontaneously

ignite in a damp and unventilated locker.

Box 64-3. FIRE PREVENTION AT SEA

1. Sniff the engine compartment before starting a gasoline engine and before starting the electric bilge blower.
2. Ventilate the bilge and run the bilge blower for at least 4 minutes before starting a gas engine.
3. Periodically inspect wiring for cracks and check electric motors for sparks.
4. Ventilate the battery compartment, and never create sparks around a battery until the surrounding space has been ventilated. Inspect and tighten battery cable connections. Never smoke around a battery.
5. Install a lightning protection system.
6. Observe all precautions when taking on fuel. Close all hatches and ports before filling the tanks, and extinguish all flames.
7. Use portable kerosene and alcohol heaters with caution and only when someone is on board.
8. Never leave the stove unattended while in use.
9. Store extra fuel on deck in approved plastic containers.
10. Store any outboard motor and its fuel tank on deck.
11. Transfer gasoline and other flammable liquids from one container to another on deck or off the boat.
12. Inboard engines require meticulous inspection and maintenance. Become an expert in examining and repairing all components of the fuel system.
13. Install a heat-activated automatic fire-extinguishing system in the engine compartment, together with smoke and flame detectors.
14. Properly store fuels, solvents, paints, brushes, and combustibles in a deck

13. Install a heat-activated automatic fire-extinguishing system in the engine compartment, together with smoke and flame detectors.
14. Properly store fuels, solvents, paints, brushes, and combustibles in a deck storage locker. Keep all rags in metal containers with the lid tightly closed. Do not keep oily rags below decks or in the engine compartment.
15. Place fire extinguishers away from the intended area of use so that they are accessible, and have them inspected and maintained annually.
16. Read the extinguishers' instructions periodically, and practice on a controlled fire away from the boat.

Another highly flammable and potentially explosive gas is hydrogen. This gas is generated while batteries are charging and thus accumulates in the battery compartment or in the compartment overhead, because the gas is lighter than air. Overcharging batteries produces excess hydrogen gas, and a spark from a nearby electric system can set off an explosion.

Used in galley stoves, liquefied petroleum gas (LPG) is also heavier than air, and a leak in the system can lead to accumulation of highly explosive gas in the bilge. Leaks in gas lines can be detected with an electronic gas detector installed beneath the stove and in the bilge. The main purpose of a pressure gauge is to demonstrate leaks, not to indicate fuel levels. After rough weather the system is tested by opening the

1528

cylinder valve with the solenoid switched on and recording the gauge reading. Next, only the cylinder valve is closed to see if pressure drops, indicating a leak. To avoid accidents, after cooking, the solenoid is switched off first, and the burner continues to flame until the line is free of gas. Once the flame is extinguished, the burner is turned off and the cylinder valve closed. Both the cylinder and the solenoid valves should be closed whenever the stove is not in use or the boat is left unattended. The stove should not be used as a cabin heater. The open flame can deplete a tightly closed cabin of oxygen and cause asphyxiation of the sleeping crew.

Stove alcohol is also potentially hazardous. Alcohol stoves become especially dangerous if one burner is accidentally extinguished and liquid alcohol pours onto the stove and is subsequently ignited by another flaming burner. A nonpressurized burner can also reignite if it is refilled while still hot. An alcohol fire can be extinguished with a fire blanket or wet towel. A grease fire on the stove can also be extinguished with these items or by liberally sprinkling the fire with baking soda. A kettle of water placed on the burner when first igniting an alcohol stove helps to contain any large flames from the excess alcohol used in priming the burner.

All recreational vessels are required to have portable fire extinguishers. The standard multipurpose dry chemical extinguisher is useful on all types of fires, class A, B, or C. It smothers a fire by preventing access to oxygen. The disadvantages are the powdery mess and destruction of circuitry in electronic equipment. Crew should know in advance how to operate the extinguisher, because it will completely discharge in a few precious seconds. The nozzle is directed to the base of the fire and the powder discharged with a sweeping, side-to-side motion. If all on board extinguishers are depleted, fires involving common combustible materials can still be brought under control by cooling with large amounts of water. Fires involving flammable or combustible liquids can be smothered to remove the oxygen (using a fire blanket if available), and electrical fires can often be controlled by cutting the electric power ([Box 64-4](#)).

Collision

Collisions are responsible for approximately half of all recreational boating accidents reported to the U.S. Coast Guard. Only capsizing and crew falling overboard cause more fatalities. Collision with another boat or with a fixed or floating object is responsible for the greatest number of nonfatal injuries and accounts for more than three times as many injuries as any other type of marine accident. The most common injuries are fractures, head, brain and neck injuries, and lacerations. Two thirds of water craft involved in collisions are open motorboats under 26 feet in length and jet-ski personal watercraft (PWC). Even though PWC are involved in more accidents, more than six times as many fatalities occur with open motorboats. Since 75% of fatalities result from drowning, the wearing of life jackets by PWC riders may explain the lower number of fatalities in this group. Approximately 80% of all reported boating accidents involve operator-controllable factors, not equipment or environmental factors. The boats generally have no major mechanical problems, and fair weather with good visibility and calm seas are the rule.

Box 64-4. GUIDELINES FOR FIRE AT SEA

1. Attack the fire immediately at the source. Detection and reaction time must be within a few minutes, before the fire burns out of control. Prepare a plan that has been shared with the crew so that everyone knows the location of equipment and their responsibilities.
2. Initiate a mayday call immediately. The purpose is to alert ships in the area that the crew may have to abandon ship.
3. Put on life jackets. Ensure that the life raft is away from the fire, and prepare to abandon ship.
4. Slow the boat to reduce relative wind, and steer to keep smoke and flames clear of the crew and vessel. Keep the fire on the downwind side of the ship, exposing the smallest amount of the boat's structure to the flames.
5. Position personnel between the fire and a clear escape route.
6. Cut off the source(s) of the fire (e.g., fuel supply, electric current). Turn off blowers, and stop the engine immediately.
7. Close the hatches, doors, and vents to all compartments free of people.
8. If you must open a hatch to discharge a portable extinguisher, beware of burning your hands or face. As fresh air enters the compartment, the fire will rise to the air source and flare up. The safest way to open a hatch is to wear gloves and stand on the hinged side of the hatch while pulling it open.
9. If the fire is too large or out of control, abandon ship before the fuel tanks explode.

The operator factors responsible for collisions include inattention and inexperience, carelessness, recklessness, excessive speed, improper lookout, and lack of boating safety education. Alcohol consumption in reported accidents accounts for at least 27% of fatalities.

The majority of recreational boating accidents occur on inland or near coastal waters, which corresponds to the commonly used areas of recreational boating.

For adventurous boaters cruising the world's oceans, collisions have become a major hazard. Encounters with whales may be the most memorable, but they are

1529

rare occurrences. The major threats to small boat cruisers are collisions with partially submerged objects or being run down by a huge commercial ship in a standard shipping route.

Regulations to prevent collisions at sea, referred to as COLREGS, define the responsibility of ships when collision is possible between two boats, as when crossing each other, overtaking, or meeting head on. Although the privileged vessel, which has the right of way over the burdened vessel, is permitted to hold course and speed, the rules require that both ships take whatever actions necessary to avoid an imminent collision. In the presence of large ships, small boats must be extra vigilant and defensive. The visibility from the pilothouse of a large vessel may be partially obstructed, so a small craft may not be seen by the lookout, show up on radar, or be granted right of way. Unfortunately, both commercial ships and solo ocean racers often run on autopilot without a lookout on deck. This is a clear violation of rule 5 of the COLREGS: "Every vessel shall at all times maintain a proper lookout by sight and hearing ..."

Radar is invaluable in poor visibility. At night or in fog the unit can be used to identify other ships, hazards to navigation, squalls, and other local weather phenomena that may endanger a vessel.

Many affordable small radar units are available for recreational boaters. One problem common to units on small boats is that during storm conditions, large commercial ships and yachts may be lost on the radar screen because of the mass of echoes from nearby tall waves. The intense reflection of radar signals from the sea is called *sea clutter*. Fiberglass and wooden boats are nearly invisible to radar. Regardless of construction, all boats should have a radar reflector mounted when in busy shipping traffic lanes, on the open sea, or under conditions of reduced visibility. Ideally, a reflector should provide consistent reflective performance in all directions; in general, the larger the reflector, the better the reflection.

To make a vessel the brightest reflection on the other vessel's radar screen, an active

transponder can be used. Mounted on the masthead, this device receives the radar signal and then transmits the signal back to the radar unit with a signal electronically enhanced and stronger than one from a passive reflector.

Another useful function of radar is the ability to maintain an electronic guard zone. The radar scans this zone, which is preset as a circle of a given radius. The radar sounds an alarm when a new target enters the guard zone. [Box 64-5](#) reviews measures to prevent collisions at sea.

Partially submerged objects, especially floating logs and cargo containers, are difficult to detect. An estimated 1000 or more shipping containers fall from the decks of merchant ships every year during storms at sea, and about half of them continue to float. The most common shipping container is 40 feet long and 8 feet wide; constructed of aluminum, steel, or wood; and capable of carrying up to 50,000 pounds of cargo. A refrigeration container weighs about 4 tons empty and may float partially submerged, even with the doors ajar, because of its thick insulation.

Box 64-5. PREVENTING COLLISIONS AT SEA

1. Post a lookout with a 360-degree view of the horizon.
2. Know the rules for steering and right of way.
3. Use radar.
4. Use Collision Avoidance Detection Radar (CARD) if available.
5. Use a radar reflector, and place it as high as possible.
6. Do not assume other boats have operational or unobstructed running lights.
7. Observe rule 7 of the COLREGS: "When a vessel has any doubt as to whether a risk of collision exists, she shall assume it does and avoid it."
8. Ask yourself, "Can I be seen?" Do not assume you are seen, even in daylight. The height of the steering station of a large commercial vessel makes it difficult if not impossible to see a small boat near the bow or alongside the ship.
9. If you hear a foghorn, stop and let the other ship steer around you.
10. If a collision threatens, sound the danger signal (five or more short

- see a small boat near the bow or alongside the ship.
9. If you hear a foghorn, stop and let the other ship steer around you.
 10. If a collision threatens, sound the danger signal (five or more short blasts on the horn), and take whatever actions necessary to save your boat.
 11. Maintain radio contact with other ships in the area. VHF channel 13 is the bridge-to-bridge channel. Use channel 16 if there is no response.
 12. Avoid shipping routes if possible, and avoid navigating in the harbor's incoming and outgoing traffic separation lanes designated for commercial traffic.
 13. When your boat is in the way of another vessel, the right of way does not automatically grant you safe passage.
 14. To avoid collision with another vessel, make early and recognizable changes in course and/or speed.
 15. Give large ships a wide berth.
 16. Observe the bearing of an approaching vessel (the direction relative to you). If the bearing does not change, and if the distance between the two boats is decreasing, you are on a collision course.

The sea is rapidly becoming littered with other types of floating cargo. A 425-foot log transport carrying 12,000 tons of 40-foot white spruce logs to British Columbia recently dumped 90% of its cargo into the Gulf of Alaska during a storm. In the same weather pattern, a Pacific storm overwhelmed four container ships en route from Japan to Seattle, causing them to lose 400 containers overboard.

Massive stumps and log debris float in the coastal waters of northern California, Oregon, and Washington

as a result of logging practices in northern river watersheds. The waterlogged stumps flow down the rivers, enter the ocean, and float just below the surface.

The sinking of the 19-ton, 43-foot schooner Lucette in the Pacific after attack by three killer whales reminds all sailors that yachts can be destroyed in unprovoked attacks.

Cruising at 10 knots and accelerating underwater to speeds up to 30 knots, there is little time for a whale to reconnoiter and reevaluate its target while attacking torpedo style. Other attacks may be a reprisal by a whale accidentally rammed while sleeping at the surface. This is probably what occurred to the cruise ship Royal Majesty, which arrived in Bermuda with a dead 60-foot finback whale balanced atop its bow.

Sailors crossing the North Atlantic in summer along a great circle route to Europe need to beware of colliding with icebergs. Every year from February to July, more than 10,000 icebergs are separated from Greenland glaciers. At least 1000 of them drift in the Labrador current south and east of Newfoundland and become a hazard to mariners above 41° north latitude. Navigation around icebergs is complicated by dense fog often present over the Grand Banks region and the difficulty of detecting icebergs with radar. Radar is 60 times less likely to pick up an iceberg than to detect a ship of the same size. Iceberg reports are broadcast twice daily by U.S. and Canadian Coast Guards. The International Ice Patrol broadcast times and frequencies can be obtained by calling 203-441-2626.

Seasickness

During storm conditions, mariners frequently consider seasickness a medical emergency and justification for medical evacuation. Each year, dozens of yachts are abandoned while still seaworthy because their exhausted and despondent crew have lost their collective will to persevere.

At the very least, seasickness (mal de mer) may be moderately disabling; it can also lead to rapid deterioration with progressive dehydration, loss of manual dexterity, ataxia, loss of judgment, and loss of the will to survive.

The underlying mechanism of mal de mer involves a conflict of sensory inputs processed by the brain to orient the body's position. Below decks the eyes oriented to the cabin sole and ceiling detect no tilt from vertical, while fluid in the inner ear's vestibular organs constantly shifts. Position sensors in the neck, muscles, and joints send additional signals depending on how persons shift and secure themselves from falling. This mix of sensory data from the eyes, inner ear, and position sensors creates a neural mismatch that activates responses and stimulates the vomiting center in the brain.

The balance center has the ability to adapt to the new environments; this is called "getting your sea legs." Medication is more effective in preventing symptoms than in reversing them after seasickness is fully symptomatic, so antimotion sickness medication should be used early before leaving port. The traveler should begin the trip well hydrated, avoid alcohol, which impairs vestibular function, and eat light meals. Many anecdotal reports favor eating carbohydrates rather than protein, but no conclusive study favors any particular food or diet. Ginger is often recommended as an antiemetic. It is safely and effectively used by women to curb nausea and vomiting in the first trimester of pregnancy. Ginger is available in 500-mg capsules; the suggested dose is 1000 mg every 6 hours. The capsules can be supplemented with gingersnap

cookies, ginger ale, and candied ginger.

Both field and laboratory experiments have documented the efficacy of acupressure in preventing seasickness. One small trial at sea showed that acustimulation suppresses the symptoms of motion sickness. Pressure should be applied on the Neiguan P6 point of the forearm. This is found two fingerbreadths proximal to the wrist joint between the two prominent finger flexor tendons. The easiest way to accomplish this is with commercially available elastic wrist straps with buttons, called "seasickness bands." The ReliefBand is a watchlike device worn over the P6 area on the ventral side of the wrist to deliver transcutaneous electrical stimulation to the median nerve. It can be used before or after the start of symptoms and offers an alternative to people sensitive to the side effects of medication. Preliminary reports suggest this modality may be as effective as commonly used drugs.

Recommendations for prevention of mal de mer include the following. Limit the time below decks. Equipment, provisions, and the galley arrangement should all facilitate the preparation of quick and easy meals. Have one or two simple meals prepared so you can stay out of the galley the first day. Keep personal items easily accessible.

After departure, stay on deck and amidships (center) or aft (toward the stern), where the pitching and rolling is less severe. Look out and obtain a broad view of the horizon using peripheral vision. This provides a stable and level point of reference. Avoid close focused visual tasks such as prolonged reading, writing, and navigation. Stay out of areas with fumes and odors that can stimulate nausea. Continue any medication for seasickness at regular intervals, and begin to taper the dose after the first day.

The early signs and symptoms of seasickness are yawning, sighing, dry mouth or salivating, drowsiness, headache, dizziness, and lethargy. Pallor, cold sweats, belching, flatulence, nausea, dry heaves, and vomiting occur after the illness has developed. The window of opportunity for early intervention is often missed because early signs are not recognized or the symptoms are denied.

TABLE 64-1 -- Medications for Seasickness

MEDICATION	DOSE	INTERVAL
Dimenhydrinate (Dramamine)	50-mg liquid/capsule/chewable tablet	4–6 hr
Meclizine (Antivert)	12.5/25-mg tablet	4–6 hr
(Bonine)	25-mg chewable tablet	4–6 hr

Cyclizine (Marezine)	50-mg tablet	4–6 hr
Cinnarizine (Sturgeron)	15-mg tablet	6–12 hr
Scopolamine (Transderm-Scop)	1.5-mg skin patch	72 hr
Promethazine (Phenergan)	12.5/25/50-mg tablet, suppository, injection	6–12 hr
Phenergan plus ephedrine	25-mg tablet of each	6–12 hr

One of the best tactics is to take the wheel and steer at the first sign of seasickness. Use the waves, clouds, horizon and distant marks as reference points. Sit or stand in the cockpit and actively posture to anticipate the boat's motion and "ride" the waves. Keep head and chest balanced over the hips.

If symptoms progress, lie down in a secure, well-ventilated bunk, face up and head still, then close your eyes and try to sleep. Parenteral antinausea medication may help. Take small amounts of water, crackers, and hard candy.

Debilitated seasick persons can easily fall or be washed overboard. They should wear a safety harness while on deck, and someone should be designated to monitor them. In storm conditions the safest place is to be secured below in a bunk. [Table 64-1](#) lists medications available for motion sickness. Time-release forms and longer-acting drugs may be preferable when storms are expected to last a few days.

Transdermal scopolamine is available by prescription. One adhesive patch is placed behind the ear several hours before departure. Scopolamine is delivered into the bloodstream at a constant rate to provide a therapeutic blood concentration for up to 3 days, with minimal side effects. The most common adverse effects are dry mouth (66%) and drowsiness (17%). The patch is contraindicated for children, persons with glaucoma, and men with prostatic hypertrophy.

Over-the-counter antihistamines have potential side effects, including drowsiness, dry mouth, blurred vision, irritability, urinary retention, dizziness, and headache. NASA astronauts use a combination of intramuscular promethazine with oral ephedrine to counter the drowsiness. A nonprescription substitute for ephedrine that is equally effective is pseudoephedrine, which is available in 30- to 100-mg tablets.

THUNDERSTORMS AND ASSOCIATED WEATHER EVENTS

Lightning is one of nature's most destructive phenomena (see [Chapter 3](#)). Boating, fishing, and swimming rank second only to playing sports on an open field as the most dangerous activities associated with a lightning strike. Although the odds that an individual will be struck and killed by lightning are about one in three million, the odds for a boat being struck are greater. A cruising sailor in Florida, the lightning capital of America, can expect at least one strike to his boat in its lifetime. Although there is no lightning-proof boat, it is possible to reduce the likelihood of a lightning strike and provide a high degree of protection for the boat and people and equipment on board.

A single thunderstorm is a small unit, generally less than 2 miles in diameter. It is brief, lasting about 30 minutes, with marked fluctuations in wind, temperature, and barometric pressure. *Waterspouts*, which are the equivalent of tornadoes at sea, may form (see later). A *squall line* is a fast moving row of violent thunderstorms. The line may be more than 100 miles long and arrives 40 to 300 miles ahead of an intense cold front. It contains most of the gusting winds and rain normally found in the front itself. It is visible on radar and to the naked eye appears as a wall of boiling black clouds arising from the sea.

Rapid growth of cumulus clouds is the primary signal indicating formation of a thunderstorm. The faster the clouds build, the more violent the resulting storm, because the steep pressure gradients within the cloud generate high winds.

Within the thunderhead are columns of rapidly sinking air, called *downdrafts*. Downdrafts along the leading edge of the thunderstorm form the gust front. This zone of advancing cold air is characterized by a sudden increase in wind speed. Very strong and highly localized downdrafts are called *downbursts*, the smallest of which are *microbursts*. Airplane pilots refer to these as *wind shear*. Downbursts are extremely intense concentrations of sinking air. On reaching the surface, they fan out radially in all directions, often generating winds at the gust front in excess of 150 knots. They are short-lived, typically lasting less than 15 minutes, and are concentrated in an area less than 3 miles across.

A single thunderstorm can produce a series of downdrafts affecting an area several miles long and can persist an hour or more. Blowing spray under or slightly ahead of the storm may be the only indicator of its presence. The gust front often precedes the microburst. The combination of these two extremely strong and shifting wind systems can blow equipment and personnel off the deck and capsize small craft.

In the United States, squalls occur predominantly during the spring and summer in

thunderstorms or towering cumulus clouds. Occasionally, they may form with the building of the cloud and not be associated with the typical rain, thunder, and lightning. These violent winds are called *white squalls*. The only warning may be the sudden appearance of a cold shifting wind with an increase in its velocity.

To avoid or prepare for the potential fury of a thunderstorm, the mariner must be aware of local weather conditions. The best source of up-to-date weather information for coastal waters is the continuous 24-hour National Weather Service (NWS) broadcast ([Box 64-6](#)). This US National Oceanographic and Atmospheric Administration (NOAA) VHF-FM radio transmission repeats recorded messages every 4 to 6 minutes. They are updated every 2 to 3 hours with the latest local information. The broadcasts can usually be received 20 to 60 miles from the transmitting antennas, which are located at 66 different locations in the United States.

The NWS uses specific terminology to broadcast a severe weather warning. These warnings can be heard on the NOAA radio transmissions ([Box 64-7](#)). Many of the newer VHF radios have a Weather Alert function, known as Weather Watch. When the radio receives a special warning signal from NOAA, it sounds a special alerting tone, signifying an urgent NOAA weather forecast. Some radios automatically tune to the active weather channel, whereas others require manual tuning.

For offshore sailors, single-sideband (SSB) high-frequency radios can receive a variety of high-seas marine weather broadcasts. The time schedules and frequencies for these transmissions can be found in the U.S. Defense Mapping Agency (DMA) Publication 177, *Radio Navigation Signals*. A less comprehensive list for specific locations can be found in *Reed's Nautical Almanac*.

**Box 64-6. NATIONAL WEATHER
SERVICE BROADCASTS**

NOAA WEATHER RADIO CHANNELS

WX-1 162.55 MHz

WX-2 162.40 MHz

WX-3 162.475 MHz

CANADA

Canadian Channel 21 161.65 MHz

WEATHER WARNINGS BY RADIO

National Bureau of Standards: WWV in Fort Collins, Colo, and WWVH in Hawaii broadcast time signals and weather warnings on 5, 10, and 15 MHz. WWV broadcasts at 8, 10, and 12 minutes after the hour. WWVH broadcasts at 47, 49, and 50 minutes after the hour.

U.S. COAST GUARD BROADCASTS

USCG VHF Voice: Broadcasts coastal and offshore forecasts and storm warnings on VHF channel 22A after an initial call on VHF channel 16.

USCG MF Voice: Broadcasts offshore forecasts and storm warnings on 2670 kHz following an initial call on 2182 kHz.

Forecasts are compiled by the NWS and broadcast by high-frequency radio facsimile via the U.S. Coast Guard from their East, Gulf, and West Coast communication centers. These marine weather charts are updated every 6 hours and available within 3 ½ hours of the valid time. The NWS has an Internet page at <http://www.nws.noaa.gov>, where all weather charts broadcast over SSB can be found. This site contains text forecasts, ocean current and surface analysis charts, wave charts, buoy reports, and prognosis charts for weather outlooks of 12, 24, 36, 48, and 96 hours. An onboard cellular connection, modem, and laptop computer are required to obtain this information. Beyond cellular range, a dedicated weather fax unit or SSB/laptop/weather fax module is needed. Details on what charts are available can be obtained from the U.S. Government publication, *Selected Worldwide Marine WX Broadcasts*, available at NOAA chart dealers.

Visualization of characteristic cloud formations at night can be accomplished with radar or night-vision binoculars. With experience a person can learn to recognize a squall line, the cloud sequence of an approaching cold and warm front, and the growth of cumulus to cumulonimbus clouds with the characteristic anvil head. In the daytime a band of low, dark, smooth tubular clouds can often be seen at the leading edge of a squall. This is a roll cloud preceding the cold front. The faster a roll cloud approaches, the stronger the wind is likely to be, and the more agitated the sea under it. When the sea can be observed beneath the roll cloud, it is about 2 miles away, and since the clouds typically move at about 25 mph, the face will arrive in

about 3 minutes. Another early warning of an approaching thunderstorm is a sharp drop in barometric pressure of about 1.5 millibars for 1 to 4 hours. Large ocean swells precede a heavy weather system, whereas chop without swells often reflects a local, more isolated, and temporary disturbance.

Box 64-7. STORM WARNINGS

Small craft advisory: generally associated with sustained winds 18 to 33 knots (19 to 38 mph) and/or sea conditions dangerous to small boats.

Gale warning: sustained winds 34 to 47 knots (39 to 54 mph).

Storm warning: sustained winds over 48 knots (55 mph). If winds are associated with a tropical cyclone, the storm warning display indicates forecast winds of 48 to 63 knots (55 to 73 mph).

Hurricane warning: sustained winds of 64 knots (74 mph) and greater as the result of a tropical cyclone.

Special marine warning: winds of 35 knots or more generally lasting less than 2 hours. These are usually associated with an individual thunderstorm or an organized series of thunderstorms, as in a squall line.

An excellent early-warning device is the SkyScan Lightning and Severe Storm Warning unit. This unit has a sophisticated receiver for listening to the characteristics of lightning and can detect and report air-to-ground lightning strikes in four different ranges of 0 to 3, 3 to 8, 8 to 20, and '20 to 40 miles. The unit can calculate the distance of a ground strike to within 1 mile 97% of the time.

Because it is often impossible to predict the power of a thunderstorm, mariners should always prepare for the worst and initiate defensive tactics ([Box 64-8](#)).

Box 64-8. DEFENSIVE MEASURES IN THUNDERSTORMS*

1. Alert everyone on board of the imminent storm threat.
2. When boating on a small pond or lake, return to shore and exit the boat.
3. If practical and time permits, take evasive action and set a course perpendicular to the expected thunderstorm track. In rough water a small boat is most stable going downwind with the seas on the stern quarter (about 45 degrees to the back of the boat).
4. Ascertain position, and identify any shoals, rocks, and other boats in the immediate area that may pose a hazard to navigation if visibility becomes severely reduced.
5. If practical, seek shelter from wind and waves in the lee (downwind) side of a land mass.
6. Secure all loose gear on deck and below, and verify that lockers, cabinets, and drawers are properly secured.
7. Close all hatches, ventilators, ports, and lazarettes to prevent flooding in the event of a knockdown or capsize. Close all seacocks not immediately required. Secure doors or boards to companionways leading below.
8. Reef the sails (reduce sail area) or lower them completely, and start the engine.
9. Pump the bilge dry, and be sure the pumps are ready for operation. Water shifting in the bilge can adversely affect the boat's stability.
10. All crew and passengers should wear foul weather gear and life jackets.
11. All crew on watch should be secured with a safety harness.
12. All remaining personnel should go below with clear knowledge of how to egress in the event of a capsize.

wear four weather gear and life jackets.

11. All crew on watch should be secured with a safety harness.
12. All remaining personnel should go below with clear knowledge of how to egress in the event of a capsize.
13. Safety gear, communication (hand-held VHF radio), and visual distress devices should be readily available.

*Measures are listed in sequence, as storm approaches.

Tall and narrow objects, with highly charged and focused electric fields, are likely to attract lightning. Structures such as a sailboat mast, radio antenna, fishing outrigger, fishing rod, and even a person standing in a motorboat make good targets. In an anchorage or marina the boat with the tallest mast is most vulnerable to a lightning strike. Satellite data have documented that storms at sea generate more lightning than previously realized, especially lightning within the clouds themselves. The most critical factor initiating the streamer is not only the height of the boat's mast, but also its electric potential. The pale-blue or green light sometimes seen in a ship's rigging, called St. Elmo's fire, is visible static electricity induced by nearby thunderclouds.

Many boats struck by lightning are destroyed by fires and explosions. A strike exiting through the bilge can instantly vaporize trapped bilge water and raise it to explosive pressures. Many boats sink or are seriously damaged by ruptured through-hull fittings or large exit holes burned in the hull. The structural integrity of the boat must be protected by providing a path of least resistance for the major current to travel through and off the boat into the water. Protection from a side flash (see later) is accomplished by taking precautions to equalize the electric potential of all the metal objects aboard. By understanding the different components of a lightning protection system (LPS), the mariner can appreciate how best to protect the boat and crew.

Metal boats are rarely damaged by lightning, because the high conductivity of the metal hull in direct contact with the water permits rapid dissipation of the electric charge. By contrast, nonconductive fiberglass and wooden boats, especially sailboats, do not provide the automatic grounding protection offered by metal hull craft.

The traditional way to protect a boat is to mount a rod on the highest part of the vessel to attract and control a strike, then safely discharge it down a path to a ground plate, usually a metal plate attached to the hull below the waterline. The more advanced systems, such as static dissipators, are designed to decrease the probability of a strike. The dissipator prevents the charge from building so that it will not attract the "leaders" approaching from a storm cloud.

On a sailboat the masthead is the obvious location to place the dissipator. On a powerboat without a dominant high structure, a special mast (air terminal) can hold an LPS. The grounded air terminal or mast will theoretically create an electrically safe zone called the *cone of protection*. The apex of this cone is the top of the mast, and the base is a circle around the boat with a radius equal to the mast height. Without additional

precautions, the cone of protection does not guarantee safety from lightning strikes.

Commercial units are designed to accept and disperse the static charge accumulating on the boat. The two most common types are a single, sharply pointed

1534

spike and a device that resembles a brush with wire bristles. However, the LPS still may be unable to keep the voltage difference between the boat and the cloud base lower than the breakdown resistance of the air gap. To protect the boat from a lightning strike, it is necessary to guide the current from the masthead containing the dissipator in as straight, direct, and short a route as possible to an underwater ground on the bottom of the hull. Without grounding, a bolt will find its way to the sea from the base of the mast, usually through the hull. The path to the ground must be of a highly conductive material of low resistance so that the current passing through will not create heat sufficient to melt the conductor itself. Copper wire with a minimum of 4 AWG (not 8 AWG, as previously suggested) is required, and a ground plate ideally made of solid copper or bronze with a dimension of at least 1 square foot is recommended. A lead keel on a sailboat makes an excellent ground plate only if it is properly connected to the base of the mast and if it is not encapsulated with fiberglass. Some motor and auxiliary sailboats use the exposed surface of the engine prop and shaft to act as a ground plate. With engine grounding, damage may occur from the heat generated by a powerful strike. Boats constructed of aluminum or metal are already grounded to the surrounding water.

Lightning can also generate a *side flash*, which is the secondary flow of current from the surrounding charged areas to some object near the path the strike follows to the water. This current is equally destructive and especially dangerous to the crew members. Grounding prevents major hull damage but does not prevent side flashes. After the current in a strike follows a designated path to the ground, another electric potential is created between the ground system and the objects surrounding it. The entire boat becomes high voltage, so the secondary electric current, the side flash, is created. The key to preventing secondary current flows is to equalize the voltages of all the metallic objects on board by establishing a common electrical ground for the entire boat, a system called *bonding*. Any area capable of collecting a large static charge, each piece of metal equipment on board, and all electronic instruments and radio equipment must be grounded to the same discharge system used to protect the boat from the effects of the initial lightning strike. This is accomplished by connecting copper wire from all metal objects to the common ground. Metal through-hull fittings are also capable of building a static charge and require connection to the ground plate. [Box 64-9](#) outlines the general principles to protect the boat from lightning damage.

Crew members may also become part of the current path if they are in contact with or come between two different metal objects that are not interconnected. The best protection in the event of a direct lightning strike, even if the boat is grounded and bonded, is to remain low in the boat (preferably in a cabin) and far away from metal

objects, wiring, and the electric conductors ([Box 64-10](#)).

Box 64-9. PROTECTING BOATS FROM LIGHTNING DAMAGE

1. Install a lightning protection system (LPS), and have it tested for conductivity from masthead to grounding plate by a marine electronic specialist.
2. Install temporary lightning protection for motorized dinghies and open small boats. Battery jumper cables connected to a railing and dropped into the water will work.
3. Keep water out of the bilge, and consider adding a large-capacity manual bilge pump. Pump the bilge dry when a thunderstorm approaches.
4. Place cone-shaped plugs next to all through-hull fittings in case of blowout. Have a handy diagram of the hull indicating location of all through-hull fittings.
5. Conduct a regular maintenance and inspection schedule. All ground pathways and bonding connections must be clean, secure, electrically sound, and free of corrosion.
6. During a severe thunderstorm, do not do anything that will alter the boat's electric potential profile, such as dropping anchor.
7. Lower, remove, or tie down the radio antenna and other similar upright devices if they are not part of the LPS.

Waterspouts are the maritime version of tornadoes. Although less common than lightning and downbursts, they are generated by the same dynamic forces found in the squall line at the leading edge of an advancing cold front, or in a rapidly building summer afternoon thunderstorm. The danger inherent in a waterspout lies in the powerful revolving winds, which may exceed 200 mph, and the very low pressure at its

center, which may cause tightly enclosed spaces to explode. Waterspouts are visible during the day, when the majority of them occur, and can also be located and tracked by radar. The earliest visible sign of a waterspout is an area of boiling water in the distance, with the spray rising upward that joins with a funnel cloud and its characteristic snakelike, gyrating appendage. Waterspouts move rapidly and usually last only 30 to 60 minutes. Preparation of the boat and crew is similar to that for a thunderstorm. Because a waterspout is relatively narrow, steering a course perpendicular to its projected path is a realistic avoidance tactic.

The best tactic for dealing with the fury of hurricanes and cyclones is to avoid them. Although recommendations include placing the boat in the so-called safe or navigable semicircle and avoiding the strongest winds surrounding the eye of the hurricane, the safest course is to stay out of their path. In the Northern Hemisphere the wind blows counterclockwise around

1535

the eye. Facing into the wind and stretching the right arm back 120 degrees will point at the eye of the hurricane. In the Southern Hemisphere the wind blows clockwise around the eye. Facing into the wind and stretching the left arm back 120 degrees will point to the eye. In the Northern Hemisphere the strongest winds are to the right side of the hurricane's path, where the forward movement over the water adds to the local wind speed; this is the more dangerous semicircle. In the Southern Hemisphere the strongest winds are on the left side of the path.

**Box 64-10. PROTECTING CREWS
FROM LIGHTNING INJURY**

1. Get out of the water. If possible, get off the water and away from the water.
2. Get off the beach. If stranded, squat down and place legs and ankles together. Keep surface area of the body in contact with the ground to a minimum. Spread people out to maximize the possibility that some will survive a lightning strike.
3. If possible, get off the boat, including boats at anchor or in a marina.
4. Remove wet suits and other wet clothing. Put on dry clothing and foul weather gear, hat and boots, and a personal flotation device. Wet bodies make good electric conductors, but wet foul weather gear may provide protection by lowering surface resistance and guiding the current around you.
5. Remove all metal articles, especially jewelry, scuba tanks, and weight belts.
6. Avoid direct contact with all metal objects, including handrails, engine, stove, rigging, and spars.
7. Do not touch any of the boat's installed electrical equipment, including navigation instruments and radios. Use a hand-held VHF radio for emergency communications during the storm.
8. Avoid contact with objects connected to the lightning protection system. Do not simultaneously touch two components connected to the system, such as the engine throttle and spotlight handle.
9. Stay away from the mast, stays, shrouds, and wet sails.
10. Stay out of areas where bridging between two highly charged areas, or side flashes, may occur. These areas include the foredeck, between the mast and the headstay, or a seat between an outboard engine and the

- shrouds, and wet sails.
10. Stay out of areas where bridging between two highly charged areas, or side flashes, may occur. These areas include the foredeck, between the mast and the headstay, or a seat between an outboard engine and the portable metal fuel tank or steering wheel.
 11. Stay within the cone of protection, a distance (the radius of a circle) from the base of the highest mast equal to the height of the mast.
 12. If caught in a storm while on a sailboard, lower the sail and mast and sit down on the board.
 13. If fishing or trawling, stop and lay the rods and trawls horizontal in the boat.
 14. Put nonessential crew and passengers below decks, in the center of the cabin. Stay out of the companionway, engine room, and head. If there is no cabin, stay low in the boat.
 15. Place the boat on autopilot to minimize contact with a metal wheel.
 16. Avoid activity that may suddenly alter your electric potential profile, such as stepping into a dinghy or stepping onto a beach from a small boat.

Hurricane track forecasting has acknowledged limits and errors. The expected track error for a hurricane is 100 miles either side of the predicted track for each 24-hour forecast period. For a 72-hour forecast, an error of 300 miles to the left or right of the predicted forecast track can be expected, and for 96 hours, 400 miles to either side is applied. That would make the storm's potential swath for destruction 800 miles wide, a considerable area to avoid if a vessel can only travel at 6 to 7 knots in storm conditions. In order to take meaningful evasive action, a hurricane needs to be monitored at least every 6 hours, which is the official forecast interval for the NWS Tropical Prediction Center. The National Hurricane Center in Coral Gables, Florida, provides advisory updates on developing tropical storms and hurricanes 24 hours a day. Voice recordings can be heard by calling 305-229-4483 or information obtained via the Internet at <http://www.nhc.noaa.gov>.

EMERGENCY COMMUNICATIONS AND DISTRESS SIGNALS

Cellular Telephones

Sailors frequently use cellular phones rather than marine radios to call for assistance. A variety of emergency services, including regional Coast Guard stations, can be called directly, and in some coastal areas, the Coast Guard can be accessed immediately by dialing *CG.

The cellular phone has several disadvantages when used in search and rescue (SAR). Currently, 10 miles is the average effective range of cellular phones, and use is restricted to high traffic areas where there are both cellular antennas and relay stations. Private cellular phone communication, in contrast to the more public broadcast over very-high-frequency (VHF) radio, excludes potential rescuers who might be in the immediate vicinity. In SAR operations, no practical way exists to maintain continuous communication with a number of rescue craft via cellular phone. The Coast Guard is unable to use a radio direction finder to locate a cellular signal, as it can with the VHF-FM signal.

Since cellular ultrahigh-frequency (UHF) signals are transmitted along line of sight, both reception and transmission can be strengthened by using an external antenna placed as high as possible on the boat. A hand-held phone's range can also be improved by standing in a high location, such as the cabin top. Signal strength can also be improved by reprogramming the phone for the best reception in a specific location using wireline (B-side) or nonwireline carriers.

1536

In the future, cellular phones will be linked to low-earth-orbit (LEO) satellites, giving them a worldwide range from anywhere at sea.

If a cellular phone is the only communications link on board, extra charged phone batteries and a waterproof pouch are needed. A comprehensive list of emergency phone numbers should include local hospitals and physicians, regional Coast Guard stations, harbor masters, and maritime towing services.

The newest communication system is the Globalstar satellite phone system. It consists of 48 LEO satellites operating at an altitude of 876 miles. When fully operational, coverage will extend from 70 degrees north latitude to 70 degrees south latitude,

covering 80% of the earth's surface. The compact and portable 13-ounce handsets easily switch from terrestrial cellular telephony to satellite telephony as required.

Marine Radios

The VHF-FM radio transceiver is the most popular, user friendly, and reliable form of marine communication. The VHF signal range is limited to line of sight and therefore depends on the height of both the transmitting and the receiving antennas. The Coast Guard places antennas along the coast, connects them with land lines to their operations centers, and is able to monitor and communicate with all vessels that have a masthead-mounted aerial and are within 25 miles of the coast. The range may even extend up to 300 miles when communicating with an aircraft. The VHF radio is ideal for near-shore emergency communication. Communication is not private, which is a distinct advantage in SAR. VHF is the open party line connecting all vessels within the signal range. Any boat in the area monitoring distress channel 16 (which they automatically do if the radio is turned on) will receive the distress call. Rescue boats and aircraft are equipped with radio direction-finding equipment that can home in on a boat's VHF-FM signal and precisely locate the caller.

The more powerful permanently installed radio is used for the initial distress call. A transmission range of approximately 15 miles can be expected between boats having masthead-mounted antennas. If a sailing vessel becomes dismasted, the VHF will be inoperable because the antenna is usually mounted at the mast top. Therefore a small folding emergency antenna should be carried that can be inserted into the VHF radio jack to allow short-range communication.

The portable hand-held radio is used for special circumstances and is taken when boarding the life raft. The range of the portable unit is up to 5 miles. To conserve batteries, the user should transmit only when a ship is in sight and whenever a message is received, even if the calling ship is not in sight. Transmission uses 15 times more battery power than does listening. Although the range is less than a high-power fixed-installation VHF radio, reliable communication can be established with any visible aircraft or vessel. If other ships are nearby, transmit a mayday message every 30 minutes on the hour and at the half hour for 3 minutes on channel 16. The new multichannel VHF survival radios are designed to be packed into a life raft or life boat. They are completely waterproof, submersible down to 10 feet, and float. The antenna, circuitry, and power are tuned for maximum range. The operating life with the lithium battery is a minimum of 8 hours.

Box 64-11. USEFUL MARINE CHANNELS	
06	Intership safety communications

71	Noncommercial intership and ship to coast
72	Noncommercial intership
78	Noncommercial intership and ship to coast
WX 1 to 3	Weather broadcast

The most important channel on the VHF band is channel 16, the distress and safety frequency (156.8 MHz). This calling frequency is used to initiate contact between any two vessels and is the only frequency constantly monitored by the Coast Guard. When a radio is not active on another channel, it is eavesdropping for distress calls on channel 16. [Box 64-11](#) lists other VHF-FM channels often used by pleasure craft.

VHF can also be used to place a direct phone call with a marine operator. MariTEL Marine Communications System has its own network of marine VHF radio towers covering coastal waters, inland rivers, and the Great Lakes. Outgoing calls are private and not monitored by other marine VHF radios. The effective ship-to-shore calling range is 50 miles, in contrast to the much shorter cellular range. To make a call, set your VHF

radio to the selected MariTEL channel for the area, key your mike (depress the VHF microphone button for 6 seconds), follow the short recorded instructions, and stand by for a marine operator. Routine transmissions and distress messages can be transmitted with relative ease ([Box 64-12](#) and [Box 64-13](#)).

When receiving a Mayday call, listen and do not interrupt. If the Coast Guard or another vessel does not respond, acknowledge the Mayday call as follows:

- Repeat the name of the distressed vessel three times.
-

1537

- Transmit your name three times and then say, "Received Mayday."
- Listen to see if any other vessel is closer and preparing to offer assistance. If not, recontact the vessel and give your position and estimated time of arrival.
- If you are able to contact the Coast Guard or another ship in the vicinity, transmit "Mayday-relay, mayday-relay, mayday-relay," then give your vessel name and location and the information you have received.

**Box 64-12. OPERATING
INSTRUCTIONS FOR VHF MARINE
RADIOTELEPHONE**

1. Turn power on and adjust the volume. Turn the squelch control knob clockwise until the static noise disappears.
2. Transmit distress calls on VHF channel 16 or single sideband (SSB) radio at 2182 kHz. All sets have a designated button that immediately selects these channels. Switch to another frequency if instructed to do so.
3. Set transmit power to high. Use low power to contact nearby boats, which will conserve the ship's battery.
4. Depress the call button on the microphone to transmit and keep it depressed throughout the message, then release the button to hear the response. You cannot transmit (talk) and receive (listen) at the same time.
5. Speak in a normal voice and normal

microphone to transmit and keep it depressed throughout the message, then release the button to hear the response. You cannot transmit (talk) and receive (listen) at the same time.

5. Speak in a normal voice and normal volume. It is unnecessary to shout. Speak slowly and distinctly. Keep text simple and terse
6. Know or estimate the boat's location before commencing transmission. Refer to any recognizable landmarks on shore.
7. Establish radio contact before the crisis is fully developed and while electronic equipment is functional.
8. Use the appropriate alerting signal. "Mayday" is the top-priority distress signal if the vessel or crew is in imminent danger and requires immediate assistance. Urgent messages relating to non-life-threatening emergencies are prefaced with the signal "Pan-Pan" (pronounced Pahn-Pahn). Seeking medical advice for a sick or injured crew member would fall into this category.
9. If there is no response, wait 5 minutes with the radio turned on, and repeat according to the probability of other ships being in the area.

For communication beyond the VHF range, a more powerful and elaborate SSB radio transmitter is required. Depending on the radio frequency band used, communication may be extended over thousands of miles. The international distress and calling frequency is 2182 kHz; located in the medium-frequency range, 2182 kHz is used for distances from 20 to 100 miles day or night. The frequency 2670 kHz is designated for distress and safety communications with the U.S. Coast Guard. On the high-frequency bands the frequencies 4125 kHz (Ch. 450), 6215.5 kHz (Ch. 650), 8291.0 kHz (Ch. 850), 12,290.0 kHz (Ch. 1250), and 16,420 kHz (Ch. 1650) have all been designated for distress and safety calls. The high-frequency transceivers can call and receive voice and digital communications to and from anywhere in the world. The best method to select an optimum emergency frequency is to listen to the quality of a radio broadcast. A station that your radio receives loud and clear will also provide good reception for your broadcast at that time. SSB is also an excellent receiver for voice weather and weather fax broadcasts.

Box 64-13. HOW TO MAKE A DISTRESS CALL AT SEA

Tell them who you are, where you are, and what is wrong.

- "Mayday, Mayday, Mayday" or "Pan-Pan, Pan-Pan, Pan-Pan."
- "This is vessel ..." Repeat name three times and radio call sign or boat registration number once.
- "We are located ..." Report position data.
- "We need assistance ..." Specify nature of emergency (injury, fire, flooding, etc.) and what type of assistance is needed.
- "The boat is ..." Provide full description of craft (type, color, size, etc.) with any distinguishing characteristics.
- "There are _ people on board."
- "This is _" (repeat boat's name), "standing by on channel _ (16 or 2182)."
- End message with "Over."

Repeat this call and listen for a response between transmissions.

On Feb. 28, 1999, AT&T closed its high-seas radio telephone stations. WLO in Mobile, Alabama, is presently the sole provider of worldwide ship-to-shore SSB high-frequency radiotelephone service in the United States. Complete information regarding their radiotelephone channels can be obtained by calling 334-666-5110 or via the Internet at www.wloradio.com.

Global Maritime Distress and Safety System

As of Feb. 1, 1999, a ship or coast station has no legal requirement to monitor the traditional distress frequencies, such as VHF channel 16 or 2182 kHz. Until the new Global Maritime Distress and Safety System (GMDSS) is in use, however, the Coast Guard and many recreational and commercial ships will continue a radio watch on these frequencies. A complete transition to the new GMDSS is not expected until at least the year 2003. The GMDSS is a worldwide infrastructure, controlled from a shore-based communications center, to coordinate the assistance of vessels in distress. This fully

automated system uses satellite and digital communication techniques. New radio equipment and different

1538

communication protocols are required. GMDSS will simplify routine communications at sea and facilitate regular weather forecasts, navigation warnings, and distress relays in the form of maritime safety information (MSI). Digital selective calling (DSC) technology permits a VHF radio to call another radio selectively using digital messages, similar to the modem on a computer. As with a direct-dial telephone call on land, only the vessel called receives the message. The usual VHF "party line" connecting boats in the area capable of monitoring the message is eliminated.

Every vessel has its own unique maritime mobile service identity (MMSI). The vessel's MMSI is manually coded into the DSC radio. Part of that number may characterize a particular group, so calls made to a group MMSI will alert everyone in the group. The digital information is carried on a designated channel; for VHF digital radios, this is channel 70. The dialing signal is also able to carry other essential information, such as the caller's identity and location and the nature of the call.

Distress messages can be sent automatically. The vessel's identity is permanently coded into the unit, and its position can be determined from the data output of a global positioning satellite (GPS) receiver linked to the radio. On a DSC-equipped radio the receiver sounds an alarm if it receives an "all ships call" (distress or otherwise), a group call, or a call specifically to that vessel. All other DSC calls are ignored.

A distress alert (equivalent to Mayday) can be sent automatically as a digital signal to a shore-based rescue coordination center (RCC). Once the alert has been sent, the radio will automatically repeat at intervals between 3 ½ and 4 ½ minutes until the RCC acknowledges receipt of the message on channel 70. Subsequent communication should continue on channel 16 or another selected frequency for voice transmission. A verbal Mayday can also be sent immediately on channel 16 after the first alert, since DSC equipped transceivers can listen simultaneously on channel 70 for DSC and Channel 16 or other channels for voice transmission. A verbal Mayday follows the same sequence as outlined in [Box 64-13](#) and includes the MMSI as part of the vessel's identification.

To make a ship-to-ship or ship-to-shore call on DSC, the nine-digit MMSI number of the station to be called must be keyed in on the radio together with a proposed working radio telephone channel for voice communication. This announcement is transmitted on channel 70 and should be acknowledged on channel 70. Four VHF channels are available for special use within the GMDSS: channel 06 is for SAR coordination, channel 13 for intership safety of navigation (bridge to bridge), channel 16 still for distress and safety, and channel 70 for DSC alerting.

The GMDSS utilizes satellite communication links such as the International Maritime

Satellite Organization (INMARSAT M) to provide long range global communication. Geostationary (geosynchronous) INMARSAT satellites cover the whole world between 70° north and 70° south latitude. The satellites pass over the equator at an altitude of 22,500 miles with an orbital period of 24 hours, allowing them to remain stationary over fixed points on Earth. They provide high-quality worldwide speech, data, and facsimile communication as well as reliable distress alerting and follow-up communication within the GMDSS. Presently the size of the equipment and power consumption make this system unsuitable for smaller recreational craft. INMARSAT Mini-M uses small units with tracking antennas that weigh a mere 15 pounds, designed for smaller commercial boats and yachts over 45 feet.

INMARSAT C offers digital data messaging (no voice) and is the only two-way marine satellite data message system approved for GMDSS safety at sea. The hardware is small enough to fit any boat. It can send a distress signal at the touch of a button and can easily be integrated with a GPS receiver. Pressing the distress key sends a message with the ship's identity and location to the nearest RCC.

NAVTEX is a worldwide land-based radio navigation warning service transmitting text messages in English to a compact onboard receiver. The unit can be programmed to receive both specific stations and message categories; it can print out area weather forecasts, gale warnings, navigation warnings, ice warnings, and distress relay messages on the assigned frequency 518 kHz. Vital messages (e.g., gale warnings, SAR information) activate an alarm in the receiver as the message is being printed.

In the field of hand-held satellite communications, the ORBCOMM LEO system, utilizing 36 LEO satellites, can provide e-mail and data transfer coverage to most of the world. The Magellan portable data-messaging radio is designed to send brief text messages using this system in a cost-effective way. It is also a fully functioning GPS receiver. The unit with a built-in telescoping antenna weighs 37 ounces and uses two AA batteries.

Emergency Beacons

Emergency position indicating radio beacons (EPIRBs) are handheld portable radio transmitters that can transmit a signal interpreted as a Mayday call ([Figure 64-1](#)). It is the satellite-linked equivalent of a 911 call for mariners in distress. In the absence of a marine radio, EPIRB is the most important piece of signaling equipment. This radio should be used only as a last resort when all other means of communication have failed to establish contact and when there is a life-threatening emergency.

EPIRB signals are transmitted on established distress frequencies 121.5/243.0 MHz or 406/121.5 MHz. The

Figure 64-1 Anatomy of a rescue. The 406-MHz emergency position indicating radio beacon (EPIRB) sends a digitally coded signal to low-earth-orbit satellite, which relays the signal to a nearby ground receiving station (LUT). The location of the EPIRB is calculated and forwarded to the nearest mission control center, which matches the EPIRB user's registration with the specific signal. These data are relayed to the local rescue coordination center, which initiates the search and rescue. (Courtesy ACR Electronics.)

signals are monitored by the global COPAS-SARSAT (search and rescue satellite-aided tracking) satellite system coordinated by the United States, Canada, France, and Russia. This system consists of a constellation of polar orbiting and geostationary satellites fitted with transponders to receive the distress signal and locate the activated beacon. The polar satellites orbit 600 miles above the earth and have an orbital time of 105 minutes.

The first-generation 121.1/243.0 EPIRBs, which are still in use, can also be monitored by SAR ground stations, aircraft, and ships with appropriate receivers.

The second-generation 406-MHz EPIRB provides the most reliable worldwide coverage. Satellites with 406-MHz transponders can store the signal in memory until a ground station is in view and then can retransmit the signal. The LEO satellites therefore can receive EPIRB transmissions from virtually anywhere in the world. These satellites are 500 miles above the earth and circle the globe every 99 minutes. The distress signal is quickly relayed to a ground station called a local user terminal (LUT), passed on to the mission control center (MCC), and relayed to the appropriate maritime rescue coordination center (MRCC). The satellites are able to compute the position of the beacon within 2 km. The 406-MHz EPIRB transmits a digital signal with a unique identification code. It can then be instantly identified through an NOAA encoded-transmission program. If the unit is properly registered with NOAA, vital information regarding the vessel can be passed on to SAR units. All registered EPIRBs are issued a dated decal that provides proof of registration and includes a unique 15-character hexadecimal code, registration expiration date, and the vessel's eight-digit registration code.

Failure to register can lead to unnecessary and tragic delays. NOAA receives many EPIRB signals daily, some in error and some justified. The signals are processed by computer and matched by updated information provided by the owner on a biannual schedule. The signals from unregistered EPIRBs are considered questionable and are not given top priority. The 406-MHz EPIRB will be required aboard all commercial vessels operating 3 or more nautical miles from shore.

The newest generation of EPIRB is the 406-MHz unit with a GPS interface. The GPIRB transmits its exact location, obtained using GPS latitude and longitude coordinates, with

the emergency EPIRB signal. It utilizes the polar orbiting satellites and the new geostationary search and rescue (GEOSAR) satellites in high earth orbit. The satellites receive the signal as soon as the beacon is activated. Position information is continually updated and stored every 20 minutes in the unit as long as it maintains a direct connection to the GPS receiver. The battery has a minimum operating life of 48 hours and operates longer in temperate climates. With this unit, accuracy is within 100 m.

All EPIRBs have a homing signal at 121.5 MHz. This is the homing frequency used by SAR vessels equipped with radio direction-finding equipment to locate precisely the craft in distress. Once activated the EPIRB is left on until the emergency is over. To update a position, it must broadcast continuously. EPIRB radio signals cannot penetrate water, wood, metal, or fiberglass, but the signals will be received from inside a life raft, on deck, or on the water's surface. A fully charged EPIRB battery will allow transmission for at least 48 hours.

A rescue team will not appear immediately after the EPIRB is activated. It may take hours or days to mobilize rescue craft. Potential delays justify carrying a second 406-MHz EPIRB when cruising in isolated areas of the ocean and far offshore. While the EPIRB is activated, it is appropriate to continue signaling by all the other methods available. EPIRBs with lithium batteries have a shelf life of 10 years, making it practical to store one in the life raft; the prudent sailor puts a second unit in the survival pack.

Visual and Sound Distress Signals

In an age dependent on electronic navigation and sophisticated electronic and satellite communication, the

1540

simplest signaling strategies and devices are often overlooked ([Box 64-14](#)).

Visual pyrotechnic distress signals have a high failure rate and age rapidly, so they require replacement according to the labeled expiration date.

Hand-held flares have varying effectiveness for attracting attention during daylight. Luminosity ratings range from 500 candlepower (CP) to 15,000 CP. The lowest rated flares are virtually invisible in daylight at ¼ mile, and the highest rated flares are only slightly more visible. For daytime use, orange smoke devices are the most effective way to attract attention. Smoke canisters are superior to hand-held smoke flares. They float and emit orange smoke for 2 to 5 minutes. Immediately after ignition the canister should be thrown in the water downwind of the craft. Smoke signals have a visible range of 1 to 3 miles in daylight, depending on the dissipating effects of the prevailing wind. Helicopter pilots find the smoke signal especially useful to indicate the strength and direction of the wind at sea level.

When using flares after sunset, consider luminosity, burn time, and altitude. Use an

aerial flare (meteor or parachute) to attract attention at night, then ignite a hand-held flare to guide a rescue craft to your location. Due to the curvature of the earth, sighting distances are limited. A high-altitude flare enables a ship beyond your line of sight to be alerted. The greater the height, the longer and further the signal can be seen by a distant viewer. A parachute flare at 1000-foot (305-m) altitude is seen as a brief flash of light on the horizon from a distance 40 miles away, but from 20 miles, it appears to be at about 500 feet above the horizon and is visible for a longer time. Luminosity and burn time are more important than altitude to help assisting craft home in on your location. The rated visible range assumes a ship in the area has an alert lookout standing on the bridge watching for and anticipating your signal on a night of optimal atmospheric conditions and calm seas.

**Box 64-14. VISUAL AND SOUND
DISTRESS SIGNALS AT SEA**

1. If other vessels are in sight, stand in an unobstructed area and slowly and repeatedly raise and lower outstretched arms as though you are flapping wings.
2. Sound a foghorn or blow a whistle continuously, or sound out SOS.
3. At night, point a flashlight at another boat and flash SOS (dot dot dot, dash dash dash, dot dot dot) repeatedly.
4. Fly the ship's ensign upside down, or fly the recognized distress flag: an orange flag with a black square under a black ball. Any square flag with a ball shape above or below is also a recognized distress signal.
5. Wave any brightly colored clothing or foul weather gear attached to a paddle or pole.
6. Use controlled flames or smoke on the vessel, or pour a dye marker in the sea near the vessel.

Whenever possible, choose flares meeting SOLAS standards (International Convention for Safety of Life at Sea). They exceed U.S. Coast Guard standards and are much more visible. The flares are easy to ignite, do not require pistol launchers, are safer to use, and have the lowest failure rate.

All pyrotechnics are hazardous and potentially injurious. They are capable of melting the rubber of the life raft and burning the skin of your hand. Some handheld red flares drip considerable ash and slag, so point them downwind while holding them high at arm's length, away from the raft or boat deck and over the water. Make certain that you are in a secure position and that the raft or boat is stable. Remove all adhesive fastenings and covers, and be sure you know from which end the rocket or flare will exit. After the signal is activated, turn your face away to protect your eyes from the intense glare. If a rocket or flare fails to ignite immediately, it may not ignite at all or there may be a lag time before firing. Hold your position and count to sixty. If there is still no ignition, throw the flare into the sea. Never look into a flare tube to see why it failed, and never put it back in the raft. Treat it as an activated and live explosive.

The parachute flare is designed to attract the attention of potential rescuers out of sight over the horizon. For practical purposes, a parachute flare has a useful range of about 10 miles regardless of its rated range or altitude. These red flares drop slowly beneath a nonflammable parachute and burn for 45 seconds. The SOLAS models burn the brightest and longest. They should be fired downwind at an angle just slightly less than vertical. The main body of the rocket is contained within the launch tube. After activating the firing mechanism, hold the tube with both hands to prevent the tube from slipping due to recoil. Use gloves or a dry cloth if your hands are wet.

The red meteor (aerial) hand-launched or pistol-launched flare should be launched downwind approximately 80 degrees above the horizon. These flares are less effective than the parachute flares because of their short burn time of 5 to 9 seconds. It is best to fire them in pairs, the first one to attract attention, the second about 10 seconds later to confirm distress and general position. They are also visible for 12 to 15 miles.

Do everything possible to attract attention with signal mirrors, flashlights, kites, or any other means before using flares. Do not fire flares in the direction of high-flying commercial aircraft. They cannot see your signal when they are flying at 30,000 feet (9144 m). Do not waste all the flares when the first ship or low-flying

aircraft appears, since it might pass close by without seeing your signals.

A signal mirror is an inexhaustible device and is definitely more effective than flares in daylight. Mirrors are especially useful when trying to attract the attention of aircraft, even those flying at high altitudes. Aim the signal at the front end of the fuselage while the airplane is still far in the distance and coming toward your vessel. The flash from a signal mirror can be seen up to 40 miles from the air on a clear day. If you hear a plane, begin signaling with the mirror, because the flashing light can be seen before you can see the plane. The mirror is also useful at night; as with reflector tape, it can reflect back a ship's searchlight, thereby making the raft or ship much easier to locate in the dark. Other shiny materials that can be used as reflectors include foil space blankets, jewelry,

eating utensils, fishing lures, and credit cards.

Radar is used by rescue ships and aircraft to accurately locate a life raft or vessel in distress. Visibility on the radar screen can be improved by using an electronic radar reflector known as a *search and rescue transponder* (SART). Once activated by an incoming radar signal (the interrogating radar), it is capable of sending back an electronic signal to any commercial radar located on a ship within a 10-mile radius and up to 50 miles on the radar screen of an aircraft flying at 3000 feet (914 m). It is much more effective than a simple radar reflector. When activated by interrogating radar, a line of 12 intense blips will appear on the radar screen radiating outward from the position of the SART. As the search vessel approaches, these blips widen to form a series of concentric circles around the transponder's position on the screen. In standby mode, the batteries have an operating life of 96 hours. The life is more than 8 hours in the operational mode. As with a radar reflector, a SART should be mounted at the highest possible point. On a raft the telescopic pole normally provided or the man overboard pole can be used as a mast to support the SART. Alternatively, it can be lashed to the top of the raft. If a radar reflector is supplied with the life raft, it should not be deployed at the same time, since it will block some of the SART signals.

Fluorescent dye marker is designed to be seen by airplanes and has a daytime visibility of 2 to 5 miles. In moderate weather it will last for a half hour; in rough weather it will rapidly dissipate. Use it whenever an aircraft is expected or if you believe you are beneath a flight path. The sea anchor will keep your drift rate the same as that of the dye.

Hand-held waterproof strobe flashers are 10 times brighter than the brightest parachute flare and can flash for hours on a single replaceable battery. Although they are not an internationally recognized distress signal, when supplemented with other recognized distress signals, they are very effective.

CREW OVERBOARD

Personal Flotation Devices

About 600 boaters drown every year because they were not wearing a personal flotation device (PFD). Drownings usually occur in less than a minute. Time is always the critical factor for survival.

Very cold water, 10° C (50° F) or less, is the great equalizer for all mariners, regardless of their swimming ability (see [Chapter 8](#)). Cold swimmers lose strength and coordination, making movement difficult. Sailors who survive a fall overboard into cold water are often too weak to climb back into the boat. Hypothermic sailors may have difficulty climbing up the cargo net or ladder of the rescue boat because of weak arms and legs.

Few boaters routinely wear PFDs and most people put them on only in stormy weather. The main reasons for veteran sailors not wearing PFDs are discomfort and inconvenience. All the type I offshore life jackets and type II near-shore life vests are bulky, uncomfortable, and awkward to wear. The common type III vest is comfortable and wearable but has poor reserve buoyancy and freeboard (distance from the water to the mouth); it cannot turn the unconscious victim face up (righting ability) and cannot support the head (body angle). It is suitable only for calm water and should be worn only by active boaters who are able to swim.

The new inflatable vests have a flat and lightweight design that allow them to lie flush against the body so they do not restrict movement. When inflated, they achieve excellent flotation. The offshore model can be purchased with an integral safety harness ([Figure 64-2](#)). Inflatable vests provide as much as 35 pounds of buoyancy, compared with 22 ½ pounds in type I and 15 ½ pounds in type III. In most cases this buoyancy floats

Figure 64-2 Comfortable, lightweight, and convenient integrated safety harness and automatic inflatable life vest. It is Coast Guard approved and features both a backup rip cord and an oral inflation system.

the head higher and makes it easier to breathe. By keeping the head and chest higher out of the water, it is easier to adopt the heat escape lessening position (HELP; see [Chapter 56](#)). With buoyancy high on the chest, there is also better righting ability and head support.

The U.S. Coast Guard has approved the manual inflation models of these vests. These are ripcord-activated carbon dioxide (CO₂) inflation systems. The automatic inflatable PFDs, despite lack of Coast Guard approval, have an extremely reliable water-activated mechanism and can always be inflated by pulling the ripcord or by oral inflation if necessary. Automatic inflation is an obvious advantage if the person entering the water is injured, semiconscious, or disoriented. The disadvantages would occur in much less likely scenarios, such as when a boat capsizes and the inflated vest impedes the exit by pinning the person to the cabin sole (which is now the ceiling), thus preventing a dive down to the open companionway. Autoinflation vests should be worn at all times by nonswimmers, because they may panic when falling overboard, and by children who may not understand or have difficulty with a manual device.

Boaters who resist wearing any type of vest may tolerate the offshore inflatable vest in a compact belt pack. It is the least cumbersome of any PFD because it is worn on the waist. After inflation, it is donned while in the water as a conventional life vest and offers 22 pounds of buoyancy.

When boating in cold weather, a float coat may be worn instead of a regular jacket. Besides providing floatation, the coat protects against hypothermia. An inflatable jacket is also highly effective for the same reasons.

Whatever style of PFD is chosen, it is important to test and wear it in the HELP position. You should float in a slightly reclining position with the water rising no higher than armpit level. The PFD should be close fitting with small arm holes to prevent it riding up on the chest. Children need to have a properly fitted size with crotch straps so they do not submerge if the vest slips up over their arms and head. Never buy an oversized PFD that a child will "grow into" over time.

An immersion suit is the ultimate protection from hypothermia and drowning. It is a combination life raft and dry suit. The suit has a watertight full-length zipper, watertight hood, face seal for wind and water protection, detachable mitts, neoprene wrist seals, integral boots, inflatable head pillow for optimum flotation angle, water-activated safety light, whistle, and buddy line. Their general bulkiness (one size fits a 110- to 300-pound person) and built-in gloves, however, make them impractical for continued wear while actively working aboard ship.

Safety Harness

A safety harness should always be worn in rough weather, at night, whenever alone on

deck, or if working on deck out of sight of the crew. In heavy weather, harnesses should also be used even when steering in the relative protection of the cockpit. The harnesses should be adjusted to fit snugly around the chest and 1 to 2 inches below the armpits. They should be constructed with webbing at least ½ inch in width with a breaking strength exceeding 3300 pounds. Tethers connect the harness to a through-bolted deck fitting or to a strong line, wire, or webbing running fore and aft. Each of these must have a breaking strength of over 4950 pounds. These specifications are based on the calculation that the force generated by a 150-pound body falling 12 feet is more than 3000 pounds. Being dragged in the water by a safety harness can be a bruising experience. Therefore tethers should be no more than 6 feet in length and fitted with highest quality snap shackles at both ends. The shackles should be easy to disconnect for quick release from a capsized boat.

Don the harness before going on deck, and secure the tether while still in the companionway. When on deck and under sail, always hook on the windward (uphill, upwind) side. If you fall, you will fall downhill the length of the tether and land on deck. If you hook onto the leeward side (downhill, downwind) you will probably be thrown overboard and dragged through the water.

Women should be careful not to wear the chest strap below their breasts. Injury may occur from the upward force that is placed on the harness when it suddenly comes under tension. Women should wear harnesses specifically designed for them. Safety harnesses are also available with an integrated inflatable vest. This convenient combination may be the most important piece of personal safety gear at sea.

Remaining Aboard

Falling overboard is the most common cause of marine fatalities in recreational boating and commercial shipping. In stormy weather the safest location is in the cabin. Virtually all "man overboard" incidents can be prevented by following these rules:

1. Remain sober, especially if you expect to go on deck for any reason.
 2. Wear nonskid footwear when working on deck.
 3. Walk in a crouched position with a low center of gravity and wide-based stance when the boat is rolling, heeling, or pitching.
 4. If the boat's motion is too violent to stand, crawl or slide along the deck.
 5. Use a safety harness as a "third hand," secured to a strong attachment point.
 6. Use a safety harness whenever going aloft in the rigging or climbing any superstructure.
 7. Avoid leaning overboard with all your weight on a lifeline or stanchion.
 8. Know the location of secure handholds and grab rails so you can find them at night.
-

9. Know the safe routes to avoid tripping on deck hardware, vents, and hatches, especially at night.

10. Do not urinate from the afterdeck in rough weather unless you are kneeling and attached with a safety harness.
11. Wear a safety harness whenever seasick, and vomit into a bucket rather than leaning overboard.
12. In heavy weather, sleep in your harness and be ready to attach the tether quickly if called on deck for an emergency.
13. In heavy weather, stay below in the cabin unless absolutely needed on deck.

Recovery of Crew Overboard

If you suddenly find yourself in the water without a safety harness, maintain a positive attitude about your survival and rescue. The will to live makes all the difference. In cold water, be prepared for violent shivering and intense pain. Do not undress. Clothing traps air, which provides insulation and buoyancy, and the trapped water next to the skin retards heat loss, as in a wet suit. If possible, cover your head, neck, and hands. Move slowly to decrease heat loss. Slowly tread water just enough to keep your head out of the water. Assume the HELP position if wearing a life jacket. If a short swim is your best chance of survival, remove extra clothing and footwear, and try to keep your head out of the water using a breast stroke or dog paddle. Up to 50% of the body's heat loss is from the head. Allow the vessel to come to you. Do not swim to the boat unless it is completely disabled and cannot return to you. Conserve your strength for the rescue. When possible, get out of the cold water and stay out of it, no matter how low the air temperature. Keep on all clothing to reduce windchill. If given the opportunity, always reboard or climb on top of a swamped or capsized boat and await rescue.

Time is the critical factor in recovering a person overboard. A well-rehearsed rescue under expert leadership with clear communication is the rescue most likely to succeed. When someone is observed falling overboard, shout "man overboard" and sound the all stations alarm (a continuous blast of the ship's whistle supplemented by continuous ringing of the general alarm bell for not less than 10 seconds, or three short whistle blasts). One or more crew members should be designated to spot and point to the victim continuously. Floating objects should be thrown overboard, including buoyant cushions, horseshoe buoys, ring buoys, and extra life jackets, in order to litter the water surrounding the victim. The gear may provide extra flotation and will help mark the area for the spotter. Unfortunately, most of these objects will drift faster in winds over 10 knots than a person can swim, so the person cannot expect to receive a PFD after falling overboard.

Special equipment is designed for locating and retrieving a person overboard. A crew overboard pole is a 12-foot flagpole that is ballasted to remain upright in rough seas. Without the drogue accessory, it will quickly drift away from the designated area. A man overboard module (MOM) automatically deploys a CO₂-activated horseshoe buoy and a 6-foot inflatable locator pole equipped with a drogue and water-activated lithium-powered light.

A variety of lights have been developed to serve as rescue beacons. The overboard marker strobe marks the site and illuminates the scene for the rescuers. It automatically activates when thrown into the water. Waterproof personal rescue strobe lights attached

to a PFD can flash for 8 hours at 1-second intervals and are visible 1 mile away. Other personal strobe lights can last up to 60 hours, with variable rates to conserve battery power. A U.S. Navy whistle has a special flat design to prevent the whistle body from holding water and dampening the sound. One should be attached to every life vest.

The water-activated UHF radio transmitter and strobe unit (ALERT) attaches to a life jacket and sets off an overboard alarm inside the boat. When the wearer falls overboard, the transmitter activates the onboard receiver, which triggers a loud alarm. The ALERT receiver can also shut down the engine and mark a position on a compatible GPS.

All onboard GPS units have an overboard function, which, if activated, will pinpoint the latitude and longitude of the person at the time of the fall. It will then give the reciprocal course to steer, the bearing, and distance back to the victim. The GPS is a powerful SAR tool, but is not a substitute for maintaining strict visual contact and using visual signal lights and markers. The inherent small degree of error with GPS is magnified in heavy winds, large seas, and strong currents, because the person may drift while the boat returns to the scene.

GPS receivers on board receive signals from U.S. Air Force satellites and then compute the location accurately to within 10 m. It may be close to impossible to locate the person in rough seas or during reduced visibility.

Rather than rely on the ship's emergency locator beacon, sailors can wear their own. A small unit can be worn by a crew member as a *personal locator beacon* (PLB). Weighing as little as 17 ounces, it also transmits on the 406- and 121.5-MHz frequencies; the battery life for this compact unit exceeds 24 hours.

The goal in overboard recovery is to return as quickly as possible to the victim using the simplest maneuver. Motorboats should reduce speed and return in a simple circle. Sailboats under power alone can return by simply circling back and approaching downwind of the victim. Establish contact by using a heaving line, such as a floating polypropylene line in a throw bag. If the boat is drifting downwind, slowly advance forward

to complete the recovery over the windward side. Placing the boat upwind of the victim entails the risk of drifting onto the person. Sailboats under sail can choose from a variety of options. The "quick stop" is designed for rapid overboard recovery. This method enables the boat to reduce speed immediately by turning into the wind while trimming in the mainsail and keeping the headsail (jib) aback. Thereafter the helmsman keeps the boat turning downwind while maneuvering to remain close to the victim. After passing abeam (to one side of the vessel at a right angle to the boat's centerline) of the victim, the boat heads into the wind to stop two to three boat lengths away from the victim at an angle of 60 degrees to the wind, with the sails luffing. The technique is similar to picking

up a mooring under sail. The boat can also be left beam to wind with the sails luffing while contact is made with the victim. The engine can be started and left in neutral, ready to be used if needed in the final approach. Rescuers must ensure all lines are aboard before engaging the engine to avoid fouling the propeller, returning to neutral when close to the victim. The main danger to the victim is being sucked under the stern while the prop is turning and the boat is moving forward under power.

The direction of approach to the victim used by the rescue boat is controversial and involves judgment based on many variables, including the sea state, wind strength, drift of the boat relative to the victim, and maneuverability of the boat. An injured or unconscious person requires assistance by a rescue swimmer who should be tethered to the boat.

The goal is to have the victim back on board as quickly as possible. Practice the different techniques and decide which method and modifications work best on your boat. The Lifesling, developed to enable one person to retrieve a person overboard, is a floating collar that doubles as a hoisting sling. The collar is deployed from a bag hung on the stern pulpit and is delivered to the victim in the water by repeatedly circling in smaller circles, similar to the way a ski boat would maneuver to deliver the tow rope to a fallen water skier. After securing the horseshoe over the head and under the arms, the victim is pulled back to the boat and hoisted in the apparatus with the assistance of a halyard and winch. If you lose sight of and are unable to find the victim, immediately call for assistance. A Mayday call on VHF-FM channel 16 will notify the Coast Guard and simultaneously alert all ships in the area monitoring this channel. The last known position should be obtained using GPS or reference to any navigational buoys and landmarks on shore. Repeat searches of the area, since it is easy to miss someone in poor visibility or choppy seas. The chances for recovery are close to 100% if the victim has a well-equipped high-visibility (orange or yellow) PFD with a personal strobe light, reflective tape, loud whistle, packet of waterproof self-launching meteor flares (Skyblazer), a pouch of fluorescent dye marker, and a personal EPIRB.

HOW TO ABANDON SHIP

Before abandoning ship, the first priority is to dress warmly and put on a life jacket. Layer on as much warm and quick-drying clothing as possible. If a survival suit is available, wear that instead of a life jacket, but bring the jacket for later use in the raft. One crew member should man the radio and broadcast a Mayday message on VHF-FM channel 16 (good up to a 20-mile range) or on SBB 2182 kHz (good beyond 50-mile range). Simultaneously, other crew should launch the life raft and locate the "abandon ship bag" (a survival kit). To guarantee that the critical survival items (VHF radio, EPIRB, SART, water maker, medical kit, signal pack) remain together with the life raft, these items should be packed into the life raft itself before departure, or they can be packed into a waterproof bag securely attached by a short line to the raft.

Each crew member should have an easily accessible prepacked waterproof bag containing extra dry clothing, personal medications, passport, prescription glasses and sunglasses, personal strobe, safety harness and tether, wallet, and any other personal valuables and necessities. If the ship's bag has been properly stocked, little else is needed from the sinking ship except synthetic blankets (not down sleeping bags, which will never dry), jerry jugs of fresh water, extra food (especially high-energy sports bars), and navigation tools. If time permits, additional communication and signaling equipment is collected from the stricken vessel, even if equipment was already placed in the bag or raft. This includes a 406-MHz EPIRB, a SART, and a waterproof hand-held VHF radio. In a life raft, a person can never have too many EPIRBs, radios, flares, and fishhooks ([Box 64-15](#)).

There are three classes of life rafts: ocean, offshore, and coastal. This classification refers to the areas in which the vessel normally operates and reflects the differences in size, design, construction, quantity of survival stores, and kinds of equipment. Another practical way to categorize life rafts is in terms of performance. A poor life raft will keep its occupants from drowning until they die of hypothermia or heatstroke. A mediocre life raft will protect the survivors from dying of exposure until they succumb to thirst and starvation. The best life raft will provide food and water, have a means of replenishing both, and be sufficiently equipped to sustain life and facilitate rescue.

[Box 64-16](#) lists the gear found in a six-man inflatable life raft approved by SOLAS for ocean service (SOLAS A). The SOLAS B raft is designated for limited service. It carries no food, water, or fishing kit. These rafts also

half the number of flares and smoke signals found in SOLAS A life rafts. An ocean-service raft is designed for use in rough offshore conditions. It is constructed with two complete, stacked inflation chambers. One flotation chamber is sufficient to support the number of people for which the raft is rated.

**Box 64-15. ABANDON SHIP BAG FOR
OCEAN PASSAGE**

SIGNALS AND COMMUNICATION

Registered 406-MHz class II
COPAS/SARSAT emergency position
indicating radio beacon (EPIRB) (carry
two if one is not packed in life raft)

Waterproof and submersible portable
VHF hand-held radio transmitter with
spare batteries

Search and Rescue Transponder
(SART)

Flares, smoke signals, horn

Kite, dye marker, signal mirror

Radar reflector

"Cyalume" chemical light sticks

Underwater flashlight with extra
batteries

Strobe flasher with spare batteries

PROTECTION

Survival suits, gloves

Expanded medical pack with extra
seasick medications, SAM splints,
narcotics, sunscreen, lip balm

Backup sea anchor and line

Expanded medical pack with extra seasick medications, SAM splints, narcotics, sunscreen, lip balm

Backup sea anchor and line

SUSTENANCE

Portable reverse-osmosis desalinator

Solar still

Fishing harpoon, spear gun with spare heads, extra fishing gear, including fishing line, wire leaders, assorted barbed hooks, sinkers, lures

Knife, sharpening stone, small cutting board, scissors, storage bags, eating utensils, nylon mesh bag, waterproof bags

Collapsible bucket, urine bottle

Comprehensive survival manual, fish identification book, cards, reading material

Collapsible water container

TOOLS

Small ax, pliers, and screwdriver

Dive mask

Duct tape

Raft patching clamps

Careful thought must be given to stowage of the life raft. The raft should be securely stowed either on deck, with hardware capable of withstanding the shearing forces in a capsize, or below in the cabin. The lid on a deck locker or lazarette is likely to open in a knockdown or capsize, making these poor storage areas for such vital gear.

**Box 64-16. LIFE RAFT EQUIPMENT
(OCEAN SERVICE)**

Inflation pump with hose

Two 4-foot paddles

Two sea anchors (one stowed inside ready for use, one outside automatically deployed)

Two bailers

Two sponges

Drogue and cord

Repair kit containing sealing clamps, patches, cement

100-foot buoyant heaving line with quoit

Floating sheath knife

Scissors

Can openers

Thermal protection bags

Provisions

Water ($\frac{1}{2}$ quart of water per person)

Graduated drinking vessel

First-aid kit (primarily for wound management)

Seasickness pills (6 per person)

Fishing kit

Survival instructions

Operating instructions

Two red parachute flares (hand held, rocket propelled, red)

Survival instructions

Operating instructions

Two red parachute flares (hand held, rocket propelled, red)

Six hand-held flares (stowed in watertight container)

Signaling mirror and whistle

Signal flashlight with spare batteries and spare bulb

Two smoke canisters

If the boat has a dinghy, prepare to tow it behind the raft. It is useful for storing additional supplies and can be used with an improvised sailing rig. Although a solid dinghy is less seaworthy in a storm than a life raft, it is far more durable against shark attack and is immune to chafe. A dinghy has more maneuverability and strength than a raft.

To launch the raft, the canister should be thrown overboard on the downwind (leeward) side of the boat and then inflated. It is dangerous to inflate a life raft with the CO₂ cartridge aboard the ship because it may become wedged in the rigging of the sinking ship or accidentally punctured. If the raft fails to inflate in the water, however, it must be brought aboard to be inflated with the hand pump.

A sharp jerk on the outstretched line coming out of the canister (the painter) triggers the CO₂ cartridge and inflates the raft. If the first pull is unsuccessful, give a second stronger tug. The painter should be attached to the boat before the raft is inflated. In the confusion surrounding an emergency, this critical step is sometimes forgotten, and after the raft inflates, it drifts away. One person with a knife should be stationed by the painter prepared to cut the line. Another

safety knife is located in a pocket by the entrance of the raft to cut the painter if the ship begins to sink after the crew has entered the raft.

Once everyone is aboard, get clear of the sinking vessel as quickly as possible by letting out all of the painter line. Risks include being struck from below by surfacing wreckage and becoming entangled with the boat's rigging as it rolls and sinks. If the boat does not sink, stay close by attaching a quick release line to it. The wreckage is always easier to spot than a small life raft, and the boat may be salvaged later.

Large-capacity rafts, usually found on commercial ships, are often mounted in a cradle with an automatic disconnect device called a hydrostatic release mechanism ([Figure 64-3](#)). This mechanism can be manually activated by pressing a button, which releases the straps holding the canister to the cradle. The canister can then be dropped overboard. In the event the boat begins to sink before the life raft is launched, a hydrostatic release mechanism will open when the vessel sinks to a depth of 10 to 15 feet, allowing the canister to float up to the surface. As the vessel sinks to the end of the painter's length, it will jerk the painter and initiate inflation. The specially designed "weak link" on the cradle where the painter is attached is designed to break and free the raft from the vessel completely before it is pulled under by the sinking boat. An unoccupied inflated raft will be blown downwind very quickly, much faster than someone in a life jacket can swim; a person in the water while a raft inflates must hold onto the raft or painter.

You can enter the raft before it is fully inflated by crawling under the collapsed canopy. When possible, try to remain dry and enter it directly from the sinking

Figure 64-3 This inflatable life raft will float free if the vessel sinks. The packing bands are designed to break when the raft is inflated. The rope painter, which is attached to the "weak link," must be secured to a cleat if the raft is manually deployed overboard. The disk-shaped hydrostatic release is set to release the raft from the cradle at water depths of 5 to 15 feet, with a button for manual release.

boat rather than from the water. All rafts are strong and stable enough so that you can jump directly onto the canopy and supporting arch tube when entering the raft. Be careful not to jump on top of the occupants or tear the canopy. The canopy serves to collect rainwater, helps to keep the raft dry, and shields survivors from the elements. When entering from the water, use the automatically deployed boarding ladder and handholds at the entrance to the raft. If the crew is forced to enter from the water, the first person into the raft should throw the heaving line to the others. The line has a rubber donut (quoit) attached to the end and will allow a person to hold on firmly. It is important to get everyone out of the water quickly. If you must swim away from the raft to help a crewmate, be certain you are attached to the craft with a safety line.

The hissing sound heard after inflation does not signify a leaking or defective raft. The relief valve is simply releasing excess gas pressure. Immediately after the release of the CO₂ /nitrogen mixture into the raft's interior space, ventilate the life raft thoroughly and periodically thereafter. The floor is inflated separately with the manual pump and provides insulation from the cold sea. Because the craft is so vulnerable to capsize (see later), it is extremely important to inventory and then secure all equipment as it comes aboard. Then check the life raft for any damage or leaks and the crew for any

life-threatening injuries. Activate the EPIRB immediately and leave it on.

The first medical action should be distribution of seasickness medication. In a life raft, everyone is susceptible to seasickness, especially in the first 24 hours. Make the raft as dry as possible, and remove wet clothing. Close the door, and huddle together to conserve heat. Do everything possible to conserve body heat, strength, and spirit as you prepare for rescue.

Life rafts have ballast pockets under the floor to trap sea water and thereby increase stability. Unfortunately, if the wind gets under the craft as it rises on a wave, it can still capsize. A capsize is most likely immediately after launching when the raft is empty. The raft may even initially inflate upside down; most rafts can be properly righted from the deck of the boat without entering the water.

No immediate danger exists if the raft capsizes with crew inside, since sufficient air is available in the space under the canopy. It is necessary to enter the water in order to right the raft, however, since it is unlikely to right itself unless rolled again by successive waves. With the raft empty, it can be righted by pulling on the righting straps at the bottom. Kneel on the downwind side with feet braced on the CO₂ cylinder, and lean back. The raft will then right itself easily when the wind catches it.

To prevent recurrent capsizes in heavy wind and seas, additional measures need to be taken. Every raft is equipped with a cone-shaped sea anchor. This device

1547

is essential in rough weather. It provides stability in high winds, helps to prevent capsizing in rough seas, is an aid in directional control of the raft, and helps to reduce drift. The benefit of reducing drift in storm conditions is controversial, since the raft may become sluggish with the sea anchor deployed. If sea room is sufficient, the occupants may be more comfortable and the raft less likely to capsize if it is allowed to drift at the same rate as the waves. Deployment of the sea anchor is automatic on some rafts. Stream the sea anchor after the raft is clear of the sinking vessel. It should be trailed somewhere in the trough between wave crests while the raft is sitting on a crest. Check that the rope does not become entangled, and protect the raft from chafe at the point where the rope is attached. Weight distribution is also critical to avoid capsize. Position most of the crew on the windward side, the same side from which the sea anchor is deployed, to act as ballast. Weight on the windward side reduces the chance of the raft being lifted and flipped over by the wind. In seas with high wave crests, be prepared to maintain the raft's balance and quickly shift as needed to prevent capsize in the other direction.

Since a survivor can quickly become separated from a capsized raft, have everyone attach a line to the handholds if capsize is possible. Whenever a craft capsizes, gather the crew in the water and check that no one is under the overturned raft. Everyone should return as quickly as possible to avoid hypothermia and to conserve precious

energy.

PREPARATION FOR RESCUE: LIFE IN THE RAFT

Having successfully abandoned ship and secured both crew and equipment in the life raft, the task of preparing for rescue begins. Panic, fear, helplessness, and hopelessness can easily defeat the best-equipped and most experienced crew. Optimistic persons are most likely to survive. The leader can set the example and improve morale by staying calm and formulating an active strategy to be rescued. Assigning meaningful duties to everyone and structuring the work and rest time will instill in the crew some sense of control over their destiny. In Pornichet, France, the Center for the Study and Practice of Survival proposes the following "seven tools of the mind to help you survive":

1. Size up the situation rationally. Analyze and evaluate all options and plan the best course of action. Consider the resources available, the time frame, and risks.
2. *Understand and control.* Get in touch with your feelings. Identify and acknowledge your fears; own and control them.
3. *Risk the least, achieve the most.* Evaluate and estimate the risks of any course of action. Ask what can be done to lessen the risk, and consider if the crew can handle the increased stress.
4. *Value your reason for living.* Find your own personal reason for wanting to survive. It will motivate you and powerfully counter any urge to give up.
5. *Imagine new ways to do things.* Use unconventional, lateral thinking. Improvise and try imaginative, creative solutions to problems. Trust your intuition.
6. *Victory comes with time.* Time is your asset, and problems often resolve themselves if given the opportunity. Avoid looking for quick solutions. Rushing a task often leads to failure.
7. *Enrich yourself with a permanent positive mental attitude.* Appreciate that you are alive, and keep your sense of humor.

Review how to use each type of distress signal. Take inventory of the signaling devices available, and agree on priorities for their use. Turn on the EPIRB and leave it on. The battery is good for 48 hours, during which time the signal should have activated an SAR operation and transmitted an updated location.

The most important duty aboard the raft is to maintain a continuous and effective lookout for rescue boats and airplanes. A watch schedule should be devised to rotate the duties every 2 hours. It is the lookout's responsibility to monitor changes in the weather, wind, and sea and look for signs of nearby land. Other crew members need to look after the well-being of the sleeping survivors. Their duties may include providing first aid and comfort to injured victims, fishing, making potable water, organizing the

stores, keeping the log, bailing, and maintaining the raft.

The raft is subject to tears, punctures, chafe, and structural deterioration, which can cause leaking air chambers and loss of watertight integrity. If the raft deflates, it begins to flex and chafe. The buoyancy chambers should be kept taut with no apparent folds. To prevent overinflation, the pressure relief valves must be operational during the daytime to let off heated expanding air, especially in the tropics. As the temperature drops at night, the raft should be reinflated with the manual pump.

The raft must be protected against sharp, pointed, and abrasive objects such as knives, tools, fishhooks, spears, fish bones and teeth, shells, belt buckles, jewelry, and pens. All pointed tools must be kept sheathed or wrapped except when in use.

Attached to the canopy are internal and external dome lights. These help survivors find the raft at night when abandoning ship and provide interior lighting. These battery-operated lights last 12 to 24 hours, so turn them off when not in use. They are not intended to be rescue lights.

Except for seasickness, probably no other condition is more debilitating than chronic sleep deprivation.

1548

Sleep deprivation causes decreased alertness with apparent blackouts of attention, which become increasingly prolonged and frequent. A groggy, inattentive lookout can easily miss the opportunity to observe and signal a passing ship. Conversely, the person may begin to hallucinate and see ships and planes. Impaired responsiveness to new situations and inability to make decisions rapidly further jeopardize the rescue.

Whenever possible, lie down and rest. Stretch out to relax muscles that are constantly working to keep the body stable in the raft. It is important to insulate the recumbent body against heat loss, especially from the cold floor of the raft. Always keep the double bottom of the floor of the raft fully inflated, and make every effort to keep the raft dry. Line the floor with sails, tarps, and extra clothing. The double layer floor also protects against the bumps of sharks, dorados, and other fish. Dry clothing protects the skin from painful saltwater boils. Apply an emollient to knees, hands, elbows, and buttocks to decrease skin abrasion. Common lubricants that moisturize the skin are petrolatum, mineral oil, and baby oil. Any area of skin breakdown should be smeared with an antiseptic or antibiotic cream and covered with a dry dressing.

Hypothermia becomes a threat with an air temperature of 0° to 10° C (32° to 50° F) or with repeated immersion in cold water (see [Chapter 6](#) and [Chapter 8](#)). This is likely if the raft repeatedly capsizes. Sustained uncontrollable shivering is the earliest clinical sign of a drop in core temperature. Other early clues of hypothermia are alterations in motor skills and changes in mental status. Manual dexterity, balance, and strength are impaired. Ability to climb back into the raft may become impossible. Changes in mental

status may involve judgment and cognitive skills.

Recognition of the early signs of hypothermia is critical. Prompt treatment usually prevents progression to profound hypothermia, which is likely to be fatal since it is untreatable in the raft. Treatment consists of preventing further heat loss by sheltering the victim from the wind, sea spray, or rain. Whenever possible, remove all wet clothing and dry the skin completely, then dress the victim in multiple layers of dry clothing. If a change of clothing is impossible, provide a vapor barrier with foul weather gear, a sail bag, or sleeping bag. If only a sail or blanket is available, wrap up the victim, covering the head, neck, and face. Let the victim shiver; if the shivering is vigorous, the heat generated internally provides the most effective method of rewarming. Calories from simple sugars and carbohydrates and ample water are necessary for the muscles to continue the shivering response.

A new SOLAS requirement for survival craft is a thermal protection suit for each crew member. These suits are ideal for keeping a person warm and dry in the survival craft. Foil space blankets are useful as sun reflectors on the canopy, and they effectively prevent heat loss from radiation. However, the major heat loss in raft survivors is by conduction through the raft floor, against which a foil blanket affords little protection.

To prevent heat-related illness (see [Chapter 10](#) and [Chapter 11](#)) and dehydration, it is imperative to drink water at regular intervals. If possible, keep drinking until the urine is clear. Mechanisms for obtaining water are discussed later.

Keep clothing on and damp to help reduce fluid losses and prolong the cooling effect. Wear long-sleeved shirts, trousers, and a hat. Clothing also protects the skin from sunburn and reduces passive heating from solar radiation. Apply a waterproof sun protection cream to exposed areas of the face, hands, arms, neck, and feet. Stay in the shade of the raft canopy, but make sure the raft is well ventilated. The best rafts have a double canopy with an air layer in between that acts as insulation from the heat of the sun. Space blankets with a reflective surface may also be tied over the canopy to reflect the sun's rays. Deflating the raft's floor chambers helps to cool the raft. It may be tempting to take a dip in cool sea water if you feel very hot. Be sure you have the strength and ability to climb back aboard and have someone watch you.

The body's requirement for water depends on body weight, individual physiology, amount of exertion, diet, ambient humidity, and temperature. The average person at rest can survive for about 12 days without consuming water; the person remains fit for only 5 to 6 days, then may become delirious. A half liter of fresh water per day doubles the survival time, and a liter a day permits almost unlimited survival. By contrast, the body can go several weeks without food (see [Chapter 53](#)), provided there is enough fresh water to drink. On a restricted diet, the human body at sea level, in the shade, and at a maximum temperature of 25° C (77° F) requires an estimated 1.3 to 1.6 quarts of water per day; at 35° C (95° F), 5 quarts are needed. Evaporative loss from the action of sunlight in an open boat in the tropics is estimated at 5 pints per day if the body is at rest. The required water supplied aboard a life raft in tins is only 1.5 quarts per person for 2 days. A minimum daily survival ration of water is considered to be 600 ml (20

ounces, or 1.25 pints).

Hand-operated, portable reverse-osmosis desalination units contain a semipermeable membrane made of three different synthetic polymers. One of the polymers, polyamide, is layered on the membrane and is responsible for the semipermeable properties. Polyamide contains negatively charged carboxylic acid side chains that project out from the surface of the polymer; these serve to repel any negatively charged chlorine ions that may try to cross the membrane. As a result, no positive cations (sodium) can pass either, because both anions and cations must pass together to maintain the charge

1549

balance on both sides of the membrane. Application of pressure to the sea water forces the water through the membrane against an osmotic gradient (reverse osmosis), creating fresh water. These units can produce 98% salt-free water from sea water at a rate of 1 ounce every 2 minutes, up to 1.2 gallons an hour. An added benefit is that the units remove bacteria, viruses, protozoa and other contaminants.

With malfunction or loss of the desalinator, solar stills can evaporate fresh water from salt water. The solar still was included in survival kits used by naval aviators during World War II. It provides about a quart of fresh water daily in temperate climates with sunshine. When inflated, the 24-inch ball containing a saltwater-soaked cloth collects fresh water after it condenses on the inner surface of the ball. The still is reusable and requires no chemicals. Unfortunately, most older solar stills are fragile and will not work in rough weather.

Rainwater can be collected with the canopy of the life raft. An exterior gutter collects and routes the water to a large container for storage. Daily washing of the canopy with sea water whenever practical helps to remove the buildup of salt deposits. In a heavy sustained downpour, the rain should rinse the canopy before the water is collected.

Ingestion of protein produces urea, and the kidneys must excrete the solute with water. Therefore, when water is in short supply, a diet rich in carbohydrates is preferred. Do not eat if water is unavailable. With 2 quarts a day or more, however, eat as desired. Fish and other sea creatures contain water with extremely low salt content in their eyes, flesh, and cerebrospinal fluid. Fish blood has a high salt concentration and is not recommended. Juices can be pressed out of the flesh by twisting pieces of fish in a cloth. The blood from sea birds and turtles is a reliable source of hydration for castaways.

Sea water is not potable. After exposure, drinking sea water is believed to be the major cause of death of life raft occupants. Ingesting sea water may hasten death rather than prevent it. Sea water is hyperosmotic at about 1000 mOsmol/L. The salt content ranges from 28 to 35 parts per thousand, whereas blood is about 8 parts per thousand. Drinking sea water usually causes immediate vomiting. If one is unlucky enough to hold it down, it increases the osmolarity of the blood and causes a shift of free water from the

intracellular space into the blood and other extracellular fluids.

In the high latitudes, old sea ice is a good source of water. Sea ice loses its salt content after 1 year. The ice is brittle, bluish in color, and has round edges. New sea ice is gray, salty, opaque, and hard. Melting the ice allows tasting and judging the salinity. If the temperature drops to freezing, sea water can be collected in a can and allowed to freeze. Fresh water freezes first. Therefore the salt concentrates in the center, forming slush surrounded by ice containing very little salt. Sea ice should not be confused with ice from an iceberg. Water from melted iceberg chunks is glacial fresh water. Chewing a piece of gum or cloth also helps to moisten the mouth and reduce thirst.

Unless survivors are assured of an early rescue or have a reverse-osmosis desalinator, they should not ingest water in the first 24 hours. After the first day, they can start drinking a minimum of 6 ounces three times a day from the water rations in the raft.

Nutrition is the last priority for survival. If the rescue will be delayed for days or weeks, plan to eat very little for the first 3 days. Thereafter, begin the lifeboat rations of carbohydrates and sugar. Save some rations until rescue is imminent, when extra energy will be needed.

Fish are usually the mainstay of a diet at sea once a survival routine has been established. The raft casts a dark shadow beneath the surface, which appears as a safe haven for a variety of fish, especially dorado ("school dolphin"). With practice and patience, fish can be taken near the sea surface with a harpoon, gaff, or spear gun. Care must be taken not to puncture the raft with these devices.

Successful fishing with a spear gun requires proficiency. Refraction makes it difficult to accurately hit the fish, so it is advised to minimize these effects by aiming straight down at the target, rather than obliquely. The ideal area to strike is located just behind the gill cover. Attach all fishing gear to the raft with a lanyard to avoid losing it. Fish away from the raft can be caught by trailing a line with a baited hook. Bait can be obtained from the first fish caught by using its guts, stomach contents, or thin strips of flesh. Lures can be made from any shiny object.

At night, fish are attracted to bright lights. Instead of a flashlight, try a signal mirror or any other shiny surface to reflect moonlight onto the water.

When bringing a fish aboard the raft, use a cloth or piece of canvas to wrap the fish. Both dolphin and wahoo, which have serrated teeth, thrash wildly when they come out of the water. Wounds from fish heal poorly and can easily become infected. Have a cutting board ready to kill the fish quickly by cutting through its spine right behind the head. A large fish can be stunned with a blow to the top of the head at eye level, and simply covering its eyes will calm it down sufficiently to position it for a quick kill.

Special care is required when bringing a shark aboard. A paddle or stick should be thrust in its mouth, and the fish held on its back over the flotation chamber tail first, until it is dead. The jaws should be cut out and thrown over the side before the fish is

dressed.

Certain fish are inherently poisonous (see [Chapter 62](#)); these are usually located around shoals and reefs in shallow waters. These include pufferfish, porcupine fish, and the ocean sunfish (mola). Any fish with spines or bristles instead of scales should not be eaten.

1550

As a general rule, do not eat any fish that smells bad. If uncertain about the safety of a fish, test it first for edibility. If it burns, stings, or tastes bad on the tip of your tongue, do not eat it. If it has an acceptable taste, try a small piece every hour for 3 to 4 hours initially, and if there are no ill effects after 12 hours, you can assume the food is edible. To save fish for future meals, cut the flesh into thin strips about an inch wide and half inch thick, and spread it out to dry in the sun on a flat surface. If you cut the strips with the fibers running the long way, the strips can be hung on a piece of string and allowed to dry in the open air under the raft canopy. Fish spoils within hours in the heat, so start drying some as soon as it is caught. Fresh-caught fish (except tuna), as well as dried turtle and bird meat, are good for days when the heat and humidity are not too high. Most ocean fish can safely be eaten raw. Freshwater fish should not be eaten raw, because they harbor parasites.

Seaweed is valuable in two ways. As a floating nest, it can harbor a variety of small edible creatures, including small fish, barnacles, crabs, and other crustaceans. All kelp and almost all brown and green seaweed are edible. Red seaweed is highly toxic, and any seaweed that tastes bitter may be one of the rare poisonous varieties. Leafy green seaweed can be dried for storage. Before eating seaweed, wash it in fresh water to eliminate any toxic plankton and salt that may be adhering to the weed. Seaweed must be chewed well and swallowed only after it becomes a soft paste. It has limited nutritive value because the carbohydrates are not digestible and the cellulose has laxative properties.

Plankton also has a high cellulose and chitin content and cannot be ingested in large quantities. Some toxic plankton are difficult to detect. The red tides that cause paralytic shellfish poisoning result from the blooms of dinoflagellates (see [Chapter 54](#)).

Many creatures follow a raft. There are reports of killer whales attacking small boats, but no documented accounts of attacks on life rafts. Other dolphins and whales may accompany the boat but are not likely to harm the survivors in a raft. Sharks can be a menace as they swim about the raft for days or even weeks and drive away other potentially edible fish. The shark's habit of frequently bumping a raft with its abrasive skin causes wear on the flotation chambers. Every effort should be made to avoid attracting sharks. Take special care to dispose of blood and offal at night, preferably when the raft is moving. Try not to create a waste trail for the sharks to follow, and bring hooked or speared fish aboard as quickly as possible.

Sea turtles' sharp claws and beaks can damage a raft or cause lacerations, so always bring them aboard cautiously by holding the hind flippers, then flipping them over onto their backs. The sea turtle can easily be killed by severing the vital arteries on the underside of the neck, with the spurting blood collected in a cup. The blood must be consumed immediately, because it coagulates in about 30 seconds. Draining the blood also preserves the quality of the meat for storage and future use. The eggs, heart, and bone marrow are edible, but the liver should not be eaten. Dry whatever meat is not immediately eaten. The bones inside the flippers have tasty marrow. Turtle eggs are rich in protein and fat. If the liver is crushed, the skimmed oil can be used as a skin oil. The shell can be used to bail the raft.

All seabirds are edible, but catching them may be more luck than skill. Their beaks and wings can be dangerous, so grab them by the feet. Float a baited hook on the water (fish guts are best), and let the bird hook itself. After the bird is hooked, throw a piece of canvas or article of clothing over the bird. With the head and beak well covered, compress the chest to suffocate the animal, or twist and quickly pull its neck. Rather than plucking the bird, slit the skin over the breastbone and peel off the skin with the feathers intact. The entire bird, except for the intestines and the small green gallbladder, is edible. The flesh may contain bioluminescent substances from ingested plankton, giving the dead bird a ghostlike glow at night, but it is nontoxic. The forewings and legs make excellent bait, and the feathers can be made into fishing lures.

RESCUE AND EVACUATION OF SICK AND INJURED SURVIVORS

Transferring personnel from a boat or a life raft to a rescue ship or helicopter entails risk for everyone involved. Rescue of personnel from a vessel in distress or from a life raft may be the most dangerous aspect of the survival ordeal.

The Automated Mutual Assistance Vessel Rescue System (AMVERS) provides resources to help any vessel in distress on the high seas. AMVERS is the only worldwide safety network available to all authorized RCCs. Participation is free, voluntary, and available to ships of all nations. More than 2700 vessels participate by being available to respond to emergencies at sea. The positions of all these ships around the world's oceans are tracked by computer and continuously updated. With these data, AMVERS creates a "surface picture" with the location of the ships in any given area. This vital information is then transmitted to the RCCs that deploy ships nearest the scene of the emergency. These ships are not designed for SAR, and their crew may have no experience or training in recovering survivors from small boats or life rafts under storm conditions.

In ship-to-ship rescue, collision between the vessels is the greatest risk. The typical scenario is a large merchant ship with limited maneuverability approaching a smaller vessel in distress, which usually has no maneuverability.

1551

Unless the rescue craft is highly maneuverable, the captain and crew experienced, and the seas relatively calm, it is much safer to use a smaller, more maneuverable craft to transfer personnel between the boats. This might include a rigid-hull inflatable boat (RHIB), a lifeboat, or even a life raft. In rough seas, a boat or raft is never secured to the rescue vessel. The constant battering of the two hulls is likely to damage and possibly sink the smaller craft. Whether to approach the rescue vessel upwind or downwind depends on the wind, sea, and size and relative drift of the two vessels. The advantages and disadvantages are similar to those for retrieving a person overboard. Becoming pinned and capsizing are risks when sitting in the lee (downwind) side of a large, rolling ship.

The transfer of personnel between ships is also hazardous if it requires the sick, injured, or exhausted crew to climb a cargo net or pilot ladder. Under the best of circumstances, it can be extremely difficult, and hypothermia is often the major obstacle.

A large rescue ship most often approaches upwind of the survival craft unless the ship's rate of drift is greater than that of the craft. This provides a calmer sea in the lee side of the rescue vessel as it slowly drifts down to the survivors' craft. If the sea anchor is deployed, be sure to pull it in to prevent entanglement in the rescue vessel's propeller. Remain calm, and do not rush to board the ship. Wait to see if a life boat or rescue swimmer is lowered to facilitate the transfer. If the raft must be lifted aboard with injured survivors, the floor must be fully inflated. Attach the lifting lines to the towing bridles on both sides of the raft, and attach two steadying lines to each side as well.

Never attempt to climb a scrambling net or pilot ladder without someone holding you on a safety line. The best way to board a rescue ladder is to wait until the craft being departed is on the crest of a wave. At that moment, transfer to the ladder. This drops the survival craft down while you are climbing up and eliminates the danger of the raft being raised up by a wave and hitting you. The safest procedure is being hoisted up to the deck in a harness by a crane.

Helicopter emergency evacuation and rescue has now become commonplace within 300 miles of the coastline. A detailed briefing is radioed to the crew when the helicopter is en route to the vessel in distress. All loose gear onboard must be well secured, including cockpit cushions, coils of line, winch handles, dive gear, hats, and clothing. Any gear not secured on deck may become a flying missile in the 100-mph winds generated by the helicopter. This debris may be sucked into the intake of the helicopter's engine or become tangled in the rotor blades.

All crew on deck should wear life jackets. Add extra clothing layers because the helicopter's downdraft creates a windchill effect. Avoid shining flashlights on the helicopter because the light may blind the pilot and rescue team; for the same reason, never fire aerial flares in the vicinity of a helicopter.

The transfer device is either a rescue basket or a Stokes litter. Selection depends on the victim's medical condition and the necessity to remain horizontal during the hoist. The horizontal position is particularly important for persons with profound hypothermia. A basket is the preferred device for lifting. It is easy to enter, especially in rough weather, and has positive flotation so that it will not sink. Just climb in it and fasten the straps. The basket will settle on the sea surface, enabling someone in the water to float into it.

A "horse collar" sling is a padded loop that is placed over the body around the back and underneath the armpits. The hoist is made with the line in front of the face. Always wear a PFD when entering the basket or hoist, and follow the directions for securing the safety straps.

The helicopter builds up static electricity traveling to the scene, and this is transferred down the cable to the basket. Allow the basket to touch the deck or the water first to discharge any static electricity. The electric shock is strong but nonlethal. The orange steadying line, which is dropped first, can be handled safely and will not produce any shock.

Unhook the hoist cable only if it becomes necessary to move a litter below decks, then set the cable free to be hauled back. When it is lowered again, allow the hook to ground on the vessel, then reattach it to the rescue device. Never attach the hoist cable or the steadying line to any part of the vessel or life raft, even temporarily.

If a helicopter picks up survivors from a life raft, the downdraft from the chopper's blades may capsize it, especially if the raft has relatively small ballast pockets. Similarly, a raft loaded to capacity with crew becomes increasingly unstable as the occupants are removed and winched aboard the helicopter. The survivors should sit on the roof and on the inflated support arch to decrease the amount of surface exposed to the downdraft. The strongest persons in the raft should be evacuated last.

The raft may also be used as an intermediate rescue platform between the distressed vessel and the helicopter. This is especially useful if the boat's mast and rigging interfere with the positioning of the helicopter or threaten to entangle the basket hoist. In this situation the raft is allowed to drift downwind attached to the distressed vessel by a line. The helicopter pilot cannot see the raft directly below. The winch operator therefore guides the rescue operation. When being winched up by cable and harness, follow directions to secure yourself properly, and keep on your life jacket. With an integrated safety harness and inflatable life vest, it is much easier to put on the helicopter's rescue

1552

harness when not encumbered by a bulky life vest. It may be preferable to leave the vest uninflated when being hoisted from the ship.

The helicopter has enormous potential for safe and effective SAR. The new H-60 Jayhawk can fly 300 nautical miles offshore, remain on scene for 45 minutes, hoist up to six people on board, and return to base at 140 knots. Use this form of evacuation judiciously, especially if it is for transfer of sick or injured victims. Communicate medical data accurately so that the appropriate method of evacuation is selected. The C-130 Hercules is the largest of the U.S. Coast Guard SAR fleet, with a range in excess of 1000 miles. It can air drop an enormous amount of lifesaving equipment, including dewatering pumps, life rafts, and survival and signaling equipment. The most recognizable airplane is the Falcon jet. This medium-range, fast-response plane flies at 350 knots and has a 2000-nautical-mile range. Sophisticated onboard electronics, including infrared scanners and surface search radar, allow the jet to fly a variety of search patterns on autopilot.

Part 10 - Travel, Environmental Hazards, and Disasters

1554

Chapter 65 - Travel Medicine

Elaine C. Jong

International travelers have unique health needs based on a person's underlying health, purpose of the trip, style of travel, and geographic destination. When individuals and groups travel to foreign locales to participate in wilderness and outdoors activities, exposure to unfamiliar people, food, sanitation, and environments may have a deleterious effect on health and interfere with the purpose and enjoyment of the trip. The multidisciplinary specialty of travel medicine uses selected principles from the fields of public health, infectious diseases, tropical medicine, and environmental and wilderness medicine, integrated with geographic and chronologic data, to formulate an approach to health risk assessment for a given journey. This chapter serves as a basic introduction to travel medicine and focuses on public health and communicable diseases. Closely related topics are covered extensively in other chapters in this book.

SOURCES OF INFORMATION

A publication of the Centers for Disease Control and Prevention (CDC), *Health Information for International Travel* (the "yellow book"), is the authoritative source of information on travel medicine and is updated annually. Two other periodicals published by the CDC and available by subscription, the *Morbidity and Mortality Weekly Report* (MMWR) and *Summary of Health Information for International Travel* (the "blue sheet," published biweekly), provide updated information on the status of worldwide disease outbreaks and changes in health conditions. However, the best way to obtain current and reliable travel health information, including vaccine requirements, malaria chemoprophylaxis, and disease outbreaks for various regions of the world is to consult the CDC Database of Health Information for International Travel website (www.cdc.gov/travel.index.htm). This website also contains links to the U.S. State Department Consular Information Sheets, for nonmedical information of interest to the traveler.

Professional societies, foundations, and private publishers are additional sources of telephone advice, topical brochures and information sheets, newsletters containing information on travel medicine topics, schedules of travel medicine meetings and continuing education courses, and other information, including lists of travel medicine clinics in the United States and abroad and English-speaking physicians worldwide. A list of resources for travel medicine information is given in the [Appendix](#) at the end of the chapter.

Standard textbooks on infectious diseases and tropical medicine and a number of monographs on travel medicine provide in-depth information on travel medicine-related subjects; many of these resources are listed in the suggested readings at the end of the chapter. A number of computer-based interactive programs for travel medicine clinics are commercially available. They are not listed here because the software and vendors are rapidly changing; the best sources of current information on travel medicine software are published reviews and "hands-on" demonstrations at medical and scientific meetings.

American travelers abroad who experience an emergency of any sort should contact the nearest U.S. consulate or embassy or call the U.S. Department of State Citizen's Emergency Center (see [Appendix](#)). If an extended stay in a given country is planned, the Citizen's Emergency Center suggests that the traveler register with the consulate or embassy shortly after arrival in the country.

Travelers should ascertain several months in advance of departure whether their regular health insurance policy covers the costs of treatment and hospitalization for illness or

injuries occurring abroad, and the costs of emergency medical evacuation back to the United States, if necessary. Medicare usually covers only health care expenses arising in the United States and its territories. Some credit card services provide worldwide medical referrals and arrangements for emergency transportation for their cardholders but do not actually cover the costs incurred. What the traveler needs is a short-term health insurance policy that specifically covers medical expenses and medical evacuation during foreign travel. Depending on the insurer, chronic medical conditions may be excluded, or covered only if they are certified to be under control for 60 to 90 days before departure. Travelers more than 70 years old may find it more difficult to get medical insurance of this kind.

TRAVEL HEALTH RISK ASSESSMENT

Pretravel medical preparation appropriate for a given traveler and trip is determined by a review of the geographic destinations, duration of the trip, style of travel, purpose of the trip, underlying health of the traveler, and

1555

access to medical care during the trip ([Box 65-1](#)). In this context, immunizations, malaria chemoprophylaxis, traveler's diarrhea, and parasitic infections must be addressed. Prevention and treatment of common ailments such as jet lag, motion sickness, sun exposure, altitude illness, insect bites, and animal bites should be reviewed. Some attention should be given to personal safety, sexually transmitted diseases, prevention of motor vehicle injury, and emergency medical evacuation. Information about the level of sanitation and environmental hazards at the destinations can be used to identify special health concerns in tropical climates and areas of extreme weather conditions, high altitude, or aquatic activities.^{[38] [39]}

Multiple destinations in several countries and travel lasting more than 3 weeks both tend to increase the complexity of the medical preparation with regard to vaccination and malaria recommendations. In addition, the content of the travel medical kit becomes more inclusive as a greater number of health needs over time are anticipated. The style of travel is an important factor in travel risk assessments. Travelers staying in urban air-conditioned hotels or well-developed resorts have less exposure to mosquitoes carrying malaria and other diseases than those living among residents in small villages or camping. If accommodations in malarious areas are likely to be in unscreened rooms, travelers should plan to take with them portable bed nets and insect repellents against mosquitoes and other biting insects. The purpose of the trip is another factor that influences exposure of the traveler to potential health hazards. Teachers, students, missionaries, relief workers, agricultural consultants, field biologists, and adventure travelers are more likely than persons on standard tourist packages and business travelers to be exposed to endemic infectious diseases transmitted by the local residents (such as hepatitis B, tuberculosis, and meningitis), insect borne diseases (such as malaria, yellow fever, leishmaniasis, filariasis, plague, and typhus), and diseases associated with animal exposure (such as rabies, leptospirosis, and anthrax).

Box 65-1. APPROACH TO MEDICAL PREPARATION FOR TRAVEL

TRAVEL INFORMATION

Geographic itinerary (countries in order of travel)

Month(s) and duration of travel in each country

Urban versus rural travel

Style of travel (hotel or resort versus hut or camping)

Purpose of travel

Access to medical care during travel

PERSONAL HEALTH

General health status

Allergies to drugs and vaccines

Age and weight

Pregnant or lactating

Impaired immune response resulting from disease, medications, or treatment

Medications taken on a regular basis

History of previous immunizations

Medical or physical conditions requiring special care

Modified from Jong EC: Med Clin North Am 76:1277, 1992.

All travelers, however, should be cautioned about the infectious hazards of sexual activity with new partners during travel, especially with commercial sex workers in host countries. Gonorrhea and chlamydia are common in the industrialized world and also have a worldwide distribution. Other sexually transmitted diseases, such as human

immunodeficiency virus (HIV) infection, syphilis, chancroid, and lymphogranuloma venereum, are more prevalent in the developing world.^{[36] [45]}

Although surveys and case reports of returned travelers confirm that attention to vaccine-preventable diseases (e.g., diphtheria, measles, polio, hepatitis, typhoid fever, and cholera) and exotic infectious diseases (e.g., malaria, schistosomiasis, leishmaniasis, and trichinosis) is appropriate, the importance of the traveler's underlying health and accidental injuries must also be emphasized.^{*} Cardiovascular diseases, motor vehicle accidents, and injuries accounted for more morbidity and mortality among American travelers and expatriates than did infectious diseases.^{[28] [29]}

Most international travelers should begin pretravel medical preparation 4 to 6 weeks before the date of departure so immunization schedules can be adequately spaced and appropriate medications and special supplies can be obtained ([Table 65-1](#)). Although the medical preparation for an international trip may be straightforward for people in good health, advance planning and consultation with a travel medicine expert are recommended for people with allergies, special health needs (pregnancy, infancy, advanced age, handicaps), or chronic or underlying health conditions (such as cardiovascular disease, respiratory conditions, compromised immune status, diabetes, renal failure, organ transplants, and seizure disorders).

TABLE 65-1 -- Vaccine Interactions

VACCINE	INTERACTION	PRECAUTION
Immune globulin	Measles/mumps/rubella (MMR) vaccine	Give these vaccines at least 2 wk before immune globulin (IG) or 3–5 mo after IG, depending on dose received
Oral typhoid vaccine	Antibiotic therapy	Do not take antibiotics concurrently
Oral typhoid vaccine	Mefloquine malaria chemoprophylaxis	Schedule an interval of at least 8 hr between oral typhoid dose and mefloquine dose
Oral typhoid vaccine	Oral polio vaccine	Oral polio vaccine (OPV) should not be taken at same time as OTV; OPV can be given 7–10 days before or 10–14 days after OTV

Rabies vaccine (HDCV) intradermal series	Chloroquine malaria chemoprophylaxis	Complete rabies vaccine (intradermal series) at least 3 wk before starting chemoprophylaxis with chloroquine; use rabies vaccine intramuscular series if 3-wk interval is not possible
Virus vaccines, live (MMR, OPV, yellow fever vaccine)	Other live virus vaccines	Give live virus vaccines on same day, or separate doses by at least 1 mo
Virus vaccines, live (MMR, OPV, yellow fever vaccine)	Tuberculin skin test (PPD)	Do skin test on same day as receipt of a live virus vaccine, or 4–6 wk after, because virus vaccines can impair the response to PPD skin test
Yellow fever	Cholera vaccine	Give the two vaccines on same day or at least 3 wk apart

From Jong EC: Immunizations for international travelers. In The travel medicine advisor, Atlanta, 1993, American Health Consultants.

IMMUNIZATIONS FOR TRAVEL

Immunizations may be divided into three categories: routine, required, and recommended.^[38] Primary vaccine schedules and booster intervals are given in [Table 65-2](#) and [Table 65-3](#). The international traveler should have all current immunizations recorded in *The International Certificates of Vaccination* as approved by the World Health Organization (WHO), a document in booklet form printed on yellow paper.^[37] The booklet has a special page for official validation of the yellow fever vaccine. Recent copies of the document (after 1988) do not contain a separate page for cholera vaccine validation because the WHO officially removed cholera vaccination from the International Health Regulations in 1973. If given, the cholera vaccination can be recorded in the space provided for "Other Vaccinations" in the newer booklets. In general, live virus vaccines and attenuated bacterial vaccines are contraindicated during pregnancy and in persons with altered immunocompetence.^[15]

Required Travel Immunizations

The required immunizations refer to those regulated by the WHO. Yellow fever vaccine may be required for entry into member countries according to current WHO regulations. Smallpox vaccine and cholera vaccine are no longer required for international travel according to WHO regulations.

Yellow Fever Vaccine.

Yellow fever is a viral infection transmitted by *Aedes aegypti* mosquitoes in equatorial South America and Africa. The endemic zones are shown in [Figure 65-1A](#) [Figure 65-1B](#). The yellow fever (YF) vaccine is a live attenuated viral vaccine that is highly immuno-protective (YF Immune, Connaught). The YF vaccine is given as a single dose for primary immunization; the booster interval is 10 years. The vaccine is contraindicated in infants less than 4 months of age because of the age-related risk of encephalitis after immunization. If possible, YF immunization should be delayed until the infant is 9 months of age or older. The vaccine is generally not recommended during pregnancy except when travel to a highly endemic area cannot be avoided or postponed by the pregnant traveler and the risk of the actual disease is thought to be greater than the theoretical risk of adverse effects from the vaccine.

Additional contraindications to receiving the vaccine include immunosuppression caused by underlying disease (e.g., malignancy, HIV infection, congenital immune deficiency) or by medical therapy (e.g., corticosteroids, cancer chemotherapy, radiation therapy, organ transplant therapy). The vaccine virus is cultured in eggs and is contraindicated in persons with a history of severe allergy to eggs (anaphylaxis). The package insert

contains instructions for skin-testing persons with an uncertain history of allergy to eggs.

If a person for whom the vaccine is contraindicated must travel to a country where yellow fever vaccine is

TABLE 65-2 -- Dosage Schedules for Routine Immunizations

VACCINE	PRIMARY SERIES	BOOSTER INTERVAL
Diphtheria and tetanus toxoids and pertussis vaccine adsorbed (DTP) (use in children <7 yr old)	4 doses* IM of vaccine: first 3 doses given 4–8 wk apart; dose 4 given 6–12 mo after dose 3	Booster at 4–6 yr of age
Haemophilus B conjugate (Hib conjugate vaccines are not considered interchangeable for the primary immunization series)		
PRP-HbOC	3 doses* IM or SC at 2, 4, 6 mo	Booster at 15 mo
PRP-OMP	2 doses* IM or SC at 2, 4 mo	Booster at 15 mo
PRP-D, PRP-HbOC, or PRP-OMP	1 dose* IM or SC at 15 mo up to 5th birthday	None
Hepatitis B (Engerix B) (accelerated schedule)	3 doses at 0, 30, and 60 days (1 ml IM in deltoid area)	4th dose is recommended at 12 mo if still at risk for hepatitis B exposure
Hepatitis B (Engerix B or Recombivax) (standard schedule)	3 doses at 0, 1, and 6 mo (1 ml IM in deltoid area)	Need for booster not determined
Influenza virus	1 dose* IM or SC annually	
Measles/mumps/rubella (MMR) [‡]	1 dose* SC at 15 mo of age or older	Boost measles vaccine at school age; boost measles vaccine <i>once</i> in adult life before international travel for people born after 1957 and before 1980
Pneumococcus (23-valent)	1 dose* SC	None (see text)

Poliomyelitis, enhanced inactivated (E-IPV) (killed vaccine, safe for all ages)	Give doses* 1 and 2 SC or IM 4–8 wk apart; give dose 3 6–12 mo after dose 2; give dose 4 to children 4–6 yr of age	Give dose <i>once</i> to persons (all ages) before travel in areas at risk
Poliomyelitis, oral (OPV) (attenuated live virus) [†]	Give doses* 1 and 2 po 6–8 wk apart; give dose 3 at 6 wk after dose 2 (customarily at 8–12 mo after dose 2); give dose 4 to children 4–6 yr of age	Give dose <i>once</i> to people less than 18 yr before travel in areas of risk
Tetanus and diphtheria toxoids adsorbed (Td) (for children >7 yr of age and for adults)	3 doses (0.5 ml SC or IM), doses 1 and 2 given 4–8 wk apart, dose 3 6–12 mo later	Routine booster dose every 10 yr

Modified from Jong EC: Immunizations for international travelers. In The travel medicine advisor, Atlanta, 1993, American Health Consultants.

IM, Intramuscularly; *SC*, subcutaneously.

*See manufacturer's package insert for recommendations on dosage.

†May be contraindicated in patients with any of the following conditions: pregnancy, leukemia, lymphoma, generalized malignancy, immunosuppression from HIV infection or treatment with corticosteroids, alkylating drugs, antimetabolites, or radiation therapy.

required for entry, a signed statement on letterhead stationery that the yellow fever vaccine could not be given to the traveler because of medical contraindications will be accepted in lieu of the vaccination statement, according to WHO regulations.

Cholera Vaccine.

The injectable cholera vaccine in current use is not highly efficacious, even when the primary series of two doses given a week or more apart is received. The WHO no longer endorses a requirement for this vaccine for entry into any country. Nonetheless, some countries still require a cholera vaccine for travelers arriving from cholera-endemic areas.^[26] If this situation is anticipated, a single cholera dose should meet this requirement and should be recorded in the traveler's *International Certificates of Vaccination* (see earlier discussion).

Travelers going to cholera-endemic or cholera-epidemic areas are encouraged to follow food and water precautions to prevent all forms of travel-associated diarrhea. A new oral cholera vaccine is presently available in Western Europe and Canada (Orachol, Swiss Serum Institute; Mutachol, Berna). At present, there are no standardized recommendations for use of this vaccine, although health care workers and relief

workers going to outbreak areas might be suitable candidates.

TABLE 65-3 -- Dosage Schedules for Travel Immunizations

VACCINE	PRIMARY SERIES	BOOSTER
Cholera (parenteral)	2 doses 1 wk or more apart (0.5 ml SC or IM); pediatric dose 0.3 ml for 5–10 yr of age, 0.2 ml for 6 mo–4 yr of age	6 mo
Hepatitis A, inactivated	3 doses given at 0, 1, and 6–12 months	None recommended
Immune globulin (hepatitis A protection)	1 dose IM in gluteus muscle (2-ml dose for 3 mo protection; 5-ml divided dose for 5 mo); pediatric dose 0.02 ml/kg for 3-mo trip, 0.06 ml/kg for 5-mo trip	Boost at 3- to 5-mo intervals depending on initial dose received
Japanese encephalitis	3 doses given on days 0, 7, and 30 (1 ml SC =3 yr old; 0.5 ml SC <3 yr old)	Booster dose may be given after 2 yr
Meningococcus (A/C/Y/W-135)	1 dose ^a SC	None (variable immunogenic response in children <4 yr of age: revaccination for this group recommended after 2–4 yr for those who continue to be at high risk).
Plague	1st dose (1 ml IM); 2nd dose (0.2 ml IM) 4 wk later; dose 3 (0.2 ml IM) 3–6 mo after dose 2	Boost if risk of exposure persists: give first 2 booster doses (0.1–0.2 ml) 6 mo apart, then give 1 booster dose at 1- to 2-yr intervals as needed
Rabies, human diploid cell vaccine (HDCV)	3 doses (0.1 ml ID) on days 0, 7, and 21 or 28	Boost after 2 yr or test serum for antibody level (must not use chloroquine prophylaxis until 3 wk after completion of ID vaccine series)
Rabies (HDCV, RVA, or PCEC)	3 doses (1 ml IM in the deltoid area) on days 0, 7, and 21 or 28	Boost after 2 yrs or test serum for antibody level
Tick-borne encephalitis	3 doses given SC on days 0, 30, and 180 days	Boost at 3- to 5-year intervals

Tuberculosis (BCG vaccine) [‡]	1 dose percutaneously with multiple-puncture disk; half strength for infants <1 mo old	Revaccination after 2–3 mo in those who remain tuberculin negative to 5 TU skin test
Typhoid, whole-cell parenteral	2 doses (0.5 ml SC or IC) 4 or more wk apart; pediatric dose (<10 yr old) 0.25 ml	Boost after 3 yr for continued risk of exposure
Typhoid Ty21A, oral	1 capsule po every 2 days for 4 doses (>6 yr old)	5 yr
Typhoid Vi Polysaccharide	1 dose SC*	2 yr
Yellow fever [‡]	1 dose (0.5 ml SC); pediatric dose 0.5 ml SC for >6 mo old	10 yr

Modified from Jong EC: Immunizations for international travelers. In The travel medicine advisor, Atlanta, 1993, American Health Consultants. ID, Intradermally; IM, intramuscularly; po, orally; SC, subcutaneously.

*See manufacturer's package insert for recommendations on dosage.

†Caution, may be contraindicated in patients with any of the following conditions: pregnancy, leukemia, lymphoma, generalized malignancy, immunosuppression from HIV infection or treatment with corticosteroids, alkylating drugs, antimetabolites, or radiation therapy.

Some practitioners recommend that travelers to cholera endemic areas who have underlying gastric conditions, such as achlorhydria or partial gastric resection, either of which may increase susceptibility to cholera infection, be immunized with cholera vaccine.

Smallpox Vaccine.

Although the last case of smallpox acquired through natural transmission was reported in 1977 and the requirement for smallpox vaccine for international travel was removed from the WHO regulations in 1982, health care providers still receive sporadic inquiries about smallpox vaccine. The vaccine is no longer available commercially. Limited supplies are released on a case-by-case basis from the CDC based on individual review. Research scientists and health care workers who work with the smallpox and closely related viruses are candidates for immunization.^[14]

Recommended Travel Vaccines

The recommended vaccines are those given to travelers depending on the travel health risk assessment. Vaccines in this category include those for hepatitis A, hepatitis B, typhoid fever, meningococcal meningitis, Japanese encephalitis B virus, and rabies.

Immunization

Figure 65-1a Yellow fever endemic zones. (From Centers for Disease Control: *Health information for international travel, 1999–2000*, Washington, DC, 1999, US Government Printing Office.)

against tick-borne encephalitis and tuberculosis (bacillus Calmette-Guerin [BCG] vaccine), or a tuberculosis skin test (purified protein derivative [PPD]), may also be recommended for some travelers. The vaccine against plague is associated with a prolonged immunization schedule and is not readily obtained. Persons at risk are usually prescribed a standby regimen of antibiotic treatment.

Hepatitis A Vaccine.

Hepatitis A is the leading vaccine-preventable disease among international travelers to the developing world. Hepatitis A is a serious viral infection with a transmission similar to polio, cholera, typhoid, and traveler's diarrhea (i.e., fecal contamination of food and water). Although up to 60% of adults over 40 years of age from industrialized countries may have immunity to hepatitis A through clinical or subclinical

Figure 65-1b

infection, most travelers less than 40 years old are susceptible.^[49] (For more information, see the CDC website: www.cdc.gov/nicidod/diseases/hepatitis.) Adventure travelers who venture off usual tourist routes may be at increased risk compared with other groups of travelers. Two new hepatitis A inactivated viral vaccines became licensed in the United States during the 1990s: Havrix (SmithKline Beecham) in 1994 and VAQTA

(Merck) in 1996. Both vaccines are safe, efficacious, and produce long-lasting immunity. Each vaccine is given by intramuscular injection into the deltoid muscle. Within 2 to 4 weeks after the first hepatitis A vaccine dose, 98% to 99% of vaccine recipients develop protective levels of antibodies. A second dose, constituting a booster dose, is given 6 to 18 months after the first dose (according to package directions), and based

1561

on mathematical modeling, it will elicit immunity lasting approximately 15 to 20 years.

Protection against hepatitis A can be obtained from immune globulin (gamma globulin) containing preformed antibodies against hepatitis A. Depending on dosage, 0.02 mL to 0.06 mL/kg body weight given by deep intramuscular injection into the gluteus maximus creates 3 to 5 months' protection respectively from this passive form of immunization. If time allows, a serum test for hepatitis A antibody should be performed in people who travel frequently, who are of foreign birth, or who are over age 40; unnecessary immunization may be avoided if a person has protective antibodies from an inapparent hepatitis A infection in the past.

Hepatitis B Vaccine.

Hepatitis B vaccine was added to the list of vaccines recommended for routine immunization of children in the United States in 1991.^{[10] [17]} However, American adults who are at high risk for exposure to hepatitis B infection because of occupation, personal activities (travel, close contact with infected people, institutionalization), or medical treatment with blood or blood-derived products are also targeted for immunization.

In many parts of Asia and Africa, up to 15% of the general population may be asymptomatic carriers of hepatitis B virus. Travelers to countries in Asia and Africa who will live and work among the residents, such as missionaries, volunteer relief workers, teachers, students, adventure travelers, and other travelers who might have intimate or sexual contact with the residents, should consider immunization against hepatitis B.

Two recombinant vaccines are available, Recombivax (Merck) and Engerix B (SmithKline Beecham). The standard dosage for both vaccines consists of injected doses at 0, 1, and 6 months. Engerix B vaccine has an approved accelerated dosage schedule of 0, 1, and 2 months. This may allow full immunization of a traveler with limited time before departure; however, a booster dose at 12 months is recommended if risk of infection continues.^{[10] [13]} A combined hepatitis A and hepatitis B vaccine (Twinrix, SmithKline Beecham) is available in Western Europe and Canada. This vaccine is pending Food and Drug Administration (FDA) approval and release in the United States.

Typhoid Fever Vaccine.

The incidence of typhoid fever among American travelers is relatively low (58 to 174 cases per 1 million travelers), but among reported cases in the United States, 62% were

acquired during international travel.^[58] Mexico, Peru, India, Pakistan, and Chile are countries in which the risk of transmission appears particularly high. Sub-Saharan Africa and Southeast Asia are also regarded as areas of increased risk for typhoid fever.

Avoidance of potentially contaminated food and drink during travel is important, even if the typhoid vaccine is received. The parenteral heat-phenol-inactivated whole-cell typhoid vaccine requires two doses given by injection 4 weeks apart for primary immunization, and a booster dose after 3 or more years. The protection against typhoid fever afforded by immunization with the parenteral whole cell vaccine ranges from 51% to 76%. The vaccine has been associated with troublesome side effects; most recipients complain of soreness at the injection site, headache, low-grade fever, and general malaise for 1 or 2 days after immunization.

The use of the parenteral whole-cell typhoid vaccine has been mostly supplanted by use of either of two modern typhoid vaccines, the oral Ty21A typhoid vaccine (Vivotif, Berna) and the parenteral purified Vi polysaccharide typhoid vaccine (Typhim Vi, Pasteur Merieux Connaught). The oral typhoid vaccine contains a live attenuated strain of *Salmonella typhi* bacteria (Ty21A). The vaccine is in capsule form and is recommended for individuals 6 years of age and older. Both the primary and booster immunization consist of a series of four capsules, one taken every other day over the course of a week. The booster interval is 5 years. A liquid suspension form of this vaccine is expected in the near future; this will facilitate administration of the vaccine to young children and to others who have difficulty swallowing capsules. Persons who have previously received the parenteral whole-cell typhoid vaccine and who now desire immunization with the oral vaccine should receive the full four-capsule series because only limited data on alternative regimens are available. Although protection rates of 43% to 96% were reported in field trials with the oral live-attenuated typhoid vaccine among residents of endemic areas, limited data are available for protection rates in people from nonendemic areas who travel to endemic areas.^[6]

The purified Vi polysaccharide typhoid vaccine consists of a single dose given by injection, and the booster interval is 2 years in the United States (3 years in Canada and abroad). The vaccine may be used in persons 2 years of age and older, and has an efficacy range in clinical field trials similar to that observed for the oral typhoid vaccine. The purified Vi polysaccharide typhoid vaccine is preferred for persons who have difficulties with swallowing capsules, who have a limited time before departure (10 days), who may be poorly compliant with the multidose outpatient regimen for oral typhoid vaccine, or who have a medical condition that is a contraindication for taking the live attenuated oral Ty21A typhoid vaccine.

Meningococcal Vaccine.

Vaccine protection against meningococcal meningitis is recommended for people going to countries or regions where outbreaks have

been reported. Meningococcal vaccine is required for travel to Saudi Arabia during the time of the annual religious pilgrimage (the hajj) to Mecca in late spring. The vaccine is also recommended for people going to live and work in certain areas of Africa (sub-Saharan) and South America (Brazil), where outbreaks of the disease are frequent among the residents.

Meningococcal polysaccharide vaccine (Menomune, Aventis) is a quadrivalent vaccine inducing immunity against serogroups A, C, Y, and W-135. A single dose appears to provide immunity for at least 3 years. Vaccine efficacy is variable in young children, and a second dose of vaccine after 2 or 3 years is recommended for children living in high-risk areas who received the first vaccine dose at less than 4 years of age.

Japanese Encephalitis Virus Vaccine.

Japanese encephalitis (JE) is a viral infection transmitted by *Culex* mosquitoes in Asia and Southeast Asia. Transmission is year round in the tropical and subtropical areas and during the late spring, summer, and early fall in temperate climates. Pigs and some species of birds are natural reservoirs of the virus, whereas the mosquito vectors breed extensively in flooded rice fields and irrigation projects. JE virus is not considered a risk for short-term travelers visiting the usual tourist destinations in urban and developed resort areas. For visitors to rural areas during the transmission season, the estimated risk for JE during a 1-month period is 1:5000, or 1:20,000 per week.^[16]

The risk of infection can be greatly decreased by personal measures that prevent mosquito bites: wearing protective clothing, using insect repellents, and sleeping under bed nets. Nonetheless, because JE has been acquired by short-term travelers to endemic rural areas, and agricultural projects bordering on urban areas can bring infected mosquitoes into the proximity of susceptible urban dwellers, the vaccine should be offered to travelers going on trips of any length to rural areas (especially areas of pig farming), and to expatriate workers, missionaries, and students who plan to live in endemic areas.^[68]

An inactivated viral vaccine (JE Vax, Biken, licensed and distributed in the United States by Connaught) consisting of three doses given by injection over the course of a month is available for administration to travelers determined to be at significant risk. A schedule consisting of doses at 0, 7, and 30 days appears to result in a higher seroconversion rate and geometric mean titer of antibody among recipients than does a 2-week accelerated schedule consisting of doses at 0, 7, and 14 days.^{[3] [16] [56] [68]} A booster dose of vaccine may be given 2 to 3 years after the primary immunization for continued risk of exposure.

Adverse reactions to JE vaccine include local pain and swelling at the injection site in about 20% of recipients, systemic symptoms (fever, headache, malaise, rash) in about 10% of recipients, and hypersensitivity reactions (mainly urticaria, angioedema, or both)

in 15 to 62 per 10,000 American vaccinees. The hypersensitivity reactions reported occurred after the first, second, or third dose of vaccine, either almost immediately afterward or with delays of up to 2 weeks after receipt of the vaccine dose. Limited data suggest that persons who have had urticarial reactions to *Hymenoptera* envenomation and to other stimuli might be at greater risk of JE vaccine-induced hypersensitivity reactions. The CDC recommends that vaccinees be directly observed for 30 minutes after receipt of JE vaccine and that they not depart on their travel until 10 days after the last dose, so that delayed adverse reactions can be detected and treated.^[16]

Rabies Vaccine.

Animal bites, especially dog bites, present a potential rabies hazard to international travelers who travel to rural areas in Central and South America, the Middle East, Africa, and Asia.^{[11] [70]} Preexposure rabies immunization is recommended for rural travelers, especially adventure travelers who go to remote areas, and for expatriate workers, missionaries, and their families living in countries in which rabies is a recognized risk.

There are three modern tissue culture-derived inactivated virus rabies vaccines available in the United States for preexposure and postexposure immunization: human diploid cell vaccine (HDCV) (RabImmune, Aventis), rabies vaccine adsorbed (RVA) (Michigan Department of Public Health, distributed by SmithKline Beecham), and purified chick embryo cell vaccine (PCEC) (RabAvert, Chiron). Preexposure rabies immunization consists of three doses (1.0 mL each) of tissue culture-derived vaccine given over the course of 1 month by intramuscular injection into the deltoid muscle. The usual booster interval for rabies vaccine is 2 years; however, if time permits, serologic testing may show persistence of protective levels of antibody and therefore the booster dose may be delayed to 3 or even 4 years after the last dose on the basis of annual testing. This sparing of vaccine doses received could be beneficial to recipients who have a long-term need for protection (veterinarians, field biologists, laboratory workers, and expatriates living in high-risk areas). The three vaccine preparations are considered interchangeable for booster doses.

Only the HDCV vaccine has an intradermal (0.1-ml dose) injection preexposure immunization schedule approved by the FDA. The smaller doses used for the intradermal series are less expensive than the intramuscular doses, but the intradermal series requires advance planning; vaccine efficacy is compromised if chloroquine prophylaxis against malaria is started within 3 weeks after the third dose of intradermal vaccine.^[55] If

there is not sufficient time before departure, one of the intramuscular vaccines should be given.

Mild local reactions to rabies vaccine are common and consist of erythema, pain, and swelling at the injection site. Mild systemic symptoms—headache, dizziness, nausea,

abdominal pain, and myalgia—may develop in some recipients. In approximately 5% of people receiving booster doses of HDCV for preexposure prophylaxis and in a few receiving postexposure immunization, a serum sickness-like illness characterized by urticaria, fever, malaise, arthralgias, arthritis, nausea, and vomiting may develop 2 to 21 days after a vaccine dose is received. The RVA vaccine is derived from virus grown in tissue culture cells in medium free of human albumin and is not associated with a serum sickness-like vaccine-associated reaction. The RVA vaccine is approved for intramuscular administration only. Data are accumulating on the incidence of reactions after immunization with this preparation. The PCEC vaccine is also prepared from tissue culture cells in medium free of human albumin.

For postexposure rabies immunization, see [Chapter 44](#) .

Tick-Borne Encephalitis Vaccine.

Tick-borne encephalitis (TBE) is a viral disease spread by ticks in Europe (Austria, the Czech Republic, Slovakia, Germany, Hungary, Poland, and Switzerland) and the newly independent states of the former Soviet Union during the months of April through August. TBE is transmitted to humans by bites from infected *Ixodes ricinus* ticks, usually found in forested areas of endemic regions. However, systemic infection after ingestion of unpasteurized dairy products from infected cows, goats, or sheep can also occur.^[50]

Vaccination against TBE is not available in the United States. An inactivated TBE vaccine manufactured by Immuno (Vienna, Austria) is available in Europe and in Canada. The vaccine is produced in chick embryo cell cultures; primary immunization consists of three doses given by subcutaneous injection over 6 months. The limited availability of the vaccine and the relatively long immunization schedule mean that most travelers from North America who anticipate a need for protection against TBE will not be able to obtain the vaccine. An inactivated TBE vaccine, Encepur, manufactured by Chiron (Behring, Germany) has a rapid immunization schedule, with primary doses given on 0, 7, and 21 days, with booster doses at 12 to 18 months and at 3 to 5 years. This vaccine is not currently available in North America.^{[3] [50]}

Travelers planning outdoor activities (hiking, biking, camping) in areas where TBE is endemic need to rely on personal measures to prevent tick bites. They should wear protective clothing when outdoors, use insect repellents containing *N,N*-diethyl-meta-toluamide (DEET) on exposed areas of skin, and treat their outer clothing with a permethrin-containing insecticide. All travelers to such areas should be advised to avoid ingestion of unpasteurized dairy products.

Tuberculosis (BCG Vaccine).

Persons going on short trips for tourism or business to countries in which tuberculosis is much more common among the general population than in the United States are not considered to be at great risk of contracting this infection, which is commonly spread from person to person by inhalation of infected respiratory droplets in closed environments. However, travelers who will live among foreign residents or who will work in foreign orphanages, schools, hospitals, or other facilities may be at significant risk of

exposure to infection with tuberculosis. Such travelers should be skin tested with tuberculin (PPD) and control antigens (such as *Candida* and *Trichophyton*) before the trip, and afterward if the original test was negative. People who convert to test positivity on the skin test can be treated with isoniazid or other drugs to prevent tuberculosis.^[6]

The BCG vaccines around the world were originally derived from in vitro attenuation of a bovine tubercle bacillus (*Mycobacterium bovis*) strain in the early 1900s in France. Subsequently, the organisms have been maintained by several laboratories under varying conditions, so currently available vaccines are not considered microbiologically identical. The BCG vaccines are used widely all over the world for childhood immunization against tuberculosis, although this has never been a public health policy in the United States. There is no consensus on the protective efficacy of BCG vaccines, and estimates of protection have varied from study to study. BCG strain differences, regional differences in mycobacterial ecology, and differences in trial methods have all contributed to the observed variation in studies of vaccine efficacy.^[6] ^[24]

Epidemiologic data suggest that the vaccine may be more useful in protecting children from disseminated extrapulmonary complications of tuberculosis than in protecting adults from primary pulmonary infection. Persons immunized with BCG vaccine test positive on PPD skin tests for many years afterward, regardless of the degree of protection conferred by the vaccine. As a result, the PPD skin test cannot be used as a reliable indicator of infection in recipients, and this situation can contribute to a delay in diagnosis in people who have contracted tuberculosis infection despite BCG vaccination.

Occasionally, children in families going abroad for extended residence are requested by the receiving country to provide proof of BCG vaccination to qualify for a visa. A BCG vaccine is commercially available in the United States and is approved by the American Academy of Pediatrics Committee on the Control of Infectious Diseases^[24] for use in children going to live in areas

in which tuberculosis is prevalent or there is a likelihood of exposure to adults with active or recently arrested tuberculosis. The vaccine is also recommended for children of tuberculous mothers. The vaccine might be considered appropriate in the case of uninfected (PPD skin test negative) health care workers who are going to work in areas where there is a high endemic prevalence of tuberculosis in the population and who will have limited access to medical diagnosis and treatment.^[6] Like other live attenuated vaccines, BCG vaccine is contraindicated in people with immunosuppression caused by congenital conditions, chemotherapy, radiation therapy, HIV infection, or another condition resulting in impaired immune responses. Pregnancy is considered a relative contraindication.^[15]

Plague Vaccine.

Plague, a bacterial disease caused by *Yersinia pestis*, is enzootic among wild rodents in countries of Africa, Asia, and the Americas. Plague is transmitted to humans by fleas or direct contact with infected animals. Person-to-person spread is common through respiratory secretions. International travelers following on standard tourist itineraries to countries in which plague is reported are unlikely to be at risk. Persons who are at high risk of exposure include field biologists and persons who plan to work or camp in rural mountainous or upland areas, where avoidance of rodents and fleas is difficult.

Plague vaccine is a killed bacterial vaccine with poorly documented protective efficacy. Primary immunization consists of three doses of vaccine given by intramuscular injection over 10 months. Side effects include pain, redness, and induration at the site of injection. Systemic symptoms consisting of fever, headache, and malaise may occur after repeated doses. An alternative to plague vaccination is the use of prophylactic tetracycline (500 mg by mouth four times a day) during periods of active exposure to plague-infected animals or humans. The efficacy of using tetracycline prophylaxis is unproven by controlled clinical trial, but inferred from use of the drug in the treatment of plague.

Routine Immunizations

Routine immunizations are those customarily given in childhood and updated in adult life, usually regardless of travel.^{[13] [17]} The assessment of immunization needs for international travel provides an opportunity for individuals to receive "missed" booster doses of the routine immunizations. This is a special concern among middle-aged and older people.^{[34] [40]}

The routine vaccines currently recommended in childhood include those against tetanus, diphtheria, pertussis, measles, mumps, rubella, poliovirus, *Haemophilus influenzae* type b (Hib), and hepatitis B.^{[13] [17]} After 7 years of age, booster doses for tetanus, diphtheria, measles, and poliovirus are given as indicated below. The recommendation for universal pediatric immunization against hepatitis B is relatively recent (see previous section on hepatitis B vaccine).^[10] Recommendations for immunization against viral influenza and pneumococcal pneumonia are based on underlying health and age.

Tetanus and Diphtheria Vaccine.

The tetanus/diphtheria vaccine (Td) is used for primary immunization and booster doses in older children and adults. Booster doses of Td vaccine given at 10-year intervals throughout life are recommended to maintain immunity. The diphtheria-pertussis-tetanus vaccine is used for immunization of children less than 7 years of age and contains different proportions of the tetanus and diphtheria vaccine antigens than those present in Td.^{[9] [13]}

Poliomyelitis Vaccine.

Poliomyelitis vaccine is usually not boosted after childhood in the United States, except for anticipated high-risk exposure through work or travel to areas in which polio is endemic or epidemic. Although the risk of polio transmission is greatest in the developing countries, sporadic outbreaks have occurred in industrialized countries among unvaccinated subpopulations, usually religious groups.

A combination of two inactivated (killed) virus polio vaccine (IPV) doses and two attenuated live-virus oral polio vaccine (OPV) doses, or an all-IPV regimen is recommended for a primary immunization series given before 18 years of age. IPV is recommended for primary immunization and for booster doses in people 18 years of age and older because of a higher risk of complications associated with OPV in older patients.^[13]

Measles, Mumps, and Rubella Vaccine.

A single dose of measles, mumps, and rubella (MMR) vaccine is recommended for all infants at 15 months of age. The Immunization Practices Advisory Committee recommends a second dose of measles vaccine in childhood on entry into grade school, middle school, or high school; this is required by law in many states. Also, persons born after 1957 should receive a second dose of measles vaccine. The second dose of measles vaccine is usually administered as MMR vaccine.^[13] ^[17] MMR vaccine is a live attenuated virus preparation, and it is contraindicated in pregnancy and in persons with compromised immunity. Transmission of naturally-occurring measles is higher among populations in developing countries than in the United States, thus travelers are at higher risk of exposure.

Haemophilus Influenzae B Vaccine.

The risk for invasive *H. influenzae* disease, including meningitis, is greatest in children less than 7 years old, and the infection is common among children in the developing world. Primary

immunization is recommended at 2 months of age or as soon as possible thereafter. Three different conjugate vaccines are commercially available against *H. influenzae* type b (Hib). The vaccines contain the antigenic polyribosyl-ribitol (PRP) moiety conjugated to a carrier protein. Two doses of PRP-OMP vaccine, or three doses of HbOC vaccine given 2 months apart, are recommended for all children less than 12 months of age. After 12 months of age, a single dose of either vaccine is sufficient for immunization. The third Hib conjugate vaccine, PRP-D, is approved for use only in children 15 months or older and is given as a single dose.

Influenza Vaccine, Pneumococcal Vaccine.

Annual immunization against viral influenza is recommended for all people over 65 years of age. Influenza vaccine is also recommended for groups of persons at increased risk from complications of viral influenza. These persons include those with chronic respiratory disease (emphysema, asthma), ischemic heart disease, transplanted organs, renal failure, and impaired immune response from congenital conditions, acquired illness, or immunosuppressive therapy. The 23-valent polysaccharide vaccine against pneumococcal pneumonia consists of a single dose and is recommended for the same groups. A booster dose at 3 to 5 years after the initial dose is recommended for certain risk groups.^[13]

In addition to the elderly and ill, this vaccine is also recommended for all health care workers and for international travelers, because prolonged air travel and exposure to crowded or extreme environments predispose them to respiratory infections.

Figure 65-2 Map of worldwide malaria transmission. (From Centers for Disease Control: Health information for international travel, 1999–2000, Washington, DC, 1999, US Government Printing Office.)

Malaria

Malaria is a mosquito-transmitted, blood-borne, parasitic infection present throughout tropical and developing areas of the world, including Mexico, Haiti, Central and South America, Africa, the Middle East, the Indian subcontinent, Asia, Southeast Asia, and Oceania ([Figure 65-2](#)). The estimated worldwide incidence of malaria is 280 million cases per year. Approximately 1000 cases per year are reported in the United States to the CDC. Although the risk to travelers is relatively low compared with other medical problems (e.g., diarrhea, respiratory problems) in travelers, malaria infection causes a severe febrile illness that is potentially fatal.

Four species of malaria commonly cause disease in humans: *Plasmodium vivax* (worldwide distribution), *P. falciparum* (worldwide distribution), *P. ovale* (western Africa), and *P. malariae* (worldwide distribution). The protozoan malaria parasites are transmitted by female *Anopheles* mosquito vectors, which tend to bite between dusk and dawn.

The incubation period for malaria is usually 1 or more weeks after the mosquito injects malaria sporozoites into the human host during a blood meal. The malaria parasites incubate, then multiply in hepatocytes. The infected hepatocytes rupture, releasing thousands of malaria merozoites into the bloodstream. The merozoites invade circulating red blood cells (RBCs) and develop into the next developmental stage,

trophozoites. Ring-shaped trophozoites within RBCs can be seen on peripheral blood smears, as can later parasite stages: schizonts (asexual reproduction) or male and female gametocytes (sexual reproduction). Diagnosis of malaria is based on

1566

Figure 65-3 Malaria regions of the world.

recognition of characteristic trophozoites, schizonts, and gametocytes on peripheral blood smears. Schizonts rupture, releasing new crops of merozoites that can infect other RBCs. Male and female gametocytes are taken up by the female mosquito during a blood meal and propagate infection in the mosquito.^{[35] [73]}

Malaria Chemoprophylaxis.

Travelers to malarious areas are usually prescribed one of several drug regimens to prevent malaria (chemoprophylaxis). However, in *P. falciparum* strains, development of drug resistance to chloroquine and other drugs has made the selection of appropriate chemoprophylaxis difficult for certain high risk destinations.^{[35] [41] [43] [72]} Drug allergies, contraindications, drug toxicity, drug interactions, underlying medical conditions, access to recommended drugs, and compliance with recommended regimens all contribute to the problem.^{[2] [46] [54] [69]}

Selection of malaria chemoprophylaxis is determined by the geographic destination and the pattern of drug resistance among malaria strains transmitted at the destination ([Figure 65-3](#)). The drug regimen is based on the risk of chloroquine-resistant falciparum malaria (CRPF). Chloroquine phosphate (Aralen, and others) is efficacious and relatively nontoxic in the few areas in which malaria is still sensitive to the drug, currently Central America west of the Panama Canal Zone, Mexico, Haiti, the Dominican Republic, and most of the Middle East. Chloroquine resistance has been reported in Yemen, Oman, Saudi Arabia, and Iran. Mefloquine (Lariam), doxycycline (Vibramycin, and others), and atovaquone/proguanil (Malarone) are considered the drugs of choice for malaria chemoprophylaxis in CRPF areas; however, in some places, such as certain border areas in Thailand where CRPF strains have developed resistance to mefloquine, doxycycline or atovaquone/proguanil are recommended for prophylaxis against CRPF.^{[35] [47] [72] [73]} Chloroquine-resistant *P. vivax* has been reported in Irian Jaya and Sumatra, Indonesia, and Papua, New Guinea.^{[1] [59] [61]} Mefloquine, doxycycline, or atovaquone/proguanil chemoprophylaxis recommended for the CRPF present in these areas is also adequate for resistant *P. vivax*. Primaquine phosphate is considered another effective alternative for prevention of CRPF, providing that a glucose-6-phosphate-dehydrogenase (G-6-PD) screening test can be done before prescribing, since the drug causes severe hemolytic anemia in G-6-PD-deficient

individuals. Doses and schedules for drugs commonly used in malaria chemoprophylaxis are given in [Table 65-4](#) .

Travelers should start taking antimalarials (chloroquine or mefloquine) with a weekly dosing regimen at least 1 or 2 weeks before departure. This allows time for familiarity with the side effects of the drug while the drug builds up to steady-state levels in the body, enables the traveler to habituate to the timing of doses, and gives the traveler time to contact his or her health care provider and switch to an alternative drug, if necessary, while still at home. Antimalarial drugs with a daily dosing schedule (doxycycline, atovaquone/proguanil, or primaquine phosphate) can be started 1 to 2 days before entering the area of malaria risk.

Travelers should be warned not to switch antimalarial regimens during the trip without the specific advice of a knowledgeable health care provider. Casual advice given by travelers from other countries or recommendations by personnel in foreign drugstores in which

TABLE 65-4 -- Malaria Chemoprophylaxis*

DRUG	DOSE
ADULTS	
Chloroquine phosphate (Aralen)	250 mg, 2 tablets/wk
	500 mg, 1 tablet/wk
Mefloquine (Lariam)	250 mg, 1 tablet/wk
Doxycycline (Vibramycin)	100 mg, 1 tablet daily
Atovaquone/proguanil (Malarone) [‡]	250 mg/100 mg, 1 tablet daily
Primaquine phosphate	30 mg base daily
Proguanil (Paludrine) (in addition to weekly chloroquine)	100 mg, 2 tablets/day
CHILDREN	
Chloroquine phosphate	8.3 mg/kg/wk po
Mefloquine	15–19 kg: ¼ tablet/wk po
	20–30 kg: ½ tablet/wk po
	31–40 kg: ¾ tablet/wk po
Proguanil (Paludrine) (in addition to weekly chloroquine)	<2 yr: 50 mg/day po

	2–6 yr: 100 mg/day po
	7–10 yr: 150 mg/day po
	>10 yr: 200 mg/day po
Atovaquone/proguanil (Malarone Pediatric) [†]	62.5 mg/25 mg,
	11–20 kg: 1 Malarone Pediatric tablet daily
	21–30 kg: 2 Malarone Pediatric tablets daily
	31–40 kg: 3 Malarone Pediatric tablets daily
	>40 kg: 4 Malarone Pediatric tablets daily (equal to 1 Malarone tablet [250 mg/100 mg])

*See general remarks and precautions in the text.

[†]Malarone product information, Glaxo Wellcome Inc., Research Triangle Park, NC, July 2000.

many antimalarial drugs are available over the counter should not be the basis for medication changes.

The usual incubation periods for malaria are 8 to 11 days for *P. falciparum*, 10 to 17 days for *P. vivax* and *P. ovale*, and 18 to 40 days for *P. malariae*. Prolonged latent incubation times of up to 3 years or more have been reported rarely, especially with the *P. malariae* species. Among cases reported in Americans, over 90% of *P. falciparum* infections and 50% of *P. vivax* infections cause clinical attacks during the first 4 to 8 weeks after return from a malaria area. Current recommendations are that chloroquine, mefloquine, and doxycycline chemoprophylactic regimens should be continued for 4 weeks after the traveler leaves a malaria area to prevent attacks of malaria in the immediate posttravel period. Atovaquone/proguanil should be continued for 7 days after leaving a malaria area, and primaquine should be taken for 2 days after leaving; both drugs appear to have activity against latent incubating hepatic stages of the malaria parasites.

Rapidly developing drug resistance among malarial parasites worldwide means that no current antimalarial drug regimen can be considered to provide complete protection. Use of personal insect precautions (repellents, protective clothing, and bed nets) and behavioral modification (limiting time outdoors) are two important adjuncts to malaria chemoprophylaxis.

Some regimens against CRPF recommended by experts are not licensed or available in the United States; even if these are not standard recommendations, the alternative regimens may be considered in special cases. For instance, mefloquine is not recommended for use in the first trimester of pregnancy, and doxycycline is contraindicated for use in pregnant women. Although mefloquine may be used in

weight-adjusted dosages in children weighing less than 15 kg, doxycycline is not recommended for children less than 8 years of age. Atovaquone/proguanil is not recommended during pregnancy due to lack of data (pregnancy category C) and is not recommended for use in children less than 11 kg. In travelers unable to take any of these drugs, a combination of weekly chloroquine plus daily proguanil may provide some protection (suboptimal) against CRPF, and this alternative regimen is considered safe in pregnant women and young children. Proguanil is not licensed or marketed in the United States and must be purchased abroad.

Another approach for travelers to CRPF areas who are unable to take the optimal chemoprophylactic drugs would be to take weekly chloroquine prophylaxis,

TABLE 65-5 -- Malaria Drugs for Standby Treatment*

DRUG	ADULT DOSE	PEDIATRIC DOSE
Pyrimethamine 25 mg/sulfadoxine 500 mg (Fansidar)	3 tablets po as single dose	2–11 mo: ¼ tablet
		1–3 yr: ½ tablet
		4–8 yr: 1 tablet
		9–14 yr: 2 tablets
		>14 yr: 3 tablets
		po as single dose
Mefloquine, 250 mg tab (Lariam)	2 tablets as single dose, followed by 2 tablets after 8–12 hr; reduce second dose to 1 tablet for adults <60 kg	15 mg/kg po as single dose (do not use in infants <15 kg)
Atovaquone/proguanil, 250 mg/100 mg (Malarone)	4 tablets as a single dose daily for 3 consecutive days	11–20 kg: 1 tablet daily × 3 days
		21–30 kg: 2 tablets as a single dose daily × 3 days
		31–40 kg: 3 tablets as a single dose daily × 3 days
		>40 kg: 4 tablets as a single dose daily × 3 days

Quinine sulfate tablets	650 mg 3 times a day for 3 days (continue for 7 days in Southeast Asia)	10 mg/kg 3 times a day for 3 days (continue for 7 days in Southeast Asia)
Plus tetracycline	250 mg 4 times a day for 7 days	>8 yr of age: 5 mg/kg of body weight po four times a day for 7 days
Or plus doxycycline	100 mg twice a day po for 7 days	>8 yr of age: 2 mg/kg of body weight po twice a day for 7 days
Or plus clindamycin	10 mg/kg three times a day for 5 days	10 mg/kg three times a day for 5 days
Or plus Fansidar	Fansidar dose above	Fansidar dose above
Halofantrine, 250 mg tab (Halfan)	2 tablets in one dose +2 tablets after 6 hr + 2 tablets after 6 more hr (total dose of 6 tablets in 12 hr); <i>repeat therapy in 7 days in nonimmune patients</i>	
Halofantrine, 2% suspension (Halfan)		8 mg/kg po for three doses, each dose 6 hr apart; <i>repeat therapy in 7 days in nonimmune patients</i>

*See general remarks and precautions in the text.

use good personal insect precautions, and carry standby drug treatment for CRPF malaria (see later discussion). Chemoprophylactic regimens using proguanil plus sulfonamide, proguanil plus dapson, and mefloquine plus sulfadoxine-pyrimethamine have been studied in areas in which there is intense transmission of multidrug-resistant falciparum malaria, but there are limited data about the efficacy and tolerance of these regimens in civilian travelers.^{[42] [53] [63]}

Standby Drug Treatment For Malaria.

In some cases a prescription for standby drug treatment for CRPF malaria, in addition to chemoprophylaxis, should be given to travelers, especially adventure and outdoor travelers going to remote areas known to have highly resistant strains of malaria. Standby drug treatment should also be given to other travelers who for any reason must take a regimen of malaria chemoprophylaxis that is suboptimal for the geographic

region. Drugs and doses used for standby treatment of malaria are given in [Table 65-5](#) .

Travelers need to familiarize themselves with the signs and symptoms of the clinical illness so they can recognize a possible attack of malaria and treat themselves if necessary ([Table 65-6](#)). In case of an illness accompanied by high fever similar to a bad case of viral influenza, the traveler should seek immediate medical care. A traveler who becomes ill while remote from health care should be instructed to use standby malaria treatment as prescribed. Because of drug resistance among *P. falciparum* parasites from most malarious areas of the world, the standby treatment (regardless of which drug regimen is selected) may result only in temporary or partial improvement from a malaria attack, thus allowing evacuation from a distant area. However, further definitive treatment of malaria as soon as possible may be necessary to eradicate the infection.

Dark urine	+	

+++ , >90% of patients; ++ , >50% of patients; + , <10% of patients.

Pyrimethamine plus sulfadoxine (Fansidar) is currently recommended by the CDC as a standby treatment for a malaria attack and can be used if the person is not allergic to sulfa drugs. Although serious and potentially fatal hypersensitivity reactions were reported in travelers taking this drug combination for CRPF prophylaxis on a weekly basis (1 case per 5000 to 8000 users), the remote risk of a significant adverse effect after taking a single treatment dose would be outweighed by the seriousness of an untreated CRPF attack. Thailand is reported to have a high prevalence of *P. falciparum*

infections resistant to Fansidar, so other drugs should be considered for standby treatment of malaria acquired there.

Mefloquine may be used in treatment doses as a standby regimen if the traveler is not already taking mefloquine for malaria chemoprophylaxis. Serious adverse side effects, including seizures and cardiac arrest, have been reported rarely for mefloquine given at treatment doses, but again, the remote risk of a significant adverse effect after taking the drug in treatment doses would be outweighed by the seriousness of an untreated CRPF attack.^[69] Mefloquine-resistant *P. falciparum* infections are being reported sporadically from countries in Southeast Asia and Africa but appear to be of most concern along the Thai-Burma (Myanmar) border.

Atovaquone/proguanil is highly efficacious in the treatment of acute, uncomplicated *P. falciparum* malaria and has been shown to be effective in areas where resistance to chloroquine, mefloquine, halofantrine, mefloquine, and amodiaquine is reported. It may be considered an alternative to Fansidar for emergency self-treatment of malaria especially in regions where *P. falciparum* strains are multi-drug resistant and are resistant to both Fansidar and mefloquine.

The regimen of oral quinine sulfate plus a second drug (tetracycline, doxycycline, clindamycin, or Fansidar) remains one of the most effective treatments for CRPF. However, this regimen should not be recommended to travelers as a standby treatment if other options are available. The development of cinchonism (ringing in the ears, headache, nausea, visual disturbance) from quinine is almost predictable during the first 3 days of treatment, and many travelers would be unable to complete the 7-day therapeutic quinine course (recommended for malaria acquired in Southeast Asia) in the field without medical assistance and supportive therapy.

Halofantrine, which is not presently available in the United States, is available in some countries of Western Europe, Africa, and Asia. Halofantrine is an effective oral drug for treatment of CRPF and Fansidar-resistant CRPF and may be prescribed as a standby treatment. The incidence of side effects is low. These include abdominal pain, pruritus, vomiting, diarrhea, headache, and rash. The drug is contraindicated in pregnant women because animal data show embryotoxic effects. Higher-than-conventional doses of halofantrine appear to be required for successful treatment of mefloquine-resistant *P. falciparum* strains being reported along the Thailand-Cambodia (Democratic Kampuchea) and the Thailand-Burma (Myanmar) borders. However, recent reports of cardiac conduction disturbances with prolongation of the PR and QT intervals on electrocardiograms of malaria patients treated with halofantrine, especially after mefloquine treatment failure, have raised concerns about the drug's safety.^[54] Some experts recommend that physicians obtain a pretravel electrocardiogram from travelers who will be prescribed halofantrine standby treatment to document that there is no underlying conduction defect that might be exacerbated by the drug.

Qinghaosu (artemisinin) and its derivatives artemether, artesunate, and arteether are a group of antimalarial drugs derived from a Chinese medicinal herb, *qing hao*. The compounds have shown remarkable efficacy during clinical trials in the treatment of severe chloroquine-resistant *falciparum* malaria and can rapidly clear parasites without

apparent significant toxicity. Artemisinin compounds are available for clinical use in China, Vietnam, and other malarious areas of Southeast Asia.^[32]

Artesunate may be given by intravenous or intramuscular injection, artemether can be given by intramuscular injection only, and various artemisinin compounds are available for administration by mouth or by suppository. At the time of writing, dosage and toxicity parameters for the oral compounds are still under investigation, so the artemisinin compounds cannot be considered in the category of standby treatment for malaria. Travelers developing severe febrile illness in multidrug-resistant malarious areas of Asia who reach medical assistance might be treated effectively with artemisinin compounds, however.^{[32] [35]}

Personal Insect Precautions.

Personal insect precautions are just as important as drugs for preventing malaria, especially if the traveler must take one of the suboptimal antimalarial drug regimens. Prevention of itching skin lesions caused by insect bites (and the possibility of secondary skin infections) and prevention of other insect-borne infections for which there are no prophylactic drugs or vaccines are other considerations. In regard to malaria prevention, exposure to mosquito vectors of malaria can be decreased by limiting time outdoors between dusk and dawn, by wearing protective clothing while outdoors, and by applying insect repellents to exposed areas of skin while outdoors.

The most effective insect repellents for skin application contain *N,N*-diethyl-meta-toluamide (DEET). Older formulations of repellents containing DEET depended on high concentrations and frequent applications to the skin for effectiveness. Concerns about DEET toxicity and the inconvenience of frequent applications led to development of repellent formulations that rely on new molecular entrapment technology to keep repellent chemicals on the surface of the skin for longer periods. It is claimed that newer insect repellents that have lower concentrations of DEET and a longer duration of adherence to the surface of the skin have decreased absorption through the skin. A wide variety of DEET-containing insect repellents are available commercially, and often may be sampled at sporting goods stores. If skin protection against the sun and insects must be used simultaneously, the sunscreen should be applied to the skin first, followed by the insect repellent.

Mosquito bed nets should be used when sleeping in unscreened rooms. The protection afforded by bed nets can be increased by application of a pyrethrum-based insecticide. Pyrethrums are insecticides related to naturally occurring alkaloids in the chrysanthemum plant family. Permethrin is a chemical derivative and is relatively nontoxic. Permethrin insecticides are suitable for treatment of external clothing and mosquito nets but are not recommended for direct skin application because they may induce skin hypersensitivity reactions.

Bed nets and external clothing can be treated by spraying or soaking with a permethrin solution and letting it air dry before use ([Figure 65-4](#) ; [Box 65-2](#)). Treated bed nets and clothing retain residual insecticide activity for weeks (sprayed) to months (soaked).^[62] In addition to repelling mosquitoes, permethrin insecticides are effective against gnats, ticks, chiggers, bedbugs, scorpions, centipedes, beetles, and flies (see [Chapter 32](#)). Permethrin insecticide coils and electric vaporizers can augment the use of bed nets indoors.

Dengue Fever.

Dengue fever is a mosquito-transmitted viral infection that occurs worldwide in tropical and subtropical zones. The areas of dengue virus transmission overlap malaria endemic areas in many parts of the world, although the vector mosquitoes are different: *Aedes aegypti* and *Aedes albopictus*. An attack of dengue fever may be clinically indistinguishable from a malaria attack, especially as self-diagnosed by travelers in the field. Acute dengue fever is characterized by high fever, headache, and severe myalgias and arthralgias, similar to malaria. Thus if a traveler is stricken while in a malarious area with an illness accompanied by a high fever, he or she should be instructed to seek medical care for diagnosis and treatment of possible malaria, or to take standby drug treatment for malaria if remote from medical care. No specific treatment is recommended for dengue fever, but if the cause of the febrile illness is malaria, early medication with antimalarial drugs may be lifesaving.

**Box 65-2. PERMETHRIN-CONTAINING
INSECTICIDES***

Permanone Tick Repellent: Contains permethrin in a pressurized spray can; repels ticks, chiggers, mosquitoes, and other bugs (Coulston International Corp., Easton, PA 18044)

Duranon Tick Repellent: Contains permethrin in a formula lasting up to 2 weeks; supplied in a pressurized spray can (Coulston International Corp., Easton, PA 18044)

PermaKill 4 Week Tick Killer: 13.3% permethrin liquid concentrate supplied in 8-oz bottle; can be diluted (? oz permethrin concentrate in 16 oz water) to be used with a pump spray bottle, or be diluted 2 oz in 1 ½ cups of water to be used to impregnate outer clothing, bed nets, and curtains (see [Figure 65-4](#)) (Coulston International Corp., Easton, PA 18044)

The true incidence of dengue fever and other arboviral infections acquired by travelers abroad is not known because the stricken travelers may not have come to medical attention or have been accurately diagnosed. Many arboviral illnesses are mild and self-limited. However, diagnosis and treatment in returned travelers with a febrile illness who do seek medical attention can be hampered by limited diagnostic tools (serologic tests, cultures) and a lack of specific therapeutic agents.^{[3] [5] [45] [68]}

Of the more than 530 arboviruses registered in the International Catalogue of Arboviruses, more than 150 are known to infect humans. Effective vaccines are available for yellow fever, Japanese encephalitis, and tick-borne encephalitis. Vaccines

for other arboviral infections have been produced but are limited to investigational

Figure 65-4 Technique for impregnating clothing or mosquito netting with permethrin solution. **A to C**, Lay jacket flat and fold it shoulder to shoulder. Fold sleeves to inside, roll tightly, and tie middle with string. For mosquito net, roll tightly and tie. **D**, Pour 2 oz of permethrin into plastic bag. Add 1 quart water. Mix. Solution will turn milky white. **E**, Place garment or mosquito netting in bag. Shut or tie tightly. Let rest 10 minutes. **F**, Hang garment or netting for 2 to 3 hours to dry. Fabric can also be laid on clean surface to dry. (Redrawn from Rose S: *International travel health guide*, Northampton, Mass, 1993, *Travel Medicine*.)

1572

use. Personal behavior and practices that limit exposure to arthropod vectors (see earlier discussion of insect precautions) are important health measures for all travelers.

TRAVELER'S DIARRHEA

The term *traveler's diarrhea* usually refers to an acute syndrome of watery diarrhea, which may be accompanied by nausea, loss of appetite, abdominal cramps, low-grade fever, and malaise (see [Chapter 52](#)). The risk of traveler's diarrhea is high (20% to 50%) among short-term travelers going from industrialized areas and northern temperate zones to tropical and developing areas. The risk of traveler's diarrhea is high wherever food storage, fuel for cooking, and sanitation are inadequate. Latin America, the Caribbean, the Middle East countries, Africa, India, Asia, the South Pacific, and the newly independent states of the former Soviet Union are recognized high-risk areas for acquisition of traveler's diarrhea. Seasonal or climatic factors may also contribute to the risk of traveler's diarrhea.

Diarrhea associated with travel can result from any of multiple causes, including a change in the normal diet, food poisoning (toxins), and infection with viruses (rotavirus and Norwalk virus), bacteria (enterotoxigenic *Escherichia coli*, *Shigella*, *Campylobacter*, *Aeromonas*, *Salmonella*, and *Vibrio*, among others), and parasites (including *Giardia lamblia*, *Entamoeba histolytica*, and *Cryptosporidium*). The worldwide prevalence of *Cyclospora*, the recently described cyanobacterium-like microorganism, as a causative agent of traveler's diarrhea is unknown.^{[18] [20] [27]}

Traveler's diarrhea usually runs a self-limited course lasting less than a week. In one study, only 8% to 15%

TABLE 65-7 -- Prevention of Traveler's Diarrhea: Drug Regimens for Adults

DRUG	DOSAGE	COMMENTS
Bismuth subsalicylate (Pepto-Bismol)	2 tablets qid	Less effective than antibiotic prophylaxis; contraindicated in people allergic to aspirin, in people on other salicylate-containing drugs, and during pregnancy; not recommended for children
Trimethoprim 160 mg and sulfamethoxazole 800 mg (Bactrim, Septra)	1 tablet/day	Contraindicated in people allergic to sulfa; may not be as effective as the quinolones in some parts of the world
Doxycycline 100 mg (Vibramycin, Doryx, etc.)	1 tablet/day	Contraindicated in pregnancy, age <8 yr; efficacy shown in Africa only
Norfloxacin 400 mg (Noroxin)	1 tablet/day	Contraindicated in pregnancy, age <18 yr, and in people allergic to quinolones; drug interaction with theophylline and caffeine

Ciprofloxacin 500 mg (Cipro)	1 tablet/day	Contraindicated in pregnancy, age <18 yr, and in people allergic to quinolones; drug interaction with theophylline and caffeine
------------------------------	--------------	---

Modified from Jong EC, McMullen R: The travel and tropical medicine manual, ed 2, Philadelphia, 1995, WB Saunders.

of persons had an episode of illness lasting longer than 1 week.^[20] Recovery without antimicrobial treatment is usual in healthy adults; however, most travelers want to avoid the inconvenience and discomfort of diarrhea and ask for medications to terminate an attack as soon as possible. Dehydration from loss of fluids and decreased oral intake is the biggest risk to health, and young children and debilitated or older people are most susceptible to this complication.^{[20] [23] [30] [65]}

Food and water precautions recommended against traveler's diarrhea aim to decrease the risk of diarrhea from all possible causes. Antimicrobial therapy is directed against the bacterial pathogens implicated most often in cases of traveler's diarrhea. Presumably such antimicrobial therapy will not alter the course of illness if the cause is toxin, virus, or parasite. If the antimicrobial used for empirical treatment of traveler's diarrhea is active against the bacteria involved, a rapid recovery may be obtained.

Prevention Of Traveler's Diarrhea

Prevention of traveler's diarrhea can be divided into three categories: food and water precautions, bismuth subsalicylate prophylaxis, and antimicrobial prophylaxis ([Table 65-7](#)). Food and water precautions include drinking only disinfected water or bottled carbonated or canned beverages; eating well-cooked foods served piping hot, baked goods, or fruits with thick skins that can be peeled by the traveler; avoiding ice cubes in beverages; and not eating salads, raw or undercooked fish and shellfish, or cheese and dairy products made from unpasteurized milk. Despite good intentions, most travelers eventually face situations in which they have no choice but to eat and drink whatever is available.

Bismuth subsalicylate (BSS) can be used to prevent traveler's diarrhea by persons going on trips of 3 weeks or less. A regimen of two tablets of BSS four times a day appears to significantly reduce the incidence of diarrhea among travelers to Mexico. Disadvantages to this regimen include cost, the bulk of the BSS in luggage, the risk of salicylism, development of a black tongue, and possible constipation.^{[18] [20]}

Some experts concede that taking a broad-spectrum antibiotic during travel can be an effective way to avoid becoming ill; this might be a reasonable strategy for a traveler who is taking a brief trip (1 week or less) to a high-risk area and cannot afford to be ill for even a single day. Travelers falling into this category might include competitive athletes, politicians, sales representatives, and people going to special events.^{[18] [20] [52]}

However, prophylaxis with antimicrobials might be considered unnecessary in most cases because more recent studies have shown that relief of diarrhea within a few hours can be obtained after a high dose of an oral antibiotic taken immediately after the onset of symptoms.^{[19] [22] [67]}

TABLE 65-8 -- Drugs for Adult Self-Treatment of Traveler's Diarrhea

DRUG	DOSAGE*	COMMENTS†
Bismuth subsalicylate (Pepto-Bismol)	30 ml (or 2 tablets) every 30 min for eight doses	Maximum recommended dose is 240 ml (16 tablets) per day
Diphenoxylate plus atropine (Lomotil)	2 tablets for first dose, then 1 after each loose bowel movement; do not exceed 8 tablets in 24 hr	Antiperistaltic drug; do not use in dysentery; available by prescription
Loperamide (Imodium)	2 caplets (2 mg each) for first dose then 1 after each loose bowel movement; do not exceed 8 caplets (16 mg) in 24 hr	Antiperistaltic drug; do not use in dysentery; sold over the counter; liquid form available for pediatric doses—use dose adjusted for weight as described on package insert
Tetracycline	2.5 g as a single oral dose	Antibiotic; do not use during pregnancy or for children <8 yr old
Doxycycline (Vibramycin, Doryx, etc.)	100 mg po every 12 hr for six doses	Antibiotic; do not use during pregnancy or for children <8 yr old
Trimethoprim/sulfamethoxazole (Bactrim, Septra)	160 mg/800 mg tablet (one double-strength tablet) every 12 hr for six doses	Antibiotic; do not use in sulfa-allergic patients
Norfloxacin (Noroxin) [‡]	400 mg tablet every 12 hr for six doses	Antibiotic; do not use during pregnancy or for teenagers <18 yr old
Ciprofloxacin (Cipro)	500 mg tablet every 12 hr for six doses	Antibiotic; do not use during pregnancy or for teenagers <18 yr old
Ciprofloxacin (Cipro) [‡]	750 mg tablet once at start of diarrhea symptoms	Antibiotic; do not use during pregnancy or for teenagers <18 yr old

Levofloxacin (Levoquin)	500 mg tablet every 24 hr for three doses	Antibiotic; do not use during pregnancy or for teenagers <18 yr old
Furazolidone	100 mg qid for 7–10 days	Antibiotic; also has activity against <i>Giardia</i>

Modified from Jong EC, McMullen R: The travel and tropical medicine manual, ed 2, Philadelphia, 1995, WB Saunders.

*Adult doses given.

†See comments in [Table 65-7](#) .

‡Unlabeled use.

The antibiotics trimethoprim-sulfamethoxazole (Bactrim, Septra), norfloxacin (Noroxin), ciprofloxacin (Cipro), and ofloxacin (Floxin) have been studied as prophylactic agents. [Table 65-8](#) summarizes antibiotic doses. The quinolone antibiotics are contraindicated in pregnancy and in persons less than 18 years of age.

Symptomatic Treatment Of Traveler's Diarrhea

Fluid replacement is the cornerstone of therapy for traveler's diarrhea. Correcting dehydration significantly lessens the general malaise of the stricken person regardless of whether antimicrobial therapy is used. Oral fluid intake should be pushed to approximate fluid losses in the stools. Maintenance of normal urine frequency, color, and volume can serve as a marker of adequate rehydration. Generally, fruit juices or flavored mineral water can be used for oral rehydration during mild to moderate diarrhea. Packets of oral rehydration salts, which can be reconstituted to make oral rehydration solution according to WHO guidelines, are increasingly available in pharmacies

throughout the world. Sports electrolyte solutions also provide adequate replacement if diluted to approximately one half to two thirds strength.

BSS in large doses (30 ml of BSS liquid or two BSS tablets by mouth every 30 minutes for eight doses) has been reported to relieve diarrhea and cramps.^{[18] [20]} A recent study suggests that in infants and young children with acute watery diarrhea, BSS at weight-adjusted doses (100 or 150 mg/kg body weight/day for up to 5 days) may be a useful adjunct to oral rehydration therapy.^[23]

The over-the-counter antiperistaltic drug loperamide (Imodium) or the combination drug diphenoxylate plus atropine (Lomotil) available by prescription may offer some relief to

people with watery diarrhea and cramps but should be avoided in those with blood or mucus in the stool or with signs of serious illness (high fever, recurrent vomiting, and increasingly severe abdominal pain).

Antibiotic Treatment of Traveler's Diarrhea

Traveler's diarrhea can be relieved within hours after empirical antibiotic therapy is instituted, with or without the concurrent use of the antiperistaltic drug loperamide. The drug regimens studied included the antibiotics trimethoprim-sulfamethoxazole and ciprofloxacin. With reports of increasing resistance to trimethoprim-sulfamethoxazole among bacterial enteropathogens such as *Shigella* species and *Campylobacter jejuni*, many experts recommend ciprofloxacin, levofloxacin, or one of the other quinolones as the drug of choice for empirical diarrhea treatment. Recommended dosages are shown in [Table 65-8](#).^{[18] [19] [20] [21] [22] [65] [66] [67]} If the traveler has started initial treatment of watery diarrhea with BSS therapy, at least 8 hours should elapse before antimicrobial therapy because BSS can impair absorption of the orally administered antimicrobial.^[57]

If blood or mucus is present in the stool, travelers should be advised to take the antibiotic prescribed for diarrhea but to refrain from using an antiperistaltic medication. If the diarrhea is caused by a susceptible bacterial species, the patient may obtain relief within a few hours after empirical treatment but should continue to take the given antibiotic for a minimum of 3 days to prevent relapse.

If the patient is ill with a bacterial pathogen resistant to the antibiotic taken, with a viral or parasitic infection, or with toxin-induced gastroenteritis, the antibiotic therapy usually does not alter the outcome of the illness, although the possible risk of antibiotic-associated side effects must always be considered. Travelers who do not respond to empirical antibiotic treatment or who have persistent diarrhea of more than 1 week's duration should have a complete work-up for bacterial and parasitic pathogens so that specific treatment may be instituted.

TRAVEL MEDICAL KIT

Traveling patients are advised to prepare a travel medicine kit appropriate to their itinerary (see [Chapter 69](#)). Such a kit should contain adequate supplies of all prescription medications normally taken, the medications for malaria and diarrhea as discussed previously, and some remedies for common problems such as headache, musculoskeletal pain, allergies, nasal and sinus congestion, cough, jet lag, and constipation. Persons prescribed one of the jet-lag drugs should be warned not to ingest alcoholic beverages concomitantly. ^[51] Travelers should be instructed to carry their prescription medications in their hand-held luggage to avoid loss, and to carry copies of their prescriptions in case replacements are needed. ^[39]

Depending on the travel itinerary, insect repellent, sunscreen, topical antibiotic ointment, antifungal cream or powder, and medications for motion sickness, allergic reactions, and high-altitude illness might be included. Female travelers should be reminded to carry personal sanitary supplies; disposable tampons and pads may be difficult to obtain in developing countries. Sexually active travelers of both sexes should take along a supply of high-quality latex condoms; those available abroad may be of lesser quality and more susceptible to leaks and rupture.

FOLLOW-UP AFTER TRAVEL

Travelers should be reminded of the importance of continuing malaria chemoprophylaxis for 4 weeks after leaving a malarious area to decrease the possibility of a clinical attack. Travelers should be instructed to alert their health care providers about the possibility of malaria in case a severe illness accompanied by high fever develops weeks, months, or even years after travel in a malaria-endemic area. Many physicians in geographic areas in which malaria is not endemic are unfamiliar with the clinical signs and symptoms of a primary malaria attack and may fail to include malaria in the differential diagnosis.^{[25] [44] [71]} A person who has traveled in a malaria-endemic area and who has taken malaria chemoprophylaxis may not donate blood for 3 years, according to current blood-banking practice.

Diarrhea or any change in normal bowel habits that persists after empirical treatment for traveler's diarrhea should prompt a thorough diagnostic workup. Drug-resistant bacterial infections, intestinal parasites, dietary changes, or hepatitis may account for the prolonged symptoms after return home.^{[4] [7] [27] [48]} However, coincidental manifestations of biliary tract disease, inflammatory bowel disease, or intestinal malignancy must be considered in cases of gastrointestinal illness

that elude diagnosis after the first round or two of diagnostic tests have been done.

Unusual skin lesions in returned travelers are often misdiagnosed in medical facilities that do not routinely see immigrants, refugees, and returned travelers. Common exotic infections in returned travelers seeking medical care include cutaneous myiasis (subcutaneous fly larvae), cutaneous larva migrans (migrating dog or cat hookworm larvae), and cutaneous and mucocutaneous leishmaniasis (protozoan parasitic infection).

Secondary bacterial infection is common with all of these conditions, and the appearance of the skin lesion may initially seem to improve after institution of standard antibiotic therapy for bacterial skin infection. However, if the skin lesion fails to completely resolve, consultation with a tropical medicine specialist might be helpful. In a series of cases reported to the CDC of cutaneous leishmaniasis in American returned travelers, the average time between seeking initial medical care for a nonhealing skin lesion and the correct diagnosis was 5 months.^[31]

Intestinal parasites, especially helminthic or worm infections, can manifest their presence by spontaneous passage of adult worms from the rectum after dwelling for months in an unsuspecting, asymptomatic host. However, a systemic parasitic infection may have signs and symptoms that are not referable to a particular organ system: fever, headache, myalgia, malaise, fatigue, and nausea. The initial differential diagnosis may be broad and includes viral, bacterial, and parasitic infections. The differential diagnosis can be narrowed after the clinician takes into account incubation time, geographic area, immunizations received, malaria chemoprophylaxis taken, dietary habits, insect and rodent exposure, animal bites, and intimate or sexual contact with foreign residents or fellow travelers.

SUMMARY

Although the potential for travel-acquired illness during or after travel exists, it appears that pretravel medical preparation and behavior modification can promote travel in good health by reducing risk of many health hazards and enabling the traveler to cope with common traveler's ailments, thus increasing the overall enjoyment of the trip.

Chapter 66 - Non-North American Travel and Exotic Diseases

Ian J. Woolley
James W. Kazura

Travelers to tropical and subtropical areas of the world where hygienic conditions may be poor may encounter infectious agents that are uncommon or are not transmitted in temperate areas of North America.^{[72] [128]} The most important consideration in the management of this problem, which is increasing as international travel expands, is appropriate preventive measures through counsel with a travel medicine specialist and prophylaxis using safe drugs and vaccines. This chapter is concerned primarily with infectious diseases that are not common in North America and with which most health professionals in North America have scant familiarity. Other chapters give specific details relevant to tick-borne diseases ([Chapter 33](#)), infectious diarrhea ([Chapter 53](#)), and travel medicine ([Chapter 65](#)). The infectious diseases considered in this chapter should not be considered a complete listing. This is especially important to keep in mind in an era when diseases once thought to be eliminated or nonexistent in North America are emerging or reemerging coincidental with large-scale movements of human and vector populations.

MAJOR VIRAL INFECTIONS

A vast number of viruses may cause disease. This section describes selected viral infections that may be acquired outside North America and for which there are effective preventive or therapeutic measures. These include the viral hemorrhagic fevers, viral hepatitis, and Japanese B encephalitis.

Major Viral Hemorrhagic Fevers

A diverse group of ribonucleic acid (RNA) viruses can produce the hemorrhagic fever syndrome ([Box 66-1](#)). Although clinical presentations vary with different etiologic agents, fever, headache, myalgias, and malaise usually characterize the syndrome, which develops over several hours to 3 to 4 days. In the full-blown hemorrhagic fever syndrome, these early disease manifestations are followed by hemorrhagic signs, including petechiae and bleeding from the gums and gastrointestinal tract.^[61] ^[83] Loss of plasma volume is usually manifested by increased hematocrit value, although hypotension and shock may occur in some individuals. Elevated blood urea nitrogen and creatinine levels herald renal dysfunction. Death most often follows intractable hypotension, bleeding, electrolyte disturbances, and renal failure. Other viral causes of this syndrome exist (e.g., Rift Valley fever) but are not discussed here. In general, the management principles are the same and largely consist of supportive therapy.

Yellow Fever

European physicians did not recognize the clinical syndrome now known as yellow fever until the late 1490s. Initially described by Columbus in the West Indies, large-scale epidemics were later observed throughout the Americas and tropical Africa in the 1700s and 1800s.^[99] After epidemic yellow fever in Texas, Louisiana, and Tennessee caused 20,000 deaths in the 1880s, the Yellow Fever Commission was organized to study the problem. Identification of the mosquito vector, *Aedes aegypti*, was followed by massive campaigns to eradicate breeding sites. This led to virtual elimination of urban yellow fever from the Americas. The last case of yellow fever acquired in the continental United States was reported in 1911. Since it is difficult if not impossible to eliminate jungle reservoirs, there continue to be 50 to 300 and 100 to 200 cases reported annually from South America and tropical Africa, respectively. ^[101] ^[148] Larger outbreaks secondary to resurgent vector populations have occurred in recent years in tropical West Africa.^[94] ^[145]

Virology and Pathophysiology.

Yellow fever is a single-stranded RNA flavivirus. Strain differences are of little clinical relevance, although they may be of use in epidemiologic studies. The pathophysiologic

mechanisms operating in viral hemorrhagic fevers are not well defined. In general, viral replication occurs at the site of inoculation. After the virus spreads to lymph nodes and monocyte-rich organs, further reproduction results in massive viremia.

The liver is the principal target organ. Pathologic studies show coagulative necrosis of hepatocytes and the appearance of various markers of cell involvement (Councilman and Torres bodies). However, the degree of physiologic derangement is usually much more severe than expected for the extent of hepatic damage seen on pathologic examination. Perivascular edema and occasional focal bleeding occur in the kidney, heart, and brain, but these changes are less severe than expected for the degree of clinical disease.

Ecology and Epidemiology.

In the Americas, primates in the forest canopy serve as hosts for the yellow fever virus. Mosquitoes of the genus *Haemogogus* transmit infection. Since this vector does not travel far from the forest, jungle yellow fever occurs when humans enter jungle areas or the forest border zones. Urban yellow fever involves a different vector, *A. aegypti*. This mosquito is highly anthropophilic, lives in and around human habitations, and prefers

domestic water storage containers for breeding. The presence of a large population of *A. aegypti* places an urban area at significant risk for epidemic spread of yellow fever once the virus is introduced from a nearby forest area. In Africa the presence of larger numbers of mosquito species that can serve as vectors has hindered complete understanding of the ecology of the disease.

At present, both the Americas and Africa have a constant low level of jungle yellow fever because of the inability to eradicate either the monkey reservoir or the mosquito vector. Overall there are about 2000 cases per year in Africa and 200 per year in the Americas.^[132] Some suggest that these rates are underestimated by at least tenfold.^[83]^[94] ^[148] Persons at risk include workers or travelers in or near the tropical rainforest canopy. The recent death of an American traveler to Brazil emphasizes the need for vaccination among those at risk.^[87] Urban yellow fever had been reduced in the Western Hemisphere through massive anti-*Aedes* campaigns. However, the benefits of these campaigns have declined and there is currently an increased threat of further outbreaks of disease. Introduction of *Aedes albopictus*, an aggressive anthropophilic dengue vector from Southeast Asia, and reemergence of *A. aegypti* into the Americas ^[31] ^[93] raise the specter of increased yellow fever transmission in the Western Hemisphere. Less intense vector control measures and a more complex ecology have made eradication of urban yellow fever in Africa even more difficult.

Clinical Presentation.

Although yellow fever may appear as an undifferentiated viral syndrome, classic disease is characterized by a triphasic pattern. The infection phase begins with sudden onset of headache, fever, and malaise, often accompanied by bradycardia and conjunctival suffusion. After approximately 3 to 4 days, victims often experience brief remission. Within 24 hours, however, the intoxication phase develops, characterized by jaundice, recrudescence fever, prostration, and, in severe cases, hypotension, shock, oliguria, and obtundation. Hemorrhage is usually manifest as hematemesis; however, bleeding from multiple sites may occur. Signs of a poor prognosis include early onset of the intoxication phase, hypotension, severe hemorrhage with disseminated intravascular coagulation (DIC), renal failure, shock, and coma. Death occurs in between one quarter and one half of all cases.^[132] Diagnosis in the infection phase is difficult. With development of the classic syndrome, the differential diagnosis narrows somewhat but still includes malaria, leptospirosis, typhoid fever, typhus, Q fever, viral hepatitis, and other viral hemorrhagic fevers. The standard means of diagnosis is evaluation for neutralizing antibodies in acute and convalescent sera (available through state health departments in the United States). Several new systems for early detection of immunoglobulin M (IgM) or viral antigen are now being evaluated for more rapid diagnosis.^[95] A specimen of whole blood (at -70° C [-57° F] on dry ice) should be sent to the state health laboratory for isolation. Growth of the virus is possible in a number of systems, including Vero cells and infant mice. The virus is most easily isolated during the first 4 days of fever.

Management.

Appropriate management of viral hemorrhagic fevers requires awareness of the

geographic distribution of the disease and travel history of the victim. In the first several days of infection, differentiation of a viral hemorrhagic fever from other infectious diseases is nearly impossible. However, the occurrence of an undifferentiated febrile syndrome in a traveler from a yellow fever-endemic area warrants a careful physical examination, thick and thin blood smears to rule out malaria, and blood cultures for bacterial pathogens (*Salmonella typhi*). In recently returned travelers, dengue serology should be considered. Progression to the intoxication phase or any sign of volume disturbance, renal failure, or hemorrhage mandates immediate admission to an intensive care unit.

There are no effective antiviral therapies for yellow fever. Supportive care should address several important problem areas. Fever should be controlled with acetaminophen, not with salicylates. Evaluation of volume status should include Swan-Ganz or central venous pressure monitoring to direct volume expansion and use of vasopressor agents. Calculation of fractional excretion of urinary sodium may help differentiate prerenal azotemia (for which volume expansion is

1580

appropriate) from acute tubular necrosis (which may require temporary dialysis). Plasma volume loss may contribute to serious electrolyte disturbances, necessitating close observation of serum electrolytes and arterial blood gases. Rapid correction of these abnormalities, which commonly include hyperkalemia and acidosis, is essential. Hypoglycemia is presumably a result of impaired hepatic gluconeogenesis.

Serial coagulation studies (including platelet count, prothrombin time, partial thromboplastin time, fibrinogen, and fibrin degradation products) should be obtained.^[7]^[28]^[38] Whole blood or fresh-frozen plasma is indicated to maintain the prothrombin time and hematocrit value at near-normal levels. If DIC is documented, the use of heparin may be considered. No controlled trials have documented the effectiveness of heparin in yellow fever, but the benefit of heparin was suggested in a small number of patients with DIC.^[7]^[120] This approach remains controversial. To reduce the risk of upper gastrointestinal hemorrhage, H₂ blockers have been suggested. Although the efficacy of intensive care treatment has not been studied for victims of yellow fever, clinical experience with dengue shock syndrome suggests that similar benefits might be obtained.

Prevention.

Avoidance of this potentially fatal infection is possible through use of the yellow fever vaccine. The vaccine strain 17D is an attenuated live virus grown in chicken embryos. Greater than 95% of persons vaccinated achieve significant antibody levels. Repeat vaccinations are recommended every 10 years, although persistent antibody titers have been detected as long as 30 to 40 years after vaccination.^[25] Yellow fever vaccine is well tolerated, with headache or malaise occurring in less than 10% of those vaccinated. Rare allergic side effects occur primarily in persons with hypersensitivity to eggs. The

vaccine is not recommended in the first 6 months of life or in other situations where live virus vaccines are contraindicated. Although pregnant women have received the vaccine without adverse effect to themselves or their infants, it is not recommended for use in this group because of possible teratogenic effects. Other means of reducing the risk of yellow fever (and any mosquito-borne disease) include liberal use of mosquito repellent and netting in endemic areas.

Treatment of severe yellow fever is difficult and often unsuccessful. Avoidance through mosquito protection measures and administration of the highly effective vaccine before entry into endemic areas is of utmost importance.

Dengue

Dengue fever has been reported since the late 1700s. Since World War II, increased attention has focused on the dengue virus, largely as a result of recognition of dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS). First noted in Southeast Asia, DHF and DSS have attained worldwide distribution in the last 30 years.^{[20] [31] [61]}

Virology and Pathophysiology.

The etiologic agent is a single-stranded RNA flavivirus, which may be one of four serotypes, denoted dengue 1 through 4. As with yellow fever, local viral replication is followed by dissemination to lymphocyte- and macrophage-rich areas, where most of the reproductive activity occurs. Infection with one virus serotype provides long-lasting protection against that type only. For the dengue 2 serotype, previous infection with a heterologous serotype may result in a more severe clinical course than noted in those experiencing dengue 2 infection without such a history. Nonneutralizing antibodies produced in response to infection with other dengue serotypes aid entrance of the virus into host macrophages.^[76] Although cases of DHF and DSS may result from "immune enhancement,"^[60] severe DHF and DSS also occur with other serotypes in the absence of previous infection with a heterologous dengue virus serotype.^{[96] [116] [117]} Pathologic studies of DHF and DSS show hemorrhage, congestion, and perivascular edema of multiple organs. The liver may show areas of focal necrosis. As with yellow fever, the extent of pathologic findings does not correspond to severity of the clinical course.

Ecology and Epidemiology.

A. aegypti is the principal vector for dengue viruses worldwide. In the Americas and Asia, viral transmission is maintained through a mosquito-human cycle without a major animal reservoir. Monkey carriers have been identified in Africa and Asia, but their importance in transmission is unclear. *A. albopictus*, an anthropophilic dengue vector from Southeast Asia, has also been recognized recently in the Western Hemisphere. Both of these mosquitoes are capable of large-scale transmission to humans in endemic areas. At present, dengue is endemic in tropical and subtropical Asia, Africa, South America, and the Caribbean basin. In the early 1920s, large epidemics occurred in Texas, where dengue infections were reported in 500,000 inhabitants. In the last 30 years, endemic transmission on the mainland United States has been documented only in Texas; however, between 1986 and 1992, 157 cases of dengue were confirmed in

American travelers by the Centers for Disease Control and Prevention (CDC).^[31]

Clinical Presentation.

Most dengue infections appear after an incubation period of 2 to 14 days either as an undifferentiated viral syndrome with fever and mild respiratory or gastrointestinal symptoms or as dengue ("break-bone") fever with bone pain, generalized myalgia, and severe headache. After 1 to 3 days a quiescent

1581

period may ensue. There may be a subsequent second episode of fever accompanied by a maculopapular or morbilliform rash that spreads outward from the chest and that ultimately desquamates. Lymphadenopathy and leukopenia occur during this phase of the illness. A distinct severe form of dengue disease referred to as either DHF or DSS may occur around the usual time of recovery. These syndromes are classified grades I to IV, according to World Health Organization (WHO) guidelines.^[143] In cases of grade I DHF the only hemorrhagic manifestation is a positive tourniquet test, in which inflation of a tourniquet to midway between systolic and diastolic pressure leads to development of petechiae distal to the tourniquet. A complete blood cell count classically shows a decreased platelet count and an increase in hematocrit value. Grade II DHF is defined as the above plus hemorrhage from any site. DSS (grade III) includes clammy skin, hypotension, or a narrow pulse pressure (less than 20 mm Hg) in a patient with DHF. An undetectable blood pressure defines grade IV DHF and DSS. Most studies have noted DHF and DSS primarily in infants and young children, usually with a history or serologic evidence of previous heterologous dengue infection.^[61] Two cases of DSS in American travelers involved young children (ages 7 years and 16 months).^{[96] [116] [117]} However, DHF and DSS may occur in adults. Of the 10 cases in the 1986 Puerto Rico outbreak, four were in adults, and of the two deaths, one was an adult.^[20]

Management.

Awareness of the local epidemiology of DHF and DSS, especially the occurrence of other cases, is important in establishing the diagnosis. The diagnosis may be confirmed by a fourfold change in antibody titer between acute and convalescent sera or by presence of anti-dengue IgM antibodies. In the United States, isolation of the virus from serum can be arranged through state health departments.^[31] Management is symptomatic. In the dengue fever syndrome, acetaminophen may be given for fever and myalgia. Salicylates should not be used. Hydration should be vigorously maintained.

Selected victims of grade I or II DHF may be managed as outpatients. However, outpatient care requires careful monitoring of hematocrit value, platelets, and electrolytes. If significant bleeding develops, hospitalization is appropriate for rapid and continuous assessment. Progression to DSS (grade III or IV) is a medical emergency and requires immediate hospitalization. There is no specific antiviral chemotherapy. Supportive measures described in the section on treatment of severe yellow fever are

appropriate.

Lassa Fever

Four viral hemorrhagic fevers—Lassa, Marburg, Ebola, and Crimean-Congo—have been associated with outbreaks of fatal person-to-person spread.^[23]^[49] Although the overall number of clinical cases in travelers caused by these viruses is small, they represent potentially significant threats as emerging diseases. They have also achieved a certain notoriety as a group as a result of media interest. Lassa fever was first recognized in 1969, when several nurses caring for febrile patients at a mission hospital in Nigeria became ill.^[46] Since that time, seroepidemiologic studies have established a large area of endemicity and a broad spectrum of clinical manifestations of infection.

Epidemiology.

The principal animal host for this virus is a rat, *Mastomys natalensis*, which prefers living in and around human dwellings. The rodents become chronically infected, secreting viral particles for long periods. Natural infection in humans occurs after rodent contamination of food and drink, inhalation of aerosolized rodent secretions, or contact with rodent material through skin abrasions. Lassa fever has been reported in several areas of sub-Saharan West Africa, and large outbreaks have been noted in Nigeria, Sierra Leone, and Liberia.^[83]^[86] Complete seroprevalence data are lacking, making definition of an endemic area impossible at this time. Secondary human infection has been reported and may occur after contact with infected secretions.

Virology and Pathophysiology.

Lassa virus is a single-stranded RNA arenavirus. Proliferation and dissemination presumably occur after initial replication at the inoculation site. As with the flaviviral diseases, the extent of end organ involvement noted at autopsy does not account for the rapid death of infected patients. Recent work in an animal model provides evidence for platelet dysfunction and an endothelial cell defect in shock caused by Lassa fever virus.^[42]^[43] DIC, believed to be a major cause of bleeding and death in patients with other viral hemorrhagic fevers, appears to play a relatively minor role in arenavirus infections.^[7]^[35]

Clinical Presentation.

Most seroconversions to Lassa virus are not accompanied by obvious symptoms.^[87] Only 5% to 14% of seroconverters experienced a febrile illness, and the fatality/infection ratio was 1:100 to 2:100. Patients hospitalized with Lassa fever show a distinct clinical syndrome. Fever, malaise, and purulent pharyngitis often develop after the insidious onset of headache. Retrosternal chest pain, possibly a result of pharyngitis and esophagitis, suggests the diagnosis. A case-control study found the combined presence of retrosternal chest pain, fever, pharyngitis, and proteinuria to be the best predictor of Lassa fever.^[85] Hemorrhagic complications (hematemesis, vaginal bleeding, hematuria, lower gastrointestinal bleeding, and epistaxis) were seen in less than 25% of patients

with Lassa fever. Non-fatal disease usually begins to resolve in 8 to

1582

10 days. The combined presence of fever, sore throat, and vomiting was associated with a poor prognosis (relative risk of death equals 5.5). Terminal stages of fatal disease were accompanied by hypotension, encephalopathy, and respiratory distress caused by stridor (presumably secondary to laryngeal edema). Laboratory indicators of a poor prognosis include an admission serum aspartate aminotransferase (AST) of greater than 150 IU/L (55% death rate) and viremia greater than 10^4 TCID₅₀ (TCID₅₀ is the titer at which sera containing the virus infects 50% of tissue culture test plates).

Diagnosis.

Establishing an accurate diagnosis is extremely difficult during the early phase of the infection. As the classic clinical syndrome develops, differentiation from other viral hemorrhagic fevers depends on serologic confirmation. Serologic diagnosis is made by indirect fluorescent antibody analysis of acute and convalescent sera or detection of Lassa-specific IgM antibody. Clotted whole blood may be sent to the CDC for viral culture if handled appropriately. If the diagnosis is suspected, the CDC should be contacted immediately for assistance in diagnosis, isolation, and management.

Management.

As mentioned above, Lassa fever has been associated with outbreaks of fatal person-to-person spread.^{[23] [126]} Secondary infection occurs through direct contact with infected persons or their secretions. The role of aerosols in person-to-person spread is unclear. Blood and body fluids should be considered infectious. In light of the potentially fatal outcome of Lassa fever and the relative ease of transmission, the CDC has published specific recommendations for management of possible or confirmed cases.^[23] If a person has (1) a compatible clinical syndrome (especially pharyngitis, vomiting, conjunctivitis, diarrhea, and hemorrhage or shock); (2) a relevant travel history, including time spent in an endemic area; and (3) prior contact within 3 weeks of presentation with a person or animal from an endemic area suspected of having a viral hemorrhagic fever, he or she should be isolated and local, state, and federal (CDC) health officials contacted. Ideally, an isolation unit with negative air pressure vented outside the hospital should be used. However, lack of a negative-pressure room alone is not a reason for transfer to another medical care facility.

The probability of transmission of Lassa fever virus to medical and nursing staff can be reduced by the use of routine blood and body fluid precautions as well as strict barrier nursing.^[63] Barrier nursing includes wearing gloves, gown, mask, shoe covers, and, if there is risk of splashing fluids, goggles whenever entering the patient's room. Decontamination of solid articles and rooms may be accomplished with 0.5% sodium hypochlorite solution. Full recommendations for the management of patients with viral

hemorrhagic fever have been published by the CDC.^[23]

Supportive care as described for the treatment of severe yellow fever is indicated for patients with signs and symptoms suggestive of a poor prognosis, including hemorrhage, volume disturbance, or hypotension. In addition to supportive measures, an effective antiviral compound, intravenous (IV) ribavirin, is available.^[84] This drug should be administered as soon as the diagnosis is suspected and is significantly more effective if given during the first 6 days of fever. Ribavirin should be administered as a 30 mg/kg IV loading dose, followed by 16 mg/kg IV every 6 hours for 4 days. Then, 8 mg/kg is given IV every 8 hours for 6 days. Persons having significant contact with a patient with Lassa fever (mucous membrane contact or a penetrating wound contaminated with infected material) should receive prophylactic ribavirin, 250 mg by mouth 3 times a day for 10 days.^[24]

Argentine and Bolivian hemorrhagic fevers are endemic to the pampas of Argentina and the Bolivian plateau, respectively.^{[83] [92]} Both are arenaviruses causing infection of humans through contact with infected rodents. Disease occurs primarily in rural areas. The clinical symptoms are similar to those of other viral hemorrhagic fevers. Management guidelines given for yellow fever may be followed. Person-to-person spread has not been significant. Strict isolation (such as is suggested for Lassa, Ebola, Marburg, and Crimean-Congo hemorrhagic fevers) is not required. Routine blood and enteric precautions are nevertheless advisable.

Ebola and Marburg Viruses

Ebola and Marburg viruses are closely related large RNA viruses known as filoviruses. They cause severe viral hemorrhagic fever syndromes with high mortality rates. Both are endemic in focal areas of central and southern Africa. Ebola virus seropositivity has been noted in Sudan, Democratic Republic of the Congo, the Central African Republic, Cote d'Ivoire, and Kenya. A strain of Ebola known as Ebola Reston has been found in monkeys imported into the United States from the Philippines. More recently, there have been outbreaks involving more than 100 deaths in Gabon and the Democratic Republic of Congo.^[4] Marburg disease is found in South Africa, Zimbabwe, and Kenya. Although Marburg disease was associated with contact with African green monkeys during the initial outbreak in 1967,^[89] no animal reservoir has been defined for either virus. Person-to-person transmission has been well documented, primarily through contaminated needles and contact with infected individuals.^{[3] [64] [89]}

Pathophysiology and Clinical Presentation.

Marburg and Ebola viruses are presumed to act through pathophysiologic mechanisms similar to other viral hemorrhagic

fevers. Work with a primate model of Ebola virus infection found no evidence for DIC

and suggested the possibility of platelet dysfunction and endothelial cell defects as important in the creation of a capillary leak syndrome leading to multisystem failure.^[43]

Patients present after an incubation period of 4 to 10 days with fever, headache, and myalgias. Diarrhea and abdominal pain occur commonly. In many victims, rash, conjunctivitis, sore throat, and chest pain appear early in the disease. As in other hemorrhagic fevers, hemorrhage, hypotension, shock, and electrolyte abnormalities mark fatal courses. The high mortality reported in various outbreaks (25% for Marburg virus and 55% to 88% for Ebola virus) emphasizes the importance of intensive supportive care.

Diagnosis and Treatment.

If these diseases are suspected, strict isolation procedures should be instituted and the local health authorities and CDC notified immediately. Diagnosis may be made on a serologic basis or by polymerase chain reaction (PCR). There appears to be no serologic cross reactivity between the two viruses. Although anecdotal reports suggest the efficacy of immune sera in therapy, this has not been consistently observed in experimental studies. There are currently no specific antiviral therapies for Marburg or Ebola virus infection.^[23] Care is supportive, and the therapeutic considerations given for treatment of severe yellow fever should be followed. Two patients with documented DIC and Marburg virus infection were given heparin and survived.^[49]

Crimean-Congo Hemorrhagic Fever

Virology and Epidemiology.

The etiologic agent of Crimean-Congo hemorrhagic fever (CCHF) is a bunyavirus. Ixodid ticks serve as both reservoirs and vectors of the virus. Infection in humans results from tick bites or direct contact with infected secretions from crushed ticks, animals, or humans. Most cases occur in individuals with occupations or living conditions that bring them in contact with domestic goats, sheep, or cattle on which ticks feed.^[32] ^[55] The disease has been observed in southeastern Europe, south central Asia, the Middle East, and much of Africa.^[2] ^[55] Nosocomial transmission through contact with infected body fluids has been well documented.^[2] ^[134]

Pathophysiology and Clinical Presentation.

Pathophysiologic mechanisms are presumably similar to those of other hemorrhagic fevers. One in five infections results in clinical disease.^[55] Among those clinically ill, mortality ranges from 15% in sporadic cases to 70% in rare hospital outbreaks.^[2] ^[55]

Diagnosis.

The diagnosis can be confirmed with acute and convalescent serologic evaluation for a fourfold rise in IgG antibody titers. The virus can be cultured from whole blood if it is drawn during the first week of symptoms and kept on dry ice (or at -70° C [-57° F])

during shipment to the CDC.

Management.

Initial management is similar to that for Lassa, Marburg, and Ebola virus infections, with strict patient isolation and notification of health authorities. Supportive therapy should be instituted as discussed for yellow fever. Although not confirmed in clinical trials, ribavirin has good activity in vitro against CCHF virus. The CDC recommends that patients believed to have CCHF receive IV ribavirin in the doses suggested for treatment of Lassa fever.^[23] Persons in contact with CCHF patients should receive prophylactic ribavirin as suggested for Lassa fever contacts. Treatment with oral ribavirin has been successfully used in a nosocomial setting when IV therapy was not available.^[44]

Hemorrhagic Fever with Renal Syndrome/Hantavirus Pulmonary Syndrome

Hemorrhagic fever with renal syndrome (HFRS) first came to the attention of Western medical science during the Korean War, when febrile illness accompanied by bleeding and renal failure developed in 3000 United Nations troops.^[144] Mortality ranged from 5% to 10%. A similar although less severe syndrome ("nephropathia epidemica") had been recognized in Scandinavia since the 1930s. More recent investigations have resulted in the identification of a group of RNA viruses, known as hantaviruses, as a cause of this syndrome. A novel infection associated with a new hantavirus, the Muerto Canyon or Sin Nombre virus, was described after a cluster of deaths in the Southwestern United States in 1993. This is hantavirus pulmonary syndrome, in which a nonspecific febrile illness is followed by shock and alveolar pulmonary edema.^[40]

Epidemiology.

The agent of HFRS causes chronic non-debilitating infections of rodents. Human infection is initiated by contact with rodent secretions or inhalation of aerosolized rodent material. The disease occurs most commonly in rural areas, although occasional urban outbreaks, presumably with the common house rat as vector, have been described.^[80]^[144] Cases have been described most frequently from the Far East, including China, Korea, Japan, and the Soviet Union, but the disease also occurs in Eastern Europe. A recent epidemiologic study from China found the highest rates of infection in men who engaged in heavy farm work and slept on the ground (rather than on raised wooden beds).^[147] The Sin Nombre agent appears to cause a chronic infection of the deer mouse, *Peromyscus maniculatus*, which is the main reservoir of the virus in the United States. Since the initial outbreak, additional cases have been described across the United States and South America.^[52]

The risk of infection is likely to be related to rodent exposure, but transmission is infrequent.

Virology and Pathophysiology.

The etiologic agent of HFRS is the prototype hantavirus, Hantaan virus, a member of the bunyavirus family. A related hantavirus, the Puumala agent, is the apparent cause of the more benign nephropathia epidemica. Other closely related viruses can cause similar, although less frequently recognized, syndromes. Seoul virus causes a milder form of HFRS in the Far East, and a recently described severe HFRS-like syndrome in Eastern Europe has been attributed to a related virus.^[89] As described above, Sin Nombre virus is the usual cause of hantavirus pulmonary syndrome (HPS) in the United States, but other hantaviruses probably cause the same syndrome.

Clinical Presentation.

As with most viral hemorrhagic fevers, infection may be asymptomatic or accompanied by a mild nonspecific illness. In the classic severe form, an initial febrile phase is associated with petechiae, proteinuria, and abdominal pain. After 3 to 5 days, a hypotensive phase occurs, with decreased platelet counts and more severe hemorrhagic phenomena. An oliguric phase follows with concomitant electrolyte abnormalities. Subsequently, a diuretic phase develops. This usually commences 10 days after the onset of illness. Death occurs from hemorrhage, hypotension, and pulmonary edema, presumably secondary to fluid overload and renal failure. With modern management, the case-fatality rate of classic HFRS is about 5%.^[144] The more benign nephropathia epidemica syndrome has a case-fatality rate of less than 1%. In this disease, hypotension, shock, and hemorrhagic manifestations are rare.

With HPS, there is usually a prodromal illness with fever and mild respiratory or gastrointestinal symptoms, followed by shock and pulmonary edema. The tempo of the disease at this stage may be rapid and require respiratory and circulatory support in an intensive care unit.

Diagnosis.

The diagnosis of HFRS, nephropathia epidemica, and HPS is confirmed by indirect fluorescent or enzyme-linked immunosorbent assay (ELISA) for antibodies in acute and convalescent sera. IgM antibody determination may also be helpful. Virus isolation is difficult, but PCR and immunohistochemical staining may be useful in affected tissues.

Management.

Care of patients with HFRS is supportive and should follow the guidelines given for yellow fever. With HFRS, renal dysfunction occurs early and may require institution of dialysis soon after diagnosis to prevent fluid overload and to correct electrolyte disturbances. Patients' secretions should be handled with care, and enteric precautions (but not strict isolation) are prudent. It is not clear whether person-to-person transmission of the virus through direct inoculation occurs. For the hantaviruses, viremia recedes and antibody levels rise as the clinical phase appears. Accordingly, nosocomial

transmission or hematogenous transmission with hantavirus infections has not been frequently documented, although presumed nosocomial transmission has been reported.^[139] ^[147]

Japanese B Encephalitis

Japanese B encephalitis has been recognized in Japan since the nineteenth century. It is the only arboviral encephalitis for which an effective inactivated vaccine has been developed. Vaccine use in Japan and elsewhere since the 1960s has resulted in a significant decrease in the disease rate. However, there is concern regarding the routine use of the vaccine for travelers because of the description of several adverse reactions described in Western countries. These tend to occur on the day after vaccination.^[29] Therefore use of the vaccine depends on a risk-benefit analysis. Relevant considerations include the duration of travel (minimum of at least 30 days), travel in an endemic area during the transmission season, and the likelihood of exposure to mosquitoes. A history of adverse reactions to the vaccine is a contraindication to its use.

Epidemiology.

Rice field-breeding mosquitoes serve as the vectors for Japanese B encephalitis. In addition to humans, birds and pigs can be infected. Pigs play an important role as amplifying hosts because they develop high-grade viremia from which large numbers of mosquitoes may be infected. Most infections in endemic areas occur in children, whereas all age groups of previously unexposed populations are at risk. Transmission of Japanese B encephalitis currently occurs in India, Southeast Asia, China, Korea, Indonesia, the Western Pacific region, eastern Russia, and Japan.^[133]

Virology and Pathophysiology.

Japanese B encephalitis is caused by a neurotropic flavivirus. After initial replication near the mosquito bite, viremia occurs, which if prolonged may seed infection to the brain.^[12] The cytopathologic effect of the flavivirus is believed to cause nerve cell destruction and necrosis.

Clinical Presentation.

Most infections do not cause clinical illness, and it has been suggested that only 1 in 300 infections results in encephalitis. Many patients recall a mild undifferentiated febrile illness, which probably coincides with the viremic phase of infection. Patients with encephalitis often report a similar prodrome. The encephalitis syndrome is not easily distinguishable from other arboviral encephalitides. The patient usually complains of headache, lethargy, fever, and confusion and may display tremors or seizures. Reported

mortality of persons with clinical encephalitis ranges from 10% to 50%.^[133] One clinical series suggested that the presence on admission of (1) unresponsiveness to pain, (2) low levels of anti-Japanese B encephalitis virus IgG or IgM antibodies (in serum or cerebrospinal fluid [CSF]), or (3) virus in CSF culture was associated with death.^[12] Of the 16 patients with fatal disease, all died within 7 days of hospitalization.

Diagnosis.

Acute and convalescent sera for antibody determination (virus neutralization or hemagglutination inhibition assays) provide the only reliable method of diagnosis. Paired sera should be sent for these assays through state health departments. Sensitive assays for determinations of IgG and IgM antibodies in serum and CSF have been developed^{[10] [11]} but are not yet widely available. Since most patients seek treatment long after the viremic phase, blood cultures are rarely positive for the virus and CSF cultures are often positive only in patients with a poor prognosis.

Management.

There is no specific therapy. The main interventions are prophylactic: vaccination and reduced arthropod exposure. Supportive care may require an intensive care unit. Since the virus is present in body fluids, especially CSF, blood and body fluid precautions should be considered. Japanese B encephalitis is only one of several of arthropod-borne viruses that may cause encephalitis in different areas of the world, for example, Murray Valley encephalitis in Australia; tick-borne encephalitis in Europe (for which a vaccine exists); and Lacrosse, West Nile, and St. Louis encephalitis in the United States.

Named Hepatitis Viruses

Although infectious hepatitis has been a well-known clinical entity for hundreds of years, it is only in the last few decades that identification of specific viral pathogens has been possible. The causes of hepatitis may be divided into two groups. Firstly, the so-called named, or more accurately, lettered viruses now include hepatitis A to G. These are associated with defined clinical syndromes and elevated liver function tests. Second, other organisms cause hepatitis as part of a more systemic infection, including Epstein-Barr virus, cytomegalovirus, toxoplasmosis, and leptospirosis. Only the former group is discussed here.

Epidemiology.

Hepatitis A virus is transmitted primarily by the fecal-oral route by either person-to-person contact or ingestion of contaminated food or water. Food items commonly associated with outbreaks are raw or undercooked clams and shellfish. Homosexual men have higher rates of seropositivity than the population at large.

Occasional cases are associated with exposure to nonhuman primates. Transmission by blood transfusion has been reported,^[98] but this is an uncommon source of infection. Hepatitis A is endemic worldwide, but underdeveloped nations have higher prevalences than those in North America. Most persons in these areas show serologic evidence of past infection with hepatitis A virus. Several recent studies suggest that hepatitis is the most common serious viral infection occurring in travelers and that hepatitis A virus is the most common identifiable cause.^{[34] [54] [58]}

Virology and Pathophysiology.

Hepatitis A virus is a picornavirus with a single-stranded RNA genome. Although the pathophysiologic mechanism has not been delineated, most infections begin with introduction of viral particles into the proximal gastrointestinal tract. Brief viremia precedes seeding of hepatocytes, where viral replication has been documented.^[54] With replication, hepatocellular necrosis is accompanied by lymphocytic infiltration. In the vast majority of cases, hepatic regeneration occurs after acute disease and no significant sequelae are observed.

Clinical Manifestations.

The incubation period ranges from 2 to 7 weeks. The infection may be asymptomatic or mild, especially in children, but also in a minority of adults. The classic syndrome includes initially anorexia, followed by nausea, vomiting, fever, and abdominal pain. These symptoms may be accompanied by hepatosplenomegaly. AST and alanine aminotransferase (ALT) levels rise within a few days of the onset of symptoms. In children, AST and ALT return to normal levels in 2 to 3 weeks, whereas in adults resolution of elevated serum aminotransferase levels may take several months. The bilirubin level rises shortly after AST and ALT elevations. Jaundice usually follows gastrointestinal symptoms by several days to a few weeks. Resolution of jaundice may take another 3 to 4 weeks. The syndrome is occasionally preceded by arthralgias and rash, but these prodromal symptoms are uncommon.^[71] Resolution of acute disease is permanent in most instances, but rare cases of relapse have been noted.^[106] It has become clear in recent years that death after acute hepatitis A is not as rare as initially believed.^[54] The fatality rate in cases reported to the CDC is 0.6%.^[24] Anti-hepatitis A antibody (primarily IgG) is detectable in the blood for many years after infection. The presence of the antibody confers immunity. Accordingly, reinfection with hepatitis A virus is not believed to occur.

Diagnosis.

The clinical presentation of hepatitis A is usually milder than other types of viral hepatitis. Consequently, the symptoms are not distinctive enough to allow a firm diagnosis, which requires detection of hepatitis A antigen in the stool or serologic evaluation for hepatitis A-specific IgM or total anti-hepatitis A virus antibody. Stool hepatitis A antigen is maximal before

the onset of symptoms but may be detected as long as 2 weeks after the onset of disease. A more practical test is measurement of hepatitis A-specific IgM antibody, which is usually present by the time symptoms are recognized and generally absent 6 months later. Measurement of anti-hepatitis A antibodies may be helpful in evaluating possible causes of past icteric episodes or for seroepidemiologic studies, but their presence does not differentiate recent from past infection.

Management.

No specific therapy exists for hepatitis A. Affected persons are usually managed as outpatients and should be instructed on enteric precautions to avoid transmission to others. Although infectivity drops sharply soon after the onset of jaundice, it is prudent to maintain enteric and blood-drawing precautions for about 2 weeks after jaundice appears. Nosocomial transmission has also been documented, but most spread probably occurs before jaundice and diagnosis.^[56]

Prevention.

Active immunization with hepatitis A vaccine is recommended for most travelers to at-risk areas. There are two inactivated hepatitis A vaccines available in the United States. Both have excellent safety and efficacy profiles. Two doses of vaccine 6 to 12 months apart appear to provide adequate antibody responses for at least 10 years. Although no specific therapy is available for hepatitis A, additional prophylactic measures may be considered.^[24] Human immunoglobulin (IG) is effective for both preexposure and postexposure prophylaxis. IG is concentrated human immunoglobulin prepared by ethanol fractionation of pooled human sera. Although human immunodeficiency virus (HIV) contamination is a theoretic risk, epidemiologic studies show no increased risk of acquired immunodeficiency syndrome (AIDS) in recipients of IG, and laboratory evaluations confirmed that the IG manufacturing process inactivates HIV.^[21] Thus IG is safe for use as prophylaxis.

Hepatitis B

The spread of hepatitis by parenteral means was noted in 1885. Recognition in the 1960s of specific viral particles (the Australia antigen) in the serum of hepatitis patients led to identification of the responsible agent.

Epidemiology.

With the widespread use of serologic markers for hepatitis B disease, it became apparent that spread occurs through exchange of blood, semen, or, rarely, saliva of infected people. Although spread is possible from persons with acute disease, the primary sources of viral particles are chronic carriers. Persons are defined as carriers if blood samples obtained 6 months apart contain hepatitis B surface antigen particles

(HB-sAg). The carrier state follows acute infection in up to 90% of infected infants and 10% of adults.^[47] Risk factors for acquisition of hepatitis B infection in the United States include IV drug use, homosexual activity, and working in health care. In the United States, most victims are adults, and the carrier rate in the general population is less than 0.5%. In many areas of the developing world, most infections occur in infancy or childhood, and chronic carriers may comprise as much as 10% to 20% of the total population. Thus travelers are more likely to be exposed to carriers than is the non-traveling population. The risk is higher in persons regularly exposed to body fluids, including medical personnel and persons with frequent sexual partners.

Virology and Pathophysiology.

Hepatitis B virus is a deoxyribonucleic acid (DNA) virus unrelated to the agent responsible for hepatitis A. Infection occurs naturally in humans and can be induced easily in some nonhuman primates. The virus cannot be grown in vitro. Most hepatitis B infections are subclinical. In those resulting in clinical disease, entry of the virus into the liver is followed by viral replication and hepatocyte necrosis. HBsAg, a viral particle, appears in the bloodstream within 3 months of infection. In most cases, IgM antibody to the core antigen appears first, followed by anti-HBsAg antibody. Antibody to a third hepatitis antigen, the e antigen (HBeAg), is present for variable periods. The course of the disease varies widely, depending on a number of factors that are not well defined. In brief, most cases are self-limited and resolve in 4 to 6 months. In these patients, anti-HBsAg or anti-HBcAg IgG antibodies can be detected for years after the episode of hepatitis. Chronic carriers do not develop anti-HBsAg antibody, but rather maintain measurable levels of HBsAg. Similarly, carriers with persistent HBeAg detectable in blood samples appear to be more infectious than carriers without circulating HBeAg. The intricate network of antibody-antigen relationships in hepatitis B is believed to play a role not only in development of acute and chronic hepatitis but also in the many extrahepatic syndromes associated with hepatitis B.^[106] Immune complex formation has been suggested as etiologic in hepatitis B-associated arthritis, rash, arteritis, and renal disease.^[53]

Clinical Presentation.

The incubation period for hepatitis B ranges from 7 to 22 weeks; however, the patient may be antigenemic for a large portion of that time. The manifestations of hepatitis B infection are similar to hepatitis A, including fever, anorexia, nausea, vomiting, and abdominal pain. In addition, a prodrome of rash, arthralgia or arthritis, and fever is seen in up to 20% of hepatitis B patients compared with their rarity in hepatitis A. Glomerulonephritis is occasionally seen. Jaundice usually appears a short time after the onset of gastrointestinal symptoms. In the self-limited disease, recovery is complete by 6 months. Some infections follow

a fulminant course; case-fatality rates are 2% or less in most series. In addition to

complete resolution or death, three other sequelae are possible with acute hepatitis B. A person may become an asymptomatic chronic carrier and remain HBsAg positive but have no detectable active hepatitis. Chronic persistent hepatitis is a term used to describe persistent, but not progressive, hepatic inflammation (usually monitored by serum transaminase levels), often with HBsAg in the serum. Persons with chronic active hepatitis may be HBsAg positive and have progressive hepatitis, which may result in cirrhosis and death directly related to liver disease. Any of these three conditions results in the presence of hepatitis B viral particles in the blood.

Diagnosis.

A variety of antigen and antibody tests have been developed for the diagnosis and monitoring of hepatitis B disease. The most practical and widely available test for diagnosis of acute disease is the assay for HBsAg. Antigen is usually present before the onset of symptoms and persists during symptomatic disease. Occasionally, HBsAg may be undetectable in patients with clinical disease caused by hepatitis B. In these cases, antibody to HBcAg is often present. Later, antibody to HBsAg will appear, but this is often long after the episode of clinical hepatitis.

Management.

Management is similar to that of hepatitis A. Prolonged viremia makes blood and body fluid precautions necessary until the absence of HBsAg antigen and the presence of antibody to HBsAg are established.^[24] For patients with chronic infection, therapy with interferon- α (IFN- α) involving three injections per week for 6 months is recommended. Even in individuals with good prognostic indicators, the response rate in terms of long-term clearance of virus and seroconversion approaches only 30%.

Prevention.

Travelers to highly endemic areas who stay for 6 or more months or have close contact with inhabitants should be vaccinated. Two types of vaccine have been available. The first vaccine was prepared from pooled human plasma using several biochemical and physical procedures that result in a suspension of HBsAg particles. The processes used in manufacturing this vaccine inactivate blood-borne human viruses,^[21] ^[24] including HIV. This vaccine is no longer produced in the United States, and its use is generally restricted to persons with allergies to yeast and severely immuno-compromised hosts. The newer hepatitis B vaccines are produced using recombinant DNA technology by introduction of a plasmid containing the gene for HbsAg into baker's yeast. After the yeast has grown, the cells are lysed and HBsAg is separated from the lysate. The recombinant HBsAg is suspended to a concentration of 10 mg/ml. The recommended dose is 1 ml (10 mg) intramuscularly, with repeat doses at 1 and 6 months. Immunogenicity is similar for both vaccine preparations if used as directed by the manufacturer.^[24] Injections into subcutaneous fat are poorly immunogenic, so the vaccine should be given in the deltoid muscle.^[138] Hepatitis B immune globulin (HBIG) is available for postexposure situations. HBIG is prepared from pooled sera by ethanol fractionation and contains high titers of antibody to HBsAg. In brief, if an unvaccinated person is exposed to blood or has sexual contact with a person known to be HBsAg

positive, he or she should receive HBIG (0.06 ml/kg body weight, intramuscularly) and the complete vaccine series (first injection in a different site from the HBIG) within 7 days of exposure. If only HBIG is available, the initial HBIG dose should be followed in 1 month by another HBIG injection. This second dose of HBIG is not required if the patient is given the vaccine series.

The remaining recommendations assume availability of vaccine. If the exposed person has been vaccinated and serologic testing is available, nothing need be done if anti-HBsAg antibody is adequate. If levels of this antibody are inadequate, a routine dose of HBIG and a booster dose of vaccine (1 ml, intramuscularly) should be given. If there is uncertainty of the HBsAg status of the source, HBsAg testing should be done. In the unvaccinated person, the vaccine series should be given immediately, and if the source proves to be HBsAg positive, HBIG should be administered as previously described. In vaccinated persons with an adequate vaccine response, no action should be taken. If the vaccine response was inadequate and the source was HBsAg positive, HBIG and a booster vaccine should be given. If the source was unknown, the vaccine series should be given to the unvaccinated individual, and nothing need be done for the vaccinated person.^[24] Risk reduction, such as advice regarding the practice of safe sex when traveling, is equally important.

Delta Hepatitis

Hepatitis with the delta agent was first suspected in 1977, when cases of severe hepatitis B disease and exacerbations of hepatitis were being evaluated.

Epidemiology.

Delta virus infection is found only in patients concomitantly or previously infected with hepatitis B.^[113] Transmission follows a pattern similar to hepatitis B.^[114] In the United States, affected populations are IV drug abusers and multiply transfused hemophiliacs.^[115] Serologic evidence of delta virus disease has been documented in the Mediterranean basin, West Africa, and parts of South America.^[113]

Virology and Pathophysiology.

The delta agent has been termed a "defective" virus because it requires hepatitis B virus activity for its own replication.^[112] ^[115]

The agent is a single strand of RNA and a 68-kD protein enclosed in a protein coat of HBsAg. The delta agent infects cells at approximately the same time as hepatitis B virus (coinfection), or it may be introduced later in the course of persistent hepatitis B infection (superinfection). In coinfecting patients the clinical picture may not differ from hepatitis B, but a higher percentage of such patients develop severe disease than those with hepatitis B alone. Patients superinfected with the delta agent develop flare-ups of

hepatitis, which may become fulminant. After the acute infection, the delta agent can cause progressive disease in previously stable hepatitis B patients. In general, infection with the delta agent worsens the prognosis of hepatitis B disease. The diagnosis can be made by detection of antibody to the delta antigen in the serum^[114] or less commonly by detection of free delta antigen in serum.^[112]

Management and Prevention.

Management of acute hepatitis consists of supportive care. Precautions against transmission are the same as for hepatitis B. There is no specific vaccine or IG for the delta agent. The best preventive measure is to be vaccinated for hepatitis B because delta agent infection cannot occur in the absence of the former virus.

Hepatitis C

As serologic methods for the diagnosis of hepatitis A, hepatitis B, and delta agent were developed, it became apparent that there was a group of persons with hepatitis for which no etiologic agent had been identified. This syndrome was previously termed non-A, non-B (NANB) hepatitis and thought to be caused by a heterogeneous group of etiologies.^[123] ^[129] ^[149] It is now clear that a majority of such cases were due to hepatitis C.

Epidemiology.

Risk factors for hepatitis C include IV drug use and, before routine testing, transfusion of blood products.^[74] ^[75] Nonparenteral routes of infection are less important than for hepatitis B. Hepatitis C is a global problem. Approximately 80% of exposed individuals develop chronic infection, which may lead to cirrhosis in 20% of subjects and hepatocellular carcinoma in up to 5% of this subset of infected persons. Rates of infection vary from 1% to 5% in most Western countries to 20% in parts of the Middle East, such as Egypt. ^[142]

Virology and Clinical Manifestations.

Hepatitis C is a single-stranded RNA virus of the *Flaviviridae* family. It was discovered in the late 1980s.^[33] Transition to chronic hepatitis after an insidious asymptomatic infection is the usual pattern. Chronic hepatitis may be asymptomatic or associated with nonspecific symptoms, such as lethargy, nausea, and abdominal discomfort. The patterns of cirrhosis and hepatocellular carcinoma when they occur do not differ significantly from that of other conditions. Extrahepatic syndromes associated with hepatitis C infection include porphyria cutanea tarda, membranous glomerulonephritis, and mixed cryoglobulinemia.

Diagnosis.

Diagnosis of hepatitis C has been a vexing problem. First-generation ELISA tests available soon after the discovery of the virus led to a significant number of false

positives. These tests have subsequently become more sensitive and specific, and radioimmunoassays (RIA or RIBA) have become available and are useful in confirmatory testing. To clarify the significance of a positive screening test, it should be repeated, and if possible, a second confirmatory test should be done (usually a RIBA). Interpretation of the significance of such tests should be tempered by the presence or absence of risk factors for infection. PCR tests for hepatitis C may also provide further evidence of infection and a direct measure of viral replication. If the PCR results are positive, it should be interpreted with several caveats. First, a minority of infected individuals clear the virus, so a negative test does not exclude past infection. Second, the serum PCR may be negative in the face of viral replication in the liver. Third, performance of PCR is operator dependent, so an experienced laboratory should be used.^{[1] [103]}

Management and Prevention.

Prevention of hepatitis C is largely dependent on risk reduction, especially with respect to drug use. Pooled immunoglobulin has been used after exposure, but this should be procured from donors screened for hepatitis C. It is, however, not generally recommended. Unlike hepatitis B, protective antibody responses have not been demonstrated. Treatment of acute hepatitis C is supportive. Treatment of chronic infection is with IFN- α , though the overall results are disappointing and side effects significant. Response rates increase to approximately 40%, however, when IFN- α is used in combination with ribavirin.^[88]

Hepatitides E, F, and G

Hepatitis E is an RNA virus provisionally placed in the *Caliciviridae* family. It is the second most common cause of viral hepatitis transmitted via the enteric route. The epidemiologic characteristics are similar to hepatitis A. This group of infections is especially important in the Indian subcontinent, the Middle East, and Africa. The incubation period varies between 2 and 6 weeks. The disease is usually self-limited but may be associated with severe illness in pregnant women.

Diagnosis in travelers from endemic areas can be made on the basis of IgM antibody to hepatitis E in serum or testing of stool for viral antigen. PCR for hepatitis E may be available in some centers. In the United States, testing for hepatitis E is best undertaken in returned

travelers with clinical hepatitis who are negative in testing for hepatitides A, B, and C. No specific therapy is of benefit. There is no association with chronic hepatitis, although a more severe illness may occur in persons with underlying liver disease. Vaccines are under development but not yet available. Prophylaxis is appropriate advice to travelers regarding ingestion of food and water in endemic areas.

Hepatitis F is a putative hepatitis virus of uncertain significance first described in France. Hepatitis G is a member of the flavivirus family with limited homology to hepatitis C. Its significance as a cause of hepatitis is also unclear.^[130]

MAJOR BACTERIAL INFECTIONS

This section reviews several bacterial diseases of relevance to the overseas traveler, including typhoid fever, meningococcal disease, pertussis, diphtheria, and tetanus. Other chapters deal with bacterial causes of gastroenteritis and diarrhea, tick-borne diseases, and zoonoses.

Typhoid Fever

Typhoid fever was recognized as a clinical entity in the 1800s and first associated with transmission by the fecal-oral route in the 1870s. Although effective treatment with chloramphenicol became possible in 1948, the disease continues to be a major cause of morbidity and mortality in the developing world.^[41]

Epidemiology.

Typhoid fever occurs worldwide, but its prevalence and attack rates are much higher in underdeveloped countries. Humans are the only host for *Salmonella typhi*, the most common cause of the typhoid fever syndrome. Nearly all cases are contracted through ingestion of contaminated food or water. Transmission occurs through a variety of mechanisms, the most common of which include contact with a chronic carrier of the organism, especially food handlers, or ingestion of untreated waste material or sewage. One expert has estimated an incidence rate of 12.5 million cases a year in the developing world (excluding China).^[41] Improved sewage and tracking of chronic carriers have markedly reduced the incidence in developed countries, although several hundred cases a year are reported to the CDC in the United States. Evaluation of cases reported between 1975 and 1984 revealed that 62% of typhoid fever cases in the United States were acquired during foreign travel. The highest attack rates occurred in persons traveling to India, Pakistan, Peru, and Chile (58 to 174 cases per 1 million travelers).^[119]

Bacteriology and Pathophysiology.

Salmonella species are gram-negative enteric bacilli. *S. typhi* is the prime cause of typhoid fever, but other species, including many of the *S. enteritidis* serotypes and some non-*Salmonella* enteric organisms such as *Yersinia* or *Campylobacter*, may cause a typhoid fever-like syndrome. *Salmonella* species are easily grown on routine bacterial culture plates, but if multiple organisms are present, media with selective growth inhibitors may be needed for optimal sensitivity. After ingestion of food or water containing the pathogen, organisms are subjected to the acid stomach environment, which results in significant bacterial killing. If the organisms get through the small intestine, several processes may occur. The bacteria may simply pass through, causing

few clinical symptoms. If the bacteria multiply and invade the mucosa, a gastroenteritis-like syndrome will result. Typhoid fever requires penetration of the intestinal mucosa and intestinal lymphatics, where replication of *S. typhi* occurs intracellularly. Soon thereafter, bacteria seed the bloodstream and are transported to reticuloendothelial cells throughout the body, where further intracellular replication can take place. After the acute episode of infection is over, *Salmonella* species may remain and asymptotically reproduce in scarred or chronically inflamed tissues. Persons may shed organisms from such foci for years and serve as a source of outbreaks while they themselves are asymptomatic. The most common site for such colonization is the chronically diseased gallbladder.

Clinical Presentation.

After exposure to the pathogen, 10 to 14 days usually passes before the onset of clinical illness. Some patients may experience gastroenteritis early in the course of disease, and abdominal pain or diarrhea may be present at the time the classic typhoid fever picture develops. Fever is usually the first sign of disease. Fever increases slowly over several days^[70] and may remain constant for 2 to 3 weeks, after which time defervescence begins. With antibiotic therapy, fever resolves more rapidly, often within 3 to 4 days.^[70] Relative bradycardia may accompany fever. Most victims also report headache, malaise, and anorexia. Rose spots (2- to 4-mm maculopapular blanching lesions) are classically described on the trunk, although they are not seen in the majority of patients. Hepatomegaly and splenomegaly have been reported in a large number of patients.^[69] ^[110] Laboratory investigations early in the course may show a high white blood cell (WBC) count, anemia, and mild elevations of serum hepatic enzyme levels, including AST, lactate dehydrogenase, and alkaline phosphatase.^[69] Later in the course of the disease, leukopenia (WBC < 3500/mm³) develops.

Uncomplicated and untreated typhoid fever resolves in 3 to 4 weeks. Several complications may herald or contribute to death. Intestinal perforation, presumably secondary to necrosis of lymphoid areas of the bowel wall, may lead to peritonitis and death. Significant gastrointestinal hemorrhage may occur but rarely is fatal.

Secondary pneumonia is common. A subgroup of patients has more severe disease, which may include myocardial involvement, mental status changes, hyperpyrexia, and multisystem failure. The overall case fatality rate has ranged from 12% to 32% in the developing world but is less than 2% in industrialized nations.^[41]

Diagnosis.

Culture of a bacterial species associated with the syndrome (most likely *S. typhi*) from a normally sterile fluid makes the diagnosis. Multiple studies have evaluated the usefulness of various diagnostic tests. In general, bone marrow culture is the most sensitive method, detecting up to 90% of cases, whereas blood cultures are less

sensitive.^[41] Both methods are most useful in the first week of disease. Stool cultures (and string test cultures) may be positive later in the course of disease but provide only circumstantial evidence of the causative agent. Work is currently being done on serodiagnostic methods, but no clear consensus has been reached on the relative usefulness of any test.^[41]

Management.

Chloramphenicol had been the mainstay of treatment for typhoid fever since the late 1940s. Ampicillin and trimethoprim/sulfamethoxazole were the traditional alternatives. In the last decade, there has been increasing multiple drug resistance so that ciprofloxacin is now the first-line antibiotic. Unfortunately, increasing resistance to quinolones has been observed, especially from the Indian subcontinent. In cases of quinolone resistance, either laboratory or clinical, ceftriaxone or other third generation cephalosporins are indicated.^[118] ^[139] Other treatment modalities include fluid support and adequate nutrition. Corticosteroids have been used empirically for many years. A single randomized double-blind study showed that administration of high-dose dexamethasone (3 mg/kg for the first dose, followed by 1 mg/kg every 6 hours for eight more doses) with chloramphenicol resulted in significantly lower mortality in patients with severe typhoid fever than in those treated with chloramphenicol alone.^[68] Severe typhoid fever was defined in this study by the presence of obtundation, delirium, stupor, coma, or shock (systolic blood pressure less than 90 mm Hg for those 12 years or older and less than 80 mm Hg in children). High-dose steroids were not recommended for those with less severe disease and should be used cautiously in those with severe disease.^[37]

Prevention.

Three vaccines exist for prophylactic use. The oldest in use is a heat-killed, acetone-precipitated vaccine. Efficacy in Americans, however, is only about 50%, and significant incidences of local inflammatory reactions and febrile responses occur in persons receiving the vaccine. Two doses of 0.5 ml are given subcutaneously separated by a 4-week interval. An oral vaccine was licensed for use in the United States in 1989. The vaccine contains the Ty21a strain of *S. typhi* and is associated with minimal side effects. The Ty21a vaccine is given as a four-dose series, with 2 days between each dose.^[141] Immunosuppression, antibiotic use, and gastroenteritis are contraindications to the use of this vaccine. A newer parental vaccine contains the Vi (virulence) polysaccharide of *S. typhi* purified from formalin-killed bacteria. It is administered as a single intramuscular injection and is therefore most useful when vaccination is required at short notice. A booster is required every 2 years.^[36] Even when the vaccine is given before travel, it is important to observe routine precautions for ingestion of food and water to prevent typhoid fever and acquisition of other pathogens by the fecal-oral route.

Meningococcal Disease

Classically, meningococcal meningitis attacks children and young adults and is often seen in epidemic form. Although the advent of effective antibiotic therapy and a useful vaccine have greatly improved the ability to deal with this disease, it remains a major

problem in many parts of the world.

Epidemiology.

Cases of meningococcal disease occur sporadically worldwide, with epidemic disease generally limited to developing nations. Epidemic situations clearly pose the greater health problem to both travelers and resident populations. Since 1970, large outbreaks have occurred in Brazil, China, the Sahel region of sub-Saharan Africa (from Mali and Burkina Faso to Ethiopia and northwestern Somalia), New Delhi, India, and Nepal.^[35] Particularly in sub-Saharan Africa and China, the disease demonstrates yearly incidence peaks and periodic massive outbreaks, the exact determinants of which are unknown. Transmission of the organism occurs by exchange of respiratory secretions; contact is believed to be important in the spread of the disease. Asymptomatic transient nasopharyngeal carriage of the meningococcus, occurring with a baseline prevalence of 5% to 10%,^[9] may increase during epidemic periods and in close contacts of cases. The secondary attack rate among household contacts of patients with sporadic disease is 2:1000 to 4:1000, whereas that in epidemics ranges from 11:1000 to 45:1000 household contacts.^[90]

Bacteriology and Pathogenesis.

Neisseria meningitidis is a gram-negative diplococcus that grows easily on several common media, including chocolate and blood agar. The organism is characterized further on the basis of serologic analysis of capsular antigens. The most common serogroups are A, B, C, Y, and W135. Serogroups A and C are often associated with epidemic disease, whereas serogroup B is the major cause of sporadic

disease in the United States.^[25] Asymptomatic persons may carry various serotypes of *N. meningitidis* in the nasopharynx for short periods of time. An antibody response is often generated to these strains during asymptomatic carriage. The conditions that cause one person to become clinically ill with invasive disease while another carrier remains healthy are not well understood. The route of entrance of the organism to the bloodstream and central nervous system (CNS) is presumably through the nasopharynx or respiratory tract.

Clinical Presentation.

Meningococcal disease may appear in a variety of forms, including, but not limited to, bacteremia with septic shock; meningitis, often accompanied by bacteremia; and pneumonia. Sustained meningococcemia may lead to severe toxemia with hypotension, fever, and DIC. In the fulminant presentation, adrenal hemorrhage may lead to Waterhouse-Friderichsen syndrome, and death may follow intractable shock. In the United States the case-fatality rate for sustained meningococcemia is generally higher than for meningococcal meningitis.^[140] There is also a clinical syndrome of chronic

meningococemia with a much more insidious onset.

Meningitis caused by *N. meningitidis* classically begins with fever, headache, and a stiff neck. It may also be accompanied by bacteremia and any of several skin manifestations, including petechiae, pustules, or maculopapular rash. In either meningitis or bacteremia, progression of petechiae to broad ecchymoses is a poor prognostic sign. As with septic meningococemia, severe meningitis may progress with mental status deterioration, hypotension, congestive heart failure, DIC, and death. The case-fatality rate of meningococcal meningitis with or without bacteremia is now estimated to be about 10%.^[140] In classic cases of meningitis or bacteremia with sepsis, the peripheral WBC count is elevated, with polymorphonuclear cell predominance. CSF typically is purulent, usually with more than 500 polymorphonuclear cells/mm³. There may be a more heterogeneous cell population and fewer cells if CSF is obtained early in the course or if the patient has been treated with antibiotics. The CSF glucose level is usually low and protein high, as in other bacterial meningitides. Gram's stain of CSF may show the gram-negative diplococci. Meningococcal pneumonia is a well-known but less common clinical entity,^[109] most recently described in military recruit populations involving serogroup Y organisms.^[77]

Diagnosis.

The presumptive diagnosis in an epidemic can be made on the basis of clinical presentation and purulent spinal fluid. The presence of characteristic bacterial forms on Gram's stain is also suggestive. A definitive diagnosis requires culture of the organism from CSF or a normally sterile fluid (usually peripheral blood). This may be impossible in the case of a patient who was previously treated. Several commercial kits for measuring meningococcal antigen are now available for use on CSF or blood samples.

Management.

Treatment of meningococcal meningitis or sepsis is a medical emergency. Fortunately, the organism remains sensitive to a large number of antibiotics. The treatment of choice is penicillin G, 300,000 units/kg/day (up to 24 million units a day), given intravenously in divided doses every 2 hours. Between 7 and 10 days of therapy for serious disease is appropriate. Ceftriaxone is an alternative antimicrobial agent. If the patient is allergic to penicillin, chloramphenicol (100 mg/kg/day) may be given, although the emergence of chloramphenicol-resistant strains of *N. meningitidis* is of great concern.^[48] Notably, antibiotic treatment before culture or hospital referral is recommended in clinically suspected cases.

Supportive care should include close monitoring for hypotension and cardiac failure. Fluids and vasoactive and cardioselective agents may be important. This type of support necessitates invasive monitors and intensive care unit technology. Development of DIC is an ominous sign. The role of heparin in this disease is still debated. Although focal bleeding and adrenal necrosis may lead to acute adrenal insufficiency, the role of replacement steroids in the treatment of Waterhouse-Friderichsen syndrome is unclear.^[5] Since the infectious agent has been found in household contacts and in those with exposure to oral secretions, contacts should receive prophylaxis to eradicate the

organism. Rifampin, 600 mg by mouth every 12 hours for four doses, is standard adult prophylaxis. Children should receive 10 mg/kg of rifampin every 12 hours for four doses if they are older than 1 month and 5 mg/kg every 12 hours for four doses if they are less than 1 month of age.^[17] More recently, alternate regimens using ceftriaxone and ciprofloxacin have also been proven to be efficacious, although rifampin remains the standard.

Prevention.

An effective meningococcal vaccine that has been available in the United States for several years contains purified polysaccharide from the bacterial capsule of *N. meningitidis* serogroups A, C, Y, and W135. No vaccine is effective for group B disease. The recommended dose is one injection of 0.5 ml subcutaneously.^[17] Clinical efficacy of more than 65% is maintained for at least 3 years in persons immunized at 4 years of age or older, although protection wanes more rapidly in children vaccinated at less than 4 years of age.^[111] The incidence of meningococcal disease in the United States is so low that mass administration of the vaccine is inappropriate; however, vaccination is recommended for persons without spleens, with specific complement deficiencies, or those planning to travel to

high-risk areas.^[16] ^[17] Epidemics have occurred since 1980 in sub-Saharan Africa; New Delhi, India; Nepal; and Saudi Arabia. Since the areas in which epidemic meningococcal disease occurs change from time to time, it is prudent to check with appropriate authorities to determine current recommendations for meningococcal vaccination before travel.

Pertussis

Pertussis, or whooping cough, was first recognized as a major threat in the 1500s. After the introduction of a vaccine in the 1940s, the incidence of pertussis dropped sharply among immunized populations. However, since recognition of rare side effects to pertussis vaccine, immunization rates have fallen. The age-specific incidence of pertussis in all age groups increased between 1981 and 1985 in the United States, with rates in persons 20 years and older increasing by thirteenfold during that period.^[22]

Epidemiology.

Pertussis is found throughout the world. The incidence is currently highest in undeveloped countries, where immunization rates are low and socioeconomic conditions predispose to many communicable diseases. Pertussis is highly infectious, with attack rates of greater than 90% in unvaccinated household contacts. In the United States, most infections and the most severe disease occur in children under 5 years old. Transmission is by airborne particles from respiratory secretions of infected persons.

Bacteriology and Pathophysiology.

Bordetella pertussis is a gram-negative coccobacillus. The organism produces several toxins when present in the respiratory tract. Pertussigen stimulates lymphocytosis and hemagglutination. Dermonecrotic toxin and tracheal cytotoxins damage respiratory epithelium. In addition, endotoxin is produced. During the course of the somewhat protracted disease, complications can occur that may cause death. The most serious of these are secondary pneumonia or fulminant encephalopathy. In addition, fits of coughing often result in pneumothorax, hemorrhage (facial, conjunctival, and CNS), and aspiration.

Clinical Presentation.

Classic pertussis develops after an incubation period of 7 to 10 days. The disease appears in three stages: catarrhal, paroxysmal, and convalescent. The catarrhal stage lasts 1 to 2 weeks and resembles an undifferentiated upper respiratory tract infection with cough and mild fever. Progression of the cough to yield the classic whoop (which results when the patient gasps for breath after a prolonged coughing episode) marks the paroxysmal stage, which again can last as long as 2 weeks. During this stage, the peripheral white blood cell count may show marked lymphocytosis. Finally, cough resolves during the convalescent stage. Death may occur from pertussis alone or from complications such as aspiration pneumonia. Recent case-fatality rates for Americans were 0.4% for all persons and 1% for patients less than 1 year old.^[22] The disease in adults is often milder, although it may show a severe classic pattern.^[81] Some investigators believe mild or atypical disease in adults may serve as a reservoir for infection of susceptible children.^[97]

Diagnosis.

Culture of the organism from a nasopharyngeal swab is the most efficient way to diagnose pertussis; however, the culture is positive most frequently early in the illness, and late cultures (after the second week of illness) are rarely helpful. For optimal recovery, Bordet-Gengou media should be used, with methicillin added to reduce overgrowth by other bacteria present in the nasopharyngeal flora. Direct fluorescent antibody techniques may also be used to evaluate nasopharyngeal swabs or sputum samples for the presence of organisms.

Management.

Treatment with antibiotics, unless begun in the incubation or catarrhal period, has little effect on the course of the disease. Antibiotics can reduce subsequent transmission to contacts, however, and should be instituted as soon as the diagnosis is made. Erythromycin, the drug of choice, should be given for at least 2 weeks. Other useful agents include doxycycline, trimethoprim/sulfamethoxazole, and chloramphenicol. In patients with severe disease, corticosteroids may provide some improvement.^[150] Perhaps more important than specific antibiotics is supportive care, including hydration,

nutrition, care to maintain adequate ventilation, and supplemental oxygen. In addition, external stimuli, which seem to exacerbate symptoms, should be kept to a minimum.

Prevention.

Immunization of children with diphtheria-pertussis-tetanus (DPT) vaccine is recommended by the CDC, since the benefits of immunization are greater than the risk of neurologic damage from the vaccine.^[26] ^[66] ^[67] Introduction of new acellular pertussis vaccines may reduce this risk even further.^[27] Vaccination is not recommended for persons older than 7 unless there is specific risk. The goal of treatment is to reduce secondary transmission. Close contacts under 7 years old who are unimmunized should be immunized, and persons who have not had a dose of DPT in 3 years should receive one. Furthermore, all close contacts under 1 year old should receive a 14-day course of erythromycin or trimethoprim/sulfamethoxazole, as should unimmunized contacts under 7 years old.^[26]

Diphtheria

Diphtheria, once a highly feared cause of morbidity and mortality in young people, can be controlled with

1593

appropriate use of a vaccine. However, according to some surveys, waning immunity has left more than 40% of American adults (18 years or older) with inadequate circulating levels of antitoxin against diphtheria. Of 15 cases of respiratory diphtheria occurring in the United States between 1980 and 1983, 11 occurred in persons 20 years of age or older.^[27] Endemic diphtheria is present in the developing world and a cause for concern among travelers. A recent outbreak in the Russian Federation and other former states of the Soviet Union, primarily involving persons older than 14, highlights the need for up-to-date immunization in travelers.^[28]

Epidemiology.

Humans are the natural host for *Corynebacterium diphtheriae*. Person-to-person spread occurs through contact with respiratory secretions or diphtheritic skin lesions. A carrier state exists in which people who have either been immunized or previously infected harbor the organism and asymptotically transmit it to others. Evidence suggests that diphtheria can be transmitted through food or water, but this is not a major route of transmission.

Bacteriology and Pathogenesis.

C. diphtheriae is a gram-positive, club-shaped bacillus. On Gram's stain, the clustered bacteria have the characteristic "Chinese letter" configuration. The organisms grow on

standard media, but to avoid overgrowth of other oral flora, selective media (Löffler's culture medium or cysteine-tellurite agar) are suggested. The presence of a lysogenic bacteriophage in some *C. diphtheriae* organisms induces production of diphtheria toxin. The toxin is produced as a single molecule with two subunits, fragments A and B. Fragment B facilitates attachment to the cell membrane of host cells, and after attachment, fragment A enters the cell. Cell death results from largescale disruption of protein synthetic capabilities.

Clinical Presentation.

The most important manifestation of diphtheria is respiratory tract infection. Illness begins after an incubation period of about a week with nonspecific symptoms of malaise, fatigue, mild sore throat, and slight fever. The classic lesion is exudative pharyngitis progressing to a greenish-gray membrane that is difficult to dislodge. This membrane may spread over the posterior pharynx, tonsils, and uvula and down the respiratory tree to involve the larynx and trachea. Any one of these areas may be involved selectively, and the severity of illness is to some extent related to the area grossly involved.

In severe disease, swollen tissues may result in a bull neck appearance. Major complications include obstruction of the respiratory tract, which may result from direct parapharyngeal swelling or laryngeal involvement in young children, and sloughing of the tracheobronchial membrane in older patients. In addition to respiratory tract damage, toxin directly injures myocardial and neural tissue. Endocarditis occurs in some patients. Early signs in the first week of disease include ST-T wave depression and atrioventricular conduction abnormalities on the electrocardiogram. Congestive heart failure and cardiac enlargement may develop. Neurologic deficits usually begin with pharyngeal and cranial nerve paralysis. Cranial nerve paralysis may progress to bilateral motor paralysis, which generally resolves over a period of 3 to 6 months.^[59] In the tropics, cutaneous diphtheria is seen frequently. The skin lesions are not consistent in appearance and range from very superficial impetigo-like lesions to deep ulcers. In most cases of cutaneous disease, absorption of toxin is not great enough to cause the multisystem involvement seen in respiratory tract disease. The prevalence of skin lesions increases the overall likelihood of coming in contact with toxigenic *C. diphtheriae*.

Diagnosis.

Reliable isolation of the organism requires a selective medium and several days of culture. Treatment should be started as soon as the patient is evaluated and is guided by clinical manifestations.

Management.

Since the toxin and not the organism mediates life-threatening clinical manifestations of diphtheria per se, neutralization of absorbed toxin is crucial.^[59] A horse-derived antitoxin is available and should be administered as soon as the diagnosis is seriously considered. A 0.1 ml test dose of intradermal antitoxin diluted to a 1:1000 concentration

(with a saline control) is observed for 20 minutes. If no reaction occurs, full doses can be given intravenously. Antitoxin should be diluted to 1:20 in saline and given no faster than 1 ml/min. For mild cases, 20,000 units may be adequate, 40,000 units for moderate cases, and as much as 80,000 to 120,000 units for severely ill patients. Erythromycin or penicillin may be given to eradicate the carrier state, although their use has no effect on the clinical course of disease. Close observation is crucial to evaluate the need for respiratory support, especially in young children. Serial electrocardiograms and neurologic evaluation establish the onset of complications. If significant conduction abnormalities are present, continuous heart monitoring should be undertaken. Strict bed rest is recommended for all patients for 2 to 3 weeks.

Prevention.

Close contacts of patients with respiratory diphtheria should receive diphtheria vaccine if they have not received at least three doses previously or if 5 or more years have elapsed since the last dose.^[26] In addition, unimmunized or partially immunized contacts should receive either intramuscular benzathine penicillin (600,000 units if younger than 6 years old, 1.2 million units if older than 6 years old) or 7 to 10 days of

1594

erythromycin (40 mg/kg/day for children or 1 g/day for adults, in four divided doses). Antitoxin is not recommended for contacts. The most important way to prevent diphtheria in adults, however, is to ensure that all adults receive a booster dose of diphtheria-tetanus toxoid every 10 years.

Tetanus

Tetanus was recognized by the early Greeks and is still a cause of infant and adult mortality. Today, the mortality approaches 90% and 40% for untreated infants and adults, respectively.^[122] Tetanus toxoid immunization has drastically reduced the incidence of disease in populations with high coverage rates.

Epidemiology.

The bacterium and its spores are ubiquitous. Approximately 10% of people in the general population carry *Clostridium tetani* in fecal flora.^[108] Person-to-person spread is not important in this disease. Disease occurs when the organism is introduced into an environment suitable for its growth, specifically, wound sites with an anaerobic environment. In the United States, most of the 75 to 90 cases each year occur in persons over 50 years old.^[124] In the developing world, the vast majority of cases are in neonates as a result of umbilical stump infections.

Bacteriology and Pathophysiology.

C. tetani is a gram-positive, anaerobic, spore-forming rod. The spores are hardy and can occasionally survive boiling for short periods. After proliferating in an appropriate anaerobic environment, *C. tetani* releases the toxin, tetanospasmin, which, in generalized disease, reaches the spinal column and CNS by hematogenous spread. The toxin is taken up by inhibitory neurons, where it interferes with release of inhibitory neurotransmitters, resulting in disinhibition of motor groups. Disinhibition of the sympathetic nervous system neurons occurs through a similar mechanism. The result is muscular spasm of varying severity and signs of sympathetic nervous system hyperactivity, including tachycardia, sweating, arrhythmias, and high blood pressure.

Clinical Presentation.

A tetanus-prone wound precedes most adult disease, which may not be evident at the time of presentation. Localized tetanus, with spasm of a focal set of muscle groups, may occur and remain localized for weeks, then slowly resolve. This form of tetanus is much less common than the generalized form, which often begins with trismus, or spasm of the masticator muscle group. Gradual onset of spasm of other muscle groups usually involves the trunk and extremities. Since the posterior muscles are stronger during spasms, the victim exhibits lumbar lordosis, with the neck and legs extended and arms flexed at the elbows (opisthotonos). Spasms seem to be exacerbated by external stimuli, such as sudden sound or light. The primary danger is loss of ability to breathe, especially during prolonged spasms. Respiratory failure is the main cause of death. The clinical picture in neonatal tetanus is similar, but begins with restlessness and failure to nurse, with progression to tetany and sympathetic overactivity. There is no definitive laboratory test to confirm the diagnosis of tetanus, but the clinical picture is adequate in the majority of cases.

Management.

Emergency medical treatment of tetanus patients should include (1) excision of the wound, (2) administration of human tetanus IG (at least 500 units, ^[6] but a range of 500 to 3000 units is commonly used), and (3) administration of an antibiotic effective against *C. tetani*, such as penicillin or metronidazole.^[121] Depending on the severity of the disease, different levels of supportive care and sedation may be appropriate. Diazepam may be given to mildly affected patients for sedation. Patients should be evaluated carefully for dysphagia. If dysphagia is present or other respiratory difficulties arise, endotracheal intubation or a tracheostomy should be performed. With prolonged spasms, hypoxia and cyanosis may occur; mechanical ventilation with pharmacologic paralysis is appropriate. At the same time, attention must be given to fluid balance and nutrition. Enteral feeding by a nasogastric tube is the least invasive way to supply both. Beta-blockers have been suggested to relieve symptoms of autonomic overactivity, such as tachycardia and hypertension, but there is no proven benefit to their prophylactic use. Sources of sensory stimulation should be reduced when the spasms are uncontrolled.

Prevention.

Although rare cases of tetanus have occurred in previously immunized persons,^[102] immunization is considered at least 99.9% effective.^[26] Several vaccine formulations are now available in the United States. Children under 7 years old may receive either DPT or DT (diphtheria and tetanus toxoid only) vaccine. A third vaccine, Td, is manufactured for use in persons at least 7 years old and consists of tetanus toxoid and a smaller amount of diphtheria toxoid than is present in the pediatric vaccines. A reduced amount of diphtheria toxoid is used in the adult preparation, since both the amount of toxoid and increasing age were found to be associated with more severe reactions to vaccination. Adults who are unimmunized should be given a series of three doses (0.5 ml intramuscularly) of Td, with the second dose 4 to 8 weeks after the first, and the third dose 6 to 12 months after the second. A booster should be given every 10 years thereafter. All travelers should know their primary immunization and stay up to date with booster doses. From the standpoint of tetanus prevention, care of wounds is crucial. The tetanus-prone wound, contaminated with dirt or feces

1595

or caused by puncture, crush, avulsion, or frostbite, should be cleaned and debrided appropriately. Persons with tetanus-prone wounds should receive 250 to 500 units of human tetanus IG if their immunization history is unknown or their immunization series is incomplete. These persons should also receive a dose of Td and complete an immunization series. Persons fully immunized and given an appropriate booster before a tetanus-prone wound should not receive tetanus IG. If they have not received a booster within 5 years, however, they should get a dose of Td.^[3]

MAJOR PROTOZOAN INFECTIONS

Malaria

Malaria, or "ague" in previous centuries, is a major cause of childhood mortality in developing countries. Travelers who are not immune (i.e., most North Americans and Europeans) are at great risk for the disease.

Epidemiology.

The four major human malaria parasites, *Plasmodium falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*, are found in most tropical developing countries where the appropriate anopheline mosquito vector exists. The degree of endemicity in a specific region may be judged by the proportion of residents who have enlarged spleens. The degree varies from a hypoendemic area, in which less than 10% of children have enlarged spleens, to hyperendemic, in which more than 50% of children have enlarged spleens.

Persons are inoculated by sporozoites when a mosquito releases the parasite during a blood meal. Sporozoites rapidly invade liver cells, where they proliferate into multiple merozoites. After 1 to 2 weeks, merozoites rupture from hepatocytes and invade red blood cells. A proportion of *P. vivax* and *P. ovale* organisms may enter a dormant phase in the liver and cause recrudescence of disease months to years later. *P. falciparum* does not enter this dormant phase. After merozoites enter a red blood cell, they may undergo asexual proliferation (schizogony) to eventually form more merozoites (which may invade other red blood cells) or sexual differentiation to form gametocytes. Merozoites cause red blood cell lysis, whereas gametocytes must be ingested by mosquitoes to continue the parasite life cycle. Development of fertilized eggs in the mosquito to form infective sporozoites takes 10 to 14 days. Travelers may be infected and develop disease from one sporozoite; cases of malaria have been reported in individuals who presumably had contact only with mosquitoes that entered an aircraft in transit through endemic areas.

Pathogenesis and Clinical Manifestations.

Rupture of erythrocytes by asexual schizonts containing merozoites is associated with fever, nausea, and severe myalgias.^[127] Cerebral malaria and other evidence of organ dysfunction, such as renal failure in falciparum malaria, are presumably related to sludging in the microvasculature by poorly deformable red blood cells or erythrocytes with parasite-induced surface molecules that adhere to the endothelium. Anoxia of surrounding tissue results.^[127] Anemia induced by all *Plasmodium* species is secondary

to hemolysis and ineffective erythropoiesis.

Clinical manifestations of malaria may first be evident within 1 to 2 weeks after the victim enters an endemic area, or sooner if infected blood obtained by transfusion or use of shared needles is the source. Although there are no pathognomonic signs, many subjects report paroxysms of chills, followed by high fever and sweating. These may last several hours and recur every 2 to 3 days. Classic periodic attacks are often not observed in severe falciparum malaria, and fever may be constant. In addition, abdominal cramps and diarrhea may be presenting symptoms. Cerebral malaria, associated with high levels of parasitemia (usually more than 10% of red blood cells infected) is characterized by high fevers, confusion, and eventually coma and death.

Diagnosis.

Malaria can be definitively diagnosed only by the presence of malaria parasite-containing red blood cells. Prophylactic medications do not exclude the possibility of being infected. Thick and thin blood smears should be made and stained with Giemsa stain for microscopic inspection. Thin films are prepared in a standard manner. Thick films are prepared by spreading a drop of blood in a 1-cm-diameter circle. The blood is allowed to dry, red blood cells are lysed with water, and the slide is stained with Giemsa stain. Various intraerythrocytic forms (schizonts, trophozoites, merozoites) should be identified. Blood smears should be obtained on initial contact with the patient and every 12 hours until they show positive results. Speciation of malaria is important when falciparum infection is a possibility because this parasite may be resistant to chloroquine and cause lethal disease. Several assays for detection of malaria antigens in blood (e.g., "dipstick" assays) may be useful in situations where expertise in microscopic detection of the parasite is not readily available.

Management

PLASMODIUM FALCIPARUM.

A major issue involved in treating falciparum malaria is sensitivity of the parasite to chloroquine.^[107] Chloroquine-resistant strains of *P. falciparum* are found in all endemic areas of the world except Central America west of the Panama Canal, islands in the Caribbean Sea, and the Middle East, including Egypt. Since no laboratory test can distinguish between sensitive and resistant strains, all persons diagnosed as having *P. falciparum* acquired outside

these areas should be treated as having chloroquine-resistant malaria. There are multiple useful drug regimens. A commonly used regimen for adults is quinine sulfate, 600 mg orally 3 times per day for 7 days, plus tetracycline, 250 mg every 6 hours for 7 days. The dose of quinine salt for children is 10 mg/kg body weight. Pregnant women and children under 8 years should not be given tetracycline. In some parts of the world,

mefloquine (Lariam) at a single dose of 1250 mg (or 15 mg base per kg) is used (the drug should not be administered if quinine has been given in the previous 12 hours). In persons believed to have chloroquine-sensitive *P. falciparum* infection, chloroquine phosphate, 1000 mg initially, should be followed by 500 mg 6 hours later and 500 mg/day for an additional 2 days. In persons with severe and complicated *P. falciparum* infection, such as those with cerebral malaria, IV quinine should be used. For quinine a loading dose of 16.7 mg base (suspended in isotonic saline) per kilogram of body weight is given intravenously over 4 hours. This is followed by 8.3 mg base per kg every 8 hours until oral medications can be taken and a full 3- or 7-day course (if infection was acquired in Southeast Asia) is completed. The loading dose is decreased to 8.3 mg/kg if mefloquine or quinine has been taken within the previous 12 hours. If IV quinine is unavailable, quinidine gluconate may be substituted. The loading dose is 10 mg/kg given in saline over 1 hour followed by continuous infusion of 0.02 mg/kg/min for up to 3 days. The patient should be switched to oral quinine as soon as possible. These medications should be administered in an intensive care unit with continuous cardiac monitoring. Exchange transfusion to lower the level of parasitemia may also be useful in this setting. Corticosteroids are contraindicated, since controlled studies show that mortality is higher when they are given.^[136]

PLASMODIUM VIVAX, P. OVALE, AND P. MALARIAE.

These infections are treated as described for chloroquine-sensitive *P. falciparum*. Since *P. vivax* and *P. ovale* may have dormant hepatic forms, primaquine phosphate, 26.3 mg daily for 14 days, should follow administration of chloroquine to eliminate extraerythrocytic hypnozoites. Individuals given primaquine should first be screened for the presence of glucose-6-phosphate dehydrogenase (G-6-PD) deficiency, since this drug may cause oxidant-induced hemolysis. If G-6-PD deficiency is severe, primaquine should not be administered and the patient should be monitored periodically for symptoms of malaria. Individuals with mild G-6-PD deficiency may be given primaquine under close supervision because hemolysis is self-limited.

Proper precautions include avoidance of contact with mosquitoes through the use of nets, sprays, and long-sleeved clothing. Travelers to endemic areas should take prophylactic medications^[18] (see [Chapter 65](#)).

African Trypanosomiasis

Trypanosoma brucei rhodesiense and *T. brucei gambiense* have provided remarkable insights into the importance of antigenic variation as a strategy used by parasites to avoid the immune response.^[135] *T. brucei gambiense* causes African sleeping sickness, and *T. brucei rhodesiense* causes an acute disease that may end in heart failure. The parasites are transmitted to humans by tsetse flies (*Glossina* species) in sub-Saharan Africa. Metacyclic promastigotes are injected into the bloodstream through the saliva of the biting tsetse fly and divide into long slender forms in the bloodstream. These eventually differentiate into short stumpy forms, which are taken up in the blood meal of the tsetse. Once in the fly, the parasite differentiates into procyclic forms. It takes approximately 3 weeks for the protozoa to develop into infective metacyclics within the

tsetse fly.

Clinical Manifestations.

In nonimmune individuals the initial sign of infection is a nodule at the site of the tsetse fly bite. This lesion becomes erythematous and painful over a period of 1 week and recedes after several days. Dissemination of the trypanosome throughout the body causes clinical symptoms, notably fever, headache, and severe malaise. On physical examination, enlarged supraclavicular and posterior cervical lymph nodes are noted. This phase of illness lasts several days and is followed by an asymptomatic period of several weeks. The acute phase may then recur. In the case of *T. brucei gambiense* infection, symptoms are less severe and evolve into a syndrome characterized by behavioral changes and chronic somnolence. *T. brucei rhodesiense* infections cause severe anemia, frequent episodes of fever, and eventual heart failure and severe CNS involvement.

Diagnosis.

Definitive diagnosis depends on identification of parasites in the blood, lymphatics, or CSF. Thick blood smears and buffy coat preparations should be stained with Giemsa stain and examined for the presence of trypanosomes. The CSF should be subjected to centrifugation and the sediment examined for parasites. Associated laboratory abnormalities include anemia, monocytosis, and elevated serum and CSF IgM levels.^[45]

Management.

Suramin* should be used for treatment of early *T. brucei rhodesiense* infection, although the drug may cause proteinuria.^[39] A test dose of 100 mg intravenously is first given to detect possible idiosyncratic reactions. If tolerated, 1 g should be given on the initial day of treatment and 3, 7, 14, and 21 days later. If CNS involvement is diagnosed or strongly suspected (CSF

*Available in the United States from the Parasitic Diseases Division of the CDC.

lymphocytosis and elevated IgM), melarsoprol (available from the CDC) should also be administered.^[39] This drug is given at an initial dose of 1.5 mg/kg of body weight, with gradually increasing doses (e.g., increase every 48 hours to 3.6 mg/kg in 2 weeks). After a week with no drug given, additional injections of 3.6 mg/kg are given every other day 3 times. This arsenical compound is toxic, causing encephalopathy and exfoliative dermatitis, and should be used only in a controlled hospital setting. For early *T. brucei gambiense* infection, pentamidine (4 mg/kg body weight intramuscularly, up to 300 mg/kg given over 7 days) is the treatment of choice. Eflornithine, 100 mg/kg every 6 hours for 14 days, should be used for more advanced cases of this infection.

South American Trypanosomiasis (Chagas' Diseases)

T. cruzi is transmitted to humans by triatomids that live in the cracks of mud-built homes in Central and Latin America. These insects are particularly common in areas of Brazil, Venezuela, and Argentina with poor socioeconomic development. The infection has been reported as far north as the southern United States. Affected individuals generally do not recall initial contact with the insects, during which time the protozoan organisms deposited on broken skin or mucous membranes in triatomid feces multiply within local macrophages. The macrophages rupture and elicit an inflammatory reaction characterized as a nodule with slightly painful satellite nodules or draining lymph nodes. A symptomatic phase, characterized by fever and diffuse lymph node enlargement, develops subsequently. Hepatosplenomegaly may also occur. In severe cases, acute myocarditis, pericarditis, or endocarditis is seen. After several months, the acute phase resolves and chronic disease appears, characterized by cardiomyopathy, megaesophagus, or megacolon.^[78] It is rare for the traveler to develop these signs and symptoms. Diagnosis during the acute phase may be made by demonstration of parasites in leukocytes in Giemsa-stained blood smears. Amastigotes of *T. cruzi* may also be present in biopsy specimens of lymph nodes or muscle. Elevated IgM antibody titers to *T. cruzi* (performed by the CDC) also support the diagnosis. In the chronic phases of Chagas' disease, the clinical findings of cardiomyopathy, megaesophagus, or megacolon, in concert with isolation of *T. cruzi* from blood, support the diagnosis. To detect trypanosomes in blood, uninfected triatomids are permitted to feed on the patient's forearm for 30 minutes. The insects are then kept for 30 days and the intestinal contents of the insects examined for *T. cruzi*. If negative, the examination may be repeated after 60 days. This test is positive in about 50% of cases. Serologic tests, including complement fixation for anti-*T. cruzi* antibodies (done at the CDC), are also

Figure 66-1 Old world leishmaniasis. (Courtesy Richard Kaplan, MD.)

useful but may be positive in long-term residents of endemic areas. Acute Chagas' disease is treated with nifurtimox, 8 to 10 mg/kg orally per day in four divided doses for 120 days. The drug is available from the CDC.

Leishmaniasis

Humans may be infected by *Leishmania* species that cause skin, mucocutaneous, or visceral disease.^[146] These intracellular parasites are transmitted by phlebotomine sandflies. Various forms of the infection occur throughout Latin and Central America, Africa, the Middle East, and Asia ([Figure 66-1](#)). Cutaneous lesions caused by *L. tropica* and *L. tropica major* are referred to as "Oriental sores" in Asia and the Middle East. In Central and South America, *L. mexicana* and *L. braziliensis* cause skin lesions characterized in the chronic phase as nonhealing ulcers that frequently become

secondarily infected by bacteria. *Espundia*, or mucocutaneous leishmaniasis caused by *L. braziliensis*, begins as a single nodule and eventually involves the oropharyngeal or nasal mucosa, where it causes severe destruction. This disease occurs primarily in residents of the Amazon basin in Brazil. *Kala-azar*, or visceral leishmaniasis, is caused by *L. donovani* in Africa and Asia. Affected individuals generally do not recall an initial skin lesion. Several months after inoculation, fever, abdominal discomfort, and weakness develop and become progressively more severe. Nausea and vomiting are protracted, the skin becomes dry and dark, and abdominal distention with hepatosplenomegaly eventually appears. This disease is rare in travelers and nonresidents of endemic areas.

MAJOR HELMINTHIC INFECTIONS

Worm infections are common among travelers to developing countries, especially among persons who spend time in rural areas. However, unlike many viral or protozoan infections, helminths rarely cause life-threatening disease and infested persons are often asymptomatic.

1598

Schistosomiasis

Three major species of schistosomes infect humans: *Schistosoma mansoni*, *S. haematobium*, and *S. japonicum*. *S. mansoni* infection occurs in South America and Africa. *S. haematobium* infection occurs primarily in Africa, especially Egypt and East Africa. *S. japonicum* infection is present exclusively in the Far East. Schistosomiasis is transmitted by freshwater snails. These snails release cercariae that penetrate the skin of humans. The cercariae rapidly transform into schistosomulae, which migrate to the lungs and eventually the portal (in the case of *S. mansoni* and *S. japonicum*) or vesical (in the case of *S. haematobium*) venous system to differentiate into adult worms. Fecund female worms release eggs, which may be passed in feces or urine. Miracidia released from this stage may then infect snails in water used for bathing, washing clothes, or other communal activities.

Signs and symptoms of infection vary among the three schistosome species. The initial presentation of *S. mansoni* infection reported in Puerto Rico includes fever, anorexia, weight loss, and abdominal pain.^[65] Hepatomegaly and splenomegaly were observed in 33% and 20% of subjects, respectively. This unusual symptom complex, which occurs in individuals with heavy infection, has been referred to as Katayama fever and appears 18 to 60 days after exposure. Travelers with light or moderate exposure, however, usually have no specific signs or only mild local dermatitis associated with contact with cercariae, the infective stage of the parasite released by snails. In persons with established infections the prevalence of clinical manifestations is low. Most individuals have no signs specifically attributable to *S. mansoni* infection. Hepatomegaly or splenomegaly, attributable to portal hypertension after granulomatous reactions to eggs deposited in the liver, occurs in 15% of subjects.^[125] Eggs may also embolize to the lungs and induce granulomatous lesions and cor pulmonale. Those at greatest risk are persons who have the heaviest intensity of infection as judged by fecal egg counts. These complications may ultimately result in esophageal and gastrointestinal varices, which cause acute blood loss. The manifestations of schistosomiasis japonicum are similar to schistosomiasis mansoni, except that Katayama fever appears to be more

frequent. In addition, there is a unique manifestation of *S. japonicum* infection attributable to embolization of eggs to the brain. Generalized or Jacksonian seizures are the major signs of cerebral schistosomiasis. Since *S. haematobium* adult worms inhabit the venous system of the genitourinary tract, the signs and symptoms of this helminth infection are primarily secondary to granulomatous reactions to eggs present in the ureters and bladder wall. Dysuria and hematuria have been reported in many individuals who reside in endemic areas. The frequency and severity of hematuria and dysuria and associated complications (such as calcification of the bladder and lower ureters and hydronephrosis) correlate directly with the intensity of infection, as judged by urinary egg output. It should be stressed that these complications are unusual in the traveler who spends little time in freshwater in endemic areas. ^[137]

All these species of schistosome infections are diagnosed by identification of eggs in urine, feces, or tissue sections. In the cases of *S. mansoni* and *S. japonicum*, microscopic inspection of feces by the Kato or formolether methods is most widely available in hospital laboratories. ^[105] *S. haematobium* eggs may be seen in urinary sediment or by more sensitive filtration techniques. ^[105] Treatment of all three species of schistosome infections is with praziquantel (40 mg/kg body weight in two divided doses for *S. haematobium* and *S. mansoni*, 60 mg/kg for *S. japonicum*). To avoid infection, travelers should be advised against swimming in freshwater lakes and rivers in endemic areas.

Filariases

Three major types of human filariasis exist. Infections caused by *Onchocerca volvulus* are manifest primarily as skin and eye disease. *Brugia malayi* and *Wuchereria bancrofti* cause lymphatic filariasis. Loa loa infection may cause skin disease. Each of these is described separately, since their ecologies and manifestations are distinctive.

Onchocerciasis.

O. volvulus is transmitted to humans by *Simulium* species of blackflies in Central America and West and Central Africa. Infective, or third-stage, larvae eventually develop into adult worms contained in deep subcutaneous nodules that are asymptomatic and may be palpable. Microfilariae are released from adult female worms and cause dermatitis as they migrate through the skin. In Central and West Africa, the organisms have a propensity to invade the eye (especially the anterior chamber and cornea), where they cause blindness. Diagnosis is based on prolonged residence in an endemic area (e.g., Peace Corps volunteers) and parasitologic identification in skin snips or slitlamp examination of the eye. ^[109]

Lymphatic Filariasis.

B. malayi and *W. bancrofti* are transmitted by mosquitoes. Infective larvae eventually develop into lymphatic-dwelling adult worms, which release microfilariae into the bloodstream. Although chronic infection and recurrent exposure are associated with a wide variety of clinical manifestations, including tropical pulmonary eosinophilia, acute lymphangitis, and elephantiasis, these manifestations are rare in nonresidents of

endemic areas.^[100] The only definitive diagnostic test is identification of parasites in the bloodstream. Since nonresidents and many residents who are infected may not have detectable parasitemia, other laboratory studies (eosinophilia, elevated serum IgE

1599

level) must be used as aids in diagnosis. Diethylcarbamazine (cumulative dose of 72 mg/kg body weight given over 2 weeks) is the treatment.^[62]

Loiasis.

Loa loa is transmitted to humans by the bites of tabanid flies that live along river edges in Central and West Africa. Microfilariae migrate in the bloodstream, whereas adult worms migrate in cutaneous tissues. The major disease manifestation is calabar swellings, which are characterized as egg-sized or smaller raised lesions, predominantly over the extremities, that are tender and surrounded by edematous skin. They may migrate and last several days. Their pathogenesis may be related to migration of adult worms or release of antigens that elicit immunologic hypersensitivity reactions. Treatment is with diethylcarbamazine at a dose of 9 mg/kg body weight/day for 3 weeks.^[62] Retreatment is occasionally required.

Intestinal Helminth Infections

Ascariasis.

Approximately 25% of the world's population is infected with *Ascaris lumbricoides*.^[79] Although this nematode contributes significantly to morbidity in children with poor nutrition, it generally does not cause significant health problems for the traveler. The helminth is transmitted by eggs contained in ingested pieces of soil, such as may be found on vegetables grown in many countries with poor hygienic conditions. It is not limited to tropical climates and occurs in North America and Europe. Ingested eggs enter the small intestine. Larvae leave the eggshell to penetrate the mucosa and eventually enter the bloodstream and lymphatics. Between 1 and 5 days after infection, they enter the liver and, at about 14 days, the lungs. The larvae then rupture through the alveoli, ascend the trachea, and return to the intestine on being swallowed. In the small intestine, adult males and females develop into macroscopic worms (12 to 25 cm long). Eggs passed via feces continue the life cycle. *Ascaris* infection is often totally asymptomatic, but several syndromes are associated with tissue and intestinal phases of infection. Persons who are recurrently exposed may develop pulmonary ascariasis, characterized by cough, wheezing, eosinophilia, and fleeting pulmonary infiltrates on chest x-ray examination.^[104] Children may suffer from intestinal or biliary tract obstruction if they repeatedly ingest eggs. Intestinal symptoms are seen mainly in persons with heavy infection, an uncommon situation in the traveler.

Diagnosis of ascariasis may be made by identification of one of several parasite stages. Adult ascarids occasionally migrate from the mouth or anus. *Ascaris* larvae may rarely

be observed in sputum or gastric washings. The most common means of diagnosis is identification of eggs in feces. Eggs are ovoid, 35 to 70 μm in diameter, and consist of an outer white shell and brownish ovum internally. The eggs are not produced until approximately 9 weeks after infection. Intestinal ascariasis is treated with mebendazole, 100 mg twice daily for 3 days. An alternative regimen that avoids the use of benzimidazoles (e.g., for treatment of pregnant women) is pyrantel pamoate (11 mg/kg body weight to a maximum of 1 g).

Hookworm.

Ancylostoma duodenale and *Necator americanus* infections occur most commonly in the tropics but also in temperate climates where sanitation is poor.^[91] Hookworm is second only to *Ascaris* in terms of the number of people infected. Humans are infected percutaneously by third-stage larvae in the soil. The larvae enter the bloodstream, pass to the lungs, and rupture the alveolar lining to eventually ascend the trachea and descend the esophagus to differentiate into adult worms. These stages contain cutting plates on the anterior end and feed on host blood obtained through their attachment sites in the upper small intestine. It has been estimated that each *N. americanus* causes 0.03 ml of blood loss per day,^[76] whereas *A. duodenale* consumes 0.26 ml per day. Iron deficiency anemia, especially in persons with low iron intake, is the major clinical manifestation of hookworm infection.^[50] The diagnosis may be made by identification of hookworm eggs in feces. The eggs are round, 40 to 60 μm in diameter, and have a "smoother" shell than do *Ascaris* eggs. Although multiple drugs are effective in treatment, mebendazole (300 mg for the first dose, followed by 100 mg twice daily for 2 days) is most readily available. Supplemental iron should be given to persons when necessary. Infection with hookworm is rare in the traveler from a developed country.

Strongyloidiasis.

Strongyloides stercoralis infection occurs in tropical and temperate regions. The infection is initiated by contact with soil containing infective third-stage larvae. The helminth follows a route within the host similar to that described for hookworms. In addition, there is an autoinfection cycle in which larvae released in the intestine may penetrate the mucosa directly and then migrate through the liver and lungs. This occurs only in immuno-compromised individuals.^[122]

Many persons with *S. stercoralis* infection are asymptomatic. Some persons, however, have cutaneous or intestinal manifestations. The former are urticarial lesions around the buttocks and waist that last 1 to 2 days.^[59] These are secondary to penetration of larvae present in the feces. Other symptoms include indigestion, abdominal cramps, and diarrhea. Diagnosis is made by identification of larvae in fresh stools or gastrointestinal washings. Rhabditiform larvae with a length of 250 μm and a width of 10 to 20 μm are most commonly observed, although filariform larvae (500 μm long) may also be present. Treatment is with thiabendazole at a dose of 25 mg/kg body weight twice daily for 2 days.

Enterobiasis.

Enterobiasis, or pinworm infection, exists in all parts of the world. Eggs are passed from female worms in the colon. Infection is transmitted by ingestion of *Enterobius vermicularis* eggs, which develop into gravid adult female worms in the large bowel. The infection is especially common in crowded settings where sanitation is poor. The diagnosis may be made by identification of adult worms migrating along the perianal area or by eggs deposited in the same area. Eggs are detected by applying a piece of sticky cellophane tape to the area and inspecting it microscopically.^[82] Treatment is with a single 100-mg dose of mebendazole.

Chapter 67 - Natural Disaster Management

Eric K. Noji

Throughout history, natural disasters have exacted a heavy toll of death and suffering ([Table 67-1](#) and [Table 67-2](#)). During the past 25 years they have claimed more than 3 million lives worldwide, have adversely affected the lives of at least 800 million more people, and have resulted in property damage exceeding \$50 billion.^{[73] [80] [103] [117]} Recent natural catastrophes have included earthquakes in Los Angeles (1994)^[67] and Kobe, Japan (1995),^{[88] [116] [148] [149]} a series of devastating hurricanes in the Caribbean in 1998 (including hurricanes Mitch and Georges), severe flooding in the central United States in 1993 and California in 1998,^{[33] [34] [35] [39]} tornadoes in Oklahoma and Texas (1999), global adverse weather conditions related to the El Niño phenomenon in 1997 and 1998, and the volcanic eruption of Mt. Soufriere on the island of Montserrat (1997).

The future appears to be even more frightening. Increasing population density in floodplains and in earthquake- and hurricane-prone areas points to the probability of future catastrophic natural disasters with millions of casualties.^{[75] [154] [163]} Many natural disasters of large magnitude occur in remote areas, far from towns and hospitals. The roads frequently become impassable, bridges collapse, and inclement weather adds to the difficulties. The more remote the area, the longer it takes for external assistance to arrive, and the more the community will have to rely on its own resources, at least for the first several hours, if not days. Friends, neighbors, and relatives conduct the initial search and rescue of victims, provide basic first aid, and transport injured victims to the nearest health care facilities.

Good disaster management must link data collection and analysis to an immediate decision-making process.^[15] The overall objective of disaster management from a public health perspective is to assess the needs of disaster-affected populations, match available resources to those needs, prevent further adverse health effects, implement disease control strategies for well-defined problems, evaluate the effectiveness of disaster relief programs, and improve contingency plans for various types of future disasters.^[57]

The effects of disasters on the health of populations are quantifiable.^[39] Common

patterns of morbidity and mortality follow certain disasters.^[162] Better epidemiologic knowledge of the causes of death and types of injuries and illnesses caused by natural disasters is essential to determine the relief supplies, equipment, and personnel needed to respond effectively.^{[2] [15] [72]} In addition, results of disaster research provide informed advice about the probable health effects of future disasters, establish priorities for action by emergency medical services, and emphasize the need for accurate information as the basis for relief management decisions.^{[15] [63]}

Proper planning and execution of disaster medical aid programs require knowledge of the types of disasters and resulting morbidity, mortality, and medical care needs. Emergency responders should be experts on how to handle the type of disaster most prevalent in their own communities because each type of disaster is characterized by different morbidity and mortality patterns and has different health care requirements.^[15] ^[113] For example, hospitals along the Gulf Coast of the United States should plan for hurricanes, whereas those in California should plan for earthquakes.^{[43] [72] [85]}

In addition, specific types of medical and health problems tend to occur at different times after a natural disaster's impact. With earthquakes, for example, the problem of severe injuries that require immediate trauma care must be handled mainly at the time and place of impact. The problem of increased risk of disease transmission can be handled later, however, because it takes longer to develop, and the greatest danger occurs with crowding and poor sanitation. Effective emergency medical response depends on anticipating the different medical and health problems and delivering the appropriate interventions when needed most.^[140]

NATURE OF DISASTER

The World Health Organization (WHO) defines *disaster* as a sudden ecologic phenomenon of sufficient magnitude to require external assistance. ^[124] ^[165] At the community level, this can be defined operationally as any community emergency that seriously affects people's lives and property and that exceeds the community's capacity to respond effectively. ^[83]

The essence of a disaster is substantial environmental damage, which may be accompanied by large numbers of casualties. This chapter refers to limited incidents creating relatively small numbers of casualties and slight environmental disturbance as *multiple casualty incidents*. The term *disaster* is reserved for incidents that cause great disruption of the physical and social environments and that require extraordinary resources and special medical care, even in the absence of mass casualties.

TABLE 67-1 -- Mortality Estimates by Type of Disaster

DISASTER TYPE	DEATHS			
	1960–1969	1970–1979	1980–1989	1990–1999
Floods	28,700	46,800	38,598	103,870
Cyclones/hurricanes	107,500	343,600	14,482	201,790
Earthquakes	52,500	389,700	53,740	98,678
Other disasters			1,011,777	2,686
TOTAL			1,119,860	407,204

TABLE 67-2 -- Selected Natural Disasters of the Twentieth Century*

YEAR	EVENT	LOCATION	APPROXIMATE DEATH TOLL
------	-------	----------	------------------------

1900	Hurricane	USA	6,000
1902	Volcanic eruption	Martinique	29,000
1902	Volcanic eruption	Guatemala	6,000
1906	Typhoon	Hong Kong	10,000
1906	Earthquake	Taiwan	6,000
1906	Earthquake/fire	USA	1,500
1908	Earthquake	Italy	75,000
1911	Volcanic eruption	Philippines	1,300
1915	Earthquake	Italy	30,000
1916	Landslide	Italy, Austria	10,000
1919	Volcanic eruption	Indonesia	5,200
1920	Earthquake/landslide	China	200,000
1923	Earthquake/fire	Japan	143,000
1928	Hurricane/flood	USA	2,000
1930	Volcanic eruption	Indonesia	1,400
1932	Earthquake	China	70,000
1933	Tsunami	Japan	3,000
1935	Earthquake	India	60,000
1938	Hurricane	USA	600
1939	Earthquake/tsunami	Chile	30,000
1945	Flood/landslide	Japan	1,200
1946	Tsunami	Japan	1,400
1948	Earthquake	USSR	100,000
1949	Flood	China	57,000
1949	Earthquake/landslide	USSR	20,000
1951	Volcanic eruption	Papua New Guinea	2,900
1953	Flood	North Sea coast	1,800
1954	Landslide	Austria	200
1954	Flood	China	40,000
1959	Typhoon	Japan	4,600
1960	Earthquake	Morocco	12,000
1961	Typhoon	Hong Kong	400

1962	Landslide	Peru	5,000
1962	Earthquake	Iran	12,000
1963	Tropical cyclone	Bangladesh	22,000
1963	Volcanic eruption	Indonesia	1,200
1963	Landslide	Italy	2,000
1965	Tropical cyclone	Bangladesh	17,000
1965	Tropical cyclone	Bangladesh	30,000
1965	Tropical cyclone	Bangladesh	10,000
1968	Earthquake	Iran	12,000
1970	Earthquake/landslide	Peru	70,000
1970	Tropical cyclone	Bangladesh	300,000
1971	Tropical cyclone	India	25,000
1972	Earthquake	Nicaragua	6,000
1976	Earthquake	China	250,000
1976	Earthquake	Guatemala	24,000
1976	Earthquake	Italy	900
1977	Tropical cyclone	India	20,000
1978	Earthquake	Iran	25,000
1980	Earthquake	Italy	1,300
1982	Volcanic eruption	Mexico	1,700
1985	Tropical cyclone	Bangladesh	10,000
1985	Earthquake	Mexico	10,000
1985	Volcanic eruption	Columbia	22,000
1988	Hurricane Gilbert	Caribbean	343
1988	Earthquake	Armenia SSR	25,000
1989	Hurricane Hugo	Caribbean	56
1990	Earthquake	Iran	40,000
1990	Earthquake	Philippines	2,000
1991	Tropical cyclone	Bangladesh	140,000
1991	Volcanic eruption	Philippines	800
1991	Typhoon/flood	Philippines	6,000
1991	Flood	China	1,500

1992	Hurricane Andrew	USA	52
1993	Earthquake	India	10,000
1995	Earthquake	Japan	6,000
1998	Hurricane Mitch	Central America	10,000

Data from Office of US Foreign Disaster Assistance: Disaster history: significant data on major disasters worldwide, 1900-Present, Washington, DC, 1999, Agency for International Development; and National Geographic Society: Nature on the rampage, our violent earth, Washington, DC, 1987, National Geographic Society.

*Disasters selected to represent global vulnerability to rapid-onset disasters.

True disasters affect a community in numerous ways. Roads, telephone lines, and other transportation and communication links are often destroyed. Public utilities and energy supplies may be disrupted. Substantial numbers of victims may be rendered homeless. Portions of the community's industrial or economic base may be destroyed or damaged. Casualties may require medical care, and damage to food sources and utilities may create public health threats.

PAST PROBLEMS IN NATURAL DISASTER MANAGEMENT

In ancient times, little mitigation was possible against the effects of disaster. Today, communications inform us rapidly of disasters and allow us to provide effective medical aid to victims. This requires adequate planning and brisk execution. Medical aid in many previous disasters has been well intentioned but poorly organized, with limited benefits.^[57] ^[124]

Health decisions made during emergencies are often based on insufficient, nonexistent, or even false information, which results in inappropriate, insufficient, or unnecessary health aid, waste of health resources, or countereffective measures.^[140] For example, large amounts of useless drugs and other consumable supplies are frequently sent to a disaster site. After the 1976 earthquake in Guatemala, 100 tons of unsorted medicines were airlifted to the country from foreign donors.^[48] ^[50] Of these supplies, 90% were of no value because they consisted of medications that had expired, were already opened, or carried labels written in foreign languages. A similar situation occurred after the 1988 Armenian earthquake, when international relief operations sent at least 5000 tons of drugs and consumable medical supplies. Because of the difficulties with identification and sorting, only 30% of the drugs were immediately usable by the health workers in Armenia; 11% were useless, and 8% had expired. Ultimately, 20% of all the drugs provided by international aid had to be destroyed.^[4] Other examples of inappropriate aid include sending mobile hospitals and teams of specialized trauma or emergency medicine specialists that arrive much too late and sending unprepared medical volunteers when nonmedical relief workers (e.g., sanitation engineers) would be more appropriate. The arrival of unprepared and inexperienced foreign personnel may damage the relief effort by tying up communication, transportation, and housing. These problems are all compounded in the vacuum created by the disaster, including the lack of communication, transportation, local supplies and support, and a decision-making structure. Because these relief operations are often conducted under the watchful eye of the media, medical relief efforts are often pejoratively called *the second disaster*.^[89] ^[114]

INFORMATION MANAGEMENT SYSTEMS FOR DISASTER RESPONSE

Over the past several years, efforts have been made to develop rapid and valid disaster damage assessment techniques.^{[152] [166]} These techniques must be able to define quickly the overall effects of the disaster impact, the nature and extent of the health problems, groups in the population at particular risk for adverse health events, specific health care needs of the survivors, local resources to cope with the event, and the extent and effectiveness of the response to the disaster by local authorities.^{[83] [145]} Guha-Sapir and Lechat^{[71] [72] [73]} have developed indicators for needs assessment in earthquakes ("quick and dirty" surveys), highlighting simplicity, speed of use, and operational feasibility. The techniques employed (e.g., systematic surveys, simple reporting systems) are methodologically straightforward. With suitable personnel and transport, estimates of relief needs can be quickly obtained.^[32] Problems may arise, however, with the interpretation of data, particularly incomplete data, and in developing countries in which predisaster health and nutritional levels are unknown.

The ultimate goal of surveillance is to prevent or reduce the adverse health consequences of the disaster itself, as well as to optimize the decision-making process associated with management of the relief effort. These epidemiologic objectives can be simply defined as the *surveillance cycle*: the collection, analysis, and response to data.^[57] The surveillance cycle must be repeated many times: immediately, with rapid assessments of problems using the most rudimentary data collection techniques; then short-term assessments involving the establishment of simple but reliable sources of data; and subsequently, ongoing surveillance to identify continuing problems and monitor response.

Field surveillance methods vary greatly by disaster setting and by the personnel and time available. Early field surveys must be simple and provide immediate answers that will directly prevent loss of life or injury. Subsequently, surveys can address issues such as the availability of medical care, assessment of the need for specific interventions, and epidemic control (a rumor clearinghouse), each of which demands more careful investigation. Surveillance must determine whether the effort is having a tangible impact on the population, or whether new strategies are needed.^[147] Surveillance becomes an iterative, cycling process in which simple health outcomes are constantly monitored and interventions assessed for efficacy.

Finally, linking postdisaster information to a decision-making process is important.^[72] In the rapid evolution of a disaster relief program, major decisions regarding relief are made early, hastily, and often irreversibly, so reliable early data to assist in making these decisions are vital. Organized data collection in

disaster situations can greatly improve decision making. Adaptable questionnaires can assist in an efficient data collection operation.

Operational decisions depend on the phase of the disaster. In the early phase of relief, basic needs of water, food, clothing, shelter, and medical care must be met, after which the long-term process of rebuilding proceeds. Relief aid can often be squandered by over-reacting to minor problems when excitement is great, needs are extensive, and scrutiny by the media is omnipresent.^[140] Because everyone in the disaster area has needs and experiences loss, the challenge of early assessment is to decide where initial interventions will prevent the greatest loss of life or severe morbidity. The postimpact phase requires information on long-term rehabilitation and restoration of health services. Epidemiologic assessment, prioritization of needs, and ordering an appropriate response can have a major impact on the community's ability to return to normalcy in both the short and longer term.

HEALTH CARE NEEDS IN SPECIFIC NATURAL DISASTERS

Natural hazards that can cause substantial property damage, economic dislocation, and medical problems include earthquakes and associated phenomena, volcanic eruptions, and extreme weather incidents, such as heat waves and blizzards. Accounts of morbidity and mortality recorded after previous disasters can predict the medical care needs of future disaster victims and provide a foundation for disaster response planning.

Floods

Floods are the most common natural disasters. They affect more people worldwide and cause greater mortality than any other type of natural disaster.^{[73] [118] [163]} They occur in almost every country, but 70% of all flood deaths occur in India and Bangladesh^[103] ([Figure 67-1](#)). In the United States, floods cause more deaths than any other natural disaster, with most fatalities resulting from flash floods.^[60]

Fast-flowing water carrying debris such as boulders and fallen trees accounts for the primary flood-related injuries and deaths. The main cause of death from floods is drowning, followed by various combinations of trauma, drowning, and hypothermia with or without submersion.^[11] Persons submerged in cold water for up to about 40 minutes have been successfully resuscitated with 100% recovery of neurologic function.^[118] Unfortunately, such resuscitations from clinical death require technologically advanced measures, which may not be available for days after a flood, even in a highly developed country such as the United States.

Among flood survivors, the proportion requiring emergency medical care is reported to vary between 0.2% and 2%.^{[139] [146]} Most injuries requiring urgent medical

Figure 67-1 During summer 1988, monsoon rains resulted in the most severe flooding ever recorded in Bangladesh. Water covered three fourths of the land area of Bangladesh, displacing up to 40 million persons from their homes. (Courtesy Centers for Disease Control and Prevention and US Public Health Service.)

attention are minor and include lacerations, skin rashes, and ulcers.^[124] However, flood-associated lacerations are frequently contaminated, so primary wound closure should be done with caution. Primary closure without careful evaluation of the wound

almost always requires reopening the wound and additional treatment within 24 to 48 hours.^[11]

Increased incidence of snakebites was reported after floods in India and the Philippines.^[158] In India, most snakebites were by cobras that had been driven by rising water to seek higher ground near towns and villages.

For some floods, substantial numbers of casualties caused by fire have been documented.^[118] Fast-flowing water can break oil or gasoline storage tanks. If the film of oil is ignited, the fire may spread to buildings on land.

From a public health viewpoint, floods may disrupt water purification and sewage disposal systems, cause toxic waste sites to overflow, or dislodge chemical containers stored above ground.^[51] In addition, makeshift evacuation centers with insufficient sanitary facilities may become substantially overcrowded.^[125] The combination of these events may contribute to increased exposure to highly toxic biologic and chemical agents. Examples include the potential for waterborne disease transmission of such agents as enterotoxigenic *Escherichia coli*, *Shigella*, *Salmonella*, and hepatitis A virus.^[139] The risk of transmission of malaria and yellow fever may be increased because of enhanced vector-breeding conditions.^[124] In 1973 Ussher^[158] reported that the most serious problems encountered after a flood in the Philippines were viral upper respiratory tract infections, which were probably caused by crowded conditions in temporary shelters.

Despite the potential for communicable diseases to follow floods, mass vaccination programs are counter-productive for a variety of reasons. They not only divert

1607

Figure 67-2 Satellite image of a hurricane and a cyclone striking Mexico simultaneously. (Courtesy World Health Organization and Office of the UN Disaster Relief Coordinator.)

limited personnel and resources from other critical relief tasks, but also may create a false sense of security and cause persons who have been vaccinated to neglect basic hygiene.^[49] Unfortunately, after floods the public often demands typhoid vaccine and tetanus toxoid, although no epidemic of typhoid after a flood has ever been documented in the United States.^[95] In addition, antibodies to typhoid after immunization take several weeks to develop, and even then, vaccination protects only moderately. Likewise, mass tetanus vaccination programs are not indicated. Management of flood-associated wounds should include appropriate evaluation of the injured person's tetanus immunization history, and the person should be vaccinated only if indicated.

The proper approach to the problem of communicable diseases is to set up an epidemiologic surveillance system so that an increase in cases of communicable diseases in the flood-stricken area can be identified quickly. Particular attention should be given to diseases endemic to the area. For example, when floods occur in areas with endemic arthropod-borne encephalitides, arthropods known to transmit the disease should be monitored and areas should be sprayed if the vector population increases significantly after the flood.

Tropical Cyclones (Hurricanes or Typhoons)

Cyclones, hurricanes, and typhoons have killed hundreds of thousands and injured millions of people during the last 30 years ([Figure 67-2](#)).^{[75] [117]} From 1900 to 1999 more than 14,000 people lost their lives in hurricanes in the United States ([Table 67-3](#)).^[56] The greatest natural disaster in U.S. history occurred on Sept. 8, 1900, when a hurricane struck Galveston, Texas, and killed more than 6000 persons.^{[59] [103]} In 1970 deaths resulting from a single tropical cyclone striking Bangladesh were estimated to exceed 250,000. As population

*Includes more than 500 persons lost on ships at sea.

†Includes 344 persons lost on ships at sea.

growth continues along vulnerable coastal areas, deaths and injuries resulting from tropical cyclones will increase.^{[70] [141]}

Although hurricane winds do great damage, wind is not the primary killer in a hurricane. Hurricanes are classic examples of disasters that trigger secondary effects such as tornadoes and flooding that, together with storm surges, can cause extraordinarily high rates of morbidity and mortality. This was seen after the 1991 cyclone and sea surge in Bangladesh, in which 140,000 persons drowned, and during Hurricane Mitch in Central

1608

America in 1998, with thousands of drowning deaths.^[66] Nine of 10 hurricane fatalities are drownings associated with storm surges.^{[58] [59] [123]} The major rescue problem is locating persons stranded by rising waters and evacuating them to higher land. Other causes of deaths and injuries include burial beneath houses collapsed by wind or water, penetrating trauma from broken glass or wood, blunt trauma from floating objects or debris, or entrapment by mud slides that may accompany hurricane-associated floods.^{[31] [74]} Many of the most severe injuries occur to persons who are in mobile homes during the storm, or those who are injured or electrocuted during postdisaster cleanup.^{[28] [29] [127]}

Most persons who seek medical care after hurricanes do not require sophisticated surgical or intensive care services and can be treated as outpatients.^{[107] [132]} The majority have lacerations caused by flying glass or other debris^[74]; a few have closed fractures and other, mostly penetrating, injuries.^{[36] [42]} Longmire et al^{[91] [92]} studied injuries associated with hurricanes Frederic (1984) and Elena (1985). They found a statistically significant increase in lacerations, puncture wounds, chain saw injuries, burns, gasoline aspiration, gastrointestinal complaints, insect stings, and spouse abuse in the 2 weeks after the hurricane. The authors concluded that minor trauma treated in the outpatient setting created an urgent demand for primary care physicians and nurses skilled in managing minor surgical emergencies. In addition, although the number of chain saw injuries was small, the time-consuming nature of treating such wounds increased significantly the demands placed on remaining emergency department personnel to treat those with other injuries. As with flood-related wounds, emergency medical care providers should be aware that wounds may contain highly contaminated material such as soil or fecal matter.^{[122] [126]} Because of this danger, primary wound closure should be done with caution.

Storm shelters are often severely crowded.^[30] As with flood disasters, this crowding

increases the probability of disease communication through aerosol or fecal-oral routes, particularly when sanitary facilities are insufficient. ^[16]

Trauma after a cyclone is not usually a major public health problem when compared with the need for water, food, clothing, sanitation, and other hygienic measures. ^[146] Studies demonstrate that sending fully equipped mobile hospitals and specialized surgical teams that arrive much too late at the disaster site is an ineffective response to a cyclone disaster. Nonmedical relief (e.g., epidemiologists, sanitation engineers, shelter, food, agricultural supplies) is probably more effective in reducing mortality and morbidity. On the other hand, field hospitals and emergency medical teams from outside the disaster-affected area may be useful in providing ongoing primary health care services to the community when all other health care facilities have been destroyed or severely damaged. ^[76] This was the case in St. Croix after hurricane Hugo ^[132] and in south Florida after hurricane Andrew. ^[157] These situations reemphasize the importance of conducting rapid assessments of public health needs before sending relief personnel and materials to a disaster. ^[125]

Tornadoes

Tornadoes are among the most violent of all natural atmospheric phenomena, as has been witnessed after recent devastating tornadoes in Oklahoma, Texas, and Alabama ([Figure 67-3](#)). ^[103] Although almost 700 tornadoes occur in the United States each year, only about 3% result in severe injuries requiring hospitalization. ^[90] Of 14,600 tornadoes studied between 1952 and 1973, only 497 caused fatalities, and 26 of these events accounted for almost half of the fatalities. ^[61] The Centers for Disease Control and Prevention (CDC) has reviewed the public health impact of tornadoes in great detail. ^[90]

The destruction caused by tornadoes results from the combined action of strong rotary winds and the partial vacuum in the center of the vortex. ^[102] For example, when a tornado passes over a building, the winds twist and rip at the outside. Simultaneously, the abrupt

Figure 67-3 Tornado striking McConnell Air Force Base, Kansas, April 26, 1991. (Courtesy US Air Force.)

pressure reduction in the tornado's eye causes explosive pressures inside the building.

Walls collapse or topple outward, windows explode, and the debris from this destruction can be driven as high-velocity missiles through the air. Buildings made of unreinforced masonry, wood frame buildings, and those with large window areas will likely have the most extensive damage.^[87] Building practices may be largely responsible for the severity of injury resulting from tornadoes.^[20]

In the last 50 years, tornadoes have been responsible for more than 9000 deaths in the United States.^[65] About 4% of all injuries sustained were fatal. For every person seriously injured or killed, approximately 44 others required some emergency medical attention.^[68]

Victims of tornado disasters show characteristic patterns of fatal and nonfatal injuries. The leading cause of death is craniocerebral trauma,^[18]^[96] followed by crushing wounds of the chest and trunk.^[6]^[139] Fractures are the most frequent nonfatal injury. Lacerations, penetrating trauma with retained foreign bodies, and other soft tissue injuries also frequently occur. A high percentage of wounds among tornado casualties are heavily contaminated.^[19]^[77] In many instances, foreign materials such as glass, wood splinters, tar, dirt, grass, and manure are deeply embedded in areas of soft tissue injury.^[96] Wound contamination appears to be a major factor contributing to the high rate of postoperative sepsis for tornado victims who require surgery, even under conditions in which patients receive highly skilled and prompt surgical debridement. Sepsis is common in both minor and major injuries; sepsis affects one half to two thirds of patients with minor wounds.^[6] In 1956 Hight et al^[77] examined the postoperative course of patients after the Worcester tornado and found sepsis in 12.5% to 23.0% of orthopedic and neurosurgical patients with lacerations, three cases of gas gangrene, but no cases of tetanus.

TABLE 67-4 -- Principal Health Effects Caused by Volcanic Eruptions

ERUPTIVE EVENT	CONSEQUENCE	HEALTH EFFECT
Explosions	Lateral blast, rock fragments	Trauma, skin burns
	Air shock waves	Lacerations from broken windows
Hot ash release	Glowing avalanches	Skin and lung burns
	Ashflows and ashfalls	Asphyxiation
	Lightning	Electrocution
	Forest fires	Burns
Melting ice, snow, and rain accompanying eruption	Mudflows, floods	Engulfing, drowning
Lava	Forest fires	Burns

Gas emissions: sulfur dioxide, carbon monoxide, carbon dioxide, hydrogen sulfide, hydrogen fluoride	Pooling in low-lying areas and inhalation	Asphyxiation, airway constriction
Radon	Radiation exposure	Lung cancer
Earthquakes	Building damage	Trauma

From Baxter PJ, Bernstein RS, Buist AS: Am J Public Health 76(suppl):84, 1986.

Three studies have looked specifically at the species of bacteria that contaminate wounds sustained during tornadoes.^{[19] [62] [81]} These revealed frequent infection with aerobic gram-negative bacilli, presumably derived from soil.

Volcanic Eruptions

Volcanic eruptions have claimed more than 266,000 lives in the past 400 years, with fatalities occurring in about 5% of eruptions.^{[17] [144]} Some of the more catastrophic eruptions in history include the eruption of Krakatoa (Indonesia), which caused 36,000 deaths; of Mt. Pelee in 1902, which caused the destruction of St. Pierre in Martinique and the deaths of 28,000 persons; of Nevado del Ruiz in Colombia, which claimed 25,000 lives; and of Mt. Pinatubo in the Philippines, with effects still ongoing because of persistent mudflows. The U.S. Geological Survey has identified about 35 volcanoes in the western United States and Alaska that are likely to erupt in the future. Most of these are in remote rural areas and are not likely to result in disaster. A few, such as Mt. Hood, Mt. Shasta, Mt. Rainier, and the volcano underlying Mammoth Lakes in California, are near population centers.^{[5] [12]} Because of the increasing population density in areas of volcanic activity, volcanic hazards are of growing concern.^{[44] [75] [86] [103]}

Eruptions have immediate life-threatening health effects through suffocation from inhalation of massive quantities of airborne ash, scalding from blasts of superheated steam, and surges of lethal gas ([Table 67-4](#)).^{[10] [13]} Pyroclastic flows and surges are particularly lethal.^[9] These are currents of extremely hot gases and particles that flow down the slopes of a volcano at tens to hundreds of meters per second and cover hundreds of square kilometers. Because of their suddenness and speed, pyroclastic flows and surges are difficult to escape.

Mudflows, or lahars, account for at least 10% of volcano-related deaths.^[161] These are flowing masses of volcanic debris mixed with water. The mud is sometimes scalding hot, and entrapped persons may sustain severe burns. A relatively minor eruption of snow-capped Nevado del Ruiz in 1985 triggered lahars from the volcano's icecap that buried more than 22,000 persons in Colombia, South America.^[144]

An indirect effect of volcanic activity is accumulation of toxic volcanic gases in deep crater lakes.^[119]^[143] Sudden release of these gases can be catastrophic; carbon dioxide released from Lake Monoun and Lake Nyos in Cameroon in 1984 and 1986, respectively, claimed 1800 lives. Other toxic effects of these gas releases include pulmonary edema, irritant conjunctivitis, joint pain, muscle weakness, and cutaneous bullae. In the rare event of a ground-level release of toxic gases or aerosols (e.g., from a vent opening to the atmosphere from the side of the volcano), equipment for monitoring atmospheric concentrations of sulfur dioxide, hydrogen sulfide, hydrofluoric acid, carbon dioxide, and other gases should be available.^[10]^[13]

A volcanic eruption may also generate tremendous quantities of ashfall.^[101]^[133] Buildings have been reported to collapse from the weight of ash accumulating on roofs, resulting in severe trauma to the occupants.^[97] Ash can also be irritating to eyes (causing corneal abrasions), mucous membranes, and the respiratory system.^[94] Upper airway irritation, cough, and bronchospasm, as well as exacerbation of chronic lung disease, are common findings in symptomatic patients.^[8] In extremely high concentrations, as in the path of a pyroclastic flow or near the volcanic vent during an ashfall, volcanic ash may cause severe tracheal injury, pulmonary edema, and bronchial obstruction, leading to death from acute pulmonary injury or suffocation.^[97] After the eruption of Mt. St. Helens in 1980, 23 immediate deaths were reported ([Figure 67-4](#)). Postmortem examinations revealed that 18 of these resulted from asphyxia.^[54] In most asphyxiated victims, the ash mixed with mucus and formed plugs, obstructing the trachea and main bronchi. Finally, delayed onset of ash-induced mucus hypersecretion or obstructive airway disease may occur.^[9]

Victims who recover from volcano-generated mudflows may have severe dehydration, burns, and eye infections.^[55] Reports of surgical care after the volcanic eruption in Colombia in 1985 showed that primary closure of wounds contaminated by mud and other volcanic material resulted in major complications.^[120] These complications included gangrene necessitating amputation, osteomyelitis, compartment syndrome, and sepsis.

Most volcanic deaths are caused by immediate suffocation and, to a lesser extent, by burns or blunt trauma. Advanced cardiac and trauma life support capabilities, even if immediately available, would probably arrive too late to save asphyxiated victims. Persons who may develop

Figure 67-4 Eruption of Mt. St. Helens, Washington State, May 18, 1980.
(Courtesy of the US Geological Survey.)

severe respiratory distress syndrome should be admitted to an intensive care unit (ICU)

for appropriate respiratory supportive measures, ranging from continuous positive airway pressure to mechanical ventilation with positive end-expiratory pressure. ^[97] Hospitals in the vicinity of both active and dormant volcanoes should be prepared to deal with a sudden influx of victims with severe burns and lung damage from inhalation of hot ash, as well as multiple varieties of trauma. ^{[8] [13]}

Earthquakes

An earthquake of great magnitude is one of the most destructive events in nature. During the past 20 years, earthquakes have caused more than a million deaths and injuries worldwide. ^[117] In the United States, approximately 1600 deaths attributed to earthquakes have been recorded since colonial times, of which more than 1000 have occurred in California ([Figure 67-5](#)). ^{[109] [142]} Hospitals and other health care facilities are particularly vulnerable to the damaging effects of an earthquake. Because of loss of power and water supply, equipment (e.g., x-ray and kidney dialysis machines, ventilators, blood analyzers) and hospital facilities (e.g., ICUs and surgical theaters) cannot function normally when they are most needed. ^{[3] [112] [130]}

Disaster medical planners should note injury type and/or diagnostic classification among survivors to determine the medical care needed. The primary cause of death and injury from earthquakes is the collapse of buildings that are not adequately designed for earthquake resistance, are built with inadequate materials, or are poorly constructed ([Figure 67-6](#)). ^{[64] [93]} Factors determining the number of people killed when a building collapses include how badly trapped they are, how

1611

Figure 67-5 Earthquake risk in the continental United States. Triangles represent active seismic areas from January 1937 to May 1997.

severely they are injured, how long they must wait for rescue, and how long they can survive without medical attention. ^{[40] [41] [115]}

Deaths resulting from major earthquakes can be instantaneous, rapid, or delayed.^[88]^[149] Instantaneous death can be caused by severe crushing injuries to the head or chest, external or internal hemorrhage, or drowning from earthquake-induced tidal waves (tsunamis). Rapid death occurs within minutes or hours and can be caused by asphyxia from dust inhalation or chest compression, hypovolemic shock, or exposure (e.g., hypothermia). Delayed death occurs within days and can be caused by dehydration, hypothermia, hyperthermia, crush syndrome, or postoperative sepsis.^[137]

As with most natural disasters, the majority of those requiring medical assistance have minor injuries such as superficial lacerations, sprains, and bruises.^[128] The next most frequent reason for seeking medical attention is simple fractures not requiring operative intervention.^[139] For example, after the 1968 earthquake south of Khorasan, Iran, only 368 (3.3%) of 11,254 persons injured required inpatient care. Hospitalized patients included those with serious multiple fractures or internal injuries, hypothermia, sepsis from wound infections, or multiple organ failure requiring surgery or other intensive care services.^[99]

More detailed inpatient information is available from data collected on 4832 patients admitted to hospitals after the 1988 earthquake in Armenia.^[115] Consistent with findings from other major earthquakes, combination injuries constituted 39.7% of the cases. Superficial trauma,

1612

such as lacerations and contusions, was the most frequently observed injury (24.9%), followed by head injuries (22%), lower extremity injuries (19%), crush syndrome (11%), and upper extremity trauma (10%).

Infected wounds and gangrene were major problems after the Armenian earthquake.^[111] Persons who have been trapped by rubble for several hours or days may also develop compartment syndromes requiring fasciotomy or amputation. These persons may have significant rhabdomyolysis and must be watched closely for signs and symptoms of crush syndrome such as hypovolemic shock, hyperkalemia, renal failure, or fatal cardiac arrhythmias.^[14]^[104]^[106] After the 1988 earthquake in Armenia, more than 1000 victims trapped in collapsed buildings developed crush syndrome as a result of limb compression; 323 developed secondary acute renal failure requiring renal dialysis.^[106]

Heavy dust is produced by crumbling buildings immediately after earthquakes. For trapped victims, this dust is a life-threatening hazard that may cause asphyxiation or upper airway obstruction.^[78] Fulminant pulmonary edema from dust inhalation may also be a delayed cause of death.^[137] Asbestos and other particulate matter in the dust are both subacute and chronic respiratory hazards for trapped victims, as well as for rescue and cleanup personnel. The degree of hazard depends on the characteristics and toxicity of the dust.^[109]

Burns and smoke inhalation from fires used to be major hazards after an earthquake. For example, after the 1923 earthquake in Tokyo, more than 140,000 persons perished, principally because of fires that broke out in a city in which most buildings were constructed from highly flammable paper (shoji) and wood material. Since 1950, however, the incidence of burns has decreased considerably. ^[41]

To maximize saving trapped victims and increase their chances of survival, search and rescue teams must respond rapidly after a building collapses. ^[105] Studies of the 1980 Campania-Irpinia, Italy earthquake^[46] ^[47] and the 1976 Tangshan, China earthquake^[167] show that the proportion of trapped people found alive declined as delay in extrication increased. In the Italian study, a survey of 3619 survivors showed that 93% of persons who were trapped and survived were extricated within the first 24 hours and that 95% of the deaths recorded occurred while the victims were still trapped in rubble. ^[47] Estimates of the survivability of victims buried under collapsed earthen buildings in Turkey and China indicate that within 2 to 6 hours, less than 50% of those buried are still alive.

Although it cannot be determined whether a trapped person dies immediately or survives for some time under the debris, more people would be saved if they were extricated sooner. Safar, ^[136] studying the 1980 earthquake in Italy, concluded that 25% to 50% of victims who were injured and died slowly could have been saved if lifesaving first aid had been rendered immediately. As suggested by these data, if any significant reduction in earthquake mortality is to be achieved, appropriate search and rescue action must be provided within the first 2 days after the impact.

Paralleling the speed required for effective search and extrication is the speed with which emergency medical services must be provided. ^[138] The greatest demand occurs within the first 24 hours. ^[150] In fact, injured people usually seek medical attention at emergency departments only during the first 3 to 5 days, after which time hospital case-mix patterns return almost to normal. ^[148] The critical importance of early emergency care was seen in the number of admissions to a field hospital after the 1976 earthquake in Guatemala. ^[48] ^[50] From day 6 on, admissions fell dramatically despite intensive efforts to find injured people in remote rural areas of the impact zone, indicating that specialized field hospitals that arrived a week or more after an earthquake are generally too late to help during the emergency phase. After the Armenian earthquake, only 22 (2.4%) of the 902 patients requiring hospitalization at a large hospital were admitted 7 or more days after the impact. ^[115]

With most earthquakes, trauma caused by the collapse of buildings is the cause of most deaths and injuries. However, a surprisingly large number of victims require acute care for nonsurgical problems, such as acute myocardial infarction, exacerbation of chronic diseases (e.g., diabetes, hypertension), anxiety and other mental health problems, respiratory disease from exposure to dust and asbestos fibers from rubble, and near drowning because of flooding from broken dams. An example of the adverse effects of an earthquake on medical conditions was observed after a magnitude 6.7 earthquake in Athens, Greece. A 50% increase in deaths from myocardial infarction was documented during the first 3 days after the earthquake, peaking on the third day. ^[84] ^[153] Finally, an earthquake may precipitate a major technologic disaster by damaging or destroying

nuclear power stations, hospitals with dangerous biologic products, hydrocarbon storage areas, and hazardous chemical plants.

As with most natural disasters, the risk of secondary epidemics is minimal, and only mass vaccination campaigns based on results of epidemiologic surveillance are appropriate after earthquakes.^[151]

PRACTICAL ISSUES IN NATURAL DISASTER RESPONSE

Mass Casualty Care

A disaster may create casualties in excess of the capacity of the local health care system. The approach to patient evaluation and treatment is quite different under disaster situations resulting in large numbers of casualties. [\[23\]](#) [\[24\]](#) [\[53\]](#) Although some principles of medical care are unchanged in a mass casualty incident, others must be altered to achieve the best overall result.[\[131\]](#) The health care system must adapt to this situation with

1613

four measures: simplifying care (austerity); rationing care (adopting a triage ethic); calling for outside help; and in circumstances of catastrophe, instituting mass care measures typical of battlefield medicine. Many compromises in work methods eliminate attention to details that would be required in less urgent situations. Physicians and nurses often perform procedures beyond the scope of their usual practices. Professional functions and roles are widely shared among physicians, nurses, and paramedics. These adaptations allow available resources to serve more victims.[\[160\]](#)

Austerity

To be effective, disaster medical care must be confined to basic measures that preserve life and function. Examinations, techniques, appliances, and drugs that are not essential to patient survival or preservation of function are luxuries. It may be necessary to perform fracture reductions and other minor surgical procedures with oral narcotic analgesia only. Orthopedic devices are often improvised. Outdated drugs are better than no drugs. The level of austerity is determined by the health care personnel, supplies, and equipment available at the disaster treatment site.

Triage And Rationing

Initial management of mass casualties includes triage, basic field stabilization, and transportation. In general, *triage* can be defined as the prioritization of patient care based on severity of injury or illness, prognosis, and availability of resources.[\[134\]](#) [\[135\]](#) The goal of triage is to select those patients in greatest need of immediate medical attention and to arrange for that treatment. It is a concept born on the world's battlefields, by which victims are classified and treated based on the seriousness of their injuries.

Military surgeons recognized that the number of victims produced in battle could overwhelm medical resources. Some persons suffer injuries that would be fatal even under ideal circumstances in which resources are unlimited. Attempts at salvaging mortally wounded individuals with heroic measures under conditions of limited personnel and supplies may deprive other victims of care for life-threatening but correctable conditions. The "walking wounded" sustain injuries that are survivable even if the provision of definitive medical care is significantly delayed. Thus, in the humanitarian interest of providing the greatest good for the greatest number of persons, methods of classification have been developed that facilitate treatment prioritization. The first victims treated are those with life-threatening injuries that can be readily stabilized without the expenditure of massive amounts of limited resources. The next priority is persons who have sustained injuries likely to cause significant morbidity, which would be appreciably lessened by early intervention. Catastrophically injured patients (e.g., those with burns involving 95% body surface area) who have a minimal chance for survival despite optimal medical care are provided comfort measures and may need to be left to die ([Box 67-1](#)). Spending time on patients who are not likely to live leaves other patients who might be saved awaiting care. If too much time intervenes, these patients also may become nonsalvageable. In addition to the nature and urgency of the patient's systemic condition, triage decisions must be sensitive to factors affecting prognosis, such as age, general health, physical condition of the patient, the qualifications of the responders, and availability of key supplies and equipment.^[131]

Triage procedures are routinely used in civilian multiple or mass casualty incidents and are essential in disaster incidents. Prioritization of victims may be needed with smaller numbers of casualties when environmental conditions, remote settings, or unusual circumstances limit availability of medical care or ease of evacuation. The decision to evacuate persons with a reasonable chance of survival before mortally injured victims may be necessary in mountain and cave rescues, or with overland transport from isolated wilderness regions. Effective triage is critical to the success of any disaster care operation and should be performed by a senior and knowledgeable provider. The essential differentiation is "now" versus "not now." In disaster triage the moribund victim unlikely to survive is classified as "not now," when in ordinary circumstances he or she would be "immediate."

Triage methods can be qualitative and quantitative.^{[82] [98] [155]} *Qualitative methods* classify patients into subjective categories (e.g., immediate, delayed, minor, expectant). Two-tier, three-tier, four-tier, and five-tier systems have been described ([Box 67-2](#)). Any qualitative triage method can be used successfully in a disaster. Each ranks patients relative to others and to the available care, and each requires periodic reconsideration for treatment.

Quantitative methods assign an objective score to each patient based on initial clinical status. Various systems based on anatomic indicators of injury severity, physiologic measurements, and mechanisms of injury have been developed to predict outcomes, including the Trauma Score.^{[37] [38]} Many emergency medical systems use the revised Trauma Score for field triage and as a guide for patient routing in tiered trauma treatment systems.^[37] Although experienced physicians frequently rely on their best medical judgment to triage patients, medically inexperienced personnel may benefit

from such an algorithmic approach to assessment and triage. Suppose that several members of an isolated mountain village were injured during an earthquake, that the village had only one health care worker, and that evacuation and treatment resources were limited. Decisions would have to be made regarding who would be evacuated first and who would be treated first. A trauma assessment based on physiologic variables could provide a relatively objective evaluation of the victim's condition and a rational basis for the allocation of scarce resources.

1614

1615

The use of such standardized scoring systems for triage decisions, however, remains to be studied in the disaster setting. Triage methods founded on scoring systems require familiarity with the scoring systems. They cannot be used by disaster medical personnel unfamiliar with their application or modification.

Box 67-1. TRIAGE CATEGORIES BY INJURY TYPE

SIMPLE TRIAGE

Immediate (Priority I)

Asphyxia

Respiratory obstruction from mechanical causes

Sucking chest wounds

Tension pneumothorax

Maxillofacial wounds in which asphyxia exists or is likely to develop

Shock caused by major external hemorrhage

Major internal hemorrhage

Visceral injuries or evisceration

Cardiopericardial injuries

Massive muscle damage

Severe burns over more than 25% of body surface area

Cardiopericardial injuries

Massive muscle damage

Severe burns over more than 25% of body surface area

Dislocations

Major fractures

Major medical problems readily correctable

Closed cerebral injuries with increasing loss of consciousness

Delayed (Priority II)

Vascular injuries requiring repair

Wounds of the genitourinary tract

Thoracic wounds without asphyxia

Severe burns over less than 25% of body surface area

Spinal cord injuries requiring decompression

Suspected spinal cord injuries without neurologic signs

Lesser fractures

Eye injuries

Maxillofacial injuries without asphyxia

Minor medical problems

Victims with little chance of survival under the best conditions

MASS CASUALTY TRIAGE WITH AN OVERWHELMING NUMBER OF INJURIES

Immediate (Priority I)

Asphyxia

Respiratory obstruction from mechanical causes

Sucking chest wounds

Tension pneumothorax

Maxillofacial wounds in which asphyxia exists or is likely to develop

Shock caused by major external hemorrhage

Sucking chest wounds

Tension pneumothorax

Maxillofacial wounds in which asphyxia exists or is likely to develop

Shock caused by major external hemorrhage

Dislocations

Severe burns over less than 25% of body surface area*

Lesser fractures*

Major medical problems that are readily treatable

Delayed (Priority II)

Major fractures (if able to stabilize)*

Visceral injuries or evisceration*

Cardiopericardial injuries*

Massive muscle damage*

Severe burns over more than 25% of body surface area*

Vascular injuries requiring repair

Wounds of the genitourinary tract

Thoracic wounds without asphyxia

Closed cerebral injuries with increasing loss of consciousness*

Spinal cord injuries requiring decompression*

Suspected spinal cord injuries without neurologic signs

Eye injuries

Maxillofacial injuries without asphyxia

Complicated major medical problems*

Minor medical problems

Victims with little chance of survival under the best conditions

Data from Office of Emergency Services, State of California.

*Conditions that have changed categories.

Box 67-2. TRIAGE RATING SYSTEM

FIVE-TIER SYSTEM (USED IN MILITARY TRIAGE)

Dead or will die

Life threatening—readily correctable

Urgent—must be treated within 1 to 2 hours

Delayed—noncritical or ambulatory

No injury—no treatment necessary

FOUR-TIER SYSTEM

Immediate—seriously injured, reasonable chance of survival

Delayed—can wait for care after simple first aid

Expectant—extremely critical, moribund

Minimal—no impairment of function, can either treat self or be treated by a nonprofessional

THREE-TIER SYSTEM

Life threatening—readily correctable

Urgent—must be treated within 1 to 2 hours

Delayed—no injury, noncritical, or ambulatory

TWO-TIER SYSTEM

Immediate—life-threatening injuries that are readily correctable on scene, and those that are urgent

TWO-TIER SYSTEM

Immediate—life-threatening injuries that are readily correctable on scene, and those that are urgent

Delayed—no injury, noncritical injuries, ambulatory victims, moribund, and dead

Mechanics of the Triage Process

Triage should begin as soon as trained medical personnel arrive on the scene. A rapid survey is performed, noting the number of victims, hazards to victims and rescuers, and the need for additional help. This information should be relayed rapidly to the communication centers responsible for the dispatch of emergency services so additional help can be mobilized as early as possible. The most qualified medical person present should be designated the provisional triage officer. The triage officer should not be assigned other duties and should not become extensively involved in patient care. During the initial survey, each victim is rapidly assessed for immediately correctable life-threatening problems, such as airway obstruction, vigorous hemorrhage, or nonfatal penetrating chest injuries. Initial care should be limited to correction of these problems; resuscitation and definitive care have no role at this stage. Care should be limited to manually opening airways and controlling external hemorrhage.^[136] Physical

Figure 67-7a Examples of disaster tags. **A**, METTAG.

hazards may influence the decision to provide further care on site or delay additional therapy until victims are transported a safe distance to a casualty collection point. As additional experienced emergency medical personnel arrive, the role of triage officer should be assumed by the most experienced and knowledgeable person present. Advanced medical knowledge is an asset in minimizing triage errors. However, field-experienced physicians are relatively rare. Successful disaster triage under mock conditions can be performed by appropriately trained advanced emergency medical technicians or by experienced nurses. Triage is a dynamic process. Continued clinical deterioration or improvement may change the initial decision to evacuate or treat a victim. Triage should be performed whenever the responsibility for a victim's care is transferred.^[159]

Adjuncts to Triage

A triage tag is a paper tag intended to show the triage category in which a patient has been classified. Most bear color codes designating triage category. All enforce the use

of the particular scheme of categorization for which they were designed, such as "immediate," "delayed," "minor," and "expectant," depending on injury severity and prognosis. Most are deliberately simple, such as the METTAG ([Figure 67-7, A](#)), and bear only minimal information to identify the patient and indicate

1616

Figure 67-7b (Figure Not Available) **B**, More detailed disaster tag. (**A**, Courtesy *Journal of Civil Defense*, Starke, Fla. **B**, Courtesy *Precision Graphics Division, Precision Dynamics Corp.*, Burbank, Calif.)

1617

triage class and site of injury. Others carry more information and serve as an abbreviated medical record (Figure 67-7, *B* (Figure Not Available)). Vayer et al^[159] reported that the tags had been used effectively in only a few multicasualty incidents. These authors recommend that triage tags be abandoned and replaced by a system of "geographic triage" that sorts casualties into areas reserved for patients of similar priority for treatment. Simultaneously, some disaster medical systems are recasting their "triage tags" as "victim tracking tags" in an elaborate evacuation system.

On-Site Medical Care

The amount and type of care administered at disaster sites depend on several factors.^[121] If the number of patients is small and sufficient prehospital personnel and transportation resources are available, on-site medical care can proceed normally, with rapid stabilization and transportation to nearby hospitals. When extrication is prolonged, potentially lifesaving interventions, such as intravenous fluids for hypovolemic shock, should be instituted.^[136] On the other hand, early rapid transportation with minimal treatment should be practiced in circumstances such as danger to rescuers and casualties from fire, explosion, falling buildings, hazardous materials, and extreme weather conditions.^[45]

With an overwhelming number of casualties that exceed transportation capacities, advanced field medical treatment may be beneficial because hours may pass before seriously injured patients can be evacuated.^[7] This may necessitate the establishment of field hospitals with operating theater capabilities.^[100] Such a field hospital may be set up in a large building such as a school or church. Casualties are brought to the field hospital from the disaster site for further assessment and initial treatment of injuries. After observation and stabilization, they are either sent home or transported to a hospital.

Evacuation of slightly injured and ambulatory persons may rapidly overwhelm local hospitals before the arrival of more severely injured victims.^[129] Under these conditions,

local treatment may be preferable to evacuation of the severely injured victims.

Communication From Disaster Site to Hospital

Local emergency communications or the disaster operations center should alert hospitals in the affected area of a possible mass or multiple casualty situation. This report should include number of injured and, specifically, number of seriously injured and number for whom ambulatory treatment is sufficient.^[22] Hospitals should report the following information to the local emergency communications center:

1. Bed availability
2. Number of casualties received thus far
3. Number of additional casualties that the hospital is prepared to accept
4. Specific items in short supply

Specific Clinical Issues

Wound infections may occur in virtually all types of disasters. Infected wounds and gangrene were major problems after the Armenian earthquake.^[111] In hurricanes or tornadoes, persons may be cut by flying glass and other potentially highly contaminated material.^[124]^[165] Because of this, all wounds should be copiously flushed with saline. Primary closure of heavily contaminated wounds may result in major complications, as occurred after the Armero volcanic eruption in Colombia. If lacerations are old (more than 6 to 12 hours) or appear contaminated, they should be treated by debridement and left open for primary delayed closure for a 3-day period.^[21] This allows an opportunity to observe the wound for the development of infection. For tetanus prophylaxis, all patients should receive a tetanus booster, and if the wound is highly contaminated, tetanus immune globulin (Hypertet) should be administered.

Victims with blunt trauma, such as those trapped by rubble for several hours or days, should be watched closely for signs and symptoms of crush syndrome, such as cardiac arrhythmias and renal failure.^[116] Fulminant pulmonary edema from dust inhalation may also be a delayed cause of mortality for victims of building collapse.^[111]

PUBLIC HEALTH PROBLEMS

Epidemics

Natural disasters are often followed by rampant rumors of epidemics, such as typhoid, cholera, or rabies, or unusual conditions, such as increased snakebites and dog bites. Such unsubstantiated reports gain great public credibility when printed as facts in newspapers or reported on television or radio. After disasters in developing countries, any disruption of the water supply or sewage treatment facilities is usually accompanied by rumors of outbreaks of cholera or typhoid. Such rumors may well reflect psychologic fears and anxieties about a disastrous event rather than an imminent problem. Although natural disasters do not usually result in outbreaks of infectious disease, they may increase disease transmission.^{[1] [140]} In addition, information on disease incidence in most developing countries is poor, and some outbreaks may have been missed by public health authorities.^{[13] [49]} The most frequently observed increases in communicable disease are caused by fecal contamination of water and by respiratory spread, such as measles in refugee camps.^{[26] [27]}

During the past 60 years, outbreaks of communicable disease after natural disasters have been unusual.

1618

Disasters can contribute to transmission of disease, however, and persons responsible for managing disaster relief operations should establish a surveillance system and institute appropriate sanitary and medical measures to prevent outbreaks.^{[15] [63] [69] [140] [164]} Mass vaccination programs are rarely necessary.^[25] A clearinghouse for rumors is helpful not only in developing countries, but also in disasters occurring in urban settings of industrialized countries.

Disposition of Dead Bodies

The public and government authorities are usually greatly concerned about the danger of disease transmission from decaying corpses ([Figure 67-8](#)). Responsible health authorities should recognize, however, that the health hazards associated with unburied bodies are minimal, particularly if death resulted from trauma.^[79] Such bodies are unlikely to cause outbreaks of diseases such as typhoid, cholera, or plague, although they may transmit agents of gastroenteritis or food poisoning to survivors if the bodies

contaminate streams, wells, or

TABLE 67-5 -- Short-Term Effects of Major Natural Disasters

EFFECTS	EARTHQUAKES	HIGH WINDS (WITHOUT FLOODING)	TSUNAMIS	FLOODS/FLASH FLOODS
Deaths	Many	Few	Many	Few
Severe injuries requiring extensive care	Overwhelming	Moderate	Few	Few
Increased risk of communicable diseases	Potential (but small) risk after all major disasters (probability rises as overcrowding increases and sanitation deteriorates)			
Food scarcity (may occur because of factors other than food shortage)	Rare	Rare	Common	Common
Major population movements (may occur in heavily damaged urban areas)	Rare	Rare	Common	Common

Modified from Emergency health management after natural disaster, Office of Emergency Preparedness and Disaster Relief Coordination, Scientific Publication No 407, Washington, DC, 1981, Pan American Health Organization.

Figure 67-8 A, Coffins lining the street in the city of Leninakan after the 1988 earthquake in Armenia. (Eric K. Noji photo.) **B**, Three horses were killed as a result of falling debris during the 1906 San Francisco earthquake. (**A**, Courtesy Eric K. Noji. **B**, Courtesy Eric Swenson, US Geological Survey.)

other water sources.^[124] Despite the negligible health risk, dead bodies represent a delicate social problem. Demands for mass burial or cremation are certainly not justified on public health grounds, and mass cremations require tremendous quantities of fuel.

Health Effects

[Table 67-5](#) outlines short-term health effects from natural disasters that require effective emergency medical care with an appropriate public health response. The overall objective of disaster management is to assess the needs of disaster-affected populations, to match resources to needs efficiently, to prevent further adverse health

effects, to evaluate relief program effectiveness, and to plan for future disasters.^[108]

All natural disasters are unique in that each affected region of the world has different social, economic, and health backgrounds. Recognition of similarities among the health effects of different natural disasters, however, can ensure that health and emergency medical relief and limited resources are well managed.^[72]

Chapter 68 - Natural and Human-Made Hazards: Mitigation and Management Issues

Sheila B. Reed

The term *hazard* is usually applied to rare or extreme events in the natural or human-made environment. Hazards can adversely affect human life or property to the extent of causing a disaster, or major disruptive situation. *Natural hazards* are caused by biologic, geologic, seismic, hydrologic, or meteorologic processes in the natural environment and include drought, flood, earthquake, volcanic eruption, and severe storms. When natural hazards affect vulnerable human settlements, structures, and economic assets, they can be disastrous, disrupting the normal functioning of a society and necessitating extraordinary emergency interventions to save lives and the environment.

Human-made hazards are derived from human interactions with the environment, human relationships and attitudes, and the use of technology. For example, transportation accidents, petrochemical explosions, mine fires, building collapses, oil spills, hazardous waste leaks, and nuclear power plant failures are disasters where the principal and direct causes are human actions. Many hazards have both natural and human components. Desertification results from arid conditions, erosion, and overgrazing; landslides may occur from poorly planned construction on unstable hillsides, and flooding may be caused by dam failures.

The distinction between many natural causes of hazards and contributions of humans to disastrous situations is becoming increasingly blurred. As populations grow and expand, pressure on land resources may force settlement in vulnerable areas, where hazards such as volcanic eruptions, earthquakes, or floods can become major disasters. Pest infestations may lead to famine in food-deficient areas, incidences of disease might become an epidemic because of overcrowding, and drought may become famine where food shortages result from combinations of lack of rainfall and displacement of people. The recent focus on global warming emanates from studies of the effects of climatic conditions and environmental pollution. Variables in these studies form such complex interactions that even computerized models have difficulty predicting the outcomes.

Hazards with a combination of causes result in complex disasters and often in complex emergencies. Whatever their causes, disasters have serious political, economic, social, and environmental implications. In less developed areas, disasters can severely set back or reverse development efforts.

DISASTER MANAGEMENT

This chapter focuses on hazards with a significant geophysical component, from a disaster management perspective. Disaster management encompasses all aspects of planning for and responding to disasters, including predisaster and postdisaster activities. It refers to the management of both the risks and the consequences of disasters. Components of disaster management include vulnerability and risk assessment, disaster mitigation and preparedness, and disaster assessment. Selection of management options depends on the type of hazard and whether the onset is likely to be slow or rapid.

[Box 68-1](#) lists the elements usually found in a disaster preparedness plan for sudden-onset hazards, such as earthquakes, volcanic eruptions, tropical cyclones, and floods. Preparedness measures for slow-onset disasters, such as drought, include early warning systems that alert authorities to precursory conditions and allow preparations to avert famine and displacement.

Slow-Onset vs. Rapid-Onset Hazards

Hazards may develop gradually and persist for a long time or may arise suddenly and be resolved rapidly. Rapid-onset hazards often occur with violent intensity and have profound effects on the surrounding environment, resulting in measurable numbers of casualties and damage. Slow-onset climatic changes brought on by deforestation, drought, desertification, or environmental pollution change the suitability of different parts of the world to agriculture and also affect the flora and fauna. The effects of slow-onset disasters are often insidious, and their impact can be measured only through environmental studies and in terms of reduction in quality of life and productivity for the affected population. The study of disaster management, which formerly focused on natural hazards, now encompasses a range of slow-onset and rapid-onset disasters and their natural and human causes.

Conservatively, an estimated 1.5 to 2 million people have been killed in rapid-onset disasters since 1946, or an average annual death toll of 35,000 to 50,000. The primary killers are earthquakes, tropical cyclones, and floods. Most deaths are concentrated in a relatively small number of communities, predominantly in poorer nations of Asia, Latin America, and Oceania. In

comparison, North America, Europe, Japan, and Australia have average annual death tolls that rarely exceed a few hundred persons.

Box 68-1. ESSENTIALS TO PREVENT OR PREPARE FOR AN EMERGENCY

1. Identification and mapping of the hazard zones; registration of valuable and movable property
2. Identification of safe refuge zones to which the population will be evacuated in case of danger
3. Identification and maintenance of evacuation routes
4. Identification of assembly points for persons awaiting transport for evacuation
5. Means of transport and traffic control
6. Shelter and accommodation in the refuge zone
7. Inventory of personnel and equipment for search and rescue
8. Hospital and medical services for treatment of injured persons
9. Security in evacuated areas
10. Formulation and communication of public warnings and procedures for communication in emergencies
11. Longer term recovery plans (e.g., social services for trauma victims)
12. Provisions for revising and updating the plan

Although no comprehensive data are available for economic losses from rapid-onset hazards, a few examples illustrate the scale of the problem. Annual worldwide losses from tropical cyclones are estimated at between \$6 and \$7 billion. For landslides the comparable figure exceeds \$1 billion. These figures only hint at the human impact of destruction. The eruption of Colombia's Nevado del Ruiz volcano in 1985 killed approximately 22,000 people and left 10,000 more homeless. Hurricane Andrew's impact on Florida in 1992 destroyed 30,000 homes, damaged 60,000, and left 350,000 people homeless, with damage estimates of \$16 billion. An earthquake in south-central India in October 1993 claimed at least 30,000 lives.

The relative human, economic, and social impacts of rapid-onset disasters are usually greatest in small, poor nations. The 1985 earthquake in Mexico City caused economic losses equivalent to about 3.5% of Mexico's gross national product (GNP). Hurricane

Allen in 1980 caused losses in St. Lucia equivalent to 89% of the nation's GNP and destroyed 90% of the nation's banana crop, which normally accounts for 80% of the country's agricultural output. One of the strongest storms in recent history, Hurricane Mitch in 1998 devastated the economies and infrastructure of Honduras and Nicaragua.

Economic losses from rapid-onset hazards are increasing at a fast pace. In the United States, damage to buildings from earthquakes, tropical cyclones, and floods was estimated to increase from approximately \$6 billion in 1978 to more than \$11 billion in 2000 without additional loss reduction measures. A major earthquake in Tokyo would probably kill more than 30,000 people, cause the collapse of 60,000 houses, and set fire to more than 400,000 homes.

Slow-onset disasters take an even greater toll, but precise figures are difficult to find. Drought currently affects more people than any other disaster; worldwide, droughts have been estimated to affect more than 18 million people each year during the 1960s, more than 24 million people during the 1970s, and 101 million from 1980 to 1989. During the early 1980s, drought affected up to 30 million people in Africa alone. Droughts have led to famines, resulting in large numbers of deaths and displacements. Increasing desertification in arid areas may be contributing to droughts. *Desertification*, or decline in biologic productivity, extends to 70% of total productive arid lands or 3.6 billion acres worldwide and may adversely affect the quality of life for 10% of the world population, including urban dwellers.

Possible global warming is predicted in the next century from increased atmospheric carbon dioxide caused by burning of fossil fuels, deforestation, and generation of methane. If this occurs, sea levels will rise and coastal cities worldwide will be inundated. A rise of 1 m (3 ? feet) in sea level could flood 15% of arable land in Egypt's Nile Delta and completely submerge the tiny islands of the Maldives, inhabited by 200,000. Hundreds of millions of people will also be affected if increased ultraviolet radiation is delivered to the earth's surface as a result of stratospheric ozone depletion caused by continued release of chlorofluorocarbons.

Although global warming and ozone depletion are threats to the future, other forms of environmental pollution, such as water and air pollution, affect life today. Massive oil spills make headlines, and adverse health effects are seen from contamination and smog. Deforestation, particularly in the tropical rainforests, is highly significant. In addition to its contribution to possible global warming, it increases vulnerability to droughts, landslides, and floods.

Assessing Vulnerability and Risk

Not all hazards become disasters. Whether or not a disaster occurs depends on the magnitude, intensity, and duration of the event and the vulnerability of the community. For example, a severe earthquake is not a disaster unless it significantly disrupts a community by creating large numbers of casualties and substantial destruction. Effective disaster management requires information about the magnitude of the risk faced and how much importance society places on the reduction of that risk. Risks are

often quantified in aggregated ways (e.g., a probability of 1 in 23,000 per

1624

year of dying in an earthquake in Iran). The importance placed on risk of a hazard is likely to be influenced by the nature of the risks faced on a daily basis. In Pakistan, where communities are regularly affected by floods, earthquakes, and landslides, people use their meager resources to protect against what they perceive to be greater risks, such as disease and irrigation failure. In California, where risk of disease is low, communities choose to initiate programs against natural disasters.

Vulnerability is often measured as the susceptibility of buildings, infrastructure, economy, and natural resources to damage from hazards. Many aspects of vulnerability, however, cannot be described in monetary terms and should not be overlooked, such as personal loss of family, home, and income and related human suffering and psychosocial problems. Although communities in developed nations may be as prone to hazards as communities in poor nations, the wealthier communities are often less vulnerable to damage. Although southern California and Managua, Nicaragua, are both prone to earthquakes, California is less vulnerable to damage because of strictly enforced building codes, zoning regulations, earthquake preparedness training, and sophisticated communications systems. In 1971 the San Fernando earthquake in California measured 6.4 on the Richter scale but caused minor damage and 58 deaths, whereas an earthquake of similar magnitude struck Managua 2 years later and reduced the center of the city to rubble, killing approximately 6000 people. Similarly, in wealthy countries, drought and resulting loss of food production and groundwater are managed by use of food surpluses and treated water, but drought in poor nations often leads to deaths from famine and to sickness and death from contaminated water supplies.

Disaster Mitigation Strategies

Mitigation involves not only saving lives and reducing injury and property losses, but also reducing the adverse consequences of hazards to economic activities and social institutions. Where resources are limited, they should be directed toward protecting the most vulnerable elements. *Vulnerability* also implies a lack of resources for rapid recovery.

For most risks associated with natural geophysical hazards, such as volcanic eruptions, tsunamis, and tropical cyclones, little or no opportunity is available to reduce the hazard itself. In these cases the emphasis must be placed on reducing the vulnerability of the elements at risk. However, for technologic and human-made hazards or slow-onset hazards such as environmental pollution and desertification, reducing the hazard is likely to be the most effective mitigation strategy.

Actions by planning authorities to reduce vulnerability can be *active*, where desired actions are promoted through incentives, or *passive*, where undesired actions are

prevented by use of controls and penalties. Mitigation options are discussed next.

Engineering and Construction.

Engineering measures range from large-scale engineering works to strengthening individual buildings and implementing small-scale community-based projects to incorporate better protection into traditional structures, such as buildings, roads, and embankments.

Physical Planning Measures.

Careful location of new facilities, particularly community facilities such as schools, hospitals, and infrastructure, plays an important role in reducing settlement vulnerability. In urban areas, *deconcentration* of elements especially at risk is an important principle. Specific procedures include hazard mapping and development of a master plan containing land use control guidelines. Hazard occurrence probabilities can be extrapolated from historical data and used to create hazard maps to show regional variation. Hazard mapping can be detailed by an inventory of people or things that are exposed or vulnerable to the hazard. In France, the Zones Exposed to Risks of Movements of the Soil and Subsoil (ZERMOS) plan produces landslide hazard maps at scales of 1:25,000 or larger that are used as tools for mitigation planning. The maps portray degrees of risk of various types of landslides, including activity, rate, and potential consequences.

Economic Measures.

The linkages among different sectors of the economy may be more disrupted than the physical infrastructure. Diversifying and strengthening the economy are important ways to reduce risk. Within a strong economy, governments can use economic incentives to encourage individuals or institutions to take disaster mitigation actions.

Management and Institutional Measures.

Building disaster protection takes time and requires support from programs of education, training, and institution building to provide the professional knowledge and competence required. Development of forecasting and warning systems are important protective measures.

Societal Measures.

Mitigation planning should aim to develop a "safety culture" in which all members of society are aware of the hazards they face, know how to protect themselves, and support the protection efforts of others and communities as a whole. Specifically, these include conducting community education programs and planning and practicing evacuation procedures.

Disaster Assessment and Postdisaster Needs

Assessments regularly conducted during the recovery process help to identify needs that lead to appropriate types of assistance. In the cases of slow-onset hazard types such as desertification, deforestation, and environmental pollution, a distinct postdisaster period usually does not exist; thus ongoing impact assessment is vital. The initial response to a rapid-onset hazardous event includes the following steps by local authorities:

1. Evacuation
2. Emergency shelter
3. Search and rescue
4. Medical assistance
5. Provision of short-term food and water
6. Water disinfection and purification
7. Epidemiologic surveillance
8. Provision of temporary lodging
9. Reopening of roads
10. Reestablishment of communications networks and contact with remote areas
11. Brush and debris clearance
12. Disaster assessment
13. Provision of inputs for recovery and rehabilitation

Nature of Hazards

Many types of natural hazards and many hazards partially rooted in natural systems exist. Many of these occur infrequently or affect only small populations. One example is the eruption of toxic gases from several volcanic lakes in Cameroon that killed 2000 people in 1984 and 1986. Other rare events such as meteor impacts may occur only once every few centuries. Other widespread but minor phenomena that damage property but do not generally cause loss of life include land subsidence and sinkholes. Some hazards, such as snowstorms, often occur in areas that are prepared to deal with them so that they rarely become disasters.

This chapter discusses 12 hazards that affect large populations and that can be categorized as follows:

Geologic hazards—(1) earthquakes, (2) tsunamis, (3) volcanic eruptions, (4) landslides

Climatic hazards—(5) tropical cyclones, (6) tornadoes, (7) floods, (8) drought, (9) winter storms

Environmental hazards—(10) environmental pollution, (11) deforestation, (12)

desertification

To plan appropriate responses to implement emergency medical care and other measures to save or restore physical and mental health of affected populations, officials first need to understand the causal phenomena, characteristics, and predictability of the hazards and the factors that contribute to vulnerability. Examination of the hazard's effects on humans, property, and the environment can promote measures to prevent or lessen casualties and destruction.

EARTHQUAKES

Earthquakes are among the most destructive and feared of natural hazards. They may occur at any time of year, day or night, with sudden impact and little warning. They can destroy buildings in seconds, killing or injuring the inhabitants. Earthquakes not only destroy entire cities but may destabilize the government, economy, and social structure of a country.

Causal Phenomena

The earth's crust is a rock layer of varying thickness from a depth of about 10 km under the oceans to 65 km under the continents. The theory of plate tectonics holds that the crustal plates, varying in size from a few hundred to many thousands of kilometers, ride on the mobile mantle. When the plates contact each other, stresses arise in the crust. Stresses occur along the plate boundaries by pulling away from, sliding alongside, and pushing against one another. All these movements are associated with earthquakes.

The areas of stress at plate boundaries that release accumulated energy by slipping or rupturing are known as *faults*. *Elastic rebound* occurs when the maximum point of supportable strain is reached and a rupture occurs, allowing the rock to rebound until the strain is relieved ([Figure 68-1](#)). Usually the rock rebounds on both sides of the fault in opposite directions. The point of rupture is called the *focus* and may be located near the surface or deep below it. The point on the surface directly above the focus is termed the *epicenter* ([Figure 68-2](#)).

The energy generated by an earthquake is not always released violently and can be small or gradual. Minor earth tremors are recorded daily in the United States, but whether they are caused by the same processes that can level a city is not known. Most damaging earthquakes are associated with sudden ruptures of the crust.

Characteristics

The actual rupture process may last from a fraction of a second to a few minutes for a major earthquake. Seismic (from the Greek *seismos*, meaning "shock" or "earthquake") waves are generated that last from less than a tenth of a second to a few minutes and cause ground shaking. The seismic waves propagate in all directions, causing vibrations that damage vulnerable structures and infrastructure.

There are three types of seismic waves. The body waves (P, or primary, and S, or secondary) penetrate the body of the earth, vibrating fast ([Figure 68-3](#)). *P* waves travel

at about 6 kilometers per second (kps) and provide the initial jolt that causes buildings to vibrate up and down. *S waves* travel about 4 kps in a movement similar to the snap of a whip, causing a sharper jolt that

1626

Figure 68-1 Elastic rebound in earthquake. **A**, Forces build up over time. **B**, Crust deforms. **C**, Crust snaps. **D**, Plates slide.

Figure 68-2 Motion of the earth's plates causes increased pressure at faults where the plates meet. Eventually the rock structure collapses and movement occurs along the fault. Energy is propagated to the surface above and radiates outward. Waves of motion in the earth's crust shake landforms and buildings, causing damage. (Courtesy Disaster Management Center, University of Wisconsin.)

1627

Figure 68-3 A, Propagation of seismic waves in an earthquake. Surface waves vibrate the ground horizontally (**B** and **C**) and vertically (**D** and **E**).

vibrates structures from side to side and usually resulting in the most destruction. *Surface waves*, the third type, vibrate the ground horizontally and vertically and cause swaying of tall buildings, even at great distances from the epicenter.

Earthquake *focus depth* is an important factor in determining the characteristics of the waves. The focal depth can be deep (from 300 to 700 km) or shallow (less than 60 km). Shallow-focus earthquakes are extremely damaging because of their proximity to the surface. The earthquake may be preceded by preliminary tremors and followed by aftershocks of decreasing intensity.

Earthquake Scales

Earthquakes can be described by use of two distinctly different scales of measurement demonstrating magnitude and intensity. Earthquake *magnitude*, or amount of energy released, is determined by use of a seismograph, which records ground vibrations. The Richter scale mathematically adjusts the readings for the distance of the instrument from the epicenter. The Richter scale is logarithmic; an increase of one magnitude signifies a tenfold increase in ground motion, or about 30 times the energy. Thus an earthquake with a magnitude of 7.5 releases 30 times more energy than one with 6.5 magnitude. The smallest quake to be felt by humans is of magnitude 3. The largest earthquakes that have been recorded under this system are 9.25 (Alaska, 1969) and 9.5 (Chile, 1960).

The earthquake intensity scale measures the effects of the earthquake where it occurs. The most widely used scale of this type is the modified Mercalli scale, which expresses the intensity of earthquake effects on people, structures, and the earth's surface in values

from I to XII ([Box 68-2](#)). Another, more explicit scale used in Europe is the Medvedev-Sponheuer-Karnik (MSK) scale.

Box 68-2. MODIFIED MERCALLI INTENSITY SCALE OF 1931

- I. Not felt except by very few persons under especially favorable circumstances.
- II. Felt only by a few persons at rest, especially on upper floors of buildings. Delicately suspended objects may swing.
- III. Felt quite noticeably indoors, especially on upper floors of buildings, but many people do not recognize it as an earthquake. Standing motor vehicles may rock slightly. Vibration similar to passing of truck. Duration estimated.
- IV. During the day felt indoors by many but outdoors by few. At night some awakened. Dishes, windows, doors disturbed; walls make creaking sound. Sensation resembles heavy truck striking building. Standing motor vehicles rocked noticeably.
- V. Felt by nearly everyone; many awakened. Some dishes, windows, etc., broken. A few instances of cracked plaster. Unstable objects overturned. Disturbances of trees, poles, and other tall objects sometimes noticed. Pendulum clocks may stop.
- VI. Felt by all; many frightened and run outdoors. Some heavy furniture moved; a few instances of fallen plaster or damaged chimneys. Damage slight.
- VII. Everybody runs outdoors. Damage negligible in buildings of good design and construction, slight to moderate in well-built ordinary structures, considerable in poorly built or badly designed structures. Some chimneys broken. Noticed by persons driving motor vehicles.
- VIII. Damage slight in specially designed structures, considerable in ordinary substantial buildings with partial collapse, great in poorly built structures. Panel walls thrown out of frame structures. Fall of chimneys, factory stacks, columns, monuments, and walls. Heavy furniture overturned. Sand and mud ejected in small amounts. Changes in well water. Persons driving motor vehicles disturbed.
- IX. Damage considerable in specially designed structures. Well-designed structures thrown out of plumb, greatly in substantial buildings with partial collapse. Buildings shifted off foundations. Ground cracked conspicuously. Underground pipes broken.
- X. Some well-built wooden structures destroyed. Most masonry and frame structures with foundations destroyed; ground severely cracked. Rails bent. Landslides considerable from river banks and steep slopes. Shifted sand and mud. Water splashed (slopped) over banks.
- XI. Few, if any, (masonry) structures remain standing. Bridges destroyed. Broad fissures in ground. Underground pipelines completely out of service. Earth slumps and land slips in soft ground. Rails bent greatly.
- XII. Damage total. Practically all works of construction are damaged greatly or destroyed. Waves seen on ground surface. Lines of sight and level are distorted. Objects are thrown upward into the air.

Location and Predictability

Most earthquakes (95%) occur in well-defined zones near the boundaries of the tectonic plates. These areas bordering the Pacific Ocean are called the *circum-Pacific belt*.

Areas traversing the East Indies, the Himalayas, Iran, Turkey, and the Balkans are called the *Alpide belt*. Earthquakes also occur along the ocean trenches, such as around the Aleutians, Tonga, Japan, and Chile and within the eastern Caribbean. Some earthquakes occur in the middle of the plates, possibly indicating where earlier plate boundaries might have been. These include the New Madrid earthquake in 1811 and the Charleston earthquake in 1816 in the United States, the Agadir earthquake in 1960 in Morocco, and the Koyna earthquake in 1967 in India.

Earthquake prediction was a constant preoccupation for early astrologers and prophets. Some signs noted by observers were buildings gently trembling, animals and birds becoming excited, and well water turning cloudy and smelling bad. Although some modern scientists claim ability to predict earthquakes, the methods are still controversial. For example, the 1995 earthquake in Kobe, Japan, which killed more than 5000, was not predicted. However, mechanical observation systems make it possible to issue warnings to nearby populations immediately after detection of an earthquake. Reasonable risk assessments of potential earthquake activity can be made with confidence based on the following:

1. Knowledge of seismic zones or areas most at risk, gained through study of historical incidence and plate tectonics
2. Monitoring of seismic activity by use of seismographs and other instruments (U.S. Geological Survey monitors 80 countries)
3. Use of community-based, scientifically sound observations, such as elevation and turbidity of water in wells and radon gas escape into well water

Earthquake Hazards

Earthquakes produce many direct and sometimes indirect effects. Landslides, flooding, and tsunamis are considered

secondary hazards and are also discussed separately in this chapter.

Fault Displacement and Ground Shaking.

Fault displacement, either rapid or gradual, may damage foundations of buildings on or near the fault area or may displace the land, creating troughs and ridges. Ground shaking causes more widespread damage, particularly to the built environment. The extent of the damage is related to the size of the earthquake, the closeness of the focus to the surface, the buffering power of the area's rocks and soil, and the type of buildings being shaken. Aftershocks may cause further damage and may recur for weeks or even years after the initial event.

Ground Failure and Liquefaction.

Seismic vibrations may cause settlement beneath buildings when soils consolidate or compact. Certain types of soil, such as alluvial or sandy soils, are more vulnerable to failure. Liquefaction is a type of ground failure that occurs when saturated soils lose strength and collapse or become liquefied. During the 1964 earthquake in Nigata, Japan, the ground beneath earthquake-resistant buildings became liquefied, causing the buildings to lean up to 45 degrees from the vertical. Most of these buildings were later jacked back into an upright position and reoccupied.

Lateral Spreads and Flow Failure.

Lateral spreads involve the lateral movement of large blocks of soil as a result of liquefaction in a subsurface layer. Lateral spreads generally develop on gentle slopes with horizontal movement of 10 to 15 feet. However, where conditions are favorable and duration of ground shaking is extended, movements can be 100 to 150 feet. During the 1964 Alaska earthquake, more than 200 bridges were damaged or destroyed by lateral spreading of flood plain deposits toward river channels. In the 1906 San Francisco earthquake, a number of major pipelines were broken by lateral spreading, hampering efforts to fight fires, which caused most of the damage to the city. In 1989 the Marina District in San Francisco, built on soft landfill, was damaged from lateral spreading.

Flow failure, in which either a layer of liquefied soil rides on top of another layer or blocks of intact material ride on top of liquefied soil, can be catastrophic. Flow failures usually form in loose, saturated sands or silts on slopes greater than 3 degrees. They can originate either on land or underwater. Some of the most damaging flow failures have occurred underwater in coastal areas, carrying away large sections of port facilities and generating large sea waves. Some flow failures on land have been as much as a mile in length and breadth, such as those induced by the 1920 earthquake in Kansu, China, which killed 200,000 people.

Landslides and Avalanches.

Slope instability may cause landslides and snow avalanches during an earthquake. Steepness, weak soils, and presence of water may contribute to vulnerability from landslides. Liquefaction of soils on slopes may lead to disastrous slides. The most abundant types of earthquake-induced landslides are rock falls and rock slides, usually originating on steep slopes.

Flooding.

Tsunamis may be generated by undersea or near-shore earthquakes and may break over the coastline with great destructive force. Other flooding may be caused by seiches (back-and-forth wave action in bays) or by failures in dams and levees.

Typical Adverse Effects

Ground shaking can damage human settlements, buildings and infrastructure (particularly bridges), elevated roads, railways, water towers, water treatment facilities, utility lines, pipelines, electrical generating facilities, and transformer stations. Aftershocks can do great damage to already weakened structures. Significant secondary effects include fires, dam failures, and landslides, which may block waterways and cause flooding. Damage may occur to facilities using or manufacturing dangerous materials, resulting in chemical spills. Communications facilities may break down. Destruction of property may have a serious impact on shelter needs, economic production, and living standards of the affected community. Depending on their level of vulnerability, many people may be homeless in the aftermath of an earthquake.

The casualty rate is often high, especially when earthquakes occur in areas of high population density, particularly when streets between buildings are narrow, buildings are not earthquake resistant, the ground is sloping and unstable, or adobe or dry stone construction is used, with heavy upper floors and roofs.

Casualty rates may be high when quakes occur at night because the preliminary tremors are not felt during sleep and people are not tuned in to receive media warnings. In daytime, people are particularly vulnerable in large unsafe structures such as schools and offices. Casualties generally decrease with distance from the epicenter. As a rule of thumb, quakes result in three times as many injured survivors as persons killed. The proportion of dead may be higher with major landslides and other secondary hazards. In areas where houses are of lightweight construction, especially with wood frames, casualties are generally much fewer, and earthquakes may occur regularly with no serious, direct effects on human populations.

The most widespread medical problems are fracture injuries. Other health threats may occur with secondary flooding, when water supplies are disrupted (earthquakes can change levels in the water table) and contaminated

water is used or water shortages exist, and when people are living in high-density relief camps, where epidemics may develop or food shortages exist.

In the aftermath of the Colombia earthquake of January 1999, which most heavily affected Armenia, the death toll was 1185, and 160,000 people were homeless, most in urban areas. About 90,500 homes in the central coffee-growing region had been affected. In Armenia, 60% to 70% of homes had been destroyed, movement was restricted by fallen debris, and unemployment rose from 12% to 35%. People were living in unsatisfactory shelters made with plastic sheeting. Many migrated from the area to other places, which may not be able to absorb them. Although international response to aid Colombia was strong, the overwhelming need continued to pose problems. Five

weeks after the earthquake, supplies of food, clean drinking water, and shelter materials were still urgently required. Communities were clamoring for support to inform them of official policies and to organize a response to the temporary shelter problem. Hygiene and sanitation services and essential medicines were badly needed. Social services were required to work toward normalizing the lives of victims, especially children.

TSUNAMIS

Tsunami is a Japanese word meaning "harbor wave." Although tsunamis are sometimes called "tidal waves," they are unrelated to the tides. The waves originate from undersea or coastal seismic activity, landslides, and volcanic eruptions. They ultimately break over land with great destructive power, often affecting distant shores.

Causal Phenomena and Characteristics

The geologic movements that cause a tsunami are produced in three major ways (see [Figure 68-4](#)). The foremost cause is fault movement on the sea floor, accompanied by an earthquake. The second most common cause is a landslide occurring underwater or originating above the sea and then plunging into the water. The highest tsunamis ever reported were produced by a landslide at Lituya Bay, Alaska, in 1958. A massive rock slide produced a wave that reached a high water mark of 530 m (1740 feet) above the shoreline. A third cause of a tsunami is volcanic activity, which may uplift the flank of the volcano or cause an explosion.

Tsunamis differ from ordinary deep ocean waves, which are produced by wind blowing over water. Normal waves are rarely longer than 300 m (984 feet) from crest to crest. Tsunamis, however, may measure 150 km (90 miles) between successive wave crests. Tsunamis travel much faster than ordinary waves. Compared with normal wave speed of around 100 kilometers per hour (kph), tsunamis in the deep water of the ocean

Figure 68-4 Tsunamis are produced in three ways. **A**, Fault movement on the sea floor. **B**, Landslide. **C**, Submarine explosion from volcanic eruption.

may travel at the speed of a jet airplane—800 kph. Despite their speed, tsunamis increase the water height only 30 to 45 cm and often pass unnoticed by ships at sea. In 1946 a ship's captain on a vessel lying offshore near Hilo, Hawaii, claimed he could feel no unusual waves beneath him, although he saw them crashing on the shore.

Contrary to popular belief, the tsunami is not a single giant wave. A tsunami can consist

of 10 or more waves, termed a *tsunami wave train*. The waves follow each other in 5- to 90-minute intervals. As tsunamis approach the shore, they travel progressively slower. The final wave speed depends on the water depth. Waves in 18 m (59 feet) of water travel about 50 kph. The shape of the near-shore sea floor influences how tsunami waves will behave. Where the shore drops off quickly

1631

into deep water, the waves are smaller. Areas with long shallow shelves, such as the major Hawaiian islands, allow formation of very high waves. In the bays and estuaries, seiches where the water sloshes back and forth can amplify waves to some of the greatest heights ever observed.

On shore, the initial sign of a tsunami depends on what part of the wave first reaches land; a *wave crest* causes a rise in the water level, and a *wave trough* causes a recession. The rise may not be significant enough to be noticed by the general public. Observers are more likely to notice the withdrawal of water, which may leave fish floundering on the sea floor. A tsunami does not always appear as a vertical wall of water, known as a *bore*, as typically portrayed in drawings. More often, the effect is that of an incoming tide that floods the land. Normal waves and swells may ride on top of the tsunami wave, or the tsunami may roll across relatively calm inland waters.

The flooding produced by a tsunami may vary greatly from place to place over a short distance, depending on submarine topography, shape of the shoreline, reflected waves, and modification of waves by seiches and tides. The Hilo tsunami of 1946, originating in the Aleutian Trench, produced 18-m waves in one location and only half that height a few miles away. The sequence of the largest wave in the tsunami wave train also varies, and the destructiveness is not always predictable. In 1960 in Hilo, many people returned to their homes after two waves had passed, only to be swallowed up in a giant bore that in this case was the third wave.

Predictability

Tsunamis have occurred in all oceans and in the Mediterranean Sea, but the great majority of them occur in the Pacific Ocean. The zones stretching from New Zealand through East Asia, the Aleutians, and the western coasts of the Americas all the way to the South Shetland Islands are characterized by deep ocean trenches, explosive volcanic islands, and dynamic mountain ranges.

Since 1900 the effects of tsunamis recorded included casualties and significant damage only locally, and nine struck areas throughout the Pacific. The Tsunami Warning System (TWS) was developed in Hawaii shortly after the 1946 Hilo tsunami and is headquartered in the Pacific Warning Center in Honolulu. It has been improved and expanded and now consists of 62 tide stations, 77 seismic stations, and hundreds of points for dissemination of information. There are 24 member countries in the Pacific

basin.

The TWS works by monitoring seismic activity from a network of seismic stations. A tsunami is almost always generated by an undersea earthquake of magnitude 7 or greater. Therefore special warning alarms sound when a quake measuring 6.5 or over occurs anywhere near the Pacific. A tsunami watch is declared if the epicenter is close enough to the ocean to be of concern. Government and voluntary agencies are then alerted, and local media are activated to broadcast information. The five nearest tide stations monitor their gauges, and trained observers watch the waves. With positive indicators a tsunami warning is issued.

The TWS met with general success in saving lives during the tsunamis of 1952 and 1957 in Hawaii. In 1960, however, two major earthquakes occurring a day apart rocked the coast of Chile in South America. The first registered 7.5 on the Richter scale and produced a small but noticeable wave in Hilo Bay. The second registered a stunning 8.5, more than 30 times the energy of the first, and authorities predicted generation of a large, destructive tsunami. When the waves hit Hilo, 15 hours after the earthquake, not all the public had taken the warnings seriously, and 61 people were killed. About 7 hours later the tsunami struck Japan, killing 180. When information of conditions in Chile reached TWS, three giant waves had destroyed villages along a 500-mile stretch of coastal South America, arriving only 15 minutes after the earthquake.

The Chilean government in recent years has experimented with use of satellite technology to provide nearly immediate warnings of potentially tsunamigenic earthquakes. Project THRUST (Tsunami Hazards Reduction Utilizing Systems Technology) can provide lifesaving tsunami hazard information in an average elapsed time of 2 minutes within its communication radius. In conjunction with this satellite communications network, historical data, model simulations, and emergency operations plans are used.

Vulnerability

The following major factors contribute to vulnerability to tsunamis:

1. Growing world population, increasing urban concentration, and larger investments in infrastructure, particularly on the coastal regions, with some settlements and economic assets on lowlying coastal areas
2. Lack of tsunami-resistant buildings and site planning
3. Lack of a warning system or lack of sufficient education for the public to create awareness of the effects of a tsunami and unpredictable intensity

Having observed relatively moderate tsunamis in 1952 and 1957, citizens at Hilo in 1960 actually converged on the coast to watch the waves come in, with catastrophic results.

Typical Adverse Effects

The force of water in a bore can raze everything in its path with pressures of up to $10,000 \text{ kg/m}^2$. The flooding

1632

from a tsunami, however, affects human settlements most, by water damage to homes and businesses, roads, and infrastructure.

Withdrawal of tsunami waves also causes significant damage. As the waves are dragged back toward the sea, bottom sediments are scoured out, collapsing piers and port facilities and sweeping out foundations of buildings. Entire beaches have disappeared and houses have been carried out to sea. Water levels and currents may change unpredictably, and boats of all sizes may be swamped, sunk, or battered.

Casualties and Public Health.

Deaths occur principally from drowning as water inundates homes or neighborhoods. Many people may be washed out to sea or crushed by the giant waves. Some injuries occur from battering by debris. Little evidence exists of tsunami flooding directly causing large-scale health problems. Malaria mosquitoes may increase because of water trapped in pools. Open wells and other groundwater may be contaminated by salt water and debris or sewage. Normal water supplies may be inaccessible for days because of broken water mains.

Crops and Food Supplies.

Flooding and damage by tsunami waves may result in the following:

1. The harvest may be lost, depending on time of year.
2. Land may be rendered infertile from saltwater incursion from the sea.
3. Food stocks not moved to high ground are damaged.
4. Animals not moved to high ground may perish.
5. Farm implements may be lost, hindering tillage.
6. Boats and fishing nets may be lost.

In July 1998 an earthquake of magnitude 7 occurred close to the northwest coast of Papua New Guinea. Although the tremor was felt over a large area, no earthquake damage was reported. Only 10 minutes after the quake, however, the first of three 7 to 10 m waves came ashore in Sandaun Province. The tsunamis struck at high speed after dark and penetrated up to 1 km inland, totally destroying villages and vegetation along 50 km of the coast. Of the 9000 people affected, more than 2000 died, mainly from being battered by debris as they were swept away in the wave.

VOLCANIC ERUPTIONS

A volcano is a vent or chimney to the earth's surface from a reservoir of molten rock, called magma, deep in the earth's crust. Approximately 600 volcanoes are active (have erupted in recorded history) in the world today, and many thousands are dormant (could become active again) or extinct (are not expected to erupt again). On average, about 50 volcanoes erupt every year. Since 1000 AD, more than 300,000 people have been killed directly or indirectly by volcanic eruptions, and at present about 10% of the world's population lives on or near potentially dangerous volcanoes.

Volcanology, the study of volcanoes, has experienced a period of intensified interest after five major eruptions in the 1980s and early 1990s: Mt. St. Helens in the United States (1980), El Chichon in Mexico (1982), Galunggung in Indonesia (1982), Nevado del Ruiz in Colombia (1985), and Mt. Pinatubo in the Philippines (1991). Although the Mt. St. Helens eruptions were predicted with remarkable accuracy, predictive capability on a worldwide basis for more explosive eruptions has not been achieved. No recognized immediate precursors to the eruption of El Chichon were known. It caused the worst volcanic disaster in Mexico's history. Ineffective implementation and evacuation measures despite sufficient warnings resulted in more than 22,000 deaths from the eruption of Nevado del Ruiz. Galunggung erupted for 9 months, disrupting the lives of 600,000 people. Despite a major evacuation effort from Mt. Pinatubo, 320 people died, mainly from collapse of ash-covered roofs. A study of these eruptions underscores the importance of predisaster geoscience studies, volcanic hazard assessments, volcano monitoring, contingency planning, and enhanced communications between scientists and authorities. The world's most dangerous volcanoes are in densely populated countries where only limited resources exist to monitor them.

Causal Phenomena

The basic ingredients for a volcanic eruption are magma and an accumulation of gases beneath an active volcanic vent, which may be either on land or below the sea. Magma is composed of silicates containing dissolved gases and sometimes crystallized minerals in a liquidlike suspension. Driven by buoyancy and gas pressure, the magma, which is lighter than surrounding rock, forces its way upward. As it reaches the surface, the pressures decrease, enabling the dissolved gases to effervesce, pushing the magma through the volcanic vent as they are released.

The chemical and physical composition of magma determines the amount of force with which a volcano erupts. Magmas that are less viscous allow gas to be released more easily. More viscous magma, perhaps containing a greater concentration of solid

particles, may confine these gases longer, allowing greater pressures to build up. This greater pressure may lead to more violent eruptions.

Types

Volcanic eruptions may be described as follows in descending order of intensity ([Figure 68-5](#)).

1633

Figure 68-5 Eruption types. **A**, Pelean. **B**, Plinian. **C**, Vesuvian. **D**, Vulcanian. **E**, Strombolian. **F**, Hawaiian. **G**, Icelandic. (Modified from *Introduction to hazards*, ed 3, New York, Disaster Management Training Programme, United Nations Development Program, UN Organization for Coordination of Humanitarian Assistance.)

Pelean.

This is the most disastrous type of eruption. The hardened plug at the volcano's throat forces the magma to blast out through a weak spot in the volcanic flank. The great force of the blast devastates most objects in its path, as occurred in the Mt. St. Helen's eruption of 1980.

Plinian.

As the pressure on the magma is released, a violent upward expulsion of gas can extend far into the atmosphere. In 1991, Mt. Pinatubo sent a plume of tephra 30 km above the surface.

Vesuvian.

As in the eruption of Mt. Vesuvius in Italy in 79 AD, this type is very explosive and occurs infrequently. The explosion of built-up magma discharges a cloud of ash over a wide area.

Vulcanian.

Lava forms a crust over the volcanic vents between eruptions, building up the volcano.

Subsequent eruptions are more violent and eject dense clouds of material. The Paracutin, Mexico, volcano originated in a cornfield in 1943 and eventually covered 260 square km. A major eruption occurred in 1947.

Strombolian.

Gases escape through slow-moving lava in moderate explosions that may be continuous. Volcanic "bombs" of clotted lava may be ejected into the sky, as occurred in the 1965 eruption of Irazu in Costa Rica.

Hawaiian.

The lava is mobile and flows freely. Gases are released quietly, as in the Kilauea, Hawaii, volcano, which has continued to erupt since 1983.

Icelandic.

Similar to the Hawaiian type, lava flows from deep fissures and forms sheets spreading out in all directions, as in the Laki, Iceland, eruption of 1783.

Characteristics

No international scale exists to measure the size of volcanic eruptions. The volcanic explosivity index (VEI) estimates the energy released in a volcanic eruption, based on measurements of the ejected matter, height of the eruption cloud, and other observations. The VEI scale ranges from 0 to 8. The largest eruption recorded was in Tambora, Indonesia, in 1815, which was a VEI of 7.

The primary volcanic hazards are associated with products of the eruption: pyroclastic flows, air-fall tephra, lava flows, and volcanic gases. The most destructive secondary hazards include lahars, landslides, and tsunamis.

Pyroclastic Flows.

Pyroclastic (meaning "fire-broken" in Greek) flows are the most dangerous of all volcanic phenomena because there is virtually no defense against them. They are horizontally directed explosions or blasts of gas containing ash and larger fragments in suspension. They travel at great speed and burn everything in their path. The flows move like a snow or rock avalanche because they contain a heavy load of dust and lava fragments that are denser than the surrounding air. Gas continues to be released as they travel, creating a continuously expanding cloud.

Pyroclastic flows are responsible for the majority of deaths associated with volcanic eruptions. The pyroclastic flows from the Mt. St. Helens eruption in 1980 moved at rates up to 870 kph, and pyroclastic deposits found 2 days after the blast at the foot of the mountain registered temperatures of more than 700° C. The greatest distance recorded by such flows in historical times is 35 km.

Air-Fall Tephra.

Tephra smaller than 2 mm is classified as ash. Almost all volcanoes emit ash, but emissions vary widely in volume and intensity. Heavy ashfalls can cause complete darkness or drastically reduce visibility. Fine material from great eruptions may travel around the world and affect world climate. Clouds of dust and ash can remain in the air for days or weeks and spread over large distances, causing difficulty in driving and breathing as well as contributing to building collapse and air traffic disruption. The largest tephra are rocks or blocks, sometimes called "bombs," which have been known to travel more than 4 km. Tephra may be hot enough to start fires when it lands on structures or vegetation.

Lava Flows.

Lava flows are formed by hot, molten lava flowing from a volcano and spreading over the surrounding countryside. Depending on the viscosity, a flow may move a few meters per hour. It is usually slow enough that living creatures can move to safety. Sometimes the edges break off, causing small hot avalanches.

Volcanic Gases.

Gas is a product of every eruption and may also be emitted by the volcano during periods of inactivity, either intermittently or continually. Volcanic gas is composed mostly of steam, although often present are large amounts of toxic sulfur dioxide, hydrogen sulfide, and smaller but measurable amounts of toxic hydrochloric and hydrofluoric acid gases. Carbon dioxide is often a major component of volcanic gas and is an asphyxiant because it is much denser than air and tends to travel to and through low-lying areas and valleys. Several mountain climbers and skiers in Japan were overcome by hydrogen sulfide fumes in a valley near the Kusatsushirane volcano, and eventually an alarm system was installed. In 1986 about 1800 people were asphyxiated by gas bursts from crater lakes in Cameroon.

Lahars and Landslides.

Enormous quantities of ash and larger fragments (tephra) accumulate after an eruption on the steep slopes of a volcano, sometimes to a depth of several meters. When mixed with water, the volcanic debris is transformed into a material resembling wet concrete that flows easily downhill. *Lahar* is an Indonesian word for debris flows or mudflows. A primary debris flow is caused by eruptive activity, such as melting of snow and ice by hot volcanic materials, and a secondary debris flow results when heavy rainfall

saturates the deposits.

The rate of flow is affected by the volume of mud and debris, the viscosity, and the slope and character of the terrain. Velocity may reach 100 kph, and distance traveled may exceed 100 km. Mudflows and debris flows can be very destructive. They have buried entire towns, such as Armero, Colombia. They can silt up waterways, causing floods and changing river courses.

Landslides and debris avalanches are common where stress from intruding magma causes fractures along cracks in the volcano. Ground deformation from swelling and hardening of volcanic material can produce landslides.

Tsunamis.

Tsunamis, described previously, are generated by movement of the ocean floor, possibly caused by a volcano. In a study of volcanic eruptions in the past 1000 years, human fatalities resulting from indirect tsunami wave hazards were as significant as those from pyroclastic flows and primary mudflows.

Location

The distribution of volcanoes, as with earthquakes, is determined by the location of geologic forces involving the tectonic or crustal plates. About 80% of the active volcanoes are located near subduction boundaries. *Subduction volcanoes* occur where denser crustal plates are shoved beneath less dense continental plates, which occurs in most of the Pacific Ocean, known as the Pacific Ring of Fire. Subduction volcanoes are found in the Aleutian Islands stretching from Alaska to Asia, Japan, the Philippines, Indonesia, and the Cascade Range in the United States. Many volcanoes are located beneath the ocean, and submarine eruptions may cause tsunamis and other effects.

Rift volcanoes occur at divergent zones where two distinct plates are slowly being separated. Rift volcanoes, such as those in Iceland and East Africa, account for about 15% of active volcanoes. *Hot spot volcanoes* are located where crustal weaknesses allow molten material to penetrate, but not necessarily on the plate boundaries. These isolated regions of volcanic activity exist in about 100 places in the world. The Hawaiian islands, in the middle of the Pacific plate, and Yellowstone Park, within the North American plate, are good examples.

Predictability

Systematic surveillance of volcanoes, begun early in the twentieth century at the Hawaiian Volcano Observatory, indicates that most eruptions are preceded by measurable geophysical and geochemical changes. Short-term forecasts of future volcanic activity in hours or months may be made through volcano monitoring

techniques that include seismic monitoring, ground deformation studies, and observations and recordings of hydrothermal, geochemical, and geoelectric changes. By carefully monitoring these factors, scientists were able to issue a high confidence forecast of the 1991 Mt. Pinatubo eruption, allowing a largely successful evacuation. The best basis for long-term forecasting (within a year or longer) of a possible eruption is through geologic studies of the past history of each volcano. Each past eruption has left records in the form of lava beds. These are deposits and layers of ash and tephra that can be studied to determine the extent of the flows and length of time between eruptions.

Problems in Eruption Forecasting and Prediction.

Although significant progress has been made in long-term forecasting of volcanic eruptions, monitoring techniques have not progressed to the point of yielding precise predictions. For the purposes of warning the public and avoiding false alarms that create distrust and chaos, ideal predictions should provide precise information concerning the place, time, type, and magnitude of the eruption. The importance of enhanced communications between scientists and authorities is also emphasized. Despite sufficient warning, evacuation orders were not issued by local authorities, which resulted in more than 22,000 deaths from lahars produced by Nevado del Ruiz. The eruption of Mt. St. Helens was adequately monitored and forecasted, but the main explosion surprised authorities because the volcano did not exhibit expected signs before eruption and the blast was lateral rather than vertical; 57 people who remained in the danger area were killed.

The greatest constraint to predictability is lack of baseline monitoring studies, which depict the full range of characteristics of the volcano. Interpretation of base-line data enables differentiation of the precursory pattern of an actual eruption from other volcanic activity, such as intrusion of magma under the surface, which is sometimes termed *aborted eruption*. Before the 1982 eruption of El Chichon, virtually nothing was known of its history of frequent and violent eruptions. No monitoring was conducted before or during the brief eruption.

Developing countries suffer the greatest economic losses from volcanic eruptions. More than 99% of eruption-caused deaths since 1900 have been in developing countries. Because of shortages of funds and trained personnel, monitoring is also poorest in these countries.

Vulnerability

Rich volcanic soils and scenic terrains attract people to settle on the flanks of volcanoes. These people are more vulnerable if they live downwind from the volcano, in the path of historical channels for mudflows or lava flows, or close to waterways likely to flood because of silting. Structures with roof designs that do not resist ash accumulation

are vulnerable even miles from a volcano. All combustible materials are at risk.

Typical Adverse Effects

Casualties and Health.

Deaths can be expected from pyroclastic flows and mudflows and to a much lesser extent from lava flows and toxic gases. Injuries may occur from impact of falling rock fragments and from being buried in mud. Burns to the skin, breathing passages, and lungs may result from exposure to steam and hot dust clouds. Ashfall and toxic gases may cause respiratory difficulties for people and animals. Nontoxic gases of densities greater than air, such as carbon dioxide, can be dangerous when they collect in low-lying areas. Water supplies contaminated with ash may contain toxic chemicals and cause illness. Deaths have also occurred indirectly from starvation and from tsunami waves.

Settlements, Infrastructure, and Agriculture.

Complete destruction of everything in the path of pyroclastic or lava flows should be expected, including vegetation, agricultural land, human settlements, structures, bridges, roads, and other infrastructure. Structures may collapse under the weight of ash, particularly if the ash is wet. Falling ash may be hot enough to cause fires. Flooding may result from waterways filling up with volcanic deposits or from melting of large amounts of snow or glacial ice. Rivers may change course because of oversilting. Ashfall can destroy mechanical systems by clogging openings such as those in irrigation systems and airplane and other engines. Communication systems could be disrupted by electrical storms developing in the ash clouds. Transportation by air, land, and sea may be affected. Disruption in air traffic from large ash eruptions can have serious effects on emergency response.

Crops in the path of flows are destroyed, and ashfall may render agricultural land temporarily unusable. Heavy ash loads may break the branches of fruit or nut trees. Livestock may inhale toxic gases or ash. Ash containing toxic chemicals, such as fluorine, may contaminate the grazing lands.

The Caribbean island of Montserrat has undergone volcanic activity for years. In June 1997 the famous Soufriere Hills volcano erupted, causing at least nine deaths. The resulting pyroclastic flows buried and destroyed seven villages. Only one third of the island is now considered relatively safe.

LANDSLIDES

Landslides are a major threat each year to human settlements and infrastructure. *Landslide* is a general term covering a wide variety of landforms and processes involving the downslope movement of soil and rock. Although

1636

landslides may occur with earthquakes, floods, and volcanoes, they are much more widespread and over time cause more property loss than any other geologic event.

Causal Phenomena

Landslides result from sudden or gradual changes in the composition, structure, hydrology, or vegetation of a slope. These changes may be natural or caused by humans and disturb the equilibrium of the slope's materials. A landslide occurs when the strength of the material in the slope is exceeded by the downslope stress. The resistance in a slope may be reduced by the following:

- Increase in water content, caused by heavy rainfall or rising ground water.
- Increase in slope angle, for new construction or by stream erosion
- Breakdown or alteration of slope materials, from weathering and other natural processes, placement of underground piping for utilities, or use of landfill

The downslope stress may be caused by the following:

- Vibrations from earthquakes (triggering some of the most disastrous landslides), blasting, machinery, traffic, or thunder
- Removal of lateral support by previous slope failure, construction, or excavation
- Removal of vegetation from fires, logging, over-grazing, or deforestation that causes loosening of soil particles and erosion
- Loading with weight from rain, hail, snow, accumulation of loose rock or volcanic material, weight of buildings, or seepage from irrigation and sewage systems

Characteristics

Landslides usually occur as secondary effects of heavy storms, earthquakes, and volcanic eruptions. The materials that compose landslides are divided into two classes:

bedrock and soil (earth and organic matter debris). A landslide may be classified by its type of movement ([Figure 68-6](#)).

Falls.

A fall is a mass of rock or other material that moves downward by falling or bouncing through the air. These are most common along steep road or railroad embankments, steep escarpments, or steeply undercut cliffs, especially in coastal areas. Large individual boulders can cause significant damage.

Slides.

Resulting from shear failure (slippage) along one or several surfaces, the slide material may remain intact or break up.

Topple.

A topple is caused by overturning forces that rotate a rock out of its original position. The rock section may have settled at a precarious angle, balancing itself on a pivotal point from which it tilts or rotates forward. A topple may not involve much movement, and it does not necessarily trigger a rockfall or rock slide.

Lateral Spread.

Large blocks of soil spread out horizontally by fracturing off the original base. Lateral spreads occur generally on gentle slopes, usually less than 6%, and typically spread 3 to 5 m but may move from 30 to 50 m where conditions are favorable. Lateral spreads usually break up internally and form numerous fissures and scarps. The process can be caused by liquefaction, in which saturated loose sands or silts assume a liquefied state. A lateral spread is usually triggered by ground shaking (as with an earthquake). During the 1964 Alaskan earthquake, more than 200 bridges were damaged or destroyed by lateral spreading of floodplain deposits near river channels.

Flows.

Flows move as a viscous fluid, sometimes very rapidly, and can cover several miles. Water is not essential for flows to occur; however, most flows form after periods of heavy rainfall. A mudflow contains at least 50% sand, silt, and clay particles. A lahar is a mudflow that originates on the slope of a volcano and may be triggered by rainfall, sudden melting of snow or glaciers, or water flowing from crater lakes. A debris flow is a slurry of soils, rocks, and organic matter combined with air and water. Debris flows usually occur on steep gullies. Very slow, almost imperceptible flows of soil and bedrock are called *creeps*. Over long periods, creeps may cause telephone poles or other objects to tilt downhill.

Predictability

The velocity of landslides varies from extremely slow (less than 0.06 m/year) to extremely fast (greater than 3 m/sec), which might imply a similar variation in predictability. In absolute terms, however, predicting the actual occurrence of a landslide is extremely difficult, although situations of high risk, such as forecasted heavy rainfall or seismic activity combined with landslide susceptibility, may lead to estimation of a time frame and possible consequences.

Estimation of landslide hazard potential includes historical information on the geology, geomorphology (study of landforms), hydrology, and vegetation of a specific area. Structural features that may affect stability include sequence and type of layering, lithologic changes, planes, joints, faults, and folds. The most important geomorphologic consideration in the prediction of landslides is the history of landslides in a given area.

The source, movement, amount of water, and water pressure must be studied. Climatic patterns combined with soil type may cause different types of landslides. For example, when monsoons occur in tropical regions, large

1637

Figure 68-6 Landslides classified by type of movement. **A**, Fall. **B**, Slide. **C**, Topple. **D**, Lateral spread. **E**, Flow.

1638

debris slides of soils, rocks, and organic matter may occur. Plant cover on slopes may have either a positive or negative stabilizing effect. Roots may decrease water runoff and increase soil cohesion, or conversely they may widen fractures in rock surfaces and promote infiltration.

Vulnerability

Settlements built on steep slopes, in weak soils, on cliff tops, at the base of steep slopes, on alluvial outwash fans, or at the mouth of streams emerging from mountain

valleys are all vulnerable. Roads and communication lines through mountainous areas are in danger. In most types of landslides, damage may occur to buildings even if foundations have been strengthened. Infrastructural elements, such as buried utility lines or brittle pipes, are vulnerable.

Typical Adverse Effects

Anything on top of or in the path of a landslide will be severely damaged or destroyed. In addition, rubble may damage lines of communication or block roadways. Waterways may be blocked, creating a flood risk. Casualties may not be widespread, except in the case of massive movements caused by major hazards such as earthquakes and volcanoes.

In addition to direct damage from a landslide, indirect effects include loss of productivity of agricultural or forest lands (if buried), reduced real estate values in high-risk areas and lost tax revenues from these devaluations, adverse effects on water quality in streams and irrigation facilities, and secondary physical effects, such as flooding.

Casualties.

Fatalities have resulted from slope failure where population pressure has prompted settlement in areas vulnerable to landslides. Casualties may be caused by collapse of buildings or burial by landslide debris. Worldwide, approximately 600 deaths occur per year, mainly in the circum-Pacific region. The estimate for loss of life in the United States is 25 lives per year, greater than the average loss from earthquakes. Catastrophic landslides have killed many thousands of persons, such as the debris slide on the slopes of Huascarán in Peru triggered by an earthquake in 1970, which killed more than 18,000 people. In January 1989, only 6 weeks after an earthquake killed 25,000 people in Armenia, another quake struck the republic of Tadjikistan, 50 km southwest of the capital city of Dushanbe. This quake registered 5.8 on the Richter scale. The earthquake triggered a landslide of hillside soils that had become wet with melted snow. The liquefied soil spilled downhill and eventually covered an area about 8 km long and 1 km wide. The total volume of mud was more than 10 million m³. The epicenter of the earthquake was located in the village of Sharora. This village and several others were engulfed with mud that killed 200 and left 30,000 homeless. Mud deposits reached a height of 25 m in Sharora, causing rescue efforts to be abandoned. Later the area was declared a national monument.

TROPICAL CYCLONES

The World Meteorological Organization (WMO) uses the generic term *tropical cyclone* to cover weather systems in which winds exceed *gale force* (minimum of 34 knots or 63 kph). Tropical cyclones are rotating, intense low-pressure systems of tropical oceanic origin. Winds of *hurricane force* (63 knots or 117 kph) mark the most severe type of tropical storm. They are called *hurricanes* in the Caribbean, the United States, Central America, and parts of the Pacific; *typhoons* in the northwest Pacific and east Asia; *severe cyclonic storms* in the Bay of Bengal; and *severe tropical cyclones* in south Indian, South Pacific, and Australian waters. For easy identification and tracking, the storms are generally given alternating masculine and feminine names or numbers that identify the year and annual sequence.

Tropical cyclones are the most devastating of seasonally recurring rapid-onset natural hazards. Between 80 and 100 tropical cyclones occur around the world each year. Devastation by violent winds, torrential rainfall, and accompanying phenomena, including storm surges and floods, can lead to massive community disruption. The official death toll in individual tropical cyclones reached 140,000 (Bangladesh, 1991), and damages approached \$10 billion in Hurricane Gilbert (1988) and Hurricane Hugo (1989). The damages from Hurricane Andrew in Florida and Louisiana in 1992 totaled \$16 billion.

Causal Phenomena

The development cycle of tropical cyclones may be divided into three stages: formation and initial development, full maturity, and modification or decay. Depending on their tracks over the warm tropical seas and proximity to land, they may last from less than 24 hours to more than 3 weeks (the average duration is about 6 days). Their tracks are naturally erratic but initially move generally westward, then progressively poleward into higher latitudes, where they may make landfall, or into an easterly direction as they lose their cyclonic structure.

Formation and Initial Development Stage.

Four atmospheric and oceanic conditions are necessary for development of a cyclonic storm ([Figure 68-7](#)), as follows:

1. A warm sea temperature (greater than 26° C [78.8° F] to a depth of 60 m [197 feet]) provides abundant water vapor in the air by evaporation.
2. High relative humidity (degree to which the air is saturated by water vapor) of the atmosphere to a

height of about 7000 m (23,000 feet) facilitates condensation of water vapor into water droplets and clouds, releases heat energy, and induces a drop in barometric pressure.

3. Atmospheric instability (an above-average decrease of temperature with altitude) encourages considerable vertical cumulus cloud convection when condensation of rising air occurs.
4. A location of at least 4 to 5 latitude degrees from the equator allows the influence of the forces as the earth's rotation (Coriolis force) takes effect and induces cyclonic wind circulation around a low-pressure center.

Figure 68-7 Cyclone formation. **A**, Warm seas (greater than 26° C [78.8° F]) cause rising humid air. **B**, Cooler high-altitude temperatures cause formation of cumulonimbus clouds. The surrounding air moves toward the central low-pressure area. **C**, Cumulonimbus clouds form into spiraling bands. The Coriolis effect causes winds to swirl around the central low-pressure area. **D**, High altitude dispels the top of the cyclonic air system. Dry high-altitude air flows down the "eye." Hurricane force winds circle around the eye.

The atmosphere can usually organize itself into a tropical cyclone in 2 to 4 days. This process is characterized by increasing thunderstorms and rain squalls at sea. Meteorologists can monitor these processes with weather satellites and radar from as far as 400 miles away from the storm. The existence of favorable conditions for cyclone development determines the cyclone season for each monitoring center. In the Indian and south Asian region the season is divided into two periods, from April to early June and from October to early December. In the Caribbean and United States, tropical storms and hurricanes reach their peak strengths in middle to late summer. In the Southern Hemisphere, the cyclone season extends from November to April or May, but occasionally cyclones occur in other months in lower latitudes.

Maturity Stage.

As viewed by weather satellites and radar imagery, the main physical feature of a mature tropical cyclone is a spiral pattern of highly turbulent, giant cumulus thundercloud bands. These bands spiral inward and form a dense, highly active central cloud core that wraps around a relatively calm and

cloud-free "eye." The eye, where light winds occur, typically has a diameter of 20 to 60 km and appears as a black hole or dot surrounded by white clouds.

In contrast to the light wind conditions in the eye, the turbulent cloud formations extending outward from the eye accompany winds of up to 250 kph, sufficient to destroy or severely damage most nonengineered structures in the affected communities. These strong winds are caused by a horizontal temperature gradient that exists between the warm core of the cyclone (up to 10° C higher than the external environment) and the surrounding areas, resulting in a correspondingly high-pressure gradient.

Decay Stage.

A tropical cyclone begins to weaken, in terms of its central low pressure, internal warm core, and extremely high winds, as soon as its sources of warm moist air begin to ebb or are abruptly cut off. This would occur during landfall, by movement into higher latitudes, or through influence of another low-pressure system. The weakening of a cyclone does not mean that danger to life and property is over. When the cyclone hits land, especially over mountainous or hilly terrain, widespread riverine and flash flooding may last for weeks. The energy from a weakening tropical cyclone may be reorganized into a less concentrated but more extensive storm system causing widespread violent weather.

Characteristics

Tropical cyclones are characterized by their destructive winds, storm surges, and exceptional level of rainfall, which may cause flooding.

Destructive Winds.

The strong winds generated by a tropical cyclone circulate clockwise in the Southern Hemisphere and counterclockwise in the Northern Hemisphere, while spiraling inward and increasing toward the cyclone center. Wind speeds progressively increase toward the core as follows:

1. 150 to 300 km from the center of a typical mature cyclone, winds of 63 to 88 kph
2. 100 to 150 km from the center, storm force winds of 89 to 117 kph
3. 50 to 100 km from the center, winds in excess of hurricane force, 117 kph or greater
4. 20 to 50 km from the center, the edge of the inner core containing winds 250 kph or greater

As the eye arrives, winds fall off to become almost calm, but they rise again just as quickly as the eye passes and are replaced by hurricane force winds from a direction nearly the reverse of those previously blowing.

The Beaufort scale is used to classify the intensity of the storms. It estimates the wind velocity by observations of the effects of winds on the ocean surface and familiar

objects. Both the United States (Saffir-Simpson Potential Hurricane Damage Scale) ([Box 68-3](#)) and Australia (Cyclone Severity Categories) use country-specific scales that estimate potential property damage in five categories. The Philippines recently increased its typhoon warning signal numbers from three ranges of wind speeds to four in order to take into account the lower standards of building structures and regional variations.

Storm Surges.

The storm surge, defined as the rise in sea level above the normally predicted astronomic tide, is frequently a key or overriding factor in a tropical storm disaster. As the cyclone approaches the coast, the friction of strong onshore winds on the sea surface, in combination with the "suction effect" of reduced atmospheric pressure, can pile up sea water along a coastline near a cyclone's landfall well above the predicted tide level for that time. In cyclones of moderate intensity the effect is generally limited to several meters, but exceptionally intense cyclones can cause storm surges up to 8 m.

Of the countries experiencing cyclonic storms, those most vulnerable to storm surges are those with lowlying land along the closed and semi-enclosed bays facing the ocean. These countries include Bangladesh, China, India, Japan, Mexico, the United States, and Australia. Prevailing onshore winds and low pressures from winter depressions in nontropical latitudes, as in countries bordering the North Sea, are also subject to storm surges that require substantial mitigation measures, such as dikes.

Rainfall Events.

The world's highest rainfall totals over 1 to 2 days have occurred during tropical cyclones. The highest 12- and 24-hour totals, 135 cm and 188 cm, respectively, have both occurred during cyclones at La Reunion Island in the southwestern Indian Ocean. The very high specific humidity condenses into exceptionally large raindrops and giant cumulus clouds, resulting in high precipitation rates. When a cyclone makes landfall, the rain rapidly saturates even dry catchment areas, and rapid runoff may explosively flood the usual water courses as it creates new ones.

The relationship between rainfall and wind speed is not always proportional. For instance, if the atmosphere over land is already saturated with moisture, rainfall will be strongly enhanced, and the cyclone will weaken slowly. If the atmosphere is dry, the rainfall will be greatly reduced, and the cyclone will decay faster. Thus landfall of even a relatively weak tropical cyclone may result in extensive flooding.

Predictability

Tropical cyclones form in all oceans of the world except the South Atlantic and South Pacific east of 140° W longitude. Nearly one quarter form between 5° and 10° latitude of the equator and two thirds between 10° and

20° latitude. It is rare for a tropical cyclone to form south of 20° to 22° latitude in the Southern Hemisphere; however, they occasionally form as far north as 30° to 32° in the more extensive warmer water of the Northern Hemisphere. They are mainly confined to the warmer 6 months of the year but have occurred in every month in the western North Pacific.

Box 68-3. SAFFIR-SIMPSON POTENTIAL HURRICANE DAMAGE SCALE

SCALE NO. 1

Winds of 74 to 95 mph. Damage primarily to shrubbery, trees, foliage, and unanchored mobile homes. No real damage to other structures. Some damage to poorly constructed signs. And/or storm surge 4 to 5 feet above normal. Low-lying coastal roads inundated, minor pier damage, some small craft in exposed anchorage torn from moorings.

SCALE NO. 2

Winds of 96 to 110 mph. Considerable damage to shrubbery and tree foliage; some trees blown down. Major damage to exposed mobile homes. Extensive damage to poorly constructed signs. Some damage to roofing materials of buildings; some window and door damage. No major damage to buildings. And/or storm surge 6 to 8 feet above normal. Coastal roads and low-lying escape routes inland cut by rising water 2 to 4 hours before arrival of hurricane center. Considerable damage to piers. Marinas flooded. Small craft in unprotected anchorages torn from moorings. Evacuation of some shoreline residences and low-lying island areas required.

SCALE NO. 3

Winds of 111 to 130 mph. Foliage torn from trees; large trees blown down. Practically all poorly constructed signs blown down. Some damage to roofing materials of buildings; some window and door damage. Some structural damage to small buildings. Mobile homes destroyed. And/or storm surge of 9 to 12 feet above normal. Serious flooding at coast and many smaller structures near coast destroyed; larger structures near coast damaged by battering waves and floating debris. Low-lying escape routes inland cut by rising water 3 to 5 hours before hurricane center arrives. Flat terrain 5 feet or less above sea level flooded inland 8 miles or more. Evacuation of low-lying residences within several blocks of shoreline possibly required.

SCALE NO. 4

Winds of 131 to 155 mph. Shrubs and trees blown down; all signs down. Extensive damage to roofing materials, windows, and doors. Complete failure of roofs on many small residences. Complete destruction of mobile homes. And/or storm surge 13 to 18 feet above normal. Flat terrain 10 feet or less above sea level flooded inland as far as 6 miles. Major damage to lower floors of structures near shore due to flooding and battering by waves and floating debris. Low-lying escape routes inland cut by rising water 3 to 5 hours before hurricane center arrives. Major

Winds of 10 to 100 mph. Shrubs and trees blown down; all signs down. Extensive damage to roofing materials, windows, and doors. Complete failure of roofs on many small residences. Complete destruction of mobile homes. And/or storm surge 13 to 18 feet above normal. Flat terrain 10 feet or less above sea level flooded inland as far as 6 miles. Major damage to lower floors of structures near shore due to flooding and battering by waves and floating debris. Low-lying escape routes inland cut by rising water 3 to 5 hours before hurricane center arrives. Major erosion of beaches. Massive evacuation of all residences within 500 yards of shore possibly required, and of single-story residences on low ground within 2 miles of shore.

SCALE NO. 5

Winds greater than 155 mph. Shrubs and trees blown down; considerable damage to roofs of buildings; all signs down. Very severe and extensive damage to windows and doors. Complete failure of roofs on many residences and industrial buildings. Extensive shattering of glass in windows and doors. Some complete building failures. Small buildings overturned or blown away. Complete destruction of mobile homes. And/or storm surge greater than 18 feet above normal. Major damage to lower floors of all structures less than 15 feet above sea level within 500 yards of shore. Low-lying escape routes inland cut by rising water 3 to 5 hours before hurricane center arrives. Massive evacuation of all residential areas on low ground within 5 to 10 miles of shore possibly required.

From National Oceanic and Atmospheric Administration: Tropical cyclones of the North Atlantic Ocean, 1871–1977, Asheville, NC, 1978, National Climatic Center.

The locations, frequencies, and intensities of tropical cyclones are well known from historical observations and, more recently, from routine satellite monitoring. Tropical cyclones do not follow the same track except coincidentally over short distances. Some follow linear paths, others recurve in a symmetric manner, and still others accelerate or slow down and seem stationary for a time. For this reason, predicting when, where, and if a storm will hit land is often difficult, especially with islands. In general, the difficulty in forecasting increases from lower to higher latitudes, whereas the margin of error in determining the cyclone center decreases as landfall approaches.

Special warning and preparedness strategies for evacuation from offshore facilities or closure of industrial plants must relate the costs and benefits of those strategies against the uncertainties of precision in the forecasts. For general community purposes that require a minimum 12 hours of preparedness time, the imprecision in forecasting the location of landfall within 24 hours should be generally tolerable, bearing in mind that highly adverse cyclonic weather usually commences about 6 hours before landfall of the cyclone.

Regrettably, progress in reducing forecasting errors has remained slow in the last two decades despite huge investments in monitoring systems. However, substantial progress has been made in the organization of

warning and dissemination systems, particularly through regional cooperation. The activities of national meteorologic services are coordinated at the international level by the WMO. Forecasts and warnings are prepared within the framework of the WMO's World Weather Watch (WWW) program. Under this program, meteorologic observational data are provided nationally, and data from satellites and information provided by the regional centers are exchanged around the world. The WWW system includes 8500 land stations, 5500 merchant ships, aircraft, special ocean weather ships, automatic weather stations, and meteorologic satellites. A tropical cyclone is first identified and then followed from satellite pictures. A global telecommunications system relays the observations.

Ultimately, however, national services are responsible for providing forecasts and warnings to the local population regarding tropical cyclones and the associated winds, rains, and storm surges. Unfortunately, many of the less developed countries, where most deaths from tropical cyclones occur, do not possess state-of-the-art warning systems.

Vulnerability

Human settlements located in exposed, low-lying coastal areas are vulnerable to the direct effects of a cyclone, such as wind, rain, and storm surges. Settlements in adjacent areas are vulnerable to floods, mud slides, or landslides from the resultant heavy rains. The death rate is higher where communications systems are poor and warning systems are inadequate.

The quality of structures determines resistance to the effects of the cyclone. Those most vulnerable are lightweight structures with wood frames, older buildings with weakened walls, and houses made of unreinforced concrete block ([Figure 68-8](#)). Infrastructural elements particularly at risk are telephone and telegraph poles, fishing boats, and other maritime industries. Hospitals may be damaged, reducing access to health care and essential drugs.

Typical Adverse Effects

Structures are damaged and destroyed by wind force, through collapse from pressure differentials, and by flooding, storm surge, and landslides. Severe damage can occur to overhead power lines, bridges, embankments, nonweatherproofed buildings, and roofs of most structures. Falling trees, wind-driven rain, and flying debris cause considerable damage.

Casualties and Public Health.

Relatively few fatalities occur because of the high winds in cyclonic storms, but many people may be injured and require hospitalization. Storm surges may cause many

deaths but usually few injuries among survivors. Because of flooding and possible contamination of water supplies, malaria organisms

Figure 68-8 How high winds damage buildings. **A**, Wind blowing into a building is slowed at the windward face, creating high pressure. The airflow separates as it spills around the building, creating low pressure or suction at the end walls, roof, and leeward walls. **B**, The roof may lift off and the walls blow out if the structure is not specially reinforced. (Courtesy Disaster Management Center, University of Wisconsin.)

and viruses may be prevalent several weeks after the flooding.

Water Supplies.

Open wells and other groundwater supplies may be temporarily contaminated by flood waters and storm surges. They are considered contaminated by pathogenic organisms only if dead people or animals are lying in the sources or if sewage is present. Normal water sources may be unavailable for several days.

Crops and Food Supplies.

The combination of high winds and heavy rains, even without flooding, can ruin standing crops and tree plantations. Food stocks may be lost or contaminated if the structures in which they were held have been destroyed or inundated. Salt from storm surges may also be deposited on agricultural lands and increase groundwater salinity. Fruit, nut, and lumber trees may be damaged or destroyed by winds, flood, and storm surges. Plantation-type crops, such as bananas, are extremely vulnerable. Erosion can occur from flooding and storm surges. Food shortages may occur until the next harvest. Tree and food crops may be blown down or damaged and must be harvested prematurely.

Figure 68-9 Aftermath of Hurricane Mitch in Honduras in 1998. (Courtesy Paul

Thompson, InterWorks.)

Communications and Logistics.

Communications may be severely disrupted as telephone lines, radio antennas, and satellite dishes are brought down, usually by wind. Roads and railroad lines may be blocked by fallen trees or debris, and aircraft movements may be curtailed for at least 12 to 24 hours after the storm. Modes of transportation, such as trucks, carts, and small boats, may be damaged by wind or flooding. The cumulative effect of all damage is to impede information gathering and transport networks.

Preparedness Measures in India

Tropical cyclones twice struck the same coastal areas of the Indian state of Andhra Pradesh. In 1978 10,000 people perished. In 1990, despite significant increases in population, fewer than 1000 died. A program of improved monitoring and warning dissemination had been developed by the Indian government. This included use of a domestic satellite, an upgraded cyclone contingency preparedness plan, and enhanced community awareness. Widespread evacuation procedures were initiated by the state counterdisaster committee 48 hours ahead of forecasted landfall. A total of 651,865 people were evacuated from 546 villages to 1098 emergency relief camps by 2019 evacuation teams using 745 transport vehicles. People had also been instructed by the media to go to the camps before the commencement of the cyclonic weather.

1998's Deadly Hurricane Season

The 1998 Atlantic hurricane season, from June 1 to Nov. 30, was one of the deadliest in 200 years, killing more than 10,000 people in eight countries and causing billions of dollars in damage. Fourteen named storms, four more than average, formed in the Atlantic Ocean, Caribbean Sea, and the Gulf of Mexico. Of these, 10 became hurricanes. Hurricane Bonnie hit the North Carolina coast and prompted disaster declarations in three states. Hurricane Georges followed a path across the U.S. Virgin Islands, Puerto Rico, the Dominican Republic, Haiti, and Cuba, killing more than 500 and causing \$5 billion in damages. Hurricane Mitch moved across Central America, killing an estimated 10,000 in Honduras and wiping out the country's infrastructure ([Figure 68-9](#)). Mitch regenerated as a tropical storm and then passed over southern Florida.

TORNADOES

Tornadoes are the most dramatic example of a class of storms, often called *severe local storms*, which includes thunderstorms and hailstorms. Severe local storms a few miles to a few tens of miles in diameter are often accompanied by unusually strong, gusty winds that can cause severe damage, by heavy local rain that can cause flash floods, and by lightning, hail, and sometimes tornadoes. These intense vortices may be only a few hundred feet in diameter but can contain winds in excess of 300 mph, capable of tearing roofs off houses and lifting houses, trees, and vehicles hundreds of feet through the air. Tornadoes have been known to occur in swarms, with as many as several dozen affecting an area of hundreds of thousands of square miles in a single day. A new 1-day record was set in the United States on Jan. 21, 1999, when 38 tornadoes were hatched in Arkansas, surpassing the previous record of 20 statewide.

Causal Phenomena

Tornadoes and other severe local storms result from intense, local atmospheric instability, usually caused by solar heating of the earth's surface, which causes intense convective columns. A tornado is a vortex in which air spirals inward and upward. It is frequently, but not always, visible as a funnel cloud hanging part or all of the way from the generating storm to the ground. The upper portion of the funnel consists of water droplets, and the lower portion usually consists of dust and soil being sucked up from the ground. The funnel size may range from a few meters to a few hundred meters in diameter and from 10 m to several kilometers high. The funnel may undergo changes in appearance during the tornado's lifetime. There may be a single well-defined funnel, multiple funnels, or funnels that appear to consist of several ropelike strands. Tornadoes may be as loud as the roar of a freight train.

Tornadoes are the most violent event associated with thunderstorms. They occur in many parts of the world but are most frequent and fierce in the United States. As many as 1000 may strike the United States each year, mostly in the central plains and southeastern states, although they have occurred in every state, mostly in the spring and summer. Of all the natural

hazards in the United States, thunderstorms with associated winds, rain, hail, lightning, and tornadoes rank first in number of deaths, second in number of injuries, and third in property damage.

The most common type of tornado is small and lasts only a minute or two, causing minor damage over a track often less than 300 feet wide and 1 to 2 miles long. Most tornado-related deaths, injuries, and property damage are caused by relatively infrequent, large, and long-lasting tornadoes with paths more than 1 mile wide and more than 100 miles long over several hours.

Predictability

Although conditions favorable to tornado formation can often be predicted a number of hours in advance, the areas in which these conditions are found may cover hundreds of thousands of square miles. It is impossible to predict where individual tornadoes will occur. When a warning is issued, a tornado has already formed and the threatened population may have only a few minutes to take cover. In the United States, when tornadoes are considered likely within a well-defined region, a tornado watch is issued. When a tornado is actually detected, either visually or on radar, a tornado warning is issued.

Vulnerability

Most injuries from tornadoes are caused by flying or falling debris, usually from destroyed structures. The quality of structures will determine resistance to the effects of the cyclone. Those most vulnerable are lightweight structures with wood frames, older buildings with weakened walls, mobile homes, and houses made of unreinforced concrete blocks. Thorough education regarding taking shelter from flying debris is essential to reduce deaths and injuries.

Examples of Tornado Outbreaks

In March 1925 a tornado struck Missouri, Illinois, and Indiana, killing 689 people. On April 11, 1965, an outbreak of at least 37 tornadoes struck Iowa, Wisconsin, Illinois, Indiana, Michigan, and Ohio, killing 271 people, injuring more than 3000, and causing \$300 million in damage. On April 3 and 4, 1974, an outbreak of 147 tornadoes struck Illinois, Indiana, Michigan, Ohio, West Virginia, Virginia, Kentucky, Tennessee, North Carolina, South Carolina, Georgia, and Alabama, killing 335 people, injuring more than 5500, affecting more than 27,000 households, and causing more than \$600 million in damage. More than half the deaths were caused by less than 5% of the tornadoes. The worst of these struck Xenia, Ohio. It cut a swath of destruction half a mile wide and 16 miles long, killed 34 people, injured 1150, and damaged or destroyed 2400 homes. On May 31, 1985, 43 tornadoes struck Ohio, Pennsylvania, New York, and southern Ontario, killing 87 people. The 1999 tornado damage season began early with multiple tornadoes in Arkansas in January. In early May, tornadoes hit Oklahoma and Kansas, killing 43, the largest number in more than a decade.

FLOODS

Throughout history, people have been attracted to the fertile lands of the floodplains, where their lives have been made easier by virtue of proximity to sources of food and water. Ironically, the same river or stream that provides sustenance to the surrounding population also renders humans vulnerable to disaster by periodic flooding. Flooding occurs when surface water covers land that is normally dry or when water overflows normal confinements. The most widespread of any hazard, floods can arise from abnormally heavy precipitation, dam failures, rapid snow melts, river blockages, or even burst water mains. However, floods can provide benefits without creating disaster and are necessary to maintain most river ecosystems. They replenish soil fertility, provide water for crop irrigation and fisheries, and contribute seasonal water supplies to support life in arid lands.

Every year in Bangladesh, large tracts of land are submerged during the monsoon season, a normally beneficial process that deposits a rich layer of alluvial soil. The floods originate from three great river systems in the Himalayan mountains: the Ganges, the Brahmaputra, and the Meghna. In summer 1988 the rivers reached their highest levels in history, and 60% of the land was flooded. At least 1500 people died in the floods, and 49 million were affected by crop loss and damaged homes.

In the aftermath of the flooding, cases of diarrheal diseases reached epidemic proportions, with 50,000 cases reported daily. The risk of other diseases, such as hepatitis, typhoid fever, and measles, was elevated because of contaminated water supplies. Destruction of almost 4 million hectares of crops and partial damage to 3 million hectares left a shortfall in annual grain requirements of 1 million tons and placed the population at risk of famine. In the flood of 1974 in Bangladesh, affecting 50% of the land, 27,500 persons perished from subsequent disease and starvation. Fortunately, timely arrival of food aid in 1988 averted a famine crisis.

Causal Phenomena

The most important cause of floods is excessive rainfall. Rain may be seasonal occurring over wide areas, or may form localized storms that produce the highest intensity rainfall. Some storms are attributed to atmospheric and oceanic processes such as the El Niño Southern Oscillation (ENSO) or strong jet streams. Melting snow is another major contributor.

Types

Flash.

These are usually defined as floods that occur within 6 hours of the beginning of heavy rainfall. This type of flooding requires rapid localized warnings and immediate response by affected communities if damage is to be mitigated. Flash floods are normally a result of runoff from a torrential downpour, particularly if the catchment slope is unable to absorb and hold a significant part of the water. Other causes of flash floods include dam failure or sudden breakup of ice jams or other river obstructions. Flash floods are potential threats particularly where the terrain is steep, surface runoff is high, water flows through narrow canyons, and severe rainstorms are likely.

River.

River floods are usually caused by precipitation over large catchment areas, by melting of the winter accumulation of snow, or sometimes by both. The floods take place in river systems with tributaries that may drain large geographic areas and encompass many independent river basins. In contrast to flash floods, river

Figure 68-10 Flooding and its causes. (Courtesy Disaster Management Center, University of Wisconsin.)

floods normally build up slowly, are often seasonal, and may continue for days or weeks. Factors governing the amount of flooding include ground conditions (the amount of moisture in the soil, vegetation cover, depth of snow, cover by impervious urban surfaces such as concrete) and size of the catchment basin ([Figure 68-10](#)).

Coastal.

Some flooding is associated with tropical cyclones (also called hurricanes and typhoons). Catastrophic flooding from rainwater is often aggravated by wind-induced storm surges along the coast. Salt water may flood the land by one or a combination of effects from high tides, storm surges, or tsunamis. As in river floods, intense rain falling over a large geographic area will produce extreme flooding in coastal river basins.

Contribution by Humans

Floods are naturally occurring hazards but can become disasters when they affect

magnitude and frequency of flooding often increase because of human actions. Settlement on floodplains contributes to flooding disasters by endangering humans and their assets. However, the economic benefits of living on the floodplain outweigh the dangers for some societies. Population pressure is now so great that people have accepted the risk associated with floods because of the greater need for a place to live. In the United States, billions of dollars have been spent on flood protection programs since 1936. Despite this, the annual flood hazard has become greater because people have built on floodplains faster than engineers can design better flood protection.

Urbanization contributes to urban flooding. Roads and buildings prevent infiltration of water, so runoff forms artificial streams. The network of drains in urban areas may deliver water and fill natural channels more rapidly than natural drainage routes, or drains may be insufficient and overflow. Natural or artificial channels may become constricted by debris or obstructed by river facilities, impeding drainage and overflowing the catchment areas. Failure to maintain or manage drainage systems, dams, and levees in vulnerable areas also contributes to flooding.

Deforestation and removal of root systems increase runoff. Subsequent erosion causes sedimentation in river channels, which decreases their capacity.

Predictability

Riverine flood forecasting estimates river level stage, discharge, time of occurrence, and duration of flooding, especially of peak discharge at specific points along river systems. Flooding resulting from precipitation, snow melt in the catchment system, or upstream flooding is predictable from 12 hours to as much as several weeks ahead. Forecasts issued to the public result from regular monitoring of the river heights and rainfall observations. Flash flood warnings, however, depend solely on meteorologic forecasts and knowledge of local geographic conditions. The very short lead time for the development of flash floods does not permit useful monitoring of actual river levels for warning purposes.

For comparison with previous flood events and conversion to warning information, assessment of the following elements should be included: flood frequency analysis, topographic mapping and height contouring around river systems with estimates of water-holding capacity of the catchment area, precipitation and snow melt records, soil filtration capacity, and (if in a coastal area) tidal records, storm frequency, topography, coastal geography, and breakwater characteristics.

An effective means of monitoring floodplains is through remote sensing techniques. The images produced by satellites can be interpreted to map flooded and flood-prone areas. Other efforts to improve forecasting are being implemented by United Nations

organizations, such as the WMO, using WWW and the Global Data Processing System. These systems are strategic when flood conditions exist across international boundaries. The great majority of river and flash flood forecasts, however, depend on observations made by national weather services for activation of flood alert warnings.

Vulnerability

At notable risk in floodplain settlements are buildings made of earth or with soluble mortar, buildings with shallow foundations, or buildings that are nonresistant to water force and inundation. Infrastructural elements at particular risk include utilities such as sewer systems, power and water supplies, and machinery and electronics belonging to industry and communications. Of great concern are food stocks and standing crops, confined livestock, irreplaceable cultural artifacts, and fishing boats and other maritime industries.

Other factors affecting vulnerability are lack of adequate refuge sites above flood levels and accessible routes for reaching those sites. Also, lack of public information about escape routes and other appropriate response activities renders communities more vulnerable.

Typical Adverse Effects

Structures are damaged by receiving the force of impact of flood waters, floating away on rising waters, becoming inundated, collapsing because of undercutting by scouring or erosion, and being struck by waterborne debris.

Damage is likely to be much greater in valleys than in open, low-lying areas. Flash floods often sweep away everything in their path. In coastal areas, storm surges are destructive both on inward travel and on outward return to the sea. Mud, oil, and other pollutants carried by water are deposited and ruin crops and building contents. Saturation of soils may cause landslides or ground failure.

Casualties and Public Health.

Currents of moving or turbulent water can knock down and drown people and animals in relatively shallow depths. Major floods may result in large numbers of deaths from drowning, particularly among young and weak persons, but generally inflict few serious but nonfatal injuries requiring hospital treatment. Slow flooding causes relatively few direct deaths or injuries but often increases the occurrence of snakebites.

Endemic disease will continue in flooded areas, but little evidence exists of floods directly causing any large-scale additional health problems besides diarrhea, malaria, and other viral outbreaks 8 to 10 weeks after the flood.

Water, Crops, and Food Supplies.

Open wells and other groundwater supplies may be contaminated temporarily

1647

by debris carried by flood waters or by salt water brought in by storm surges. They are contaminated by pathogenic organisms, however, only if bodies of people or animals are caught in the sources or if sewage is present. Normal sources of water may not be available for several days.

An entire harvest may be lost along with animal fodder, resulting in long-term food shortages. Food stocks may be lost by submersion of crop storage facilities, resulting in immediate food shortages. Grains quickly spoil if saturated with water, even for a short time. Most agricultural losses result from the inundation of crops or stagnation by standing water, as in the 1988 Bangladesh flood.

Large numbers of animals, including draught animals, may be lost if they are not moved to safety. This may reduce the availability of milk and other animal products and services, such as preparation of the land for planting. These losses, in addition to possible loss of farm implements and seed stocks, may hinder future planting efforts.

Floods bring mixed results in terms of their effects on the soil. In some cases, land may be rendered infertile for several years after a flood because of erosion of the topsoil or salt permeation, as in the case of a coastal flood. Heavy silting may have adverse effects or may significantly increase fertility of the soil.

In coastal areas, where fish provide a source of protein, boats and fishing equipment may be lost or damaged.

On the positive side, floods may flush out pollutants in the waterways. Other positive effects include preserving wetlands, recharging groundwater, and maintaining the river ecosystems by providing breeding, nesting, and feeding areas for fish, birds, and wildlife.

DROUGHT

Of all natural disasters, droughts potentially have the greatest economic impact and affect the greatest number of people. They invariably have a direct and significant impact on food production and the overall economy. Due to the slow onset of droughts, their effects may accumulate over time and linger for many years. Their impact may be less obvious than that of other natural hazards but may be spread over a wider geographic area. Because of the pervasive effects of droughts, assessing their impact and planning assistance become more difficult than with other natural hazards.

No universal definition exists for drought. In general, drought is a temporary reduction in water or moisture availability that is significantly below the normal or expected amount for a specified period. Because droughts occur in nearly all regions of the world and have varying characteristics, however, working definitions must be regionally specific and focus on the impacts, which result from discrepancies between the supply and demand for water.

Droughts are most often associated with low rainfall and semiarid climate. However, they also occur in areas with normally abundant rainfall. Humans tend to stabilize their activities around the expected moisture environment. Thus, after many years with above-average rainfall, people may perceive the first year of average rainfall as a drought. A rainfall level that meets the needs of a pastoralist may constitute a serious drought for a farmer growing corn. To define drought in a region, it is necessary to understand both the meteorologic characteristics and the human perception of drought.

Types

Meteorologic.

Meteorologic drought results from a shortfall in precipitation and is based on the degree of dryness relative to the normal or average amount and on the duration of the dry period. This comparison must be region specific and may be measured against daily, monthly, seasonal, or annual rainfall amounts.

Hydrologic.

Hydrologic drought involves a reduction of water resources, such as streams, groundwater, lakes, and reservoirs. It involves data on availability and offtake rates in relation to the normal operations of the system (domestic, industrial, irrigated agricultural) being supplied. One impact is competition between users for water in these

storage systems.

Agricultural.

Agricultural drought is the impact of meteorologic and hydrologic droughts on crops and livestock production. It occurs when soil moisture is insufficient to maintain average plant growth and yields. The impact of agricultural drought is difficult to measure because of the complexity of plant growth and the possible presence of other factors that may reduce yields, such as pests, weeds, low soil fertility, and low crop prices.

Famine drought can be regarded as an extreme form of agricultural drought in which food shortages are so severe that large numbers of people become unhealthy or die. However, famine disasters usually have complex causes, such as political conflict. Although scarcity of food is the main factor in a famine, death can result from other complicating influences, such as disease or lack of access to water and other services.

Socioeconomic.

Socioeconomic drought correlates the supply and demand of goods and services with the three other types of drought and emphasizes the relationship between drought and human activities. When the supply of some goods or services, such as water, hay, or electric power, is weather dependent, drought may cause shortages.

1648

Causal Phenomena

The reasons for lack of rain are not well understood. Displacement of the normal path of the jet stream may steer rain-bearing storms elsewhere. Recent research has focused on *teleconnection*, or linkages to global interactions, between the atmosphere and the oceans. Sea surface temperature anomalies (SSTAs) influence heat and moisture, such that warm surface water may create air conditions favorable for a cyclone formation. A large-scale SSTA is linked to ENSO events in the Pacific. These involve the periodic (every 2 to 7 years) invasion of warm surface waters into the normally colder waters off the coast of South America. Droughts of 1982–1983 in Africa, Australia, India, Brazil, and the United States coincided with a major El Niño.

Human causes of drought that include land use practices that give rise to desertification, such as deforestation, overcultivation, overgrazing, and mismanagement of irrigation, are thought to result in greater persistence of drought. Traditional drought coping systems in Africa, such as pastoralists' use of seasonal grazing lands and farmers' use of fallow periods, have been reduced because of population pressures and economic policies (see Desertification).

Droughts vary in terms of intensity, duration, and coverage. Droughts tend to be more severe in drier areas of the world because of low mean annual rainfall and longer duration of dry periods. In dry areas, drought builds up slowly over several years of poor

rainfall. Dry conditions in the African Sahel over a 16-year period led to widespread famine in 1984–1985. The quarter century of drought conditions in the Sahel was interrupted by heavy rains in 1994. The area affected by drought in a country has important implications for food security. Larger countries, such as India and Brazil, are rarely completely affected by drought, but smaller countries may be totally affected ([Figure 68-11](#)). Worldwide food availability may be adversely affected by drought in grain-exporting nations.

Figure 68-11 Victims of drought in Ethiopia. (Courtesy United Nations.)

Predictability

Modern meteorologic monitoring and telecommunications systems can prevent casualties from drought-induced food shortages. The slow onset of drought allows a warning time between the first indications, usually several months, and when the population will be affected. In 1987, satellite imagery and rainfall reports indicated areas within Ethiopia with below-normal moisture and allowed timely intervention to avert a major food shortage. Longer-term prediction requires analysis of a century of rainfall data, which do not exist for some parts of the world.

Satellite Data.

Satellite remote sensing is a powerful tool for detecting the characteristics of drought from a distance. In addition to the unique vantage point and condensed view, remote sensing provides a permanent and historical record. The National Oceanic and Atmospheric Administration (NOAA) satellites use the Advanced Very High Resolution Radiometer (AVHRR) to provide twice-daily coverage of the planet's surface. These data are available at many receiving stations around the world. NOAA has developed crop-monitoring technology for large areas of the Sahel. The Normalized Difference Vegetation Index (NDVI) use the satellite data to indicate areas of stressed vegetation, which can help predict food shortages when combined with local weather data and crop information.

Vulnerability

Although drought is more likely in dry areas with limited rainfall, physical factors such as the moisture retention of soil and timing of rains influence the degree of crop loss. Dependency on rain-fed agriculture increases vulnerability. Farmers unable to adapt with repeated plantings may experience crop failure. Livestock-dependent populations without adequate grazing territory are also at risk. Those dependent on stored water resources or irrigation are more vulnerable to water shortages and may face competition

for water.

Drought-related effects are more severe in countries with yearly food deficiencies and in largely subsistence-level farming and pastoralist systems. Food shortages have the greatest impact where malnutrition already exists. Most food shortage-related deaths occur in the semiarid countries of sub-Saharan Africa, whereas in more developed countries the consequences are largely economic. Adverse effects may be more serious where drought response has not been adequately planned and where assistance measures may be poorly targeted or ineffective.

Typical Adverse Effects

The effects of drought can be grouped as economic, environmental, and social. Economic effects include losses

1649

in crops, dairy and livestock, timber and fisheries, national economic growth, and income for farmers and others. Decreased tourism, loss of hydroelectric power and increased energy costs, increased food prices, unemployment, and losses of revenue to governments are other economic effects. Environmental losses include damage to animals, fish, and plant species and habitat; wind and water erosion of soils; reduced water quality or altered salination; and reduced air quality from dust and pollutants. Social effects include food shortage (malnutrition, famine), loss of human life, conflict between water users, health problems from decreased water flow, decline in living conditions, increased poverty, social unrest, and population migration for employment.

WINTER STORMS

Winter storms feature strong winds, extreme cold, ice storms, and heavy snowstorms. These are often deceptive killers because most deaths are indirectly related to the storm, such as from traffic accidents and hypothermia. In the United States, for deaths related to ice and snow, about 70% occur in automobiles, and 25% are people caught out in a storm. The majority are males over 40 years old. For deaths related to cold, 50% are people over 60 years old, more than 75% are males, and about 20% occur in the home.

When temperatures are below freezing, everyone is at potential risk from winter storms. In areas of the world where roads are rarely maintained to mountainous areas, such as in Lebanon, Iraq, and Russia, local populations cope by storing provisions for the winter months. In more heavily populated areas, individual and societal precautions must be taken to avoid the effects of winter storms. The cost of cleaning up after winter storms and loss of business during the storm can have significant economic impact.

Causal Phenomena

Cold air and below-freezing temperatures in the clouds and near the ground are necessary to make snow and ice. Moisture is needed to form clouds and precipitation. The source of moisture may be air blowing across a body of water, such as a large lake or the ocean. *Lift*, or the required force needed to raise the moist air to form the clouds and cause precipitation, can occur when warm air collides with cold air and is forced to rise over the cold dome. The boundary between the warm and cold air is called a *front*. Lift might also occur from air flowing up a mountainside.

Strong Winds.

Strong winds that sometimes accompany winter storms can create blizzard conditions with blinding wind-driven snow, severe drifting, and dangerous windchill factor. Strong winds with these intense storms and cold fronts can knock down trees, utility poles, and power lines. Storms near the coast can cause coastal flooding and beach erosion, as well as sink ships at sea. Winds descending from mountains can gust to 100 mph or more, damaging roofs and other structures.

The windchill factor is based on the rate of heat loss from exposed skin caused by combined effects of wind and cold. As the wind increases, heat is carried away from the body at an accelerated rate, driving down the body temperature. Animals are also

affected by windchill.

Extreme Cold.

Extreme cold often accompanies a winter storm or is left in the aftermath. What constitutes extreme cold varies in different areas. For example, in areas unaccustomed to winter weather, cold may be extreme only at the freezing mark. Freezing temperatures can cause severe damage to citrus fruit crops and other vegetation.

Prolonged exposure to cold can cause frostbite (damage to body tissue caused by tissue being frozen) or hypothermia (low body temperature) (see [Chapter 6](#) and [Chapter 7](#)). Infants and elders are most susceptible.

Ice Storms.

Even a small amount of ice poses a significant hazard to motorists and pedestrians. Accumulations of ice can bring down trees, electrical wires, telephone poles and lines, and communication towers. Communication and power can be disrupted for days while utility companies work to repair extensive damage.

Snowstorms.

Snow may fall as flurries, showers, squalls, blowing snow, or blizzards, where winds over 35 mph and blowing snow reduce visibility. Sleet (raindrops that freeze into ice pellets before reaching the ground) can accumulate and cause problems. Heavy snow can immobilize a region and paralyze a city. Travelers can be stranded and emergency services disrupted. In rural areas, homes and farms may be cut off for days, and livestock may die if unprotected. The probability of avalanches increases in the mountains.

Predictability

Although winter storm patterns are known in most areas of the world, predicting the intensity and characteristics of winter storms is not an exact science. The effects of El Niño on the winter storm patterns of 1998 are still being debated. Typical U.S. storm patterns include the "Nor'easter," which affects the mid-Atlantic coast to New England from low-pressure areas off the Carolina coast. Research is continuously underway to improve forecasting tools and techniques. For example, the Stormscale Research and Application Division of the National Severe Storms Laboratory at the University of Oklahoma provides feedback for the National

The capacities of most national weather services allow individuals and public services to prepare for winter storms. Winter storm watches and warnings and winter weather advisories are normally issued in most vulnerable areas.

Vulnerability

Lack of a preparedness plan by individuals and communities or lack of understanding of the effects of winter storms, increases vulnerability. Failure to heed warnings lack of communication facilities to receive warnings, and insufficient preparation to cope with the cold or possible isolation from heavy snow can lead to casualties. For example, a person stranded in a vehicle or home during a winter storm without a storm survival kit or with inadequate heat or food and water may become hypothermic or dehydrated. Lack of protection for infrastructure, utilities, and houses can result in damage, loss of service, and roof collapse from heavy snow. Downed trees may cause later forest fires. Motorists unaccustomed to driving in winter storms cause more accidents. People living in uninsulated or unheated buildings are at greater risk for hypothermia.

The 1998 Ice Storm

A storm of unprecedented impact began on January 5, 1998, and ultimately damaged about 18 million acres of rural and urban forests throughout Maine, New Hampshire, Vermont, upstate New York, and southeastern Canada. The storm severely impacted the dairy industry, maple sugar industry, small businesses, public facilities, and infrastructure. Power outages lasted for up to 23 days. Thousands of people required shelter for an extended period, and nine people died in the United States.

The causal factors of the storm were a combination of natural and human made. Population and urbanization had recently increased in the area. Cold surface temperatures were overrun by a warm moist tropical air mass, resulting in record rainfall of 2 to 6 inches. Below-freezing temperatures caused the rain to freeze on contact, producing ice accumulations of more than 3 to 4 inches. These factors were intensified by the long duration and significant scope of the storm, resulting in severe flooding and ice damage. Much of the damage could not be assessed until the spring thaw. As a result of the storm, the Federal Emergency Management Agency (FEMA) reviewed the mitigation measures in place and made new recommendations.

ENVIRONMENTAL POLLUTION

The world population is expected to be 8.3 billion by 2050, increasing by 86 million people annually. Despite the pressures placed on natural resources by the expanding population, many poor countries still desperately need the benefits accompanying industrialization and economic growth. In general, people in developing countries are much more vulnerable to the effects of environmental degradation because they are poorer and depend more directly on the land.

Causal Phenomena

Various parts of the environment are subjected to the effects of toxic (poisonous) chemicals produced in manufacturing, such as paint and metal production, and the burning of fossil fuels, such as gasoline, coal, and oil. Some of these chemicals are heavy metals, such as lead, which are essentially nondegradable. Other toxic compounds, such as pesticides, are purposely introduced into the environment. Toxic chemicals may accumulate and affect the quality of air and water. Other pollutants of importance are from biologic sources, such as human wastes, soil sediments, and decaying organic matter.

Air Pollution.

Much of the world's urban population breathes polluted air at least part of the time. Sulfur dioxide, a major pollutant, is a corrosive gas harmful to humans and the environment. Electricity generation using fossil fuels is the key source of this compound in industrialized countries. In developed countries the burning of fossil fuels also contributes. Other air pollutants include nitrogen oxides, carbon dioxide (CO₂), and lead, mainly from vehicle exhaust.

Marine Pollution.

Sewage is the major cause of ocean pollution. Raw sewage containing human excreta and domestic wastes is disposed of in large quantities directly into the ocean. In the summer of 1993, thousands of ocean beaches were closed in the United States because of high levels of pathogens from human and animal wastes. Industrial effluents are also piped into the ocean. Other pollutants include marine litter, oil spills, and dumped chemical compounds, such as those containing mercury and radioactive substances.

Freshwater Pollution.

Human waste and other domestic wastewaters are often discharged directly into nearby bodies of water, particularly in urban areas. In developing countries this waste may be completely untreated. Industrial effluents from papermaking, chemical, metalworking, textile, and food-processing industries reach bodies of water by direct discharge or by leaching from dumps.

Clearing the land for agriculture and using irrigation, fertilizers, and pesticides have seriously affected water quality in many countries. Unprecedented deforestation has led to soil erosion, causing accelerated

1651

runoff and sediment deposits in riverbeds. The sediment level in rivers may increase 100-fold in deforested areas during rainy seasons.

Runoff of nitrogen from fertilizers, particularly in industrialized nations, renders some water unfit to drink without treatment. Use of irrigation systems may lead to increased salinity of water sources and saltwater intrusion on coastal areas where water is withdrawn. Approximately 25% of the world's pesticide production is used in developing countries, mainly on cash crops. Accumulations of pesticide toxins are found in food, soil, and water. Although data on Africa are lacking, studies in Asia indicate that rivers and lakes in Indonesia and Malaysia have very high levels of polychlorinated biphenyls (PCBs) and some pesticides.

Ozone Depletion

Ozone is a form of oxygen composed of three atoms of oxygen. Most atmospheric ozone is concentrated in the upper atmosphere, or stratosphere. The ozonosphere, or the ozone layer, is 11 to 24 km above the earth. Ozone screens out harmful wavelengths of ultraviolet radiation (UV-B) that originate from the sun, protecting life on Earth (see [Chapter 14](#)). Ultraviolet light is associated with increased non-melanoma skin cancer, ocular cataracts, and deterioration of the retina and cornea. In addition, oceanic phytoplankton are reduced, with damage to fish larvae and young fish. Since fish provide 14% of the animal protein consumed worldwide (60% of that in Japan), the impact could be significant. Thinning of the ozone layer is caused by chlorofluorocarbons (CFCs), chemicals used in refrigeration, foam products, and aerosol propellants. The CFCs that damage the ozone layer may also contribute to global warming. Although they compose a fraction of greenhouse gases, they account for 20% of the warming trend caused by radioactive trapping potential (10,000 times greater than that of CO₂).

Global Warming

Global temperatures appear to be higher today than they have been since 1862, when temperatures were first recorded by instrumentation. The last 15 years include the six hottest temperatures ever recorded. One explanation for this increase is perhaps a global warming caused by the greenhouse effect.

The term *greenhouse effect* is used to describe the role of atmospheric gases, such as CO₂, methane, and water vapor, in trapping radiation that would otherwise leave the atmosphere. Without this canopy of gases and clouds, the temperature of the earth would be extremely cold. The atmospheric gases therefore behave similarly to a greenhouse.

Since the beginning of the Industrial Revolution in the late eighteenth century, CO₂ in the atmosphere has increased by almost 25%, mainly from combustion of coal, oil, natural gas, and gasoline. A strong scientific consensus states that buildup of greenhouse gases is warming the global atmosphere. Computer models used to examine the climatic effects of increasing CO₂ suggest that if it doubles, global temperatures would increase on average by 3° to 5° C.

Trees play a vital role in recycling CO₂ by taking it in, transforming it chemically, storing the carbon, and releasing oxygen into the air. When trees are cut down, left to decay, or burned, they release stored carbon to the air as CO₂. Recently in Central Africa, virgin rainforests were found to have air pollution levels comparable to those in industrial areas. A major cause of this pollution is the fires that rage for months across huge stretches of land to clear shrubs and trees for the production of crops and grasses. Deforestation has been estimated to account for 20% of total atmospheric content of CO₂. The effects of acid rain (pollutants that are held in the clouds and fall back to Earth in rainwater) and air pollution in Europe, Canada, and the United States also contribute to the increase of CO₂.

Another greenhouse gas is methane. *Methane* is generated by bacteria as they break down organic matter. It is emitted largely by landfills, cattle, and fermenting rice paddies. The concentration of methane gas in the atmosphere has doubled in the past 200 years, mainly because of expanded animal husbandry and rice cultivation, more landfills, and leaking natural gas pipelines.

The greenhouse effect is still a subject of controversy in the scientific community. Both the magnitude and the timing the warming and future climatic changes are uncertain. The status can be summarized as follows:

Fact: Greenhouse gases are responsible for keeping the planet warmer than it would be otherwise.

Fact: Concentrations of greenhouse gases are increasing at unprecedented rates.

Theory: Continued greenhouse gas emissions will lead to global warming.

Characteristics and Typical Adverse Effects

Air Pollution.

Pollution of the troposphere (lower atmosphere) is damaging to agricultural crops, forests, aquatic systems, buildings, and human health. Primary pollutants often react to form secondary pollutants (acidic compounds), a frequent cause of environmental damage. The following effects are possible:

1. Crop and vegetation damage by injury to plant tissue, increasing susceptibility to disease and drought
 2. Decline in forests caused by leaf damage by acidic compounds, acidic soils, and stresses of multiple pollutants
-

1652

3. Damage to aquatic ecosystems so that they no longer support life
4. Degradation of building materials, such as metal, stone, and brick
5. Adverse impact on human health by damage to respiratory tracts

Marine Pollution.

Marine pollution has the following major effects:

1. Spread of pathogens from human wastes, including viruses and protozoa that cause hepatitis, cholera, typhoid, and other infectious diseases
2. Release of undegradable materials, such as plastics and netting, that may injure marine mammals
3. Oil pollution from oil spills
4. Spread of hazardous chemicals and radioactive substances into the marine ecosystem where they may accumulate in seafood

Freshwater Pollution.

Freshwater pollution results in the following adverse effects:

1. Untreated wastewater carries viruses and bacteria from human feces into human drinking water, which can result in illness or even in infant mortality
2. *Eutrophication*, or decay of organic matter, which decreases oxygen levels in water, upsetting the balance of the aquatic ecosystem
3. Adverse health effects in persons drinking untreated water from tainted sources
4. Water acidification, which reduces water's capacity to support aquatic life

5. Runoff sediment from eroded soil deposits in drainage basins, reducing the basins' capacity and exacerbating flooding
6. Salinization from irrigation, with harmful effects on downstream agriculture
7. Pesticides and fertilizer chemicals, which accumulate in water and affect tissues in living organisms

Global Warming.

The impacts of global warming are still uncertain. Computer models are unable to make reliable predictions of regional changes. The following changes *may* occur.

RISE IN SEA LEVEL.

Melting of the Arctic ice sheets and alpine glaciers could cause the seas to expand and sea levels to rise. Depending on the degree of global warming, the seas may rise 30 cm to 2 m by 2075, jeopardizing coastal settlements and marine ecosystems. A rise of 1 m in sea level could flood 15% of arable land in Egypt's Nile Delta and would flood 12% of Bangladesh, displacing 11 million people. The tiny island of the Maldives, inhabited by 200,000, would be submerged.

CLIMATE CHANGE.

Natural disasters such as superhurricanes could become common. A temperature increase of a few degrees in tropical seas can intensify hurricane production. The warmer oceans may increase the El Niño phenomenon near the coast of Peru. ENSO inhibits phytoplankton growth, causes fish and shellfish to migrate or die, and forces higher forms of life (e.g., birds, humans) dependent on these sealife to migrate or die.

Other climatic changes could lead to warmer and drier conditions in middle latitudes, higher temperatures in semitropical and tropical areas, and higher rates of evaporation. Rainfall patterns may also change. The combined effects of increased CO₂ and climate changes may alter plant and animal productivity. Plants may grow faster and larger but may have reduced nutritive value.

CHANGES IN ECOSYSTEMS.

In warmer climates, grasslands, savannas, and deserts may expand, rendering them vulnerable to increased degradation through erosion and fire. Animal species that do not adapt to the temperature increases may have to relocate to survive, which would be difficult, given population pressures on land. Plant species unable to adapt would perish.

PUBLIC HEALTH IMPACT.

Global warming may affect mortality because of heat stress and may increase the incidence of respiratory diseases, allergies, and reproductive illnesses. Geographic ranges of vector-induced diseases (e.g., mosquito-borne malaria, yellow fever) and

parasitic diseases might increase.

Measurement

Air and Water Pollution.

Pollutants are measured worldwide, but to a much lesser degree in developing countries. The most comprehensive data collection system is the Global Environment Monitoring System (GEMS) of the United Nations Environmental Programme (UNEP), which provides data on sulfur dioxide and particulate matter in urban air and contaminants in water resources. Pollution production is related to per capita consumption, so that as countries develop, pollution also tends to increase.

Ozone Depletion.

Ozone levels are regularly monitored each year, especially in the Southern Hemisphere, where a seasonal ozone hole opens over Antarctica every year. Twenty million tons of CFCs were manufactured and have either escaped or will escape to the atmosphere.

Greenhouse Effect.

Greenhouse gas emissions are regularly measured throughout the world. Even if the exact levels of future greenhouse emissions were available, however, predicting the effects on global climate

would be difficult. Climatic models are used to study climate change, but the models differ in their interpretation of the various interactions in the earth's systems, partly because information put into the system is incomplete or poorly understood.

Risk Reduction Measures

Air and Water Pollution.

Most nations are acting individually to control air pollution. Basic requirements are (1) to set ambient air quality standards that measure pollutants away from the source and set controls on acceptable levels and (2) to require that every source of an air pollutant meet certain emission limits. In some cases, humans may have to develop the technologies to make the latter possible.

Pollution control of coastal areas in the past has proved that recovery is possible to some extent. The banned pesticide DDT, which was present in many forms of marine life, is now decreasing in concentration. Most strategies for protecting the oceans must

address broader ranges of pollutants from sewage to industrial effluents. More national and international efforts should focus on establishing policy for protection of coastal areas.

Improvement of soils can decrease the possibility of water contamination by toxic chemicals and decrease runoff, thereby lessening silting and sedimentation of waterways. Establishing terraces and contour bounds, stabilizing sand dunes, building check dams, and planting trees and shrubs can help to stabilize soil. Watershed mapping, management, and protection are also of vital importance in ensuring a safe and plentiful drinking water supply. Proper systems to dispose of human waste should be promoted.

Regulations must be established and enforced by government agencies to protect citizens against the toxic effects of pesticides and other chemicals. Improvement of soils will also help to absorb and degrade toxins. Further studies must be made on the effects of pesticide residues. Farmers may use crop types resistant to pests or an integrated approach to pest management requiring less pesticide.

Ozone Depletion.

International cooperation to limit CFC emissions should reduce production and use of CFCs in industrialized nations by 50% from 1986 levels, with developing countries allowed to increase their use slightly. Research is addressing the need for CFC substitutes, for minimizing loss to the atmosphere, and for recycling. Countries can regulate import and use of aerosols and disposal of refrigeration units.

Global Warming.

Since burning of fossil fuels (at least in theory) is the primary cause of global warming, developed countries are mainly at fault, and poorer countries are more likely to be the victims. Scientists estimate that 20% of greenhouse gases (mainly CO₂) are generated by deforestation, however, a trend occurring at a devastating rate in developing countries, particularly in tropical rainforests. Since global warming could affect the entire planet, steps can be taken to prepare for its effects and to prevent its acceleration, as follows:

1. Reduce the rate of deforestation. Plant trees to solve community needs for wood, such as fuel wood, or to provide profits for individual farmers with agroforestry.
2. Increase energy production and use. Promote energy efficiency in urban areas, and support renewable energy sources, such as wind, water, geothermal, and solar power. These may be of great use in areas where no electricity sources exist.
3. Develop regulations to curb pollution from traffic emissions and industry in urban areas.

Education is a vital tool for environmental awareness. By understanding the relationships of ecosystems and the long-term effects of degradation, people are

motivated to act. Women's groups in India have established a tree protection lobby. Their motto is "trees are not wood," a concept that promotes trees as a vital part of the ecosystem involving CO₂ exchange to the air and a root system to hold down the soil. Education regarding the environment should begin in the early grades. Education for adults may take place in farmers' cooperatives, women's cooperatives, and village settings or may accompany programs to distribute seeds and tools.

Trying to Save the Black Sea

The Black Sea, named for the dark clouds and fierce storms that affect its shores each autumn, faces an even darker future. The residues of modern agriculture and industry now threaten its marine life and the air quality of its bordering countries of Bulgaria, Romania, Turkey, and parts of the new Commonwealth of Independent States. The Black Sea is particularly vulnerable to pollution, since it collects 10 times more water per square meter of surface area than any other sea or ocean. It is fed by several major rivers, which deposit many of the pollutants. The most important is the Danube, which flows through eight highly industrialized countries, all using chemically intensive agricultural practices.

In addition, the Black Sea has natural pollutants—organic matter collected over thousands of years, now decaying and diminishing the supply of oxygen in the water vital to life. In the unique two-stratum structure of the sea, where salt water from the Mediterranean forms a bottom layer and fresh water a top layer, toxic hydrogen sulfide from the decomposing matter remains on the bottom layer, where oxygen is not present. Construction of irrigation works and dams has reduced the flow of fresh water into the Black Sea, so the

1654

toxic layer that was previously 200 m below the surface has now risen to a depth of only 80 to 100 m.

Further deterioration of the Black Sea and air pollution from industries around it could be economically disastrous to the surrounding countries that depend on it to draw tourists. The resource-poor country of Bulgaria has developed a 20-year plan to save the sea and to bolster tourism, as follows:

1. A total ban on discharge of any pollutants into the sea
2. Regulation of development of concentrated industrialization in the coastal zone
3. Environmental monitoring by 20 different institutions in coordination with UNEP
4. Restricting the inflow of fertilizers and the building of dams
5. Proliferation of blue mollusks to eat plankton, which use up the precious oxygen; shellfish cultivation also a possibility
6. Holding a convention to assess the sea's environmental problems and develop a plan that would be closely linked to the international effort to address the pollution

problems of Europe's major rivers

DEFORESTATION

Deforestation is the removal or damage of vegetation in a region that is predominantly tree covered. Deforestation is a slow-onset hazard that may contribute to disasters caused by flooding, landslides, and drought. Deforestation reaches critical proportions when large areas of vegetation are removed or damaged, harming the land's protective and regenerative properties. The rapid rate of deforestation in some parts of the world is a driving force in the yearly increase of flood disasters in these areas.

Approximately 17 million hectares of tropical forests and woodlands are converted into agriculture, pasture lands, or other uses every year. This includes 7.3 million hectares of tropical forest (6.1 million hectares of moist forest) and 3.8 million hectares of open and savanna woodland. Less than 10% of the land being deforested is replanted every year. Although the amount of forest land coming under protection or conservation is growing, the future still poses problems because of rapidly increasing pressures of development and exploitation.

Causal Phenomena

The spread of agriculture, firewood collection, and unregulated timber harvesting are the principal and immediate reasons for deforestation. Beneath the obvious causes are fundamental problems in development, such as the use of inefficient agricultural practices, insecure land tenure, rising unemployment, rapid population growth, and failure to regulate and preserve forest lands.

Farming.

The major cause of forest loss is the spread of farming. Land may be cleared for commercial ventures such as sugarcane, coffee, or rubber plantations, which is a principal cause of deforestation in Central America. In tropical rainforests, both legal and illegal colonists are trying to farm the former jungle lands, where soil conditions are fragile. Up to 90% of the nutrients are in vegetation rather than in the soil. When the forest is cut and burned, a nutrient surge occurs in the soil, lending initial fertility. After cropping and exposure to sun and rain, however, soil fertility rapidly declines, and the area becomes unproductive, perhaps prompting the farmer to slash and burn new forest areas.

Many traditional people in the Amazon Basin, Central Africa, and Southeast Asia still practice shifting cultivation techniques, allowing fallow periods between cropping for soils to regenerate. This practice becomes unsustainable if populations increase to the extent of forcing people into smaller areas. Insecure land tenure or fixed land titles may

also force overuse of the land.

Because of crowded conditions in cities and farm areas, many people migrate to areas of marginal fertility, where they must keep moving their fields to produce sufficient food. Where this occurs, the migrant farmer may damage timber, wildlife, and human resources. In Venezuela, which has a high rate of unemployment and rising numbers of landless peasants, 30,000 families live and farm in national parks, forest reserves, and other legally protected areas. An influx of cultivators who settled on the watershed above the Panama Canal has caused increased silting of a major reservoir that supplies Panama City.

Grazing.

In Central and South America, large areas of tropical forest have been cleared to create grazing lands. A major portion of this can be attributed to economic enterprises designed for meat production. The Brazilian government has granted large land concessions to both domestic and foreign corporations wanting to raise cattle in the Amazon area. In Central America, virgin forest is being destroyed by ranchers who intend to export beef to the United States.

Firewood Collection.

Firewood collection can contribute to the depletion of tree cover, particularly in lightly wooded areas. Because of a lack of alternative fuels and fuel-efficient stoves, this is especially a problem in Africa and in Asian highland countries such as Nepal. In areas of dense woods, dead material may fill local requirements for fuel. The outright destruction of trees for fuel occurs most commonly around cities and towns, where commercial markets

1655

for firewood and charcoal exist. Well-organized groups and individuals bring fuel wood by vehicle, pack animal, and cart into many cities, hastening local deforestation.

FUEL WOOD CRISIS.

About 100 million people in developing countries cannot meet their minimum needs for energy, and almost 1.3 billion consume fuel wood resources faster than they are being replenished. In parts of West Africa today, some urban families spend one fourth of their income on wood or charcoal for cooking. In India, firewood is subsidized for the poor to prevent starvation.

Logging.

Extensive logging in humid tropical forests, particularly in Asia and in temperate and

mountainous forests, is conducted by large multinational corporations for export or to fill building needs in cities. The procedure usually involves either "clear cutting" or "creaming," or selective logging, of the forest's small proportion of valued species. Creaming, even though a less radical alternative to clear cutting, still causes significant damage to vegetation and wildlife that is not apparent from the statistics. A study in Indonesia revealed that logging operations damaged or destroyed about 40% of trees left behind. The roads created by logging operations may encourage settlers to enter the forest and begin slash and burn agriculture, so that eventually even more of the forest is lost.

Characteristics

Trees play a vital role in regulating the earth's atmosphere, ecosystems, and weather systems. They recycle CO₂, a gas now increasing in the atmosphere and thought to contribute to global warming. They release moisture to the air, thus contributing to rainfall and moderating local and global climate. Their roots trap nutrients, improve soil fertility, and trap pollutants, keeping these from the water supply. They provide habitats for species, engendering diversity. They nurture traditional cultures by giving shelter, wood, food, and medicinal products. These benefits are lost as trees are destroyed.

The root systems of vegetation help retain water in the soil, anchor the soil particles, and provide aeration to keep soil from compacting. When vegetation dies, the nutrients go back to the soil. When root systems are removed, soil becomes destabilized. Water tends to flow off the top of the soil instead of percolating in, and it carries valuable topsoil along with it. This soil eventually forms sediment in the drainage basins.

Deforestation poses the most immediate danger by its contribution to the following hazards:

1. Destabilized soils are more susceptible to landslides and may increase the landslide risk in areas vulnerable to earthquakes and volcanoes.
2. Loss of moisture from deforestation may contribute to drought conditions, which in turn may trigger famines. Soil nutrients may also be lost through erosion of topsoil, resulting in decreased food production and possible chronic food shortages.
3. Erosion and dry conditions, combined with loss of vegetation and soil compaction, result in desertification and unproductive lands.
4. Dryness may accelerate the spread of fires.
5. Loss of CO₂ from dying trees and fires may add to global warming.
6. Deforestation of watersheds, especially around smaller rivers and streams, can increase the severity of flooding, reduce stream flows, evaporate springs in dry seasons, and increase the amount of sediment entering waterways.

Of all the hazards associated with deforestation, flooding may be the most serious. Usually, curative measures, such as dredging and dam building, are taken over preventive measures to solve flooding problems. As flooding worsens in developing countries, more attention is given to protection of watersheds. In India, flood damages between 1953 and 1978 averaged \$250 million per year. Today, even more people live

in flood-prone areas. Flood problems may not be lessened without reforestation of the increasingly denuded hills of northern India and Nepal.

Predictability

Measurement and monitoring of forested areas may be conducted through ground-level sampling and aerial or satellite surveys. Each method has drawbacks. Ground sampling is tedious and difficult to extrapolate, aerial surveys are expensive, and satellite imagery poses difficulty in distinguishing forest from other vegetation. Combinations of methods usually produce the best results. Vague definitions in the study of deforestation still make exact determinations and forecasting difficult. Three different prediction methods follow:

1. One type of study predicts future deforestation rates by extrapolating present rates of deforestation into the future. If the present rate of deforestation at 6.1 million hectares per year were to continue, the tropical moist forests would be completely cleared in 177 years. Where deforestation is more acute, the losses will be more serious. Cote d'Ivoire and Nigeria annually lose about 5.2% of their forests, and Costa Rica, Sri Lanka, and El Salvador lose between 3.2% and 3.6%. Each of these countries could lose all forests between the years 2007 and 2017.
 2. Another forecast for 43 tropical countries was made using a mathematical model, which assumed that when forests in a country fell to a critical
-

1656

level, governments would take action to prevent further deforestation.

Considerably more optimistic, the results predicted deforestation rates to decrease to between 0.9 and 3.7 million hectares per year in 2030.

3. Perhaps the bleakest theoretic forecast incorporates the effects of population growth and increasing consumption, which might be assumed to increase the rate of deforestation worldwide. However, growth of economies and technologies at the same time may assist to curtail the deforestation process if governments take appropriate action.

Typical Adverse Effects

The specific impacts of deforestation include the following:

1. Loss of soil fertility in the tropics and loss of productive capacity
2. Soil erosion and deposition of sediment
3. Increased runoff
4. Reduction in rainfall and increase in temperature
5. Destruction of biodiversity and traditional cultures
6. Loss of "free" goods, such as fuels, food, and medicines
7. Exacerbation of other disasters

Economic Impact.

Most developing countries are already importers of forest products, especially paper. Because the amount of wood and wood products available per person in the world is falling and thus increasing in price, combined with shortages of foreign currencies, import of forest products may be increasingly prohibitive for these countries. Commercially marketed firewood is becoming more scarce, and prices are climbing. Wood for construction is also scarce in many countries, which adversely affects the availability of housing.

Risk Reduction Measures

Various types of forest management, reforestation, and community participation can reduce deforestation. Most governments now recognize the vital importance of national forestry programs. Foresters help people meet their basic needs for forest products, and not always from the traditional forest or concentrated woodlot. For instance, forestry practiced by many farmers on their lands has been shown to be more environmentally effective. Reforestation has become intrinsically interwoven with other government policies that affect the population. Forestry therefore should be considered an integral part of land use and natural resource planning sectors of government.

Forests should be viewed by governments as capital resources to be managed. Management of the system should discourage concessionaires or other land users from practices that are not sustainable. Good management encourages highly selective harvesting without undue waste of remaining trees, especially in tropical forests. For any country to address its loss of forests and ensure that forests will yield economic benefits well into the future, the following steps must be taken:

1. Forest law or basic forest policy must be written that clearly states the objective of long-term sustainable management of the forest.
2. Forest regulations or management guidelines must be written and followed.
3. Sufficient financial and human resources must be allocated.

Forest management must be considered in the broadest sense of land use planning to include solutions for people as well as for trees. Compromises between complete destruction of the forests and complete conservation might entail regulated clearing of forests for shifting cultivation, habitation, or hunting; voluntary and intentional protection of forests or individual species by designating areas for reserves or national parks; and enrichment of the forest with species from other places. The last option may be considered risky, since pests and other species-specific problems may accompany introduction of new species.

Many unresolved scientific issues in forest management remain. How can the ever-expanding areas of secondary vegetation and degraded soils be managed to be more productive for the local people? Since most primary forests have disappeared, what type of forest can be established that would be stable and productive and that

would ensure the conservation of biologic diversity? What further types of basic ecologic research are needed to manage natural forests?

Social Forestry in Thailand

A project was begun in 1980 by Thailand's Royal Forestry Department (RFD) aimed at restoring the depleted forests. In just one generation since 1960, Thailand's forests had been reduced by half as its population doubled. The challenge facing the government was to restore the forests while permitting the expanding population to earn a living through farming.

The 8000 Thais living on 10,000 hectares near Nakhon Ratchasima on the Khorat Plateau had used slash-and-burn agriculture for years, destroying the forest. To develop the project, a survey was conducted for an entire year to determine the cropping patterns of the settlers and their expectations for the future. The RFD discovered that most wanted to remain on the land and farm. The 60% of the land suitable for farming would be used as incentive to encourage permanent settlement. The remaining 40% would be reforested by the RFD to prevent erosion of the hillsides and destruction of watersheds. The plan called for village

1657

councils to be formed and infrastructural inputs provided, such as roads, schools, and health centers.

The trees planted by RFD grew rapidly and prompted villagers to plant 3.5 million seedlings. Complementary projects were initiated, including beekeeping, cottage industries, and crop diversification. The RFD provided training to its own staff, including experience with successful social forestry programs in other countries.

Many problems remain in Thailand. During the past 30 years the total amount of forest replanted is equivalent to only 1 year of cutting. Much timber is being harvested for profit without permits. Relentless population growth and poverty place constant pressure on forest resources. However, the government is committed to future projects of this kind. The national policy in Thailand is to return 40% of the country to forest, which is crucial if Thailand is to become a major exporter of timber again.

DESERTIFICATION

Desertification is defined as land degradation in arid, semiarid, and dry subhumid areas resulting mainly from human actions. Poor land use is a significant contributing factor, but desertification can also be caused by natural cycles of climate change. It affects both developed and developing regions, including Africa, the Middle East, India, Pakistan, China, Australia, the Commonwealth of Independent States, the central and southwestern United States, and many Mediterranean countries. A slow-onset disaster, desertification worsens conditions of poverty, brings malnutrition and disease, and destabilizes the social and economic bases of affected countries.

Causal Phenomena

Role of Climate.

Vulnerability to desertification and the severity of its impact are partially governed by climatic conditions of an area. The lower and more uncertain the rainfall, the greater is the potential for desertification. Other influencing factors are seasonal patterns of rainfall and high temperatures that increase evaporation, land use, and the type of vegetation cover.

The world's drylands are found in two belts centered approximately on the Tropic of Cancer and the Tropic of Capricorn (23.5 degrees north and south of the equator, respectively) and cover one third of the earth's surface. More than 80% of the total area of drylands is found on three continents: Africa (37%), Asia (33%), and Australia (14%). The drylands can be further classified into hyperarid, arid, and semiarid zones, depending on the average amount of rainfall received per year. Other factors, such as temperature and soil conditions, must be considered when determining the dryness ratio.

Both natural and human-derived climatic changes may contribute to desertification. Natural effects, such as long-term climatic cycles and the basic Earth-sun geometry, have resulted in drier conditions in the Sahara. Human influence is associated with the predicted global warming trend and local climatic changes, in which deforestation has reduced the moisture-holding capacity of soil and has decreased cloud formation. The result is less rainfall and higher temperatures.

Despite the common misperception that desertification is caused by the desert advancing itself, land degradation can occur at great distances from deserts. Desertification usually begins as a spot on the land where land abuse has been excessive; from that spot, land degradation can spread outward with continued abuse (

[Figure 68-12](#)). Desertification does not cause drought but may result in greater persistence or susceptibility to drought. Drought, on the other hand, contributes to desertification and increases the rate of degradation. When the rains return, however, well-managed lands recover from droughts with minimal adverse effects. Land abuse during periods of good rains and its continuation during periods of deficient rainfall contribute to desertification.

Role of Land Use Management.

Desertification can be caused by five main types of poor land use: overcultivation, cash cropping, overgrazing, deforestation, and poor irrigation practices.

OVERCULTIVATION.

Overcultivation damages the structure of the soil or removes vegetation cover, leaving the soil vulnerable to erosion. Reasons for overcultivation include drought, increasing demand for food because of population growth, cropping on marginal range lands unsuitable for long-term production, land tenure restrictions confining sectors of the population to marginal lands, mechanized farming, and expansion of cash cropping.

CASH CROPPING.

Although a large part of agricultural production in developing countries fills subsistence needs, some cash crops are grown for foreign exchange. A feature of most cash crops, however, is their extreme demand for nutrients and optimum conditions. Degradation of land occurs directly through improper management of such crops and indirectly by displacing subsistence crops and pastoralism to marginal lands.

OVERGRAZING.

Overgrazing is a major cause of desertification (range lands account for 90% of desertified lands) and occurs when too many animals are pastured. The number of cattle in Niger, for example, increased an estimated 450% between 1938 and 1961 and an additional 29% by 1970, when the majority were killed by starvation. Livestock density increases when

Figure 68-12 Comparison of healthy and desertified regions. (Modified from *Introduction to hazards*, ed 3, New York, 1997, *Disaster Management Training Programme*, United Nations Development Program, UN Organization for Coordination of Humanitarian Assistance.)

herd sizes grow too large in wet years and cannot be sustained in dry years. Lucrative markets for meat, such as Nigeria and the Middle East, have resulted in cattle ranches, where concentrated activity threatens land, with poor returns for the investment.

Better veterinary care has decreased mortality rates. Deep wells increase availability of water, allowing larger, less mobile herds that congregate in the well area and degrade the vegetation and soil.

DEFORESTATION.

Land is cleared for agriculture, livestock, and fuel wood production. Deforestation is the first step toward desertification, removing vegetative barriers and exposing land to sun, wind, and rain. In

Africa, demands for fuel wood and charcoal exert considerable stress on wood resources.

POOR IRRIGATION MANAGEMENT.

The concept of using irrigation to ward off the threat of crop failure during drought has been promoted by many development agencies. Ironically, poor management of irrigation projects has been a cause of desertification. In some cases, productivity falls and soils become salinized, alkalized, or waterlogged. The major problem is usually inadequate drainage, and damage may be irreversible. A key example is the Greater Mussayeb irrigation project in Iraq, begun in 1953. By 1969, waterlogging was widespread, and two thirds of the soil was saline. In 1970 a project to reclaim the salinized land was begun, but by 1976, because of technical and organizational limitations, the project still had not been successful. Egypt, Iraq, and Pakistan have lost more than 25% of their irrigated areas to salinization and waterlogging.

Role of Government Policy.

Population growth and economic expansion also contribute to desertification. As populations grow, government and multilateral policies must promote increased food production through appropriate technologies that prevent soil degradation and erosion. Government policy should also address the causes of poverty, or disadvantaged peoples will place more stress on land to obtain needed resources. Some governments choose to expand cash crop cultivation to improve foreign currency holdings rather than promote food security for the poor, or they fail to resolve conflicts over scarce resources. Policies may mandate land uses that are difficult to enforce and that result in breakdown of customary land tenure or natural resource management institutions.

Characteristics

The two main characteristics of desertification, the degradation of soil and degradation of vegetation, have the same result: reduction of productivity.

Degradation of Vegetation.

Vegetation in arid lands adapts to the cycle of water availability by adjusting its growth. The drier the area, the farther apart plants grow. Some plants grow only during the rainy seasons. Degradation of vegetation occurs initially in the early stages of desertification with deforestation but continues after soil fertility declines.

The two main forms of vegetation degradation are (1) overall reduction of density of the vegetation cover, or biomass, and (2) a more subtle change in types of vegetation to less productive forms. For example, range land perennial grasses may be replaced by less palatable annual varieties, or more saline-tolerant crops, such as barley, may be substituted for traditional crops because of low yields from waterlogging and salinization.

Degradation of Soil.

Soil degradation occurs in four major ways: water erosion, wind erosion, soil compaction, and waterlogging, which results in salinization and alkalinization.

WATER EROSION.

Vegetation normally protects soil from being washed away by rain and also from splash erosion by raindrops. The raindrops move the soil particles and pack them together on the surface, sealing the pores and thereby decreasing infiltration and increasing runoff. *Sheet erosion* is a more serious form of erosion in which fine layers of topsoil carrying soil nutrients are washed away. Unless the nutrients are replenished artificially, crop yields decline. Gullies are created by the runoff and, unless reclaimed by conservation measures, render the land unusable.

WIND EROSION.

Wind erosion occurs when finer components of the soil, such as silt, clay, and organic matter that contain most of the nutrients, are blown away, leaving behind the less fertile sand and coarse particles. Sand itself may start to drift, forming dunes, but this accounts for a minor proportion of the effects of wind erosion. Strong winds may form dust storms that damage crops by shredding leaves.

SOIL COMPACTION.

Nearly complete compaction can occur when soil of poor structure is compressed by heavy machinery or by hooves of large herds of animals. A less serious form of compaction, called *surface crusting*, results when high-speed mechanical cultivation or dry season cultivation turns particles into thin powder, which then forms a crust when pelted with raindrops. Crusting and compaction make the soil less permeable for germination of new plants.

WATERLOGGING (SALINIZATION AND ALKALINIZATION).

These effects result from poor management of irrigation and water supplies in general. When the soil is waterlogged, the upward movement of saline in groundwater leaves salt on the surface when the water evaporates.

Predictability

Desertification is a direct socioeconomic threat to more than 200 million people and a less direct threat to 700 million, but data are still insufficient to quantify the extent of the problem and its progression. Databases are incomplete or do not exist for many countries. More information is needed on the characteristics and status of dryland ecosystems. An understanding of climatic changes, including the effects of possible global warming, is crucial to predictability.

1660

Socioeconomic indicators showing trends in human health, income, and welfare must be collected to understand related issues.

The International Soil Reference Centre and UNEP support the Global Assessment of Soil Degradation (GLASOD), which uses a geographical information system (GIS) to access data for different areas of the world and estimate land degradation.

Rate and Scope

Although the numbers remain controversial, yearly losses to desertification are estimated at 1.0 to 1.3 million hectares of irrigated land, 3.5 to 4.0 million hectares of rainfed cropland and 4.5 to 5.8 million hectares of range land. These estimates represent an increase from estimates in 1994 of 3.4% and indicate that the situation is worsening.

Desertification affects drylands in more than 100 countries but is concentrated in Asia and Africa, which account for 70% of all desertified land. Scientists have tried to quantify the areas desertified on a worldwide basis. The physical damage can be measured in reduced productivity of soils and loss of vegetation. The number of casualties cannot be scientifically extrapolated, but deaths occur, directly from famine or indirectly from reduced standards of living.

ACKNOWLEDGMENTS AND RESOURCES

This chapter draws on several publications, especially *Introduction to Hazards*, third edition, 1997, a teaching module prepared for the Disaster Management Training Programme of the United Nations Development Program (UNDP) and UN Organization for Coordination of Humanitarian Assistance (OCHA). Another background document is *Natural Hazards: Causes and Effects*, published by the Disaster Management Center of the University of Wisconsin. I would like to thank Paul Thompson and Jim Good of InterWorks for their collaboration on this project and Robert L. Southern of Weather Associates for his input on the tropical cyclone section.

Part 11 - Equipment and Special Knowledge

1662

Chapter 69 - Wilderness Preparation, Equipment, and Medical Supplies

Steven C. Zell
Philip H. Goodman

The foremost challenges of wilderness recreation are the prevention and management of injury and illness. Medical care may be greatly delayed for the injured person many hours from civilization. Unnecessary suffering can be minimized by educating the traveler, planning each trip carefully, and carrying appropriate medical and nonmedical emergency supplies.

Large expeditions usually enlist experienced medical professionals in logistic planning. Unfortunately, most smaller groups trekking into the wilderness do not have access to this expertise. Even when a physician is a party member, he or she is usually not specifically trained in wilderness medicine. This text details medical management in the wilderness setting. This chapter is intended to complement that material by summarizing recommendations for selecting medical provisions for a variety of wilderness experiences. The first part of the chapter is an overview of important preventive measures and risk factors for wilderness travel. The second part highlights assembly of the medical kit, providing recommendations for its comprehensive, basic components. The latter is primarily directed toward persons engaging in low-risk wilderness travel lacking medical expertise. The index for expedition travel (see [Figure 69-2](#)) is intended specifically for groups having persons with medical experience. Based on defined categories of travel risk, which is a function of trip duration and remoteness from medical care, prescription medical supplies appropriate to the task at hand are denoted to allow a more sophisticated selection. The chapter concludes with an update

describing specific high-technology items that are not standard to the basic wilderness medical kit but that may be necessary as a function of a group's outdoor interest and activities.

Before any travel in the wilderness, it is important to understand the epidemiology of wilderness injuries. However, it is difficult to make statements on the precise statistical risk of injuries and illness associated with outdoor travel. In the absence of any required reporting of medical problems, information has come from special interest groups and providers of emergency medical services (EMS) in national parks. Hopefully, future wilderness epidemiologic data will characterize injuries and illness patterns.

Despite such limitations, the proportion of accidental injuries to illness occurring during travel is remarkably constant. Data on outdoor travel suggest that traumatic injury, generally of a minor nature, exceeds medical illness of participants by roughly threefold. When reviewing injury patterns, most are attributable to soft tissue damage (e.g., abrasions, contusions, lacerations), sprains, or strains; serious dislocations or bony fractures account for less than 5% of all trauma. The lower extremities are by far the most likely to be involved in minor orthopedic injury, emphasizing the importance of appropriate footwear selection.

Most medical illnesses reported by wilderness travelers are attributable to nonspecific syndromes, such as gastroenteritis or upper respiratory illness. Both may result from crowded conditions, precluding adequate preemptive hygiene measures. Other commonly reported medical problems include headache (exacerbated by high altitude), dyspepsia resulting from local food intolerance, dermatitis, sunburn, dehydration or heat-related illness from inadequate fluid intake, and allergic reactions, mostly related to insect stings.

The outdoor travel literature shows that most deaths are attributable to sudden cardiac arrest, likely a function of the number of older travelers venturing outside. After excluding deaths from cardiac causes, drowning remains the number one cause of accidental death among outdoor participants. Ice and rock climbing has a unique array of injuries, including rare traumatic death from severe head trauma. Environmental issues predominantly relate to high altitude and extremes of temperature. A participant's awareness of environments and events is critical to make certain that appropriate first-aid equipment, not routinely found in most kits, is available to deal with relevant emergencies. Recommendations for such unique supplies are covered in the section on specific equipment purchases.

PREPARING FOR TRAVEL

General Preparedness

The trip coordinator is responsible for assessing the health limitations of the group (see [Appendix A](#)). The coordinator should confidentially but frankly discuss medical problems with each candidate and require a medical evaluation if uncertainty exists. Safety of the individual and the group are the coordinator's first priorities. [Box 69-1](#), [Box 69-2](#), [Box 69-3](#) give checklists for general preparedness.

1663

Box 69-1. CHECKLIST FOR GENERAL PREPAREDNESS

Physical conditioning

Immunizations (especially tetanus)

Planning of potential rescue and evacuation routes and leaving an itinerary with person to initiate rescue if group does not return on time

Proper clothing and equipment

Medical-alert medallion or card (illness, allergy, medication)

Water disinfection (chemicals or devices)

Sunglasses, sunscreen, and adhesive blister pads

Historical appraisal of weather conditions: National Climatic Data Center
(<http://www.ncdc.noaa.gov>)

Precipitation and temperature short-term forecasts: National Weather Service
(<http://www.nws.noaa.gov>)

Immediate weather updates/current conditions: The Weather Channel
(<http://www.weather.com>)

Precipitation and temperature short-term forecasts: National Weather Service
(<http://www.nws.noaa.gov>)

Immediate weather updates/current conditions: The Weather Channel
(<http://www.weather.com>)

Box 69-2. CHECKLIST OF PRETRAVEL MEASURES FOR DEVELOPING COUNTRIES

Predetermine local sources of medical help

Important phone numbers for obtaining up-to-date travel warnings

Centers for Disease Control and Prevention: International Traveler's Hotline
(<http://www.cdc.gov>)

Department of State Citizens Emergency Center 202-647-5225

Immunization information and advice

Local health department/travel medicine clinics

International Society of Travel Medicine (ISTM) Clinic Directory—available by request (contact: Secretariat/ISTM 770-736-7060)

USPHS booklet: *Health information for international travel, 1999–2000 ed*, U.S. Government Printing Office, Washington, DC (item #017-023-00202-3), 202-512-1800

Required immunizations as defined by the World Health Organization

Yellow fever: listing of countries requiring this vaccine found in USPHS publication above

Immunizations requiring an update

Tetanus-diphtheria

Measles (if born after 1956 and unvaccinated), mumps, and rubella

Polio

Influenza/pneumococcal (for elderly and immunocompromised)

Immunizations for special circumstances

Hepatitis A immune globulin or vaccine

Hepatitis B

Rabies

Hepatitis A immune globulin or vaccine

Hepatitis B

Rabies

Meningococcal vaccine

Typhoid fever

Japanese encephalitis

Box 69-3. GUIDELINES DURING TRAVEL PERIODS IN UNDERDEVELOPED COUNTRIES

General recommendations

Contact U.S. embassy on arrival.

Avoid ice, unboiled or unbottled water, and uncooked food.

Avoid wading or swimming in lakes and canals of populous regions.

Avoid blood transfusions and use of needles. Adhere to safe sex guidelines, especially in Africa and Southeast Asia.

Take necessary precautions against insects, especially mosquitoes:

Avoid nocturnal travel.

Use a repellent containing DEET.

Sleep in a well-screened area.

Initiate recommended chemoprophylaxis based on travel itinerary.

Malaria: On return, continue medications for another 4 weeks.

Traveler's diarrhea.

Fitness

HEALTHY PARTICIPANTS.

Active, healthy individuals should begin a graduated exercise program at least 2 months before departure to minimize the deleterious effects of muscular, metabolic, and mental fatigue. This is especially important for persons going to high altitude; aerobic capacity in a sedentary person drops about 4% for each 300 m (1000 feet) above the 1200-m (4000-foot) level, but the loss is only half as great in an aerobically fit individual (see [Chapter 1](#)). Careful stretching of muscle groups may increase efficiency and lessen the likelihood of soft tissue injury during exertion and minor accidents.

1664

If excessive environmental heat (see [Chapter 10](#) and [Chapter 11](#)) is anticipated, preparatory exercise in a hot, humid environment (simulated with sweat clothing) for 1 hour daily for at least 7 days before departure will increase plasma volume (aldosterone effect) and sweat rate while lowering myocardial oxygen demand and sweat sodium content. This acclimatization will be lost within a week if not maintained.

PERSONS WITH PREEXISTING MEDICAL PROBLEMS.

Participants with preexisting cardiopulmonary disease and those with a few selected medical problems delineated below deserve special attention.

Persons with asthma and chronic obstructive pulmonary disease (COPD) may experience difficulty as a result of hypoxia from high altitude or secondary to reactive airway disease from noxious stimuli. Wheezing during travel may be triggered by exercise undertaken in cold, dry air. Poor air quality, a by-product of fossil fuel burning, along with winds that can "stir up" larger particulate matter such as dust or sand, can be irritating. Besides carrying a β -agonist metered dose inhaler, asthmatic travelers should carry a 2-week course of an oral steroid (e.g., prednisone) plus a broad-spectrum oral antibiotic.

For persons with COPD, concerns relate to outdoor travel at high altitude and alveolar hypoxia. Studies of aircraft pressurized to 8000-foot altitude reveal that persons with moderately severe COPD (forced expiratory volume in 1 second [FEV₁] of less than 50% at sea level) may have significant dyspnea; this serves as an indication regarding the altitude to which such persons can safely travel. Absolute contraindications to high-altitude travel include persons with pulmonary hypertension and cor pulmonale, recent pulmonary embolism, sickle cell disease, and sleep apnea. Persons with mild to moderate COPD who have adequate pulmonary reserve should be advised to not sleep above 3048 m (10,000 feet) because of nocturnal desaturation.

Outdoor adventure travel adversely limits exercise endurance and can provoke angina in persons with underlying heart disease. There is great debate concerning the evaluation and advice a physician should provide to persons with cardiovascular disease. Persons with predictable angina of mild to moderate level may engage in outdoor travel if able to exercise by Bruce protocol for at least 9 minutes; however, such

individuals must pace themselves proportionately to the expected declines in available oxygen that limits work capacity at higher altitude (see [Chapter 1](#)). As a guideline, activity levels should be titrated to not exceed a heart rate that is roughly 75% of one's ischemic threshold. For persons with unstable angina, congestive heart failure, or valvular disease such as aortic stenosis, vigorous adventure travel is contraindicated.

Other disorders deserve comment. A person with a history of transient ischemic attacks can participate in outdoor travel with attention to proper hydration and use of aspirin to maintain desirable blood viscosity. A person taking a proton pump inhibitor for management of acid reflux has an increased risk for acquiring water-borne enteric infections. As a result, meticulous attention to water quality is essential; dubious drinking water should be both filtered and disinfected (see [Chapter 51](#)), with consideration given to carrying a fluoroquinolone to treat diarrhea empirically. Outdoor travel often disrupts normal meal schedules of diabetics. During air travel, an insulin-dependent diabetic should take his or her daily dose of insulin and eat according to the local time (departure) schedule. For a diabetic traveling eastbound across multiple time zones, the day is effectively shortened, so on arrival, the person should eat and administer insulin according to local time but reduce the dose by one third. For travel westbound, the days will be lengthened. A second dose of insulin after 18 hours of travel may be administered following glucose monitoring, if indicated (glucose > 240 mg/dl). Human immunodeficiency virus (HIV) infection should not preclude outdoor travel so long as an HIV-positive person pays meticulous attention to water disinfection and receives immunizations against pneumonia, influenza, hepatitis A, and hepatitis B.

Many prescription drugs predispose to heat, cold, and altitude-related illnesses. Diuretics contract intravascular volume and may thus impair heat transfer to the skin or may exacerbate dehydration and hypokalemia resulting from fluid loss from exertion or diarrhea. Such persons should carry a packaged electrolyte replacement (oral rehydration solution) and a source of potassium (dried orange slices or bananas). The anticholinergic action of antihistamines, phenothiazines, and tricyclic antidepressants may result in hypothalamic dysfunction and diminished sweating. Whenever possible, alternative preparations should be considered for use during wilderness travel. Alcohol should generally be avoided because it induces peripheral vasodilation and may lead to net heat gain in hot environments and excessive heat losses in cool, windy, or wet conditions. In addition, alcohol's effects on judgment and sensory perception may result in failure to acknowledge early symptoms of environmental illness.

Patients with serious medical allergies or active illnesses should have an appropriate medical identification bracelet, anklet, medallion, or wallet card and store their personal medications in a protected but accessible location in their pack. Persons with cardiac disease should carry a copy of their most recent electrocardiogram. Everyone should carry a complete medicine list in some form during foreign travel.

Oral Hygiene and Health.

Mild sore throat and a foul taste are common when traveling in the mountains and in cool weather, probably because of mouth breathing and enhanced loss of moisture from the upper respiratory tract. Carry a supply of hard candies or medicated lozenges (e.g., Cepacol, Chloraseptic). Saline spray may be used to keep nasal passages hydrated.

Since treatment of early caries and loose fillings (which may trap expanding air) can prevent this, each party member should have a dental examination before the trip. On the trail, frequent brushing may be impractical; flossing after meals, rinsing well with water, and chewing sugar-free gum will help maintain oral hygiene en route. Toothache is common at high altitude. Temporary filling materials, such as Cavit (see [Chapter 23](#)), can be obtained in small squeeze tubes and applied to a tooth with a wet cotton applicator to prevent sticking.

Urine containers may be appropriate if prolonged adverse weather is a possibility. Funnel-like devices that connect to urine containers (e.g., Lady-J, available from Campmor; see [Appendix B](#)) are helpful for women. Groups camping in a delicate ecology or when close to a lake or river should use a lightweight, portable commode with disposable plastic holding bags.

Hikers whose feet sweat excessively may benefit from talc or medicated powder (e.g., tolnaftate; see [Table 69-2](#)). Keeping feet and socks dry minimizes the tendency to blister formation and reduces heat loss in the cold.

Travelers to cold and aquatic environments are especially prone to dry skin. Regular application of a lubricating lotion such as Eucerin, Lubriderm, or Keri lotion may help forestall microtrauma and epidermal cracking.

Education in First Aid and Wilderness Safety.

Participants should be encouraged to take general courses in first aid and wilderness safety. Agencies that offer general and specialized training in skiing, mountaineering, river-rafting, and other types of wilderness medicine are listed in [Appendix C](#). Locally organized programs may be found through the American Red Cross, sporting goods stores, and continuing education departments of local colleges.

Before departure, the trip coordinator should review the emergency supplies with the rest of the group. The proper use of mechanical devices should be demonstrated, and indications for the use of medications should be discussed. Groups planning an extended or high-risk outing may wish to conduct an exercise of mock injury evaluation and management.

Factors in Trip Planning

The primary considerations in planning a trip relate to: (1) the maximum anticipated

delay in obtaining medical assistance, (2) duration of an outing, (3) risks imposed by environmental extremes, and (4) hazardous recreational activities that require use of specialized equipment and supplies.

Availability of Medical Care.

The longer the maximum anticipated delay in obtaining advanced medical assistance, the more likely the irreversible loss of neurologic function, limb, or life. The anticipated delay must take into account that in very rural areas, the nearest physician or hospital may not be equipped to handle a major wilderness injury or illness. An extreme case example is the planning of emergency access to a recompression chamber for members of a deep-sea diving expedition. A more typical example is a deeply penetrating arm laceration. As the hours pass, the likelihood of infection grows. If the victim can reach advanced medical help within an hour, it will suffice to control bleeding and apply a sterile dressing held in place by improvised cravats or tape. If definitive care is several hours away, irrigation with water containing a topical disinfectant is desirable. If the delay in care will be over 6 hours, a decision will have to be made whether to close the wound in the field or to evacuate the victim to medical care (see [Chapter 18](#)). The estimate of the anticipated delay depends on the type of rescue services, method of contact, terrain and weather, and number of able (carrying) persons. Party members should agree in advance on simple emergency distress signals, such as whistle or flashlight bursts in groups of three. Usually, uninjured party members have to make contact with outside agencies.

Manually evacuating the victim is an option but requires a relatively mobile victim or at least six carriers if the victim is immobilized. In this regard, it is important to know whether other groups might be trekking in the same vicinity. If access is controlled by permit, the administering agency should be asked about the itinerary of neighboring parties. The decision to carry a victim out must be based on a realistic appraisal of the hours it would take messengers to reach aid vs. a manual evacuation effort to traverse the greatest distance or worst foreseeable weather and terrain.

Trip Duration.

The likelihood of mishap rises as the trip duration increases. This is partly attributable to unpredictable weather and the cumulative effects of fatigue and overuse syndromes. In addition, long trips usually involve extensive planning, significant financial investment, and time away from work. Party members are therefore reluctant to cut the trip short and are more willing to continue in the face of mild medical disability and equipment failure. Groups planning to be away from civilization for more than a week should have a maximally diversified list of medical and contingency items.

Weather, terrain, and activity interact and increase the risk of illness or injury. Particularly hazardous combinations include winter climbing, mountaineering, skiing, and white-water kayaking. The anticipated ranges of weather and terrain must be figured into estimates of the maximum delay to medical assistance (see earlier discussion). U.S. and global historical summary data indicating temperature ranges, winds, and duration, type, and amount of precipitation can be obtained from the National Climatic Data Center (see [Box 69-1](#) and [Appendix C](#)). State and national park services and state climatology offices are also sources of such information about their territories. The National Weather Service office nearest the travel site can provide short-term forecasts and in many regions broadcasts weather information between 162.40 and 162.55 MHz VHF (see [Appendix C](#)).

Expedition Travel: Special Equipment and Supplies for High-Risk Groups.

Medically trained individuals traveling with a group at high risk of trauma or illness may wish to carry supplies requiring special expertise for proper use ([Box 69-4](#) and [Box 69-5](#)). Some of the necessary skills may be acquired in advanced first aid, paramedic, or nursing classes. Intramuscular and intravenous (IV) medications should be administered only by those with formal training in the indications, dosing, and risks of those drugs. Inclusion of a limited supply of emergency oxygen or IV saline may be reasonable to carry for a high-risk expedition. Adequate rehydration can generally be accomplished in a conscious person with a motile bowel using commercially available oral rehydration packets. Thus a comprehensive supply and variety of IV solutions (e.g., antibiotics, pain medicines, dextrose in saline) is predominantly a component of either a medical base support camp or for situations of search and rescue (see [Chapter 25](#)). Items such as surgical tools, chest tubes, and mechanical suction devices would be appropriate only for extremely high-risk expeditions and military excursions.

**Box 69-4. CHECKLIST FOR HIGH-RISK
OUTINGS: DEVICES REQUIRING
SPECIAL MEDICAL TRAINING**

Airway, nasopharyngeal (impaired mental status; resuscitation)

Cricothyrotomy cannula or catheter (e.g., Abelson cannula—see [Appendix B](#))

Chest tube set (chest trauma; empyema—practical only on major expeditions)

Glucose testing strips and buccally absorbed glucose preparation (if diabetic on trip; strips must be protected from freezing)

Ophthalmoscope with blue filter and fluorescein strips to stain corneal lesions (retinal hemorrhages; anterior eye examination—practical only on expeditions)

Oxygen (hypoxemia, shock, cerebral/pulmonary edema, impaired mental status)

Sphygmomanometer (aneroid, plastic housing—practical only on expeditions)

Stethoscope

Suction device (mechanical) (clearing oral cavity; chest tube drainage—practical only on expeditions)

Surgical tools (practical only on remote expeditions)

**Box 69-5. CHECKLIST FOR HIGH-RISK
OUTINGS: MEDICATION REQUIRING
SPECIAL MEDICAL TRAINING**

GENERAL USE

Intravenous (IV) solutions (isotonic)
and tubing (for hydration, route for IV
medications)

Needles and syringes (for IV hydration
and emergency injectables)

Antibiotic, potent oral with
wide-spectrum coverage (e.g.,
ciprofloxacin)* or injectable
(ceftriaxone)*

β -Agonist metered-dose inhaler (for
asthma, anaphylactic reaction)*

Ophthalmic anesthetic*

***HIGH RISK OF INSECT
BITES/ALLERGIES***

EpiPen*

Diphenhydramine oral (for allergic
reaction, mild sedation/insomnia)

Oral corticosteroid*

HIGH RISK OF TRAUMA

Fentanyl patch (Duragesic) applied to
skin on chest when mental status
precludes oral narcotics*

Alprazolam (Xanax) for sedation*

precludes oral narcotics*

Alprazolam (Xanax) for sedation*

HIGH RISK OF ALTITUDE ILLNESS

Acetazolamide for mountain sickness*

Corticosteroid oral or injection (e.g., dexamethasone) (cerebral edema)*

Furosemide tablets for pulmonary edema*

Nifedipine for pulmonary edema*

HIGH RISK OF SNOWBLINDNESS

Ophthalmic cycloplegic (e.g., cyclopentolate 1%) (for pain from snowblindness)*

Ophthalmic corticosteroid-antibiotic combination (e.g., Maxitrol) (recommended for short-term use in snowblindness *only* if blue filter ophthalmoscopic examination using fluorescein stain rules out herpetic keratitis)*

*See [Table 69-2](#) and [Table 69-3](#) for comments on considerations of dispensing medication.

A host of recreational activities have inherent risks that may dictate specialized equipment beyond a basic medical kit. Mountain climbing not only poses a risk from traumatic injury but also subjects the climber to high-altitude illness, thus requiring portable oxygen or a pressure (Gamow) bag for treatment of victims suffering the ill effects of extreme altitude. Extreme cold exposure might dictate the need for technical devices to provide warmed IV fluids and humidified oxygen. Adventures in white-water sports place the participants at risk from freshwater drowning, and such expeditions might consider carrying adjuncts for airway management. Cycling poses soft tissue injuries from abrasions that require occlusive water-based gel dressings for optimal wound care. Travel to underdeveloped nations in which mosquitoes transmit deadly

infectious diseases requires specialized equipment, such as protective netting for sleeping and chemical insecticides or repellents. [Table 69-1](#) lists common recreational activities and identifies specialized equipment that may be considered for high-risk expeditions (see [Box 69-8](#)).

ASSEMBLING THE MEDICAL KIT

Organizational Levels

The emergency kit may be broken down into five components (see [Box 69-6](#) , [Box 69-7](#) , [Box 69-8](#) , [Box 69-9](#) , [Box 69-10](#)): (1) a personal medical kit, (2) a more comprehensive community medical kit, (3) medical kits for expeditions and the medically trained, (4) specialized equipment and supplies to deal with environmental and recreational hazards, and (5) items stored in the vehicle. The components

TABLE 69-1 -- Recreational Activities Requiring Specialized Equipment

RECREATIONAL ACTIVITY	SPECIALIZED EQUIPMENT					
	HIGH ALTITUDE	COLD EXPOSURE	WATER SPORTS	BICYCLING	CLIMBING AND HIKING	THIRD WORLD TRAVEL
Backpacking		X	X		X	
Mountain climbing and expeditions	X	X	X		X	X

International travel and trekking			X		X	X

Recommended specialized equipment for each recreational activity is denoted by an X in the appropriate column and itemized in [Box 69-8](#) . Lists are comprehensive and intended for groups at a distance from medical help or involved in a high-risk adventure; not all items may be needed for low-risk travel. Purchase of specialized equipment should be based on the foundation of a comprehensive medical kit as highlighted in [Box 69-6](#) .

of a well-equipped first-aid medical kit designed for the management of trauma and common medical problems are itemized in [Box 69-6](#) . Such a kit consists of nontechnical items that promote wound management and permit stabilization of extremity injuries, while including useful over-the-counter medicines to deal with common medical complaints. For persons without the time or desire to create such a comprehensive medical kit, consideration can be given to a host of commercially packaged wilderness first-aid kits (see [Figure 69-1](#) and [Appendix B](#)). Experienced groups involved in high-risk expedition travel having participants with medical knowledge may wish to consider carrying the basics recommended in [Box 69-7](#) . Further tailoring of this medical kit may be achieved via the index for expedition travel ([Figure 69-2](#)) that helps guide selection of prescription medicines as a function of trip duration and remoteness from medical care.

Items Carried on the Person.

The purpose of carrying a minimum amount of items on one's person relates to the ever-present danger of separation from travel partners. A sudden fall, avalanche, or swamping can quickly separate victim and gear. In anticipation of this, experienced wilderness travelers need to carry a bare minimum of items on their person at all times (see [Box 69-9](#)). Such supplies provide protection from the elements, permit self-treatment of minor traumatic injuries, and help signal for help for purposes of search and rescue. These typically include assorted adhesive compress strips, knife or razor blade, butane lighter or matches (preferably the waterproof, strike-anywhere type), plastic whistle, small reflective mirror, length of thin nylon

1668

1669

Figure 69-1 Prepackaged wilderness first-aid kits are available from many manufacturers. Kits are neatly organized and rugged, with detachable inner pouches that are useful for

day trips. Bags are water resistant to allow for white-water use. A surprisingly large amount of first-aid material can be carried, as shown in the illustration.

1670

	Description of outing			
	Day trip	1-2 days	3-5 days	7-10 days
Maximum interval to medical care				
Less than 24 hours	1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100			
24-48 hours		1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100		
48-72 hours			1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100	

Figure 69-2 Recommendations for prescription medicines for expedition travel based on the duration of outing (vertical columns) and the maximum interval to medical care (horizontal rows). Itemized numbers refer to recommended topical and systemic medicines found in [Table 69-2](#) and [Table 69-3](#), respectively.

cord, and bandanna (which can double as a cravat or sling). A nonperishable source of quick high-energy food may be of value during isolation to maintain strength. These items can be compactly stored inside a plastic bag or small stuff sack and may be carried in either a pocket or a small fannypack (zippered, passport-size waist belts are comfortable and inexpensive). As noted previously, all travelers should carry some form of identification, and those with serious medical allergies or active illnesses should have an appropriate medical alert bracelet, anklet, medallion, or wallet card. Those with a history of bee, wasp, or other anaphylactic allergy should carry at least two preloaded syringes of 1:1000 aqueous epinephrine solution (EpiPen; Ana-Kit) in a cool dark compartment and should inform others in the party of the medicine's location and proper usage.

Box 69-6. CONTENTS OF A COMPREHENSIVE MEDICAL KIT

WOUND MANAGEMENT

Irrigation syringe with 18-gauge needle

Povidone-iodine solution USP 10%

Wound closure strips

Butterfly closures

Tincture of benzoin

Alcohol pads

Moleskin

Antiseptic towelettes

Scalpel with no. 11 or 15 blade

Latex or non-latex surgical gloves

OVER-THE-COUNTER MEDICATIONS

Acetaminophen (Extra Strength Tylenol)

Ibuprofen 200 mg (Nuprin)

Diphenhydramine (Benadryl)

Pseudoephedrine (Sudafed)

Ranitidine (Zantac 75)

Simethicone (Mylanta II antacid)

Loperamide (Imodium AD)

Rectal glycerine suppositories

Saline eye wash

Glucose paste

Rectal glycerine suppositories

Saline eye wash

Glucose paste

Hydrocortisone cream 1%

Tinactin antifungal cream

High-SPF sunscreen and lip balm

Aloe vera gel

Neosporin ointment

BANDAGING MATERIALS

Lamino Trauma Dressing

4 × 4 sterile dressing pads

Eye pad

Cotton-tipped applicators

Nonadherent sterile dressing

Elastic bandage wrap with Velcro closure

Adhesive cloth tape

Band-Aids

3-inch sterile gauze bandage

MISCELLANEOUS EQUIPMENT

Folding scissors

Forceps for removal of splinters and ticks

Thermometer

Cavit temporary dental filling

SAM splint

Triangular bandage and safety pins

Plastic resealable (Zip-Lock) bags

Cavit temporary dental filling

SAM splint

Triangular bandage and safety pins

Plastic resealable (Zip-Lock) bags

PRESCRIPTION MEDICINES*

Selection function of trip duration/interval to care

*See [Table 69-2](#) and [Table 69-3](#) .

MEDICALLY TRAINED**

Comprehensive first-aid kit for the management of trauma (see [Box 69-6](#))

Medical devices requiring specialized training (see [Box 69-4](#))

Appropriate prescription medications for general illness (see [Table 69-2](#) and [Table 69-3](#))

Prescription medications for specific injuries/illness (see [Box 69-5](#))

Repair materials (see [Table 69-4](#))

Indicated equipment based on recreational and environmental hazards (see [Box 69-8](#))

Box 69-8. SPECIALIZED EQUIPMENT FOR RECREATIONAL AND ENVIRONMENTAL ACTIVITIES

HIGH ALTITUDE

Gamow Bag and accessories

Gamow Tent

Breathing Bladder

Portable air compressor

EPAP mask with headstrap

Sportstat portable pulse oximeter

COLD EXPOSURE

External thermal stabilizer bag

Res-Q-Air

Hot-Sack IV Warmer

Grabber Warmers

Hotronic Foot Warmers

Space Thermal Reflective Survival Bag

Low-reading thermometer

Adhesive climbing skins

Life-link adjustable ski/probe pole

AvaLung avalanche vest

Tracker DTS (digital transceiving system) avalanche beacon

WATER SPORTS

CPR Microshield

WATER SPORTS

CPR Microshield

Katadyn or MSR WaterWorks filter

BICYCLING

All-Terrain Cyclist Kit

Hydrogel occlusive dressing

MOUNTAIN CLIMBING AND HIKING

SAM Splint

Air-Stirrup ankle brace

TROPICAL AND THIRD WORLD TRAVEL

Sawyer Extractor

Permethrin repellent

TropicScreen mosquito net

Oral rehydration salts packets

Box 69-9. CONTENTS OF A PERSONAL MEDICAL KIT

ON-PERSON ITEMS

Identification/pencil and notepad
Hat and sunglasses
Topographical map/compass
Swiss Army knife or razor blade
Nylon cord
Whistle and small reflective mirror
Lighter or waterproof matches
Poncho and space blanket
Adhesive compress and tape
Bandanna
Nonperishable high-carbohydrate energy bar

IN-PACK ITEMS

Personal first-aid and hygiene material
Survival guide/first-aid booklet
Prescription medications, labeled (in plastic or water-proof aluminum box)
Over-the-counter medications noted in the comprehensive first-aid kit (see [Box 69-6](#))

Box 69-10. CHECKLIST: RECOMMENDED IN-VEHICLE EMERGENCY SUPPLIES

FIRST-AID KIT

As for trail, but include large burn dressings

Boards for splint construction

Backboard, short or folding long (e.g., Junkin—see [Appendix B](#))

RESCUE AND SURVIVAL

Avalanche probe poles, collapsing*

Bags, large plastic

Blankets, wool and "space" blankets

Climbing rope and hardware†

Candles, long-burning

Flashlight

Food and water (in canteen)

Ice ax†

Matches (waterproof) or lighter

Radio, citizens band

Rope

Saw with metal-cutting blade

Small stove, pot or coffee can, and utensils

Ski climbing skins, snowshoes*

Tarp, plastic

Toilet paper

Tarp, plastic

Toilet paper

AUTOMOTIVE

Aluminum foil to cover windows (minimizes heat loss or gain)

Cables to jump battery

Chains with tighteners (with repair links and special pliers)*

Fire extinguisher

Flares, 10-minute (at least six) (can also serve as fire starter)

Gloves

Oil, extra can

Shovel, metal or Lexan with short or collapsing handle

Tool kit (consider inclusion of a small ax)

Tow chain or cable

Wheel chock or wedgeblocks

*Winter weather supplies.

†Mountain terrain supplies (special training needed).

Personal Items Carried in the Pack.

Certain basic contingency "essentials" should be carried on virtually every venture. In addition to one's personal first-aid, hygiene, and clothing items, a flashlight, coins for telephone calls, and extra pair of sunglasses are recommended. Extra clothing, food, and water should be carried in proportion to the risk associated with the trip.

A host of over-the-counter medications may be useful for wilderness travel, especially for low-risk outings of short duration. Some commonly required nonprescription items that may be of value are listed in [Box 69-6](#) . Of prime importance is the control of pain associated with trauma. For mild to moderate pain, aspirin, acetaminophen, or a nonsteroidal antiinflammatory drug is effective. Decongestants are helpful in treating symptoms associated with upper respiratory infections, and their antihistaminic effects are useful for the treatment of allergies and insomnia. Gastrointestinal complaints necessitate antacids and an antidiarrheal agent.

Saline eyewash is helpful for irritated eyes and in removing foreign objects. Antiseptic cream or ointment is useful in treating superficial infections of the skin, and a steroid ointment is of value for treatment of certain rashes or contact dermatitis. Aloe vera gel is useful for treatment of frostbite and injuries from burns or excessive sun exposure.

Frequently needed first-aid material and personal medications are carried in stuff sacks or plastic box containers. Medication containers should be stored in an accessible but thermally and physically protected location in each individual's pack because capsules and suppositories may melt if exposed to extreme heat. Dressings, bandages, and adhesive materials should be kept in a plastic bag within their container to protect them from moisture.

Medications should be stored in unit dose sheets or screw-top plastic bottles labeled with the patient's and physician's names, generic and trade drug names, dispensing information, and expiration date. Medications

1671

requiring a prescription with directions for their use ([Table 69-2](#) and [Table 69-3](#)) should be secured in a watertight plastic or aluminum box. The trip coordinator should ask each member of the party to check that any expired medications are replaced and that capsules and suppositories are intact.

Community Supplies Carried in the Pack.

As mentioned previously, traumatic injuries represent the greatest concern during wilderness travel. A comprehensive medical kit is the most important community item (see [Box 69-6](#)). Emphasis is placed on the management of wounds and stabilization of injuries through appropriate bandaging. Suture material is not recommended on the list of items because of the likelihood of subsequent infection. Large wounds are best treated with sterile pressure dressings.

Bulky and heavy items, including most stock first-aid and contingency supplies, should be labeled and distributed among the members of the group for storage and transport. A cross made from strips of tape or cloth should be placed on the pack overlying the compartment containing the first-aid items. This allows ready access by any member of the party in an emergency situation. Repair materials are best kept in clearly labeled stuff sacks, or aluminum or plastic boxes independent of the first-aid and medical supplies.

Items Stored in the Vehicle.

A complete emergency kit in the vehicle (see [Box 69-10](#)) is highly recommended. It will facilitate further stabilization of an injured person evacuated to a trailhead. The vehicle

kit should also provide material necessary to deal with accidents encountered along the highway and to cope with the environment if the occupants are stranded by automotive trouble or natural disaster. Several large burn dressings and a neckboard with strapping will fit in a standard trunk or other recess. Although only large vehicles can accommodate the usual full-length backboard, a folding backboard is now available from Junkin Safety Appliance Co. (see [Appendix B](#)). The remaining contents of an emergency kit will fit in a medium (6 inches W x 12 inches L x 9 inches H) or large (8 inches W x 18 inches L x 14 inches H) war surplus ammunition box or a toolbox of similar size.

Selecting Contingency Supplies: Advanced Expedition Planning

Individuals with medical training involved with risky wilderness travel may opt to tailor their own medical kit. Adventurous expeditions may wish to include a host of prescription medications that require advanced knowledge (see [Box 69-5](#)) and carry special devices requiring medical training (see [Box 69-4](#)). In addition, specialized equipment to handle expected environmental and recreational hazards should be considered (see [Box 69-8](#)). An appropriate emergency kit is adequate in content but not too heavy or bulky. Attempting to carry all possible medical supplies and equipment to handle any conceivable emergency is not practical.

An alternative approach is as follows: Assess the group's trip risk on the basis of proximity to support (a function of interval to medical care) and comfort level of handling unanticipated traumatic injury or medical illness (cumulative probability related to trip duration). [Figure 69-2](#) itemizes recommended prescription medicines as highlighted in boxes formed by the intersection of the latter two factors in bold. Specialized equipment purchases ([Box 69-8](#)) are then added on as dictated by unique recreational activities ([Table 69-1](#)).

Using a Wilderness Index.

The wilderness index for expedition travel serves to assist group participants with advanced first aid or medical training in the selection of appropriate prescription medications. The latter serve to augment the contents of the comprehensive medical kit that includes only over-the-counter medicines. In [Figure 69-2](#) a unique "square" of recommended prescription medicines is found at the intersection of the horizontal row "Duration of Outing" and the vertical column "Maximum Interval to Medical Care." Numbers refer to specific medical items, topical and systemic, found in [Table 69-2](#) and [Table 69-3](#), respectively. The drug doses listed in [Table 69-3](#) are intended for nonpregnant, young, or middle-aged adults in good health. Reduced doses are often necessary for children, the elderly, and those with end-organ disease (especially renal, hepatic, and cardiac). The personal physician should modify the doses appropriately.

The rationale for medicine selection among a host of prescribed items is based on one's expected time frame for support and rescue in the event of unexpected injury and the cumulative likelihood of experiencing a medical illness as trip duration increases. A low-risk outing (e.g., a day hike) is one in which the interval to medical care is short (<4 hours) and trip duration (<1 day) places one at low likelihood of acquiring a medical

illness. Therefore expectations for a prompt rescue and medical support preclude the need to carry most prescription medicines, since traumatic injury or a life-threatening allergic reaction become of prime concern. In such circumstances, pain control and management of anaphylaxis take precedence. A moderate-risk trek (e.g., a 1-day "ski-in" with 2 nights winter camping) will have an interval to medical care that is longer (4 to 12 hours) and a trip duration that increases chances for medical illness. With a "ski-out" time of 4 to 12 hours plus added time to return with organized help, expectations are that an ill group member will not receive sophisticated rescue efforts until the following day. In such instances,

TABLE 69-2 -- Topical Medication

CLASSIFICATION*	RECOMMENDED	EXAMPLES/BRANDS	INDICATIONS
1. Corticosteroid cream, potent topical	High-potency fluorinated compounds (e.g., betamethasone, fluocinolone, halcinonide)	Synalar-HP 0.2%	Rash, swelling due to plant (poison oak, ivy) contact and insect bites
		Diprosone 0.05%	
		Lidex 0.05%	

2. Antibiotic, ophthalmic	Sulfonamide-containing preparation	Sulamyd 10% ointment	Conjunctivitis; snowblindness; corneal abrasion
3. Corticosteroid-antibiotic combination, ophthalmic ointment	Dexamethasone with neomycin and polymyxin	Maxitrol	To reduce inflammatory pain due to snowblindness; to temporarily control disabling allergic conjunctivitis
4. Cycloplegic, ophthalmic	Cyclopentolate 1%	Cyclogyl 1%	To reduce pain (relaxes iris) due to snowblindness
5. Antibiotic/antiinflammatory, ear canal	Antimicrobial plus hydrocortisone 1%	Acetic acid 2% plus hydrocortisone 1% (VoSol HC)	Ear pain (worsened by pulling, itching, discharge)
6. Anesthetic, ophthalmic	Proparacaine 0.5%	Ophthaine, Ophthetic	To facilitate eye examination for foreign body, abrasion, or burn

7. Fluorescein strips, ophthalmic	Fluorescein	Fluoro-I-Strip	To distinguish herpetic keratitis, foreign body, corneal abrasions, and corneal burn (snowblindness)
-----------------------------------	-------------	----------------	--

C, Common, > 10%; O, occasional, 1%-10%; R, rare, < 1%; D, dose-related.

*Numbers refer to the classification scheme in [Figure 69-2](#).

narcotics to control pain, an antibiotic to prevent infection from soft tissue injuries, and antiemetics or antidiarrheals to control gastrointestinal upset and preserve fluid and electrolyte balances become paramount. A high-risk outing (e.g., a weeklong expedition with mountain climbing) precludes seeking formal help within a 12-hour period and has a long trip duration, with the added challenge of encountering bothersome medical illness. With such an expedition, nonthreatening problems (e.g., athlete's foot, infected blisters, dermatitis, asthma, bronchitis, sinusitis) are apt to occur, limiting performance and enjoyment. Besides carrying those medicines noted above for low- and moderate-risk treks, one should have treatments to manage more persistent medical illness, to include a full course of oral antibiotics for upper respiratory, abdominal, and soft tissue infections, oral and potent topical steroids for dermatologic problems, and assorted ophthalmic and otic medications to deal with bothersome infections or allergic reactions of vital sensory organs.

A Sample Journey.

The month is April and the goal is a 21-mile round-trip cross-country ski tour to the top of Mt. Whitney (elevation 4418 m [14,495 feet]) in the Sierra Nevada mountains. The team consists of four cross-country skiers who have completed an American Red Cross advanced first-aid course and an avalanche seminar offered to the public by the National Ski Patrol System. The trip duration will be 3 days and 2 nights, depending on weather and snow conditions. The base camp will be at 3810 m (12,500 feet). Were a skier to become disabled en route, one of the others would remain with the victim while the remaining two would ski out to the nearest telephone or source of help (no longer

than an 8-hour downhill ski from the farthest point along the route). Helicopter evacuation to the nearest hospital would usually be accomplished within the next 2 to 4 hours, making the maximum interval to medical care within 12 hours. The trip poses risks related to trauma, cold injury, avalanche danger, snow-blindness, and high-altitude illness. With the possibility

1674

1675

TABLE 69-3 -- System

CLASSIFICATION*	RECOMMENDED	EXAMPLES/BRANDS	INDICATIONS	CONTRAINDICATIONS
1. Epinephrine, intramuscular	Auto-injecting epinephrine for injection; a single dose delivered from the auto-injector	EpiPen	Emergency intramuscular use to treat anaphylactic reaction to stinging insects, medication, or foods	None for short-term use in indicated settings
2. Acetazolamide	Acetazolamide	Diamox	Prevention and treatment of acute mountain sickness (headache, sleep disturbance, lassitude, nausea, incoordination)	Concurrent diuretic medications; severe renal impairment
				<i>Caution:</i> Toxicity (lethargy, incoordination) may develop with the use of aspirin or other salicylates

3. Corticosteroid, oral	Prednisone	Prednisone, generic	Anaphylaxis or severe or disseminated allergic reactions (including contact dermatitis); severe asthma; moderate cerebral edema	None for short indicated setting
4. Analgesic, oral narcotic	Acetaminophen 500 mg with hydrocodone (5 or 7.5 mg)	Vicodin, Lortab	Moderate to severe pain; severe cough	Respiratory difficulty; injury; other severe alcohol; narcotic
5. Antibiotic, oral for skin, respiratory, or urinary infection	Amoxicillin 500 mg with clavulanate 125 mg	Augmentin	Infection: skin, respiratory, urinary	If allergic to penicillin, cephalosporins, cephalexin, trimethoprim/sulfamethoxazole, or levofloxacin
6. Antibiotic, oral, for traveler's diarrhea	Ciprofloxacin 750 mg	Cipro	Prolonged loose stooling and cramps, fever and weakness	
7. Antiemetic/antinausea, rectal suppository	Promethazine 25 mg suppository	Phenergan	Severe nausea, vomiting	Hypothermia; hypotension; from injury, illness, drugs; high fever; phenothiazine

8. Sedative, oral	Alprazolam 0.125 mg	Xanax	Sleeplessness; anxiety, severe jet lag; muscle spasm	Coexisting sedatives, alcohol, drugs,
9. Asthma inhaler	Albuterol MDI	Proventil; Ventolin (17-g metered-dose inhalers)	Wheezing, cough in setting of cold air or bronchitis	None for short-term use; indicated settings
10. Antibiotics, extended spectrum	Ceftriaxone for intramuscular injection; ciprofloxacin (above) plus metronidazole (below)	Rocephin injectable; Cipro (above); Flagyl	Severe infection with fever, change in mental status, overwhelming infection	None for short-term use; indicated settings
11. Corticosteroid, for intravenous injection	Dexamethasone	Decadron phosphate, 4 mg/ml in prefilled 2.5-ml syringes	High-altitude cerebral edema; anaphylaxis in poorly responsive person	None for short-term use; indicated settings
12. Diuretic, for intravenous injection	Furosemide	Lasix, 10 mg/ml in 4-ml syringes	High-altitude cerebral edema or pulmonary edema	Known sulfa allergy, dehydration, vomiting, hemorrhage

13. Nifedipine	Nifedipine	Procardia or generic, 30-mg sustained-release tablets	High-altitude pulmonary edema (lowers pulmonary artery pressure by causing arterial dilatation)	Severe dehydration, loss, or hemorrhage
14. Amphetamine stimulant	Dextroamphetamine 5 mg	Dexedrine	Life-threatening mental fatigue	None in indication
15. Opiate analgesic patch	Fentanyl patch	Duragesic Transdermal System, 20 cm ² patch containing 5 mg of fentanyl (releasing 50 µg/hour)	Severe, prolonged (>24 hr) painful disorder or injury	Bowel obstruction, respiratory depression, difficulty breathing with impaired consciousness

16. Antibiotic for giardiasis and amebiasis	Metronidazole 500 mg	Flagyl	Profuse diarrhea delayed >2 weeks (<i>Giardia</i> suspected), or dysentery in areas endemic for <i>Entamoeba histolytica</i> (amebiasis suspected)	None for short indicated setting

C, Common, <10%; O, occasional, 1%–10%; R, rare, <1%; D, dose-related.

*Numbers refer to the classification scheme in [Figure 69-2](#).

†Allergy, pregnancy, and breast-feeding are always assumed contraindications, unless otherwise indicated.

‡Doses listed in [Table 69-3](#) are intended for nonpregnant, young, or middle-aged adults in good health. In all situations, the traveler's personal physician should recommend appropriate doses.

§Traveler's diarrhea is usually mild and subsides spontaneously within 4 days—reserve antibiotics for indications above and for treatment of dysentery (blood and mucus). During diarrhea, avoid milk products and solids, but maintain fluid intake and electrolytes—the U.S. Public Health Service recommends drinking alternately from each glass: (1) 8 oz fruit juice with ½ tsp honey, corn syrup, or sugar with a pinch of table salt, and (2) 8 oz carbonated or boiled water with ¼ tsp baking soda. Alternatively, packets of electrolyte powder (to mix with water) may be useful for isolated, high-risk travel.

TABLE 69-4 -- Repair Supplies to Consider for Wilderness Travel

ITEM	DESCRIPTION, QUANTITY, WEIGHT*	COMMENT
Needle or sewing awl	With heavy thread (1 oz)	Clothing, pack repair
Screwdrivers	Flat and Phillips No. 2 (3–6 oz)	For skis, No. 3 "posidrive" (or filed-down No. 2 Phillips)
Tape, duct or reinforced strapping	1–2 inches wide, 5 yards (2 oz) (per person per trip)	
Wire	Braided steel, 3–6 ft (2 oz)	Repair of binding, boot, snowshoe, and pack
Awl	On multifunction knife (2 oz) (per person per trip)	Repair of clothing, pack, shelter
Visegrip pliers	5-inch (5–8 oz)	
Glue	Two-component epoxy, or meltable nylon glue stick (1 oz)	
Spare bale and screws	Two	Repair of ski binding
"P-tex" ski base stick	Meltable No. 1 (1 oz)	Repair of plastic ski base
Spare ski tip	Plastic or aluminum (3–5 oz)	
Spare crampon wrench	No. 1 (one)	
Knife sharpener	Diamond-bar, ceramic, or stone (2–3 oz)	

*Quantity is per group unless specified; weight given is per individual item, in ounces (35 oz = 1 kg = 2.2 lb).

of an overnight stay until rescue arrives, medicine selection focuses on pain control for traumatic injury. Appropriate topical medicines include those for managing corneal injury from snowblindness. Systemic medicines of value include a limited supply of antibiotics to prevent infection of soft tissue injuries plus specialized medicines for prevention and treatment of acute mountain sickness. The following steps refer to the index for expedition travel (see [Figure 69-2](#)).

1. Determine the maximum interval to medical care. In the example given, "4–12 hours" would be found at the left of the figure, representing the square denoting the intersecting horizontal row.
2. Determine the trip duration. In the example, "2–3 days" would be found at the figure's top and denote the corresponding vertical column of intersection.
3. Find the "square" itemizing recommended topical and systemic medicines. On the index, the intersection of the horizontal and vertical columns defines a square suggesting prescription items. Note the reference numbers listed and find the

suggested medicines in the tables recommended in the figure legend.

Finally, emphasis must be placed on the recreational and environmental hazards likely to be encountered during travel. In this example, the dangers relate mainly to high altitude and cold exposure. Specialized equipment that may be of value under the conditions described is listed in [Box 69-8](#) . Because of proximity to a medical center able to provide prompt helicopter evacuation, a Gamow Bag would not be mandated for the treatment of high-altitude illness. In addition, the need to carry technical equipment to provide warmed IV solutions or humidified oxygen is offset by a prompt helicopter rescue. However, frostbite can occur rapidly, and an individual might wish to carry a Grabber Warmer because of its low weight and ease of packing (see section for product descriptions). Additionally, certain repair equipment should be carried, as denoted in [Table 69-4](#) .

Eyewear (see also [Chapter 22](#))

The appropriate use of sunglasses and goggles will protect eyes from sunlight, wind, and dust. The major variables to consider when buying sunglasses are durability and safety, light transmission, photochromicity (darkening with increasing sun intensity), and polarization. Lenses for aquatic, desert, snow, and high-altitude use should absorb 85% to 95% of visible light and essentially all (greater than 99%) ultraviolet (UV) radiation. This degree of visible light absorption can be easily achieved with polycarbonate, glass, or plastic lenses. (The wilderness trekker may need to carry another, less dark pair for use while driving a vehicle.) Most outdoor equipment retailers offer a wide selection of nonprescription lenses. In addition, customized lens/frame combinations can be obtained from an eye-care specialist in nonprescription or prescription configurations. Soft contact lenses that absorb UV radiation are also available.

Although plastic lenses are lightweight, they scratch more readily than other materials (despite improved coatings) and are generally not recommended for extensive

wilderness trekking. Glass lenses are available with the best photochromic properties and can be coated for greater than 99% UV absorption, but they are heavy, susceptible to breakage, and moderately susceptible to scratching. The most durable lenses are made of polycarbonate and are lightweight and shatterproof. In addition, polycarbonate lenses absorb greater than 99% of UV light and, in just the past few years, have become available with photochromicity, polarization, and antireflective coatings. For these reasons, polycarbonate is presently the preferred material for serious wilderness sports. Polycarbonate models that absorb at least 99% UV are manufactured under such brand names as All Weather, Bolle, Coyote (polarized), Gargoyles, Gentex, Learjet, Ski-Optics, Suncloud, Transitions (photochromic), and Wings.

Polarization decreases reflected solar glare from horizontal water, snow, and ice surfaces and is highly desirable for winter mountaineering, skiing, and aquatic

wilderness sports. Polarized lenses are now available in many colors. An external clip-on flip-up plastic polarizer can be added to any lenses. These clip-on polarizers absorb an additional 50% of the remaining transmitted light (increasing visible light absorption from, say, 90% to 95%) and may be of additional benefit in very bright conditions.

Frame construction is an important feature for extended wilderness travel. Frames should be composed of nylon, Lexan, silicone-graphite, or metal, rather than plastic. High-impact frames (such as RecSpecs) with polycarbonate lenses are available for hazardous sports, such as climbing, white-water venturing, and hang-gliding. Frames with springs are break-resistant and self-adjusting. Frame hinges should have a bolt and nut rather than a pin. For extended wilderness use, nuts should be sealed with Loctite and pins sealed with cyanoacrylate glue.

Other considerations include optical gradient and mirroring, frame construction, color, peripheral features, and price. Gradient lenses may be darker (or mirrored) at the top or bottom to preferentially block direct or reflected sunlight, respectively. This feature is desirable for aquatic, desert, and high-altitude travel but probably unnecessary for most backpacking activity. The choice of lens color is based largely on personal preference. Although yellow or rose lenses may appear to enhance contrast or hazy (flat) light conditions, research studies have found no consistent benefit. Sunglass models with side shields and nose protectors are recommended for snow, desert, and aquatic terrain. Retention (neck) straps are recommended for any activity involving climbing or skiing. For water sports, a lanyard may be attached from the frame over the back to a belt loop. A pair of high-quality sunglasses from an outdoor retailer generally costs between \$50 and \$170 (the more expensive models are often priced for their fashionable appearance rather than optical merit). Sunglasses with a custom configuration from an eyecare specialist can cost up to \$250.

Because the technology is rapidly evolving, the serious outdoor traveler may have difficulty finding an outdoor retailer with the "ideal" pair of sunglasses: polycarbonate lens with 100% UV and greater than 85% visible light absorption, polarization, photochromicity, antireflective coating, and springing nylon frame. It may be worthwhile to consult an eyecare specialist to research the latest products and customize the features to suit your needs.

Medical Supplies

Wound Care Material.

Needles and other surgical tools may be crudely "sterilized" by being rubbed vigorously with a prepackaged towelette containing alcohol, chlorhexidine (Hibistat), povidone-iodine (Betadine), or benzalkonium chloride. After the instruments are rubbed with alcohol or Hibistat towelettes, the residual alcohol can be ignited for additional effect. Flame sterilization to red hot may also be acceptable. A less efficient method is to immerse the tool in boiling water for about the same duration recommended to disinfect water for drinking.

Forcefully ejecting irrigant solution from a 20- or 35-ml syringe through an 18- or 19-gauge needle generates pressures adequate to dislodge bacteria and microscopic particles from contaminated wound surfaces. Unfortunately, the literature does not specify how "clean" an irrigant solution must be. Since the primary goal of irrigation is the removal of debris, it seems reasonable that water pure enough to drink should be adequate for irrigation, especially if povidone-iodine solution to achieve a 1% to 10% concentration is added.

Significant advances in wound care include Tegaderm adhesive dressings and Spenco 2nd Skin. Tegaderm is a transparent 3 × 3-inch adhesive covering for clean wounds that provides a barrier to water, dust, and dirt while allowing oxygen to penetrate. It can be left in place for several days provided that no wound complications arise. Spenco 2nd Skin is a polyethylene oxide gel laminate for placement over blistering skin and burns. 2nd Skin reduces friction damage to the underlying skin and may offer additional protection by redistributing pressure and absorbing exudate. It is an excellent product to carry, especially for bicycling, in which abrasion injuries are common.

Topical Medications.

Sweat, water, wind, dirt, and friction inherent in wilderness travel diminish the efficacy of topical sunscreens and corticosteroids. For this reason, sunscreen products containing methoxycinnamates in combination with oxybenzones are recommended to provide high substantivity, or "staying power" (see [Chapter 14](#)). A sunscreen sun protection

1680

factor (SPF) of at least 15 is recommended for wilderness travel by anyone even mildly susceptible to sunburn, since the goal is to prevent the burn entirely.

Topical corticosteroids are especially useful for contact dermatitis and insect bites. They may alleviate suffering and obviate the need for systemic drugs. Maximally potent fluorinated corticosteroid preparations (e.g., betamethasone, fluocinolone, fluocinonide, halcinonide) are recommended (see [Table 69-2](#)) for use under the harsh circumstances of wilderness travel; it is extremely unlikely that any complications would result from short-term use.

Intravenous and Classified Drugs.

Injectable drugs are rarely needed for the management of wilderness-associated trauma and illness, as most emergencies can be managed by either oral or transdermal application of medicines. IV medications are temperature sensitive, fragile, expire quickly, and require monitoring of vital signs because of potency and immediate onset of action. Narcotic analgesics should be used to treat pain only if mild analgesics such as aspirin and acetaminophen are inadequate, mental status is not clouded (as might occur with head trauma), and respiratory distress is not present (unless it is due solely to

discomfort). Oral narcotic-containing products are appropriate for moderately severe pain. If indicated by the circumstances, more potent dermal delivery systems of narcotics can be achieved (e.g., fentanyl patch) when oral administration is not possible. A short-acting central nervous system amphetamine stimulant (see [Table 69-3](#)) may be justifiably carried during extremely high-risk activity, such as winter mountaineering, in which the participant might have to overcome fatigue to assist in a rescue effort or to reach aid. The small quantity prescribed on a one-time basis is unlikely to be associated with abuse.

Specific Equipment Purchases

This section reviews specialized items that are not basic to the comprehensive medical kit but may be needed for certain high-risk recreational activities. [Box 69-8](#) itemizes such equipment. Descriptions of products, usage, and indicated circumstances are given here. Suppliers and their unique products are listed in [Appendix B](#).

High-Altitude Exposure (see also [Chapter 1](#)).

The Gamow Bag ([Figure 69-3](#)) is a portable hyperbaric chamber resembling a large sleeping bag with a window. It has been shown to be effective for the treatment of high-altitude pulmonary and cerebral edema. Constructed of nylon, the bag is foldable and has a packing weight of 14.5 pounds. Inflated, it is 7 feet long and has

Figure 69-3 Gamow Bag. Attached is the foot pump required to pressurize the compartment to 2 pounds per square inch. Four windows are strategically located to permit observation. Entry is via a lengthwise zipper.

a diameter of 21 inches. The bag is pressurized with a foot pump at a rate of 10 to 20 strokes per minute and has relief valves pressurized to 2 pounds per square inch, allowing the venting of expired air. In a situation such as a remote clinic with electricity, a mechanical compressor can be used to avoid the fatiguing task of foot pumping.

A Breathing Bladder has been introduced. One end of this large nylon bag connects to a face mask, and the other to one of the pressure relief valves of the Gamow Bag. The patient inhales uncontaminated air from the Gamow Bag, and the exhaled air flows down a plastic tube into the bladder. This obviates the need for manual foot pumping of the bag for a 15- to 30-minute period until the bladder becomes full. It is then necessary to operate the foot pump again to repressurize the bag. The bladder is an excellent alternative for expeditions at very high altitude that are far from medical evacuation and when a prolonged period of resuscitation is anticipated.

The recently developed Gamow Tent operates on the same principles as the Gamow Bag. It is nearly 50% larger, and the added height allows a victim to sit upright.

The aforementioned devices are expensive and intended for expeditions going to extreme altitude (greater than 4267 m [14,000 feet]) or in dangerous situations that prevent an easy, rapid descent (e.g., ice climbing on a steep glacial crevasse).

Cold Exposure (see also [Chapter 6](#) and [Chapter 7](#)).

Equipment purchases for cold exposure relate to the stabilization and resuscitation of victims with accidental exposure hypothermia. For most travel, removal of an individual from exposure and prevention of further heat loss are sufficient measures when medical assistance is nearby. Persons engaging in low-risk travel can use a sleeping bag wrapped with a space emergency blanket to provide a capsule that preserves heat and allows

1681

Figure 69-4 The AvaLung (Black Diamond, Ltd.). A lightweight vest designed to improve avalanche survival. Victims are able to draw air from even a dense snowpack via the front using an air exchange mouthpiece. A one-way valve permits exhalation of carbon dioxide expelled through the vest back.

thermal recovery. The latter product is made of a lightweight material capable of reflecting and retaining over 80% of radiated body heat. Another helpful product is the Grabber Warmer. Useful in the prevention of frostbite, this small pad undergoes a chemical reaction on exposure to the air, producing heat. Grabber Warmers can maintain a temperature of 66° C (150° F) for 7 hours or more. They can be placed in gloves, shoes, and pockets for the prevention of frostbite.

For more serious expeditions involving high-risk travel or distant from medical rescue or assistance, several highly sophisticated products may be of value. Of value in circumstances of high avalanche danger is a lightweight vest with a breathing tube that permits extraction of oxygen and release of carbon dioxide when trapped under snow ([Figure 69-4](#)). Such a device can significantly prolong survival chances until the victim is found by another person appropriately manned with an avalanche beacon and/or extendable ski pole. For victims of severe exposure hypothermia, elevation of core temperature and prevention of further body heat loss may be critical. Inhalation of warm, humidified air provides an excellent method of heat exchange and is now possible with portable field units. The Res-Q-Air ([Figure 69-5](#)) provides warm, saturated air by using

a

Figure 69-5 The Res-Q-Air system for delivery of warm, saturated air. The unit is portable and battery run for use in the field. Its use requires minimal training. Temperature is adjusted by a single control dial.

battery-operated device that requires a small amount of water and delivers heat for inhalation via an attached hose and face mask. The unit is simple to operate, has a temperature control valve, and runs for 1 hour on battery power. It is small (9 × 3 × 2 inches), weighs 4 ½ pounds, and is portable. In the event that emergency IV fluids may be required, an IV bag warmer, the Hot-Sack, can be used. This product comes in a soft, rugged portable case and has its own battery power source. Temperature within the bag remains at 37° C (98° F) so that IV fluids are kept warm. The bag has a protective sleeve to place over IV tubing to maintain warmth.

Advanced expeditioners and persons involved in cold water search and rescue should consider the purchase of a Hypothermic Stabilizer Bag. This product consists of an internal, high-pile fabric that wicks water to allow quick drying of hypothermic victims. The thermal properties far exceed those of an equivalent-thickness conventional down sleeping bag, and the product requires no additional insulation underneath for support and comfort. A key feature involves the ability to perform complete cardiopulmonary resuscitation through an access window over the chest. The stabilizer's outer cover is made of water-resistant material and has carrying handles to allow for safe transport of the victim ([Figure 69-6](#)).

Water Disinfection (see also [Chapter 51](#)).

The key design features of a filtration system that produce acceptable water for consumption are (1) adequate pore size of the filter to remove bacteria and protozoan cysts (0.2 mm or less), (2) filter element that either has activated charcoal or is impregnated with silver or iodine for local antibacterial action, (3) pump-feed mechanism that forces water through the filter housing, (4) device that can be easily disassembled and cleaned for proper maintenance, and (5) product having durability and simplicity of use. Noteworthy filters

Figure 69-6 Hypothermic Stabilizer bag. This excellent prehospital transport device allows passive rewarming of victims suffering from cold exposure and is especially useful in cold water immersion because of the drying ability of its high-pile fabric. The unit weighs only 12 pounds and measures 12 × 13 inches when packaged in a portable case.

that have most of the desirable features include the Katadyn water filter, PUR filter, and MSR Water-Works.

Bicycling.

Several prepackaged medical kits for the cyclist can be purchased. Persons who want to upgrade a basic first-aid kit to treat cycling injuries should consider the abrasions and minor burns likely to be encountered. Proper wound management requires a protective pad that is nonadherent, cools the skin, and absorbs exuded fluids. A number of breathable water-based gels, such as Spenco 2nd Skin, exist for this purpose.

Mountain Climbing and Hiking.

In wilderness travel above the treeline or on shipboard, the inclusion of more advanced splinting products should be considered. The SAM splint weighs only 4 ounces. Its coated aluminum strip unfolds to provide rigid longitudinal support. It can also be configured as a cervical collar, although the injured neck may require additional immobilization. At least two SAM splints are needed to stabilize an entire extremity. More elaborate devices include an air-stirrup ankle brace having an inner liner of adjustable air cells blown up through a valve. If activity will predispose to high risk of femoral fracture and a traction splint is desirable, the Kendrick traction device should be considered.

Third World Travel.

Travelers to underdeveloped countries are at risk of infection from a host of diseases transmitted by insect bites. For travel outside of urban areas, the risks are especially great when sleeping unprotected in the outdoors. A lightweight bed net that can enclose two persons should be carried. Further protection against mosquitoes can be achieved by spraying the nets with permethrin. For bites from certain insects and snakes, the Sawyer Extractor may be of value. Several topical medications that combine an anesthetic (benzocaine) along with a cooling agent (menthol), such as Sawyer's Sting Aid or Itch Balm Plus, may be helpful in dealing with bites or minor allergic rashes. Because of the high risk of traveler's diarrhea, oral rehydration packets should be carried. Commercially prepackaged units contain essential elements that allow oral

rehydration when combined with 1 L of disinfected water.

SUMMARY

The trip coordinator for travel in the outdoors should review the health status and experience of potential participants, emphasize preventive measures, and carefully review risk factors imposed by environmental extremes and recreational activities. An array of supplies to deal with potential problems can be appropriately tailored to augment the contents of the basic medical kit. Based upon trip duration and remoteness from medical care, specific prescription medications may be chosen and dispensed by knowledgeable and responsible individuals. Such efforts may forestall serious disability or discomfort while one awaits search and rescue efforts, or permit a sick group member to continue travel in the setting of non-life-threatening medical illness.

Suggested Readings

Adventurous Traveler Bookstore, 245 South Champlain St., P.O. Box 64769, Burlington, VT 05406-4769; 800-282-3963. Web site: www.adventuroustraveler.com. A complete source of outdoor travel books, maps, videos and CD-ROMs.

American Red Cross: *Emergency response*, ed 3, St Louis, 1999, Mosby Staywell (available from local offices of the ARC). Accepted guidelines for advanced first aid, best reviewed in a classroom format before travel.

Auerbach PS: *Medicine for the outdoors*, ed 3, New York, 1999, Lyons Press. Web site: www.lyonspress.com (800-836-0510). This is the "bible" on wilderness medicine for laypersons. It covers all situations and environments and is meant to be carried by anyone who will treat an illness or injury outdoors.

Backer H: Medical limitations to wilderness travel, *Emerg Med Clin North Am* 15:17, 1997.

Backer HD et al: *Wilderness first aid*, Sudbury, Mass, 1998, Jones and Bartlett. A layman's wilderness first-aid guide written as a collaborative effort between the Wilderness Medical Society and the National Safety Council.

Bowman W: *Outdoor emergency care: comprehensive first aid for non-urban settings*, ed 3, Lakewood, Colo, 1998, NSPS (133 S. Van Gordon, Lakewood, CO 80228; 303-988-1111). Web site: www.nsp.org. Developed for ski patrollers, provides an up-to-date, comprehensive guide to the prevention, recognition, and management of injuries and illness encountered in nonurban settings. Highly recommended reading for participants in all varieties of skiing.

Darvill F: *Mountaineering medicine*, ed 14, Berkeley, Calif, 1998, Wilderness Press (2440 Bancroft Way, Berkeley, CA 94704; 510-843-8080). Web site: www.wildernesspress.com. Lightweight, easily carried, reminder of the principles of first aid and basic medical care for the mountain environment.

Gentile DA et al: Wilderness injuries and illnesses, *Ann Emerg Med* 21:853, 1992.

Hackett P: *Mountain sickness: prevention, recognition and treatment*, New York, American Alpine Club (113 E. 90th Street, New York, NY 10028). Thorough review. Recommended reading for travelers to high altitude.

Lentz M et al: *Mountaineering first aid*, ed 4, Seattle, 1996, The Mountaineers (306 Second Ave West, Seattle, WA 98119; 800-553-4453). Web site: www.mountaineers.org. Good review of mountaineering first aid, most appropriate for classroom or individual reading in advance of departure.

Montalvo R et al: Morbidity and mortality in the wilderness, *West J Med* 168:248, 1998.

Olsen LD: *Outdoor survival skills*, La Vergne, Tenn, 1998, Ingram Trade. Chapters on shelter, fire, water,

plants and special skills on how to build a lean-to, and how to harvest and prepare plants in the wild.

Wilderness Medicine Letter (3595 E. Fountain Blvd. Ste A1, Colorado Springs, CO 80910; 719-572-9255). Web site: www.wms.org. The newsletter of the Wilderness Medical Society. Reviews of recent publications, notification of events and meetings, official position statements, and commentary by experts in the field. Highly recommended reading for physicians serving as advisors to travelers.

Wilkerson J, editor: *Medicine for mountaineering and other wilderness activities*, ed 4, Seattle, 1992, The Mountaineers (306 Second Ave. West, Seattle, WA 98119; 800-553-4453). Web site: www.mountaineers.org. Comprehensive coverage of the prevention, recognition, and advanced field management of mountaineering injuries and illnesses. Many sections are easily understood by general readers, but chapters on medical illness require familiarity with medical terminology and concepts, and a working knowledge of basic first aid is assumed. Recommended that a single copy be carried by the person responsible for medical care of a large group on an extended or high-risk mountaineering outing.

Wilkerson J, Bangs C, Hayward J: *Hypothermia, frostbite and other cold injuries*, Seattle, 1986, The Mountaineers (306 Second Ave. West, Seattle, WA 98119; 800-553-4453). Web site: www.mountaineers.org. Excellent overview that explains, in lay terms, the metabolic disturbances underlying cold injury, as well as practical methods of preventing and treating these disorders. Especially welcome is the chapter on immersion injuries containing valuable information for persons involved in aquatic sports. Highly recommended reading for all travelers to cold weather, mountain, and aquatic wilderness environments.

M. Broken bones	(YES)	(NO)

9. List any medical problems, illnesses, injuries, or chronic conditions that you have presently or have had in the last 3 years (be as specific as possible):

10. List any MEDICATIONS that you are currently taking (include the dosing, if possible):

Modified from Green P: The outdoor leadership handbook, Tacoma, Wash, 1982, Emergency Response Institute.

APPENDIX: Suppliers Listed in Text and Tables

1684

Many of the products cited in this chapter can be found in outdoor equipment retail stores or pharmacies. The sources listed below provide specialized products referred to in the text.

1. **Adventure Medical Kits**, P.O. Box 43309, Oakland, CA 94624; 800-324-3517. Web site: www.adventuremedicalkits.com. Supplier of well-designed medical kits that are prepackaged for a range of specific recreational activities, such as bicycling, white-water rafting, and backcountry travel.
2. **Black Diamond Equipment, Ltd.**, 2084 East 3900 South, Salt Lake City, UT 84124; 801-278-5552. Web site: www.avalung.com. Manufacturer of the AvaLung, which is the first and only active avalanche safety device that may enable the avalanche victim to breathe while waiting to be excavated.
3. **Campmor**, P.O. Box 700, Saddle River, NJ 07458; 800-226-7667. Web site: www.campmor.com. Lady-J urinal guide.
4. **Chinook Medical Gear, Inc.**, 3455 Main Ave., Durango, CO 81301; 800-766-1365. Web site: www.chinookmed.com. The most complete catalog retailer for wilderness medical supplies; carrier of the Gamow Bag; good beginning source for the person in need of a wide variety of medical supplies.
5. **Gilbert Surgical Instruments, Inc.**, P.O. Box 458, Bellmawr, NJ 08031; 609-933-2770. Abelson Emergency Cricothyrotomy Cannula.
6. **Grabber Performance Group**, 4600 Danvers Drive SE, Grand Rapids, MI 49512; 616-940-1940. Manufacturer of a variety of packaged miniheaters with accessories useful for preventing cold-related injuries of the hands, feet, and face.
7. **Junkin Safety Appliance Co.**, 3121 Millers Ln., Louisville, KY 40216; 502-775-8303. Folding aluminum full-length backboard, 15 lb.
8. **MARSARS/Great Eastern Marine, Inc.**, 205 Myrtle St., Shelton, CT 06484-4015; 203-924-7315. Manufacturer of water and ice rescue equipment; a hypothermic stabilizer bag and additional accessory heat packs are available.
9. **Mountain Safety Research**, P.O. Box 24547, Seattle, WA 98124; 206-624-7048. Web site: www.msrcorp.com. Manufacturer of high-performance and lightweight stoves, as well as the Water-Works filtration system.
10. **National Ski Patrol System, Inc. (NSP)**, 133 S. Van Gordon, Ste. 100, Lakewood, CO 80228; 303-988-1111. Various first-aid supplies and equipment for winter skiing and mountaineering sold by catalog to NSP members.
11. **Outdoor Research**, 1000 1st Ave. S, Seattle, WA 98134; 800-421-2421. Web site: www.orgear.com. Diverse array of tote bags, medical travel kits, and stuff

- sacks useful for international travel.
12. **Patagonia, Inc.**, P.O. Box 150, Ventura, CA 93002; 805-643-8616. Web site: www.patagonia.com. Capilene underclothing; variety of outdoor clothing.
 13. **Recreational Equipment, Inc. (REI)**, 800-426-4840. Web site: www.rei.com. Thermax under-clothing; variety of sunglasses, outdoor gear and clothing.
 14. **Res-Q Products, Inc.**, P.O. Box 661, Quathiaski Cove, BC, Canada VOP 1N0. Contact: Robert Douwens. Web sites: www.hypothermia.org (educational site) or www.hypothermia-ca.com. Res-Q-Air and IV HOT-SACK plus accessories; sophisticated equipment for the serious expedition traveler to areas of extreme cold.
 15. **Seaberg Co.**, 4909 South Coast HWY #245, Newport, OR 97365; 541-867-4726. Web site: www.samsplint.com. SAM folding splint, 4 oz.
 16. **Travel Medicine Inc.**, 351 Pleasant St., Suite 312, Northampton, MA 01060; 800-872-8633. Web site: www.travmed.com. Specializing in educational books and handy supplies for international travel; source of insect repellents, clothing, and nets for mosquito protection.

APPENDIX: Sources of Information about Wilderness Emergencies

1. **American River Touring Association**, 24000 Casa Loma Rd., Groveland, CA 95321; 800-323-2782. Web site: www.arta.org. Nonprofit organization that sponsors basic and leadership courses for river-rafting and kayaking.
2. **Emergency Response Institute**, 1819 Mark Street N.E., Olympia, WA 98506; 360-491-7785. Publishes books and sponsors symposia on search and rescue, emergency preparedness, survival, and outdoor leadership.
3. **Forest Laboratories Inc.**, NY; attention: Dr. J.M. Schor; 909 3rd Avenue, New York, NY 10022; 212-421-7850. Information on the availability of buccal morphine sulfate preparation.
4. **National Association for Search and Rescue (NASAR)**, 4500 Southgate Pl. #100, Chantilly, VA 20151; 703-222-6277. Web site: www.nasar.org. Educational association that provides conferences, symposia, and training in search and rescue and emergency response, including communications; sponsors *Rescue* magazine (JEMS

1685

- Communications, 1947 Camino-Vida Roble, Suite 200, Carlsbad, CA 92008; 619-431-9797).
5. **National Climatic Data Center**, 151 Patten Avenue #120, Asheville, NC 28801-5001; 828-271-4800. Web site: www.ncdc.noaa.gov. Provides historical weather summaries for U.S. and many foreign cities; small fee for materials. Telephone first to determine availability of relevant data.
 6. **National Ski Patrol System, Inc. (NSP)**, 133 S. Van Gordon, Ste. 100, Lakewood, CO 80228; 303-988-1111. Web site: www.nsp.org. Sponsors training programs in winter emergency care, avalanche, and ski mountaineering, some that are open to the public; sells equipment and first-aid supplies through catalog to NSP members.
 7. **National Weather Service** in city near region of travel; for further information, write: Attn. W/OM 15 x 2, Silver Spring, MD 20910. Web site: www.nwss.noaa.gov. The NWS nearest the travel site can provide forecasts and in many regions provides broadcasts over NOAA Weather Radio on frequencies between 162.40 and 162.55 MHz, including 3- to 5-day forecasts and avalanche warnings.
 8. **Outward Bound Training Institute**, 800-477-2627. Web site: www.cobs.org. Nonprofit educational organization that uses the mountain, river, and ocean wilderness settings to provide stimuli for personal development; separate leadership training courses available.
 9. **Sierra Club**, P.O. Box 52968, Boulder, CO 80321-2968; 415-977-5522. Web site:

- www.sierraclub.org'.
10. **Undersea and Hyperbaric Medical Society**, 10531 Metropolitan Ave., Kensington, MD 20895; 301-942-2980. Web site: www.uhms.org. Nonprofit organization that sponsors workshops and meetings on the prevention and treatment of diving injuries and illnesses treatable with hyperbaric oxygen. Publishes bimonthly newsletter, *Pressure*, and two research publications, *Undersea Biomedical Research* and *Journal of Hyperbaric Medicine*.
 11. **Wilderness Education Association**, Department of Recreation Resources, Colorado State University, Fort Collins, CO 80523; 970-491-6591. Nonprofit educational organization that sponsors, in conjunction with colleges, a 5-week National Standards Program for Outdoor Leadership Certification.
 12. **Wilderness Medical Society**, 3595 E. Fountain Blvd. Ste A1, Colorado Springs, CO 80910; 719-572-9255. Web site: www.wms.org. Nonprofit organization of medical and related professionals interested in the prevention and treatment of wilderness injuries and illnesses. Publishes quarterly newsletter, *Wilderness Medicine Letter*, covering wilderness medicine meetings, literature review, field management, and position statements. Publishes *Wilderness and Environmental Medicine* (formerly *Journal of Wilderness Medicine*), the official academic publication of the society.

Chapter 70 - Selection and Use of Outdoor Clothing

John Gookin

The Inuit people do not have a word for *luck* because leaving things to chance is not part of their mind-set. They travel prepared for whatever conditions they might encounter and are particularly meticulous about mending and replacing clothing. In a blizzard, they can remain warm until the storm passes.

What to wear and what to carry are strategic issues. You can decide whether to carry everything needed to remain comfortable in any extreme or to use a "travel light, freeze at night" strategy. To gain competency in this skill area, you need quality clothing and must know a multitude of ways to use layers with finesse. Experience and the ability to adjust are more dependable than specialized gear, so learn how to use your gear well instead of buying new "perfect" gear.

BASIC CONSIDERATIONS

The expected length of the expedition affects the selection of an outdoor wardrobe. If you are merely ducking outdoors in nonextreme weather to grab an armload of firewood, cotton clothing is an excellent choice because it absorbs sweat once you are back inside. When you are outside and initiate aerobic activities combined with rest, your metabolic rate alternately increases and decreases, which calls for adjustable insulation. For example, a cross-country skier usually wears little more than undergarments and wind gear while skiing but adds an inch or two of insulation while resting. Clothing must be durable enough to last the entire expedition.

Level of activity is another important factor. For instance, carrying a backpack is always aerobic exercise. The more aerobic the activities, the more versatile clothes need to be. The ideal situation is to regulate layers and activity so that you work at peak performance without wasting moisture and energy to sweating or shivering.

PRINCIPLES OF CLOTHING USE

Choose clothing appropriate to the local climate (explained in Clothing Systems for Different Climates). Choose fabrics for properties such as insulation and breathability (explained in Material Properties of Outdoor Clothing). Carry enough layers that you can adapt to different work levels and climatologic extremes. Climatologic data can be obtained from a variety of sources. You can use such information in selecting gear that will allow you to be comfortable during average highs and lows; however, you should also prepare to survive the extremes.

Dress in layers because many thin layers are easier to fine-tune than one or two thicker garments. Layers need to fit comfortably on top of one another without binding. Use an outer layer that will protect you from the environment. In hot weather, one layer may be all you need. In cooler weather, choose inner layers of appropriate thicknesses so that you can continuously adjust them. For instance, at -29°C (-20°F) alongside a fjord (a wet, cold environment), you should wear expedition-weight undergarments, two or three insulation layers, and a snow-proof parka and pants.

Anticipate changes in body temperature and climate and adjust layers accordingly. As you begin to walk up a steep hill, remove layers and ventilate (open) zippers *before* you overheat. Expose more skin around the head, neck and wrists. Take off your gloves. Walk in the shade instead of the sun. Turn your head slightly so that you face into the breeze. Do what you can to keep from sweating.

You do more than avoid discomfort when you prevent sweating in cold conditions. You keep your insulation drier, fluffier, and warmer for when you slow down. Garments remain cleaner for extended use. Experienced expeditioners know that this strategy is not just for peak performance during work cycles; it helps achieve a lower metabolic rate and therefore conserves energy and water.

Add clothing layers as you head over a windy pass or downhill. Always add insulation to trap heat before resting in cold weather. If you begin to feel cold and begin shivering or feel a chill, add one or more layers.

In a warm climate, as the temperature rises, adjust layers before becoming overheated or sunburned. Plan a sun-exposed hike for the hours of the day when the angle of the sun is least and ultraviolet radiation (UVR) is filtered by more atmosphere. If necessary and if it is safe, hike at night, when it is not as hot.

MATERIAL PROPERTIES OF OUTDOOR CLOTHING

Outdoor clothing is made from various fabrics woven of various fibers. A fiber is a single strand of threadlike material. Sometimes, fabrics encase loose fill of down or synthetic fibers. Certain fleece fabrics contain a woven layer with bulky fibers attached on one side, like a

1687

pile rug. The following four material properties pertain to fibers and fabrics:

1. The thicker the material, the greater the insulative value, as long as the material stays dry. Thickness of an inch or more in any layer is rarely needed with modern materials.
2. The following qualities of fiber reaction to moisture are important:
 - a. Ease of "wicking" action: hydrophilic fabric transfers moisture from the body surface *to* the material; hydrophobic fabric transfers moisture from the body surface *across* the fabric to other clothing or to the air.
 - b. Evaporative ability: rate of drying.
 - c. "Moisture regain": amount of moisture a material can absorb before it feels cold. With a higher moisture regain, the fabric will be more functional for high levels of activity in cold or wet environments.
 - d. Amount of insulative value a material retains when wet.
3. The less the thermal conductance, the better the insulation.
4. Tighter weaves and coated fabrics help block wind, which decreases convective cooling but allows more perspiration to accumulate in insulation layers.

Commonly used clothing materials for outdoor activities are nylon, polyester, polypropylene, wool, cotton, and down and synthetic fiber fill. The four important properties are different for each of these materials.

Wool is a good insulator because it is a poor conductor of heat. It has moderate affinity for absorbing moisture but can absorb a great deal—about 35% to 55% saturation—before it feels wet. Its evaporative ability (speed of drying) is poor compared with that of polypropylene, but its fiber structure allows it to suspend water vapor without decreasing insulation. In summary, wool does not absorb water easily, is warm when damp, but when dripping wet feels cold.

Cotton feels great in summer when, for example, a hiker is struggling up a steep grade

with a heavy pack and there is a light breeze. However, cotton may do more harm than good in any environment where conservation of heat is needed. In fact, mountaineers say, "Cotton kills." Cotton loses up to 90% of its insulative value when wet; it is hydrophilic, and its moisture regain is poor. (Hence, it makes a great towel.) On the plus side, cotton is excellent for abrasion resistance, it blocks UVR to a certain degree (wet white cotton transmits considerable UVR), and it helps keep a person cool. It is also quiet, making it quite useful for hunters and soldiers.

Polypropylene, like cotton, wicks moisture well, but unlike cotton, it has very low thermal conductance and is hydrophobic. These properties make it popular as an underlayer material for active outdoor enthusiasts. Great versatility of form, smooth feel, and easy maintenance have elevated polypropylene to a favored underwear material. Many of the new polyester fibers, such as Capilene and Thermax, perform just as well.

Polyester is justifiably the most widely used material in outdoor clothing. The fibers can be formed into several thicknesses and configurations, thereby fashioning underwear garments, insulation layers such as the popular fleece jackets, and even outer-layer wind- and moisture-protective gear. New "windstopper" fabric adds both insulation and wind protection in one simple layer. Polyesters are poor heat conductors (good insulators), high in moisture regain (absorb water without feeling cold), and hydrophobic. Polyester has replaced wool as the principal insulative layer material, usually as zippered or pullover jackets. Styles with longer fleece offer better protection against the wind. When polyester is designed as an outer (protective) layer, fibers are woven more densely, and a water- or wind-repellent sheath, often made of nylon and Lycra, is laminated to it. The outer surface can be sprayed with a water-repellent substance such as Ultrex. Some 80% of polyester fleece used in outdoor gear is processed from recycled plastic bottles.

Cotton/polyester blends are used for a great deal of nonexpedition outdoor gear. This combination provides a good fabric for temperate climates because it blends the properties of both fabrics. It does not perform well in either very hot or very cold climates. In particular, this fabric is used by many people who routinely work outdoors and who desire the comfort of cotton blended with the higher performance of polyester; for example, it is used in the uniforms of park rangers.

Nylon absorbs little water, so it allows moisture to evaporate quickly. It also has good moisture regain. Because of durability, it is often the material preferred for outerwear. However, unless nylon is tightly knit, it does not screen wind and water well. It can be coated to provide more wind and water repellency but at the expense of breathability. In any type of material, protection against moisture and ability to breathe become a trade-off. No material can do both in ideal fashion when intensity of activity exceeds 50% of maximum oxygen consumption, the level that a fit person can sustain for hours. W.L. Gore Company's high-profile Gore-Tex Teflon base was first laminated to nylon in outerwear garments that were breathable as well as water resistant.

Down is an excellent insulator when dry. Goose down has a great loft rating (measured in cubic inches of fill power per ounce). Down with a higher loft rating is composed of more pure down and fewer feathers. However, as with cotton, moisture regain is very

low. Down is hydrophilic, and its drying rate is dismally

1688

slow. Down is even worse than cotton in a cold, wet environment because the loft all but disappears when it is soaked. It is nearly impossible to dry a soaked down sleeping bag in the field.

Synthetic fiber fill has many of the insulating benefits of down, but it is hydrophobic and has a high moisture regain and good evaporative qualities. Synthetics lose loft over time because the fibers break down with use and washing; synthetic fiber clothing and sleeping bags should be stored in a noncompressed state. Synthetic fibers are more dense than down. Some fiber fill, such as Qualofil, is less dense than other synthetics, but in general the denser fiber fills are more durable, retaining their loft for longer periods.

TYPES OF LAYERS

There are three types of layers based on function. Outer layers protect from direct contact with the elements, such as thorns, rain, wind, and sun. A base layer is used against the skin for a small amount of insulation combined with vapor transport away from the body. Insulation layers are generally added as needed between the inner and outer layers.

Base Layer

Long Underwear.

Polypropylene and polyesters are preferable because of low cost, good insulating ability, and evaporative ability. Wool is still an excellent choice for long underwear but is harder to find and more difficult to care for. Fabrics containing cotton are hydrophilic and do not transport vapor well. Cotton is inappropriate for the base layer. A fabric with some stretch is needed so that it will flex with motion. In general, the softer the fabric, the faster it wears out. Long johns come in three weights: light, medium, and expedition (heavy). These weights are discussed in Clothing Systems for Different Climates.

Socks.

Wool with 10% to 15% nylon added for strength is an excellent choice for socks. A small amount of Spandex adds stretch that assists with fit. Polyester fleece socks are an alternative to wool; they perform better in damper conditions but generally wear out faster. Fit your boots with two pairs of socks for a more comfortable fit and more insulation, if that is what you need. An additional pair of very thin polypropylene socks worn next to the skin can help wick moisture and lessen friction on the skin. The entire sock combination needs to be comfortable and matched perfectly to the fit of the boots. Carry two changes of socks while backpacking and one spare pair of wool socks so that you can wear dry socks in camp and in the sleeping bag. If you must routinely wade through water, neoprene socks, Seal Skin socks, or fleece socks function better than wool.

Gloves.

Light polypropylene, wool, silk, or fleece gloves work well when the conditions are moderately cold or when finger dexterity is required. Fingerless versions are also available. Gloves of polyester/Lycra combinations provide a tighter, more conforming fit to enhance fine finger movements. Synthetic gloves come in many weights. In colder

temperatures, mittens provide more efficient insulation. Thin glove liners are often used in combination with an insulating mitten layer and mitten shells.

Mittens come in polypropylene, fleece (pile), wool, or nylon-lined synthetic fiber fill (which works like a sleeping bag). Mittens are more efficient insulators than gloves because they expose less surface area around the fingers. You can add a layer of mittens on top of light "glove liners" so that you can use your fingers without baring them directly to the elements. Mittens used as a layer on top of polypropylene gloves do not need to be particularly thick.

Insulation Layers

Shirts, jackets, and sweaters should be made of suitable synthetic material, which can be woven or fleece. Vests can be used, but most layers should have long sleeves. Wool shirts work well. Large pockets with buttons or Velcro are handy for carrying items such as sunglasses or a compass. Shirts should open completely in the front or at least have a half-zipper for ventilation. A turtleneck protects the neck, as do neck warmers and mufflers. Be sure that insulation layers fit comfortably on top of all other layers so that when worn together, they allow freedom of movement. Fleece jackets have become a common insulating layer because of their versatility. A fleece jacket, pulled fuzzy-side out and wrapped around some clothes, also makes a nice pillow.

Pants made of fleece work well, but wool is acceptable. The advantages of wool pants are that they tend to have pockets and they stay up better. Fleece pants should have reinforcements at the knees and buttocks. Full or partial lateral leg zippers are convenient for changing pants over boots. Consider using suspenders with fleece pants if they tend to slide down over other clothing.

Hats are used for shade or insulation. Hats used for shade should have at least a 4-inch brim and be made of material that blocks UVR. In windy conditions, hats need to be tied onto the head. Hats used for insulation should be made of pile, Orlon, polypropylene, wool, or wool-polypropylene and should be large enough to cover the ears. A small bill helps shade the eyes. "Bomber" caps with bills and pull-down earflaps are popular. A balaclava covers the entire head and neck but has a large hole for the face. You should also protect your face from cold wind; a balaclava configuration, a scarf, or a neoprene face mask does this. One useful

combination is a ski hat with a neck warmer (a tubular scarf that rings the neck) that can be pulled up to cover most of the lower face. On expeditions, some people carry a thin polypropylene balaclava for sleep and a thick fleece balaclava to wear during the day. The fleece balaclava can also be rolled up and worn like a stocking cap. Be certain that any cold-weather hat system works in combination with your glasses and goggles without collecting moisture that fogs lenses. Although these small layers for your head may seem trivial, strategically it is much more important to cover bare skin than it is to

add insulation elsewhere.

Outer Layer

Parka.

A noninsulated nylon parka is often used on top of clothing systems. If it is uncoated, it is called a *wind jacket* or *wind shirt*. If it is coated with urethane or rubber, it is called a *rain jacket*. Parkas made with Gore-Tex or one of the other selectively permeable membranes are common because they are versatile. The parka should have a hood with a drawstring, a two-way zipper down the front with an overlying weather flap closed with snaps or Velcro, a cloth flap to protect the chin from the metal zipper pull, and enough pockets to contain frequently needed items.

Zippered ventilation openings at the armpits make a parka more versatile. It helps even more if the armpit openings are large enough so that the parka can be converted into a vestlike garment during warm conditions by inserting the arms through the openings and tucking the sleeves inside the parka.

Nylon Pants.

Uncoated nylon pants are called *wind pants* and work best in dry conditions. Coated nylon pants, called *rain pants*, work best in wet conditions but trap perspiration. Gore-Tex is a good choice in many conditions because of its versatility, but do not expect it to perform as well in environmental extremes. Long, zippered side openings are useful for donning pants without removing the boots, as well as for ventilation.

Mitten Shells.

Mitten shells are nylon shells that fit over mittens or gloves. They are very light and add a layer of wind or water protection. For many travelers, this is the first hand layer they add to their pack as conditions get colder because they are light and add such versatility to the clothing system. Some people ski wearing mitten shells over bare hands so that they can dissipate heat but retain a snow and wind barrier.

Boots.

Boot selection depends on the planned activity, the expected foot hazards (such as sharp rocks and cactus spines), and the anticipated environmental temperatures. For light hiking, when no more than a day pack is carried, a light boot with good ankle support is sufficient. In hot weather, high-topped trail-running shoes might be ideal. Boots made of leather or fabric such as Gore-Tex are light and adequate for trail hiking but not durable enough for rocky terrain. Backpacking boots have shanks in the midsoles. A shank is a stiffener for the foot platform. For moderate terrain or loads up to 30% to 40% of body weight, choose sturdy leather hiking boots with a steel or fiberglass half-length shank and lug soles. For loads over 50% of body weight, use a boot with a three-quarter-length or full-length shank to help support the feet. A full-length shanked

boot is stiff and is considered to be a very specialized boot. Most backpackers are fine carrying a heavy load in rough terrain with a high-quality boot with a three-quarter-length shank.

A high-quality boot has fewer seams, making it easier to seal. It is made of excellent leather; some manufacturers use only specific pieces of cowhide, offering a more consistent product. It is sufficiently soft on the inside, so that it "breaks in" quickly. Beware of boots that are so stiff that they do not mold to the shape of the foot: these boots feel harder than others when flexed.

Fit is crucial to boot selection. Different brands are built on different lasts (forms) based on regional foot norms. European lasts are often narrower, German lasts are wider, and American lasts are moderate. Once you find a specific brand of boot that fits well, there is a good chance their other models will also fit the same foot shape. A boot needs to be roomy enough to accommodate the desired numbers of socks. Boots must be long enough so that the toes do not strike the front of the boot during downhill walking. Test this fit by walking down a steep ramp or kicking a wall in the boot shop. If your toes hit the front on the first kick, the boot is either too short or laced too loosely. Boots should be laced tightly enough that the heel does not move up and down much, but not so tightly that circulation is restricted and the toes cannot be wiggled easily.

In extreme cold, the Canadian type of pak-boot (such as the Sorel) with a removable inner felt liner is a good choice for light snowshoeing and other nontechnical outdoor activities. On extremely cold expeditions, consider replacing the felt liner with a nylon-clad polyester fiber fill bootie with a closed cell foam sole. These dry much more easily than the felt liners and last for years.

Special double ski boots are available for ski touring or for skiing at ski areas. These consist of an outer shell and an inner liner. The shells are leather or plastic; leather shells flex more, whereas plastic shells are hydrophobic. The liners are leather or foam; leather liners last longer but are not as warm, whereas foam liners are hydrophobic and are used by many professionals. Foam liners are warm, but they weigh more. Plastic and foam boots are easier to manage while camping in the snow because you do not have to keep them from

freezing when they are off the feet. Double ski boots offer tremendous insulation and ankle support but are too warm for many skiing conditions.

Plastic hiking boots with foam or leather liners were originally designed for snow and ice mountaineering. They are an excellent option in wet, cold conditions. Lighter, more flexible versions of plastic boots have been developed, so some people are now using them instead of leather boots for hiking in temperate climates. They are water resistant and warm but sometimes too warm; sweat accumulation can occur.

Care of leather boots is critical to continued fit and insulation. Such boots should stay sealed with commercial sealants to keep the leather waterproof and supple. Dry leather tends to get hard, absorb more water, and shrink more than well-oiled leather. Nikwax and Biwell are good sealants if the boot manufacturer has no specific recommendations. An inner seal that treats leather on the inside of boots helps keep them softer and increases their longevity.

Gaiters and Overboots.

Gaiters are long nylon tubes that cover the lower leg and upper part of the boot. They are designed to keep snow, sand, and gravel out of boots and socks. They extend to just below the knee, open at the side or in front with a zipper or Velcro, and have a strap that fits under the boot sole to keep them snug on the boots and drawstrings at the top to hold them up. Gaiters with a front opening closed by a wide Velcro flap are easy to put on and take off. Shorter versions that extend to just above the ankle are adequate for summer hiking. A simple, durable gaiter design is the tube gaiter, which is merely a tube of nylon slipped on your ankle before you pull your boots on. However, tube gaiters are not as convenient as other gaiters because the boots need to be removed before the gaiters.

Special insulated overboots or lined gaiters are especially warm for their weight. A "supergaiter" is a gaiter that attaches along the seam between the sole and the

TABLE 70-1 -- General Climates

	TEMPERATURE	WET[‡]	DRY[‡]
Extremely hot	High above 46° C (115° F)	Rare because water lessens temperature extremes	Desert in summer
Hot	High above body temperature	Rainforest	Desert in summer
Temperate	Temperature between freezing and body temperature	Deciduous forest	Inland mountain
		Coastal forest	Forest
		Maritime mountain	Desert in winter
Cold	Low below freezing temperature of water	Coast at high latitude	Inland mountain
		Coastal mountain	Tundra
Extremely cold	Low below -29° C (-20° F)	Rare because cold air cannot carry much moisture	Alpine winter

*Humidity usually above 50%.
†Humidity usually below 50%.

High latitude
and altitude

boot, covering the entire top of the boot, and is insulated. Supergaiters need to be matched exactly to the boot to stay on in typical mountaineering conditions.

Vapor Barrier Systems

Vapor barrier systems involve the use of waterproof garments and sleeping bag liners close to the skin to prevent the saturation of outer clothing and sleeping bags with sweat (with a resulting reduction in insulating value), reduce sweating, and decrease the body's water requirement. Vapor barriers seem to work better in very cold weather than at moderate temperatures. A light garment of polypropylene or similar material should be worn next to the skin with the waterproof garment layered over this. People with hyperhidrosis and those who object to a clammy feeling next to the skin may not like a vapor barrier system.

CLOTHING SYSTEMS FOR DIFFERENT CLIMATES

Different systems are needed in different climates. The climates addressed here will merely be called *hot*, *temperate*, or *cold* in combination with *dry* or *wet* ([Table 70-1](#)). *Extreme* is used to address rare cases that go beyond the norms experienced by most outdoor enthusiasts. *Hot* is any temperature warmer than 38° C (100° F). *Extremely hot* is a temperature above 46° C (115° F). *Temperate* includes temperatures from 0° to 38° C (32 to 100° F), roughly from the freezing point of water to normal human body temperature. *Cold* is any temperature below 0° C (32° F). *Extremely cold* is any temperature below -29° C (-20° F).

Wet refers to the maritime climate, common to coastal areas, where humidity is generally high, averaging well above 50%. Insulation does not dry easily in this environment. *Dry* refers to a more continental climate, where the humidity is generally low, averaging at or below 50%. Insulation dries more easily in this environment.

1691

Another significant climatologic factor in clothing performance is wind. Wind chills and heats humans more quickly than calm air because of convection. A wet wind can drive the rain into and under clothing layers, whereas a dry wind is the ultimate drying tool for clothing.

Clothing systems for hot, dry weather protect against the sun and wind; thin layers are chosen for cover from UVR. These may be certain blends of cotton or treated synthetics. Long cotton pants and shirts promote cooling by trapping perspiration and protect from sun and thorns. Loose layers allow better air circulation. Hats with brims on all sides provide shade for the head and neck. A large bandanna can be draped over a hat to shade the sunny or windward side of the head and face.

During exercise in moderate heat, short sleeves and pants may be appropriate. Choose short pants before short sleeves while hiking because the legs generate considerable heat. Hot weather climbers have adopted the type of clothing worn by gymnasts, whereas many backpackers wear runners' gear. Nylon shorts and Lycra or cotton sports bras are standard for backpackers in moderately hot weather.

Hot, wet conditions are more challenging because humidity reduces evaporative cooling. Clothing needs to allow maximal cooling, and activities need to be regulated until you are adequately acclimatized to the heat. Use strategies such as seeking shade

when possible; pouring water over the wrists, head, or clothing; and donning long loose-fitting clothes for shade if one must be in the sun.

In extremely hot conditions, clothing considerations become subordinate to changes in behavior. Avoid the most intense heat of the day, particularly when you are active. Indigenous people in extremely hot climates habitually rest or sleep during the middle of the day but are active during the beginning and end. They have adapted to the realities of the heat.

Hot environments are often also dusty. Eye protection should include sunglasses that are scratch resistant and block 100% of UVR. In dusty conditions, goggles are essential; ski goggles converted to desert goggles work better if the lens is replaced with clear plastic. The goggles need a carrying case and a spare lens; use the old lens as much as possible and save the new lens for special situations when the most visibility is needed.

Temperate conditions require a clothing system that allows you to be active in warm, sweat-producing conditions but that still provides warmth during cool nights. Many backpackers wear nylon shorts and cotton tee-shirts while hiking in these conditions. These clothes are rugged. The nylon shorts dry quickly. The cotton shirts may need to be taken off after a hike if the moisture feels wet and cold. In a more maritime climate, the outerwear needed is coated nylon rain gear. In a cold rainforest, a long raincoat, such as an anorak or a cagoule with a rubber coating, may be preferable. Wind gear (uncoated nylon) may suffice for dry conditions. Many people choose Gore-Tex outerwear for temperate conditions because it keeps them reasonably dry in rainstorms but does not collect sweat unless it is soaked. Polypropylene long johns and a thin fleece jacket or a heavy polyester shirt are often sufficient insulation in temperate conditions. If more than this is needed, it is often more versatile to carry thin polypropylene gloves and a balaclava than to carry an extra jacket. In general, it is more efficient to cover bare skin before adding more insulation to areas already covered.

If you need to wear pants because of brush, consider hiking in uncoated nylon wind pants. Sweatpants or anything else with a loose weave snags and tears in heavy brush. A good option is to wear work pants of a cotton/polyester blend. These are the same pants worn by many park rangers. Compared with jeans or canvas pants, they dry quickly, yet are very durable. The cotton pockets do not dry very quickly.

Cold conditions require an inner layer of long johns, an outer layer of nylon, and several insulation layers. The thickness of the long johns depends on the ambient temperature and level of activity. Since undergarments are not a layer repeatedly put on or taken off during normal activities, a weight that is thin enough in which to comfortably work should be chosen. If you cool easily, conditions are damp, and it is windy, err on the side of heavier long johns. Some people carry two different weights on an expedition and wear the expedition-weight clothes in cooler conditions but switch to the medium-weight or lightweight clothes in warmer weather. The practice of carrying different weights adds versatility, but eventually you should be able to predict what clothing will be needed to keep a lighter pack on shorter trips. It is so easy to fine-tune a cold-weather clothing system to insulate or ventilate that the weight of long johns is not critical. Outerwear can

consist of uncoated wind gear in cold, dry conditions. Use Gore-Tex or coated nylon in cold wet conditions but pay special attention to ventilating layers when necessary to evaporate perspiration.

Extreme cold tends to be dry because air below -40°C (-40°F) holds no moisture. Exceptions include high-latitude coastlines and some areas with "ice-fog" from hot springs or wood smoke. Dry conditions make it easier to insulate in many ways. Gear tends to stay dry and "fluffed up" at temperatures below -23°C (-10°F). This advice is for living and moving in the range of -23° to -40°C (-10 to -30°F) in snowy conditions. When temperatures fall below this, when conditions are also wet, or when it is also windy, it takes superb gear, considerable experience, and absolute discipline to keep body parts from quickly freezing.

1692

Clothing systems for extreme cold do not include an easy option of adding layers in the middle of the system. Use a system like that described for dry, cold weather but add a second down or fiber fill insulation layer that can be worn on the outside. This outer insulation system needs to be cut large enough to allow freedom of movement when worn over every other layer. It can usually be covered with thin nylon, but for working in brush, it needs to be tear resistant. This extra layer supplements rather than replaces the cold-weather system. This is important because if you purchase a parka meant to work by itself at -29°C (-20°F), it will be challenging to use it in combination with a cold-weather clothing system. The additional layers should be 1 to 2 inches thick, not 4 to 6 inches thick.

The parka should be insulated with a thin layer of down or synthetic fill. It should be cut so that it does not allow a cold draft on the torso. Some parkas have waist-level snow-guards with drawstrings (like a draft tube on a sleeping bag but not insulated) that control this draft, but other parkas are cut longer (thigh to knee length) and intentionally allow air to circulate, helping keep you drier. Both strategies work fine, but the shorter parkas with the snow-guards are lighter. The sleeves should be longer than normal to help cover the wrists better. Wrists should be protected with a system that is snug but not tight, since tight fits can impair both circulation and function. The parka hood should move with the head, have at least one drawstring, cover the neck, and have a "snorkel" or "tunnel" to keep the wind off the face. (It is called a *snorkel* because it creates a tube through which to look that moves with the head.) Fur or fleece edges on the tunnel provide more wind protection and conduct less heat when touched. Outside pockets should be big enough to carry overmitts. Many outer pockets have two compartments: one inside the insulation for warming hands and another outside the insulation for storing gear. Inner pockets should be large enough to store lots of clothing so that it can be dried out while walking around camp. This drying system works quickly in extreme cold and dry, cold conditions because the ambient air is so dry and the temperature differential drives the moisture out of the clothing. It is critical that the parka be donned while the wearer is still warm, not only to trap heat but also to supply enough heat to warm up the parka.

Insulated overpants should be rugged enough for the local conditions, should be long enough to overlap the booty system (explained later), and should have coated seat and knee patches to protect the pants from wear and moisture when you sit or kneel. The nylon layers of overpants tend to slide over one another so easily that it is hard to keep them up. Suspenders are better than belts or cord-locks for this purpose. Some pants come with integral cord-locks: if this cord-lock slips, replace it with the flat style of cord-lock that does not slip. Full-length zippers allow you to pull pants on and off, even while wearing skis. Half-length zippers may allow pants to go on and off over boots; this is the minimal standard for extreme cold-weather overpants. Some people use fleece pants as overpants in extreme cold. This works, but they collect snow more easily. Again, pants need to go on and off without removing any other layers.

Insulated overmitts can be fleece or synthetic fiber fill with nylon covers on all sides of the mittens. Thin nylon is usually fine on the back, but a coarser weave of nylon in the palm helps prevent wear and adds friction for grabbing objects. Some mitts use textured vinyl on the palm, although the vinyl tends to crack and wear. Fleece is usually more durable, but synthetic fill (which works like a hand-sized sleeping bag) is warmer. Gauntlet length helps seal the wrists; adjustments in the hand and wrist areas allow a custom fit and scoop up less of the fluffy snow common in these conditions. Fur or fleece on the back of one mitt is nice for wiping your nose without cooling it down as much. Some overmitts are partially leather; be sure this is treated with oil or silicone, or it will collect moisture that will allow it to freeze.

You should be able to wear insulated overboots over your work boots (such as leather ski boots) and over fiber fill booties when not wearing your work boots. Some overboots allow walking, skiing, or snowshoeing. These boots are nearly all nylon on the outside with synthetic fiber-fill insulation. The outside requires a durable coarse-weave sole so that you do not slide on snow as easily. The upper part needs to overlap any insulated pants and attach like an insulated gaiter to the top of the calf. The upper part does not need to be thick, but it does need some insulation. The key to keeping this insulated gaiter up usually is not the drawstring at the top; it is mostly the drawstrings around the foot and ankle. Inner booties can be worn in one or two layers inside the overboots. Booties with closed cell foam insoles often work as one layer. Some people prefer to use two layers of booties without integrated insoles so that they can sleep in the booties. (Booties with foam insoles accumulate sweat in a sleeping bag.) In this case, people tend to cut insoles out of old closed-cell foam sleeping pads to fit in the overboots. The best way to do this is to put a piece of notebook paper inside each overboot, then put them on over your booties. Walk around the room, then pull the papers out to use as patterns. The patterns will be much larger than your feet, providing better coverage inside the overboots. This booty system is very comfortable to wear around camp, offering the opportunity to dry out both feet and leather boots. If the parka does not have a place to store boots inside it, tie the laces together and hang the boots around your neck, keeping them near your chest. Once they are dry, they can either be put back on or stored wrapped in a sleeping bag.

Chapter 71 - Backcountry Equipment for Health Care Professionals

John Gookin

BASIC PRINCIPLES FOR CHOOSING OUTDOOR EQUIPMENT

Backcountry equipment can be crucial on an expedition or during an evacuation. Health professionals who operate in the backcountry need reliable gear. They need to know how to use it well, maintain it, and repair it. These tools must be used routinely for them to become valuable.

Choices can be overwhelming. When outfitting yourself, use these basic principles:

- *Reliability is always important.* Choose equipment that breaks less, uses readily available maintenance supplies, is rebuildable, comes with spare parts, and is simple to use.
- *Maximal performance level is rarely important.* A common error is to dwell on finding a tool that puts out 5% more performance but is more complicated (less reliable). Those last few percentage points rarely matter. Choose high-end gear, but do not be overly concerned about absolute peak performance.
- *Lightweight gear breaks more easily.* Backpacking and mountaineering equipment needs to be cared for better than car camping equipment. Either carry lightweight gear and be careful with it or carry heavy gear and be less careful with it.
- *Experience is more important than having the perfect tool.* If you purchase a \$200 headlamp and leave it on a shelf so that it will not get dirty, you will gain no experience in how to use it. Choose tools that you will be willing to use routinely.
- *Simple tools work better and are less problematic.* A Swiss army knife or intricate pocket multitool performs many tasks but may be inadequate. The knife on a multitool probably performs only half as well as a simple lockback knife for most camp tasks. (Performance includes how easy it is to cut things, how easy it is to maintain control of the instrument, and how easy it is to keep it clean.) The pliers on a multitool typically have 5% to 50% of the torque (depending whether you are grabbing a tent pole or a nut) of the 6-inch channel locks that many mountaineers

choose for pot grips.

- *People perform in crises the same as in training.* When a crisis puts you in fight-or-flight mode, it is important to have access to equipment that is part of your routine if you want to perform well.
- *Everyone does not need the same gear.* There can be strength in diversity on a team. If everyone has different tools on an expedition, then the team has a greater selection of tools to match to the more challenging tasks.

HEADLAMPS, NIGHT VISION GEAR, AND LANTERNS

When light is needed in the backcountry, electric headlamps are the only reasonable tool. Some headlamps are brighter than others but consume batteries faster; others feature better light distribution, durability, water resistance, and maintenance. A simple reliable headlamp is easy to find. However, the perfect headlamp does not exist because every choice has trade-offs.

The brightest headlamps available are too bulky for expeditions. Many lightweight headlamps are designed for expedition use. Search-and-rescue groups may have access to Wheat Lamps, TAG Lights, or other lights that use small automotive batteries; these are excellent lights with roughly ten times the light output of lightweight headlamps. There are many excellent headlamps with bright lights.

A good headlamp has a spare bulb stored in it, is weather resistant, and has smooth light distribution. If you are comparing lights in a shop, take them into a dark room and walk around. If the lamp zooms (a nice option) walk around with the lamp zoomed out to about 30 degrees (a third of a quarter of the space around you). Look for even light distribution instead of a small bright spot. It is even preferable to have a light with many bright spots and lines (projected from the filament) than it is to have just one ultrabright spot. A good field of illumination provides even lighting in front of you and well into your peripheral vision. A poor field of illumination provides one bright spot; the two problems with this are lack of illumination in your periphery and overintensity of the bright spot, making it harder for your eyes to catch details in the shadows.

Weatherproof headlamps perform well in most conditions. If submerged, they should be taken apart in the sun to dry out the interior. The Petzl zoom is an example of a weatherproof lamp used by many "wet cavers," but some hard-core cavers think waterproof is the required level of performance. Waterproof lamps have O-rings or other gaskets to make them submersible.

Some inexpensive waterproof headlamps, such as the Eveready Waterproof Headlamp, are available; they are very waterproof but do not provide the zoom feature.

Dive headlamps can be very reliable light sources. Some of the headlamps breaking into the backpacking market were originally developed as dive lights. However, many have narrow beams that not only give poor peripheral vision but also feature a

concentrated bright spot that significantly diminishes the ability to see detail in darker areas. (They work great if you are only looking through a facemask.) Some dive lights require special tools just to change a bulb. If you carry a light like this, carry a spare headlamp that you can use until it is convenient to service your dive light. Be sure to occasionally lubricate the O-rings on the light. If the O-rings begin to show cracks from age, replace them early before they leak.

Batteries

AA batteries are common in lightweight headlamps. If you are doing things where you constantly need light, such as caving or winter expeditioning, consider larger batteries to keep costs down. If a brighter light is needed to search for a lost child in the chaparral, then a bigger, brighter light that uses bigger batteries is necessary. C batteries are much lighter in weight than D batteries, but cost about the same. D batteries are much less expensive to run per lumen-hour, but their weight necessitates an external battery pack and a wire connection.

Lithium batteries put out a lot of light per weight of the battery, but they are expensive, and their odd voltage (a lithium D-cell is 3 volts instead of the traditional 1.5 volts) can require a different bulb. In cold conditions, lithium batteries work much better than alkaline batteries. Headlamps with remote battery compartments worn inside the parka, like the Petzl Mega, seem to work fine with ordinary alkaline cells at -40° C (-40° F). Some people use the "hands-free" model of headlamp made by Easter Seal, run a lithium 3-volt D cell in it for bright use, and then switch in a 1.5-volt alkaline D cell for finding things in their pack and other low-light tasks. Using a dim light better preserves night vision, and an alkaline D cell lasts a long time when burning at such low wattage.

Battery compartments can be mounted on the head or torso. Torso-mounted batteries keep batteries warmer for better performance in subfreezing temperatures, but the wire can be a nuisance.

On an expedition, disposable alkaline cells yield roughly double the light per weight of rechargeable batteries. Rechargeable batteries make sense only with a reliable charging system. Before you buy a solar charging system, learn from others how many charge cycles their rechargeable batteries have lasted and whether they have to run down the cells before recharging.

Buy "big name" alkaline cells. Cheap brands tend to have fewer and less consistent amp hours.

Carry an inexpensive battery voltmeter to test any loose (unpackaged) battery going into a headlamp or radio. Even when you use fresh batteries out of a sealed container, it is not a bad idea to test the batteries. One poor battery causes reduced performance in the entire set. Be sure to keep batteries in sets that do not mix new and old.

Light Bulbs

Bulbs dictate brightness and battery consumption. Halogen bulbs emit whiter light than tungsten and krypton filaments but usually consume power at much higher rates. Bright bulbs consume batteries faster, and when the bulbs fade, they do so quickly. A fading 4AA headlamp with a ½-watt bulb provides less than a minute of dimming time before going to total darkness, whereas less "hot" bulbs allow up to half an hour of dimming light that might allow you to reach a convenient location before changing batteries. Some headlamps, such as the Petzl "Duo," have a cool bulb and a hot bulb that can be switched on and off quickly. This is a very nice feature that has the benefit of adding the redundancy of two bulbs.

Light-Emitting Diodes and Fluorescent Lights

There are new lights with light-emitting diodes (LEDs) and fluorescent tubes as bulbs. These are potentially the best lights for smooth light and efficient battery use. LEDs are almost indestructible, but fluorescent tubes are impact sensitive. Custom prototypes of each cost hundreds of dollars but perform well. LED headlamps may become the new state of the art.

Lightless Travel

Any serious outdoor enthusiast should become familiar with night travel in certain conditions without artificial light. On snow-covered or moonlit nights, you can sometimes see more by not using a headlamp. One person with a headlamp can ruin night vision for everyone else, especially when it is shone at close range once in a while. It takes 30 minutes for the iris, rods, and brain to completely adapt to low light. For a brief moment of light to view a map, some options that save night vision are to: (1) use a red filter, (2) cover the light with your hand and let only a little light sneak out between your fingers, (3) close one eye but be ready for some short-term depth perception problems, (4) squint your eyes enough that little light gets inside, or (5) let someone else look at the map and you keep the bright light from ruining your night vision. Nautical charts are often labeled "red light readable" specifically so that a red light can be used to look at the chart. This is done

1695

by adding blue to the red ink; otherwise, a red light would make the red parts look like the white parts. If you have never tried using a red light for occasional use, learn its strengths and limitations. It is hard to beat a full-moon hike down a canyon, but it is not good to accidentally ski off a drop with a full pack and sled. Practice but be careful.

Night Vision Gear

Night vision gear can aid distant observation during a search, especially on a moonlit night. It can also be used to travel, with significant limitations. You can walk faster with a \$10 headlamp than with a \$5000 night vision device (NVD). Climbing or skiing with night

vision equipment is problematic and unsafe unless stealth is preferable to wearing a headlamp for military reasons.

NVDs are small video cameras and TV screens that amplify existing light. Some have infrared (IR) LEDs for use in total darkness, but typical IR LEDs work effectively only to a range of 1 to 2 m. You can (tediously) read instructions in a booklet with these LEDs but not much else.

Night vision gear comes in monocular and binocular versions. Some of the monoculars are telescopic, like a rifle scope. Monoculars are better for sitting in one place and observing; they preserve night vision in the "off" eye and are simpler, lighter and less expensive. Binoculars, or night vision goggles (NVGs), are made for use while traveling; they fit on the head like an oversized dive mask. Despite being binocular, they do not offer depth perception. They work very well on a starry night as long as the forest cover does not shadow the starlight. You can climb rocks with NVGs but need to constantly alter the focus from near to far. The greatest limitation of traveling with NVGs is in flat light, especially on sand or snow because you cannot see the telltale shadows that define terrain. It is easy to walk off a cliff when traveling with NVGs in flat light or full darkness.

American NVDs evolved through different generations. First-generation NVDs from the Vietnam era had good optics, but the electronics could not handle changing light intensities, so the light amplification had to be constantly adjusted. Most are no longer available because the screens burned out when a bright spot overilluminated them. Second-generation devices automatically adjust to light levels but very slowly. A second-generation unit is a functional choice if you are not in a hurry to see things. Be certain to observe how the unit operates to be sure that there are no dead spots on the screen, and if possible, compare several units before selecting the one that works best. Third-generation devices are quick to respond to light levels and have noticeably better clarity. They are light-overload protected, so a bright spot will not burn out part of the TV screen. Rebuilt third-generation military models may be purchased for high-end performance. New models generally are not as rugged as the rebuilt military units refitted with new sensors.

Russian-surplus NVGs are available at bargain-basement prices, but their performance is poor and inconsistent. They are better than nothing, but lack optical clarity, and the poor response to overillumination makes them problematic for practical functions.

Accessories are important. A dust-proof case and lens cap are invaluable. Some night vision gear uses uncommon batteries. An important accessory in cold conditions is an Arctic battery adapter that allows you to keep the battery in your pocket so that it will function better. Sometimes lithium batteries can be used in the cold, but an Arctic adapter allows the use of less expensive and more readily available batteries. Lithium batteries deliver more hours of use with an Arctic adapter in the cold.

The new thermal imagers are very sensitive in the IR range but do not capture the visible light spectrum. They are better than classic NVDs at spotting lost people, since they highlight objects (such as people) that are warmer than the environment. However,

they are very expensive. Thermal imagers are available in handheld modes that weigh about 5 pounds and are also fitted on some helicopters used by the military, fire fighters, and power companies. These are often referred to as FLIRs (forward-looking IR). For a major search operation, a handheld thermal imager may be borrowed from the state emergency management coordinator or local military security team. Basic training on use of the device is important before sending it into the field. Have the operators sit on one side of a valley while you direct "lost" people to walk around across the valley. Have the wanderers sit behind different types of bushes and mimic other possible situations so that the operators can learn the patterns. A handheld thermal imager on a cool night can image a human being from 5 to 10 km. In hot weather, use this device in the morning, before the sun starts heating things up. You will quickly notice that south-facing rocks look warmer than north-facing rocks and that humans glow brightly.

Lanterns are valuable for base camp-type operations and on long trips in dark winter conditions. Coleman Peak 1 lanterns burn Coleman fuel, which yields more light per pound of fuel than any battery-powered lamp. It makes sense to use the same fuel for stoves and lanterns. There are small lanterns that burn unleaded gasoline, but they are not as small as the Peak 1 lantern. If you carry a gas lantern, be sure to carry plenty of spare mantles and use the plastic case. These cases come apart easily; many people buy a piece of stout bungee cord and tie it around the case, from top to bottom, to help it stay together in a pack or sled.

1696

Electric fluorescent lamps or lanterns burn more efficiently and provide a smoother, more useable light. Solar rechargeable lamps are a great idea as long as plenty of sunlight is available for charging. Most solar rechargeable lamps do not function well during travel because they need to be held at a proper solar angle during the same hours that one tends to be doing other things.

STOVES AND COOKING GEAR

Camp stoves are valuable for heating water, improve nutrition and hydration, and help keep spirits up in rough weather. The general standard is to burn white gas in a self-cleaning multifuel stove. White gas is also sold as Coleman fuel, stove fuel, or naphtha in different parts of the world. White gas burns hot; it can be argued that some liquid fuels burn hotter than others, but the differences are minor. Liquid-fuel backpacking stoves burn significantly hotter than small propane stoves. A hot stove is faster and is more reliable in bad weather. Multifuel stoves tend to work better in cold weather because they have fuel preheating loops in the fuel line. A self-cleaning stove has an internal cleaning needle that reams out the gas jet. A stove that requires a handheld external cleaning needle is a poor choice because it requires more maintenance to operate. Although it is easy to rationalize that occasional maintenance is not a problem, these clogged jets are more problematic in tough conditions when there is a greater need for the stove to perform at higher levels of heat and reliability.

Gas cartridge stoves are a quick and easy option for three-season use (anytime but winter.) They are turned on and lit like a gas range. However, the typical gas stove puts out roughly half the heat of a good liquid fuel stove. This is a great first stove for a backpacker because it is virtually maintenance free. Hotter fuels are available in some countries.

Kerosene stoves do not burn as clean as white gas stoves, so they need more frequent cleaning. They are harder to light in the cold but still light at subzero temperatures. This fuel is "thicker," so it is more stable (off-gasses less and ignites at a higher temperature) than white gas.

Multifuel stoves can burn many liquid fuels but generate more soot with fuels other than white gas. Although you may have heard all sorts of precautions about burning lower-grade fuels in these stoves, in the short run this is no problem. At -29°C (-20°F), it may take some priming to get #2 diesel fuel to burn blue, but it works once the burner head and preheating loop are warm.

Types of stoves include free-standing models and the lighter models that attach to a fuel bottle. Recent advances in the attached stoves have made them stable and reliable enough to capture most of the backpacking market. Be sure to choose a stove that simmers well. If you do not want to research which stove is better at simmering than the rest, buy a top-of-the-line MSR multifuel stove. The model chosen is not as important as how well the stove is used and maintained.

Stove Hazards

Burns are the most common stove or cooking injury. Backpacking stoves often tip over. Burns commonly come from spilled pots of scalding water, from using bare hands near a flame or frying pan, and occasionally directly from burning stove fuel. To minimize spills, do the following:

1. Supervise the stove area so that no one tips over a pot.
2. Do not allow people to sit in the impact area around a burning stove.
3. Use a ladle instead of pouring from the pot.
4. Do not carry a pot of boiling water over humans.
5. Do not pour boiling water into a cup that is in someone's hand.

All stoves generate noxious fumes. While a stove is being primed, the cold fuel burns poorly and creates a black cloud that should be avoided. Do not prime a stove in an enclosed sleeping area. Indoor cooking is reasonable in a well-ventilated tent or snow cave as long as the stove is primed outdoors first. Even then, the stove fumes give some people headaches.

Fatalities from cooking in closed tents have been related to carbon monoxide. This is avoidable with ventilation, even though ventilation may be hard to accomplish when, for example, you are leaning against the side of the tent to keep it from collapsing from wind pressure while your tentmate is melting snow to drink.

Burns from spilled fuel are usually related to open fuel bottles near lit stoves in warm weather. Unfortunately, people tend to push or throw a burning fuel bottle instead of merely setting the cap back on to quickly extinguish the flame. Once the burning bottle is spilled, the fire grows quickly.

Stove Accessories

Fuel bottles come in many sizes and materials. A 1-L aluminum bottle is standard. On long expeditions, carry full gallon cans of stove fuel rather than a bag full of aluminum bottles. Carry at least one aluminum bottle for controlled pouring or to attach to the stove. Save space by crushing the empty gallon can. Plastic fuel bottles lack the durability of aluminum and do not attach to newer, lightweight stoves.

A windscreen is a valuable accessory in bad weather. A wildland fire fighter may be able to provide an old "shake 'n' bake" (aluminum/fiberglass blanket). In a raging blizzard, use a square meter of the blanket to completely enclose the stove and bake using a "backcountry

microwave" technique in full blizzard conditions. In deep snow, you can build a small snow kitchen that keeps the wind and snow away from the stove, decreases cooking time, saves fuel, and decreases wear and tear on the stove.

A stove base can help stabilize a stove, keep it from sinking into the snow, and protect the ground from heat and fuel. An after-market stove base can be purchased or constructed from an 8-inch square of thin plywood. Set the stove on the pad and trace the footprints. Drill holes halfway into the wood for the stove feet. Some people glue a thin layer of tin or aluminum to the top to make it fireproof. In very cold conditions, glue a piece of an old closed cell foam pad to the bottom of the base, and consider making the base wider to serve as a better snowshoe for the stove.

Fuel and time are wasted when you cook a pot of food and then set it on the cold snow or ground. An extra piece of plain closed cell foam is useful as a pot trivet when cooking in the snow. Pot grips should be substantial. A 6-inch pair of channel locks are the best grips used to prevent dropping a pot.

Repair kits are critical. Stopping to sew a small pant leg tear from a crampon might keep a person from tripping later. Replacing the bulb in a headlamp might allow the group to move twice as fast. Maintenance habits affect what spare parts are carried in a repair kit. If all the gaskets and O-rings are replaced on each stove and headlamps are replaced every year, you will not need to carry those spare parts. If maintenance is performed only when equipment breaks, then it will be necessary to carry a complete expedition repair kit. To learn which parts are usually needed, ask the manufacturer or speak to someone who repairs stoves and lamps for an outfitter.

Cooking dishes vary from an unused pot at home to specialized nesting backpacker ware. On an extended trip, stainless steel pots are durable and easy to clean. Good aluminum and titanium pots are available, but stainless steel is the common standard. Nesting pots pack better for larger groups, and also offer more versatile sizes. Nonstick coatings are attractive on frying pans, but since little soap is used when backpacking for environmental reasons, expect sand and grit to wear down the nonstick coatings. Cooking utensils can include pot grips (6-inch channel locks), a serving spoon, a ladle for dishing out hot water, and a spatula. Stainless steel tools are more durable, but lighter weight plastic and aluminum utensils are available. As with any gear, lighter weight equipment needs more care and cannot be used for as many tasks as heavy duty gear. Most people that go on a lot of expeditions do not skimp on utensils.

Eating utensils need to be simple, durable, and easy to clean. They need to be able to withstand an occasional boiling to keep them clean. A spoon is the eating utensil of choice among backpackers. Lexan spoons are very light. Stainless steel spoons are more durable and can also help scrape a pot or unscrew a large-slotted screw. Bowls should be of a large enough volume so that when the meal is divided, you receive a full portion so that the pot can be used for its next function. Some travelers prefer a Tupperware-type bowl with a lid to carry leftovers as trail food. Mugs should carry at least 16 ounces. In hot weather, when hot drinks are not usually fixed, it may work to carry one dish to use as cup and bowl and drink only from a water bottle.

Fire-Starting Tools

Starting fires can be challenging. Catalogs are full of flints and steels, and all sorts of equipment. The smartest device to carry and use is a cigarette lighter. Break off the childproof plastic barrier by the striker in cold weather; this barrier can eat a hole under your thumbnail as you try to strike the lighter. Carry the primary lighter in a handy location. Carry a spare lighter deep in the pack where it cannot get wet. For all-weather reliability, carry an electronic piezo lighter. Some of these lighters have waterproof caps and should last a long time. Cheaper lighters still work but work only a few months after exposure to saltwater.

KNIVES, MULTITOOLS, SAWS, AND SHOVELS

Expedition tools should include a Swiss army knife, a pocket multitool with pliers, or both devices. The more a tool is hybridized, the less it can perform any single function. To reattach ski bindings, you want a real screwdriver to apply the torque and control. A good tool kit includes duct tape, baling wire, an awl (to drill holes), a standard screwdriver, a Phillips screwdriver, and channel locks or pliers.

Knives need to be simple, durable, strong, and easy to clean. An excellent choice is a Swiss Army brand model that is all metal and only has 4 blades: knife, awl, and two flat screwdrivers with bottle and can openers. An all-metal Swiss Army knife can be dropped in the pot during routine sterilization of camp utensils. This sterilization involves taking every utensil (already thoroughly cleaned) and dropping it in a pot of boiling water. Once the pot begins to boil again, the bacteria on the utensils are killed. Knives with plastic covers tend to lose their plastic parts when boiled.

An alternative knife choice is a simple ultralight lockback knife with a 3-inch blade. Larger blades are too big for most camp chores, and smaller blades cannot adequately perform certain tasks, such as cutting cheese. Smaller blades also tend to allow food to penetrate the hinge and thus are harder to keep clean. "Ultralight" knives are light because their cases are made of composite resins; they are strong, durable, and easy to clean. Locking knives are illegal to carry on some

1698

international flights. Pack knives in checked luggage or expect them to be temporarily confiscated by the airlines.

Knife maintenance starts with keeping a knife clean. Even the best stainless steel corrodes if food or dirt is left on it. When a knife becomes dirty, it should be cleaned quickly. Occasional sterilization keeps it even cleaner. Occasional lubrication with a Teflon-based lubricant (the kind used on camming devices and fishing reels) helps tools open easier and minimizes corrosion in the joints. If a tool is immersed in salt water, it should be rinsed in fresh water and the joints relubricated. The lubrication not only greases the joint but also displaces water. Joints are more prone to corrosion because of electrolysis between different metals in the tool. Clean knives work better than dirty ones.

Knives should be sharpened as needed. Ceramic sticks are good for a quick sharpening

because they reform just the edge of the blade rather than grinding it down. Sharpening with a whetstone too often leads to thinning and reshaping of the blade.

Multitools come in many configurations and sizes. Full-sized multitools work much better than smaller ones. Microtools may look appealing, but they lack the torque and control to do many tasks well. A multitool should have all the tools already mentioned. Brand names such as Buck, Gerber, Leatherman, Schrade, SOG, and Victorinox have stronger steel, better machining, and tighter rivets. Cheap tools are available but do not perform well or last long.

Choose the multitool that fits your specific needs by performing these comparisons with different models at the same time:

1. Open all accessories. Blades that lock open are generally more controllable than nonlocking blades. Blades that are difficult to open when new may be impossible to open after a few expeditions.
2. Determine which tools will really be used. Having more little tools usually is inconsequential. The blades are much more important.
3. Tightly grip the pliers of each and crank on a 1-inch piece of wood or around a fat tent pole, torquing one set of pliers against the other. Some tools have sharper handle corners than others: the smoother edges often allow a better grip, providing more control, better fit, and less pain. In general, there is more torque with a larger tool or with the compound leverage of some pliers such as the SOG. In general, a torque wrench shows no measurable difference between the pliers of different full-sized multitools.

Once you purchase a multitool, practice performing some household tasks with it. It takes a lot of finesse and composure to use these tools; for example, practice bolting a pack frame back together tightly so that you will not strip the nuts, practice using the awl to drill a neat hole in a tent pole, and practice whittling a new spoon.

Saws are used for improvising splints and litters out of local wood, clearing trails, or cutting firewood. Some Swiss Army knives have saws, but they can cut only small wood. Another simple saw is a little cable saw, which is lightweight and works in an emergency but is not the tool of choice for extended wood cutting because it is hard to use and wears out. Some backpacker-type saws fold up. These devices use conventional saw blades, as on a bow saw (thin, flat steel with big teeth.) When assembled and tightened securely, these saws can cut big pieces of wood quickly. In general, the triangular Sven-Saw with an all-metal frame is a reliable saw for the trail. For an emergency, a cable saw or Swiss Army knife saw will work fine.

Shovels are used for digging cat holes for human waste and building fires. Small, folding shovels, such as the Udigit, work well and are very durable. A cheaper option is a simple plastic gardening trowel, but they are not very rugged, especially once they have been used a year or two. If something bigger is needed, the Boy Scout shovel with the oak handle or a military entrenching tool (E tool) works well. If you will be moving snow, consider the small but unbreakable Life Link Lexan shovels or the larger, extendable

aluminum ski-touring shovels such as the Voilé shovel.

WATER CONTAINERS

Carry 1 to 2 L of water storage on any hike, and add 5 to 10 L of water storage per day for "dry camping." *Dry camping* means camping away from a water source, such as in the desert or high on a ridge. Since water weighs roughly 2 pounds/L, most people camp near water and use their larger water containers to keep a ready supply in the "kitchen."

A clean 1-L IV bottle is an excellent personal water bottle. It packs well and is lightweight, and the price is right. Many serious adventurers use these as their primary water bottles on short expeditions. On long expeditions, the use of something more durable, such as a Nalgene bottle, is standard. Narrow-mouthed bottles work, but wide-mouthed bottles fill faster and are easier to deal with if the liquid is frozen.

Larger quantities of water can be carried in large inexpensive plastic water containers available at any camping store. The accordion styles are generally more durable than the square plastic ones. These containers are used only for hauling water from the stream to the kitchen and not for long-range transport.

A more rugged option is an MSR Dromedary or another nylon water bag, which can be stuffed inside a pack. A 5-L dromedary is an excellent addition to the pack, even if you only need to carry an extra liter or

1699

two of water. The advantage of a nylon water bag over a case of water bottles is that the nylon container collapses, making it more versatile.

There are medium-sized (2- to 3-L) heavy duty plastic water vessels that are not expedition grade like the nylon vessels. However, they are especially handy in hot weather because they hold an amount of water that is between the classic 1-L bottle and the big water tanks needed for dry camping.

A drinking tube can be obtained for many of these bags so that you can sip while walking without having to open the pack. Drinking tubes freeze quickly in very cold conditions but are very helpful in hot, dry conditions. Neoprene sleeves help minimize, but not eliminate, freezing in drinking tubes.

In cold weather, some people put their water bottles in insulated sleeves. If you buy one,

be sure it encloses the whole bottle. Foam sleeves can be made from old sleeping pads and contact cement or can be fashioned from a large insulated mitten or booty. It helps to pack water near the body to capitalize on body heat. This works down to -20°C (-29°F), but in even lower temperatures, it is best to carry a minimum of water, since frozen water makes not only the water but also the container unavailable. Thawing frozen water bottles is a painfully slow process and uses a lot of fuel. Frozen containers often break because people try to chip out the ice or they try to warm the plastic near a fire, melting the plastic too. Thaw a frozen water container by putting it in a pot of hot water. Once part of the ice in the container melts, pour cold water out of and hot water into the bottle.

Disinfect all drinking water (see [Chapter 51](#)). This holds true for the containers as well. If you use a filter instead of iodine or chlorine, you must occasionally disinfect the water containers or bacterial growth may occur. Water bottles that have carried sugar drinks support bacterial growth in warm weather. Drinking tubes and the threads on bottle lids are especially prone to bacteria. Between trips, clean glass and hard plastic water containers by running them through the dishwasher. Soft nylon water containers can be run through the washing machine. Soft plastic containers need to be scrubbed by hand. Before long-term storage, rinse with super-chlorinated water (one teaspoon of bleach in a liter of water) and dry thoroughly to minimize mold and bacterial growth. Before using a stored water container, quickly rinse it with tap water to get rid of distasteful odors.

BACKPACKS

Internal-frame packs are the current standard and an excellent choice for many situations. With careful packing, internal-frame packs are easier to carry than the older external-frame packs. Choose a volume that you will use often. Packing all of your gear takes a lot of care; if the pack is overloaded, it does not handle well.

External-frame packs are easier and faster to load. Some people can carry a heavy load (more than 50% of body weight) more easily with an external-frame pack. Many people attach a daypack as a top storage compartment so that it can be detached for lesser loads in camp. Although many soft (internal-frame) packs have top pockets that detach as fanny packs, they are smaller and perform less well compared with a good stand-alone daypack. External-frame packs are generally easier for finding specific items such as tools, clothing, or food during a hike because the packing system is more compartmentalized.

Size is the first consideration. A total of 3000 to 4000 in³ is a great size for a day pack. For packing overnight gear, 5000 in³ is a better size. For a week's journey, 6000 in³ is preferable. On an extended expedition, at least 7000 in³ is needed. In winter, allow more storage space for extra clothing layers. If you carry medical equipment plus gear, you will need a large pack. Extra volume makes it easier to pack and to find things. One can always add pockets to some packs, but this should be done primarily to make access more convenient, not to carry more weight. Pockets tend to flop around on packs and are a less efficient way to carry heavy items. (The flopping causes slight jolting with every step.) Slightly bigger packs have as many advantages as disadvantages; choose a general size range and then shop for a style you really like.

Suspension systems vary from a simple webbing belt and shoulder straps (inadequate) to well-padded systems that wrap around the torso. For full loads (more than 40% of body weight) choose a system that comfortably rests the weight on the hips but snugly pulls the load toward the back. Choose thick padding on the hips and shoulders, and a fit that easily adjusts while walking to take the pressure off hot spots. Carrying heavy loads is never easy, but a good suspension system makes carrying them more bearable ([Figure 71-1](#)).

Comfort features on packs include adjustable stays (straps that position the load), a lumbar pad, and a hip suspension system to fit the body. Trying on a pack is essential. Put in as much weight as intended for the expedition and hoist the pack up and over obstacles and especially down some stairs. If you cannot make the pack fit comfortably, try another, perhaps one with more adjustments. Certain adjustments, such as shoulder strap height, can be fitted once and then not changed much, but other features, such as

side stays (load adjustment straps), need to be easily adjustable while walking down the trail because they can help distribute weight better, making it less fatiguing to haul the load. A sternum strap holds the shoulder straps together, helping them wrap around the torso better. On men, the sternum strap should cross the nipples.

1700

Figure 71-1 Backpack suspension system. (Redrawn from Harvey M: *The National Outdoor Leadership School's wilderness guide: the classic handbook*, New York, 1999, Fireside.)

Women need to position this strap above or below the breasts for comfort. This is obviously a function of personal anatomy and the angle of the shoulder straps and can only be determined by active trial. Basic comfort may seem like a luxury, but on the trail, how well one carries a load has direct bearing on how much energy can be put into hauling essential gear and how much energy remains to enjoy the wilderness.

Pack Accessories

Extra pockets can be great additions. These are left at home for lighter trips or when hauling a pack up a big wall. Some packs come with integral map pockets, water bag holders, crampon straps, ice tool straps, and other pockets. If these accessories are used, then the weight is justifiable. However, they can diminish the basic comfort that encourages use of the pack. One should carry $\frac{3}{4}$ " nylon tape lash straps for attaching things like sleeping pads to the pack. Fastex buckles make these lash straps easier to use. Buy the straps 50% longer than you think you need so that they can be used for other applications. Lash points allow attachment of items such as ice axes and foam pads without squeezing them inside. Lash points do not weigh much and add a lot of versatility to any pack.

Stuff sacks should be used to compartmentalize the gear. They should be slightly oversized so that they can change shape more easily when packing. Thin, coated nylon is a good material for stuff sacks; in general, thinner is better because of weight and stuffability. The heavy stuff sacks on the market are soft luggage and entirely too heavy to use as backpack compartments. Mesh bags offer good options for a see-through bag; even a mosquito head net can be used for a stuff sack in the day pack and can double as a bug net. Use a large (18 x 12 x 12 inch) stuff sack for clothes, a medium to large size for food (actual size depends on whether you need to carry food for 1 or 10 days), and two small sacks for toiletries and for the "possible bag." A possible bag has all of the little items needed during the day: compass, pocket knife, lip balm, sunscreen, insect repellent, and such. While most of these stuff sacks usually fit into the main compartment of a pack, the possible bag is typically carried in the small pocket of the

day pack so that it is always available.

Packing a backpack is as important as choosing one. Pack heavy objects low and forward to avoid having to lean further forward to balance the hoisted load. Pack fuel below food because sooner or later, the fuel will leak. Avoid lashing loose objects on the outside of the pack; rattling hardware is a nuisance and causes routine jolting. Balance the pack so that left and right are equal. Stuff items such as sleeping bags into "compression stuff sacks," or stuff sleeping bags and parkas into the bottom of the pack. Internal-frame packs do not allow very good accessibility, so pack carefully. A nice option is to choose a pack that has a large top pocket that becomes a fanny pack. Keep items needed for short day hikes in the fanny pack so that they are readily accessible. In cold weather, shed a big clothing layer as the hike begins but put it back on before resting. Therefore you should leave room in the packing system for such practicalities. In wet climates, consider waterproofing the pack by lining it with a tough garbage bag.

Adjust the pack to fit comfortably. It is best to store the pack with the straps "adjusted out" so that they will not become misshapen. When donning the pack, adjust the hip belt to get the pack to the correct height and to rest the weight on the hips. Then adjust the shoulder strap length and tighten the adjusters that pull the pack

1701

forward to the shoulders. With slight increases and decreases in these adjusters, you can shift pressure for more comfort. If you do not follow this routine, you will put more pressure on the shoulders than necessary.

TENTS

Tents can be as simple as centered-pole tarps, such as Black Diamond's Megamid or Mountain Hardware's Kiva, which work fine in most environments. In bug seasons, use a tent with mosquito netting. In muddy conditions, a tent with a floor is important. Choose a name-brand manufacturer from a reliable outfitter. Traditionally, North Face and Sierra Designs have offered state-of-the-art tents for decades, but some of the new lines, such as Mountain Hardware, are proving to be more innovative with the same quality workmanship. Less expensive brands may be fine for family camping but are not as high-quality as the other tents typically used by mountaineers above tree-line. Plan on purchasing a tent for a decade's use.

Tent fabrics range from cotton to Gore-Tex, with nylon being the norm. Cotton tents are heavy but are not considered expedition gear, even when dry. Gore-Tex is a fine option for traveling light but never breathes as well or lasts as long as a classic fly-canopy system. Many large expeditions use Gore-Tex tents to control weight. Most people purchase a tent with an uncoated canopy (the fabric that is the ceiling) and a urethane-coated rainfly (the fabric on the top.) This provides ventilation by allowing perspiration to move through the canopy while keeping the occupant dry. Check for coating on a fabric by trying to suck air through it; uncoated nylon allows air to pass through easily. One fabric option sometimes available by special order is an "expedition" or "outfitter" floor. This heavier fabric strengthens the most vulnerable part of the tent.

For extra convenience and room, get a top-end state-of-the-art dome tent with a vestibule, such as a North Face VE-25. Use aluminum poles because they are lighter and stronger than fiberglass poles. Avoid pole sleeves; get a tent that has pole clips on the canopy. A rain fly with adjustable bottom straps is welcome in cold conditions when the nylon gets stiff and tight. You can cook in the vestibule with extreme care about fuel and fumes. The tent should be easy to set up in dark or windy conditions.

Backpacking tents are small. Expect space to be tight if teammates are large or there is a lot of gear. Try a tent for size before buying. Fill it with pads and sleeping bags and some extra gear, and use it for a while before committing to it.

Accessories can make a tent more versatile. A thin nylon ground cloth under the tent keeps the bottom cleaner and more waterproof and helps protect it from rocks and sticks. A nice accessory is a mesh shelf across the top, or mesh pockets on the sides. These help keep loose gear organized, making it easier to move in and get comfortable without the frustration of losing items such as glasses and mitten shells. A single vestibule is an obvious accessory, but some tents can handle two vestibules. This is

excellent for base camping.

Choose tent stakes according to the ground into which they will be driven. In hard dirt, thin aluminum stakes work fine. In softer dirt, larger-diameter plastic stakes hold much better. In sand or snow, long stakes reach down into the more compressed damp sand, or very large stakes act as "dead men." A dead man is a stick or stake about a foot long, buried sideways with a string looped around it. The stake needs to be at a right angle to the direction of the string. Compress the sand or snow and let it set up for a few minutes so that it will hold. If you use a disposable stick and tie it off above ground, the dead man can be left in the ground. This is especially nice in snow because the snow "sinters" (crystallizes together), making it hard to dig out the stick. In windy conditions, it takes more than tent stakes to hold down a tent. You may need to tie the sides of the tent to rocks, logs, and bushes or may even need to sit in the tent to hold it down as a front passes through.

To set up a tent, tie it down so that it is taut and make the knots adjustable. A trucker's hitch (see [Chapter 72](#)) is the first knot to be mastered if you wish to excel at setting up tents. As the fabric stretches as a result of heat or moisture, retighten the knots. Tie the tent to stakes, trees, rocks, or dead men. In inclement weather, how tightly the tent is secured controls the flapping that can eventually shred any tent.

Care of a tent includes routine seam-sealing of the outside of the rainfly and tent bottom. Seam-sealer prevents the capillary action that allows water to seep into the tent through the threads and seams. Routine seam-sealing does not mean adding more sealant every time the tent is used. Rather, sealant should be reapplied as it is noticed to crack and wear. You need to apply seam sealer to a dry tent; it will not adhere to moisture. Keeping a tent out of the sun and gently cleaning it after use makes the nylon fabric last longer. Storing the tent in a cool, dry place minimizes mildew and fabric rot. Keeping zippers clean on a daily basis and lubricating them helps them last longer. Lubricate them with a commercial product or in a pinch use lip balm or candle wax. Zippers are often the first thing to fail; careful attention to not stressing zippers can postpone this inevitable failure point. Carry a spare zipper slider, a spare zipper "stop," and nylon repair tape.

SLEEPING BAGS

Materials for sleeping bags include only a few options. Insulation can be one of the spins of polyester fiber fill, or it can be goose down. Fiber fill bags are often

1702

referred to as *synthetic bags*. Covers can be uncoated nylon or Gore-Tex. The most common bag is fiber fill with an uncoated cover, but there is no need to be limited by convention.

Down bags are lighter and stuff much better than synthetic bags. In a continental climate (away from the oceans), a down bag can be both luxurious and practical, especially in dry, cold conditions. Once soaking wet, however, a down bag will not regain full insulation until tumbled in a cool dryer with a tennis shoe to fluff it up. Name-brand manufacturers usually provide high-quality goose down; other brands may provide more feathers and less fill power (rated in cubic inches per ounce of down.)

Fiber fill or synthetic bags include Polarguard 3D, Polarguard HV, Lite Loft, Thinsulate, and Qualofil fibers. Polarguard HV is one of the tougher fiber fills because it has a casing of "scrim" around the bats, like a sausage casing: it handles repeated washings better than others. Polarguard 3D is lighter and stuffs better but is not as resilient, losing more fluff than Polarguard HV after repeated washings. Qualofil performs almost as well as down when new because it has four hollow tubes running down its core, providing a structure that fluffs it up; however, it does not withstand repeated washings. A sample of 200 Polarguard HV bags, which are some of the toughest fiber fill bags, used continuously for 6 months and washed once a month, appear to have roughly half to two thirds the thickness of a new bag. This represents a decade of use for a typical weekend hiker.

Uncoated nylon breathes better than Gore-Tex but also absorbs moisture from rain or the ground more quickly. Some people prefer a Gore-Tex cover on a down bag, but more people use a Gore-Tex bivouac sack on their bags so that they have the option of adding that extra layer for warmth or leaving it at home.

Bag warmth is rated by temperature, which has no commonality from one manufacturer to another. One retailer might rate a bag at -7°C (20°F) (meaning it ought to keep you warm on such a night when new), and another retailer might sell the identical bag with it labeled as a -1°C (30°F) bag. Use any temperature rating to get in the ballpark, and

choose a temperature rating that is conservatively below what is necessary. To compare one bag to another, it needs to be the same style; for instance, compare the insulation weight, with three pounds of Dacron being significantly warmer than two pounds of the same insulation.

Shape can be as important as thickness. Any decent bag has a differential cut, meaning the nylon on the outside is cut bigger than the nylon on the inside. This detail is one of the fundamental differences between a top-brand sleeping bag and a discount bag. An efficient bag is mummy shaped, just like the human body. A bag that has too much extra space will be hard to heat and will have cold spots as you shift during the night. You will be unable to comfortably maneuver in a bag that fits too tightly. Most people cannot easily change socks while zipped up in a sleeping bag. Draft tubes make a bag much more efficient. One draft tube runs along the zipper. When testing a bag, see whether that draft tube naturally lays across the cold zipper, or if it only ends up there when you wake up and move it there. A draft tube between the chest and neck helps keep the torso's body heat in the bag as you roll around; it requires an adjustable draw cord to work well. Even in a summer-weight bag, this adjustable option is smarter to carry than the equivalent weight in insulation. The last draft tube encircles the face. This also needs an adjustable draw cord. In very cold conditions, you will draw this cord so tightly that only the mouth and nose are exposed; make sure the draw cord works easily at that range because when you wake up too cold or too hot in the middle of the night, you do not want a desperate struggle to adjust the cord. Most important, a bag needs to fit the body, with no pressure on the toes, but a minimum of extra space.

Sleeping pads add warmth and comfort to a sleeping system. A simple closed cell foam pad (closed cell foam does not allow air to pass through it), such as a Ridge Rest, insulates a person from the ground and is very reliable. An open cell foam pad is inadequate for backpacking because it absorbs water. In cold weather, it makes sense to have two pads under the torso. Tests at the Teton Science School have shown that a typical "three-season" bag is improved more by adding ground insulation than by adding more loft to the bag. Many winter campers carry a full-length pad and an extra half-pad that is their "sit-upon" during the day and serves to double-insulate the torso at night. An inflatable pad, such as a Thermarest, is a very effective insulator because it is constructed of open cell foam but is waterproof with a coated nylon cover. Cheap inflatable air mattresses with no foam grow cold quickly because of convective cooling to the ground. The risk with the best inflatables is puncture; a slow leak can be devastating. Always carry a repair kit; many expeditioners carry Shoe Goo (a "liquid rubber" compound) seam-grip instead of the contact cement that comes in a Thermarest repair kit because these substances hold better when applied in the marginal gluing conditions typical to an expedition.

Bivouac sacks are not essential but increase the number of options and provide a quick tent substitute for a short trip. The classic style has a coated nylon bottom, Gore-Tex top, and zipper with a small rain cover over it and is cut big enough to contain a sleeping pad and bag. Some have small wands (poles) to hold them up. For camping in a maritime (wet) climate, the wands are important. If you use this sack just to keep a down bag

off the snow in a snow cave, it does not require wands. Mosquito netting adds an important option for sleeping out on a warm night when you do not wish to be zipped tightly in the bag.

Using a sleeping bag carefully is important. If you become too warm, loosen the draft tubes and unzip a bit of the bottom of the zipper first. Compared with being too cold, being too warm at night is not a problem for most people. Increase warmth by going to bed warm, even if you have to go for a short run or dig snow for a while. Close the draw cords tighter, until you reach the limits of good breathing. Breathing inside a bag provides short-term heat but adds water vapor that diminishes insulation and causes evaporative cooling. Many bags have just as much insulation on the top as on the bottom. You can sleep in a bag placed upside down to use the mummy hood to trap the heat around the head; this is much warmer. Add clothing layers to increase warmth: it is obvious that an extra pile jacket will keep you warmer but this works only if it fits loosely and does not impair circulation. Any clothing that covers bare skin has a pronounced warming effect, so gloves and a hat help contain body heat. Specialized gear, such as Dacron booties and pile balaclavas, are simple but very effective ways to help sleep warmer. Sleeping strategies, such as overlapping sleeping pads to prevent cold spots or even cuddling together, are often overlooked. Hydration and nutrition are essential to sleeping warmer on a cold night. You can also place hot water bottles in the groin area to help maintain warmer body temperature on a cold night, but most people first try simpler maneuvers.

Chapter 72 - Ropes and Knot Tying

Loui H. Clem
Steve Hudson

Although ropes are among the oldest tools known to man, the evolution of ropes for different purposes has been a long and complex process. From aboriginal peoples twisting a few plant fibers together to make a cord to the multitude of rope materials and designs available today, ropes have been a part of our lives for thousands of years. The foundation for selecting a rope is being able to assess the characteristics required for its intended use.

No rope should ever be used to support a human life unless it has been specifically built for that purpose. Stories abound of towropes being used (fatally) as climbing ropes, utility ropes coming apart when used as handlines, and natural fiber ropes rotting away to nothing. One good way to be certain that a rope is designed for life-safety purposes is to check whether it is certified to any life-safety standards, such as the Union of International Alpine Associations (UIAA), Cordage Institute (CI), American Society for Testing and Materials (ASTM), or National Fire Protection Association (NFPA).

Options for life-safety ropes include dynamic ropes for lead climbing falls, low-stretch ropes for low fall factors (see Fall Factors), and static ropes for minimal fall factors. Each rope construction type and material has pros and cons for specific applications. It is important to understand the performance characteristics of rope types to be able to select the right rope for the job.

ROPES

Rope Construction Types

Rope construction types historically found in life-safety applications include laid, eight-strand plaited, double-braid, and kernmantle. Kernmantle can be further broken down into more specific designs of static, low stretch, and dynamic.

Laid Rope.

Although laid ropes have largely been replaced by newer technology, it is one of the oldest and most familiar designs and may still be found on rescue trucks, especially in rural areas. Laid ropes are manufactured by twisting bundles of fiber (usually three) around one another and resemble the design of the old manila ropes. These ropes tend to untwist slightly under loading, which causes them to spin and kink. They also tend to have high elongation properties, which can be a disadvantage when trying to position a constant load. More important, in laid rope construction, the supporting fibers are directly exposed to grit and abrasion. There is no protective covering to help reduce wear on the load-bearing strands ([Figure 72-1](#)).

Eight-Strand Plaited Rope.

Eight-strand plaited ropes are not heavily used in rescue, but because plaited ropes were marketed to rescuers for a time and because some may still be in service, it is prudent to recognize their existence. Interweaving eight bundles of rope yarn creates an eight-strand plaited rope. Because these ropes are woven together loosely, they are very easy to handle. However, for the same reason, they are limp, knots tend to jam, and they do not hold up well. Their popularity was short lived because they are very susceptible to abrasion and "picking" (snagging) of bundles against rocks and building edges ([Figure 72-2](#)).

Double-Braid Rope.

A double-braid rope consists of a braid of rope inside a larger, hollow braided rope. Because of the rather soft construction, this is an easy rope to splice or with which to tie knots and is therefore popular for marine use. Double-braid ropes are susceptible to abrasion and to picking of the individual bundles. It is also easy for grit and other material to penetrate to the rope's interior. The outer sheath braid of this rope sometimes slips on the inner core braid when a person is rappelling or climbing ([Figure](#)

72-3).

Kernmantle Rope.

The German word *kernmantle* means "core" (*kern*) and "sheath" (*mantle*). Kernmantle rope sheaths are braided around the core and their design is crucial to the hand, knotability, and abrasion resistance of the rope. A tightly woven sheath will prove more durable than a loose one, but this feature must be finely balanced to maintain knotability. Other variables include fiber denier, number of strands in the braid, and angle of weave.

The core of a kernmantle rope primarily determines the elongation, force absorption, and strength properties of the rope. In the following descriptions of three common constructions, it should be noted that the terms "dynamic," "low stretch," and "static" are technically misnomers, in that all the ropes are "dynamic" at least to some degree. However, these are the industry-standard terminology and are quite useful in relating the degree of elongation inherent in each type of rope.

DYNAMIC KERNMANTLE ROPE.

A well-designed dynamic rope is a must for "lead climbing" or in other situations

1705

Figure 72-1 Laid rope.

Figure 72-2 Eight-strand plaited rope.

Figure 72-3 Double-braid rope.

in which there is a numerically high fall factor. This rope is designed to absorb the shock load in such a fall, thereby reducing the effects of the fall. This translates to the rope being very stretchy: as much as 30% elongation at 10% of minimum breaking strength (see Rope Strength).

Thus a dynamic kernmantle rope would be very difficult to use effectively for positioning

heavy loads (such as a rescue load), contending with changing loads (i.e., loading a patient midface on a rock wall), or rigging into a haul system (in which energy would be wasted with each pull because of the inherent elongation). It would also be very difficult to use effectively under high tension (as in a highline). Dynamic kernmantle ropes also tend to have a lower tensile strength than static or low-stretch kernmantle ropes because of the same design characteristics that allow it to stretch. Furthermore, dynamic kernmantle designs are often softer and have a lower percentage of sheath than static

Figure 72-4 Dynamic kernmantle rope.

Figure 72-5 Static kernmantle rope.

kernmantle ropes, making them more susceptible to abrasion and wear ([Figure 72-4](#)).

STATIC KERNMANTLE ROPE.

A static kernmantle rope is designed to be very strong and to have minimal stretch: as little as 3% to 6% at 10% of minimum breaking strength. For consistent strength, inner bundles run continuously and unbroken throughout the length of the rope, usually in a near-parallel manner to reduce stretch and spin. This load-carrying core is protected from dirt, abrasion, and cutting by a tightly braided outer sheath. Static kernmantle ropes are ideal for lowering and raising heavy loads (as in rescue), work positioning, and fall protection. Static ropes should not be subjected to a fall factor greater than 0.25 unless additional force absorption provisions are made in the system ([Figure 72-5](#)).

LOW-STRETCH KERNMANTLE ROPE.

Low-stretch kernmantle ropes elongate 6% to 10% at 10% breaking strength, fulfilling the needs not met by highly dynamic climbing ropes or very stable static kernmantle designs. This is achieved using a different core construction and a better sheath/core relationship and typically gives such ropes a softer profile than static lines. However, these same characteristics decrease abrasion resistance and make it a less desirable rope for positioning. Low-stretch ropes are often used for belaying heavy loads, especially where low fall factor potential exists.

Fall Factors

Fall factors can be calculated by dividing the fall distance by the length of the rope

between the load and

1706

the anchor or belay. Thus a 3-foot fall on a 10-foot rope would be a fall factor of 0.3, a 3-foot fall on a 3-foot rope would be a fall factor of 1.0, and a 3-foot fall on a 100-foot rope would be a fall factor of 0.03. This formula assumes that the fall takes place in free air without rope drag across the rock face or through intermediate equipment ([Figure 72-6](#)).

The danger of a high fall factor on a low-stretch or static rope is not that the rope will break but that the high-impact forces may subject the person to great discomfort and possible injury or death. A static rope transfers more of a shock load to the anchors than a dynamic rope, increasing damage potential there as well.

Another concern in any impact load situation is the effect such forces have on equipment such as belay devices, rope grabs, or ascenders. Some of these devices can damage a rope when subjected to relatively low-impact forces. The study of impact forces and ways that different pieces of equipment relate to different constructions of rope when subjected to such forces is fairly complicated. Two general rules of thumb are to

Figure 72-6 Fall factors.

(1) design and operate your rope systems to minimize the potential for high-impact forces and (2) exercise great caution in selecting belay methods.

Rope Size

Just as no single type of rope is appropriate for all activities, no single size fits all conditions. Purchasing the largest rope in the hope that it will fit all situations because it is so strong could lead to problems in working with the rope and the auxiliary equipment. Rope strength and elongation are actually the more critical determinations, and size considerations should follow.

Rope Strength

Rope strength is a fairly misunderstood topic. Strength of life safety rope is usually referred to as *minimum breaking strength*. Unfortunately, reported numbers do not necessarily reflect numbers adequate for comparison. Variations in test methods, as well as in analysis of results, provide marketing fodder that can create great confusion.

One way to report strength is as the rope's "ultimate, or maximum, breaking strength," which is the highest score of a given rope in a series of tests. An alternative is to list the "average breaking strength" of several tests. A more conservative method is to define *breaking strength* at a value two or three standard deviations below the average test result. Another method is to list a "minimum breaking strength" and then define *minimum* as not greater than 10% below the average. Often, figures for tensile or breaking strength are reported without any explanation as to whether they are average or minimum or whether some other measure was used. Simply stated, "breaking strength" might refer to any one of these reporting methods, or even to another.

To add to the confusion, a number of factors affect test results. The rate at which the pull is applied to the rope, the temperature, the humidity, the diameter of the object to which the rope is attached, and other factors all have an effect on test results. Thus unless ropes are tested in exactly the same way, results cannot be meaningfully compared.

One common test method that has been adopted by several standards organizations is "CI-1801" from the Cordage Institute (CI). CI-1801 for life-safety rope is specific and gives a common baseline from which to attain results. This standard also calls for a very conservative reporting method, wherein *minimum breaking strength* is defined as three standard deviations below the mean of several break tests. This helps normalize the results. In addition to type of construction, the strength of a rope comes from the amount of nylon used to make it; similar rope constructions of the same diameter should have similar strengths if they have the same amount and quality of nylon.

1707

Results from laboratory tests may differ greatly from rope performance in real-world applications, which cannot be consistently and accurately quantified. A knotted rope loaded over a building edge, for example, may not come close in strength to a rope loaded in a laboratory tensile test machine.

It is clear that a rope should be stronger than the force of the intended load, but how much stronger? The ratio of a rope's strength to load is often called a *design factor*. If the strength of a rope is 2500 pounds and the load is 500 pounds, then the design factor is 5:1. The design factor takes into consideration only the new condition of an item as it is designed to perform. When translating a design factor into a system safety factor, factors such as age, wear and tear, dry/wet condition, and system rigging should be considered.

A rope system is only as strong as its weakest link. The ratio between the weak link in a system and the load to be applied is known as the *system safety factor*. System safety factors also take into account the way that loads are applied to a system. For instance, redirectional pulleys, rigging angles, and mechanical advantage systems can all increase the forces within a system.

Generally, component design factors tend to be very high, often as high as 15:1. Once the real world is factored into an actual system, the remaining system safety factor may be half that value. As a rule, the higher the probability of and consequences of failure, the higher the safety factor should be.

Rope Fiber

Before the development of synthetic fiber ropes, the standard for many years was rope made of natural fibers, such as manila. Natural-fiber rope degrades in strength even when carefully stored, lacks the ability to absorb shock loads, lacks continuous fiber along the length of the rope, and has low strength compared with certain artificial fibers. For these reasons, natural-fiber ropes are no longer considered appropriate for life-safety applications. Synthetic fibers, including polyolefin, aramids, ultra-high-modulus polyethylene (UHMPE), polyester, and nylon, are more commonly used in modern-day rope making.

Polyolefin.

Polyolefin (polypropylene or polyethylene) fiber ropes are used when their flotation property is desired, such as in water rescue. They also have good resistance to most acids. However, polyolefin fibers rapidly degrade, especially under ultraviolet exposure. Because the fiber has low abrasion resistance, strength, life expectancy, and melting point, it is a poor choice for most life-safety applications.

Aramids.

Aramids, commonly known by the trade name *Kevlar*, are extremely strong fibers and resist high temperatures. However, aramid is very susceptible to internal and external abrasion. Because it cannot absorb dynamic energy and breaks if bent too tightly (such as in a knot or rappel device), it is dangerous to use in life-safety applications.

UHMPE.

UHMPE, more commonly known by trade names *Spectra* and *Vectran*, is a newer type of high-modulus lightweight fiber. It has better abrasion resistance than aramid but still has too little stretch to absorb dynamic energy. UHMPE fibers also have too low a melting point to safely be used with most rappelling equipment. In addition, they tend to be very slippery and do not hold knots well under high tension.

Polyester.

Polyester fibers are used in many ropes. Dacron (DuPont) has a melting point of about 249° C (480° F), which is in the range of nylon 6.6 and above the melting point for nylon 6. Polyester fiber has a high tensile strength even when wet, low elongation at break, and can be as effectively UV stabilized as nylon. These factors make polyester rope well suited for marine applications, such as for boat rigging lines, and makes it an interesting choice for life safety. However, polyester fiber has low dynamic energy absorption, which means that the fiber cannot handle shock loads or repeated loading as well as nylon fiber.

Nylon.

Nylon is the most common and most suitable fiber for general life-safety use. Nylon is approximately 10% stronger than polyester, but nylon fiber may lose as much as 10% to 15% of its strength when wet. However, it regains its strength when it dries. Nylon can handle about twice as much shock loading per pound as polyester when both are wet.

Nylon strongly resists most chemicals, but certain alkalis, acids, or bleaches can cause degradation, especially in high concentrations. For the high-angle technician, the source of most damaging acids are batteries, including lead acid and so-called "sealed" or dry-cell batteries. Users must scrupulously protect ropes from direct contact with batteries or exposure to acid fumes or residues that might be found in vehicle storage compartments, trunks, and garage floors. Industrial users should take special storage and handling precautions because of chemicals used in their rescue environments.

Service Life

The service life of a rope cannot be determined in advance. How long a rope lasts depends on a large number of variables, including individual care, frequency of use, type of hardware used, speed of descent on rappels, exposure to abrasion, local climate, and type of loading. DuPont claims at least a 10-year shelf life for nylon, and rope tests have confirmed that an unused

rope can last up to 10 years without significant strength loss. Used ropes degrade more quickly.

Any rope can fail after poor care or under extreme conditions, such as shock loading and sharp edges. A shock load of 0.25 fall factor for a static rope or 1.5 fall factor for a dynamic rope will likely cause internal, invisible damage to the rope, although damage may also be caused under lower fall factors. Regardless of how long it has been in service, you should immediately discard a rope when it becomes cut, when abrasion

has caused significant wear to the sheath, after a hard shock load, when you suspect chemical contamination, or any time you are in doubt about the rope.

KNOTS

The medical professional encounters many knots in the course of his or her career. From the square knot in a stitched laceration to neck ties at administrative functions, practical and symbolic representations of knots abound.

In modern society, knots are used as a form of expression, in art, as mathematical structures, and for security purposes. Determination of "good" vs. "bad" in the analysis of a knot lies solely in the knot's ability to achieve the purpose for which it was created. Therefore you may find that several of the good and clever knots you have learned are useless when it comes to functioning in the wilderness.

Uses

Knots are applied in several ways in the wilderness environment. They are used to stake out tents or shelters, tie flies to fishing lines, create suspended "bear-proof" gear caches, and occasionally to tie things together.

In wilderness medical evacuation, knots take on great significance. Many medical professionals find themselves working alongside rescue technicians in steep terrain where knots are used for the safety of rescue personnel and for patient evacuation. Improvisational medical techniques often involve knots. Knotted rope or fabric can be used to secure a splint, create a hasty patient-transport device, or provide secure shelter to persons in precarious environmental situations.

How Knots Work

The theory behind a "lotta knot" is that if you cannot tie it right, at least tie it big. In a lotta knot, the greater the mass of rope and the more twists and turns it takes in relation to itself, the higher the probability that the knot will hold.

Eventually the rope user learns that certain types of twists and bends hold better than others; the reason the lotta knot works is because the larger mass increases the odds of getting a bend to hold in the mix. There are many disadvantages to the lotta knot, however. It takes up a lot of rope and is very difficult to tension. The varying twists and turns are not conducive to tightening the knot or positioning it properly. Finally the lotta knot often fails to perform altogether.

The internal friction of a knot is essentially what holds the lotta knot together. This friction can be attained by the rope taking twists and turns around itself or from friction

against another object, such as a capstan or another rope.

The serious professional should take knot tying seriously because in a wilderness rescue, lives may depend on this skill. One should be able to select the correct knot without hesitation, tie knots correctly the first time, and be able to tie knots with gloved hands, on muddy or icy rope, in the dark, and under stress. Finally, one should be able to ascertain by looking at a knot whether it is tied correctly.

Categories of Knots

The most practical way to select a particular knot is to first evaluate what role that knot is expected to perform. For the purposes of this book, knots are addressed based on five basic functions: stopper knots, end-of-line knots, midline knots, knots to join two ropes, and safety knots.

There are subsets of knots for the terminology purist. A knot that is tied around something (e.g., a tree, a standing rope, or the rail of a litter), that conforms to the shape of the object around which it is tied, and that does not keep its shape when the object around which it is tied is removed is called a *hitch*. In its simplest form, a *loop* is a section of rope that crosses itself. A *tied loop* is a knot that forms a fixed eye or loop in the end of a rope. Regardless of the name or the way in which the terminology applies, there are basic rules that apply to any of these ties.

When working with rope, it is critical to be aware of the type of material into which the knot is tied. Some fibers have a low coefficient of friction and require special considerations in knot tying. Knots that are effective on rope do not always perform well in webbing or sling material.

Anatomy of a Knot.

Common baseline terminology follows:

The *working end* of the rope is the section used to tie or rig the knot.

The *standing part* (or *end*) of the rope is the section not actively used to form the knot or rigging.

The *running end* (or simply the *end*) is the free end of the rope.

A *line* is a rope in use. For example, a rope used to rappel is a rappel line.

A *bight* of rope is formed when the rope takes a U-turn on itself so that the running end and standing end run parallel to each another. The U portion, where the rope bends, is referred to as the *bight*.

A *loop* of rope is made by crossing a portion of the standing end over (or under) the running end. Note that a loop closes, as compared to a bight. Thus many knots that

form a loop from a bight in the standing part of the rope are named *something on a bight*, such as *figure 8 on a bight*.

The *tail* of a rope is the (usually short) unused length of rope that is left over once the knot is tied.

1709

Figure 72-7 Figure-8 knot.

Figure 72-8 Overhand knot.

Stopper Knot.

A stopper knot is often used in rappelling. Before an end of the rope is thrown down for the rappel, a stopper knot is tied into the end to prevent the rappeller from rappelling off the end should the rope not reach the ground. Stopper knots are also used in other applications to perform a similar function.

The most common stopper knot is a figure 8 ([Figure 72-7](#)). When two ropes are used in tandem, the stopper knot should be tied into both lines together. A simple overhand knot ([Figure 72-8](#)) may also be used for this

Figure 72-9 Double bowline.

purpose, but its relatively low bulk makes it less desirable than a figure 8.

End-of-Line Knot.

Perhaps the most common use of a knot is to make a loop in the end of a rope to anchor, tie in, or attach the rope to something. Borrowed from mariners, bowlines have been used by mountaineers for years. However, this knot can "capsize" into a slipknot quite easily when the tail is pulled; therefore the "double bowline" (or high-strength bowline) is preferred ([Figure 72-9](#)).

Many people prefer to use forms of the figure 8 for multiple applications on the theory that they have to learn only one knot. This may prove limiting to a technician who would like to become a rope professional. Some people feel that the figure 8 is easier to tie and easier to check than other knots. In truth, the redundant nature of the figure 8 retrace can make it deceiving to visually inspect, a factor that has resulted in accidents.

Midline Knot.

Knots are often used to form loops in the middle of the rope, for clipping into, for grasping, or for bypassing a piece of damaged rope. A figure 8 on a bight ([Figure 72-10](#)) is often used for this purpose and works well as long as the load is attached to the bight. However, if the rope below the knot is loaded, the knot deforms and weakens.

More preferable by far is the butterfly knot ([Figure 72-11](#)). The butterfly can be pulled effectively either from the loop or from below the knot without negative effect. Caution must be taken with this knot, however, because if the loop is not big enough and not loaded, it can pull out under tension.

Knots To Join Two Ropes.

Tying a knot that will not untie itself is very important when joining two ropes, particularly since the knotted ends are unlikely to be in a place where they can be constantly monitored. The overhand bend is proclaimed by many in the climbing

Figure 72-10 Figure 8 on a bight.

Figure 72-11 Butterfly knot.

Figure 72-12 Double fisherman's bend.

community to be the preferred choice for joining two ropes. However, this knot may untie while in use and is not deemed secure enough for rescue purposes. Instead, the more secure double fisherman's bend ([Figure 72-12](#)) should be used. This bend is very effective for joining

Figure 72-13 Double-sheet bend.

Figure 72-14 Single-sheet bend.

ropes of relatively equal diameter. Care should be taken to ensure that the two halves of the bend nestle against each other and that there is enough tail protruding from the knot to keep the knot from unraveling. This knot is also used to join two ends of a short length of cordage for use as a Prusik (see Hitches).

When ropes of unequal diameter are joined, the double-sheet bend ([Figure 72-13](#)) is a more effective tie. This is a bulkier alternative, and although perhaps not quite as strong, it can be easier to untie and in the case of joining ropes of different diameters, is preferred.

Knot Safety

Every knot should be checked (preferably by someone other than the person who tied it) to ensure that it is tied properly and monitored at intervals thereafter. Many knots have a tendency to loosen, and some can even change forms, for instance, into a slipknot.

A safety knot can help prevent mishaps. A safety knot is an overhand knot ([Figure 72-14](#)) or barrel knot ([Figure 72-15](#)) tied into the tail of the rope after the knot is tied. This safety knot is placed to keep the knot from deforming or unraveling.

1711

Figure 72-15 Barrel knot.

Figure 72-16 Prusik hitch. **A** to **C**, Tying sequence for the Prusik knot. **D**, Two-wrap Prusik knot. **E**, Three-wrap Prusik knot.

Hitches

Hitching refers to a method of tying a rope around itself or an object in such a way that the object is integral to the support of the hitch. Hitches are seldom used in rescue and should be considered for use only by a skilled technician because there are severe consequences when a hitch comes untied. Specifically, the disintegration of a hitch results in immediate release of whatever load it is holding.

One of the most commonly used hitches is the Prusik hitch ([Figure 72-16](#)). A Prusik is a sliding hitch by which a cord can be attached to a rope and slid up and down the rope for positioning. However, under tension, the hitch will not slide. A Prusik is created by tying a length of cordage into a loop by means of a double fisherman's bend. Wrapping

the loop around the main rope and through its own loop two or three times and then pulling it tight forms the hitch.

Another fairly common hitch used in climbing and rescue applications is the clove hitch. This hitch can be useful when trying to shorten the distance between two objects, such as the climber's belay and the climber or the litter rail and the rescuer.

Figure 72-17 Trucker's hitch.

No discussion of knots would be complete without mention of the trucker's hitch, useful for pulling a cord tight across something, such as a load in the bed of a pickup truck (hence the name), or securing a patient snugly into a litter ([Figure 72-17](#)).

KNOT AND ROPE STRENGTH

Knots inevitably reduce the strength of a rope to some degree. Knot strength is affected by the tightness of bends as well as by the "pinching" effect that a knot has on itself.

The strength of any given knot is directly proportional to the strength of the material into which it is tied. Knot strengths are usually expressed in terms of "efficiency ratio." That is, a knot rated at 85% efficiency is said to maintain about 85% of the reported breaking strength of the rope.

Some individuals and agencies have reported that any knot reduces the strength of a rope by at least 50%. This information is erroneous because the efficiency of any knot depends on which knot is used, which rope it is tied into, whether it is tied correctly, and how it is cared for. Most knots recommended for use in wilderness rescue reduce the strength of a typical rescue rope to no less than 65% of that rope's minimum breaking strength. Most commonly used knots are even more efficient, in the range of 80%.

Unfortunately, accurate data on knot efficiencies are hard to find. Comprehensive testing that takes into account statistically significant sampling, differences between rope fibers, construction and diameter, static vs. dynamic loading, and other variables is virtually nonexistent.

1712

Figure 72-18 A and B, Clove hitch. C, Clove hitch with draw loop for temporary attachment.

The following data, taken from many different sources and reflecting limited testing, should be referenced for trend information only.

The relative breaking strength of kernmantle design ropes with knots follows:

Double fisherman's bend	65%–70%
Bowline	70%–75%
Figure 8 on a bight	75%–80%
Overhand knot	60%–65%

The best way to know the strength of a knot on a given rope is to actually test the type of knot you use on the types of rope you use and test enough samples using statistical analysis to provide a reasonable margin of error.

ADDITIONAL KNOTS

See [Figure 72-18](#) , [Figure 72-19](#) , [Figure 72-20](#) for additional knots.

Figure 72-20 Round turn and two half-hitches.

LEARNING MORE ABOUT ROPES AND KNOTS

For more information on using ropes to move patients, we suggest the second edition of *High-Angle Rescue Techniques* by Hudson and Vines, supplemented by training through a respectable course. A good basic vertical class on rappelling and ascending a rope requires a minimum of 2 to 3 days. After a basic rope skills class is completed, regular practice is required to maintain proficiency. Many excellent advanced classes in patient movement by rope or vertical rescue are offered. Figure on at least a week of training for a beginning class on rope rescue.

Chapter 73 - Wilderness Navigation Techniques

Steven C. Carleton

Many environmental illnesses occur as a consequence of becoming lost. Even well-prepared individuals may suffer hypothermia, heat stroke, frostbite, immersion foot, sunburn, dehydration, starvation, and a variety of other conditions if they become separated from the resources of their expedition or have an unanticipated extension of their time outdoors. This chapter discusses use of the magnetic compass for route finding, application of celestial navigation techniques for determination of direction and position, navigation with the global positioning system (GPS), and use of alternative methods for recovering when lost.

All of navigation boils down to two processes: determination of direction and establishment of position. In the wilderness setting the determination of direction and fixing of position are challenging. Generally, routes and landmarks are provided by a map, but local knowledge from memory may have to suffice. Usually, direction is derived from a magnetic compass, but other methods of direction finding can be exploited when the compass is forgotten, lost, damaged, or unreliable. Generally, *lines of position* (LOPs) are established by trails or by bearings to identifiable landmarks; however, shorelines, firebreaks, power lines, altimeter readings, and relative bearings to celestial bodies or radio sources can substitute. Finally, position can be fixed through the use of technologies such as GPS or with the time-tested methods of celestial navigation and triangulation of bearings. None of these navigational techniques is prohibitively expensive or so equipment-intensive as to be incompatible with a hiker's kit. Each method requires an understanding of its practice and limitations. Nothing substitutes for preparation, but effective wilderness navigation can be practiced using nothing more than the clues offered by the environment and the wits of the navigator.

COMPASS NAVIGATION AND DEAD RECKONING

The directional properties of lodestone (magnetite) were recognized by a variety of civilizations in ancient times. References to the use of a directional magnetized needle at sea appear in Chinese literature dating from the twelfth century. Descriptions of the magnetic compass in European writings followed in the thirteenth century, by which time it was noted that a needle stroked on lodestone pointed to the vicinity of the North Star.^[1] ^[29] Discovery of the magnetic compass was a seminal event in the exploration of the planet; the compass allowed reasonably accurate steering in all weather and permitted development of a fundamental process in navigation, the process of *dead (deduced) reckoning*. Dead reckoning is the estimation of current location based on knowledge of the direction, rate, and time of travel from a known starting point. Whenever traveling in the wilderness, dead reckoning should be practiced so that a general awareness of position is never lost. Estimates of time of travel, rate of travel, and direction of travel should be recorded whenever possible.

Magnetic Dip, Deviation, and Declination

The directional properties of the compass result from the interaction between magnetized iron in the compass needle and the magnetic lines of force generated by metals in the Earth's core. These lines of force have vertical and horizontal components. The vertical component is termed *magnetic inclination*, or *dip*. Dip causes a compass needle to incline downward from horizontal, potentially to a degree that interferes with the ability of the needle or card to pivot freely. Dip is 90° at the magnetic poles and 0° at the magnetic equator. Most modern compasses are manufactured to compensate for the average dip likely to be encountered in the region of intended use. Others allow a small weight to be moved along the indicator needle to compensate for dip in any region of use.^[27]

The horizontal component of the magnetic lines of force causes the compass needle to point to the Earth's north magnetic pole. Unfortunately, the Earth's magnetic and geographic poles do not correspond in location, and the Earth's magnetic lines of force are not straight lines but meander in an irregular fashion dictated by irregularities in the density of the core. The irregular directionality of the Earth's magnetic field is called *magnetic declination*. The compass needle is also influenced by local magnetic forces. These forces may result from natural sources such as ore deposits, or from artificial sources such as ferromagnetic metals in vehicles, equipment, and clothing fasteners. The displacement of the compass needle resulting from local magnetic influences is termed *deviation*. As a result of magnetic declination and deviation, compasses point to geographic north only when used with care in selected locations. In general, compasses

point northward but not exactly due north.

Direction in compass navigation is expressed in three ways: (1) *true direction*, or direction measured in

1714

reference to the Earth's meridians and geographic poles; (2) *magnetic direction*, or direction measured in reference to the Earth's magnetic poles; and (3) *compass direction*, or direction as measured by the magnetic compass. Magnetic direction varies from true direction by the sum of declination and deviation. Compass direction varies from magnetic direction by the quantity of deviation.^{[5] [22]} The definitions of magnetic and compass direction point out the necessity for minimizing preventable sources of compass deviation when taking bearings. For practical purposes, when preventable sources of deviation are minimized and the compass is used with caution, magnetic direction and compass direction can be considered the same.

Wandering lines of points with equal magnetic declination can be graphed on representations of the Earth's surface. These are called *isogonic lines*. Lines representing points on the surface of the Earth where the magnetic declination is zero, and magnetic north and true north are aligned, are termed *agonic lines*. In the Americas an agonic line follows a relatively straight, slanting course extending from the east coast of Victoria Island in north-central Canada through western Lake Superior, along the east coast of Florida, and traversing South America from the Gulf of Venezuela to the southeastern coast of Brazil. At locations east of the agonic line, the compass needle declines to the west (counterclockwise) of true north; at points west of the agonic line, the compass needle declines to the east (clockwise) of true north. By convention, magnetic declination is given a positive sign when east and a negative sign when west (Figure 73-1 (Figure Not Available)). Declination is quantified

Figure 73-1 (Figure Not Available) Schematic representation of North America showing declination at various locations as the difference between true north ("N" on the compass rim) and magnetic north (tip of the compass needle). (From Seidman D: *The essential wilderness navigator*, Camden, Me, 1995, Ragged Mountain Press.)

as the number of degrees of arc between true and magnetic north.

For example, in southwestern Ohio, the current magnetic declination is negative 4.5°, or 4.5° west. This means that a compass needle actually points 4.5° to the west of true north, and that the true bearing given by the needle is 355.5°. When the needle is aligned to 360° on the compass rim, any magnetic bearing taken with a compass will be 4.5° greater than the true bearing. To correct from magnetic to true, 4.5° must be subtracted from any indicated magnetic bearing.

The mnemonic "declination east, compass bearing least; declination west, compass bearing greatest" may be helpful in converting magnetic direction to true direction when taking a bearing. Restated, to convert from magnetic to true while taking a bearing from

the compass, add east declination to the compass bearing, or subtract west declination from the compass bearing. If converting from a true bearing taken from map to a magnetic bearing on the compass, subtract east declination from the compass bearing, or add west declination to the compass bearing. The interconversion between magnetic and true bearings is an essential skill in compass navigation. Failure to recognize the relationship will result in significant errors when following a map route by compass because directional references on the map are based on true direction. At a location where the magnetic declination is 10°, travel over a straight course derived from a map and guided by compass bearings will result in a 0.18-mile error for each mile traveled if the declination is not considered.^[14]

Magnetic declination for any location can be determined by reference to the *Isogonic Chart for Magnetic Declination* produced every 5 years by the United States Geologic Survey (USGS). In the United States, magnetic declination varies from +23° in Washington state to -22° in Maine ^[23] (see Figure 73-1 (Figure Not Available)). On standard USGS 7 ½-minute and 15-minute squares, magnetic declination is indicated by a pointer next to the pointer indicating true north at the bottom of the map. Without recourse to an *Isogonic Chart*, declination for any location in the Northern Hemisphere can be empirically determined with reasonable accuracy by comparing the magnetic bearing of north with the true bearing as indicated by a line pointing to the star Polaris. Polaris lies up to 45 minutes of arc (0.75°) away from true north at most times of day, but this offset is negligible for wilderness navigation situations. Declination at any location also can be determined by comparing the magnetic bearing of a prominent landmark with the true bearing between the observer's known location and the location of the landmark as read from a map.^[3]

Compass Types

The three compass types used in land navigation are the fixed-dial compass, magnetic card compass, and

baseplate compass ([Figure 73-2](#)). The simplest compass is the fixed-dial, which utilizes a magnetized needle balanced on a pivot and enclosed in a case that is graduated around its periphery into 360°. The magnetic card compass utilizes a magnetized needle or wire fixed to a circular card that is graduated around its periphery from 0° to 360°. The housing of the compass is marked with a line, the lubber line, that allows magnetic bearings to be determined when the line is pointed at an object of interest. The lensatic compass used by the military, which has a lens for magnification of the compass card and sights for alignment to distant objects, is a magnetic card compass. The most useful compass for land navigation is the baseplate compass,^{[14] [17] [25] [28]} which consists of a fixed-dial compass (or capsule) mounted to a baseplate in a manner that allows the capsule to rotate in relation to the baseplate. The baseplate is marked with a line used to indicate the direction of travel. This line functions in a manner identical to the lubber line of the magnetic card compass. The capsule of the compass has an orienting arrow inscribed on its lower surface that points to the graduation

denoting north on the capsule rim. On different models, this graduation may be labeled "0°," "360°," or "N." Rotation of the capsule such that the compass needle is superimposed on the orienting arrow and points to "N" on the capsule rim allows the user to easily read the magnetic bearing indicated by the direction-of-travel line. As long as the direction-of-travel line is followed and the needle remains superimposed on the orienting arrow, the user is assured of maintaining the desired magnetic bearing during travel.

Many baseplate compasses allow the orienting arrow to be adjusted relative to the rim of the capsule to compensate for magnetic declination. When this feature is present, the orienting arrow is rotated such that

Figure 73-2 The three basic compass types. From left to right: Fixed dial compass, magnetic card compass, baseplate compass. Note the deviation in indicated north resulting from local magnetic influences.

the "N" graduation on the capsule rim points to true north when the orienting arrow points to magnetic north. When the adjusted compass is rotated to align the needle with the orienting arrow, bearings as read on the capsule rim will represent true, rather than magnetic, bearings. Baseplate compasses have other features particularly suited for use with a map, including plotting scales, a straight edge, and often a protractor and magnifier.^[28]

Correction for declination when using a fixed-dial or magnetic card compass requires addition or subtraction of the declination, as appropriate, from the magnetic bearing indicated by the compass rim or lubber line.

Compass Use

The magnetic compass is most useful for determining the cardinal directions and for establishing bearings for use in route finding and back-bearings for use in returning to a known starting location. A *back-bearing* is the reciprocal of the bearing followed on the out-bound leg of a journey (out-bound bearing minus 180°). Any route can be subdivided into legs that can be defined by magnetic bearing lines. Ideally, each leg should pass between prominent, identifiable landmarks that will remain recognizable even in the dark or in poor weather. However, even when weather or lighting conditions prevent visual acquisition of the landmark from a distance, careful compass work should permit the user to reach the objective. Early in the course of travel over each leg, the observer should visually check the back-bearing of the direction of travel to become familiar with the view of the starting point as it will appear on the return journey. If possible, the bearing and back-bearing of each leg of a route, and the landmarks

defining each leg, should be recorded on paper rather than trusted to memory.

Use of the compass in this manner permits the user to easily return to the desired direction of travel if an obstacle to the intended route is encountered. The course around the obstacle is recorded as a series of legs of known direction and estimated (by stride) length. When permitted by the terrain, right-angle detours are the simplest to follow. The user returns to the intended route by traveling the reciprocal of the course of the detour for the same lateral distance as that required to bypass the obstacle^[5] ([Figure 73-3](#)). Return to the intended course is greatly augmented by using *natural ranges*. A natural range is formed by two landmarks lying along the same bearing line, one of intermediate distance from the viewer and one of greater distance—for example, a large tree or rock formation several kilometers distant, and the silhouette of a hill or mountain on the horizon. As the traveler deviates from the intended course, the near and far landmarks will fall out of line. When the traveler returns to the

1716

Figure 73-3 Use of the compass to return to an intended route when faced with an obstacle. A course 90° to the intended course is walked for a known number of steps, the obstacle is bypassed, and the original course is regained by walking the reciprocal course of the initial detour for the same distance. (From *Department of the Army: Map reading and land navigation, Field Manual 21–26, Washington, DC, 1987, Headquarters, Department of the Army.*)

intended route, the objects forming the natural range will return to alignment.

Use of a compass with a map allows the user to orient the map to the environment and relate bearings taken from the map to bearings measured with the compass. Correction for declination is essential when the compass is used for this task if true bearings are to be used in plotting a route. However, there is no absolute need for the use of true bearings in navigation; it is only important that the map and compass agree. Agreement can be accomplished either by correcting the compass to the map or by correcting the map to the compass. If a baseplate compass with declination adjustment is used, it is simplest to correct the compass to the map and use true bearings for all subsequent travel. With any other type of compass, it may be easier to use magnetic bearings exclusively. If the declination is known or can be determined observationally, magnetic meridians can be drawn on the map to be used in place of the true meridians represented by the map margins. These magnetic meridians will form an angle with the true meridians equal to the declination angle. A map modified in this manner permits magnetic bearings, rather than true, to be taken from the map for use in following a course. The internal consistency of this method is often much less confusing than the method requiring conversion between true bearings and compass bearings. The choice between the use of true or magnetic bearings should be made in advance of travel. Plotting magnetic meridians on a map requires a pencil, straight edge, flat surface, and

protractor, items unlikely to be available in a field emergency. ^[27] ^[28]

To orient a map with a baseplate compass corrected for declination, the compass capsule is rotated such that "N" on the capsule rim is aligned to the direction of travel arrow. An edge of the baseplate parallel to the direction of travel arrow is then placed on one of the vertical borders of the map. The map, with the compass in place, is then rotated until the compass needle is superimposed on the orienting arrow on the base of the capsule. True north on the map is now aligned with true north on the planet.

To orient a map that has been modified with magnetic meridians using an uncompensated baseplate compass, the compass capsule is rotated until "N" on the capsule rim aligns with the direction-of-travel arrow. An edge of the compass parallel to the direction-of-travel arrow is placed on one of the magnetic meridians plotted on the map. The map, with the compass in place, is rotated until the compass needle is superimposed on the orienting arrow. True north on the map now corresponds to true north in the surrounding landscape. ^[14] ^[25] ^[27] ^[28] If an uncompensated compass of other type is used, the north-south line of the compass face or lubber line is superimposed on a magnetic meridian, and the map and compass are rotated in concert until the indicator needle points to "N."

Once a map is oriented to the environment, back-bearings from landmarks that are visible both on the map and in the landscape can be used to obtain a positional fix by *resection*, or *triangulation*. ^[25] Each back-bearing

1717

Figure 73-4 Establishing a magnetic fix by crossing the back bearings from two prominent landmarks. This process is known as resection.

from a landmark represents an LOP that can be plotted on the map. The point of crossing of two or more LOPs fixes the position of the observer ([Figure 73-4](#)). Alternatively, the intersection between the LOP represented by a bearing line and a shoreline, river-bank, road, firebreak, or celestial position line can be used to fix position on a map.

Make-shift Compasses

A field-expedient compass can be fabricated with relative ease. Items containing iron, nickel, or cobalt are suitable for use as an indicator needle. Iron in the form of a steel

needle, pin, wire, staple, or paper clip is most commonly available. Most of these items are magnetized as purchased. If not, they can be magnetized by stroking them on a magnet salvaged from an electric motor or radio speaker, on a magnetized screwdriver or similar item, on a piece of silk, or on a dry cell battery terminal. A dry cell also can be used to magnetize a needle by wrapping an insulated wire tightly around the needle and connecting the ends of the wire to the battery terminals. Expect sparks and heat. Trial and error will often yield a suitable magnetizer. The indicator needle is floated in water by placing it on a wood chip, leaf, slip of paper, or small piece of cork or closed-cell foam. The container, which may be the cupped palm of the hand or a puddle, should be protected from the wind ([Figure 73-5](#)). A compass so constructed will reliably indicate a magnetic north-to-south line. Determination of directions may require external cues, such as the general direction of sunrise or sunset.

Figure 73-5 Makeshift compass constructed from a plastic cup, straight pin, and foam packing peanut. Note the correspondence between north as indicated by the makeshift device and the commercial compass.

CELESTIAL NAVIGATION

Celestial navigation exploits the predictable relationship between the apparent positions of selected celestial bodies and the surface of the earth. The influence of celestial navigation on world history is immense. Millennia before European culture conceived of celestial navigation as a means for facilitating exploration, commerce, and military domination of the seas, the cultures that populated the numerous discreet island archipelagoes of the Pacific Basin were making open ocean voyages over thousands of miles guided by memorized "star paths."^[1] The use of simple altitude measuring devices (the Greek gnomon, Arab kamal, and Chinese stretch board) for the qualitative determination of latitude was practiced by mariners in antiquity. As the Age of Exploration dawned, competing governments of Western Europe devoted enormous energy to systematization of celestial navigation, funding legions of astronomers in the development of coordinate systems and accurate tables of stellar, solar, lunar, and planetary positions. Instruments such as the mariner's astrolabe, quadrant, octant, and sextant permitted accurate and reproducible quantitative measurement of the altitude of celestial bodies, and accurate clocks became available to permit the ready determination of longitude.^[1] ^[29]

Celestial navigation has its greatest utility and easiest application at sea. Standard celestial practice depends on the availability of a sea horizon as a reference point for the measurement of altitude. The horizon reference for land navigation is necessarily artificial (a plumb bob, bubble level, or level reflective

1718

surface). Positions resulting from celestial fixes, even with scrupulous technique, are only approximations of the navigator's actual position. Errors of several miles are common. This is of little consequence in the open ocean, even as landfall approaches; the target destination is generally large enough to be seen from many miles distant. This degree of imprecision may prove troublesome on land, but the accuracy of celestial navigation should still suffice for most wilderness situations.

Although developed for use on trackless seas, celestial navigation has a long and rich tradition of use on land. Lewis and Clark established the positions of landmarks during their exploration of the American West by celestial observation. Various expeditions that led to the discovery of the North and South Poles depended entirely on celestial observations for confirmation of position and direction. Celestial navigation techniques can be applied in a wilderness setting at a variety of levels. Traditional navigation, in which sextant observations lead to the fixing of terrestrial position, can be accomplished

with relatively little equipment but requires considerable preplanning. Simplified celestial techniques requiring little or no equipment are well suited to field-expedient navigation and can provide accurate directional information in the absence of a compass. In particular, an understanding of the movement of the sun and several prominent stars can allow accurate route finding without recourse to technology. To understand the relationship between the position of a celestial body and the position of an observer on Earth, it is necessary to discuss the various coordinate systems that are used to describe terrestrial position, celestial position, and the appearance of the sky from the Earth's surface (horizon coordinate system).

Figure 73-6 Meridians of longitude including the Prime Meridian, and parallels of latitude as measured north and south of the equator in degrees of arc from the center of the Earth. (From *Department of the Air Force: Survival-training edition, Manual 64-3, Randolph AFB, Texas, 1969, Air Training Command.*)

Terrestrial Coordinates

In the terrestrial coordinate system, the earth has a North Pole and a South Pole that define its axis of rotation. This axis passes through Earth's center. Any plane that passes through the center of the Earth describes a circle on the surface called a *great circle*. The equator is the great circle described by the plane that passes perpendicular to the earth's axis. The great circle of a plane that contains the Earth's axis is termed a *meridian*. Meridians always run due north and south and converge at the poles. The *Prime Meridian* is the great circle that passes through Greenwich, England. Greenwich was assigned the Prime Meridian by treaty in 1884, in recognition of the work on astronomy and navigation performed at the Greenwich Royal Observatory.

Every point on the Earth's surface lies on a meridian. The angular measurement, or arc, between the Prime Meridian and the meridian of any other point on the planet's surface is the *longitude* (?) of that point. Longitude is measured in degrees, minutes, and seconds of arc, east or west of the Prime Meridian, from 0° through 180°. The angular measurement between the plane of the equator, as measured north or south from the center of the earth to a point on the surface, is the *latitude* (L) of that point ([Figure 73-6](#)). All points at the same latitude form a *parallel* of latitude. Latitude is measured in degrees, minutes, and seconds of arc from 0° through 90° north or south. As such, the latitude of the equator is 0°, whereas that of each pole is 90° north or south, respectively. Every point on the surface of the Earth is defined by a specific longitude and latitude.

A *nautical mile* (1852 m, 6076 feet, or 1.15 statute miles) is the distance on a great circle that subtends an angle of 1 minute of arc as measured from the center of the Earth. A degree of arc (60 minutes of arc) is thus

60 nautical miles, and 1 second of arc is equal to about 100 feet. It must be recognized that 1 minute of latitude will always equal 1 nautical mile, whereas 1 minute of longitude will only equal 1 nautical mile at the equator. At all points north or south of the equator, 1 minute of longitude will be less than 1 nautical mile, owing to the convergence of the meridians toward the poles.

Longitude bears a special relationship to time. Within reasonable standards of accuracy, the earth rotates once about its axis in 24 hours. As such, our planet moves through 360° of longitude in 24 hours, or 15° each hour, or 1° for every 4 minutes of time. It is this fact that establishes the conventions by which sundials work, clocks run, and time is defined. It also forever links the modern practice of celestial position finding to the accurate keeping of time.

Celestial Coordinates

To a terrestrial observer the sky appears to be an immense hollow sphere with the Earth at its center, and the stars painted on its inner surface. The sphere rotates about the Earth once daily. The sun, moon, and planets wander across the background of stars on concentric spheres of their own. This is exactly the conception of the universe forwarded by Ptolemy in the second century and is termed the *geocentric model*. This theory was highly popular with the Catholic Church; challenging it led to the burning of scores of intellectuals during the Spanish Inquisition. It held sway until the sixteenth century, when it was replaced, gingerly, by an equally incorrect heliocentric (sun-centered) model. The geocentric model, although false, is a useful construct for ordering the heavens and is the model used in the definition of celestial coordinates.

The celestial coordinate system plays off of the terrestrial coordinate system. The terrestrial poles are projected outward to the surface of the imaginary celestial sphere to form the north and south celestial poles. The terrestrial equator is similarly projected outward to form the celestial equator, or *equinoctial*. The celestial correlate to latitude is *declination* (unrelated to magnetic declination in compass use). The declination of a celestial body is the angle measured from the center of the earth (and geocentric universe) north or south of the celestial equator from 0° through 90° of arc. Declinations north of the celestial equator are positive (+), whereas those south of the celestial equator are negative (-). The declinations of the celestial poles are thus +90° and -90°, respectively, whereas that of the celestial equator is 0°. The declinations of the sun, moon, four navigational planets (Venus, Mars, Jupiter, and Saturn), and 57 navigational stars are listed in the daily pages of the *Nautical Almanac*.^{[7] [13]}

The celestial correlate to longitude is less intuitive and requires some explanation. Projections of terrestrial meridians onto the celestial sphere form *celestial meridians*. Projection of the Greenwich meridian onto the celestial sphere forms the Greenwich celestial meridian. Projection of an observer's meridian onto the celestial sphere forms the local celestial meridian ([Figure 73-7](#)). A meridian on the surface of the celestial sphere that contains a celestial body and the celestial poles and is perpendicular to the

celestial equator is termed the *hour circle* of that body. Hour circles converge toward the celestial poles in a manner identical to meridians on Earth. As the celestial sphere rotates about its polar axis, the hour circles of all celestial bodies appear to rotate above a terrestrial observer, rising in the east, sweeping overhead, and setting in the west. A reference hour circle on the celestial sphere called the *first point of Aries*, or the hour circle of Aries, substitutes for the terrestrial Prime Meridian. The first point of Aries is represented by an hour circle that intersects the celestial equator at the point at which the sun crosses it at the moment of the vernal equinox. The angular measurement between the hour circle of a celestial body and the Greenwich celestial meridian is defined as the *Greenwich hour angle* (GHA) of the body. GHA is the celestial equivalent of longitude and is measured westward from the Greenwich celestial meridian from 0° through 360°. The Greenwich hour angle of Aries (GHA^{Aries}) is the angle between the Greenwich celestial meridian and the hour circle of Aries at any given second in time. The GHAs for Aries and for the sun, moon, Venus, Mars, Jupiter, and Saturn are listed for each hour of

Figure 73-7 Diagram showing the celestial meridian of an observer on the Earth's surface, and the celestial meridian corresponding to the hour circle of an observed star. (From Bowditch N: *The American practical navigator. An epitome of navigation*, Washington, DC, 1984, Defense Mapping Agency Hydrographic/Topographic Center.)

1720

each day of a year in daily pages of the *Nautical Almanac*. Interpolation tables permit determination of hour angles for each second of the year.^{[13] [22]}

The GHAs for the 57 navigational stars are defined by their predictable and nearly constant relationship to the hour angle of Aries. The angular measurement between the hour circle of Aries and the hour circle of any of the navigational stars is called the *sidereal hour angle* (SHA) of that star. The GHA of each of the navigational stars is thus equal to the sum of the hour angle of Aries and the SHA of the star in question ($GHA^{\text{star}} = GHA^{\text{Aries}} + SHA^{\text{star}}$).

In the practice of celestial navigation the hour angle of a celestial body is ultimately defined in reference to the observer's local celestial meridian. The angular measurement between the local celestial meridian and the hour circle of a body is the *local hour angle* (LHA) of that body. LHA, like GHA, is measured westward from the local celestial meridian from 0° through 360°. The LHA of a celestial body equals the GHA of the body plus the observer's longitude if east, or minus the observer's longitude

if west ($LHA = GHA + \text{east}$? $LHA = GHA - \text{west}$?). When a celestial body is on an observer's meridian, its GHA equals the longitude of the observer's position.^[1]

Horizon Coordinate System

The horizon coordinate system defines celestial position from the point of view of an Earth-bound observer. The point on the celestial sphere directly over the observer's head is the *zenith*. The point on the celestial sphere directly beneath the feet of the observer is the *nadir*. The zenith and nadir lie on a line that includes the observer's terrestrial position and the Earth's center. The plane that passes through the center of the Earth perpendicular to this line is the observer's *celestial horizon*. The celestial horizon lies parallel to the observer's visible horizon. Any great circle on the celestial sphere formed by a plane passing perpendicular to the celestial horizon is termed a *vertical circle* ([Figure 73-8](#)). Vertical circles converge at the observer's zenith and nadir in a manner analogous to the convergence of the terrestrial and celestial meridians at their poles. Three of the infinite number of potential vertical circles for any surface position are of particular importance: (1) the *principal vertical*, that vertical circle lying on the observer's celestial meridian; (2) the *prime vertical*, that vertical circle passing through points due east and west of the observer; and (3) the vertical circle containing a celestial body of interest ^[13] ([Figure 73-8](#)).

The angular measurement between an observer's celestial horizon and a celestial body is the *altitude* of that body. Altitudes are expressed in degrees, minutes, and seconds of arc from 0° (the horizon) through 90° (the zenith). In the traditional practice of celestial navigation, altitudes are measured using a sextant, octant, or

Figure 73-8 Schematic representation of the horizon coordinate system showing the observer's zenith and nadir, the celestial horizon, the prime and principal vertical circles, the elevated pole (P_n), and the altitude and azimuth of the body observed. (From Hobbs RR: *Marine navigation: piloting and celestial and electronic navigation*, ed 4, Annapolis, Md, 1998, Naval Institute Press.)

quadrant. Altitude, as measured by an instrument in reference to the horizon, is termed *sextant altitude* (H_s), regardless of the type of instrument used. H_s , once corrected for various atmospheric and geometric factors, is termed *observed altitude* (H_o). The corrections to be applied are tabulated in the *Nautical Almanac*. The true altitude of a body can be calculated for any given terrestrial position at any instant of time through application of spherical trigonometry. This altitude is termed *calculated altitude* (H_c).^[1]

The other determinant of the observed position of a celestial body is the angular measurement along the celestial horizon between true north and the vertical circle including the body. This angle is termed the *azimuth* (Z_n) of the body and is measured

clockwise from 0° through 360° (see [Figure 73-8](#)).

CELESTIAL LINES OF POSITION

Celestial Methods for Latitude

The simplest celestial LOP is derived from the *noon sight*, or *meridian altitude of the sun*. This method dominated celestial navigation from the seventeenth century the late 1800s. The noon sight is simple but inflexible. It is very adaptable to wilderness navigation, requiring minimal math and little equipment. The noon sight allows direct determination of latitude by measuring the altitude of the sun at the moment that it passes the observer's meridian. The instant of solar meridian passage is termed *local apparent noon* (LAN), and is that moment when the sun achieves its greatest altitude.

1721

The sun is observed with the sextant for a brief period of time preceding LAN until the altitude ceases to increase and begins to fall. The maximum sextant altitude so determined is corrected using *Almanac* data to yield H_o , which is then converted to *zenith distance* (ZD). Zenith distance is the angular distance between observer's zenith and the body; thus, $ZD = 90^\circ - H_o$. The algebraic sum of ZD and the declination of the sun (from the *Nautical Almanac*) at the approximate time of observation equals the observer's latitude by the formulas below^[7] ^[18] :

1. $L = ZD + d$, when L and d have the same sign and $L > d$
2. $L = d - ZD$, when L and d have the same sign and $d > L$
3. $L = ZD - d$, when L and d have different signs

Since the declination of the sun changes very slowly on an hourly basis, accuracy is acceptable if the sun's declination is known for merely the approximate time of observation; exact time is not required. The noon sight requires only the sun's declination and precise altitude. Determination of latitude by meridian passage can be accomplished through observation of any celestial body of known declination, although observation is easiest with the sun.

Another extremely simple observation to determine latitude involves measuring the altitude of Polaris (also known as *a-Ursae Minoris*, the "Pole Star" or "North Star"). Polaris rotates about the true north celestial pole on a very short radius (between 44 and 45 minutes of arc in 1999). At two times each day, the altitude of Polaris will be equal to the altitude of the true pole, and that altitude will equal the latitude of the observer. The altitude of Polaris most closely approximates the altitude of the pole, and

thus latitude, when the constellations *Ursae Majoris* (the Big Dipper) and Cassiopeia are positioned as indicated by [Figure 73-9](#) . For the remainder of the day, there will be a predictable discrepancy ranging from 0 to 45 minutes of arc between the measured altitude of the star and the latitude of the observer. The *Nautical Almanac* has a brief table that corrects for this discrepancy, allowing an observer to determine accurate latitude by the altitude of Polaris at any time when the star is visible and a suitable horizon is available. The Polaris sight requires GMT to within several minutes, a precise measurement of altitude, and data from the *Nautical Almanac*.^{[1] [2]}

The latitude obtained by the noon sight or Polaris sight represents the simplest available celestial LOP. This line can be used to determine a fix if coupled with a sight that yields longitude or with another LOP obtained by any other method. In land navigation, this second LOP might represent a river, shoreline, road, trail, compass bearing, or radio bearing that crosses the determined latitude line at a single point.

Figure 73-9 Diagram indicating the appearance of the north circumpolar sky at the two times of day when the observed altitude of Polaris is equivalent to the latitude of the observer. (From *Department of the Air Force: Survival-training edition, Manual 64-3, Randolph AFB, Texas, 1969, Air Training Command.*)

Celestial Methods for Longitude

Following invention of the chronometer by John Harrison in 1735, longitude could be directly determined by measuring the altitude of any celestial body of known coordinates at a precisely known instant of time. This method, termed the *time sight*, revolutionized exploration but involves formidable mathematics. A simpler alternative exists that is readily adaptable to the wilderness setting. This traditional technique for establishing longitude is called the *equal altitude method*. The equal altitude method requires accurate timekeeping, the ability to measure altitude with precision, and data from the *Nautical Almanac*. At a convenient interval before the meridian passage of the body (1 to 2 hours), the altitude of the body is taken and the Greenwich Mean Time (GMT) is noted. The sextant is left at the altitude setting of the first observation. After the body passes the meridian, it is observed until it falls to the exact altitude of the first reading. The time is again noted. Meridian passage will have occurred at the midpoint between these two

times. The GMT of meridian passage is then known. At the moment of meridian

passage, the LHA of the body equals zero, and the GHA of the body (from the *Nautical Almanac*) equals the observer's longitude. In theory, the instant of meridian passage could be found by noting the moment the body reached maximum altitude, achieving the same result. This is highly inaccurate in practice because of the extremely slow rate of change of altitude in the minutes immediately surrounding LAN.^[18]

Altitude-Intercept Method

The observed position of a celestial body also can be reconciled with an observer's position on the Earth's surface through the application of spherical trigonometry. A *navigational triangle* can be constructed on the surface of the Earth that has as its vertices the nearest (or elevated) terrestrial pole, the assumed or estimated position of the observer, and the *geographic position* (GP) of the body being observed. The GP is that point on the surface of the earth that lies directly beneath the body at the instant of observation. The body lies at the zenith of an observer at the GP and has a measured altitude of 90° .

A second observer taking a simultaneous measurement of the altitude of the same body from a remote location finds the altitude to be less than 90° to an extent proportional to the distance between the site of observation and the GP. If the altitude of the body from the vantage of the second observer is 50° , that observer's position is $50^\circ \times 60$ nautical miles per degree, or 3000 nautical miles, from the GP of the body. The second observer's location lies somewhere on a *circle of equal altitude* for the body in question. A small segment of this circle, on a scale of dozens of miles, would appear as a straight line on a chart or map. This line is a celestial line of position.^[1] ^[18] The concept of the celestial LOP was developed by Thomas H. Sumner in 1837 in a moment of astonishing intellectual clarity during a gale at sea. Celestial LOPs were originally called "Sumner lines" in recognition.

Before the 1900s, navigational triangles were solved laboriously using logarithmic and trigonometric tables in a process called *sight reduction*. Currently, sight reduction can be accomplished in minutes through the use of published tables of solutions called sight reduction tables. Sight reduction yields the calculated altitude (H_c) and azimuth (Z_n) for the observed body as they should appear from the observer's assumed position. Armed with H_c and Z_n , the navigator then compares H_o with H_c . If the two are identical, the observer is on the LOP containing the assumed position. When the two altitude values vary, the difference represents the number of nautical miles between the LOP of the assumed position and the LOP of the actual position of the observer. The direction of this difference is given by Z_n . Whether the difference is toward or away from the observed body is neatly summarized in the mnemonics GOAT (greater observed angle, toward), and Coast Guard Academy (calculated greater, away). The results are plotted on a map or plotting sheet. Each observation reduced by this method yields a single, celestial LOP. With two observations of suitable bodies, two LOPs result that will cross. The crossing point is a fix, or the observer's actual position.

This graphical method of navigation is termed the *altitude-intercept method*. It was invented by a French naval officer, Marcq St. Hilaire, in 1875. The logic of the method is beautiful; the navigator assumes that he is somewhere that he knows he is not, then

proves how wrong he must be.^[2]

Sight reduction tables are published by the governments of the United States and United Kingdom and are available in varying degrees of detail. Inspection tables, such as *Hydrographic Office Publication Numbers 229 and 249 (H.O. 229 and H.O. 249)* allow solutions with minimal recourse to math; all possible solutions are available in the inspection tables, requiring only simple interpolations. Inspection tables tend to be large and bulky, but the few pages covering the latitudes of a planned expedition can be copied and carried with ease. Other tables are quite compact (e.g., *H.O. 211, H.O. 208, the S-Table*), some as few as 9 pages in length, but require serial additions or subtractions to yield a solution, increasing the possibility of error. A compact sight reduction table is included in commercial editions of the *Nautical Almanac*, eliminating the need to purchase and carry additional tables. Solution of the navigational triangle by formula and calculator is possible but beyond the scope of this chapter.

The altitude-intercept method of navigation is highly flexible but not intuitive. The mathematics are daunting, although the method can be used in a "cook-book" manner with success. The interested reader is referred to several of the general references for further details.^{[1] [7] [13] [18]}

Small, military surplus, aeronautical sextants with reliable artificial horizons are readily available and permit very accurate celestial altitude measurements on land. Small box sextants, which fit into a pocket, also can be used to accurately measure altitudes using a dish of water, oil, or mercury to provide a reflective artificial horizon ([Figure 73-10](#)). Any quartz wristwatch set to GMT with a known rate of error is sufficient to the task of time keeping. Copies of *Nautical Almanac* pages for the dates of a planned excursion provide all of the needed astronomical data, and other tables from the *Almanac* provide sight corrections and data for interpolation. The *Almanac* itself also can be carried. A map, plotting sheet, or lined paper and a pencil permit the resulting LOPs to be plotted in context

1723

Figure 73-10 A selection of portable altitude measuring devices for celestial navigation. Clockwise from top: box sextant, A-10 aeronautical sextant, pocket transit with clinometer. The box sextant requires a separate artificial horizon such as a reflective dish of water for land use. The A-10 sextant and pocket transit have intrinsic bubble levels. Use of the pocket transit requires averaging of multiple altitude measurements to achieve acceptable accuracy. A quarter is included in the image to provide scale.

Figure 73-11 A complete portable kit for celestial navigation. Clockwise from upper right: scientific calculator, pencil, A-10 aeronautical sextant, folded copies of almanac daily pages and sight reduction pages from H.O. 249, protractor/straight edge, plotting sheets, and topographic map. The sight reduction pages and calculator can substitute for one another. The topographic map and plotting sheets can substitute for one another, although the map is more useful for land navigation. Not included in the image is an accurate watch set to Greenwich Meridian Time. A quarter is included to provide scale.

to the area being traveled. The minimum required equipment is surprisingly portable and shown in [Figure 73-11](#) .

For practice, I routinely carry the following equipment on trips: (1) aeronautical sextant (the A-10 model, widely available, is the smallest and lightest), (2) the *Nautical Almanac*, (3) photocopies of *H.O. 249* pages covering the latitudes of the planned trip, (4) watch set to GMT, (5) pencil, (6) photocopied plotting sheet, (7) small protractor with a straight edge, and (8) pocket scientific calculator with various formulae on an index card (see [Figure 73-11](#)). Although forming the basis for considerable hilarity among companions, this equipment routinely allows determination of direction to within 2° and position to within 2 miles.

The Minimalist Celestial Fix

The training manual published by the U.S. military as *Air Force Manual 64-3*^[4] contains detailed instructions for fabrication of a "fishline sextant." This simple device, when used in conjunction with an accurate watch set to GMT, protractor, and limited *Nautical Almanac* information, allows the user to determine latitude by measuring the altitude of Polaris, and longitude by timing the meridian passage of overhead stars. Although I have not tested the accuracy or ease of use of this method, it has the necessary elements required to yield useful positional information and is claimed to allow determination of a fix with an accuracy of 10 miles. The reader is referred to this manual for specifics of the method.

CELESTIAL METHODS FOR DIRECTION FINDING

Shadow Methods

The axis of rotation of the Earth is inclined at about 23.5° from the orbital plane of the solar system. It is this phenomenon that results in the seasons, the variable path of the sun through the sky with each season, and the terrestrial definitions of the tropics, temperate zones, and Arctic and Antarctic zones. The apparent path of the sun is lower in the sky, and shadows cast by the sun are longer, at any given time of day in winter than in summer. A plot of the tips of shadows cast in daylight by a vertical object (a gnomon) on any given date results in a curved line called a *declination curve*. The declination curve is so-named because shadow lengths are proportional to the declination of the sun on the date of the plot. The shadows used in plotting a declination curve will be shortest at noon, when the sun is at its greatest altitude, and longest near sunrise and sunset. A family of declination curves can be plotted empirically for various dates and can then be used in subsequent years to predict shadow lengths for future dates and times. The shadows themselves can be plotted to indicate the direction of the sun, which will give the approximate time of day. This is the principle by which sundials were constructed before the discovery of trigonometry. A family of declination curves will be useful for any point on the Earth's surface near the same latitude as the location where they were plotted. The curves will not be accurate

1724

Figure 73-12 The Universal Pocket Navigator (UPN). Enter the Selector Table with arguments for the approximate date and the approximate latitude as determined from the background map. Stick a pin or toothpick vertically in the center line at the cross mark indicated by the Selector Table to serve as a gnomon. The tip of the gnomon should stand above the figure by the length indicated by the gnomon scale. Hold the figure horizontally, and rotate your body until the shadow of the tip of the gnomon lies on the appropriate lettered curve (from the Selector Table). The arrow now points north. (From Owendoff RS: *Better ways of pathfinding*, Harrisburg, Penn, 1964, The Stackpole Co.)

at more distant latitudes because the altitude of the sun changes with the latitude of the observer. This lack of universality can be overcome by moving the gnomon to compensate for changes in latitude. Since the advent of plane and spherical trigonometry, declination curves and gnomon positions can be calculated for any date and location. ^[26]

The sundial is most commonly used to tell time but also can be used as a sun compass to indicate direction. Shadows cast in the morning hours point westward, whereas those in the afternoon point eastward. The variation between the rising and setting points and due east or west are predictable for any date and latitude (see section on Amplitudes). The shortest shadow cast by the sun occurs at LAN and always lies on a due north-south line. Alternatively, a north-to-south line can be found by bisecting the angle between two points on a declination curve that are at equal distances from the gnomon. Knowing this, a sun compass can be constructed that indicates true direction with a high degree of accuracy whenever the shadow tip of the appropriately positioned gnomon lies on the declination curve for the approximate date of observation. Such a sun compass is included as [Figure 73-12](#).^[26] This sun compass has a scale to compensate for the latitude of the user. A copy of this sun compass, a pin or toothpick greater than 1 inch in length, and sunshine are all that are necessary to determine the cardinal directions with an accuracy greater than that commonly achievable with a magnetic compass ([Figure 73-13](#)).

In the absence of a copy of [Figure 73-12](#), the same principle can be applied to construct a sun compass on the fly. Any flat surface (e.g., a chip of wood, piece of

Figure 73-13 Use of the Universal Pocket Navigator to find north. The selector chart was entered with the date of October 25 and the assumed latitude of 40°, yielding declination curve "L" and gnomon position "14." Note the correspondence between magnetic north and north as indicated by the center line of the figure. The magnetic declination at the sight of observation was 4 ½° west. The UPN reading corresponds to true north.

bark, scrap of paper) is placed horizontally in the sun and a gnomon of convenient length is stuck in the surface in a vertical position. The tip of the shadow cast by the gnomon is marked at various times beginning shortly after sunrise, and a curve is traced between the marks. At some point the sun will pass the meridian, and the shadow will begin to lengthen again. A line between the base of the gnomon and the point of closest approach of the curve represents solar noon and runs due north to due south. Whether the shadow at noon points north or south will depend on whether the observer

Figure 73-14 A makeshift suncompass inscribed on a scrap of paper. The declination curve has been empirically determined by tracing a line through points representing the tip of the gnomon shadow at various times throughout the day. On subsequent days, rotation of the figure such that the shadow tip touches the curve will orient the line connecting the base of the gnomon to the point of closest approach of the curve to point north. (From Owendoff RS: *Better ways of pathfinding*, Harrisburg, Penn, 1964, The Stackpole Co.)

is in the Northern Hemisphere, the southern hemisphere, or the tropics. The actual direction indicated by the shadow is easily determined by noting the general direction of sunrise, which is on the eastward side of the sun compass. The remaining afternoon portion of the curve can either be completed freehand as a mirror image of the morning curve, or by continued observation and marking of shadow tips ([Figure 73-14](#)). On subsequent days the sun compass is reoriented to true north by rotating the horizontal surface until the tip of the gnomon's shadow touches the curve. A sun compass prepared in this manner is highly portable and remains accurate for many days until there is significant change in the latitude of the traveler or in the declination of the sun. New curves can be prepared on the same compass as needed.

Other methods of direction finding by shadows are significantly less accurate. The direction of travel of a shadow tip over the period of an hour or so will point generally eastward throughout the day.^[5] The accuracy of this method is degraded in direct proportion to the length of time before or after noon that the observations take place, and in inverse proportion to the declination of the sun. Errors of greater than 30° are possible when conditions are unfavorable, such as at higher latitudes and during winter when the path of the sun is low in the sky. However, errors incurred during morning hours tend to be canceled by reciprocal errors incurred during afternoon hours as long as the rate of change in latitude while traveling is relatively slow during the period of observation.^[26] The shortest shadow cast by a vertical gnomon through the course of the day lies on a north-south line at all latitudes. The point of closest approach of a declination curve to the gnomon may be difficult to accurately determine when the rate of change of the sun's altitude around LAN is slow. As an alternative method, a line bisecting the angle between any two shadows of equal length cast by a vertical gnomon lies on a north-south line at all latitudes.

An ordinary analog wristwatch or pocket watch can be used to give rough north-south direction using the shadow technique. Since a conventional watch has a 12-hour cycle of rotation, the hour hands rotates at 30° per hour, or twice the rate of the apparent angular movement of the sun. Thus, if the hour hand of the watch is aligned with the shadow of a vertical object (i.e., hand is pointing directly at the sun), the bisected angle between the hour hand and 12 o'clock on the dial yields a line that runs generally north to south. At times before 0600 or after 1800, the larger of the two possible angles between the hour hand and 12 o'clock should be used. This method is fraught with errors that increase in magnitude when the sun's altitude is high (tropical or subtropical latitudes; late spring, summer, and early fall months). It is also subject to errors that

result from differences between zone time and local time, and from the *equation of time* (the difference between mean solar time and true solar time). However, the watch method can be useful as a direction finder if the potential for inaccuracy is kept in mind, and if techniques are used to reduce avoidable errors. Correspondence between direction determined by the watch method and true direction will be greatest between latitudes of 40° to 60° in the winter months. Accuracy is improved if the watch is set to local solar time at the approximate longitude of observation rather than zone time (local solar time = GMT + east longitude expressed in time; local solar time = GMT - west longitude expressed in time [where 15° of longitude = 1 hour]). Directional errors are further reduced by tilting the watch face to lie in the plane of the sun's apparent path rather than in the horizontal plane.^[10] ^[26] ^[27] A digital watch also may be used if the indicated time is drawn as an analog clock face on paper or in the dust.

Direction by Amplitudes

The *amplitude* of a heavenly body is the angular measurement between the body when on the horizon and the observer's prime vertical circle. When the body is rising, the amplitude is reckoned from due east; when the body is setting, the amplitude is reckoned from due west. The amplitude is designated as north or south depending on the relative position of the body on the horizon and the prime vertical circle. The amplitude will always be north when the declination of the body is positive, and vice versa. For objects of constant declination (the "fixed stars"), amplitude is constant. For the sun, moon, and planets, amplitude varies with seasonal

1726

variations in the declination of these bodies. Knowledge of the amplitude of the sun for various dates is useful as a means of determining direction at sunrise and sunset. Amplitude of the sun is zero on the dates of the spring and fall equinoxes, and the sun rises due east and sets due west of an observer at any latitude between the Arctic and Antarctic circles on those dates.^[1] ^[7] When in the tropics, the amplitude of any body equals its declination. Outside of the tropics, the amplitude of a body is always larger than the declination of the body.^[3]

The formula for calculating the amplitude of any body at rising or setting (altitude = 0) is known as Napier's rule^[1] ^[19] ^[20] :

Given latitude (L) and declination (d), solve for amplitude (A):

$$A = \sin^{-1} (\sin d / \cos L)$$

The maximum amplitude for the sun at a given latitude is calculated by entering the maximum declinations of the sun occurring at the solstices ($\pm 23.5^\circ$) into the formula.^[1] The amplitude for any date is calculated by entering the declination of the sun on the

date of interest.

For most of the year in most of the world, the sun's amplitude lies within 30° of due east and west. In fall and winter in the Northern Hemisphere, the sun rises and sets south of east and west, whereas in the spring and summer the opposite is true. Maximum amplitudes occur at the solstices, and minimum amplitudes occur at the equinoxes.

A useful table of amplitudes for the sun or other selected celestial body can be easily calculated by Napier's rule and carried on an index card to provide a directional reference in the area of intended travel. The approximate latitude of the area of travel can be determined from a map. The declinations of the body to be used for the dates of travel can be located in the *Nautical Almanac*. A ready-made table of amplitudes covering latitudes from 0 degrees to 77 degrees, and declinations from 0 degrees to 24 degrees, is available in Bowditch's *American Practical Navigator*^[1] as Table 27.

Direction by Observation of Circumpolar Stars

Polaris provides the most reliable directional indicator in the night sky. Polaris can be used to indicate direction within a degree of true north at any location above 10° north latitude. Use of the star becomes progressively more difficult as its altitude increases above 60° north because of difficulty relating the star's azimuth to the horizon. A stick with a string tied to the end and weighted with a bolt or washer can be used to find the point on the horizon representing north in this setting. The stick is held such that the string hangs in a line from Polaris to the horizon. The point of intersection of the string with the horizon indicates north.^[3]

The Big Dipper (*Ursae Majoris*) can be used to identify Polaris or true north by extending a line from the "Pointers" (α -*Ursae Majoris*, or Dubhe, and β -*Ursae Majoris*, or Merak) toward the north celestial pole. These stars form the leading edge of the Dipper. The distance between them multiplied by 5 indicates the approximate position of Polaris. When the Dipper is low in the sky or below the horizon, a similar process can be followed in identifying north from the constellation Cassiopeia. Cassiopeia has the appearance of a flattened letter "M" when above the pole, and "W" when below. If a line drawn between the stars forming the feet of the "M" (β -*Cassiopeiae*, or Caph, and ϵ -*Cassiopeiae*) is assigned length "X," a perpendicular line of length "2X" extending from the trailing star will indicate approximate north^[4] (Figure 73-15 (Figure Not Available)).

In the Southern Hemisphere there is no conspicuous star that marks the south celestial pole. However, the distinctive asterism of the Southern Cross can be used to point to the approximate location of the pole and thus to indicate south. The Southern Cross consists of four stars. The declination of the crossbar is approximately -60°. The long axis of the cross lies on a line that passes within 3° of the south celestial pole. The distance to the approximate pole from the star forming the base of the cross (α -*Crucis*, or Acrux) is approximately 5 times the length of the long axis of the cross (Figure 73-16 (Figure Not Available)). At latitudes where the cross is visible but the south celestial pole is below the horizon, the long axis of the Southern Cross indicates south when the

constellation is vertically oriented.^[3] ^[4] ^[28]

When the Southern Cross is below the horizon or too low in the sky for reliable observation, the bright stars Canopus (*α-Carinae*) and Achernar (*α-Eridani*) can be used to find south. If a line between these stars is considered

Figure 73-15 (Figure Not Available) The azimuth of Polaris is always within 45 arc minutes of true north. Lines as indicated from "the Pointers" of the constellation Ursa Major, or from the trailing star of the constellation Cassiopeia, also can be used to find north when Polaris is obscured by clouds or below the horizon. (From Burch D: *Emergency navigation, Camden, Me, 1986, International Marine Publishing Co.*)

1727

to represent the base of an equilateral triangle, the apex of the triangle points to the approximate location of the south celestial pole^[3] ^[4] (see Figure 73-16 (Figure Not Available)).

Direction by Observation of Other Stars

It should be clear from the amplitude formula that any object with a known declination of less than plus or minus 5° could be used to give a reasonably accurate indication of east at the time of rising, or west at the time of setting. By virtue of its brightness and of the familiarity of the constellation in which it is located, the star *δ-Orionis* (Mintaka) [declination -0°, 18 minutes] is particularly useful in this regard. Mintaka is the leading star in the belt of the constellation Orion. It rises due east and sets due west at any latitude from which it is observed (Figure 73-17 (Figure Not Available)). Unfortunately, the visibility of Mintaka at rising or setting is limited to the months of October through April. When the star is obscured by haze or clouds at rising or the time of rising is missed, the location of the rising can be extrapolated. Within 1 to 2 hours of the rising time, hold a straight edge connecting the star to the horizon at the rising angle of the star, where rising angle = 90° - latitude. The point at which the straight edge touches the horizon indicates the position the star occupied when on the horizon. Because the rising and setting angles of any body are the same, the same technique can be used to determining the point on the horizon where the star will set.^[3]

The constellation Scorpius is prominent in the southern sky at mid-northern latitudes during the summer. This constellation contains a distinctive reddish star, Antares (*α-Scorpii*), at the position of the neck of the scorpion. To the east of Antares the tail of the scorpion

Figure 73-16 (Figure Not Available) Determination of south by circumpolar stars. The long axis of the Southern Cross almost lies along a radius extending from the south celestial pole at the distance indicated in the figure. The apex of an equilateral triangle with the stars Achernar and Canopus forming the vertices of the base also approximates the position of the south celestial pole. (From Burch D: *Emergency navigation, Camden, Me, 1986, International Marine Publishing Co.*)

hangs toward the horizon. Three stars just before the sharp bend in the tail of the figure

(ϵ -, μ -, and ν -*Scorpii*) form a nearly straight line. The stars comprising the head and claws of the figure (β , δ [Dschubba] and ρ -*Scorpii*) lie in a fairly straight line located immediately to the west of Antares. The configuration of the constellation is such that the stars forming the linear array of the tail point due south when the line of the head and claws has passed the meridian and is perpendicular to the horizon (Figure 73-18 (Figure Not Available)).^[3]

In the Carolinas Islands of the South Pacific, the bearings at rising and setting of 32 prominent stars

Figure 73-17 (Figure Not Available) Determination of true west by observation of the setting point of the star Mintaka (declination zero) in the belt of the constellation Orion. The rising point of the same star indicates true east. (From Burch D: *Emergency navigation, Camden, Me, 1986, International Marine Publishing Co.*)

Figure 73-18 (Figure Not Available) Determination of south by observation of the constellation Scorpio. When the best-fit line connecting the stars forming the head and claws of the figure is perpendicular to the horizon, the linear array of stars in the tail of the asterism points south. (From Burch D: *Emergency navigation, Camden, Me, 1986, International Marine Publishing Co.*)

1728

are memorized by navigators to permit determination of direction at sea. The fidelity of this "star compass" for direction finding is demonstrated by the ability of these navigators to make successful landfall on minute atolls after open ocean voyages of hundreds of miles.^[11] Memorization or recording of the rising or setting azimuths of a few prominent stars at the latitude of a planned trip would afford the same directional reference to the land navigator in case the compass or other navigational aid was lost or damaged. These azimuths could be precalculated in minutes using Napier's rule.

Finally, observation of the movement of any overhead celestial body relative to a fixed reference (e.g., a branch, guy line, the "fishline sextant") over a span of 15 to 20 minutes (4° to 5° of movement) will give a reasonably accurate indication of east and west.

NAVIGATION WITH A POCKET RADIO

Radio transmission and reception are inherently directional. This is particularly evident with reception in the broadcast band (500 to 1600 kHz) and is a principle that is more apparent in inexpensive portable radios than in larger, more expensive models. Radio navigation was used extensively in aviation from the 1930s through the 1950s. There are anecdotal reports of successful sailings from the West Coast of the United States to Hawaii using only an AM radio and jet contrails for navigation.^[21]

The internal antenna of the typical pocket AM radio is formed by a ferrite bar wrapped in multiple loops of wire. This ferrite-loop antenna responds most strongly to radio waves when oriented perpendicular to them. Reception is minimized when the antenna is oriented parallel to the transmitted radio waves (i.e., pointed at the transmission tower of the station). The point of minimum radio reception, or *null point*, can be used to find the direction to a source of radio transmission with surprising precision.^{[3] [27]} Use of this technique assumes that a broadcast band station is audible, and that the geographic location of the radio transmission can be identified by listening to the station. Once these conditions are met, the procedure for establishing a direction line that runs through the broadcast source and the observer is relatively easy. Radio homing does not determine true direction but can identify the direction to safety. When used in conjunction with a map, radio bearings act as LOPs and multiple bearings to different stations can result in a fix. The procedure for navigation by radio bearings follows:

1. If not known, determine the orientation of the radio's internal antenna. This can be done by opening the case and looking for the antenna (a dark gray or black bar wrapped in fine copper wire), or by rotating the radio while listening to a station and determining the plane of rotation that results in a null point (rotation about the long axis of the antenna will not change the reception, whereas rotation perpendicular to the long axis will result in nulling).
2. Select an audible AM station and listen until the location of the station is identified. Hold the radio in a manner that allows the long axis of the internal antenna to act as a pointer. Rotate the radio parallel to the ground until the radio signal becomes faintest or disappears. Nulling of the signal can be augmented by tuning to the fringes of the station frequency if the reception is strong.
3. The actual direction to the source of radio transmission will be one of the reciprocal bearings of the LOP connecting the observer and the station location. The bearing that actually points to the radio source can be determined if the observer has even a crude understanding of their position relative to the station (e.g., generally north of, vs. generally south of). The bearing to the broadcast source also can be determined by serially checking the null point of the station while traveling. The angle over which nulling occurs becomes greater as the signal weakens with increasing distance from the source. Thus, if the angle over which

the signal nulls is widening as travel progresses, the observer is moving away from the radio source. If the angle over which the station nulls narrows as travel progresses, the observer is moving toward the source.

4. If a compass is available, determine the azimuth of the null point. Keep the compass far enough from the radio to avoid influencing the needle with the radio's metal parts. A compass allows the magnetic bearing to the station to be determined. This bearing can then be followed to safety without further use of the radio.
5. If a map and compass are available, orient the map using the compass and draw a line through the broadcast source on the map at the azimuth of the null point. Extend this line to the edges of the map. Your location is somewhere on or near this line. If you have a map but no compass and can properly orient the map by natural cues, place the radio on top of the broadcast location on the map and rotate it until the signal nulls. Draw a line parallel to the internal antenna through the broadcast location and extend it to the map margins. Again, your position lies somewhere on this line. When two (or more) stations can be tuned and identified, the LOPs connecting the observer to each radio source will cross, and a fix is obtained at the point of crossing. The uncertainty of this fix will be least when the angle between two position lines is close to 90° or when the angles between three position lines are close to 120° .

NAVIGATION WITH THE GLOBAL POSITIONING SYSTEM

The NAVSTAR Global Positioning System exploits the logical framework of celestial navigation in using a predictable extraterrestrial reference for the determination of terrestrial position. In GPS navigation, artificial satellites substitute for celestial bodies as reference points. Calculation of position is based on *circles of equal distance* from the satellites.

The current system consists of a constellation of 27 satellites (24 operational, 3 spares) in six orbital planes (four functioning satellites per orbital plane). The orbital planes are inclined to the earth's equator by 55°. The orbital paths of the satellites are nearly circular and have an altitude of approximately 20,000 km with an orbital period of 11 hours, 58 minutes. At any given time, five to eight satellites are available in line-of-sight to a receiver anywhere on the surface of the earth.^{[8] [15]}

The method of position determination using GPS depends on calculation of the range between the satellite and receiver. GPS signals are transmitted on two L-band frequencies by each satellite: L1 (1575.4 MHz) and L2 (1227.6 MHz).^[6] Transmitted information includes the precise time as kept onboard the satellite by multiple atomic clocks, a satellite ephemeris (catalog of predicted positions), and data concerning corrections for atmospheric propagation of radio signals and satellite clock errors. The GPS receiver decodes the positional data for each satellite and compares the timing information transmitted by the satellite with time as kept by the receiver's onboard clock. The signal received is in the form of a pseudorandom code. The GPS receiver shifts the code contained in memory to match the received code in phase. The duration of the shift represents the time required for the satellite signal to reach the receiver, usually on the order of 50 to 60 milliseconds. Since distance = speed × time, the transit time of the signal allows a calculation of the distance between receiver and satellite.^[12] At any given instant a GPS receiver in contact with a NAVSTAR satellite will lie on the surface of a sphere of equal distance from the satellite. The intersection of this sphere of equal distance with the surface of the Earth forms a circle of equal distance, analogous to the circle of equal altitude in celestial navigation. The intersection of two such circles occurs at two points. The intersection of three such circles occurs at a single point of latitude and longitude on the surface ^{[8] [15] [16] [24]} ([Figure 73-19](#)). This is the position of the receiver. If the intersection of the sphere of equal distance of a fourth satellite is added, the approximate altitude of the receiver also can be determined. Software allows the GPS receiver to choose the optimal group of four satellites for position determination among the subset of satellites within the line-of-sight of the receiver.

Figure 73-19 Illustration of a GPS fix from the intersection of three circles of equal distance from three separate satellites. (From Monahan K, Douglass D: *GPS instant navigation*, Bishop, Calif, 1998, Fine Edge Productions.)

As currently configured, two levels of service are provided by the GPS system: the Precise Positioning Service (PPS) and the Standard Positioning Service (SPS). Currently, PPS is available only to military users. It provides positional accuracy of 15 m, velocity accuracy of 0.1 m/sec, and time accuracy of 100 nanoseconds. SPS provides civilian users with positional accuracy to 100 m 98% of the time, to 50 m 65% of the time, and to 40 m 50% of the time. Altitude accuracy is relatively poor at 150 m. The relative inaccuracy of the SPS system results from the intentional introduction of timing errors into the broadcast signal from the satellites on frequency L1. The degradation of precise data from the satellites is termed *selective availability* (SA) and is controllable from the ground. One year after public availability of GPS signals was granted in 1994, SA was formally implemented. SA has been turned off periodically since that time for obscure reasons, permitting civilian users to achieve military accuracy with commercial receivers. In the first decade of the twenty-first Century, SA will be phased out and a new frequency (L5) will be added to the signals broadcast by the third generation of NAVSTAR satellites. This will allow even greater accuracy to the civilian user.^[8] The limitations in accuracy imposed by SA have been overcome by an ingenious

1730

Figure 73-20 Screen images from a common portable GPS receiver showing various navigation screens. *Screen A* displays the time, the terrestrial coordinates and altitude of the observer's position, and the direction and velocity of travel. *Screen B* shows the bearing and distance to a selected waypoint (CAMP), the track made good by the observer, the velocity of travel, and a graphical representation of deviation from the intended course. *Screen C* shows the distance and bearing to the selected waypoint in compass format. (Courtesy GARMIN International, Olathe, Kan.)

method of error reduction developed by commercial users. This is termed *differential GPS* (DGPS). DGPS utilizes a fixed receiver at a precisely known position that broadcasts corrections between the established position of the fixed receiver and the

position as determined by GPS. Specially equipped mobile GPS receivers receive the correction factor from the differential receiver and apply it to their position. DGPS permits 1- to 3-meter positional accuracy, and 3-meter altitude accuracy.

Global Navigation Satellite System (GLONASS), a Soviet-era system, has marginally better satellite coverage in higher northern and southern latitudes ($>50^\circ$) and no SA. Positional accuracy is 30 meters. GLONASS receivers are not widely available, however, and the system offers no compelling advantages over GPS for the surface navigator.

GPS reaches its greatest utility when used in conjunction with a topographic map and compass. The raw output of the receiver is in latitude and longitude to the nearest second of arc, or in Universal Transverse Mercator (UTM) grid coordinates as used on topographic maps. This information is somewhat abstract in isolation, but software included with the receiver permits the user to understand absolute and relative position and perform sophisticated navigational feats, even in the absence of other aids to navigation. When used with a map, GPS allows the user to plot position and route at will, determine bearings to landmarks, and enter the locations of landmarks into memory for use as *waypoints*. Even without a map, GPS allows the user to determine precise position, approximate altitude, bearing and linear distance to established waypoints, deviation from the intended course to a waypoint, and velocity of travel.

Waypoint navigation is a feature of particular utility in wilderness navigation. Waypoints can be entered into the GPS receiver manually via a keypad, or current position can be entered and stored as a waypoint with a single key-press. Groups of waypoints can be stored as a route. As a course is walked, waypoints can be stored and labeled with reference to a prominent landmark or terrain feature. On the return route, the receiver sequentially gives the bearing and distance to any waypoint within the stored route and displays a graphical representation of the deviation of the current course from the course needed to reach the waypoint ([Figure 73-20](#)). The receiver informs the user that a waypoint has been reached by sounding an alarm. Theoretically, this allows a user to follow a route in white-out conditions or in total darkness, using no visual references other than the display of the GPS receiver. Most current receivers have memory capacity sufficient for the storage of several hundred waypoints. Identification of a large number of waypoints on a complex route essentially allows the user

to follow a "breadcrumb route" on return to their objective.^[15]

All receivers can calculate the heading of travel and thus provide the user with a method of determining a true bearing and the cardinal directions by walking a brief, straight course. Speed of travel is displayed, and estimated time en route at the current speed is given. Simple moving maps highlighting a desired route are available on many models and permit the user to "walk the line" of a route on the receiver's graphic display. Some newer units incorporate low-resolution, digitized maps and display the user's position on

the map image. When applied with common sense and routine awareness of approximate location, GPS renders it virtually impossible to become or remain lost and effectively eliminates much of the pathfinding challenge inherent to wilderness travel.

In practice, GPS should be applied to a wilderness trek in the following manner: Before embarking on a trip, the user should enter into the receiver the precise location of various important landmarks on the intended route of travel. These locations can be obtained from a trail guide or a USGS topographic map. The waypoints obtained in this manner are labeled and stored as a route within the receiver's memory. At the beginning of the trip, the location of the nearest town or source of assistance also is entered as a waypoint, as would the location of the trailhead where the trip is begun. The trip then progresses using map, compass, established trails, or the GPS receiver to follow the intended route. When pausing to camp, the position of the camp would be named and entered as yet another waypoint. At any time the bearing and distance to any waypoint of interest is available to the user. If, in a spasm of self-reliance, the user decides to lay aside the GPS receiver and pursue traditional methods of route finding, and he or she becomes lost, reactivation of the receiver allows the direction and distance to safety to be immediately determined.

GPS suffers from several limitations. Most receivers have a battery life of between 15 and 30 hours. Dead batteries yield a useless receiver. The receivers are relatively fragile, and many are not waterproof or even particularly water-resistant. Obstruction of the sky by terrain features or heavy foliage interferes with the reception of satellite signals and may render the receiver unable to acquire a sufficient number of satellites to provide a fix. Still, GPS is unsurpassed in ease of use, accuracy, and utility for wilderness navigation. Reliance on GPS as the sole navigational resource for any wilderness expedition is a grave error, however. As with all high-tech methodology, a GPS receiver can be easily disabled. The more self-contained methods of navigation discussed in earlier sections should be utilized whenever possible to maintain positional awareness and navigational skill should the GPS receiver fail.

CONCLUSION

The body of literature covering the topic of navigation is immense. Many techniques for determining direction and position exist in addition to those described above. Several of the references^{[1] [3] [9] [26] [27]} catalog these methods. It is sufficient to the task of navigation if the above methods are understood in terms of how they work, even if why they work remains obscure. Practice is essential, and the reader is encouraged to increase his or her familiarity with the motion of celestial bodies, the inconstancy of the earth's magnetic field, and the use of a variety of common navigational aids. The study of land navigation should be a routine component of the preparation for any wilderness expedition.

Chapter 74 - Children in the Wilderness

Judith R. Klein
Barbara C. Kennedy

Once the realm of a few adventurous individuals, the wilderness today attracts an ever-broadening range of explorers. This includes many in the pediatric age group, as parents seek to share the joys and lessons of wilderness travel with their children. In 1990, of the estimated 11 million people participating in backpacking and wilderness camping, nearly 25% were under 17 years of age.^[65] Millions of other children annually visit national parks and recreation areas or travel to developing countries.

Wilderness travel with children requires special preparation and places extra demands on parents. However, it also affords unique opportunities. Parents and children interact in a setting distant from the stresses of work and school. Isolated from the distractions of computers, television, and modern life, children experience new environments, interact with individuals of different cultural heritage, and participate in activities that enrich their lives. These activities bring families together as they learn to rely on one another for support and entertainment.

Physicians and other health care professionals can encourage and facilitate such undertakings by providing preventive health and treatment guidelines for those planning wilderness travel with children. This chapter focuses on how children differ from adults and how to prevent, recognize, and treat the medical problems children are likely to encounter in a wilderness setting. Because wilderness travel may encompass travel to foreign countries, risk avoidance, pediatric travel immunizations and prophylaxis, and common pediatric medical problems associated with travel and developing countries are

also reviewed.

WHAT MAKES CHILDREN DIFFERENT

Size and Shape

Children differ from adults in a variety of physical, physiologic, and psychologic ways. The most obvious difference is size. During development, children may grow from the average 7-pound baby to a 140-pound adolescent, a twentyfold difference. Accordingly, medications and fluids must be calculated on an individual basis, based on the weight of the child ([Table 74-1](#)).

This variation in size also influences a child's risk of developing serious complications from envenomations. Many snakes, spiders, scorpions, and poisonous marine animals deliver the same unit dose of venom regardless of the victim's size. Children often experience greater toxicity because of the increased dose of venom per kilogram of weight.

Children also have a larger body surface area (BSA) to mass ratio than adults. For example, a 7-pound infant has 2.5 times more BSA per unit weight than a 140-pound adult. In addition to the larger BSA, the part of the body most often left exposed, the head, takes up a larger proportion of the body in a young child ([Figure 74-1](#)). As a result, children experience greater exposure to environmental factors, such as cold, heat, and solar radiation. They are also more likely to have toxic effects from topical agents, such as insect repellents and medications.

Musculoskeletal System

A child nearly doubles in height between birth and 2 years and again between 2 and 18 years, and bone-remodeling potential is much greater than in adults. Because of the active osteogenic potential of the periosteum, nonunion or permanent angulation deformities at the metaphysis are unusual in children, and fractures heal quite rapidly; a fractured femur typically heals in 3 weeks in a newborn compared with 20 weeks in a 20-year-old. The strong, pliable periosteum also permits the development of greenstick and buckle fractures, which are not seen in the adult population. A fracture with intact periosteum is more stable, with little swelling or crepitus. If nondisplaced, it is often incorrectly dismissed as a sprain.

Children have an open growth plate, or physis, at the ends of long bones that connects the metaphysis to the epiphysis ([Figure 74-2](#)). The growth plates consist of soft cartilaginous cells that have the consistency of rubber and act as shock absorbers. They protect the joint surfaces from the grossly comminuted fractures seen in adults. However, because the growth plate is more vulnerable to injury than the strong

ligaments or capsular tissues that attach to the epiphysis, a true sprain in a child is rare. Any significant juxtaarticular tenderness in a child should be assumed to be a growth plate injury. Such an injury is most common at the ankle (lateral malleolus), the knee (distal femur), and the wrist (distal radius). Physeal fractures have been classified into five Salter-Harris groups (see [Figure 74-2](#)). Salter-Harris I and II fractures generally heal without complications. However, Salter-Harris III and IV fractures often require open reduction of displaced fractures to realign the

joint and growth plates and to permit normal growth. A Salter-Harris V fracture has a poor prognosis; the impaction and crushing of some or all of the growth plate may result in a bony bridge that inhibits further growth or causes unequal, angulated growth. Consequently, any significant injury, especially if it involves the growth plate, requires full evaluation in a medical facility.

Cardiovascular and Respiratory Systems

The basic physiologic parameters change greatly during the transition from infancy to childhood to adulthood. These differences are important to recognize to avoid unnecessary and potentially harmful interventions in healthy children but also to intervene when abnormal vital signs are present. For example, a blood pressure of 65/35 mm Hg, pulse rate of 160 beats/min, and respiratory rate of 40 breaths/min are considered ominous vital signs for an adult. However,

TABLE 74-1 -- Average Weights for Age

AGE (YR)	WEIGHT	
	kg	lb
1	10	22
3	15	33
6	20	44
8	25	55
9 ½	30	66
11	35	77

Modified from National Center for Health Statistics: Am J Clin Nutr 32:607, 1979.

Figure 74-1 Body proportions.

these vital signs are normal in a 2-month-old infant.^[28] Although blood pressure readings may not be available in a wilderness setting, it is possible to assess the strength of the pulse and determine the pulse and respiratory rate of an ill child. In general, infants and children have greater respiratory and heart rates and lower blood pressure than adults ([Table 74-2](#)).

Thermoregulation

Because environmental extremes are often encountered when traveling in wilderness areas, it is important to recognize that thermoregulation is less efficient in children than in adults (see [Chapter 4](#)). A number of physiologic and morphologic differences make children more susceptible than adults to heat illness^[65] (see [Chapter 10](#) and [Chapter 11](#)). During exercise, children generate more metabolic heat per unit mass than do adults. Children also have lower cardiac output at a given metabolic rate, resulting in a lower capacity to convey heat from the body core to the periphery. Because of their larger BSA/mass ratio, children also gain heat more rapidly from the environment than do adults when ambient temperature exceeds skin temperature. Under these same conditions, cooling from conduction, convection, and radiation ceases to be effective, leaving evaporation (sweating) as the only effective means of heat dissipation. Unfortunately, children have a lower capacity for evaporative cooling, possibly because of decreased sweat volume, regional differences in sweat patterns, and a higher sweat point (the rectal temperature when sweating starts). Finally, children acclimatize to hot environments at a slower rate than adults.

Figure 74-2 Salter-Harris classification of physeal fractures.

TABLE 74-2 -- Age-Specific Resting Heart Rate and Respiratory Rate*

AGE	HEART RATE (BEATS/MIN)	RESPIRATORY RATE (BREATHS/MIN)
0–5 mo	140 ± 40	40 ± 12
6–11 mo	135 ± 30	30 ± 10

1–2 yr	120 ± 30	25 ± 8
3–4 yr	110 ± 30	20 ± 6
5–7 yr	100 ± 20	16 ± 5
8–11 yr	90 ± 30	16 ± 4
12–15 yr	80 ± 20	16 ± 3

*Mean rate ± 2 SD.

Children are also at greater risk for hypothermia (see [Chapter 6](#)). Their larger BSA/mass ratio causes them to cool more rapidly than adults in cold environments. Children have less subcutaneous fat and thus less "natural" insulation. Infants in particular have an inefficient shivering mechanism.^[19] Humans are poorly adapted to a cold environment and must rely on adaptive behavioral responses, such as seeking shelter and dressing appropriately, to maintain body heat. Infants and young children are not capable of these responses and must rely on their caregivers to provide shelter and appropriate clothing.

Immunology and Infections

Children experience a greater number of infections than adults. The average 1-year-old has six to eight infections per year, whereas the average adult has only three to four infections per year. Infections in children tend to be more severe. The younger the child, the more likely that a given infection represents a first exposure. A first-exposure infection is more likely to cause fever and produce severe symptoms than a reexposure, in which the infection is modified by the antibodies produced from the first exposure. Young children are also less likely to have cross-reacting antibodies from a previous infection with an antigenically related organism.

Many common respiratory or viral infections produce more severe symptoms in children because of anatomic differences. The pediatric bronchioles, eustachian tubes, and larynx are narrower and therefore more easily obstructed by edema and mucus. This obstruction worsens the symptoms, prolongs clearance of infection, and increases the risk of secondary infection. Pertussis, or whooping cough, is a classic example of the differences in severity of infection between children and adults. Nearly 20% of infants with pertussis have severe complications, such as pneumonia, seizures, or encephalopathy; adult pertussis, although a common cause of chronic cough, is generally indistinguishable from a common cold.^[48]

TABLE 74-3 -- Age-Specific Expectations for Wilderness Travel

AGE	EXPECTATION	SAFETY ISSUES
0–2 yr	Distance traveled depends on the adults; child carriers used	Provide "safe play area," e.g., tent floor, extra tarp laid out; bells on shoes; ipecac syrup
2–4 yr	Difficult age; stop every 10–15 minutes; hike ½-2 miles on own	Dress in bright colors; teach how to use whistle; ipecac syrup
5–7 yr	Hike 1–3 hr/day; cover 3–4 miles over easy terrain; rest every 30–45 minutes	Carry whistle: three blows = "I'm lost"; carry own pack with mini-first-aid kit and water
8–9 yr	Hike a full day with easy pace; cover 6–7 miles over variable terrain; if over 4 feet tall, can use framed pack	As for 5–7 years; teach map use and route finding; precondition by increasing maximum distances by 10%/wk or less; watch for overuse injuries; keep weight of pack 20% or less of body weight
10–12 yr	Hike a full day at moderate pace; cover 8–10 miles over variable terrain	As for 8–9 yr
Teens	Hike 8–12 miles at adult pace; may see a decrease in pace or distance with growth spurt	As for 8–9 yr

GENERAL CONSIDERATIONS AND EXPECTATIONS

Children of different ages have different needs and abilities. Expectations regarding distances of travel, pace, and safety issues vary depending on age ([Table 74-3](#)).

First 2 Years

Travel Expectations.

Since they are typically carried, children in their first 2 years of life can travel long distances, depending on the adult's hiking abilities. However, they require attention and care almost all their waking hours. Most children are content in front carriers (infants less than 6 months) or back carriers (older infants and toddlers) and can easily travel for hours at a time. Because of their increased risk of illness and limited communication skills, however, infants must be watched closely for signs of infection, hypothermia, hyperthermia, and altitude illness. Parents must be prepared to give prompt treatment or evacuate to seek medical attention should signs of serious illness develop. Evacuation plans should be formulated before departure.

Entertainment in this age group is simple. A few small toys, which can be attached to the carrier on a short string, the natural surroundings, and a little parental attention provide ample amusement. A toddler can spend hours examining rocks, leaves, and sticks and rarely tires of a parent's undivided attention. If a child is comforted by a pacifier, it can be attached to the child's shirt or carrier, with extras packed for emergencies.

Safety.

As babies become more active with rolling, crawling, and then walking, they require constant attention. Bells attached to their shoes may function as an alerting device, ringing when they are on the move. These children are often considered "grazing creatures," putting everything they come across into their mouths. When they are not being carried, it is best to have a child-proofed area for them to play in, such as a tent floor or an extra tarp laid out. Toxic ingestions are common in this age group, and parents should be prepared. Syrup of ipecac should be included in the pediatric first-aid kit to induce emesis after certain toxic ingestions.

Food and Drink.

Nourishment in the first 2 years is fairly simple. Infants in their first 4 to 6 months require

only breast milk or formula. As long as the mother remains healthy, breast-feeding is the safest and most convenient way to feed an infant. If the mother is not nursing or not available, formula may be used. Formula is most conveniently carried in a powdered form and mixed as needed. The water for formula may be boiled once a day and stored in individual bottles with airtight lids. The powder for the formula is added just before feeding. Any unused, reconstituted formula should be discarded after 2 to 3 hours at room temperature.

Baby cereals can be carried conveniently in a dry form to be mixed with formula or breast milk. Dry cereals mixed with breast milk or formula have a higher nutritional value than ready-to-feed cereals in jars. Jars of commercial pureed foods may be carried, but the empty jars must be packed out. Once a jar of baby food has been opened, it should be used for only that meal. Without refrigeration, opened jars of baby food spoil quickly. Some families prefer to bring a hand grinder and make their own pureed foods (see Suggested Readings).

By 9 to 12 months, many babies are eating finger foods. Parents should be cautioned to avoid any hard round foods, such as peanuts or candies, which may cause choking. Up to 1 year of age, honey should be

avoided because of an increased risk of botulism. Parents may also want to avoid citrus foods, which may cause rashes around the mouth and in the diaper area. Any new foods should be tested at home first to be certain the baby will accept it when away from home.

All water for drinking must be disinfected by boiling, iodination, or the use of small-pore filters, depending on the water source. Chronic iodide poisoning and neonatal goiter have been associated with prolonged ingestion of large amounts of iodine; small amounts ingested for water disinfection appear safe. Nonetheless, if both boiled water and iodinated water are available, it is prudent to use boiled water for infants and small children. In addition, infants and small children often reject the taste of iodinated water. Iodine must be kept out of reach of small children; severe acute toxicity can occur with an ingestion of only 2 to 4 g.

Diapers.

Most children under age 2 years are in diapers, either disposable or cloth. Soiled diapers in a wilderness environment require special care. Thin paper diaper liners may be purchased to help collect the stool. The stool and liner should be buried in a trench at least 6 inches deep and 200 feet from any water source. If disposable diapers are used, they should be packed out after the stool has been removed and buried. The used disposable diaper should be wrapped and placed in a double bag for packing out. To reduce weight, urine-soaked diapers may be set out in the sun to dry before repacking. Superabsorbent diapers may be left on babies much longer and still keep them dry but

cannot be dried out as easily.

On longer trips, some families prefer to use cloth diapers, which may be washed out and reused. Cloth diapers must be changed more frequently, since they are not as absorbent. Washing cloth diapers is labor intensive and requires an abundant supply of water. A washbasin is needed, and the diapers must be washed in hot soapy water. The diapers should be rinsed at least twice to remove irritating soap residue and the wastewater dumped at least 200 feet from a water source.

Equipment.

Since infants and young children are not capable of extended hikes, they are typically transported in carriers. Excellent front and back carriers are available. Most front carriers work well from infancy until an age when babies can sit, typically 6 to 9 months ([Figure 74-3](#)). A front carrier must extend up high enough in the back to support the baby's head completely. Once a child is sitting well, back carriers are more ideal ([Figure 74-4](#)). Back carriers function on the same principle as framed backpacks, redistributing the weight off the shoulders and onto the hips. Many back carriers are able to stand alone and can double as a highchair. Children must be strapped into back carriers, since it is easy for a child to be catapulted out of a carrier if the adult bends over or falls.

Figure 74-3 Young infant in front carrier.

Figure 74-4 Toddler in back carrier.

Sleeping bags are available for infants and toddlers. In a warm climate a few blankets generally suffice, and in a colder climate an insulated snowsuit is often adequate. Children, including young infants, need their own sleeping pads. Such pads protect them from hard, rough ground under the tent and insulate them from the cold ground at night.

Shoes for young children should protect their feet and allow for full range of movement. The best shoes for toddlers are lightweight and flexible. They need shoes that stay on well, since children often flip their

shoes off while in a carrier. Velcro-strapped shoes stay on well and are easy to put on and take off. Since children often lose shoes, an extra pair should be included.

Two to 4 Years

Travel Expectations.

Children 2 to 4 years old are the most challenging to take into the wilderness. Two-year-olds become easily frustrated and throw temper tantrums. By 2 years of age, children are becoming too heavy to carry for prolonged periods, but they are still incapable of hiking long distances on their own. They are just gaining bladder and bowel control, and accidents are frequent. Despite these difficulties, wilderness trips with this age group can be successful with appropriate planning, preparation, and readjustment of expectations.

A key ingredient to successful wilderness trips with small children is to keep things slow, simple, and flexible. This is the age of independence and assertion. The children need to be given some control and allowed to set a pace. Adults should encourage young children to express their natural curiosity and enthusiasm for the outdoors by letting them stop to explore their surroundings. Parents should expect to stop at least every 15 minutes while hiking. If a diversion or a stimulus is needed to get the children hiking again, parents can begin a story or favorite song and continue it while hiking. With patience and plenty of time, parents can expect children in this age group to travel 1 to 2 miles over easy terrain.

Safety.

Unfortunately, 2- to 4-year-olds are notorious for exploring their environment by wandering off or putting objects in their mouths. These young children must be watched closely and cautioned to keep wild mushrooms, plants, stones, and any nonedible item out of their mouths. Parents should continue to carry syrup of ipecac in the first-aid kit for potential toxic ingestions. Children should be kept within sight at all times, since their desire to explore often defies good judgment and exceeds their physical abilities. Although attacks are rare, mountain lions may view small children as easy prey and can strike quickly. Parents should discourage their children from wandering ahead unaccompanied.

When selecting campsites, dangerous features, such as steep drop-offs and fast or

deep water, should be avoided. Children should be dressed in brightly colored clothing. Older children may carry a whistle to call for help when they are lost. The standard distress signal is three blows to indicate "I'm lost" or "I need help"; the response is two blows to indicate "help is coming." Parents should teach children to stay put when they discover they are lost and to wait for rescue. If children panic and start running, they increase the chance of being injured and separated farther from the family.

Food.

The diet of 2- to 4-year-olds is usually simple but individualized. They tend to have strong preferences and dislikes. Unfortunately, most children at this age do not care for the convenient "all-in-one-pot" cooking common around campfires. Foods should be tested at home for acceptability. Nutritious snacks, such as raisins, granola bars, bagels, crackers, string cheese, and fruit bars, can be packed. These snacks sometimes become a child's meal. Small children should not be given items that may cause choking, such as peanuts, grapes, hard candies, or hot dogs. Adults should be trained in basic cardiopulmonary resuscitation (CPR) and know how to assist a choking child.

Toileting.

Most children become toilet-trained by the end of their third year. Accidents are common, however, and parents need to be prepared with extra dry clothing. Children should be taught correct toileting procedures for the wilderness environment. Stools should be deposited at least 200 feet from a water source, buried in a hole approximately 6 inches deep, and completely covered. Many families carry a special trowel for this purpose. Some groups staying in one location for more than a day dig a specific toileting trench, 12 to 18 inches deep, to be used multiple times. They then add enough dirt after each use to cover all waste. Children need help learning to squat over the trench and to bury their stools.

It may be years before children gain reliable nighttime bladder control, so parents should be prepared for accidents. Cotton and down sleeping bags should be avoided, because they lose their insulating abilities and take a long time to dry when wet. Fortunately, many synthetic bags are available with fills such as Polarguard, Quallofil, and Hollofil, which maintain warmth and loft when wet.

School Age (5 Years and Older)

Travel Expectations.

Once children enter the school years, their abilities and attention span increase dramatically. This enables them to participate more actively in many outdoor activities. Children are hungry for knowledge and readily absorb information about nature and outdoor activities. They enjoy being included in the initial planning, as well as in the field activities such as setting up camp, cooking, and cleaning up. School-age children can understand maps and often enjoy following their progress from one point to another.

This is an ideal age to explain to them the rules of living in and traveling through wilderness areas. The examples and rules parents set for appropriate wilderness behavior at this age may become lifetime lessons.

When parents are planning for hiking trips, they must have appropriate expectations for children's differing abilities (see [Table 74-3](#)). Children enrolled in organized sports activities are likely to have greater endurance in the wilderness. An individual child's hiking ability can be estimated by hikes around the neighborhood

1740

or in a local park. If this becomes a routine, the children become preconditioned, increase their endurance, and learn to pace themselves. Parents can test methods for motivating their children. It is better to underestimate than overestimate a child's ability.

Safety.

School-age children can learn to become more self-sufficient and in tune with their surroundings. They can be taught to recognize landmarks in their environment and thus are less likely to become lost. Children should be encouraged to view their surroundings from different angles. They should periodically turn around to see where they came from and where they are going. As children advance in the school years, they can learn survival skills, such as how to maintain warmth, build a shelter, secure food and water, and use a signal mirror, map, and compass. They should still carry a whistle and know how to use it appropriately.

Equipment.

Children like to feel important, capable, and independent. These feelings are enhanced if they are allowed to carry some of their own gear. Even 5-year-olds like to carry their own soft backpacks. Items they can carry in the packs include snacks, a favorite small toy, tissues or a handkerchief, sunscreen, a small trash bag, and a whistle. As the children grow, the contents of their backpacks should reflect their increasing independence, with more self-care and survival items. In addition to the preceding items, they may carry their own water bottle, a mini-first-aid kit (adhesive bandages, wipes, personal medication), insect repellent, and other survival items as they learn to use them. The maximum weight of these packs should be 20% of the child's body weight until he or she has had significant backcountry experience and has proved that more can be carried comfortably. Once children reach 4 feet in height, they can be fitted for a framed backpack. Internal-framed backpacks tend to be more comfortable than external-framed packs. When a backpack is properly fitted, the waistband should rest at the hips and the shoulder strap adjusted so that the weight is carried on the hips, not the shoulders. With a framed pack, children can carry even more of their gear. The total weight should be gradually increased to allow the child to become comfortable with heavier loads.

ENVIRONMENTAL ILLNESSES

Dehydration

Children are at greater risk of dehydration than are adults. Since BSA/weight ratio of a child is greater than that of an adolescent or adult, insensible fluid losses through the skin account for a larger percentage of total fluid losses as the size of the child decreases. In addition, the sodium concentration of children's sweat is generally less than that of an adult, leading to greater relative free water loss. Infants are unable to report thirst, an important marker of fluid deficit, increasing their risk of dehydration. Children are often preoccupied and fail to report or meet their need for fluids.

Symptoms.

A 2% decrease in body weight through fluid loss results in mildly increased heart rate, elevated body temperature, and decreased plasma volume. Water losses of 4% to 5% of body weight reduce muscular work capacity by 20% to 30%.^[66] Symptoms of dehydration include weakness, fatigue, nausea, vomiting, and ultimately lethargy. Dehydration also predisposes a child to other environmental hazards, such as hypothermia, hyperthermia, and acute mountain sickness.

Treatment.

Caregivers must provide fluids and coax children to hydrate themselves frequently. For short (less than 2 hours) periods of activity, water is as efficacious a rehydration solution as carbohydrate-electrolyte drinks.^[44] A child eating a normal diet does not require electrolyte replacement unless sweating is prolonged or excessive. By closely monitoring a child's urine output, fluid deficits can be recognized and promptly managed. A child with decreased urine output or dark concentrated urine needs extra fluids.

Hypothermia

Children cool more rapidly than adults because of their proportionally large BSA and often lack the knowledge and judgment to initiate responses that will maintain warmth in a cold environment (see [Chapter 6](#)). It is also more physiologically difficult for them to maintain their body temperature in cold climates. As a result, parents participating in cold weather recreation with children should be able to recognize, treat, and, preferably, prevent hypothermia and frostbite.

Hypothermia is defined as a core body temperature below 35° C (95° F). At this temperature the body no longer generates enough heat to maintain body functions. The condition is considered mild when the core temperature is 33° C (91.4° F) or above, moderate at temperatures between 28° C (82.4° F) and 32° C (89.6° F), and severe when it is less than 28° C. The signs and symptoms of hypothermia are variable ([Table 74-4](#)). The most important clue to significant hypothermia is altered mental status. The child who begins to undress, stumble, or make inappropriate remarks should be evaluated promptly for hypothermia. Shivering is not a reliable marker of the severity of hypothermia. Physicians should caution parents that hypothermia can develop at moderate temperatures if adverse climatic conditions are compounded by illness, fatigue, dehydration, inadequate nutrition, or wet clothing.

Prevention.

When preparing for cold weather activities, children should dress in layers to allow clothing to be added or subtracted as necessary ([Figure 74-5](#)). This

TABLE 74-4 -- Signs and Symptoms of Hypothermia*

TEMPERATURE	SIGNS/SYMPTOMS
Mild: 33°–35° C (about 91°–95° F)	Sensation of cold, shivering, increased heart rate, progressive incoordination in hand movements, poor judgment, mild ataxia, slurred speech, confusion
Moderate: 28°–32° C (about 82°–90° F)	Loss of shivering, inability to walk or follow commands, paradoxical undressing, increasing confusion, decreased arrhythmia threshold
Severe: <28° C (<82° F)	Rigid muscles, progressive loss of reflexes and voluntary motion, hypotension, bradycardia, hypoventilation, dilated pupils, increasing risk of fatal arrhythmias, appearance of death

*Data from adult subjects.

Figure 74-5 Layering of clothing for cold environments.

avoids excessive perspiration while maintaining warmth. An inner, wicking layer should be followed by a middle, insulating layer, and then by an outer, protective layer.

Clothing that maintains low thermal conductance when moist is particularly important. Conductive heat loss may increase fivefold in wet clothing and up to 25-fold if the child is completely immersed in water. Wool retains warmth when wet because of its unique ability to suspend water vapor within the fibers; however, it is heavier than synthetics and takes much longer to dry. Cotton has a high thermal conductance that increases greatly when wet and is therefore a poor choice for wilderness activities in cold weather. Newer synthetic materials (polypropylene, Capilene, Thermax, Coolmax) wick moisture away from the skin and dry quickly, making them ideal for an inner layer. The middle, insulating layer may incorporate wool, polyester pile, Thinsulate, or similar materials. Windproof and water-resistant outer garments (Gore-Tex) decrease heat loss from convection and keep children dry. Hats and mittens are essential; the uncovered head of a child dissipates up to 70% of total body heat production at ambient temperatures of 5° C (41° F).

Treatment.

For the hypothermic child, field rewarming begins with limiting further exposure to the cold environment. Wet clothing should be removed, and the child's head and neck should be protected from further heat loss. Placing the child with a normothermic person in a sleeping bag insulated from the ground provides external warming. Hot water bottles, insulated to prevent burns, may also be placed at the axillae, neck, and groin. If the child is alert, oral hydration with warm fluids containing glucose repletes glycogen and corrects dehydration, which frequently accompanies hypothermia. Signs of severe hypothermia dictate immediate evacuation as conditions permit; rescuers should handle the victim gently to prevent arrhythmias.

Frostbite

Localized cold injury results in frostbite (see [Chapter 7](#)). Predisposing factors include wet skin, constricting garments that hinder blood circulation, fatigue, contact with cold metal, and windchill. If skin temperature drops below 10° C (50° F), cutaneous sensation is generally abolished, and injury may go unnoticed. Skin cooled to -4° C (24.8° F) freezes.

Frostbite has traditionally been divided into degrees of injury similar to burns. First-degree injury manifests with numbness, erythema, and edema without tissue loss.

Second-degree frostbite results in superficial blistering, whereas third-degree injury produces deeper blisters containing bloody fluid. Fourth-degree injury extends through the dermis to subcuticular tissues. In children, frostbite that extends into bone may affect the growth plate and result in skeletal deformities. ^[34]

Treatment.

All wet and constricting clothing should be removed and hypothermia treated aggressively. Rapid

1742

rewarming, the primary treatment for frostbite, should be initiated as soon as possible. This is best accomplished by immersion of the frostbitten area in water warmed to 40° to 42° C (104° to 107.6° F). This narrow temperature range maximizes rewarming speed while preventing further injury from a burn wound. Thawing usually takes 30 to 45 minutes and is complete when the skin is soft and pliable. Although field rewarming is indicated unless evacuation occurs quickly, great care should be taken to avoid refreezing. Refreezing causes much more damage than delayed thawing. Vigorous rubbing should also be avoided because it is ineffective and potentially harmful. After thawing, blister fluid should be aspirated to prevent further contact with tissue-damaging prostaglandins and thromboxanes, and a sterile dressing should be applied.

Hyperthermia

Families participating in wilderness activities in hot climates must take special precautions to avoid heat illnesses (see [Chapter 10](#)). Children do not tolerate the demands of exercise in the heat as well as adults. They generate more heat per kilogram and are less able to disperse heat from the core to the periphery. Parents planning wilderness ventures with children in hot climates can follow some simple guidelines for avoiding heat illness. The most obvious entails reducing the duration and intensity of activities under conditions of high climatic heat stress, keeping in mind that the risk of heat illness depends on relative humidity, wind velocity, and radiant heat, as well as standard dry bulb thermometer temperature ([Figure 74-6](#)).

Prevention.

Children should be fully hydrated before prolonged exercise and actively encouraged to drink fluids at regular intervals. Infants and neonates are most vulnerable to heat illness. Under high climatic heat stress, infants fed undiluted cow's milk or formula

Figure 74-6 Activity levels based on temperature and relative humidity.

may develop marked salt retention and dehydration. They should be given extra water or dilute feedings. The lower osmolar load of breast milk appears to protect against heat illness and hyponatremia.

Since their mechanisms of evaporative heat loss (sweating) are immature relative to those of an adult, children should be encouraged to engage in activities in the shade to maximize other means of dissipating heat, such as radiation (skin-to-air gradient). Also, since sweat evaporated from clothing contributes less to cooling than sweat evaporated from skin, children should remove sweat-soaked clothing and wear dry, lightweight, loose-fitting clothing. Finally, children acclimatize to the heat slower than adults, often taking 10 to 14 days to acclimate fully. The intensity and duration of exercise should be gradually increased over this period.

Symptoms and Treatment.

Early signs and symptoms of heat illness include flushing, tachycardia, weakness, mild confusion, headache, and nausea. Vomiting often occurs in children. Sweating may be present or absent and should not be relied on as a clinical indicator of the severity of hyperthermia. If heat illness develops, children should be removed from obvious sources of heat, including direct sunlight, and have their clothing removed. Convective cooling can be increased in the field by vigorous fanning after spraying or sprinkling the victim with water. If available, ice packs or cold compresses placed at the groin, axilla, and scalp will aid cooling. If the child is alert, dehydration may be corrected with oral fluids. Progression of symptoms or failure to respond to treatment mandates immediate evacuation (see [Chapter 11](#)).

Sun Damage

The hazards of overexposure to sunlight include sunburn, photoaging, skin cancer, and phototoxic and photoallergic reactions (see [Chapter 14](#)). Preventing ultraviolet (UV) damage to the skin should begin in childhood, since 80% of a person's lifetime sun exposure occurs before 21 years of age.^[3] Recent evidence suggests that the risk of developing malignant melanoma is at least double if a person has had one or more severe sunburns in childhood. This risk is even higher if a child is light skinned with a propensity to burn rather than tan.^{[22] [51] [76]} Tolerance to sun exposure is determined by the amount of melanin in the skin and the ability of the skin to produce melanin in response to sunlight. In general, children have lower melanin levels and thinner skin than adults and are at greater risk of sun damage.^[35]

The ultraviolet wavelengths UVA and UVB are principally responsible for the harmful effects of solar radiation. UVB is primarily responsible for suntan and sunburn and also

promotes the development of skin cancer and aging of the skin. UVB increases 4% for every 305-m (1000-foot) gain in elevation over sea level. Therefore a

1743

backpacker at 3050 m (10,000 feet) will have a 40% increase in UVB exposure. UVA, which is 10 to 100 times more abundant than UVB, is only 0.001 as potent at inducing sunburn. It is also less affected than UVB by changes in season or solar zenith angle. UVA is primarily responsible for photosensitivity reactions and solar urticaria. It also contributes to skin cancer and skin aging. A number of drugs often used in adolescence, such as tetracycline, vitamin A derivatives (Retin-A, Accutane), and nonsteroidal antiinflammatory drugs (NSAIDs), increase the risk of photosensitivity reactions and the need for UVA protection. Sunscreens should protect against both UVA and UVB.

The harmful effects of UV radiation from the sun can be reduced if parents are educated regarding the dangers of sun exposure and encouraged to use sun-protective clothing and sunscreens early in their children's lives.^[3]^[77] Studies indicate that regular use of a sunscreen with a sun protection factor (SPF) of at least 15 for the first 18 years of life reduces a person's lifetime risk of developing nonmelanoma skin cancer by 78%.^[22]

Prevention.

The most effective means of preventing sun damage is avoidance of excessive sun exposure and the use of protective clothing. Midday hours, particularly around bodies of water, at high altitude, and at the equator, are the most dangerous in terms of quantity of UV exposure. Shady areas should be used for activities during these times. Hats with wide brims and neck drapes help to protect the face and neck from sun exposure. Clothing made from tightly woven fabrics is more protective; loosely woven fabrics, such as that in most T-shirts, have an SPF of only 5. Most clothing loses even more of its protective effect when wet. High-SPF (25 to 30) clothing is cool and lightweight, dries quickly, and can maintain its full SPF capabilities even when wet.

Proper eye protection is often overlooked in infants and young children. Excessive UV light, particularly during snow and water activities, can result in UV keratitis and corneal burns with even brief exposures. Properly fitting sunglasses that transmit fewer than 10% of UV rays should be part of a child's outdoor activity armamentarium. Side shields and polarizing lenses are particularly important on the snow.

SUNSCREENS.

Most sunscreens have ingredients such as paraaminobenzoic acid (PABA), PABA esters, cinnamates, salicylates, and anthranilates that protect the skin from sun damage by absorbing primarily UVB. Dibenzoylmethane absorbs only UVA. Benzophenones block UVB and to a lesser degree UVA.^[32] Sunscreens that combine ingredients that protect the skin from both UVB and UVA are the most effective. Micronized titanium dioxide, which reflects UV light similar to the sun block zinc oxide, is almost colorless

but retains the ability to scatter sunlight.

The SPF is a measure of a sunscreen's effectiveness. It is measured in terms of the minimal dose (in length of time) of UV radiation required to cause skin erythema. Sunscreens with SPF of 30 or higher provide a superior degree of photoprotection and almost completely prevent the cellular changes seen with sunburn. ^[31]

Water-resistant sunscreens maintain their effectiveness for up to 40 minutes of water immersion, whereas waterproof sunscreens maintain their effectiveness for up to 80 minutes of water immersion. ^[32] Either should be reapplied if longer times are spent in the water or if the water is turbulent. Excessive sweating and rubbing of the skin are also indications for reapplication.

Treatment.

When sunburn occurs, the mainstays of treatment are cool compresses, topical antipruritics, and NSAIDs. ^[32] A high-potency topical steroid, betamethasone dipropionate, may work synergistically with NSAIDs to reduce the UVB-induced erythema by as much as 42% to 58% if used early in the burning process. ^[30] Strong topical steroids should be used judiciously, since just a 7-day course may suppress the hypothalamic-pituitary-adrenal axis. As always, the best cure is prevention.

High-Altitude Illness

High-altitude illness comprises a continuum from acute mountain sickness (AMS) to life-threatening conditions such as high-altitude pulmonary edema (HAPE) and high-altitude cerebral edema (HACE). AMS usually develops within 24 hours of ascent. The incidence and severity depend on individual susceptibility, as well as the rate of ascent and the altitude attained. The sleeping altitude is particularly important to the development of symptoms. The true incidence of high-altitude illness is unknown but is probably 10% to 20% at 2500 m (8202 feet) in adults and children (see [Chapter 1](#)).

Symptoms.

The cardinal symptoms of AMS are a bitemporal, throbbing headache, anorexia, and malaise. Children appear particularly prone to nausea and vomiting. Other symptoms include dizziness, dyspnea on exertion, and fragmented sleep. Infants may display nonspecific findings such as irritability, poor feeding, and sleep disturbance. Manifestations of severe AMS include dyspnea at rest and ataxia, which presage HAPE and HACE, respectively.

Prevention.

The best method of preventing high-altitude illness is to allow for acclimatization through a graded ascent ([Box 74-1](#)). After day trips to higher altitude, children should return to lower altitude to sleep to aid acclimatization. A high-carbohydrate diet may also help

reduce the risk of high-altitude illness.

Acetazolamide reduces the incidence of AMS in adults.^[36] Pretreatment mimics the acclimatized state by inducing a hyperchloremic metabolic acidosis, allowing

1744

for a compensatory increase in respiration. Clinical experience suggests that it is also beneficial in children. The primary indication for acetazolamide prophylaxis in children is a history of recurrent AMS despite graded ascent.^[70] Acetazolamide is given at 5 mg/kg/day, in two divided doses, up to a maximum daily dose of 250 mg. It should be started 24 hours before ascent and continued while at altitude. Side effects include dehydration, nausea, and somnolence; paresthesias may be particularly bothersome in children.

**Box 74-1. RECOMMENDATIONS FOR
PREVENTING HIGH-ALTITUDE
ILLNESS**

1. Avoid abrupt ascent to a sleeping altitude higher than 3000 m (9843 feet).
2. Spend 2 or 3 nights at 2500 to 3000 m before going higher.
3. Avoid abrupt increases of greater than 500 m (1640 feet) in sleeping altitude per night.

Modified from Klocke DL, Decker WW, Stepanek J: Mayo Clin Proc 73:988, 1998.

Dexamethasone also prevents or reduces symptoms of AMS in adults, but experience with its use in children is limited.

Treatment.

Treatment of mild AMS requires prompt recognition of symptoms, cessation of ascent, and time for acclimatization to occur. *Proceeding to higher altitude in the presence of symptoms is strongly contraindicated and may lead to the life-threatening conditions HAPE and HACE.* Symptomatic therapy includes rest, acetaminophen for headache, and descent. Promethazine (Phenergan) may be used to relieve nausea and vomiting. The dose is 0.2 to 0.5 mg/kg every 6 hours, preferably per rectum. Descent is

unequivocally the most successful treatment for AMS and is mandatory if symptoms progress or fail to improve. Although descent should proceed as far as necessary for improvement, 500 to 1000 m (1640 to 3281 feet) is often sufficient. If immediate descent is not possible, oxygen should be administered if available. Limited studies examining dexamethasone and acetazolamide for the treatment of AMS suggest that both are effective.^[26] Dexamethasone should probably be reserved for patients with deterioration of consciousness, truncal ataxia, or severe vomiting, the hallmarks of HACE. These symptoms of HACE or any symptoms of HAPE demand immediate descent and possible evacuation.

Bites and Stings

Bites and stings often occur in the pediatric age group. In 1995 the American Association of Poison Control Centers recorded 77,368 calls regarding bites and envenomations; 44% involved patients 17 years of age or younger.^[38] Remarkably, major morbidity occurred in less than 0.1% of cases, with no deaths in patients less than 17 years of age. This emphasizes the need for appropriate triage to determine which children require aggressive therapy. Harmful interactions between children and surrounding fauna can be limited by education and judicious use of protective clothing, sturdy footwear, and appropriate chemical barriers.

Snakes.

Most snakebites can be prevented. Children up to 10 years of age are particularly likely to handle snakes and have a higher rate of bites than any other age group.^[14] They also have more severe envenomation syndromes than do adults.^[74] Children should be instructed not to handle snakes, reach blindly into crevices, or turn over rocks and fallen limbs. A useful adage is that hands and feet should never go where the eyes cannot see. When walking through endemic areas, hikers should stay on trails and wear long, loose pants and boots that extend above the ankle. Campsites should be on open ground, away from woodpiles or rockpiles.

If a bite occurs, the child should back away from the snake and be calmed. Agitation and movement of the bitten extremity will encourage venom circulation. The wound should be cleansed rapidly and any constricting items of clothing or jewelry removed from the extremity. The bitten extremity should be immobilized promptly and positioned below the level of the heart. No incision over the bite should be made. The use of mechanical suction (e.g., Extractor, Sawyer Products, Safety Harbor, Fla.) has been shown in animal studies to safely remove up to 30% of injected venom if applied within 3 minutes for 30 to 60 minutes.^[7] However, there is a possibility that its use may worsen local venom effects. Parents traveling to snake-infested areas should consider adding such a product to their medical kit (see [Chapter 38](#) , [Chapter 39](#) , [Chapter 40](#)). All pediatric victims of potentially poisonous snakebites should be transported to a medical facility for prompt evaluation.

Hymenoptera.

Hymenoptera stings (bees, wasps, hornets, and ants) are the most common cause of

envenomation in children. Although Hymenoptera venom possesses intrinsic toxicity, the amount delivered is small, and multiple stings are necessary for significant human morbidity. However, the venom components are potent antigens capable of producing IgE-mediated anaphylaxis in sensitized individuals. Although children appear less susceptible to systemic reactions than adults, physicians should educate parents in the management of Hymenoptera stings, particularly if a child has had a previous severe reaction.

Hymenoptera stings usually produce local pain, swelling, and erythema. A stinger should be removed as quickly as possible by whatever means available, since rapid removal of the stinger is much more important than the method of extraction. ^[73] Within 20 seconds, 90% of venom sac contents are discharged into

1745

the victim, and within 1 minute, 100%.^[62] Applying ice or cool compresses reduces pain and swelling. Elevation and immobilization are indicated for large local reactions on extremities. In older children, oral antihistamines may provide additional symptomatic relief.

**Box 74-2. RECOMMENDATIONS FOR
AVOIDING MOSQUITOES AND USING
REPELLENTS**

1. Wear long-sleeved shirt and pants.
2. Minimize outdoor activities at dusk.
3. Use mosquito netting to cover the heads of infants and children, and in sleeping area.
4. Spray clothing, netting, and screens with permethrin preparations (Permanone, Duranon).
5. Use insect repellents with no more than 35% diethyltoluamide (DEET) on exposed skin only, avoiding children's hands.
6. Apply DEET products over any other creams such as sunscreen to minimize absorption and maximize repellent effect.
7. Keep DEET out of reach of small children.

Early signs of a systemic reaction include generalized pruritus, urticaria, angioedema,

bronchospasm, and laryngeal edema. Their presence mandates medical evaluation. Epinephrine is the drug of choice for systemic sting reactions and should be administered in the field if available (0.01 mg/kg subcutaneously of 1:1000 aqueous concentration). Parents may prefer a spring-loaded automatic injector that delivers 0.3 mg (EpiPen) or 0.15 mg (EpiPen Jr.) of epinephrine subcutaneously when triggered by pressing the device against the thigh. EpiPen Jr. is used for children up to 15 kg and EpiPen for larger children and adults. Since up to half of all patients with anaphylactic reactions have no forewarning, epinephrine belongs in all wilderness medical kits (see [Chapter 36](#) and [Chapter 37](#)).

Mosquitoes.

Mosquitoes are not only a nuisance but also a vector for disease (see [Chapter 32](#)). Steps can be taken to avoid mosquitoes ([Box 74-2](#)). A proper wardrobe provides an excellent physical barrier to mosquitoes. This should include ankle-high footwear, pants cinched at the ankles or tucked into socks, a long-sleeved shirt, and a full-brimmed hat. Mosquito netting draped over a child's hat will protect the face and neck without the toxic side effects occasionally seen with repellents ([Figure 74-7](#)). Mosquito netting, especially in the sleeping area, has been found to reduce the mosquito attack rate by 97%.^[75]

Repellents containing diethyltoluamide (DEET) are effective against mosquitoes, ticks, blackflies, and many other arthropods. Although generally of low toxicity, DEET is absorbed cutaneously, and toxic encephalopathy attributed to its use has been reported. Children may be at particular risk because of their greater

Figure 74-7 Mosquito netting draped over child's hat.

BSA/mass ratio (see [Chapter 65](#)). However, with proper application, it is an excellent repellent. High concentrations of DEET may cause dermatitis with erythema, bullae, skin necrosis, and residual scarring. Although products containing 100% DEET are commercially available, long-acting formulations of 35% DEET appear equally effective in protecting against mosquitoes, with less potential for toxicity. It is prudent to avoid using products containing higher than 35% DEET in children. DEET products can be applied over other creams, such as sunscreen, to minimize absorption and maximize repellent effect. Parents should also be cautioned to keep DEET out of the reach of small children, since ingestions may be fatal.^[75]

The pesticide permethrin, available as a 0.5% spray (Permanone, Duranon Tick Repellent), is safe and effective against arthropods, especially ticks. Unlike DEET

repellents, these permethrin products are applied to fabric or netting, not to skin. Permethrins as a class have low toxicity in mammals. The combination of DEET applied to exposed skin and permethrin treatment of clothing is particularly effective in protecting against mosquito bites and ticks. The protective effect of mosquito netting is greatly enhanced when the netting is impregnated with permethrin.^[75] These effects are longer lasting with permethrin soaks (up to 20 washings) than with permethrin spraying of clothing or netting.

Ticks.

As with mosquitoes, ticks serve as vectors for disease, most notably Lyme disease (see [Chapter 33](#)). Transmission of the Lyme spirochete, *Borrelia burgdorferi*, typically requires 48 to 72 hours or more of tick contact.^[64] Tick checks should be conducted regularly while traveling through wilderness areas. A tick embedded in skin should be grasped with forceps close to

1746

the skin surface and gentle traction applied. Use of alcohol or open flames for tick removal is strongly discouraged, because these techniques are unreliable and may induce tick salivation or regurgitation into the wound. A vaccine against Lyme disease is now available for children over age 15 years who have frequent or prolonged exposure to ticks in Lyme-endemic areas.

FOREIGN TRAVEL WITH CHILDREN

Visits to foreign countries provide superb educational, social, and cultural experiences for children. Unfortunately, traveling with children to wilderness or rural areas within developing nations entails the risks of not only wilderness travel but also poor sanitation conditions, with exposure to bacteria, viruses, protozoa, and helminths not usually seen in the developed world. Parents should be aware of the greater risk of traveling to a developing country with a child under 2 years or less than 15 kg.

The physician provides guidance and information to parents planning foreign travel. The Internet provides both physician and traveler with up-to-the-minute information ([Table 74-5](#)). Preparation for foreign travel with children includes identification and avoidance of risky endeavors, administration of appropriate immunizations and prophylactic medications, knowledge of common childhood diseases and their treatment, and posttravel follow-up by an informed physician.

General Recommendations

Physicians should emphasize to families that risk avoidance is the most important aspect of safe travel ([Box 74-3](#)).^[20] Parents should select transport, activity, and overnight settings carefully to avoid unnecessary hazards. Freshwater swimming should be avoided in developing countries to prevent parasitic infections

such as schistosomiasis. Where swimming is appropriate, parents should provide close supervision. In one study in Washington state, drowning was the leading cause of pediatric mortality in the wilderness, followed by closed head injury and exposure.^[47] Since traumatic injury is the leading cause of morbidity and mortality among children, great effort should be made to prevent it.^[56] Protective devices, such as car seats, helmets, personal flotation devices, and protective clothing and pads, should be used as often as possible ([Figure 74-8](#)).

Skin protection is vital in the outdoors, particularly in tropical environments. The use of closed shoes can prevent infection with hookworm, *Strongyloides*, the agents of cutaneous larva migrans, and other parasites that enter the skin. Clothing should be selected based on ambient temperature and expected conditions; even in hot, sunny climates, light clothing should cover as much BSA as possible to provide protection from parasites, insects, and UV light. Sunscreen should be used liberally and reapplied every few hours, particularly after swimming.

Parents should take great care in selecting foods and safe drinking water for themselves and their children,

who are particularly vulnerable to disease and diarrhea ([Box 74-4](#)). All foods should be well cooked, canned, or peelable. All milk products should be pasteurized or boiled. Water should never be consumed from the tap; only bottled, 1-minute-boiled, or chemically treated (iodine) *and* microfiltered (0.2 µm pore size) water should be ingested (see [Chapter 51](#)). In certain areas, even bottled water is suspect. Breast-feeding is safest for young infants. If formula is used, only properly disinfected water should be used for its preparation. Frequent handwashing, particularly with infants and toddlers and especially around mealtimes, will successfully interrupt the fecal-oral passage of disease.

Box 74-3. RECOMMENDATIONS FOR AVOIDING RISKS DURING TRAVEL

1. Select appropriate settings: supervised swimming, safe campsites, protective devices.
2. Protect skin: sunscreen, repellents, protective clothing, closed shoes.
3. Eat and drink cleanly: water disinfection, careful food selection.
4. Avoid bugs and wild animals: clothing, netting, repellents, vigilance.

Modified from Fischer PR: Infect Dis Clin North Am 12:355, 1998.

Box 74-4. RECOMMENDATIONS FOR PREVENTING TRAVELER'S DIARRHEA

1. Eat only well-cooked vegetables, meat, and seafood.
2. Eat only fruit that can be peeled.
3. Drink only disinfected or boiled water, carbonated drinks, hot tea, or coffee.
4. Drink or eat only pasteurized dairy products.
5. Avoid ice cubes, or use only those made from disinfected water.
6. Breast-feed infants.
7. Prepare formula with disinfected or boiled water only.
8. Wash hands thoroughly before eating or preparing food.
9. Brush teeth with disinfected water.
10. Beware of food from street vendors.

Figure 74-8 Appropriate helmet use.

Parents should also focus their efforts on avoiding contact between children and insects or wild animals. Mosquitoes and ticks can be avoided by avoiding outdoor activities between dusk and dawn and by wearing protective clothing and repellent (see [Box 74-2](#)). As mentioned, DEET is an effective repellent but should not be used at concentrations greater than 35% in children because of the probable risk of toxicity.^[20] Children's hands should be free of DEET to prevent accidental eye and mouth contact. Outer clothing and bed netting should be treated with permethrin. Parents should check for ticks daily when in tick-infested areas. Children should be warned to watch where they place their hands and feet (in crevices, unattended shoes, sleeping bags) to avoid the unexpected arthropod or snake.

Immunizations

Foreign travel with children requires advance planning because vaccines recommended for travel to certain countries may take up to 6 weeks to complete. The Centers for Disease Control and Prevention (CDC) Internet site (see [Table 74-5](#)) provides current information on immunizations and prophylaxis based on the following:

1. Countries of travel
2. Length of time in each country
3. Location of destinations (rural vs. urban)
4. Time of year
5. Type of lodging and eating facilities
6. Previous immunizations
7. Age and weight of the child

Vaccines may be categorized as routine (polio, diphtheria-tetanus-pertussis, *Haemophilus influenzae* B, hepatitis B, measles-mumps-rubella, varicella), routine for travel (hepatitis A, immunoglobulin), geographically indicated or required (yellow fever, typhoid, meningococcus, Japanese encephalitis, cholera, Lyme disease), and indicated for extended stay (rabies)^[69] ([Table 74-6](#) and [Table 74-7](#)).

TABLE 74-6 -- Categories of Vaccines for Children

TYPE OF VACCINE	EXAMPLES
Routine	Polio, diphtheria-tetanus-pertussis (DTaP), <i>Haemophilus influenzae</i> (Hib), measles-mumps-rubella (MMR), varicella-zoster virus (VZV), hepatitis B

Routine for travel (developing countries)	Hepatitis A or immune globulin (IgG)
Required or geographically indicated	Yellow fever, typhoid, meningococcal, Japanese encephalitis, cholera, Lyme disease
Extended stay	Rabies

Modified from Thanassi WT, Weiss EL: Emerg Med Clin North Am 15:43, 1997.

1748

TABLE 74-7 -- Vaccines for Children Who Travel

VACCINE	DESCRIPTION	DOSING	COMMENTS/CONTRAINDICATIONS
ROUTINE			
Polio ⁺	OPV: live attenuated, oral IPV: inactivated, injection	IPV at 2, 4 mo; OPV at 12–18 mo, 4–6 yr; may accelerate to q 4–8 wk x 3 doses	IPV at 2 and 4 mo decreases risk of polio in undiagnosed immunocompromised infants; AAP recommendation may change to IPV only
Diphtheria-tetanus-pertussis ⁺	DTP: D, T toxoid + whole cell P	DTaP recommended at 2, 4, 6, 15–18 mo and 4–6 yr; Td booster at age 12, then q 10 yr	May accelerate to dose every 4 wk x 3 doses if necessary; decreased incidence of vaccine-related reactions with DTaP
	DTaP: DT toxoid + acellular P		
	Td: booster		
<i>Haemophilus B</i> ⁺	Hib polysaccharide: protein conjugate	0.5 ml IM at 2, 4, 6, 12–15 mo	Typically given as combination with DTaP

Hepatitis B	Recombivax HB: inactivated viral antigen	3 doses: 0, 1, 6 mo	Some protection after just 1 or 2 doses; may accelerate Engerix-B to 0, 1, 2, 12 mo
		<11 yr: 0.25 ml IM	
		>11 yr: 0.5 ml IM	
	Engerix-B: same	3 doses 0, 1, 6 mo	
		<11 yr: 0.5 ml IM	
		>11 yr: 1.0 ml IM	
Measles-mumpsrubella [‡]	Live attenuated viruses	0.25 ml IM at 12–15 mo, then booster at 4–6 or 11–12 yr	May accelerate to 6–12 mo, repeat 1 mo later, then per usual schedule; give at least 2–3 wk before IgG
Varicella	Live attenuated virus	12 mo-12 yr: 0.5 ml SC as single dose	Give at least 2–3 wk before IgG; may be given with MMR using different sites; avoid if immunocompromised
		>12 yr: 2 doses 4–8 wk apart	

ROUTINE FOR TRAVEL

Hepatitis A	Havrix: inactive virus (720ELU)	>2 yr: 2 × 0.5 ml doses 6–12 mo apart	Preferred for hepatitis A protection if over age 2 yr
	Vaqta (24U)		Protects in 4 wk after dose 1
Immune globulin (IgG)	Antibodies	<2 yr: 0.02 ml/kg for <3 mo of travel; 0.06 ml/kg q 5 mo and 3 days before travel	Hepatitis A protection for those under age 2 yr; beware of timing with live virus vaccines

REQUIRED OR GEOGRAPHICALLY INDICATED

Yellow fever	Live virus	>9 mo: 0.5 ml SC at least 10 days before departure; booster q 10 yr	Required for parts of sub-Saharan Africa, of tropical South America; may give at 4–9 mo if traveling to epidemic area; under 9 mo: risk of vaccine-related encephalitis
Typhoid	Heat inactivated	6 mo-2 yr: 2 x 0.25 ml SC 4 wk apart, booster q 3 yr	Fever, pain with heat killed; significantly fewer side effects with ViCPS and Ty21a; important for Latin America, Asia, Africa; vaccine not a substitute for eating and drinking cleanly
	ViCPS: polysaccharide	2–6 yr: 0.5 ml IM x 1 booster q 2 yr	
	Ty21a: oral live attenuated	>6 yr: 1 capsule q 2 days x 4; booster q 5 yr	
Meningococcal	Serogroups A, C, Y, W-135: polysaccharide	>2 years: 0.5 ml SC; booster in 1 yr if 1st dose after age 4 yr, otherwise in 5 yr	Use for central Africa, Saudi Arabia for the Hajj, Nepal, and epidemic areas; minimal efficacy under age 2 yr
Japanese encephalitis	Inactivated virus	1–3 yr: 0.5 ml SC at 0, 7, 14–30 days	Indicated for parts of India and rural Asia if stay > 1 mo; no safety data for under age 1 yr; high rate of hypersensitivity
		>3 years: 1.0 ml SC at 0, 7, 14–30 days	
		Last dose > 10 days before travel	
Cholera	Inactivated bacteria	>6 mo: 0.2 ml SC	Vaccine of questionable efficacy; not recommended by CDC or WHO; do not use under 6 mo
Lyme disease	LYMERix: antigenic protein	>15 yr: 0.5 ml IM at 0, 1, 12 mo	Indicated for frequent, prolonged exposure to Lyme-endemic area, not brief exposures

EXTENDED STAY

Rabies	HDCV: human diploid cell	1 ml IM in deltoid muscle at 0, 7, 21–28 days if > 1 mo stay	If exposed and immunized: give vaccine, 1 ml IM at 0, 3 days
			If exposed and unimmunized: give rabies Ig (RIG), 20 IU/kg half at site and half IM; give vaccine, 1 ml IM at 0, 3, 7, 14, 28 days

Consult Centers for Disease Control and Prevention (CDC) for current and specific vaccine recommendations.

AAP, American Academy of Pediatrics; IM, intramuscularly; SC, subcutaneously; q, every; WHO, World Health Organization; ±, consider.

*DtaP, poliovirus vaccine, and *Haemophilus influenzae* type b vaccine may be given at 4-week intervals if necessary to complete the recommended schedule before departure.

†Measles: two additional doses given if younger than 12 months of age at first dose.

TABLE 74-8 -- Recommended Timing and Sequence of Nonroutine Immunizations for Foreign Travel[†]

4–6 WEEKS BEFORE DEPARTURE	1 WEEK AFTER INITIAL VISIT	WEEK OF DEPARTURE
Hepatitis A (need second dose 6–12 mo later)		or Immune globulin for hepatitis A prevention
Yellow fever		
Typhoid-heat inactivated or ViCPS or Ty21a (oral, 1 capsule q 2 days × 4)		Typhoid: heat inactivated
Meningococcal		Meningococcal (if not given at initial visit)
Japanese encephalitis	Japanese encephalitis	Japanese encephalitis
Rabies	Rabies	Rabies

*Give only immunizations indicated for area of travel, length of stay, and age of child. Simultaneous administration of routine and travel-related vaccines is acceptable with the exception of yellow fever with cholera (yellow fever at least 3 weeks before cholera) and MMR or VZV with IgG. Administer IgG at least 3 weeks after these live virus vaccines (see [Table 74-7](#)).

The risk of acquiring diseases covered by many routine childhood immunizations (diphtheria, pertussis, tetanus, measles, polio, hepatitis B) is greater in developing nations. Consequently, children who have not completed their primary series of immunizations may require an acceleration of the vaccination schedule or extra doses to maximize protection before travel.

Ideally, a visit to the physician to discuss travel plans and begin immunizations should be made 4–6 weeks before travel. Not all immunologic agents recommended for travel are compatible, and some require multiple doses. Therefore the selection of immunizations to be given at any one time and the interval between immunizations are important ([Table 74-8](#)). In general, all toxoid, recombinant, inactivated, and live attenuated vaccines may be given simultaneously. Exceptions are those against yellow fever and cholera, which should not be given simultaneously or within 3 weeks of each other. Alternatively, the cholera vaccine can be omitted, since its effectiveness is limited.^[54] Live attenuated vaccines should be given either simultaneously or at least 30 days apart to avoid reduced immunoreactivity to each vaccine. Administration of immune globulin interferes with the humoral response to the live attenuated virus vaccines such as measles, mumps, and rubella (MMR) and varicella. If immune globulin is given first, these vaccinations should be delayed by at least 6 weeks, and preferably 3 months, to obtain an adequate immunogenic response. When both are needed for travel, it is best to give MMR or varicella vaccine first; immune globulin can be given closer to the time of travel, at least 2 weeks and preferably 4 weeks later. Immune globulin does not interfere with antibody production induced by live viral vaccines against polio (oral vaccine) or yellow fever and may be given at the same visit. Travel vaccines that require multiple doses or early administration include hepatitis A, inactivated typhoid, Japanese encephalitis, rabies, yellow fever, and MMR (if immune globulin is to be given near the time of departure).

Malaria Prophylaxis

The risk of acquiring malaria during visits to developing countries in the tropics is significant (see [Chapter 65](#)). Even areas where the overall risk is relatively low may have foci of intense transmission. Children under 5 years are particularly vulnerable and represent the largest proportion of fatalities from this disease. Of the 30,000 to 50,000 cases of malaria acquired by travelers from Europe and North America per year, most occur among visitors to sub-Saharan Africa (82%) and Asia (8%).^[39]

Protective measures to prevent mosquito bites help interrupt the transmission of malaria but are not fool-proof (see [Box 74-2](#)). Therefore chemoprophylaxis is highly recommended for travelers to countries where malaria is endemic. *Plasmodium vivax* and *P. falciparum* are the two most abundant species responsible for malaria. The most lethal species, *P. falciparum*, has developed widespread resistance to chloroquine and in some areas (rural Thailand, Cameroon, Indonesia) resistance to mefloquine.^[6] Therefore the choice of prophylactic agent depends on the presence of resistant malaria in the area of travel.

Chloroquine (Aralen) is still the drug of choice for travelers to the few areas where

chloroquine-resistant strains of *P. falciparum* are not a problem (Central America west of the Panama Canal, Haiti, Dominican Republic, and Middle East) or areas where *falciparum* malaria does not occur (Egypt). Chloroquine prophylaxis should be given weekly starting 1 week before travel and continued for 4 weeks thereafter. Chloroquine is passed through breast milk, although not in sufficient quantities to protect an infant. Therefore a breast-fed infant should receive chloroquine prophylaxis in the standard recommended doses ([Table 74-9](#)). Chloroquine is not readily available in liquid form in the United States. The powder, which is extremely bitter, may be suspended in a syrup or mixed with food. Instant pudding effectively masks the bitter taste and makes the medicine more palatable. An acceptable-tasting syrup (Nivaquine) is available in most developing countries. Chloroquine should be kept out of the reach of children. As little as

1751

TABLE 74-9 -- Malaria Chemoprophylaxis

MEDICATION	INDICATIONS	DOSING
Mefloquine (Lariam)	Travel to chloroquine-resistant areas Child > 15 kg	Given weekly: 1 wk before to 4 wk after travel
	Avoid in child with epilepsy or psychiatric illness	15–19 kg: ¼ tablet
		20–30 kg: ½ tablet
		30–40 kg: ¾ tablet
		>40 kg: 1 tablet (250 mg)
Doxycycline	Alternative to mefloquine in chloroquine-resistant areas if contraindication to mefloquine	2 mg/kg/day up to 100 mg/day 1–2 days preexposure and 4 wk after exposure; photosensitivity possible
	>8 yr of age only	
Chloroquine (Aralen) (liquid: Nivaquine)	Travel to chloroquine-sensitive areas	5 mg/kg/wk up to 500 mg for 1 wk before and 4 wk after exposure; 10 mg/ml liquid available outside United States
	(Caribbean, Central America north of Panama, Middle East)	

	Safe in children under 15 kg	
Proguanil (Paludrine)	Take with chloroquine when possible, particularly in Africa	Give daily while taking chloroquine
	Not available in United States	<2 yr: 50 mg/day
		2–6 yr: 100 mg/day
		7–10 yr: 150 mg/day
		>10 yr: 200 mg/day
Pyrimethamine-sulfadoxine (Fansidar)	Prepare for treatment if symptoms develop and medical attention > 24 hr away	Single dose:
	Contraindicated if age < 2 mo or sulfa allergy	2 mo-1 yr: ¼ tablet
		1–3 yr: ½ tablet
		4–8 yr: 1 tablet
		9–14 yr: 2 tablets
		>14 yr: 3 tablets
Atovaquone (250 mg) + proguanil (100 mg) (Malarone)	Prepare for treatment in Fansidar-resistant areas (parts of Southeast Asia, Amazon basin)	Dose per day × 3 days
	Not available in United States	11–20 kg: 1 tablet
		21–30 kg: 2 tablets
		31–40 kg: 3 tablets
		>40 kg: 4 tablets
Primaquine	Prevention of relapse with <i>Plasmodium vivax</i> or <i>P. ovale</i>	0.3 mg/kg/day for 14 days after leaving area
	Use after prolonged stay in malaria-endemic area	
	Avoid if glucose-6-phosphate dehydrogenase deficient	

Data from Red book: report of the Committee on Infectious Disease, Elk Grove Village, Ill, 1997, American Academy of Pediatrics.

1 g may be fatal in small children.^[49] If a toxic chloroquine ingestion occurs, syrup of ipecac should be administered immediately to provoke emesis, and the child should be transported promptly to a medical facility.

Proguanil (Paludrine) is not available in the United States but is widely available overseas. It is recommended for use with chloroquine, particularly in chloroquine-resistant areas if mefloquine and doxycycline are contraindicated. This would include children less than 15 kg and those under age 8 years with epilepsy or psychiatric disorders. Unfortunately, this regimen is only 40% to 60% effective and should not be used unless alternative therapies are contraindicated.

For children over 15 kg traveling to chloroquine-resistant areas, mefloquine (Lariam) is the preferred agent. It is started 1 week before travel and given weekly during travel and for 4 weeks after return. Mefloquine should be avoided in children with psychiatric illnesses, epilepsy, or underlying cardiac arrhythmias. Doxycycline may be used in children over age 8 years with contraindications to mefloquine. Unlike mefloquine, however, doxycycline must be given daily. Side effects include diarrhea and photosensitivity. Since neither of these agents can be used in small children (less than 15 kg), parents should seriously consider the risks of acquiring malaria before traveling to a malaria-endemic area with an infant or toddler.

If a child develops an acute febrile illness in a malaria-endemic area where medical care is not immediately available, pyrimethamine with sulfadoxine (Fansidar) may be used as standby treatment.^[4] Fansidar is given as a one-time dose. Prophylaxis with this drug is not recommended because of the risk of Stevens-Johnson syndrome. Fansidar should not be given to infants less

than 2 months old or to children allergic to sulfa medications. Atovaquone with proguanil (Malarone) is an alternative standby treatment that has been used successfully in Fansidar-resistant areas (parts of Southeast Asia and the Amazon basin).^[41] ^[52] Studies have also demonstrated the efficacy of this preparation as prophylaxis against *P. falciparum*, but this use has not yet gained widespread acceptance.^[37] ^[63] Malarone is not available in the United States. All patients who take Fansidar or Malarone for presumptive treatment of malaria should be transported to a medical facility as soon as possible for definitive care.

Primaquine is an antimalarial drug used to prevent emergence of *P. vivax* and *P. ovale* after heavy exposure or prolonged (many months) exposure to mosquitoes. Routine chemoprophylaxis does not kill the exoerythrocytic stages of these *Plasmodium* species. Primaquine is taken daily for 2 weeks after leaving a malarial area. Primaquine should not be given to anyone with glucose-6-phosphate dehydrogenase (G6PD) deficiency.

TRAVEL-RELATED PROBLEMS

After boredom and restlessness, motion sickness and eustachian tube dysfunction are the most common problems of children during travel. Parents can minimize the first two problems by preparing small activity packs or bags with paper, pencils, crayons, cards, travel puzzles, or small toys.

Motion Sickness

Motion sickness can occur with air, land, or sea travel, particularly in children ages 2 through 12 years. Emotional upset, noxious odors, and ear infections can make the symptoms worse. Children experiencing motion sickness are often pale and diaphoretic and feel nauseated and weak. They may vomit, but unfortunately this does not provide prolonged relief. Children known to be susceptible to motion sickness should be seated in the middle or near the front of the boat, plane, or car, where motion is minimized. They should be encouraged to look at objects far away and avoid focusing on close objects, such as books. Some children obtain significant relief from using headphones to listen to music or stories.

Dimenhydrinate (Dramamine, 1 to 1.5 mg/kg) administered 1 hour before departure and repeated every 6 hours can help children known to be prone to motion sickness. If dimenhydrinate is not available, diphenhydramine (Benadryl, 1.25 mg/kg every 6 hours) may also be effective. Both medications may cause drowsiness, and diphenhydramine occasionally causes paradoxical hyperexcitability in children. Scopolamine patches should not be used because children are particularly susceptible to the side effects of belladonna alkaloids. Whether patches release too much scopolamine and consequently produce serious side effects in children is not known.^[49]

Eustachian Tube Dysfunction

Eustachian tube dysfunction causes discomfort that results from a pressure disequilibrium between the eustachian tube and the surrounding atmospheric pressure. About 15% of children have this problem, particularly during airplane descent. Swallowing often helps relieve the pressure disequilibrium and may be facilitated by drinking or, for the breast-fed infant, by nursing. Older children may chew gum or yawn to equalize middle ear and atmospheric pressure. Contrary to popular belief, decongestants are not useful with eustachian tube dysfunction in children and may cause paradoxical drowsiness.^[9]

Most airline cabins are pressurized to provide an oxygen concentration of 17% to 18%, not the 21% of sea-level air. Supplemental oxygen may be necessary for children with

congenital heart disease or pulmonary disease (asthma, bronchopulmonary dysplasia) if cyanosis or respiratory distress develops.

Traveler's Diarrhea

Traveling to wilderness areas or developing countries requires leaving behind modern sanitation and reliably disinfected tap water (see [Chapter 52](#)). Unfortunately, this places travelers at increased risk for diarrheal illness. Traveler's diarrhea affects 25% to 50% of adult travelers from low-risk to high-risk countries. In one pediatric study, 40% of children under age 2 years developed prolonged diarrhea during travel in tropical or subtropical areas.^[50] Young children are at greater risk for traveler's diarrhea and its complications because of relatively poor hygiene, immature immune systems, lower gastric pH, more rapid gastric emptying, and difficulties with adequate hydration.^[16]

Traveler's diarrhea has been defined as greater than three unformed stools in a day or any number of such stools when accompanied by symptoms such as fever, abdominal cramping, vomiting, or blood or mucus in the stools.^[50] In small children the course tends to be more severe and prolonged, lasting from 3 days to 3 weeks. Traveler's diarrhea can be caused by preformed toxins, viruses, invasive bacteria, or parasites ([Table 74-10](#)). Enterotoxigenic *Escherichia coli* is responsible for 50% of traveler's diarrhea. Rotavirus and Norwalk-like viruses account for another 30%.^[5] *Shigella* remains the most common cause of invasive diarrhea.

Prevention.

Standard recommendations for prevention of traveler's diarrhea are based primarily on known potential vehicles for transmission of the illness (see [Box 74-4](#)). Transmission is through fecal-oral contamination, with water, food, and fingers the most common sources. Careful selection and preparation of food and beverages can decrease the risk of acquiring traveler's diarrhea. Washing hands thoroughly before eating decreases bacterial carriage and also reminds children about the need for precautions. According to the

TABLE 74-10 -- Causes of Traveler's Diarrhea in Children

AGENT	EXAMPLES
Preformed toxin	Enterotoxigenic <i>Escherichia coli</i> *
	<i>Staphylococcus aureus</i>
	<i>Bacillus cereus</i>
Viral	Rotavirus*
	Norwalk agent*

	Adenovirus
	Enterovirus
	Influenza
	Hepatitis
Bacterial	<i>Shigella*</i>
	<i>Campylobacter</i>
	<i>Salmonella</i>
	Enteroinvasive <i>Escherichia coli</i>
	<i>Yersinia enterocolitica</i>
	<i>Vibrio cholera</i>
Parasitic	<i>Giardia lamblia</i>
	<i>Entamoeba histolytica</i>
	<i>Cryptosporidium</i>

*Most common.

"boil it, cook it, peel it, or forget it" rule, all raw vegetables and salads should be avoided, meats and seafood well cooked, and fruits properly peeled (see [Chapter 51](#)).

Box 74-5. SIGNS OF DEHYDRATION IN CHILDREN

MILD-MODERATE (5%–10%)

Irritability
Sunken eyes
Dry mucous membranes
Extreme thirst

SEVERE (>10%)

Lethargy
Extremely sunken eyes
Extremely dry mucous membranes
Inability to consume oral liquids
Cool, mottled extremities
Rapid thready pulse
Tachypnea

Modified from Treatment of diarrhoea: manual for physicians and other senior health workers, Geneva, 1995, World Health Organization.

Treatment.

The major cause of morbidity and mortality in infants and small children with diarrhea is dehydration^[4] ([Box 74-5](#)). According to the World Health Organization (WHO), dehydration is best categorized as mild-moderate or severe.^[72] This distinction is based on changes in behavior and mental state, quality of mucous membranes, oliguria or

anuria, changes in vital signs, and decreasing peripheral perfusion. Children young enough to be wearing diapers should have some urine output at least every 8 hours. If not, they are probably dehydrated.

Box 74-6. HOMEMADE ORAL REHYDRATION SOLUTION

1 teaspoon (5 g) salt

1 cup (50 g) rice cereal

1 quart (1 L) disinfected water

Data from World Health Organization.

The cornerstone of therapy is oral rehydration therapy (ORT), which can be used alone successfully in 90% to 95% of cases, especially if instituted early.^[23] ORT is as effective as intravenous hydration in mild-moderate dehydration from diarrhea. Parents traveling to developing countries or wilderness areas with children should carry a prepared powdered oral rehydration solution (ORS) or a recipe for a homemade solution ([Box 74-6](#)). Powdered ORS is readily available in most developing countries through WHO and may be obtained in the United States from Jianas Brothers, Kansas City, Missouri (816-421-2880). Although earlier studies reported rice-based ORS as more effective in reducing stool output than standard glucose-based ORS,^[46] ^[53] more recent studies demonstrated that any advantage from rice-based ORS is lost after 6 hours of rehydration.^[18] ^[45] Rice ORS has lower osmolality and higher concentration of organic solutes; therefore the osmotic gradient across the intestinal lumen is lower and intestinal sodium transport decreased, theoretically resulting in less stool water. Because of hydrolysis of its starches, however, rice-based ORS is stable only for 12 hours, after which it must be discarded and a new solution made.^[58]

For rapid treatment of mild-moderate dehydration, 50 to 100 ml/kg of ORS should be administered over the first 4-hour period, followed by maintenance solution to provide for basic fluid requirements and to replace ongoing losses.^[5] ^[58] Ideal ORS should contain 75 to 90 mEq/L of sodium, 2% to 2.5% carbohydrate, and 20 mEq/L of potassium (Table 74-11 (Table Not Available)). If a solution with more than 3% glucose is used, the osmotic pressure exerted by glucose in the intestinal lumen produces fluid losses greater than fluid absorption, thereby exacerbating diarrhea. Most colas and juices contain nearly 10% to 15% glucose or carbohydrate and are not appropriate rehydration solutions.^[25] ^[42] The high sodium concentration in the ORS poses a risk for hypernatremia if the solution is used for maintenance fluids or to prevent dehydration.

For maintaining hydration, alternating ORS with a fluid that has less sodium, such as water or breast milk, will avert hypernatremia.

TABLE 74-11 -- Field Treatment of Dehydration in Children

(Not Available)

Modified from Goepf J, Santosham M: Principles Pract Pediatr Updates 1:1, 1993.

Alternatively, a separate solution containing 50 to 60 mEq/L sodium can be used. Maintenance fluid volumes are 75 to 150 ml/kg/day. An additional 10 ml/kg, or 4 ounces, can be given for each diarrheal stool and 5 ml/kg, or 2 ounces, for each episode of emesis.^[35] If vomiting develops, most children will still tolerate ORS if given in small volumes (5 to 10 ml) every 5 minutes. Feeding of solid food, particularly complex carbohydrates, should be continued during and after diarrhea because it promotes enterocyte regeneration.^[9] ^[19] ^[57] Severe dehydration requires prompt medical attention and administration of intravenous fluids for rehydration.

Although oral hydration should be the cornerstone of therapy for diarrhea and dehydration, medications may be helpful. Antimotility agents such as loperamide and diphenoxylate are of no proven efficacy, according to the American Academy of Pediatrics (AAP) guidelines for acute gastroenteritis.^[1] In general, they should be avoided; however, loperamide may be used with older children if fever, bloody stool, and abdominal distention are absent^[17] (see [Table 74-12](#)). Other antidiarrheal agents (e.g., bismuth) have not been shown to be effective in children and should be avoided, particularly in those under 2 years.

Antibiotic chemoprophylaxis remains controversial for adults and is not recommended for children.^[1] The use of antibiotics should be limited to children with fever, bloody stools, or abdominal distention in whom invasive bacterial diarrhea is suspected.^[27] Under age 3 to 6 months, the risk of bacteremia with *Salmonella* infection is significant, so antibiotic treatment is also indicated. With increasing bacterial resistance to trimethoprim-sulfamethoxazole, azithromycin is now the drug of choice for treatment of bacterial diarrhea.^[29] ^[67] The dose is 10 mg/kg on day 1, then 5 mg/kg once daily for 5 days. Although quinolones (e.g., ciprofloxacin) can be used in children over age 12 years and perhaps younger, increasing bacterial resistance to quinolones makes azithromycin an even better choice. If symptoms do not improve rapidly, parents should seek immediate medical attention for their children. *Salmonella typhi* infection, or typhoid fever, if suspected, should be managed immediately in a hospital setting with quinolones or third-generation cephalosporins.

Respiratory Infections

Respiratory tract infections are common in the pediatric population. Most infections,

such as acute otitis media (AOM), sinusitis, pharyngitis, croup, bronchiolitis, and bronchitis, involve the upper respiratory tract. The majority of these infections are viral in etiology; the remainder are usually the result of infections with *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Moraxella catarrhalis*. Since definitive diagnoses based on otoscopy and auscultation of the lungs often cannot be made during wilderness travel, parents must rely on symptoms and the presence of fever to determine whether treatment is necessary. The presence of high fever, otalgia, facial pain, sore throat without cough or rhinorrhea, or mucopurulent nasal discharge lasting longer than 10 days likely merits both antimicrobial and symptomatic treatment. However, 20% to 80% of AOM and 50% of streptococcal pharyngitis cases resolve without intervention. ^[12] ^[13] Furthermore, antibiotic treatment of certain upper respiratory infections, such as bronchitis, bronchiolitis, croup, and most pharyngitis, does not shorten the course, minimize symptoms, or decrease complications. ^[43]

With increasing use of antibiotics, bacterial resistance to these agents has risen dramatically. From 10% to 30% of *S. pneumoniae* infections are resistant to penicillin and 5% to 20% to macrolides such as erythromycin. ^[11] Up to 20% of *H. influenzae* and 70% of *M. catarrhalis* infections are resistant to amoxicillin. However, testing has demonstrated sensitivity to high-dose amoxicillin, even among resistant strains. First-line therapy for these infections is therefore high-dose amoxicillin at 60 to 80 mg/kg. ^[67] Second-line therapy is high-dose amoxicillin-clavulanate (same amoxicillin component dosing), cefuroxime, or ceftriaxone. ^[43] Uncomplicated AOM in children over 2 years may be treated for 5 to 7 days; otherwise the standard treatment for AOM is 10 days and, for sinusitis, 14 days. Exudative pharyngitis with fever and lymphadenopathy but without cough can be treated for 10 days with penicillin or amoxicillin, or for 5 days with azithromycin.

Fever of Undetermined Origin

High fever that develops in a child during the course of foreign travel may be the result of a common infection (e.g., AOM, pharyngitis) or the manifestation of a

tropical disease. If malaria is suspected, the child should immediately be taken to the closest medical facility. If this cannot occur within 24 hours, any child over 2 months old should be given Fansidar as standby treatment (see [Table 74-9](#)).

Salmonella typhi infection, more commonly known as typhoid fever, can also present with high fever, paradoxical bradycardia, and at least initially, without diarrhea. Children who appear ill with high fevers may have invasive typhoidal disease and should be treated in a medical facility. *Salmonella* resistance is rising in developing countries, but strains are typically susceptible to quinolones (over age 12 years) and third-generation cephalosporins (e.g., cefixime, ceftriaxone).

Dengue fever, caused by a mosquito-borne arbovirus, can also cause high fever,

headaches, and severe myalgias (see [Chapter 66](#)). With the exception of recurrent dengue, which can result in hemorrhagic complications, the treatment of dengue fever is purely symptomatic.

Rashes

Identification of rashes in the pediatric population is an art. Although parents cannot be expected to become familiar with all types of rashes, they should learn to distinguish common rashes from potentially dangerous exanthems. Petechial, purpuric, or mucosal lesions are markers for potentially serious disease and should prompt parents to seek medical attention immediately. Standard dermatologic textbooks with photographs can be used to instruct parents to recognize common viral exanthems and rashes caused by varicella, scabies, and contact dermatitides (poison oak, poison ivy). Scabies can be abolished safely with permethrin. Contact dermatitis can be treated with 1% hydrocortisone cream.

Soft Tissue Injuries

Soft tissue injuries are extremely common among children, particularly as they become more ambulatory (see [Chapter 18](#)). All wounds sustained in the wilderness should be thoroughly irrigated with clean water and explored to ensure that no foreign bodies remain. In general, lacerations should not be sutured in the backcountry due to the risk of infection. They should be covered with a water-resistant dressing, splinted if located over a joint, and observed. If no evidence of infection develops over 4 to 5 days, the laceration may be repaired by delayed primary closure.

PEDIATRIC WILDERNESS MEDICAL KITS

When a family travels in remote areas, any medical kit must be adapted to meet the special needs of children. Actual items carried vary depending on the ages of the children, preexisting medical conditions, length of travel, specific environmental conditions encountered, and medical sophistication of the adults. Although individual preference plays a role in assembling a medical kit, certain items are essential for management of common problems during wilderness travel with children ([Box 74-7](#)).

Box 74-7. PEDIATRIC WILDERNESS MEDICAL KIT: BASIC SUPPLIES

1. Identification and basic health information for child: past medical history, medications, allergies, blood type, weight
2. First-aid supplies: adhesive bandages, gauze pads, gauze roll, tape, nonadherent dressings, moleskin/Spenco 2nd skin/Nu Skin, benzoin, alcohol wipes, povidone-iodine solution for dilution and disinfection, safety pins, tweezers, lightweight malleable splint (SAM splint), syringe (20–35 ml), 18-gauge plastic catheter for wound irrigation
3. Oral rehydration salts
4. Sunscreen: SPF of 15 or greater
5. Insect repellent: DEET <35%
6. Whistle for child
7. For infant <3 mo: rectal thermometer, bulb syringe

To reduce weight and bulk, medications selected for a wilderness medical kit should have multiple uses ([Table 74-12](#)). For example, diphenhydramine is effective for allergic symptoms, pruritus, motion sickness, nausea, and insomnia. Desitin, best

known for its use in preventing diaper rash, is also an excellent sunscreen, since it contains 40% zinc oxide. A broad-spectrum antifungal cream, such as miconazole or clotrimazole, covers not only tinea infections (ringworm, jock itch, athlete's foot), but also *Candida* infections (diaper rash, vaginitis).

Most children can chew tablets once their first molars are present (about 15 months of age). Before that time, chewable medications or tablets can be crushed between two spoons and mixed with food. Liquid medications add excess weight and the potential for leaks; they should be carried in powder form only for children under 6 months. Medication can be camouflaged in a food such as instant pudding.

Painful musculoskeletal injuries are a potential complication of wilderness activities, and pain medication for children should be included in every medical kit. Acetaminophen not only relieves minor aches and pains but also is effective for fever control. It is well tolerated by most children and available in many pleasant-tasting forms for children unable to swallow pills: chewable 80- or 160-mg tablets, elixir, and concentrated drops. Ibuprofen appears to be more effective than acetaminophen for pain and fever control. Its duration of action is 6 to 8 hours vs. 4 to 6 hours for acetaminophen.

TABLE 74-12 -- Pediatric Wilderness Medical Kit: Medications

MEDICATION	INDICATION	DOSE
TOPICAL MEDICATION		
Antibiotic or antiseptic ointment (e.g., bacitracin-polymyxin)	Superficial skin infections	Apply as directed qd-tid
Topical corticosteroid (e.g., 1% hydrocortisone)	Contact or atopic dermatitis, insect bites, sunburn	Apply to affected areas bid-tid (use sunscreen aggressively; avoid >1% on face)
Antifungal cream (e.g., clotrimazole, miconazole)	Yeast at diaper area, groin, scalp, feet; ringworm	Apply bid for 7–10 days and for several days after rash has resolved
Desitin cream	Sunscreen, diaper area erythema	Apply thick coat as sunscreen or thin coat for diaper area
Permethrin (Elimite)	Scabies, lice, treatment for clothing and mosquito netting	Apply 5% cream from chin to soles of feet and wash after 8–14 hr; do not use <2 mo of age or on eyes, nose, or mouth

Anesthetic eye drops (e.g., proparacaine) [‡]	Removal of superficial ocular foreign body	1 drop in affected eye for removal of foreign body; must patch eye for protection for at least 1 hr
Antibiotic eye ointment (e.g., erythromycin) [‡]	Purulent conjunctivitis, suspected corneal abrasion	Use as directed tid-qid

ORAL MEDICATIONS

Diphenhydramine	Allergic symptoms, pruritus, insomnia, nausea, motion sickness	1.25 mg/kg/dose every 6 hr up to 25–50 mg/dose; may cause paradoxical restlessness in children
12.5 mg/5 ml elixir		
25- or 50-mg capsules		
Acetaminophen	Fever control, pain	15–20 mg/kg every 4–6 hr up to 650 mg/dose
80 mg/0.8 ml drops		
160 mg/5 ml elixir		
80- and 160-mg chewable tabs		
or Ibuprofen	Fever control, pain, antiinflammatory	10 mg/kg/dose every 8 hr up to 600 mg/dose
40 mg/1 ml drops		
100 mg/5 ml elixir		
50- or 100-mg chewable tabs		
100- or 200-mg caplets		
Acetaminophen with codeine [‡]	Severe pain, severe cough	As for acetaminophen, or 0.5–1 mg/kg of codeine every 4–6 hr
120 mg acetaminophen and 12 mg codeine/5 ml elixir		
Dimenhydrinate (Dramamine)	Motion sickness	1–1.5 mg/kg/dose 1 hr before departure and every 6 hr thereafter; may cause drowsiness
12.5 mg/5 ml elixir		
50-mg chewable tabs		

ORAL ANTIBIOTICS (CHOOSE APPROPRIATE ACCORDING TO CHILD'S AGE)

Amoxicillin [‡]	Otitis media, sinusitis, pharyngitis, pneumonia, urinary tract infection (UTI)	60–80 mg/kg/day for upper respiratory infection (URI) or divided tid for pneumonia
125- or 250-mg chewable tabs		
250-mg capsules		
Amoxicillin-clavulanate (Augmentin)	Resistant acute otitis media (AOM), sinusitis, animal bites, soft tissue infections	Same as amoxicillin dosing divided bid
200- and 400-mg chewable tabs		
200 and 400 mg/5 ml elixir		
Azithromycin (Zithromax) [‡]	AOM, sinusitis, pharyngitis, pneumonia, traveler's diarrhea, skin infections, animal bites	10mg/kg on day 1, then 5 mg/kg/day qd x 5 days
125 and 250 mg/5 ml elixir		
250-mg tabs (best)		
Ciprofloxacin (Cipro) [‡]	Approved for >8 yr of age: UTI, traveler's diarrhea, aquatic wounds	20–30 mg/kg/day divided bid up to 500 mg bid
100-, 200-, 500-mg tabs		

OTHER PREPARATIONS

Epinephrine (premeasured) [‡]	Anaphylaxis, severe asthma	0.15 mg SC up to 15 kg; 0.3 mg SC if over 15 kg
0.15 mg (EpiPen Jr.)		
0.3 mg (EpiPen)		
Syrup of ipecac	Induce vomiting for noncaustic ingestions in alert child	15 ml followed by 1–2 glasses of water; may repeat in 20 min if no emesis
Oral rehydration packet (ORS)	Dehydration	See Table 74-11 (Table Not Available)

FOREIGN TRAVEL

Loperamide	Nonbloody, minimally febrile, significant diarrhea over 2 years of age (not recommended by AAP)	13–20 kg: 1 mg tid
1 mg/5 ml		20–30 kg: 2 mg bid
1-mg capsules		>30 kg: 2 mg tid
Appropriate malaria prophylaxis if indicated [†]		See Table 74-9
Pyrimethamine-sulfadoxine (Fansidar) [‡]	Standby treatment for malaria if immediate medical attention unavailable	See Table 74-9

TRAVEL TO HIGH ALTITUDE

Acetazolamide (Diamox) [‡]	Recurrent acute mountain sickness (AMS) despite graded ascent	5 mg/kg/day divided bid up to 250 mg/day
30 or 50 mg/ml suspension		
125-mg tabs		
Promethazine (Phenergan) [†]	Nausea and vomiting associated with AMS	0.25–0.5 mg/kg/dose every 6 hr up to 25 mg/dose
12.5 or 25 mg/suppository		

SNAKE-INFESTED AREAS

Extractor (negative-pressure suction device) [‡]	Poisonous snakebites	Apply per instructions within 3 min of bite
---	----------------------	---

qd, Every day; *bid*, twice daily; *tid*, three time daily; *SC*, subcutaneously.

*Administration of this medication by other than trained medical personnel is strongly discouraged given the risk of overuse and subsequent worsening of eye injury; if significant eye irritation persists, medical attention must be sought to evaluate for corneal injury.

[†]Available by prescription only.

[‡]Sawyer Products, Safety Harbor, Fla.

Ibuprofen is available in many forms: infant drops (40 mg/1 ml), children's elixir (100 mg/5 ml), 50- or 100-mg chewable tablets, and 100- or 200-mg caplets. Tylenol with codeine combines a centrally acting agent, codeine, with a peripherally acting analgesic, acetaminophen. It is indicated for treatment of moderate to severe pain. Acetaminophen has the added effect of fever control, and codeine has antitussive properties. Codeine can cause respiratory depression, particularly in children under 12 months of age, and may elevate intracranial pressure, especially in the presence of head injury; its use should be avoided in these situations. Dosing is based on the codeine component: both

the liquid formulation (12 mg/5 ml) and tablets (10, 20, or 30 mg of codeine per tablet) are given at 0.5 to 1 mg/kg up to every 6 hours.

Two or three antibiotics will cover most bacterial infections in children. Age, allergies, intolerance, and past experience must be taken into account when antibiotics are selected. Given increasing bacterial resistance to common antibiotics, antimicrobial choices should be reevaluated periodically to ensure that infections likely to be encountered can be successfully treated with these agents. All oral antibiotics require a prescription. Amoxicillin is available in pleasant-tasting chewable tablets (125 and 250 mg) and in powdered form for suspension (125 and 250 mg/5 ml) Given current resistance patterns, high-dose therapy with 60 to 80 mg/kg divided three times daily is indicated. Amoxicillin is well tolerated by most children. Amoxicillin-clavulanate (Augmentin) provides excellent coverage for recurrent pharyngitis, soft tissue infections, animal bites, and infections when a resistant organism is anticipated. The most common side effect is diarrhea, but this has been reduced with newer formulations, available in 200- and 400-mg (amoxicillin component) chewable tablets and in 200 and 400 mg/5 ml liquid. Dosing is 60 to 80 mg/kg divided twice a day. Azithromycin (Zithromax) is a long-acting macrolide without the gastrointestinal side effects of erythromycin. It is effective for treatment of AOM, sinusitis, pharyngitis, lower respiratory infections, traveler's diarrhea, and common animal bites. It is particularly useful in children with penicillin allergy. Dosing is extremely convenient because of azithromycin's long half-life: a 10 mg/kg initial dose

on day 1 is followed by 5 mg/kg/day for 5 days. Ciprofloxacin (Cipro) has a broad spectrum of coverage and is useful for treatment of bacterial diarrhea, complex urinary tract infections, and wounds acquired in an aquatic environment. Its use has been discouraged in children under 12 years because of a potential problem with arthropathic effects on weight-bearing joints. However, a study involving more than 600 children found only a 1.3% rate of reversible arthralgia and no evidence of arthropathy.^[60] Nonetheless, ciprofloxacin should not be routinely recommended for children under 12 years unless a special situation arises in which the benefits of its use outweigh the risks.

Syrup of ipecac should also be included in every pediatric medical kit. Small children tend to explore their environment with hands and mouths. If toxic ingestions are recognized within 30 minutes and there is no contraindication to induced emesis (caustic agent or solvent, altered mental status, less than 1 year of age), ipecac should be administered immediately. One tablespoon or 15 ml should be given with one or two glasses of water; this dose may be repeated in 20 minutes if emesis does not occur.

Parents of children with special medical conditions should carry a pertinent medical summary and have resources to access specialty physicians in destination countries. A generous supply of necessary medications with instructions for worsening symptoms must be included in the medical kit. An extra supply of all essential medications should be kept with either parents or patient in case the medical kit is lost or separated from the

patient when the medication is needed. Some travelers in endemic areas for hepatitis B and acquired immunodeficiency syndrome (AIDS) carry their own needles and syringes for emergency use. The International Association for Medical Assistance to Travelers (417 Center St., Lewiston, NY 14692; 716-754-4883) has a directory of qualified physicians worldwide who speak English.

INFANTS AND YOUNG CHILDREN

A family traveling with an infant must be particularly vigilant in monitoring their child's state of health. Infants become hypothermic, hyperthermic, septic, and dehydrated more rapidly than adults or older children. A thermometer and appropriate lubricant should be included in the medical kit for monitoring rectal temperature. A temperature greater than 38° C (100.4° F) in a child less than 3 months of age requires evacuation for medical evaluation. Digital thermometers are recommended, since they are less likely to break, are easy to read, and are three to four times faster than a glass thermometer. Some emit an audio alarm when the reading is ready.

Infants are less tolerant of problems with excess mucus; a bulb syringe is handy for suctioning mucus from the oropharynx and nasal passages. A few drops of saline solution (¼ tsp of salt in 1 cup of water) instilled into the nares a few minutes before aspiration help to loosen mucus. Nasal aspiration should be reserved for times of most need, such as before feeding and sleep, since the procedure is irritating to the child. Other uses for a clean bulb syringe include flushing foreign bodies from ears and administering enemas.

Away from the conveniences of home, diapers tend to be changed less frequently; consequently, diaper rash may become a problem. A good barrier cream (e.g., Desitin) may be helpful and should be started at the first signs of irritation. If the rash progresses despite appropriate treatment, an antifungal cream (e.g., miconazole, clotrimazole) may be used.

Lost Children

Lost children in the wilderness is a common, preventable problem. Children should be taught to recognize landmarks and to turn around and look backward periodically to familiarize themselves with the terrain. Those who are capable of reading a compass and topographic map should carry these at all times. Young children should wear brightly colored clothing to facilitate a search should they become lost. They should carry a whistle around their necks and should be taught the universal signal for help: three blows in a row. It should be emphasized to the child that the whistle is intended for emergency use only. All children should either know or carry with them a piece of paper with their parents' name, address, and phone number. Older children who venture without their parents should always inform an adult where they are going, with whom, and when they expect to return.

Programs such as "Hug a Tree" instruct children in the basics of survival and orienteering when lost: stay in one place to facilitate any search, take advantage of the

natural shelter provided by a tree, and feel the security of a large natural protector. By "hugging a tree" and not wandering, children can make signals from rocks or branches to indicate their location. Children should be taught to avoid becoming wet, to wear a hat, and to stuff pine needles or dry grasses into their clothes to insulate themselves if they are cold. Children can practice making temporary shelters out of logs, branches, and leaves to experience the warmth and protection of these natural features.

Homesickness

Most children will experience some degree of distress when faced with separation from home, particularly when they will not be accompanied by a parent. Predisposing factors to the depression and anxiety referred

1759

to as "homesickness" include young age, little prior separation experience, high parental separation anxiety, great perceived distance from home, few initial positive experiences after separation, preexisting anxiety or depression, and little perceived control over the situation.^[71] Parents should introduce short periods of separation from home and family that lead up to longer periods. They should discuss the exciting aspects of the adventure to come and encourage active decision making regarding activities and destination. Parents should also alleviate their own separation anxiety and ensure positive early postseparation experiences for their child. The presence of familiar faces, such as friends or favorite playmates, can significantly reduce a child's feeling of homesickness. The child will remember favorite games and meals as fun experiences.

Chapter 75 - Women in the Wilderness

Kenneth F. Trofatter Jr.
Barbara D. Dahl

Problems common and unique to a woman might diminish the wilderness experience or place her at risk. This chapter emphasizes a practical approach to the evaluation, management, and impact assessment of gynecologic and obstetric conditions of women undertaking short-term or long-term wilderness activities. A framework is provided for the diagnosis and the selection of empiric therapy, based on historical and physical observations, under circumstances in which limited medical care and resources are available. Preexisting conditions are also addressed, with consideration of access to a medical facility in the field.

PREPARATION FOR THE WILDERNESS EXPERIENCE

The goal of preparation is to anticipate and recognize problems rather than to address them for the first time under suboptimal circumstances. A high priority is to identify medical problems that could be exacerbated by physical demands and the wilderness setting. These must be evaluated in relation to characteristics of the environment, length of the excursion, additional conditioning and acclimation, and difficulty in accessing more sophisticated medical care. For physically challenging conditions and prolonged stays, women should undergo thorough medical assessment ([Box 75-1](#)).

After historical information is collected, a comprehensive physical examination is performed, with special attention to the cardiovascular and respiratory systems, musculoskeletal system, genitourinary tract, and breasts. Other recommended tests include: Pap smear, vaginitis screening, pregnancy test, urinalysis, hemoglobin/hematocrit (Hgb/Hct), and urine culture and screening for sexually transmitted infections (STIs) and hepatitis. Additional screening, as indicated by age, medical status, and risk factors, include electrocardiogram (ECG) with stress testing, pulmonary function tests, mammogram if over age 40 or with strong family history of breast cancer, and thyroid panel. Bone densitometry should be considered in perimenopausal and postmenopausal women and in young women with a history of fractures or abnormal menses consistent with a hypoestrogenic state.

In anticipation of a wilderness trip, supplemental iron, vitamins, and calcium are recommended ([Table 75-1](#)). Maintenance medications should provide optimal control of medical conditions and cover planned time, emergency needs, and expected dose adjustments. Contraceptive needs should be reviewed and options explored. Hormonal replacement therapy should be discussed with postmenopausal women at risk for osteoporosis. [Box 75-2](#) lists basic supplies for hygienic and anticipated therapeutic needs. Special considerations for pregnancy are discussed in a separate section.

PHYSIOLOGIC ADAPTATIONS

Women at Altitude

Recent studies have found no difference in the incidence of acute mountain sickness (AMS) in women and men.^[57] Differences in how men and women respond to altitude may be hormonally mediated. Adaptation to high altitude involves a series of physiologic responses triggered by hypoxemia. The sigmoidal shape of the oxyhemoglobin dissociation curve prevents a drop in the oxygen saturation below 90% until an altitude of about 2400 m (8000 feet) in healthy individuals. At higher altitudes, hypoxia stimulates respiratory, cardiovascular, and hematologic changes that depend on both degree of hypoxia and time.

The earliest and probably most important response to altitude is an increase in minute ventilation caused by increases in tidal volume and respiratory rate. This hypoxic ventilatory response (HVR) is mediated by chemoreceptors in the carotid bodies, which respond to a decrease in arterial oxygen pressure (PaO_2) and signal the respiratory center in the medulla to increase ventilation.^[141] HVR has been closely related to adequacy of acclimatization and the risk of developing AMS.^[58] ^[83] ^[135] The degree of HVR to a given PaO_2 varies among individuals and is genetically influenced. The HVR is inhibited by respiratory depressants, such as alcohol and sedatives and stimulated by respiratory stimulants, such as caffeine and cocoa. Progesterone is a potent respiratory stimulant and acts primarily through activation of peripheral arterial chemoreceptors.^[26] ^[60] ^[61]

Progesterone is produced by all steroid-forming glands, including the ovaries, testes, and adrenal cortex, and by the corpus luteum and placenta in the pregnant female. Ovariectomy in female cats lowers the carotid sinus nerve response to hypoxia and likewise decreases HVR, although translation of carotid nerve activity in the central nervous system (CNS) into ventilation was similar in ovariectomized and intact animals.^[152] Exogenous progesterone and estrogen administration to male rats living at 3600 m (12000 feet)

TABLE 75-1 -- Examples of Medications for Women's Health

INDICATION	MEDICATION*	DOSE
------------	-------------	------

Nutritional supplements	Ferrous sulfate	300 mg qd-tid
	Calcium carbonate	1250 mg qd
	Multivitamin	1 tablet qd
Headache/pain	Acetaminophen	325 mg, 1 or 2 q3-4h
Dysmenorrhea/pain	Ibuprofen	200 mg, 1–4 q4-6h
Nausea/vomiting	Promethazine (tablet or suppository)	25 mg q4-6h
Urinary tract infection	Ampicillin	250–500 mg qid
	Trimethoprim/sulfamethoxazole	160 mg/800 mg bid
Yeast vulvovaginitis	Miconazole (cream or suppository)	One applicator hs × 3–7 days
	Fluconazole	150 mg single dose
Bacterial vaginosis	Metronidazole (tablets)	250–500 mg bid-tid
	Metronidazole or clindamycin (vaginal gel)	One applicator hs × 3–7 days
Urine pregnancy test kit	As needed	
Menstrual regulation or breakthrough bleeding	Conjugated estrogen (Premarin)	2.5 mg qd
	Medroxyprogesterone acetate	5–10 mg qd

qd, Daily; *bid*, twice daily; *tid*, three times daily; *qid*, four times daily; *q*, every; *h*, hour; *hs*, at bedtime.

*Suggested medications or equivalent depending on tolerance, allergy history, and patient preferences.

significantly inhibited norepinephrine and dopamine turnover in the carotid sinus, thus stimulating the afferent chemoreflex.^[44] In pregnant females, HVR is enhanced and most likely driven by higher progesterone levels. Mean P_{O_2} value at 4,400 m (14,500 feet) in nonpregnant women is 51 mm Hg (carbon dioxide pressure [P_{CO_2}] 28 mm Hg) vs. 59 mm Hg (P_{CO_2} 23 mm Hg) in pregnant women.^[64] Increased ventilation is a key factor in adapting to altitude in pregnancy, as evidenced by the linear correlation between birth

weight and maternal ventilatory rate.^[110] Despite higher levels of progesterone in women, particularly in the luteal phase of the menstrual cycle, when progesterone levels increase approximately tenfold, no difference has been observed between males and nonpregnant females in the incidence of AMS, although one study has reported a lower incidence of gastrointestinal (GI) and cardiovascular symptoms in females vs. males at altitude.^{[57] [62]} To date, no study has been done comparing HVR and the incidence of AMS in premenopausal women in follicular vs. luteal phases.

Box 75-1. ASSESSMENT OF A WOMAN'S HEALTH: SCREENING HIGHLIGHTS

Menstrual history: age of menarche, regularity, characteristics, timing, extent of blood flow (length, amount), intermenstrual bleeding, perimenstrual symptoms (e.g., dysmenorrhea, headache, premenstrual syndrome), plans for managing periods (hygienic, therapeutic)

Sexual history: age of coitarche, number of partners, sexual orientation, sexually transmitted infections, contraceptive history, plans for sexual activity in the wilderness, dyspareunia

Gynecologic history: ovarian cysts, uterine fibroids, endometriosis, cervical dysplasia, surgical history, pelvic pain, vaginal discharge, vaginal infections and treatment, pregnancy and complications

Breast: galactorrhea, discharge, masses, surgery

Gastrointestinal/urinary tract: ulcers, irritable bowel syndrome, gallbladder disease, constipation, urinary tract infections, kidney stones, stress incontinence, urgency incontinence

Musculoskeletal/skin: injuries (exercise related and accidents), limitations, muscle cramps, joint pain and swelling, arthritis, rashes, acne, sun sensitivity, hirsutism, hair loss

Exposure to abuse: battering, sexual harassment, sexual assault

Habits: smoking, alcohol, illicit drug use

Current problems: condition, medications, status of control, complications

Immunizations: measles, mumps, rubella, polio, diphtheria, tetanus, hepatitis, others

Family history: thyroid disease, hypertension, autoimmune disorders, diabetes, breast and gynecologic malignancies, osteoporosis

Allergies: general, drug related, bite and sting sensitivity

Nutritional: eating disorders, weight changes, food sensitivities, dietary preference (e.g., vegetarianism), caloric intake, assessment of mineral and vitamin intake in diet, supplements (e.g., iron, vitamins, calcium) including homeopathic compounds

breast and gynecologic malignancies, osteoporosis

Allergies: general, drug related, bite and sting sensitivity

Nutritional: eating disorders, weight changes, food sensitivities, dietary preference (e.g., vegetarianism), caloric intake, assessment of mineral and vitamin intake in diet, supplements (e.g., iron, vitamins, calcium) including homeopathic compounds

Box 75-2. BASIC SUPPLIES FOR WOMEN'S HYGIENE

STANDARD

Sanitary napkins or tampons (store in plastic bag)

Toilet paper (store in plastic bag)

Cotton underwear

Matches or cigarette lighter (to burn toilet paper after use)

Plastic trowel (to bury feces)

Toiletries (soap, small towel, toothbrush and paste, dental floss, comb)

Moisturizing lotion (unscented, to prevent skin chapping/cracking)

OPTIONAL

Urinal guide (if long periods of poor weather are anticipated)

Vaginal speculum and gloves (if trained medical professional accompanies expedition)

Premoistened towelettes (convenient for cleaning/washing when water is limited or weather precludes bathing)

Cardiovascular adaptations to altitude also occur early and are mediated by release of catecholamines. Hypoxia stimulates a sympathoadrenal release of epinephrine and norepinephrine, resulting in elevated heart rate, cardiac output, and mean arterial pressure (MAP). This catecholamine-mediated response was studied in females at 4300 m (14,000 feet). Norepinephrine levels rose steadily during the initial days at altitude, reached a plateau at 4 to 6 days, and remained elevated for the duration at altitude.^[97] Norepinephrine levels correlated with increased heart rate and MAP. This response,

previously demonstrated in males, reflects elevation in whole body sympathetic nerve activity at altitude. ^[95] ^[96] No difference was found in the sympathetic response to hypoxia between follicular-phase and luteal-phase subjects; however, for a given norepinephrine level, heart rates and MAPs were lower for follicular vs. luteal subjects, possibly reflecting effects of hypoxia and ovarian hormones on adrenergic receptors.

Other circulatory changes at altitude include decreased plasma volume from dehydration, increased insensible water loss, and fluid shifts into the extravascular space. Euvolemia is usually regained with adequate hydration and acclimatization. ^[52] Also, hypoxic pulmonary vasoconstriction results in increased pulmonary vascular resistance and increased pulmonary artery pressure. Cerebral blood flow (CBF) also increases at altitude. Although hypoxic vasodilation and hypocapnic vasoconstriction both contribute to regulating CBF, the hypoxic response is thought to dominate at altitudes over 3800 m (12,500 feet). ^[71] ^[125]

Hematologic changes occur at altitude in response to hypoxia. Within hours, erythropoietin levels increase, with red blood cell mass increasing a few days later. The higher the altitude, the greater the increase in Hct and blood viscosity, which may actually be detrimental to oxygen transport despite an increase in O₂-carrying capacity. ^[70] This hypoxia-induced polycythemia is associated with chronic mountain sickness. ^[150] Recent animal studies suggest that, under hypoxic conditions, female ovarian hormones reduce erythropoietin levels and hypoxic-induced polycythemia. ^[44] It is not known whether this hormonally mediated effect is significant in human females at altitude.

Hot and Cold Environments

Because of the lower sweat rate in females compared with males, women rely more heavily on dimensional characteristics and circulatory mechanisms for heat dissipation in hot environments. ^[137] ^[138] Females adapt more easily to hot, wet environments than do males because of this lower sweat rate and decreased risk of dehydration. ^[9] ^[98] In hot, dry environments, however, a higher sweat rate is advantageous because perspiration decreases the risk of hyperthermia, provided adequate fluid replacement is available. With acclimation to dry heat, women are able to increase the sudorific response to equal that of men. ^[165] With similar acclimatization and physical training, women tolerate physical activity in hot environments at least as well as men. ^[51] ^[63] ^[69] Thus women planning wilderness expeditions to hot, dry destinations are advised to plan a 1- to 2-week acclimation period in a hot environment. ^[10]

Adaptation of females to hot temperatures may also depend on menstrual phases. Some evidence suggests that women in the follicular phase of the menstrual cycle may adapt better to hot environments than women in the luteal phase. The resting core temperature in women is approximately 0.4° C higher during the luteal phase than during the follicular phase. ^[49] Also, the threshold core temperature for the onset of thermoregulatory responses, such as sweating and vasodilation, is increased during the luteal phase. Therefore women in the luteal phase may have more difficulty in reaching thermal equilibrium in hot environments. ^[29] ^[122]

In moderately cold environments, women on average adapt better than men, partly because of thicker subcutaneous fat. At extreme cold temperatures, however, women may be at a disadvantage because of the decrease in insulation from lower muscle mass. Although adaptation to cold environments depends more on body size, physical fitness, and degree of acclimation than on gender, exercise performed during cold exposure may be more effective in maintaining body heat in women than men.^[55] ^[99]

CONTRACEPTION

Women of reproductive age who anticipate having a heterosexual relationship while in the wilderness should strongly consider a reliable and convenient form of contraception, especially for extended excursions ([Box 75-3](#)). Pregnancy is a relative contraindication

1764

to both brief and prolonged wilderness experiences because of the frequent, inconvenient, and life-threatening complications that can occur. Any form of hormonal contraception or an intrauterine device should be used for at least 3 months before departure to minimize risk of complications.

Box 75-3. CONTRACEPTIVE OPTIONS

HORMONAL

Oral contraceptives

Monophasic combination pills

Multiphasic combination pills

Monophasic progestin-only pills

Injectable

Depo-Provera
(medroxyprogesterone), 150 mg
intramuscularly every 3 months

Implantable

Norplant system (levonorgestrel),
six Silastic implants
subcutaneously

Norplant system (levonorgestrel),
six Silastic implants
subcutaneously

BARRIER

Condom and spermicide
Diaphragm and spermicide
Contraceptive sponge
Cervical cap and spermicide
Female condom

INTRAUTERINE DEVICE (IUD)

ParaGard-T (copper enveloped)
Progestasert system (IUD containing
progesterone)

EMERGENCY CONTRACEPTION

Preven (0.05 mg ethinyl estradiol +
0.25 mg levonorgestrel/tablet), two
tablets within 72 hours postexposure;
repeat dose in 12 hours

Hormonal Contraceptives

Combination (estrogen and progestin) oral contraceptives (OCs), either monophasic or multiphasic, offer the most reliable, convenient, cost-effective, and sensible risk/benefit ratio for the healthy reproductive-age woman. Brand selection should be done with a qualified health care professional. Previous experience of use, complications of therapy, menstrual history, and skin type should be considered. For example, women with histories of irregular cycles and polycystic ovary syndrome may be better suited to brands with low androgenic side effects. Failure rates with optimal use are extremely low (1%), but may be worsened by concomitant drug therapy, substance abuse, chronic GI disturbance, and changes in dietary habits or weight. ^[160] Common side effects include nausea, vomiting, weight gain, and breakthrough bleeding. Other potential benefits include normalization of cycles, fewer midcycle ovulatory (i.e., mittelschmerz)

and perimenstrual (e.g., dysmenorrhea, headaches) symptoms, lighter menstrual flow, suppression of ovarian cyst formation, reduced risk for endometrial cancer, prevention of osteoporosis, and increased bone mass. OCs may decrease the risk of acquiring certain STIs but cannot be relied on for this. Major contraindications include history of thromboembolic disease, certain autoimmune disorders with thromboembolic risk factors, uncontrolled hypertension, hepatic dysfunction, and cigarette smoking.^{[50] [105] [164]}

If a thrombotic or thromboembolic event is suspected in the field, OC use should be suspended and aspirin taken while awaiting evacuation. High altitude is a potential risk factor for thromboembolic events, but increased risk from use of OCs or hormonal replacement therapy has not been systematically studied. As a precaution, women planning high-altitude excursions should consider a combination pill containing the lowest dose of ethinyl estradiol (20 µg) or its equivalent.

Progestin-only OCs are not generally recommended for the wilderness traveler because of higher failure rates (4% to 9%), increased frequency of irregular and unpredictable bleeding, and potentially deleterious effects on bone density over time from suppression of ovarian estrogen production. The progestin-only injectable Depo-Provera (medroxyprogesterone) and the implantable Norplant system (six Silastic capsules containing levonorgestrel, 36 mg/capsule) have similar drawbacks. Although extremely convenient for maintenance contraception, problems include weight gain, irregular bleeding, headache, fatigue, and abdominal pain, especially early in therapy.^{[129] [140]} Prolonged use of progestin-only methods may be associated with reduced bone mass, which could be hazardous for women involved in strenuous physical activities.^[151]

Depo-Provera (150 mg intramuscularly) is administered every 3 months, so extended wilderness experiences would necessitate transport and storage of the drug in its glass container and syringes for administration. Once Depo-Provera is injected, it cannot be removed. Side effects and complications, such as irregular bleeding, must be dealt with for an indefinite period, possibly a year or longer, until its effects on the hypothalamic-pituitary axis have dissipated. Similarly, once the Norplant system is placed, it cannot be readily removed in a wilderness setting unless a trained health care provider and adequate surgical supplies are available. Furthermore, subcutaneous location of the 34-mm capsules, usually on the inner aspects of the upper arm, could be traumatized by certain strenuous wilderness activities. Once implants are removed, however, cyclic hormonal activity and menstruation return almost immediately.

Irregular bleeding with a long-term progestin-only OC can usually be managed with oral estrogen (e.g., Premarin,

2.5 mg daily) for 21 to 25 days sequentially. Estrogen administration results in rapid cessation of bleeding. Within days after discontinuation, a menstrual-like withdrawal bleed should occur in the continued presence of the progestin. If the withdrawal bleed persists beyond the length of a normal period, or if irregular bleeding recurs and persists, the course of estrogen therapy is simply repeated for another cycle. No withdrawal bleed indicates that progestin has fallen below biologically active levels, with

unreliable contraceptive activity.

Barrier Contraceptives

The barrier contraceptive methods have the widest safety profile, excluding latex allergy and method failure resulting in pregnancy, but all have the same disadvantages for regular use in a wilderness setting. Failure rates even under ideal use with a spermicidal foam or gel are relatively high, estimated at 20% with "typical use" and 6% to 9% with "perfect use." The compounds in barrier devices are variably susceptible to extremes of heat or cold, which may compromise their tensile strength and effectiveness. Some couples find these methods inconvenient and messy which might discourage compliance in an environment not conducive to cleanup. Bulk and weight complicate transport of sufficient spermicidal compound. Barrier methods decrease risk of gonorrhea, chlamydial infection, and human immunodeficiency virus (HIV) but offer minimal protection against human papillomavirus (HPV) or genital herpes simplex virus (HSV).

Intrauterine Devices

An intrauterine device (IUD) is a highly effective and convenient form of contraception, especially for the parous woman in a stable relationship. ^[38] ^[47] Ideally it should be inserted at least 3 months before departure. Complications occur most often within the first month after initial insertion and when the device is replaced. IUDs are occasionally associated with increased menstrual flow, dysmenorrhea, intermenstrual spotting, and expulsion. However, the ParaGard-T copper-enveloped IUD and the Progestasert system, which has a reservoir with 36 mg of progesterone and conforms to the endometrial cavity, carry minimal risk for these side effects. Once inserted, the ParaGard-T is effective for 10 years or longer. The Progestasert system requires annual replacement.

The most serious risk, affecting 1% of IUD users, is acute or indolent pelvic infection that might become clinically significant and even life threatening in the wilderness. The risk for this is greatest within the first month after insertion or replacement and among women at increased risk for STIs. Women with multiple partners, previous pelvic infections, unrecognized chlamydial infection or gonorrhea, recurrent episodes of bacterial vaginosis, or tobacco use are at highest risk. ^[113] When acute pelvic inflammatory disease (PID) occurs, with lower abdominopelvic pain, peritoneal signs, purulent vaginal discharge, and fever, the IUD should be removed immediately by simple traction on the string protruding from the external cervical os. Broad-spectrum antibiotics should be started. Evacuation is mandatory when the device cannot be removed. Pelvic infection should be suspected, even without fever and peritoneal signs, if irregular bleeding occurs, particularly when accompanied by pelvic discomfort and discharge. When the IUD is removed at this stage, the infection may respond to therapy with oral or simple parenteral antibiotics (see later discussion).

Another potentially serious risk for IUD users is pregnancy, occurring in approximately one of 100 users per year. Both intrauterine and extrauterine (ectopic) pregnancies can occur with an IUD in place. Unfortunately, the latter is more common, but the risk is still

only half that in women who use no contraception. Confirmed or suspected pregnancy in a woman with an IUD is an indication for immediate evacuation.

Emergency Contraception

In the event of unanticipated or careless sexual activity, suspected contraceptive failure, or sexual assault, consideration should be given to emergency post-coital contraception.^[53] ^[54] In the wilderness setting the only practical approach is hormonal therapy, ideally starting within 72 hours after exposure. Preven and several combination OCs reduce the risk of pregnancy by at least 75%.^[157] ^[158] Treatment regimens with standard OC formulations include Ovral (0.05 mg ethinyl estradiol and 0.50 mg norgestrel), two tablets; Lo-Ovral (0.03 mg ethinyl estradiol and 0.30 mg norgestrel), four tablets; and Nordette or Levlen (0.03 mg ethinyl estradiol and 0.15 mg levonorgestrel), four tablets. The dose is repeated 12 hours later. Common side effects include nausea, vomiting, irregular bleeding, cramping, and headache, but these are usually transient and can be managed symptomatically. Administering an antiemetic 1 hour before each dose is recommended.^[7]

SEXUAL ASSAULT

Sexual assault of women in the wilderness is fortunately a rare occurrence. Wilderness morbidity and mortality statistics are limited, but one study of eight National Park Service areas in California over 3 years reported only one incident of sexual assault.^[108] Many incidents are probably not reported, however, since only 7% of all rapes are reported.^[35]

The best defense against sexual assault is not going into the wilderness with unfamiliar people. The chance of meeting an assailant is quite low. A woman traveling into the wilderness alone or with someone she does

1766

not know well is advised to tell friends or family exactly where and with whom she is traveling and when she anticipates returning.

If sexually assaulted, the woman is advised to seek medical attention as soon as possible. Most emergency departments are prepared to handle the evaluation and treatment of sexual assault victims. It may be impossible to reach a medical facility for many hours or even days, but an attempt should be made to preserve potential evidence. If a medical facility can be reached in a few hours, the woman should try not to eat, drink, urinate, or defecate. Women are also advised to avoid douching, gargling, brushing teeth, or changing clothes. If clothes are removed, clothes should be placed in a paper bag and brought to the medical facility.

VAGINITIS

Vaginitis is a frequent indication for seeking medical care and a common incidental finding at gynecologic evaluation. Although rarely dangerous in healthy women, vaginitis can compromise the wilderness experience. Environmental conditions and constraints on hygiene can contribute to vaginitis and diminish the efficacy of therapy. Self-diagnosis of vaginitis is often incorrect, leading to inappropriate treatment selection.

In premenopausal women, more than 90% of infectious causes of vaginitis are bacterial vaginosis (40% to 50%), candidiasis (20% to 25%), and trichomoniasis (15% to 20%). Symptoms include vaginal discharge, itching, erythema, and irritation of the vagina, introitus,

TABLE 75-2 -- Differential Diagnosis of Vulvovaginitis

FACTORS	NORMAL	BACTERIAL VAGINOSIS	VULVOVAGINAL CANDIDIASIS	TRICHOMONIASIS	ATROPHIC VAGINITIS
Discharge	White, clear, finely granular	Gray-white, thin, homogenous, adherent, frothy	White, thick, curdlike, adherent	Gray to yellow-green, occasionally frothy, adherent	Thin, clear to serosanguineous
pH	3.8 to 4.2	>4.5	=4.5	>4.5	>4.5
Amine odor	Absent	Present	Absent	Variably present	Usually absent
Primary complaints	None	Malodorous discharge	Pruritus, irritation	Severe pruritus, discharge, dyspareunia, dysuria	Burning, soreness, dyspareunia
Microscopic appearance	Normal epithelial cells, lactobacilli	"Clue cells," no WBCs	Budding yeast, hyphae, spores	Trichomonads, many WBCs (PMNs)	Small, round (parabasal) epithelial cells, many PMNs
Other findings and diagnostic features	None	Minimal vulvar involvement	Vulvar and vaginal erythema, predisposing medical conditions	Intense vulvovaginal erythema, "strawberry cervix," other STIs	Atrophy of vulva and vaginal epithelium

WBCs, White blood cells; *PMNs*, polymorphonuclear neutrophil leukocytes; *STIs*, sexually transmitted infections.

and vulva. Therefore most vaginitis of clinical significance is more accurately described as vulvovaginitis. Severe manifestations are intense discomfort, swelling, dyspareunia, dysuria, and urinary retention. The medical history, pelvic examination, and evaluation of vaginal fluid provide the diagnosis of vaginitis ([Table 75-2](#)). Recent evidence suggests that accurate diagnosis of the most common causes of vaginitis can often be done without a vaginal speculum.^[22] Because diagnostic capabilities in the wilderness are limited, clinical features can help guide diagnosis and treatment of vaginitis and improve the chance of therapeutic success.

Bacterial Vaginosis

Bacterial vaginosis (BV) is the most prevalent cause of vaginitis, affecting as many as two thirds of women attending sexually transmitted disease (STD) clinics and 12% to 25% of premenopausal women undergoing gynecologic evaluation. The most common complaints of women with BV are discharge and odor, itching, and irritation of the vulva and vagina. More than 50% of women with BV do not complain of symptoms or are unaware that symptoms result from a treatable condition.

The cause of BV is uncertain and may be multifactorial. BV is characterized by an overgrowth (100 to 1000-fold) of bacterial species in the vagina and GI tract and a dramatic reduction in lactobacilli, especially the predominant hydrogen peroxide-producing species.^[155] The organisms implicated in BV are risk factors for upper genital tract infection, premature labor and delivery, and postoperative wound infections in women.^[30]

1767

Local defects in host immunity may contribute to recurrent and persistent cases.^[31]

The discharge accompanying BV is typically thin, watery, grayish white, frothy, and homogenous (not flocculent), uniformly coating the vaginal walls and introitus. More than 50% of women with BV complain of a fishy odor, particularly during menstruation and immediately after unprotected sexual intercourse. Blood and semen can alkalize the vagina and volatilize a variety of amines (e.g., cadaverine) produced by anaerobic organisms. The diagnosis of BV is confirmed by the presence of three of the following: (1) discharge, (2) pH greater than 4.5, (3) release of amines (fishy odor) when discharge is exposed to 10% potassium hydroxide (KOH) ("whiff test"), and (4) microscopic detection of "clue cells" (epithelial cells coated with bacteria) in saline solution. Microscopic appearance of pure BV is characterized by few if any leukocytes and few motile, curved rods (lactobacilli).

The antimicrobial agent most successful in treating BV is metronidazole, which can be administered orally (500 mg 2 or 3 times daily for 5 to 7 days) or as a 0.75% vaginal gel

(once or twice daily for 5 days).^[75] These regimens have initial response rates in excess of 90%. Single-dose oral treatment with metronidazole (2.0 g) yields initial response rates of 80% to 90% but is accompanied by higher recurrence rates within 1 month of treatment. This regimen should be considered when drug supplies are limited or when the GI side effects of oral metronidazole are not well tolerated. Clindamycin (300 to 600 mg orally twice daily for 5 to 7 days or 2% vaginal gel daily for 7 days) has comparable efficacy, but disadvantages are expense, deleterious effects on normal vaginal lactobacilli, and increased risk for pseudomembranous enterocolitis, which could be life-threatening in the wilderness. Cure rates of 67% have been achieved with ampicillin (250 to 500 mg 4 times daily for 7 days) and amoxicillin (250 to 500 four times daily for 7 days), but again, deleterious effects on the normal vaginal flora often are followed by an overgrowth of yeast organisms.

Yeast (Candida) Vaginitis

Symptomatic yeast infections, more often referred to as *vulvovaginal candidiasis* (VVC), are the second most frequent cause of vaginitis and account for about 25% of cases. From 80% to 90% of these result from overgrowth of *Candida albicans*. *C. glabrata* and *C. tropicalis* account for most of the remainder and are of growing concern because of increased resistance to over-the-counter (OTC) antifungal preparations used to treat presumed "yeast infections," an incorrect presumption more than half the time. Risk factors for yeast infections include pregnancy, hormonal therapy, recent antibiotic use, corticosteroid therapy, postovulatory phase of menstrual cycle, frequent coitus, condom use, and intravaginal use of spermicidal compounds.^{[41] [128] [142]} The presence of gonorrhea, chlamydial infection, and BV are negative risk factors. Recurrent or recalcitrant yeast infections should suggest depressed cell-mediated immunity and frequently affect women with undiagnosed or poorly controlled diabetes, pregnancy, HIV infection, lymphoproliferative disorders, and autoimmune diseases.

The most common complaint of women with VVC is vulvar pruritus or burning, not vaginal discharge.^[131] In more severe cases, redness, irritation, burning, soreness, swelling, and external dysuria are variably present. The characteristic white, flocculent ("cottage cheese"), adherent discharge is often diagnostic but is not consistently present or visible externally. The yeast discharge is thicker than that seen with BV or trichomoniasis, is usually not frothy or malodorous, and often has a pH of 4.5 or less, unless a mixed infection is present. About 50% of yeast infections are confirmed by direct microscopic examination of the discharge diluted in saline; however, diagnosis is most reliably accomplished by detection of budding yeast, hyphae, or spores using a slide preparation with 10% KOH added to lyse background epithelial cells and bacteria.

The foundation of treatment for VVC is a variety of azole derivatives, many of which (e.g., butoconazole, clotrimazole, miconazole, tioconazole) are available OTC as topical creams, vaginal tablets, and suppositories. Prescription compounds for local application do not provide a significant advantage over these in most cases. Therapy periods range from 1 to 14 days, depending on the formulation and severity of the infection. Generally a treatment regimen of at least 3 days results in a greater initial response rate and a lesser chance of immediate recurrence. Symptoms related to inflammatory vulvar involvement will respond most rapidly to the topical creams, although their application at

first may be accompanied by burning pain. Oral fluconazole (150 mg, single dose) has been approved for VVC and is a convenient therapeutic agent to include in the basic pharmacopoeia of a wilderness expedition. Women with frequent recurrences or predictable outbreaks at specific times in their cycle, most often premenstrually, should consider prophylactic suppressive therapy with fluconazole (150 mg orally) or clotrimazole (500 mg vaginal tablet) weekly.

Trichomonas Vaginitis

Trichomonas vaginalis is a single-celled parasite that causes vaginitis in 2 to 3 million women annually in the United States.^[67] It is predominantly sexually transmitted and is found most often in individuals with multiple sexual partners and those with a history of or current STIs. Diagnosis and treatment of a woman and her sexual partner are best accomplished at a screening visit before departure on a wilderness excursion. Unlike BV and yeast vaginitis, detection of *Trichomonas*, even in asymptomatic women, is an indication for treatment and for more complete STI screening.

1768

Symptoms and physical findings accompanying *Trichomonas* infections are highly variable. The organism can be carried asymptotically for extended periods, but most women will develop clinically significant disease over time, often during or immediately after menstruation. The most common complaints include severe vulvovaginal pruritus, dyspareunia, and dysuria. Physical examination often reveals intense erythema of the vagina and introitus and petechial lesions of the cervix ("strawberry cervix"). The vaginal discharge is typically gray or yellow-green, somewhat cloudy, and variably frothy and malodorous. The presence of the latter two findings frequently indicates a mixed infection with the amine-producing organisms seen in BV.^[91] The pH of vaginal fluid is usually above 5.0 and frequently exceeds 6.0.

The clinical features of trichomoniasis overlap sufficiently with those of BV and yeast vaginitis to make them impractical alone for even presumptive diagnosis.^[59] The diagnosis is confirmed by microscopic detection of the motile parasites on simple saline wet mount. Polymorphonuclear neutrophil leukocytes (PMNs) are usually present in high concentration and can interfere with microscopic diagnosis when the organisms are nonmotile. Under these circumstances, culture is now recognized as the most sensitive diagnostic technique, although not likely to be available in a wilderness setting.

Because of the diagnostic difficulties, empiric therapy is justified in the wilderness. Metronidazole is the only drug approved for trichomoniasis in the United States. It is administered in a single oral dose (2 g) and in severe cases or single-dose failures for a week (500 mg bid) or longer. For optimal results, sexual partners should be treated simultaneously and sexual activity curtailed during therapy. To minimize GI side effects, metronidazole should be taken with plenty of water. This may not reduce the unpleasant metallic taste but may reduce the risk of nausea, vomiting, and gastric irritation. Because a disulfiram-like effect is possible, alcohol should be avoided while taking

metronidazole. At present, metronidazole 0.75% vaginal gel is not appropriate for treatment of trichomoniasis.

Atrophic Vaginitis

Atrophic vaginitis occurs in postmenopausal and hypoestrogenized premenopausal women, such as some amenorrheic athletes and women on ovarian suppressive therapy with gonadotropin-releasing hormone (GnRH) agonists. The presumed etiology is lost estrogen effect on the vaginal epithelium, accompanied by reduction in epithelial cell glycogen, an important substrate for lactobacilli, with subsequent overgrowth of nonacidophilic organisms. Symptoms include burning or soreness, dyspareunia, and vaginal discharge that is often watery or even serosanguineous.^[21] ^[120] It should be suspected in women of any age with vulvovaginal atrophy. Typically the vagina is uniformly erythematous and may have areas of petechial changes. The pH of the vagina usually exceeds 5 (often 6 to 7) and microscopic evaluation of the discharge reveals small, round, immature epithelial cells (parabasal cells), increased PMNs, and a paucity of lactobacilli. Treatment includes the use of topical or oral estrogen replacement therapy.

Noninfectious Vulvovaginitis

Certain noninfectious causes of vulvovaginitis result from environmental exposures that cause local irritative or allergic reactions. These may be of greater significance when attention to personal hygiene is limited.^[59] Common causative agents include latex condoms, spermicidal compounds, soaps, detergents, fabric softeners, deodorant products, menstrual pads and tampons, and topical medications such as antimycotics and povidoneiodine. Exclusion of an infectious etiology and identification of the source of the reaction usually make the diagnosis. Once a potentially offending cause, such as a recent change in laundry detergent, is identified, the first step in management is removal from exposure. Treatment is usually symptomatic (pain relief, antihistamines, Sitz baths). Topical corticosteroids are rarely indicated and may initially exacerbate symptoms.

URINARY TRACT INFECTIONS

In sexually active adolescent and adult women, bacterial bladder infections (cystitis) are the most common manifestation of urinary tract infection (UTI) and a frequent source of medical complaints.^[16] They occur more frequently in women than men, presumably because of the shorter length of the urethra, its location in proximity to the vagina and enclosed within the introitus, and trauma secondary to sexual activity. Women with recurrent vaginitis, particularly BV; congenital or acquired genitourinary tract abnormalities; diaphragm use and use of spermicidal compounds; poor hygiene; and cigarette abuse are at increased risk for developing UTIs, as are pregnant women.^[45] ^[56] ^[120] ^[153] About 5% of pregnant women develop asymptomatic bacteriuria, 20% of whom progress to upper tract disease. Wilderness conditions, with restricted access to fluid, deferred voiding, and less attention to personal hygiene, increase the potential for development of UTIs. Attention to maintenance of urinary tract health should be a primary goal of the female wilderness traveler.

Common symptoms of cystitis include urinary frequency, urgency, dysuria, hematuria, foul-smelling or cloudy urine, and low back discomfort.^[68] ^[90] Some women develop UTIs in relation to phase of the menstrual cycle or after sexual activity. Upper tract involvement, or pyelonephritis, should be suspected with accompanying fever, chills, malaise, flank pain, and occasionally, nausea and vomiting. Under wilderness conditions, symptoms, elevated urine pH (7 to 8), and indirect evidence of

TABLE 75-3 -- Antibiotic Regimens for Urinary Tract Infections

TYPE OF INFECTION	SELECTED ANTIBIOTICS	LENGTH OF TREATMENT
Cystitis (acute)	Ampicillin, 250 to 500 mg qid	3–7 days
	Amoxicillin, 500 mg tid	
	Cephalexin, 500 mg qid	
	Nitrofurantoin,* 100 mg qid	
	Sulfamethoxazole/trimethoprim,* 1 or 2 tablets bid	

Prophylaxis	Any of the above: 1 pill/day or 1 pill after coitus	Indefinitely
Pyelonephritis [†] (outpatient care)	Amoxicillin, 500 mg tid	10–14 days
	Cephalexin, 500 mg qid	
	Ciprofloxacin, [‡] 500 mg bid	
	Sulfamethoxazole/trimethoprim, [*] 1 or 2 tablets bid	

bid, Twice daily; *tid*, three times daily; *qid*, four times daily.

*Contraindicated for use near term in pregnancy.

†Serious infections require parenteral antibiotics.

‡Contraindicated during pregnancy and lactation.

pyuria (leukocyte esterase) or bacteria (nitrites) on urine dipstick test suggest UTI. Under ideal conditions, microscopic confirmation of pyuria and culture of organisms from a clean urine specimen are still the best methods for confirming the diagnosis and assessing the antibiotic sensitivity of etiologic bacteria.

Management of UTIs includes both prophylactic and therapeutic measures. Women should drink at least six to eight glasses (48 to 64 oz) of noncarbonated fluid per day. Under dehydrating conditions, sufficient fluid should be ingested to generate voiding at least every 3 to 4 hours while awake.^{[116] [145]} Women should void when the urge arises or on a regular schedule and not risk bladder overdistention. They should be reminded to wipe from front to back after urination and defecation and to void after sexual intercourse. Treatment of symptomatic cystitis usually requires a 3- to 7-day course of antibiotics ([Table 75-3](#)).^[73] Treatment of pyelonephritis usually requires a 10- to 14-day course of oral therapy or, when indicated, parenteral antibiotics until symptoms have resolved for 24 hours, followed by oral therapy to complete the 10 to 14 days.^[136] Recurrent cystitis should be treated for longer than 3 days, and prophylactic therapy should be considered on an ongoing basis or after precipitating events such as coitus. Persistent problems eventually warrant urologic evaluation.^[43] Pregnant women often require longer courses of therapy; pyelonephritis in pregnancy warrants suppressive therapy throughout gestation.

MENSTRUATION

Normal Cycle

Menstrual cycle disturbances are among the most frequent indications for which women seek medical care. Among highly trained female athletes and in environments that impose extreme physical and psychologic demands, such disturbances can be found in as many as 50% of women not taking OCs. Understanding bleeding abnormalities requires a basic understanding of the normal menstrual cycle ([Figure 75-1](#)). Normal cycles occur at regular intervals, require ovulation, and typically average 28 days (range 21 to 35 days). By convention the first day of the menstrual cycle corresponds to the first day of the menstrual period, which usually lasts about 4 days (range 3 to 7 days). The onset of menstrual bleeding represents desquamation of the functional endometrium, resulting from progesterone withdrawal in the absence of conception during the previous cycle, and coincides with recruitment of a new group of primordial follicles for maturation. The first stage of the menstrual cycle, up to the time of ovulation, is referred to as the follicular phase, or endometrial proliferative phase. The second stage is the luteal phase, or endometrial secretory phase.

Follicular recruitment depends on the presence of follicle-stimulating hormone (FSH) released from the pituitary as the consequence of pulsatile release of GnRH by the hypothalamus.^[46]^[124] FSH stimulates transformation of a primordial follicle into a primary follicle with a primary oocyte surrounded by a layer of granulosa cells.^[88] Under the mitogenic influence of FSH, granulosa cells replicate to several layers, producing the secondary or preantral follicle. The granulosa cell layer is surrounded by a basement membrane that provides clear separation from the stromal theca cells. The theca cells are the primary source of androgens, predominantly androstenedione and testosterone, which are converted to the estrogens estrone and estradiol, respectively, by aromatization in the granulosa cells, an event also stimulated by FSH. Estrogens in turn enhance production of their own receptors and receptors for FSH, further stimulating granulosa cell division, aromatase activity, and more estrogen production.

Figure 75-1 Normal human ovarian and endometrial (menstrual) cycle. (Modified from Shaw ST Jr, Roche PC: *Menstruation*. In Finn CA, editor: *Oxford reviews of reproduction and endocrinology*, vol 2, Oxford, UK, 1980, Oxford University Press.)

With adequate estrogen the follicle secretes and accumulates fluid, displacing the oocyte and surrounding granulosa cells eccentrically, forming the tertiary (antral) or mature follicle.^[108] Without sufficient estrogen, androgens arrest maturation of the follicle at the preantral stage and promote its atresia.^[66]

In addition to their mitogenic and aromatase-enhancing effects, estrogen and FSH stimulate production of receptors for luteinizing hormone (LH) on the theca cells and on the granulosa cells in the late follicular phase. LH, which is also released from the pituitary in response to pulsatile hypothalamic GnRH, stimulates uptake of cholesterol, a primary precursor of androgens, by the theca cells and is essential for adequate estrogen production. Significant expression of LH receptor on the granulosa cells is not achieved until late in the follicular phase and prepares the dominant follicle to respond to a midcycle surge in release of LH from the pituitary and the subsequent rupture of the follicle and release of the oocyte (ovulation). The

1771

events leading up to ovulation itself are complex.^{[80] [89] [160]} Elevated circulating levels of estrogen, predominantly estradiol, trigger release of both LH and FSH by direct effect on the pituitary, with a rapid drop in circulating estrogen. This event precedes ovulation by 26 to 32 hours, resulting in resumption of meiosis by the oocyte and weakening of the follicular wall.

The preovulatory presence of sufficient LH receptors on the granulosa cell is essential for their next steroidogenic role, the production of progesterone, in the second phase of the menstrual cycle. Their readiness for this role is anticipated by the rise in production of 17-hydroxyprogesterone (17-OHP) just before ovulation.^[128] After ovulation, LH stimulates 3 β -hydroxysteroid dehydrogenase activity, resulting in production of progesterone from cholesterol-derived pregnenolone at the ovulatory site, now the corpus luteum (CL). This luteinization results in progesterone production that peaks 7 to 8 days after ovulation. Progesterone induces the secretory phase of endometrial development, preparing for implantation of the embryo. With conception and the production of adequate human chorionic gonadotropin (hCG) by embryonic trophoblasts, the CL persists, enlarges, and increases its production of progesterone and estrogen.^[2] With no conception the CL loses its sensitivity to LH and FSH, degenerates (luteolysis), and decreases production of progesterone and estrogen.^[101]

Without hormonal support the functional endometrium degenerates and is again shed with menstruation. The drop in these hormones is also a signal to resume release of FSH and LH from the pituitary with recruitment of more follicles. In normal menstrual cycles the luteal phase (from ovulation to menses) is 14 days (\pm 2 days).

Although the primary feedback loop for production of reproductive hormones is directly between ovary and pituitary, the hypothalamus plays an integral role in maintaining responsiveness of the pituitary by the pulsatile release of GnRH. Pulsatility maintains pituitary GnRH receptors. Loss of pulsatility results in down-regulation of these receptors, with inhibited secretion of FSH and LH. The pulse generator for the rhythmic release of GnRH is located in the arcuate nucleus of the hypothalamus.^[32] It is influenced by numerous neurotransmitters and steroid hormones. During the menstrual cycle, pulsatile release of GnRH occurs hourly during the follicular phase and every hour and a half during the luteal phase. Factors that disrupt the normal pulsatile release of GnRH or reduce the ability of the pituitary to respond to it are the major contributors to menstrual cycle abnormalities in premenopausal women.^[24]

Abnormal Uterine Bleeding

Abnormal uterine bleeding (AUB) can be loosely defined as any aberration in the normal menstrual bleeding pattern in premenopausal women and as any bleeding episode in postmenopausal women. The most common causes of AUB are problems related to pregnancy and hormonal contraceptive therapy. Initial evaluation of AUB in any premenopausal woman includes a urine or serum screen for hCG, regardless of contraceptive history. Nonpregnancy-related causes of abnormal bleeding can be divided into episodes in ovulatory women, in anovulatory women, and from extrauterine causes, either ovulatory or anovulatory.

Historical information is useful in developing a presumptive etiology and empiric therapeutic approach for AUB, particularly in the absence of laboratory resources. Past history includes age at onset of menses, regularity of menses, usual length of period and blood flow, perimenstrual symptoms, medical problems, pregnancy history, STI history, surgical history, and basic endocrinologic review of systems.^[72] The current problem is then characterized by changes in the frequency of bleeding, amount of flow, new symptoms, relationship to activities, recent sexual history, systemic symptoms, weight change, change in medications or use of other health-related products, and change in exercise patterns.

Ovulatory Women.

When the premenopausal woman who has consistently had regular cyclic menses presents with a history of progressively increasing amount and duration of menstrual flow, the most common causes are uterine fibroids, particularly submucosal (just beneath the endometrium) fibroids, endometriosis, and adenomyosis (endometriosis of the uterine muscle wall). These conditions are frequently associated with progressive dysmenorrhea and are more likely to occur with advancing age. Occasionally an endometrial polyp or IUD, either of which can be accompanied by endometritis, results in a similar presentation. The use of certain medications (e.g., estrogens, warfarin,

non-steroidal antiinflammatory drugs [NSAIDs]) or homeopathic compounds should always be part of the evaluation of AUB, as well as clues to an acquired blood dyscrasia such as idiopathic thrombocytopenic purpura or leukemia. Otherwise healthy women with a history of heavy menstrual bleeding from the time of menarche should be evaluated for inborn coagulation disorders, most often von Willebrand's disease. An abrupt change in the duration or amount of blood flow should suggest a corpus luteal cyst, often associated with unilateral lower abdominal discomfort, or acute PID, often accompanied by more diffuse abdominal pain and systemic symptoms. Hyperplasia of the endometrium is unusual in ovulating women, and malignancies of the uterus or ovaries (estrogen secreting) are rare. Perimenopausal women who are still ovulatory may have progressively more periods, which may be accompanied by changes in flow and duration, with or without the underlying causes noted.

A regularly cyclic woman with intermenstrual or postcoital bleeding should also be evaluated for cervicovaginal

1772

infections, such as BV, yeast, *Trichomonas*, and condylomata. Endocervical polyps, cervical dysplasia, and even invasive cervical carcinoma can occur in this group. When precipitated by coitus, profuse bleeding and dyspareunia can result. Acute pelvic or abdominal pain that accompanies bleeding with coitus should suggest penetrating trauma, an uncommon but potentially life-threatening emergency. Acute pain with coitus and not usually accompanied by bleeding is more likely to be the result of PID, rupture of an ovarian cyst, or torsion of the adnexa.

A clear history and the supportive physical findings limit the differential diagnosis and therapy, although codependent conditions may be present. A synergistic relationship between bleeding and infection is often found in women with prolonged bleeding or short intervals between bleeding episodes. Endometritis can develop from loss of protective cervical mucus and ascending infection by pathogenic organisms that have proliferated in a more alkaline (blood-induced) vaginal environment. Endometritis in turn can precipitate heavier, more frequent, and more symptomatic bleeding. Unfortunately, many women with AUB first present for medical care at this stage. Unless they have been attentive to abnormalities from the onset, a diagnosis based on history alone is difficult. For example, an ovulatory woman with menorrhagia from uterine fibroids may suddenly develop intermenstrual bleeding (from the fibroids or endometritis), which is difficult to distinguish from accompanying chronic anovulation.

Anovulatory Women.

Anovulatory AUB is more common than ovulatory abnormalities among women who partake in wilderness experiences. Anovulatory bleeding problems can be divided into those occurring with adequate estrogen production and those accompanied by low estrogen production. The former, often characterized by hypersecretion of gonadotropins and frequent heavy bleeding, is usually seen in women with polycystic

ovary syndrome (PCOS). In contrast, anovulation in the absence of normal estrogen production usually results from inadequate release of gonadotropins from the pituitary, often presents with complete amenorrhea, and may result from physical conditioning. Hypoestrogenism can have significant effects on a woman's participation in strenuous wilderness experiences.

Female Athletic Triad.

The American College of Sports Medicine first coined the term *female athletic triad* in 1992, but the interrelated components of the triad—disordered eating, amenorrhea, and osteoporosis—had been recognized for many years.^[117] The disorder usually begins with either weight control for participation in activities that emphasize physical appearance, such as cheerleading and dance, or weight loss precipitated by excessive exercise without sufficient caloric or nutritional intake. The eating disorder may evolve into frank anorexia or bulimia and may worsen with starvation, limited variety of nutritional intake, overeating and purging (vomiting, laxatives, enemas), and use of diet pills, appetite suppressants, and diuretics.^[36] Unless the syndrome begins before menarche, as usually occurs in female gymnasts or ballet dancers, it is usually preceded by menstrual irregularity before frank amenorrhea. Prolonged amenorrhea usually signals inadequate ovarian estrogen production secondary to deficient gonadotropin secretion. Since estrogen plays an integral role in promoting bone growth, loss of bone density (osteoporosis) can evolve rapidly at this point, particularly if the diet is also deficient in the minerals and vitamins necessary for skeletal integrity and if the exercise program is vigorous. Skeletal stress accompanying physical exertion is usually characterized by high rates of bone turnover.

The consequences of the triad range from impaired performance to life-threatening conditions. Electrolyte imbalances, vitamin and mineral deficiencies, and loss of bone and muscle mass result in loss of strength and endurance. This sets the stage for multiple or recurrent stress fractures and major musculoskeletal injury. Reduced net bone formation can result in failure to achieve optimal growth and peak bone mass, scoliosis, and increased risk for serious osteoporotic complications later in life. Electrolyte imbalances, combined with weight-reducing drugs, can result in lethal arrhythmias and cardiomyopathies. Depression, coupled with an uncompromising and distorted body image, may lead to suicide attempts.

Management of young women with the female athletic triad may be difficult because many of its characteristics are valued and encouraged in the athlete: competitive nature, high self-expectations, obsessive-compulsive or perfectionist tendencies, and self-critical attitudes. The woman must understand the balance between healthy and unhealthy expression of these characteristics in terms of her goals, current well-being, and long-term health consequences. Those at risk for the triad can often be identified by a vigilant health care provider or physical trainer and offered help before full manifestation of the condition.^[40] Unfortunately, the condition often goes unrecognized or is ignored until a serious complication has occurred and mandates intervention.

Physically active women and individuals involved in their training and health care should be educated about the female athletic triad. Athletic training should include ongoing

assessment of weight, growth, and menstrual history. Women involved in high-risk activities, such as dancing, figure skating, gymnastics, and running, should be considered for baseline and periodic assessment of bone density. ^[19]

1773

The steps in reversing the condition include temporary reduction in exercise, increased and balanced caloric intake, and a diet rich in calcium (1200 to 1500 mg/day) and vitamins. Counseling should be offered to deal with obstacles to physical and long-term rehabilitation. To reduce their risk of skeletal injury, amenorrheic women with osteoporosis who are unwilling to reduce their physical activity should receive nutritional counseling and hormonal replacement therapy at levels currently recommended to treat postmenopausal women. ^[34] Recent studies have indicated that the bis-phosphonates, such as alendronate (5 to 10 mg daily), and to a lesser degree, selective estrogen receptor modulators (SERMs), such as raloxifene (30 to 150 mg daily), can improve bone density and decrease fracture risks in women not receiving estrogen replacement therapy. ^[37] ^[42]

Wilderness Risks.

The major risks of AUB to the wilderness participant depend on the etiology, severity, and chronicity of the process. Heavy and prolonged bleeding can result in significant blood loss, chronic iron deficiency, and infectious morbidity. These can impair endurance, prolong acclimatization, particularly at altitude, and increase susceptibility to acute cardiopulmonary decompensation. As an aesthetic measure, efforts should be made to maintain personal hygiene, thoroughly wash or not wear bloody clothing, and either store tampons or sanitary napkins in sealed containers or dispose of them away from camp and supply sites. There is no evidence that menstrual blood is an olfactory attractant to bears and sharks. In amenorrheic hypoestrogenized women, nutritional deficiency and osteoporosis can result in impaired endurance and prolonged acclimatization, susceptibility to acute deterioration in electrolyte status, particularly in high temperature and humid or aquatic environments, cardiac decompensation, and complicated musculoskeletal injury at exertional levels below the threshold expected by training.

PREGNANCY AND CHILDBIRTH

Pregnancy is considered a relative contraindication to wilderness activities unless access to medical care is available in the field or provisions are made for rapid evacuation. Even though prior pregnancy experience is a relatively good predictor of outcome after the first trimester, pregnancy is still characterized by its unpredictability. No interval during pregnancy is considered absolutely safe. Mortality rates are currently less than eight per 100,000 live births. Many women with infertility and "high-risk" medical problems (e.g., diabetes, hypertension, autoimmune disorders) are conceiving and carrying pregnancies to viability. These women have become more active wilderness participants, appreciating the benefits of regular exercise in their medical management. Women with chronic medical conditions should discuss the potential consequences of pregnancy in a wilderness setting with their health care providers.

Physiologic Changes Accompanying Pregnancy

Hormonal changes accompanying pregnancy result in physiologic adaptations affecting every organ system within weeks of conception. For example, progesterone has smooth muscle relaxation effects that help to maintain uterine quiescence, but these also contribute to vasomotor instability, hypotension, gastric reflux, and constipation. Estrogens stimulate hepatic production of many hormone binding globulins and of coagulation factors II, V, VII, VIII, IX, X, XII, and fibrinogen, which contribute to the hypercoagulable state of pregnancy. Both estrogen and progesterone stimulate rapid uterine hypertrophy, as well as pancreatic β -cell hyperplasia that leads to hyperinsulinemia, increased peripheral glucose utilization, and susceptibility to hypoglycemia in early pregnancy.

During pregnancy, cardiac output increases 30% to 50%, much by the end of the first trimester, from an increase in stroke volume secondary to an increase in preload. The balance comes from a gradual increase in maternal heart rate that usually peaks between 24 and 28 weeks' gestation. Uterine blood flow increases from 50 to more than 500 ml/min, corresponding to an increase from about 1% to 15% to 20% of total cardiac output. Systemic vascular resistance (SVR) decreases, primarily from the low-resistance placental vascular bed, the equivalent of a large arteriovenous shunt, and also from the peripheral vasodilatory effects of progesterone, estrogen, and other factors. Decreased SVR is reflected by a fall in MAP, with a nadir in the midtrimester. Without this midtrimester pressure drop, placental abnormalities may be manifested later in pregnancy as fetal growth restriction and preeclampsia. Because of the dramatic hemodynamic changes, women with known or unrecognized cardiovascular disease may decompensate under the stress of pregnancy. This is particularly true during labor and in the immediate postpartum period, when cardiac output can increase an additional

20% to 60% because of exertion, pain, and fear. Sudden increases in SVR and intravascular volume resulting from uterine involution and autotransfusion immediately after delivery place further demands on the cardiovascular system.

Healthy women who regularly participate in moderate exercise during pregnancy are usually able to meet cardiovascular demands. The benefits of regular exercise outweigh the risks, except in women who have predisposing risk factors or contraindications, such as incompetent cervix; history of preterm labor, delivery, or premature rupture of membranes; bleeding; cardiac

1774

disease; or preeclampsia.^[11] Because of the incursions on cardiac reserves demanded by the pregnancy, however, even well-conditioned athletes have limits on strenuous activity.^[74] ^[82] Exceeding this limit could have deleterious effects on fetal status because of decreased uterine perfusion, increased uterine contractions, maternal acidosis, and hypoglycemia. ^[12] ^[143]

Total blood volume increases 40% to 50% during normal pregnancy, most during the first half of pregnancy, from a rapid expansion of plasma volume. Plasma volume peaks at about 32 weeks' gestation, despite high levels of renin, angiotensin, and aldosterone, findings usually associated with hypertension and decreased intravascular volume in the nonpregnant state. The compensatory mechanism appears to be pregnancy-related refractoriness to the vasoconstrictor effects of angiotensin II, an effect mediated by progesterone, perhaps placental-derived prostaglandins, and atrial natriuretic peptide. By 20 weeks' gestation, in response to an increase in plasma erythropoietin, red cell mass continues to expand until term and eventually reaches levels one-third higher than in the nonpregnant state. A disproportionate increase in plasma volume over red cell mass results in the so-called physiologic anemia of pregnancy. Fetal demands in the second half of pregnancy are an additional drain on iron stores and often produce true iron deficiency. Trained athletes may be at greater risk for this because of iron losses from mechanical hemolysis, intestinal bleeding, hematuria, sweating, low intake, or poor intestinal absorption.^[33]

Respiratory system changes in normal pregnancy more than compensate for the physiologic anemia to maintain fetal and maternal homeostasis. Progesterone directly stimulates the respiratory center and increases its sensitivity to CO₂, resulting in a 30% to 40% increase in tidal volume (TV). Respiratory rate (RR) does not change significantly, but as a result of TV changes, minute ventilation (TV × RR) increases 25% to 30%, despite a slight decrease in total lung capacity. A 20% reduction of functional residual capacity, resulting from decreases in both expiratory reserve volume and residual volume, completes the picture of relative hyperventilation with a compensated respiratory alkalosis. Many of these changes are completed by the end of the first trimester; their sum is a dramatic 50% increase in alveolar ventilation, increased PaO₂, 30% increase in minute O₂ uptake, and significant decrease in P_{CO2}. The overall effect is to increase the O₂-carrying capacity of maternal blood to accommodate fetal and

maternal metabolic needs, while facilitating diffusion of CO₂ from the fetus. For the wilderness traveler, these changes lead to higher O₂ saturation under hypoxic conditions, such as at altitude.

Significant changes in the urinary system account for many of the complaints and complications of pregnancy. Beginning in the first trimester, the ureters become dilated, elongated, and more tortuous, presumably under the influence of progesterone. Further dilation of the proximal ureters occurs when the uterus reaches the level of the pelvic brim at about 20 weeks' gestation and compresses the ureters. Frequently at this stage, women present for the first time with pyelonephritis, more often on the right than on the left due to dextrorotation of the uterus by the descending colon. Contributing to the risk of upper tract infection, vesicoureteral reflux occurs secondary to decreased competency of the ureterovesical junction. This is exacerbated by a progressive decrease in bladder capacity and doubling of intravesicular pressures (from 10 to 20 cm H₂O) during gestation. These factors also contribute to frequent complaints of urinary incontinence that plague pregnant women.

Integumentary and musculoskeletal changes can have a significant impact on the well-being of the pregnant wilderness traveler. Under the influence of estrogen, proliferation and dilation of small arterioles in the skin helps to compensate for increased demands to remove heat generated by maternal and fetal metabolism. Because of these inherent changes, pregnant women have a limited capacity to respond further to heat stress and are at increased risk for hyperthermia in hot and humid environments. Estrogen and other pregnancy-associated hormones also increase sensitivity of the skin to damage by sun exposure, particularly in fair-skinned individuals, and to the risk of pyogenic granulomata of extremities and gums resulting from trauma and inflammation. Some pregnant women have a predisposition to develop skin hyperpigmentation in a nonuniform distribution because of excessive melanin deposition in the dermis and epidermis. This is enhanced by sun exposure; often affects the face (melasma), midline abdomen (linea nigra), nipples, axillae, and perineum; and may require a prolonged period for resolution after delivery. It may never resolve completely.

Striae gravidarum, or "stretch marks," may be the most notorious superficial effects of pregnancy. These result from breaks in dermal collagen and frequently occur on the abdomen, buttocks, thighs, and breasts. Striae are not necessarily associated with skin stretching and may be found before significant uterine growth or weight gain has occurred, reflecting their underlying hormonal basis. Hair loss during pregnancy, as well as nail brittleness and loss of adhesiveness between the nail and nail bed, may also increase the risk of sun exposure and trauma, respectively, for the pregnant wilderness traveler.

Weight gain, weight redistribution, and ligamentous relaxation may pose the greatest risks, even to the well-conditioned pregnant woman.^[6] Overall weight gain during pregnancy is usually about 20 to 35 pounds. Some weight gain is important during pregnancy to

avoid a catabolic state and may be more important to the highly conditioned athlete who enters pregnancy with limited fat stores. This weight increases stress on the weight-bearing skeleton and ligaments throughout the body and may accumulate more rapidly than conditioning can handle. Much of the weight gain is contributed by uterine and fetal growth, resulting in forward displacement of the center of gravity. This is usually accompanied by progressive lordosis of the lower spine and increased strain on spinal ligaments, disks, and paravertebral muscles. When lumbar lordosis is exaggerated, traction and compression on the sciatic nerves can cause significant pain and weakness in the buttocks and lower extremities. Changes in the lower spine are frequently followed by compensatory flexion of the cervical spine. This in turn can place traction on the median and ulnar nerves, resulting in pain, paresthesias, and weakness of the upper extremities.

The challenges of weight gain are accompanied by dramatic changes in ligamentous support throughout the body. Under the influence of relaxin and other hormones, ligaments become more compliant and hydrophilic. Benefits of this include relaxation in the sacroiliac joints and symphysis pubis to facilitate delivery, but hormonal effects on other ligaments can lead to complications. For example, fluid retention by the flexor retinaculum in the wrist can cause compression of the median nerve, resulting in carpal tunnel syndrome, a common complaint of pregnancy. This may be more than just a nuisance to the wilderness traveler, because pain and hand weakness can compromise activities, such as climbing and canoeing, that require hand strength and endurance. Even more troublesome, pelvic girdle instability, accompanied by weight gain, shift in center of gravity, and spinal lordosis, usually leads to gait and balance disturbances. These not only predispose to more frequent falls during pregnancy under far less strenuous conditions than those encountered in many wilderness settings, but also lead to an increase in the severity of trauma accompanying these falls. The anterior cruciate ligament is especially prone to severe trauma, accounts for 3 to 4 times more injuries in women than men, and is especially susceptible to trauma in the active pregnant woman.^[166] Difficult terrain also poses a risk to the pregnant wilderness traveler.

Unless there are other medical or pregnancy-related contraindications (e.g., risk for premature labor, incompetent cervix, multiple gestation, bleeding), exercise and specialized training should be encouraged throughout pregnancy, taking precautions to avoid prolonged exposure to extremes in temperature, dehydration, hypoglycemia, prolonged anaerobic conditions, and excessive skeletal stress.^[79] ^[147] Active and physically fit women tolerate labor better than inactive women. A program specifically designed for pregnant women, including exercises to strengthen the abdominal and back muscles, and careful attention to posture may reduce the risks related to changes in skeletal support.

Wilderness Participation.

Pregnant women are more susceptible to altitude sickness, more likely to develop severe symptoms, and may require longer periods of adjustment before exertional

activities can be undertaken. Gradual progression to higher altitudes and limited activity until completely comfortable will minimize symptoms and allow for fetal compensation. A pregnant woman must maintain adequate fluid intake throughout this process, since reduced O₂ saturation combined with decreased uterine perfusion secondary to dehydration could endanger the fetus. Depending on the altitude, gestational age, maternal Hgb levels, and degree of training, even the well-acclimated pregnant woman may find that endurance and ability to participate in strenuous activity at altitude are limited.^[13] When a trip is planned, frequent rest periods should be scheduled. A higher incidence of preeclampsia and fetal growth restriction has been found among women at higher elevations and may reflect the limits of the placenta and fetus to extract O₂ even from well-conditioned individuals.^{[119] [171]}

Although swimming is considered an excellent form of exercise for pregnant women, scuba diving is potentially hazardous. The fetus is at risk from nitrogen bubbles in the fetal-placental circulation during decompression on ascent. Most authorities consider pregnancy a contraindication to diving.^[23] Diving is compromised by increased abdominal girth, difficulty breathing due to engorgement of the mucous membranes of the nose and oropharynx, and increased buoyancy secondary to fat deposition. Higher levels of body fat also increase the risk of decompression sickness, since nitrogen tends to be retained in these tissues. Dyspnea may be exaggerated and lead to panic, even in the experienced diver who is pregnant.^[113] As with exertion at high altitude, the pregnant woman may have limited ability to maintain anaerobic metabolism for prolonged periods because of fetal needs. The pregnant woman should also limit prolonged nondiving immersion in cold water that might lead to hypoventilation and hypothermia.

Acclimation to environments characterized by high temperatures, particularly with high humidity, may be especially difficult for the pregnant woman and even dangerous to the fetus. Hyperthermia has been shown to be teratogenic in various animal models and a higher incidence of birth defects, particularly neural tube defects, have been found among offspring of women who experienced hyperthermia by environmental exposure or febrile illness in the first trimester.^[132]²¹⁰ Later in pregnancy the fetus depends on the woman to eliminate excess heat. Elevation of ambient temperature decreases

the heat gradient and the ability of the pregnant woman to dissipate heat. Elevated humidity exacerbates this situation by decreasing the contribution of perspiration to heat loss. This increases the risk of elevated maternal core temperature, which further raises fetal metabolic activity and heat generation. Hyperthermia increases the risk of premature labor, particularly with dehydration and loss of electrolytes. Fetal stress, resulting from decreased uterine perfusion secondary to compensatory peripheral vasodilation and depletion of intravascular volume, further increases the likelihood of preterm labor.

Preparation for Pregnancy

The woman who is pregnant and plans to participate in wilderness activities or who anticipates a wilderness delivery needs thorough medical evaluation and counseling before departure. The evaluation begins with the obstetric history and complications for which she is at high risk for recurrence, including preterm labor, premature rupture of membranes, preeclampsia, gestational diabetes, fetal growth restriction, group B β -hemolytic streptococcal colonization, UTIs, chorioamnionitis, blood group isoimmunization, thromboembolic events, surgical delivery, and postdelivery complications. A complete physical examination should be conducted.

Laboratory evaluation before departure includes standard blood work recommended by the American College of Obstetricians and Gynecologists: complete blood count, blood type and antibody screen (and screen of partner if the woman is Rh negative or isoimmunized), and basic serology (rapid plasma reagin, rubella, hepatitis B, HIV). Serologic screening for HSV-2 should be considered in the woman with no history of genital herpes because of the potential for first-time outbreaks during pregnancy in women with unrecognized infection.^[14] ^[104] Individuals at risk and those not previously evaluated should also be offered Hgb electrophoresis to assess for hemoglobinopathies. Urinalysis and urine culture are performed because of the high frequency of asymptomatic infections during pregnancy that complicate outcome. Vaginal fluid should be assessed for BV, since treatment early in pregnancy may prevent premature rupture of membranes and preterm labor. A Pap smear is often done as well. A woman beyond 15 weeks' gestation before departing should be offered biochemical screening (e.g., maternal serum α -fetoprotein, estriol, hCG) to assess for certain congenital and chromosomal abnormalities. Abnormal biochemical markers may indicate complications such as fetal growth restriction and preeclampsia, resulting primarily from early abnormalities in placentation that can become clinically significant later in gestation. These conditions also increase the risk for premature delivery, as well as for maternal and fetal morbidity and mortality.

Since diabetes arises as a complication of the hormonal milieu in at least 3% of all pregnancies, routine screening is indicated in any woman who is not diabetic before pregnancy. Oral administration of a 50-g glucose challenge in the nonfasting state is usually done at 24 to 28 weeks' gestation, followed by a plasma glucose determination 1 hour later. Values of 140 mg/dl or greater (but less than 200 mg/dl) warrant further evaluation with a fasting 3-hour oral glucose tolerance test using a 100-g glucose challenge. If the fasting value before administration of the glucose load is 120 mg/dl or greater, or if the 1-hour challenge is 200 mg/dl or more, the woman is considered diabetic and should not have the 3-hour test done. Otherwise, values of 90 mg/dl or greater while fasting, 190 mg/dl or more at 1 hour, 165 mg/dl or greater at 2 hours, and 145 mg/dl or more at 3 hours are considered abnormal. Two abnormal values or persistent elevation of the fasting level indicate diabetes. If departure is planned before 24 to 28 weeks' gestation, the 1-hour challenge can be done using a portable plasma glucose meter. If the woman has significant risk factors (age 35 or older, obesity, family history, steroid use, PCOS, other endocrinopathy such as thyroid disease) the 1-hour and possibly the 3-hour tests should be administered early, regardless of gestational age.^[100] If the woman had gestational diabetes with a previous pregnancy, it is best to assume she will have it again. Proper dietary counseling and regular blood sugar monitoring with a portable plasma glucose monitor should be conducted throughout the

pregnancy. Insulin, sufficient syringes, and alcohol wipes should be included with the basic medical supplies in the event glycemic control deteriorates. The goal is to maintain fasting plasma glucose levels at 90 mg/dl or less and lower than 120 mg/dl 2 hours after meals. Physical conditioning reduces but does not eliminate the risk of developing diabetes during pregnancy. Women with pregestational diabetes of any duration should have a baseline ECG and possibly an echocardiogram before participation in any wilderness-related activities.

The pregnant wilderness traveler should have an obstetric sonogram before departure for additional risk assessment. Early in the pregnancy, sonography can accurately confirm gestational age, viability, intrauterine location, and number of babies. It is also useful in ruling out the presence of an ectopic pregnancy, adnexal mass, or molar pregnancy that could lead to life-threatening complications. In midtrimester an ultrasound is useful not only in estimating gestational age, but also in determining the presence of major fetal abnormalities, the location of the placenta in relationship to the cervix, and the cervical length and integrity of the internal cervical os. Beyond 20 weeks' gestation, normal fetal growth and blood flow patterns in the umbilical and middle cerebral arteries can be assessed by

1777

Doppler velocimetry. Normal results indicate lower risk for complications, such as intrauterine growth restriction, preeclampsia, and preterm labor.^[38] Any findings that significantly increase maternal or fetal risk are contraindications to elective wilderness travel during pregnancy.

Prolonged wilderness excursions during pregnancy, particularly those extending into late second and third trimesters, should include preparations for ongoing assessment and even emergency delivery. Routine antepartum care usually includes visits to a health care provider at least monthly until 26 to 28 weeks, every 2 weeks thereafter until 36 weeks, then weekly until delivery. Beyond the due date, more frequent visits are often recommended. Routine visits focus on uterine activity, vaginal discharge, abdominopelvic pain, bleeding, headaches, symptoms of UTI, current medications, and fetal activity.

The basic antepartum examination includes measurements of blood pressure, weight, and uterine size (height of uterine fundus above symphysis) and subjective assessments of peripheral edema and reflexes. Urine is tested at each visit with a multitest strip that provides estimates of glycosuria, proteinuria, pH, and presence of nitrites. For the wilderness traveler, elevated pH and presence of nitrites may be associated with UTIs under circumstances that might preclude culture capabilities.^[156] In Rh-negative women with Rh-positive partners the antibody screen is often repeated at 26 to 28 weeks, before the administration of Rh-immune globulin for prophylaxis against third-trimester sensitization. If an antibody screen cannot be done, Rh-immune globulin should be administered empirically. Maternal Hgb and Hct are frequently done in each trimester to assess need for iron supplementation. Since many women require supplemental iron during pregnancy, this should be taken prophylactically under

circumstances that obviate determination of Hgb levels, unless the woman has a contraindication, such as hemochromatosis.

Basic supplies for the pregnant wilderness traveler might include a diary to record progress, reminders of scheduled testing, and complications; tape measure; stethoscope; sphygmomanometer; urine test strips; and prenatal vitamins and iron. Other supplies include a glucometer with test strips, Rh-immune globulin, a calcium supplement, and basic medications for the most common pregnancy complaints: an antiemetic such as promethazine, prochlorperazine, or chlorpromazine for nausea and vomiting; acetaminophen for headaches and pain; stool softener for constipation; and antibiotics to cover UTIs and vaginitis. In addition to the basic medical supplies, the pregnant woman should have changes in clothing size and possibly shoe size. When delivery in the wilderness is planned or a strong possibility, special preparations need to be made ([Box 75-4](#)).

**Box 75-4. SUPPLIES FOR
MANAGEMENT OF WILDERNESS
DELIVERY**

STANDARD

Clean towels

Surgical sponges

Surgical gloves

Umbilical cord clamps

Suction bulb

Suture kit

Scalpel

Scissors

Syringes and needles

Local anesthetic

Injectable oxytocin

Injectable and oral methylergonovine

Oral analgesics (e.g., ibuprofen,

Local anesthetic

Injectable oxytocin

Injectable and oral methylergonovine

Oral analgesics (e.g., ibuprofen, acetaminophen with codeine)

Oral broad-spectrum antibiotic

Sanitary napkins

OPTIONAL

Injectable magnesium sulfate

Intravenous fluids and administration supplies

Injectable narcotic

Naloxone

Misoprostol

Prostaglandin F_{2a}

Injectable antibiotic

Neonatal mask and Ambu bag

Complications

Miscarriage.

Women who are pregnant or become pregnant for the first time while in the wilderness are at high risk for complications. Approximately 15% to 25% of all pregnancies abort spontaneously during the first trimester, and this number may exceed 60% to 70% in the true primigravida.^[134] Reasons may be related to immunologic naivete to paternal antigens expressed by the fetal tissues. In contrast, isolated miscarriages in women who have successfully carried pregnancies are often the result of chromosomal abnormalities. Pending miscarriage in the first trimester is usually preceded by embryonic demise and accompanied by a reduction or loss in early pregnancy-related symptoms, such as breast tenderness and nausea. Bleeding and uterine contractions eventually occur and accompany expulsion of the products of conception. Under most circumstances, hemorrhage during miscarriage is self-limited and not life-threatening but at times can be heavy, especially if fetal death does not precede the event and occurs late in the first trimester or during the second trimester, or if the expulsion

process is prolonged or incomplete. Spontaneous abortion after the first trimester is

1778

much riskier but less common. It also can result from chromosomal abnormalities or fetal anomalies but is more likely to be caused by chorioamnionitis, UTIs, severe abnormalities of placentation, poorly controlled maternal medical conditions, or cervical incompetence.

Any acute and significant blood loss in a physiologically hostile environment can compromise the endurance of the most highly trained individual. Under wilderness conditions, control of significant maternal hemorrhage accompanying miscarriage may be difficult unless provisions, facilities, and medicinal supplies are available. Uterine curettage is the method most often used to complete evacuation of the uterus when medical facilities are available. Once empty, uterine involution, spontaneous or aided by uterine massage, is usually sufficient to impede bleeding from the implantation site. In the absence of the ability to perform curettage, treatment with methylergonovine (0.2 mg orally or intramuscularly) can enhance uterine contractions, accelerate expulsion of products of conception, and promote uterine involution to maintain hemostasis. Methylergonovine should not be used in patients with hypertensive disorders, underlying vascular disease, and certain cardiac abnormalities unless the benefits clearly outweigh the risks of acute generalized vasoconstriction. As an alternative, prostaglandin F_{2a} (250 µg intramuscularly) or misoprostol (100 µg orally or vaginally) can be administered with less risk of cardiovascular compromise.

Ectopic Pregnancy.

Far more dangerous than miscarriage, ectopic pregnancy must always be considered a life-threatening emergency that requires immediate medical attention. Ectopic pregnancy refers to implantation at any location outside the uterine cavity, most often (more than 95%) the fallopian tube. Hemorrhage resulting from ectopic pregnancy is still the leading cause of death in the first trimester. The incidence of ectopic pregnancy has tripled over the past 30 years and now exceeds one of every 100 pregnancies.^[121] This increase is directly proportional to the rise in incidence of acute and chronic PID. The most common predisposing risk factors include a history of infections, multiple sexual partners, early age of onset of sexual activity, delayed childbearing, and previous IUD use. Independent risk factors are a history of abdominal and tubal surgery, including previous tubal sterilization procedures, endometriosis, DES exposure, and pregnancy by assisted reproductive interventions. Regardless of the etiology, an ectopic pregnancy increases the risk for another ectopic pregnancy approximately tenfold. A woman with a history of ectopic pregnancy should not intentionally plan to conceive again in the wilderness and should have her intrauterine pregnancy confirmed sonographically before departure.

Most women with a tubal ectopic pregnancy become symptomatic before 12 weeks' gestation and present with complaints of abdominal pain and altered menses. Early

pregnancy symptoms may be minimal or absent. The pain often begins unilaterally with sudden onset and is usually severe, distinguishable from the cramping, intermittent pain accompanying miscarriage by its persistence and intensity. Clinical findings include a tender adnexal mass, nontender cervix, small to slightly enlarged nontender uterus, and absence of high-grade fever. Low-grade temperature elevation to 38° C (100.4° F) may occur in as many as 20% of women with ectopic pregnancy. When intraperitoneal hemorrhage accompanies rupture of the tube, the pain becomes diffuse with peritoneal signs of tenderness, guarding, and rebound. Shoulder pain from diaphragmatic irritation may be present as well. Pelvic examination at this point usually elicits discomfort with movement of the cervix and uterus. Fullness of the cul de sac posterior to the uterus and abdominal distention suggest significant intraperitoneal blood loss.

Vaginal bleeding accompanying an ectopic pregnancy usually follows a variable period of amenorrhea. It often begins with minimal flow of blood darker than that seen during miscarriage and results from inadequate progesterational support of the decidualized endometrium. Uterine cramping may ensue, with passage of organized clot and tissue in the form of a decidual cast resembling products of conception, leading to the mistaken diagnosis of spontaneous abortion. However, cessation of pain is typical with completion of miscarriage and quite atypical with passage of a decidual cast concurrent to an ectopic pregnancy. With rupture of an ectopic pregnancy, heavier, bright-red bleeding may occur vaginally and if accompanied by significant intraperitoneal hemorrhage, may rapidly result in hemodynamic decompensation that only can be controlled surgically. The differential diagnosis of ectopic pregnancy includes normal intrauterine pregnancy with a corpus luteal cyst or hemorrhagic corpus luteum, threatened or incomplete abortion, PID, adnexal torsion (usually associated with adnexal enlargement from a benign or neoplastic process), endometriosis, UTI or ureteral stone, degenerating fibroid, and appendicitis. Although simultaneous intrauterine and ectopic pregnancies were once considered to be extremely rare, the incidence is now estimated at one in 6000 in the general population and greater than one in 100 among recipients of assisted reproductive techniques.

The diagnosis of ectopic pregnancy is considered presumptively in any woman with a positive pregnancy test, abnormal bleeding, and abdominal pain. In a full-service medical care facility the first step in management is to assess serum hCG levels and ascertain location of the pregnancy. An intrauterine pregnancy can usually be confirmed by transvaginal sonography once the serum hCG exceeds 1000 mIU/ml, corresponding

to 2 to 3 weeks after conception or 4 to 5 weeks from the last normal menstrual period (LMP). In contrast, absence of an intrauterine pregnancy at hCG levels of 1000 mIU/ml or greater suggests ectopic pregnancy. In the absence of sonography, serum progesterone level greater than 25 ng/ml indicates a viable intrauterine pregnancy, greatly reducing the chance of an ectopic pregnancy.^[149] Progesterone level less than 25 ng/ml is not diagnostic under these circumstances because it cannot differentiate nonviable intrauterine pregnancy from ectopic pregnancy.

In a wilderness setting that precludes the ability to perform a sonogram and quantitative determinations of hCG and progesterone, plans for evacuation must be made at first suspicion of the diagnosis. In extraordinary circumstances when the diagnosis is questionable, evacuation is not readily possible, and an experienced health care provider is available, the only technique that might offer some reassurance is culdocentesis. Needle aspiration of serous fluid from the posterior cul de sac argues against but does not exclude an ectopic pregnancy, since more than 75% of symptomatic cases with an ectopic pregnancy will have some degree of intraperitoneal hemorrhage. The presence of nonclotting blood confirms intraperitoneal hemorrhage and in approximately 95% of cases indicates ectopic pregnancy. The remainder usually result from bleeding of the corpus luteum.

Treatment options for ectopic pregnancy are not usually available in the wilderness. In the past, management of ectopic pregnancy has been exclusively surgical. Once an ectopic pregnancy is symptomatic, and when peritoneal signs or evidence of hemodynamic instability are present, laparoscopic or open abdominal procedures are still necessary. In recent years, however, medical therapy with methotrexate has proved useful in management of early, unruptured ectopic pregnancies.^[148] Women with known risk factors who are attempting to become pregnant are encouraged to be followed proactively. They can often have the diagnosis of ectopic pregnancy confirmed by hCG and transvaginal sonography within 35 days from the LMP and before significant symptoms and tubal rupture. If the adnexal mass is less than 4 cm and the patient is minimally symptomatic and hemodynamically stable, single-dose methotrexate therapy (50 mg/m² intramuscularly) is effective and reduces the need for surgical intervention, thereby maximizing the opportunity for preservation of the fallopian tube. The quantitative hCG is followed serially until undetectable. If there is a slow fall or plateau in hCG levels and the woman is still stable, the dose can be repeated, usually no sooner than 1 week after the initial dose. Methotrexate is less likely to be effective when the ectopic mass is more than 4 cm, there is fetal cardiac activity, the woman is symptomatic, or significant free peritoneal fluid is present. Methotrexate is contraindicated when the woman is hemodynamically unstable, has active pulmonary disease, or is not willing to return for follow-up.

enzymes, and low platelets.

Later Pregnancy.

Common conditions that do not cause problems until 20 weeks' gestation or later cannot be optimally managed in most wilderness settings ([Box 75-5](#)). The safest course of action is to make plans for immediate evacuation. Second- and third-trimester bleeding could simply be the result of cervical effacement, labor, cervical polyps, coital trauma, or vaginitis, but it could also be much more dangerous if the source is placenta previa or placental abruption. Historical information and physical findings may suggest an etiology, but a definitive diagnosis is not possible without verification.

PLACENTA PREVIA.

When evaluating bleeding, placenta previa always must be given primary consideration. Placenta previa results from implantation of the placenta in the lower uterine segment over or near the internal cervical os. It occurs in approximately one of 200 births. Risk increases with age and parity, multiple gestations, women who have submucosal fibroids or have had multiple dilation and curettage procedures (D&Cs) or cesarean sections, and in cigarette smokers.^{[1] [65]} The classic presentation of placenta previa is painless, sudden, heavy, and bright-red vaginal bleeding.^[17] It may occur with exertional activity, straining on the toilet, or intercourse but also occurs at rest with no obvious precipitating factor. Many women report awakening at night in a pool of blood as the initial manifestation of a placenta previa, probably the result of stretching of the lower uterine segment and implantation site by a bladder that has become distended while sleeping. Uterine contractions may accompany the bleeding and may be the

precipitating cause if they have been significant enough to initiate cervical effacement. Physical examination is limited until the placental location has been ascertained by sonography. The uterus is usually nontender, and the baby is often in a lie well out of the pelvis because the placenta displaces the presenting

1780

part. Digital examination of the cervix and simple speculum examination of the vagina are contraindicated, unless capabilities are available for immediate delivery, because they could disrupt the placental interface from the lower uterine segment, resulting in catastrophic hemorrhage. Interestingly, women who bleed for the first time with a placenta previa may have significant blood loss, but the bleeding is often self-limited and rarely compromises fetal well-being. The course of subsequent bleeds is much less predictable. Once a woman with a complete placenta previa has bled significantly, she should probably be hospitalized until delivery. In most instances, cesarean section is required for safe delivery.

PLACENTAL ABRUPTION.

Placental abruption is defined as separation of the placenta from the maternal interface before delivery. Risk factors include hypertensive disorders (e.g., preeclampsia, chronic hypertension), other chronic diseases with vascular compromise (e.g., diabetes, renal disease, certain autoimmune disorders), coagulation disorders (presence of lupus anticoagulants or anticardiolipin antibodies, protein S or C deficiencies, factor V Leiden, antithrombin III deficiency), trauma, chorioamnionitis, advanced maternal age, multiparity, and cigarette abuse.^[106] ^[123] One of the most common causes of placental abruption in recent years has been cocaine use.

Placental abruption is highly variable in presentation, depending on the location and the extent of the separation and hemorrhage. About 80% of placental abruptions result in visible bleeding accompanying the onset of other symptoms. Twenty percent result in concealed subchorionic hemorrhage that may not become apparent until many days after the event. Unlike placenta previa, abruption is usually accompanied by sudden onset of sharp pain. The pain may be focal and continuous, intermittently intensifying with the frequent uterine contractions and irritability that usually accompany and can extend the placental separation. Severe abruptions may be accompanied by prolonged tetanic contractions with extravasation of hemorrhage into the myometrium (Couvelaire uterus); these may compromise uterine involution after delivery. Fetal compromise is much more common with placental abruption than with placenta previa. Traumatic separation of the placenta results in a greater likelihood of disrupted placental vasculature, resulting in fetal blood loss into the subchorionic clot or into the maternal circulation as a fetal-maternal hemorrhage. This can be a major cause of blood group isoimmunization that can affect future pregnancies.

Diagnosis of placental abruption is usually based on clinical signs and symptoms and maternal history. Standard sonography is not as useful a diagnostic tool as it is with

placenta previa, because small abruptions may be difficult to differentiate from placental tissue and normal placental vascular channels. Magnetic resonance imaging (MRI) and Doppler modalities are more useful but are rarely necessary as diagnostic tools. No laboratory tests are diagnostic for placental abruption, but abnormalities of coagulation studies may suggest small abruptions and may help ascertain the extent of consumptive coagulopathy in large abruptions. A Kleihauer-Betke screen should also be done to assess fetal cells in the maternal circulation. Rh-negative unsensitized women should be given Rh-immune globulin when an abruption is suspected or confirmed. In view of the association with cocaine use, urine toxicologic screens are almost routine in the absence of other causes of placental abruption. If delivery is necessary or deemed inevitable, route of delivery is determined by the degree of fetal or maternal compromise and the prospects for vaginal delivery.

PREMATURE LABOR.

Despite the advances that have been made in obstetric and neonatal care in the past 50 years, rates of preterm delivery, defined as delivery before 37 completed weeks' gestation, have not changed, persisting in the range of 8% to 10% of all pregnancies in the United States. It is still the leading cause of perinatal morbidity and mortality. Preterm labor, defined as regular uterine contractions resulting in progressive cervical change, as assessed by effacement, dilation, and softening, complicates twice as many pregnancies as actually progress to preterm delivery. Symptoms of preterm labor include mild and menstrual-like to painful uterine contractions, intermittent low back pain or pressure, pelvic pressure, increase in vaginal discharge resulting from effacement with compression of endocervical glands or leaking of amniotic fluid, and bloody "show." The more common risk factors for preterm labor and delivery include premature rupture of membranes, subclinical or overt chorioamnionitis, UTI, substance abuse (tobacco, cocaine, amphetamines), preeclampsia, multiple gestation, hydramnios, dehydration, constipation, chronic stress, and incompetent cervix.^[102] The pregnant wilderness traveler is at risk for several of these factors and should strive to reduce their occurrence.

Thorough evaluation and management of preterm labor cannot be done in most wilderness settings. Some empiric measures can be taken, however, based on the woman's symptoms and palpation of uterine contractions alone, while awaiting evacuation or to prepare for delivery if evacuation is delayed or impossible. Pelvic examination should be avoided unless placenta previa has been previously excluded and sterile supplies are available. If done by an experienced person, cervical examination should determine dilation, effacement, and consistency, as well as the station and presentation of

the baby. Once it has been concluded that the woman is in preterm labor and evacuation is required, examinations should not be repeated unless delivery appears imminent. If she clearly has ruptured membranes, characteristics of the fluid should be noted (clear, bloody, meconium stained), but no internal vaginal examination should be

performed initially to minimize risks of introducing infection.

Interim measures for managing preterm labor include the following: encourage the woman to empty her bladder and rectum; place her at rest on her side; make sure she is kept warm and comfortable; and provide oral hydration with 32 to 64 ounces of fluid over an hour. These measures alone will decrease uterine activity in as many as one third of women having preterm contractions. If available, a broad-spectrum antibiotic, preferably one with coverage of both group B β -hemolytic streptococci and anaerobic organisms, should be given orally or parenterally.^[126] Parenteral corticosteroids, if available, are useful in accelerating fetal lung maturity in anticipation of premature delivery. Administration of β -methasone (12 mg intramuscularly; repeat dose in 12 to 24 hours) or dexamethasone (6 mg intramuscularly every 6 hours for four doses) has become an accepted part of empiric therapy when the estimated gestational age is less than 34 weeks. Many common medications have tocolytic activity, but each should be administered only after careful consideration of their potential risks and side effects ([Box 75-6](#)). Of these, the prostaglandin synthetase inhibitors are most likely to be part of the routine supplies on a wilderness excursion and are also probably the safest to use in combination with initial measures of rest and hydration. If preterm labor cannot be stopped before evacuation, guidelines exist for management of delivery, as detailed later.

Box 75-6. MEDICATIONS IN COMMON USE FOR TOCOLYSIS

MAGNESIUM SULFATE

Calcium antagonist (MgSO_4), 4–6 g IV over 20–30 min (or IM in split doses to buttocks), followed by continuous infusion of 2–4 g/hr \times 12–24 hr.

Interrupt or decrease infusion if deep tendon reflexes cannot be elicited or respiratory compromise develops.

Effects are readily reversible by calcium gluconate in emergency circumstances.

Do not use in combination with nifedipine.

TERBUTALINE SULFATE

β -Sympathomimetic, 0.25 mg SC initially, then every 1–4 hr.

Repeat dosing should be withheld in the presence of maternal hypotension, tachycardia, or chest pain.

Before administration, the woman should be well hydrated, but care must be taken

β -Sympathomimetic, 0.25 mg SC initially, then every 1–4 hr.

Repeat dosing should be withheld in the presence of maternal hypotension, tachycardia, or chest pain.

Before administration, the woman should be well hydrated, but care must be taken not to fluid overload once therapy has begun because of risk for pulmonary edema.

NIFEDIPINE

Calcium channel blocker, 10 mg SL every 20 min \times 1 to 4 doses, then 10–20 mg PO q6h.

Decrease dose or frequency for maternal hypotension. Do *not* use in combination with MgSO₄.

INDOMETHACIN

Prostaglandin synthetase inhibitor, 50–100 mg per rectum initially, then 25–50 mg PO q6h.

Do not use for more than 24 to 48 hours because of effects on fetal urine output (decreased production of amniotic fluid), potential for masking fever, and possible premature closure of the fetal ductus arteriosus.

Safe for use in combination with magnesium, terbutaline, and nifedipine.

IBUPROFEN

Prostaglandin synthetase inhibitor, 600–800 mg PO initially, then 400–800 mg PO q6h.

Appears to have much less effect on fetal urine output and ductus arteriosus than terbutaline but can mask fever.

Safe for use in combination with magnesium, terbutaline, and nifedipine.

IM, Intramuscularly; *IV*, intravenously; *SC*, subcutaneously; *SL*, sublingually; *PO*, orally; *q6h*, every 6 hours.

Pregnancy-induced hypertensive disorders include preeclampsia, eclampsia, and HELLP syndrome. These disorders complicate 10% or more of all pregnancies and are responsible for 15% to 20% of maternal mortality in the United States. Although guidelines have been put forth for their definition, the etiology of these conditions and the differences between them are unknown. Variability in presentation and unpredictability in course characterize these disorders. All are specific to pregnancy, despite mimicking nonpregnancy-related diseases, and do not begin to resolve until the baby and placenta are delivered. Generalized vasospasm and hypersensitivity to vasoconstrictors are typically present.^{[86] [162]} Major risk factors for preeclampsia include nulliparity, obesity, previous history of preeclampsia, underlying hypertension or chronic renal disease, pregestational diabetes, autoimmune

1782

disorders, antiphospholipid antibody syndrome, maternal age over 40, multiple gestation, molar pregnancy, hydrops fetalis, intrauterine growth restriction, and oligohydramnios.^{[20] [39] [115] [161]} Genetic predisposition for preeclampsia is supported by the strong association of family history and identification of certain genetic markers, such as angiotensinogen gene T235, associated with disease expression.^{[77] [111] [112]}

The diagnosis of preeclampsia is based on the triad of hypertension, proteinuria, and edema. Hypertension is defined as systolic blood pressure of 140 mm Hg and higher or diastolic blood pressure of 90 mm Hg or higher measured on two separate occasions 6 or more hours apart. Proteinuria is defined as 300 mg or greater in 24 hours or the presence of 0.1 g/L (1 + or greater) by dipstick on at least two random urine specimens 6 hours apart. Edema is considered significant to the diagnosis of preeclampsia only if it is generalized or if the woman has gained 5 pounds in a week. The strict diagnosis of preeclampsia requires the presence of hypertension with proteinuria, edema, or both. Women meeting these criteria have at least mild preeclampsia.

Diagnostic criteria for severe preeclampsia require only one of the following: blood pressure of 160 mm Hg systolic and higher or 110 mm Hg diastolic and higher on two occasions at least 6 hours apart; proteinuria (5 g/24 hours or higher); oliguria (400 ml/24 hours or higher); persistent epigastric pain; pulmonary edema or cyanosis; impaired liver function of unclear etiology; thrombocytopenia (less than 100,000/mm³); and eclampsia (grand mal seizures). Most cases of severe preeclampsia are associated with intrauterine growth restriction or abnormalities of fetal umbilical (increased resistance) and middle cerebral (decreased resistance) arterial flow consistent with relative placental insufficiency.^[18] Eclampsia, as a subset of severe preeclampsia, is a major cause of maternal and fetal morbidity and mortality worldwide, occurring in about one of 2000 pregnancies in the United States. Although difficult to anticipate, the presence of visual disturbances, severe headache, irritability, epigastric or right upper quadrant pain, nausea and vomiting, and cerebral dysfunction must be considered predictors of eclampsia.^{[92] [169]} Only about half of women complain of these symptoms before seizure, and as many as one third will not have a seizure until the postpartum period, sometimes

as the first significant event suggesting preeclampsia. ^[15]

The most serious subset of severe preeclampsia, occurring in about 10% of cases, is HELLP syndrome, or *hemolysis, elevated liver function enzymes, and low platelets*.^[93] ^[133] Hemolysis is defined as an abnormal peripheral smear consistent with a microangiopathic process, total bilirubin greater than 1.2 mg/dl, and lactic dehydrogenase (LDH) greater than 600 U/L. Elevated liver enzymes include aspartate aminotransaminase greater than 70 U/L and LDH greater than 600 U/L. Low platelets generally refer to levels less than 100,000/mm³, although some women with the other manifestations of the syndrome will maintain platelet counts above 100,000/mm³.^[76] Unlike severe preeclampsia/eclampsia, HELLP syndrome tends to affect older, white, and multiparous women. Onset of most cases of HELLP syndrome is before 37 weeks' gestation; as many as 15% of cases present before 26 weeks. Although 80% of women will have the diagnosis of preeclampsia made before delivery, more than 50% will not develop the most severe manifestations of HELLP syndrome until 1 to 2 days postpartum. During this time, mobilization of extracellular tissue fluid can suddenly precipitate pulmonary edema because of delayed renal recovery. Renal failure, disseminated intravascular coagulation, sepsis, hepatic hematoma and rupture, adult respiratory distress syndrome, and retinal detachment have been reported.^[139]

If preeclampsia is suspected, plans should be made for immediate evacuation from the wilderness setting. While awaiting evacuation, the woman should be placed at rest and have free access to fluids. If magnesium sulfate is available, it should be administered in the same manner as described for preterm labor (see [Box 75-6](#)) to decrease the risk for seizures.^[169] Because of the increased likelihood of renal compromise with preeclampsia, magnesium toxicity must be carefully monitored by assessment of deep tendon reflexes. Antihypertensive medications should be administered with great caution or not at all, since preeclampsia is often accompanied by intravascular volume depletion (even with an excess of total body water) by the time the condition is recognized. Antihypertensive agents that cause vasodilation can greatly reduce MAP, placing the baby at risk for acute placental insufficiency when the placental perfusion may already be compromised. Indications for administration of an antihypertensive drug include persistent blood pressure greater than 160 mm Hg systolic or 110 mm Hg diastolic. The goal should not be to normalize blood pressure, but to maintain it in the range of 140/90 mm Hg. The α/β blocking agent labetalol administered in incremental doses (20, 40, and 80 mg intravenously at 10- to 20-minute intervals, up 300 mg) is widely used for this purpose. If a pregnant woman has a seizure, the airway should be maintained, oral cavity protected, woman positioned on her side, and no efforts made to restrain the myoclonic activity. If magnesium sulfate is available, it is still the treatment of choice for eclamptic seizures and should be administered as previously described. Alternatively, a loading dose of diphenylhydantoin (20 mg/kg intravenously no faster than 50 mg/min) or lorazepam (1 to 2 mg intravenously) can be given.

Management

Delivery.

For many reasons, a wilderness delivery at term should rarely be "planned." If it is planned, only multiparous women who have had uncomplicated pregnancies, labor and delivery, and postpartum courses and who are willing to accept the risks of unexpected fetal and maternal complications should consider this as an option. A pregnant woman planning a wilderness experience of any duration that will carry beyond 20 weeks' gestation should include emergency provisions and plans. The location, duration of stay, and distance will dictate the extent of these plans from medical care facilities, convenience of evacuation routes, and ease of communication with and availability of evacuation support.

When the woman is in labor preparing for delivery, either a health care provider or the person with the most childbirth experience who is willing to assist in the delivery should be identified as team leader and "midwife." Participatory roles for other members of the party should be defined in cooperation with the pregnant woman. Requests for privacy and intimacy should be respected to the extent possible.

By necessity and practicality, delivery in the wilderness dictates a laissez-faire approach. Excessive intervention (e.g., repeated cervical examinations, artificial rupture of membranes, augmentation of uterine contractions by oxytocin or nipple stimulation, manual cervical dilation) is neither warranted nor appropriate, since delivery cannot be expedited for concerns of fetal distress, and such intervention may increase maternal and fetal risks. To the extent possible, a clean, comfortable, and quiet site is prepared for the delivery. If clean and sterile supplies and medications are available, these should be brought to this location and inventoried by the team leader (see [Box 75-3](#)). Otherwise, clean towels, clothing, bedding, soap, and water should be made readily accessible.

Figure 75-2 Ascertaining fetal position by Leopold's maneuvers. **A**, First maneuver. Assess part of fetus in upper uterus. **B**, Ascertain location of fetal back. **C**, Identify presenting part. **D**, Determine descent of presenting part.

Fetal position should be determined. In late third-trimester pregnancies, this can be accomplished by external abdominal palpation using Leopold's maneuvers ([Figure 75-2](#)). In preterm pregnancies this may first require internal digital examination, but fetal position is extremely important because the risk of malpresentation (breech, transverse, or compound lie) is inversely proportional to gestational age, as is the disparity between fetal head and abdominal circumferences. At term the incidence of breech presentation is approximately 3%, whereas it may exceed 25% under 30 weeks' gestation. If the woman reports fetal activity, or if this is visible or palpable on abdominal examination, evaluation of fetal heart activity is usually unnecessary. If the woman or the examiner

cannot detect fetal activity, and since fetal activity frequently diminishes with onset of labor, viability is assessed by auscultation. A stethoscope or the ear can be positioned over the location of the baby's back and shoulder. A stethoscope bell placed on the abdomen with minimal pressure is usually more sensitive than the diaphragm. Normal fetal heart rate at term usually falls to between 120 and 160 beats/min. Under most wilderness situations, once viability is confirmed, further auscultation is probably unnecessary and may even provoke anxiety because of the inherent difficulties of fetal heart rate detection with unamplified methods, subtle changes in fetal position, descent of the presenting part, and the increasing discomfort of labor as it progresses.

If facilities are available to perform an emergency cesarean section in the wilderness, intermittent fetal heart rate monitoring is done for 1 or 2 minutes every 20 to 30 minutes during the first stage of labor and every 10 to 15 minutes during the second stage. However, even under these highly unlikely circumstances, cesarean section should be considered only with persistent fetal bradycardia or with failure to progress in labor.

1784

In the early stages of labor or with spontaneous rupture of membranes in the absence of regular uterine contractions, rest interspersed with brief periods of ambulation, fluid intake, and frequent light meals should be encouraged. Prophylactic antibiotics should be started, especially when there has been premature rupture of membranes. Antibiotic coverage is the same as that recommended for preterm labor. Digital cervical examination is usually not necessary at this point and is contraindicated with rupture. As labor becomes more active, as gauged by increased frequency, regularity, and strength of uterine contractions, pelvic pressure, and discomfort level, the safest approach is to limit oral intake to clear liquids only. The GI tract becomes quiescent with active labor, and any stomach contents present at the outset will likely be present at the end. Since vomiting is not unusual, especially during the "transition" phase of labor, clear liquids minimize discomfort and decrease risk of aspiration. Intermittent ambulation may also decrease the discomfort associated with contractions and can be continued, if the woman desires, until she feels the need to push. During this time she should also be reminded to empty her bladder because she may not be able to differentiate the sensation to void from that of pressure from the presenting fetal part. A full bladder not only adds to the discomfort of labor but can also impede descent of the baby into the pelvis, prolonging the process.

Although some women become irritable as labor intensifies before complete dilation and do not want to be touched, others appreciate low back or extremity massage between contractions. Assistance with breathing and relaxation techniques to distract, maintain composure, and preserve the energy that will be required during the second stage of labor are also beneficial. During labor, no oral pain medication should be given, and parenteral narcotics, although acceptable, should be administered sparingly (ideally, intravenously with the onset of a contraction) unless naloxone is available to manage the fetal depression that may result. If a skilled health care provider is managing the delivery and pain is intolerable, a paracervical block can be considered once the cervix has reached 7 to 8 cm of dilation. This should only be done if the provider has

performed the procedure previously. The cervix is usually completely effaced at this point, so care must be taken not to inject the baby or inject the anesthetic agent intravenously.

When the woman begins to feel involuntary efforts to push with contractions, cervical examination should be performed with a clean or sterile glove or freshly washed hands. At the same time that cervical dilation and effacement are assessed, the presenting fetal body part should be identified, determining its station in relation to the ischial spines in midpelvis. If the cervix is completely dilated and effaced so that no cervical tissue is palpable between the presenting part and the vaginal wall, the first stage of labor is complete, and the woman can begin pushing with contractions. If the cervix is not completely dilated, the woman should be encouraged not to push with contractions so that she does not become exhausted. She also risks entrapping the cervix between the presenting part and the pelvis, which can lead to cervical edema and thickening, although this usually results from cephalopelvic disproportion. If membranes have ruptured, presence or absence of meconium should be noted. If membranes have not ruptured, they should not be ruptured intentionally, particularly if the baby is premature or in a breech presentation.

Usually, once the cervix is completely dilated, the desire to push is involuntary, and pain is less of an issue until the moment of delivery. Pushing is done only with uterine contractions. At the onset of a contraction the woman takes in a deep breath, expels this, and then taking in another deep breath and holding this, bears down without releasing air as if straining to have a bowel movement. Most contractions are long enough to permit two or three attempts at this maneuver. Proper pushing is evident by expansion of the introitus and rectum during the effort and should not be accompanied by tensing of the extremities. Once the contraction is over, she should expel any held air and begin restful breathing, trying to relax completely to conserve energy and recover for the next contraction. The woman may push in any position in which she feels comfortable. However, she should avoid laying flat on her back because uterine compression of the inferior vena cava can lead to hypotension and decreased uterine perfusion. Common positions include semirecumbent, with back and head elevated and legs drawn up or supported at the knees during contractions; lateral recumbent, with superior leg flexed and supported during contractions; squatting; sitting; kneeling on all fours; and standing while being supported from behind around the torso. These positions can also be used for the actual delivery, as long as the attendant has adequate access. Once the presenting part reaches, distends, and remains at the vaginal introitus between contractions, final preparations are made for the delivery. A delivery position should be selected that allows control of the presenting part, protection of the perineum, and room to accomplish completion of the birth with as little trauma to the baby as possible. Delivery should be performed during a contraction.

Vertex Delivery.

The most common fetal presentation is the cephalic (or vertex) presentation, with the fetal head facing the perineum (occiput anterior) (Figure 75-3 (Figure Not Available)). When the perineum begins to distend with a contraction, the woman should be instructed to bear down. Intentional cutting of an episiotomy in a wilderness setting is

not recommended. Spontaneous lacerations are

1785

Figure 75-3 (Figure Not Available) Management of vaginal vertex delivery. **A**, Control delivery of fetal head by upward pressure on chin with countertraction on occiput until symphysis is cleared. **B**, Delivery of anterior shoulder by downward traction on fetal head. **C**, Delivery of posterior shoulder by upward traction on fetal head. (Modified from Pritchard JA, MacDonald PC: *Williams obstetrics*, ed 16, New York, 1980, Appleton-Century-Crofts.)

more likely to occur along tissue planes that are less vascular and less likely to extend into the rectum. The perineum should be supported between the rectum and the introitus by the index finger and thumb of the nondominant hand while the fetal head is maintained in flexion until the crown has just begun to clear the symphysis. The woman stops pushing while the attendant exerts steady inward and upward pressure at the perineum against the fetal chin, thereby extending the head and completing its delivery while protecting the perineum. Once delivered, the fetal head will usually rotate laterally to align itself with the shoulders. The infant's mouth and nose should be cleaned by bulb aspiration or simple swabbing with a clean gauze or cloth. This step is especially important when meconium is present to prevent aspiration of this fluid when the baby is free to take its first breaths. Once the oropharynx is cleaned, the fetal neck should be palpated to ascertain the presence of a nuchal cord. If present, one or more loops of umbilical cord are often loose enough to be slipped over the baby's head before completion of the delivery. If they cannot be slipped over the head but are not tight, the baby can frequently be delivered through the loops. If the cord is tightly applied around the neck, the attendant should doubly clamp or tie a section of one loop, cut between the clamps, and then deliver the baby.

In the final stages of delivery the woman resumes pushing while steady downward (toward the maternal sacrum) traction is applied with hands cupping both sides of the fetal head. When the anterior shoulder has cleared the symphysis, the perineum should again be supported while the head is elevated and the posterior shoulder delivered. The rest of the baby's body usually

1786

follows without effort. The baby is held below the perineum (to prevent loss of blood to the placenta from the baby) while the oropharynx is again cleaned and the baby dried. Usually, rubbing the baby dry is sufficient to stimulate breathing and crying. The umbilical cord should then be doubly clamped or tied and then severed. The baby should be thoroughly dried, wrapped in clean, dry, and warm fabric with its head covered and given to the mother if she desires. If the baby does not cry within 10 to 15 seconds after delivery, has obvious airway obstruction, or is premature, the umbilical cord should be cut immediately and resuscitative efforts begun.

Shoulder Dystocia.

If there is difficulty delivering the anterior shoulder (shoulder dystocia) by the method outlined, immediate steps should be taken to accomplish this. True shoulder dystocia occurs in less than 1% of deliveries, is rare in uncomplicated labors, but is a substantial cause of fetal and maternal morbidity.^[144] Shoulder dystocia is often anticipated when the fetal head snaps back tightly and fails to rotate after its delivery. If available, other individuals can assist. Throughout the steps necessary to accomplish delivery, excessive traction on the fetal head is avoided because it may stretch the brachial plexus, resulting in an Erb's or Klumpke's palsy. The first step is to position the woman so that the buttocks are elevated to allow at least 12 inches of free space beneath the perineum to maneuver. Both legs should then be flexed upward to the chest (McRobert's maneuver) while the woman is supported in a semirecumbent position behind her back. Delivery should then be attempted again by downward traction on the fetal head.

If the shoulder is still impacted against the symphysis, pressure applied with the fist or heel of the hand just above the symphysis in the midline may reduce it sufficiently to accomplish the delivery. The assistants should not push on the uterine fundus because this can further impact the shoulder. If these maneuvers fail, an episiotomy should be cut to admit several fingers or the hand beneath the posterior shoulder. Once the hand has been inserted, the baby should be rotated by applying pressure to the shoulder and scapula (Wood's maneuver). The corkscrew rotation will deliver the posterior shoulder as it turns anteriorly, the anterior shoulder will dislodge, and the baby can be delivered without further difficulty. If this rotational maneuver fails, the posterior arm is delivered by grasping it along the forearm and sweeping it across the chest and out the vagina. This technique may fracture the humerus or the clavicle but is preferable to losing the baby because of inability to complete a delivery. Once the posterior arm is out, the anterior shoulder can usually be displaced downward, or the baby can then be rotated, allowing completion of the delivery. This approach is preferable to intentionally fracturing the clavicle, which can be technically difficult and does not provide as much room for the delivery.

If the baby is in a vertex presentation but facing the symphysis (occiput posterior), the labor is often more prolonged and uncomfortable, particularly in the lower back. The delivery is basically accomplished as described, however, except the final maneuvers to deliver the fetal head are extension first, then flexion. Perineal and introital trauma is a greater risk with an occiput posterior delivery. Management of this fetal presentation by the wilderness birth attendant should be a minor challenge compared with delivery of a breech baby.

Breech Delivery.

Since most wilderness deliveries will be "unexpected" and more likely to be premature, the baby also will more likely be in a breech lie. Other than chance and prematurity, the greatest risk factors for a baby to be in a breech presentation are unsuspected congenital fetal anomalies, chromosomal abnormalities, and maternal uterine

abnormalities. Each of these adds a new level of challenge to the birth attendant. Under the best of circumstances, delivery of a breech carries a threefold to fourfold greater risk than a vertex presentation for morbidity resulting from prematurity, congenital abnormalities, and trauma at delivery. The trauma often results from disproportion between the larger fetal head and the smaller body circumference of a premature infant. This disproportion can lead to entrapment of the head and is especially problematic when the fetal body has negotiated an incompletely dilated cervix.

Breech babies come in many forms: frank breech (hips flexed, knees extended, buttocks presenting), complete breech (both hips and both knees flexed, buttocks and feet presenting), incomplete breech (one hip flexed, one hip partially extended, both knees flexed, buttocks and feet presenting), and footling breech (hips and knees extended, feet presenting). Regardless of the form, the approach in a wilderness setting demands patience. No effort should be made to deliver a breech baby until the presenting part is visible at the introitus and the cervix is completely dilated. Membranes should not be artificially ruptured in breech presentations. As the amniotic sac balloons into the birth canal, it helps to dilate the cervix completely. This facilitates descent of the baby, providing a lubricated smooth surface against which the body can freely move, and cushions the umbilical cord against compression in the birth canal.

When the cervix is completely dilated, the woman is instructed to push. Regardless of the type of breech presentation, the safest course is to allow the body to be extruded to at least the level of the umbilicus by maternal efforts alone (Figure 75-4 (Figure Not Available)). This increases the

1787

Figure 75-4 (Figure Not Available) Management of vaginal breech delivery. **A**, Downward traction at ankles until buttocks clear the introitus. **B**, Traction on pelvic girdle until an axilla becomes visible. **C**, Delivery of posterior shoulder and arm. **D**, Delivery of anterior shoulder and arm with downward traction. **E**, Cradling the baby on forearm, finger is inserted into mouth or against chin. **F**, Delivery completed by outward traction while maintaining fetal head in flexed position. (Modified from Pritchard JA, MacDonald PC: *Williams obstetrics*, ed 16, New York, 1980, Appleton-Century-Crofts.)

1788

chance that the fetal head has begun to pass through the pelvic inlet. A baby in a frank or complete breech lie should have the posterior leg delivered by gently grasping the thigh and flexing the leg at the knee as it is rotated medially and toward the introitus. The baby should then be rotated to the sacrum anterior position, then another 45 degrees in the same direction to facilitate delivery of the other leg using the technique described for the first. The legs and buttocks can be wrapped in a clean towel to provide a firmer grip and decrease trauma to the baby. The delivery from this point is the same as for footling breech presentations. The upper legs should be grasped on each side with the index fingers crossing the infant's pelvic girdle and both thumbs positioned just above the crease of the buttocks. Using gentle side-to-side rotational motion over an arc

of 90 degrees outward and downward, traction should be applied while the mother pushes, until the upper portion of a scapula is visible at the introitus. With the baby's body rotated 45 degrees toward the opposite side, the arm is delivered by flexion and medial rotation across the chest. The baby is rotated to the opposite side in the same position, and the other arm is then delivered. If assistants are present, the woman should be helped into the McRobert's position, with hyperflexion at the hips to maximize the space between the symphysis and the sacrum.

Maintaining the baby in the same plane as the vagina, the birth attendant reaches palm up between the baby's legs and into the vagina, supporting the baby's entire body on the forearm while placing the second and fourth fingers over the infant's maxillae and placing the middle finger into the mouth or on the chin. The other hand is positioned over the infant's upper back so those fingers are overlying each shoulder. If there is sufficient room, the middle fingers can be applied to the fetal occiput. Then with the woman pushing, the baby's head is flexed downward, completing the delivery. Firm suprapubic pressure can help to maintain the head in flexion. During this final stage the baby's body should not be elevated more than 45 degrees above the plane of the vagina to avoid hyperextension of the head. If the fetal head cannot be delivered because the cervix is incompletely dilated, the cervix can be cut at the 2 and 10 o'clock positions (Dührssen's incisions) to provide sufficient room to complete the delivery. Once delivered, if the baby breathes and cries spontaneously or with minimal stimulation, cutting the umbilical cord can be delayed while the baby is dried. This allows some of the blood retained in the placenta from umbilical vein compression (common with breech deliveries) to return to the baby. On the contrary, if the baby is clearly depressed, the umbilical cord should be immediately clamped and cut and neonatal resuscitation begun.

Neonatal Resuscitation

The first steps in neonatal resuscitation are to dry the baby thoroughly, keep the baby warm, and clear the nose and mouth of excess fluid. Respiratory effort and heart rate (by auscultation or palpation at the base of the umbilical cord) are then assessed. If breathing spontaneously with pulse greater than 100 beats/min, the baby should be kept warm and observed. If the pulse falls below 100 beats/min and respiratory effort is poor, the next step is to improve ventilation. If further stimulation of the baby by rubbing with a towel or flicking the heels fails to elicit improvement in respiratory effort and pulse, the next step is to provide ventilatory support, ideally by applying positive-pressure ventilation with a neonatal mask and Ambu bag (preferably with oxygen). If this is available, gentle (15 to 30 cm H₂O) and rapid (40 to 60 breaths/min) ventilation should be performed for 30 seconds and the heart rate reassessed. If no equipment is available, the resuscitator's mouth is placed over the infant's nose and mouth, and rapid shallow breaths are delivered at a rate of 30–40/min. If this restores heart rate and respiratory effort, the baby should be observed for deterioration in status and the maneuvers repeated as necessary until support is available.

If the baby's heart rate falls below 60 beats/min, full infant cardiopulmonary resuscitation (CPR) should be started. Cardiac compression is performed by (1) placing both thumbs on the sternum just above the xiphoid and facing the fetal head, (2) gently stabilizing

this position with the other fingers around the chest, and (3) supplying compressions to a depth of $\frac{1}{2}$ to $\frac{3}{4}$ inch at a rate of approximately 90/min. Care should be taken not to deliver compression to the baby's ribs. Ventilation should be continued simultaneously as described. If the heart rate after 30 seconds of chest compression is 80 to 100 beats/min, the resuscitator continues with ventilatory support only. If the heart rate is over 100 beats/min, the person discontinues CPR and observes. If the heart rate is still less than 80 beats/min, CPR is continued.

Delivery of Placenta

Once the baby is delivered and stabilized, attention is redirected to the mother. The first step is to assess the status of placental separation. The heel of the non-dominant hand is placed just above the symphysis to hold the uterus in position, then the fingers are cupped to apply pressure to the uterine fundus while providing gentle, steady downward traction on the umbilical cord. If this maneuver does not promote placental separation, as indicated by a gush of bleeding, lengthening of the cord, and descent of the placenta into the vagina, efforts should be interrupted until these signs ensue. When the placenta does descend, the mother should be instructed to push once again to complete

1789

the third stage of labor. Rotating the placenta several times once it has passed through the introitus will usually result in complete extrusion of the attached chorioamniotic membranes. With signs of placental separation but resistance to extraction, the hand should be placed through the vagina and into the cervix. If the placenta is filling the cervix, it should be grasped and gently extracted. If the placenta does not separate spontaneously or is adherent to the uterine wall (placenta accreta), no effort should be made to separate it manually in a wilderness setting, since this could precipitate uncontrollable hemorrhage. Excessive traction on the umbilical cord also could result in uterine inversion, causing vasomotor collapse and hemodynamic decompensation.

Once placental expulsion has occurred, the uterus can be gently massaged abdominally to promote contraction and involution. Usually this is sufficient to control hemorrhage from the placental bed. If this is ineffective, it may be necessary to explore the uterus manually for retained placenta while compressing the fundus externally until it contracts. Additional measures to aid uterine involution and control bleeding include administration of oxytocin (10 to 40 U intramuscularly), nipple massage to promote endogenous release of oxytocin, methylergonovine (0.2 mg intramuscularly or orally every 2 to 4 hours), prostaglandin F_{2a} (250 µg intramuscularly), misoprostol (100 to 200 µg orally every 4 to 6 hours), and prostaglandin E₂ (20-mg suppository every 2 hours).^[6] If none of these measures is successful, and if bleeding from a laceration has been eliminated as a source, the uterus can be packed with clean sponges or towels until additional medical assistance arrives.

Once the placenta is removed and uterine bleeding controlled, maternal damage is assessed and repaired. The most common sites of lacerations are the perineum,

periurethral tissues surrounding the external meatus, lower vagina, and cervix. Significant cervical lacerations in unhurried deliveries are rare unless uncontrollable pushing has occurred before complete dilation. Other lacerations from a spontaneous delivery usually occur along tissue planes that do not disrupt vital areas; they will heal naturally or can be repaired later. Significant bleeding at any of these sites can usually be easily controlled by direct pressure. If available, application of ice packs to the perineum for the first 12 to 24 hours after delivery provides relief.

During the postpartum period the woman should be encouraged to drink fluids and void frequently. Bladder overdistention resulting from impaired sensation and pain after delivery is a common cause of permanent bladder dysfunction. It may also contribute to uterine subinvolution and continued blood loss. Once the baby has stabilized after delivery, the mother should begin breast-feeding, which also helps control excessive postpartum blood loss. After a wilderness delivery a broad-spectrum antibiotic, if available, should be continued for 24 to 48 hours. If the mother is Rh negative and the baby's blood type is Rh positive or unknown, Rh-immune globulin should be given within 48 to 72 hours after delivery.

Perimortem Cesarean Section

In the rare event that a pregnant woman with a viable baby sustains a lethal injury while partaking in a wilderness trip, performing a perimortem cesarean section should be considered.^[84] Ordinarily this procedure is done in a full-service medical facility when death is imminent and while CPR is being performed on the woman or when skilled medical personnel deem that the pregnancy is interfering with resuscitative efforts. In the wilderness, cesarean section should only be considered at the moment of maternal death, when surgical technique is irrelevant and speed is of the essence.

In skilled hands the entire procedure can be performed in 30 seconds or less. A vertical incision is made in the midline abdomen from the umbilicus to the symphysis. The incision is rapidly extended through subcutaneous tissues and fascia. The rectus muscles are bluntly separated in the midline and the peritoneum entered. The uterus is then incised vertically from fundus to bladder reflection. Once a site of entry into the uterine cavity is obtained, two fingers are inserted and the incision extended by blunt dissection to avoid sharp injury to the baby. Membranes are ruptured, the baby is delivered, and neonatal resuscitative efforts are initiated.

Breast-Feeding

Unless the baby is too premature or too unstable to nurse, breast-feeding should be encouraged as soon as possible after birth. Benefits include promotion of uterine contractions that control hemorrhage at the placental insertion site, encouragement of maternal-newborn bonding, provision of easily digestible and balanced nutritional support for the baby, and transmission of antibodies (IgA) that protect the enteric mucosa against invasion by colonizing bacteria.^{[94] [146]} Long-term benefits for the baby include decreased incidence of allergies, enteric infections, UTIs, otitis media, childhood obesity, and diabetes, as well as psychologic and perhaps cognitive advantages.* Benefits for the mother include more rapid return to prepregnancy weight, enhanced

bone remineralization, and reduced risk of ovarian cancer and premenopausal breast cancer.^[5]

*References ^[85] ^[87] ^[130] ^[132] ^[154] ^[167] .

1790

During the first 24 hours after delivery, frequent brief feedings are recommended (every 2 to 3 hours; 5 minutes on each breast, alternating first breast). Although a small amount of breast fluid (colostrum) is present initially, it contains electrolytes, minerals, and a high concentration of protein and protective IgA antibodies. The length of time spent at nursing and the interval between feedings can be increased as milk production is established over the next 2 to 3 days. The feeding schedule is typically 10- to 15-minute periods on each breast 8 to 12 times per day. It should be made clear to the mother that babies are not restricted to this regimen. Because babies have an innate urge and ability to suck, and mothers have an innate urge to mother, breast-feeding should require little formal education. However, first-time mothers often think they will not be able to breast-feed, will not provide sufficient nutrition to their babies, or will encounter frustrations and difficulties. Patience, relaxation, simple modifications in technique, and reinforcement of the benefits of nursing are beneficial. Mothers are reassured when they see that their baby is gaining weight and voiding five or six times daily and thus is receiving adequate nutritional and fluid support. Nursing women should be instructed to drink plenty of fluids (2 L/day); increase their caloric intake by 500 to 600 kcal/day, including a total protein intake of 60 to 70 g/day; and consume foods rich in calcium (1200 mg/day).

Several conditions can interfere with breast-feeding or cause maternal frustration. Breast engorgement 48 to 72 hours after delivery, signifying the onset of milk production accompanied by lymphatic obstruction, can cause pain and low-grade fever, interfere with the baby latching on, and inhibit milk letdown. Frequent feedings and warm compresses just before nursing help to stimulate milk letdown. Cool compresses after nursing, a supportive nursing bra, and acetaminophen usually provide symptomatic relief until milk production and newborn consumption are in equilibrium and lymphatic obstruction is resolving. Engorgement usually resolves within 24 to 48 hours.

Sore and cracked nipples are a frequent complaint of woman nursing for the first time.^[25]^[27] Short frequent feedings with several rotations between breasts at each sitting can be beneficial. After each feeding, gently cleansing with water and then applying a small amount of milk, expressed from the breast and spread around the areola to dry, help protect the nipples. Lanolin formulations designed for breast-feeding women can be used as well. Dry absorbent nursing pads should be placed over the nipples between feedings. If contact with clothing or even the nursing pads creates discomfort, breast shells can be used to prevent surface contact. Occasionally, nipple shields can be beneficial, as well as for the infant who has difficulty latching on to the breast.^[168]

Mastitis occurs in 2% to 3% of lactating women and should not be confused with breast engorgement since it rarely occurs until at least 3 to 4 weeks postpartum.^[81] Unlike

breast engorgement, mastitis is usually unilateral and accompanied by localized pain, erythema, brawny edema, fever, and malaise. It is more common among women who report painful and cracked nipples and who participate in vigorous exercise- and work-related upper body activities.^[48] These women should be encouraged to empty their breasts by nursing or pumping before these activities and to wear a properly fitting and supportive bra as preventive measures for mastitis. Women who develop mastitis should continue to nurse from the affected breast and may benefit from warm compresses and pumping between nursings. They should be placed on a course of antibiotics (e.g., dicloxacillin 500 mg or cephalexin 500 mg four times daily) for 10 to 14 days, with coverage for *Staphylococcus*, *Streptococcus*, and *Escherichia coli*, the most common isolates from affected breasts. Failure to improve or worsening while on this regimen, as determined by consolidation, widening of erythema and induration, and abscess formation, occurs in 10% to 15% of women. Incision and drainage may be required.^[136]

Certain substances, prescription drugs, and maternal medical conditions may affect breast-feeding. Excessive alcohol consumption and cigarette smoking should be avoided because of the deleterious effects on lactation and toxic effects on the baby. Street drugs should always be avoided because of the potentially harmful effects on mother and baby and the unknown chemicals used to prepare the drugs or enhance their effects. Infectious diseases (e.g., HIV, hepatitis B) acquired through intravenous drug use are transmitted in body fluids, including breast milk, and can have devastating effects in a newborn during the first year of life. Women with active tuberculosis should not breast-feed until they have received at least 2 months of therapy.

Few data address the safety of most prescription and OTC drugs in lactating women and their babies. Many new drugs become available each year, but few of these have been systematically evaluated in women, with even fewer tested in pregnant or lactating women because of ethical and liability concerns. In 1994 the American Academy of Pediatrics published a summary of recommendations for the use of drugs by lactating women ([Box 75-7](#)).^[4] Despite some controversy, this list is an excellent general guideline for drug use in lactating women. When given a choice of agents to prescribe or recommend in pregnancy or during lactation, health care providers should always consider those products with which there is the most clinical experience.

Box 75-7. CATEGORIZATION OF DRUG USE BY LACTATING WOMEN

CONTRAINDICATED

Amphetamines
Aspirin (high dose)
Bromocriptine
Cytotoxic agents
Ergotamine
Lithium
Radiopharmaceuticals

EFFECTS UNKNOWN BUT OF CONCERN

Antianxiety drugs
Antidepressants
Antipsychotics
Metronidazole
Psychotropics

AFFECTING MILK SUPPLY

Decongestants
Diuretics
Combination oral contraceptives

USUALLY CONSIDERED COMPATIBLE WITH BREAST-FEEDING

Analgesics

USUALLY CONSIDERED COMPATIBLE WITH BREAST-FEEDING

Analgesics

Antiasthmatics

Antibiotics

Anticoagulants

Anticonvulsants

Antiemetics

Antihistamines

Antihypertensives

Antithyroids

Corticosteroids

Digoxin

Narcotics

Oral contraceptives

Sedatives

Chapter 76 - Elders in the Wilderness

Blair Dillard Erb

Too many people live their lives by the calendar.
John Glenn, senior astronaut^[22]

Seniors in our society are encouraged to remain mentally, physically, and socially active. They perceive this recommendation as a welcome invitation to live life to its fullest. In response, elders in increasing numbers have come to enjoy the fellowship, camaraderie, and adventure of wilderness activities. Unfortunately, health risk associated with high-performance activities increases with age because of altered physiologic function, unrecognized impairments, or effects of illnesses and their treatment.

To reduce risk, seniors should be advised to temper their enthusiasm with the caution derived from the wisdom of experience. John Glenn made his second space flight safely at age 77 because of thoughtful planning and training. A maxim from his aeronautical colleagues reminds us, "There are old pilots, and there are bold pilots, but there are no old, bold pilots."

This review examines the risks, pathology, treatment, and, most important, prevention of health problems of elders as they venture into the wilderness.

THE AGING PROCESS

Aging is a natural consequence of life's continuum. It results in anatomic, biochemical, and physiologic alterations in function. Degenerative disorders and diseases occur that include a variety of problems, such as atherosclerotic and cerebrovascular diseases; chronic obstructive pulmonary disease; emphysema; diabetes mellitus; arthritis; emotional, mood, and memory disorders (e.g., depression, Alzheimer's disease); impaired thermoregulation; and increase in medication intake. These may affect individual performance and increase medical risk in the wilderness. The cumulative effect of these changes on elders subjected to stressful environmental factors results in a major increase in health risk and health care demand.^[9]

Every organ system of the body is affected to some degree by the aging process. Anatomic changes are usually organ specific, occurring in a way that is unique to the organ and the disease. Organs appear to age independently of each other and not necessarily in a parallel fashion. For example, glomerular filtration rate (GFR) and renal blood flow (RBF) decrease with age, but many elders have normal serum creatinine levels because there is a concomitant loss of muscle mass and creatinine production.

Physical and physiologic alterations may evolve so slowly that they may not be apparent for many years, yet result in functional and anatomic changes. The degree of loss of function in various physiologic systems can be approximated by using the "1% rule," which states that "most organ systems lose function at roughly 1% per year after the age of 30 years."^[18] Some age-related morphologic changes and their resulting functional changes include the following:

Cardiovascular system: elongation and tortuosity of aorta and arteries, thickening of arterial intima, fibrosis of arterial media, sclerosis of cardiac valves, especially aortic and mitral

Functional results: decreased cardiac output of 20% to 30% by age 70 years; decreased maximal heart rate of 6 to 10 beats/min/decade

Lung: decreased elasticity, decreased activity of cilia, and reduced volume

Functional results: decreased vital capacity of roughly 30 ml/year after age 30 years

Kidney: increase in number of abnormal glomeruli

Functional results: compensatory reduction in muscle mass neutralizing creatinine elevation; proteinuria

Gastrointestinal tract: decreased gastric hydrochloric acid, reduced salivary flow, and decreased number of taste buds

Functional results: modified appetite, food intake, and motility

Musculoskeletal system: decreased height and weight, loss of skeletal calcium, sarcopenia, increased ratio of fat to muscle mass, reduced elasticity in connective tissue, decreased viscosity of synovial fluid, loss of cartilaginous surfaces, and hypertrophic changes in joints

Functional results: osteoporosis, degenerative joint disease, failure to thrive (FTT) syndrome, loss of muscle mass and strength of 20% by age 65 years

Central nervous system: reduced brain mass, brain weight, decreased cortical cell count

Functional results: impaired cerebral function; decreased nerve conduction; loss of agility; and sensory impairment, including taste, smell, and touch

Eyes: decreased translucency of the lens and decreased size of the pupil, potential increase in intraocular pressure, and arcus senilis

1796

Functional results: decreased vision, including color and night vision, and impaired accommodation

Ears: loss of auditory neurons and atrophy of cochlear hair cells.

Functional results: decrease in hearing, primarily affecting high tones, especially frequencies greater than 2000 Hz

Skin: flattening and atrophy, attenuation of undulations in the dermal rete pegs, loss of cytoplasm of basal keratinocytes, and loss of dermal collagen

Functional results: decreased skin thickness, risk of dermoepidermal separation, decreased resistance to tear, and loss of elasticity

Inasmuch as aging reflects a time dimension, injuries and illnesses that occur along the path of life may produce cumulative anatomic scars, which, when combined with the degenerative changes of aging, may result in a functionally impaired elderly person. The risk may be greatly exaggerated by wilderness ventures. The challenge to health professionals is to determine the extent of that risk and to take appropriate action.

CLASSIFICATIONS OF ELDERS

For purposes of identifying elderly individuals at risk, it is useful to divide them into groups. Barry and Eathorne^[3] suggest classifying elders as the *hale* and the *frail*. This is a clever play on words but not very useful from a medical perspective. Smith,^[27] as reported by Howley, recommends classifying individuals according to chronologic age: (1) *athletic ola* (less than 55 years of age), (2) *young ola* (55 to 75 years of age), and (3) *old ola* (greater than 75 years). However, this scheme focuses only on chronologic age and implies from a limited perspective that there is uniform functional change that may be quantified by age in years.

I prefer a comprehensive classification that defines three factors: (1) *chronologic*: simple time-based classification in years, (2) *pathologic*: describing morphologic and anatomic changes, and (3) *functional*: defining functional changes that may modify or impair an individual.

ETIOLOGY OF THE AGING PROCESS

Why do some individuals age faster than others? Lifestyle and genetic predisposition are the most commonly incriminated "causes," but this does not explain the biologic basis for aging.^[13] Somehow, and often indirectly, genetic events may determine longevity. For example, there is an increased risk of development of Alzheimer's disease in the presence of an allele of apolipoprotein E (ApoE) gene, which encodes a carrier of cholesterol.^[2] Support for genetic determination of tissue longevity is scant.

Most biologists believe that the processes of aging are multifactorial. Stochastic theories suggest that deoxyribonucleic acid (DNA) damage and damage to proteins occurs from a variety of sources, such as reactive oxygen species including superoxide, the hydroxyl radical, and hydrogen peroxide. Mitochondria are an important source of reactive oxygen species and a major site of damage.

Other theories on the aging process include cellular changes, autoimmune mechanisms, neuroendocrine factors, and even a "biological clock," but Strehler^[30] feels that the cause should explain the progressive deleterious and intrinsic changes universal within the species.

For example, some animals, usually cold-blooded fish or amphibians, which may grow to an indeterminate size, may have an indeterminate lifespan, whereas warm-blooded animals with a limited or fixed size after maturation may die at a more predictable time and at an actuarially determined rate.^[31]

Questions concerning the nature and cause of aging include the following:

- Does aging affect everybody? Yes, but with considerable variation.
- Is aging a disease? Are there decrements in or natural losses of function and anatomic content representing "normal aging"? If so, there must be such a thing as "abnormal aging."
- Is aging genetically programmed as a sequence of events? Evidence suggests that genetic events may influence longevity, especially by modifying various influences such as cholesterol and blood sugar.
- Is aging a result of natural selection? Darwin's laws of natural selection and evolution have been considered, but in the 2 to 3 million years of human existence, there have been too few old humans in any generation until recently to provide proof of a selective advantage favoring genetic expressions related to aging.
- Is there a finite number of population doublings of human fibroblasts? Hayflick suggested that there are 50 doublings of fibroblasts during their lifespan. If, for example, the lifespan of fibroblasts is 18 months, 50 doublings would result in a

predicted lifespan of approximately 75 years.

- Is an individual responsible for personal longevity? Lifestyle factors, such as lack of exercise, dietary habits, tobacco use, and drug and alcohol use, not only influence anatomic and functional characteristics but may have deleterious effects on health and length of life. In perhaps the clearest summation of these theories, Hayflick suggests that the ultimate effect from the many factors influencing and affecting human life is that we simply exceed our reserve capacity. This lends support to the mountaineering dictum, "Always keep your reserve," which is particularly appropriate for elders.

DEMOGRAPHY OF ELDERS AND THE WILDERNESS

Extended lifespans during the twentieth century have resulted in changes in the composition by age of the populations of Western civilizations. The median age in the United States in 1900 was 23 years, rose to 30 years in 1950, and reached 33 years in 1990. Predictions for changes in life expectancy forecast a median age of 36 years in the year 2000, and 41 years by 2025. Persons over 65 years were the fastest growing segment (22.3%) of the U.S. population between 1980 and 1990, when the total persons over 65 years of age was 35.1 million.^[6] Estimates predict that by the year 2030, the number of individuals 65 years and over will reach 70 million in the United States alone.^[1]

It is not simply the size and growth of this group of seniors that is responsible for its changing medical needs, but rather changes in the characteristics of the lifestyle and activities adopted by them. Of the 18 million persons between ages 65 and 74, most are retirees, and many devote their new leisure time to outdoor activities. The largest increases in elders between 1980 and 1990 occurred in regions of the United States most commonly associated with an active outdoor lifestyle: mountain states 44%, Pacific states 31%, and southern Atlantic states 34%. By contrast, the population of elders in the north central area increased only 11.4%.^[6] ^[11]

Leaf^[21] reported three locations in the world, all in relatively remote mountainous areas (the Caucasus Mountains in Georgia, the Andes in Equador, and the Karakoram range in Pakistani-controlled Kashmir), where individuals frequently live to ages beyond 100 years. Speculation suggests that this is due to a combination of factors, including genetic selection and a physically active lifestyle.

Figure 76-1 President George Bush celebrating his 75th birthday with a parachute jump. He remarked, "Even old guys can still do stuff." (*Newsweek*, June 21, 1999. Photo courtesy George Bush Presidential Library.)

WHY ELDERS VENTURE INTO THE WILDERNESS

Most members of Western industrialized cultures adhere to principles of hard work, family and fiscal responsibility, and delayed gratification. As retirement years approach, seniors begin to collect their "rewards." These include the pleasures and benefits of recreational activities. Nash^[24] suggests that the personal reasons for elders to venture into the wilderness are for enjoyment of nature, for physical fitness, for tension reduction, for tranquility and solitude away from noise and crowds, for experiences with friends, for enhancement of skill and competency, and for excitement or even risk-taking ([Figure 76-1](#)).

As a result, outdoor recreational activities selected in the U.S. National Park System in order of decreasing frequency include: driving for pleasure, sightseeing, walking for pleasure, picnicking, stream/lake/ocean/pool swimming, and motorboating. Less common recreational activities include backpacking, off-road motorcycling, exploration, kayaking, and cross-country skiing.^[5] Although the venture frequency of the latter group is much less than the former, the risk per venture is much greater. These ventures often take place in difficult and inaccessible areas under extraordinary environmental circumstances and, in the event of an emergency, may invoke search and rescue services and/or a medical intervention.

ENVIRONMENTAL STRESSES AND ELDERS

Potential physiologic stresses encountered in the great diversity of outdoor wilderness activities are legion. They include extremes of heat and cold, high altitude, water immersion, tropical humidity, and desert aridity. The common denominator in nearly all of these ventures

1798

is physical activity, often at extreme levels. To compound the complexity, with any environmental stress, the physician may be dealing with an elder afflicted with subclinical disease or manifest disease.

When the physiologic demands from environmental stresses are added to the increase and prevalence of disease associated with aging, risk for illness and injury is multiplied. The complete package of age, conditioning, environment, and nature of the activity must be considered when an elder is advised or treated in the wilderness.

Heat (see [Chapter 10](#))

Tolerance to heat depends on physiologic factors: (1) characteristics of the host, including health status and medications, frequency and duration of exposure, and history of recent acclimatization; and (2) additional environmental factors. Industry has considered levels for permissible exposure limits (PEL), threshold limit values (TLV), and standards for maximal exposure, but there has been no consensus on an exact environmental stress index for heat.

Elders in a hot wilderness setting may have personal host characteristics, in addition to the environment, that further limit tolerance and safety. Weight; fractionated body mass; cardiovascular, renal, or pulmonary problems; and the presence of various medications may influence individual response to heat.

Regulation of body heat may be affected by altered function of the thermoregulatory center located in the anterior preoptic hypothalamic nuclei, by deranged skin sensors, or by medications used to treat various diseases, including anticholinergics, β -blockers, antipsychotic medications, and major tranquilizers. Side effects influence adaptation of sweat mechanisms to thermal stress. Diuretics may produce hypovolemia with loss of adequate subcutaneous circulation for heat dissipation. Because elders as a rule consume more medications than younger persons, it is very important to approach heat

injury preventatively rather than after hyperthermia occurs.

The cardiovascular system plays a major role in heat regulation through heat dissipation. Circulatory abnormalities, peripheral vascular disease, hypertension, and reduced cardiac output may modify heat dissipation, resulting in vulnerability to heat injury. Functional capacity as measured by maximal $\dot{V}O_2$ consumption ($\dot{V}O_{2\text{ max}}$) decreases 5% to 15% per decade after age 25 years. β -Blockers and calcium channel blockers may also influence cardiac output by modifying heart rate and myocardial contractility.

To prevent heat-related illness in the elderly, it is prudent to suggest a regular exercise program in heat. A regular program of physical activity consisting of 60 to 100 minutes of low-intensity exercise per day for 7 to 14 days at tolerable heat levels before the planned exposure should result in significant adaptation in normal individuals. The exercise level should require an oxygen consumption of less than 50% of the individual's $\dot{V}O_2$ max. Experience teaches us that a degree of adaptation results from frequent and extended periods of exposure. Acclimatization to heat yields a more beneficial response to concomitant exercise. This includes lower heart rate, enhanced tolerance to physical activity, predictable core temperature in response to heat stress, increased sweat rate, and decreased sodium loss through sweating.

Additional environmental factors, such as high humidity, high winds, and infrared and ultraviolet radiation exposure, may modify levels of individual tolerance to heat, partly through skin changes. It is valuable to teach individuals to be aware of the environment and whether the skin feels warm, cold, or damp. It also is helpful to advise the prospective wilderness venturer that, as a general rule, it takes a breeze of greater than 5 knots (5.75 mph) to be appreciated against the skin of the face. This may serve as a body signal reflecting one of the features that may add to the process of heat dissipation (see Body Signals, [Box 76-2](#)).

Characteristics of Elders Vulnerable to Heat Exposure

1. Host characteristics: obesity, decreased physical functional capacity
2. Infrequent heat exposure
3. Altered thermoregulatory center in the hypothalamus or insensitive skin sensors
4. Metabolic and serum electrolyte abnormalities
5. Heart disease, coronary artery disease, pulmonary disease, diabetes, and renal disease
6. Peripheral vascular disease
7. Multiple medications, often in combination: anticholinergics, antipsychotics, tranquilizers, and β -blockers
8. Alcohol

Prevention of Heat Injury in the Elderly

1. Maintain adequate hydration.
2. Assess the health status, with particular emphasis on history, cardiovascular

- status, obesity, and previous history of problems associated with heat exposure.
3. Maintain adequate nutritional status—food, fluid, and electrolyte intake.
 4. Use estrogen replacement therapy where indicated (see Clinical Medicine, Menopause).
 5. Participate in a proper acclimatization program.
 6. Avoid the use of superfluous medication.

Cold (see [Chapter 6](#))

Cold exposure is poorly tolerated among the elderly, and body temperature is more difficult to control in elders than in younger people. Peripheral vasoconstrictive response to cold is diminished. Systolic hypertension

1799

through stimulation of the sympathetic nervous system is exaggerated in a cold environment. Cardiac workload is increased, and consequently, in the presence of coronary artery disease, angina is frequently precipitated by exertion and cold. Four avoidance factors for persons with coronary artery disease are exertion, exposure to cold, eating excessively, and emotional extremes, any one of which can precipitate angina. These factors are referred to as "the four Es of angina." An elder individual should remember that any one of these can induce angina and should be particularly careful not to combine any two of these potential ischemia-producing factors.

With aging, diminished metabolic rate occurs. When associated with age-related reduction in muscle mass, the shivering response is blunted and there is reduced capacity for heat generation.

Exhaustion added to hypoglycemia and dehydration compounds the problem of impaired metabolic function, making the elder individual more vulnerable to the effects of cold. Adequate food intake is essential for maintaining body heat and may become critical. Other physical environmental influences, such as wind, humidity, ultraviolet and infrared radiation, and altitude, should be factored into the exposure equation. The wind chill index provides a useful teaching device for reminding the explorer about the hazards of combining cold and wind. The classic combination of cold, dampness, wind, and exhaustion may prove fatal, especially in an elder with decreased physical reserve.

Medical conditions may contribute to hypothermia. Cardiovascular disease, metabolic diseases such as hypothyroidism and diabetes, compromised nutritional status, and modified thermoregulatory responses resulting from central nervous system disease or medication may influence heat conservation.

Heat loss may also be increased by damp, wet clothing. All persons should be cautioned to carry ample clothing for changes after saturation with moisture.

The fundamental mechanism for heat conservation, peripheral vasoconstriction, may be

enhanced to some small degree by long-term adaptation to cold, resulting in more effective protective function. When an elder recognizes intolerance to cold, he or she may begin a program of gradual increase in exposure to cold. However, prevention of cold injury is best achieved through a learning process derived from experience. Elders should never venture unaccompanied into the cold wilderness. Judgment and independent responsibility may be impaired by elders who find themselves lost or in a rescue situation.

Characteristics of Elders Vulnerable to Cold Exposure, Cold Injury, and Frostbite

1. Peripheral vascular disease (impaired vasoconstriction)
2. Hypertension (cold-induced)
3. Heart disease, including coronary artery disease, decreased cardiac output, congestive heart failure
4. Metabolic diseases (diabetes, obesity, hypothyroidism)
5. Hematologic disorders (anemia, dysproteinemias)
6. Pulmonary disease (cold-induced asthma, chronic obstructive pulmonary disease)
7. Drugs and alcohol
8. Medications, particularly β -blockers and tranquilizers

Prevention of Cold Injury in the Elderly

1. Avoid exhaustion during wilderness ventures.
2. Limit exposure.
3. Carry and wear adequate clothing, including rain gear.
4. Stay dry and avoid damp undergarments from excessive sweating.
5. Maintain adequate nutrition with high carbohydrates and fat. Carry adequate food for the trip.
6. Maintain adequate fluid intake. Do not consume cold ice or snow!
7. Participate in a preexpedition physical training program. Avoid exhaustion.
8. Pay attention to medication effects.
9. Avoid alcohol and illicit drugs.
10. Always maintain access to an adequate shelter.

Altitude

Demographic data for altitude illness among the elderly are limited. Most studies have been on healthy, vigorous young males. However, Houston,^[15] Honigman,^[14] and others studied the general population at moderate altitude (2000 to 3000 m [6562 to 9843 feet]) elevation at ski resorts in Colorado. Predictors of mountain sickness included chronic residence at altitude greater than 1000 m (3281 feet) before a high-altitude venture, underlying lung problems, previous history of acute mountain sickness ($p < 0.05$) and, surprisingly, age younger than 60 years. This apparent paradox probably is due to natural self selection among the small group of elderly individuals who expose themselves to altitude and activity.

Hackett^[12] reported that aging reduces physiologic components of the gas exchange process, such as vital capacity and hypoxic ventilatory drive, that maintain oxygenation.

Older persons are known to have a lower arterial P_{O_2} because of thickening of the pulmonary alveolar-capillary membrane.^[19]

Although 25% of visitors to moderate altitude develop some degree of mountain sickness, data reflect a protective effect from living at moderate elevations of 1500 to 2000 m (4921 to 6562 feet), which is consistent with empiric observations that staging of altitude ascent reduces the incidence of acute mountain sickness.

Honigman found that most frequent predictors of acute mountain sickness are: (1) altitude of residence

1800

greater than 1000 m, (2) history of previous episode of acute mountain sickness, (3) age less than 60 years, (4) poor or average physical condition, and (5) lung disease.

Decreased fitness, alcohol intake, excessive activity within the first 12 hours after arriving at altitude, preexisting cardiopulmonary disease, and medication increase the risk of altitude illness among elders. Alcohol tolerance is so variable that total abstinence during a wilderness venture is recommended. It is prudent to avoid sedatives and hypnotics at high altitude.

Characteristics of Elders Vulnerable to Altitude Illnesses

1. Abrupt ascent in altitude from near sea level to 3000 m (9843 feet) or greater, without an extra night for acclimatization for every additional 600 to 900 m (1969 to 2953 feet) of continuing ascent
2. History of previous episode of altitude sickness
3. Preexisting lung disease characterized by decreased capacity and decreased hypoxic ventilatory response
4. Preexisting cardiovascular disease
5. Metabolic abnormalities associated with diabetes and renal disease
6. Medication that influences respiratory drive
7. Low physical functional capacity
8. Obesity

Prevention of Altitude Sickness in Elders

1. Avoid strenuous physical activity at altitude if there is a history of acute mountain sickness.
2. Limit the intensity of physical activity in the presence of cardiovascular disease.
3. Limit physical activity in the presence of pulmonary disease, especially if there is decreased vital capacity.
4. Avoid significant physical activity for at least 12 hours after arrival at an altitude of 2500 m (8202 feet) or more above sea level, and delay physical activity for an

- additional 24 hours for every 600 to 900 m additional altitude.
5. Be aware of all medications and their effect on hypoxic ventilatory drive.

CLINICAL MEDICINE IN ELDERS

Wilderness medicine can be simply defined as "traditional medicine in a nontraditional setting." Nature of the site, environmental conditions, and type of activity affect care, search and rescue, transportation, and medical support. When elder age is a factor, an additional set of concerns is added, including reduction in physical reserve, increase in rate of physical deterioration during exercise, and therefore reduction in margin of safety. Enhanced skills of analysis, planning, intervention, and action are demanded of the rescuers and medical team.

There are two important occasions when elders and wilderness leaders should consider health/medical evaluation for elderly venturers: (1) during the planning phase before the venture and (2) following symptoms that may occur during or after the venture. Components of the pretrip evaluation are based on the characteristics of the individual and on the nature of the proposed venture. These are discussed in the Medical Examination section. Evaluation after the onset of symptoms and/or for intervention and disposition requires clinical judgment dictated by the specific problem or symptom and is considered in discussions of specific illnesses.

Cardiovascular Disease

Age-related changes in the cardiovascular system affect heart rhythm, myocardial pump function, and afterload. With aging, there is progressive reduction in the number of pacemaker cells in the sinoatrial (SA) node, increase in myocyte cell volume per nucleus in both ventricles, increase in peripheral vascular resistance, and increase in aortic impedance from loss of elasticity. Increased levels of circulating catecholamines are associated with aging, especially with stress, but β -adrenergic vasodilation decreases with age. This is important for exercise tolerance in elders.

Cardiac rhythm disturbances range from the nuisance effect of premature systoles to significant rhythm disturbances, such as atrial fibrillation, to potentially life-threatening ventricular arrhythmias. An elder who is aware of symptoms related to an arrhythmia should seek evaluation by a physician before a wilderness venture. The evaluation should include history of onset of symptoms and initiating factors, physical examination with emphasis on auscultation of the mitral and aortic valves, electrocardiogram, ambulatory monitoring if there is a history of heart disease or light-headedness, and possibly an echocardiogram.

Valvular changes, especially of the aortic and mitral valves, may be recognized by auscultation and confirmed by echocardiography, and perhaps by cardiac catheterization. The subject with a prosthetic cardiac valve may be at risk during

prolonged ventures with exposure to inclement weather or infectious diseases among fellow venturers or diseases among the local populace.

The presence of pump failure, either systolic or diastolic, may be indicated by recent weight gain, shortness of breath, orthopnea, or ankle edema. It is confirmed by physical examination, electrocardiography, echocardiography, and chest x-ray. Although digitalis, diuretics, and angiotensin I-converting enzyme (ACE) inhibitors may relieve symptoms of systolic dysfunction, the subject with heart failure should limit remote wilderness ventures to those activities that do not cause excessive shortness of breath, that is, to the point of requiring

1801

breathing through the open mouth, or excessive fatigue.

Peripheral vascular disease, claudication, symptomatic carotid disease, and aortic aneurysms warrant caution in regard to the difficulty of return or evacuation in the event of incapacity.

Coronary Artery Disease

A heart attack is the ultimate medical emergency. In the United States, approximately 1.5 million persons sustain myocardial infarctions annually, 30% of whom do not survive. Of these victims, 50% die within the first hour of the onset of chest pain. If a victim survives the first hour, which may be the time required to initiate a search and rescue, there may be approximately an 85% chance of survival expected subsequently.

Only half of persons with myocardial infarction have premonitory symptoms, but interrogation about this during a medical history could alert one to the likelihood of myocardial infarction. The history should include a detailed assessment of risk factors for coronary artery disease. Subsequent physical examination and testing may provide recommendations aimed at reducing life-threatening cardiac events.

Many physiologic stresses related to environmental extremes have as a common denominator an increase in catecholamine output with a concomitant rise in heart rate, blood pressure, and cardiac output. This results in increased cardiac work load and myocardial oxygen demand.

Since the myocardium depends almost entirely on aerobic metabolism, workload is reflected in myocardial oxygen consumption. Delivery of oxygen (O_2) to the myocardium in response to workload demands depends on coronary blood flow. Hence, integrity of the coronary arteries is essential for a viable response to wilderness stresses.

Knowledge of the existence and extent of coronary artery disease will influence

physician recommendations for the nature and level of activity, expected tolerance to environmental stresses, and recommendations as to the degree of remoteness, level of exertion, and environmental factors that the individual should consider in the proposed wilderness ventures.

The Preventure Assessment

Since there is no absolutely risk-free activity for a person with significant cardiovascular disease, prevention is the fundamental principle for reducing risk. Before vigorous outdoor activity by an elder, the physician should: (1) question the individual regarding planned activities, (2) have a knowledge of the planned activity and be aware of anticipated exertion and environmental circumstances, (3) have a thorough understanding of previous history of coronary artery disease and other illnesses, and (4) be prepared to make specific recommendations regarding physical activity and exposure (see Medical Examination).

There are currently no published guidelines to aid in advising elderly individuals intending to venture into the wilderness, but the American College of Cardiology 26th Bethesda Conference produced "Recommendations for Determining Eligibility in Competitive Athletes with Cardiovascular Abnormalities." These guidelines divide patients into two categories: (1) those with mildly increased risk, having a left ventricular ejection fraction (LVEF) of greater than 50% (or revascularization of such lesions), and (2) those with a substantially increased risk, having a LVEF of less than 50%, exercise-induced myocardial ischemia, exercise-induced complex ventricular arrhythmias, and occlusive lesions of greater than 50% in one or more coronary arteries.

Transposing the recommendations for athletes to the elderly, persons with mildly increased risk are advised to restrict activities to levels of low dynamic activity, that is, activities requiring an energy expenditure equivalent to walking, and a low moderate static level equivalent to lifting less than 15 to 20 pounds. Those persons with substantially increased risk are advised to participate only in low-level dynamic and static activities.

Persons with atrial fibrillation but without structural heart disease, and who can maintain an appropriate heart rate response to exercise, have no limitations. For persons with atrial fibrillation, structural heart disease, and an appropriate rate response to exercise, activities consistent with the limitations of the structural heart disease are allowed. Persons with atrial fibrillation requiring anticoagulation should not participate in activities risking physical contact and injury.

In considering these recommendations, one must remember that these guidelines were developed for competitive athletes and are not necessarily applicable to recreational activities. Nevertheless, the guidelines provide a framework for an initial evaluation.

A fascinating philosophical discussion dealing with the limitations of wilderness activities in subjects who have undergone cardiac surgery appeared in a series of letter exchanges and editorials in the *Journal of the American Medical Association*. The

conclusion returned the decision-making process to the clinical judgment of the cardiologist on a case-by-case basis.^[26]

Hypertension

Hypertension, the "silent killer," is an important marker for potential cardiovascular problems among elders. Cardiovascular mortality was shown to be 3 times as high in hypertensive elders compared with those with normal blood pressure. Complications include angina, myocardial infarction, left ventricular hypertrophy, heart failure, stroke (both ischemic and

1802

hemorrhagic), and renal failure. The most widely accepted values of blood pressure considered to represent hypertension are systolic above 140 mm Hg or diastolic over 90 mm Hg. In the health survey for England,^[25] systolic blood pressure over 160 mm Hg was observed in 35% of men and 37% of women aged 65 to 74, increasing to 41% and 49%, respectively, after age 75 years. Isolated systolic hypertension is almost exclusively a disorder of elders with a prevalence of 0.8% at age 50 years, 12.6% at 70 years, and 23.6% at 80 years.^[29]

There is an increased effect of oral sodium intake on blood pressure in the elderly. An increase of 100 mmol/day is associated with a 10- to 15-mm Hg rise in systolic pressure, compared with a 4- to 5-mm Hg rise in younger adults who ingest the same sodium load.^[20] In elders, isolated systolic hypertension is recognized as a predictor of stroke.

Treatment of hypertension is mandatory before an elder ventures into the wilderness. Useful medications, however, may cause significant side effects. Diuretics, an integral part of treatment, may deplete volume and electrolytes such as potassium and sodium. β -Blockers, of particular value for the systolic component, may limit heart rate response to activity or modify body temperature control during exposure to heat or cold. Calcium channel blockers are of value in treatment of hypertension, but headache, flushing, and edema are reported in about one third of patients taking them. The least complicated treatment for hypertension is control of obesity and restriction of dietary sodium intake.

Treatment of hypertension in the elderly includes all of the foregoing with the caveat that exertion in the wilderness setting may magnify the physiologic and pharmacologic effects of medications.

Gastrointestinal Disorders

The gastrointestinal tract maintains relatively normal function during the aging process. Constipation, however, is a frequent complaint among 26% of elderly men and 34% of elderly women. There is a difference between the medical definition and elder perception of constipation and their need for laxatives. Normal frequency of bowel

movements varies between three defecations per day and three per week. However, laxatives are used by 15% to 30% of elders on a regular basis. When such individuals find themselves in the wilderness, away from the convenience of their bathroom, alteration in bowel habits, even to the point of fecal impaction, may occur. Therefore it is prudent to obtain a detailed history of habits and medication before embarking on a wilderness venture. Dietary fruit, fiber, and grain with stool softeners for elders during a wilderness venture may help avoid impaction, rectal fissure, hemorrhoidal bleeding, leaking incontinence, and chafing.

An increased prevalence of several gastrointestinal disorders is noted among elders. These include malignancies of colon and pancreas, gastric ulceration that may bleed, especially after nonsteroidal antiinflammatory drug (NSAID) ingestion, and *Helicobacter pylori* infection. Prospects for bleeding or obstruction from colon malignancies, bleeding from gastric ulcers, and possible perforation of ulcers should alert the individual or group leader to the seriousness of remote adventures and urgency for medical attention. A surgical emergency may arise from an incarcerated or strangulated inguinal or ventral hernia.

Diarrhea among elders contracted in Third World countries may be severe, leading to dehydration, gastrointestinal bleeding, or perforation of a hollow organ. Exacerbation of diverticulitis or acute cholecystitis, with or without pancreatitis, persistent or unusual abdominal pain, vomiting, bleeding, and worsening dehydration are reasons for ending the venture and initiating evacuation to medical care.

When traveling to remote Third World countries, it is prudent for expeditions to carry intravenous (IV) fluids and to consider appropriate antimicrobial prophylaxis or medications for the presumptive treatment of infectious diarrhea.

Genitourinary Disorders

Elders are particularly vulnerable to urinary tract disorders, including infections, obstructions, and ureteral, renal, or bladder stones. Bladder infections in women are common in remote settings because of dehydration and difficulty with hygiene. Incontinence after hysterectomy is frequent, and discomfort from chafing and bladder infection may be present. It is prudent for women to carry medicated skin pads and cotton diapers. Men may incur bladder infections from benign prostatic hypertrophy with obstruction. Anticholinergic medications may induce bladder relaxation with subsequent retention. Terazosin hydrochloride, an α_1 -selective adrenoreceptor blocking agent, may improve urine flow in instances of obstruction resulting from benign prostatic hypertrophy by reducing bladder outlet obstruction without affecting bladder contractility.

Dehydration from fluid loss or inadequate oral replacement may precipitate infection. Adequate fluid intake is the key to genitourinary health in the wilderness, but the participant must be cautioned about water quality.

Menopause

Menopause in women is a normal phenomenon associated with aging. Rather than occurring as a discrete event, the menopause transition may take place over a period of several years beginning around 40 years or as late as 50 to 55 years of age. Also known as the climacteric, this is a time in life when the opportunity for leisure activities may be greatest. Women who participate in wilderness activities must deal with the symptoms

1803

and somatic changes of menopause in addition to the physical and environmental stresses of the wilderness.

Symptoms that foretell the onset of menopause include vasomotor flushing, night sweats, insomnia, vaginal dryness, and variation in menstrual cycle and flow. Convention accepts that 12 months of cessation of menses is confirmation of menopause.

As ovarian production of estrogen declines, the androgen/estrogen ratio changes dramatically. Gonadotropin feedback results in increased follicle-stimulating hormone (FSH) in a range of up to 30 MIU/ml. Progesterone secretion is variable and may either increase or decrease.^[28] Resulting anatomic changes from these hormonal alterations may affect lipid ratios, the coronary arteries, cortical and trabecular bone, and changes in body fat distribution with a shift in fat towards the center of the body. Changes in cognitive function have also been reported.

Vulnerability to osteoporotic fractures is a serious hazard for the elderly woman in the wilderness. In trabecular bone found in the spinal column, resorption and formation occur 4 to 8 times as fast as that of cortical bone. As a result, there is an increased risk of compression fracture of the spine or fracture of hip in the event of a fall.

Hormonal replacement therapy should be considered for menopausal or postmenopausal women or in those who have had surgical hysterectomy. The three classic indications for hormone replacement therapy are: (1) for symptoms related to estrogen deficiency, such as vasomotor symptoms or genitourinary tissue atrophy; (2) for prevention or treatment of osteoporosis; and (3) for prevention of a cardiovascular morbidity and mortality, all of which may occur in the wilderness setting.

Combinations of estrogens and progestins may be used in treatment.^[17] Examples include:

Daily estrogen as 0.625 mg conjugated estrogen or 1 mg micronized estradiol

Daily progestin as 2.5 mg medroxyprogesterone acetate or 0.35 mg norethindrone

Transdermal route of administration may be convenient in the wilderness setting, reducing some of the packing load.

Musculoskeletal Disorders

Musculoskeletal disorders are a leading cause of morbidity among elders. In the wilderness, joint stress associated with extended hiking, injuries from repetitive motion, falls, and other trauma, when superimposed on the aging body, can induce functional impairments. Limitations in mobility and from pain lead to a loss of satisfaction or success or even to significant hazards during wilderness ventures.

Arthritis is among the most common causes of chronic disability in elders. About 15% of the U.S. population in 1990 reported having arthritis. More significant is a reported prevalence of nearly 50% among persons 65 years of age or older.

Musculoskeletal conditions with increased incidence in adults over age 50 years include osteoarthritis, osteoporosis, polymyalgia rheumatica, giant cell arteritis, gout (especially associated with diuretic use), and other crystal-associated arthritides such as calcium pyrophosphate deposition disease, basic calcium phosphate deposition disease, rheumatoid and other inflammatory arthritides, and spinal stenosis.

The aging joint undergoes degenerative changes in its components. Cartilage has very little ability to heal. Therefore injuries to cartilage tend to accumulate with age, leading to irreversible damage and osteophyte formation, developing into hypertrophic osteoarthritic change in joints of the extremities and spine.

Skeletal muscle undergoes specific age-related changes with loss of muscle mass. Changes in hormones, growth hormone/insulin-like growth factor-1 (GH/IGF-1), the androgen/estrogen ratio, cytokines/growth factor, interleukin-6, and free radical production may be related to these atrophic changes.

The syndromes causing loss of muscle mass in elders are either (1) intrinsic: sarcopenia, resulting in diminished reserves of muscle mass, or (2) extrinsic: failure to thrive (FTT) syndrome, from diseases and/or increased metabolic demands.

Prevention and treatment of sarcopenia and FTT include a regimen of regular exercise, including both aerobic training and strength training. Progressive resistance training (PRT) is effective in the treatment of sarcopenia. Lean mass is lost along with bone mass at menopause. Estrogen replacement appears to be helpful in some postmenopausal women. Evidence supporting testosterone replacement for FTT in elderly men is lacking.

A detailed history and physical examination, with emphasis on prior and present symptoms, is of value for an elder contemplating physical activity and essential for an elder planning remote wilderness activities. Although radiologic studies and laboratory tests may help establish a diagnosis, a common tendency is to rely too heavily on the

radiograph to explain symptoms. Joint aspiration and synovial fluid analysis helps in the diagnosis of metabolic or inflammatory arthritides.

Treatment of arthritis in a layered stepwise manner begins with rest, acetaminophen, NSAIDs, and topical capsaicin. Elders especially must be cautioned about the gastric irritation from NSAIDs and their danger in the presence of comorbid conditions and anticoagulant therapy.

Intraarticular corticosteroids may help reduce inflammation. Injection serves the extra function of providing access for aspiration of synovial fluid from a joint

effusion. Total joint replacement (TJR) for hips and knees has been used with increasing frequency for the management of severe intractable and progressive pain.

Physical therapy before and after the onset of symptoms, including body weight reduction, PRT, aerobic conditioning, and spa therapy, may be effective in treatment or during preparation for a wilderness venture. Corsets, braces, and canes prescribed by the treating specialist should be used, but the layperson is cautioned against self-prescription.

A conditioning program before the venture may help prevent musculoskeletal problems or may precipitate symptoms that alert the individual to a problem not previously recognized. It is better for symptoms to occur at home and serve as a warning for potential future untoward events than to occur in a remote location far from medical care. Since degenerative changes in the dorsolumbar and cervical spine may become symptomatic, it is appropriate to carry a backpack during a conditioning program before a hiking venture. At least one and preferably two hiking sticks are recommended for hiking activities.

Growth Hormone in Elders

With advancing age, there are decreases in lean body mass, body fat, and protein synthesis. GH deficiency is associated with changes in body composition and protein metabolism similar to those of aging. With advancing years, men and women with no clinical evidence of pituitary abnormalities show decreases in GH secretion and serum levels of IGF-1. Administration of recombinant human GH (rhGH) to these GH/IGF-1-deficient elders has been reported to result in improvements in nitrogen balance, increase in lean body mass, and decrease in percent body fat. Studies also suggest that there may be an increase in lumbar vertebral bone density, but no significant change in the mineral density of the radius or proximal femur.

Long-term administration of GH has been reported to cause some side effects, including

edema, hypertension, carpal tunnel syndrome, and arthralgia.

Further studies are needed to determine if normalization of GH and IGF-I levels in healthy elders will lead to improvements in the physical and functional quality of their lives. The prospect of improved muscle mass and strength for elders considering wilderness activities should be followed closely by those interested in human performance.

Neurologic Disorders and the Senses

Organic neurologic disorders, clinically apparent or subclinical, are frequent among elders. Symptoms of neurologic problems may be precipitated by minor activities or environmental stresses in the wilderness. Physical activity to which a participant may be unaccustomed, especially when extreme environmental conditions are superimposed, can make subtle changes more apparent. However, if a victim responds with denial, the result can be devastating.

A history of ischemic or hemorrhagic stroke that in the past resulted in a degree of paresis, especially when accompanied by symptoms such as dizziness, changes in rational thought, or seizure, should alert leaders to potential problems in a wilderness venture.

Altitude, especially above 2500 m (8202 feet), may induce changes in mentation not apparent at lower levels. Leaders should be especially diligent in the assessment of individuals with a previous history of altitude sickness or who are taking medications, including anticoagulants, for cerebrovascular disease.

Our senses are our warning system for hazards in the wilderness. The five classical sensory "instruments" send signals to the central nervous system during interpretation of the physical environment. With age, these sensors undergo functional degeneration. Up to 75% of elders have visual and auditory impairments not reported to their physicians. Changes may be subtle. Again, the aging rule is a 1% loss per year after age 30 years of physiologic function in most organ systems.

Vision.

There is decreased visual acuity caused by morphologic changes in the lens, choroid, retina, rods and cones, and other neural elements, and by an increase in intraocular pressure. Night vision and color vision are noticeably decreased after age 50 years. Hypoxia, to which the elder's eye may be sensitive, may cause tunnel vision. This may be a valuable "body signal" indicating an altitude that may be hazardous to the individual.

The most troublesome ophthalmologic effects of age are glaucoma and changes in refractive power. Increased intraocular pressure may be associated with halos and declining vision. This is a serious medical condition warranting continuing care by an ophthalmologist (see [Chapter 22](#)). Manifestations and treatment of farsightedness

range from purchasing a pair of nonprescription "reading glasses" to elaborate multipower prescription lenses. Negotiating rough terrain may be difficult using bifocals. An older person walking on a wooded trail may be unable to see the roots and rocks in his or her path. The wilderness is no place for a broken hip. Trifocals and various lens designs have been tried, but experience suggests that trail glasses should be configured for distance, with separate reading glasses for close-up work, such as map reading. Decreased tear secretion and "dry eyes" may affect elders in a dusty wilderness environment.

1805

Hearing.

Hearing problems are common in elders, affecting 60% of Americans over age 65 years. Presbycusis may be the result of previous middle ear infection, vascular disease, exposure to noise, or the natural loss of sensitivity and distortion of signals associated with advancing age. Acoustical trauma may have caused a permanent reduction in sensitivity to high-frequency sound, and the failure to hear the "click pitch" of consonants may obscure communications. Problems with sound localization may result in loss of directional hearing. Confused sound signals cannot be processed as accurately by an aging brain. Add tinnitus and a hostile environment, and the hearing sense loses its value as an important survival tool.

Taste and Smell.

Some lingual papillae are lost because of age, diminishing the ability to taste. Salivary secretion is reduced. Dentures may cover secondary taste sites. Olfactory bulbs also undergo significant atrophy with age. Combined taste and olfactory sensory deprivation may account for decreased "pleasure" of trail food taste.

Touch.

In addition to assisting in fine movement needed for technical work, sensitivity of touch against a hostile environment may be lifesaving. For example, conventional wisdom holds that the threshold for feeling a gentle breeze against the cheek is about 5 miles per hour.

Impairment of cold awareness, which originates from stimuli at the end bulbs of Krause in the skin, along with age-attenuated metabolic adaptation to cold, can interfere with signals that trigger an individual to assume cover.

There is a "sixth sense" built into the aging wilderness adventurer derived from years of experience and exposure, study, and review of wilderness activities. This is *wisdom!* As a result of assimilating and processing these data, elders frequently acquire a reputation

for survival. One who develops this aura is affectionately known as a "salty dog."

Neuropsychiatric Disorders

Situational stresses are often superimposed on environmental stresses during wilderness ventures. Difficulties with group interaction, changes in rational thought in individuals with organic brain disease, or behavioral upheaval from bipolar states can jeopardize the health and safety not only of the individual but also of an entire group.

Problems associated with drug abuse or alcoholism are a danger to the individual and are potentially devastating to the group. Subtle alcoholism may become full-blown withdrawal psychosis during a hypoxic event or during extreme physical exertion. Drug use in elders may not be "recreational," but withdrawal from ethical drugs may be quite severe. Leaders of wilderness ventures must recognize the danger of disruptive psychiatric problems and attempt to prevent them by careful screening before the venture.

As people age, a variety of cognitive disorders become apparent, including progressive dementia, confusional states, and cognitive disorders resulting from psychiatric syndromes. Symptoms may be precipitated in vulnerable individuals by physical or environmental stresses of the wilderness. The two usual sources of information concerning the status of patients are patients' families and the patients themselves. It is rare for a family member to approach the physician with concerns about the cognitive function of a relative; thus an interview and brief mental status testing should be included in the medical evaluation.

A cognitive examination should provide the examiner with insight into prior cognitive skills and personality traits to serve as a baseline. Included should be the nature of the subject's memory at that time, the interval since onset of symptoms, the nature of onset (slow or sudden), and current state of cognitive function.

Frontotemporal dementia, such as Pick's disease, may manifest itself early with a change in personality with inappropriate and often volatile behavior. Alzheimer's disease is frequently manifested by apathy and decline in ability to learn new information.

Physician assessment of cognitive function and neuropsychiatric disorders may identify potential disaster during wilderness undertakings.

Diabetes Mellitus and Other Metabolic Disorders

Type II ("adult-onset") diabetes mellitus, whether requiring insulin or controlled by oral hypoglycemic medication, is not necessarily a contraindication to wilderness activities; however, other problems related to diabetes may increase risk of medical emergencies. Cardiovascular disorders, coronary artery disease, cerebrovascular disorders, peripheral and autonomic neuropathy, nephropathy, poor wound healing and/or infection, and vulnerability to frostbite and cold injury all may be associated with this

metabolic disorder.

Insulin-dependent (type I) diabetes is a very different situation because of the additional problems with caloric intake and energy expenditure. Hypoglycemic episodes may lead to accidents from mental confusion. The vestibular apparatus in elders is particularly sensitive to such episodes. The "buddy system" should be deployed to assist the insulin-dependent diabetic in the wilderness.

1806

Pharmacology, Pharmacokinetics, and Polypharmacy

Older people are the major consumers of all categories of medications. Health status and pharmacokinetics of elders alter drug choices, dosages, prospects for adverse reactions, and even therapeutic goals. Physician assessment of elders before wilderness activities should include careful review of all medications.

Age-related physiologic changes may influence pharmacokinetics: reduced gastric acid production and altered gastric emptying, affecting absorption; reduced splanchnic blood flow, affecting first pass (or presystemic) clearance; reduced body water, serum albumin, body fat, and body mass, affecting protein binding; changes in hepatic size and blood flow, affecting hepatic clearance; and reduced glomerular filtration rate and renal tubular function, affecting renal clearance.

As a result, physicians recognize that it is almost always prudent to begin with a lower starting dose and lower maintenance dose of certain prescribed medications in elderly patients.

Renal clearance of some drugs is reduced as a result of aging. The clinical significance of altered renal clearance resulting in elevated blood levels is, of course, related to the drug. Drugs with a very narrow therapeutic ratio should be carefully monitored. These include antibiotics such as gentamicin, streptomycin, and kanamycin; β -blockers such as atenolol and sotalol; cardiac glycosides such as digoxin; and psychotropic drugs such as lithium.

Hepatic clearance of drugs is of even more concern in the elderly because of a silent reduction in clearance capacity of up to 50% or more in this age group. Causes of reduced hepatic clearance include reduction of absolute liver size, decrease in hepatic blood flow, and perhaps altered enzyme activities. Benzodiazepines, nitrazepam, chlordiazepoxide, midazolam, and colabazepam, eliminated primarily by oxidation, should be reduced in dosage. Oxazepam, eliminated by glucuronidation, also should be given in reduced dosage.

Comorbidity, the presence of multiple pathologic problems, makes drug choice particularly important because of the prospects of worsening a coexisting disease when a prescription is given for another disease condition. For example, thiazide diuretics

may worsen control of diabetes; calcium channel blockers may result in ankle edema; β -blockers may increase symptoms of peripheral vascular disease; dopamine blockers given as antiemetics may exacerbate parkinsonism; and NSAIDs may render hypertension, heart disease, or renal failure more difficult to control.

Counseling, packaging labels, diaries, and supervision are important instruments for proper control of toxic and side effects of medications in elders.

Excessive use of medicines is often seen.^[26] "Polypharmacy" represents a less-than-desirable state of duplication of medications, failure to recognize potential drug interactions, and inadequate attention to pharmacokinetics and pharmacologic principles.^[25] Alcohol abuse frequently compounds the problem of polypharmacy. It is a great help to have each participant carry all presently consumed medications to his or her physician for review before the wilderness venture.

PHYSICAL ACTIVITY AND ELDERS

The common denominator among wilderness ventures is physical activity. For elders, the demands of certain physical activities may be excessive. The physical workload of a wilderness venture depends on its nature and the characteristics of its component parts. For example, is it a walking venture or a climb? What is the nature of the terrain? What is the altitude? What is the environmental temperature? It is prudent for elders to examine plans for a prospective wilderness venture and to select activities consistent with their personal capacity and tolerance.

Wilderness activities can be classified according to their physical, technical, and environmental characteristics. The skill, judgment, and capacity of all participants, elders included, can then be matched with the characteristics of the venture to determine if individual capacity is adequate for the demands.

One classification of wilderness ventures ranges from extreme physical demands to minimal demand and includes:

1. Extreme performance ventures, such as Himalayan trekking or climbing major peaks
2. High-performance ventures, such as remote hunting activity, particularly at high altitude or under stresses of heat, dust, or cold. Jungle trekking is also an environmentally and physically stressful venture.
3. Recreational activities. Trail walking is generally considered recreational but because of endurance and risks may present physiologic hazards. Alpine hiking, National Park trail walking and forest-based orienteering may fit this classification.
4. Therapeutic activities. These may be recommended for persons with illness or disability. For more than a century, physical activity has been recommended for certain individuals with cardiovascular disease and other physical limitations to improve functional capacity.

Although this classification is very general, it can be helpful to match the physical and intellectual demands of specific wilderness ventures with individuals of varied skill, judgment, and physical capacity.

Successful participation by elders in wilderness activities depends on the capacity of the individual to tolerate the physical workload. After examining the nature of the wilderness venture and the characteristics of its environment, each participant should match his or her personal capacity with the characteristics of the venture being considered. Review of the functional capacity and experience of an individual may be used for personal classification. One classification considers:

Group A: Demonstrated high-performance individuals—athletes in training, mountaineers continually active and in training, workers in heavy physical tasks, etc.

Group B: Healthy, vigorous individuals—athletes, active hunting guides, etc.

Group C: Healthy, "deconditioned" individuals—young to middle aged, healthy, business and professional people who are moderately active.

Group D: Those with risk factors—individuals at risk because of age or because of lifestyle, smoking, excessive alcohol, or because of factors not under their control. Most elders are in Group D.

Group E: Those who are manifestly ill—subjects at any age with chronic illness or physical limitations, such as heart disease, diabetes, or neuromuscular or orthopedic problems.

Although this classification is general, it serves as a starting place for more precise recommendations for a specific adventure. The populations presenting to the physician may fit the distribution curve as shown in [Box 76-1](#) .

Metabolic Classifications

The workload of the venture and the functional capacity of the individual can be defined with precision by using a metabolic classification. The energy requirement of activities as derived from oxygen consumption studies may be used to match the demands of an activity with the functional capacity of an individual. Energy cost may be defined by oxygen consumption ($\dot{V}O_2$), or calories, or METs. These units are simply different ways of expressing the same data based on oxygen consumption. The term "MET" is useful because it represents the energy cost of an easily definable physical activity, sitting. One MET, the energy cost of sitting quietly, is defined by convention as 3.5 ml/ O_2 /kg body weight/min. Multiples of the MET may be used to define the energy cost of various activities or tasks. An activity requiring twice the metabolic cost of sitting is a 2 MET activity; a 3 MET activity represents 3 times the energy cost of sitting, or 10.5 ml/ O_2 /kg/min.

Walking 3 miles per hour on a level surface is a 3 MET activity. Each 2.5% grade increase increases the energy cost one additional MET when walking 3 miles per hour. Hence, walking up a 2.5% grade at 3 miles per hour is a 4 MET activity. Most activities

of daily living (ADLs) are less than 3 METs. Tables of the energy cost of various activities have been established. Components of tasks and activities in the wilderness can be defined in METs.

This unit may also be used to define the functional capacity of the individual. Using the same system of measuring O_2 consumption of an individual on a treadmill or cycle ergometer, the maximal physical work capacity (PWC_{max}) may be determined in METs. The average 40-year-old man in the United States has a PWC_{max} of 10 METs, or 35 ml/ O_2 /kg/min. Hence, this

1808

provides a useful scale from 1 MET (the energy cost of sitting) to 10 METs (the PWC_{max} of the average 40-year-old male).

Box 76-1. WILDERNESS VENTURES

CLASSIFICATION OF WILDERNESS VENTURES

1. Extreme-performance ventures: may exceed 12 METs
2. High-performance ventures: up to 10 to 12 METs
3. Recreational activities: up to 8 to 10 METs
4. Therapeutic activities: highly individualized

Ventures are classified according to physical and intellectual difficulty.

Energy cost studies using $\dot{V}O_2$ or MET values help indicate metabolic difficulty.

CLASSIFICATION OF PARTICIPANTS IN WILDERNESS VENTURES

Group A = demonstrated high-performance individuals

Group B = healthy, vigorous individuals

Group C = healthy "deconditioned" individuals

Group D = those with risk factors

Group E = those who are manifestly ill

Group C = healthy "deconditioned" individuals

Group D = those with risk factors

Group E = those who are manifestly ill

The functional capacity, also measured in METs of participants in ventures, provides a useful basis for matching participants with appropriate activities and helps determine the extent of a preventive medical examination.

DISTRIBUTION CURVE FOR WILDERNESS ADVENTURERS

This normal curve may be roughly applied to a classification scheme for grouping wilderness venturers according to their functional characteristics.

As individuals age, they lose about 1 MET of PWC_{max} per decade after 40 years of age, so the average capacity of a 70-year-old man is approximately 7 METs.

Tolerance to physical activity among females has been increasing for two decades and is now accepted as being about 1 to 2 METs less than that of a male of the same age. Physically active and conditioned females, however, are now of approximately the same capacity as males.

Matching Individuals with Activities

An individual who plans to participate in a wilderness venture has often already been through a form of natural selection. For example, one who aspires to participate in an expedition to Mount Everest will in all likelihood have already participated in a similar activity and will have proven his or her capacity to function at an extreme level of performance. This subject would likely be in group A or B. An individual who may not

have been involved recently in high level activities or who has become "deconditioned" is in group C. There may still be the desire to participate, perhaps as a reaffirmation of youth or vigor in some form of exciting or hazardous activity.

Box 76-2. BODY SIGNALS

Participants in wilderness activities should learn to read the physiologic "body signals" that help an individual recognize impending medical problems from environmental stresses.

PRIMARY

Cardiovascular

Heart rate: used to estimate physiologic effect of physical workload

Pounding in head: possibly related to physiologic or pathologic systolic hypertension

Chest pain: physiologic or pathologic

Fluttering in chest: arrhythmia

Respiratory

Mouth breathing: >60% of maximal physical work capacity

Breathing too hard to talk: >85% of maximal physical work capacity

Cough: dry air; early high-altitude pulmonary edema

Cheyne-Stokes respiration: altitude

Cyanosis of nailbeds, nose, or ear lobes: consider hypoxia

SECONDARY

Musculoskeletal

Tremulousness: quadriceps weakness and cramps, consider volume depletion and hyponatremia

Shivering: cooling, body temperature >35.5° C (96° F)

Musculoskeletal

Tremulousness: quadriceps weakness and cramps, consider volume depletion and hyponatremia

Shivering: cooling, body temperature $>35.5^{\circ}\text{C}$ (96°F)

Stopped shivering with confusion: possibly further dangerous cooling, body temperature probably $<33.9^{\circ}\text{C}$ (93°F)

Sweating: air temp/humidity or heavy physical work above 7 METs

Gastrointestinal

Abdominal distention (with flatus): altitude

Dry mouth: dehydration

Loss of appetite: altitude and/or dehydration

Genitourinary

Urinary frequency: altitude ("hochdiurese" of Alpine mountaineers)

Sensory

Tubular vision: altitude/hypoxia

Loss of color discrimination: hypoxia

Loss of night vision discrimination: hypoxia

Visual central white spot: hypoxia

Sense of touch: wind against cheek >5 mph

Taste: diminished with dehydration and hypoxia

>Smell: diminished with dehydration and hypoxia

Neurologic

Headache: altitude, cerebral edema

Lack of analytic decisiveness: altitude and hypoxia

Confusion and irrational behavior: altitude, hypoxia, and possible cerebrovascular abnormalities

Particular attention should be directed toward any individual at risk of illness or injury (group D) even though manifest evidence of disease may not have been displayed. For example, cardiovascular risk factors such as smoking, fat-laden diet, and high blood

pressure may warrant a precise medical examination to determine a level of functional capacity considered safe for the individual, even if a symptomatic disease is already present.

Group E includes persons with definite manifestations of illness. Outdoor activities have been used as a form of physical therapy for persons with various illnesses, including cardiovascular diseases. Persons in this category should be individualized as far as assessment is concerned and require a high degree of medical evaluation and supervision.

Elders are encouraged to "read" their personal physiologic responses to activity using "body signals" such as mouth breathing, which occurs at about 60% of maximal capacity, and sweating, which occurs under standard conditions at around 7 METs, depending on the environment. Some "body signals" are listed in [Box 76-2](#).

1809

Physical Conditioning to Prepare Elders for Wilderness Ventures

After an elder considering a wilderness venture determines his or her personal classification, it may be prudent to obtain a medical examination. A physical conditioning program may be recommended to increase individual reserve capacity. As a rule of thumb, an individual considering an 8-hour activity can tolerate an energy cost of approximately one fourth to one third of his or her maximal physical work capacity (PWC_{max}). If the demands for a venture exceed prospective tolerance, PWC_{max} can be enhanced about 15% by a 3- to 6-month graduated conditioning program.

A conditioning program should include flexion and extension exercises during the warm-up, an active aerobic cardiovascular conditioning component, and a cool-down component. The aerobic component should last at least 20 minutes at a level about 50% of individual PWC_{max} . Some persons can learn to count the pulse corresponding to this level of activity. This provides a useful monitoring technique. Mouth breathing is a useful body signal for marking the intensity of activity. Consequently, if the subject keeps the intensity below that requiring mouth breathing, the aerobic activity should be in a range below 60% of the individual maximal capacity. This level of conditioning is helpful and reasonably safe for seniors, although not at a level of intensity sufficient for conditioning competitive athletes.

The American College of Sports Medicine has developed a position paper on exercise and physical activity for older adults that should be reviewed by the serious student of the subject.^[4] This includes endurance training to help maintain and improve cardiovascular function, and strength training to help offset loss of muscle mass. Additional benefits from regular exercise include improved bone health, reduction of risk from osteoporosis, improved postural stability, and increased flexibility and range of

motion. Psychologic benefits and alleviation of depressive symptoms may also occur.

MEDICAL EXAMINATION

By the time an individual qualifies for the designation "elder," that person has usually made some arrangements for medical care, examination, and advice. However, as an elder considers a venture into the wilderness, there is often confusion, or at least insecurity, over the prospect of developing some form of medical problem. A medical examination may be necessary.

Components of the Medical Examination

A survey of wilderness leaders served as the basis for developing specific components for medical examination for prospective participants in wilderness activities.^{[8] [9]}

There are five categories of characteristics included in the health examination:

1. *Personal characteristics*, which provide a profile of the subject regarding age; gender; education; occupation; status as volunteer or recruit; history of a recent or remote similar venture; use of tobacco, alcohol, drugs, or steroids; history of psychological or interpersonal problems especially during wilderness ventures; and history of athletics.
2. *Historical features*, such as illness, with particular emphasis on cardiovascular, pulmonary, musculoskeletal, and neurologic problems; problems associated with a previous venture; history of a successful similar venture; intolerance to altitude, heat, or cold; psychologic problems; accidents; and pertinent family history.
3. *Medical examination* to include examination of heart rate, blood pressure, precise cardiac examination (including auscultation), examination of peripheral pulses and carotid arteries, auscultation of the chest, abdominal palpitation with rectal examination, musculoskeletal system with range of motion of joints and back, and height and weight.
4. *Physiologic examination*, which is only rarely required, depends largely on the nature of the venture and may range from simple simulation of the planned activity to functional aerobic testing for $\dot{V}O_2$ max using a treadmill, cycle, or step ergometry. Functional testing with electrocardiographic monitoring is frequently used for diagnostic testing and for predicting cardiovascular response to exercise. Testing by running for speed or endurance and evaluation of dynamic strength and agility are rarely used but are interesting during skill assessment. Testing for hypoxic ventilatory response (HVR) may be primarily of research interest but nonetheless should be considered if precision is needed for elders going to high altitude.
5. *Psychologic interviews* are largely dependent on the skill and technique of the examiner but should attempt to uncover a history of previous difficulties with group

interaction and team activities, or problems with physical and environmental stress or remote adventures.

In the survey of wilderness leaders, the best single predictor of a successful venture was found to be a history of a similar successful venture and the psychologic profile of the individual. The most important part of the medical examination before a wilderness venture was determined to be an in-depth interview by an examiner experienced not only in medical care but also in the nature of the venture. After the interview, appropriate medical, laboratory, radiographic, and physiologic studies may be performed.

1810

TABLE 76-1 -- Components of Medical Examination for Various Classifications of Participants According to the Nature of the Venture

CLASSIFICATION OF CHARACTERISTICS OF PARTICIPANT	CLASSIFICATION OF WILDERNESS VENTURE			
	EXTREME PERFORMANCE	HIGH PERFORMANCE	RECREATIONAL	THERAPEUTIC
A. Demonstrated high performance	2,3,(5)	2,3,(5)	2	*
B. Healthy, vigorous	2,3,4,(5)	2,3,(5)	(2)	(2)
C. Healthy "deconditioned"	1,2,3,(4),(5)	2,3,(4),(5)	2,(4)	2,(3),(4)
D. Risk factors	1,2,3,(4),(5)	1,2,(3),(4),(5)	2,(3),(4),(5)	2,(3),(4),(5)
E. Illness	*	*	1,2,(3),(4),(5)	1,2,(3),(4),(5)

Category of component features of medical examination (see text): 1, personal characteristics; 2, medical historical features; 3, medical features; 4, physiologic studies; 5, psychologic features. All categories of component features should be considered in the examination of prospective participants, but features enclosed in parentheses are of prime importance.

*Individualized assessment indicated.

Figure 76-2 A pair of Gray Eagles. (Courtesy John Duckworth, MD.)

To assist in determining the content of a medical examination, [Table 76-1](#) matches the individual with the venture and identifies the components of the medical examination that may be needed. Elders are included in their appropriate classification, according to performance characteristics derived from the five categories. Most commonly, they fit in categories D or E.

COUNSELING AND TEACHING ELDERS BEFORE WILDERNESS VENTURES: THE GRAY EAGLES

The drive, determination, and spirit of the individual who loves the wilderness are powerful. Aging seems only to sharpen this desire and to deepen its significance. One focused observation of aging individuals in the wilderness was that of the "Gray Eagles," the brainchild of retired Memphis pathologist Dr. John Duckworth and retired Kraft Food executive Mr. John Johnson.¹⁷ Formalized in 1987, the Gray Eagles began taking 10-day cross-country wilderness hiking trips into the mountains of the western United States ([Figure 76-2](#)). Their experiences have been invaluable in providing a unique opportunity to learn about groups of elders in the wilderness. Experience emphasizes the need for: (1) preselection based on experience, interviews, and medical history; (2) a stringent 6-month conditioning program with good boots, well "broken in" with 100 miles of use; (3) walking with a

1811

backpack, unless contraindicated, weighing one third of total body weight; (4) orientation meetings that include features of safety, review of risk, and recognition of clinical problems, such as the symptoms of hypothermia, hyperthermia, hypoxia, and fatigue; (5) the "three season" principle for packing clothes because of the prospects of weather change; and (6) orientation sessions with officials in the area to determine safety precautions unique to the region and to let the officials know of the presence of the Gray Eagles.

Using a detailed approach to preparation, the Gray Eagles have had very few medical problems. Of interest, however, is the observation that one successful year involving participation by an elderly person does not guarantee that the next year will be uneventful. With increasing age causing reduction of reserve, tolerance may change dramatically, and vascular symptoms may go from tolerable to intolerable with environmental stress.

The most potentially serious problems confronted by the Gray Eagles have been behavioral problems from organic brain syndrome not previously recognized, but precipitated by the environmental and physical stress of the venture.

EPILOGUE

Time is a peculiar dimension. It is difficult to define other than by changes that take place during its passage. Changes in anatomy, physiology, and function take place with time.

Seasons change from the promise of spring, to the full glory of summer, to a time of reflection in fall just before winter, the season of death.

Similarly, there is a time of day at dusk and sunset for reflection on the satisfaction of time well spent. The optimist sees sunset as sunrise in reverse.

Remember, the elderly still climb mountains: it's just that their definition of mountains has changed.^[10]

Chapter 77 - Medical Liability and Wilderness Medicine*

Carolyn S. Langer

The following is an excerpt from the standard "fine print" found on the back of cruise passengers' tickets:

CARRIER NOT LIABLE FOR
PASSENGER'S MEDICAL CARE

(a) Medical Services on Vessel. The Carrier does not undertake that a physician or medical personnel will be aboard the Vessel. If the Vessel does carry a physician or medical personnel, then they are independent contractors and work directly for the Passengers.

(b) Consent of Treatment. If, in the opinion of the Carrier, a Passenger in need of medical or surgical services is unable to request it, the Passenger hereby expressly consents to such treatment, if any, and to pay the cost thereof charged by the Vessel's physician or other physician or medical personnel designated by the Carrier who in doing so is acting on behalf of the Passenger.

(c) Treatment at Passenger's Risk. All medicines and all medical or surgical services furnished by the Vessel's physician, if any, or any other physician or medical personnel (all of whom are engaged by the Passenger as independent contractors) or ship's officers, employees or agents of the Carrier, shall be and are accepted by and at the Passenger's sole risk and expense, and the Carrier shall not be responsible for the quality, nature or consequence thereof.

(d) Passenger's Obligation to Report Medical Conditions. Before this Ticket is issued, the Passenger must report to the Carrier or its general agent, all pre-existing illness, disabilities or pregnancy and all other conditions for which the Passenger

may require medical attention during the course of the Cruise. If any such condition arises after the Ticket is issued, the Passenger must report all such conditions to the Carrier, Purser or Vessel's Master or physician, if any, before boarding, or if the Passenger has boarded the Vessel, then before the Vessel leaves port. The Carrier, Vessel and the Vessel's physician, if any, shall have no liability in connection with any such condition.

(e) Lack of Obligation to Examine Passenger. Neither the Carrier, nor the Vessel's physician, if any, has any obligation to examine any Passenger for any purpose prior to boarding or sailing.

(f) Refusal of Passage. The Carrier reserves the right to refuse passage to a Passenger who has failed to give proper notice of any disability, illness, pregnancy or other condition requiring special care, attention or treatment or who in the Carrier's sole opinion is physically or mentally unfit for the Cruise. In such event, the Passenger is not entitled to any refund of fare.

In recent years, personal wealth, general interest, increased leisure time, and sophisticated marketing have led to expanded participation by the general public (with an aging population) in expeditions and cruises to remote environments, including wilderness areas. Such travel poses a higher risk of injury and illness (than does travel in urban areas) and often involves exposure to extreme weather conditions, limited access to medical personnel and supplies, and extended patient management due to scarce medical evacuation capabilities. What are the medical-legal ramifications for tour operators and trip physicians? Historically the probability of a lawsuit was low because participants were younger, more physically fit, and more experienced adventurers who tended to be greater risk takers with an awareness of and a willingness to assume these risks. However, the increased involvement of a less prepared and marginally aware general population in these wilderness pursuits has undoubtedly generated a concomitant increase in exposure to liability. To minimize this liability, tour operators and trip physicians must implement sound risk management strategies for medical clearance, education, and provision of medical services to trip participants.

TORT LAW AND THE DOCTRINE OF NEGLIGENCE

Case Study: Snakebite and Medical Malpractice

On August 11, a victim sustained a rattlesnake bite on the index and middle fingers of his left hand. Suction cups and a tourniquet were immediately applied, and the victim was transported to the hospital within 15 minutes. Another 15 minutes passed before Dr. A arrived. Dr. A proceeded to treat the patient by injecting antivenin into the base of the fingers bitten by the snake and into the left deltoid, despite an instruction sheet accompanying the antivenin that cautioned, "Do not inject serum into a finger or toe." Dr. A packed the patient's hand in ice and admitted him to the hospital. Two days later the patient was sent home with instructions to keep the hand in ice.

Eight days later the victim's two fingers, hand, and arm were edematous, discolored, and odorous from gangrene. Dr. B assumed care of the patient, applying a heating pad and injecting antibiotics. Nevertheless, on

* From Levinson J, editor, Ger E, medical editor: *Safe passage questioned: medical care and safety for the polar tourist*, Centreville, Md, 1998, Cornell Maritime Press.

1813

September 9, the two fingers required amputation. Is Dr. A liable for medical malpractice?

In tort law, members of society owe a duty to others to act reasonably and in a way that will not hurt another person or his or her property. In the context of wilderness medicine, redress for a private civil wrong is typically sought under the negligence doctrine. To bring a cause of action under a negligence theory, the plaintiff (the party filing the claim) must establish the following four elements:

1. Duty: The defendant has a duty to use due care as a reasonably prudent person would under similar circumstances. For example, a plaintiff could argue that a trip physician owes the participants a duty to demonstrate the "knowledge, skill, and care customarily exercised by a reasonable and prudent physician under similar circumstances, given the prevailing state of medical knowledge and available resources." ^[3] To meet this duty, physicians must typically adhere to the standard of care prevailing within the medical community.
2. Breach of duty: Defendants breach their duty when they fail to conform to the duty of care or to act in accordance with norms or standards of practice. This breach

may occur either through commission or omission of certain acts. For example, a physician may breach the duty of care by failing to diagnose or treat a condition (omission) or by improperly treating a patient (commission).

3. Causation: The plaintiff must further prove that the defendant's conduct was the direct, foreseeable, and proximate cause of the resulting injury. In other words, absent the defendant's conduct, the harm would not have occurred. Establishing causation is often the most problematic step for plaintiffs. For example, an injured traveler might allege that a trip leader or medical practitioner breached the duty of care by delaying medical evacuation, but the defendant could argue that the injury had already occurred and that any delay in evacuation neither caused nor aggravated the injury.
4. Damages: Finally the plaintiff must demonstrate damages, that is, harm to the individual's person, property, or interests for which the redress is customarily a monetary award. Awards may encompass special damages (e.g., out-of-pocket losses, medical expenses, lost earnings), general damages (pain and suffering), and punitive damages. Punitive damages are rare in the medical context because the plaintiff must prove that the defendant's conduct exceeded simple negligence and was grossly negligent, reckless, or malicious. Nonetheless, physicians should be aware that their insurance policies generally do not provide malpractice coverage for punitive damages.

Medical malpractice is a specific form of negligence occurring during the execution of a physician's professional or fiduciary duties. Medical malpractice can be defined as medical care that falls below the standard of care expected of a reasonably prudent physician under similar circumstances, resulting in foreseeable harm to the patient. In all negligence suits the plaintiff bears the burden of proof in establishing the requisite four elements under a "more probable than not" standard. In other words, the plaintiff must establish that there was a greater than 50% probability that the defendant's breach of duty caused the harm.

In the snakebite case presented earlier the first element is clearly demonstrated. Dr. A's actions established a physician-patient relationship and an acceptance of the duty to render care. Establishing the second and third elements is more problematic. The court held that Dr. A did not breach his duty. The court elaborated, "There are wide variations in accepted methods of treatment of rattlesnake bites. The method of treatment chosen and used by the defendant was an acceptable method of treatment." (This point is debatable, but in general there are frequently "medical experts" who will take a contrary position.) In other words, even though physicians must act with the level of skill and learning possessed by minimally qualified members of the profession, they are judged by reference to the beliefs of the school that they follow, provided that it is a recognized school of practice in the medical community.

The court further held that the plaintiff failed to establish causation. Expert testimony showed that "rattlesnake bites in extremities always present some chance of tissue destruction" and that the most probable cause of tissue death in the two distal phalanges was the rattlesnake venom. Thus Dr. A was found not liable.

Each state has its own body of statutory, regulatory, and case law (in addition to federal

law). Thus, although this chapter presents general legal and risk management principles, physicians should always familiarize themselves with the laws and precedents in their own states before implementing policies and procedures related to wilderness or travel medicine.

LIABILITY CONCERNS IN WILDERNESS MEDICINE

The remainder of this chapter examines how the legal doctrines apply in the unique circumstances of wilderness medicine. Not surprisingly, increased participation of the general population in adventure travel has led to higher—and in many cases unrealistic—expectations on the part of the public. Some unseasoned travelers to remote destinations anticipate the same level of medical resources (including personnel, equipment, medications, and evacuation capabilities) to which they

1814

have access in their own large, urban tertiary care medical centers. It is therefore vital for tour operators and trip physicians to understand the duty and standard of care to which they must adhere and to educate trip participants regarding the risks of travel.

DUTY TO WARN AND EDUCATE TRIP PARTICIPANTS

Case Study: Duty to Warn

A middle-aged male traveler booked a tour to Bolivia through a travel agent. In the trip brochure the tour operator represented itself as an experienced and reputable company and stated that it researched all locations to which it arranged tours and "would care for participants from 'portal to portal.'"^[6] In addition, the travel agent asked both the tour operator and local health agencies about health requirements and necessary precautions. During the trip, the traveler developed high altitude cerebral edema after flying from Chile (at sea level) to La Paz, Bolivia (elevation 3960 m [13,000 feet]), in less than 1 hour. He subsequently sued the travel agent and tour organizer for failure to warn him of the health risks associated with his travel.

In general there is no duty to warn of dangers that are as obvious to the participant as to the organizer. Obvious dangers might include possible seasickness or airsickness, substandard sanitation, and poor environmental conditions. Moreover, travel agents and tour operators have no duty to investigate potential vacation sites (not even those where conditions and terrain are dangerous) or lower standards of medical care in foreign countries. However, they do have a duty to warn travelers of known unreasonable risks or dangers, such as political turmoil and criminal attacks, that are foreseeable or likely to occur. Typically, to incur this duty to warn, the travel agent or tour operator must have actual or constructive notice of the hazardous condition arising from their knowledge of special circumstances (e.g., prior occurrences). In addition, travel agents and tour operators may contractually expand their duty to warn through representations made in brochures or other advertisements. In the case mentioned earlier, for example, the court recognized that tour organizers are not insurers of the safety of tourists with whom they contract and need not warn of obvious hazards. Nonetheless, in this case the travel organizer contractually expanded its obligation through its representations and brochures and created a reasonable expectation on the part of the tourist that it would research the risks of high altitude travel and warn him of accompanying dangers.

Even in the absence of liability, trip organizers and medical practitioners have incentive to prevent travel-associated injury or illness because they suffer financially and ethically when a tourist experiences physical or financial loss, fellow travelers are inconvenienced, or the reputation of the company or medical practice is potentially damaged. Sound risk management principles dictate that travel companies provide as much useful information as feasible to prevent adverse consequences. Companies lacking the wherewithal to research health hazards may benefit from the assistance of a medical adviser. Depending on the nature of the trip, some or all of the following

information may be useful to participants:

1. Environmental conditions (e.g., climate, altitude, terrain)
2. Activity level (type, intensity, duration, and frequency of activity or exertion required)
3. Specific health hazards (e.g., tropical diseases, marine envenomation, frostbite, heat injuries)
4. General health information (e.g., safety of local food and water, local medical resources)
5. Known risks (e.g., political unrest, high crime areas)
6. Recommended immunizations

MEDICAL CLEARANCE OF TRIP PARTICIPANTS

Tour operators have no duty to medically screen trip participants. Travelers have a responsibility to exercise due caution for their own safety. Nonetheless, do tour operators have the right or an incentive to screen participants? Medical clearance of travelers may serve several beneficial purposes. It can function to educate participants about potential health hazards, thereby reducing their risk of harm. Medical screening affords the participant's private physician the opportunity to better manage the patient's care. It also may enable a tour operator to arrange accommodations in advance for participants with special needs. Moreover, medical clearance may reduce the tour operator's liability, costs, and inconvenience.

On the other hand, medical screening has certain disadvantages. Some authorities consider medical screening useless because a high-risk patient with a strong desire to go on a trip may ignore the inherent dangers and conceal any significant medical history (or shop around for a physician willing to grant the medical clearance). In addition, since the enactment of the Americans with Disabilities Act (ADA) of 1990, many tour operators fear discrimination suits for medically screening out disabled persons. However, with a proper understanding of the legal issues underlying medical clearance and the ADA, tour operators and physicians can safeguard the interests of all parties involved.

The Americans with Disabilities Act

Title III of the ADA prohibits all places of public accommodation and services operated by private entities

1815

from discriminating against the disabled. Furthermore, a public accommodation may not apply eligibility criteria that screen out an individual or any class of individuals with disabilities "unless such criteria can be shown to be necessary for the provision of the goods, services, facilities, advantages, or accommodations."^[8] For example, "a cruise line could not apply eligibility criteria to potential passengers in a manner that would screen out individuals with disabilities unless the criteria are 'necessary.'"^[9]

A public accommodation is not required to permit an individual to participate in services when the individual poses a direct threat to the health or safety of others. This determination that the participant poses a significant risk must be an individualized

assessment using reasonable judgment based on current medical knowledge or the best available objective evidence. Although the "direct threat exception" to the ADA permits exclusion of participants only when they are a threat to others, the "safety exception" may justify excluding individuals when they pose a threat to themselves. The "safety exception" holds that a public accommodation may impose legitimate safety requirements that are necessary for safe operations. As an example, the regulations cite as a valid screening criterion the requirement for all participants in a recreational rafting expedition to meet a necessary level of swimming proficiency.

For screening criteria to be valid, however, they must be uniformly applied to all prospective participants, not merely to those with disabilities. Moreover, they must be based on actual risks, not on mere speculation, stereotypes, or generalizations about a person or class of persons with a particular disability. A tour organizer could not, for example, categorically exclude all persons with a history of angina from a high altitude trip but rather must afford individuals with documented, well-controlled angina an opportunity to establish their fitness and eligibility for the trip.

Even when screening criteria are valid and the prospective participant cannot meet those requirements, a public accommodation must make reasonable modifications in policies and practices or must accommodate the disabled individual unless such modifications would fundamentally alter the nature of the goods, services, or facilities offered. For example, a cruise line could be required (as a reasonable modification) to provide an individual who relies on a wheelchair for mobility with a stateroom on the same level as the restaurant. However, a mountain trek would not be required to transform to a bus tour to accommodate this same individual.

Medical Screening

To minimize the potential for discrimination claims, tour operators should provide physicians granting medical clearance as much information as possible regarding the physical demands of the trip. Tour organizers must provide detailed information concerning environmental conditions, specific health hazards, health and living conditions in the destination site, and availability of local medical resources. Companies should be as specific as possible in describing environmental conditions (e.g., altitude in feet, temperature in degrees). Trip organizers also must delineate the type, intensity, duration, and frequency of activity (e.g., bus tour, mild walking [1.6 to 3 km or 1 to 2 miles per day], vigorous hiking [specify distance and terrain], backpacking [specify weight of gear], trekking to remote areas [e.g., 24 hours from definitive medical care], climbing, swimming, canoeing, etc.).

The health care professional in turn must tailor the medical history and examination to the physical demands of the trip. The physician should become familiar with the patient's medical history, including any medications that could interact with the environment to which the patient is traveling. If applicable, the medical practitioner should advise the patient to bring extra medications or medical equipment (a spare pair of eyeglasses, extra hearing aid batteries, an anaphylaxis kit, etc.) in case complications or exacerbations occur. The physician also should inform the patient of applicable first aid procedures. The physician may need to inform the trip organizer of special needs or

accommodations as well.

Because patients and their physicians may be hesitant to disclose confidential medical information to a travel company, medical clearance forms should emphasize functional abilities and limitations rather than diagnoses. If medical clearance forms request sufficiently detailed information about the prospective participant's medical fitness to meet the physical demands of the trip, travel companies frequently do not need to know about specific medical diagnoses. Companies that do request confidential medical information should disclose this information only to employees who have a need to know and should ensure that the company medical adviser or trip physician safeguards this information in a locked file. The company also may want to encourage high-risk patients to share medical information with trip leaders or bring along key medical records. Even though a company-employed medical adviser or private family physician makes determinations about medical fitness and medical clearance, the travel company bears the legal responsibility for excluding disabled participants or for failing to accommodate their needs.

PROFESSIONAL LIABILITY, MEDICAL MALPRACTICE, AND GOOD SAMARITAN LAWS

In addition to those complaints arising from a lack of proper health warnings, injured trip participants commonly base claims on the company's failure to provide adequate medical services and facilities and the

1816

negligent delivery of medical care. Historically, tour operators and cruise ships have had no obligation to ensure the health or safety of participants or to provide health care—particularly physicians' services—on trips. Trip organizers should nonetheless ascertain the appropriate standard of care for their particular circumstances by determining the medical resources that other companies have provided on similar expeditions to similar destinations. Companies generally have the duty to staff trips to remote locations with personnel who have "significant training to provide adequate first aid and medical care until evacuation can be arranged."⁴ Typically these staff members are emergency medical technicians (EMTs) or laypersons with basic first aid training. Organizers of trips to locales with readily available medical care may have a lesser obligation to furnish staff trained in first aid. In the event of an adverse medical outcome, travel company employees are judged by a "reasonably prudent person" standard; that is, they have the duty to use reasonable care to furnish such aid and assistance as an ordinarily prudent person or trip leader would under similar circumstances.

Several professional medical organizations, such as the American College of Emergency Physicians and the Wilderness Medical Society, are currently seeking to define and establish standards of care for the provision of medical services on cruise ships and expeditions. In the meantime, many companies voluntarily staff physicians on their trips (and publicize that they have done so) for the comfort and convenience of the participants or to provide a competitive marketing advantage. Travel companies that advertise the presence of trip physicians and medical facilities in brochures, contracts, and other correspondence to participants or prospective participants contractually expand their obligation by creating an implied or express contract for the availability of certain medical services. At a minimum, it is expected that trip physicians will have the resources and capability to evaluate and manage emergencies and, when necessary, will arrange for more definitive care for the types of injuries and illnesses that might be reasonably anticipated on these types of trips.¹¹

Who, if anyone, is liable when the physician commits medical malpractice? Is the

physician protected by Good Samaritan laws? Although Good Samaritan laws vary from state to state, most of these laws generally hold physicians and other personnel free from liability when assisting in an emergency, provided their conduct was not grossly negligent (a higher threshold than simple negligence), wanton, or willful. Other provisions common to many Good Samaritan laws include the requirement to render care in an emergency or at the scene of an emergency, to act in good faith, to provide services gratuitously, and to have no preexisting duty to the victim to respond or provide aid. For example, if a physician happens upon a stranger in need of emergent care while hiking up a mountain and provides medical care, his or her services would most likely fall within the purview of Good Samaritan laws.

On the other hand, does the physician acting as the "trip physician" lose his or her Good Samaritan protection? A typical custom in the adventure travel industry is to offer physicians generous discounts on trips in exchange for the provision of medical support for fellow participants. Many of these physicians are under the mistaken impression that they are covered by Good Samaritan laws in the event of a malpractice claim. The discounted fee, however, is the equivalent of compensation, and these physicians, along with those on straight salaries, would in all likelihood be considered independent contractors with a preexisting duty to render medical care to fellow participants.

This potential exposure to malpractice claims has two important risk management implications for expedition physicians. First, physicians must familiarize themselves with the medical issues that they are likely to encounter on their trips and must possess the knowledge and skills to diagnose and treat relevant medical disorders. A physician employed on a cruise to known endemic areas, for example, must be familiar with the diagnosis and treatment of tropical diseases. A physician with a mountain trekking group should be able to recognize the signs and symptoms of high altitude sickness and be proficient in the management of this condition. In determining the standard of care, a jury would expect the physician to anticipate foreseeable medical problems, assess the patient, and administer first aid measures as a reasonably prudent physician would under similar circumstances, taking into account the remote location, the extremes of environment, and the limited capability to transport medical equipment on the trip.

Physicians should not assume that their medical malpractice insurance policies cover claims arising out of medical services rendered on trips. Many insurance policies carry limitations on coverage for care delivered outside the scope of a physician's normal practice or beyond a certain geographic area. In these cases trip physicians should seek extended coverage through their own insurance policies or through the tour organizer.

The negligence of a physician generally will not be imputed under a theory of respondeat superior (master-servant relationship) to the tour organizer or carrier. Many courts have noted that the relationship between a trip member and a physician is not a traditional activity over which a cruise ship or tour organizer has control. Moreover, a shipping or travel company is not in the business of providing medical services to participants and does not possess the requisite expertise to

supervise a physician brought along for the convenience of the participants. Nonetheless, once the carrier or tour organizer goes about hiring a physician, it owes a duty to participants to exercise reasonable care in the selection of a competent and qualified physician. To the extent that the company fails to discharge this duty, it may be subject to a cause of action for the negligent hiring of an incompetent physician. Therefore cruise lines and tour operators should ensure that trip physicians are proficient in general medical care, emergency treatment, and the medical management of diseases endemic to the destination site.

Furthermore, travel companies and cruise ships should brief trip physicians on available resources, host country medical facilities, and evacuation procedures. Finally, companies should conduct formal credentialing of prospective trip physicians, verifying medical school graduation, board certification, and state licensure and researching any history of disciplinary actions.

DUTY TO RESCUE AND ABANDONMENT DOCTRINE

A physician who is on an expedition to Alaska and approaching the summit of Denali happens upon a trekker with multiple fractures and hypothermia. Does the physician have an obligation to treat the victim or attempt a rescue?

Abandonment is the unilateral termination of the physician-patient relationship by the physician without adequate notice to the patient, despite the need for ongoing medical care. Generally a physician has no legal duty to provide care for or to rescue endangered strangers. "The law imposes no liability upon those who stand idly by and fail to rescue a stranger who is in danger."¹⁵ Moreover, abandonment occurs only in the presence of an established physician-patient relationship. Thus the physician who refuses to enter into a physician-patient relationship and initiate treatment will not be held liable for abandonment.

Traditionally, once an individual initiated a rescue attempt, he or she could abandon rescue efforts at any time. "[The] motives in discontinuing the services are immaterial ... [The rescuer] may without liability discontinue the services through mere caprice or because of personal dislike or enmity toward the [victim]."¹⁷ However, if by giving aid the rescuer has put the victim in a worse position than before the attempt to aid, the rescuer may be liable. For example, the victim may have relied on the rescuer's efforts to his or her detriment, foregoing other opportunities to obtain assistance during the rescuer's intervention.

The best risk management tool is to assume that physicians who either implicitly or explicitly agree to treat patients create a duty to provide continuity of care. Given these circumstances, physicians can generally avoid liability for abandonment under the following conditions:

1. The physician and patient mutually consent to terminate the relationship.
2. The patient dismisses the physician.
3. The victim no longer requires care, recovers, or dies.
4. The physician dies or is disabled.
5. Further rescue efforts would place the rescuer's life in danger.
6. The physician gives the patient reasonable notice of his or her intent to withdraw from the care of the patient and, particularly in an emergency, continues to treat the patient until another qualified health care provider takes over the case.

Improper termination of the physician-patient relationship may lead to a cause of action for breach of contract or professional negligence, as well as for abandonment.

STANDING ORDERS AND MEDICAL KITS

There is tremendous variability in the medical expertise of trip leaders and participants and in the resources, including medical equipment and supplies, that accompany treks and trips into the wilderness. The delivery of medical care by nonphysicians represents one of the most problematic and controversial issues for trip organizers. Absent any representations to the contrary in travel brochures or other documents sent to participants, there is no implied or express contract to provide medical care to trip participants. Nonetheless, because of the nature of the business proprietor—customer relationship, trip leaders have some preexisting duties, namely, to exercise due care in the performance of their duties and in facilitating evacuations when feasible, as would be considered reasonable under the circumstances. In other words, if they have made no claims to the contrary, trip leaders and staff have no duty to render care beyond basic first aid services that an ordinary layperson could provide.

May a nonmedical trip leader or an EMT, paramedic, or other allied health care provider render medical services beyond the scope of his or her training or certification? One state board of registration in medicine defines the practice of medicine as^[10] :

Conduct, the purpose or reasonably foreseeable effect of which is to encourage the reliance of another person upon an individual's knowledge or skill in the maintenance of human health by the prevention, alleviation, or cure of disease and involving or reasonably thought to involve an assumption of responsibility for the other person's physical or mental well being: diagnosis, treatment, use of instruments or other devices, or the prescription or administration of drugs for the relief of diseases or adverse physical or mental conditions.

1818

A person who holds himself out to the public as a physician or surgeon, or with the initials M.D. or D.O. in connection with his name, and who also assumes responsibility for another person's physical or mental well being, is engaged in the practice of medicine. The practice of medicine does not mean conduct ... engaged in by persons licensed by other boards of registration with authority to regulate such conduct; nor does it mean assistance rendered in emergency situations by persons other than licensees.

Most states require that an EMT or paramedic act under the supervision of a physician. Supervision usually entails direct observation, radio or telephone communication, or

written guidelines, protocols, or standing orders (although usually with reasonable access to a physician who can respond to questions and provide requested guidance). These statutes were enacted under the assumption that physician consultation would be fairly accessible. Even with the advent of cellular telephones and telemedicine, however, many trekkers and travelers to remote regions cannot easily obtain physician consultation. In general, trip leaders and staff who practice beyond the scope of their education, training, and certification could be engaging in the unlawful practice of medicine.

Even in an emergency situation, it is unclear whether the Good Samaritan statutes protect trip leaders and staff. As previously discussed, travel companies and their trip leaders are to a certain extent compensated for safeguarding the safety and welfare of participants. Therefore it seems most likely that courts would use a reasonable care standard in determining the negligence of trip leaders. In other words, the court would determine how a reasonable trip leader with similar education, training, and certification would respond in similar circumstances, taking into account the emergent nature of the victim's illness or injury, the remoteness of their location, the scarcity of medical equipment, the limited means of evacuation, and the inaccessibility of definitive medical care.

On many expeditions and treks into the wilderness, medical kits stocked with prescription drugs, including controlled substances, are brought along. Again, failure of nonmedical trip leaders to provide these medications would not be considered negligence when doing so is in violation of the law, particularly when the trip organizer did not create the peril and provided adequate advance warnings to trip participants. If a nonphysician dispenses these drugs, it could very likely constitute the unlawful practice of medicine. Moreover, physicians who do not accompany the travelers but who nonetheless write the initial prescriptions to stock the medical kits expose themselves to lawsuits arising out of any malpractice on the part of the trip leader with regard to use of those medications. For example, a nonmedical trip leader might improperly diagnose and dispense medications or might overlook certain drug interactions. Additionally, physicians who write prescriptions to stock medical kits face the risk of being disciplined by their respective state boards of medicine for inappropriate prescribing practices.

This legal dogma of course is of little comfort to trip leaders who find themselves in emergency situations. In some instances trip leaders on overseas travel have been known to purchase or to recommend that participants purchase medications that would require a prescription in the United States but that are available over the counter in foreign countries. Although the purchase and use of these medications is legal on foreign soil, travelers should be cautioned about the potential lack of guarantees regarding the safety, quality, and efficacy of locally procured drugs. If the nonphysician trip leader chooses to dispense medications, whether originally stocked in the medical kit before departure from the United States or obtained abroad, a court would in all likelihood judge any adverse consequences in accordance with a "due care" standard. That is, a trip leader who dispensed medications with resultant harm to the patient would be expected to demonstrate the due care of a reasonably prudent person under similar circumstances, taking into account the emergent nature of the medical condition, the remoteness of the trip, the availability of definitive medical care, and so forth. To avoid these awkward situations, trip organizers should adhere to the following basic risk

management principles:

1. Do not advertise medical capabilities and resources beyond the scope of expertise of trip staff members or those resources readily accessible in the country.
2. Emphasize the need for trip participants to bring along an adequate supply of their own prescription drugs, and even verify that they have done so.
3. Caution trip participants about the lack of safeguards concerning the safety, quality, and efficacy of medications obtained overseas.

If trip organizers choose to equip staff members with medical kits, one expert in wilderness medicine recommends that the contents of the kit be based on the following factors^[2] :

- The environmental extremes encountered during the trip
- Endemic diseases
- The medical expertise of the medical officer
- The medical expertise of the expedition members
- The number of people on the trip
- The responsibility for local health care
- The length of the trip
- The distance from definitive medical care
- The availability of rescue (i.e., helicopter)

MEDICAL RECORD KEEPING IN WILDERNESS MEDICINE

Good record keeping is of paramount importance in the practice of wilderness medicine. The medical record is both a health care document and a legal document. Although storage space and the portability of medical records on trips to remote locations are often limited, trip physicians should nonetheless strive to be as thorough as possible in documenting medical care. The medical record functions as a complete, written, and chronological record of a patient's medical history, condition, and treatment. In medical malpractice claims, which are frequently litigated years after the alleged occurrence, these records may be the only written source from which the sequence of events and subsequent treatment can be reconstructed. Moreover, memories fade and witnesses become less available over time. Therefore courts tend to give tremendous weight to the written record and will often assume that documented events occurred and undocumented events did not occur, particularly when the oral testimonies of the litigants conflict.

Although the length and content of entries will vary with the specific circumstances, notes should at a minimum include the patient's chief complaint, the results of the physical examination (including normal findings), an assessment, and a treatment plan. The key point to remember in the creation of medical records is that they may be used to prove or disprove that the medical practitioner adhered to the appropriate standard of care. Therefore physicians should record sufficient details to reflect their thought processes and to justify the care provided under the circumstances. Moreover, physicians should document events chronologically and as soon as feasible after the delivery of medical care. Once notes have been entered into the chart or record, the medical practitioner should never alter or write over the original notes. Pages should not be removed or inserted. If corrections are necessary, the physician should place a single line through the error, enter the correction, and initial and date the correction. Addenda should be placed after the last entry in the chart. Of course, notes should always be legible, signed, and dated by the health care provider making the entry. Upon completion of the trip, the company should treat these medical records as confidential information and should place them in locked medical files, granting access to designated personnel (company medical advisers or others with a need to know) only. Some states have explicit laws or regulations that dictate the minimum period for retention of medical records. In the absence of such laws, travel companies and cruise lines should store medical records for the period of time corresponding to the statute of limitations for tort claims in their states, which is usually a couple of years.

CONCLUSION

The services of physicians on cruises and expeditions can be invaluable to the safety and welfare of participants. The expanded participation of higher risk individuals on trips to more remote regions of the world increases the liability exposure of health care providers. Legal issues, particularly causation, become more complex when medicine is practiced in these unconventional settings. By following the risk management principles outlined in this chapter, physicians can continue to provide effective care while minimizing their liability.

Chapter 78 - Ethics of Wilderness Medicine

Kenneth V. Iserson

Ethics is the application of rules and principles to guide human action. Bioethics is the area of ethics that applies specifically to health care providers and biomedical researchers. It involves the encounter between the patient and the health care provider, biomedical research, and health care policy. Wilderness medicine, however, is not directly comparable to either the medicine delivered in health care facilities or even the care delivered by urban emergency medical services. Wilderness medicine is unique, and its special attributes provide unique ethical problems ([Table 78-1](#)). For example, a hospital's working environment is rarely a factor considered by the hospital-based practitioner in the determination of what medical care to deliver, but the working environment is of major concern in the wilderness. Similarly, whereas patients are usually known to the hospital practitioner and arrive requesting care, neither condition is true in the wilderness setting. Even more striking are the differences between the hospital and the wilderness setting with regard to equipment availability, personnel training, the need for evacuation or rescue, and the provision for the security of those involved. All these differences can lead to unique ethical dilemmas.

This chapter first provides an overview of ethical values in general and the values applied to bioethics. It then describes and provides a model for bioethics decision making. Next is an adaptation of the model for the bioethics of wilderness medicine, which includes the ethics of wilderness health care providers, researchers, and in some cases, makers of health care policy. Finally, unique dilemmas in wilderness medicine are discussed.

APPLICATION OF RULES, PRINCIPLES, AND ACTION GUIDES TO HUMAN ACTIVITIES

Individuals' values, which are acquired throughout life from many sources, develop into their ethical action guides. In everyday situations, some individuals may be unaware that these values are guiding their actions. However, when facing situations that are rarely encountered, often termed *ethical dilemmas*, people may question how they should apply their values to solve practical problems. These situations may often develop in wilderness medicine, since the settings often encompasses scenarios and practitioners who must demonstrate expertise outside the usual scope of their medical specialties.

Both patients' and clinicians' values control patient-clinician encounters. When patients express their values, clinicians can get an impression of the patients' views about necessary treatment, desired quality of life, and other complex attitudes that control the willingness to seek and accept medical care. Whether these expressions are deemed valid is based on the clinicians' "bedside" determination of patients' decision-making capacity. The clinicians' own values, both personal and professional, are also part of the relationship and sometimes conflict with the patients' values.

Ethical discussions often revolve around applying ethical rules in a consistent manner or in a way that could be applied by all practitioners in the same situation (*universalizability*). Ethical decisions derived from accepted principles, rules, or values should be applied uniformly (consistently) across all scenarios. If an accepted rule is that patients with decision-making capacity may make their own decisions about health care, this rule should be applied to all situations, not just when it is convenient for the health care provider. Likewise, if the rule is truly ethical, all health care providers, not just by a privileged or unique group, must be able to apply it to practice.

Sources of Values

The basic elements of any ethical discussion are personal values. Values are the guideposts used to structure an individual's actions in life. They signify what a person's duties and responsibilities are, what is important to the person, and how the person interacts with others. Thomas Aquinas said that the three vital things for each person are "to know what he ought to believe; to know what he ought to desire; and to know what he ought to do."^[1]

Personal values derive from many sources: family, society, school, religion, the media, and professional training and related interactions. Family and religion generally guide the development of values in the formative years. For nearly everyone, these values

form the bedrock on which his or her life is structured. Emphasizing the importance of early childhood learning is the maxim, "If you control a child's life until the age of 6 years, he is yours forever." Additional significant influences are the media, schooling, and society. In this electronic age, the media begin to influence an individual's values early in life. Secular education broadens a

TABLE 78-1 -- Differences Among Hospital Practice, Emergency Medical Services, and Wilderness Medicine

	HOSPITAL PRACTICE	EMERGENCY MEDICAL SERVICES	WILDERNESS MEDICINE*
Environment	Controlled, known, static	Partly controlled, partly known, changeable	Uncontrolled, partly known, changeable
Patient	Known, requests care	Unknown, sometimes requests care	Unknown, sometimes requests care
Equipment	Sophisticated	Adequate	Rudimentary
Security	Safe	Usually safe	Questionable

Rescue	No	Rare	Common

*Includes search and rescue.

child's experiences and values beyond the small world of the home. Finally, societal pressures continue to influence most individuals' value systems throughout life. Taken as a whole, different individuals' values derived from these multiple sources may conflict, leading to disagreements over which action to take when ethical dilemmas arise.

Professional schooling and interactions often further refine how a person's previously learned values are applied. For example, one reason that medical students take anatomy courses is to destroy an ingrained cultural value against mutilating the dead. This allows them to accept and acquire the values of beneficial mutilation (surgery), handling the dead (resuscitations, pathology, transplants), and invading another's body (every invasive medical procedure).^[11] In addition, when exposed to clinical practice, medical students, nurses, medics, and other health care providers learn to adopt the values of their preceptors. In any residency program the majority of trainees behave

remarkably like the faculty. Trainees learn intrinsic professional values.

Values in Modern Biomedical Ethics

Another category of values, sometimes referred to as the *Georgetown bioethics catechism*, has emerged as an ideal for modern medicine, especially in the United States. These values include autonomy, beneficence, nonmaleficence, and distributive justice.

For the past 2 decades in the United States, the overriding professional and societal bioethical value has been a patient's autonomy. *Autonomy* recognizes an adult's right to accept or reject recommendations for his or her personal medical care (even to the extent of refusing all care) in the presence of appropriate decision-making capacity (see Decision-Making Capacity and Consent). Current bioethical opinion demands that clinicians respect patient autonomy. This is the counterweight to the long-practiced paternalism (or parentalism) of the medical profession, wherein what was "good" for the patient was determined solely by the physician. Coupled with paternalism is coercion, the threat or use of violence to influence behavior or choice. The august figure in white (or in a medic's or search-and-rescue uniform) who implies that there will be dire consequences if medical recommendations are not followed remains a potent force against patient autonomy.

At the patient's bedside, *beneficence*, the act of doing good, and *confidentiality*, the holding of information in confidence, have been long-held and nearly universal tenets of the medical profession. Likewise, *personal integrity*, the adherence to one's own moral and professional standards, is basic to thinking and acting ethically. The basic tenet taught to all medical students is *nonmaleficence*, or "First, do no harm." This credo, often stated in the Latin form, "*Primum non nocere*," derives from the historical knowledge that patients' encounters with physicians can be harmful as well as helpful. It recognizes every physician's fallibility.

The concept of *comparative* or *distributive justice* suggests that comparable individuals and groups in society should share equitably in the benefits and burdens of that society. Many society-wide decisions about the allocation of limited health care resources are based on this principle. Yet it is a fallacy to extrapolate from this valid principle to the idea that simply because a need to limit health care resource expenditures exists, individual clinicians can arbitrarily limit or terminate care on a case-by-case basis for individual patients.^[18]

Decision-Making Capacity and Consent

A significant concern in the wilderness setting is whether patients have decision-making capacity, thus retaining their autonomy to make reasonable health care decisions. Many ethical dilemmas in emergency medical care revolve around ascertaining a patient's decision-making capacity, often linked with consent to

(or more often refusal of) a medical procedure. Since a basic canon of both ethics and law, as stated by Justice Cardozo,^[23] is, "Every human being of adult years and sound mind has a right to determine what shall be done with his own body," these decisions about what action to take can often be made clearer by understanding what is meant by *decision-making capacity* and how it relates to consent. (Note that the term *competent* is often used, when *capacity* is really what is meant. *Competent*, meaning "possessing the requisite natural or legal qualifications," is a legal term and can be determined only by the court. ^[21])

**Box 78-1. COMPONENTS OF
DECISION-MAKING CAPACITY**

Knowledge of the options

Awareness of the consequences of each option

Appreciation of personal costs and benefits of options in relation to relatively stable values and preferences

Modified from Buchanan AE: The question of competence. In Iserson KV et al, editors: Ethics in emergency medicine, ed 2, Tucson, Ariz, 1995, Galen Press.

Capacity refers to a patient's decision-making ability as determined by clinicians. Capacity is always decision-specific rather than global. Although an inebriated person, for example, may have the capacity to refuse to have stitches put into a small laceration, especially with evidence that he has previously refused similar treatments without remorse, the same individual may not have the capacity either to accept an elective operation of any sort or to refuse an emergency lifesaving procedure or operation. To have adequate decision-making capacity in any particular circumstance, a person must understand the available options and the consequences of acting on the various options and be able to compare any option he or she chooses against the costs and benefits related to a relatively stable framework of personal values and priorities^[3] ^[4] (see [Box 78-1](#)). This last requirement is the most difficult to understand and requires a subjective interpretation. The easiest way to assess it is to ask why an individual made such a decision. Disagreement with the physician's recommendation is *not* in itself grounds for

determining whether a person is incapable of making his or her own decisions. In fact, even the refusal of lifesaving medical care may not prove the person incapable of making valid decisions, if it is made on the basis of firmly held religious beliefs, as in the case of a Jehovah's Witness refusing a blood transfusion.

A person must be permitted to consent to or refuse any medical intervention (implicitly or explicitly) if he or she has decision-making capacity for that decision and if the clinician respects the patient's autonomy. Three general types of consent exist: presumed, implied, and informed. *Presumed consent*, sometimes called *emergency consent*, covers the necessary lifesaving procedures that any reasonable person would wish to have if lacking decision-making capacity; controlling hemorrhage and securing an airway in an unconscious victim of a fall are common examples. *Implied consent* is when a person with decision-making capacity cooperates with a procedure, such as holding out an arm to donate blood or to allow initiation of an intravenous line. *Informed consent* is when a person who retains decision-making capacity is given all the pertinent facts regarding the risks and benefits of a particular procedure, understands them, and voluntarily agrees to undergo the procedure.^[9]

Questions applying to consent in the wilderness setting can be difficult. Does the victim have the capacity to understand the situation? Will decision-making capacity be questioned only if a person refuses "good" medical care? Also, unresolved even in standard medical practice, what procedures require informed, as distinct from implied, consent? The requirement to obtain informed consent varies in practice and law from area to area. This variation stems from differing local practice standards and state law and disparities in physician training. Determining decision-making capacity and providing an opportunity for a victim to consent to a procedure when appropriate are crucial to respecting a patient's autonomy.

Security: Another Value Applicable to Wilderness Medicine

Given the unique setting of wilderness medicine, the value of security must also be applied. *Security* (safety) signifies a measure of responsibility toward oneself, one's companions, and the patient. This responsibility is to avoid risking the wilderness team's safety from the environment, from victims, and from their own poor judgment. This is a concept far removed from normal medical practice. However, this value is of paramount importance in wilderness medicine. Security is the responsibility of any wilderness medical provider, even if he or she is not officially designated a provider but must take over in a medical crisis on the basis of special knowledge or skills. Decisions about rescue, evacuation, stopping of group travel, or even attempts to perform certain medical interventions must include security considerations.

Security is wilderness medicine's controlling value in most circumstances. Concerns about safety are applied in the following order: oneself, other team members, and then the patient. Ethical theory supports this hierarchy. Beneficence by medical personnel does *not* imply a need to endanger oneself. Indeed, if medical skills are to be useful, medical personnel must be able

to render care. In addition, inherent in any leadership position is a responsibility to protect one's team. Therefore the team members' safety is the second responsibility. Finally, the patient's security should be ensured but never at the expense of the medical team's safety. This is to say that in unknown or unknowable circumstances, the medical leader may have to weigh potential risks vs. benefits. All risks must be considered in these "calculations," since otherwise, these concerns are often ignored. An example is the case in which a badly injured trekker may survive if evacuated by aeromedical transport. The helicopter team is willing to attempt a pickup, if requested. The wilderness medical care provider must determine whether local conditions are sufficiently safe, balanced against the chance of benefit to the patient, to justify the request.

A unique ethical problem that arises in wilderness settings—and has often led to disasters—is for the team, especially the nonmedical team leader, to ignore or override the medical person's decision. Individual team members have been harmed and multiple team members lost, often because of factors other than team members' safety and well-being.^[16] ^[22]

In the language of ethics, utilitarian thinking plays a dominant role in wilderness ethics. Utilitarianism is the philosophy that promotes the greatest good (or happiness) for the greatest number of individuals. In wilderness medicine, it promotes the well-being of the many over the well-being of the individual. This can be defended by simply recognizing the unique aspects of wilderness medical practice, such as the uncontrolled environment, unfamiliarity with the patient, rudimentary equipment, and changeable situations—all contributing to safety concerns. Heeding the value of security is especially important because the majority of people who are in the wilderness have risk-taking personalities, leading them to downplay security in favor of adventure.

Ethical Dilemmas

Health care professionals commonly apply their values without much deliberation. They act instinctively based on their prior behavior and training. Values are constantly (although not necessarily consistently) applied to everyday decisions. Of course, most decisions are not ethical decisions. Ethical dilemmas arise with conflict between two seemingly equivalent values that are represented by different and mutually exclusive possible actions. A graphic depiction of this situation is the practitioner between a rock and a hard place. The practitioner has a profound decision to make. That is where ethical decision making comes into play.

An example of a bioethical dilemma in wilderness medicine may help illustrate ethical decision making. A distress call has been received from anxious relatives or by radio from a plane flying over a wilderness area. The victim is in a hazardous area (such as on an active volcano) or more commonly, is caught in terrible weather (snow or a thunderstorm). The clinician directing a search-and-rescue team must decide how to respond to the call in a setting that may put the team in danger. The standard bioethical

value of beneficence directly competes with the wilderness bioethical value of security. Each has a strong pull on the decision maker, with each value providing good arguments for sending or not sending the rescue team. Although the value of security may often be considered paramount in the wilderness setting, the emotional and altruistic pulls of beneficence make this a difficult choice. Considering this case, a word should first be said about rights and duties in relation to health care.

Although the word *rights* is glibly used in many situations in society, a personal right is present only if another person or society as a whole has an identifiable *duty* to the individual. For example, if all U.S. citizens had a right to health care, the government would have the duty to provide this care. Health care providers would have a corresponding duty to deliver this care. However, except in limited circumstances, such as emergency departments and prisons, no such legal right currently exists. Morally and practically, citizens do not have the right to *health*, and how much health care people are owed is unresolved.^[17] Correspondingly, no health care practitioner has a duty to provide all the health care people desire. Practitioners do, however, have a duty to provide security, when possible, for those they direct in wilderness settings. This may provide part of the answer for this case; yet other factors may be involved.

Since the ethical dilemma arises when two or more seemingly "correct" actions appear to have equal benefits, the choice of actions should be examined first. How are these proposed "correct" actions determined in the first place? After that, which of these actions is the more ethically acceptable?

Solving the Bioethical Dilemma

Deciding on an Action in the Standard Setting.

Jonsen et al^[15] have suggested four groups of factors to consider when determining a course of action in the face of a bioethical dilemma in the standard clinical paradigm. These include the medical indications for the action, the patient's (or surrogate's) preferences, consideration of the quality of life, and other contextual factors. These have been seen as an "ethical square," with the top two boxes weighing more heavily (Figure 78-1 (Figure Not Available)).

In a broad sense, *patient wishes* equate to *patient autonomy*. In a growing number of instances, however, especially at the end of life, surrogate decision makers, rather than the patient, may exercise this autonomy. This may also be true in the wilderness setting, albeit with less legal backing. Many critically ill patients in

health care facilities have an advance directive (durable power of attorney for health

care) naming a surrogate to make health care decisions if they lack decision-making capacity. Finding such advance directives in the wilderness setting would be rare and in emergency situations, may not be valid, especially if the message is in an unusual form, such as a tattoo or MedicAlert jewelry.^[8] ^[14] Most people do not have advance directives. Those that do carry them do so only if they believe themselves to be terminally ill. Wilderness patients rarely belong to that group. More frequently, though, people without terminal illnesses wear nonstandard advance directives. Experience has shown that these cannot be relied on to reflect a person's current wishes (e.g., tattoos) or can easily be misinterpreted (e.g., do-not-resuscitate jewelry).^[12] ^[14] Furthermore, it is not the wilderness practitioner's job to interpret either nonstandard legal or quasilegal documents that are not part of his or her training. Standard forms, such as area- or state-wide prehospital do-not-resuscitate forms or advance directives, if present, should be followed. Many of these, however, are specifically not applicable after trauma.^[9] ^[10]

If a person lacks decision-making capacity, a spouse, close friend, or medical care provider makes critical decisions for the patient, acting in his or her "best interest." Parents normally act as decision makers for minor children. Rarely, a court-appointed guardian has been named to replace parents. A child may also be an "emancipated minor," meaning that he or she lives alone and is self-supporting. Two key issues arise in children's medical care. First, children should not be denied emergency care simply because no permission is available. In these cases, *emergency* is defined broadly. Anything that causes pain or that may increase the child's morbidity or mortality should be treated. In wilderness situations, reasonable efforts to get parental consent usually do not apply if they are not already on the scene. They may have given blanket consent to treat their child, but that is not required if an emergency exists. Second, if the child is old enough to understand the situation and cooperate, it is both ethically important and good medical practice to have him or her assent to the proposed treatment. The assent is the agreement but does not constitute legal permission, since the child is under age.^[9]

Medical indications are often more straightforward in the wilderness setting than they are in standard health care. In the wilderness, treatment is basic, injuries and illnesses are generally acute, and intervention is normally life preserving rather than death prolonging. Standard clinical algorithms are used by the clinicians for their appropriate level of training and expertise. In remote areas, of course, questions may arise about

Figure 78-2 Wilderness medicine's ethical triangle.

whether the ophthalmologist should attempt to reduce a hip dislocation or whether the nurse should attempt to establish a surgical airway. These dilemmas should, when

feasible, be decided with input from the patient or surrogate. As a matter of proper planning, behavior in critical scenarios must be decided in advance. Normally, however, medical indications are clear.

Bioethicists normally feel most comfortable helping resolve cases using only the medical indications and patient (or surrogate) wishes, which are all above the double line in Figure 78-1 (Figure Not Available) . When these factors are ambiguous, however, two other sets of factors must be considered: contextual factors and quality of life. In the wilderness setting, the primary contextual factor is safety. This may overshadow all other considerations involved in a victim's treatment. Other contextual factors include everything from financial implications of various treatments to the effect of various options on other trip members. In the standard medical situation, this is admittedly a fuzzy area. Related to these, and even more nebulous, are quality-of-life factors. These relate to the nature of a person's current and presumed future existence as viewed by others. If a person has decision-making capacity, his or her own view of life is comfortably built into personal autonomy. In the wilderness setting, time and circumstances usually do not allow clinicians to make quality-of-life judgments.

Deciding on an Action in the Wilderness.

The importance of security factors in the wilderness setting leads to the altered diagram of decision making for ethical problems in wilderness medicine ([Figure 78-2](#)). This includes three groups of factors to consider when deciding on a course of action in the wilderness setting: patient autonomy, security, and medical indications. Within

Figure 78-3 A rapid approach to emergency ethical problems. (Modified from Iserson KV: *An approach to ethical problems in emergency medicine*. In Iserson KV et al, editors: *Ethics in emergency medicine*, ed 2, Tucson, Ariz, 1995, Galen Press.)

this decision model, the security factors must be given the most weight.

Security factors include the safety of the medical and rescue personnel and victim, proposed procedures, and the evacuation method. As mentioned previously, the security of the medical team is a valid consideration because of the inherent risk-taking nature of people in the wilderness. In recent legal actions pertaining to wilderness injuries, the law has recognized a "doctrine of reasonable implied assumption of risk." This implied risk is also part of an acceptable concept of wilderness triage. Wilderness triage takes place when the same injuries or illnesses that would cause minimal morbidity in a medically sophisticated environment inevitably cause death if they occur in the wilderness. A fractured femur in the lone wilderness traveler or an abdominal gunshot wound in a remote area is often a virtual death sentence. This is a risk that

wilderness adventurers take, although not always with a clear understanding of the enormity of the risk.

Both standard bioethics and wilderness medical ethics often involve difficult situations with no "correct" answer. Usually, more than two possible actions exist. This is the wilderness ethical and standard bioethical dilemma. What should the practitioner do?

Bioethical Decision-Making Process^[13]

Using an Algorithm as a Guide for a Decision.

In bioethics, although disagreements may arise regarding the optimal course of action using a specific set of values, general agreement often exists as to what constitutes ethically wrong actions. The method of ethical case analysis described in [Figure 78-3](#) is designed to

1826

provide the emergency practitioner with prompt assistance in selecting an ethically correct, although not necessarily a theoretically "best," course of action.^[12] This method applies equally well in both the wilderness setting and the normal hospital setting.

The first step in using the algorithm in [Figure 78-3](#) is to use a known precedent. This is the simplest solution to an ethical dilemma but requires planning in advance, including reading and thinking about ethical problems. Many physicians and other health care professionals are not prepared to do this. Just as with any emergency procedure, wilderness medicine physicians and health care professionals should be prepared with a course of action for the most common ethical dilemmas likely to occur in the wilderness setting.

With no precedent, the second step is to "buy time." What action is not harmful to the patient that provides time for the consultation or information gathering needed to refine the action plan? In a wilderness medical setting, this might mean placing a person's arm in a sling for comfort while deciding whether an inexperienced provider should attempt to reduce a dislocation or fracture.

With no precedent on which to rely and no way to "buy time," the health care professional must select a possible course of action and test it for ethical viability. The impartiality test, universalizability test, and interpersonal justifiability test are drawn from three different philosophical theories. First, the impartiality test is applied. The practitioner asks whether he or she would have this action performed if in the patient's place. In essence, this is a form of the Golden Rule, "Do unto others as you would have done unto you." According to John Stuart Mill,^[20] this espouses "the complete spirit of the ethics of utility." Second, the universalizability test asks if the health care professional would feel comfortable having all practitioners perform this action in all relevantly similar circumstances. This generalizes the action and asks whether

developing a universal rule for the contemplated behavior is reasonable. This is merely a restatement of Kant's categorical imperative ("Act as if the maxim of thy act were to become by thy will a universal law of nature."). Finally, the interpersonal justifiability test asks if the practitioner can supply good reasons to others for his or her action. Will peers, superiors, or the public be satisfied with the action taken and reasons for it? This test uses David Gauthier's basic theory of consensus values as a final screen for a proposed action.^[6] If all three tests can be answered in the affirmative, the health care professional can have reasonable assurance that the proposed action falls within the scope of morally acceptable actions. If, however, the proposed action fails any of these tests, the algorithm must be applied to another proposed action.

Box 78-2. ETHICAL DILEMMAS IN WILDERNESS CARE

STANDARD OF CARE DILEMMAS

Limited resources: The standard of care differs. What should be brought into the field? How are resources distributed?

Cultural: Are Western standards of care and attitudes appropriate when treating locals in a foreign country?

Nontrained personnel: How much authority is delegated to nontrained personnel?

PRIORITY IN CARE DILEMMAS

Triage choices: Who should be rescued first? (Those most injured or ill? Injured or ill rescuers? Those with the best chance of survival? Women and children? Those with important information, such as scientists who have collected data? Those who do not volunteer to stay behind?)

ETHICAL DILEMMAS IN WILDERNESS MEDICINE

With its unique setting and mode of practice, wilderness medicine provides practitioners with ethical dilemmas that are rarely seen by most other providers. These dilemmas can be grouped into three categories: standards of care, priority in care, and the decision-making process ([Box 78-2](#)). As might be expected, some of the issues in each group deal with provider-patient dilemmas, whereas others have more to do with group or governmental policies. Also, the unusual circumstances found in wilderness settings may result in ethical decisions different from those in standard medical settings. The ethical decision-making process used to puzzle through these dilemmas, however, is similar to that used in other settings; wilderness medical care's unique setting and issues sometimes obscure this basic truism.

Application of Values

In wilderness medicine, ethical dilemmas arise, and values must be applied to patient-clinician interactions,

1827

group activities, and public wilderness policies. In this setting the unique position of wilderness medical practitioners must be recognized. These dilemmas have few parallels in other areas of medical practice, except perhaps battlefield medical practice or medical care during major, widespread disasters. These dilemmas may include providing euthanasia for potentially nonfatal medical conditions, abandoning patients, and prioritizing medical care between original patients and rescue team members. A limited discussion of the ethical dilemmas involved in each of these follows.

Standard of Care Dilemmas

Limited Resources.

In the wilderness setting, resources are limited. Medical equipment is usually confined to supplies that can be carried into the field on foot or in some cases on horseback or by helicopter. Wilderness rescue personnel may have limited medical skills. The combination of limited skills and limited availability of supplies and equipment gives rise to ethical dilemmas. What should be included in wilderness medical kits? Their composition is resource allocation at its most basic. Who decides?

Rarely do people consider advanced decision making a part of medical care. However, it is very much a part of wilderness medicine. For example, decisions regarding the contents of medical kits made well in advance rather than during triage affect the patient's care. Although the individual wilderness traveler usually determines what is carried into the field, he or she generally fails to realize that this decision may set a limit on treatment. Any traveler into a wilderness area must assume that the contents of the medical kit will be the only resources available for medical treatment. When equipment is selected for organized wilderness excursions or search-and-rescue teams, however, the decision may be made by the group, a medical committee, or the medical director or advisor. The selection still limits the medical care that can be given.

Although commercially available standardized medical kits are usually designed on the basis of "medical" criteria, it is vital to recognize that some types of treatment will be implicitly unavailable because of what is excluded from these kits. Decisions must be made concerning what to include in field medical kits, yet no one is expected to carry a fully stocked emergency department into the field. Clearly identifying the ethical dilemmas entailed in compiling these kits helps team members in their decisions. For example, if a decision not to carry antiarrhythmic medications or a defibrillator is made and if a team member suffers a cardiac rhythm abnormality, there will be little that can be done for him or her. Some people may omit medical kit items that will foreseeably be useful, such as intravenous solutions. As the medical person on one doomed expedition to the Himalayan peak Nanda Devi recalled, "[My] irritation grew as [I] remembered [being] pressured into leaving intravenous fluids behind."²²¹ This preexpedition resource decision may doom a team member. It helps if team members know in advance that these decisions were made—and even participate in making them.

Explicit triage decisions, although harder to make, are often easier to recognize as ethical dilemmas. These are discussed later in the chapter.

Cultural Differences.

Many wilderness emergencies occur in places outside of the United States or other Western countries. Are Western standards of care and attitudes appropriate when treating locals in a foreign country? Whose values control medical treatment and other actions?

Three circumstances may present ethical dilemmas in the delivery of medical care during wilderness expeditions to remote areas. The first is a lack of cultural sensitivity. Aggressive offers to care for disease or injury may frustrate or anger local patients or providers, whose methods of treatment fit within the region's cultural milieu and may be as good as or better than "modern" medicine. Temporarily replacing or upstaging traditional healers and their healing methods may degrade them in the eyes of the local population.

The second situation is when medical problems occur that are beyond the capabilities of an expedition's practitioners. After offering the care for which they are competent, practitioners may feel obligated to attempt treatments beyond their knowledge or

abilities. An internist may face treating a gunshot wound to the chest, a psychiatrist may encounter a complicated obstetric emergency, or a paramedic may confront an epidemic. Often without any direction except a moral compass, these caregivers may be tempted to stretch their abilities beyond the limits of patient safety. Cultural ethical concerns should be considered when deciding which course of action to pursue.

The third situation relates to the larger question of the fairness of chance encounters: a woman's life is saved through the luck that a passing trekker could treat her pyelonephritis; after a surgeon relocates a hip, a man will continue to provide for his family; and a paramedic happens to be on hand to intubate a child with epiglottitis. These situations in themselves rarely encompass ethical issues. The larger question, which may be more philosophical than practical, is how these interventions interfere with the balance of life in the area. Are chance encounters an aberration or simply a part of life? One of the most common situations in this category is a wilderness team from a developed country leaving medications behind with individuals who would not normally have access to them. Beyond the questions of the medications' efficacy, continued availability, and safety in inexperienced hands, there are the

1828

ethical concerns about interfering and altering the life balance in other cultures. Trekkers who traverse areas that others commonly visit do not face this dilemma, since medications are routinely distributed by the succession of groups. This question arises, however, in expeditions entering rarely visited areas, such as remote areas in Papua-New Guinea or the Amazon basin.

How Much Authority Is Given to Nontrained Personnel?

Wilderness travelers face ethical dilemmas when they encounter medical situations for which they are untrained. This is certainly not restricted to laypersons. Medics, physician assistants, nurses, and physicians may quickly find themselves out of their depth in a wilderness setting. This occurs when they treat patients with conditions comfortably treated only in an urban environment or when an illness or injury is beyond the scope of personal experience and knowledge. In deciding whether to intervene in such a situation, the person planning to help must weigh the chance of benefiting the patient (value of beneficence) against the chance of doing the recipient of care harm (nonmaleficence).

The following hypothetical case illustrates both the questions raised in this type of dilemma and the application of the rapid decision-making model (see [Figure 78-3](#)). A backcountry excursion sets out with a medical provider who is unprepared for orthopedic emergencies. When a group member dislocates her shoulder, the provider may be unwilling to go beyond his level of training by attempting a shoulder relocation, although the victim (as well as the rest of the party) may encourage the attempt. Another member of the party with even less training volunteers to attempt the maneuver; the clinician is in a double bind, seemingly forced to either overextend his or

her skills or to acquiesce to even less knowledgeable medical care for the victim.

How could this dilemma be resolved using the rapid decision-making model? (See [Figure 78-3](#) .) The first step would be to anticipate such a situation in advance and plan a course of action. Since orthopedic trauma is common in the wilderness, any medical provider should expect to face such a situation. (Note that planning may obviate this ethical dilemma, as it does in many other situations, since the provider may then learn the requisite orthopedic knowledge and skills in advance or may abandon plans to assume this wilderness medical role.) Whether or not the skill level is unchanged, the provider may also decide on an ethical course of action after discussing in advance the potential problem with knowledgeable peers or acquiring information from other sources. Perhaps the provider decides to act in such a situation (a paradigm or model case). It is reasonable to base intervention on (1) determining whether the patient has decisional capacity, (2) informing the patient fully and honestly of the apparent situation and options, and (3) acquiescing to the patient's desires, whether attempting relocation or simply securing the arm in place. Honest acceptance of the patient's autonomy to control her medical care often resolves a seemingly difficult ethical dilemma. Yet the circumstances in this case may be that the provider believes the "experienced" layman offering to help may actually have no knowledge at all. The provider must then decide whether the paradigm case for which he prepared a response is similar enough to the current circumstances to use that response. If it is, the dilemma is resolved, and that rule should be followed.

If, however, the provider believes that the current situation differs significantly from his paradigm case or if from lack of foresight he simply failed to decide in advance on an ethical course of action, he should go to step two: buying time. In the scenario presented, buying time may consist of making the patient comfortable before contacting help or thinking through the problem. Help may be available to organized wilderness excursions through radio or cellular telephone communication. The assistance may be experienced advice about other actions to resolve the dilemma or orthopedic advice on ways to reduce the shoulder. Sometimes, however, no help is available or not enough time can be bought to secure help. The health care provider must make a decision to act: go to step three.

At this stage, the provider attempts to choose an action (by applying [Figure 78-2](#)) that is ethically acceptable, even if it is not the optimal action he might select if more time were available to consider the problem. Possible actions in this case might include attempting a reduction, allowing the lay person to attempt a reduction, simply immobilizing the victim's shoulder, leaving the victim and going for help, or ignoring the situation and leaving the decision to someone else. The provider must first choose a course of action (remembering that not deciding is also a course of action) and then decide whether the choice falls within the scope of ethically acceptable behavior. If, for example, the proposed action is shoulder immobilization, the three tests of impartiality (Golden Rule), universalizability (should every practitioner do as I plan to do?), and interpersonal justifiability (would I be ashamed to have my actions publicized?) should be applied to this action. If the action passes all three tests, it is probably ethically acceptable and may be used. Remember that ethically acceptable actions may differ with the

circumstances or the wilderness group involved.

Health care policy is another aspect of this type of ethical dilemma. Restricting medical practitioners from fully using their skills and knowledge may limit wilderness medical care. Paramedics, for example, are told that in some jurisdictions, on penalty of losing

1829

their licenses, they may not reduce fractures, perform cricothyrotomies, or in a few locations, perform endotracheal intubations. Emergency medical technicians, first aiders, first responders, and the like are more severely restricted. Nurses may not know what procedures their licenses allow, and physicians are constantly concerned about liability. In general, many practitioners in wilderness settings feel that the laws and administrative policies under which they work restrict their actions. This attitude and their subsequent behavior may lead to substandard care for victims of wilderness injury or illness. The Wilderness Medical Society and other groups have begun working to overcome these limitations. At present, however, an ethical dilemma may exist when practitioners face medical situations in the field that they know how to treat but that exceed their licenses or official certifications. A clear conflict may exist between the law and ethical responsibility. Practitioners have to decide the best course of action, preferably in advance of the problem.

Priority in Care Dilemmas

Triage takes on new dimensions in wilderness settings. Ethical dilemmas easily arise when health care providers face not only triage among victims but also critical decisions about whether to help victims at all. These settings also produce situations in which the rescuers or other members of the party may be placed in danger by helping an injured person.

Triage Choices: Whom to Rescue First and How to Distribute Resources.

Medical practitioners, especially those in fields of surgery and emergency care, are familiar with medical triage in which multiple patients need care and in which patients must be sorted by severity of injury, availability of resources, and possibility of successful treatment. These triage decisions have their own unique set of ethical dilemmas. Wilderness triage is unusual on several counts and may present ethical dilemmas markedly different from those encountered in nonwilderness environments.

Three ethical dilemmas result from wilderness triage questions that are unlikely to occur elsewhere except for battlefield settings.^[5] The first dilemma arises when, providing care for a group, the wilderness practitioner knows all the victims and may have personal ties to at least one. This is unlike normal triage scenarios and complicates any decision about who gets treated, especially if resources are limited. For example, in an outbreak of giardiasis in a party of 12, the provider may have only enough metronidazole (Flagyl) to treat 5 people. Another, more serious example would be a lightning strike in the midst

of six people, with only one other individual capable of providing assistance. In each case, the medical practitioner applying triage criteria may be torn between medical and personal concerns.

A second ethical triage dilemma arises in what may be termed the "us vs. them" situation. Members of both the wilderness party and local population may be in the victim pool to be triaged. To whom does the provider owe primary responsibility? Some may argue that the implicit or explicit contract between the provider and group members warrants treating group members first. If the battlefield is considered analogous, the same contract exists there. The Geneva Convention specifies that patients are always to be triaged for medical care on the basis of medical need and the ability to treat. Whether military caregivers follow this dictum in practice is moot. The wilderness caregiver must carefully consider this issue before venturing into the field.

Finally, ethical dilemmas arise because not all team members are equal. If triage among team members is necessary, treatment on the basis of pure medical necessity is not always realistic. In the giardiasis example, will the sickest patients be treated or will treatment be given to the less sick guide and translator, who are essential people needed to get the party safely out of the wilderness? The greatest good for the greatest number, or the concept of group safety, must prevail. However, this may be neither a comfortable nor an intuitively obvious decision.

An ethical dilemma also arises when a rescue team member is injured while out in the field. The question is asked whether rescue teams should treat their injured team member before, or instead of, victims. Wilderness rescue is an inherently dangerous operation. Although the safety record of some organized and experienced rescue groups has been excellent, this is not universal, particularly with ad hoc rescue attempts.^[7] An ethical dilemma arises when rescuers themselves become victims. Where should the team's priorities lie? Again, an analogy can be drawn with triage parameters in emergency care. The principle of triage is that as long as resources are available, the most seriously injured are treated first. Those that cannot be saved with available resources or evacuated in time to be saved are given only comfort measures. This situation logically and morally prevails in wilderness medical care. However, emotion rather than reason often influences actions, so the wilderness health care provider must ensure that ethical decision making prevails.

Issues of Survival.

In some situations, the lives of expedition members may be put at immediate risk if an injured person receives optimal assistance. One well-known example was the high-altitude climber in the Peruvian Andes, Simon Yates, who, while trying to lower his injured climbing partner, Joe Simpson,^[24] down to base camp, found himself in a situation in

which he had to either cut the lowering rope tethering his partner, almost assuredly killing him, or risk also dying himself (unbelievably, Simpson survived):

I couldn't help him, and it occurred to me that in all likelihood he would fall to his death. I wasn't disturbed by the thought. In a way I hoped he would fall. I knew I couldn't leave him while he was still fighting for it, but I had no idea how I might help him. I could get down. If I tried to get him down I might die with him. It didn't frighten me. It just seemed a waste. It would be pointless.... The knife! The thought came out of nowhere. Of course, the knife. Be quick, come on, get it.... I reached down again, and this time I touched the blade to the rope. It needed no pressure. The taut rope exploded at the touch of the blade, and I flew backwards into the seat as the pulling strain vanished.... I was alive, and for the moment that was all I could think about.... There was no guilt, not even sorrow.... I was actually pleased that I had been strong enough to cut the rope. There had been nothing else left to me, and so I had gone ahead with it. I had done it.... I was alive because I had held everything together right up to the last moment. It had been executed calmly.... I should feel guilty. I don't. I did right.

In another example, a diver may surface and suffer from an air embolism. Review of the ethical considerations in wilderness medicine's ethical triangle, it is found that both medical indications and possibly the patient (autonomy) influence the decision to transport the victim more rapidly to a recompression chamber. This example demonstrates again that in the wilderness setting, security factors are primary in making ethical decisions. Unless the safety of the other divers can be guaranteed, the boat should not leave the area until the other divers are safely on board.

Issues of Direct Life-Threatening Situations for the Provider.

Health care providers in a wilderness setting often have the opportunity to literally rescue others, which directly supports their underlying motivation to be of help to others. However, situations arise in which providing help puts the caregiver (or the entire team) at significant risk. This has already been discussed in *Safety: Another Value Applicable to Wilderness Medicine*. Wilderness medical leaders commonly decline to enter a dangerous situation to attempt to rescue a patient. However, a more direct and powerful ethical issue arises when the caregiver must directly and explicitly sacrifice the patient for personal or team safety. (This is somewhat analogous to the difference between passive and active euthanasia.) This occurs, for example, when a helicopter hoisting a patient encounters difficulties that endanger the craft. Standard procedure is to cut the hoist line, sacrificing the patient. In the abstract, the safety of the helicopter crew (and possibly rescuers on the ground) outweighs that of the patient. Yet in reality, the conflict between safety and beneficence may not be intrinsically clear to the health care provider; an answer in favor of safety contradicts all professional education and experiences. This conflict must be resolved in advance or within a few seconds during the event if anyone is to survive. In the analogous scenario of the battlefield, the question is raised, "How many medics do you sacrifice to save one infantryman?" So too with rescuers.

Decision-Making Dilemmas

Health care decisions are generally the responsibility of the adult with decision-making capacity. If a patient lacks the ability to make these decisions, health care providers normally seek a surrogate decision maker, an advance directive, or the counsel of a bioethics committee or colleague. These resources are rarely available in the wilderness setting. Health care decisions can therefore become more problematic.

Unavailability of a Surrogate or a Family Member.

When a person needing health care in the wilderness lacks decision-making capacity because of illness or injury, the health care provider must make decisions based on knowledge of the patient's values (often from a relatively brief period of interaction), the values of the group, or the provider's own perceptions of what is in the patient's best interest. When family or close friends are present, they may act as surrogates to make decisions for the patient, but this is much less frequent in the wilderness setting than in the urban environment. The wilderness medical provider must therefore be prepared to make difficult decisions without this guidance.

Advance Directives.

To allay the problems of the absence of surrogate decision makers or knowledge about a patient's wishes, health care providers for organized expeditions, especially those in which significant risk of danger exists, may want to request that each team member complete an advance directive. However, as explained earlier, the normal forms of advance directive (durable power of attorney for health care and living will) may not suffice in the wilderness setting. Rather, a more specific directive should be used. It should detail how aggressive each individual would want the team to be in trying to extract them from a dangerous situation if the victim (1) had a reasonable chance of survival given available resources, (2) had a reasonable chance of survival but with serious physical disability, (3) had a reasonable chance of survival but with serious brain injury, or (4) had a poor chance of surviving. Any directive given by a team member would of course be tempered by the need to ensure the safety of other team members, but such a directive might give the medical provider a better idea of each team member's desires. Indeed, just discussing these scenarios with the team may be beneficial in elucidating attitudes and health care desires in the wilderness.

Some team members might want to use a durable power of attorney, naming a surrogate within the team, for use with or in place of the more specific directive.

Euthanasia.

Controversy continues to rage in society and medicine over the concept of active euthanasia (so-called mercy killing). In wilderness medicine, however, euthanasia may be less ethically problematic, although it is a very sensitive issue to discuss and a devastating event for those involved. Active euthanasia may be an ethically acceptable alternative in the rare situation when a patient will die either because he or she cannot be rescued from the wilderness environment or because the survival of group members would be jeopardized by attempting to evacuate or remain with him or her until help arrives. The seriously injured person on a high-altitude climb with inclement weather quickly approaching and the injured caver in a flooding cave are two examples. In these cases, euthanasia is based on the beneficence of relieving suffering in a doomed individual (although many in the medical profession believe that mercy killing violates professional principles), security for other members of the party (not creating more victims), and perhaps patient autonomy (although some psychiatrists might argue that by asking for death a person demonstrates a lack of decision-making capacity).^[2] Indeed, a particularly difficult situation is the psychiatric patient who cannot be made to continue out of the wilderness and who will endanger the group and himself or herself if either remains. This has happened at least once in the dual peril of war and wilderness, when British soldiers of the 111th Indian Infantry Brigade in Burma euthanized their own during World War II.^[25] In nonwar situations, however, any episodes of active wilderness euthanasia have gone unreported.

Further complicating the preceding scenarios is the question of whether such patients should be simply left to die (passive euthanasia) or more humanely killed (active euthanasia). This question should be given serious consideration, since many incidents of passive euthanasia in wilderness settings occur, especially in high-risk or remote areas. Passive euthanasia has occurred, for example, at least several times on Everest expeditions when unconscious, hypothermic climbers were left to die when conditions made it difficult or impossible to get them down.^[22] The ethical question of what is best for the injured individual almost always comes in direct conflict with other team members' lack of confidence in their (or their medical person's) prognosis and their unwillingness to implement active euthanasia. The lack of certainty about prognosis may sometimes be justified. For example, during a recent disastrous Everest expedition, a physician-climber who was left for dead (active euthanasia was not discussed among team members) survived by eventually making it back to camp on his own.

Dilemmas in Wilderness Policies

Ethical decision making plays a part in policies governing wilderness medicine. The values of beneficence and nonmaleficence make proposed and actual rules for wilderness medical practice untenable. These policies include no-rescue areas, prohibition of motorized vehicles in wilderness areas, prohibition of environmental destruction, and restriction of medical providers' roles (see How Much Authority Is Given to Nontrained Personnel?).

Motorized Vehicle Restrictions and Environmental Protection in Wilderness Areas.

A policy occasionally imposed on wilderness medical practice is that of no motorized

vehicles in designated wilderness areas. This rule has logical roots but is enforced only intermittently. When it is used to hinder rescue efforts or delay needed medical care, however, it defeats a basic purpose of society: the assurance of citizens' welfare.

A related issue is the basic tenet of wilderness travel that the environment should be left at least as pristine as it was found. Situations arise, however, when preservation of a wilderness area must be weighed against pain and suffering or life and death. Helicopter pads chopped into the forest or a new entryway blasted into a cave are only two examples. The preservation of wilderness areas is an important goal, but so is the preservation of human life and values, and these should not be overridden to reach a symbolic goal. Human life is a priority.

No-Rescue Areas.

Perhaps the most pernicious concept proposed to govern wilderness medical care is that of the "no-rescue area," into which adventurers would go with the foreknowledge that no rescue would be available.^[19] Akin to playing Russian roulette, people entering these wilderness areas would put life and limb at risk while society condoned and presumably enforced a requirement not to assist those in need. This macho concept disregards patient and societal beneficence and individual autonomy. Those familiar with advance directives, such as health care powers of attorney or living wills, know that patients in extremis often countermand their preconceived instructions. To prevent wilderness trekkers from doing the same to preserve their life contradicts basic ethical values.

Chapter 79 - The Changing Environment

James K. Mitchell

Three miles southwest of the Kremlin, not far from Moscow's Olympic Stadium, lies the Novodevichiy Cemetery, one of the most celebrated burying places in Russia. Amid ornate memorials to former leaders like Gromyko and Khrushchev, and to giants of the arts, such as Chekhov and Shostakovich, stands a white marble pedestal carrying the sculpted head of Vladimir Illich Vernadsky (1863–1945). Little known in the West, Vernadsky was a prescient observer of the emerging role of humans as makers of the global environment. It was he who first announced that we are living at a time when the power of humankind to change the earth now rivals that of geologic processes.^[6] In the past, students of natural history could regard the human life span as a mere blink of a cosmic eye that witnessed little environmental change. Today we are faced with the prospect that the planet may be fundamentally transformed by humans, perhaps within a few decades, but more probably over the space of one or two generations.

This situation has not come about all at once, or equally everywhere. On a global scale, it has gradually built up over centuries, although the local manifestations of increased human agency have been sometimes masked by other processes. For example, conversion of "natural" ecosystems to "managed" ecosystems is a dominant feature on the global scale, but in some parts of the world (especially the United States and Western Europe) managed ecosystems are also being abandoned. Such is the case in New Jersey, where hilltop nineteenth-century farmlands have largely reverted to regrowth forests.^[75]

The complications of environmental change might best be appreciated with the aid of a time machine such as the one envisioned by H.G. Wells in 1935. Imagine, for a moment, being in a mature pine forest in southern New England. What might be observed as the machine slips into the past at this location?

The surrounding landscape comes clearly into view. The pine trees shrink slowly down into youth as the years wind back, since most of today's pines trace their origin to the abandonment of farmlands at or near the turn of the century. The pines disappear entirely in the late nineteenth century and are replaced by shrubs and eventually by

grasses. By the mid-1800s the local vicinity is completely open and appears as a shifting mosaic of agricultural crops and pasture, rotated in time and space. This is the high tide of farming in New England. Thereafter, the sequence goes into reverse. By the eighteenth century, trees begin to return, connecting the remnant patches of presettlement vegetation. Gradually the forest closes in and traces of human presence fade. Little breaks the monotony, apart from occasional fires started by lightning or Native Americans clearing seasonal cultivation patches, or major windstorms that topple weaker trees. As the sixteenth century approaches, clearly the landscape is essentially similar from decade to decade.

The time traveler's dominant impression is one of change. The preceding sequence of changes has been documented by many analysts of the New England landscape.^[14A] ^[44A] ^[62] The sequence might be different elsewhere but is no less dynamic.^[80] Sometimes the changes are sudden and dramatic, and sometimes they are slow and imperceptible.^{*} Sometimes they are "natural" (e.g., storms) and sometimes they are caused by humans (e.g., example, forest clearance). For the bulk of human history, natural changes have seemed to dominate, although in fact people have been major shapers of the environment for millennia.^[13A] ^[43] ^[74A] ^[80] A casual observer of the New England landscape might conclude that the well-wooded 1990s scene is more "natural" than the cleared fields of the 1850s. However, today's scene is just as much a product of human choices as that of the nineteenth century, albeit different in composition and appearance.

In any event, deciding whether human or natural factors are responsible for a given environmental change is often difficult; both factors tend to operate interdependently ([Figure 79-1](#)). It is widely believed

*Arguments between uniformitarians (who give primacy to continuous, small-scale changes) and catastrophists (who favor change as a function of intermittent large-scale events) have continued for more than a century (Oldroyd DR: *Thinking about the earth: A history of ideas in geology*, Cambridge, 1996: 131–144). Although the uniformitarian position has dominated among earth scientists, recent evidence in support of catastrophic explanations is compelling. For example, the fossil record indicates that mass extinctions have occurred throughout the globe at many times in the past. (See Martin PS, Klein RG, editors: *Quaternary extinctions: a prehistoric revolution*, Tucson, 1984, University of Arizona Press.) Some analysts argue that the age of dinosaurs ended 65 million years ago when a massive meteor collided with the earth, perhaps striking the Gulf of Mexico near the Yucatan Peninsula. (See Alvarez W, Asaro F: What caused mass extinction? *Sci Am* 263:78, 1990.) The impact may have thrown sufficient dust into the atmosphere that solar radiation was reflected back into space, causing global temperatures to plummet. A similar although smaller effect was noted in 1992 when volcanic Mt. Pinatubo in the Philippines spewed ash, dust, and gases into the atmosphere and lowered mean global temperature by an estimated 2° C (3.6° F). (See Dutton EC, Christy JR: Solar radiative forcing at selected locations and evidence of global lower troposphere cooling following eruptions of El Chichon and Pinatubo, *Geophys Res Lett* 19:2313, 1992.)

Figure 79-1 Human and natural forces for environmental change. (Modified from Kates RW, Turner BL II, Clark WC: *The great transformation*. In Turner BL II, editor: *The earth as transformed by human action*, Cambridge, UK, 1990, Cambridge University Press.)

that people have reached a critical threshold as environmental modifiers; they are able to equal or surpass the effects of nature. Portentous changes are becoming manifest in the entire biosphere. We can at last begin to speak of a human "transformation" of the global environment.^[37] ^[75]

This chapter addresses environmental change and its human dimensions, with special attention to implications for environmental and wilderness medicine. What types of changes are likely to occur? How will they affect the natural environment, especially wilderness areas? What will be the consequences for society in general and for medical practitioners in particular? Can anything be done to improve our chances of successfully negotiating this impending time of dislocation and discontinuity? ^[46]

ISSUES OF ENVIRONMENTAL CHANGE

In recent years a number of environmental change issues have come to prominence. They include climate change, stratospheric ozone depletion, erosion of biodiversity, population growth, and burgeoning pollution. These issues affect all environments, from urban centers

Figure 79-2 Variations of mean global temperature during the past 10,000 years. Horizontal line represents present global average temperature. (Modified from Henderson-Sellers A, Robinson PJ: *Contemporary climatology*, New York, 1991, Wiley.)

to remote wilderness areas. In the discussion that follows, they are examined on a variety of scales. Although each scale is characterized by different expressions of change, all are interconnected. Local changes can aggregate to produce global effects, and global changes have many different disaggregated local effects.^[75]

Climate Change

Weather is the state of the atmosphere at any specific time. Climate is the average weather pattern at a particular location. Weather and climate are usually described by such measures as temperature, precipitation, pressure, humidity, and wind speed and direction. In most parts of the world these measures have been recorded for less than a century, so the actual historical record of direct observations is relatively brief compared with the human tenure of the earth. However, scientists are often able to extend the historical record by constructing synthetic climate data from other evidence, such as tree rings, fossils, concentrations of plankton in ocean sediments, pollen in sedimentary rocks, and isotopes of carbon and oxygen in rocks and glacial ice. For example, narrow intervals between annual growth rings in trees and thin layers of organic material in lake sediments usually indicate cold, dry conditions. Clues like these permit investigators to open a window on past climates.

[Figure 79-2](#) illustrates trends in average global temperature during the past 10,000 years. Note that the global temperature has been in flux throughout this period. Not only has weather varied about long-term average conditions, but the averages themselves have changed over time. For example, during the most recent ice age (about 10,000 years ago), average global temperatures were approximately 6° C (10.8° F) cooler than

at present.^[25] In other words, a massive environmental change (the Wisconsin ice age) was connected with a

1835

relatively small climatic change. It is worthwhile remembering that regional changes in climate may or may not parallel global changes. For example, between 2600 and 2700 years ago—roughly at the time of Socrates and Confucius—North America was colder and wetter than the continental average since the end of the Wisconsin glaciation, whereas conditions in Europe were warmer and drier. Fortunately, the climate has remained within a range that sustains life for most of the earth's history, and the changes have occurred at very slow rates over thousands to millions of years.

Currently a broad consensus exists among atmospheric scientists that global temperatures may rise significantly in coming decades.^[44] One indicator of this trend is the fact that 1998 and 1999 are widely believed to have been the two warmest years of this century. Although the global climate system is enormously complex, two factors point toward warming. First, it is known that certain greenhouse gases warm the atmosphere by trapping short-wave radiation reflected from the earth's surface when it is heated by solar radiation. Second, atmospheric concentrations of these gases, which include carbon dioxide, methane, and nitrous oxide, are steadily increasing. Normally the materials in greenhouse gases pass through long biogeochemical cycles between natural sources and natural sinks. For example, sulfur enters the atmosphere as sulfur dioxide from volcanic eruptions and washes back to the oceans in the form of mildly acid rainfall whose constituents are later incorporated into bottom sediments. Human activities can increase source loads (e.g., emissions) and reduce the absorptive capacities of natural sinks. In the case of carbon dioxide, the greenhouse gas about which there is most concern, both processes are at work simultaneously. Emissions of carbon dioxide have been increasing as energy-hungry societies burn petroleum hydrocarbons, coal, and wood. At the same time, forests that usually absorb huge amounts of atmospheric carbon dioxide continue to be cleared—although at rates that are less than predicted a decade ago.

Atmospheric scientists are currently struggling to estimate how climate might change as greenhouse gases accumulate. For this purpose they rely heavily on general circulation models (GCMs) that mathematically simulate the global climate system. The chemistry and physics of climate are complex and the models, although increasingly sophisticated, are still imperfect. Their accuracy is constrained both by the limits of current knowledge about the dynamics of the atmosphere and by the computational power of the most advanced supercomputers. They are also hedged with other limitations. For example, the present generation of GCMs is too coarse to provide more than a broad-gauge portrayal of atmospheric conditions in a lattice of regions over the earth's surface. They do not reveal storm systems that bring most of the weather to middle and high latitudes. They also do not incorporate the role of clouds as reflectors and absorbers of energy. They do

TABLE 79-1 -- Effects of Global Climate Change in Different Latitudes

INDICATOR	LATITUDINAL ZONES IMPACTED		
	LOW	MIDDLE	HIGH
Biological productivity	-	?	+
Precipitation	+	-	+
Food production	-	+	+
Malaria transmission	0	+	0

+, Increase; -, decrease; 0, no change; ?, uncertain.

not satisfactorily account for all of the carbon dioxide that is believed to have been liberated into the atmosphere through human activities. Nonetheless, many have considerable confidence in the accuracy of GCMs because of their relative success in replicating present and past climates.

The Intergovernmental Panel on Climate Change (IPCC), a joint United Nations-World Meteorological Organization committee of leading earth scientists, has synthesized existing research on climate change. Their initial conclusions pointed to a probable rise in mean global temperatures of about 0.3° C (0.54° F) per decade to 10° C (18° F) above the present value by 2025 and to 30° C (54° F) above the present value by 2100. More recently, these values have been revised downwards to take account of atmospheric aerosol feedback effects that were not included in the original (1990) calculations. The refined estimates are nonetheless still sobering. If nothing is done to alter present patterns of energy use and land use, there will be twice the preindustrial age (mid-eighteenth century) concentration of greenhouse gases in the atmosphere by 2030. This will probably raise mean global temperature about 0.2° C (0.36° F) per decade to 2° C (3.6° F) above the present value by 2100.^[27] (See also: http://www.doc.mmu.ac.uk/aric/ace/gcc_10.html.)

Although the IPCC estimates embody a consensus about global warming, the level of agreement declines as researchers attempt to forecast the resulting impacts, especially at regional and local levels. An enhanced greenhouse effect would have a greater effect on the global climate than would temperature alone. Solar radiation provides the energy that drives the climate system. The effects of a warmer atmosphere could produce a cascade of changes in many climate variables. For example, precipitation patterns might change in ways that do not mirror temperature fluctuations.

GCMs generally indicate that lower latitudes and lower elevations will be less affected by anticipated climate changes than will upper latitudes and higher elevations. However, the most recent generation of climate change impact simulations paints no simple pictures.^{[1] [56]} Different combinations of effects would be likely at different latitudes (... [Table 79-1](#)). Probably a mosaic of regional

and local changes will occur along a spectrum from strongly positive to strongly negative depending on how, when, and where they occur. For example, tropical islands might experience heavier precipitation combined with more frequent severe storms and rising sea levels. The net impacts of such changes are difficult to assess. For Malé and other heavily populated lowlying islands of the Indo-Pacific Ocean, the results could be disastrous, whereas other places, such as highstanding islands of the Caribbean, could see offsetting agricultural benefits.^[58]

More than any other factor, the rate of climate change is of concern to humans. General circulation models indicate that absolute changes in temperature will be smaller than those that have occurred at other times during the earth's history. However, the anticipated climate changes would still occur at a rate and magnitude that are unprecedented in human experience. Whereas past changes usually occurred slowly enough for plants and animals to adapt or migrate, examples of mass extinctions after rapid change exist. Many scientists fear that today and in the future, insufficient time and undeveloped areas will be available for plants and animals to make similar adjustments.

Although changes of average climate would have important long-term consequences, variations in extreme weather might produce the most immediate and significant impacts.^[45] Droughts, floods, and tropical cyclones are unusual events in today's climate. If mean climates change, changes in the frequency and severity of these extremes would probably also occur and become manifest well before the permanent shifts could be confirmed.^[24] The geographic distribution of such events would also be affected. As a result, natural hazards would be likely to pose increased risks to society. Moreover, exposure and vulnerability to extreme events would probably be exacerbated because populations at risk might respond to the new conditions on the basis of outdated information and assumptions.^[17] We might find that our previous experience prepared us to "fight the last war" rather than the new one.

Stratospheric Ozone Depletion

The stratosphere is a distinct layer of the upper atmosphere that occurs between 9 and 35 miles above the ground. It contains significant concentrations of ozone (O_3), a gas that is formed when solar radiation splits ordinary oxygen atoms.^{*} The stratospheric ozone layer absorbs most of the ultraviolet (UV) radiation from space that would otherwise damage plant and animal species.

During the 1970s and 1980s, researchers discovered that stratospheric ozone was being lost and that the ozone layer was thinning to the point of disappearance, particularly in polar regions.^{[22A] [48]} Chlorofluorocarbons (CFCs) were held to be at fault. For decades, these synthetic compounds had been manufactured in large quantities, mainly for use as aerosol propellants and refrigerants. Once CFCs escape into the atmosphere, they remain stable until reaching the stratosphere, where they decompose

under the action of UV radiation. Chlorine atoms are released and bond with ozone atoms, breaking them down into oxygen and other products. As a result, the ozone shield is weakened or removed.

If the ozone layer is sufficiently depleted, intensity of UV radiation that reaches the earth's surface could be significantly increased. This could have deleterious consequences for human populations and for plant and animal species. For humans, increased incidence of skin cancer, cataracts, and immune system suppression are three recognized effects of high UV exposure. Although humans might take precautions to protect themselves against UV radiation, such as reducing time spent outdoors or adding sun blocks, glasses, and clothes, nonhuman species may not be able to make the necessary adaptations. Serious disruption of human and agricultural systems is possible.

During their winter seasons, the Antarctic^[59] and to a lesser extent the Arctic^[42] ^[72A] ^[74] have experienced elevated levels of UV radiation. "Ozone holes" have been clearly traced to CFCs, and an international agreement, the Montreal Protocol, was reached to phase out CFC usage by 1996. Much progress has been made towards that goal, but these compounds are still being produced in some developing countries and the substitute chemicals that were introduced elsewhere may also contribute to global warming.^[38] In any case, chlorine atoms are extremely long lived in the stratosphere, perhaps persisting for 100 to 200 years. There will continue to be some potential for additional ozone depletion in the decades to come.

Erosion of Biodiversity

Loss of species or the habitats that support them is a controversial and potentially serious global problem that comes under the heading "erosion of biodiversity." Biodiversity is not an agent of change like greenhouse gas buildup or ozone depletion. It is an index against which environmental changes can be assessed.^[26] ^[72] Like climate change and ozone depletion, biodiversity has a range of dimensions from global to local.^[30] Two aspects of biodiversity that are of great importance are numbers and interconnections of species.

Estimates of the number of existing species are wide ranging because the state of knowledge about the

*Ozone also accumulates near ground level as a by-product of the photochemical modification of exhaust gases from automobiles and other sources of pollution. Concentrations of this type of ozone are sometimes reported in local news media, but the ground-level "ozone problem" should not be confused with the stratospheric one.

planet's biologic resources is both uneven and incomplete.^[73] It is estimated that the earth hosts between 5 and 15 million species. About 1.75 million of these have been named.^[40] Higher order mammals and birds in temperate ecosystems are well

documented, but insects, worms and micro-lifeforms in tropical regions^[19] are far less known. In the United States, approximately 100,000 species are recognized, ^[18] but only about one fifth of these have been surveyed to date.^[73]

Paleobiologic research indicates that the number and type of species have varied greatly over time. New species evolve through adaptive genetic mutations, whereas others perish because of competitive pressures of natural selection. Emergence and disappearance rates depend on the speed and direction of environmental change and the ability of species to adjust. What is most troubling about the recent record is the disappearance of so many species. "Between 1600 and 1994, at least 484 species of animals and 654 species of plants (mostly vertebrates and flowering plants) became extinct. The rate of extinction in groups such as birds and mammals also increased dramatically during this period. Nearly three times as many species of birds and mammals became extinct between 1810 and 1994 (112 species) as were lost between 1600 and 1810

TABLE 79-2 -- Percentage of U.S. Species at Risk

(38 species).^[64] Plant losses are presumed to have been much greater. On some oceanic islands, such as Hawaii, the disappearance of native animal species is almost total. Of 269 extinct Hawaiian species, most were either invertebrates (135) or plants (105). A majority of the rest are birds (15) and land snails (11).^[73] Commercial forestry and fishing have proved particularly injurious to biodiversity because they harvest desirable species and destroy undesirable species at the same time.^[29] Agriculture and animal husbandry also contribute to species extinctions, especially by modifying the habitats that support biota. Particular concerns have been expressed about threats to tropical forests and the near extinction of some marine species, such as the northern cod and the blue whale. However, the problem is general in scope and may be most important for the "noncelebrity" species that do not elicit much human compassion.

In the United States it is estimated that about 32% of all species are now under serious pressure, sometimes to the point of threatened extinction^[73] ([Table 79-2](#)). However, the picture varies widely among particular groups of species ([Table 79-3](#)). Denizens of freshwater ecosystems, such as shellfish, crustaceans, amphibians, and fish, are far more likely to be in danger than are flowering plants, conifers, mammals and birds. Likewise, on the U.S. mainland, loss of biodiversity is more acute in Sunbelt states and east of the Mississippi River than in states of the northern Great Plains and the northern Rocky Mountains.

For many people, the protection of threatened species is a moral imperative. For others it is a luxury. Quite apart from moral issues, the rising rate of species extinction has practical implications.^[65] For example, loss of the planet's genetic stock hampers the search for wild strains of domestic crops that are resistant to pests and diseases that plague high-yield domestic varieties.

The so-called Green Revolution, which has helped alleviate world hunger in recent decades, owes much of its success to introduction of resistant wild genetic strains into commercial agriculture.

Biodiversity is also important in the stability of global ecosystems. For example, the extent to which entire species can be eliminated from an ecosystem before it collapses is unknown. Likewise, the extent to which some nominally "wild" species may thrive under human management while others succumb is hotly debated. ^[21] Most ecologists believe that ecosystems containing a wide diversity of organisms are more resilient to change than those with few species. Regardless of the degree of resilience, biodiversity and environmental change may be connected by negative feedback relationships. Thus,

environmental change may lead to loss of biodiversity that in turn produces lowered resistance to pressures for further change.

Despite intuitive, theoretic, and case study arguments in favor of preserving biodiversity, it has been difficult to agree on standardized measures of biodiversity or its loss. Deforestation of South American rainforests is a case in point. The Amazon Basin is one of the world's premier wilderness regions and is also regarded as its most important source of biodiversity. Perhaps impelled by dramatic and widely-publicized reports of forest clearances by ranchers, homesteading farmers, and mineral firms in Brazil during the late 1980s, levels of international concern about the loss of biodiversity in Amazonia have been high. However, as in most developing countries, comprehensive and reliable data on Brazilian deforestation are difficult to secure and interpret.^[71] ^[82]

"Up to 1988, the best estimates suggest that 6–7% of the forest has been subject to at least one cutting in the past 30 years. Inclusion of secondary forest, known to have been deforested prior to 1960, but with advanced secondary forest that satellite imagery cannot differentiate from primary forest, raises the estimate by roughly 100,000 km². The latest estimates from INPE, the Brazilian Space Agency, show that deforestation had grown to about 472,000 km² in 1994, including the deforestation that occurred prior to 1960. It should be emphasized that all of this remaining 372,000 km² of deforestation (9% of the total forest) should not be interpreted as land that has been deforested and transferred to agricultural use for ever. Land that has been cleared and later abandoned will often return to forest cover, even if used for pasture, although there is some uncertainty about the length of the process of forest recovery from pasture abandonment to mature forest."^[20]

Population Growth

Human population is one of the primary driving forces behind contemporary environmental change. Beginning with the Reverend Thomas Malthus (1766–1834), many people have argued that rising populations must eventually deplete resources and degrade environments because the earth is, for all intents and purposes, a closed system.^[36] This does not mean that it will be impossible for the earth to hold additional human populations. If the record of the last four centuries provides a demographic lesson, it is that the global carrying capacity is highly elastic—up to some as yet unreached limit.^[13] Leaving aside the argument that human ingenuity can make possible the support for larger populations indefinitely, clearly from the perspective of burdens on the physical environment, how people live is more important than the number of people. All other things being equal, richer societies place heavier burdens on the physical environment than poorer ones. For example, the United States, with just 5% of the global population, consumes approximately 25% of the world's energy resources.^[14]

The global population has undergone unprecedented growth in the last several centuries ([Figure 79-3](#)). By 1800 the earth's population was approximately 1 billion. By 1920 it had doubled. Three billion was reached in 1960, and the present estimate is over 5 billion. The United Nations estimates that more than 8 billion people will be on Earth by the year 2025.^[76] Numbers may level out to between 12 and 15 billion by 2100. Most of the new growth is likely to occur in developing countries of Asia, Africa, and

Latin America ([Table 79-4](#)). The recent experience of China suggests that the process of development can itself perpetuate or increase historical rates of population growth, at least until economic conditions improve significantly.

The composition of future populations is an increasing concern of governments and individuals. In places like Japan and Eastern Europe, natural increase is now well below the rate necessary to replace existing populations, whereas in the United States, increasing numbers are maintained largely by immigration. As a result, the fraction of national populations that is more than 65 years old is growing rapidly in the more developed world. Meanwhile, increasing expertise in genetic manipulation holds out the prospect of significantly longer lifespans for populations that can afford the kind of scientific research and medical care that will make this possible. In other words, some parts of the world's population will become increasingly healthier and older, and others may remain caught in a cycle of short sickness-prone lives followed by early deaths. Quite apart from the staggering societal impacts that such a change would produce, the implications for wilderness are considerable. For those who can be assured of longer lives, the quality of life experience—including the quality of their environments—may become of foremost importance. Wilderness areas would be among the most cherished places and decisions about their future all the more portentous. Among developing countries, a different future might

obtain, perhaps dominated by intense pressure to convert all available resources into supports for survival. Although such scenarios are not difficult to envision, they carry with them a danger of indulging in stereotypical dichotomizations that ignore possibilities for a range of more nuanced outcomes.

Pollution

Unwanted by-products of production and consumption that exceed the absorptive capacity of the environment are known as *pollution*. Pollution comes in many

Figure 79-3 Global population (1700–2020). (Modified from Demeny P: *Population*. In Turner BL II, editor: *The earth as transformed by human action*, Cambridge, UK, 1990, Cambridge University Press.)

From Demeny P: Population. In Turner BL II, editor: The earth as transformed by human action, Cambridge, UK, 1990, Cambridge University Press.

forms, including solid physical materials, liquid chemical compounds, and energy (e.g., thermal pollution). Some pollutants (such as certain isotopes of plutonium) are highly toxic even in small amounts. Many materials that are beneficial in small amounts can be deleterious in large quantities. For example, phosphorus is a nutrient that limits biologic productivity in coastal and marine ecosystems. Small amounts of phosphorus can increase algal growth at the bottom of marine food chains. When larger amounts of phosphorus-rich runoff from fertilizers or septic systems enter these environments,

1840

the entire population of algae can begin a period of explosive growth ("bloom"). Extensive blooms can produce "red tides" or "brown tides."^[12] This occurs when algae prevent light from penetrating coastal waters and the decomposition of dead algae consumes dissolved oxygen. Large fish kills are a frequent result.

The preferences of people for quick and convenient disposal of pollutants into available environmental sinks (e.g., soil, streams, groundwater, oceans, atmosphere) have sometimes been validated by incomplete science. For decades in the United States and elsewhere, scientists advised policymakers that "the solution to pollution is dilution." As a result, physical and chemical wastes have been released into environments that had finite capacities for absorbing them. Once the absorptive capacities were reached, a variety of serious problems occurred. These included biologically "dead" rivers (e.g., Cleveland's Cuyahoga River), "dead" lakes (e.g., Lake Erie), and "dead" seas (e.g., the sewage sludge dumping ground in the New York Bight off the coasts of New Jersey and Long Island). Although some of these conditions can be reversed, the processes are slow, costly, contentious, and often incomplete. Also, a growing body of evidence suggests that the aggregate effect of pollution may be jeopardizing the functioning of fundamental Earth systems. Buildup of atmospheric carbon dioxide is an excellent

example of this process.

Despite a large volume of evidence, the effects of pollutants on receiving environments are not fully known.^[14] This is partly because of a lack of scientific knowledge about the normal (unpolluted) functioning of some environments, such as deep oceans and tropical forests. The sheer volume and variety of materials released into the environment and their interactions complicate the study of effects of any single pollutant. Sometimes the effects of pollutants are subtle, long delayed, and far removed from the point of origin, making it difficult to connect causes and consequences. Sometimes experts disagree about evidence of pollution impacts collected in the field and evidence acquired from laboratory experiments. Even the impacts of well-studied events, such as the *Exxon Valdez* tanker grounding, are in dispute.^{[7] [55]} Nonetheless, there is a broad consensus that the absorptive capacity of receiving media is not inexhaustible and that pollution is a growing world problem that is pushing society against the limits of environmental resilience.

IMPACTS OF ENVIRONMENTAL CHANGE ON WILDERNESS AREAS

The task of assessing environmental change impacts in wilderness areas poses particularly difficult challenges to researchers. To begin with, the term *wilderness* is rarely used by scientists. For example, readers of the voluminous reports of the Intergovernmental Panel on Climate Change^[27] might search in vain for references to wilderness impacts. Instead, there are comments about the effects of climate fluctuations on specific types of ecosystems, land covers or land uses—such as forests or nature reserves—some of which may be defined as wildernesses by different interest groups. The lack of references to wilderness in the scientific literature can be explained by the emergence of a widely shared conviction among scientists that no part of the world is now truly "natural." As one prominent ecologist puts it: "Overall, any clear dichotomy between pristine ecosystems and human-altered areas that may have existed in the past has vanished."^[78] In other words, our environments are arranged on a continuum from intensely human-constructed places, such as cities, to places where the human presence is small, intermittent, or nonexistent, such as wilderness areas. Most places show evidence of both human and natural influences.

If scientists shy away from the term *wilderness*, the same cannot be said of political leaders and the general public. Unfortunately in this larger arena there is little agreement about meanings of wilderness. "Naturalness" and "remoteness" are two commonly mentioned wilderness attributes, but measures of both can be highly subjective. Depending on the definition adopted, a wilderness area might include some of the world's most biologically productive ecosystems (e.g., tropical forests of the Brazilian Amazon Basin) together with some of its least productive (e.g., Sahara Desert) and some of those that have been thoroughly transformed by human activities (e.g., so-called urban wilderness areas, such as Portland, Oregon's Forest Park). Some analysts have attempted to cut through this Gordian knot by equating wilderness with uninhabited areas or roadless places, but neither of these indicators is comprehensive in scope when it comes to accounting for all the places that humans perceive as "wild."

In view of the potential for confusion that exists in discussions of such a complex concept, it is worthwhile to briefly consider the philosophical and evolutionary background of the term.

The notion of wilderness can be found in several of the world's earliest cultures,^[63] but formulation of a powerful philosophical and political movement that espouses the value of unaltered natural areas did not occur until the nineteenth and early twentieth centuries in the United States.^[67] Although the wilderness movement subsequently diffused elsewhere, widespread public concern for the preservation of wild lands remains a characteristically American preoccupation,^[68] perhaps because the contrast between juxtaposed human-dominated landscapes and ostensibly "natural" ones is so

apparent in the United States (e.g., California's

1841

Central Valley and Sierra Nevada mountains; Florida's Everglades and Gold Coast). Yet despite the volume of public debate about wilderness, the concept itself remains poorly defined, even in the United States.⁴⁰

However, most analysts recognize that the term refers to places that have some or all of the following three characteristics: few or no permanent resident human populations, unmanaged biogeochemical systems, and no significant modification by modern technology. Places that meet these criteria might include deep oceans, high mountains, deserts, circumpolar lands, certain oceanic islands, coastal fringes, most areas of active vulcanicity, and some of the world's great forests (e.g., taiga and tropical rainforests).⁴¹

The three criteria are best regarded as necessary but not sufficient to identify an area as wilderness. Spatial dimensions must also be taken into account. An acre of wetland that is surrounded by shopping malls would not be considered wilderness even if it is in biologically pristine condition. As a rule of thumb, a wilderness should encompass at least several square miles.

If the foregoing criteria were to be applied to the United States, they would include a great diversity of environments. Most would be marginal lands and waters, that is, beyond the boundaries of areas that are permanently settled at present and perhaps without prospects for human occupancy or use in the long term. Some protected areas within the ecumene (inhabited lands) might also qualify as wilderness because they are administered as such. However, most protected areas, such as national parks, national forests, and national recreational areas, would probably not meet all three major wilderness criteria because they are often subject to intensive management of residual plant and animal populations, as well as to human visitors.^[41]

Conversion of Wilderness

In many parts of the world, the frontiers of wilderness areas are being pushed back as land is converted to managed uses. Economic growth and population increases are the ultimate driving forces of this conversion at the global scale. At local and regional levels a variety of conversion processes are apparent. These include resource extraction industries, such as mining and forestry, agriculture, animal husbandry, tourism, and commercial and residential uses.^[50] These processes are not confined to land. They also affect freshwater and shallow water marine environments. Tourism is exerting pressure on coral reefs in Belize, Kenya, and many other countries.

Most land conversion is driven by demands for additional cropland. The highest levels of land conversion are found in developing countries with rapidly growing populations (see [Table 79-5](#)). Most of the world's prime agricultural lands have been brought under cultivation, so attention has turned to other terrains that are spatially and agriculturally

marginal. [3] Often these are wilderness areas. For example, during the last four decades, many formerly unpopulated parts of Sumatra and Borneo have been settled by government-sponsored "transmigrants" from the heavily populated Indonesian island of Java.

Land conversion may fragment existing wilderness areas by dividing them into smaller blocks. This process is well advanced in the Amazon rainforest of Brazil, where new long-distance, government-built roads bring settlers.[49] As a result, ecologic "islands" that may not be sustainable are created. Forest edge environments replace deep forest ones. The islands may be too small to retain the previous diversity of species. Governments often attempt to protect such islands by designating them as parks or wilderness areas, but this may be insufficient to prevent further changes. In any case, to be effective, such places often require intensive management of ecosystems and visitors, which defeats the objective of designating them as wilderness in the first instance. Moreover, the management actions may ripple through the ecosystems in unforeseen ways, perhaps contributing to the long-term conversion process.

Human Penetration of Wilderness Areas

Wilderness areas may be degraded without being converted to other uses. This usually occurs in one of three ways: direct impacts from increasing human presence; indirect effects of conventional industrial technologies in adjacent areas, and global effects of innovative, powerful, and often high-risk technologies.

Direct Impacts.

Few parts of the planet have not been explored by humans at ground level. Formerly remote areas are being penetrated for a variety of reasons. Canada's James Bay is slowly being altered by a huge hydropower scheme; gold prospecting has intruded into the innermost recesses of Amazonia and Angola;

*The definition included in the Wilderness Act (1964) is typically vague: "... an area where the Earth and its community of life are untrammelled by man, where man himself is a visitor who does not remain." For practical purposes, "roadless areas" are often used as an indicator of wilderness in North America. Even in a well-researched region like North America, exhaustive inventories of the species present in wilderness areas are generally lacking whereas at the global level only the approximate distribution of wilderness areas has been mapped. See the assessment of McClosky M and Spalding H: A reconnaissance-level inventory of the amount of wilderness remaining in the world, *Ambio* 18:223, 1989.

†How should formerly developed areas that have reverted to unmanaged states be classified? Many such areas can be found in Western Europe and North America (e.g., the Adirondack Mountains of New York). Often, radical differences exist between predevelopment conditions and reverted conditions. For the purposes of this discussion, such areas are considered wilderness.

REGION	VEGETATION TYPES	PERCENTAGE CHANGES

and Philippine coral reefs are subject to cyanide poisoning in pursuit of aquarium fish.^[16]

The penetration of wilderness is facilitated by modern industrial technologies, especially transportation technologies. For example, road building encourages invasion of wilderness areas for recreation, resource extraction, or other purposes. The roads themselves have environmental impacts ranging from vegetation clearance to drainage impedance, but their roles as conduits of change are even more significant. They bring new people, exotic materials, and different lifestyles to remote places. Similar inroads are made by boats and aircraft and their support facilities.

As economic gain is an important incentive for wilderness penetration, recreational and esthetic needs are also increasing visitation. Hunting and fishing have long attracted visitors to wilderness areas like the Boundary Waters Canoe Area of northern Minnesota. Such pursuits are being reinforced by "ecotourism." An increasing number of

people want to visit remote areas to appreciate pristine beauty. For many people who formerly might have sought out Yellowstone National Park and the Grand Canyon, the destinations of choice include places such as Antarctica, the high Himalaya, Amazonia, and even Siberia. The more remote the destination, the more attractive. Since most ecotourists want to visit the wilderness for only brief periods, they are whisked in and out by the most modern transportation technologies.

1843

Visits from ecotourists can change wilderness environments. Seemingly insignificant impacts that are repeated can eventually become major problems. In the Masai Mara Reserve of Kenya's Serengeti Plains, the savanna ecosystem has been altered by successive photographic safaris. Safari camps require open campfires; fuel wood is scavenged from fallen trees that would otherwise provide important ecologic niches for local plants and animals. Climbing expeditions on Mt. Everest have reported large volumes of garbage left by earlier expeditions. Decomposition is slow in the dry mountain air. The scarring of scientific sites in Antarctica by discarded refuse and vehicle tracks is well known. Even the Galapagos Islands, the one-time archetypical wilderness of Charles Darwin, are succumbing to the effects of their popularity with ecotourists. Geographers from the United States are assisting the government of Ecuador in carrying capacity studies that will be the basis for land use regulations and other development controls to limit further degradation of these internationally valued sites.

Indirect Impacts.

One of the most potent indirect impacts on wilderness areas follows the introduction (inadvertent or intentional) of nonnative species. Negative impacts have been demonstrated in the United States countless times, such as after the introduction of English sparrows, Asian gypsy moths, and Africanized "killer" bees. One recent example occurred in Glacier National Park. Pack trips within the park were curtailed because horses were introducing exotic species of grasses picked up from stable feed and passed through the digestive tract within the feces.

The problems of small islands and introduced species are legendary. Guam's experience with the brown tree snake is a good example.^[51] These snakes are native to New Guinea, but several managed to travel to Guam on airplanes in 1962. They thrived in the absence of native snakes or predators. Now Guam has as many as 30,000 brown tree snakes per square mile, and they have devastated native bird species. These snakes are beginning to show up in the Hawaiian Islands, where conditions are also favorable for colonization. The potential outcome is discouraging, although efforts to intercept the snakes are being increased.

High-Risk Technologies.

Technologic risks are an increasingly familiar threat to modern industrial society. Such

risks are usually perceived as limited to accidents in urban industrial zones like Bhopal, India, where more than 3000 people died after the accidental release of methylisocyanate gas in 1984. However, some technologies have the potential to affect very large areas at great distances from the point of origin, up to and including the entire global environment.

Biotechnology exemplifies the powerful, high-risk technologies. Through genetic engineering, new organisms are being created, primarily for agricultural purposes. Nuclear technologies are another example. Like biotechnologies, they are characterized by considerable uncertainty about potential impacts. For decades after World War II, a massive nuclear war between the United States and the Soviet Union was a serious possibility that would have brought catastrophic changes to the earth as a whole.^[60] Many military nuclear facilities were located in remote areas throughout the United States and the Soviet Union. With the end of the Cold War, this threat has diminished, although regional nuclear conflicts among lesser powers are still possible. The risks for nuclear weapons accidents still remain. Nuclear bombs have been lost at sea, improperly managed nuclear wastes have exploded in the Ural Mountains and elsewhere, and military nuclear wastes are buried on small Pacific islands, often within reach of rising sea levels. Environmental contamination around nuclear weapons manufacturing plants in the United States has been reported, and nuclear submarine propulsion systems have been discarded into the Arctic Ocean north of Russia.

Civilian uses of nuclear technologies pose risks to wilderness areas. Accidents like the explosion and fire at the Chernobyl nuclear power station have had global repercussions. Deposition of highly radioactive fallout in Arctic areas of Scandinavia demonstrates that no wilderness is immune from the effects of major nuclear accidents.^[4] The proposed placement of a repository for high-level nuclear waste in Yucca Mountain in the middle of semiarid Nevada provides another example of the connection between high-risk technologies and wilderness areas.^[11]

CONSEQUENCES OF ENVIRONMENTAL CHANGE

Research on global environmental change continues to reveal an ever greater number of connections between human and natural systems. Linkages among species in a given ecosystem, among different ecosystems, and among global biogeochemical systems have been described. Providing details about all vulnerable systems is not possible, but the range of interconnections can be illustrated by a few examples.

Scientists have recently explored the likely impacts of environmental changes on users of wilderness areas in northern Canada. In one case, rising temperatures and increased precipitation were judged likely to pose few problems for rafters and canoeists on the Mackenzie River, but accompanying forest fires were seen as much greater threats. Further north on Bathurst Island, the likelihood of increased winter snowfall combined

1844

with larger summer insect populations seemed likely to stress the existing large caribou herds to a point where hunting might have to be curtailed. Throughout the region, a shift from consumptive uses of wilderness lands (e.g., hunting) to nonconsumptive ones (e.g., scenic tourism) is a potential outcome.^[8]

Coral reefs provide a second illustration of environmental change effects. Such reefs are among the most prized wilderness ecosystems. Major reefs, such as the Great Barrier Reef of Australia and the reefs off Belize, are national and international treasures. Coral reefs cover only 0.17% of the ocean floor—an area about the size of Texas.^{[22] [67A] [78A]} However, the importance of such reefs far exceeds their physical extent. Their biologic diversity is second only to that of tropical forests; their productivity is among the highest in the world; they protect adjacent lands from wave action, nourish valuable fish populations, and generate millions of dollars in tourist revenues.

When subject to physical or chemical stress, coral "bleaches," losing color as a consequence of biochemical changes. Such stresses may be caused by fluctuations in sea level, temperature, or salinity and by pollution. Although reefs sometimes recover, bleaching often leads to death of the coral organisms and decomposition or disintegration of the reefs. In 1987, marine scientists began to notice high levels of coral bleaching and mortality off Puerto Rico. A worldwide pattern of severe coral bleaching began to emerge.^[9] Some scientists interpreted the problem as a harbinger of global warming, but it is unclear that this is the case. Nonetheless, coral reefs are vulnerable to temperature changes and sea level increases so that the threat of future damage is considerable. The best estimate now available is that sea level may rise an average of 1

m by 2100. Healthy reefs can grow upward by as much as 10 cm per decade, which may allow some reefs to adjust to rising sea level. However, if reefs are unhealthy—the evidence of bleaching suggests that many are—the rate of inundation may well exceed the coral's ability to keep pace.^[70]

Among the stresses that afflict coral reefs are coral mining for cement, dredging for navigation, coral collection for aquariums, and disruption by divers and commercial fishing. Many places also experience significant biochemical effects from coastal pollution and sediment or pollution runoff from land.

The loss of coral reefs is already significant. Estimates suggest that 5% to 10% of the world's living reefs have been destroyed by human activities. An additional 60% are thought to be at risk over the next 20 to 40 years.^[81] The consequences for society are potentially enormous. The physical protection of coastlines could be drastically reduced. The locally rich fisheries of coral islands could be diminished to the impoverished levels that typify deep oceans. Prized tourist attractions would disappear together with the revenues they generate. Opportunities for the recovery of medicinal products from reef organisms could well be lost. Finally, the genetic resources of the planet could be further eroded. These are just some of the consequences of environmental change for one type of wilderness area. Similar, perhaps larger, effects may occur elsewhere.

Environmental Change and Medical Emergencies

The causes and characteristics of many medical emergencies, and perhaps also the appropriate responses, are directly and indirectly connected with the environment in which they occur. This text contains many examples of emergency medicine challenges that are posed by environments in general and wilderness environments in particular. In some cases, an environmental agent causes a medical emergency (e.g., reptile bites, altitude sickness, wild animal attacks). In others, the environment affects the treatment of problems that are not environmentally created (e.g., wilderness trauma and surgical emergencies, hunting injuries, wilderness medical liability). In many cases, the environment serves as both agent and context. Inasmuch as the process of environmental change is global in scope, it probably will also affect emergency medicine. A number of examples follow.

Increasing human penetration of wilderness areas is steadily driving up the number of wilderness emergencies. For example, the number of climbers seeking to scale Mt. McKinley (Denali) has increased by 250% in the 20 years between 1978 and 1998.^[77] In 367 U.S. national parks, the number of search and rescue missions per million visits has climbed from 12 (1987) to 19.4 (1991). More than 5000 rescues occurred in 1991—a 78% increase over a 5-year period.^[54] The cost of a single rescue in Denali averages about \$55,000 and can exceed \$100,000; throughout the country the National Park Service spent over \$3 million on search and rescue operations in 1991. Personnel from the Park Service, the U.S. military, and volunteers may be exposed to high risk when called on to retrieve inexperienced and underequipped parties. Given the rising cost of such operations, it has been proposed that individuals who participate in risky adventures should post rescue bonds before departing into the wilderness. The combination of increasing populations and projected changes in environmental

conditions can only add to the costs and difficulties of search and rescue in wilderness areas in the future.

As settlement advances into wilderness areas, new patterns of disease are likely to form. For example, African land conversion from unmanaged wetlands to

1845

irrigated agriculture may spread the range of schistosomiasis and other water-borne diseases that are associated with drainage canals.^[66] Likewise, more people may be exposed to virulent diseases of wilderness ecosystems. Conversion of tropical forest in Africa may increase exposure to malaria carried by mosquitoes, onchocerciasis (river blindness) carried by simulium flies, and trypanosomiasis (sleeping sickness) carried by tsetse flies.

Pollutants often migrate into wilderness areas ahead of people. Air pollution is particularly mobile. Higher smokestacks have been a common means of diluting airborne pollutants, but they also allow these materials to disperse more widely. Trees and lakes in New York's Adirondack Mountains have been affected by acid rains transported from the Ohio Valley, and once-clear vistas in the Grand Canyon have been obscured by smoke from a distant coal-fired power plant. The growing severity of winter haze in the Arctic is a further problem.^{[72A] [74]} Although the Arctic is a remote area, increasing haze has been observed there for almost a century. This smog consists of many different industrial pollutants that originate far to the south in industrial areas, especially the heavy manufacturing industries of Russia. Intense cold is perhaps the most obvious environmental health hazard in the Arctic, but the buildup of industrial air pollutants may also have significant health effects, both directly on the body and indirectly through uptake by food sources in the Arctic environment.

The effect of weather on human mortality has long been a focus of biometeorologic research.^[32] A range of medical conditions that are weather related are listed in [Box 79-1](#). For example, well-established linkages exist between high summer temperatures and human mortality, especially among the elderly.^[34] Although "global warming" need not mean that all parts of the Earth will experience significantly elevated temperatures, some researchers are convinced that summer heat waves are likely to become more extreme, leading to increased mortality from this cause.^[35]

The medical effects of UV radiation have already been noted. Further erosion of the stratospheric ozone layer will undoubtedly increase the likelihood of cataracts, skin cancers, and immune system diseases. Reduction of biodiversity threatens to reduce the availability of natural materials that have medicinal value. Ethnobotanists are currently working with traditional shamans in Amazonia to catalog the medicinal properties of plants in tropical forests. Marine species are also an important source of new medicines. Scientists have recently extracted from sharks a powerful agent against bacteria, fungi, and parasites that may spur research into naturally occurring antibiotics.

The "ozone hole" is a dramatic example of the expanding capacity of humans to modify the biosphere

Modified from Kalk LS, Davis RE: Ann Assoc Am Geographers 79:44, 1989.

Usually the process is inadvertent, and wilderness areas are not singled out for attention. Sometimes, however, the very remoteness and isolation of wilderness areas encourages dramatic environmental changes. Such was the case in northwest Alaska in 1962 when the U.S. government buried 15,000 pounds of radioactive soil at Point Hope.^[52] The project was conducted by the U.S. Geological Survey acting in conjunction with the Atomic Energy Commission. The intent was to study effects of Arctic environments on radioactive isotopes. However, the burial was illegal; no public hearings were held, no markers were erected, and high-level wastes instead of low-level wastes were included. When the land was returned to the Inupiat (Eskimos) in 1971, they were not informed about the buried soils. They now attribute current elevated cancer rates to living and hunting for many years in a contaminated area. Government officials reject this view. The Point Hope case is not an isolated example. There is significant evidence that metropolitan governments have often tended to regard wilderness peripheries and their populations as dispensable when issues of national security and the welfare of metropolitan residents are at stake.^[15]

Complexity and Uncertainty

Although we have ample reason to be concerned about the environmental changes that lie ahead for wilderness areas, the subject is hedged with complexity and uncertainty.

The potential for change exists, but it is difficult to be certain how fast and how far such changes will proceed. The following two cases illustrate some of the dimensions of complexity and uncertainty.

The north (Na Pali) coast of the Hawaiian island of Kauai is representative of wilderness areas that are particularly vulnerable to climate change. It is one of the most remote and beautiful places in Hawaii, accessible only on foot, from the ocean, or by air, weather permitting. The potential for increased rainfall, storminess, and sea level rise could radically alter this wilderness. For example, increased rainfall on Kauai's massive central peak, Mount Waialeale ("the wettest place on Earth"), would make hiking on steep Na Pali access trails that are already subject to erosion and landslides difficult. The few available campsites near beaches may be eliminated by rising sea level. Sea caves that can be entered only by inflatable small powerboats during calm conditions may become inaccessible. Flash floods in Na Pali streams may erode archaeological sites, and increased moisture in the air would add to the mistiness that is now only an occasional feature of the area. Offshore waters host migrating whales that can be seen from the coast, but increased soil erosion might add to sediment loads and discourage these highly valued mammals.

As the Na Pali coast becomes increasingly hazardous to visitors on foot, larger numbers may try to enter by helicopter, with more high technology-dependent visitors and fewer low technology-dependent ones. Health and safety emergencies may increase, or the mix of emergencies may change. Already the skies over Na Pali are crowded with noisy aircraft. Several crashes and deaths occur every year. Leptospirosis from Na Pali streams is now a health hazard and may become worse. The bacteria were introduced from Southeast Asia in imported rats and pigs. In 1989 the Hawaiian Islands reported 66 cases of leptospirosis, with two resulting deaths.^[53] Despite the potential for problems, no one can yet say with certainty which, if any, of these changes will come about. Nonetheless, we see strong indications that the Na Pali coast will not remain in its present state.

A second case that illustrates the complex interplay of environmental linkages and the potential for problems is provided by the highlands of Papua New Guinea.^[2] Since the sweet potato was introduced to this area in the 1500s, it has become a staple crop for residents of remote mountain valleys. Sweet potatoes are susceptible to frost damage and tend to deplete mountain soils. In response to these constraints, villagers have developed specialized social and agricultural adjustments, including the practice of "mounding" and a complex system of resource exchanges between residents of higher elevations and lower elevations. Global warming might reduce the frost hazard, but increased precipitation or increased UV radiation could also threaten crop survival. There is currently no way of confirming the extent and severity of possible changes. However, a delicately worked out system of human ecology like this one would not remain unaffected by climate changes of the types that are anticipated in the next several decades.

WHAT MIGHT BE DONE ABOUT LIMITING ENVIRONMENTAL CHANGE?

At the beginning of this chapter it was suggested that change is a dominant, perhaps "normal," feature of the world's landscapes and environments. What is different about the present era of environmental change is the extent to which it is directly attributable to human decisions and actions. It seems unlikely that people will stand by and do nothing if the anticipated changes are perceived as threatening, especially if they are also perceived as caused by humans. However, also likely are responses to environmental change that will not be motivated solely by concern about environmental hazards, such as medical emergencies in wilderness areas. Recognition is growing throughout the world that improved environmental quality is an appropriate goal for all countries, not just developed ones. Therefore public policies toward the environment will seek both to mitigate risks such as those connected with environmental emergencies and to secure rewards by safeguarding and enhancing valued resources such as wilderness areas. Let us briefly examine some recent developments that provide clues to future public policies.

Changes in Environmental Science and Policymaking

Traditional conceptions of wilderness have emphasized the value of nature in a pristine condition, a condition that must be protected and preserved against human modifications. As argued herein, such a view does not square with the vast bulk of scientific knowledge that recognizes the pervasiveness of past human impacts on natural systems and looks towards future environments that are even more completely human-dominated. Such recognition implies that science and society might pay attention to both the restoration of degraded environments and the preservation of little disturbed ones. Environmental management policies might focus on the redevelopment of so-called brown-fields, as well as development of more familiar greenfield sites. Both of these trends are clearly detectable in practice. Restoration ecology has become a new

growth area in the environmental sciences and a new entry in the tool kit of environmental managers.^[33] The implications for wilderness areas of such a shift are considerable. On the one hand, a restored watershed is not the same as one that has never been allowed to deteriorate; neither is a hand-reared endangered species the same as one that survives without direct human help. On the other hand, it is possible

that environments might be restored to states that are functionally equivalent to wilderness. This raises fascinating—but as yet unanswerable—questions. Would the availability of human-constructed alternatives to natural areas mean a slackening in political pressures to preserve "authentic" wilderness? Would "synthetic wildernesses" contain suites of medical risks similar to other kinds of wilderness? It is simply not possible to answer these questions at present. At this point, we must interpret and manage wilderness as it now exists using a more or less conventional battery of environmental policies, programs, and initiatives.

International Actions

The first Earth Day (April 22, 1970) ushered in an important era of environmental politics in the United States.^[10] The immediate result was a striking increase in public awareness of environmental issues. The United Nations Conference on the Human Environment (Stockholm, 1972) played a similar role on the international stage. In June 1992 the United Nations Conference on Environment and Development (UNCED) marked the twentieth anniversary of the Stockholm meeting and focused attention squarely on the global environment and emerging issues of environmental change. Several significant international agreements that addressed the task of slowing environmental change were signed^[23] :

1. The Rio Declaration, a broad agreement on principles of environmental management and development
2. The Convention on Climate Change, a nonbinding treaty for industrialized and developing countries that is intended to stabilize and eventually reduce greenhouse gas emissions
3. The Convention on Biodiversity, a nonbinding treaty that establishes a framework to preserve the planet's biologic diversity and to share products derived from genetic stocks

These agreements are unusual because they broadly and directly link issues of environmental management to issues of economic development and because they took place under the glare of international publicity in a global forum. Many other international agreements are more narrowly targeted and have been signed without such fanfare. They include, for example, the Montreal Protocol on CFCs, the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), the London Dumping Convention, the World Heritage List, and various agreements about the protection of Antarctica. (CITES aims to limit trafficking in endangered species, and the Dumping Convention bans ocean disposal of wastes.)

Important as are agreements among governments, they do not constitute the only kind of international action to limit environmental change. Increasingly, nongovernmental organizations (NGOs) have become significant international policy actors. Such organizations can serve as catalysts for responsible environmental management by marshaling public support for governmental agreements. They can also take action themselves, as in the case of so-called debt-for-nature swaps.

Debt-for-nature swaps were first begun in 1987 as an innovative way to accomplish

three goals: to ease the debt burdens of developing countries, to relieve the international banking community of risky development loans, and to protect important environmental resources in debt-ridden developing countries. The mechanism operates as follows. An environmental organization purchases some of the debt of a developing country from a lien-holding institution. Since no one expects the loans to be paid back in the near future, they have lost their luster as financial instruments and can be purchased well below face value. The organization then forgives the debt in return for the debtor country's agreement to undertake environmental protection measures. These may include establishing preservation areas or deferring environmentally destructive development proposals. Debt-for-nature swaps offer one means for private organizations in the developed world to make a direct commitment to limiting unwanted environmental changes in developing countries. However, at present they fall short of being an adequate solution because the amount of debt greatly exceeds the funds that are available for buy-backs.

At the start of the twenty-first century, NGOs have begun to pioneer even more important roles in the shaping of international environmental policy. Perhaps the most potentially far-reaching of these has been the rise of broad-based coalitions of environmental, human rights and labor groups to oppose what they perceive as the hegemony of the World Trade Organization (WTO). The collapse of recent WTO meetings in Seattle (December 1999) as a result of such opposition may be the opening engagement of a much broader global campaign towards striking a better balance between a desire for open markets and a potentially stronger impetus towards environmental protection and social equity. If it develops as forecast, the movement will be complex and changeable. For example, one dimension may involve challenges to scientific protocols, standards, and labels on which many U.S. and international food safety regulations are based, as in the cases of genetically

modified foods and "mad cow disease" (spongiform bovine encephalitis). Another form may include wage rates, import quotas, and workplace environmental protections that affect the manufacture of goods in emerging Third World markets. Yet another dimension may be concerned with regulating the differential burden of greenhouse gas contributions to the global atmosphere or the constitutional rights of women and minorities.

National Actions

Because national states retain sovereignty over most of the resources within their borders, they are still the most powerful institutions for managing the global environment. For example, the U.S. government has authority to regulate pollution, manage federal lands, and control waste disposal.^[61] It also has important supervisory and review powers over the actions of state governments. Finally, it has strong indirect influence on economic factors that are deeply implicated in environmental issues.

The federal government's record of regulating environmental change in wilderness areas is complex and illustrates both the strengths and limitations of existing national level public initiatives. Approximately 4.5% of U.S. territory (104 million acres) is now included in the National Wilderness System together with about 10,700 miles of free-flowing waters that are part of the Wild and Scenic Rivers system.^[14] The purpose of these designations is to protect the relevant areas against significant modification by humans. Most of the designated wildernesses are in Alaska (60%), and the bulk of the rest are in the 11 westernmost coterminous states. Typically, a wilderness area is embedded within—and surrounded by—other

TABLE 79-6 -- National Environmental Lobbying Organizations

(Not Available)

Modified from Mitchell RC, Mertig AG, Dunlap RE: Soc Nat Resources 4:219, 1991.

types of public land, such as National Forests, National Parks, or Fish and Wildlife Reserves. Many types of human uses and human activities are permitted in the surrounding lands, which have spillover effects on the wilderness areas. Wilderness management is usually in the hands of the same agencies that administer the surrounding public lands, so management has often been a neglected stepchild of those agencies. Moreover, recent research has disclosed that the boundaries of wilderness areas are often ill-suited to permit the survival of many species that they contain. Especially in the case of migratory animals or those with large territorial ranges, what happens to them outside the wilderness is just as important as what happens within. So it makes little sense to restrict efforts for limiting environmental change to wilderness areas alone. Such efforts usually need to be applied to the private lands and waters that interdigitate with the federally managed wilderness and nonwilderness areas. In other words, holistic management principles that can be applied across governmental boundaries both within and between countries are necessary.

Together with business and industry, environmental interest groups are important nongovernmental participants in shaping U.S. environmental policy. Although direct action groups such as Greenpeace often receive publicity in the mass media, most U.S. environmental groups are political lobbying organizations. As shown in Table 79-6 (Table Not Available), membership in the major environmental organizations has increased greatly in the last two decades, especially during the Reagan presidency, when environmental issues were widely perceived to have been ignored by the U.S. government.^[47]

New environmental interest groups are also joining the fray. For example, the American Medical Association has recently formed an Environmental Health Task Force that is charged with studying harmful environmental issues such as waste disposal and ozone depletion. In addition, the National Association of Physicians for the Environment was established in April 1992 to educate physicians about environmental hazards to human

health and to develop recommendations for policymakers. ^[31]

Local Actions

One of the most popular environmental slogans of recent years is "Think Globally, Act Locally." This advice recognizes that most environmental issues need to be addressed at the grassroots level if they are to be resolved successfully. In local communities, the effects of environmental problems are most forcefully felt by individuals, and the "not in my back yard" (NIMBY) syndrome is a powerful deterrent to projects with perceived negative impacts on environment and health. ^[69] For example, opposition to creating sites for sanitary landfills has raised garbage disposal costs to the point that recycling has become an accepted part of daily activities for many Americans. In other words, the political pressure of the NIMBY syndrome has yielded significant environmental benefits.

Many different kinds of local initiatives can affect the rate at which wilderness areas change. Formal measures such as planning and zoning regulations or restrictions on the availability of public utilities are obvious examples. Less conventional approaches may also be significant. Some local communities in the United States have sought to discourage further development of fragile remote areas by informing prospective newcomers about the discomforts and drawbacks of rural living.*

Nontraditional leaders are an emerging facet of local environmental activism. In the United States, women play key leadership roles in many local environmental groups. The same is true in developing countries such as India (the Chipko Movement) and Kenya (the Greenbelt Movement).^[39] Chico Mendes, a Brazilian rubber-tapper who urged a slowdown in clearance of Amazonian forests, is another widely heralded example.

Looking across the range of environmental change issues and responses, new institutions and new philosophies of human-nature relations are emerging and are being linked to a broad range of public concerns. Issues of environmental change are now seen as intertwined with issues of economics and security. In other words, the principle of diversity in natural systems, which imparts resilience in the face of stress, is now being replicated in social systems. This is a hopeful sign at a time when environmental changes are unprecedented in rate and magnitude.

SUMMARY

Environmental change has been a characteristic feature of the earth's history, but today the changes are unprecedented in human experience. Nonetheless, people are capable of taking positive steps to confront and manage anticipated changes, despite the complexity and uncertainty. During the next several decades, wilderness areas will be particularly affected by environmental transformations that occur within and around them—perhaps more so than at any comparable period in the past. Like other sectors of society, emergency medicine and emergency medical systems will face new challenges as a result. Wilderness medical systems may need to be redesigned with particular attention to improving their flexibility.

APPENDIX: Drug Stability Information

1852

Sarah R. Williams

Stability data on drug products are derived from studies done in controlled environmental conditions. It is often difficult to ascertain whether a drug product can be safely used after storage under conditions other than those specified by the manufacturer. Stability of drug products is also related to the drug's container. If, for example, a parenteral drug packaged in a syringe for ready use is frozen, the drug may be fully potent, but the sterility of the product may be lost. Hairline cracks in the syringe may have resulted from freezing. Thus, for most of the drug products listed, stability and sterility cannot be guaranteed if products are stored under conditions other than those recommended by the manufacturers. Slight variations in packaging and formulation between brands may influence the drug's stability. The following guide should be supplemented with drug packaging information provided by the manufacturer.

Acetaminophen (Elixir, Drops, Tablets)

Store below 40° C (104° F), preferably between 15° and 30° C (59° and 86° F). Avoid freezing. Stability after freezing is unknown.

Acetaminophen with Codeine (Tablets, Elixir)

Store below 40° C (104° F), preferably between 15° and 30° C (59° and 86° F). Protect from light and moisture. Do not refrigerate or freeze.

Acetazolamide (Capsules, Tablets, Oral Solution, Injection)

Capsules and Tablets.

Store at room temperature (15° to 30° C [59° to 86° F]).

Oral Solution.

An extemporaneous oral formulation of acetazolamide 25 mg/ml in a 1:1 mixture of Ora-Sweet, Ora-Plus, or cherry syrup (diluted 1:4 with simple syrup) was stable at 94% of initial concentration for up to 60 days. Temperatures tested were 5° and 25° C (41° and 77° F), and the solutions were protected from light.

Reconstituted Powder for Injection.

Store at room temperature (15° to 30° C [59° to 86° F]). It should be used within 24 hours because it does not contain preservatives. Conservatively, it is stable for 12 hours at room temperature, but if refrigerated, it is stable for 3 days. Other research has demonstrated 90% potency for 1 week at ambient conditions, 4 weeks when refrigerated, and 8 weeks when frozen (admixed with 50 ml dextrose 5% in water [D5W], 100 ml sodium chloride [NaCl] injection, 50 ml lactated Ringer's [LR] injection, or 45 ml LR injection with 5 ml sodium bicarbonate [NaHCO₃] 5%). It should not be frozen if combined with LR or NaHCO₃ because the solution becomes turbid.

Acetic Acid Solution

Store in airtight container, between 20° and 25° C (68° and 77° F).

Albuterol (Tablets, Syrup, Inhaled Formulations)

Tablets and Syrup.

Store between 2° and 25° C (36° and 77° F). Protect tablets from excessive moisture.

Aerosol Inhaler.

Store between 15° and 30° C (59° and 86° F). Do not expose to excessive temperatures (49° C [120° F]) for more than 1 to 2 days due to explosion danger of the chlorofluorocarbons. Do not puncture or incinerate aerosol containers.

Inhalation Solution and Capsules for Inhalation.

Store between 2° and 30° C (36° and 86° F). Inhalation solution is light yellow to clear; discard if discolored.

Aloe (Gel, Ointment, Laxatives)

Topical.

Aloe vera has been used for burns, wounds, and pruritus. It consists of substances capable of producing topical anesthesia, bactericidal activity, and increased local microcirculation, but actual therapeutic capability is not clear. Lotions are for external use only.

Laxative.

Aloe acts as a stimulant laxative if taken internally due to anthraquinone glycosides. Aloe laxatives (Nature's Remedy) should be stored at room temperature. Avoid humidity and temperatures over 38° C (100° F).

Aluminum Acetate (Otic and Topical Preparations)

Otic Solution.

A clear colorless liquid comprised of acetic acid 2% in aqueous aluminum acetate solution. Store below 30° C (86° F) and avoid freezing.

Topical Solution.

Virtually indefinitely stable. Partially used irrigation solutions have high potential contamination rates. Label extemporaneously prepared solutions

1853

with a 7-day expiration date, which is consistent with the shelf life recommended by the manufacturer.

Antacids

Aluminum hydroxide gel suspension should not be frozen. Avoid freezing Milk of Magnesia. On freezing, many antacids separate into water and gel layers, which may not affect therapeutic value but may affect taste and prevent re-formation of the emulsion, even with shaking.

Aspirin (Tablets, Oral Solution, Suppositories)

Tablets.

Do not crush. Aspirin is stable in dry air but gradually hydrolyzes to salicylate and acetate and gives off a vinegar odor.

Oral Solution.

An extemporaneous oral solution can be made from a commercial buffered effervescent tablet (Alka-Seltzer) with 90 ml of water.

Suppositories.

Store between 2° and 15° C (36° and 59° F).

Atropine Injection

Store at room temperature (15° to 30° C [59° to 86° F]). Atropine sulfate 1 mg/ml solution packaged in Tubex (0.5 ml and 1 ml) has been shown to be stable for 3 months. Atropine methylnitrate 10 mg/ml solution is stable for 6 months when stored in dark bottles at room temperature.

Azithromycin (Tablets, Capsules, Suspension, Injection)

Capsules and Tablets.

Store below 30° C (86° F).

Suspension.

Single-dose packets should be stored at room temperature (5° to 30° C [41° to 86° F]) and, if reconstituted with 60 ml of water, should be used immediately. Discard multiple-dose suspension after 10 days.

Injection.

Store under 30° C (86° F). After preparation, it is stable for 24 hours at room temperature and 7 days if refrigerated.

Bacitracin (Topical, Injection)

Topical.

If in aqueous solution, must be refrigerated and is stable only 1 week due to oxidation. However, it is stable in anhydrous bases (paraffins, petrolatum, white wax, lanolin). Therefore it is stable in its common ointment form but is rapidly inactivated in water. Calamine, benzocaine, and zinc oxide have been combined with bacitracin without affecting its stability. Store topical lotion between 15° and 30° C (59° and 86° F).

Injection.

Store sterile powder for injection between 2° and 15° C (36° and 59° F), and protect from light. If refrigerated, it is stable for 1 week after reconstitution.

Bismuth Subsalicylate (Tablets, Suspension)

Store at room temperature and avoid heat greater than 40° C (104° F). Suspension should not be frozen.

Butorphanol Tartrate (Injection, Nasal Solution)

Store below 30° C (86° F). Inspect parenteral drug for particulate matter or discoloration before use (if container permits). Protect from light and do not freeze.

Calcium Chloride Injection

10% solution. Drug pH is altered significantly if frozen or exposed to temperatures over 40° C (104° F). The product should not be used if either occurs.

Cephalexin (Capsules, Tablets, Oral Suspension)

Store at room temperature (15° to 30° C [59° to 86° F]) in tight containers.

Suspension.

Stable after mixing for 2 weeks if refrigerated between 2° and 8° C (36° and 46° F).
Keep tightly closed. Shake well before using.

Ceftriazone Injection

Store sterile powder for injection at or below room temperature (25° C [77° F]). Protect from light. The color of solution ranges from light yellow to amber, depending on concentration, length of storage, and diluent. Once mixed, intramuscular (IM) and intravenous (IV) solutions remain greater than 90% potent for up to 10 days if refrigerated at 4° C (39° F). Potency is affected by diluent, concentration, and temperature. IM and IV preparations may maintain greater than 90% stability for as short as 1 to 3 days, respectively, at room temperature. If reconstituted with D5W or 0.9% NaCl solution and then frozen at -20° C (-4° F), preparations have been stable for 26 weeks in polyvinylchloride (PVC) or polyolefin containers. Thaw at room temperature before using. Unused thawed solutions should be discarded. Do not refreeze. Ceftriazone may be incompatible with other antimicrobials; do not mix.

Charcoal, Activated

Sealed aqueous suspensions may be stored for at least 1 year. Keep in well-sealed metal or glass containers.

Ciprofloxacin (Capsules, Tablets, Injection)

Protect medication from intense ultraviolet light, such as sunlight. Store tablets below 30° C (86° F). Store microcapsules and suspension diluent below 25° C (77° F), but do not freeze.

Injection.

Store between 5° and 25° C (41° and 77° F) and IV infusion between 5° and 30° C (41° and 86° F). Avoid temperatures over 40° C (104° F). When medication

1854

is diluted for injection, it is stable for 2 weeks at room temperature, below 30° C (86° F) or when refrigerated between 2° and 8° C (36° and 46° F). Do not freeze.

Exposure to excessive sunlight may cause phototoxicity in persons on this medication.

Cyclopentolate Hydrochloride Ophthalmic Solution

Store between 15° and 30° C (59° and 86° F) in airtight containers.

DEET-Containing (Diethyl Methylbenzamide) Insect Repellents

DEET is the best all-purpose insect repellent. It is colorless and has a faint pleasant odor, is practically insoluble in water, but is miscible with alcohol. Store in airtight containers. DEET may be toxic internally. Do not store near fire or open flame. Avoid contact with plastic or rayon. If in a propellant can, avoid temperatures of 49° to 54° C (120° to 130° F) due to explosion danger.

Dermabond (2-Octyl Cyanoacrylate) Topical Skin Adhesive

Should be used immediately after crushing the glass ampule, since it will not flow freely after a few minutes. Store below 30° C (86° F), away from moisture and direct heat.

Dexamethasone Injection

4 mg/ml injection. A clear colorless to light yellow solution that is sensitive to light and extremes of temperature. Do not store at high temperature for long periods. It maintains full potency for 6 months up to 40° C (104° F) and up to 3 months at 50° C (122° F). Do not use after freezing.

Dextroamphetamine (Tablets, Elixir, Capsules)

Tablets.

Store in well-sealed containers.

Elixir and Extended-Release Capsules.

Store in tight, light-resistant containers, below 40° C (104° F), preferably at 15° to 30° C (59° to 86° F). Do not freeze elixir.

Dextrose (Oral, Injection)

Oral.

Store in well-filled airtight containers.

Injection.

Store 50% parenteral dextrose below 25° C (77° F). Do not freeze or expose to extreme heat. Do not use if cloudy. Discard unused portions.

Diazepam (Injection, Capsules, Tablets)

Protect from light, and store at a room temperature less than 40° C (104° F), preferably 15° to 30° C (59° to 86° F). Avoid freezing. When frozen, diazepam tends to flocculate and precipitate. Reheat with warm water; if no precipitate is visible, the product may be used.

Digoxin Injection

Digoxin has been shown to be stable at room temperature for 3 months in Tubex cartridges. Protect from light, and store between 15° and 25° C (59° and 77° F). Use diluted injection immediately. This product is compatible with most IV infusion fluids.

Diltiazem (Capsules, Oral Solution, Injection)

Capsules.

Store at room temperature (15° to 30° C [59° to 86° F]). Protect from excess humidity.

Oral Solution.

12 mg/ml solution prepared in Ora-Sweet, Ora-Sweet SF, or Ora-Plus or in a 1:4 mixture of cherry syrup and simple syrup was more than 92% potent for up to 60 days at either 5° or 25° C (41° or 77° F). 1 mg/ml solution prepared from dextrose, fructose, mannitol, and sorbitol (but not lactose) remained potent for a minimum of 50 days at 25° C (77° F).

IV Solution.

Should be preferably stored between 2° and 8° C (36° and 46° F), without freezing, but may be stored at room temperature for up to 1 month and then discarded.

Diphenhydramine (Tablets, Elixir, Injection)

Drug in tablet, elixir, and injection (10 mg/ml) form is stable after freezing. Container should be checked for cracks or leakage. Store in light-resistant container, preferably between 15° and 30° C (59° and 86° F).

Domeboro (Astringent and Otic Solutions)

Astringent Solution.

Do not cover compress or wet dressing with plastic; allow to breathe.

Otic Solution.

A clear colorless liquid. Store below 30° C (86° F). Avoid freezing.

Dopamine Hydrochloride Injection

Protect from light. Do not use if there is yellow, pink, purple, or brown discoloration of the solution, which indicates decomposition. Store at room temperature. Brief exposure to temperatures of 40° C (104° F) is tolerated, but excessive heat should be avoided. Do not freeze. Stable at least 24 hours after diluted for injection.

Doxycycline (Capsules, Tablets, Syrup, Suspension, Injection)

Oral Formulations.

Store capsules, tablets, syrup, and suspension below 30° C (86° F), preferably between 15° and 30° C (59° and 86° F). Store delayed release capsules between 15° and 25° C (59° and 77° F). Suspension is stable for 2 weeks after reconstitution at room temperature.

Injection.

1855

Frozen, reconstituted 10 mg/ml solution for injection in sterile water is stable for 8 weeks when stored at -20° C (-4° F). After thawing, excess heating is not recommended. Do not refreeze. Protect from light. The infusion should be completed within 6 to 48 hours (brand and diluent dependent) if not refrigerated.

Epinephrine Injection (Salts, Solutions)

Epinephrine darkens on exposure to light and air. Oxidation causes a color change to pink, then brown. Epinephrine should be stored at 25° C (77° F); avoid freezing. Heat above 40° C (104° F) and exposure to light may inactivate the product.

Erythromycin (Tablets, Suspensions, Topical, Injection)

Oral Formulations.

Erythromycin estolate and erythromycin ethylsuccinate (EES 200 and 400) liquid suspensions maintain their potency for 14 days at room temperature. Refrigeration maintains optimal taste. Tablets should not be crushed.

Topical.

Stable for 2 years stored between 15° and 30° C (59° and 86° F). Store pledgets between 15° and 30° C (59° and 86° F) and ointment under 27° C (81° F). Gel should also be stored at room temperature. An extemporaneous topical solution made from tablets with hydroalcoholic vehicle as a 2% solution was stable for 60 days at 25° C (77° F). A 2.7% preparation in E-Solve was stable for 4 months when refrigerated between 4° and 8° C (39° and 46° F).

Injection.

Erythromycin lactobionate injection is stable at room temperature in dry form. After reconstitution a 5% solution is stable for 2 weeks if refrigerated but should be used within 24 hours due to possible contamination. Prepared IV solution should be used within 8 hours.

Estazolam Tablets

Store below 30° C (86° F). Stable for 3 years after date of manufacture.

Fluocinolone Acetonide and Fluocinonide (Ointment, Shampoo)

Ointment.

Store in a tight container below 40° C (104° F), preferably between 15° and 30° C (59° and 86° F). Avoid freezing.

Shampoo.

Stable for 3 months after extemporaneous formulation.

Furazolidone (Tablets, Liquid)

Store in light-resistant container. Exposure to strong light may cause darkening. Do not expose to excessive heat. May crush tablets and administer in spoonful of corn syrup.

Furosemide (Oral Formulation, Injection)

Furosemide products should be stored at controlled room temperature (15° to 30° C [59° to 86° F]). Discoloration may occur when exposed to light. Do not use if discolored.

Oral Formulations.

Tablets and solutions should be stored in tightly closed light-resistant containers. Discard oral solution bottles 60 days after opening.

Injection.

Protect containers from light. May be used after refrigeration, barring evidence of cracking, leaking, or other damage to glass. All intact ampules or syringes, when returned to room temperature, should be vigorously shaken to redissolve any constituents that may have crystallized out of solution; stability should not be affected. When packaged in Tubex cartridges (2 ml of 10 mg/ml), potency was retained for 3 months at room temperature.

Gamma Benzene Hexachloride (Lotion, Shampoo)

The lotion and shampoo become thick when frozen but do not lose effect. The effect of high temperatures is unknown. Protect from light. Spray should not be exposed to temperatures below -2° C (28° F) or above 54° C (129° F).

Glucagon Injection

In powder form, glucagon should be refrigerated, but it is stable at room temperature for several weeks. When diluent is added to powder, the resulting solution may be used for up to 3 months, if refrigerated. Thawing will not affect activity. Cloudy or thick diluent should not be used. Do not use if stored at temperatures greater than 35° C (95° F) for an extended period.

Hydrocortisone (Tablets, Suspension, Topical Cream, Injection)

Oral Preparations.

Store below 40° C (104° F), preferably 15° to 30° C (59° to 86° F). Protect suspension from light and do not freeze.

Topical.

Do not refrigerate.

Injection.

Do not freeze. Only use reconstituted solutions if clear, and discard after 3 days.

Hydroxypropyl Methylcellulose Topical Ocular Solution

Store at room temperature (15° to 30° C [59° to 86° F]) in tight containers. Do not freeze.

Ibuprofen Tablets

1856

Store at room temperature (15° to 30° C [59° to 86° F]). Protect from light.

Intravenous Solutions (D5W, D5NS, etc.)

Effects of freezing these solutions are unknown. Incomplete resolubilization, especially with electrolyte solutions, seems a real danger.

Ketoconazole (Shampoo, Tablets)

Shampoo.

Should be stored at or below 25° C (77° F). Protect from light.

Oral Tablets.

Should be protected from moisture and stored at room temperature (15° to 30° C [59° to 86° F]).

Lidocaine Injection

Lidocaine 1% injection is a relatively stable drug, but excessive heat or cold decreases shelf life. It should be stored between 15° and 40° C (59° and 104° F). It may be used after thawing, provided the container is completely intact and the solution remains clear. Lidocaine with epinephrine exposed to temperatures over 40° C (104° F) for a long period should not be used due to loss of epinephrine effect.

Loperamide Hydrochloride Capsules

Store at room temperature (15° to 30° C [59° to 86° F]). Do not mix oral solution with other solvents.

Lorazepam (Tablets, Injection)

Both oral and parenteral formulations should be protected from light.

Tablets.

Should be stored at room temperature (15° to 30° C [59° to 86° F]) in tightly closed bottles.

Injection.

IM/IV formulations should be refrigerated and kept in a carton to protect from light. No potency loss occurs through IV tubing.

Mannitol Injection

5% to 25% injection is stable at higher air temperatures. Solutions of 15% or higher crystallize at lower temperatures but will resolubilize when warmed to 80° C (176° F). Sterility cannot be guaranteed if frozen.

Meperidine Hydrochloride (Injection, Oral Solutions)

Injection (100 mg/ml) may be used after thawing if the solution shows no signs of precipitation or cloudiness and if the ampules or vials show no signs of cracking or leaking. It should be stored between 15° and 30° C (59° and 86° F) and protected from light. Neither injection nor oral solutions should be frozen.

Midazolam (Injection, Oral Solution)

Midazolam appears stable over a wide temperature range.

Morphine Sulfate (Injection, Solution, Soluble Tablets)

Exposed to air, morphine sulfate loses its water; it may darken on prolonged exposure to light. Store between 15° and 30° C (59° and 86° F) and avoid freezing. Freezing does not affect potency but may create insoluble particles.

Injection.

Store in syringes or glass and protect from light. Parenteral midazolam, 2 mg/ml (hydrochloride salt) in 0.9% NaCl injection, was stable in polypropylene infusion-pump syringes at both 5° and 30° C (41° and 86° F) for 10 days. A 3 mg/ml concentration maintained at least 90% stability for 1 week when stored in disposable polypropylene syringes in 20°, 32° and 60° C (68°, 90°, and 140° F). A 40 mg/L solution in 0.9% NaCl was stable when protected from light at 21° C (70° F) over 24 hours, with no loss in glass or laminate containers and less than 2% loss in PVC bags.

Oral Solution.

2.5 mg/ml of injectable midazolam and flavored dye-free syrup maintained greater than 90% of the original concentration throughout a 56-day trial period at temperatures of 7°, 20°, or 40° C (45°, 68°, or 104° F).

Nalbuphine Hydrochloride Injection

Injection for IM, subcutaneous (SC), or IV use should be protected from light. Store at room temperature (15° to 30° C [59° to 86° F]).

Naloxone Hydrochloride Injection

Should be protected from light during storage (0.4 mg/ml). Should not be used after being frozen. Store between 15° and 30° C (59° and 86° F).

Neosporin Ointment

Store between 15° and 25° C (59° and 77° F).

Nifedipine (Capsules, Tablets, Injection)

All preparations should be protected from light.

Oral Formulations.

Protect capsules and tablets from moisture. Store capsules between 15° and 25° C (59° and 77° F) and tablets below 30° C (86° F).

Injection.

Store below 25° C (77° F). Ready-to-use infusion retains potency for only 1 hour in daylight and 6 hours in artificial light. Keep in container until absolutely ready to use.

Nitroglycerin (Sublingual Tablets, Spray, Topical, Injection)

1857

Protect from light; do not remove vials from the outer storage carton until use. Store at room temperature (15° to 30° C [59° to 86° F]), unless otherwise specified below. Protect from moisture. Do not freeze. Avoid excessive heat (40° C [104° F]).

Oral Preparations.

Keep sublingual (SL) tablets in original glass container, tightly capped. Discard cotton once removed. Store at room temperature (15° to 30° C [59° to 86° F]). Protect from moisture, heat, cold, and humidity. Discard unused SL tablets after 6 months.

Translingual spray has guaranteed potency for 4 years from the date of manufacture. Store below 50° C (122° F).

Topical Ointment.

Tube should be kept tightly closed and stored at controlled room temperature (15° to 30° C [59° to 86° F]).

Injection.

Nitroglycerin solutions (diluted in D5W or 0.9% NaCl solutions in glass containers) are stable for up to 2 days at room temperature and up to 7 days when refrigerated. Extemporaneous solutions of nitroglycerin in concentrations ranging from 0.035 to 1 mg/ml were stable in glass for up to 70 days at room temperature or 6 months when refrigerated. Brief exposure up to 40° C (104° F) does not adversely affect the potency or stability of the solution.

Norfloxacin (Tablets, Ophthalmic Solution)

Tablets.

Should be stored in tightly closed containers. Avoid temperatures above 40° C (104° F).

Ophthalmic Solution.

Should be protected from light and stored at room temperature (15° to 30° C [59° to 86° F]).

Ofloxacin (Tablets, Otic Solution, Injection)

Tablets.

Store below 30° C (86° F) in a well-closed container.

Otic Solution.

Store between 15° and 25° C (59° and 77° F).

Injection.

Protect from light, freezing, and excessive heat. Store single-use vials and premixed bottles at room temperature (15° to 30° C [59° to 86° F]). Store premixed minibags at or below 25° C (77° F); brief exposure to 40° C (104° F) will not affect it.

Penicillin GK Injection

Stable in powder form for 2 to 3 years if stored at no greater than 30° C (86° F). Higher temperatures cause decreased potency.

Phenobarbital Injection

Not stable in aqueous solutions. Do not use if there is precipitation. Protect from light.

Phenylephrine (Nasal/Ophthalmic Solutions, Injection)

Do not use if brown or if there is precipitation. Store parenteral solution below 40° C (104° F), preferably between 15° and 30° C (59° and 86° F). Protect from light and freezing.

Phenytoin (Tablets, Injection)

Oral Preparations.

Store at room temperature (15° to 30° C [59° to 86° F]). Avoid exposure to moisture and light.

Injection.

Stable if no precipitation or haziness. A precipitate may form when refrigerated or frozen but will dissolve when warmed to room temperature. A faint yellow color has no effect on potency. More stable in normal saline than in D5W. Infuse within 2 hours of mixing the solution.

Polysporin Ointment

Store between 15° and 25° C (59° and 77° F).

Potassium Permanganate Astringent Solution

Diluted form is used to clean wounds, ulcers, abscesses, and dermatoses. Use 0.1% solution in water diluted 1:10 to provide a 0.01% solution. Undiluted potassium permanganate is composed of dark-purple or near-black crystals or granular powder and is soluble in cold and boiling water. It is incompatible with iodides, reducing agents, and most organic substances and may be explosive if it contacts organic or other oxidizable substances.

Povidone-Iodine Solution

Do not heat because iodine concentration may either decrease due to interaction with dissolved oxygen or increase due to water evaporation. Store below 42° C (108° F). Do not freeze. Protect from light.

Prednisone (Tablets, Oral Solution, Suspension)

Protect from light. Store tablets under 40° C (104° F), preferably between 15° and 30° C (59° and 86° F). Store oral solution and concentrate between 15° and 30° C in a tight container. Suspension prepared using 50 mg of prednisone powder, 100 mg of sodium benzoate, and a sufficient quantity of simple syrup to bring the volume to 100 ml was stable for 12 weeks at room temperature. Shake well.

Procaine Penicillin G Injection

1858

Should be refrigerated but is stable at room temperature for 6 months. Higher temperatures increase hydrolysis and decrease potency. May be frozen and retain potency.

Prochlorperazine (Injection, Solution, Tablets, Capsules)

Store in tight, light-resistant containers. Store between 15° and 30° C (59° and 86° F) and avoid freezing. Discard discolored (nonpotent) solution.

Promethazine (Injection, Tablets, Solution, Suppositories)

Protect from light. Store oral and parenteral products between 15° and 30° C (59° and 86° F). Store suppositories between 2° and 8° C (36° and 46° F). Avoid freezing.

Pseudoephedrine, Pseudoephedrine/Tripolidine (Tablets, Capsules)

Pseudoephedrine Tablets and Capsules.

Store between 15° and 25° C (59° and 77° F) in a dry place and protect from light.
Should not be crushed.

Tripolidine.

Store between 15° and 30° C (59° and 86° F) and protect from light.

Sodium Bicarbonate Injection

Do not freeze. Do not use if product has been frozen.

Sodium Sulfacetamide (Ophthalmic Solution and Ointment)

Ophthalmic Solution.

Store in a light-resistant container in a cool place, between 8° and 15° C (46° and 59° F). Discard if solution darkens (brown color).

Ophthalmic Ointment.

Do not freeze. Store between 15° and 30° C (59° and 86° F).

Temazepam Capsules

Store in a tight, light-resistant container, between 15° and 30° C (59° and 86° F).

Tetanus Toxoid Injection

Do not use after freezing. Should be refrigerated but remains stable for months when stored at room temperature.

Tetracaine Hydrochloride Ophthalmic Solution and Topical Lidocaine/Epinephrine/Tetracaine (LET)

Ophthalmic solution.

Protect ampules from light. Refrigerate between 2° and 8° C (36° and 46° F) to prevent crystallization and oxidation. Stable for a few days at room temperature (15° to 30° C [59° to 86° F]). If returned to cool storage, stability is as labeled by the manufacturer.

Topical LET.

Anesthetic solution stored in amber glass containers is stable for 4 weeks at approximately 18° C (65° F) and for 26 weeks if refrigerated (4° C [39° F]).

Tetracycline (Tablets, Topical Solution, Injection)

Outdated products may cause renal tubular disease.

Tablets.

Store between 15° and 30° (59° and 86° F). Stable at room temperature; darkens on exposure to moist air or sunlight.

Topical.

Solution prepared with diluent from the manufacturer is stable for 2 months at room temperature.

Injection.

Reconstituted solutions are stable at room temperature for 12 hours (6 to 12 hours in D5W).

Tolnaftate Topical Antifungal

Store between 2° and 30° C (36° and 86° F). Do not freeze. May solidify at low temperatures but liquefies easily when warmed; its potency is not affected. Aerosol products are under pressure. Do not puncture or place in proximity to heat or flame.

Triazolam Tablets

Store at controlled room temperature (15° to 30° C [59° to 86° F]). Protect from light.

Trimethoprim/Sulfamethoxazole (Tablets, Suspensions, Injection)

Protect from light. Do not refrigerate.

Oral Preparations.

Store tablets and suspensions in a dry place, between either 15° and 25° C (59° and 77° F) or 15° and 30° C (59° and 86° F), depending on the formulation.

Injection.

Should be used within 4 or 6 hours (depending on dilution in D5W). Injection (16 mg/80 mg per ml) has been shown to maintain greater than 90% stability for over 60 hours when stored in polypropylene syringes. Discard if cloudy or with precipitate. Use within 24 hours if using multiple-use vial for injection.

Zinc Salts

Zinc oxide is practically insoluble in alcohol and water but dissolves in dilute mineral acids. Store zinc acetate in airtight containers and zinc chloride and sulfate in airtight nonmetallic containers. Zinc sulfate ophthalmic

1859

solutions should be stored below 40° C (104° F) in tight containers; avoid freezing.

Figure 1-1 Increasing altitude results in decrease in inspired P_{O_2} (P_{iO_2}), arterial P_{O_2} (P_{aO_2}), and arterial oxygen saturation (S_{aO_2}). Note that the difference between P_{iO_2} and P_{aO_2} narrows at high altitude because of increased ventilation and that S_{aO_2} is well maintained while awake until over 3000 m (9840 feet). (Data from Morris A: *Clinical pulmonary function tests: a manual of uniform lab procedures*, Intermountain Thoracic Society, 1984; and Sutton JR et al: *J Appl Physiol* 64:1309, 1988.)

Figure 1-2 Change in minute ventilation, (\dot{V}_E) end-tidal carbon dioxide (P_{ACO_2}), and arterial oxygen saturation (SaO_2) during 5 days' acclimatization to 4300 m (14,104 feet). (Modified from Huang SY et al: *J Appl Physiol* 56:602, 1984.)

Figure 1-3 Rahn-Otis diagram, with recent data from extreme high altitude. Note that after acclimatization, alveolar oxygen is higher because of lower alveolar carbon dioxide. Point A is average alveolar gases in unacclimatized subjects (1 hour's exposure) to 3800 m (12,464 feet). Point B is after acclimatization to 3800 m (12,464 feet). (Data from Malconian MK et al: *Aviat Space Environ Med* 64:37, 1993; Rahn H, Otis AB: *Am J Physiol* 157:445, 1949; and West JB et al: *J Appl Physiol* 55:688, 1983.)

Figure 4-1 Impulses from a recording of peripheral neurons that includes a single warm fiber and a single cold fiber. In recording **A**, a shield was periodically placed in front of and then moved away from the skin site that was innervated by the warm fiber. The discharge stops immediately when the skin is shielded from the radiation source. In recording **B**, the shield was simultaneously placed in front of the skin site innervated by both the warm fiber and the cold fiber. This caused excitation of the cold fiber and inhibition of the warm fiber. (From Hensel H, Kenshalo DR: *J Physiol [Lond]* 204:99, 1969.)

Figure 4-2 Effect of temperature on intracellular activity of three different types of hypothalamic neurons. Each vertical column represents the same neuron at the three temperatures shown. **A**, Low-slope temperature-insensitive neuron; **B**, moderate-slope temperature-insensitive neuron; **C**, warm-sensitive neuron. The thermosensitivity in each case was 0.06 (**A**), 0.5 (**B**), and 1.1 impulses $s^{-1} \text{ } ^\circ\text{C}^{-1}$ (**C**). All three types of neurons displayed depolarizing prepotentials, and action potentials occurred when the prepotentials reached threshold. As exemplified in **C**, putative postsynaptic potentials (especially IPSPs) were often observed in all neuronal types. (From Griffin JD, Kaple ML, Chow AR, Boulant JA: *J Physiol* 492:231, 1996.)

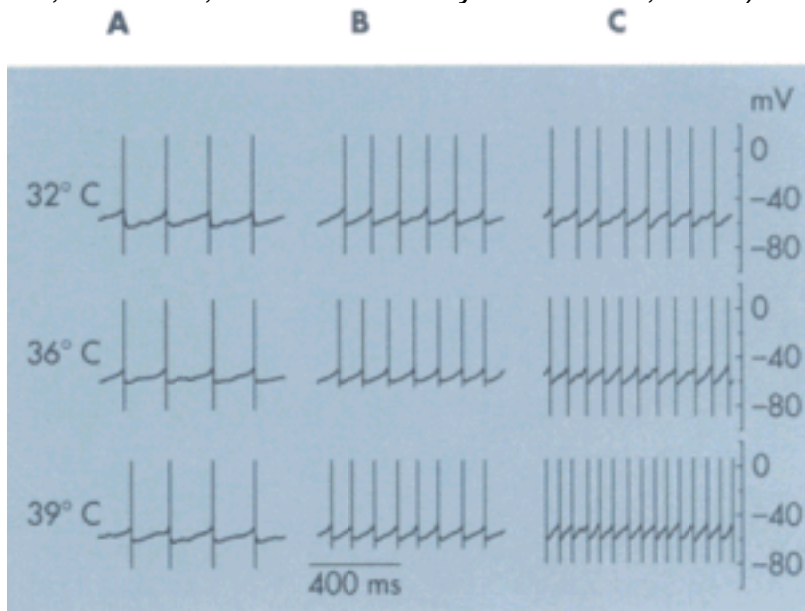

Figure 4-3 The response of a warm-sensitive preoptic nucleus-anterior hypothalamic area neuron to changes in temperature, glucose concentration, and osmotic pressure. The large downward arrows indicate changes in the media bathing the neurons. (From Boulant JA, Silva NL: *Brain Res Bull* 20:871, 1988.)

Figure 4-4 A schematic diagram denoting a suggested neuronal network to account for thermoregulation. **A**, The peripheral inputs and the site of the preoptic nucleus-anterior hypothalamic area (PO/AH)—the rectangle. **B**, Neuronal connections in the PO/AH. **C**, The firing rates of the warm-sensitive (*W*) and cold-sensitive (*C*) PO/AH neurons at different body (brain) temperatures. Synapses not shown as inhibitory are assumed to be excitatory. Details about the functioning of this system are in the text. *AC*, Anterior commissure; *CC*, corpus callosum; *Cer*, cerebellum; *C*, relays input from peripheral cold receptor; *NRM*, nucleus raphe magnus; *OC*, optic chiasm; *Pit*, pituitary; *SR*, subceruleus region; *W*, relays input from peripheral warm receptor. (Concepts and information for this figure from Boulant JA, Curras MC, Dean JB: *Neurophysiological aspects of thermoregulation*. In Wang LCH, editor: *Advances in comparative and environmental physiology*, vol 4, Berlin, 1989, Springer-Verlag; Brück K, Hinckel P: *Thermoafferent networks and their adaptive modifications*. In Schönbaum E, Lomax P, editors: *Thermoregulation: physiology and biochemistry*, New York, 1990, Pergamon Press; and Hammel HT: *Annu Rev Physiol* 30:641, 1968.)

Figure 6-5 Neutrality is the pH of water at any given temperature. At 25° C (77° F) the neutral pH of water is 7.0; at 37° C (98.6° F) it is 6.8. Ectotherm's physiologic 0.6 pH offset from neutral water progressively diminishes if the arterial blood gases are temperature corrected. After the in vitro sample is warmed in the analyzer to 37° C, do not mathematically correct the reported values to reflect the in vivo temperature.

Figure 6-6 In this patient, ventricular fibrillation developed during a code 3 transport by emergency medical services to the emergency department. Note the pronounced J wave after the QRS complex.

Figure 8-5 The relationship between subcutaneous fat thickness in 10 men and the decline in rectal temperature during 30-minute immersions in stirred water at 15° C (59° F). Skinfold thickness is mean of readings at biceps, abdomen, subscapular, and subcostal sites. T_{re} , rectal temperature. (From Keatinge WR: *Survival in cold water*, Oxford, UK, 1969, Blackwell Press.)

Figure 8-6 Factors influencing total thermal balance during increases in metabolic heat production (e.g., voluntary exercise and involuntary shivering).

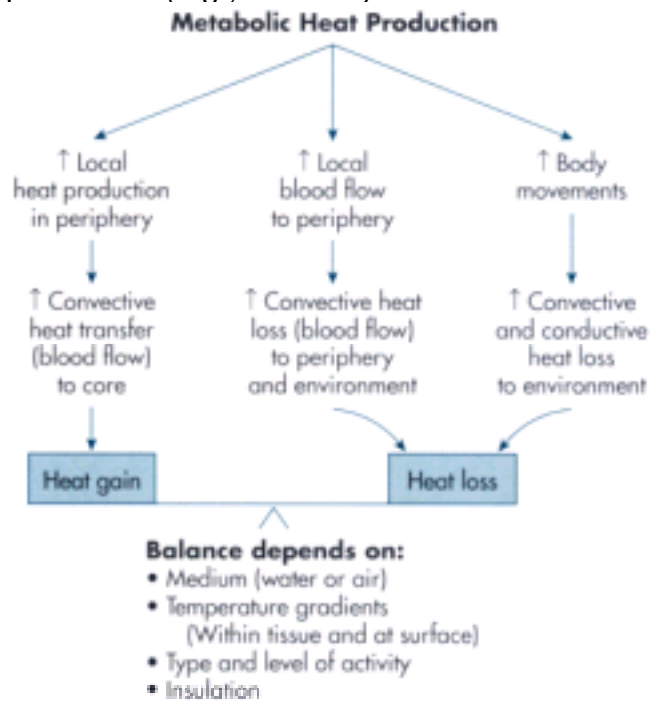

Figure 8-7 Effectiveness of shivering heat production in preventing onset of hypothermia during exposure to **A**, 10° C (50° F) air; **B**, 15° C (59° F) water; **C**, 28° C (82.4° F) water; and **D**, 8° C (46.4° F) water. *T_{es}*, esophageal temperature.

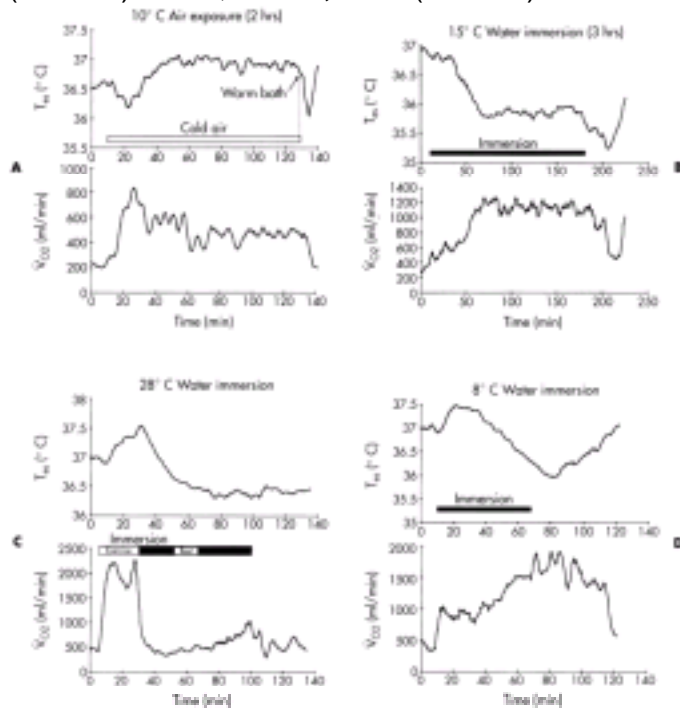

Figure 8-8 Schematic presentation of survival time at different core/brain temperatures. Bottom line, prediction based on a Q_{10} of 2. Middle line, prediction based on the Q_{10} of 3. Top line, prediction based on the Q_{10} effect plus other factors, such as changes in neurotransmitter release (i.e., glutamate and dopamine). Actual survival times are from both neurosurgical and accidental hypothermia cases. Most of these cases fall outside the range predicted based on Q_{10} alone; thus some other factors must also contribute to survival.

Figure 8-9 Schematic representation of theoretic times to cerebral injury and/or death after sudden onset of anoxia. Examples include anoxia induced by myocardial infarction at normal core temperatures, hypothermia-induced cardiac arrest during immersion hypothermia, ischemia-induced cardiac arrest after cold water near drowning (CWND), and electrically induced arrest after protective cooling for neurosurgery. Note that the times shown are representational; actual survival times may vary.

Figure 8-10 U.S. Coast Guard crew keep a hypothermia victim in a horizontal posture during rescue operations.

Figure 8-11 Immersion hypothermia victim in a semihorizontal posture during helicopter basket hoist.

Figure 8-13 Schematic illustration of the effectiveness of various rewarming techniques under shivering and nonshivering hypothermic conditions. Dashed line (at 30° C) indicates approximate core temperature at which shivering is spontaneously abolished. Ex, External rewarming.

Figure 8-14 Effect of water temperature on maximum breath-hold duration in young, physically fit human subjects (80 men and 80 women). First submersion was sudden after sitting comfortably in air at a mean temperature of 11.3° C (52.34° F). Second submersion followed 2 minutes of acclimatization to the water. The last 10 seconds of the acclimatization was accompanied by 10 seconds of hyperventilation. (From Hayward JS et al: *J Appl Physiol* 56:202, 1984.)

Figure 8-15 Predicted calm water survival time (defined as the time required to cool to 30° C [86° F]) in lightly clothed, nonexercising humans in cold water. The graph shows a line for the average expectancy and a broad zone that indicates the large amount of individual variability associated with different body size, build, fatness, physical fitness, and state of health. The zone would include approximately 95% of the variation expected for adult and teenage humans under the conditions specified. The zone would be shifted downward by physical activity (e.g., swimming) and upward slightly for heavy clothing or protective behaviors (e.g., huddling with other survivors or adopting a fetal position in the water). Specialized insulated protective clothing (e.g., survival suits, wet suits) is capable of increasing survival time from 2 to 10 times (or more) the basic duration shown here. In the zone where death from hypothermia is highly improbable, cold shock on initial immersion can potentiate death from drowning, particularly for those not wearing flotation devices. (From US Coast Guard: *Addendum to the National Search and Rescue (SAR) Manual, COMDTINST M16120.5 and COMDTINST M16120.6, 1995.*)

Figure 8-16a Antiexposure garments. **A**, Float coat. **B**, Aviation coveralls with personal flotation device.

Figure 8-16b C, Boat crew coveralls or snowmobile suit. **D**, Short wet suit worn as an undergarment. **E**, Full wet suit with personal flotation device. **F**, Insulated dry suit. **G**, Immersion suit. Garments **A** to **C** are loose-fitting, closed-cell foam-insulated wet suits; garments **D** and **E** are tight-fitting closed-cell foam-insulated wet suits; garments **F** and **G** are closed-cell foam-insulated dry suits.

Figure 8-17 A comparison of mean rectal temperature cooling rates in lean male subjects in calm vs. rough seas at 10.7° C (51.26° F). The flight suit, used as a control garment, is equivalent to light clothing. (From Steinman AM et al: *Aviat Space Environ Med* 58:550, 1987.)

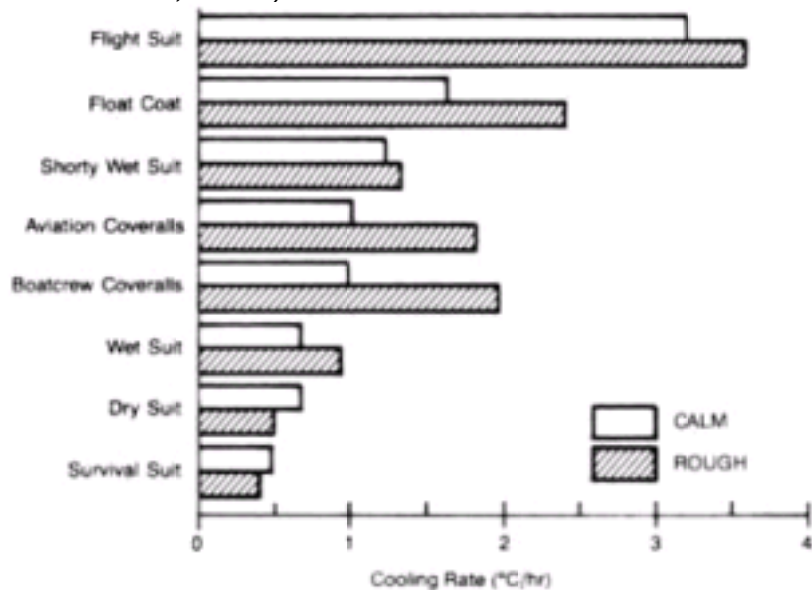

Figure 8-18 Mean linear cooling rates ($^{\circ}\text{C/hr}$) for lean men in three survival environments: *water* = immersion in 6.1°C (42.98°F) breaking waves; *boat* = 5 minutes immersion in 6.1°C water followed by exposure to 7.7°C (45.86°F) air atop an overturned boat with continuous 28- to 33-km/hr wind, water spray, and occasional breaking waves; *raft* = exposure to 7.7°C air in an open, one-person life raft, preceded by 5-minute immersion in 6.1°C water. AC, Air crew coveralls; BC, boat crew coveralls; FS, flight suit (lightweight clothing); NI, intact, non-foam-insulated "dry" coveralls; NX, NI with a 5-cm tear in the left shoulder, thus permitting water to leak into the suit and degrade its insulation; WS, wet suit. Blank squares indicate combinations of garment and environment that were not tested. (From Steinman AM, Kubilis P: *Survival at sea: the effects of protective clothing and survivor location on core and skin temperature*, USCG Rep No. CG-D-26-86, Springfield, 1986, Va, National Technical Information Service.)

Figure 8-19 Predicted survival time for individuals wearing the boatcrew coverall (see [Figure 8-16](#)) for **A**, immersion in rough seas vs. water temperature; and **B**, exposure to air at 20 km/hr under wet conditions (clothing wetness of 1550 g/m^2) vs. air temperature. The lower and upper boundaries of the shaded regions represent predictions for lean and fat individuals, respectively. (From Tikuisis P: *Aviat Space Environ Med* 68:441, 1997.)

Figure 8-20 Prediction of survival time for an average individual under various degrees of clothing protection (See [Figure 8-16](#)). **A**, Immersion in rough seas vs. water temperature; *low* = nude, flight suit, float coat, aviation coverall, boat crew coverall, torn coverall; *medium* = short wet suit, full wet suit; and *high* = dry coverall, dry suit. **B**, Exposure to air at 20 km/hr under wet conditions vs. air temperature; *low* = nude, flight suit, aviation coverall; *medium* = float coat, boat crew coverall, short wet suit, full wet suit, dry coverall, torn coverall; and *high* = dry suit. (From Tikuisis P: *Aviat Space Environ Med* 68:441, 1997.)

Figure 9-1 Polar air travel is fraught with the ever-present danger of a crash. Sudden and unpredictable weather changes, lack of navigational aids and extreme cold add to the extremely challenging flying conditions. *(Courtesy Stephen Warren.)*

Figure 9-2 Trauma and rescue teams are frequently composed of volunteers and at least one experienced and trained individual. This rescuer is practicing for possible extrication of a victim from a crevasse. (*Courtesy Betty Carlisle, MD.*)

Figure 9-3 Clothing is an important topic in polar medicine. A researcher prepares to go out for extended period in ambient temperature of -56.7°C (-70°F). Total weight of clothes 25 lbs. Notice multiple layers for each area of the body. (Courtesy Stephen Warren.)

Figure 9-4 Increased numbers of nongovernmental Antarctic expeditions have created increased awareness of the continent, as well as occasional requests for assistance. A lone traveler departs from South Pole in an attempt to do a solo traverse of Antarctica. (Courtesy Betty Carlisle, MD.)

Figure 10-1 Stress and the hypothalamic-pituitary-adrenal axis. Under basal conditions (1) the anterior pituitary secretes the immunostimulants prolactin, growth hormone, thyroid-stimulating hormone (TSH), and gonadotropin-releasing hormone, leading to the secretion of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and testosterone. Severe stress (2) acts on the paraventricular nucleus in the hypothalamus, producing CRF (3), downregulating the secretion of the immunostimulants and gonadal hormones, and (4, 5) upregulating the secretion of the immunosuppressors β -endorphin, α -melanocyte-stimulating hormone, and ACTH, the latter of which upregulates the secretion of the immunosuppressor cortisol. Stress also (6) activates the sympathetic nervous system, and catecholamines are secreted. These further downregulate the production of immunostimulants and (7) may reduce splanchnic blood flow sufficiently to cause ischemia of the intestinal vascular bed, local damage to the gut wall, and the leakage of lipopolysaccharide (LPS) into the circulation. LPS in turn (8) causes the production of the powerful immunosuppressors TNF and IL-1. TNF and IL-1 are also secreted within the hypothalamus in direct response to stress, leading to their participation (9) in a positive feedback loop, augmenting the secretion of CRF and resulting in even greater immunosuppression. NOTE: Moderate stress may have the opposite effect and increase the secretion of immunostimulants. (From Gaffin SL, Hubbar RW: *Wilderness Environ Med* 4:312, 1996.)

(From Montain SJ et al: *Int J Sports Med* 19:87–91, 1998.)

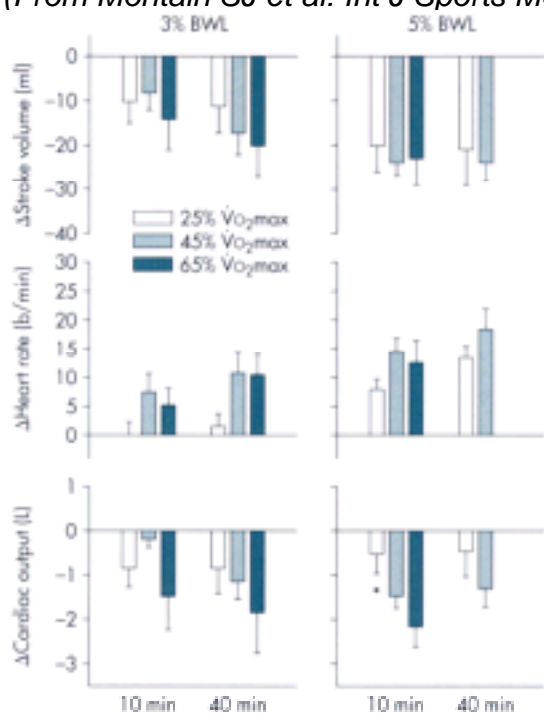

Figure 12-1 Burned ruins of the foundry in Wallace, Idaho, furnish mute testimony to the destructive force of the 1910 fires. The cottage on the terrace was the only one left standing in that part of town. (Courtesy the USDA Forest Service. Photo by R.H. McKay.)

Figure 12-2 Some lightning fires in wildernesses and national parks are now allowed to burn under observation to perpetuate natural ecosystems. (*Courtesy the USDA Forest Service.*)

Figure 12-3 These burned-over and wind-thrown trees resulted from the intense behavior of the 1910 forest fire near Falcon, Idaho. *(Courtesy the USDA Forest Service. Photo by J.B. Halm.)*

Figure 12-4 In an attempt to avoid the intense heat of this brush fire in southwestern Colorado, four firefighters took refuge in the fireline, in the foreground at point *A*. Affected by intense convective and radiant heat and dense smoke, one individual ran into the fire and died at point *B*. Another individual ran approximately 1000 feet down the ridge, where his body was found at point *C*. The third fatality was a person who remained at point *A*; he died a short time after this position was overrun by fire. The only survivor also remained in a prone position at point *A* with his face pressed to the ground. At one point he reached back and threw dirt on his burning pants legs. The survivor sustained severe burns to the back of his legs, buttocks, and arms. The deaths of the other three individuals were attributed to asphyxiation. (*Courtesy the USDA Forest Service.*)

Figure 12-5 Combustion is a process involving the combination of heat, oxygen, and fuel. An understanding of the variation of these three factors is fundamental to an understanding of fire behavior.

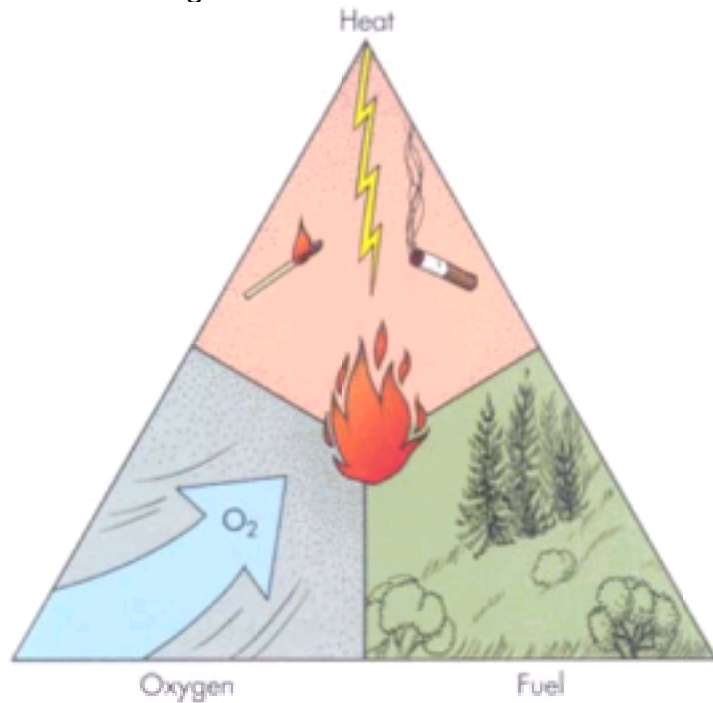

Figure 12-6 Fuels and people upslope or downwind from a fire receive more radiant heat than on the downslope or upwind side.

Figure 12-7 An aluminized fire shelter, carried in a waist pouch, is deployed by firefighters as a last resort to provide protection from radiant heat and superheated air. (Courtesy the USDA Forest Service.)

Figure 12-8 Fuels and people on the slope opposite a fire in a narrow canyon are subject to intense heat and spot fires from airborne embers.

Figure 12-9 The parts of a fire are described in terms of its left flank, right flank, head, and rear. There may also be unburned islands within the fire and spot fires ahead of the fire. The safest travel routes generally involve lateral movement on contours away from the fire's flank or movement toward the rear of the fire. Moving in front of a headfire should be avoided. The burned area inside the fire's perimeter can offer a safe haven, if the flaming perimeter can be safely penetrated by an individual.

Figure 12-10 Fire climate regions of North America, based on geographic and climatic factors, are as follows: (1) interior Alaska and the Yukon, (2) north Pacific Coast, (3) south Pacific Coast, (4) Great Basin, (5) northern Rocky Mountains, (6) southern Rocky Mountains, (7) Southwest (including adjacent Mexico), (8) Great Plains, (9) central and northwest Canada, (10) sub-Arctic and tundra, (11) Great Lakes, (12) Central States, (13) North Atlantic, (14) Southern States, and (15) Mexican central plateau. The bar graphs show the monthly and annual precipitation for a representative station in each of the fire climate regions. Months on the map indicate fire seasons. (From Schroeder MJ, Buck CC: *Fire weather, Agricultural Handbook 360, 1970, USDA Forest Service.*)

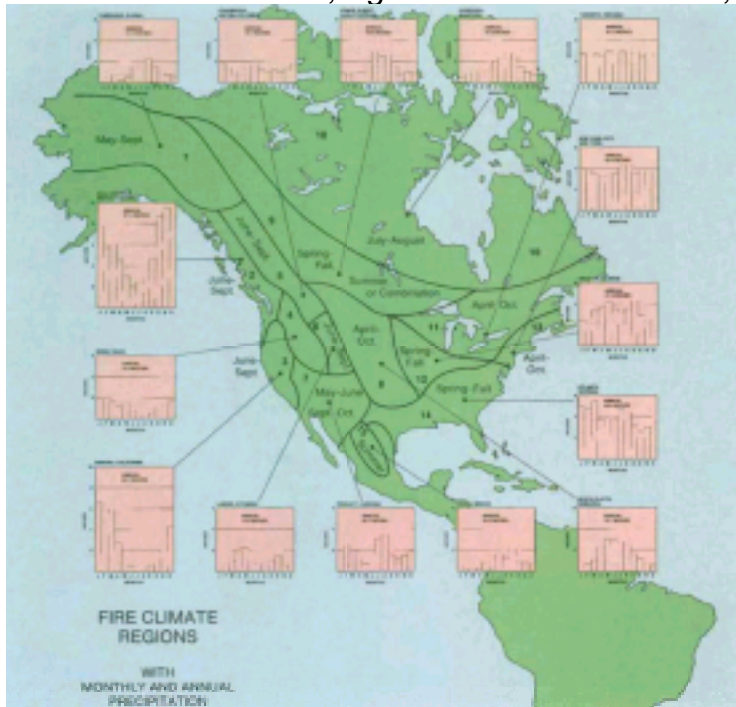

Figure 12-11 Chutes, chimneys, and box canyons created by sharp ridges provide avenues for intense updrafts (like a fire in a stove) and rapid rates of spread. People should avoid being caught above a fire under these topographic conditions.

Figure 12-12 Cross-sectional view of a wind-driven crown fire. People are most at risk on the downwind side of a wind-driven fire. This type of fire is caused by winds that increase in velocity with increasing elevation above the ground.

Figure 12-13 Cross-sectional view of a plume-dominated crown fire. People are at risk around the complete perimeter of this type of fire because the fire can spread intensely or spot in any direction. This form of crown fire develops when wind velocities are relatively low or when velocities decrease with elevation above the ground. The convection plume above this type of fire may rise to 7600 to 9100 m (25,000 to 30,000 feet) above the ground.

Figure 12-14 The annual death toll for persons who died from all causes while involved in fighting wildland fires from 1990 to 1998 (133 total deaths).

Figure 12-15 Ranger Pulaski led 42 men and 2 horses to this mine tunnel near Placer Creek in northern Idaho to seek refuge from the 1910 fire. One man who failed to get into the tunnel was burned beyond recognition. All the men in the tunnel evidently were unconscious for a period of time. Five men died inside the tunnel, apparently from suffocation. The remainder of the crew was evacuated to the hospital in Wallace, where all recovered. *(Courtesy the USDA Forest Service. Figure 19-3 Improvised cricothyroid airway device can be created by cutting barrel of syringe at 45-degree angle at its midway point. (*From Auerbach PS, Donner HJ, Weiss EA: Field guide to wilderness medicine, St Louis, 1999, Mosby.*)

Figure 19-4 Cricothyroid membrane is found in the depression between the Adam's apple (thyroid cartilage) and the cricoid cartilage. (From Auerbach PS, Donner HJ, Weiss EA: *Field guide to wilderness medicine*, St Louis, 1999, Mosby.)

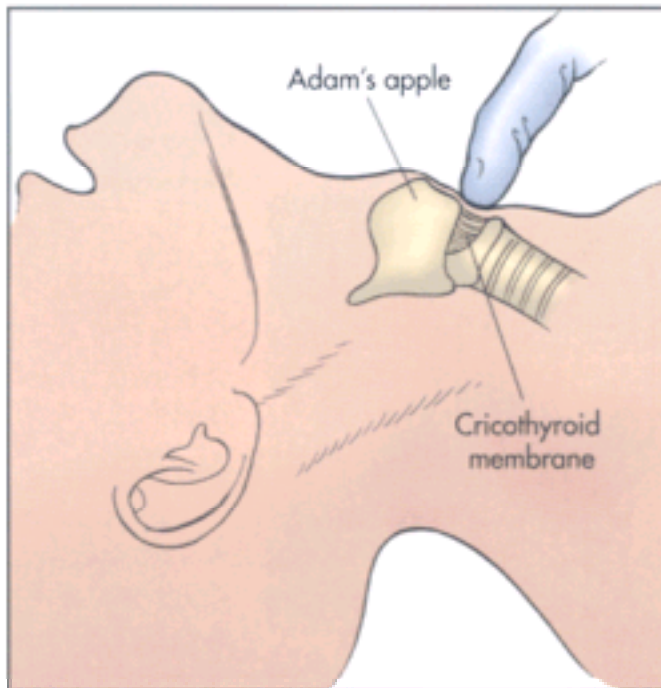

Figure 19-5 Cricothyroidotomy. **A**, Locate cricothyroid membrane and make a vertical 1-inch incision through the skin. **B**, Insert pointed end of improvised cricothyrotomy tube through the membrane. (From Auerbach PS, Donner HJ, Weiss EA: *Field guide to wilderness medicine*, St Louis, 1999, Mosby.)

Figure 19-6 Improvised cardiopulmonary resuscitation (CPR) barrier is created using a latex or nitrile glove. Make a slit in the middle finger of the glove.

Figure 19-7 Anterior epistaxis from one side of the nasal cavity can be treated using nasal packing soaked in a vasoconstrictor. Vaseline-impregnated gauze or strips of nonadherent dressing can be packed in the nose so that both ends of the gauze remain outside the nasal cavity.

Figure 19-8 Packing the back of the nose. Insert a Foley catheter into the nose and gently pass it back until it enters the back of the throat. After the tip of the catheter is in the victim's throat, carefully inflate the balloon with 10 to 12 ml of air or water from a syringe. Inflation should be done slowly and should be stopped if painful. After the balloon is inflated, gently pull the catheter back out until resistance is met.

Figure 19-9 **A**, Finger of glove is attached to needle or catheter to create flutter valve. **B**, Flutter valve allows air to escape. **C**, Flutter valve collapses to prevent air entry. (From Auerbach PS, Donner HJ, Weiss EA: *Field guide to wilderness medicine*, St Louis, 1999, Mosby.)

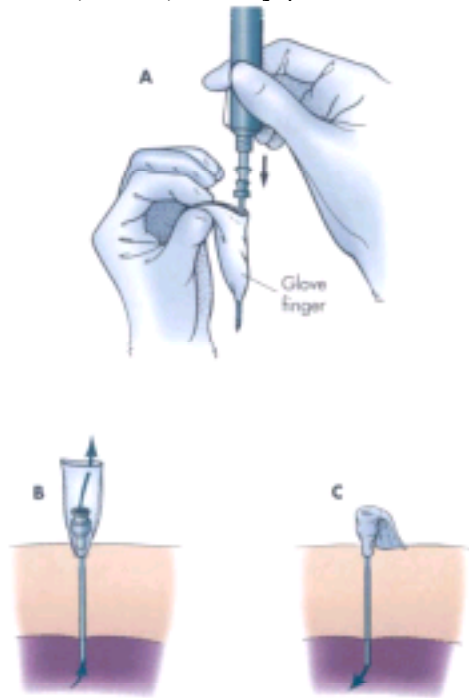

Figure 19-10 Inverted pack used as spine board. (From Auerbach PS, Donner HJ, Weiss EA: *Field guide to wilderness medicine*, St Louis, 1999, Mosby.)

Figure 19-11 Malleable aluminum splint cervical collar. **A**, Place a vertical bend in the malleable aluminum splint approximately 6 inches from one end to form a vertical pillar. Then, add bilateral flares to make the splint comfortable for the victim where it rides against the lower mandible. **B**, Place the anterior pillar securely beneath the victim's chin and wrap the remaining length of the splint around the victim's neck. **C**, Side view of cervical collar fashioned from SAM splint. **D**, Frontal view. The end is angled inferiorly to provide an adequate chin-to-chest distance.

Figure 19-12 Head immobilized on a padded shovel.

Figure 19-13 Short board using an inverted pack system. The backpack waistbelt can be seen encircling the head.

Figure 19-14 Improvised snowshoe short board. A well-padded snowshoe is prerigged with webbing and attached to the victim as shown. This system can also be used in conjunction with long board systems, such as the continuous loop system.

Figure 19-15a Continuous loop, or "mummy," litter made with a climbing rope. **A**, Rope is laid out with even **U**-shaped loops. **B**, Stiffeners such as skis and poles are placed underneath the victim to add structural rigidity. It is important to pad between the stiffeners and the victim. **C**, A sleeping bag may be used in addition to the foam pads.

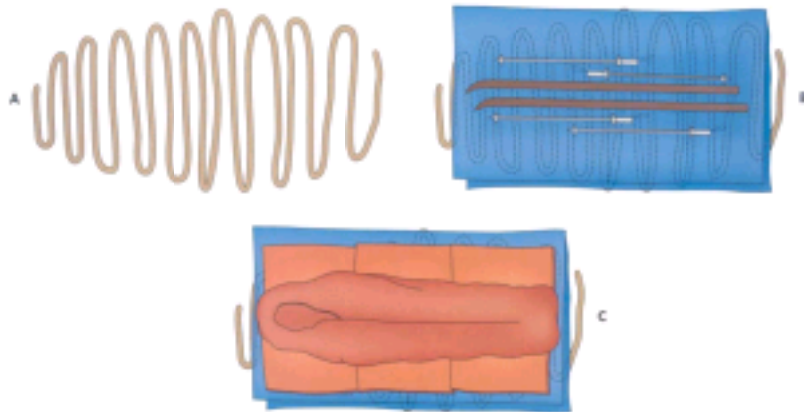

Figure 19-15 D, Loop of rope is brought over each shoulder and tied off (see text).

Figure 19-16 Backpack frame litter.

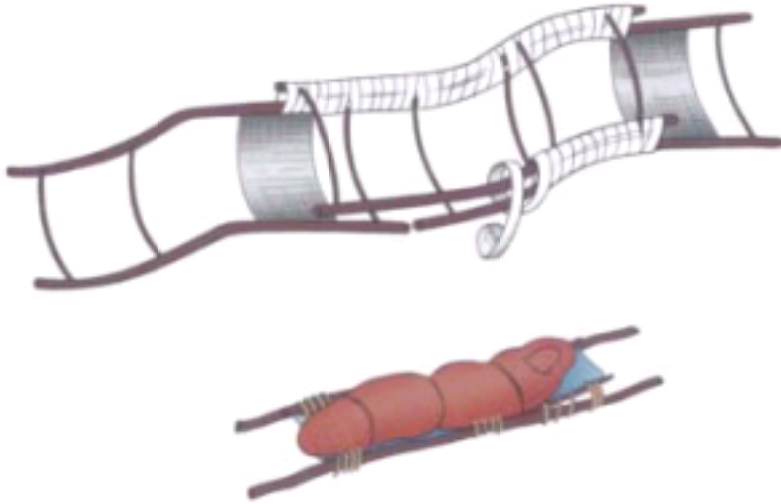

Figure 19-17 Improvised head bed.

Figure 19-18 Double runner ankle hitch. **A** and **B**, Two webbing loops (runners) are laid over and under the ankle. **C**, Completed double runner ankle hitch. The beauty of this system is its infinite adjustability. The traction can be easily centered from any angle, ensuring in-line traction.

Figure 19-19 S-configuration hitch for traction splinting.

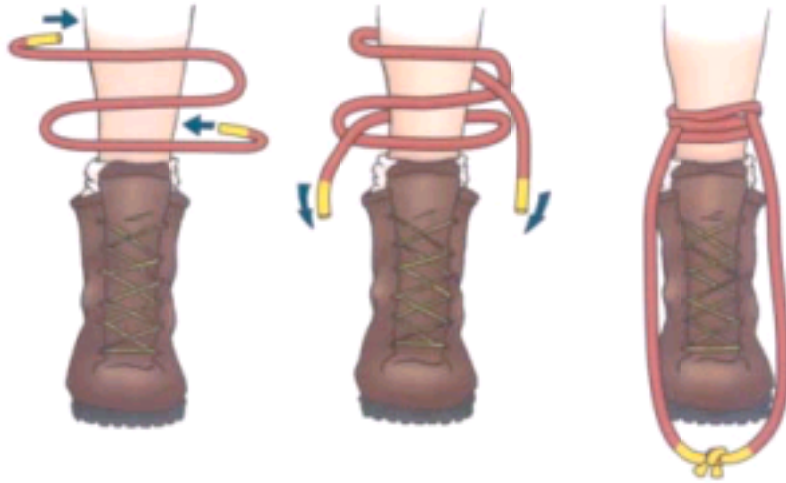

Figure 19-20 Traction using cut boot and cravat.

Figure 19-21 Buck's traction. Duct tape stirrups are added to a small foam pad that is wrapped around the leg. The entire unit is wrapped with an Ace bandage. This system helps distribute the force of the traction over a large surface area.

Figure 19-22 Double ski pole system with prefabricated cross-bar and webbing belt traction. A prefabricated drilled ski section is used to attach the ends of two ski poles. Traction is applied with a webbing belt and sliding buckle.

Figure 19-23 Single ski pole system. An adjustable telescoping ski pole is used as the rigid support. A stirrup is attached to a carabiner placed over the end of the pole. Traction is applied by elongating the ski pole while another rescuer provides manual traction on the victim's leg. Additional padding and securing follow (not shown).

Figure 19-24 Prefabricated drilled tent pole section and bent tent stake. The ski pole section is used to stabilize the end of a double ski pole traction system. This can be improvised on site if necessary. The bent tent stake serves as a distal traction anchor if a tent pole is used as the rigid support.

Figure 19-25 A Prusik knot made from a small-diameter cord is used as an adjustable distal traction anchor. Although two wraps are shown in the illustration, an additional wrap adds further security when applied to a smooth surface, such as a kayak paddle.

Figure 19-26 Two Prusik wraps are shown. Three or four wraps provide additional friction and security. If the Prusik knot slips, it can be easily taped in place.

Figure 19-27 Tent pole traction with trucker's hitch. A bent tent stake is placed into the end of the tent pole as the distal traction anchor. A simple trucker's hitch is used to provide traction.

Figure 19-28 Proximal anchor using cam lock belt. The belt is applied as shown. A ski pole is used laterally as the rigid support. Duct tape is useful for securing components. Padding is helpful but is not always necessary if the victim is wearing pants.

Figure 19-29 Life jacket proximal anchor. An inverted life jacket worn like a diaper forms a well-padded proximal anchor. A kayak paddle is rigged to the life jacket's side adjustment strap.

Figure 19-30 Folding Ensolite padding often provides better visualization of the extremity than does a circumferential wrap.

Figure 19-31 Tripod splint for unreduced anterior shoulder dislocation. This splint holds the arm in abduction when adduction is not possible. Additional padding should be added where necessary and the splint secured to the arm with an elastic wrap or other bandaging material.

Figure 19-32 Humerus splint. Used in conjunction with a sling and swath, this splint adds extra support and protection for a fractured humerus.

Figure 19-33 Forearm splint. These splints are used for the treatment of wrist or forearm fractures. The sugar-tong splint (**A**) prevents pronation and supination and has the advantage of greater security and protection than the volar splint (**B**) because of its anterior-posterior construction.

Figure 19-34 Lower leg and/or ankle splint. A sugar-tong splint can be used to immobilize fractures of the tibia, fibula, or ankle.

Figure 19-35 Posterior arm splint. This splint is cut from of a 5- to 9-gallon plastic fuel or water can (jerry can). When used with appropriate padding, this forms an excellent splint for injured or fractured elbows.

Figure 19-36 Webbing sling. An 8-foot length of 1-inch tubular or flat webbing is used to form a functional arm sling. A Crazy Creek Chair can be used to improvise both upper and lower extremity splints. Its inherent integral strapping system precludes the need for additional straps or tape.

Figure 19-37 Functional knee and lower leg immobilizer. Wrap a sleeping pad around the lower leg from the mid thigh to the foot. Fold the pad so that the top of the leg is not included in the splint. This provides better visualization of the extremity and leaves room for swelling. A full-length pad forms a very bulky splint and may need to be trimmed before rolling. Because of the conical shape of the lower extremity and the effects of gravity, foam pad lower extremity splints tend to work their way inferiorly when the victim ambulates. A simple solution is to use "duct tape suspenders" to keep the splint from migrating downward.

Figure 19-38 Techniques for pinning the arm to the shirt as an improvised sling. **A**, With a short-sleeved shirt the bottom of the shirt is folded up over the injured arm and secured to the sleeve and upper shirt. **B**, With a long-sleeved shirt or jacket the sleeved arm is simply pinned to the chest portion of the garment.

Figure 19-39 Scalp laceration closed using dental floss. (From Auerbach PS, Donner HJ, Weiss EA: *Field guide to wilderness medicine*, St Louis, 1999, Mosby.)

Figure 20-6 Examples of shotgun rounds. *Left to right*, 12-gauge slug round, empty 12-gauge plastic round, plastic 12-gauge wadding, and number six shotgun pellets.

Figure 20-7 A, A leghold trap set. **B** and **C**, A leg hold trap sprung. **D** and **E**, How to release a trap that has been sprung by standing on each end of the trap and compressing the spring.

Figure 20-8 An example of an antipersonnel mine manufactured by the Soviet Union.

Figure 20-9 Above, A directional type mine used against unarmored vehicles or personnel. Below, An improvised mine, or booby trap, manufactured from a hand grenade and materials at hand.

Figure 20-10 Arrow wound to the left side of the neck near the mandible. The shape of the wound resembles the blades of the broad-head as shown in [Figure 20-4](#) .

Figure 20-11 A, Close-range 12-gauge shotgun wound to the right side of the upper chest. The large central wound was caused by the plastic wadding, and the pellets have struck at an angle toward the shoulder. The patient was turning to the right when shot. The external appearance of the wound indicates a massive injury to the chest. **B**, Chest radiograph of the patient in **A**. No pellets have penetrated the chest, and there was no pneumothorax, pulmonary contusion, or vascular injury. The injury was totally superficial, and the patient was admitted for observation and local wound care.

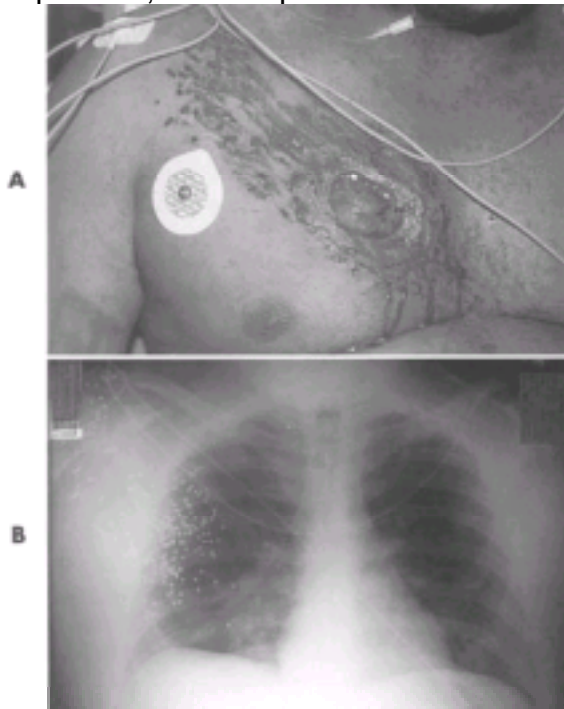

Figure 20-12 A to D, Removal of a fishhook that has penetrated a fingertip. **E**, "Press-and-yank" method of fishhook removal.

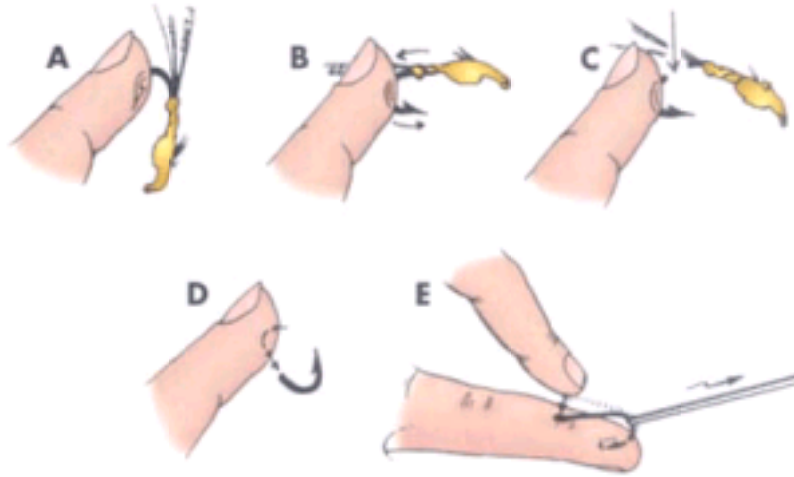

Figure 20-13 A, Male patient with a multipronged fishing spear through the foot. He said he saw something move and he speared it. **B**, Same patient with the spear being cut off in the emergency department with a bolt cutter. The patient was taken to the operating room to have the remainder of the spear removed.

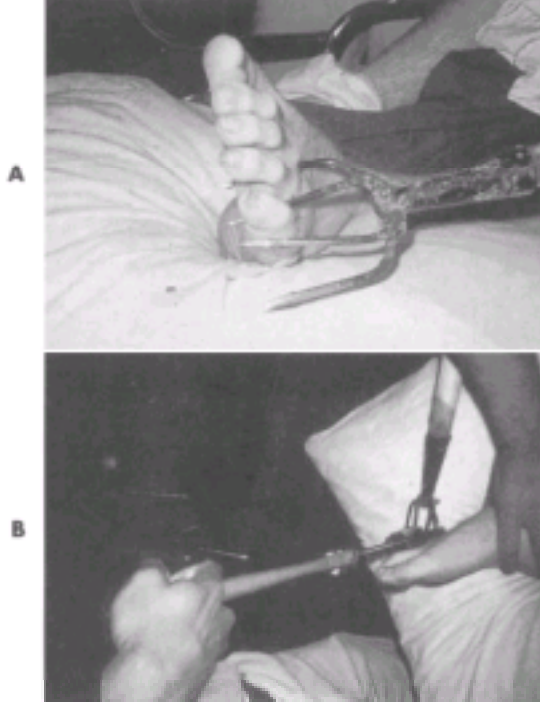

Figure 21-1 Wedge compression fracture from axial or flexion loading at the thoracolumbar junction.

Figure 21-2 Improvisation of an ankle wrap to be used for traction.

Figure 21-3 To control pain, a fractured humerus should be stabilized manually until a splint can be applied.

Figure 21-4 Nursemaid's elbow most commonly occurs when a longitudinal pull is applied to the upper extremity. Usually the forearm is pronated. There is a partial tear in the orbicular ligament, allowing it to subluxate into the radiocapitellar joint. (From Rockwood CA Jr, Wilkins KE, King RE, editors: *Fractures in children*, ed 3, Philadelphia, 1991, JB Lippincott.)

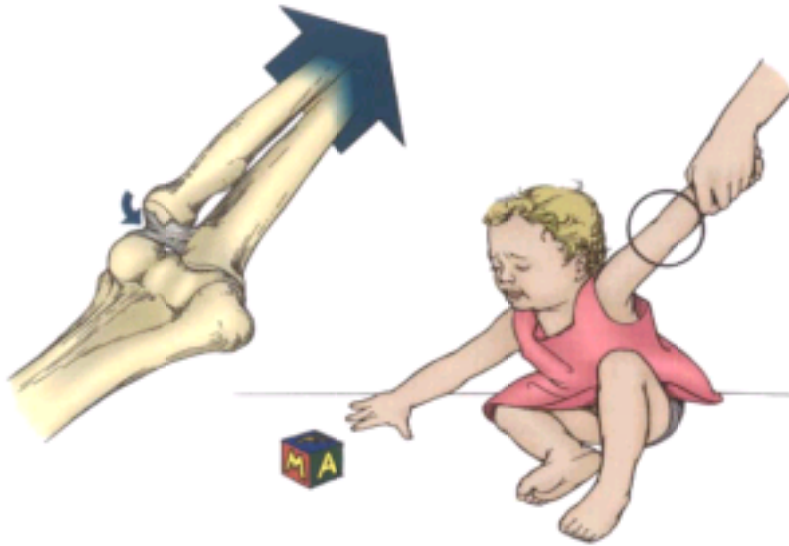

Figure 21-5 Reduction of nursemaid's elbow injury. *Left*, the forearm is supinated. *Right*, the elbow is then hyperflexed. The rescuer's thumb is placed laterally over the radial head to feel the characteristic snapping as the ligament is reduced. (From Rockwood CA Jr, Willkins KE, King RE, editors: *Fractures in children*, ed 3, Philadelphia, 1991, JB Lippincott.)

Figure 21-6 Technique for reduction of a complete fracture of the forearm. **A**, Initial fracture position. **B**, Hyperextend fracture to 100 degrees to disengage the fracture ends. **C**, Push with the thumb on the distal fragment to achieve reduction. (**B** and **C** modified from Levinthal DH: *Surg Gynecol Obstet* 790, 1933. **A** to **C** from Green N, Swiontkowski MF: *Skeletal trauma in children*, vol 3, ed 2, Philadelphia, 1998, WB Saunders.)

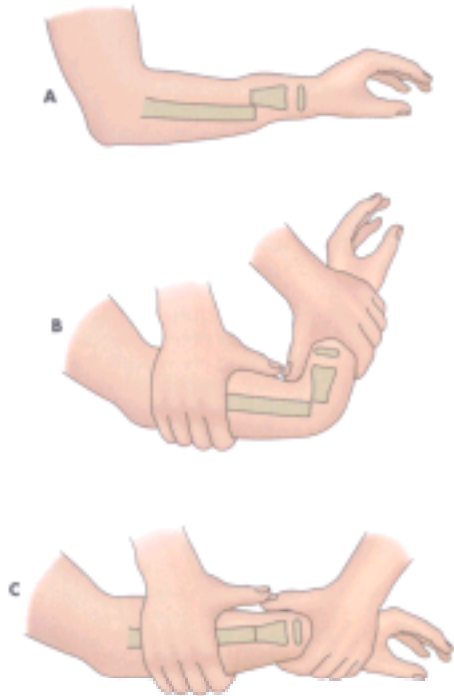

Figure 21-7 The scaphoid (navicular) bone sits in the "anatomic snuffbox" of the radial aspect of the wrist

Figure 21-8 Technique for closed reduction of the sternoclavicular joint. **A**, The patient is positioned supine with a sandbag placed between the two shoulders. Traction is then applied to the arm against countertraction in an abducted and slightly extended position. In anterior dislocation, direct pressure over the medial end of the clavicle may reduce the joint. **B**, In posterior dislocation, in addition to the traction it may be necessary to manipulate the medial end of the clavicle with the fingers to dislodge the clavicle from behind the manubrium. **C**, In a stubborn posterior dislocation, it may be necessary to sterilely prepare the medial end of the clavicle and use a towel clip to grasp around the medial clavicle to lift it back into position. (From Rockwood CA Jr, Green DP, Bucholz RW, editors: *Rockwood and Green's fractures in adults*, ed 3, Philadelphia, 1991, JB Lippincott.)

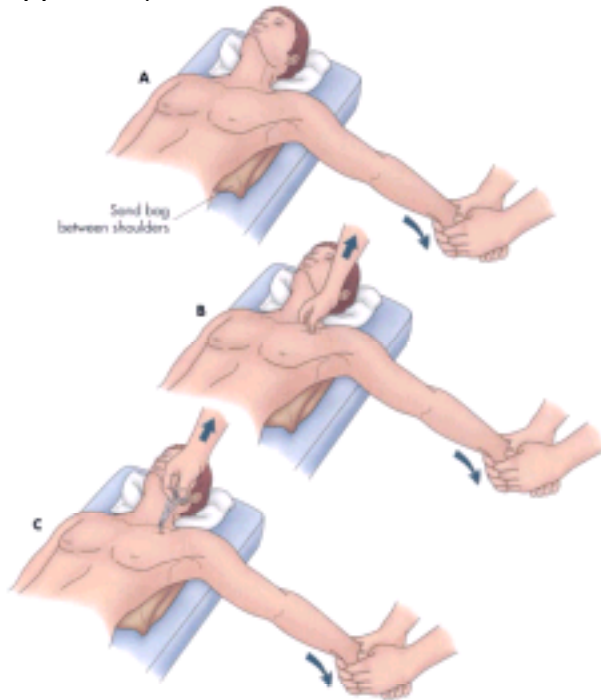

Figure 21-9 Acromioclavicular joint surgery. **A**, Normal anatomy. **B**, Second-degree injury. **C**, Third-degree injury.

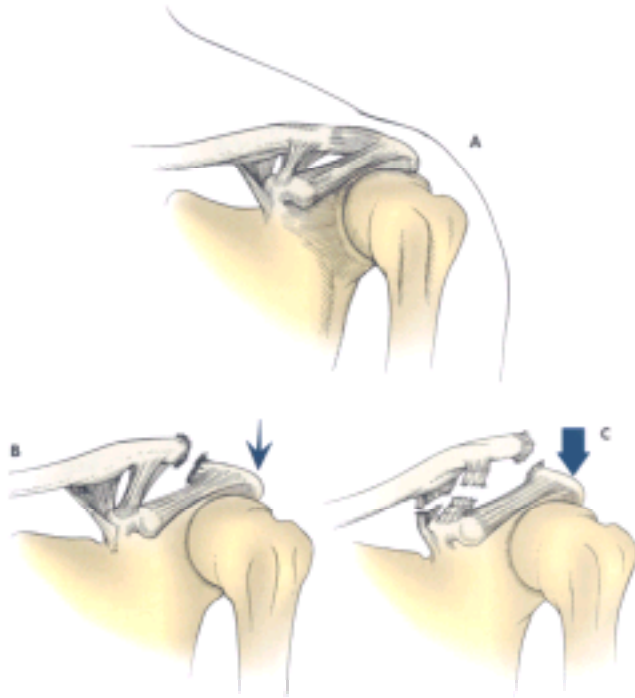

Figure 21-10 Traction and countertraction for dislocated shoulder reduction.

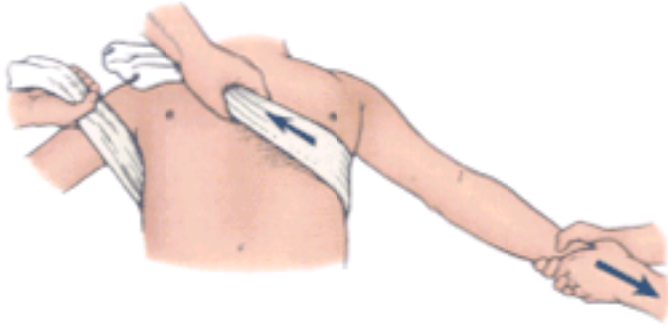

Figure 21-11 Pulling on the hanging arm to relocate a dislocated humerus. (*From Auerbach PS: Medicine for the outdoors: the essential guide to emergency medical procedures and first aid, ed 3, New York, 1999, The Lyons Press.*)

Figure 21-12 Milch technique of closed reduction of anterior glenohumeral dislocation with the patient prone. The arm can be manipulated in the same manner with the patient supine. (Redrawn from Lacey T II, Crawford HB: *J Bone Joint Surg* 34A:108, 1952. In Browner BD et al: *Skeletal trauma*, vol 2, ed 2, Philadelphia, WB Saunders, 1998.)

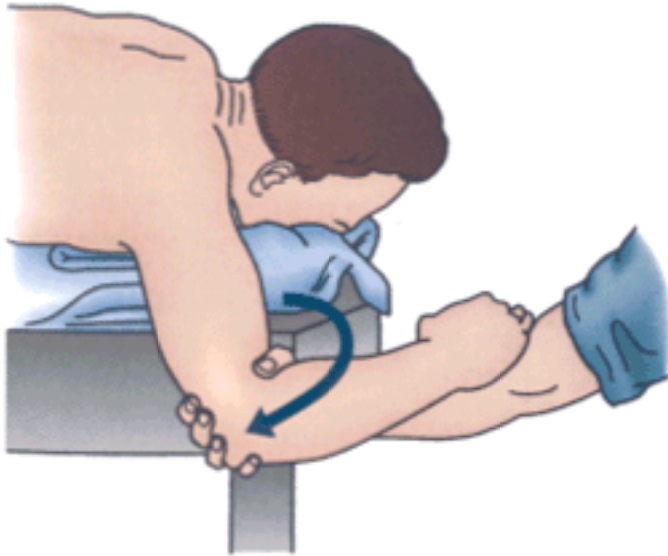

Figure 21-14 Repositioning a dislocated shoulder. Attached to the victim's forearm with a strap, rope, or sheet, the rescuer uses his body weight to apply traction, leaving his hands free to manipulate the victim's arm. A second rescuer applies countertraction, or the victim can be held motionless by fixing the chest sheet to a tree or ground stake. (From Auerbach *PS: Medicine for the outdoors: the essential guide to emergency medical procedures and first aid*, ed 3, New York, 1999, The Lyons Press.)

Figure 21-16 A, Pushing the lower edge of the scapula toward the spine while an assistant pulls downward on the hanging arm to assist in the relocation of a dislocated humerus. **B**, The downward pull on the arm may be slightly forward to help put the humerus back in the shoulder socket. (*From Auerbach PS: Medicine for the outdoors: the essential guide to emergency medical procedures and first aid, ed 3, New York, 1999, The Lyons Press.*)

Figure 21-18 Parvin's method of closed reduction of an elbow dislocation. The patient lies prone on a stretcher, and the physician applies gentle downward traction on the wrist for a few minutes. As the olecranon begins to slip distally, the physician lifts up gently on the arm. No assistant is required, and if the maneuver is done gently, no anesthesia is required. (Redrawn from Parvin RW: *Closed reduction of common shoulder and elbow dislocations without anesthesia*, Arch Surg 75:972, 1957. In Rockwood CA Jr, Green DP, Bucholz RW, editors: *Rockwood and Green's Fractures in adults*, ed 3, Philadelphia, 1991, JB Lippincott.)

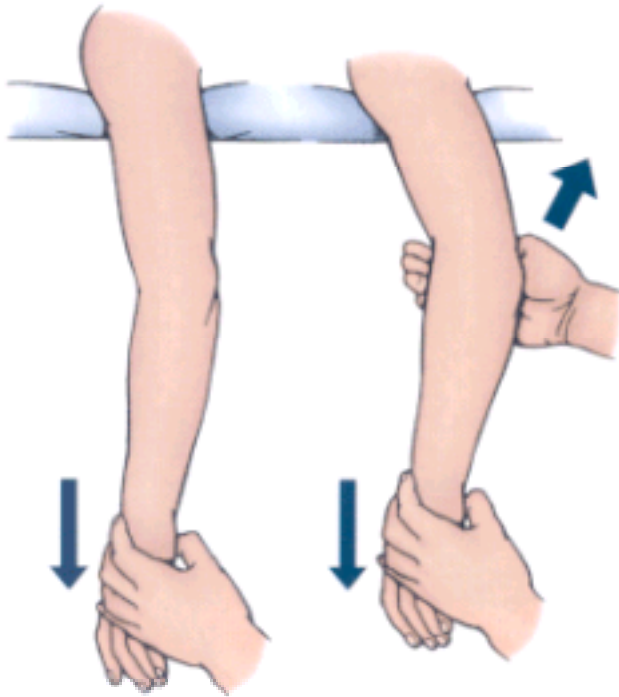

Figure 21-20 The single most important element preventing reduction in a complex MCP dislocation is interposition of the volar plate within the joint space, and it must be extricated surgically. (From Rockwood CA Jr, Green DP, Bucholz RW, editors: *Rockwood and Green's Fractures in adults*, ed 3, Philadelphia, 1991, JB Lippincott.)

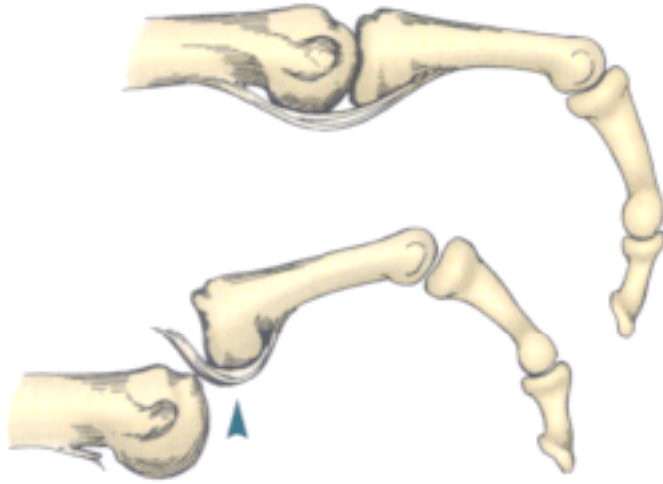

Figure 21-21 Taping the thumb for immobilization. **A**, The buddy-taping method. **B**, A thumb-lock; if possible, padding should be placed between the thumb and forefinger. (From Auerbach *PS: Medicine for the outdoors: the essential guide to emergency medical procedures and first aid*, ed 3, New York, 1999, The Lyons Press.)

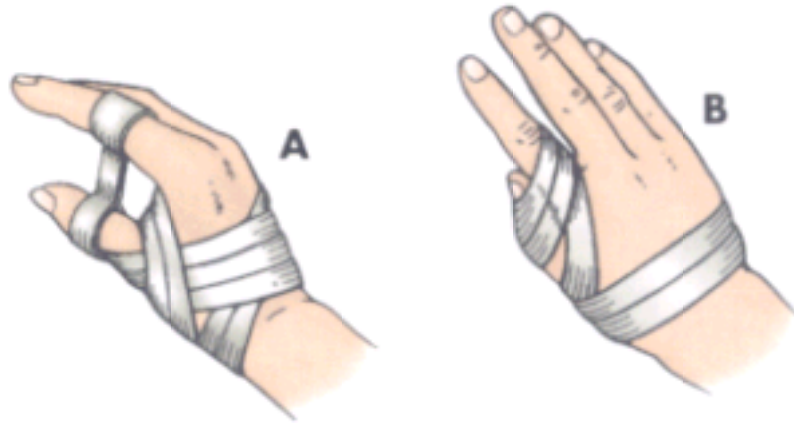

Figure 21-22 Buddy-taping method to immobilize a finger. (From Auerbach PS: *Medicine for the outdoors: the essential guide to emergency medical procedures and first aid*, ed 3, New York, 1999, The Lyons Press.)

Figure 21-23 Rotary subluxation of the PIP joint. The condyle of the head of the proximal phalanx is button-holed between the lateral band and central slip, both of which remain intact. (From Rockwood CA Jr, Green DP, Bucholz RW, editors: *Rockwood and Green's Fractures in adults, ed 3, Philadelphia, 1991, JB Lippincott.*)

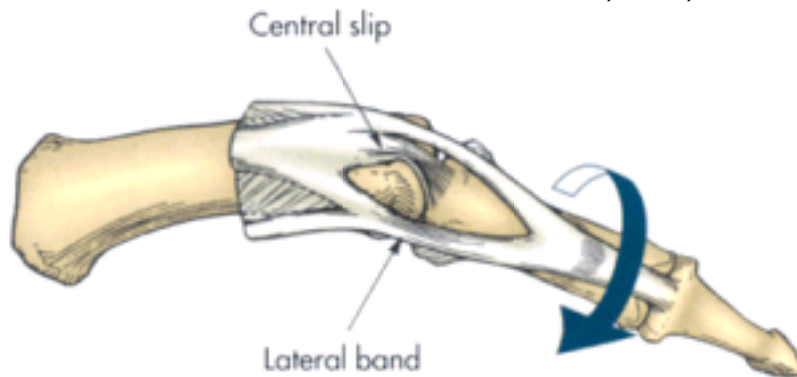

Figure 21-24 The three types of injury that cause a mallet finger of tendon origin. *Top*, The extensor tendon fibers over the distal joint are stretched without complete division of the tendon. Although there is some drop of the distal phalanx, the patient retains weak active extension. *Center*, The extensor tendon is ruptured from its insertion on the distal phalanx. There is usually a 40- to 45-degree flexion deformity, and the patient has loss of active extension at the distal joint. *Bottom*, A small fragment of the distal phalanx is avulsed with the extensor tendon. This injury has the same clinical findings as that shown in the center drawing. (From Rockwood CA Jr, Green DP, Bucholz RW, editors: *Rockwood and Green's Fractures in adults*, ed 3, Philadelphia, 1991, JB Lippincott.)

Figure 21-25 Mallet finger can be treated by immobilizing the DIP joint with a dorsal padded aluminum splint **(A)**, a volar unpadded aluminum splint **(B)**, a Stack splint **(C)**, a modified Stack splint **(D)**, or an Abouana splint **(E)**. Note that each of these splints uses a three-point fixation principle. (From Rockwood CA Jr, Green DP, Bucholz RW, editors: *Rockwood and Green's Fractures in adults*, ed 3, Philadelphia, 1991, JB Lippincott.)

Figure 21-28 Ligament complexes of the ankle.

Figure 21-29 Taping a sprained ankle. **A**, Strips of adhesive tape are placed perpendicular to each other to **(B)** lock the ankle with a tight weave. **C**, The tape edges are covered to prevent peeling. (From Auerbach *PS: Medicine for the outdoors: the essential guide to emergency medical procedures and first aid*, ed 3, New York, 1999, The Lyons Press.)

Figure 21-30 Taping for arch support. **A**, Fix an anchor strip under the heel. **B**, Attach strips across the bottom of the foot. **C**, Lock the crosspieces. Figure 23-14 A simple bandage can be used to temporarily stabilize a jaw fracture.

Figure 23-15 Structures that may be injured by facial lacerations. **A**, The lacrimal drainage system. **B**, The parotid duct. **C**, A line drawn through the lateral canthus of the eye. Facial nerve injuries posterior to this line should be repaired as soon as possible. 1–5, branches of cranial nerve VII. (Redrawn from *Oral and maxillofacial surgery services in the emergency department*, Rosemont, IL, 1992, American Association of Oral and Maxillofacial Surgeons.)

Figure 23-16 Technique for infiltration of a local anesthetic.

Figure 23-17 Technique for blocking the inferior alveolar nerve near the mental foramen. The shaded teeth will be anesthetized.

Figure 23-18 When administering the inferior alveolar block, the target area **(A)** lies on the medial surface of the mandibular ramus, halfway between the rescuer's thumb and forefinger. Keep the syringe parallel to the occlusal plane, as shown in **B**.

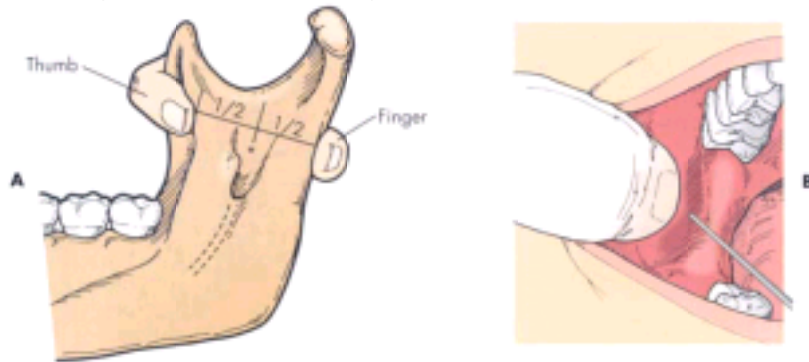

Figure 25-1 Functional hierarchy of the Incident Command System commonly used in SAR in the United States. (From Cooper DC, LaValla PH, Stoffel RC: *SAR fundamentals: basic skills and knowledge to perform search and rescue, ed 3 (rev)*, Cuyahoga Falls, Ohio, 1996, National Rescue Consultants.)

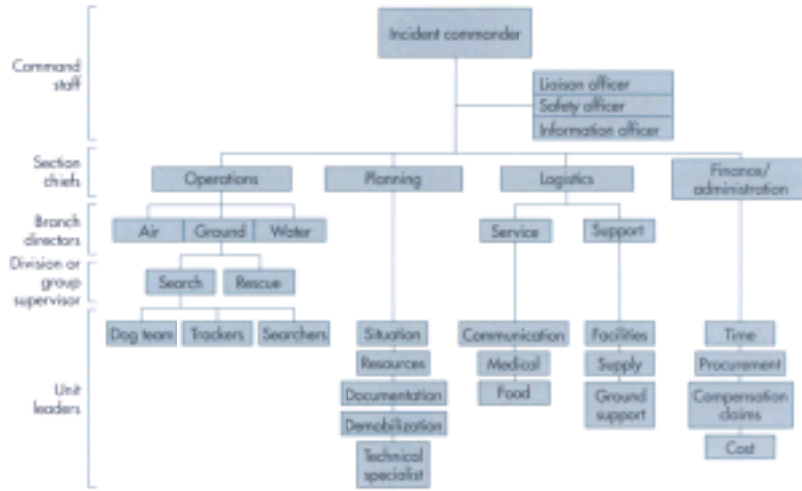

Figure 25-2 The time-specific components of a SAR event vary with the type of incident. Note that all components take place in both incidents but require different amounts of time. **A**, Typical rescue operation. **B**, Typical search operation.

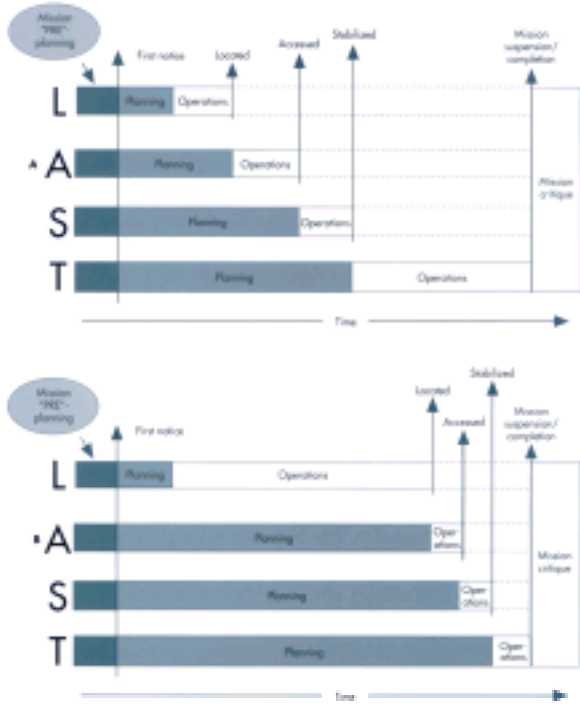

Figure 25-3 Urgency Determination Form.

Search Urgency

Remember the lower the number the more urgent the response!!

Date Completed: _____
 Line Completed: _____
 Name: _____

A. SUBJECT PROFILE _____

Age _____

Very Young _____ 1
 Very Old _____ 1
 Other _____ 2-3

Medical Condition _____

Known or suspected injury or illness _____ 1-2
 Healthy _____ 3
 Known injury _____ 3

Number of Subjects _____

One alone _____ 1
 More than one (unless separation suspected) _____ 2-3

B. WEATHER PROFILE _____

Existing hazardous weather _____ 1
 Predicted hazardous weather (8 hours or less) _____ 1-2
 Predicted hazardous weather (more than 8 hours) _____ 2
 No hazardous weather predicted _____ 3

C. EQUIPMENT PROFILE _____

Inadequate for environment _____ 1
 Questionable for environment _____ 1-2
 Adequate for environment _____ 3

D. SUBJECT EXPERIENCE PROFILE _____

Not experienced, not familiar with the area _____ 1
 Not experienced, knows the area _____ 1-2
 Experienced, not familiar with the area _____ 2
 Experienced, knows the area _____ 3

E. TERRAIN & HAZARDS PROFILE _____

Known hazardous terrain or other hazards _____ 1
 None or no hazards _____ 2-3

TOTAL _____

If any of the seven categories above are rated as a one (1), regardless of the total, the search would require an emergency response.

--- The total (below) needs FROM 7 to 21 with 7 being the most urgent. ---

8-11: Emergency Response 12-16: Moderate Response 17-21: Evaluate & Investigate

Figure 25-4 Map used to brief ground team. *(Photo courtesy Spectra Communications, Inc.)*

Figure 25-5 Even though the personal equipment necessary is dictated by both the rescue environment and the needs of the specific situation, it includes head, hand, foot, and eye protection as a minimum.

Figure 25-6 Rescuer wearing a personal flotation device (PFD) and helmet often used for rescue in and around moving water.

Figure 25-7 Example of ½-inch, nylon, static, kernmantle rope of the type commonly used in rescue. Rescue rope should be checked over its entire length for damage before use.

Figure 25-8 *Left*, Tubular webbing with cross section visible. *Right*, Flat webbing used in anchor sling.

Figure 25-9 Full-body harness. Note that the harness encompasses both the pelvis and the thorax.

Figure 25-10 Various types of carabiners. *Top to bottom:* (1) RSI Big hook, steel, screw locking hinged gate; (2) alloy, offset D, screw locking hinged gate; (3) RSI Twist Link, steel, screw locking hinged gate; (4) SMC extra large, rescue, steel, screw locking hinged gate; (5) Tri-link, steel, triangular, screw lock; (6) Auto-lock, swivel-mount, steel, quarter twist locking hinged gate (NFPA 1983 certified). Note that locking carabiners should always be locked when in use.

Figure 25-11 Example of figure-8 plate descending device (with "ears") commonly used in rescue.

Figure 25-12 RSI Super Rack brake bar rack in use.

Figure 25-13 **A**, Gibbs ascender applied to rope. When the eye of the cam is pulled, the cam squeezes the rope and holds fast. When the cam is released, the device can be moved on the rope. **B**, Gibbs ascender dismantled with shell around rope. Note cam (*upper left*) and pin (*bottom*). **C**, Clog handled ascender. Although used where climbing a fixed rope is required, handled ascenders are rarely used in rescue. **D**, A 3-wrap Prusik hitch can often be used in lieu of a mechanical ascender.

Figure 25-14 Two types of pulleys commonly used for rescue. *Top*, 2-inch double pulley. *Bottom*, 2-inch, "Prusik-minding." Note that rescue pulleys are applied to rope by removing the carabiner and swiveling the side plate to allow the introduction of the rope.

Figure 25-15 Time progression or the "anatomy" of a search from a searcher's (operational) perspective. The process is actually a continuous cycle that pauses in the planning and preparation phase until an incident occurs.

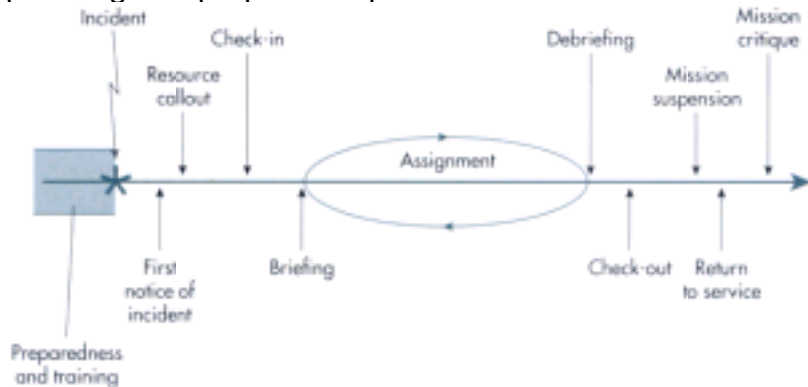

Figure 25-16 Runout. **A**, This phenomenon begins with an offshore sandbar. As waves roll in, the water level builds up behind the bar until a section gives way. **B**, As the sandbar "dam" gives way, the water develops a very rapid current running seaward. The recommended action is to swim across the current until out of the pull.

Figure 25-17 Rip. A depression in the beach floor concentrates returning water into a strong current. To escape, a person should ride with the current or swim to the side and out of the pull.

Figure 25-18 Undertow. This hazard develops on a steep beach where the water returns rapidly seaward after being tossed up by the wave action. A person should never fight this action but should relax and rise on the next wave.

Figure 26-1 A, Blanket drag. **B**, Fireman's drag. Both techniques are intended to be used when expeditious transport over a short distance is required. (From Auerbach *PS: Medicine for the outdoors: the essential guide to emergency medical procedures and first aid*, ed 3, New York, 1999, Lyons Press.)

Figure 26-2 Classic fireman's carry: a single rescuer technique for short distance transport only. The rescuer must use his or her legs for lifting. (*From Auerbach PS: Medicine for the outdoors: the essential guide to emergency medical procedures and first aid, ed 3, New York, 1999, Lyons Press.*)

Figure 26-3 Web sling (tied into a loop) used to carry a victim. The rescuer must use his or her legs for lifting

Figure 26-4 Backpack carry.

Figure 26-5 Single-rescuer split coil carry. Note that the coil can be tied in front of the rescuer, and the wrists of the victim can be bound and wrapped around the rescuer's neck for more stability.

Figure 26-6 Tragsitz harness in use.

Figure 26-7 A, Four-handed seat used to carry a person. In this technique the upper body is not supported. **B**, Alternative four-handed seat that helps support the victim's back. (From Auerbach *PS: Medicine for the outdoors: the essential guide to emergency medical procedures and first aid*, ed 3, New York, 1999, Lyons Press.)

Figure 26-29 The CMC Litter Shield protects the victim from falling debris while allowing access to the head and face.

Figure 26-30 Litter-carrying sequence. **A**, Six rescuers are usually required to carry a litter, but rescuers may need relief over long distances (greater than 0.4 km, or ¼ mile). **B**, Relief rescuers can rotate into position while the litter is in motion by approaching from the rear. **C**, As relief rescuers move forward, others progressively move forward. **D**, Eventually the rescuers who are furthest forward can release the litter (peel out) and move to the rear. Rescuers in the rear can rotate sides so that they alternate carrying arms. Carrying straps (webbing) also can be used to distribute the load over the rescuers' shoulders. In most cases the litter is carried feet first, with a medical attendant at the head monitoring airway, breathing, level of consciousness, and so on.

Figure 26-31 Smith Safety Products (SSP) Thermal Fleece Patient Bag (model 323) was designed to provide thermal protection for the SSP HD Rescue Stretcher but also offers limited protection from falling debris. (Courtesy Smith Safety Products, Inc.)

The Jayhawk, a variant of the UH-60 Blackhawk, is a medium-range helicopter used for search and rescue, drug interdiction, and maritime law enforcement. *(Courtesy US Coast Guard.)*

Figure 27-6 MBB BK-117 with rear clamshell doors open. (Courtesy Susan Lockman, Stanford Lifelight.)

Figure 27-7 Weight calculation aboard aircraft.

Maximum take-off weight ^a	_____
Less basic empty weight ^b	- _____
Less fuel on board ^c	- _____
Less pilot and crew	- _____
Less medical gear ^d	- _____
Maximum "patient payload"	= _____

^aMaximum take-off weight is certificated for each aircraft type and can be found in the operating manual.

^bBasic empty weight includes added avionics, permanent equipment, fluids, and unusable fuel. It is different for each aircraft and is recorded in the aircraft's operating manual.

^cThe quantity of fuel on board depends on the mission needs. Divide round-trip distance by cruise speed to yield time en route. Add time for warm-up, climb, approach, and a 30-minute reserve (VFR) to yield total engine time. Multiply total engine time by rate of fuel consumption to yield total fuel consumed. Fuel weight 6 lb/gal.

^dMedical gear includes carry-on and nonpermanent items.

Figure 27-8 A, U.S. Coast Guard C-130 Hercules aircraft. This long-range aircraft is used for ice patrol, fisheries management, and search and rescue. **B**, Coast Guard HH-65 Dolphin helicopter. This short-range light-lift helicopter is used for near-shore search and rescue, maritime fisheries enforcement, and law enforcement. (*Courtesy US Coast Guard.*)

Figure 27-9 A, Atmospheric pressure vs. altitude. **B**, Alveolar (P_{AO_2}) and arterial (P_{aO_2}) oxygen tensions vs. altitude.

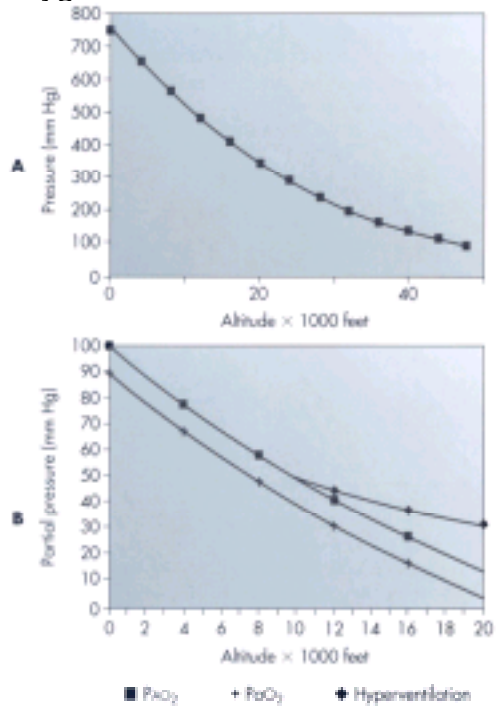

Figure 27-10 Arterial oxygen tension (PaO_2) at altitude vs. PaO_2 at sea level. Locate the sea-level PaO_2 on the x axis and intersect with the cruise altitude (on the diagonal). Read across to find the PaO_2 at altitude (y axis).

Figure 27-11 Axes of movement in aviation.

Figure 27-12 Fraction of inspired oxygen required to maintain oxygen tension at 90 mm Hg (varying with altitude).

P_b	Altitude	F_{iO_2}									
	0	0.21	0.30	0.40	0.50	0.60	0.70	0.80	0.90	1.00	
760	2000	0.23	0.32	0.43	0.54	0.65	0.76	0.86	0.97	FF	FF
707	4000	0.25	0.35	0.47	0.59	0.70	0.82	0.94	FF	FF	FF
654	6000	0.27	0.38	0.51	0.63	0.76	0.89	FF	FF	FF	FF
609	8000	0.29	0.41	0.55	0.68	0.83	0.97	FF	FF	FF	FF
564	10000	0.31	0.45	0.60	0.75	0.90	FF	FF	FF	FF	FF
523	12000	0.34	0.49	0.65	0.82	0.98	FF	FF	FF	FF	FF
483	A-a	1.5	75	150	222	293	364	435	507	579	

Calculated from the alveolar air equation under standard temperature and pressure conditions. P_b : Positive pressure required; P_b : barometric pressure (mm Hg); Alt: altitude (feet); A-a: alveolar-central oxygen gradient (mm Hg).
 X axis: sea level altitude
 Y axis: F_{iO_2} required to maintain $PO_2 = 90$ mm Hg
 To calculate the F_{iO_2} necessary to maintain $PO_2 = 90$ mmHg at a specific altitude, choose the value on the Y axis closest to that necessary to maintain $PO_2 = 90$ mmHg at sea level (altitude = 0 ft) and follow the corresponding line across to the new altitude (X axis). The proper F_{iO_2} is the Y value corresponding to the new X value.

Figure 27-13 Helicopter safety. **A**, Safe approach zones. **B**, The proper way to approach or depart a helicopter.

Figure 27-14 Aeromedical helicopter accident rate, 1972 to 1991. (From Preston N: *J Air Med Transport* 11:14, 1992.)

Figure 28-1 Line chart showing windchill and state of comfort under varying conditions of temperature and wind velocity. The numbers along the left margin of the diagonal center block refer to the windchill factor, that is, that rate of cooling in kilocalories per square meter per hour of an unclad, inactive body exposed to specific temperatures and wind velocities. Windchill factors above 1400 are most hazardous.

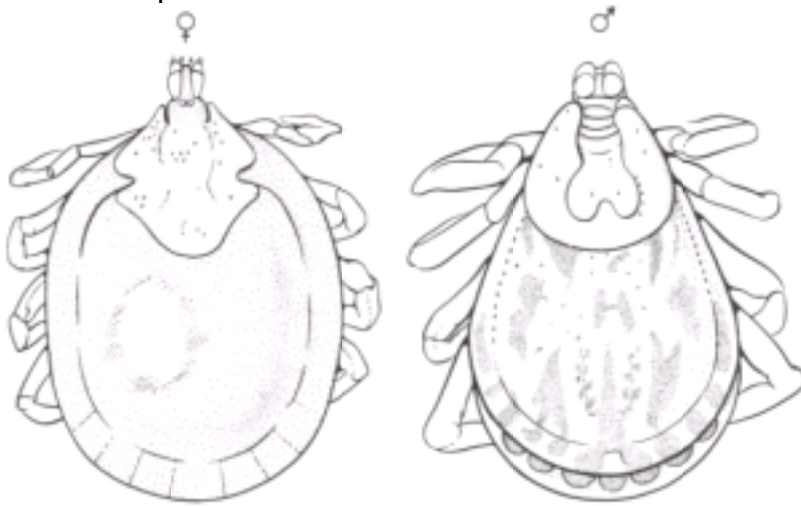

Figure 33-2 Tick anatomy. **A**, Dorsal aspect. **B**, Ventral surface.

Figure 33-3 Lone star tick (*Amblyomma americanum*), implicated in cases of tick paralysis in North America. (Courtesy Sherman Minton, MD.)

Figure 33-4 Life cycle of *Ixodes scapularis*. The cycle of ixodid ticks typically spans 2 years and includes three blood meals in the spring. The adult female tick releases her eggs, which hatch as six-legged larvae; during the summer, the larvae take a blood meal that lasts approximately 2 days. Larval ticks then enter a dormant phase with cooler fall weather. The ticks then molt in the spring, entering the second phase of their life cycle as eight-legged nymphal ticks. In the late spring or summer, nymphal ticks take a blood meal that typically lasts for 2 to 3 days. The nymphal ticks then molt as eight-legged adults in the fall. The adults mate on white-tailed deer; after mating the male dies, but the female takes one more blood meal before she lays her eggs and dies. (Modified from Habicht et al: *Sci Am* 257:78, 1987.)

Figure 38-9 Western pygmy rattlesnake (*Sistrurus miliarius streckeri*) is one of the smaller rattlesnake species of North America. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

Figure 38-10 Southern copperhead (*Agkistrodon contortrix contortrix*) has markings that make it almost invisible when lying in leaf litter. (Courtesy Michael Cardwell and Carl Barden Venom Laboratory.)

Figure 38-11 Cottonmouth water moccasin (*Agkistrodon piscivorus*) exhibiting its threat display. This snake is found most often around standing water sources in the southeastern United States. (Courtesy Sherman Minton, MD.)

Figure 38-12 Cantil (*Agkistrodon bilineatus*) is a close relative of the copperheads (*A. contortrix*) and cottonmouths (*A. piscivorus*) of the United States. This pit viper is found in Mexico and Central America. (Courtesy Michael Cardwell and William W. Lamar.)

Figure 38-13 Texas coral snake (*Micrurus fulvius tenere*) has a highly potent venom but is secretive, and bites are uncommon. (Courtesy Michael Cardwell and the Gladys Porter Zoo.)

Figure 38-14 Comparison of Texas coral snake (*Micrurus fulvius tenere*) with harmless Mexican milk snake (*Lampropeltis triangulum annulata*). Coral snake (*bottom*) has contiguous red and yellow bands, whereas the milk snake has its red and yellow bands separated by black. (Courtesy Charles Alfaro.)

Figure 38-15 Sonoran coral snake (*Micruroides euryxanthus*) is also known as the Arizona coral snake. No documented fatality has followed a bite by this species. (Courtesy Michael Cardwell and Jude McNally.)

Figure 38-16 Gila monster (*Heloderma suspectum*) is one of only two known venomous lizards and the only species found in the United States. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

Figure 38-17 Mexican beaded lizard (*Heloderma horridum*) is located south of the Gila monster's range in Mexico. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

Figure 38-18 Pit viper's head. Note the elliptic pupil and the heat-sensing pit for which these reptiles are named. Viewed from above, the head has a distinctly triangular shape. Many nonvenomous snakes also possess triangular-shaped heads, however, this is not a reliable means of differentiation. (*Marlin Sawyer, 1994.*)

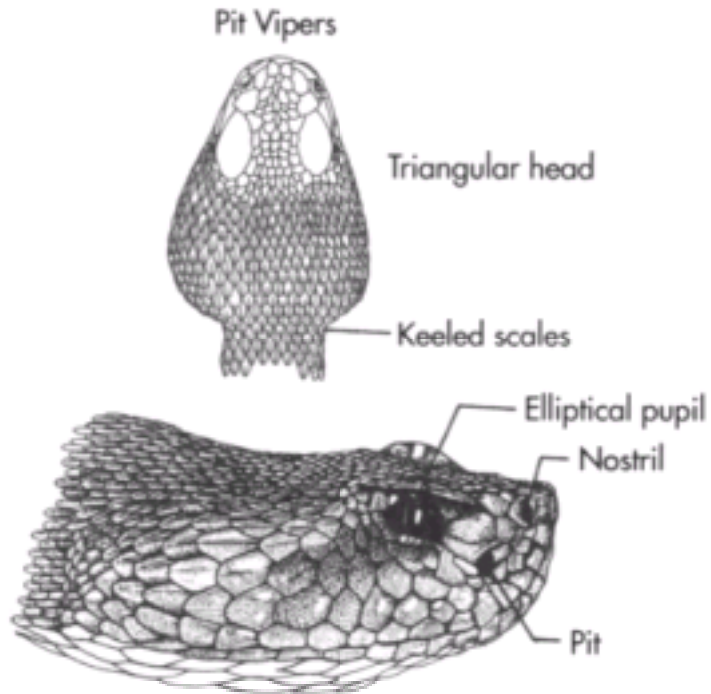

Figure 38-19 Paired heat-sensing pits of the pit vipers used to help the snake locate its prey, direct its strike, and probably determine the volume of venom to be expended. (Marlin Sawyer, 1994.)

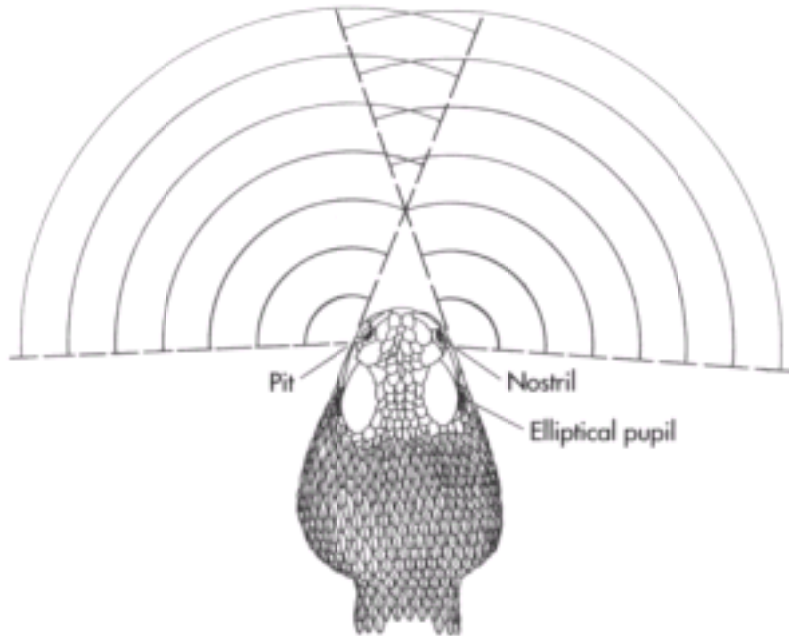

Figure 38-20 Venom delivery apparatus of a pit viper. Venom is produced in large venom glands just posterior to the eyes and is passed through a duct system into the hollow, anterior fangs when the snake bites. (*Marlin Sawyer, 1994.*)

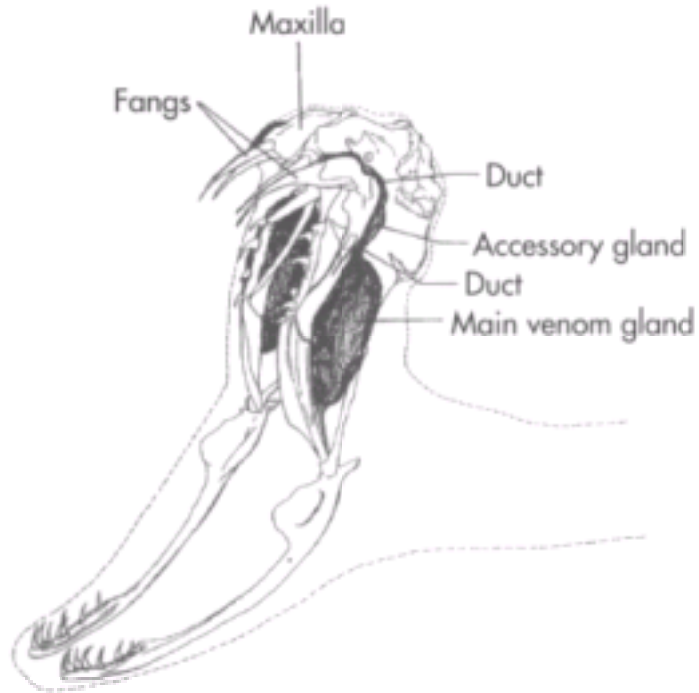

Figure 38-21 Rattlesnake skull. Replacement fangs are behind the primary, functional fangs. The smaller teeth of the palatine, pterygoid, and mandibular bones are used for gripping food. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

Figure 38-22 Coral snake's skull. Note the slightly enlarged anterior fang that is fixed in its upright position. (*Marlin Sawyer, 1994.*)

Figure 38-23 Subcaudal scale pattern of pit viper vs. a harmless snake. Pit viper (here, a rattlesnake) has a single scale that spans the ventral side of its tail, just distal to the anal plate, whereas harmless colubrid snake has a double row of scales. Coral snakes also possess a double row of subcaudal scales. (*Marlin Sawyer, 1994.*)

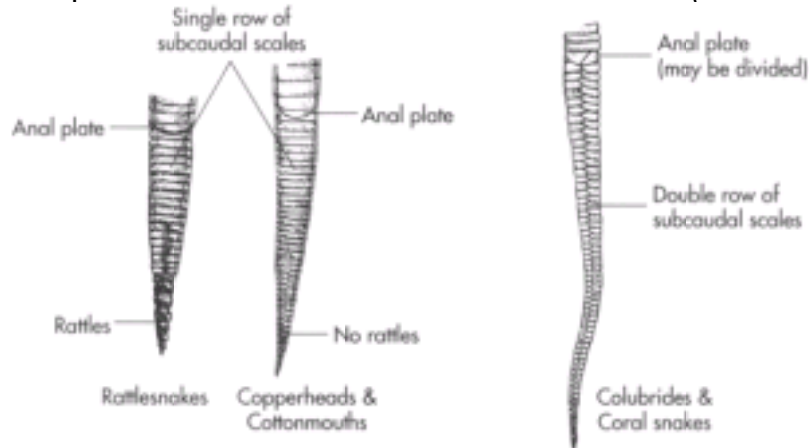

Figure 38-24 Mottled rock rattlesnake (*Crotalus lepidus lepidus*) bite in a young man at 24 hours. Note the exudation of red cells into the soft tissues remote from the bite site. The man was bitten on his left thumb. (Robert Norris, MD.)

Figure 38-25 Hemorrhagic bleb at the site of a western diamondback rattlesnake (*Crotalus atrox*) bite at 24 hours. (Robert Norris, MD.)

Figure 38-26 A, Soft tissue swelling, hemorrhagic blebs, and early necrosis after red diamond rattlesnake (*Crotalus ruber*) bite to the long finger (day 2). Victim received 10 vials of antivenom 6 hours after the bite and 10 more vials for severe thrombocytopenia on day 2. **B**, Seven weeks later. Note the degree of necrosis. (Sean Bush, MD.)

Figure 38-27 Rarely indicated fasciotomy in a victim of severe rattlesnake bite (*Crotalus viridis helleri*). Compartment pressures were greater than 60 mm Hg despite aggressive antivenom therapy. (Robert Norris, MD.)

Figure 38-28 Teeth of the helodermatid lizards are grooved to aid instillation of venom during a bite. These teeth are loosely adherent and may become dislodged in the bite wound. (*Courtesy Michael Cardwell/Extreme Wildlife Photography.*)

Figure 39-1 Chinese cobra (*Naja atra*). Cobras are among the world's most venomous snakes, dangerous by virtue of potent venom and distribution in densely populated regions. (Sherman Minton, MD.)

Figure 39-2 The monocellate cobra (*Naja kaouthia*) is one of many cobra species whose venom is known to cause significant local necrosis. (Courtesy Michael Cardwell and Carl Barden Venom Laboratory.)

Figure 39-3 The African red spitting cobra (*Naja pallida*) is capable of spraying its venom with great accuracy for distances up to 3 m. (Courtesy Michael Cardwell and Carl Barden Venom Laboratory.)

Figure 39-4 The king cobra (*Ophiophagus hannah*) is the largest of the venomous snakes, can reach lengths of up to 5 m, and is widely distributed in Asia. (Courtesy Michael Cardwell and Carl Barden Venom Laboratory.)

Figure 39-5 Cobralike ringhals (*Hemachatus haemachatus*) of Africa spreads a hood when threatened and can also spit venom. Some specimens feign death, as shown here, causing bites in unsuspecting keepers. (*Michael Cardwell and Cape Town Snake Park.*)

Figure 39-6 Green mamba (*Dendroaspis angusticeps*). These large, slender arboreal African snakes are quick, alert, and often dangerous. (Sherman Minton, MD.)

Figure 39-7 Relatively large anterior fangs of green mamba (*Dendroaspis angusticeps*). Elapids tend to have smaller fangs than do most viperids, but some, as shown here, can be quite large. (Courtesy Michael Cardwell and Carl Barden Venom Laboratory.)

Figure 39-8 Many-banded krait (*Bungarus multicinctus*). Kraits are widely distributed in southern Asia and have highly lethal neurotoxic venoms. They are nocturnal and rarely aggressive. (Sherman Minton, MD.)

Figure 39-9 Amazonian coral snake (*Micrurus spixii*). This South American species demonstrates how color patterns can be misleading in identification of coral snakes outside the United States. its red and yellow bands are separated by black rather than being contiguous. (Courtesy Michael Cardwell and Extreme Wildlife Photography.)

Figure 39-10 Coastal taipan (*Oxyuranus scutellatus*) Australia's largest venomous snake can reach a length of 3 m and can be aggressive. Its range is largely in semitropical Queensland. (*Sherman Minton, MD.*)

Figure 39-11 Death adder (*Acanthophis antarcticus*). This viperlike Australian snake is actually an elapid with highly neurotoxic venom. (Courtesy Michael Cardwell and William W. Lamar.)

Figure 39-12 Tiger snake (*Notechis scutatus*). This highly venomous elapid snake is found in the densely populated eastern part of Australia. (*Sherman Minton, MD.*)

Figure 39-13 Pelagic sea snake (*Pelamis platurus*) is the most widely distributed sea snake and the only species found in American waters. (Sherman Minton, MD.)

Figure 39-14 Nose-horned viper (*Vipera ammodytes*) is an important cause of snakebites in Europe, but cases are rarely fatal. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

Figure 39-15 Russell's viper (*Daboia russellii*). Plentiful in agricultural regions of southern Asia, these large vipers are a leading cause of fatal snakebites. (Sherman Minton, MD.)

Figure 39-16 Desert horned viper (*Cerastes cerastes*). These relatively small Egyptian vipers are highly adapted to their desert environment. Bites are rarely fatal. (Courtesy Michael Cardwell and *The Living Desert*.)

Figure 39-17 Puff adder (*Bitis arietans*). This large African viper is widely distributed and extremely dangerous. As shown here, its color pattern allows it to blend into background leaf clutter. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

Figure 39-18 Gaboon viper (*Bitis gabonica*). This impressive African viper possesses the longest fangs of any venomous snake, up to 5 cm. It can deliver massive quantities of highly toxic venom. (Courtesy Michael Cardwell and Carl Barden Venom Laboratory.)

Figure 39-19 Chinese green tree viper (*Trimeresurus stejnegeri*) is found in southern and eastern Asia. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

Figure 39-20 Wagler's pit viper, temple viper (*Tropidolaemus wagleri*). This Asian pit viper is popular with amateur snake keepers. (Courtesy Michael Cardwell and William W. Lamar.)

Figure 39-21 Urutu (*Bothrops alternatus*). This large, dangerous South American pit viper is responsible for many severe bites in its distribution. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

Figure 39-22 Eyelash viper (*Bothriechis schlegelii*) is found in southern Mexico, Central America, and northern South America and is popular with amateur snake keepers. (Courtesy Michael Cardwell and Carl Barden Venom Laboratory.)

Figure 39-23 Bushmaster (*Lachesis muta*) is the largest pit viper, up to 3.6 m and is found in southern Central America and northern South America. (Courtesy Michael Cardwell/Extreme Wildlife Photography.)

Figure 39-24 Boomslang (*Dispholidus typus*) is the most dangerous of the rearfanged colubrid snakes. This arboreal snake is widely distributed in Africa. (*Sherman Minton, MD.*)

Figure 39-25 Bite of a small Australian elapid snake (*Hemiaspis signata*) resulting in localized swelling with some discoloration but no systemic symptoms. (Sherman Minton, MD.)

Figure 39-26 Sharply demarcated necrosis, sometimes extensive, often follows bites by both African and Asian cobras. (*Sherman Minton, MD.*)

Figure 39-27 Bite of a Southeast Asian water snake (*Enhydrina plumbea*), generally considered to be nonvenomous. Swelling and ecchymosis were still present after 24 hours. (Sherman Minton, MD.)

Figure 39-28 First-aid measures for venomous snakebites.

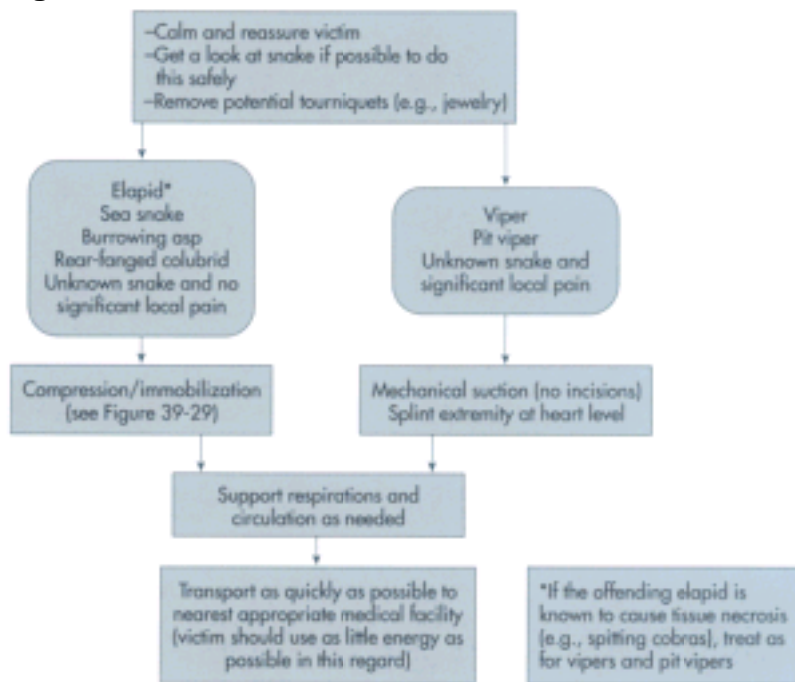

Figure 39-29 Australian compression and immobilization technique has proved effective in the management of elapid and sea snake envenomations. Its efficacy in viper bites has yet to be evaluated clinically.

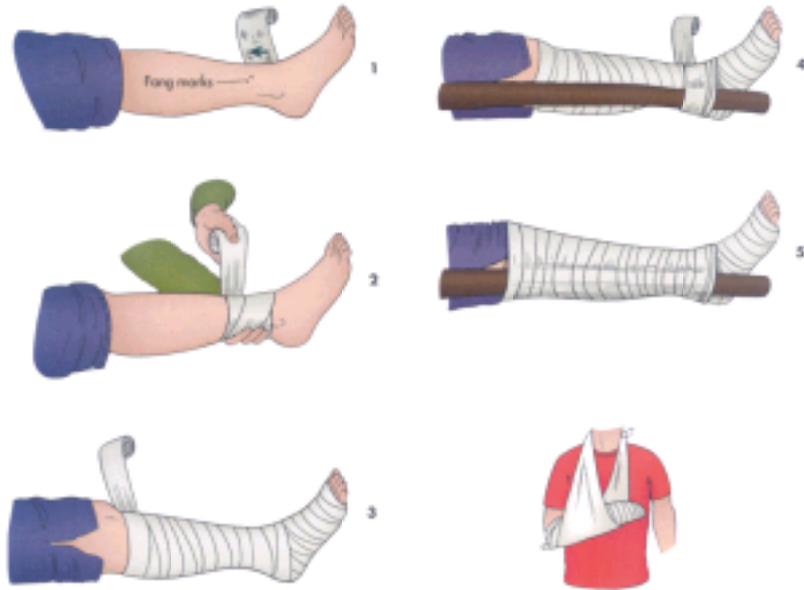

Figure 39-30 The Extractor device. The efficacy of this device for applying mechanical suction to snakebites in the field continues to be studied.

Figure 39-31 Guidelines for the hospital management of venomous snakebite.

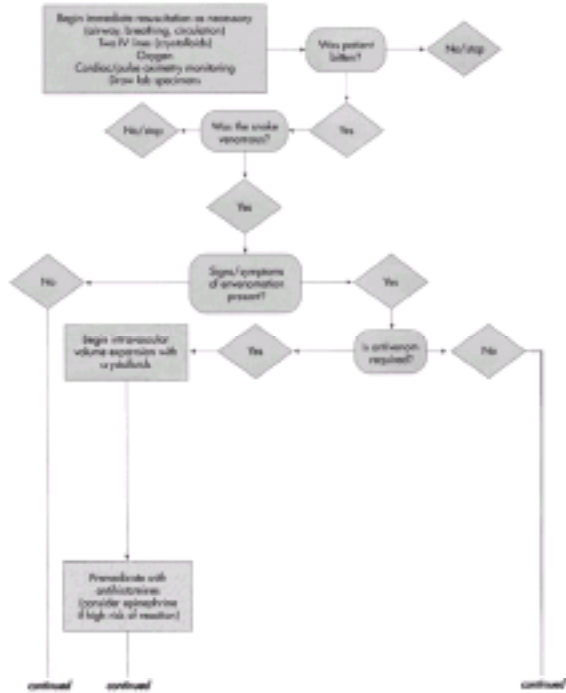

Figure 39-31

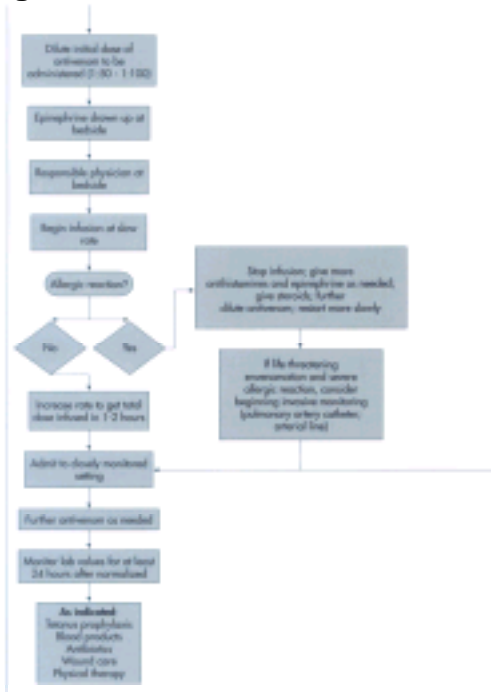

Figure 39-31

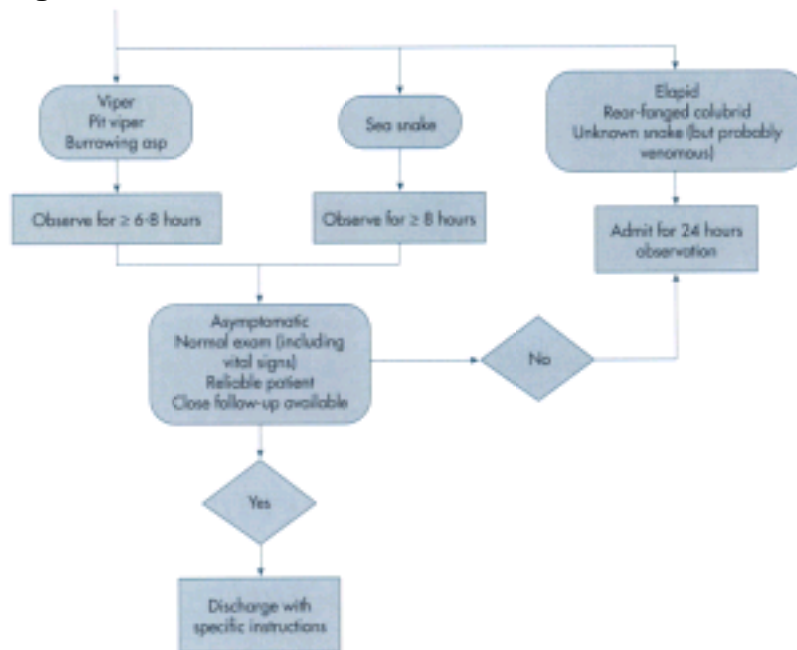

Figure 40-1 Schematic diagram of an IgG molecule. The antigen-binding region (Fab portion) is present at the amino-terminal end. The effector region (Fc portion) interacts with the immune system cells and resides at the carboxyl end of IgG. Note the disulfide bridge.

Figure 40-2 Proteolytic cleavage of IgG results in predictable substituent fractions. Pepsin digestion produces Fc and Fab₂ fractions. Fab₂ consists of two Fab portions connected by a disulfide bridge. Molecular weight of Fab₂ is 100,000 daltons.

Figure 40-3 Proteolytic cleavage of IgG results in predictable substituent fractions. Papain digestion of IgG yields the Fc and two Fab segments for each IgG molecule. Molecular weight of Fab is 50,000 daltons.

Figure 48-12 Cardiac glycosides bind to and inhibit the membrane-bound enzyme $\text{Na}^+ - \text{K}^+$ ATPase in cardiac myocytes (shown), baroreceptor cells, and skeletal muscle cells. Inhibition of $\text{Na}^+ - \text{K}^+$ ATPase in cardiac myocytes results in accumulation of intracellular Na^+ , which results in accumulation of Ca^{2+} within myocytes via $\text{Na}^+ - \text{Ca}^{2+}$ exchangers. The resultant increase in intracellular Ca^{2+} stimulates further release of Ca^{2+} from the sarcoplasmic reticulum. The increased intracellular Ca^{2+} interacts with troponin C of the actin-myosin complex to cause increased contractions, seen as increased automaticity (e.g., premature ventricular contractions on electrocardiograms). Inhibition of membrane-bound enzyme $\text{Na}^+ - \text{K}^+$ ATPase in baroreceptor cells and skeletal muscle cells contributes to increased vagal tone and hyperkalemia, respectively.

Figure 48-21 Principal steps in hydrocyanic acid poisoning and detoxification. 1, Breakdown of cellular respiration resulting from the binding of cyanide to cytochrome oxidase. 2, Conversion of the ferrous (Fe^{2+}) form of hemoglobin to the ferric (Fe^{3+}) form (methemoglobin) by the use of nitrites. 3, Preferential binding of cyanide to methemoglobin, liberating cytochrome oxidase and restoring cellular respiration. 4, Providing exogenous thiosulfate to aid in formation of the less toxic thiocyanate via various sulfurtransferases, such as rhodanese. Thiocyanate is then excreted from the body. The reaction is slowly reversible via the enzyme thiocyanate oxidase, and rebound may occur.

Figure 57-6 A to D, Cross sections of the brain of a 31-year-old male sport diver who suffered an arterial gas embolism, dying 4 days after the accident and extended hyperbaric oxygen treatment. Bubble-induced infarcts are found throughout the brain in the distribution of both the carotid and vertebral arteries. (*Kenneth W. Kizer, MD.*)

Figure 57-7 An example of a large modern hyperbaric chamber. Preferably, a hyperbaric chamber for treating decompression sickness or arterial gas embolism should have a pressure capability of at least 6 ATA (165 fsw) and should have space for an attendant to provide ongoing "hands-on" care and repeated neurologic examinations. It must have provisions for supplying 100% oxygen and other gases for treatment of the stricken diver.

Figure 57-8 Dalton's law of partial pressures. The total pressure exerted by a mixture of gases is the sum of the pressures that would be expected by each of the gases if it alone were present and occupied the total volume.

Figure 57-9 Logo for Divers Alert Network. *(Courtesy Divers Alert Network.)*

Figure 57-10 Examples of U.S. Navy decompression tables. Dark shading represents oxygen breathing; light shading represents air breathing. **A**, USN Treatment Table 5, oxygen treatment of type-1 decompression sickness. **B**, USN Treatment Table 6, oxygen treatment of type-2 decompression sickness. (Modified from *Department of the Navy: U.S. Navy diving manual, vol 2, rev 2, Flagstaff, Ariz, 1988, Best Publishing Company.*)

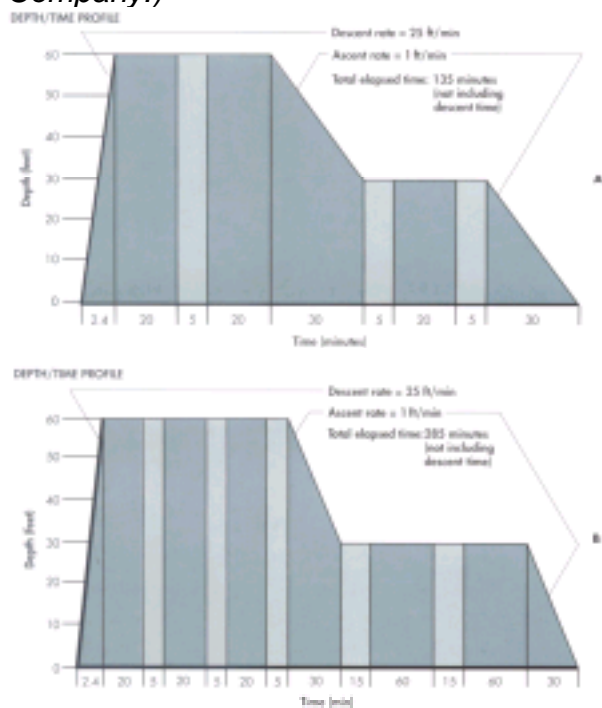

Figure 59-1 Effects of hyperbaric oxygen on the oxygen content of arterial blood. The blood oxygen content (Ca_{O_2}) under normal conditions is approximately 20 ml/dl and is carried almost exclusively by hemoglobin. The normal oxygen extraction (AV difference) is approximately 5 ml/dl or about one quarter of the total Ca_{O_2} . During HBOT, dissolved O_2 in plasma can be increased to provide the entire AV difference without unloading O_2 from hemoglobin.

Figure 59-2 Multiplace hyperbaric chamber. Multiplace chambers allow more than one patient at a time to receive hyperbaric oxygen. Attendants may accompany the patients during treatments. *(Courtesy Duke University Photography. Photo by Les Todd.)*

Figure 59-3 Monoplace hyperbaric chamber. Monoplace chambers hold a single patient, usually in an environment of pure oxygen. Attendants remain outside the chamber during treatment.

Figure 59-4 Effects of recompression therapy on gas bubble size. The relative bubble volume and diameter are plotted as a function of recompression depth (pressure in atm). The greatest effect occurs on bubble volume during the initial 2- to 3-atm pressure change. As the volume of the bubble decreases, the partial pressure of nitrogen (P_{N_2}) rises inside it. This allows N_2 to diffuse more rapidly down its concentration gradient into the tissue, where the P_{N_2} is lower. The addition of O_2 breathing lowers P_{N_2} in the tissue, thereby increasing the gradient for N_2 elimination.

Figure 59-5 U.S. Navy oxygen recompression tables for treatment of DCS. Oxygen breathing periods are indicated in green; air breaks are shown in blue. The rate of compression to 60 FSW is 25 feet/min (2.4 min). US Navy Table 5 requires 135 minutes and Table 6 requires 285 minutes, excluding time of compression. U.S. Navy Table 6 may be extended up to two O₂ cycles at 60 FSW and two O₂ cycles at 30 FSW.

Figure 59-6 The effects of oxygen on the dissociation of CO from carboxyhemoglobin (COHb). Oxygen breathing at 1.0 atm decreases the half-life of COHb to 60 minutes from approximately 300 minutes in air. HBO at 2.5 atm reduces the half-life to 30 minutes, allowing most of the COHb to be removed from the body within 90 minutes.

Figure 59-7 Hyperbolic relationship between oxygen concentration and time in tissue oxygen toxicity. Typical pressure-time curves for the CNS and lung are shown for comparison. The threshold for CNS toxicity is approximately 1.4 atm and for pulmonary toxicity is approximately 0.5 atm.

Figure 61-55 Skin rash caused by a bristleworm. (*Photo by Paul Auerbach, MD.*)

Figure 61-57 Venom apparatus of the cone snail.

Figure 61-59 Algorithmic approach to marine envenomation. *A gaping laceration, particularly of the lower extremity, with cyanotic edges suggests a stingray wound. Multiple punctures in an erratic pattern with or without purple discoloration or retained fragments are typical of a sea urchin sting. One to eight (usually two) fang marks are usually present after a sea snake bite. A single ischemic puncture wound with an erythematous halo and rapid swelling suggests scorpionfish envenomation. Blisters often accompany a lionfish sting. Painless punctures with paralysis suggest the bite of a blue-ringed octopus; the site of a cone shell sting is punctate, painful, and ischemic in appearance. †Wheal and flare reactions are nonspecific. Rapid (within 24 hours) onset of skin necrosis suggests an anemone sting. "Tentacle prints" with cross-hatching or a frosted appearance are pathognomonic for box-jellyfish (*Chironex fleckeri*) envenomation. Ocular or intraoral lesions may be caused by fragmented hydroids or coelenterate tentacles. An allergic reaction must be treated promptly. ‡Sea snake venom causes weakness, respiratory paralysis, myoglobinuria, myalgias, blurred vision, vomiting, and dysphagia. The blue-ringed octopus injects tetrodotoxin, which causes rapid neuromuscular paralysis. §If *immediately* available (which is rarely the case), local suction can be applied without incision using a plunger device, such as The Extractor (Sawyer Products, Safety Harbor, Fla.). As soon as possible, venom should be sequestered locally with a proximal venous-lymphatic occlusive band of constriction or (preferably) the pressure immobilization technique, in which a cloth pad is compressed directly over the wound by an elastic wrap that should encompass the entire extremity at a pressure of 9.33 kPa (70 mm Hg) or less. Incision and suction are not recommended. ¶Early ventilatory support has the greatest influence on outcome. The minimal initial dose of sea snake antivenin is one to three vials; up to ten vials may be required. ?The wounds range from large lacerations (stingrays) to minute punctures (stonefish). Persistent pain after immersion in hot water suggests a stonefish sting or a retained fragment of spine. The puncture site can be identified by forcefully injecting 1% to 2% lidocaine or another local anesthetic agent without epinephrine near the wound and observing the egress of fluid. Do not attempt to crush the spines of sea urchins if they are present in the wound. Spine dye from already-extracted sea urchin spines will disappear (be absorbed) in 24 to 36 hours. **The initial dose of stonefish antivenin is one vial per two puncture wounds. ††The antibiotics chosen should cover *Staphylococcus*, *Streptococcus*, and microbes of marine origin, such as *Vibrio*. ‡‡Acetic acid 5% (vinegar) is a good all-purpose decontaminant and is mandated for the sting from a box-jellyfish. Alternatives, depending on the geographic region and indigenous jellyfish species, include isopropyl alcohol, bicarbonate (baking soda), ammonia, papain, and preparations containing these agents. §§The initial dose of box-jellyfish antivenin is one ampule intravenously or three ampules intramuscularly. ¶¶If inflammation is severe, steroids should be given systematically (beginning with at least 60 to 100 mg of prednisone or its equivalent) and the dose tapered over a period of 10 to 14 days. ***An alternative is to apply and remove commercial facial peel materials. ??An alternative is to apply and remove commercial facial peel materials followed by topical soaks of 30 ml of 5% acetic acid (vinegar) diluted in 1 L of water for 15 to 30 minutes several times a

day until the lesions begin to resolve. Anticipate surface desquamation in 3 to 6 weeks.

Figure 64-1 Anatomy of a rescue. The 406-MHz emergency position indicating radio beacon (EPIRB) sends a digitally coded signal to low-earth-orbit satellite, which relays the signal to a nearby ground receiving station (LUT). The location of the EPIRB is calculated and forwarded to the nearest mission control center, which matches the EPIRB user's registration with the specific signal. These data are relayed to the local rescue coordination center, which initiates the search and rescue. (Courtesy ACR Electronics.)

Figure 64-2 Comfortable, lightweight, and convenient integrated safety harness and automatic inflatable life vest. It is Coast Guard approved and features both a backup rip cord and an oral inflation system.

Figure 64-3 This inflatable life raft will float free if the vessel sinks. The packing bands are designed to break when the raft is inflated. The rope painter, which is attached to the "weak link," must be secured to a cleat if the raft is manually deployed overboard. The disk-shaped hydrostatic release is set to release the raft from the cradle at water depths of 5 to 15 feet, with a button for manual release.

Figure 69-1 Prepackaged wilderness first-aid kits are available from many manufacturers. Kits are neatly organized and rugged, with detachable inner pouches that are useful for day trips. Bags are water resistant to allow for white-water use. A surprisingly large amount of first-aid material can be carried, as shown in the illustration.

Figure 69-2 Recommendations for prescription medicines for expedition travel based on the duration of outing (vertical columns) and the maximum interval to medical care (horizontal rows). Itemized numbers refer to recommended topical and systemic medicines found in [Table 69-2](#) and [Table 69-3](#), respectively.

		Duration of outing		
		Day outing	2-3 days	>3 days
Maximal interval to medical care or rescue	<4 hours	Topical 1 Systemic 1	Topical 1,2 Systemic 1-3	
	4-12 hours	Topical 1 Systemic 1	Topical 1-3 Systemic 1-5	Topical 1-5 Systemic 1-9
	>12 hours		Topical 1-4 Systemic 1-6	Topical 1-7 Systemic 1-16

Figure 69-3 Gamow Bag. Attached is the foot pump required to pressurize the compartment to 2 pounds per square inch. Four windows are strategically located to permit observation. Entry is via a lengthwise zipper.

Figure 69-4 The AvaLung (Black Diamond, Ltd.). A lightweight vest designed to improve avalanche survival. Victims are able to draw air from even a dense snowpack via the front using an air exchange mouthpiece. A one-way valve permits exhalation of carbon dioxide expelled through the vest back.

Figure 69-5 The Res-Q-Air system for delivery of warm, saturated air. The unit is portable and battery run for use in the field. Its use requires minimal training. Temperature is adjusted by a single control dial.

Figure 69-6 Hypothermic Stabilizer bag. This excellent prehospital transport device allows passive rewarming of victims suffering from cold exposure and is especially useful in cold water immersion because of the drying ability of its high-pile fabric. The unit weighs only 12 pounds and measures 12 x 13 inches when packaged in a portable case.

Figure 73-10 A selection of portable altitude measuring devices for celestial navigation. Clockwise from top: box sextant, A-10 aeronautical sextant, pocket transit with clinometer. The box sextant requires a separate artificial horizon such as a reflective dish of water for land use. The A-10 sextant and pocket transit have intrinsic bubble levels. Use of the pocket transit requires averaging of multiple altitude measurements to achieve acceptable accuracy. A quarter is included in the image to provide scale.

Figure 73-11 A complete portable kit for celestial navigation. Clockwise from upper right: scientific calculator, pencil, A-10 aeronautical sextant, folded copies of almanac daily pages and sight reduction pages from H.O. 249, protractor/straight edge, plotting sheets, and topographic map. The sight reduction pages and calculator can substitute for one another. The topographic map and plotting sheets can substitute for one another, although the map is more useful for land navigation. Not included in the image is an accurate watch set to Greenwich Meridian Time. A quarter is included to provide scale.

Figure 73-12 The Universal Pocket Navigator (UPN). Enter the Selector Table with arguments for the approximate date and the approximate latitude as determined from the background map. Stick a pin or toothpick vertically in the center line at the cross mark indicated by the Selector Table to serve as a gnomon. The tip of the gnomon should stand above the figure by the length indicated by the gnomon scale. Hold the figure horizontally, and rotate your body until the shadow of the tip of the gnomon lies on the appropriate lettered curve (from the Selector Table). The arrow now points north.

(From Owendoff RS: *Better ways of pathfinding, Harrisburg, Penn, 1964, The Stackpole Co.*)

SELECTOR CHART		Northern Hemisphere					
Latitude	Dec 22	Jan 22	Feb 22	Mar 22	Apr 22	May 22	Jun 22
0°	08h	08h	18	07	08	16	24
10°	29h	38h	48	37	21	35	44
20°	68h	68h	74	57	41	56	71
30°	102	102	111	82	64	117	128
40°	132	132	141	112	124	137	148
50°	162	162	171	142	160	173	184
60°	192	192	201	172	190	203	214
West for reverse work			251	251	268	268	284
		Jul 22	Aug 22	Sep 22	Oct 22	Nov 22	
		Jun 22	May 22	Apr 22	Mar 22	Feb 22	Jan 22
		Southern Hemisphere					
In Southern Hemisphere, the arrow points to the south, and west (p.m.) is interchanged with east (p.m.)							

Figure 73-13 Use of the Universal Pocket Navigator to find north. The selector chart was entered with the date of October 25 and the assumed latitude of 40°, yielding declination curve "L" and gnomon position "14." Note the correspondence between magnetic north and north as indicated by the center line of the figure. The magnetic declination at the sight of observation was 4 ½° west. The UPN reading corresponds to true north.

Figure 73-14 A makeshift suncompass inscribed on a scrap of paper. The declination curve has been empirically determined by tracing a line through points representing the tip of the gnomon shadow at various times throughout the day. On subsequent days, rotation of the figure such that the shadow tip touches the curve will orient the line connecting the base of the gnomon to the point of closest approach of the curve to point north. (From Owendoff RS: *Better ways of pathfinding*, Harrisburg, Penn, 1964, The Stackpole Co.)
