

Wilderness Medicine 4th edition (February 15, 2001) by Paul S. Auerbach (Editor) By Mosby

By OkDoKeY

Auerbach: Wilderness Medicine, 4th ed., Copyright © 2001 Mosby, Inc.

- Frontmatter

■ Title Page

■ Copyright Page

■ Contributors

■ Foreword

■ Preface

+ Part 1 - Mountain Medicine

+ Part 2 - Cold and Heat

+ Part 3 - Fire, Burns, and Radiation

+ Part 4 - Injuries and Medical Interventions

+ Part 5 - Rescue and Survival

+ Part 6 - Insects, Animals, and Zoonoses

+ Part 7 - Plants

+ Part 8 - Food and Water

+ Part 9 - Marine Medicine

+ Part 10 - Travel, Environmental Hazards, and Disasters

+ Part 11 - Equipment and Special Knowledge

+ Part 12 - Special Populations and Considerations

+ Appendix: Drug Stability Information

– **Part 1 - Mountain Medicine**

+ 1 - High-Altitude Medicine

+ 2 - Avalanches

+ 3 - Lightning Injuries

– Part 2 - Cold and Heat

+ 4 - Thermoregulation

+ 5 - Nonfreezing Cold Injuries

+ 6 - Accidental Hypothermia

+ 7 - Frostbite

+ 8 - Immersion into Cold Water

+ 9 - Polar Medicine

+ 10 - Pathophysiology of Heat-Related Illnesses

+ 11 - Clinical Management of Heat-Related Illnesses

– **Part 3 - Fire, Burns, and Radiation**

+ 12 - Wildland Fires: Dangers and Survival

+ 13 - Emergency Care of the Burned Victim

+ 14 - Exposure to Radiation from the Sun

– Part 4 - Injuries and Medical Interventions

- + 15 - Wilderness Injury Prevention**
- + 16 - Principles of Pain Management**
- + 17 - Emergency Airway Management**
- + 18 - Wilderness Trauma and Surgical Emergencies**
- + 19 - Wilderness Improvisation**
- + 20 - Hunting and Other Weapons Injuries**
- + 21 - Orthopedics**
- + 22 - The Eye in the Wilderness**
- + 23 - Dental and Facial Emergencies**

Part 5 - Rescue and Survival

24 - Wilderness Emergency Medical Services and Response Systems

25 - Search and Rescue

26 - Litters and Carries

27 - Aeromedical Transport

28 - Wilderness Survival

29 - Jungle Travel and Survival

30 - White-Water Medicine and Rescue

31 - Cave Rescue

– **Part 6 - Insects, Animals, and Zoonoses**

- + [32 - Protection from Blood-Feeding Arthropods](#)
- + [33 - Tick-Borne Diseases](#)
- + [34 - Spider Bites](#)
- + [35 - Scorpion Envenomation](#)
- + [36 - North American Arthropod Envenomation and Parasitism](#)
- + [37 - Non-North American Arthropod Envenomation and Parasitism](#)
- + [38 - North American Venomous Reptile Bites](#)
- + [39 - Non-North American Venomous Reptile Bites](#)
- + [40 - Antivenins and Immunobiologicals: Immunotherapeutics of Envenomation](#)
- + [41 - Bites and Injuries Inflicted by Domestic Animals](#)
- + [42 - Bites and Injuries Inflicted by Wild Animals](#)
- + [43 - Bear Attacks](#)
- + [44 - Wilderness-Acquired Zoonoses](#)
- + [45 - Emergency Veterinary Medicine](#)

– Part 7 - Plants

+ 46 - Seasonal Allergies

+ 47 - Plant-Induced Dermatitis

+ 48 - Toxic Plant Ingestions

+ 49 - Mushroom Toxicity

+ 50 - Ethnobotany: Plant-Derived Medical Therapy

— Part 8 - Food and Water

51 - Field Water Disinfection

52 - Infectious Diarrhea from Wilderness and Foreign Travel

53 - Nutrition, Malnutrition, and Starvation

54 - Seafood Toxidromes

55 - Seafood Allergies

– Part 9 - Marine Medicine

- + 56 - Submersion Incidents**
- + 57 - Diving Medicine**
- + 58 - Emergency Oxygen Administration**
- + 59 - Principles of Hyperbaric Oxygen Therapy**
- + 60 - Injuries from Nonvenomous Aquatic Animals**
- + 61 - Envenomation by Aquatic Invertebrates**
- + 62 - Envenomation by Aquatic Vertebrates**
- + 63 - Aquatic Skin Disorders**
- + 64 - Survival at Sea**

– **Part 10 - Travel, Environmental Hazards, and Disasters**

+ 65 - Travel Medicine

+ 66 - Non-North American Travel and Exotic Diseases

+ 67 - Natural Disaster Management

+ 68 - Natural and Human-Made Hazards: Mitigation and Management Issues

– **Part 11 - Equipment and Special Knowledge**

+ 69 - Wilderness Preparation, Equipment, and Medical Supplies

+ 70 - Selection and Use of Outdoor Clothing

+ 71 - Backcountry Equipment for Health Care Professionals

+ 72 - Ropes and Knot Tying

+ 73 - Wilderness Navigation Techniques

– Part 12 - Special Populations and Considerations

+ 74 - Children in the Wilderness

+ 75 - Women in the Wilderness

+ 76 - Elders in the Wilderness

+ 77 - Medical Liability and Wilderness Medicine

+ 78 - Ethics of Wilderness Medicine

+ 79 - The Changing Environment

– Appendix: Drug Stability Information

- [Acetaminophen \(Elixir, Drops, Tablets\)](#)
- [Acetaminophen with Codeine \(Tablets, Elixir\)](#)
- + [Acetazolamide \(Capsules, Tablets, Oral Solution, Injection\)](#)
- [Acetic Acid Solution](#)
- + [Albuterol \(Tablets, Syrup, Inhaled Formulations\)](#)
- + [Aloe \(Gel, Ointment, Laxatives\)](#)
- + [Aluminum Acetate \(Otic and Topical Preparations\)](#)
- [Antacids](#)
- + [Aspirin \(Tablets, Oral Solution, Suppositories\)](#)
- [Atropine Injection](#)
- + [Azithromycin \(Tablets, Capsules, Suspension, Injection\)](#)
- + [Bacitracin \(Topical, Injection\)](#)
- [Bismuth Subsalicylate \(Tablets, Suspension\)](#)
- [Butorphanol Tartrate \(Injection, Nasal Solution\)](#)
- [Calcium Chloride Injection](#)
- + [Cephalexin \(Capsules, Tablets, Oral Suspension\)](#)
- [Cetirizine Injection](#)
- [Charcoal, Activated](#)
- + [Ciprofloxacin \(Capsules, Tablets, Injection\)](#)
- [Cyclopentolate Hydrochloride Ophthalmic Solution](#)
- [DEET-Containing \(Diethyl Methylbenzamide\) Insect Repellents](#)
- [Dermabond \(2-Octyl Cyanoacrylate\) Topical Skin Adhesive](#)
- [Dexamethasone Injection](#)
- + [Dextroamphetamine \(Tablets, Elixir, Capsules\)](#)
- + [Dextrose \(Oral, Injection\)](#)
- [Diazepam \(Injection, Capsules, Tablets\)](#)
- [Digoxin Injection](#)
- + [Diltiazem \(Capsules, Oral Solution, Injection\)](#)
- [Diphenhydramine \(Tablets, Elixir, Injection\)](#)
- + [Domeboro \(Astringent and Otic Solutions\)](#)
- [Dopamine Hydrochloride Injection](#)

- + [Doxycycline \(Capsules, Tablets, Syrup, Suspension, Injection\)](#)
- [Epinephrine Injection \(Salts, Solutions\)](#)
- + [Erythromycin \(Tablets, Suspensions, Topical, Injection\)](#)
- [Estazolam Tablets](#)
- + [Fluocinolone Acetonide and Fluocinonide \(Ointment, Shampoo\)](#)
- [Furazolidone \(Tablets, Liquid\)](#)
- + [Furosemide \(Oral Formulation, Injection\)](#)
- [Gamma Benzene Hexachloride \(Lotion, Shampoo\)](#)
- [Glucagon Injection](#)
- + [Hydrocortisone \(Tablets, Suspension, Topical Cream, Injection\)](#)
- [Hydroxypropyl Methylcellulose Topical Ocular Solution](#)
- [Ibuprofen Tablets](#)
- [Intravenous Solutions \(D5W, D5NS, etc.\)](#)
- + [Ketoconazole \(Shampoo, Tablets\)](#)
- [Lidocaine Injection](#)
- [Loperamide Hydrochloride Capsules](#)
- + [Lorazepam \(Tablets, Injection\)](#)
- [Mannitol Injection](#)
- [Meperidine Hydrochloride \(Injection, Oral Solutions\)](#)
- [Midazolam \(Injection, Oral Solution\)](#)
- + [Morphine Sulfate \(Injection, Solution, Soluble Tablets\)](#)
- [Nalbuphine Hydrochloride Injection](#)
- [Naloxone Hydrochloride Injection](#)
- [Neosporin Ointment](#)
- + [Nifedipine \(Capsules, Tablets, Injection\)](#)
- + [Nitroglycerin \(Sublingual Tablets, Spray, Topical, Injection\)](#)
- + [Norfloxacin \(Tablets, Ophthalmic Solution\)](#)
- + [Ofloxacin \(Tablets, Otic Solution, Injection\)](#)
- [Penicillin GK Injection](#)
- [Phenobarbital Injection](#)
- [Phenylephrine \(Nasal/Ophthalmic Solutions, Injection\)](#)
- + [Phenytoin \(Tablets, Injection\)](#)

- [Polysporin Ointment](#)
- [Potassium Permanganate Astringent Solution](#)
- [Povidone-Iodine Solution](#)
- [Prednisone \(Tablets, Oral Solution, Suspension\)](#)
- [Procaine Penicillin G Injection](#)
- [Prochlorperazine \(Injection, Solution, Tablets, Capsules\)](#)
- [Promethazine \(Injection, Tablets, Solution, Suppositories\)](#)
- +
- [Pseudoephedrine, Pseudoephedrine/Tripolidine \(Tablets, Capsules\)](#)
- [Sodium Bicarbonate Injection](#)
- +
- [Sodium Sulfacetamide \(Ophthalmic Solution and Ointment\)](#)
- [Temazepam Capsules](#)
- [Tetanus Toxoid Injection](#)
- +
- [Tetracaine Hydrochloride Ophthalmic Solution and Topical Lidocaine/Epinephrine/Tetracaine \(LET\)](#)
- +
- [Tetracycline \(Tablets, Topical Solution, Injection\)](#)
- [Tolnaftate Topical Antifungal](#)
- [Triazolam Tablets](#)
- +
- [Trimethoprim/Sulfamethoxazole \(Tablets, Suspensions, Injection\)](#)
- [Zinc Salts](#)
- [ACKNOWLEDGMENTS](#)
- [SUGGESTED READINGS](#)

NOTICE

Pharmacology is an ever-changing field. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the licensed prescriber, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the publisher nor the editor assumes any liability for any injury and/or damage to persons or property arising from this publication.

Permission to photocopy or reproduce solely for internal or personal use is permitted for libraries or other users registered with the Copyright Clearance Center, provided that

the base fee of \$4.00 per chapter plus \$.10 per page is paid directly to the Copyright Clearance Center, 222 Rosewood Drive, Danvers, MA, 01923. This consent does not extend to other kinds of copying, such as copying for general distribution, for advertising or promotional purposes, for creating new collected works, or for resale.

Contributors

Javier A. Adachi MD

Fellow,
Department of Infectious Diseases,
Center for Infectious Disease,
The University of Texas-Houston Medical School and School of Public Health,
Houston, Texas;
Universidad Peruana Cayetano Heredia,
Lima, Peru

Michele Adler BPharm, Cert. Hoft. Hons. Post. Grad. Dip. Ed.

Lecturer in Horticulture,
Horticultural Consultant,
University of Melbourne-Burnley College,
Richmond, Victoria, Australia

Robert C. Allen DO, FACEP

Lt. Col. USAF,
Group Surgeon,
720th Special Tactics Group,
Air Force Special Operations Command,
Hurlburt Field, Florida

Christopher J. Andrews BE, MBBS, MEngSc, PhD, DipCSc, EDIC

Clinical Associate Lecturer,
University of Queensland,
St. Lucia, Queensland, Australia;
Registrar in Anaesthesia,
The Mater Hospital,

South Brisbane, Queensland, Australia

Betsy R. Armstrong MA

Chief Operating Officer,
Women of the West Museum,
Denver, Colorado

Richard L. Armstrong

Senior Research Scientist,
Cooperative Institute for Research in Environmental Sciences,
National Snow and Ice Data Center,
University of Colorado,
Boulder, Colorado

E. Wayne Askew PhD

Professor,
Division of Foods and Nutrition,
College of Health,
University of Utah,
Salt Lake City, Utah

Dale Atkins BA Geography

Avalanche Scientist and Forecaster,
Colorado Avalanche Information Center,
Boulder, Colorado

Paul S. Auerbach MD, MS

Clinical Professor of Surgery,
Division of Emergency Medicine,
Stanford University School of Medicine,
Stanford, California;
Venture Partner,
Delphi Ventures,
Menlo Park, California

Howard D. Backer MD, MPH

Emergency Department,
Kaiser Permanente Medical Center,
Hayward, California;
Currently, Medical Consultant and Epidemiologist,

Immunization Branch,
Division of Communicable Disease Control,
California Department of Health Services

James P. Bagian BSME, MD

Clinical Assistant Professor of Preventive Medicine and Community Health,
University of Texas Medical Branch,
Galveston, Texas;
Adjunct Assistant Professor of Military and Emergency Medicine,
Uniformed Services University of the Health Sciences,
F. Edward Hebert School of Medicine,
Bethesda, Maryland;
Director,
National Center for Patient Safety,
Veterans Health Administration,
Ann Arbor, Michigan;
Colonel,
U.S. Air Force Reserve 920th Rescue Group,
Patrick Air Force Base,
Florida

H. Bernard Bechtel MD

Staff,
South Georgia Medical Center,
Valdosta, Georgia

Greta J. Binford PhD

Research Associate,
Department of Biochemistry and Center for Insect Sciences,
University of Arizona,
Tucson, Arizona

Warren D. Bowman Jr. MD, FACP

Clinical Associate Professor of Medicine Emeritus,
University of Washington School of Medicine,
Seattle, Washington;
National Medical Director Emeritus,
National Ski Patrol System,
Denver, Colorado;

Past President,
Wilderness Medical Society,
Colorado Springs, Colorado

Leslie V. Boyer MD

Assistant Professor,
Department of Pediatrics,
University of Arizona Health Sciences Center;
Medical Director,
Arizona Poison and Drug Information Center,
Tucson, Arizona

George Braitberg MBBS, FACEM

Senior Fellow,
Department of Medicine,
Director of Emergency Medicine, Consultant Medical Toxicologist,
University of Melbourne,
Parkville, Victoria, Australia;
Consultant Medical Toxicologist,
National Poison Centre,
Austin and Repatriation Medical Centre,
Heidelberg, Victoria, Australia

Robert K. Bush MD

Professor of Medicine,
University of Wisconsin-Madison;
Chief of Allergy,
William S. Middleton VA Hospital,
Madison, Wisconsin

Sean P. Bush MD, FACEP

Staff Emergency Physician and Venom Specialist, Associate Professor of Emergency
Medicine,
Loma Linda University Medical Center and School of Medicine,
Loma Linda, California

Frank K. Butler Jr. MD

Director of Biomedical Research,
U.S. Naval Special Warfare Command;
Attending Ophthalmologist,
Naval Hospital Pensacola,

Pensacola, Florida

Michael L. Callaham MD, FACEP

Chief,
Division of Emergency Medicine,
Professor of Emergency Medicine,
University of California, San Francisco,
San Francisco, California

Steven C. Carleton MD, PhD

Assistant Professor,
Department of Emergency Medicine,
University of Cincinnati College of Medicine;
Medical Director,
University Air Care,
University Hospital, Inc.,
Cincinnati, Ohio

Betty Carlisle MD

Emergency Physician,
South Bend, Washington

Richard F. Clark MD

Associate Professor of Medicine,
University of California,
San Diego;
Director,
Division of Medical Toxicology,
Department of Emergency Medicine,
University of California,
San Diego Medical Center,
San Diego, California

Loui H. Clem

Littleton, Colorado

David A. Connor MD

Clinical Toxicologist,
Department of Medical Toxicology,
Good Samaritan Regional Medical Center,

Phoenix, Arizona

Donald C. Cooper BS, MS, MBA, NREMT-P

Deputy Fire Chief,
Cuyahoga Falls Fire Department,
Cuyahoga Falls, Ohio

Mary Ann Cooper MD

Associate Professor,
Department of Emergency Medicine,
University of Illinois at Chicago,
Chicago, Illinois

Larry I. Crawshaw PhD

Professor,
Department of Biology,
Portland State University;
Professor,
Behavioral Neuroscience,
Oregon Health Sciences University,
Portland, Oregon

Barbara D. Dahl MD

Attending Physician,
Kaiser Santa Clara Emergency Department,
Stanford/Kaiser Emergency Medicine Residency Program,
Santa Clara, California;
Department of Emergency Medicine,
St. Rose Hospital,
Hayward, California

Daniel F. Danzl MD

Professor and Chair,
Department of Emergency Medicine,
University of Louisville School of Medicine,
Louisville, Kentucky

Richard C. Dart MD, PhD

Associate Professor of Surgery, Medicine and Pharmacy,
University of Colorado Health Sciences Center;
Director,
Rocky Mountain Poison and Drug Center,
Denver Health Authority,
Denver, Colorado

Kathleen Mary Davis BS Forestry, MS Forestry

Chief,
Natural Resources,
Southern Arizona Office,
National Park Service,
Phoenix, Arizona

Kevin Jon Davison ND, LAc

Maui East-West Clinic, Ltd.,
Haiku, Maui, Hawaii

Anne E. Dickison MD

Clinical Associate Professor of Anesthesiology and Pediatrics,
University of Florida College of Medicine;
Faculty Pediatric Intensivist and Anesthesiologist,
Shands Teaching Hospital at the University of Florida,
Gainesville, Florida

Mark Donnelly MD

Resident,
Department of Emergency Medicine,
University of Rochester Medical Center,
Rochester, New York

Howard J. Donner MD

Clinic Physician,
Telluride Medical Center,
Telluride, Colorado

Herbert L. DuPont MD

Chief,
Internal Medicine Service,

St. Luke's Episcopal Hospital;
H. Irving Schweppe, Jr., M.D. Chair in Internal Medicine;
Vice Chairman,
Department of Internal Medicine,
Baylor College of Medicine;
Mary W. Kelsey Professor of Medical Sciences,
The University of Texas Health Sciences Center at Houston,
Houston, Texas

Thomas J. Ellis MD

Director of Orthopedic Trauma, Assistant Professor,
Oregon Health Sciences University,
Portland, Oregon

John H. Epstein MD, MS

Clinical Professor of Dermatology,
Department of Dermatology,
University of California, San Francisco,
San Francisco, California

William L. Epstein MD

Professor of Dermatology, Emeritus,
University of California, San Francisco,
San Francisco, California

Blair D. Erb MD

Past President,
Wilderness Medical Society,
Colorado Springs, Colorado;
The Study Center;
Jackson-Madison County General Hospital,
Jackson, Tennessee

Timothy B. Erickson MD

Director,
Emergency Medicine Residency Program,
Director,
Division of Clinical Toxicology,
Associate Professor,
University of Illinois at Chicago,

Chicago, Illinois

Murray E. Fowler DVM

Professor Emeritus,
Zoological Medicine,
University of California School of Veterinary Medicine,
Davis, California

Mark S. Fradin MD

Clinical Associate Professor,
Department of Dermatology,
University of North Carolina School of Medicine,
Chapel Hill, North Carolina

Bryan L. Frank MD

Senior Clinical Instructor,
Medical Acupuncture for Physicians Program,
Continuing Education Office,
University of California,
Los Angeles School of Medicine;
President,
American Academy of Medical Acupuncture,
Los Angeles, California;
President,
Integrated Medicine Seminars, L.L.C.,
Richardson, Texas

Luanne Freer MD

Clinical Assistant Professor of Emergency Medicine,
George Washington University,
Washington, D.C.;
Chief of Staff,
Yellowstone Park Medical Services,
Yellowstone National Park, Wyoming;
Emergency Physician,
Bozeman, Montana,
Idaho Falls, Idaho

Steven P. French MD

Research Director,
Yellowstone Grizzly Foundation,
Jackson Hole, Wyoming;
Member,
Bear Specialists Group,
World Conservation Union;
ER Medical Director (Retired)

Stephen L. Gaffin PhD

Research Physiologist,
Thermal and Mountain Medicine,
U.S. Army Research Institute of Environmental Medicine,
Natick, Massachusetts

Douglas A. Gentile MD, MBA

Attending Physician,
University of Vermont College of Medicine,
Burlington, Vermont

Gordon G. Giesbrecht PhD

Professor,
Health, Leisure and Human Performance Research Institute;
Associate Professor,
Department of Anesthesia,
Faculty of Medicine,
University of Manitoba,
Winnipeg, Manitoba, Canada

Philip H. Goodman MD, MS, FACP

Professor of Medicine,
Chief, Division of General Internal Medicine and Health Care Research,
University of Nevada School of Medicine,
Reno, Nevada

John Gookin

Curriculum Manager,
Senior Staff Instructor,
The National Outdoor Leadership School (NOLS),
Lander, Wyoming;
Associate Faculty,

University of Utah,
Salt Lake City, Utah

Kimberlie A. Graeme MD

Clinical Assistant Professor,
Section of Toxicology,
Division of Emergency Medicine,
Department of Surgery,
University of Arizona College of Medicine,
Tucson, Arizona;
Fellowship Director,
Department of Medical Toxicology,
Good Samaritan Regional Medical Center,
Phoenix, Arizona;
Attending Physician,
Mayo Clinic Hospital,
Scottsdale, Arizona

Peter H. Hackett MD

Affiliate Associate Professor,
Department of Medicine,
University of Washington School of Medicine,
Seattle, Washington;
Emergency Department,
St. Mary's Medical Center,
Grand Junction, Colorado

Murray P. Hamlet DVM

Chief, Research Programs and Operations Division,
U.S. Army Research Institute of Environmental Medicine,
Natick, Massachusetts

Susan L. Hefle PhD

Assistant Professor,
Department of Food Science and Technology,
University of Nebraska,
Lincoln, Nebraska

John P. Hegggers PhD, FAAM, CWS (AAWM)

Professor, Surgery (Plastic),
ILT-UTMB Medical School,
University of Texas Medical Branch;

Director of Clinical Microbiology,
Directory of Microbiology Research,
Shriners Burns Institute,
Galveston, Texas

David Heimbach MD

Professor of Surgery,
University of Washington School of Medicine,
Seattle, Washington

Henry J. Herrmann DMD, FAGD

Private Practice,
Falls Church, Virginia

Ronald L. Holle MS

Meteorologist,
Global Atmospheric, Inc.,
Tucson, Arizona

IX

Rivkah S. Horowitz MD, PhD

Clinical Assistant Professor of Medicine,
Brown University School of Medicine,
Providence, Rhode Island;
Attending Physician,
Lawrence and Memorial Hospital,
New London, Connecticut

Frank R. Hubbell DO

Clinical Instructor,
University of New England College of Osteopathic Medicine,
Biddeford, Maine

Steve Hudson

President,
Pigeon Mountain Industries, Inc.,

LaFayette, Georgia

Kenneth V. Iserson MD, MBA

Professor of Surgery,
University of Arizona College of Medicine;
Director, Arizona Bioethics Program,
University of Arizona,
Tucson, Arizona

Michael E. Jacobs MD

Private Practice in Internal Medicine and Gastroenterology;
United States Coast Guard Licensed Captain;
Professional Sailor,
Martha's Vineyard, Massachusetts

Elaine C. Jong MD

Clinical Professor of Medicine,
Director,
Hall Health Primary Care Center/University of Washington Student Health Service,
University of Washington School of Medicine,
Seattle, Washington

Lee A. Kaplan MD

Associate Clinical Professor of Medicine/Dermatology,
University of California, San Diego,
San Diego, California;
Private Practice in Dermatology,
Dermatologist Medical Group,
La Jolla, California

James W. Kazura MD

Professor, Division of Geographic Medicine,
Case Western Reserve University School of Medicine,
Cleveland, Ohio

Barbara C. Kennedy MD

Assistant Professor,
University of Vermont College of Medicine;
Attending Physician,
Fletcher Allen Health Care,

Burlington, Vermont

Sean Keogh MRCP, FRCSEd, FACEM, FFAEM

Consultant, Emergency Medicine,
Auckland Hospital,
Auckland, New Zealand

Kenneth W. Kizer MD, MPH

Distinguished Professor of Military and Emergency Medicine,
Uniformed Services University of the Health Sciences,
Bethesda, Maryland;
President and Chief Executive Officer,
The National Quality Forum,
Washington, D.C.

Judith R. Klein MD

Resident, Emergency Medicine,
Stanford University,
Stanford, California

Donald B. Kunkel MD (deceased)

Associate in Pharmacology and Toxicology,
Health Sciences Center,
University of Arizona,
Tucson, Arizona;
Medical Director,
Samaritan Regional Poison Center,
Samaritan Regional Medical Center,
Phoenix, Arizona

Jason E. Lang MD

Clinical Instructor,
University of Vermont College of Medicine;
Chief Resident in Pediatrics,
Fletcher Allen Health Care;
Burlington, Vermont

Carolyn S. Langer MD, JD, MPH

Instructor in Occupational Medicine,
Lecturer in Occupational Health Law,

Harvard School of Public Health,
Boston, Massachusetts

Patrick H. LaValla

President,
ERI International,
Olympia, Washington

x

Raúl E. López PhD

Research Meteorologist (Retired),
National Severe Storms Laboratory,
National Oceanic and Atmospheric Administration,
Norman, Oklahoma

Roberta A. Mann MD

Medical Director,
Torrance Memorial Burn Center and Wound Healing Center,
Torrance Memorial Medical Center,
Torrance, California

Ariel D. Marks MD, MS, FACEP

Staff Physician,
Emergency Department,
Sequoia Hospital,
Redwood City, California

Vicki Mazzorana MD, FACEP

Clinical Assistant Professor of Emergency Medicine,
Department of Surgery,
Stanford University School of Medicine,
Stanford, California

Robert L. McCauley MD

Professor of Surgery and Pediatrics,
University of Texas Medical Branch;
Chief, Plastic and Reconstructive Surgery,

Shriners Burns Institute,
Galveston, Texas

Jude T. McNally RPh, ABAT

Managing Director,
Arizona Poison and Drug Information Center,
University of Arizona College of Pharmacy,
Tucson, Arizona

James Messenger

Lieutenant, EMT-P,
Cuyahoga Falls Fire Department,
Cuyahoga Falls, Ohio;
Rescue Specialist,
F.E.M.A. Ohio Task Force 1 (OH TF-1)

Timothy P. Mier BA

Lieutenant,
Cuyahoga Falls Fire Department,
Cuyahoga Falls, Ohio

Sherman A. Minton MD (deceased)

Professor Emeritus,
Microbiology & Immunology,
Indiana University School of Medicine,
Indianapolis, Indiana;
Research Associate,
Department of Herpetology,
American Museum of Natural History,
New York, New York

James K. Mitchell PhD

Professor of Geography,
Rutgers University,
Piscataway, New Jersey

Daniel S. Moran PhD

Visiting Lecturer,
Sackler Faculty of Medicine,
Tel Aviv University,

Tel Aviv, Israel;
Head, Physiology Unit,
Heller Institute of Medical Research,
Chaim Sheba Medical Center,
Tel Hashomer, Israel

John A. Morris Jr. MD

Professor of Surgery,
Director, Division of Trauma,
Vanderbilt University School of Medicine,
Nashville, Tennessee

Robert W. Mutch BA, MSF

Fire Management Consultant,
Fire Management Applications,
Missoula, Montana

Andrew B. Newman MD, FCCP

Clinical Associate Professor of Medicine,
Stanford University School of Medicine,
Stanford, California

Eric K. Noji MD, MPH

Chief, Epidemiology, Surveillance and Emergency Response Branch,
Bioterrorism Preparedness and Response Program,
National Center for Infectious Diseases,
Centers for Disease Control and Prevention (CDC),
Atlanta, Georgia

Robert L. Norris Jr. MD

Associate Professor of Surgery/Emergency Medicine,
Stanford University School of Medicine;
Chief, Division of Emergency Medicine,
Stanford University Hospital,
Stanford, California

Edward J. Otten MD, FACMT

Professor of Emergency Medicine and Pediatrics, Director,
Division of Toxicology,
University of Cincinnati,
Cincinnati, Ohio

Naresh J. Patel DO

Fellow, Allergy/Immunology,
Department of Medicine,
University of Wisconsin-Madison,
Madison, Wisconsin

Claude A. Piantadosi MD

Professor,
Department of Medicine (Pulmonary),
Duke University Medical Center,
Durham, North Carolina

Richard N. Rausch PhD

Postdoctoral Fellow,
Department of Biology,
Portland State University,
Portland, Oregon

Sheila B. Reed MS Education

Consultant, International Disaster Management,
Middleton, Wisconsin

Robert C. Roach PhD

Research Associate Professor,
New Mexico Highlands University,
Las Vegas, New Mexico;
Director, The Hypoxia Institute,
Montezuma, New Mexico

Martin C. Robson MD

Professor of Surgery,
Division of Plastic Surgery,
Department of Surgery,
University of South Florida,

Tampa, Florida

Sandra Schneider MD

Professor and Chair,
Department of Emergency Medicine,
University of Rochester;
Strong Memorial Hospital,
Rochester, New York

Bern Shen MD, MPhil

Institute for Health Policy Studies,
University of California, San Francisco,
San Francisco, California

David J. Smith Jr. MD

Professor and Section Head,
Department of Plastic Surgery,
University of Michigan Medical Center,
Ann Arbor, Michigan

Alan M. Steinman MD, MPH

Fellow, American College of Preventive Medicine;
Board of Directors,
Marine Safety Foundation

Robert C. Stoffel

President, Emergency Response International, Inc.,
Cashmere, Washington

Jeffrey R. Suchard MD

Assistant Clinical Professor of Medicine,
Division of Emergency Medicine,
University of California,
Irvine Medical Center,
Orange, California

Mark F. Swiontkowski MD

Professor and Chairman,
Department of Orthopaedics,

University of Minnesota,
Minneapolis, Minnesota

Eric A. Toschlog MD

Division of General Surgery,
Department of Surgery,
East Carolina University,
The Brody School of Medicine,
Greenville, North Carolina

Kenneth F. Trofatter Jr. MD, PhD

3M Clinical Professor,
Department of Obstetrics, Gynecology, and Women's Health,
University of Minnesota Medical School,
Minneapolis, Minnesota

Karen B. Van Hoesen MD

Assistant Clinical Professor,
Department of Emergency Medicine;
Director, Diving Medicine Center;
Director, Hyperbaric Medicine Fellowship,
University of California, San Diego,
San Diego, California

Foreword

"Everything to hope, with but little to fear"

Food was scarce and the hunter was determined to bring back meat for his hungry friends. Thousands of bison swarmed over the prairie, and it did not take him long to shoot a fat male. As he watched the animal die, blood pouring from its mouth, he failed to see the grizzly bear until it was 20 steps away. He had no time to reload his clumsy gun, but could only retreat. There was no good place to hide—no trees, no bushes, only the nearby river. As soon as he turned, the bear charged after him, roaring open-mouthed and covering the ground with frightening speed. Fortunately, the riverbank was low and the hunter plunged into the water and turned to face the bear, hoping it would not follow. The bear rushed to within 20 feet, sized up the situation, turned away and ran off as fast as it had charged. Meriwether Lewis had just escaped with his life.

The Lewis and Clark Expedition had been 11 months on the trail and was more than a thousand miles from its base. There was no contact with the outside world and no possibility of help. Supplies of food had run low, and the group depended on their hunters for meat. The native population had not always been friendly. The explorers could not speak the local languages and relied on interpreters. Attacks by ferocious animals were a daily danger.

On June 16, 1804, 2 days after the bear attack, a critical point was reached in their journey. The outcome would not depend on their hunting skills and luck but on their medical knowledge. The leaders described the situation later in their diaries:

June 12, 1805: The interpreter's woman very sick. One man has a felon rising on his hand; the other, with the toothache, has taken a cold in the jaw, &c. (Clark)

June 13, 1805: A fair morning. Some dew this morning. The Indian woman very sick. I gave her a dose of salts. We set out early. (Clark)

June 14, 1805: A fine morning. The Indian woman complaining all night, and

excessively bad this morning. Her case is somewhat dangerous. Two men with the toothache, two with tumors, and one with a tumor and light fever. (Clark)

June 15, 1805: Our Indian woman sick and low spirited. I gave her the bark and applied it externally to her region, which revived her much. (Clark)

June 16, 1805: Found the Indian woman extremely ill and much reduced by her indisposition. This gave me some concern, as well for the poor object herself—then with a young child in her arms—as from the consideration of her being our only dependence for a friendly negotiation with the Snake Indians, on whom we depend for horses to assist us in our portage from the Missouri to the Columbia River. (Lewis)

Sacagawea, a 17-year-old Shoshone Indian with a 6-month-old baby, was married to one of the interpreters, Toussaint Charbonneau. She had been critically ill for several days and was not responding to treatment.

Meriwether Lewis, who was in modern terms the "trip doctor" and the leader, took over her care. He had studied medicinal botany and had sought advice from America's leading physician, Dr. Benjamin Rush, before taking command of the group, but he was not a physician. Nonetheless, his knowledge of medical problems in the wilderness was not much different from that of many doctors of the time. Few doctors had medical degrees, and many were only apprenticed to an older physician for a few years before practicing on their own. The decision not to have a physician on the trip was made with the agreement of President Thomas Jefferson, who was the moving force behind the expedition.

Sacagawea was suffering from abdominal pain and vomiting. She was febrile and nearly unconscious. Clark had treated her empirically with bleeding, salts, and abdominal poultices. In taking control of the case, Lewis did everything that a modern doctor would do under the same circumstances. He took a history, examined the patient, came to a diagnosis, and prescribed such treatment as was available. He concluded that her problem was due to "an obstruction of the mensis in consequence of taking cold"—a diagnosis strange to our thinking but one that suggests a careful and detailed history. At that time, men did not naturally discuss such intimate details of the lives of women. He prescribed poultices and doses of mineral waters and laudanum.

Sacagawea improved greatly and was able to get up and take a walk. Within 2 days she was back to normal. Her recovery was vital for the expedition because she was the key to opening the route to the Pacific Ocean. She had been captured while a child, taken hundreds of miles to the East, and was now on the verge of returning to her own country. Without her ability to

interpret the language of the Shoshones, the expedition might have failed. When they finally met the Shoshones, Sacagawea found that her brother, now grown to manhood, was the chief of the tribe. Further progress of the expedition was assured. Lewis had achieved his two aims: recovery of his patient and salvage of the expedition.

For many years, President Jefferson had visions of opening a water route to the West Coast, wresting the lucrative fur trade from the British and French, and finding the mythical Northwest Passage. The Spanish and British had similar aspirations to send explorers to the West Coast. In 1793, Alexander Mackenzie crossed the spine of the Rocky Mountains farther north, through an area so inhospitable that it was useless for trade. In the same year, a French botanist, André Michaux, supported by the American Philosophical Society, tried to travel up the Missouri River but failed. Two obstacles prevented further American attempts from coming to fruition: Congress would not appropriate money, and France and Spain controlled the land west of the Mississippi River.

Knowledge of the geography of the country was limited and naïve. No one—British, French, Canadian, Spanish, or American—understood the vastness and complexity of the land. They were all blind men feeling a continental elephant. The British and Spanish had superficially explored the West Coast as far as Alaska. In 1792, Captain Gray, an adventurous American sailor, had discovered and named the Columbia River, which obviously flowed from the distant peaks. Exploration was confined to the coast, and people could only guess at what lay beyond the mountains that divided the country. Since fur traders had long used the lower reaches of the Missouri River to bring their trophies to St. Louis and New Orleans, Jefferson thought, why not an expedition that would ascend the Missouri, make a short portage across the mountains, and continue down the Columbia to the coast?

Until 1800, Spain controlled the territory west of the Mississippi through which an expedition would have to move. Rule of the land passed to France from 1800 to 1803, until Napoleon sold the territory to the United States in the Louisiana Purchase. Suddenly the United States had dominion over a vast expanse of land from the Missouri to the Pacific.

In 1802, Jefferson secretly persuaded Congress to appropriate \$2500 for an expedition "for the purpose of extending the external commerce of the U.S." The expedition was also called a "literary pursuit," slim camouflage for an act of commercial imperialism that amazingly achieved its objectives with almost no loss of life, and without starting a war with Britain, Spain, or the Indians.

President Jefferson chose his private secretary, Captain Meriwether Lewis, to lead the expedition. Lewis was an experienced army officer with knowledge of wilderness travel and a proven record of leadership. In addition, he was a member of a distinguished Virginia family and a close friend of the President. Lewis, in turn, chose his former commanding officer, William Clark, to be his co-leader. Time proved them to be the perfect team, as leaders, scientists, observers, and diarists—and occasionally as physicians.

President Jefferson organized the preparations meticulously. Lewis was dispatched to Philadelphia by Jefferson to learn celestial navigation, botany, and zoology, and become proficient in the preservation of biologic specimens. He visited Benjamin Rush, the leading physician of his day and physician to President Jefferson, to find out what medications he should take and how to treat the diseases he might encounter.

Rush prepared a list of 14 questions for Lewis to answer and gave him 10 pieces of advice on how to maintain his own health. The questions to be answered concerned the health, morals, and religious practices of the Indians. Rush wanted Lewis to inquire about the diseases of these people and how they were cured. When did their women start and stop menstruating? How long were their children suckled? What were their sexual mores and habits? Rush was particularly interested in knowing if any of the religious ceremonies of the Indians were similar to those of Judaism because there was a belief, in some circles, that the lost tribe of Israel had ended up in the American West.

Rush advised rest after strenuous exercise, moderation in drink and food, and the liberal use of purges, to both prevent and cure ailments. He told them to wear flannel next to the skin, especially in cold and wet weather, and advised that the men wear shoes without heels, since they would be less fatiguing than shoes with higher heels. The advice about purging, bleeding, and sweating conformed with the current theories of medical practice. Rush outspokenly believed that blood, bowel contents, and sweat contained the causes of disease that could be removed.

Based on advice from Rush, the medical dispensary of the expedition contained a liberal supply of Rush's Pills, a potent mixture of calomel and jalap, both laxatives strong enough to empty the bowels of the hardest frontiersman. Numerous drugs, herbs, and instruments, including laudanum for pain, medications for eye problems, four penis syringes for treating venereal disease, and lancets for bleeding, were packaged in a specially constructed wooden chest. The total cost of the medical supplies was \$96.69.

The Corps of Discovery, as the expedition was called, spent the winter of 1803–1804 in Camp Dubois, north of St. Louis, on the east bank of the Mississippi River (the west bank was not yet in the United States) and opposite the mouth of the Missouri River, training and equipping for the long and uncertain journey.

Captain Clark, 23 army privates, four sergeants, Drouillard (a French-Indian hunter), York (William Clark's slave), and Lewis' Newfoundland dog Seaman pushed out onto the Missouri River on May 14, 1804. Lewis joined the group a few days later. They sailed in a 55-foot keel boat and two smaller pirogues. They struggled upstream, poling, rowing, sailing, and hauling the boats by hand. The weather was hot, with frequent summer storms. Thick clouds of mosquitoes were a constant plague. The food was bad and often scarce. Although generous supplies of some foods had been taken, the prime source of meat was obtained by hunting. At first they were lucky. There were vast herds

of buffalo, deer, and elk. Game could often be shot within a short distance of camp. Such profusion would not last long after the opening of the West.

The men were young, strong, and chosen for their wilderness skills. There were hunters, boatmen, carpenters, interpreters, and French voyageurs, as healthy and adventurous a group of young men as could be found. However, despite their strength, diseases plagued them constantly: diarrhea, fevers, near starvation, skin infections and boils, cuts from knives, sunburn, snakebites, dislocated shoulders, and feet lacerated from cactus spines. Only luck saved them from being killed by grizzly bears. A sleeping sergeant was bitten on the hand by a wolf. Sacagawea had a difficult labor but gave birth 10 minutes after receiving a concoction of rattlesnake rattles. Diarrhea and intestinal infections came to be expected. The men took few sanitary precautions, although the army knew that troops that remained on the move and dug latrines far from camp remained healthier than did those that stayed in one camp for a long time. Perhaps their mobility saved them from some problems. During the two periods they stayed in camps, medical problems were more common than when they were on the move.

On August 17, 1804, Sergeant Charles Floyd developed abdominal pain that progressed over the next 3 days. During that time, he continued to work on the boat, but the pain became worse, shock developed, and on August 20, he died. Before he died, he said to Captain Clark, "I am going to leave you. I want you to write me a letter." He died "with composure" and was buried with military honors on a bluff overlooking the river, where there is now a monument to his memory. He was the only fatality in the Corps and the first U.S. soldier to die west of the Mississippi. The diagnosis is uncertain, although his symptoms suggest a ruptured appendix. Lewis described the symptoms as "bilious choleric," but there was no record of an examination. We do not know if Floyd's abdomen was tense, distended, or painful. Neither Lewis nor Clark was a doctor, and although Lewis was knowledgeable about herbs and probably knew how to treat wounds and accidents, he was not trained to diagnose illnesses or to make a physical examination. If the diagnosis was, indeed, a ruptured appendix, Sergeant Floyd would not have survived, even had he been in Philadelphia under Benjamin Rush's care.

The first winter was spent in a collection of huts surrounded by a wooden stockade, near a Mandan Indian village. The weather was bitterly cold, and the supply of food ran low. The Indians were friendly, but they too had very little food; some members of the expedition helped them by going out on hunting excursions. Although the temperature dropped to -38° F, none of the Corps members sustained damaging frostbite. A Mandan boy, stranded out overnight and left for dead, was brought in with frozen feet. After a few days, the boy's toes became gangrenous and Clark "sawed off his toes." The endurance of another Indian amazed the soldiers. Stranded overnight in freezing weather, with no food and only the clothes on his back, he had neither frostbite nor hypothermia. The Mandans slept with their feet towards the campfire, to prevent frostbite during the night, but could not stave off frostbite while hunting with only thin moccasins on their feet.

Prairie plums, cherries, and gooseberries supplemented the protein diet and contained enough vitamin C to prevent scurvy. As winter gave way to spring, thousands of buffalo

returned and meat became available. The strength and health of the men improved. When they were about to set out again on the river on April 7, 1805, Lewis was able to write to Jefferson, "I can foresee no material or probable obstruction to our progress, and entertain therefore the most sanguine hopes of complete success.... With such men I have everything to hope, and but little to fear." At the same time he wrote to his mother, "... not a whisper of discontent or murmur is to be heard among them, but all act in unison, and with the most perfect harmony." The Corps, which had experienced disciplinary problems, a desertion, and the need for floggings, was now a tough, unified group, confident in their officers and prepared to embark on an endeavor more difficult than they could ever imagine.

The journey westward through the Bitterroot Mountains was a constant struggle. Food was scarce; sometimes there was none. After days of pushing their way through fallen timber, along barely discernible trails, they staggered, half starved, into the territory of the Nez Perce Indians. At first, the Nez Perce wanted to kill the strange intruders, but an old woman, who had been befriended by a white person while a prisoner in the East, persuaded them to spare their lives. The Indians became loyal friends, supplying and guiding the expedition.

Like many others of his day, Jefferson thought the portage from the Missouri River to the Columbia River would be short; perhaps there would be a direct connection between the two rivers. The "connection" was,

xvi

in fact, 340 miles long, with 60 of them over "tremendous mountains" covered with snow. The journey down the Snake River and into the valley of the Columbia River was a relief, drifting downstream instead of hauling supplies on reluctant, stumbling horses, up mountains and through forests. Salmon became part of the diet and, in place of deer or elk, dogs became a common and, for many, a favorite food.

On November 7, 1805, Clark saw the sea. "Ocian in view! O! the joy!," he wrote in his diary. The explorers searched a long time for a good campsite until choosing what became Fort Clatsop, their log cabin camp for the winter. Like Fort Mandan, it was built to keep out inquisitive Indians. Lewis had been ordered by Jefferson to take every precaution against fighting with the Indians and had been very successful in avoiding trouble. The Clatsop Indians were not aggressive and had already traded with western sailors; but in some ways, they were too friendly, bringing girls to the camp, a temptation the men could not resist. They paid for their indulgence with the acquisition of venereal disease, repeating their experiences of the previous winter at the Mandan village.

The winter at Fort Clatsop was cold and wet. Between November 4 and March 25, only 12 days were free of rain and only six were sunny. The diet was often nothing but spoiled elk, alternated with pounded fish and a handful of roots. A whale washed up on the shore, and the blubber and oil provided a pleasant new taste. There was the usual toll of accidents. One man cut his leg badly with a knife. Another developed severe low

back pain that crippled him for weeks until he was cured by a sweat bath, alternating heat with cold.

In March 1806 the Corps of Discovery launched their canoes on the river and set their course for home. Their delight was great but their troubles were not over. Crossing the mountains at first proved to be impossible because of deep, lingering snows. The expedition had to wait for several weeks, bargaining and competing with the Nez Perce in athletic contests and horse races. The trinkets they had brought as trade goods had been used up. One service remained that could be traded for food or horses—medical aid. Clark proved to be a popular doctor with the Indians. He treated their sore eyes, set their fractures, and tried to cure a chief who was paralyzed by treating him in a sweat bath. However, he did not always treat with grace, calling one patient "a sulky bitch." Lewis had twinges of conscience in allowing the Indians to think that Clark was a doctor but excused the mild deception as necessary to get the horses and food they needed to continue.

After the expedition finally crossed the mountains and left the Nez Perce guides behind, they divided into two groups—one to explore the Yellowstone River, and the other, led by Lewis, to go north along the Marias River.

All went well with Lewis and the three men with him until they met a party of Blackfoot Indians, the most warlike tribe in the area. After nervous greetings, the two groups spent the night around the same campfire. The next morning, the braves tried to steal a gun and horses. One of Lewis' men ran after the thief who had stolen his gun and stabbed him to death, and Lewis shot and killed the horse thief. It was the first time anyone in the Corps of Discovery had killed an Indian. Lewis and his men mounted their horses and made a dramatic escape, riding more than 100 miles in 24 hours before joining up with the rest of the expedition.

A few weeks later, one of the hunters, Cruzatte, who had bad eyesight, and Lewis were hunting a wounded elk in thick willows and riverside brush. Cruzatte thought he saw an elk, shot, and hit the buckskin-clothed Lewis in the buttock. The treatment Lewis gave himself was as good as might be given today under similar circumstances. Drains were inserted into the entrance and exit wounds, which were dressed. The bullet was found in Lewis' clothing, so no attempt had to be made to find it in the wound, which was the standard treatment of the day. Fortunately, the wound did not become infected, and within a few weeks, before the end of the voyage, Lewis was completely healed.

On September 23, 1806, the expedition reached St. Louis. They had been away for 2 years and 4 months and had journeyed more than 8000 miles. Lewis reported to the President:

In obedience to your orders we have penetrated the Continent of North America to the Pacific Ocean, and sufficiently explored the interior of the country to affirm with confidence that we have discovered the most practicable rout which does exist across the continent by means of the navigable branches

of the Missouri and Columbia Rivers.

Looking back, one can only be amazed at the medical success of the expedition, which returned with the loss of only one man. Was it skill? Was it luck? Was the trip a tribute to the endurance and resistance of the human body to cold, heat, starvation, insects, injuries, and medications that could have done more harm than good? The bear that attacked Meriwether Lewis turned away at the end of a bluff charge. The wolf that bit the sleeping sergeant was not rabid. When rattlesnakes struck, no serious injuries resulted. The cuts by knives and wounds from prickly pears caused no major infections. No man became blind. No limbs were lost to frostbite. The lead ball shot into Lewis was recovered in his clothing, so there was no dirty surgery. Sacagawea recovered, perhaps because the water that Lewis gave her from a mineral spring restored her electrolyte losses. Pompey, Sacagawea's son, recovered from a life-threatening abscess in his neck without the benefit of antibiotics. When Lewis used his penknife to bleed a man, septicemia did not follow.

XVII

The medicine chest contained little of therapeutic value except opium and laudanum. Peruvian bark, related to quinine, could have been useful for malaria, but there is no evidence that malaria was a problem. The ferocious laxatives fortunately caused little but discomfort. Tartar emetic was not needed because no man ingested poison. The lancets for bleeding were, mercifully, used sparingly.

Could a modern doctor have done better? Not much. Some illnesses might have been shortened, some pain relieved, but many more medications would have been dispensed, more lacerations sutured, and perhaps even snakebite antivenom administered. Sergeant Floyd might only have been saved by a heroic operation under imperfect circumstances. So, the expedition would still probably have returned with the loss of one man and the medical bill would have been much greater than 96 dollars and 69 cents.

Preface

This fourth edition of *Wilderness Medicine* is designed to be a great improvement over the previous edition. It is necessarily expanded in girth in order to accommodate additional topics of relevance to medical professionals called upon to rescue, diagnose, and treat victims in outdoor environments. The specialty of wilderness medicine continues to mature, as most of the active participants in its progress come to agree on the body of knowledge that must be mastered to promote its science and create effective practitioners.

Outdoor pursuits comprise the fastest growing segment of recreational life in the United States, and perhaps the world. Men and women of all nationalities have become travelers and adventurers in unprecedented numbers, and the related encounters with risk and danger have kept pace. The widely publicized tragedies that afflict climbers on Mount Everest, victims of avalanches, and explorers in hazardous seas regularly heighten our awareness of the powerful natural forces that prevail despite our best intentions and preventive efforts. As we climb into rarified air, sled over thin ice, eschew safety ropes and helmets, and stretch the limits of our diving decompression algorithms, we will be reminded of our vulnerability and limitations on a planet that shows no mercy in its most terrifying moments. Therein lies the relevance, challenge, and opportunity for wilderness medicine.

In seeking to understand the pathophysiology of high altitude, we witness the beauty of pristine rock faces and summits. While we learn to repel sharks, we marvel at the rainbow colors of the barrier reefs. In the quest for a cure for malaria, the tropical scientist gazes into the emerald canopy of the rainforest. As we battle forest fires and survive the lightning and fierce winds of a thunderstorm, our attention is drawn to a herd of bison stampeding across a grass prairie that stretches as far as the imagination. No medical specialty or healthcare-related avocation is more connected to this planet than is wilderness medicine. My colleagues and I, and everyone else involved in outdoor health and wilderness medicine, could not be more fortunate.

Wilderness medicine is presented here by experts and devotees. For example, the integration of basic science and clinical art is blended brilliantly in the chapters on heat-related illness. In recognition of our aging population, a new chapter is devoted to

elders. A significant upgrade to the content is embodied by the nonmedical topics, such as the information on navigation, clothing, backcountry equipment, and ropes and knot tying. Wilderness medicine practitioners have long recognized that essential survival skills may need to be deployed by healers when outfitters and guides cannot function at full capacity. The physician who can recite everything there is to know about exposure to the sun and treatment of dehydration must also be able to pitch in and gather water; knowing how to avoid a shark attack is just as important as knowing how to treat a shark attack victim.

A new information age is upon us. The Internet allows us to link "many to many," and to collect information from disparate locations in a hugely expedited fashion. However, it isn't yet a perfect filter for the reliability of the content, and so there is still much to be said for sitting down with a good book. *Wilderness Medicine* is meant to be a reference, but also to be a stimulus for inquiry and adventure. The publisher and I have worked hard to keep it to a manageable size, and the addition of color images throughout the book and emphasis on practical matters make this the most complete and relevant edition to date.

Wilderness Medicine has become a life's work, and will continue to grow. In addition, the Wilderness Medical Society; the journal *Wilderness and Environmental Medicine* (recently accepted into the *Index Medicus*); a plethora of continuing medical education programs in wilderness medicine, diving medicine, adventure and travel medicine, and outdoor health; *Field Guide to Wilderness Medicine*; the book for laypersons *Medicine for the Outdoors*; and all of the opportunities yet to come by virtue of television and the Internet have propelled this 20-year effort into an established medical discipline for as long as there will be wilderness.

I am grateful for Kathy Falk and Rick Dudley, my editors for this fourth edition. The contributors, some of whom have been with this book since its inception and who continue to learn, teach, and enhance this field, share my enormous thanks and respect. With great pleasure, I can now observe the activities of my children, and the children of many of the contributors, as they continue to increase their appreciation for the wilderness and outdoor health. In the continuing endeavor of *Wilderness Medicine*, I am in many ways the luckiest editor on Earth.

Part 1 - Mountain Medicine

2

Chapter 1 - High-Altitude Medicine

Peter H. Hackett
Robert C. Roach

Millions of persons visit recreation areas above 2400 m (7874 feet) in the American West each year. Hundreds of thousands visit central and south Asia, Africa, and South America, many traveling to altitudes over 4000 m (13,124 feet).^[234] Increasingly, physicians and other health care providers are confronted with questions of prevention and treatment of high-altitude medical problems ([Box 1-1](#)), as well as the effects of altitude on preexisting medical conditions. Despite advances in high-altitude medicine, significant morbidity and mortality persist ([Table 1-1](#)). Clearly, better education of the population at risk and those advising them is essential. This chapter reviews the basic physiology of ascent to high altitude, as well as the pathophysiology, recognition, and management of medical problems associated with high altitude. Much of the information presented in this chapter is drawn from major high-altitude physiology and medical studies of the last 40 years, with an emphasis on the last decade (see the recent reviews by Houston,^[139] Nakashima,^[246] Richalet,^[272] and West^[355]).

DEFINITIONS

High Altitude (1500 to 3500 m [4921 to 11,483 feet])

The onset of physiologic effects of diminished $P_{I_{O_2}}$ includes decreased exercise performance and increased ventilation (lower arterial P_{CO_2}) ([Box 1-2](#)). Minor impairment exists in arterial oxygen transport (Sa_{O_2} at least 90%), but high-altitude illness is common with rapid ascent above 2500 m (8202 feet) ([Table 1-2](#)).

Very High Altitude (3500 to 5500 m [11,483 to 18,045 feet])

Maximum arterial oxygen saturation falls below 90% as the arterial P_{O_2} falls below 60 torr ([Table 1-3](#) ; [Figure 1-1](#)). Extreme hypoxemia may occur during exercise, sleep, and high-altitude illness. This is the most common range for severe altitude illness.

Extreme Altitude (over 5500 m [18,045 feet])

Marked hypoxemia and hypocapnia manifest at extreme altitude. Progressive deterioration of physiologic function eventually outstrips acclimatization. As a result, no permanent human habitation is above 5500 m (18,045 feet). A period of acclimatization is necessary when ascending to extreme altitude; abrupt ascent without supplemental oxygen for other than brief exposures invites severe altitude illness.

ENVIRONMENT AT HIGH ALTITUDE

Barometric pressure falls with increasing altitude in a logarithmic fashion (see [Table 1-2](#)). Therefore the partial pressure of oxygen (21% of barometric pressure) also decreases, resulting in the primary insult of high altitude: hypoxia. At approximately 5800 m (19,030 feet), barometric pressure is one half that at sea level, and on the summit of Mt. Everest (8848 m [29,029 feet]) the inspired pressure of oxygen is approximately 28% that at sea level (see [Figure 1-1](#) and [Table 1-2](#)).

The relationship of barometric pressure to altitude changes with the distance from the equator. Thus polar regions afford greater hypoxia at high altitude, as well as extreme cold. West^[354] has calculated that the barometric pressure on the summit of Mt. Everest (27° N latitude) would be about 222 torr instead of 253 torr if Everest were located at the latitude of Mt. McKinley (62° N). Such a difference, he claims, would be sufficient to render an ascent without supplemental oxygen impossible.

In addition to the role of latitude, fluctuations related to season, weather, and temperature affect the pressure-altitude relationship. Pressure is lower in winter than in summer. A low-pressure trough can reduce pressure 10 torr in one night on Mt. McKinley, making climbers awaken "physiologically higher" by 200 m (656 feet). The degree of hypoxia, then, is directly related to the barometric pressure and not solely to geographic altitude.^[354]

Temperature decreases with altitude (average of 6.5° C per 1000 m [3281 feet]), and the effects of cold and hypoxia are generally additive in provoking both cold injuries and altitude problems.^{[269] [351]} Ultraviolet light penetration increases approximately 4% per 300-m (984-foot) gain in altitude, increasing the risk of sunburn, skin cancer, and snowblindness. Reflection of sunlight in glacial cirques and on flat glaciers can cause intense radiation of heat in the absence of wind. We have observed temperatures of 40° to 42° C in tents on both Mt. Everest and Mt. McKinley. Heat problems, primarily heat exhaustion, are often unrecognized in this usually cold environment. Physiologists have not yet examined the consequences of heat stress or rapid, extreme changes in environmental temperature combined with the hypoxia of high altitude.

Above the snow line is the "high-altitude desert," where water can be obtained only by melting snow or ice. This factor, combined with increased water loss

TABLE 1-1 -- Incidence of Altitude Illness in Various Groups

STUDY GROUP	NUMBER AT RISK PER YEAR	SLEEPING ALTITUDE (m)	MAXIMUM ALTITUDE REACHED (m)	AVERAGE RATE OF ASCENT*	PERCENT WITH AMS	PERCENT WITH HAPE AND/OR HACE	REFERENCE
Western State visitors	30 million	~2000	3500	1–2	18–20	0.01	[134]

*Barometric pressure is approximated by the equation $P_B = \text{Exp}(6.6328 - \{0.1112 \times \text{altitude} - [0.00149 \times (\text{altitude}^2)]\})$, where altitude = terrestrial altitude in (meters/1000 or km). P_{iO_2} is calculated as the $P_B - 47$ (water vapor pressure at body temperature) \times fraction of O_2 in inspired air. The F_{iO_2} at sea level related to the given altitude is calculated as $P_{iO_2} / (760 - 47)$. Similar calculations for F_{iO_2} at different altitudes may be made by substituting ambient P_B for 760 in the equation.

Data are mean values and (range) or ±SD, where available. All values are for subjects age 20 to 40 years who were acclimatizing well.

*Data for altitude residents from Loeppky JA, Caprihan A, Luft UC: VA/Q inequality during clinical hypoxemia and its alterations. In Shiraki K, Yousef MK, editors: *Man in stressful environments*, Springfield, Ill, 1987, Charles C Thomas.

†Data for acute exposure from McFarland RA, Dill DB: *J Aviat Med* 9:18, 1938.

‡Data for chronic exposure during Operation Everest II data are from Sutton JR et al: *J Appl Physiol* 64:1309, 1988.

§The second data set for acclimatized subjects studied during acute exposure to the simulated summit of Everest is from Richalet JP et al: Operation Everest III (COMEX '97), *Adv Exp Med Biol* 474:297, 1999.

Figure 1-1 Increasing altitude results in decrease in inspired P_{O_2} (P_{IO_2}), arterial P_{O_2} (P_{aO_2}), and arterial oxygen saturation (S_{aO_2}). Note that the difference between P_{IO_2} and P_{aO_2} narrows at high altitude because of increased ventilation and that S_{aO_2} is well maintained while awake until over 3000 m (9840 feet). (Data from Morris A: *Clinical pulmonary function tests: a manual of uniform lab procedures*, Intermountain Thoracic Society, 1984; and Sutton JR et al: *J Appl Physiol* 64:1309, 1988.)

through the lungs from increased respiration and through the skin, commonly results in dehydration that may be debilitating. Thus the high-altitude environment imposes

multiple stresses, some of which may contribute to or be confused with the effects of hypoxia.

Box 1-2. GLOSSARY OF PHYSIOLOGIC TERMS

P_B	Barometric pressure (torr)
P_{O_2}	Partial pressure of oxygen
$P_{I_{O_2}}$	Inspired P_{O_2} [$0.21 \times P_B - 47$ torr (vapor pressure of H_2O at $37^\circ C$)]
$P_{A_{O_2}}$	P_{O_2} in alveolus
$P_{a_{CO_2}}$	P_{CO_2} in alveolus
$P_{a_{O_2}}$	P_{O_2} in arterial blood
$P_{a_{CO_2}}$	P_{CO_2} in arterial blood
$S_{a_{O_2}} \%$	Arterial oxygen saturation % (HbO_2 / total Hb $\times 100$)
R	Respiratory quotient (CO_2 produced/ O_2 consumed)

Alveolar gas equation: $P_{a_{O_2}} = P_{I_{O_2}} - P_{a_{CO_2}} / R$

ACCLIMATIZATION TO HIGH ALTITUDE

Rapid exposure to the altitude at the summit of Mt. Everest causes loss of consciousness in a few minutes and death shortly thereafter. However, climbers ascending Mt. Everest over a period of weeks without supplemental oxygen have experienced only minor symptoms of illness. The process by which individuals gradually adjust to hypoxia and enhance survival and performance is termed *acclimatization*. A complex series of physiologic adjustments increases oxygen delivery to cells and improves their hypoxic tolerance. The severity of hypoxic stress, rate of onset, and individual physiology determine whether the body successfully acclimatizes or is overwhelmed.

Individuals vary in their ability to acclimatize, no doubt reflecting certain genetic polymorphisms. Some adjust quickly, without discomfort, whereas acute mountain sickness (AMS) develops in others, who go on to recover. A small percentage fail to acclimatize even with gradual exposure over weeks. The tendency to acclimatize well or to become ill is consistent on repeated exposure if rate of ascent and altitude gained are similar. Successful initial acclimatization protects against altitude illness and improves sleep. Longer-term acclimatization (weeks) primarily improves aerobic exercise ability. These adjustments disappear at a similar rate on descent to low altitude. A few days at low altitude may be sufficient to render a person susceptible to altitude illness, especially high-altitude pulmonary edema (HAPE), on reascent. The improved ability to do physical work at high altitude, however, persists for weeks.^[198] Persons who live at high altitude during growth and development appear to realize the maximum benefit of acclimatization changes; for example, their exercise performance matches that of persons at sea level.^[237] No genetic adaptation to high altitude in humans has yet been confirmed, but recent reports of normal pulmonary artery pressures and normal birth weights in Tibetans suggest selection of genetic traits for life at high altitude.^{[100] [238] [372]}

Ventilation

By reducing alveolar carbon dioxide, increased ventilation raises alveolar oxygen, improving oxygen delivery (see [Figure 1-1](#)). This response starts at an altitude as low as 1500 m (4921 feet) ($P_{IO_2} = 124$ torr; see [Table 1-2](#)) and within the first few minutes to hours of high-altitude exposure. The carotid body, sensing a decrease in arterial P_{O_2} , signals the central respiratory center in the medulla to increase ventilation. This carotid body function (hypoxic ventilatory response [HVR]) is genetically determined^[352] but influenced by a number of extrinsic factors. Respiratory depressants, such as alcohol and soporifics, as well as fragmented sleep, depress the HVR. Agents that increase general metabolism, such as caffeine and coca, as well as specific respiratory stimulants, such as progesterone^[182] and almitrine,^[114] increase the HVR.

(Acetazolamide, a respiratory stimulant, acts on the central respiratory center rather than on the carotid body.) Physical conditioning apparently has no effect on the HVR. Numerous studies have shown that a good ventilatory response enhances acclimatization and performance and that a very low HVR may contribute to illness^[277] (see Acute Mountain Sickness and High-Altitude Pulmonary Edema).

Other factors influence ventilation on ascent to high altitude. As ventilation increases, hypocapnia produces alkalosis, which acts as a braking mechanism on the central respiratory center and limits a further increase in ventilation. To compensate for the alkalosis, within 24 to 48 hours of ascent the kidneys excrete bicarbonate, decreasing the pH toward normal; ventilation increases as the negative effect of the alkalosis is removed. Ventilation continues to increase slowly, reaching a maximum only after 4 to 7 days at the same

6

altitude ([Figure 1-2](#)). The plasma bicarbonate concentration continues to drop and ventilation continues to increase with each successive increase in altitude. This process is greatly facilitated by acetazolamide (see Acetazolamide Prophylaxis).

A way to appreciate the importance of the ventilatory pump at increasing altitude is to plot values for alveolar oxygen and carbon dioxide on the Rahn-Otis diagram ([Figure 1-3](#)). This approach clearly contrasts the effects of acute and chronic hypoxic exposure and can be used to assess the degree of ventilatory acclimatization.^[265] As ventilation increases, the decrease in alveolar carbon dioxide allows an equivalent increase in alveolar oxygen. The level of ventilation ($\sim P_{ACO_2}$) is therefore what determines alveolar oxygen for a given inspired oxygen tension, according to the alveolar gas equation: $PAO_2 = P_{IO_2} - P_{ACO_2} / R$. The paramount importance of hyperventilation is readily apparent from the following calculation: the alveolar P_{O_2} on the summit of Mt. Everest (about 33 torr) would be reached at only 5000 m (16,404 feet) if alveolar P_{CO_2} stayed at 40 torr, limiting an ascent without supplemental oxygen to near this altitude. [Table 1-3](#) gives the measured arterial blood gases resulting from acclimatization to various altitudes.

Figure 1-2 Change in minute ventilation, ($\bullet V_E$) end-tidal carbon dioxide (P_{ACO_2}), and arterial oxygen saturation (SaO_2) during 5 days' acclimatization to 4300 m (14,104 feet). (Modified from Huang SY et al: *J Appl Physiol* 56:602, 1984.)

Circulation

The circulatory pump is the next step in the transfer of oxygen, moving oxygenated blood from the lungs to the tissues.

Systemic Circulation.

Increased sympathetic activity on ascent causes an initial mild increase in blood pressure, moderate increase in heart rate and cardiac output, and increase in venous tone. Stroke volume is low because of decreased plasma volume, which drops as much as 12% over the first 24 hours^[365] as a result of the bicarbonate diuresis, a fluid shift from the intravascular space, and suppression of aldosterone.^[25] Resting heart rate returns to near sea level values with acclimatization, except at extremely high altitude. Maximum heart rate follows the decline in maximal oxygen uptake with increasing altitude. As the limits of hypoxic acclimatization are approached, maximum and resting heart rates converge. During Operation Everest II (OEII), cardiac function was appropriate for the level of work performed and cardiac output was not a limiting factor for performance.^[268] ^[331] Interestingly, myocardial ischemia at high altitude has not been reported in healthy persons, despite extreme hypoxemia. This is partly because of the reduction in myocardial oxygen demand from reduced maximal heart rate and cardiac output. Pulmonary capillary wedge pressures are low, and there has been no evidence of left ventricular dysfunction or abnormal filling pressures in humans at rest.^[101] ^[158] On echocardiography, the left ventricle is smaller than normal because of decreased

Figure 1-3 Rahn-Otis diagram, with recent data from extreme high altitude. Note that after acclimatization, alveolar oxygen is higher because of lower alveolar carbon dioxide. Point A is average alveolar gases in unacclimatized subjects (1 hour's exposure) to 3800 m (12,464 feet). Point B is after acclimatization to 3800 m (12,464 feet). (Data from Malconian MK et al: *Aviat Space Environ Med* 64:37, 1993; Rahn H, Otis AB: *Am J Physiol* 157:445, 1949; and West JB et al: *J Appl Physiol* 55:688, 1983.)

stroke volume, whereas the right ventricle may become enlarged.^[331]

Pulmonary Circulation.

A prompt but variable increase in pulmonary vascular resistance occurs on ascent to

high altitude as a result of hypoxic pulmonary vasoconstriction, which increases pulmonary artery pressure. Mild pulmonary hypertension is greatly augmented by exercise, with pulmonary pressure reaching near-systemic values,^[101] especially in persons with a previous history of HAPE. During OEII, Groves et al^[101] demonstrated that even when associated with a mean pulmonary artery pressure of 60 torr, cardiac output remained appropriate and right atrial pressure did not rise above sea level values. This suggested that right ventricular function was intact in spite of extreme hypoxemia and hypertension.

Administration of oxygen at high altitude does not completely restore pulmonary artery pressure to sea level values, an indication that increased pulmonary vascular resistance does not result solely from hypoxic vasoconstriction.^[101]^[156] The explanation is likely vascular remodeling with medial hypertrophy. See Stenmark et al^[328] for a recent review of molecular and cellular mechanisms of the pulmonary vascular response to hypoxia, including remodeling.

Cerebral Circulation.

Cerebral oxygen delivery is the product of arterial oxygen content and cerebral blood flow (CBF) and depends on the net balance between hypoxic vasodilation and hypocapnia-induced vasoconstriction. CBF increases, despite the hypocapnia, when P_{aO_2} is less than 60 torr (altitude greater than 2800 m [9187 feet]). In a classic study, CBF increased 24% on abrupt ascent to 3810 m (12,501 feet) and then returned to normal over 3 to 5 days.^[312] More recent studies have shown considerable individual variation,^[30]^[31]^[166] but overall, cerebral oxygen delivery and global cerebral metabolism are well maintained with moderate hypoxia.^[67]

Blood

Hematopoietic Responses to Altitude.

Ever since the observation in 1890 by Viault^[345] that hemoglobin concentration was higher than normal in animals living in the Andes, scientists have regarded the hematopoietic response to increasing altitude as an important component of the acclimatization process. On the other hand, hemoglobin concentration has no relationship to susceptibility to high-altitude illness on initial ascent.

In response to hypoxemia, erythropoietin is secreted and stimulates bone marrow production of red blood cells.^[309] The hormone is detectable within 2 hours of ascent, nucleated immature red blood cells can be found on a peripheral blood smear within days, and new red blood cells are in circulation within 4 to 5 days. Over a period of weeks to months, red blood cell mass increases in proportion to the degree of hypoxemia. Iron supplementation can be important: women who take supplemental iron at high altitude approach the hematocrit values of men at altitude^[122] ([Figure 1-4](#)).

Overshoot of the hematopoietic response causes excessive polycythemia, which may actually impair oxygen transport because of increased blood viscosity. Although the

"ideal" hematocrit at high altitude is not established, phlebotomy is often recommended when hematocrit values exceed 60% to 65%. During the American Medical Research Expedition to Mt. Everest (AMREE), hematocrit was reduced by hemodilution from $58\% \pm 1.3\%$ to $50.5\% \pm 1.5\%$ at 5400 m (17,717 feet) with no decrement in maximum oxygen uptake and an increase in cerebral functioning.^[299] The increase in hemoglobin concentration seen 1 to 2 days after ascent is due to hemoconcentration secondary to decreased plasma volume rather than a true increase in red blood cell mass. This results in a higher hemoglobin concentration at the cost of decreased blood volume, a trade-off that might impair exercise performance. Longer-term acclimatization leads to an increase in plasma volume, as well as in red blood cell mass, thereby increasing total blood volume.

Oxyhemoglobin Dissociation Curve.

The oxyhemoglobin dissociation curve plays a crucial role in oxygen transport. Because of the sigmoidal shape of the curve, SaO_2 % is well maintained up to 3000 m (9843 feet) despite a significant decrease in arterial P_{O_2} (see [Figure 1-1](#)). Above that altitude, small changes in arterial P_{O_2} result in large changes in arterial oxygen saturation ([Figure 1-5](#)).

In 1936, Keys et al^[173] demonstrated an in vitro right shift in the position of the oxyhemoglobin dissociation curve at high altitude, a shift that favors the release of oxygen from the blood to the tissues. This change occurs because of the increase in 2,3-diphosphoglycerate

Figure 1-4 Hematocrit changes on ascent to altitude in men and in women with and without supplemental iron. (Modified from Hannon JP, Chinn KS, Shields JL: *Fed Proc* 28:1178, 1969.)

Figure 1-5 Oxyhemoglobin dissociation curve showing effect of 10-torr decrement in P_{aO_2} (shaded areas) on arterial oxygen saturation at **A**, sea level, and **B**, near 4400 m (14,432 feet). Note the much larger drop in S_{aO_2} at high altitude. (Modified from Severinghaus JW et al: *Circ Res* 19:274, 1966.)

(2,3-DPG), which is proportional to the severity of hypoxemia. In vivo, however, this is offset by alkalosis, and at moderate altitude little net change occurs in the position of the oxyhemoglobin dissociation curve. On the other hand, the marked alkalosis of extreme hyperventilation, as measured on the summit and simulated summit of Mt. Everest (P_{CO_2} 8 to 10 torr, pH greater than 7.5), shifts the oxyhemoglobin dissociation curve to the left, which facilitates oxyhemoglobin binding in the lung, raises S_{aO_2} %, and is thought to be advantageous.^[297] This concept is further supported by observing that when persons with a very left-shifted oxygen-hemoglobin curve, caused by an abnormal hemoglobin (Andrew-Minneapolis), were taken to moderate (3100 m [10,171 feet]) altitude, they had less tachycardia and dyspnea and remarkably had no decrease in exercise performance.^[127]

Tissue Changes

The next link in the oxygen transport chain is tissue oxygen transfer, which depends on capillary perfusion, diffusion distance, and driving pressure of oxygen from the capillary to the cell. The final link, then, is use of oxygen within the cell. Banchero^[13] has shown that capillary density in dog skeletal muscle doubled in 3 weeks at a barometric pressure of 435 torr. A recent study in humans noted higher-than-normal muscle capillary density, although it was impossible to determine whether this was an adaptation to high altitude or to physical training.^[253] Ou and Tenney^[256] revealed a 40% increase in mitochondrial number but no change in mitochondrial size, whereas the study of Oelz et al^[253] showed that high-altitude climbers had normal mitochondrial density. During OEII, a significant reduction in muscle size was noted, and although no de novo synthesis of capillaries or mitochondria occurred, capillary density and the ratio of mitochondrial volume to contractile protein fraction increased, primarily as a result of the atrophy.^[199] Nevertheless, this change decreased the diffusion distance for oxygen.

Sleep At High Altitude

Disturbed sleep is common at high altitude. Reite et al^[270] studied six men during a 12-day stay at 4300 m (14,108 feet). All subjects complained of disturbed sleep. Compared with sea level control studies, stages 3 and 4 sleep were reduced, stage 1 time increased, and stage 2 did not change. More time was spent awake, with a significant increase in arousals and slightly less rapid eye movement (REM) time. The subjective complaints of poor sleep were out of proportion to the small reduction in total

sleep time. Five of the six had periodic breathing. Interestingly, the arousals were not necessarily related to periodic breathing. One subject had periodic breathing for 90% of the night and no recorded arousals. With more extreme hypoxia, sleep time was dramatically shortened and arousals increased, without a change in ratio of sleep stages but with a reduction in REM sleep.^[5] Presumably, the mechanism of the arousals is cerebral hypoxia. Periodic breathing appears to play only a minor role in altering sleep architecture at high altitude.^[296]

Periodic Breathing.

Periodic breathing is primarily a nocturnal phenomenon, characterized by hyperpnea followed by apnea ([Figure 1-6](#)). Respiratory alkalosis during hyperpnea acts on the central respiratory center, causing apnea. During apnea, SaO_2 % decreases, carbon dioxide level increases, and the carotid body is stimulated, causing a recurrent hyperpnea and apnea cycle. Persons with a high HVR have more periodic breathing, with mild oscillations in SaO_2 %, ^[184] whereas persons with a low HVR have more regular breathing overall but may suffer periods of apnea with extreme hypoxemia distinct from periodic breathing.^[114] As acclimatization progresses, periodic breathing lessens but does not disappear and SaO_2 % increases (Figure 1-7 (Figure Not Available)). ^[5] ^[333] Periodic breathing has not been implicated in the etiology of high-altitude illness, but a chaotic pattern without apparent periodicity was found in HAPE-susceptible subjects. ^[91] Eichenberger et al^[81] have also reported greater periodic breathing in those with HAPE, secondary to lower SaO_2 %.

Acetazolamide, 125 mg at bedtime, diminishes periodic

Figure 1-6 Respiratory patterns and arterial oxygen saturation (SaO_2) with placebo and acetazolamide in two sleep studies of a subject at 4200 m (13,776 feet). Note pattern of hyperpnea followed by apnea during placebo treatment, which is changed with acetazolamide. (Modified from Hackett PH et al: *Am Rev Respir Dis* 135:896, 1987.)

Figure 1-7 (Figure Not Available) Sleep oxygenation improves with acclimatization to same altitude. Top line is maximum and bottom line is minimum SaO_2 in an acclimatized person. Shaded area is maximum and minimum SaO_2 values for new arrival at 5360 m (17,581 feet). (Modified from Sutton JR et al: *N Engl J Med* 301:1329, 1979.)

breathing, improves oxygenation, and is a safe and superior agent to use as a sleeping

aid (see [Figure 1-6](#) and Figure 1-7 (Figure Not Available)). If insomnia is due to causes other than periodic breathing, diphenhydramine (Benadryl, 50 to 75 mg) or the short-acting benzodiazepines, such as triazolam (Halcion, 0.125 to 0.25 mg) and temazepam (Restoril, 15 mg), can be used. However, these are potentially dangerous in ill persons at high altitude because of resulting respiratory depression, and they may decrease oxygenation even in persons who are acclimatizing

Figure 1-8 On ascent to altitude, $\dot{V}O_2$ max decreases and remains suppressed. In contrast, endurance time (minutes to exhaustion at 75% of altitude-specific $\dot{V}O_2$ max) increases with acclimatization. (Modified from Maher JT, Jones LG, Hartley LH: *J Appl Physiol* 37:895, 1974.)

well. Bradwell et al^[44] showed that acetazolamide (500 mg slow-release orally) given with temazepam (10 mg orally) improved sleep and maintained SaO_2 %, counteracting a 20% decrease in SaO_2 % when temazepam was given alone. A new, nonbenzodiazepine hypnotic, zolpidem (Ambien, 10 mg) was recently shown to improve sleep at 4000 m (13,123 feet) without adversely affecting ventilation.^[32]

Exercise

Maximal oxygen consumption drops dramatically on ascent to high altitude (see references ^[92] and ^[278] for recent reviews). Maximal oxygen uptake ($\dot{V}O_2$ max) falls approximately 10% for each 1000 m (3281 feet) of altitude gained above 1500 m (4921 feet). Those with the highest sea level $\dot{V}O_2$ max values have the largest decrement in $\dot{V}O_2$ max at high altitude, but overall performance at high altitude is not consistently related to sea level $\dot{V}O_2$ max.^[253] ^[273] ^[356] In fact, many of the world's elite mountaineers have quite average $\dot{V}O_2$ max values, in contrast to other endurance athletes.^[253] Acclimatization at moderate altitudes enhances submaximal endurance time but not $\dot{V}O_2$ max ([Figure 1-8](#)).^[92] Preliminary recent work suggests that genetic factors may play a role in determining exercise performance in mountaineers at high altitude. Montgomery et al identified a polymorphism in the gene encoding angiotensin converting enzyme (ACE) that was strongly related to mountaineering performance in 25 British mountaineers.^[233] The

mechanism by which an ACE gene polymorphism could enhance exercise performance at high altitude is unknown but provides interesting and important direction for further

investigations.

Oxygen transport during exercise at high altitude becomes increasingly dependent on the ventilatory pump. The marked rise in ventilation produces a sensation of breathlessness, even at low work levels. The following quotation is from a high-altitude mountaineer:

After every few steps, we huddle over our ice axes, mouths agape, struggling for sufficient breath to keep our muscles going. I have the feeling I am about to burst apart. As we get higher, it becomes necessary to lie down to recover our breath.^[222]

In contrast to the increase in ventilation with exercise, at increasing altitudes in OEII, cardiac function and cardiac output were maintained at or near sea level values for a given oxygen consumption (workload).^[268] Although related to decreased oxygen transport, the exact limiting factors to exercise at high altitude remain elusive. Wagner^[350] has proposed that the pressure gradient for diffusion of oxygen from capillaries to the working muscle cells may be inadequate. Another concept is that increased cerebral hypoxia from exercise-induced desaturation is the limiting factor.^[57] Mountaineers, for example, become lightheaded and their vision dims when they move too quickly at extreme altitude ([Figure 1-9](#)).^[353]

Training at High Altitude.

Optimal training for increased performance at high altitude depends on the altitude of residence and the athletic event. For aerobic activities (events lasting more than 3 or 4 minutes) at altitudes above 2000 m (6562 feet), acclimatization for 10 to 20 days is necessary to maximize performance.^[202] For events occurring above 4000 m (13,123 feet), acclimatization at an intermediate altitude is recommended. Highly anaerobic events at intermediate altitudes require only arrival at the time of the event, although mountain sickness may become a problem.

The benefits of training at high altitude for subsequent performance at or near sea level depend on choosing the training altitude that maximizes the benefits and minimizes the "detraining" inevitable when maximal oxygen uptake is limited (altitude greater than 1500 to 2000 m [4921 to 6562 feet]). Hence, data from training above 2400 m (7874 feet) have shown no increase in subsequent sea level performance. Balke, Nagle, and Daniels^[12] returned subjects to sea level after 10 days' training at 2000 m (6562 feet) and demonstrated an increase in aerobic power, plasma volume, and hemoglobin concentration, with faster running times. More recent work suggests training benefits from intermittent altitude exposure^[192] and from training at low altitude while sleeping at high altitude.^{[11] [194] [329]} Coaches

Figure 1-9 Calculated changes in the P_{O_2} of alveolar gas and arterial and mixed venous blood as oxygen uptake is increased for a climber on the summit of Mt. Everest. Unconsciousness develops at a mixed venous P_{O_2} of 15 torr. DMO_2 , Muscle O_2 diffusing capacity. (Modified from West JB: *Respir Physiol* 52:265, 1983.)

and endurance athletes from around the world are convinced of the benefits of training and/or sleeping at moderate altitude to improve sea level performance.^{[10] [40] [71]} The benefit appears to be due to enhanced erythropoietin production and increased red cell mass, which requires adequate iron stores, and thus usually iron supplementation.^[204]
^[285] ^[330]

HIGH-ALTITUDE SYNDROMES

High-altitude syndromes are illnesses attributed directly to hypobaric hypoxia. Exact mechanisms, however, are unclear. For example, all persons at a given high altitude are hypoxic and those with AMS are barely more hypoxemic than those who are well.^[99] ^[132] Also, there is a delay from the onset of hypoxia to the onset of high-altitude illness. These two facts have led to the conclusion that hypoxia induces time-dependent processes that are responsible for AMS, in contrast to the syndrome of acute hypoxia.

Considerable overlap exists among the high-altitude syndromes, and terminology and classification of high-altitude illness remain somewhat confusing. Sudden exposure to extreme altitude may result in death from acute hypoxia (asphyxia), whereas more gradual ascent to the same altitude may result in AMS or no illness at all. Where symptoms of acute hypoxia end and AMS begins is vague, as reflected in the classic experiments

11

of Bert.^[37] In terms of altitude illness, the general concept of a spectrum of illness with a common underlying pathogenesis is well accepted and provides a useful framework for discussion. We find it useful to separate the syndrome into neurologic and pulmonary components. For the neurologic syndromes, the spectrum progresses from AMS to high-altitude cerebral edema (HACE). In the lung, the spectrum includes pulmonary hypertension, interstitial edema, and HAPE. These problems all occur within the first few days of ascent to a higher altitude, have many common features, and respond to descent and oxygen. Longer-term problems of altitude exposure include high-altitude deterioration and chronic mountain sickness.

Neurologic Syndromes

The numerous neurologic syndromes at high altitude reflect the nervous system's sensitivity to hypoxia. The spectrum of clinical effects ranges from subtle cognitive changes to death from gross cerebral edema. Acute hypoxia is also included here because it is essentially a neurologic insult. We consider AMS and HACE as manifestations of a common underlying pathophysiology of vasogenic edema, but we give special consideration to high-altitude headache, which might have a number of mechanisms. Acute hypoxia and cognitive dysfunction are related to neurotransmitter dysfunction, whereas the focal neurologic syndromes, such as transient ischemic attack

(TIA) and stroke, are related to secondary ischemia.

Acute Hypoxia

Acute, profound hypoxia, although of greatest interest in aviation medicine, may also occur on terra firma when ascent is too rapid or when hypoxia abruptly worsens. Carbon monoxide poisoning, pulmonary edema, overexertion, sleep apnea, or a failed oxygen delivery system may rapidly exaggerate hypoxemia. In an unacclimatized person, loss of consciousness from acute hypoxia occurs at an SaO_2 of 40% to 60% or at an arterial P_{O_2} of less than about 30 torr.^[36] Tissandier, the sole survivor of the flight of the balloon Zenith in 1875, gave a graphic description of the effects of acute hypoxia:

But soon I was keeping absolutely motionless, without suspecting that perhaps I had already lost use of my movements. Towards 7,500 m, the numbness one experiences is extraordinary. The body and the mind weakens little by little, gradually, unconsciously, without one's knowledge. One does not suffer at all; on the contrary. One experiences inner joy, as if it were an effect of the inundating flood of light. One becomes indifferent; one no longer thinks of the perilous situation or of the danger; one rises and is happy to rise. Vertigo of the lofty regions is not a vain word. But as far as I can judge by my personal impression, this vertigo appears at the last moment; it immediately precedes annihilation—sudden, unexpected, irresistible. I wanted to seize the oxygen tube, but could not raise my arm. My mind, however, was still very lucid. I was still looking at the barometer; my eyes were fixed on the needle which soon reached the pressure number of 280, beyond which it passed. I wanted to cry out "We are at 8,000 meters." But my tongue was paralyzed. Suddenly I closed my eyes and fell inert, completely losing consciousness.^[37]

The ascent to over 8000 m (26,247 feet) took 3 hours, and the descent less than 1 hour. When the balloon landed, Tissandier's two companions were dead.

The prodigious work that Paul Bert conducted in an altitude chamber during the 1870s showed that lack of oxygen, rather than an effect of isolated hypobarica, explained the symptoms experienced during rapid ascent to extreme altitude:

There exists a parallelism to the smallest details between two animals, one of which is subjected in normal air to a progressive diminution of pressure to the point of death, while the other breathes, also to the point of death, under normal pressure, an air that grows weaker and weaker in oxygen. Both will die after having presented the same symptoms.^[37]

Bert goes on to describe the symptoms of acute exposure to hypoxia:

It is the nervous system which reacts first. The sensation of fatigue, the weakening of the sense perceptions, the cerebral symptoms, vertigo, sleepiness, hallucinations, buzzing in the ears, dizziness, pricklings ... are

the signs of insufficient oxygenation of central and peripheral nervous organs.... The symptoms... disappear very quickly when the balloon descends from the higher altitudes, very quickly also ... the normal proportion of oxygen reappears in the blood. There is an unfailing connection here.^[37]

Bert was also able to prevent and immediately resolve symptoms by breathing oxygen.

Acute hypoxia can be quickly reversed by immediate administration of oxygen; rapid pressurization or descent; or correction of an underlying cause, such as relief of apnea, removal of a carbon monoxide source, repair of an oxygen delivery system, or cessation of overexertion. Hyperventilation increases time of useful consciousness.

High-Altitude Headache

Headache is generally the first unpleasant symptom consequent to altitude exposure and is sometimes the only symptom.^[134] It may or may not be the harbinger of AMS, which is defined as the presence of headache plus at least one of four other symptoms, in the setting of an acute altitude gain.^[281] One could argue that it is the headache itself that causes other symptoms, such as anorexia, nausea, lassitude, and insomnia, as is commonly seen in migraine or tension headaches, and that mild AMS is essentially due to headache. Whether an

Figure 1-10 (Figure Not Available) Proposed pathophysiology of high-altitude headache. CNS, Central nervous system; eNOS, endogenous nitric oxide synthase; NO, nitric oxide. (Modified from Sanchez del Rio M, Moskowitz MA: *High altitude headache*, *Adv Exp Med Biol* 474:145, 1999.)

isolated headache is any different from the headache of moderate to severe AMS is unsettled until we have a better understanding of the pathophysiology. Because moderate to severe AMS is associated with vasogenic edema, and because headache by itself might not be, we choose to consider high-altitude headache as a separate category, pending further investigation. The term *high-altitude headache* (HAH) has been used in the literature for decades, and studies directed toward the pathophysiology and treatment of HAH have been reported.² Obviously, these are to an extent studies of AMS as well. Headache lends itself to investigation better than some other symptoms; headache scores have been well validated.^[164]

In general, the literature suggests that HAH can be prevented by the use of nonsteroidal antiinflammatory drugs,^{[46] [50]} as well as the drugs commonly used for prophylaxis of AMS, acetazolamide and dexamethasone. Some agents appear more effective than others, with ibuprofen and aspirin apparently superior to naproxen.^{[46] [49] [51]} A serotonin agonist (sumatriptan, a 5-HT₁ receptor agonist) was reported to be effective for HAH prevention and/or treatment in some studies^{[48] [343]} but not in others.^[27] Interestingly, oxygen is often immediately effective for HAH in subjects with and without AMS,

indicating a rapidly reversible mechanism of the headache.^{[22] [108]}

The response to many different agents might reflect multiple components of the pathophysiology or merely the nonspecific nature of analgesics in some studies. As Sanchez del Rio and Moskowitz^[298] have pointed out, different inciting factors for headache may result in a final common pathway, such that the response to different therapies is not necessarily related to the initial cause of the headache. They recently provided a useful multifactorial concept of the pathogenesis of HAH, based on current understanding of headaches in general.^[298] They suggest that the trigeminovascular system is activated at altitude by both mechanical and chemical stimuli (vasodilation, nitric oxide and other noxious agents), and in addition, the threshold for pain is likely altered at high altitude (Figure 1-10 (Figure Not Available)).^[298] If AMS and especially HACE ensue, altered intracranial dynamics may also play a role, via compression or distension of pain-sensitive structures.

Acute Mountain Sickness

Although the syndrome of AMS has been recognized for centuries, modern rapid transport and the proliferation of participants in mountain sports have increased the number of victims and therefore public awareness (see [Table 1-1](#)). The incidence and severity of AMS depend on the rate of ascent and the altitude attained (especially the sleeping altitude), length of altitude exposure, level of exertion,^[283] and inherent physiologic susceptibility. For example, AMS is more common on Mt. Rainier because of the rapid ascent, whereas HAPE is uncommon because of the short stay (less than 36 hours). Age has a small influence on incidence,^[106] with the elderly somewhat less vulnerable.^[282] Women apparently have the same^[280] or a slightly greater incidence of AMS^{[106] [134]} but may be less susceptible to pulmonary edema.^{[64] [323]} It is useful clinically to classify AMS as mild or moderate to severe on the basis of symptoms ([Table 1-4](#)). Importantly, AMS can herald the beginning of life-threatening cerebral edema.

Diagnosis.

The diagnosis of AMS is based on setting, symptoms, physical findings, and exclusion of other illnesses. The setting is generally rapid ascent of unacclimatized

*References ^[27] ^[46] ^[48] ^[49] ^[50] ^[108] ^[267] ^[343] .

TABLE 1-4 -- Classification of Acute Mountain Sickness

	CLINICAL CLASSIFICATION			
	HAH	MILD AMS	MODERATE TO SEVERE AMS	HACE

Symptoms	Headache only	Headache + 1 more symptom (nausea/vomiting, fatigue/lassitude, dizziness or difficulty sleeping)	Headache + 1 or more symptoms (nausea/vomiting, fatigue/lassitude, dizziness or difficulty sleeping)	±Headache
				Worsening of symptoms seen in moderate to severe AMS
		All symptoms of mild severity	Symptoms of moderate to severe intensity	
LL-AMS score*	1–3, headache only	2–4	5–15	
Physical signs	None	None	None	Ataxia, altered mental status
Findings	None	None	Antidiuresis, slight increase in temperature, slight desaturation, widened A-a gradient, elevated ICP, white matter edema (CT, MRI)	HAVE common: +chest x-ray, rales, dyspnea at rest; elevated ICP; white matter edema (CT, MRI)
Pathophysiology	Cerebral vasodilation, activation of trigeminovascular system†	Same as HAH, plus early vasogenic edema	Vasogenic edema	Advanced vasogenic cerebral edema

*The self-report Lake Louise AMS score.

†See Figure 1-10 (Figure Not Available) and a recent review (reference [298]).

persons to 2500 m (8202 feet) or higher from altitudes below 1500 m (4921 feet). For

partially acclimatized persons, abrupt ascent to a higher altitude, overexertion, use of respiratory depressants, and perhaps onset of infectious illness^[243] are common contributing factors.

The cardinal symptom of early AMS is headache, followed in incidence by fatigue, dizziness, and anorexia.^{[106] [134] [321]} The headache is usually throbbing, bitemporal or occipital, typically worse during the night and on awakening, and made worse by Valsalva's maneuver or stooping over. A good appetite is distinctly uncommon. Nausea is common. These initial symptoms are strikingly similar to an alcohol hangover. Frequent awakening may fragment sleep, and periodic breathing often produces a feeling of suffocation. Although sleep disorder is nearly universal at high altitude, these symptoms may be exaggerated during AMS. Affected persons commonly complain of a deep inner chill, unlike mere exposure to cold temperature, accompanied by facial pallor. Other symptoms may include vomiting, dyspnea on exertion, and irritability. Lassitude can be disabling, with the victim too apathetic to contribute to his or her own or the group's basic needs. Any symptom suggestive of AMS should be considered caused by altitude unless proven otherwise.

Pulmonary symptoms vary considerably. Everyone experiences dyspnea on exertion at high altitude; it may be difficult to distinguish normal from abnormal. Dyspnea at rest is distinctly abnormal, however, and presages HAPE rather than AMS. Cough is also extremely common at high altitude and not particularly associated with AMS. Recent work suggests that altitude hypoxia actually lowers the cough threshold, as measured with an inhaled citric acid stimulus.^[209] However, any pulmonary symptom mandates careful examination for pulmonary edema.

Specific physical findings are lacking in mild AMS. Early authors described tachycardia, but Singh et al^[321] noted bradycardia (heart rate less than 66 beats/min) in two thirds of 1975 soldiers with AMS. Blood pressure is normal, but postural hypotension may be present. Rales localized to one area of the chest are common (5% to 20% incidence)^[201] and probably represent pulmonary vascular congestion. A slight increased body temperature with AMS was recently reported.^[200] Funduscopic examination reveals venous tortuosity and dilation; retinal hemorrhages may or may not be present and are not diagnostic; they are more common in AMS than non-AMS subjects at 4243 m (13,921 feet).^[105] Absence of the normal altitude diuresis, evidenced by lack of increased urine output and retention of

fluid, is an early finding in AMS although not always present.^{[25] [110] [284] [321] [335]}

More obvious physical findings develop if AMS progresses to HACE. Typically, with onset of HACE, the victim wants to be left alone; lassitude progresses to inability to perform perfunctory activities, such as eating and dressing; ataxia develops; and finally, changes in consciousness appear, with confusion, disorientation, and impaired judgment. Coma may ensue within 24 hours of the onset of ataxia. Ataxia is the single

most useful sign for recognizing the progression from AMS to HACE; all persons proceeding to high altitudes should be aware of this fact.

Differential Diagnosis.

AMS is most commonly misdiagnosed as a viral flulike illness, hangover, exhaustion, dehydration, or medication or drug effect. Unlike an infectious illness, uncomplicated AMS is not associated with fever and myalgia. Hangover is excluded by the history (see Alcohol and Altitude). Exhaustion may cause lassitude, weakness, irritability, and headache and may therefore be difficult to distinguish from AMS. Dehydration, which causes weakness, decreased urine output, headache, and nausea, is commonly confused with AMS. Response to fluids helps differentiate the two. AMS is not improved by fluid administration alone; body hydration does not influence susceptibility to AMS (contrary to conventional wisdom).^[7] Hypothermia may manifest as ataxia and mental changes. Sleeping medication can cause ataxia and mental changes, but soporifics may also precipitate high-altitude illness because of increased hypoxemia during sleep.

Carbon Monoxide.

Carbon monoxide poisoning is a danger at high altitude, where field shelters are designed to be small and windproof. Cooking inside closed tents and snow shelters during storms is a particular hazard.^[342] The effects of carbon monoxide and high-altitude hypoxia are additive. A reduction in oxyhemoglobin caused by carbon monoxide increases hypoxic stress, rendering a person at a "physiologically higher" altitude, which may precipitate AMS. Because of preexisting hypoxemia, smaller amounts of carboxyhemoglobin produce symptoms of carbon monoxide poisoning. These two problems may coexist. Immediate removal of the victim from the source of carbon monoxide and forced hyperventilation, preferably with supplemental oxygen, rapidly reverse carbon monoxide poisoning. Persistent unconsciousness in the setting of carbon monoxide exposure at high altitude can be due to either severe carbon monoxide poisoning or high-altitude cerebral edema. The management is nearly the same and includes coma care, oxygen, descent, and evacuation to a hospital.

Pathophysiology.

Although the basic cause of AMS is hypobaric hypoxia, the syndrome is different from acute hypoxia. Because of a lag time in onset of symptoms after ascent and lack of immediate reversal of all symptoms with oxygen, AMS is thought to be secondary to the body's responses to modest hypoxia. In addition, even though an altitude of 2500 to 2700 m (8202 to 8859 feet) presents only a minor decrement in arterial oxygen transport (SaO_2 is still above 90%), AMS is common and certain individuals may become desperately ill. An acceptable explanation of pathophysiology must therefore address lag time, individual susceptibility to even modest hypoxia, and how acclimatization prevents the illness.

Findings documented in mild to moderate AMS that relate to pathophysiology include relative hypoventilation,^{[212] [236]} impaired gas exchange (interstitial edema),^{[99] [188]} fluid

retention and redistribution,^{[25] [284] [335]} and increased sympathetic activity.^{[19] [23]} In mild to moderate AMS, limited data suggest that intracranial pressure (ICP) is not elevated.^{[125] [366]} In contrast, increased ICP and cerebral edema are documented in moderate to severe AMS, reflecting the continuum from AMS to HACE.^{[140] [180] [213] [321] [361]}

Relative hypoventilation may be due primarily to a decreased drive to breathe (low HVR) or may be secondary to ventilatory depression associated with AMS.^{[236] [277]} Persons with quite low HVR are more likely to suffer AMS than are those with a high ventilatory drive.^{[131] [212] [236]} For persons with intermediate HVR values (most people), ventilatory drive probably has no predictive value.^{[225] [277]} The protective role of a high HVR most likely results from overall increased oxygen transport, especially during sleep and exercise.

Pulmonary dysfunction in AMS includes decreased vital capacity and peak expiratory flow rate,^[321] increased alveolar-arterial oxygen difference,^{[99] [132]} decreased transthoracic impedance,^[163] and a high incidence of rales.^[201] These findings are compatible with interstitial edema, that is, increased extravascular lung water, most likely related to fluid retention and an increased interstitial water compartment. The fact that exercise can contribute to interstitial edema at altitude was recently confirmed.^[6] Whether this can be considered a mild form of HAPE is unclear. The fact that nifedipine effectively prevents HAPE but does not prevent AMS or the increased A-a oxygen gradient observed in AMS^[132] speaks against the increased lung water of AMS being related to HAPE, but the issue deserves further study.

The mechanism of fluid retention may be multifactorial. Renal responses to hypoxia are variable and depend on plasma arginine vasopressin (AVP) concentration and sympathetic tone.^{[128] [335]} Persons with AMS had elevated plasma or urine AVP levels in some studies,^{[23] [321]}

but cause and effect could not be established. Other studies showed no AVP elevation.^[25] The usual decrease in aldosterone on ascent to altitude does not occur in persons with AMS, and this may contribute to the antidiuresis.^[25] The renin-angiotensin system, although suppressed compared with its activity at sea level in both AMS and non-AMS groups, was more active in persons with AMS.^[19] Atrial natriuretic peptide (ANP) is elevated in AMS. Although this is most likely compensatory, elevated plasma ANP levels may contribute to vasodilation and increased microvascular permeability.^{[19] [359]} One factor that can explain many of these changes is increased sympathetic activity, which reduces renal blood flow, glomerular filtration rate, and urine output, and suppresses renin.^[335] Increased sympathetic nervous system activity is also consistent with the greater rise in norepinephrine noted in subjects with AMS.^[23] See Krasney^[177] for a discussion of the critical role of central sympathetic activation on the kidney and its role in the pathophysiology of AMS. Whatever the exact mechanism, it seems that renal water handling switches from net loss or no change to net gain of water as persons become ill with AMS. The effectiveness of diuretics in treating AMS also supports a pivotal role for fluid retention and fluid shifts in the pathology of AMS.^{[99] [321]}

Persons with moderate to severe AMS or HACE display white matter edema on brain imaging and elevated ICP.³ Possible mechanisms include cytotoxic edema with a shift of fluid into the cells, or vasogenic (interstitial) edema from increased permeability of the blood-brain barrier (BBB), or both. The classic view that hypoxia causes failure of the adenosine triphosphate (ATP)-dependent sodium pump and subsequent intracellular edema^[137] is untenable, given the newer understanding of brain energetics; ATP levels are maintained even in severe hypoxemia.^[315] The evidence now favors vasogenic brain edema as the cause of AMS/HACE. Hackett et al^[118] point out that reversible white matter edema, with sparing of the gray matter, is characteristic of vasogenic edema (see [Figure 1-13](#)). The fact that dexamethasone is so effective for AMS also suggests vasogenic edema because this is the only steroid-responsive brain edema. In addition, a model of AMS in conscious sheep exposed to 10% oxygen for several days supports the vasogenic brain-swelling hypothesis. Krasney et al^[179] have shown that cerebral capillary pressure rises, which causes filtration of fluid across the BBB and an increase in wet-to-dry cerebral tissue ratio. The pathophysiology may be similar to hypertensive encephalopathy, in which loss of vascular autoregulation results in increased pressures transmitted to the capillaries with resultant white matter edema.^{[189] [190]} Because prolonged cerebral vasodilation by itself, however, is not sufficient to induce vasogenic edema, Hackett^[104] and Krasney^[178] have proposed the additional factor of increased BBB permeability in the pathophysiology of AMS. Possible mechanisms of altered BBB permeability in AMS/HACE include vascular endothelial growth factor (VEGF), inflammatory cytokines, products of lipid peroxidation, endothelium-derived products, such as nitric oxide, and direct neural and humoral factors known to affect the BBB. For a complete discussion of the mechanisms of BBB permeability and their possible role in altitude illness, see the recent reviews by Drewes,^[77] Hackett,^[104] Hossman,^[135] and Schilling^[304] ([Figure 1-11](#)).

The question of whether mild AMS, especially headache alone, is due to vasogenic cerebral edema is not yet answered (see High-Altitude Headache). Recent magnetic resonance imaging (MRI) studies demonstrated brain swelling in all subjects ascending rapidly to moderate altitude, regardless of the presence of AMS.^{[162] [244]} The change in brain volume was greater than that expected from increased cerebral blood volume alone (resulting from vasodilation), but the individual components of blood and brain parenchyma could not be determined with MRI. Therefore whether edema was present was not established. Regardless, the changes in the ill and the well groups were similar. Interestingly, Kilgore et al^[174] did show a small but significant increase in T2 signal of the corpus callosum, hinting that vasogenic edema was starting, and the increase in the AMS group was twice that of the non-AMS group, though not quite statistically significant. Although still very much an open question, the literature to date does not confirm that mild AMS or headache alone is related to brain edema.

To summarize, moderate to severe AMS and HACE represent a continuum from mild to severe vasogenic cerebral edema. Headache alone, or the earliest stages of AMS, might be related to edema or could be related to other factors, such as cerebral vasodilation or a migraine mechanism; further research is needed to clarify this issue.

INDIVIDUAL SUSCEPTIBILITY AND INTRACRANIAL DYNAMICS.

What might explain individual susceptibility to AMS? Correlations of AMS with HVR, ventilation, fluid status, lung function, and physical fitness have been weak at best. Ross^[294] hypothesized in 1985 that the apparent random nature of susceptibility might be explained by random anatomic differences. Specifically, he suggested that persons with smaller intracranial and intraspinal cerebrospinal fluid (CSF) capacity would be disposed to develop AMS because they would not tolerate brain

*References ^[118] ^[140] ^[180] ^[194] ^[213] ^[321] .

16

Figure 1-11 Proposed pathophysiology of acute mountain sickness. *BBB*, Blood-brain barrier; *CBF*, cerebral blood flow; *CBV*, cerebral blood volume; *HVR*, hypoxic ventilatory response; *iNOS*, inducible nitric oxide synthase; *Pcap*, capillary pressure; *VEGF*, vascular endothelial growth factor.

swelling as well as those with more "room" in the craniospinal axis. The displacement of CSF through the foramen magnum into the spinal canal is the first compensatory response to increased brain volume, followed by increased CSF absorption and decreased CSF formation. Studies have shown that the increase in ICP for a given increase in brain volume is directly related to the "tightness" of the brain in the cranium (the brain volume:intracranial volume ratio) and to the volume of the spinal canal.^[313] Thus the greater the initial CSF volume, the more accommodation that can take place in response to brain edema. Increases in volume are "buffered" by CSF dynamics. In light of our present understanding of increased brain volume on ascent to altitude, his hypothesis is very attractive. Preliminary data that showed a relationship of preascent ventricular size or brain volume:cranial vault ratios and susceptibility to AMS support this hypothesis, and the idea deserves further study.^[104]^[373] [Figure 1-11](#) incorporates this concept into the pathophysiology.

Natural Course of Acute Mountain Sickness.

The natural history of AMS varies with initial altitude, rate of ascent, and clinical severity. Singh et al^[321] followed the illness in soldiers airlifted to altitudes of 3300 to 5500 m (10,827 to 18,045 feet). Incapacitating illness lasted 2 to 5 days, but 40% still had symptoms after 1 week and 13% after 1 month. Nine soldiers failed to acclimatize in 6 months and were considered unfit for duty at high altitude.^[321] Chinese investigators

report that a percentage of lowland Han Chinese stationed on the Tibet Plateau cannot tolerate the altitude because of persistent symptoms and must be relocated to the plains.^[367] Persistent anorexia, nausea, and headache may afflict climbers at extreme altitude for weeks and can be considered a form of persistent AMS. The natural history of AMS in tourists who sleep at more moderate altitudes is much more benign. Duration of symptoms at 3000 m (9840 feet) was 15 hours, with a range of 6 to 94 hours.^[68] Most individuals treat or tolerate their symptoms as the illness resolves over 1 to 3 days while

acclimatization improves, but some persons with AMS seek medical treatment or are forced to descend if symptoms persist. A small percentage of those with AMS (8% at 4243 m [13,921 feet])^[106] go on to develop cerebral edema, especially if ascent is continued in spite of illness.

Treatment.

The proper management of AMS is based on early diagnosis and acknowledgment that initial clinical presentation does not predict eventual severity ([Box 1-3](#)). Therefore proceeding to a higher sleeping altitude in the presence of symptoms is contraindicated. The victim must be carefully monitored for progression of illness. If symptoms worsen despite an extra 24 hours of acclimatization or treatment, descent is indicated. The two indications for immediate descent are neurologic changes (ataxia or change in consciousness) and pulmonary edema.

Mild AMS can be treated by halting the ascent and waiting for acclimatization to improve, which can take from 12 hours to 3 or 4 days. Acetazolamide (125 to 250 mg twice a day orally) speeds acclimatization and thus terminates the illness if given early.^[99] Symptomatic therapy includes analgesics such as aspirin (650 mg), acetaminophen (650 to 1000 mg), ibuprofen^[46] or other nonsteroidal antiinflammatory drugs, or codeine (30 mg) for headache. Prochlorperazine (Compazine, 5 to 10 mg intramuscularly) can be given by an appropriate route for nausea and vomiting and has the advantage of augmenting the HVR.^[255] Promethazine (Phenergan, 50 mg by suppository or ingestion) is also useful. Persons with AMS should avoid alcohol and other respiratory depressants because of the danger of exaggerated hypoxemia during sleep.

Descent to an altitude lower than where symptoms began effectively reverses AMS. Although the person should descend as far as necessary for improvement, descending 500 to 1000 m (1640 to 3281 feet) is usually sufficient. Exertion should be minimized. Oxygen, if available, is particularly effective (and supply is conserved) if given in low flow (0.5 to 1 L/min by mask or cannula) during the night. Hyperbaric chambers, which simulate descent, have been used to treat AMS and aid acclimatization. They are effective and require no supplemental oxygen. Lightweight (less than 7 kg) fabric pressure bags inflated by manual air pumps are now being used on mountaineering expeditions and in mountain clinics ([Figure 1-12](#)). An inflation of 2 psi is roughly

equivalent to a drop in altitude of 1600 m (5250 feet); the exact equivalent depends on initial altitude.^[168]^[279] A few hours of pressurization result in symptomatic improvement and can be an effective temporizing measure while awaiting descent or the benefit of medical therapy.^[168]^[242]^[258]^[286]^[338] Long-term (12 hours or more) use of these portable devices would be necessary to resolve AMS completely.

**Box 1-3. FIELD TREATMENT OF
HIGH-ALTITUDE ILLNESS**

***HIGH-ALTITUDE HEADACHE AND MILD
ACUTE MOUNTAIN SICKNESS***

Stop ascent, rest, acclimatize at same altitude

Acetazolamide, 125 to 250 mg bid, to speed acclimatization

Symptomatic treatment as necessary with analgesics and antiemetics

or Descend 500 m or more

***MODERATE TO SEVERE ACUTE
MOUNTAIN SICKNESS***

Low-flow oxygen, if available

Acetazolamide, 125 to 250 mg bid, with or without dexamethasone, 4 mg po, IM, or IV q6h

Hyperbaric therapy

Or Immediate descent

HIGH-ALTITUDE CEREBRAL EDEMA

Immediate descent or evacuation

Oxygen, 2 to 4 L/min

HIGH-ALTITUDE CEREBRAL EDEMA

Immediate descent or evacuation

Oxygen, 2 to 4 L/min

Dexamethasone, 4 mg po, IM, or IV
q6h

Hyperbaric therapy

HIGH-ALTITUDE PULMONARY EDEMA

Minimize exertion and keep warm

Oxygen, 4 to 6 L/min until improving,
then 2 to 4 L/min

Nifedipine, 10 mg po q4h by titration to
response, or 10 mg po once, followed
by 30 mg extended release q12 to 24h

Hyperbaric therapy

or Immediate descent

PERIODIC BREATHING

Acetazolamide, 62.5 to 125 mg at
bedtime as needed

Figure 1-12 The HELP System (Live High, Boulder, Colo.) uses breathing bladder technology to minimize the pumping necessary to circulate air in the hyperbaric compartment.

The use of diuretics has a sound basis because of fluid retention associated with AMS.

Acetazolamide is of unquestionable prophylactic value and is now commonly and successfully used to treat AMS as well. Acetazolamide may be helpful in part because of its diuretic action; its multiple modes of action are discussed later. Singh et al^[321] successfully used furosemide (80 mg twice a day for 2 days) to treat 446 soldiers with all degrees of AMS; it has not since been studied for treatment. Furosemide induced a brisk diuresis, relieved pulmonary congestion, and improved headache and other neurologic symptoms. Spironolactone, hydrochlorothiazide, and other diuretics have not yet been evaluated for treatment.

The steroid betamethasone was initially reported by Singh et al^[321] to improve symptoms of soldiers with severe AMS. Since then, dexamethasone was found to be very effective for treatment of all degrees of AMS. Dexamethasone is effective for treatment of moderate to severe AMS.^{[86] [116] [171]} Hackett et al^[116] used 4 mg orally or intramuscularly every 6 hours, and Ferrazinni et al^[86] gave 8 mg initially, followed by 4 mg every 6 hours. Both studies reported marked improvement within 12 hours, with no significant side effects. Symptoms increased when dexamethasone was discontinued after 24 hours.^[289] Dexamethasone should be started in conjunction with descent or hyperbaric treatment,^[171] if possible, and continued until the victim is down to low altitude. Although the mechanism of action of dexamethasone is not clear, it probably acts by improving brain capillary integrity and diminishing vasogenic edema.^[65] Dexamethasone seems not to improve acclimatization because symptoms recur when the drug is withdrawn. Therefore an argument could be made for using dexamethasone to relieve symptoms and acetazolamide to speed acclimatization.^[35]

Prevention.

Graded ascent is the surest and safest method of prevention, although particularly susceptible individuals may still become ill. Current recommendations for persons without altitude experience are to avoid abrupt ascent to sleeping altitudes greater than 3000 m (9843 feet) and to spend 2 to 3 nights at 2500 to 3000 m (8202 to 9843 feet) before going higher, with an extra night for acclimatization every 600 to 900 m (1969 to 2953 feet) if continuing ascent. Abrupt increases of more than 600 m (1969 feet) in sleeping altitude should be avoided when over 2500 m (8202 feet). Day trips to higher altitude, with a return to lower altitude for sleep, aid acclimatization. Alcohol and sedative-hypnotics are best avoided on the first 2 nights at high altitude. Whether a diet high in carbohydrates reduces AMS symptoms is controversial.^{[62] [124] [337]} Exertion early in altitude exposure contributes to altitude illness,^[283] whereas limited exercise seems to aid acclimatization.

ACETAZOLAMIDE PROPHYLAXIS.

Acetazolamide is the drug of choice for prophylaxis of AMS. A carbonic anhydrase (CA) inhibitor, acetazolamide slows the hydration of carbon dioxide:

The effects are protean, involving particularly the red blood cells, brain, lungs, and kidneys. By inhibiting renal carbonic anhydrase, acetazolamide reduces reabsorption of bicarbonate and sodium and thus causes a bicarbonate diuresis and metabolic acidosis starting within 1 hour after ingestion. This rapidly enhances ventilatory acclimatization. Perhaps most important, the drug maintains oxygenation during sleep and prevents periods of extreme hypoxemia (see [Figure 1-6](#)).^[114]^[332]^[336] Because of acetazolamide's diuretic action, it counteracts the fluid retention of AMS. It also diminishes nocturnal antidiuretic hormone (ADH) secretion^[56] and decreases CSF production and volume and possibly CSF pressure.^[310] Which of these effects is most important in preventing AMS is unclear. Numerous studies taken together indicate that acetazolamide is approximately 75% effective in preventing AMS in persons rapidly transported to altitudes of 3000 to 4500 m (9843 to 14,764 feet).^[84]

Indications for acetazolamide prophylaxis include rapid ascent (1 day or less) to altitudes over 3000 m (9843 feet); a rapid gain in sleeping altitude, for example, moving camp from 4000 m (13,123 feet) to 5000 m (16,404 feet) in a day; and a past history of recurrent AMS or HAPE. Numerous dosage regimens have been effective.^[74]^[80] Smaller doses (125 to 250 mg twice a day) starting 24 hours before ascent work as well as higher doses started earlier.^[223] A 500-mg sustained action capsule of Diamox taken every 24 hours is probably equally effective and results in fewer side effects because of lower peak serum levels.^[363] Most authors recommend continuing for the first day or two at high altitude, and some suggest daily acetazolamide the entire time at high altitude.^[43] This hardly seems necessary once acclimatization is established and the danger of AMS has passed. Spironolactone^[165]^[186] and other diuretics have shown equivocal results for AMS prevention.

Acetazolamide has side effects, most notably peripheral paresthesias and polyuria, and less commonly nausea, drowsiness, impotence, and myopia. Because it inhibits the instant hydration of carbon dioxide on the tongue, acetazolamide allows carbon dioxide to be tasted and can ruin the flavor of carbonated beverages, including beer. A sulfa drug, acetazolamide carries the usual precautions about hypersensitivity, crystalluria, and bone marrow suppression.

DEXAMETHASONE.

Dexamethasone is also useful for prevention of AMS. The initial chamber study in 1984 was with sedentary subjects.^[167] The drug reduced the incidence of AMS from 78% to 20%, comparable with previous studies with acetazolamide. Dexamethasone was not as effective in exercising subjects on Pike's Peak,^[289] but subsequent work has shown effectiveness comparable with acetazolamide.^[84]^[195]^[374] The combination of acetazolamide and dexamethasone proved superior to dexamethasone alone.^[374] Because of potential serious side effects and the rebound phenomenon, dexamethasone is best reserved for treatment rather than for prevention of AMS, or

used for prophylaxis when necessary in persons intolerant of or allergic to acetazolamide.

High-Altitude Cerebral Edema

HACE is characterized clinically by a progression to encephalopathy in the setting of AMS or HAPE. As discussed previously, AMS is essentially a neurologic disorder, probably related to brain swelling, and HACE appears to be the extreme form of AMS; the distinction between AMS and HACE is therefore inherently blurred.

Clinical Presentation.

The hallmarks of HACE are ataxic gait, severe lassitude, and altered consciousness, including confusion, impaired mentation, drowsiness, stupor, and coma. Headache, nausea, and vomiting are frequently, but not always, present. Hallucinations, cranial nerve palsy, hemiparesis, hemiplegia, seizures, and focal neurologic signs have also been reported.^{[120] [140] [321]} Retinal hemorrhages are common but not diagnostic. The progression from mild AMS to unconsciousness may be as fast as 12 hours but usually requires 1 to 3 days. Cyanosis or a gray pallor is common. Arterial blood gas study or pulse oximetry reveals exaggerated hypoxemia. Clinical examination, chest radiography, and autopsy have often demonstrated pulmonary edema; indeed, isolated HACE without HAPE is uncommon.^{[103] [118]}

The following case report from Mt. McKinley illustrates a clinical course of HACE, in conjunction with HAPE:

H.E. was a 26-year-old German lumberjack with extensive mountaineering experience. He ascended to 5200 m (17,061 feet) from 2000 m (6562 feet) in 4 days and attempted the summit (6194 m [20,323 feet]) on the fifth day. At 5800 m (19,030 feet) he turned back because of severe fatigue, headache, and malaise. He returned alone to 5200 m (17,061 feet), stumbling on the way because of loss of coordination. He had no appetite and crawled into his sleeping bag too weak, tired, and disoriented to undress. He recalled no pulmonary symptoms. In the morning H.E. was unarousable, slightly cyanotic, and noted to have Cheyne-Stokes respirations. After 10 minutes on high-flow oxygen H.E. began to regain consciousness, although he was completely

Figure 1-13 Magnetic resonance image of patient with high-altitude cerebral edema. Increased T2 signal in splenium of corpus callosum (*arrow*) indicates edema.

disoriented and unable to move. A rescue team lowered him down a steep slope, and

on arrival at 4400 m (14,436 feet) 4 hours later he was conscious but still disoriented, able to move extremities but unable to stand. Respiratory rate was 60 breaths/min and heart rate was 112 beats/min. Papilledema and a few rales were present. SaO_2 % was 54% on room air (normal is 85% to 90%). On a nonrebreathing oxygen mask with 14 L/min oxygen, the SaO_2 % increased to 88% and the respiratory rate decreased to 40 breaths/min. Eight milligrams of dexamethasone were administered intramuscularly at 4:20 PM and continued orally, 4 mg every 6 hours. At 5:20 PM H.E. began to respond to commands. The next morning H.E. was still ataxic but was able to stand, take fluids, and eat heartily. He was evacuated by air to Anchorage (sea level) at 12:00 PM. On admission to the hospital at 3:30 PM, roughly 36 hours after regaining consciousness, H.E. was somewhat confused and mildly ataxic. Arterial blood gas studies on room air showed a P_{O_2} of 58 torr, pH of 7.5, and P_{CO_2} of 27 torr. Bilateral pulmonary infiltrates were present on the chest radiograph. Magnetic resonance imaging of the brain revealed white matter edema, primarily of the corpus callosum ([Figure 1-13](#)). On discharge the next morning H.E. was oriented, bright, and cheerful and had very minor ataxia and clear lung fields.

Pathophysiology.

The pathophysiology of HACE is a progression of the same mechanism as AMS (see Acute Mountain Sickness, Pathophysiology and [Figure 1-11](#)). The early brain swelling of AMS becomes much more severe. In cases similar to this, lumbar punctures have

revealed elevated CSF pressures, often more than 300 mm H_2O ^[140] ^[361] ; evidence of cerebral edema on CT scan and MRI^[118] ^[176] ; and gross cerebral edema on necropsy.^[72] ^[73] Small petechial hemorrhages were also consistently found on autopsy, and venous sinus thromboses were occasionally seen.^[72] ^[73] Well-documented cases have often included pulmonary edema that was not clinically apparent.

Whereas the mild brain swelling of AMS and reversible HACE is most likely vasogenic, as the spectrum shifts to severe, end-stage HACE, gray matter (presumably cytotoxic) edema develops as well, culminating in death. As Klatzo^[175] has pointed out, as vasogenic edema progresses, the distance between brain cells and their capillaries increases, so that nutrients and oxygen eventually fail to diffuse and the cells are rendered ischemic, leading to intracellular (cytotoxic) edema. Raised ICP produces many of its effects by decreasing cerebral blood flow, and brain tissue becomes ischemic on this basis also.^[219] Focal neurologic signs caused by brainstem distortion and by extraaxial compression, as in third and sixth cranial nerve palsies, may develop,^[291] making cerebral edema difficult to differentiate from primary cerebrovascular events. The most common clinical presentation, however, is change in consciousness associated with ataxia, without focal signs.

Treatment.

Successful treatment of HACE requires early recognition. At the first sign of ataxia or change in consciousness, descent should be started, dexamethasone (4 to 8 mg intravenously, intramuscularly, or orally initially, followed by 4 mg every 6 hours) administered, and oxygen (2 to 4 L/min by vented mask or nasal cannula) applied if available (see [Box 1-3](#)). Oxygen can be titrated to maintain SaO₂ at greater than 90% if oximetry is available. Comatose patients require additional airway management and bladder drainage. Attempting to decrease ICP by intubation and hyperventilation is a reasonable approach, although these patients are already alkalotic and overhyperventilation could result in cerebral ischemia. Loop diuretics, such as furosemide (40 to 80 mg) or bumetanide (1 to 2 mg), may reduce brain hydration, but an adequate intravascular volume to maintain perfusion pressure is critical. Hypertonic solutions of saline, mannitol, or oral glycerol have been suggested but rarely are used in the field. Controlled studies are lacking, but empirically the response to steroids and oxygen seems excellent if they are given early in the course of the illness and disappointing if they are not started until the victim is unconscious. Coma may persist for days, even after evacuation to low altitude, but other causes of coma must be considered and ruled out by appropriate evaluation.^[140] Sequelae lasting weeks are common^{[118] [140]}; longer-term follow-up has been limited. Prevention of HACE is the same as for AMS.

Focal Neurologic Conditions without Cerebral Edema

Various localizing neurologic signs, transient in nature and not necessarily occurring in the setting of AMS, suggest migraine, cerebrovascular spasm, TIA, local hypoxia without loss of perfusion (watershed effect), or focal edema. Cortical blindness is one such condition. Hackett et al^[113] reported six cases of transient blindness in climbers or trekkers with intact pupillary reflexes, which indicated that the condition was due to a cortical process. Treatment with breathing of either carbon dioxide (a potent cerebral vasodilator) or oxygen resulted in prompt relief, suggesting that the blindness was due to inadequate regional circulation or oxygenation. Descent effected relief more slowly. Other conditions that could be attributed to spasm or "transient ischemic attack" have included transient hemiplegia or hemiparesis, transient global amnesia, unilateral paresthesia, aphasia, and scotomas.^{[41] [196] [274] [364]}

The occurrence of stroke in a young, fit person at high altitude is uncommon but tragic. A number of case reports have described climbers with resultant permanent dysfunction.^{[55] [138] [322]} Factors contributing to stroke may include polycythemia, dehydration, and increased ICP if AMS is present; increased cerebrovenous pressure; cerebrovascular spasm; and perhaps coagulation abnormalities. Stroke may be confused with HACE. Neurologic symptoms, especially focal abnormalities without AMS or HAPE, suggest a cerebrovascular event and mandate careful evaluation.

Clinical Presentation

E.H., a 42-year-old male climber on a Mt. Everest expedition, awoke at 8000 m (26,247 feet) with dense paralysis of the right arm and weakness of the right leg. On descent the paresis cleared, but at base camp (5000 m [16,404 feet]) severe vertigo developed, along with extreme ataxia and weakness. Neurologic consultation on return to the United States resulted in a diagnosis of multiple small cerebral infarcts, but none was visible on CT scan of the brain. The hematocrit value 3 weeks after descent from the mountain was 70%. Over the next 4 years, signs gradually improved, but mild ataxia, nystagmus, and dyslexia persist. The focal and persistent nature of the cerebral symptoms and signs, although multiple, indicates a cerebrovascular, rather than an ICP, cause. The hematocrit value on the mountain was greater than 70%, high enough for increased viscosity and microcirculatory sludging to contribute to ischemia and infarction.

Treatment of stroke is supportive. Oxygen and steroids may be worthwhile to treat any AMS or HACE component. Immediate evacuation to a hospital is indicated. Persons with TIAs at high altitude should probably be started on aspirin therapy and proceed to a lower altitude. Oxygen may quickly abort cerebrovascular spasm and will improve watershed hypoxic events. When oxygen is not available, rebreathing

to raise alveolar P_{CO_2} may be helpful by increasing cerebral blood flow.

Cognitive Changes at High Altitude

If cerebral oxygen consumption is constant, what causes the well-documented, albeit mild, cognitive changes at high altitude? The cognitive changes may be related to specific neurotransmitters that are affected by mild hypoxia. For example, tryptophan hydroxylase in the serotonin synthesis pathway has a high requirement for oxygen ($K_m = 37$ torr).^[61]^[94] Tyrosine hydroxylase, in the dopamine pathway, is also oxygen-sensitive. Gibson^[94] suggested that a decrease in acetylcholine activity during hypoxia might explain the lassitude. In a fascinating study, Banderet^[14] showed that increased dietary tyrosine reduced mood changes and symptoms of environmental stress in subjects at simulated altitude. Further work with neurotransmitter agonists and antagonists will help shed light on their role in cognitive dysfunction at altitude and could lead to new pharmacologic approaches to improve neurologic function.

High-Altitude Pulmonary Edema

The most common cause of death related to high altitude, HAPE, is completely and easily reversed if recognized early and treated properly. Undoubtedly HAPE was misdiagnosed for centuries, as evidenced by frequent reports of young, vigorous men suddenly dying of "pneumonia" within days of arriving at high altitude. The death of Dr. Jacottet, "a robust, broad-shouldered young man," on Mt. Blanc in 1891 (he refused

descent so that he could "observe the acclimatization process" in himself) may have provided the first autopsy of HAPE. Angelo Mosso wrote,

From Dr. Wizard's post-mortem examination ... the more immediate cause of death was therefore probably a suffocative catarrh accompanied by acute edema of the lungs.... I have gone into the particulars of this sorrowful incident because a case of inflammation of the lungs also occurred during our expedition, on the summit of Monte Rosa, from which, however, the sufferer fortunately recovered.^[241]

On an expedition to K2 (Karakorum Range, Pakistan) in 1902, Crowley^[66] described a climber "suffering from edema of both lungs and his mind was gone." In the Andes, physicians were familiar with pulmonary edema peculiar to high altitude,^[160] but it was not until Hultgren^[147] and Houston^[136] that the English-speaking world became aware of high-altitude pulmonary edema (see Rennie^[271] for a recent review). Hultgren^[157] then published hemodynamic measurements in persons with HAPE, demonstrating that it was a noncardiogenic type of edema. Since that time, many studies and reviews have been published,^[16] ^[93] and HAPE is still the subject of intense investigation.

The incidence of HAPE varies from less than 1 in 10,000 skiers in Colorado to 1 in 50 climbers on Mt. McKinley and was higher (15%) in some regiments in the Indian Army (see [Table 1-1](#)). Individual susceptibility, rate of ascent, altitude reached, degree of cold,^[269] physical exertion, and use of sleeping medications are all factors implicated in its occurrence. Younger persons seem more susceptible.^[324] Although HAPE occurs in both genders, it is perhaps less common in women.^[64] ^[153] ^[323]

Clinical Presentation

D.L., a 34-year-old man, was in excellent physical condition and had been on numerous high-altitude backpacking trips, occasionally suffering mild symptoms of AMS. He drove from sea level to the trailhead and hiked to a 3050-m (10,007-foot) sleeping altitude the first night of his trip in the Sierra Nevada. He proceeded to 3700 m (12,140 feet) the next day, noticing more dyspnea on exertion when walking uphill, a longer time than usual to recover when he rested, and a dry cough. He complained of headache, shivering, dyspnea, and insomnia the second night. The third day the group descended to 3500 m (11,483 feet) and rested, primarily for D.L.'s benefit. That night D.L. was unable to eat, noted severe dyspnea, and suffered coughing spasms and headache. On the fourth morning, D.L. was too exhausted and weak to get out of his sleeping bag. His companions noted that he was breathless, cyanotic, and ataxic but had clear mental status. A few hours later he was transported by helicopter to a hospital at 1200 m (3937 feet). On admission he was cyanotic, oral temperature was 37.8° C (100° F), blood pressure 130/76 torr, heart rate 96 beats/min, and respiratory frequency 20 breaths/min. Bilateral basilar rales were noted up to the scapulae. Findings of the cardiac examination were reported as normal. Romberg's and finger-to-nose tests revealed 1+ ataxia. Arterial blood gas studies on room air revealed P_O₂ 24 torr, P_{CO}₂ 28 torr, and pH 7.45. The chest radiograph showed extensive bilateral patchy infiltrates ([Figure 1-14, C](#)). D.L. was treated with bed rest and supplemental oxygen. On discharge to his sea level home 3 days later, his pulmonary infiltrates and rales had cleared, although his

blood gas values were still abnormal: P_{O_2} 76 torr, P_{CO_2} 30 torr, and pH 7.45. He had an uneventful, complete recovery at home. D.L. was advised to ascend more slowly in the future, staging his ascent with nights spent at 1500 m and 2500 m (4921 feet and 8202 feet). He was taught the early signs and symptoms of HAPE and was advised about pharmacologic prophylaxis.

This case illustrates a number of typical aspects of HAPE. Victims are frequently young, fit men who ascend rapidly from sea level and may not have previously suffered HAPE even with repeated altitude exposures.

HAPE usually occurs within the first 2 to 4 days of ascent to higher altitudes (above 2500 m [8202 feet]), most commonly on the second night.^[103] The earliest indications of the illness are decreased exercise performance and increased recovery time from exercise. The victim usually notices fatigue, weakness, and dyspnea on exertion, especially when he or she is trying to walk

Figure 1-14 A, Typical radiograph of high-altitude pulmonary edema (HAPE) in 29-year-old female skier at 2450 m (8036 feet). **B**, Same patient 1 day after descent and oxygen administration, showing rapid clearing. **C**, Bilateral pulmonary infiltrates on radiograph of patient with severe HAPE after descent (case presented in text). **D**, Ventilation and perfusion scans in person with congenital absence of right pulmonary artery after recovery from HAPE.

TABLE 1-5 -- Severity Classification of High-Altitude Pulmonary Edema

GRADE	SYMPTOMS	SIGNS	CHEST FILM
1 Mild	Dyspnea on exertion, dry cough, fatigue while moving uphill	HR (rest) < 90–100; RR (rest) < 20; dusky nail beds; localized rales, if any	Minor exudate involving less than 25% of one lung field

2 Moderate	Dyspnea, weakness, fatigue on level walking; raspy cough; headache; anorexia	HR 90–100; RR 16–30; cyanotic nail beds; rales present; ataxia may be present	Some infiltrate involving 50% of one lung or smaller area of both lungs
3 Severe	Dyspnea at rest, productive cough, orthopnea, extreme weakness	Bilateral rales; HR > 110; RR > 30; facial and nail bed cyanosis; ataxia; stupor; coma; blood-tinged sputum	Bilateral infiltrates > 50% of each lung

Modified from Hultgren HN: High altitude pulmonary edema. In Staub NC, editor: Lung water and solute exchange, New York, 1978, Marcel Dekker. HR, Heart rate; RR, respiratory rate.

uphill; he or she often ascribes these nonspecific symptoms to various other causes. Signs of AMS, such as headache, anorexia, and lassitude, are present about 50% of the time.^[153] A persistent dry cough develops. Nail beds and lips become cyanotic. The condition typically worsens at night, and tachycardia and tachypnea develop at rest. Dyspnea at rest and audible congestion in the chest herald to the victim the development of a serious condition. In contrast to the usual 1- to 2-day gradual onset, HAPE may strike abruptly, especially in a sedentary person who may not notice the early stages.^[347] Orthopnea is uncommon (7%). Pink or blood-tinged, frothy sputum is a very late finding. Hemoptysis was present in 6% in one series.^[159] Severe hypoxemia may produce cerebral edema with mental changes, ataxia, decreased level of consciousness, and coma. Hultgren^[159] reported an incidence of HACE of 14% in those with HAPE at ski resorts.

On admission to the hospital, the victim does not generally appear as ill as would be expected based on arterial blood gas and radiographic findings. Elevated temperature of up to 38.5° C (101.3° F) is common. Tachycardia correlates with respiratory rate and severity of illness ([Table 1-5](#)).^[157] Rales may be unilateral or bilateral and usually originate from the right middle lobe. Concomitant respiratory infection is sometimes present.

Pulmonary edema sometimes presents with predominantly neurologic manifestations and minimal pulmonary symptoms and findings. Cerebral edema, especially with coma, may obscure the diagnosis of HAPE.^[107] Pulse oximetry or chest radiography confirms the diagnosis. The differential diagnosis includes pneumonia, pulmonary embolism or infarct, and sometimes asthma. Complications include infection, cerebral edema, pulmonary embolism or thrombosis, and such injuries as frostbite or trauma secondary to incapacitation.^{[16] [107] [154]}

TABLE 1-6 -- Hemodynamic Measurements during High-Altitude Pulmonary Edema (HAPE) and after Recovery in Two Subjects and in a Group of 31 Control Subjects

	HAPE*	RECOVERY*	CONTROLS†
SaO ₂ %	58.0	84.0	89.0

Mean pulmonary artery pressure (mm Hg)	63.0	18.0	21.3
Wedge pressure (mm Hg)	1.5	3.5	7.1
Cardiac index (L/m ²)	2.5	4.4	4.1
Pulmonary vascular resistance (dyne/cm ⁻⁵)	1210.0	169.0	169.0
Mean arterial blood pressure (mm Hg)	82.0	—	96.0

*HAPE and recovery values from Penalzoza D, Sime F: *Am J Cardiol* 23:369, 1969.

†Mean values from 31 normal subjects studied at 3700 m; from Hultgren HN, Grover RF: *Annu Rev Med* 19:119, 1968.

Hemodynamics.

Hemodynamic measurements show elevated pulmonary artery pressure and pulmonary vascular resistance, low to normal pulmonary wedge pressure, and low to normal cardiac output and systemic arterial blood pressure ([Table 1-6](#)).^{[155] [260]}

Echocardiography demonstrates high estimated pulmonary artery pressures, tricuspid regurgitation, normal left ventricular function, and variable right-sided heart findings of increased atrial and ventricular size.^{[117] [254]}

The electrocardiogram usually reveals sinus tachycardia. Changes consistent with acute pulmonary hypertension

have been described, such as right axis deviation, right bundle branch block, voltage for right ventricular hypertrophy, and P wave abnormalities.^{[16] [153]} Atrial flutter has been reported, but ventricular arrhythmias have not.

Laboratory Studies.

Kobayashi et al^[176] reported clinical laboratory values in 27 patients with HAPE. This report confirms typical mild elevations of hematocrit and hemoglobin, probably secondary to intravascular volume depletion and perhaps plasma leakage into the lung. Elevation of the peripheral white blood cell count is common, but rarely is it above 14,000 cells/ml³. The serum concentration of creatine phosphokinase (CPK) is increased. Most of the rise in CPK has been attributed to skeletal muscle damage, although in two patients, CPK isoenzymes showed brain fraction levels of 1% of the total, which according to the authors may have indicated brain damage.^[176]

Arterial blood gas studies consistently reveal respiratory alkalosis and marked hypoxemia, more severe than expected for the patient's clinical condition. Respiratory or

metabolic acidosis related to hypoxemia has not been reported. Therefore arterial blood gas studies are not essential if noninvasive pulse oximetry is available to measure arterial oxygenation. At 4200 m (13,780 feet) on Mt. McKinley, the mean value of arterial P_{O_2} in HAPE was 28 ± 4 torr. Values as low as 24 torr in HAPE are not unusual. Arterial oxygen saturation values in our HAPE subjects ranged from 40% to 70%, with a mean of $56\% \pm 8\%$.^[307] Arterial acid-base values may be misleading in patients taking acetazolamide because this drug produces significant metabolic acidosis.

Radiologic Findings.

The radiologic findings in HAPE have been described in original reports.^{[157] [206] [348] [349]} Findings are consistent with noncardiogenic pulmonary edema, with generally normal heart size and left atrial size and no evidence of pulmonary venous prominence, such as Kerley's lines. The pulmonary arteries increase in diameter.^[348] Infiltrates are commonly described as fluffy and patchy with areas of aeration between infiltrates, and in a peripheral location rather than central. Infiltrates may be unilateral or bilateral, with a predilection for the right middle lung field, which corresponds to the usual area of rales. Pleural effusion is quite rare. The x-ray findings generally correlate with the severity of the illness and degree of hypoxemia. A small right hemithorax, absence of pulmonary vascular markings on the right, and edema confined to the left lung are the basis for a diagnosis of unilateral absent pulmonary artery syndrome.^[109] The x-ray findings of HAPE are presented in [Figure 1-14](#).

Clearing of infiltrates is generally rapid once treatment is initiated. Depending on severity, complete clearing may take from one to several days. Infiltrates are likely to persist longer if the patient remains at high altitude, even if confined to bed and receiving oxygen therapy. Radiographs taken within 48 hours of return to low altitude may confirm a diagnosis of HAPE.

Pathologic Findings.

More than 20 autopsy reports of persons who died of HAPE have been published.* Of those whose cranium was opened, more than half had cerebral edema. All lungs showed extensive and severe edema, with bloody, foamy fluid in the airways. Lung weights were two to four times normal. The left side of the heart was normal. The right atrium and main pulmonary artery were often distended. Proteinaceous exudate with hyaline membranes was characteristic. All lungs had areas of inflammation with neutrophil accumulation. The diagnosis of bronchopneumonia was common, although bacteria were not noted. Pulmonary veins, the left ventricle, and the left atrium were generally not dilated, in contrast to the right ventricle and atrium. Most reports mention capillary and arteriolar thrombi and alveolar fibrin deposits, as well as microvascular and gross pulmonary hemorrhage and infarcts. The autopsy findings thus suggest a protein-rich, permeability type of edema, with thrombi or emboli. Confirmation of HAPE as a permeability edema was obtained by analysis of alveolar lavage fluid by Schoene et al.^{[306] [307]} These authors found a 100-fold increase in lavage fluid protein levels in patients with HAPE compared with well control subjects and patients with AMS.^[307] The lavage fluid also had a low percentage of neutrophils, in contrast to findings in adult respiratory distress syndrome. Further evidence for a permeability edema was a 1:1

ratio of aspirated edema fluid protein to plasma protein level found by Hackett et al.^[112] In addition, the lavage fluid contained vasoactive eicosanoids and complement proteins, indicative of endothelium-leukocyte interactions.

Mechanisms of High-Altitude Pulmonary Edema.

The search continues for the mechanism triggering the pulmonary vascular leak. An acceptable explanation for HAPE must take into account three well-established facts: excessive pulmonary hypertension; high-protein permeability leak; and normal function of the left side of the heart. One mechanism that is consistent with the facts is failure of capillaries secondary to overperfusion edema ([Figure 1-15](#)).

ROLE OF PULMONARY HYPERTENSION.

Excessive pulmonary artery pressure (PAP) is the sine qua non of

*References ^[8] ^[72] ^[247] ^[319] ^[321] ^[361] .

Figure 1-15 Proposed pathophysiology of high-altitude pulmonary edema. *HPV*, Hypoxic pulmonary vasoconstriction; *HVR*, hypoxic ventilatory response; *Pcap*, capillary pressure; *PHTN*, pulmonary hypertension.

HAPE; no cases of HAPE have been reported without pulmonary hypertension. All persons ascending to high altitudes or otherwise enduring hypoxia, however, have some elevation of PAP. The hypoxic pulmonary vasoconstrictor response (HPVR) is thought to be useful in humans at sea level because it helps match perfusion with ventilation. When local areas of the lung are poorly ventilated because of infection, atelectasis, or some other cause, the HPVR directs blood away from those areas to well-ventilated regions. In the setting of global hypoxia as occurs with ascent to high altitude, HPVR is presumably diffuse and all areas of the lung constrict, causing a restricted vascular bed and an increase in PAP, which is of little if any value for ventilation-perfusion matching at high altitude. The degree of HPVR varies widely among individuals (as well as among species). Presumably those with a greater HPVR have a greater percentage of muscularized arterioles, constrict more units (a greater amount) of the circulation, and have a more restricted vascular bed and a greater rise in PAP. Although other factors, such as the vigor of the ventilatory response and subsequent arterial P_{O_2} , may help determine the ultimate degree of pulmonary hypertension, HPVR appears to be the dominant factor. Because all persons with HAPE have excessive pulmonary hypertension, but not all those with excessive pulmonary

hypertension have HAPE, it appears that pulmonary hypertension is a necessary factor but in itself is not the cause of HAPE.

OVERPERFUSION.

Hultgren^[148] suggested that in those who develop HAPE, the hypoxic pulmonary vasoconstriction is uneven and the microcirculation in an unconstricted (relatively dilated) area is subjected to high pressure and flow, leading to edema. The unevenness could be due to anatomic characteristics, such as distribution of muscularized arterioles, or to functional factors, such as loss of HPVR in severely hypoxic regions.^[148] Uneven perfusion is suggested clinically by the typical patchy x-ray appearance and is supported by lung scans during acute hypoxia that show uneven perfusion in persons susceptible to HAPE.^[346] Persons born without a right pulmonary artery are highly susceptible to HAPE (see [Figure 1-14, D](#)),^[109] supporting the concept of overperfusion of a restricted vascular bed as a cause of edema, because the entire cardiac output flows into one lung. Staub,^[326] in an accompanying editorial, supported the concept of overperfusion edema

but pointed out that hydrostatic edema generally produces a low-protein transudate. Other causes of overperfusion of the pulmonary circulation include left-to-right shunts, such as atrial septal defect (ASD), ventricular septal defect (VSD), and patent ductus arteriosus (PDA).

PERMEABILITY FACTORS.

Endothelial damage from shear forces,^[287] as well as stress failure of the capillary membrane,^{[357] [358]} has therefore been invoked to explain the high-protein permeability leak from overperfusion. A recent preliminary study has found activity of adhesion molecules on ascent to high altitude,^[82] which indicates interaction of leukocytes and endothelium. The lavage fluid findings of inflammatory mediators also point to the possible endothelial involvement, as do a number of animal studies that failed to produce permeability edema with overperfusion alone but succeeded when the pulmonary vascular bed was embolized with microspheres.^[98]

The overperfusion hypothesis is consistent with recent clinical trials of vasodilators intended for prevention and treatment of HAPE. Presumably, when pulmonary vasoconstriction is relieved, flow becomes more homogeneous, and because overall PAP is reduced, microvascular pressure also drops. The rapid reversibility of the illness is also consistent with this mechanism.

Other factors contributing to increased hydrostatic pressure, such as exercise or a high salt load with subsequent hypervolemia, could also play a role in HAPE. The effective use of diuretics and vasodilators also supports a rationale for reducing hydrostatic pressure. A recent study found that an intravenous α -adrenergic blocker, phentolamine,

was effective in reducing PAP in HAPE, [117] which raises the possibility that pulmonary venous constriction, which is sympathetically mediated, could be a factor. Any degree of venous constriction could significantly contribute to increased microvascular pressure. Experiments that convincingly demonstrate the validity of the preceding hypotheses are obviously difficult to perform in humans and await a successful animal model of HAPE. For now, the exact site and mechanism of the leak in HAPE remain enigmatic.

CONTROL OF VENTILATION.

As in AMS, control of ventilation may play a role in the pathophysiology of HAPE. Victims have been shown to have a lower HVR than persons who acclimatized well, [115] [211] but not all persons with a low HVR become ill. Thus low HVR appears to play a permissive, rather than causative, role in the development of HAPE. A brisk HVR, and therefore a large increase in ventilation, appears to be protective. Persons who tend to hypoventilate are more hypoxemic and presumably suffer greater pulmonary hypertension. Possibly more important, a low HVR may permit episodes of extreme hypoxemia during sleep (see [Figure 1-6](#)). Supporting this concept is the frequency with which the onset of HAPE occurs during sleep, especially in persons who have ingested sleep medications. [103] [115] In addition, a HAPE victim with a low HVR does not mount an adequate ventilatory response to the severe hypoxemia of the illness and may suffer further ventilatory depression through CNS suppression. Such persons, when given oxygen, show a "paradoxical" increase in ventilation. [115]

HAPE Susceptibility.

Persons susceptible to HAPE (HAPE-s) show an abnormal rise of PAP and pulmonary vascular resistance during a hypoxic challenge at rest [169] [370] and during exercise, and even during exercise in normoxia. [83] [169] The response of PAP in HAPE-s may be related to greater alveolar hypoxemia secondary to lower HVR. [115] [133] [214] Recent work established a direct link in HAPE-s between the rise in PAP and greater sympathetic activation (as measured by microneurographic recordings in the peroneal nerve during hypoxia). [78] The authors concluded that sympathetic overactivation might contribute to HAPE. Also, smaller and less distensible lungs have been noted in HAPE-s. [83] [133] [327] Another characteristic of HAPE-s is reduced nitric oxide synthesis during hypoxia, suggesting impaired endothelial function. [302] Additional preliminary studies suggest that HAPE-s subjects are characterized by impairment of respiratory transepithelial sodium and water transport, which in mice is related to a genetic defect in the amiloride-sensitive sodium channel (aEnaC). [300] [303] Further evidence for a genetic component to HAPE susceptibility comes from study of major human leukocyte antigen (HLA) alleles in 28 male and 2 female subjects with a history of HAPE compared with HLA alleles in 100 healthy volunteers. [121] The HLA-DR6 and HLA-DQ4 antigens were associated with HAPE, and HLA-DR6 with pulmonary hypertension. These preliminary findings suggest that an immunogenetic susceptibility may underlie the development of HAPE, at least in some cases. In summary, overactivation of the sympathetic nervous system in response to hypoxia, a low HVR, small lungs, and impaired pulmonary nitric oxide synthesis apparently combine to render a person susceptible to HAPE. The role of genetically determined impairment of respiratory epithelial sodium and water transport and the link between components of the major histocompatibility complex and HAPE

provide exciting avenues for further investigation into the pathophysiology of HAPE.

TREATMENT.

Early recognition is the key to successful outcome, as with other high-altitude illnesses (see [Box 1-3](#)). The therapy for HAPE depends on the severity of the illness and on the environment. In the wilderness,

where oxygen and medical expertise may not be available, persons with HAPE should be evacuated to a lower altitude as soon as possible. However, because of augmented pulmonary hypertension and greater hypoxemia with exercise, exertion must be minimized. If the disorder is diagnosed early, recovery is rapid with a descent of only 500 to 1000 m (1640 to 3281 feet) and the victim may be able to reascend slowly 2 or 3 days later. In high-altitude locations with oxygen supplies, bed rest with supplemental oxygen may suffice,^[208] but severe HAPE may require high-flow oxygen (4 to 6 L/min or more) for more than 24 hours. Hyperbaric therapy is equivalent to low-flow oxygen and can help conserve oxygen supplies.^[279]

Oxygen immediately increases arterial oxygenation and reduces PAP, heart rate, respiratory rate, and symptoms. When descent is not possible, oxygen (or a hyperbaric bag) can be lifesaving. Rescue groups should make delivery of oxygen to the victim, by airdrop if necessary, the highest priority if descent is slow or delayed. If oxygen is not available, immediate descent is lifesaving. Waiting for a helicopter or rescue team has too often proved fatal. Because cold stress elevates PAP, the victim should be kept warm.^[54] The use of a mask providing pressure (resistance) on expiration (EPAP) was shown to improve gas exchange in HAPE, and this may be useful as a temporizing measure.^{[187] [305]} The same is accomplished with pursed-lip breathing. An unusual case report suggested that a climber may have saved his partner's life by postural drainage to expel airway fluid.^[38]

Drugs are of limited necessity in HAPE because oxygen and descent are so effective. Medications that reduce pulmonary blood volume, PAP, and pulmonary vascular resistance are physiologically rational to use when oxygen is not available or descent delayed. Singh et al^[321] reported good results with furosemide (80 mg every 12 hours), and greater diuresis and clinical improvement occurred when 15 mg parenteral morphine was given with the first dose of furosemide. Their use, however, has been eclipsed by recent results with vasodilators. The calcium channel blocker nifedipine (30 mg slow release every 12 to 24 hours or 10 mg orally repeated as necessary) has proved effective in reducing pulmonary vascular resistance and PAP,^[24] as have hydralazine and phentolamine.^{[117] [254]} The vasodilators can cause hypotension, but they avoid the danger of CNS depression from morphine and possible hypovolemia from diuretics. Nifedipine does not quickly improve oxygenation, however, and clinical improvement is much better with oxygen and descent than with any of these drugs. Nifedipine and perhaps other vasodilators appear to be useful adjunctive therapy but

are no substitute for definitive treatment (see [Box 1-3](#)).

After evacuation of the victim to a lower altitude, hospitalization may be warranted for severe cases. Treatment consists of bed rest and oxygen (sufficient to maintain SaO_2 % greater than 90%), and rapid recovery is the rule. A rare instance of progression to adult respiratory distress syndrome has been reported, but it was impossible to exclude other diagnoses completely.^[376] Antibiotics are indicated for infection when present. Occasionally, pulmonary artery catheterization or Doppler echocardiography is necessary to differentiate cardiogenic from high-altitude pulmonary edema. Endotracheal intubation and mechanical ventilation are rarely needed. A HAPE victim demonstrating unusual susceptibility, such as onset of HAPE despite adequate acclimatization, or onset below 2750 m (9023 feet), might require further investigation, such as echocardiography, to rule out an intracardiac shunt. In children, undiagnosed congenital heart disease is worth considering ([Figure 1-16](#)). Hospitalization until blood gases are completely normal is not warranted; all persons returning from high altitude are at least partially acclimatized to hypoxemia, and hypocapnic alkalosis persists for days after descent. Distinct clinical improvement, radiographic improvement over 24 to 48 hours, and an arterial P_{O_2} of 60 torr or an SaO_2 % greater than 90% are adequate discharge criteria. Patients are advised to resume normal activities gradually and are warned that they may require up to 2 weeks to recover complete strength. Physicians should recommend preventive measures, including graded ascent with adequate time for acclimatization, and should provide instruction on the use of acetazolamide or nifedipine for future ascents. An episode of HAPE is not a contraindication to subsequent high-altitude exposure, but education to ensure proper preventive measures and recognition of early symptoms is critical.

Figure 1-16 Chest x-ray of severe HAPE in a 4-year-old girl with a small previously undiagnosed patent ductus arteriosus that predisposed her to HAPE.

PREVENTION.

The preventive measures previously described for AMS also apply to HAPE: graded ascent, time for acclimatization, low sleeping altitudes, and avoidance of alcohol and sleeping pills. The role of exertion in HAPE may be overemphasized. Reports from North America have included hikers, climbers, and skiers, all of whom were exercising vigorously. Menon et al^[221] clearly showed that sedentary men taken abruptly to high altitude were just as likely to become victims of HAPE. Nonetheless, because PAP rises

with increasing level of exercise, prudence dictates no overexertion for the first day or two at altitude. Considerable clinical experience (but no data) suggests that acetazolamide prevents HAPE in persons with a history of recurrent episodes. Nifedipine (20 mg slow release every 8 hours) prevented HAPE in subjects with a history of repeated episodes.^[24] The drug should be carried by such individuals and started at the first signs of HAPE or, for an abrupt ascent, started when leaving low altitude.

Reentry Pulmonary Edema

In some persons who have lived for years at high altitude, HAPE develops on reascent from a trip to low altitude.^[79] Authors have suggested that the incidence of HAPE on reascent may be higher than that during initial ascent by flatlanders,^{[19] [150]} but data on true incidence are difficult to obtain. Children and adolescents are more susceptible than adults.^[79] Hultgren^[149] found a prevalence of HAPE in Peruvian natives of 6.4 per 100 exposures in the 1-to-20 age group, and 0.4 per 100 exposures in persons over 21 years. The phenomenon has been observed most often in Peru, where high-altitude residents can return from sea level to high altitude quite rapidly. Cases have also been reported in Leadville, Colorado,^[308] but reports are conspicuously absent from Nepal and Tibet, perhaps because such rapid return back to high altitude is not readily available.^[368] Severinghaus^[311] has postulated that increased muscularization of pulmonary arterioles that develops with chronic high-altitude exposure generates an inordinately high PAP on reascent, causing the edema.

OTHER MEDICAL CONCERNS AT HIGH ALTITUDE

High-Altitude Deterioration

The world's highest human habitation is at approximately 5500 m (18,045 feet), and above this deterioration outstrips the ability to acclimatize.^[172] The deterioration is more rapid the higher one goes above the maximum point of acclimatization. Above 8000 m (26,247 feet), deterioration is so rapid that, without supplemental oxygen, death can occur in a matter of days. Life-preserving tasks, such as melting snow for water, may become too difficult, and death may result from dehydration, starvation, hypothermia, and especially neurologic and psychiatric dysfunction.^[295]

Loss of body weight is a prominent feature of high-altitude deterioration. Body weight is progressively lost because of anorexia and malabsorption during expeditions to extreme high altitude. Pugh^[262] reported a 14- to 20-kg body weight loss in climbers on the 1953 British Mt. Everest Expedition. Nearly 30 years later, with improvement in food and cooking techniques, climbers on AMREE still lost an average of 6 kg.^[42] This was due in part to a 49% decrease in fat absorption and a 24% decrease in carbohydrate absorption. During OEII, in which the "climbers" were allowed to eat foods of their choosing ad libitum, they still suffered large weight losses: 8 kg overall, including 3 kg of fat and 5 kg of lean body weight (muscle).^{[141] [292]} At 4300 m (14,108 feet), weight loss was attenuated by adjusting caloric intake to match caloric expenditure.^[52] Thus significant weight loss with prolonged exposure to high altitude may be overcome with adequate caloric intake, but decreased appetite is a problem.^{[170] [341]} At very high altitudes, an increase in caloric intake may not be sufficient to completely counteract the severe anorexia and weight loss.

At extreme altitude, Ryn^[295] reported an incidence of acute organic brain syndrome in 35% of climbers going above 7000 m (22,966 feet), in association with high-altitude deterioration. This syndrome, which includes impaired judgment or frank psychosis, could directly threaten survival.

Children at High Altitude

Children born at high altitude in North America appear to have a higher incidence of complications in the neonatal period than do their lower-altitude counterparts.^[250] In populations better adapted to high altitude over many generations, neonatal transition has not been as well scrutinized, but there does appear to be some morbidity.^[360] High-altitude residence does not clearly affect eventual stature, but growth and development are slowed.^{[69] [235]} In the developing world, confounding factors such as nutrition and socioeconomic status make these issues difficult to assess.^[145] Children

residing at high altitude are more likely to develop pulmonary edema on return to their homes from a low-altitude sojourn than are lowland children on induction to high altitude.

Lowland children traveling to high altitude are just as likely to suffer AMS as are adults. No data indicate that children are more susceptible to altitude illness, although diagnosis can be more difficult in preverbal children.^[371] Despite this somewhat reassuring fact, very conservative recommendations are made regarding taking children to high altitude; it should be made clear that these opinions are not based on the science.^[28]^[261] Durmowicz et al^[79] showed that children with respiratory infections were more susceptible to HAPE.

Children can be given acetazolamide or dexamethasone as necessary for AMS/HACE. The dosage of acetazolamide for prevention or treatment of AMS in children is 5 mg/kg/day in divided doses.

High-Altitude Syncope

Syncope within the first 24 hours of arrival appears to be common at moderate altitude^[248] but is rarely observed in mountaineers at higher altitudes; it is a problem of acute induction to altitude. The mechanism is an unstable cardiovascular control system, and it is considered a form of neurohumoral (or neurocardiogenic) syncope.^[89] An unstable state of cerebral autoregulation may also play a role.^[375] These events appear to be random and seldom occur a second time. Preexisting cardiovascular disease is not a factor in most cases. Postprandial state and alcohol ingestion might be contributing factors. Altitude syncope has no direct relationship to high-altitude illness.

Alcohol at High Altitude

Two questions regarding alcohol are frequently asked: (1) does alcohol affect acclimatization, and (2) does altitude potentiate the effects of alcohol? A recent epidemiologic study indicated that 64% of tourists ingested alcohol during the first few days at 2800 m (9187 feet).^[134] The effect of alcohol on altitude tolerance and acclimatization might therefore be of considerable relevance. Roeggla et al^[290] determined blood gases 1 hour after ingestion of 50 g of alcohol (equivalent to 1 liter of beer), at 171 m (561 feet) and again after 4 hours at 3000 m (9843 feet). A placebo-controlled, double-blind paired design was used. For the 10 subjects, alcohol had no effect on ventilation at the low altitude, but at high altitude it depressed ventilation, as gauged by a decreased arterial P_{O_2} (from 69 to 64 mm Hg) and increased P_{CO_2} (from 32.5 to 34 mm Hg).^[290] Whether this degree of ventilatory depression would contribute to AMS, and whether repeated doses would have greater effect, was not tested. Nonetheless, the authors argue that alcohol might impede ventilatory acclimatization and should be used with caution at high altitude.

Conventional wisdom proffers an additive effect of altitude and alcohol on brain function. McFarland,^[216] who was concerned about the interaction in aviators, wrote "... the alcohol in two or three cocktails would have the physiological action of four or five drinks at altitudes of approximately 10,000 to 12,000 ft." Also, "Airmen should be informed that the effects of alcohol are similar to those of oxygen want and that the combined effects on the brain and the CNS are significant at altitudes even as low as 8,000 to 10,000 ft."^[216] His original observations were made on two subjects in the Andes in 1936. He found that blood alcohol levels rose more rapidly and reached higher values at altitude but noted no interactive effect of alcohol and altitudes of 3810 and 5335 m (12,501 and 17,504 feet).^[217] Most subsequent studies refuted the increased blood alcohol concentration data except at the highest altitudes, over 5450 m (17,881 feet). Higgins et al,^{[129] [130]} in a series of chamber studies, found blood alcohol levels were similar at 392 m (1286 feet) and 3660 m (12,008 feet), and they noted no synergistic effects of alcohol and altitude. Lategola et al^[191] found that blood alcohol uptake curves were the same at sea level and 3660 m (12,008 feet), and performance on math tests showed no interaction between alcohol and altitude. In another study of 25 men, performance scores were similar at sea level and at a simulated 3810-m (12,501-foot) altitude, with blood alcohol level of 88 mg%.^[59] Performance was not affected by hypoxia, only by alcohol, and older subjects were more affected. When more demanding tasks were tested, Collins^[58] found that a blood alcohol level of 91 mg% affected performance, as did an altitude of 3660 m (12,008 feet) during night sessions when the subjects were sleep deprived, but there was no significant altitude/alcohol interaction. In the one study in which Collins et al^[60] were able to discern some altitude effect, there was a simple additive interaction of altitude (hypoxic gas breathing) and alcohol. He concluded that performance decrements resulting from alcohol may be increased by altitudes of 3660 m (12,008 feet) if subjects are negatively affected by that altitude without alcohol. All of these aviation-oriented studies used acute hypoxia equivalent to no more than 3500 m (11,483 feet). Perhaps the highest altitude (without supplemental oxygen) at which alcohol was studied was 4350 m (14,272 feet), on the summit of Mt. Evans in Colorado. Freedman et al^[88] found that alcohol affected auditory evoked potentials the same as in Denver; that is, no influence of altitude was detectable.

In summary, the possibility of interactions between alcohol and altitude deserves study. The limited data on blood gases at altitude after alcohol ingestion support the popular notion that alcohol could slow ventilatory acclimatization. Considerable data, however, refute the belief that at least up to 3660 m (12,008 feet), altitude potentiates the effect of alcohol. How altitude and alcohol might interact during various stages of acclimatization in individuals at higher altitudes is still unknown.

Thrombosis: Coagulation and Platelet Changes

Autopsy findings of widespread thrombi in the brain and lungs have led to investigations of the clotting mechanism at high altitude. Changes in platelets and coagulation have been observed in rabbits, mice, rats, calves, and humans on ascent to high altitude.^[126] A report from OEII found no changes in concentration or inhibition of coagulation factors; significant altitude illness did not develop in OEII subjects. A remarkable case

was reported by O'Brodivich et al.^[252] In one of the women in this chamber study, disseminated intravascular coagulation developed within 1 ½ hours of exposure to hypobaric hypoxia (PB = 410 torr, about 4600 m [15,092 feet]). The platelet count had decreased by 93,000/mm³, and the activated partial thromboplastin time (aPTT) had shortened by 10 seconds. When symptoms of AMS developed, the study was discontinued. The exact mechanism is unknown. The woman and other subjects showed a shortening of the aPTT, perhaps secondary to the increase in procoagulant VII:C.

Singh et al.^[318] reported that patients with HAPE had increased fibrinogen levels and prolonged clot lysis times, attributed to a breakdown of fibrinolysis. These authors also reported thrombotic, occlusive hypertensive pulmonary vascular disease in soldiers who had recently arrived at high altitude.^[317] These findings, plus autopsy data, prompted Dickinson et al.^[72] to conclude that "hypercoagulability of the blood and sequestration of platelets in the pulmonary vascular bed provoke pulmonary thrombosis, and may contribute to the pathogenesis of HAPE."

A series of experiments by Bärtsch et al.^{[17] [18] [20] [21]} however, carefully examined this issue in well subjects and in those with AMS and HAPE. They concluded that HAPE is not preceded by a prothrombotic state and that only in "advanced HAPE" is there fibrin generation, which abates rapidly with oxygen treatment. They considered the coagulation and platelet activation as an epiphenomenon rather than as an inciting pathophysiologic factor. Fibrin formation would, however, contribute to worsening of edema because of vascular obstruction, increased vascular permeability, and derangement of surfactant function.^[26]

Thrombotic and embolic events in mountaineers may be explained on the basis of dehydration, polycythemia, cold, constrictive clothing, and venous stasis from prolonged periods of weather-imposed inactivity. A role for hypoxia-induced abnormal clotting in the pathogenesis of these events, especially stroke, is not established.

Peripheral Edema

Edema of the face, hands, and ankles at high altitude is common, especially in females. Incidence of edema in at least one area of the body in trekkers at 4200 m (13,780 feet) was 18% overall, 28% in females, 14% in males, 7% in asymptomatic trekkers, and 27% in those with AMS.^[105] Although not a serious clinical problem, edema can be bothersome. The presence of peripheral edema demands an examination for pulmonary and cerebral edema. In the absence of AMS, peripheral edema is effectively treated with a diuretic. Treatment of accompanying AMS by descent or medical therapy also results in diuresis and resolution of peripheral edema. The mechanism is presumably

similar to fluid retention in AMS but may also be merely due to exercise.^[224]

Immunosuppression

Mountaineers have observed that infections are common at high altitude, slow to resolve, and often resistant to antibiotics.^[243] On AMREE in 1981, serious skin and soft tissue infections developed. "Nearly every accidental wound, no matter how small, suppurred for a period of time and subsequently healed slowly."^[299] A suppurative hand wound and septic olecranon bursitis did not respond to antibiotics but did respond to descent to 4300 m (14,108 feet) from the 5300-m (17,389-foot) base camp. Nine of 21 persons had significant infections not related to the respiratory tract. Most high-altitude expeditions report similar problems.

Data from OEII indicated that healthy individuals are more susceptible to infections at high altitude because of impaired T lymphocyte function; this is consistent with previous Russian studies in humans and animals.^[220] In contrast, B cells and active immunity are not impaired. Therefore resistance to viruses may not be impaired, whereas susceptibility to bacterial infection is increased. The degree of immunosuppression is similar to that seen with trauma, burns, emotional depression, and space flight. The mechanism may be related, at least in part, to release of adrenocorticotrophic hormone, cortisone, and β -endorphins, all of which modulate the immune response. Intense ultraviolet exposure has also been shown to impair immunity. Persons with serious infections at high altitude may need oxygen or descent for effective treatment. Impaired immunity because of altitude should be anticipated in situations in which infection could be a complication, such as trauma, burns, and surgical and invasive procedures.

High-Altitude Pharyngitis and Bronchitis

Sore throat, chronic cough, and bronchitis are nearly universal in persons who spend more than 2 weeks at an extreme altitude (over 5500 m [18,045 feet]).^[209] All 21 members of AMREE suffered these problems.^[299] Only two of eight subjects in OEII (where the temperature was greater than 21° C [70° F] and relative humidity was greater than 80%) developed cough, and only above 6500 m (21,325 feet). Only four had sore throat. Obviously, factors other than hypoxia are involved. In the field, these problems usually appear without fever or chills, myalgias, lymphadenopathy, exudate, or other signs of infection. Whether these are infections is debatable. The increase in ventilation, especially with exercise, forces obligate mouth breathing at altitude, bypassing the warming and moisturizing action of the nasal mucous membranes and sinuses. Movement of large volumes of dry, cold air across the pharyngeal

mucosa can cause marked dehydration, irritation, and pain, similar to pharyngitis. Vasomotor rhinitis, quite common in cold temperatures, aggravates this condition by necessitating mouth breathing during sleep. For this reason, decongestant nasal spray is one of the most coveted items in an expedition medical kit. Other countermeasures

include forced hydration, hard candies, lozenges, and steam inhalation.

High-altitude bronchitis can be disabling because of severe coughing spasms. Cough fractures of one or more ribs are not rare; two climbers on AMREE had such fractures. Purulent sputum is common. Response to antibiotics is poor; most victims resign themselves to taking medications such as codeine and do not expect a cure until descent. A recent study of high-altitude bronchitis on Aconcagua revealed that bronchitis developed in 13 of 19 climbers above 4300 m (14,108 feet).^[264] Mean sputum production was 6 teaspoons per day. All reported that onset was after a period of excessive hyperventilation associated with strenuous activity. Although an infectious etiology is possible, experimental evidence suggests that respiratory heat loss results in purulent sputum and sufficient airway irritation to cause persistent cough.^[215] This is supported by the beneficial effect of steam inhalation and lack of response to antibiotics. Many climbers find that a silk balaclava or similar material that is porous enough for breathing but that traps some moisture and heat effectively prevents or ameliorates the problem.

Chronic Mountain Polycythemia

In 1928, Carlos Monge^[231] described a syndrome in Andean high-altitude natives that was characterized by headaches, insomnia, lethargy, plethoric appearance, and polycythemia greater than expected for the altitude. Known variously as Monge's disease, chronic mountain polycythemia, or chronic mountain sickness, the condition has now been recognized in all high-altitude areas of the world.^{[183] [229] [259]} Both lowlanders who relocate to high altitude and native residents are susceptible. Chinese investigators reported that 13% of lowland Chinese males and 1.6% of females who had relocated to Tibet developed excessive polycythemia (hemoglobin level greater than 20 g/dl blood).^[369] The incidence in Leadville, Colorado, is also high in men over 40 and distinctly low in women.^[181] The increased hematopoiesis is apparently related to greater hypoxic stress, which may be due to a number of causes, such as lung disease, sleep apnea syndromes, and idiopathic hypoventilation. A diagnosis of "pure" chronic mountain polycythemia excludes lung disease and is characterized by relative alveolar hypoventilation and respiratory insensitivity to hypoxia.^[229] Some studies suggest that even for the degree of hypoxemia, the red blood cell mass is excessive, implying excessive amounts or overactivity of erythropoietin.^[362] Increasing age is also an important factor.^[230]

Regardless of the exact mechanism, therapy is routinely successful. Descent to a lower altitude is the definitive treatment. Supplemental oxygen during sleep is valuable. Phlebotomy is a common practice, provides subjective improvement (without significant objective changes), and is generally recommended when hematocrit is greater than 60% or hemoglobin level is greater than 20 g/dl blood.^[362] The respiratory stimulants medroxyprogesterone acetate (20 to 60 mg/day) and acetazolamide (250 mg twice a day) have also been shown to reduce the hematocrit value by improving oxygenation.^[182] The response to respiratory stimulants emphasizes the contribution of hypoventilation to chronic mountain polycythemia.

High-Altitude Flatus Expulsion

High-altitude flatus expulsion (HAFE) is the unwelcome spontaneous passage of colonic gas at altitudes above 3000 m (9843 feet).^[9A] The mechanism has been postulated to relate to the expansion of intraluminal bowel gas at the decreased atmospheric pressure of altitude. Affected individuals may benefit from the oral administration of digestive enzymes or simethicone and a preferential carbohydrate diet.

High-Altitude Retinopathy and Ultraviolet Keratitis

See [Chapter 22](#) .

Fingernail Changes

A white transverse band visible across the fingernail plates may correspond to duration of altitude-related hypoxia. This has been observed (Figure 1-17 (Figure Not Available)) in a 34-year-old climber who spent approximately 6 weeks at or above 5500 m (18,045 feet) climbing on Mt. Everest.^[16] It

Figure 1-17 (Figure Not Available) This photograph was taken 3 months after return to low altitude. A white transverse band grew out from the nail beds and was due to exposure to extremely high altitude. (From Hutchison SJ, Amin S: *N Engl J Med* 336:229, 1997.)

was hypothesized that the white band may have been an effect of hypoxia and catabolic stress.

COMMON MEDICAL CONDITIONS AND HIGH ALTITUDE

Persons with certain preexisting illnesses might be at risk for adverse effects upon ascent to high altitude, either because of exacerbation of their illnesses or because these illnesses might affect acclimatization and susceptibility to altitude illness. Certain populations also require special consideration, such as the pregnant and the elderly. This section presents an overview of current knowledge regarding these issues. Despite the importance of the interaction of altitude and common medical conditions, research has so far been limited. See the recent review by Hackett^[102] for a more complete discussion. Conditions that can be aggravated by high-altitude exposure are listed in [Box 1-4](#).

Respiratory Diseases

Chronic Lung Disease.

Although oxygen saturation remains above 90% in a normally acclimatizing, healthy, awake person until at an altitude over 3000 m (9843 feet) (see [Figure 1-1](#)), persons with hypoxemic lung disease reach this threshold at a lower altitude that depends on the baseline blood oxygen values. As a result, these persons might have altitude-related problems at lower altitudes than would healthy individuals. In terms of their lung disease, improved airflow will result from decreased air density at high altitude, but hypoxemia, pulmonary hypertension, disordered control of ventilation, and sleep-disordered breathing could all become worse. Unfortunately, few data are available to guide the clinician advising such a person undertaking a trip to altitude. Hypoxic gas breathing at sea level can predict oxygenation at high altitude, but this does not always correlate with symptoms and is not convenient. Sea level P_{O_2} values of 68 and 72 torr successfully classified more than 90% of the subjects with a P_{aO_2} greater than 55 torr at simulated altitudes of 1525 m (5004 feet) and 2440 m (8006 feet), respectively.^{[95] [96]} Such predictions have been further refined with the addition of spirometry.^[76] A P_{aO_2} of 55 torr results in a saturation of 90% at high altitude, where there is slight alkalosis. These data suggested that persons with P_{aO_2} values lower than these at sea level might require supplemental oxygen at modest altitudes. However, in the only clinical study to date, Graham and Houston^[97] found that eight subjects with chronic obstructive pulmonary disease (COPD) tolerated 1920-m (6300-foot) altitude quite well. Persons with cor pulmonale or angina were excluded. The subjects had only minor symptoms on ascent, despite the fact that mean P_{aO_2} declined from 66 at sea level to 51 mm Hg while at rest and from 63 to 47 mm Hg with exercise. The patients did acclimatize, with a drop in P_{CO_2} , and a corresponding increase in P_{aO_2} over 4 days, the same response as seen in healthy persons. The authors concluded that travel to this

moderate altitude is safe for such patients. They speculated that these persons might have been partially acclimatized because of their hypoxic lung disease and were therefore less likely to develop AMS. Unfortunately, no further investigations with sicker patients or at higher altitudes have yet been reported.

**Box 1-4. ADVISABILITY OF EXPOSURE
TO HIGH AND VERY HIGH ALTITUDE
FOR COMMON CONDITIONS
(WITHOUT SUPPLEMENTAL OXYGEN)**

PROBABLY NO EXTRA RISK

Young and old

Fit and unfit

Obesity

Diabetes

After coronary artery bypass grafting
(without angina)

Mild chronic obstructive pulmonary
disease (COPD)

Asthma

Low-risk pregnancy

Controlled hypertension

Controlled seizure disorder

Psychiatric disorders

Neoplastic diseases

Inflammatory conditions

CAUTION

Moderate COPD

CAUTION

Moderate COPD

Compensated congestive heart failure (CHF)

Sleep apnea syndromes

Troublesome arrhythmias

Stable angina/coronary artery disease

High-risk pregnancy

Sickle cell trait

Cerebrovascular diseases

Any cause for restricted pulmonary circulation

Seizure disorder (not on medication)

Radial keratotomy

CONTRAINDICATED

Sickle cell anemia (with history of crises)

Severe COPD

Pulmonary hypertension

Uncompensated CHF

Persons with COPD who become uncomfortable at altitude should be treated with oxygen therapy. Oxygen should also be considered for those predicted to become severely hypoxemic.^[33] To adjust oxygen therapy at altitude for persons already on supplemental oxygen, F_{iO_2} is increased by the ratio of higher to lower barometric pressure (see [Table 1-2](#)). Oxygen also improved hemodynamics (lowered blood pressure) and decreased pulsus

paradoxus and pulse pressure in COPD patients at a simulated altitude of 2438 m (7999 feet).^[34] With the advent of simple and inexpensive pulse oximetry, patients can be counseled to monitor their oxygen saturation, determine the need for oxygen, and titrate their own oxygen use.

Interestingly, reports of persons with COPD developing altitude illness are absent from the literature. On the other hand, the issue has not been specifically addressed. Any degree of pulmonary hypertension might be expected to increase the likelihood of HAPE, and although this has been clearly demonstrated in other conditions (see High-Altitude Pulmonary Edema), it has not yet been reported with pulmonary hypertension associated with COPD. No research has yet addressed the use of medications such as acetazolamide or medroxyprogesterone in these patients, to determine if respiratory stimulants might improve altitude tolerance.

Cystic Fibrosis.

Children with cystic fibrosis have been reported to do poorly at high altitude,^[325] and hypoxic testing has also tried to predict the need for supplemental oxygen upon ascent in this condition.^[251] As with COPD, such tests are not particularly useful and tend to underestimate the oxygen requirements because they are done only during rest and while awake. Supplemental oxygen should be available for these children, and oxygen saturation monitoring might be desirable in certain circumstances. The physician should be liberal with the use of antibiotics and adjunctive therapy for exacerbations at high altitude, given the likely danger of greater hypoxemia and greater difficulty treating infections at high altitude.

Asthma.

The available literature suggests that asthmatics do well at high altitude, both residents and sojourners, primarily because of decreased allergens and pollution.^{[39] [316] [344]} Indeed, high altitude as a treatment for asthma has been popular in Europe for many decades. However, because altitude exposure often includes exercise (and cold), asthmatics with exercise-induced bronchospasm rather than allergic asthma might have problems at altitude. Matsuda et al^[210] investigated the effect of altitude on 20 asthmatic children with exercise-induced bronchospasm in a hypobaric chamber simulating 1500 m (4921 feet) but with the temperature and humidity held constant. Except for the increased respiratory rate during exercise, as expected, all other physiologic variables were unchanged compared with sea level. The authors concluded that the modest altitude of 1500 m (4921 feet) does not exacerbate exercise-induced asthma. Future work will hopefully evaluate asthmatics at higher altitudes and in the field, where humidity and temperature are lower.

In the presence of bronchoconstriction at high altitude, however, hypoxemia is likely to be greater than at low altitude, and for this reason there could be an association

between asthma and HAPE or AMS. Reassuringly, no such relationship has yet been reported. Mirrakhimov^[227] investigated the effect of acetazolamide in 16 asthmatic patients taken to 3200 m (10,499 feet). Acetazolamide showed the same benefits as in nonasthmatics, with higher oxygen saturation and fewer AMS symptoms compared with the placebo control group. Seven of the eight asthmatics in the control group developed symptoms of AMS, a rather high incidence, but without a nonasthmatic control group for comparison, whether this incidence was abnormal is unknown.

Persons with asthma ascending to high altitude should be advised to be at maximum function before ascent; to continue on their usual medications, including steroids; and to have steroids and bronchodilators with them in the event of an exacerbation. Because airway heat loss can be a trigger for bronchospasm, the use of an airway warming mask might be helpful but is unproven.^[293] In summary, the available data, although limited, suggest that high altitude does not exacerbate asthma, and it actually improves allergic asthma. Further work needs to determine if asthma might have any influence on susceptibility to AMS and HAPE; anecdotally, this does not seem to be the case. Although it seems likely that a severe asthma attack at high altitude would be more dangerous than at low altitude, no data are available to answer this question. Although caution and adequate preparation are necessary, asthma is not a contraindication to high-altitude travel.

Sleep Apnea and Sleep-Disordered Breathing

Persons with snoring, sleep apnea syndrome, and sleep-disordered breathing (SDB) who become mildly hypoxemic at sea level may become severely hypoxemic at high altitude. This could contribute to high-altitude illness and aggravate attendant problems, such as polycythemia, pulmonary hypertension, cardiac arrhythmia, or insomnia. On the other hand, changes in ventilatory control and breathing secondary to altitude hypoxia might conceivably improve certain apnea syndromes. Fujimoto et al^[91] suggested that SDB at high altitude was related to altitude illnesses, including HAPE, but whether the SDB was present before altitude exposure was not determined. The chaotic breathing pattern during sleep that these investigators found in HAPE-s subjects was clearly different from the usual periodic breathing of high altitude. In fact, periodic breathing (Cheyne-Stokes) is considered benign, has not been related to AMS or HAPE, and is associated with a brisk HVR, which is generally considered beneficial at altitude.^[114] Patients with SDB being treated with continuous positive airway pressure (CPAP) should be aware that the hypobaria of high altitude decreases the delivered pressure of CPAP machines that do not have

pressure-compensating features. Therefore they might need to adjust their machines. The error is greater the higher the altitude and the higher the initial pressure setting.^[90] For those not being treated with CPAP but who exhibit hypoxemia during sleep at low altitude, the physician might want to consider supplemental nocturnal oxygen during an altitude sojourn.

Cardiovascular Conditions

Hypertension.

In healthy persons rapidly ascending to high altitude, the change in blood pressure, if any, is variable, depending on magnitude of hypoxic stress, cold, diet, exercise, and genetic factors. Most studies report a slight increase in blood pressure, associated with increased catecholamine activity and increased sympathetic activity.^[266] One well-controlled study showed an increase in blood pressure at 3500 m (11,483 feet) from a mean of 105/66 mm Hg at sea level to 119/77 mm Hg at 3 days, 111/75 mm Hg at 3 weeks, and back to 102/65 mm Hg on return to sea level.^[207] Pugh^[263] reported transient increases in blood pressure in athletes at the 1968 Olympics in Mexico City. Certain individuals, however, appear to have a pathologic response upon induction to high altitude. For example, arterial hypertension develops in 10% of lowland Chinese who move to Tibet.^[314] The authors consider this a form of altitude maladaptation and treat the condition by returning the affected individuals to low altitude. After a period of at least months, however, down-regulation of adrenergic receptors results in attenuation of the initial blood pressure response. This mechanism is thought to be the reason that long-term residents of high altitude have lower blood pressure than their sea level counterparts.^{[151] [288]} Apparently for the same reason, chronic altitude exposure has also been shown to inhibit progression of hypertension.^[228]

As for the effect of short-term altitude exposure on preexisting hypertension, studies have generated mixed results. In general, the response in hypertensives is similar to those without hypertension, that is, a small increase in blood pressure, with an exaggerated response in some individuals. The greater the hypoxic stress (the higher the altitude), the greater the change in blood pressure. Altitudes less than 3000 m (9843 feet) seem to result in little if any change.^[282] Palatini et al^[257] studied 12 normotensives and 12 untreated mild hypertensives with 24-hour ambulatory blood pressure monitoring at sea level, after 12 hours at 1210 m (3970 feet), and after 1 ½ to 3 hours at 3000 m (9843 feet). The authors concluded that the increase of blood pressure in both normotensives and hypertensives was not important at 1210 m (3970 feet) but could become so at 3000 m (9843 feet). However, individual variability was great; the maximum change was 17.4 mm Hg for systolic and 16.3 for diastolic blood pressures. Two other studies were able to demonstrate a slightly greater blood pressure response in hypertensives compared with normotensives upon ascent to 2572 m (8439 feet) and 3460 m (11,352 feet).^{[69A] [301]} Again, these authors also noted important individual variation, with some subjects increasing their systolic blood pressure by as much as 25 mm Hg at rest and 40 mm Hg during exercise, compared with sea level measurements. The important question of whether the blood pressure would continue to increase over the first 2 weeks at high altitude, as it does in normotensives, has not yet been addressed. At a more modest altitude, Halhuber^[119] claimed a significant reduction in the blood pressure of 593 persons with hypertension after 14 days at 1700 to 2000 m (5578 to 6562 feet) in the Alps. A similar study of hypertensives at higher altitude will hopefully be accomplished.

Patients receiving antihypertensive treatment should continue their medications while at

high altitude. Because some persons may unpredictably become markedly hypertensive acutely,^[152] blood pressure monitoring should be considered, especially in those with labile hypertension or those who become symptomatic at altitude. Hypertension in short-term high-altitude sojourners for the most part should be considered transient and should not be treated because it rarely reaches dangerously high levels and will resolve on descent. Given the large number of hypertensive patients visiting ski resorts and trekking at high altitude, however, the occasional person with an exaggerated response will require treatment.^[152] Because the mechanism appears to be increased α -adrenergic activity, an α -blocker might be the best choice of therapy for these individuals. A preliminary report also suggested that nifedipine might be useful and superior to atenolol.^[70] There is no evidence to date to suggest that hypertensive patients are more likely to develop high-altitude illnesses. Although requiring some caution, hypertension does not seem to be a contraindication to high-altitude exposure.

Arteriosclerotic Heart Disease.

Lifelong residence at high altitude appears to offer some protection from coronary artery disease (CAD) and the attendant acute coronary artery events,^[226] perhaps in part resulting from increased myocardial vascularity.^[53] Other factors that might explain this finding, such as genetics, fitness, and diet, have not been adequately evaluated. The effect of acute, transient exposure to high altitude on the healthy heart also appears to be benign. Various avenues of research have indicated that the healthy heart tolerates even extreme hypoxia quite well, all the way to the summit of Mt. Everest (P_{aO_2} less than 30 torr). Numerous electrocardiograms (ECGs), echocardiograms, heart catheterizations, and exercise tests have failed to demonstrate any evidence of cardiac ischemia or cardiac dysfunction in healthy persons at high altitudes. This could partly be due to the marked reduction in maximal exercise with increasing altitude,

which reduces maximal heart rate and myocardial oxygen demand, and also due to the increased coronary blood flow. A person with CAD, however, may not have the same adaptive capacities. For example, diseased coronary arteries might have limited ability to vasodilate and might actually constrict because of unopposed sympathetic activation.^[193] What, then, are the risks, and what to advise those with CAD considering a visit to high altitude?

Surprisingly little literature is available to help the physician advise such persons. Does high altitude provoke acute coronary events or sudden death? In the United States, no evidence from state or county mortality statistics suggests an increased prevalence of acute coronary events in visitors to high-altitude locations. In Europe, Halhuber^[119] reported an incidence of only 0.2% for myocardial infarction in 434 patients with CAD taken to altitudes between 1700 and 3200 m (5578 and 10,499 feet) for 4 weeks in the Alps. He also reported a very low incidence of sudden death in 151,000 vacationers in the Alps, 69,000 of whom were over age 40. In contrast are data from Austria claiming a higher rate of sudden cardiac death in the mountains, compared with the overall risk of

sudden cardiac death.^[47] However, the altitudes were rather low (1000 to 2100 m [3281 to 6890 feet]), and no increased risk was evident in men who participated regularly in sports. The authors suggested that abrupt onset of exercise in sedentary men combined with altitude stress might induce cardiac sudden death, but whether altitude contributed at all is unclear. In summary, limited data suggest no increased risk for sudden cardiac death or myocardial infarction at altitudes up to 2500 m (8202 feet).

Another important question is whether altitude will exacerbate stable ischemia. The slight increase in heart rate and blood pressure on initial ascent to altitude might exacerbate angina in those with coronary artery disease, as described by Hultgren.^[152] One study evaluated nine men with stable exercise-induced angina by exercise treadmill test at 1600 m (5250 feet; Denver), and within the first hour of arrival at 3100 m (10,171 feet).^[239] Cardiac work was slightly higher for a given workload at high altitude compared with low altitude, and as a result, the onset of angina was at a slightly lower workload. They found that a heart rate of 70% to 85% of the rate that produced ischemia at low altitude was associated with angina-free exercise at 3100 m (10,171 feet), and they suggested that angina patients at altitude adjust their activity level based on heart rate, at least on the day of arrival.^[239] Brammel et al^[45] reported similar results and also suggested that those with angina need to reduce their activity at high altitude to avoid angina episodes. In a more recent study, Levine et al^[193] investigated 20 men who were much older than those in the previous investigations (mean age 68 ± 3 years) and performed symptom-limited exercise tests. With acute exposure to 2500 m (8202 feet), the double product (heart rate times systolic blood pressure) required to induce 1 mm ST depression was decreased about 5%, but after 5 days of acclimatization at 2500 m (8202 feet), this value was unchanged from sea level. The degree of ischemia (maximal ST segment depression) was the same at sea level, with acute altitude exposure, and after 5 days at 2500 m (8202 feet). Also, no new wall motion abnormalities on echocardiography were seen at high altitude. Only one subject exhibited increased angina at altitude, and one person with severe CAD developed a myocardial infarction after maximal exercise at 2500 m (8202 feet). The authors concluded that CAD patients who are well compensated at sea level do well at a moderate altitude after a few days of acclimatization, but that acutely angina threshold may be lower and activity should be reduced.^[193] Finally, a study of 97 elderly persons visiting 2500 m (8202 feet), many with CAD and abnormal ECGs, found no new ECG changes and no events suggestive of ischemia. In contrast to the Levine study, these subjects did not do exhaustive exercise tests but merely their usual activities, which included walking in the mountains.^[282] Taken altogether, these various investigations indicate that those with CAD, including the elderly, generally do well at the modest altitude of 2500 m (8202 feet), but that reducing their activities the first few days at altitude is wise.

To address the question of whether altitude might provoke cardiac arrhythmia, Levine et al,^[193] in their study mentioned above, found that premature ventricular contractions (PVCs) increased 63% on acute ascent but returned to baseline after 5 days of acclimatization. A simultaneous rise in urine norepinephrine in these subjects indicated that sympathetic activation was the cause of the increased ectopy. They observed no increase in higher-grade ectopy, however, and no changes in signal-averaged ECG suggestive of a change in fibrillation threshold; in other words, the PVCs appeared benign. Halhuber^[119] also found increased ectopy in his subjects and also no serious

adverse events. In addition, Alexander^[2] described asymptomatic PVCs and ventricular bigeminy in himself while trekking to 5900 m (19,358 feet). Subsequent evaluation found no evidence of heart disease, and the event prompted him to thoroughly review the subject of altitude, age, and arrhythmia. Although no dangerous arrhythmias have ever been reported in high-altitude studies, persons with troublesome or high-grade arrhythmia have not been evaluated upon ascent to high altitude. The available evidence would suggest that patients whose arrhythmias are well controlled on medication should continue the medication at altitude, whereas those with poorly controlled arrhythmias might do better to avoid visiting high altitude.

In terms of advising persons with CAD or high likelihood of CAD about altitude exposure, the stress of

high altitude on the coronary circulation appears to be minimal at rest but significant in conjunction with exercise. Ideally, no one with known CAD or even risk factors for CAD should undertake unaccustomed exercise at any altitude and especially at high altitude. Therefore advising an exercise program at sea level before exercising at altitude is prudent. The same technique of risk stratification that is commonly used at sea level can be applied for providing advice for high altitude.^[146] Using the standard recommendations, asymptomatic men over age 50 with no risk factors require no testing. For asymptomatic men over age 50 with risk factors, an exercise test is recommended to determine risk status before exercising at high altitude and then further evaluation as indicated. Patients with previous myocardial ischemia, bypass surgery, or angioplasty are considered high risk only if they have a strongly positive exercise treadmill test. Patients with multiple-vessel bypass grafts who were asymptomatic and with normal exercise tests at sea level have successfully visited altitudes over 5000 m (16,404 feet). High-risk patients may require coronary angiography to establish appropriate management. Alexander^[4] has proposed different criteria for those with CAD at high risk at altitude: an ejection fraction less than 35% at rest, a fall in exercise systolic blood pressure, ST segment depression greater than 2 mm at peak heart rate, and high-grade ventricular ectopy. For these persons, he recommends ascent to no more than 2500 m (8202 feet) and proximity to medical care. Both sets of recommendations, although reasonable, need to be validated with outcome studies.

HEART FAILURE.

Although information on the effect of high altitude on heart failure is scant, physicians in resort areas have noted a tendency toward acute decompensation in those with a history of heart failure within 24 hours of arrival. Those with CAD and low ejection fractions (less than 45%), but without active heart failure, actually did quite well, as gauged by exercise tests during acute exposure to 2500 m (8202 feet).^[85] Compared with 23 control subjects, the decrement in exercise performance was similar, and no complications or signs of ischemia developed. Although these results are encouraging for such patients, they made no observations past the first few hours at altitude. One concern is that those with heart failure might be more likely to retain fluid at altitude,

especially if AMS were to develop, and that this could aggravate failure. Supporting this notion, Alexander et al^[3] found that ejection fraction declined at altitude during an exercise study in patients with angina, with an increase in end-diastolic and systolic volume as measured by two-dimensional echo. Ventricular contractility was not depressed, however, and these changes were attributed to fluid overload. Patients with heart failure need to be informed about possible consequences of high-altitude exposure. In particular, they need to avoid AMS, which is associated with fluid retention, and they need to continue their regular medications and be prepared to increase their diuretic should symptoms of failure exacerbate. Acetazolamide prophylaxis may be useful to consider in terms of speeding acclimatization, inducing a diuresis, and preventing AMS, but its efficacy in these patients remains untested.

PULMONARY VASCULAR DISORDERS.

Because of the danger of HAPE, pulmonary hypertension (of any etiology) is at least a relative contraindication to high-altitude exposure. In addition, hypoxic pulmonary vasoconstriction will most likely exaggerate preexisting pulmonary hypertension and could lead to greater symptomatology in those with congenital cardiac defects, primary pulmonary hypertension (PPH), and related disorders. This caution also applies to unilateral absent pulmonary artery, granulomatous mediastinitis, and restrictive lung diseases, all of which have been associated with HAPE.^{[109] [275] [340]} As Hultgren^[152] has observed, however, some patients with PPH are able to tolerate high altitude, and hypoxic gas breathing can be used to identify an individual's response to hypoxia if clinically indicated. Persons with PPH who must travel to high altitude might benefit from calcium channel blockers, isoproterenol, and/or low-flow oxygen. A recent report highlighted the increased susceptibility to HAPE in those with pulmonary hypertension; a lowland woman with pulmonary hypertension secondary to fenfluramine developed two episodes of HAPE.^[245] The first episode was at 2300 m (7546 feet) and the second one at only 1850 m (6070 feet), with skiing up to 2350 m (7710 feet). Other conditions warranting caution include bronchopulmonary dysplasia, recurrent pulmonary emboli, mitral stenosis, and kyphoscoliosis. Whether pulmonary hypertension is primary or secondary, patients should be made aware of the potential hazards of high altitude, including right heart failure and HAPE.

Sickle Cell Disease

Sickle cell crisis is a well-recognized complication of high-altitude exposure.^[87] Even the modest altitude of a pressurized aircraft (1500 to 2000 m [4921 to 6562 feet]) causes 20% of persons with hemoglobin SC and sickle-thalassemia genetic configuration to have a vasoocclusive crisis.^[203] High-altitude exposure may precipitate the first vasoocclusive crisis in persons previously unaware of their condition. Persons with sickle cell anemia and a history of vasoocclusive crises are advised to avoid altitudes over 1800 m (5906 feet) unless they are taking supplemental oxygen. Persons with sickle cell disease who live at high altitude in Saudi Arabia have twice the incidence of crises, hospitalizations, and complications

as do Saudis at low altitude. Splenic infarction syndrome has been reported more commonly in those with sickle cell trait than in those with sickle cell anemia, probably because sickle cell disease produces autosplenectomy early in life. Frequent reports in the literature emphasize the need to consider splenic syndrome caused by sickle cell trait in any person with left upper quadrant pain, even at an altitude of only 1500 m (5921 feet).^[185]^[203] A number of authors have suggested that nonblack persons with the trait may be at greater risk for splenic syndrome at high altitude than are black persons.^[185] Treatment of splenic syndrome consists of intravenous hydration, oxygen, and removal to a lower altitude.^[339] The overall incidence of problems in persons with the trait is low, however, and no special precaution other than recognition of the splenic syndrome is recommended. The U.S. Army, for example, does not consider soldiers with the trait unfit for duty at high altitude.^[75]

Pregnancy

In high-altitude natives, pregnancy-induced hypertension is four times more common than in low-altitude pregnancies, preeclampsia is more common, and full-term infants are small for gestational age.^[234]^[235] These problems raise the issue of whether short-term altitude exposure may also pose a risk. So far, there is no evidence that these problems, or others such as spontaneous abortion, abruptio placentae, or placenta previa, can result from a sojourn to high altitude.^[249] Unfortunately, however, few data exist on the influence of a high-altitude visit during pregnancy on the mother and the fetus. For moderate altitude, the research to date has been reassuring.^[143]^[144] Artal et al^[9] studied seven sedentary women at 34 weeks gestation. Maximal and submaximal exercise tests were completed at sea level and 6000 feet (1829 m) after 2 to 4 days of acclimatization. They reported the expected decrease in maximal aerobic work but found no difference from sea level in fetal heart rate responses, or in maternal lactate, epinephrine, and norepinephrine levels. In a small number of subjects, the authors considered it safe for women in their third trimester of pregnancy to engage in brief bouts of exercise at moderate altitude. A similar conclusion was reached in a study of 12 pregnant subjects who exercised after ascent to 2225 m (7300 feet). The authors found no abnormal fetal heart rate responses and considered the exercise at altitude benign for both mother and fetus.^[29] Huch^[143] also concluded that short-term exposure, with exercise, was safe during pregnancy. In summary, the available data, though limited, indicate that short-term exposure to altitudes up to 2500 m (8202 feet), with exercise, is safe for a lowland woman with a normal pregnancy.

Another avenue of research has been alteration of blood gases during pregnancy. Human and animal studies with acute hypoxic challenge, as well as oxygen-breathing studies, have drawn two conclusions: (1) that a compromised placental-fetal circulation could be unmasked at high altitude, and (2) that a fetus with a normal placental-fetal circulation seems to tolerate a level of acute hypoxia far exceeding a moderate altitude exposure.^[15]^[63]^[276]

Based on the available research, it seems prudent to recommend that only women with

normal, low-risk pregnancy undertake a sojourn to altitude. For these women, exposure to an altitude at which SaO₂ will remain above 85% most of the time (up to 3000 m [9843 feet] altitude) appears to pose no risk of harm, but further study is needed to place these recommendations on a more solid scientific footing. An ultrasound or other assessment may be useful to rule out the more common complications before travel. Of course, it is not the altitude per se that determines whether the fetus becomes stressed but rather the maternal (and fetal) arterial oxygen transport. A woman with HAPE at 2500 m (8202 feet), for example, is much more hypoxemic than a healthy woman at 5000 m (16,404 feet). Therefore a strategy for preventing altitude illness, especially pulmonary edema, must be explained and implemented. Similarly, carboxyhemoglobin from smoking, lung disease, and other problems of oxygen transport will render the pregnant patient at altitude more hypoxemic and physiologically at a higher altitude. Consideration of a high-altitude sojourn in the developing world, or in a wilderness setting, raises other issues that may be more important than the modest hypoxia. These include remoteness from medical care should a problem arise, the quality of available medical care, the use of medications for such important things as malaria and traveler's diarrhea (many of which are contraindicated in pregnancy), and the risks of trauma.

Chapter 2 - Avalanches

Knox Williams
Betsy R. Armstrong
Richard L. Armstrong
Dale Atkins

An avalanche is a mass of snow that slides down a mountainside. In the United States, approximately 100,000 avalanches occur annually, of which about 100 cause injury, death, or destruction of property. Based on reported incidents in the 1990s, about 200 people a year are caught in avalanches (that is, they are bodily involved in the moving snow or its effects). Of these, 75 are partly or wholly buried, 18 sustain injury, and 24 are killed. Average annual property damage is approximately \$520,000. This chapter describes the properties of the mountain snowpack that contribute to avalanche formation and describes avalanche safety techniques.

PROPERTIES OF SNOW

Physical Properties

Although snow cover appears to be nothing more than a thick, homogeneous blanket covering the ground, it is in fact one of the most complex materials found in nature. It is highly variable and goes through significant changes in relatively short periods of time.

In nature, snow cover is variable on both the broad geographic scale (Antarctic snow is quite different from snow found in the Cascade Mountains of North America) and on the microscale (where snow conditions may vary greatly from one side of a rock or tree to the other). All snow crystals are made of the same substance, the water molecule, but local environmental conditions control the type and character of snow found at a given location. At a single site the snow cover varies from top to bottom, resulting in a complex layered structure.

Individual layers may be quite thick or very thin. In general, thicker layers represent consistent conditions during one storm, when new snow crystals falling are of the same type, wind speed and direction vary little, and temperature and precipitation are fairly constant. Thinner layers, perhaps only millimeters in thickness, often reflect conditions between storms, such as the formation during fair weather of a melt-freeze crust, a period of strong winds creating a wind crust, or the occurrence of surface hoar, the winter equivalent of dew. Delicate feather-shaped crystals of surface hoar deposited from the moist atmosphere onto the cold snow surface overnight offer a beautiful glistening sight as they reflect the sun of the following day. However, they are very fragile and weak, and once buried by subsequent snowfalls, they may be major contributors to avalanche formation.

One property of snow is strength, or hardness, which is of great importance in terms of avalanche formation. Snow can vary from light and fluffy, easy to shovel, and especially delightful to ski through, to heavy and dense, impossible to penetrate with a shovel, and hard enough to make it very difficult for a skier to carve a turn, even with sharp metal edges. The arrangement of the ice skeleton and the changing density (mass per unit volume) produce this wide range of conditions. In the case of snow, density is determined by the volume mixture of ice crystals and air. The denser the snow layer, the harder and stronger it becomes, as long as it is not melting.

The density of new snow can have a wide range of values. This depends on how closely the new snow crystals pack together, which is controlled by the shape of the crystals. The initial crystals have a variety of shapes, and some pack more closely together than others ([Figure 2-1](#)). For example, needles pack more closely than stellars and as a

consequence may possess a density 3 to 4 times that of stellars.

Wind can alter the shape of new snow crystals, breaking them into much smaller pieces that pack very closely together to form wind slabs. These in turn may possess a density 5 to 10 times that of new stellars falling in the absence of wind. Because these processes occur at different times and locations at the surface of the snow cover and are buried by subsequent snowfalls, a varied, nonhomogeneous layered structure results. Therefore what may seem to the casual observer to be minor variations in atmospheric conditions can have an important influence on the properties of snow.

After snow has been deposited on the ground, the density increases as the snow layer settles vertically or shrinks in thickness. Because an increase in density equals an increase in strength, the rate at which this change occurs is important with respect to avalanche potential. Snow can settle simply because of its own weight. It is highly compressible because it is composed mostly of empty airspace within an ice skeleton of snow crystals. In a typical layer of new snow, 85% to 95% of the volume is empty airspace. Individual ice crystals can move and slide past each other, and because the force of gravity causes them to move slowly downward, the layer shrinks. The heavier the snow above and the warmer the temperature, the faster this settlement proceeds.

At the same time, the complex, intricate shapes that characterize the new snow crystals begin to change. They become rounded and suitable for closer packing. Intricate crystals change because they possess a shape

Figure 2-1 International classification of solid precipitation. (From the *International Association of Scientific Hydrology*.)

that is naturally unstable. New snow crystals have a large surface area/volume ratio and are composed of crystalline solid close to its melting point. In this aspect, snow crystals are almost unique among materials found in nature. Surface energy physics dictates that this unstable condition will change; the warmer the temperature, the faster the change. Under very cold conditions, the original shapes of the snow crystals are recognizable after they have been in the snow cover for several days or even a week or two. As temperatures warm and approach the melting point, such shapes disappear within a few hours to a day. Changes in the shape or texture of snow crystals are examples of initial metamorphism. The geologic term *metamorphism* defines changes that result from the effects of temperature and pressure. As the crystal shapes simplify,

they can pack more closely together, enhancing further settlement ([Figure 2-2](#)).

The changes generally occur within hours to a few days. The structure of snow cover changes over a period of weeks to months via other processes. Settlement, which may initially have been rapid, continues at a much slower rate. Other factors begin to exert dominant influences on metamorphism. These factors include the difference in temperature measured upward

Figure 2-2 Settlement. As the crystal shapes become more rounded, they can pack more closely together and the layer settles or shrinks in thickness.

Figure 2-3 When an insulating layer of snow separates the warm ground from the cold air, a temperature gradient develops across the snow layer.

or downward in the snow layer, called the *temperature gradient*.

Averaged over 24 hours, snow temperatures generally are coldest near the surface and warmest near the ground at the base of the snow cover, creating a temperature gradient across a snow layer sandwiched between cold winter air and relatively warm ground ([Figure 2-3](#)). The temperature gradient crosses both ice and large void spaces filled with air. Within the ice skeleton, the temperature adjacent to the ground is warmer than that of the snow layer just above, and this pattern continues through the snow cover in the direction of the colder surface.

Warm air contains more water vapor than does cold air; this holds true for the air trapped within the snow cover. The greater the amount of water vapor, the greater the pressure. Therefore both a pressure gradient and a temperature gradient exist through the snow cover. When a pressure difference exists, the difference naturally tends to equalize, just as adjacent high and low atmospheric pressure centers cause movement of air masses. Pressure differences within snow cause vapor

Figure 2-4 In the temperature-gradient process, ice sublimates from the top of one grain, moves upward as water vapor, and then is deposited on the bottom surface of the grain above. If conditions allow this process to continue long enough, all of the original grains are lost as the recrystallization produces a layer of totally new crystals.

to move upward through the snow layers. The air within the layers of the snow cover is saturated with water vapor, with a relative humidity of 100%. When air moves upward to a colder layer, the amount of water vapor that can be supported in the airspace diminishes. Some vapor changes to ice and is deposited on the surrounding ice grains. We witness a similar process when warm, moist air in a heated room comes in contact with a cold windowpane. The invisible water vapor is cooled to its ice point, and some of the vapor changes state and is deposited as frost on the window.

[Figure 2-4](#) shows how the texture of the snow layer changes during this temperature-gradient process. Water molecules sublime from the upper surfaces of a grain. The vapor moves upward along the temperature (and vapor) gradient and is deposited as a solid ice molecule on the underside of a colder grain above. If this process continues long enough (it continues as long as a strong temperature gradient exists), all grains in the snow layer are transformed from solid to vapor and back to solid again; that is, they totally recrystallize. New crystals are completely different in texture from their initial form. They become large, coarse grains with facets and sharp angles and may eventually evolve into a hollow cup form. Examples of these crystals are shown in [Figure 2-5](#). The process is called *temperature-gradient metamorphism*, or kinetic metamorphism, and well-developed crystals are commonly known as *depth hoar*.

Depth hoar is of particular importance to avalanche formation. It is very weak because there is little or no cohesion or bonding at the grain contacts. Depth hoar or temperature-gradient snow layers can be compared to dry sand. Each grain may possess significant strength, but a layer composed of grains is very weak and friable

Figure 2-5 **A**, Mature depth hoar grains. Facets and angles are visible. Grain size: 3 to 5 mm. **B**, Advanced temperature-gradient grains attain a hollow cup-shaped form. Size: 4 mm. (*A and B*, Polarized-light photos by Doug Driskell.)

because the grains lack connections. Thus depth hoar is commonly called "sugar snow." Depth hoar usually develops whenever the temperature gradient is equal to or

greater than about 10° C (18° F) per meter. In the cold, shallow snow covers of a continental climate, such as that of the Rocky Mountains, a gradient of this magnitude is common within the first snow layers of the season. Therefore a layer of depth hoar is frequently found at the bottom of the snow cover, and the resulting low strength becomes a significant factor for future avalanches.

In the absence of a strong temperature gradient, a totally different type of snow texture develops. When the gradient is less than about 10° C per meter, there is still a vapor pressure difference and upward movement of vapor through the snow layers, but at a much slower rate. As a result, water vapor deposited on a colder grain tends to cover the total grain in a more homogeneous manner, rather than showing the preferential deposition characteristic of depth hoar. This process produces a grain with a smooth surface of more rounded or oblong shape. Over time, vapor is deposited at the

47

Figure 2-6 In the equilibrium metamorphism process, ice molecules sublimate from crystal points (convexities) and redeposit on flat or concave areas of the crystal.

Figure 2-7 Equitemperature grain growth. In the presence of weak temperature gradients, bonds grow at the grain contacts.

grain contacts (concavities), as well as over the remaining surface of the grain (convexity) ([Figure 2-6](#)). Connecting bonds formed at the grain contacts give the snow layer strength over time ([Figure 2-7](#)). Bond growth, called *sintering*, yields a cohesive texture, in complete contrast to the cohesionless texture of depth hoar. This type of grain has been referred to by various terms (destructive metamorphism, equitemperature metamorphism, and equilibrium metamorphism) but can generally be described as fine-grained or well-sintered (bonded) snow. Rounded and interconnected grains are shown in [Figure 2-8](#) .

The preceding paragraphs describe the "big picture" in terms of what happens to snow layers after they have been buried by subsequent snowfalls. If the layer is subfreezing (i.e., if no melt is taking place), one of the two processes described previously is

occurring, or perhaps

Figure 2-8 Bonded or sintered grains resulting from equitemperature metamorphism. Grain size: 0.5 to 1 mm. (*Polarized-light photo by Doug Driskell.*)

a transition exists between the two. Within the total snow cover, these processes may occur simultaneously, but only one can take place within a given layer at a given time. Both processes accelerate with warmer snow temperature because water vapor is involved. The temperature gradient across the layer determines whether the process involves the growth of weak depth hoar crystals or the development of a stronger snow layer with a sintered, interconnected texture.

Slab Avalanche Formation

There are two basic types of avalanche release. The first is point-release, or loose snow, avalanche ([Figure 2-9](#)). A loose snow avalanche involves cohesionless snow and is initiated at a point, spreading out laterally as it moves down the slope to form a characteristic inverted V shape. A single grain or a clump of grains slips out of place and dislodges those below on the slope, which in turn dislodge others. The avalanche continues as long as the snow is cohesionless and the slope is steep enough. This type of avalanche usually involves only small amounts of near-surface snow.

The second type of avalanche, the slab avalanche, requires a cohesive snow layer poorly anchored to the snow below because of the presence of a weak layer. The cohesive blanket of snow breaks away simultaneously over a broad area ([Figure 2-10](#)). A slab release can involve a range of snow thicknesses, from the near-surface layers to the entire snow cover down to the ground. In contrast to a loose snow avalanche, a slab avalanche has the potential to involve very large amounts of snow.

To understand the conditions in snow cover that contribute to slab avalanche formation, it is essential to reemphasize that snow cover develops layer by layer. Although a layered structure can develop by metamorphic

Figure 2-9 Loose snow or point-release avalanche. (USDA Forest Service photo.)

processes, distinct layers develop in numerous other ways, most of which have some influence on avalanche formation. The layered structure is directly tied to the two ingredients essential to the formation of slab avalanches: the cohesive layer of snow and the weak layer beneath. If the snow cover is homogeneous from the ground to the surface, there is no danger of slab avalanches, regardless of the snow type. If the entire snow layer is sintered, dense, and strong, stability is very

Figure 2-10 Slab avalanche. (From USDA Forest Service: *The snowy torrents*. Photo by Alexis Kelner.)

high. Even if the entire snow cover is composed of a very weak layer of depth hoar, there is still no hazard from slab avalanches because the cohesionless character does not allow propagation of the cracks necessary for slab avalanches to form. However, the combination of a basal layer of depth hoar with a cohesive layer above, for example, provides exactly the ingredients for slab avalanche danger. For successful evaluation of slab avalanche potential, information is needed about the entire snowpack, not just the surface. A hard wind slab at the surface may seem strong and safe to the uninitiated, but when it rests on a weaker layer, which may be well below the surface, it may fail under the weight of a skier and be released as a slab avalanche.

Many snow structure combinations can contribute

to slab formation. One scenario involves thick layers of weak snow, which result from development of depth hoar early in the season. The typical combination of climatic factors that produce these layers is early winter snowfalls followed by several weeks of clear, cold weather. Even at higher elevations in the mountains, snow cover on the slopes with a southerly aspect may melt off during a period of fair weather. However, in October and early November, the sun angle is low enough that steep slopes with a

northerly aspect receive little or no direct heating from the sun. Snow remains on the ground but not without change. Snow on north-facing slopes experiences optimal conditions for depth hoar formation; a thin, low-density snow cover (maximum opportunity for vapor flow) is sandwiched between the warm ground, still retaining much of its summer heat, and the cold air above. This snow layer recrystallizes over a period of weeks. When the first large storm of winter arrives in November, cohesive layers of wind-deposited snow accumulate on a very weak base, setting the scene for a widespread avalanche cycle. [Figure 2-11](#) describes other combinations that result in brittle or cohesive layers of snow on a weak layer.

Mechanical Properties

How Snow Deforms on a Slope.

Almost all physical properties of snow can be easily seen or measured. A snowpit provides a wealth of information regarding these properties, layer by layer, throughout the thickness of the snow cover. However, even detailed knowledge of these properties does not provide all the information necessary to evaluate avalanche potential. The current mechanical state of the snow cover must be considered. Unfortunately, for the average person these properties are virtually impossible to measure directly.

Mechanical deformation occurs within the snow cover just before its failure and the start of a slab avalanche. Snow cover has a tendency to settle simply from its own weight. When this occurs on level ground, the settlement is perpendicular to the ground and the snow layer densities and gains in strength. The situation is not so simple when snow rests on a slope. The force of gravity is divided into two components, one tending to cause the snow layer to shrink in thickness, and a new component acting parallel to the slope, which tends to pull the snow down the slope. Downslope movement within the snow cover occurs at all times, even on gentle slopes. The speed of movement is slow, generally on the order of a few millimeters per day up to millimeters per hour within new snow on steep slopes. The evidence of these forces is often clearly visible in the bending of trees and damage to structures built on snow-covered slopes. Although the movement is slow, when deep

Figure 2-11 Snow layer combinations that often contribute to avalanche formation.

snow pushes against a rigid structure, the forces are significant and even large buildings can be pushed off their foundations.

Snow deforms in a highly variable fashion. It is generally described as a viscoelastic

material. Sometimes it deforms as if it were a liquid (viscous) and at other times it responds more like a solid (elastic). Viscous deformation implies continuous and irreversible flow. Elastic deformation implies that once the force causing the deformation is removed, some small part of the initial deformation is recovered. The elasticity of snow is

50

Figure 2-12 Depending on prevailing conditions, snow may deform and stretch in a viscous or flowing manner, or it may respond more like a solid and fracture.

not so obvious, primarily because the amount of rebound is very small compared with that of more familiar materials.

In regard to avalanche formation, it is important to know when snow acts primarily as an elastic material and when it responds more like a viscous substance. These conditions are shown in [Figure 2-12](#). Laboratory experiments have shown that conditions of warm temperatures and slow application of force favor viscous deformation. We see examples of this as snow slowly deforms and bends over the edge of a roof or sags from a tree branch. In such cases, the snow deforms but does not crack or break. In contrast, when temperatures are very cold or when force is applied rapidly, snow reacts like an elastic material. If enough force is applied, it fractures. We think of such a substance as brittle; the release of stored elastic energy causes fractures to move through the material. In the case of snow cover on a steep slope, forces associated with accumulating snow or the weight of a skier may increase until the snow fails. At that point, stored elastic energy is released and is available to drive brittle fractures over great distances through the snow slab.

The slab avalanche provides the best example of elastic deformation in snow cover. Although the deformation cannot actually be seen, evidence of the resultant brittle failure is clearly present in the form of the sharp, linear fracture line and crown face of the slab release ([Figure 2-13](#)). The crown face is almost always perpendicular to the bed surface, evidence that snow has failed in a brittle manner.

To fully understand the slab avalanche condition or the stability of the snow cover, its mechanical state must be considered. Snow is always deforming downslope, but throughout most of the winter the strength

Figure 2-13 The consistent 90-degree angle between crown face and bed surface of the avalanche shows that slab avalanches result from an elastic fracture. (Photo by A. Judson.)

of the snow is sufficient to prevent an avalanche. The snow cover is layered, and some layers are weaker than others. During periods of snowfall, blowing snow, or both, an additional load, or weight, is being applied to the snow in the starting zone, the snow is creeping faster, and these new stresses are beginning to approach the strength of the weakest layers. The weakest layer has a weakest point somewhere within its continuous structure. If the stresses caused by the load of the new snow or the weight of a skier reach the level at which they equal the strength of the weakest point, the snow fails completely at that point ([Figure 2-14](#)). This means that the strength at that point immediately goes to zero. This is analogous to what would happen if someone on a tug-of-war team were to let go of the rope. If the remainder of the team were strong enough to make up for the lost member, not much would change immediately. The same situation exists with the snow cover. If the surrounding snow has sufficient strength to make up for the fact that the strength at the weakest point has now gone to zero, nothing happens beyond perhaps a local movement or settlement in the snow. If, however, the surrounding snow is not capable of doing this, the area of snow next to the initial weak point fails, and then the area next to it, and the chain reaction begins.

As the initial crack forms in the now unstable snow, the elastic energy is released, which in turn drives the crack further, releasing more elastic energy, and so forth. The ability of snow to store elastic energy is essentially what allows large slab avalanches to occur. As long as the snow properties are similar across the avalanche starting zone, the crack will continue to propagate, allowing entire basins, many acres in area, to be set in motion within a few seconds.

Figure 2-14 Slab avalanche released by a skier. (Photo by R. Ludwig.)

Figure 2-15 The three parts of an avalanche path: starting zone, track, and runout zone. *(Photo by B. Armstrong.)*

AVALANCHE DYNAMICS

The topic of avalanche dynamics includes how avalanches move, how fast they move, and how far and with how much destructive power they travel. The science of avalanche dynamics is not well advanced, although much has been learned in the past few decades. Measured data for avalanche velocity and impact pressure are still lacking. Although any environmental measurement presents its own set of problems, it is obvious that opportunities for making measurements inside a moving avalanche are extremely limited. Although avalanche paths exist in a variety of sizes and shapes, they all have three distinct parts with respect to dynamics ([Figure 2-15](#)). In the starting zone, usually the steepest part of the path, the avalanche breaks away, accelerates down the slope, and picks up additional snow. From the starting zone the avalanche proceeds to the track, where it remains essentially constant and picks up little or no additional snow as it moves; the average slope angle has become less steep and frequently the snow cover is more stable than in the starting zone. (However, a study from Switzerland in 2000 showed that a significant amount of snow could be entrained into the avalanche from the track.) Small avalanches often stop in the track. After traveling down the track, the avalanche reaches the runout zone. Here the avalanche motion ends, either slowly as it decelerates across a gradual slope, such as an alluvial fan, or abruptly as it crashes into the bottom

of a gorge or ravine. As a general rule, the slope angle of starting zones is 30 to 45 degrees, of the track is 20 to 30 degrees, and of the runout zone is less than 20 degrees.

Few actual measurements of avalanche velocities have been made, but enough data have been obtained to provide some typical values for the various avalanche types. For the highly turbulent dry-powder avalanches, the velocities are commonly in the range of 75 to 100 mph, with rare examples in the range of 150 to 200 mph. Such speeds are possible for powder avalanches because large amounts of air in the moving snow greatly reduce the forces resulting from internal friction. As snow in the starting zone becomes dense, wetter, or both, movement becomes less turbulent and a more flowing type of motion reduces typical velocities to the range of 50 to 75 mph. During spring conditions when the snow contains large amounts of liquid water, speeds may reach only about 25 mph ([Figure 2-16](#)).

In most cases, the avalanche simply follows a path down the steepest route on the slope while being guided or channeled by terrain features. However, the higher-speed

avalanche may deviate from this path. Terrain features, such as the side walls of a gully, which would normally direct the flow of the avalanche around a bend, may be overridden by a high-velocity powder avalanche ([Figure 2-17](#)). The slower-moving avalanches, which travel near the ground, tend to follow terrain features, giving them somewhat predictable courses.

Because avalanches can travel at very high speeds, the resultant impact pressures can be significant. Smaller and medium-sized events (impact pressures of 1 to 15 kilopascals [kPa]) have the potential to heavily damage wood frame structures. Extremely large avalanches (impact pressures of more than 150 kPa) possess the force to uproot mature forests and even destroy structures built of concrete.

Some reports of avalanche damage describe circumstances that cannot be easily explained simply by the impact of large amounts of fast-moving dense snow. Some observers have noted that as an avalanche passed, some buildings actually exploded, perhaps from some form of vacuum created by the fast-moving snow. Other reports indicate that a structure was destroyed by the "air blast" preceding the avalanche because there was no evidence of large amounts of avalanche debris in the area. However, this is more likely to be damage resulting from the powder cloud, which may only comprise a few inches of settled snow yet contributes significantly to the total impact force. The presence of snow crystals can increase the air density by a factor of three or more. A powder cloud traveling at a moderate dry avalanche speed of 60 mph could have the impact force of a 180-mph wind, well beyond the destructive capacity of a hurricane.

Figure 2-16 A dry-snow avalanche may have a slowing motion and travel near the surface or, with lower density snow and higher velocities, the turbulent dust cloud of the powder avalanche develops.

IDENTIFYING AVALANCHE PATH CHARACTERISTICS

Characteristics such as elevation, slope profiles, and weather determine whether a mountain can produce avalanches. The ingredients of an avalanche, snow and a steep enough slope, are such that any mountain can produce an avalanche if conditions are exactly right. To

54

Figure 2-17 The large powder cloud associated with a fast-moving dry-snow avalanche.
(Photo by R. Armstrong.)

be a consistent producer of avalanches, a mountain and its weather must work in harmony.

Elevation

Mountains must be at high enough latitudes or high enough in elevation to build and sustain a winter snow cover before their slopes can become avalanche threats. Temperature drops steadily with elevation. This has the obvious effect of allowing snow to build up deeper and remain longer at higher elevations before melting depletes the snow cover. A less obvious effect of the temperature and elevation relationship on avalanche formation is the demarcation called *treeline*. This is the level above which the combined effects of low temperature, strong winds, and heavy snowfall prevent tree growth.

The treeline can be quite variable in any mountain range, depending on the microclimates. On a single mountain, treeline is generally higher on south slopes than on north slopes (in the northern hemisphere) because more sunshine leads to warmer average temperatures on southern exposures. Latitudinal variation in the elevation of treeline ranges from sea level in northern Alaska to almost 3658 m (12,000 feet) in the

Sierras of southern California and the Rockies of New Mexico.

Mountains that rise above treeline are more likely to produce avalanches. Dense timber anchors the snowpack so avalanches can seldom start. Below treeline, avalanches can start on slopes having no trees or only scattered trees, a circumstance arising either from natural causes, such as a streambed or rockslide area, or from human-made causes, such as clearcuts. Above treeline, avalanches are free to start, and once set in motion, they can easily cut a swath through the trees below. The classic avalanche path is one having a steep bowl above treeline to catch the snow and a track extending below treeline. Avalanches run repeatedly down the track and ravage whatever vegetation grows there, leaving a scar of small or stunted trees that cuts through larger trees on either side.

Slope Angle

In snow that is thoroughly saturated with water, so that a slush mixture is formed, the slope needs only to have a slight tilt to produce an avalanche. For example, a wet-snow avalanche in Japan occurred on a beginner slope at a ski area. The slope was only 10 degrees, but the avalanche was big enough to kill seven skiers. This extreme applies only to a water-saturated snowpack, which behaves more like a liquid than a solid.

A more realistic slope is 22 degrees, the "angle of repose" for granular substances, such as sand and dry, unbonded snow. Round grains will not stack up in a pile having sides much steeper than 22 degrees before gravity rearranges the pile. Dry-snow avalanches have occurred on slopes of 22 to 25 degrees; these are rare because snow grains are seldom round and seldom touch without forming bonds. A useful minimum steepness for producing avalanches is 30 degrees. Avalanches occur with the greatest frequency on slopes of 30 to 45 degrees. These are the angles in which the balance between strength (the bonding of the snow trying to hold it in place) and stress (the force of gravity trying to pull it loose) is most critical. On even steeper slopes, the force of gravity wins; snow continually rolls or sloughs off, preventing buildup of deep snowpacks. Exceptions exist, such as damp snow plastered to a steep slope by strong winds.

Orientation

Avalanches occur on slopes facing every point of the compass. Steep slopes are equally likely to face east or west, north or south. There are factors, however, that cause more avalanches to fall on slopes facing north, northeast, and east than those facing south through west. These relate to slope orientation with respect to sun and wind. The sun angle in northern hemisphere winters causes south slopes to get much more sunshine and heating than do north slopes, which frequently leads to radically different snow covers. North slopes have deeper and colder snow covers, often with a substantial layer of depth hoar near the ground. South slopes usually carry a shallower and warmer snow cover, laced with multiple ice layers formed on warm days between storms. Most ski areas are built on predominantly north-facing slopes to take advantage of deeper and longer-lasting snow cover. At high latitudes, such as in Alaska,

the winter sun is so low on the horizon and heat input to south slopes is so small that there are few differences in the snow covers of north and south slopes.

The effect of the prevailing west wind at midlatitudes is important. Storms most often move west to east, and storm winds are most frequently from the western quadrant: southwest, west, or northwest. The effect is to pick up fallen snow and redeposit it on slopes facing away from the wind, that is, onto northeast, east, and southeast slopes. These are the slopes most often overburdened with wind-drifted snow. The net effect of sun and wind is to cause more avalanches on north- through east-facing slopes.

Avalanche Terrain

The frequency with which a path produces avalanches depends on a number of factors, with slope steepness a major factor. The easiest way to create high stress is to increase the slope angle; gravity works that much harder to stretch the snow out and rip it from its underpinnings. A slope of 45 degrees produces many more avalanches than one of 30 degrees. However, specific terrain features are also important.

Broad slopes that are curved into a bowl shape and narrow slopes that are confined to a gully efficiently collect snow. Those having a curved horizontal profile, such as a bowl or gully, trap blowing snow coming from several directions; the snow drifts over the top and settles as a deep pillow. On the other hand, the plane-surfaced slope collects snow efficiently only if it is being blown directly from behind. A side wind scours the slope more than loads it.

The surface conditions of a starting zone often dictate the size and type of avalanche. A particularly rough ground surface, such as a boulder field, will not usually produce avalanches early in the winter, since it takes considerable snowfall to cover the ground anchors. Once most of the rocks are covered, avalanches will pull out in sections, the area between two exposed rocks running one time, and the area between two other rocks running another. A smooth rock face or grassy slope provides a surface that is too slick for snow to grip. Therefore full-depth avalanches are distinctly possible; if the avalanche does not run during the winter, it is likely to run to ground in the spring, once melt water percolates through the snow and lubricates the ground surface.

Vegetation has a mixed effect on avalanche releases. Bushes provide anchoring support until they become totally covered; at that point they may provide weak points in the snow cover, since air circulates well around the bush, providing an ideal habitat for the growth of depth hoar. It is common to see that the fracture line of an avalanche has run from a rock to a tree to a bush, all places of healthy depth hoar growth.

A dense stand of trees can easily provide enough anchors to prevent avalanches. Reforestation of slopes devoid of trees because of logging, fire, or avalanche is an effective means of avalanche control. Scattered trees on a gladed slope offer little if any

support to hold snow in place. Isolated trees may do more harm than good by providing concentrated weak points on the slope.

FACTORS CONTRIBUTING TO AVALANCHE FORMATION

The factors that contribute to avalanche release are terrain, weather, and snowpack. Terrain factors are fixed; however, the state of the weather and snowpack changes daily, even hourly. Precipitation, wind, temperature, snow depth, snow surface, weak layers, and settlement are all factors determining whether an avalanche will occur.

Snowfall

New snowfall is the event that leads to most avalanches; more than 80% of all avalanches fall during or just after a storm. Fresh snowfall adds weight to existing snow cover. If the snow cover is not strong enough to absorb this extra weight, avalanche releases occur. The size of the avalanche is usually related to the amount of new snow. Snowfalls of less than 6 inches seldom produce avalanches. Snows of 6 to 12 inches usually produce a few small slides, and some of these harm skiers who release them. Snows of 1 to 2 feet produce avalanches of larger size that present a considerable threat to skiers and pose closure problems for highways and railways. Snows of 2 to 4 feet are much more dangerous, and snowfalls greater than 4 feet produce major avalanches capable of large-scale destruction. These figures are guidelines based on data and experience and must be considered with other factors to arrive at the true hazard. For example, a snowfall of 10 inches whipped by strong winds may be serious; a fall of 2 feet of feather-light snow in the absence of wind may produce no avalanches.

Snowfall Intensity

The rate at which snowfall accumulates is almost as important as the amount of snow. A snowfall of 3 feet in one day is far more hazardous than 3 feet in 3 days. As a viscoelastic material, snow can absorb slow loading by deforming or compressing. Under a rapid load, the snow cannot deform quickly enough and is more likely to crack, which is how slab avalanches begin. A snowfall rate of 1 inch per hour or greater sustained for 10 hours or more is generally a red flag indicating danger. The danger worsens if snowfall is accompanied by wind.

Rain

Light rain falling on a cold snowpack invariably freezes into an ice crust, which adds strength to the snow cover. At a later time, the smooth crust could become a

sliding layer beneath the new fall of snow. Heavy rain (usually an inch or more) greatly weakens the snow cover. First, it adds weight. An inch of rain is the equivalent in weight to 10 to 12 inches of snow. Second, it adds no internal strength of its own (in the form of a skeleton of ice, as new snow would), while it dissolves bonds between snow grains as it percolates through the top snow layers, reducing strength even further.

New Snow Density and Crystal Type

A layer of fresh snow contains only a small amount of solid material (ice); the large majority of the volume is occupied by air. It is convenient to refer to snow density as a percentage of the volume occupied by ice. New snow densities usually range from 7% to 12%. In the high elevations of Colorado, 7% is an average value; in the more maritime climates of the Sierras and Cascades, 12% is a typical value. Density becomes an important factor in avalanche formation when it varies from average values.

Wet snowfalls or falls of heavily rimed crystals, such as graupel, may have densities of 20% or greater. A layer of heavier-than-normal snow presents a danger because of excess weight. Snowfall that is much lighter than normal, 2% to 4% for example, can also present a dangerous situation. If the low-density layer quickly becomes buried by snowfall of normal or high density, a weak layer has been introduced into the snowpack. By virtue of low density, the weak layer has marginal ability to withstand the weight of layers above, making it susceptible to collapse. Storms that begin with low temperatures but then warm up produce a layer of weak snow beneath a stronger, heavier layer.

Density is closely linked to crystal type. Snowfalls consisting of graupel, fine needles, and columns can accumulate at high densities. Snowfalls of plates, stellars, and dendritic forms account for most of the lower densities.

Wind Speed and Direction

Wind drives fallen snow into drifts and cornices from which avalanches begin. Winds pick up snow from exposed, windward slopes and drive it onto adjacent, leeward slopes, where it is deposited into sheltered hollows and gullies.

A speed of 15 mph is sufficient to pick up freshly fallen snow. Higher speeds are required to dislodge older snow. Speeds of 20 to 50 mph are the most efficient in transporting snow into avalanche starting zones. Speeds greater than 50 mph can create spectacular banners of snow streaming from high peaks, but much of this snow is lost to evaporation in the air or is deposited far down the slope away from the avalanche starting zone.

Winds play a dual role in increasing avalanche potential. First, wind scours snow from a large area (of a windward slope) and deposits it in a smaller area (of a starting zone). Wind can thus turn a 1-foot snowfall into a 3-foot drift in a starting zone. The rate at

which blowing snow collects in bowls and gullies can be impressive. In one test at Berthoud Pass, Colorado, the wind deposited snow in a gully at a rate of 18 inches per hour. Another wind effect is that blowing snow is denser after deposit than before. This is because snow grains are subjected to harsh treatment in their travels; each collision with another grain knocks off arms and sharp angles, reducing size and allowing the pieces to settle into a denser layer. The net result of wind is to fill avalanche starting zones with more and heavier snow than if the wind had not blown.

Temperature

The role of temperature in snow metamorphism is played over a period of days, weeks, and even months. The influence of temperature on the mechanical state of the snow cover is more acute, with changes occurring in minutes to hours. The actual effect of temperature is not always easy to interpret; whereas an increase in temperature may contribute to stabilization of the snow cover in one situation, it might at another time lead to avalanche activity.

In several situations an increase in temperature clearly produces an increase in avalanche potential. In general, these include a rise in temperature during a storm or immediately after a storm, or a prolonged period of warm, fair weather such as occurs with spring conditions. In the first example, the temperature at the beginning of snowfall may be well below freezing, but as the storm progresses, the temperature increases. As a result, the initial layers of new snow are light, fluffy, low density, and relatively low in strength, whereas the later layers are warmer, denser, and stiffer. Thus the essential ingredients for a slab avalanche are provided within the new snow layers of the storm: a cohesive slab resting on a weak layer. If the temperature continues to rise, the falling snow turns to rain, a situation not uncommon in lower-elevation coastal mountain ranges. Once this happens, avalanches are almost certain because as the rain falls, additional weight is added to the avalanche slope, but no additional strength is provided as it is whenever a layer of snow accumulates.

The second example may occur after an overnight snowstorm that does not produce an avalanche on the slope of interest. By morning, the precipitation stops and clear skies allow the morning sun to shine directly on the slopes. The sun rapidly warms the cold, low-density new snow, which begins to deform and creep downslope. The new snow layer settles, becomes more dense, and gains strength. At the same time, it is stretched downhill and some of the bonds between the grains are pulled apart; thus the snow layer becomes weaker. If more bonds are broken by stretching than are

formed by settlement, there is not enough strength to hold the snow on the slope and an avalanche occurs.

In these first two examples, the complete snow cover generally remains at temperatures below freezing. A third example occurs when a substantial amount of the winter's snow

cover is warmed to the melting point. During winter, sun angles are low, days are short, and air temperatures are cold enough that the small amount of heat gained by the snow cover during the day is lost during the long cold night. As spring approaches, this pattern changes, and eventually enough heat is available at the snow surface during the day to cause some melt. This melt layer refreezes again that night, but the next day more heat may be available, so that eventually a substantial amount of melting occurs and melt water begins to move down through the snow cover. As melt water percolates slowly downward, it melts the bonds that attach the snow grains and the strength of the layers decreases. At first the near-surface layers are affected, with the midday melt reaching only as far as the uppermost few inches, with little or no increase in avalanche hazard. If warm weather continues, the melt layer becomes thicker and the potential for wet snow avalanches increases. The conditions most favorable for wet slab avalanches occur when the snow structure provides the necessary layering. When melt water encounters an ice layer or impermeable crust, or in some cases a layer of weak depth hoar, wet slab avalanches are likely to occur.

Depth of Snow Cover

Of the snowpack factors contributing to avalanche formation, this is the most basic. When the early-winter snowpack covers natural anchors, such as rocks and bushes, the start of the avalanche season is at hand. North-facing slopes are usually covered before other slopes. A scan of the terrain usually suffices to weigh this clue, but another method can be used to determine the time of the first significant avalanches. Long-term studies show a relationship between snow depth at a study site and avalanche activity. For example, along Red Mountain Pass, Colorado, it is unlikely that an avalanche large enough to reach the highway will run until close to 3 feet of snow covers the ground at the University of Colorado's snow study site. At Alta, Utah, once 52 inches of snowpack have built up, the first avalanche to cover the road leading from Salt Lake City can be expected.

Nature of the Snow Surface

How well new snow bonds to the old snow surface is a key factor in determining whether an avalanche will release within the layer of new snow or deeper in the snowpack. A poor bond, usually new snow resting on a smooth, cold surface with snowfalls of 1 foot or more, almost always produces a new-snow avalanche. A strong bond, usually onto a warm, soft, or rough surface, may produce nothing at all, or if weaknesses lie at deeper layers of the snow cover, a large snowfall will cause avalanches to pull out older layers of snow in addition to the new snow layer. These avalanches have more potential for destruction. A cold, hard snow surface offers little grip to fresh, cold snow. Ice crusts are commonly observed to be avalanche-sliding surfaces. The crust could be a sun crust, rain crust, or a hardened layer of firm snow that has survived the summer. Firm layers are especially dangerous in early winter when first snows fall.

Weak Layers

Any layer susceptible to collapse or failure because of the weight of the overburden is a

weak link. Of the snowpack contributory factors, this is the most important, since a weak layer is essential to every avalanche. The weak layer releases along what is called the failure plane, sliding surface, or bed surface.

One common weak layer is an old snow surface that offers a poor bond for new snow. Another weak layer that forms on the snow surface is hoar frost, or surface hoar. This is the solid equivalent of dew. On clear, calm nights, it forms a layer of feathery, sparkling flakes that grow on the snow surface. The layer can be a major contributor to avalanche formation when buried by a snowfall. Many avalanches have been known to release on a buried layer of surface hoar, sometimes a layer more than 1 month old and 6 feet or more below the surface.

A weak layer that is almost always found in the snowpacks that blanket the Rocky Mountains and occasionally the Cascades and Sierra Nevadas is temperature-gradient snow, or depth hoar. The way to decide whether a temperature-gradient layer is near its collapse point is to test the strength of the overlying layers and the support provided around the edges of the slope. This is no easy task. One method is to try jumping on your skis while standing on a shallow slope. Collapse is a good indication that similar snow cover on a steeper slope will produce an avalanche. Often skiers and climbers cause inadvertent collapses while skiing or walking on a depth hoar-riddled snowpack. The resulting "whoomf" sound is a warning of weak snow below.

Finally, a weak layer can be created within the snow cover when surface melting or rain causes water to percolate into the snow and then fan out on an impermeable layer, thereby lubricating that layer and destroying its shear strength. Combining the contributory factors on a day-by-day basis is the avalanche forecaster's art. Every avalanche must have a weak layer to release on, so knowledge of snow stratigraphy, or layering, and what sort of applied load will cause a layer to fail is the essence of forecasting.

SAFE TRAVEL IN AVALANCHE TERRAIN

The first major decision often faced in backcountry situations is whether to avoid or confront a potential avalanche hazard. A group touring with no particular goal in mind will probably not challenge avalanches. For this group, being able to recognize and avoid avalanche terrain is sufficient education. In the other extreme, mountaineering expeditions that have specific goals and are willing to wait out dangerous periods or take severe risks to succeed need considerably more information.

The ability to travel safely in avalanche terrain requires special preparations, including education and possession of safety and rescue equipment. The group should have the skills required to anticipate and react to an avalanche.

Identifying Avalanche Terrain

Because most avalanches release on slopes of 30 to 45 degrees of pitch, judging angle is a prime skill in recognizing potential avalanche areas. An inclinometer is an instrument used to measure slope angles. Some compasses are also equipped for this purpose; a second needle and a graduated scale in degrees can be used to measure slope angles. A ski pole may be used to judge approximate slope angle. When dangled by its strap, the pole becomes a plumb line from which the slope angle can be "eyeballed."

Evidence of fresh avalanche activity identifies avalanche slopes: the presence of fracture lines and the rubble of avalanche snow on the slope or at the bottom. Other clues are swaths of missing trees or trees that are bent downhill or damaged, especially with the uphill branches removed. Above treeline, steep bowls and gullies are almost always capable of producing avalanches.

Route Finding

Good route-finding techniques are necessary for safe travel in avalanche terrain ([Figure 2-18](#)). The object of a good route in avalanche country is more than avoiding avalanches. It should also be efficient and take into account the abilities and desires of the group when choosing a route that is not overly technical, tiresome, or time consuming. The safest way to avoid avalanches is to travel above or below and well away from them. When taking the high route, the traveler should choose a ridgeline that is above the avalanche starting zones. It is safest to travel the windward side of the

ridge. The snow cover is usually thinner and windpacked, with rocks sticking through: not the most pleasant skiing, but safe. Cornice collapses present a very real hazard; they should be avoided by staying on the roughened snow more to windward.

Skiers taking the low route in the valley should not linger in the runouts of avalanche paths. Even though it is unlikely that a skier traveling along the valley could trigger an avalanche high up on the slope, the skier should not boost the odds of getting caught in an avalanche released by natural forces far above. Slopes of 30 degrees or more should be avoided. By climbing, descending, and traversing only in gentle terrain, avalanche terrain can be avoided.

Stability Evaluation Tests

Skiers can perform several tests of stability. On a small slope that is not too steep (and therefore will not avalanche), the skier can try a ski test by skiing along a shallow traverse and then setting the ski edges in a hard check. Any cracks or settlement noises indicate that the same slope, if steeper, would have probably avalanched, and on the steeper slope it would have taken less weight or jolt to cause the avalanche.

Another test is to push a ski pole into the snow, handle end first. This helps to feel the major layering of the snowpack. For example, the skier may feel the layer of new snow, midpack stronger layers, and depth hoar layers, if the pole is long enough. Hard-snow layers and ice lenses resist penetration altogether. This test reveals only the gross layers; thin weak layers, such as buried surface hoar or a poor bond between any two layers, cannot be detected. Thus the ski pole test has limited value.

A much better way to directly observe and test snowpack layers is to dig a hasty snowpit. (This is an excellent use of the shovel that, in the next section, we recommend the skier carry.) In a spot as near as possible to a suspected avalanche slope without putting the traveler at risk, a pit 4 to 5 feet deep and 3 feet wide should be dug. With the shovel, the uphill wall is shaved until it is smooth and vertical. Now the layers of snow can be observed and felt. The tester can see where the new snow touches the layer beneath, poke the pit wall with a finger to test hardness, and brush the pit wall with a paintbrush to see which layers are soft and fall away and which are hard and stay in place after being brushed. By grabbing a handful of depth hoar, the skier can see how large the grains are and how poorly they stick together.

The shovel shear test gauges the shear strength between layers and thus locates weak layers. First a column of snow is isolated from the vertical pit wall. Both sides and the back of the column are cut with the shovel or a ski, so that the column is free standing. The dimensions are a shovel's width on all sides. The tester inserts the shovel blade at the back of the column and gently pulls forward on the handle. An unstable slab will shear loose on the weak layer, making a clean break; the poorer the bond, the easier the shear. A five-point scale is used to rate the shear: "very easy" if it

Figure 2-18 Four ski-touring areas showing the safer routes (*dashed lines*) and the more hazardous routes (*dotted lines*). Arrows indicate areas of wind loading. (From USDA Forest Service: *Avalanche handbook, Agricultural Handbook 489, USDA. Photo by Alexis Kelner.*)

breaks as the column is being cut or the shovel is being inserted; "easy" if a gentle pull on the shovel does the job; "moderate" if a slightly stronger shovel-pry is required; "hard" if a solid tug is required; "very hard" if a major effort is needed to break the snow. Generally, "very easy" and "easy" shears indicate unconditionally unstable snow, "moderate" means conditionally unstable, and "hard" and "very hard" mean stable.

The value of the shovel shear test is that it can find thin weak layers undetectable by any other method. Its

shortcoming is that it is not a true test of stability, since it does not indicate the amount of weight required to cause shear failure.

A test that does a better job of indicating actual stability is the Rutschblock, or shear block, test. This test is calibrated to the skier's weight and the stress he or she would put on the snow. Again, a snowpit is dug with a vertical uphill wall, but the pit must be about 8 feet wide. By cutting into the pit wall, the skier isolates a block of snow that is about 7 feet wide (a ski length) and goes back 4 feet (a ski pole length) into the pit wall. Both sides and the back are cut with a shovel or ski so that the block is free standing. Wearing skis, the skier climbs around and well uphill from the isolated block and carefully approaches it from above. With skis across the fall line, the skier gently steps onto the block, first with the downhill ski and then the uphill ski, so that he or she is standing on the isolated block of snow. If the slab of snow has not yet failed, gently flexing the knees applies a little more pressure. Next some gentle jumps are tried. The stress should be by jumping harder until the block eventually shears loose or crumbles apart.

The interpretation of the results is: "extremely unstable" if the block fails while the skier is cutting it, approaching it from above, or merely standing on it; "unstable" if it fails with a knee flex or one gentle jump; "moderately stable" if it fails after repeated jumps; and

"very stable" if it never fails but merely crumbles. These are objective results that help answer the bigger question—will it slide?—and help the mountain traveler decide how much risk to take.

Avalanche Rescue Equipment

Shovel.

The first piece of safety equipment the skier or climber should own is a shovel. It can be used to dig snowpits for stability evaluation and snow caves for overnight shelter. A shovel is also needed for digging in avalanche debris, since such snow is far too hard for digging with the hands or skis.

The shovel should be sturdy and strong enough to dig in avalanche debris, yet light and small enough to fit into a pack. There is no excuse for not carrying a shovel. Shovels are made of aluminum or high-strength plastic and can be collapsible. Many good types are available in mountaineering stores.

Probe.

Several pieces of equipment are designed specifically for finding buried avalanche victims. The first is a collapsible probe pole. Organized rescue teams keep rigid poles in 10- or 12-foot lengths as part of their rescue caches. The recreationist can buy probe poles of tubular steel that come in 2-foot sections that fit together to make a full-length probe. Ski poles with removable grips and baskets can be screwed together to make an avalanche probe. Survivors of an accident use probes to search for buried victims.

Avalanche Cord.

An avalanche cord is orange or red rope, approximately 50 feet long, that can be coiled and attached to a belt. When traveling in avalanche terrain, a skier or climber strings the cord out behind. The idea is that if an avalanche releases and the victim is buried, the cord will float and some portion of it will come to rest on the surface. Rescuers follow the cord, or probe in the immediate area, to locate the victim.

Avalanche cords have saved many lives in the past, but now they are obsolete and have virtually disappeared from use. They have been replaced as personal rescue devices by avalanche beacons, which are far more reliable. Avalanche cords always had severe limitations: tests done in the early 1970s by the International Vanni Eigenmann Foundation of Milan, Italy, showed that avalanche cords were only marginally effective. In tests performed by attaching an avalanche cord to a sandbag dummy tossed onto an avalanche path, a portion of the avalanche cord was visible on the surface only 40% of the time.

Avalanche Rescue Beacon.

Avalanche rescue beacons, or transceivers, have become the most-used personal rescue devices worldwide. When used properly, they are a fast and effective way to locate buried avalanche victims. In the United States, these have become standard issue for ski area patrollers involved in avalanche work and for helicopter-skiing guides and clients. They are also commonly used by highway departments, search and rescue teams, and an increasing number of winter recreationists. Since beacons were introduced in the United States, they have saved at least 30 lives. Beacons save at least two or three lives per winter.

Transceivers act as transmitters that emit a signal on a frequency of 457 kHz. (This is now the world-standard frequency. The old frequency of 2.275 kHz is no longer used, and all beacons using this frequency have been—or should be—retired.) A buried victim's unit emits this signal, while the rescuers' units receive the signal. The signal carries 30 to 46 m (100 to 150 feet) and, once picked up, guides searchers specifically to the buried unit.

Beacon technology is evolving rapidly and improving the beacons on the market. Two types of beacon have emerged: analog, which processes the signal in the traditional way to allow for a stronger (louder) signal as the receiving beacon approaches the sending beacon; and digital, which uses a computer chip to process the signal to display a digital read-out of the range to the buried unit.

Both types operate on the same frequency and therefore are compatible with one another. However, different search techniques may be necessary to use each type most efficiently. Therefore special training and

practice are required before the user attains proficiency. The main brands available in the United States are Ortovox, Pieps, Tracker, and SOS.

Merely possessing a beacon does not ensure its lifesaving capability. Frequent practice is required to master a beacon-guided search, which may not be straightforward. Skilled practitioners can find a buried unit in less than 5 minutes once they pick up the signal. Since speed is of the essence in avalanche rescue, beacons are obvious lifesavers. The best proven rescue equipment is a beacon for a quick find and a shovel for a quick recovery ([Box 2-1](#)).

Box 2-1. AVALANCHE TRANSCEIVER SEARCH

INITIAL SEARCH

1. Have everyone switch their transceivers to "receive" and turn the volume on "high."
2. If enough people are available, post a lookout to warn others of further slides.
3. Should a second slide occur, have rescuers immediately switch their transceivers to "transmit."
4. Have rescuers space themselves no more than 30 m (100 feet) apart and walk along the slope parallel to one another.
5. For a single rescuer searching within a wide path, zigzag across the rescue zone. Limit the distance between crossings to 30 m.
6. For multiple victims, when a signal is picked up, have one or two rescuers continue to locate the victim while the remainder of the group carries out the search for additional victims.
7. For a single victim, when a signal is picked up, have one or two rescuers continue to locate the victim while the remainder of the group prepares shovels, probes, and medical supplies for the rescue.

LOCATING THE VICTIM

With practice, the induction line search is more efficient than the conventional grid search. An induction line search requires a 457 kHz transceiver.

Induction line search (preferred method)

When an induction line search is used, the rescuer may initially follow a line that leads away from victim ([Figure 2-19](#)). Remember to lower transceiver volume if it is too loud because the ear detects signal strength variations better at lower volume settings.

1. After picking up a signal during the initial search, hold the transceiver horizontally (parallel with the ground) with the front of the transceiver pointing forward (see [Figure 2-19, A](#)).
2. Holding the transceiver in this position, turn until the signal is maximal (maximum volume), then walk five steps (about 5 m [16 feet]), stop, and turn again to locate the maximum signal (see [Figure 2-19, B](#)). When locating the maximum signal, do not turn yourself (or the transceiver) more than 90 degrees in either direction. If you rotate more than 90 degrees to locate the maximum signal, you will become turned around and follow the induction line in the reverse direction.
3. Walk another five steps, as described above, and then stop and orient the

- again to locate the maximum signal (see [Figure 2-19, B](#)). When locating the maximum signal, do not turn yourself (or the transceiver) more than 90 degrees in either direction. If you rotate more than 90 degrees to locate the maximum signal, you will become turned around and follow the induction line in the reverse direction.
3. Walk another five steps, as described above, and then stop and orient the transceiver toward the maximum signal. Reduce the volume.
 4. Continue repeating the above steps. You should be walking in a curved path along the "induction line" toward the victim (see [Figure 2-19, C](#)).
 5. When the signal is loud at minimum volume setting, you should be very close to the victim and can begin the pinpoint search (see below).

Grid search

1. When a signal is picked up, stand and rotate the transceiver, which is held horizontally (parallel with the ground), to obtain the maximum signal (loudest volume). Maintain the transceiver in this orientation during the remainder of the search.
2. Turn the volume control down until you can just hear the signal. Walk in a straight line, down the fall line from the victim's last-seen location, until the signal fades.
3. When the signal starts to fade, turn 180 degrees and walk back toward the starting position. The signal will increase in volume and then fade again. Walk back to the point of loudest volume/maximum signal, which should be in the middle of two fade points.
4. At this point, turn 90 degrees in one direction or the other. From that position, reorient the transceiver (held parallel with the ground) to locate the maximum signal. After orienting the transceiver to the maximum signal, reduce the volume, and begin walking forward. If the signal fades, turn around 180 degrees and begin walking again.
5. As the signal volume increases, repeat steps 3 and 4 until you have reached the lowest volume control setting on the transceiver. This time, when you return to the middle of the fade points (maximum signal strength), you should be very close to the buried victim and can now begin pinpointing him or her.
 - a. While stationary, orient the transceiver to receive the maximum signal (loudest volume). At this point, turn the volume control all the way down.
 - b. Maintain the transceiver in this orientation and sweep the transceiver from side to side and back and forth just above the surface of the snow.
 - c. Find the signal position halfway between fade points (i.e., the loudest signal). At this point, you should be very close to the victim's position and can begin to mechanically probe. Speed is essential.

Figure 2-19 Induction line search. (From Auerbach PS et al: *Field guide to wilderness medicine*, St Louis, 1999, Mosby.)

Airbag.

In 1995 a new rescue device made in Germany was introduced in Europe. It was the ABS Avalanche Airbag System and was designed specifically for guides and ski patrollers. The user wears the airbag in a pack and deploys it by pulling a rip cord. This releases a cartridge of nitrogen gas that escapes at high velocity and draws in outside air through jets; it is capable of inflating two 75-L airbags in 2 seconds. This gives the avalanche victim buoyancy and cushioning against impact with trees or rocks. To operate the device, the user must be able to grab and pull the rip cord.

By 1999, there had been 18 documented avalanche incidents in the Alps that involved 31 people equipped with airbags. In one case the airbag failed to work, and three other people failed to pull the rip cord, but all four survived anyway. There were 27 people with inflated airbags, and of these, 14 were not buried, 9 were partially buried, and 4 were bodily buried but a portion of the airbag remained on the surface, allowing for a quick recovery. All 27 survived.

Airbags will be available in the United States by 2000. They are an additional rescue device available to the backcountry adventurer and someday may become

a viable alternative to beacons, although they should never replace good judgment.

AvaLung.

In 1996, Dr. Thomas Crowley received a patent for an emergency breathing device to extract air from the snow surrounding a buried avalanche victim. Called the AvaLung, it is worn as a vest by the user. If buried, the victim can breathe through a mouthpiece and flex-tube connected to the vest. The victim can inhale oxygenated air coming from the surrounding snow, which passes through a membrane in the vest. The exhaled air, rich in carbon dioxide, passes through a one-way valve and into another area of the snow surrounding the victim to slow the effects of carbon dioxide narcosis caused by contaminating the air space.

The AvaLung will be marketed by Black Diamond Equipment, Ltd., in 2000. It has

worked well in simulated burials, allowing the victim to breathe for 1 hour in tightly packed snow. It has yet to be proven in an actual avalanche burial. In time, the AvaLung may prove to be a lifesaver among avalanche professionals, but only as an instrument of last resort.

Crossing Avalanche Slopes

Travel through avalanche country always involves risk, but certain travel techniques can minimize that risk. Proper travel techniques might not prevent an avalanche release but can improve the odds of surviving. The timing of a trip has a lot to do with safety. Most avalanches occur during and just after storms. Waiting a full day after a storm has ended can allow the snowpack to react to the new snow load and gain strength.

Before crossing a potential avalanche slope, the skier or hiker should get personal gear in order by tightening up clothing, zipping up zippers, and putting on hat, gloves, and goggles. A person should be padded and insulated if trapped. If a heavy mountaineering pack is carried, the straps should be loosened or slung over one shoulder only so that the pack can be easily discarded if the person is knocked down. A heavy pack makes a person top-heavy, making it difficult to swim with the avalanche. The skier should remove pole wrist straps and ski runaway straps because poles and skis attached to a victim hinder swimming motions and only serve to drag the victim under. Finally, a person wearing a rescue beacon should be certain it is transmitting.

If possible, the person should cross low on the slope, near the bottom or in the runout zone. Crossing rarely causes a release in the starting zone far above. The greater risk is getting hit by an untimely natural release from above. If crossing high without reaching the safety of the ridge is necessary, the starting zone should be traversed as high as possible and close to rocks, cliff, or cornice. Should the slope fracture, most of the sliding snow will be below and the chance of staying on the surface of the moving avalanche will be better. Invariably, the person highest on the slope runs the least risk of being buried.

A person who must climb or descend an avalanche path should keep far to the sides. Should the slope fracture, escaping to the side improves the chance of surviving. Only one person at a time should cross, climb, or descend an avalanche slope; all other members should watch from a safe location. Two commonsense principles lie behind this advice. First, only one group member is exposed to the hazard, leaving the others available as rescuers. Second, less weight is put on the snow. All persons should traverse in the same track. This not only reduces the amount of work required but also disturbs less snow, which lowers the chance of avalanche release.

Skiers and climbers should never drop their guard on an avalanche slope. They should not stop in the middle of a slope, but only at the edge or beneath a point of protection, such as a rock outcropping. It is possible for the second, third, or even tenth person traversing or skiing down a slope to trigger the avalanche. Trouble should always be anticipated, and an escape route, such as getting out to the side or grabbing a tree, should be kept in mind.

Survival of Victims

Escaping to the Side.

The moment the snow begins to move around the person, he or she has a split second to make a decision or make a move. Whether on foot, skis, or snowmobile, the person should first try to escape to the side of the avalanche or try to grab onto a tree. Staying on one's feet or snow machine gives some control and keeps the head up. Escaping to the side gets the person out altogether or to a place where the forces and speeds are less. Turning skis or the snow machine downhill in an effort to outrun the avalanche is a bad move, since the avalanche invariably overtakes its victims.

The person should shout and then close the mouth. Shouting alerts companions to what is happening. Clamping the mouth shut and breathing through the nose prevents inhalation of a mouthful of snow.

Swimming.

A person knocked off his or her feet should attempt to swim with the avalanche. Cumbersome or heavy gear should be discarded. Ski poles should be tossed away; with luck, the avalanche will strip away the skis. The victim should get away from the snow machine. Swimming motions with the arms and legs increase the freedom to maneuver the body. The purpose is to maintain a position near the surface. Any swimming motions will do, but if the person has been thrown forward and is being carried head first downhill, the breast stroke with the arms (similar to body surfing) should be used; if being carried down feet first, the person

should try to roll onto his or her back and attempt to "tread water" with the arms and legs.

Reaching the Surface.

Avalanches come to a stop when they flow out onto more gentle terrain. A victim may have a second or two when he or she feels the sensation of slowing down. This is a crucial point in the ordeal, the best chance to reach the surface. The person should thrust upward with swimming motions and try to burst through to the surface. Unless very deeply buried at this time, the person will probably know which way is up. All possible strength should be exerted to get the head, an arm, or even a hand above the surface. Even if the person cannot get his or her head out, being near the surface greatly improves the odds for survival. If any clue is on the surface, it gives the rescuers something to see. A hand should be used to clear a breathing space over the mouth.

Rescue by Survivors

Marking the Last-Seen Point.

A survivor or eyewitness to an accident needs to act quickly and positively. The rescuer's actions over the next several minutes may mean the difference between life and death for the victim. First, the victim's last-seen point should be fixed and marked with a piece of equipment, clothing, a tree branch, or anything that can be seen from a distance downslope. It is most often safe to move out onto the bed surface of the avalanche that has recently run. It is dangerous when the fracture line has broken at mid-slope, leaving a large mass of snow still hanging above the fracture.

Searching for Clues.

The fall line should be searched below the last-seen point for any clues of the victim. The snow should be scuffed by kicking and turning over loose chunks to look for anything that might be attached to the victim or that will give the victim's trajectory and narrow the search area. Shallow probes should be made into likely burial spots with an avalanche probe, ski, ski pole, or tree limb. Likely spots are the uphill sides of trees and rocks, and benches or bends in the slope where snow avalanche debris is concentrated. The toe of the debris should be searched thoroughly; many victims are found in this area.

Rescue Beacons.

If the group was using beacons, all survivors must immediately switch their units to receive mode. While making the fast scuff-search for visual clues, survivors should at the same time search the debris, listening for the beeping sound coming from the buried beacon. When they pick up the signal, they will be able to narrow the search area quickly. If skilled in this kind of search, they will pinpoint the burial site in a few minutes.

Probing.

Probing avalanche debris is a simple but slow method for searching for buried victims. A probe line is composed of up to a dozen rescuers with avalanche probes, or sounding rods, who stand elbow to elbow on the avalanche debris. Ideally, probes should be 3 to 4 m (10 to 13 feet) long. Once the whole area is probed without a find, the proper decision is to do it again. In rescues with enough manpower, shovelers stand nearby to check out any possible strike. The line does not stop in such an event but continues to march forward with its methodical "down, up, step" cadence.

Coarse probing is 4 to 5 times faster than the more thorough technique called fine probing. For a coarse probe, probers straddle a distance of 50 cm and are spaced 75 cm apart ([Figure 2-20](#)). This leaves 25 cm between the toes of adjacent probers. Probes are pushed into the center of the straddled span. Upon command from the leader, the line advances one step, about 70 cm. (Where terrain is steep or probers are

few, an alternative is to stand "fingertip-to-fingertip." Probers probe first on one side of their body, then on the other.) This method gives about a 70% chance of finding the victim.

After several passes of coarse probing with no results, a fine probe is done, usually when the objective is body recovery. For this method the line is arranged as for coarse probing. Each searcher probes in front of the left foot, in the center of the straddled position, and in front of the right foot. On signal the line advances 30 cm and repeats the three probes. This method gives a 100% probability of finding a victim. The probe holes are spaced 25 by 30 cm, or 13 probes per square meter. On average, 20 searchers can fine probe an area 100 x 100 m (328 x 328 feet) in 16 to 20 hours.

Avalanche Guard.

If the threat of a second avalanche exists, one person should stand in a safe location to shout out a warning. This gives the searchers a few seconds to flee to safety. Rescues are often carried out in dangerous conditions, and self-preservation should be a major consideration.

Going for Help.

A difficult question in rescues is when to seek outside help. If the accident occurs in or near a ski area and there are several rescuers, one person can be sent to notify the ski patrol immediately. If only one rescuer is present, the correct choice becomes harder. The best advice is to search the surface hastily but thoroughly for clues before leaving to notify the patrol. If a patrol phone is close, the rescuer should notify the patrol and then return immediately to resume the search.

If the avalanche occurs in the backcountry far from any organized body of rescuers, all party members should remain at the site. The guiding principle in backcountry rescues is that survivors search until they

Figure 2-20 A, Coarse, and B, fine avalanche probing.

cannot or should not continue. When deciding when to stop searching, the safety of the search party must be weighed against the decreasing survival chances of the buried

victim.

One exception exists to the rule of all party members staying to search. When there are a large number of survivors, two people can go out to secure help and the search party will still have a sizable rescue force on hand.

Three-Stage Rescue.

A full-scale operation is divided into three stages. The first stage is the hasty search column. This group, composed of as many people as are on hand, heads swiftly to the site carrying probes, shovels, and first-aid equipment. They scuff the avalanche for clues and probe likely areas in hopes of making a quick find. The person reporting the avalanche often accompanies this column back to the site.

The second stage brings the main body of rescuers to the site. They carry bulkier equipment needed for search, resuscitation, and evacuation: more probes and shovels, toboggans, sleeping bags, resuscitation equipment, medical supplies, and a trained avalanche dog and handler, if available. Ideally, stage two should begin 10 to 15 minutes after stage one.

The third stage brings in support for stages one and two, in the case of a prolonged rescue. Included are fresh rescuers to take over for cold and tired searchers, hot food and drink, tents, warm clothing, and lights.

Avalanche dogs and handlers can provide additional search power.

THE MODERN AVALANCHE VICTIM

Avalanche deaths have increased in the United States each decade since 1950. [Figure 2-21](#) shows annual deaths; [Figure 2-22](#) shows these numbers averaged over 5-year periods. From 1950 to 1999, 571 people have died in avalanches. Of these, 471 (82%) were men and 54 (10%) were women. (Interestingly, not all accident reports list the gender of the victim.) The average age of all victims is 28 years. The youngest was 6; the oldest, 66.

[Figure 2-23](#) shows the activity groups for the victims. Most victims (83%) were pursuing some form of recreation at the time of their accident, with climbers, ski tourers, snowmobilers, and lift skiers heading the list. The distinction between ski tourers and lift skiers is that lift skiers pursue their sport in and around developed ski areas and rely on lifts to get them up the hill. This category includes skiers who leave the area boundary or ski into "closed" areas within the ski area boundary. The ski tourers category includes ski mountaineers, backcountry skiers, helicopter skiers, and snowcat skiers. Miscellaneous recreation includes hikers, snowshoers, and persons playing in the snow. Among nonrecreation groups, avalanches strike houses (residents), highways (motorists and plow drivers), and the workplace (ski patrollers and others whose job puts

Figure 2-21 Avalanche fatalities in the United States from the winters of 1950–1951 to 1998–1999.

them at risk). Since 1950, 15 states have registered avalanche fatalities ([Figure 2-24](#)).

Statistics of Avalanche Burials

Numerous factors affect a buried victim's chances for survival: time buried, depth buried, clues on the surface, safety equipment, injury, ability to swim with the avalanche, body position, snow density, presence of airspace, and size of airspace. A victim who is uninjured and able to fight and swim on the downhill ride usually has a better chance of ending up only partly buried, or if completely buried, a better chance of creating an airspace for breathing. A victim who is severely injured or knocked unconscious is like a ragdoll being rolled, flipped, and twisted. Being trapped in an avalanche is a

life-and-death struggle, with the upper hand going to those who fight the hardest.

Avalanches kill in two ways. First, serious injury is always possible in a tumble down an avalanche path. Trees, rocks, cliffs, and the wrenching action of snow in motion can do horrible things to the human body. About one third of all avalanche deaths are caused by trauma, especially to the head and neck. Second, snow burial causes suffocation in two thirds of avalanche deaths. The problem of breathing in an avalanche does not start with being buried. A victim being carried down in the churning maelstrom of snow has an extraordinarily hard time breathing. Inhaled snow clogs the mouth and nose; suffocation occurs quickly if the victim is buried with the airway already blocked. Snow

Figure 2-22 Avalanche fatalities in the United States averaged by five-winter periods, 1950–1951 to 1998–1999.

Figure 2-23 Avalanche fatalities in the United States from 1950–1951 to 1998–1999 by activity categories.

Figure 2-24 Avalanche fatalities in the United States from 1950–1951 to 1998–1999 by state.

Figure 2-25 Length of time buried for U.S. avalanche fatalities and survivors in direct contact with the snow (not in a structure or vehicle) from 1950–1951 through 1998–1999.

that was light and airy when a skier carved turns in it becomes viselike in its new form. Where the snow might have been 80% air to begin with, it might be less than 50% air after an avalanche. The snow is much less permeable to airflow, making it harder for the victim to breathe.

Snow sets up hard and solid after an avalanche. It is almost impossible for victims to dig themselves out, even if buried less than a foot deep. Hard debris also makes recovery very difficult in the absence of a sturdy shovel. The pressure of the snow in a burial of several feet sometimes is so great that the victim is unable to expand his or her chest to draw a breath. Warm exhaled breath freezes on the snow around the face, eventually forming an ice lens that cuts off all airflow. It takes longer than snow-clogged airways, but the result is still death by suffocation.

Another factor that affects survival is the position of the victim's head; that is, whether they were buried face up or face down. The most favorable position is face up. Data from a limited number of burials show the victim is twice as likely to survive if buried face up rather than face down. If buried face up, an airspace forms around the face as the back of the head melts into the snow; if buried face down, an airspace cannot form as the face melts into the snow.

The statistics on survival are derived from a large number of avalanche burials. In compiling these figures, we have included only persons who were totally buried in direct contact with the snow. We have not included victims buried in the wreckage of buildings or vehicles, since such victims can be shielded from the snow to allow sizable airspaces. Under favorable circumstances such as this, some victims have been able to live for days. In 1982, Anna Conrad lived for 5 days at Alpine Meadows, California, in the rubble of a demolished building, the longest survival on record in the United States.

A completely buried victim has a poor chance of survival. [Figure 2-25](#) shows decreasing survival with increasing burial time. In the first 15 minutes, more persons are found alive (87%) than dead. Between 16 to 30 minutes, an equal number are found dead and alive. After 30 minutes, more are found dead than alive and the survival rate continues to diminish. The important point is that speed is essential in the search. In favorable circumstances, buried victims can live for several hours beneath the snow; therefore rescuers should never abandon a search prematurely. A miner in Colorado who was buried by an avalanche near a mine portal was able to dig himself out after being buried for approximately 22 hours and nearly 1.8 m (6 feet) deep. However, after several hours the diminishing probability of finding a live victim should be weighed against the safety of the search party.

Survival is interrelated with both time and depth of burial, as shown in [Figure 2-26](#).

Survival probabilities diminish with increasing burial depth. To date, no one in the United States who has been buried deeper than 2.1 m (7 feet) has been recovered alive.

Statistics of Rescue

A buried victim's chance of survival directly relates not only to depth and length of time of burial but also to

Figure 2-26 Depth of burial for U.S. avalanche fatalities and survivors and percentage survival for victims in direct contact with the snow (not in a structure or vehicle) from 1950–1951 through 1998–1999.

TABLE 2-1 -- Type of Rescue for Buried Avalanche Victims in Direct Contact with Snow, Based on a Sample of 682 Burials in the United States from 1950–1951 to 1998–1999

	SELF-RESCUE	RESCUE BY PARTY MEMBERS	RESCUE BY ORGANIZED TEAM	TOTAL
Found alive	49 (16%)	186 (64%)	57 (20%)	292
Found dead	—	84 (22%)	306 (78%)	390

type of rescue. [Table 2-1](#) compiles the statistics on survival as a function of type of rescue. Buried victims rescued by party members or groups at the accident site have a much better chance of survival than those rescued by organized rescue groups, time being the major influencing factor. Of those found alive, 64% were rescued by party members and 20% by an organized rescue party.

[Table 2-2](#) describes methods of rescue for buried avalanche victims. Seventy-three percent of victims (108 of 147) who were buried with a body part (such as a hand) or an attached object (such as a ski tip) protruding from the snow were found alive. In some cases this was simply good luck, but in many cases it was the result of actively fighting or swimming with the avalanche or of thrusting a hand upward when the avalanche began to slow down. Either way, this statistic shows the advantages of a shallow burial: less time required to search, shorter digging time, and the possibility of attached objects or body parts being visible on the debris. Of the fatalities in this category, many were

skiing alone, with no one to spot the hand or ski tip and provide rescue.

TABLE 2-2 -- Method of Locating (First Contact) Buried Avalanche Victims, Based on a Sample of 748 Avalanche Burials in the United States from 1950–1951 to 1998–1999

METHOD	FOUND ALIVE	FOUND DEAD	TOTAL
Attached object or body part	108	39	147
Hasty search or spot probe	26	38	64
Coarse or fine probe	22	139	161
Rescue transceiver	36	58	94
Avalanche cord	1	0	1
Acoustic contact	26	1	27
Avalanche dog	6	34	40
Other (digging, bulldozer)	17	14	31
Found after long time span	0	41	41
Inside vehicle	30	10	40
Inside structure	22	28	50
Method not known	19	33	52
TOTAL	313	435	748

Organized probe lines have found more victims than any other method, but because of the time required, most victims (86%) are recovered dead. Only 22 people were found alive by this method, with 139 recovered dead.

Rescue transceivers are an efficient method to locate victims, but two problems have limited the number of survivors who were wearing beacons. First, few who wear beacons are well practiced in the art of using them instantly and efficiently to save a life; and second, even with a quick pinpointing of the burial location, extricating

the victim from deeper burials may take too long to save a life. Therefore, since the first transceiver rescue in 1974, only 38% (36 of 94) of buried victims found with transceivers have been recovered alive. The more practice and experience with transceivers on the part of the rescuers, the faster the find and recovery.

Despite the sound-insulating properties of snow, 26 victims who were shallowly buried were able to yell and be heard by rescuers (acoustic contact). An unfortunate case was

the man whose moans were heard but who was dead when uncovered 20 minutes later.

Trained search dogs are capable of locating buried victims very quickly, but because they are often brought to the scene only after extended periods of burial, there have been few live rescues. In the March 1982 avalanche disaster at Alpine Meadows, California, a dog made the first live recovery of an avalanche victim in the United States. Since then, dogs have effected five additional live recoveries.

A trained avalanche dog can search more effectively than can 30 searchers. Search dogs move rapidly over avalanche debris, using their sensitive noses to scan for human scent diffusing up through the snowpack. Dogs have found bodies buried 10 m (33 feet) deep but have also passed over some buried only 2 m (6 ½ feet) deep. They are not 100% effective. Search and rescue teams and law enforcement agencies work closely with search dog handlers, and trained avalanche dogs are becoming common fixtures at several ski areas in the western United States.

These statistics point out the extreme importance of rescue skills. Organized rescue teams, such as ski patrollers, must be highly practiced. They must have adequate training, manpower, and equipment to perform a hasty search and probe of likely burial spots within a minimum time span. For backcountry rescues the message is clear that a buried victim's best hope for survival is to be found by his or her companions. The need to seek outside rescue units practically ensures a body recovery mission.

Chapter 3 - Lightning Injuries

Mary Ann Cooper
Christopher J. Andrews
Ronald L Holle
Raúl E López

HISTORICAL OVERVIEW

Humans have always viewed lightning with awe and trepidation. Priests, the earliest astronomers and meteorologists, became proficient at weather prediction, interpreting changes in weather as omens of good or bad fortune, sometimes to the advantage of their political mentors. As a spectacular celestial event, lightning was often depicted in ancient cultures and religions.^[52] A roll seal from Akkadian times (2200 BC) portrays a goddess holding sheaves of lightning bolts in each hand.^[52] Next to her, a weather god drives a chariot and creates lightning bolts by flicking a whip at his horses, while priests offer libations. A relief found on a castle gate in northern Syria (900 BC) depicts the weather god Teshub holding a three-pronged thunderbolt.

Beginning around 700 BC, Greek artists began to incorporate lightning symbols representing Zeus's tool of warning or favor. Aristotle noted that lightning resulted from the ignition of telluric fumes that made up storm clouds. Roman mythology saw lightning as more ominous than did the Greeks, with Jupiter using thunderbolts as tools of vengeance and condemnation so that Romans who were struck were denied burial rituals. Several Roman emperors wore laurel wreaths or sealskin to ward off lightning strikes. Important matters of state were often decided on observations of lightning and other natural phenomena. Both Seneca and Titus Lucretius discussed lightning in their treatises on natural events, and Plutarch noted that sleeping persons, having no spirit of life, were immune to lightning strikes.^[52] The Norsemen named their thunder god Thor. Thursday is named for him.

In Chinese mythology the goddess of lightning, Tien Mu, used mirrors to direct bolts of lightning. She was one of the deities of the "Ministry of Thunderstorms" of ancient Chinese religion. Lightning also played a role in Buddhist symbolism.

Although lightning is most frequently rendered as fire, it has also been represented as stone axes hurled from the heavens. French peasants carry a *pierre do tonnerre*, or lightning stone, to ward off lightning strikes. The Yakuts of eastern Asia regard rounded stones found in fields hit by lightning as thunder axes and often use the powdered stones in medicines and potions. In Africa the Basuto tribe views lightning as the great thunderbird Umpundulo, flashing its wings in the clouds as it descends to Earth.

Some Native American cultures had the Thunderbird in their religions. The Navajo have a story about the hero Twins who used "the lightning that strikes straight" and "the lightning that strikes crooked" to kill several mythical beasts that were plaguing the People (Navajo) and in the process created the Grand Canyon. ^[13] The art of the native Australians incorporates lightning symbols as well.

MYTHS, SUPERSTITIONS, AND MISCONCEPTIONS^[33]

The Roman Pliny noted that a man who heard thunder was safe from the lightning stroke. In general this is true because the light and strike precede the noise, depending on the distance from the lightning strike. However, some victims of direct hits report a sledge-hammer-like effect of the force while seeing a bright light and occasionally hearing a loud noise. Others who receive side flashes or ground current report both seeing the flash and hearing the stroke, indicating that the main stroke was some distance away.

Many myths about lightning still persist today, including the notion that lightning strikes are invariably fatal. According to an American study of cases reported in the lightning literature since 1900, lightning strike carries a mortality of 30% and morbidity of 70%.^[29] A slightly different statistical interpretation of the same data yielded a mortality figure of 20%.^[2] ^[8] Because literature reports are usually biased toward the severe or interesting cases, a review of cases will tend to overestimate the mortality rate. In reality, mortality may be as low as 5% to 10%.^[25]

Most people suspect that the major cause of death would be from burns. However, the only cause of immediate death is from cardiac arrest.^[29] Persons who are stunned or lose consciousness without cardiopulmonary arrest are highly unlikely to die, although they may still have serious sequelae.^[31] Unfortunately, delayed causes of death include suicide induced by the life changes from disabilities wrought by lightning.

Most people know to seek shelter when storm clouds roll overhead. Few realize that one of the most dangerous times for a fatal strike is before the storm.^[35] Lightning may travel nearly horizontally as far as 10 miles or more in front of the thunderstorm and seem to occur "out of a clear blue sky," or at least when the day is still sunny. The faster the storm is traveling and

the more violent it is, the more likely that a fatal strike will occur. Another time underestimated for the potential danger of lightning is the end of a thunderstorm, which has been shown to be as dangerous as the start of the storm.

The "30–30 rule" is now recommended for lightning safety.^[37] If you see lightning and can count to 30 seconds before you hear the thunder, you are already in danger and should be seeking shelter. Activities should not be resumed for at least 30 minutes after

the last lightning is seen and the last thunder heard.^[37] ^[117] To calculate your distance from lightning, take the number of seconds between the "flash" and the "bang" (flash-to-bang method) and divide by 5 to find the number of miles.^[116] The problem with the flash-to-bang method is that it is sometimes difficult to match the correct thunder to the correct lightning flash in an active storm. In addition, many people forget to divide by 5 and so overestimate the miles (and their safety factor) by a factor of five.

The distance between successive lightning flashes may be as little as a few yards or as much as 5 miles plus or minus another 5 miles (a count of 50 seconds) depending on the terrain and other local geographic factors.^[86] One way to teach children lightning safety is to use the following phrase: "If you see it, flee it; if you hear it, clear it."

Winter lightning (thunderblizzard), although rare, is usually more dangerous because it tends to be much more powerful than summer lightning.

Most people believe that they are immune from lightning strikes when inside a building. Unfortunately, a significant proportion of injuries occurs to persons who are in their homes or places of employment.^[1A] ^[6] ^[43] ^[105] ^[110] Side flashes strike people through plumbing fixtures, telephones, and other appliances attached to the outside of the house by metal conductors.^[1A] Portable cellular phones offer protection from the electrical effects, although victims may suffer acoustic damage from the static in the earpiece similar to having a firecracker go off next to their ear.^[6] With a hard-wired phone, they may suffer neurocognitive deficits,^[32] ^[36] ^[103] death, or a myriad of other lightning-related problems because the phone system in most houses is not grounded to the house's electrical system and acts as a conduit for lightning either to come into the home or to exit from it. Telephone companies include warnings in their directories against using telephones during thunderstorms.

Taking shelter in small sheds, such as hikers' leantos or those on golf courses, especially above tree level on a mountain, can be especially dangerous when lightning splashes onto the inhabitants. Unfortunately, the most recently published *NFPA Journal* (National Fire Protection Association) discusses protection that may be effective for the shelter but may actually increase the lightning risk to any inhabitants who seek shelter in them.

The "crispy critter" myth is the belief that the victim struck by lightning bursts into flames or is reduced to a pile of ashes.^[35] In reality, lightning often flashes over the outside of a victim, sometimes blowing off the clothes but leaving few external signs of injury and few if any burns.

Two other myths held by the public and many physicians are: "If you're not killed by lightning, you'll be OK," and, "If there are no outward signs of lightning injury, the damage can't be serious."^[35] Medical literature, because of lack of follow-up case reports, also implies that there are few permanent sequelae of lightning injury. However, in the last few years it has become apparent that several permanent sequelae may occur.² In addition, many lightning victims with significant sequelae had no evidence acutely of burns. Peripheral neuropathy, chronic pain syndromes, and neuropsychologic symptoms, including severe short-term memory difficulty, difficulty processing new

information, depression, and posttraumatic stress disorder, may be debilitating.^{[36] [102] [103]} Further study is needed to elucidate how malingerers may be distinguished from real victims of lightning injury.^{[60] [61]}

Occasionally, lightning victims show pathognomonic skin changes that are not true burns but have a fernlike pattern. At one time, these patterns were thought to be imprints of the surrounding vegetation transferred onto the victim's skin by the lightning. Actually these fernlike patterns resemble fractals or the kind of pattern that can be obtained from placing a photographic plate in a strong electromagnetic field, which is what lightning produces for a short time around the victim.^{[62] [121]} They do not follow the distribution of nerves or blood vessels. Although they have been photographed and well described in the literature, no histologic study has been reported to explain the structure of the marking. It has been postulated that the pattern is caused by the forceful extravasation of red blood cells from the capillaries as they contract, similar to a bruise, which would also explain the evanescent nature of the markings.

A myth still prevalent is that the lightning victim retains the charge and is dangerous to touch, since he or she is still "electrified." This myth has led to unnecessary deaths by delaying resuscitation efforts.^[35]

Medical literature and practice are plagued by myths that grew out of misread, misquoted, or misinterpreted data and continue to be propagated without further investigation. Not the least of these is the tenet that lightning victims who have resuscitation for several hours may still successfully recover. This belief seems to be grounded in the old idea of suspended

*References ^[1] ^[5] ^[28] ^[30] ^[33] ^[36] ^[47] ^[98] ^[102] ^[103] ^[110] ^[115] ^[122] ^[123] .

animation—the concept that lightning is capable of shutting off systemic and cerebral metabolism, allowing rescuers a longer period in which to resuscitate the patient. This concept, credited to Taussig,^[113] actually appeared some time before her article. In addition, the case recounted by Taussig that is the basis for this myth, when searched to its source, was a case report by Morikawa and Steichen.^[94] The case does show a somewhat longer resuscitation period than usual, but not as miraculous as reported in Taussig's paper or as propagated in subsequent references to her paper.

In a study of lightning survivors, Andrews, Colquhoun, and Darveniza^[4] have shown increasing prolongation of the QT interval, bringing up the theoretic possibility of torsades as a mechanism for the suspended animation reports. There is new evidence from animal experiments to support the teaching that respiratory arrest may persist longer than cardiac arrest.^{[2] [38] [39]} One study, in which Australian sheep were hit with simulated lightning strokes, showed histologic evidence of greater damage to the respiratory centers than to the cardiac center in the fourth ventricle.^[2] Prolonged assisted ventilation may in some cases be successful after cardiac activity has returned.

Another series of animal experiments by Cooper and Kotsos^[38] ^[39] with hairless rats has shown that it is possible to obtain the skin changes (keraunographic markings), primary and secondary arrest with prolonged respiratory arrest, and temporary lower extremity paralysis with simulated lightning strike.

Several booklets listing precautions for personal lightning protection appeared in the late 1700s and early 1800s. One of the superstitions listed was that humans, by their presence, could attract lightning to a nearby object. A book of the times, *Catechism of Thunderstorms*, illustrated other myths. Lightning was said to follow the draft of warm air behind a horse-drawn cart, so that coachmen were cautioned to walk their horses slowly through a storm. Other precautions listed included seeking shelter away from tall trees and sheaves of corn if caught in the open and installing lightning rods for the protection of buildings and ships.

Historically, many remedies for resuscitation of lightning victims have been offered. On July 15, 1889, Alfred West testified in a New York court that he was revived by "drawing out the electricity" when his feet were placed in warm water while his rescuer pulled on Mr. West's toes with one hand and milked a cow with the other.^[10]

Other early attempts at resuscitation included friction to the bare skin, dousing the victim with a bucket of cold water, and chest compression. An early attempt at cardiopulmonary resuscitation was given in 1807 when mouth-to-mouth ventilation was used for lightning victims and it was proposed that gentle electric shocks from galvanic batteries passed through the chest might be successful in resuscitating a victim of lightning.^[16] Before that, Benjamin Franklin had purposely electrocuted a chicken during a lightning experiment and reported successful resuscitation with mouth-to-beak ventilation.^[50]

A myth in current treatment is that lightning injuries should be treated like other high-voltage electric injuries. Although lightning as an electric phenomenon follows the same laws of physics, the injuries seen with lightning are very different from high-voltage injuries and should be treated differently if iatrogenic morbidity and mortality are to be avoided.^[9] ^[34]

"Lightning never strikes the same place twice." In reality, the Empire State Building and the Sears Tower are hit dozens of times a year, as are mountaintops and radio-television antennas. If the circumstances facilitating the original lightning strike are still in effect in an area, the laws of nature will encourage further lightning strikes.

Other myths^[35] :

1. Victims may have "internal burns": There may be cellular damage and certainly nervous system damage but rarely, if ever, internal burns such as those suffered with high-voltage electrical injuries. However, some physicians use this euphemism with patients to explain their pain and neurologic injuries.
2. Wearing rubber-soled shoes, raincoats, etc., will protect a person: If lightning has burned its way a mile or more through the air, which is a superb insulator, it is

foolish to believe that a fraction of an inch of rubber or composite material will serve as an adequate insulator.

3. The rubber tires on an auto are what protects a person from lightning injury: See entry 2 above. Electrical energy goes along the outside of a metal conductor (the car body) and dissipates through the rainwater to the ground or off the axles or bumper of the car.
 4. Wearing metal around the head or as cleats on shoes will increase the risk or "attract lightning": There is no evidence to support this. Secondary burns on the soles of the feet where metal cleats or grommets heat up have been reported, but there is no evidence that a person increases his or her risk by wearing these.
 5. Carrying an umbrella increases the risk: This is true if a person's height becomes greater by holding an umbrella.
 6. Lightning always hits the highest object: False. Lightning only "sees" objects about 30 to 50 meters from its tip. In addition, several pictures exist of lightning hitting halfway down a flagpole or at the bottom of the space shuttle gantry.
 7. There is no danger of lightning injury unless it is raining: False. Although lightning only occurs as
-

76

a result of thunderstorms, it can travel 10 or more miles in front of the thundercloud and seem to "come out of the blue" to strike a person or object long before the rain comes down in their area. Nearly 10% of lightning occurs when there is no rain falling in the area of the strike. It has also been known to reach over a mountain ridge and "hit out of the blue" from the thunderstorm that was on the other side of the peak and was neither visible nor audible to the victim.

8. Lightning may occur without thunder: Whenever there is lightning, there is thunder, and vice versa. Sometimes it will appear that there is lightning without thunder because thunder is seldom heard more than 10 miles from the lightning stroke or may be blocked by buildings or mountains.

INCIDENCE OF INJURY

Spatial Distribution of Lightning in the United States

The distribution of cloud-to-ground lightning across the United States is known because of deployment and operation for the last decade of automatic real-time lightning detection networks. On the average, over 20 million cloud-to-ground flashes are detected each year in the United States.^[69] On a shorter time scale, more than 50,000 flashes per hour are sometimes detected during summer afternoons over the United States.^[40]

A multiyear climatology of lightning from detection network data shows that central Florida always has the greatest number of flashes per area in a given year ([Figure 3-1, A](#)). Flash density decreases to the north and west from there. Flash densities over Missouri, Iowa, and Illinois during the 1993 Mississippi River flood rivaled Florida.^[93] In addition to the general features in [Figure 3-1](#) , important local variations occur along the coast of the Gulf of Mexico, where sea breezes enhance lightning frequency.^[81] ^[119]

Additional important maxima and minima are found in and around the regions in the western United States with mountains and large slopes in terrain.^[81] ^[89]

Temporal Distribution of Lightning in the United States

Lightning is most common in summer months ([Figure 3-2, A](#)). About two thirds of the flashes occur in June, July, and August. In the southeastern states, lightning occurs quite often during all months of the year. A primary ingredient for lightning formation is a significant amount of moisture in the lower and middle levels of the atmosphere; this fuel for thunderstorms is consistently found in humid subtropical and tropical regions. Mechanisms to lift the moisture into thunderstorms are necessary. Especially along coastlines and mountain slopes, updrafts are produced almost daily that provide favored locations for thunderstorms.

Lightning is most common in the afternoon ([Figure 3-2, B](#)). Nearly half of all lightning occurs from 1500 through 1800 local standard time (LST). [Figure 3-2, B](#) , combines regional results during the summer for Arizona,^[120] northeast Colorado and central Florida,^[81] and central Georgia.^[80] There is no publication to date showing diurnal variation of lightning over the entire United States with detection network data. Lightning is at a maximum in the afternoon because the updrafts necessary for thunderstorm formation are strongest during the hours of the day when surface temperatures are

highest, which results in the greatest vertical instability.

Lightning Around the World

Lightning detection systems similar to the U.S. network have been installed over part or all of about two dozen countries on every continent except Antarctica. Some have been in operation for up to a decade. At this time, there is no compilation of cloud-to-ground lightning flashes from such networks covering more than one country. Instead, [Figure 3-1, B](#), shows the worldwide map of total lightning developed from the satellite-borne Optical Transient Detector (OTD), which measures both cloud-to-ground and cloud flashes.^[26] Flash densities have been calculated statistically using OTD data to estimate that there are over 1.2 billion lightning flashes of all types around the world every year.

Most lightning is over tropical and subtropical continents, and there is far more lightning over land than the oceans. Some of the highest frequencies are much greater than found in the United States over Florida and other Gulf Coast locations.

Lightning is an afternoon phenomenon nearly everywhere, as was shown for the United States. At higher latitudes, most lightning occurs during the summer months. In Southeast Asia and surrounding regions toward the equator, maximum lightning activity during the year is influenced primarily by the monsoon and coincides generally with the months of heaviest rainfall.

U.S. Lightning Casualties in Storm Data

Every month, each National Weather Service (NWS) office in the United States compiles a list of damaging or notable weather phenomena occurring within the office's area of responsibility. This list is sent to National Oceanic and Atmospheric Administration (NOAA) headquarters, then to NOAA's National Climatic Data Center (NCDC) in Asheville, NC. These lists are combined at NCDC and *Storm Data* is published.

From 1959 to 1994, *Storm Data* had 3239 deaths, 9818 injuries, and 19,814 property-damage reports caused by

Figure 3-1 A, Cloud-to-ground flashes per square kilometer per year in the United

States from a network of lightning detection antennas from 1989–1996. **B**, Total flashes per square kilometer per year for the world from May 1995 to April 1999 from the Optical Transient Detector. (**A** from Huffines GR, Orville RE: *J Appl Meteor* 38:1013, 1999; **B** courtesy Hugh Christian, NASA/Marshall Space Flight Center.)

lightning. Each report has some or all of the following: year, month, day, time, state and county, as well as number, gender, and location of fatalities and injuries, and amount and type of damage.

Lightning-related casualties and damages are often less spectacular and more dispersed in time and space than other weather phenomena. Therefore lightning deaths, injuries, and damages have been found to be underreported.^{[66] [88] [92] [111]} Factors contributing to the underreporting include the fact that most casualty events involve only one person or object, the fact that *Storm Data* relies on newspaper clipping services for lightning events, internal inconsistency within *Storm Data* in tabulation of individual occurrences into summary tables, lack of an accepted definition of lightning vs. "lightning-related" deaths, and inconsistency in the listing of medical diagnoses.^{[84] [92] [111]} Regardless, *Storm Data* is the only consistent national data source for several decades. [Table 3-1](#) shows that lightning is second only to flash floods and floods in weather-related deaths during the 30-year record.

Spatial Distributions of Lightning Casualties

The lightning casualty distribution (deaths and injuries combined) is shown from 1959 to 1994 in [Figure 3-3, A](#). The general pattern has similarities to the distribution of lightning in [Figure 3-1](#), but Florida has twice as many casualties as any other state. Many of the other high numbers of casualties are from populous eastern states. It is preferable to use casualties for these results because the number of deaths is not very large and there is no obvious reason to expect differences in the geographic distribution of deaths vs. injuries.

The lightning hazard is shown better when population is taken into account ([Figure 3-3, B](#)). The maximum rate of lightning casualties shifts from populous eastern

Figure 3-2 A, Monthly distribution of U.S. cloud-to-ground lightning from 1992 to 1995 from a lightning detection network. **B**, Hourly distribution of cloud-to-ground lightning from networks in four U.S. locations. **C** and **D**, Monthly and hourly distributions of lightning casualties from 1959 to 1994 in the United States. states to Rocky Mountain and plains states. The top two rates are from Wyoming and New Mexico; these states were 35th and 21st in number of casualties. Wyoming had most of its casualties in the 1960s and 1970s, and almost none since then.

Southeastern states often have high rankings in both casualties and casualty rates ([Figure 3-4, A and B](#)). The only states in the top 10 of both casualties and casualty rate are Florida, Colorado, and North Carolina. Detailed listings of deaths and injuries by state, as well as death and injury rates per state, are in Curran et al.^[41] This reference also contains information on the distribution of lightning damage reports, which has a high concentration over the plains states.

Two lightning fatality studies for the United States had substantially similar results to [Figure 3-3](#) . Duclos and Sanderson^[44] used data from the National Center for Health Statistics, and Mogil et al^[92] used *Storm Data*. Single-state maps by county were compiled for Florida,^[44] North Carolina,^[75] Michigan,^[48] and Colorado.^{[82] [87]} In other countries, fatalities divided by political boundaries were

Figure 3-3 Rank of each state in lightning casualties (deaths and injuries combined) from 1959 to 1994. **A**, Casualties per state. **B**, Casualties weighted by state population. (From Curran EB, Holle RL, López RE: *Lightning fatalities, injuries, and damage reports in the United States from 1959–1994*, NOAA Tech Memo NWS SW-193, 1997.)

Figure 3-4 A, Number of casualties, deaths, and injuries. **B**, Ratio of injuries to deaths from 1959 to 1994 in the United States. (From Curran EB, Holle RL, López RE: *Lightning fatalities, injuries, and damage reports in the United States from 1959–1994*, NOAA Tech Memo NWS SW-193, 1997.)

developed for Canada by Hornstein,^[68] for Singapore by Pakiam et al,^[101] for Australia by Coates et al,^[27] and for France by Gourbière et al.^[55]

Monthly Variations of U.S. Casualties

By month, lightning casualties peak during July ([Figure 3-2, C](#)). The percentages increase gradually before July, then decline more quickly after the maximum. Cloud-to-ground flashes show similar features ([Figure 3-2, A](#)). Seasonal maps of lightning casualty rates in Curran et al^[41] show the summer patterns to be similar to annual maps. During other seasons, lightning casualty rates are higher in southern states. Casualty rates in the northeast are low except during the summer, whereas they are highest on the West Coast during autumn and winter.

A July maximum was also found in prior *Storm Data* studies, as well as a slower increase before and a faster decrease after July.^{[44] [48] [82] [87] [92]} August maxima were found in Florida by Duclos et al^[44] and Holle et al.^[64] January has the largest number of Australian fatalities, resulting from the reversal of seasons from the United States.^[27] The Singapore fatality maxima in November and April are similar to the annual cycle of local thunderstorms.^[101]

Time of Day Variations of U.S. Casualties

By time of day, most lightning casualties occur in the afternoon ([Figure 3-2, D](#)); two thirds occur between 1200 and 1800 LST. They show a steady increase toward a maximum at 1600 LST, followed by a slower decrease after the maximum. Lightning flashes in [Figure 3-2, B](#) , showed a faster increase to the afternoon maximum than shown here for casualties. Lightning occurs most often in the afternoon because the ground is heated most strongly by the sun during that time period. As a result, vertical cumulus clouds form and produce lightning when they are tall enough to have tops colder than freezing temperatures. Narrower distributions of casualties centered in the afternoon are apparent in the Rockies, Southeast, and Northeast compared with the broader time series in the plains and Midwest.^[41]

In the evening and at night (1800 to 0559 LST), casualties are most frequent in the plains, upper midwest, and some populous eastern states.^[41] Of the 29 deaths from 0000 to 0559 LST, 59% occurred when people were in a house set on fire by lightning, and 21% occurred when people were camping in tents. Casualties in the morning are spread widely across the country. Casualties during the afternoon resemble [Figure 3-2, D](#) , since these are the most frequent hours for deaths (67%) and injuries (63%).

In winter, casualties are spread erratically through the day.^[41] Spring casualties occur during nearly the same afternoon hours as for the year, but there is a secondary peak before noon. Summer casualties follow the annual cycle. Autumn casualties have a broad afternoon peak and a secondary morning peak. The casualties are spread more widely through the day outside of the summer months. This spread can be attributed to two factors. First, lightning is less concentrated during the afternoon because the ground is not heated as much as in summer. As a result, more thunderstorms are formed by large-scale traveling disturbances. Second, the number of casualties, especially in winter, is much smaller, so that distributions are affected more by a small number of cases.

Maximum lightning impacts from 1400 to 1600 LST were documented by Duclos and Sanderson,^[44] Ferrett and Ojala,^[48] and López and Holle.^[87] Duclos and Sanderson^[44] found an 1800 LST peak in North Carolina deaths.

Additional Storm Data Information

[Table 3-2](#) shows that males were much more frequent lightning casualties than were females. Similar ratios were found in the United States,^{[44] [45] [64] [75]} Singapore,^[101] and England and Wales.^[46]

The most common situation was for only one victim to be involved in a lightning incident. This is an important contributor to the underreporting of lightning casualties. For incidents involving deaths only, 91% had just one fatality; the largest single case resulted from the 1963 crash of an airliner in Maryland that killed 81 people. The largest number of injuries at one event was 90 at a Michigan campground.^[48] The same

tendency for single victims was noted in the United States,^[87] Singapore,^[101] and Australia.^[27]

According to *Storm Data*, nearly half of all lightning damages are between \$5000 and \$50,000.^[41] However, these amounts are much larger than insured losses paid for claims by homeowners and small businesses.^[66] ^[73]

Storm Data Trends in Lightning Casualties

From 1959 to 1994, *Storm Data* shows a slow decrease in lightning deaths, while injuries increase ([Figure 3-4](#)). As a result, the ratio of injuries to deaths steadily increases. The typical ratio of injuries to deaths had been between 2:1 and 4:1. However, an uncertainty exists, since more injuries are missed than are deaths.^[66] ^[88] ^[92] Cherington et al^[25] found that a ratio of 10 injuries to one death applied in a thorough search of Colorado hospital and emergency room visits. There are additional injuries

TABLE 3-2 -- Casualty Information in Storm Data from 1959 to 1994

TOPIC	DEATHS	INJURIES	CASUALTIES
Males	84%	82%	83%
One victim per event	91%	68%	68%

to persons whose visits are not documented by a medical clinic or if they are not treated. As a result, it is likely that a 10:1 ratio of injuries to deaths is the better estimate.

After population growth was taken into account (normalization), several major trends were identified.^[83] ^[84] A 30% decrease in the number of deaths per million persons was attributed to improved forecasts and warnings, better awareness of the lightning threat, more substantial buildings available for safe refuge, and/or other socioeconomic changes. An additional 40% reduction in normalized deaths may be due to improved medical care and emergency communications. The injury rate decreased only 8%; this lowered rate may be due to transfer of some potential deaths into injuries as a result of better emergency communications, medical attention, and other factors.

Notable decreases in deaths were documented with long-term data sets in England and Wales,^[46] England and Wales compared with Australia,^[53] and Singapore.^[101] Australian deaths increased during the years 1825 to 1918, then decreased through 1991.^[27]

Twentieth-Century Trends in Lightning Deaths

Another difficulty in determining the number of casualties and deaths is changes in reporting systems since the turn of the last century. Beginning in 1900, the Bureau of the Census established a national registration of vital statistics for deaths that included

states, Washington, D.C., and large cities; annual death statistics, including lightning as a cause of death, have been compiled and published by the U.S. government. Although only 10 states and several cities reported to the Bureau of the Census in 1900, the number of states increased gradually until all states and Washington, D.C., were covered by 1935. *Mortality Statistics* was published before

Figure 3-5 A, Annual lightning deaths reported by Bureau of the Census and Public Health Service from 1900 to 1991 (red). Solid blue line is population of reporting states and District of Columbia; dashed is total population of contiguous United States and District of Columbia. **B**, Time series of lightning deaths normalized by population of reporting states (red) and exponential function (blue) fitted to data. (From López RE, Holle RL: *J Climate* 11:2070, 1998.)

1937 and the series *Vital Statistics of the United States* was published after that. Starting with the 1945 records published in 1947, data collection was changed from the Bureau of the Census to the Public Health Service. Since then, data have come from the National Center for Health Statistics, Centers for Disease Control and Prevention, Public Health Service, of the Department of Health and Human Services.^{[85] [104]}

The number of lightning deaths reported since 1900 is shown in [Figure 3-5, A](#) . During the first 20 years, annual deaths increased from less than 100 to about 450 because of an increase in reporting states. In comparing the increase in deaths with the increased reporting population, the fatality increase appears exceptionally large. During the 1920s and 1930s there were about 400 lightning deaths per year, whereas recently it has been less than 100 per year. There has been a persistent drop in deaths since 1944. The same dramatic decline since 1940 was noted by others.^{[12] [44] [92]}

The effect of changes in population can be taken into account by dividing by the population. [Figure 3-5, B](#) , shows the number of lightning deaths per million people per year. In the earlier part of the series, year-to-year fluctuations are relatively large, probably because of random inclusion of reporting states with different demographic and climatic conditions. However, since 1925, the fluctuations are consistently smaller and more regular, and they decrease as the death rate decreases. The normalized time series and an exponential curve fitted to the data indicate a decrease during the twentieth century from more than 6 to a low of 0.4 deaths per million people.

Effect of Rural-to-Urban Migration

Before the turn of the last century, lightning deaths appeared to occur often in rural settings.^[63] Since then, the

percentage of the U.S. population in rural areas (but not the actual population) has dramatically decreased. [Figure 3-6, A](#) , shows that the percentage of the population

living in rural areas since 1890 decreased from 60% in 1900 to 25% in 1990. The only significant departures from the exponential decrease were a slowing in the 1930s and early 1940s during the Great Depression, and an acceleration of the trend in the 1950s and 1960s with increased urbanization after World War II and the Korean War.

The rural population curve is superimposed on the adjusted normalized lightning-death plot in [Figure 3-6, B](#). The remarkable agreement leads to a conclusion that the secular exponential decrease in population-adjusted deaths is closely related to the relative reduction in rural population. This long-term decrease has been noted by several authors, and a decrease in rural population has been hypothesized as a factor, together

Figure 3-6 A, Percent of contiguous U.S. population living in rural areas since 1890 (*solid line*), and an exponential function fitted to data (*dashed line*). **B**, Adjusted yearly lightning deaths normalized by population, as in **A**. *Dashed line*, Percent of population in rural areas. (From López RE, Holle RL: *J Climate* 11:2070, 1998.)

Figure 3-7 Time series of yearly lightning deaths normalized by population for United States and Canada (**A**) and Spain (**B**).

with improved home electrical systems, which include substantial grounding, as well as medical treatment, education, and meteorologic warnings.^{[12] [44] [83] [87] [92]} These factors are also linked to the decrease in rural population resulting from emigration to cities or enhanced urbanization of rural areas.

Similar decreases in lightning death rates have been found in two other countries. [Figure 3-7, A](#), shows the decrease for the last century in Canada compared with the United States. The Canadian death rate is probably less because of the lower flash rate for this higher-latitude country. Both the United States and Canada had a proportional shift of people from rural to urban regions. In contrast, the shift to urban population for Spain was delayed by several decades ([Figure 3-7, B](#)) because of a national policy of maintaining rural populations. However, when industrialization began, the lightning death rate plunged.

Types of Lightning Casualty Incidents

The preceding analyses suggest a link between the shift from rural to urban settings and the number of lightning casualties. *Storm Data* has the location of lightning victims since 1959, but the categories are not especially helpful because 40% of its locations are unknown. It is necessary to go beyond location to discover a person's activity to better

identify the type of incident.

A key to understanding the influence of the urban migration can be found in analysis of Kretzer (1895), who documented 1043 lightning deaths and injuries from 1891 to 1894. An overall impression was developed for each entry as to whether the situation was rural or urban.^[63] It was not possible to make this determination in roughly one third of the cases. The verbal narratives in *Storm Data* from 1991 to 1994 were used in a similar analysis. Events were subdivided by type of incident based on both activity and location.^[63]

In the 1890s, rural deaths were much more frequent than urban ([Figure 3-8, A](#)). Indoor fatalities were the most frequent; 23% of all deaths were inside houses. The next largest types were outdoors and agricultural incidents, whereas recreation and sports incidents were virtually nonexistent.

In the 1990s, rural settings account for a much smaller proportion of casualties ([Figure 3-8, B](#)), and agricultural incidents are much less frequent than 100 years ago. Only 2% of modern deaths were to people inside houses, one tenth of the percentage a century earlier. Outdoors has become the largest type of incident, with the most frequent incidents occurring under or near trees (15% of all deaths) and in the yard or garden of a house. A high percentage of incidents occurs during recreation; these cases are dominated by beach, water, and camping situations. Sports incidents involve participating in and observing sporting events; many involved golf.^[63]

Figure 3-8 Types of U.S. lightning casualty incidents (%) from 1891 to 1894 compared with 1991–1994. (From Holle RL, López RE, Navarro BC: *U.S. lightning deaths, injuries, and damages in the 1890s compared to the 1990s*, National Oceanic and Atmospheric Administration Tech Memo, ERL pending, 2000.)

These comparisons agree with the influence of the rural-to-urban migration on lightning casualties in the United States. Rural casualties are now half as frequent as urban cases. The inside of a house is no longer as dangerous as it was. This trend is most likely a result of grounding by modern wiring and plumbing. Recreation and sports have become relatively greater contributors to the population at risk from lightning.^{[27] [82] [87]}

Worldwide Lightning Fatalities

Cautious extrapolation of U.S. results to the world can be considered. There were over 400 lightning deaths a year early in the twentieth century in the United States, at a rate exceeding 6 deaths per million people (see [Fig. 3-5](#) and [Fig. 3-7](#)). These often occurred in agricultural incidents in rural settings or inside buildings before widespread installation of wiring and plumbing.

Since the rates and trends are similar in Canada and Spain, they can be considered typical of much of Europe and other industrialized, urbanized countries. However, many

people around the world rely on labor-intensive agriculture and live in dwellings with minimal grounding. The earlier rates from the United States could be appropriate for populous tropical and subtropical areas of Africa, South America, and Southeast Asia, where there is frequent lightning.

About 100 lightning deaths per year currently occur in the United States. This number would be approximately 1000 if the U.S. population was still rural, practiced labor-intensive agriculture, and lived in dwellings with minimal lightning protection. So it might be reasonable to expect that the worldwide lightning death rate is at least 10,000 per year, since a large number of people live in such situations. A ratio of 5 to 10 injuries per death gives a worldwide total of 50,000 to 100,000 injuries a year from lightning.

EARLY SCIENTIFIC STUDIES AND INVENTION OF THE LIGHTNING ROD^[49] ^[50]

The study of electric phenomena is often traced to the publication of Gilbert's *De Magnete* in London in 1600. Experiments in France and Germany and by members of the Royal Society of London led to the invention of the Leyden jar in 1745.

Benjamin Franklin is generally regarded as the father of electric science and during his lifetime was known as the American Newton. The reason he was accepted into the French and English courts around the time of the American Revolution was not because he was an ambassador from America but because he was considered to be one of the foremost scientists of his time. Franklin was elected to every major scientific society at the time and received medals of honor from France and England for his scientific contributions.

Before his work, it was thought that two distinct types of electric phenomena existed. Franklin's work unified these two forces, and he is responsible for renaming them as positive and negative charges.^[50] He also proved with numerous experiments that lightning was an electric phenomenon and that thunderclouds are electrically charged, as demonstrated by the famous kite and key experiment.^[49] He invented the lightning rod and announced its use in 1753 in *Poor Richard's Almanack*:

It has pleased God in his Goodness to Mankind, at length to discover to them the Means of securing their Habitation and other Buildings from Mischief by Thunder and Light- ning. The Method is this: Provide a small Iron Rod (It may be made of the Rod-iron used by the Nailers) but of such a Length, that one End being three or four Feet in the moist Ground, the other may be six or eight Feet above the highest Part of the Building. To the upper End of the Rod fasten a Foot of brass Wire the Size of a common Knitting-needle, sharpened to a fine Point; the Rod may be secured to the House by a few small Staples. If the House or Barn be long, there may be a Rod and Point at each End, and a middling Wire along the Ridge from one to the other. A House thus fur- nished will not be damaged by Lightning, it being attracted to the Points, and passing thro the Metal into the Ground with- out hurting any Thing. Vessels also, having a sharp pointed rod fix'd on the Tops of their Masts, with a Wire from the Foot of the Rod reaching down, round one of the Shrouds, to the Water, will not be hurt by Lightning.

In the 1750s and 1760s, the use of lightning rods became prevalent in the United States for protection of buildings and ships. Some scientists in Europe urged the installation of lightning rods on government buildings, churches, and other high buildings. However, religious advocates maintained that it would be blasphemy to install such devices on church steeples, since the churches received divine protection. Because of this divine protection, some towns chose to store munitions in their churches, leading on more than one occasion to significant destruction and loss of life when the churches were hit by lightning.

Part of the delay in installing lightning rods in England may have been due to British distrust of the scientific theories of the upstart, newly independent United States. Years and numerous unsuccessful trials with English designs were required before the Franklin rod became accepted on Her Majesty's ships and buildings.^[16]

At one time, lightning rods were theorized to be diffusers of electric charges that could neutralize a storm cloud passing overhead, thus averting a lightning stroke. This theory was in part an outgrowth of the observation of St. Elmo's fire, an aura appearing around the tip of lightning rods and ships' masts during a thunderstorm. This phenomenon is caused by an electron discharge that results from the strong electromagnetic field induced around the glowing object.

Properly installed lightning rods and lightning protection systems do not "attract" lightning, but protect a building by allowing the current from a lightning strike that would have occurred, regardless of the protection system, to flow harmlessly through the system to the ground instead of into or through the building, which often causes more extensive damage.^[51] It has not been uncommon for charlatans to take advantage of the fear of lightning and the danger of lightning-caused fires. In the past, they drove from farm to farm offering to "discharge" the lightning rods on the barns and homes for a fee. Lightning protection still remains an area of great controversy, with few of the lightning codes verified by true research. Some of the recent codes (written by the lightning protection industry) now do more to protect buildings and shelters but unfortunately may actually increase the risk for those seeking "shelter" in bus, pool, rain, or golf types of structures, not only by increasing the sheltering person's effective height but also by increasing the chances of side-flash from the lightning protection wiring. Systems that claim to "predict" lightning rather than detect it have yet to prove the scientific validity of their technology by achieving patents. The public is recommended to follow the caveat emptor principle whether it applies to protection of shelters or detection/prediction of lightning by "warning" systems.

The first Lightning Rod Conference was held in London in 1882. Recommendations from this conference were published that year and again in 1905. Further progress in the study of the properties of lightning came with the technical development of Sir Charles Vernon Boy's rotating camera and Dufour's high-speed cathode ray oscillograph, which helped delineate physical properties of lightning, including the direction and speed of the strokes.

Certain countries developed codes of practice for lightning protection (Germany 1924,

1929, Britain 1943, British colonies 1965). A variety of materials, including copper, aluminum, and iron, are recommended by these codes, which also specify the measurements and construction of the protective system, depending on the height, location, and construction of the structure to be protected. The most recent U.S. code revision was the National Fire Protection Act of 1993, written by lightning protection practitioners.

Lightning strokes vary in power and frequency, depending on the terrain and geographic location.^[90] Complicated formulas have been devised to take into account the relative frequency of strikes in an area; the height, construction, and design of the building; and the degree of protection desired, depending on whether it is a storage shed, house, school, hospital, or munitions factory.^[73]

A lightning protection system should be designed to take into account these factors plus the economic considerations of construction. Including a system in the initial design and construction is always easier and less expensive than modifying a completed building. In addition, except where prohibited by code, the owner may decide that a lightning protection system is not worth the expense, for example, for a mountain retreat that is seldom visited.^[73] ^[90] An excellent noncommercial source for discussion of these risks is www.lightningsafety.com.

PHYSICS OF LIGHTNING STROKE

Lightning Discharge^{[51] [52] [53] [90] [114] [118]}

The study of lightning discharge and formation is extremely complex and involves an entire branch of physics and meteorology. We therefore illustrate here the simplified and most common mechanism of thundercloud formation and lightning strike.

Thunderstorms can be created by a number of factors that produce vertical updrafts. These ingredients are usually caused by cold fronts, large-scale upward motions, sea and lake breezes, lifting by mountains, and afternoon heating of warm, moist air ([Figure 3-9, B](#)).^{[52] [114]}

As warm air rises, turbulence and induced friction cause complex redistribution of charges within the cloud ([Figure 3-9, C](#)). Water droplets and ice crystals within the cloud acquire and increase their individual charges. A complex layering of charges, with large potential differences between the layers, results from the interaction between charged particles and internal and external electrical fields within the cloud.

Generally lower layers of the thundercloud become negatively charged relative to the earth, particularly when the storm occurs over a flat surface. The earth, which normally is negatively charged relative to the atmosphere, has a strong positive charge induced as the negatively charged thunderstorm passes overhead. The induced positive charge tends to flow as an upward current into trees, tall buildings, or people in the area of the thunderstorm cloud and may actually course upward as "upward streamers."

Normally, discharge of the potential difference is discouraged by the strong insulatory nature of air. However, when the potential difference between charges within the clouds or between the thundercloud and ground becomes sufficient, the charge may be dissipated as lightning.

A lightning stroke begins as a relatively weak and slow downward leader from the cloud ([Figure 3-9, D](#)). Although the tip of the leader may be luminous, the stepped leader itself is barely discernible with the unassisted eye. The leader travels at about one-third the speed of light (1×10^8 m/sec), and the potential difference between the tip and the earth ranges from 10 to 200 million volts. The leader ionizes a pathway that contains superheated ions, both positive and negative, thus forming a plasma column of very low resistance. It travels with relatively short branched steps, going down about 50 m (164 feet) and then retreating upwards. The next time it goes down, it fills the original ionized path but branches at the end to go down another 50 m and then retreat again. This up-and-down, poly-branching process continues until the leader comes to within 30 to

50 m (98 to 164 feet) of the ground. Since lightning follows this ionized path, its tip "sees" only objects within about a 30- to 50-m radius, meaning that the hill or tower 200 feet (61 m) away from a person will not be "seen" by the lightning as a potential target.

As the tip of the lightning gets closer to the earth with the large potential at its tip, more concentrated areas of induced charge accumulate up on earth, particularly at the peaks of tall, relatively sharp objects. Several upward streamers ([Figure 3-9, E](#)) may rise vertically from these objects toward the downward leader head. Ultimately one, or a small number, of the upward streamers will contact the downward leader, thus completing a lightning channel of low resistance between cloud and ground. The process of the downward leader joining with the upward streamer(s) is called *attachment*. There is often more than one point of attachment to the ground.^[107]

As the low-resistance channel is formed by attachment, the potential difference between cloud and ground effectively disappears and the energy available is dissipated in an avalanche of charge between cloud and ground. This avalanche is referred to as the *return stroke* ([Figure 3-9, F](#)) and is highly luminous. Subsequent to the discharge through the return stroke, the channel remains attached for a small amount of time, and with quick redistribution of charge from other regions of the cloud to the top of the channel (via J- and K-intracloud streamers), further return strokes may occur. Thus a lightning flash may be made up of multiple

86

Figure 3-9 **A**, Warm, low-pressure air rises and condenses into a cumulonimbus cloud. **B**, Typical anvil-shaped thundercloud. **C**, Water droplets within the cloud accumulate and layer changes. **D**, Relatively weak and slow-stepped downward leader initiates the lightning strike. **E**, Positive upward streamer rises from the ground to meet the stepped leader. **F**, Return stroke rushes from the ground to the cloud.

strokes (1 to 30, mean 4 to 5) and is perceived by the eye as flickering of the main channel.

When a very tall building is involved, or when high mountains rise into the clouds, the leader stroke may initiate from the building or mountain rather than from the cloud. In such cases, a joining stroke is rarely seen initiating from the cloud. The channel of ions formed by the leader stroke is maintained as a continuous stroke as the return stroke (misnamed in this instance) travels in the same direction from the ground or object to the cloud, dissipating the charge difference.

The tip of the downward leader is the most luminous of the sequence of strokes in each lightning discharge, since a huge amount of energy must be expended to overcome air resistance and ionize a channel. Because of the relative slowness and brilliance of the leader, lightning is perceived as traveling from the cloud to the earth, although the vast majority of energy is actually dissipated in the opposite direction with the return strokes. The direction of the return stroke is not visually perceived because of its tremendous speed and is recognized merely as an instantaneous brightening

87

or flickering of the ionized pathway. Lightning may vary in color, either from the excitation of nitrogen atoms in the atmosphere (radiant light energy released as a bluish or reddish afterglow), or because the particles of dust through which the lightning passes are high in ion or mineral content.

Diameter and Temperature of Lightning^[52] ^[114]

Many techniques could be used to measure the diameter or temperature of the lightning stroke. Unfortunately, all measurement techniques have artifact problems. Visual measurement of the stroke using standard photography usually shows the diameter of the main body of the stroke to be about 2 to 3 cm.

The diameter of the arc channel is sometimes measured indirectly, using measurements of holes and strips of damage that lightning produces when it hits aluminum airplane wings, buildings, or trees. Measurements vary from 0.003 to 8 cm, depending on the material destroyed, with hard metallic structures sustaining smaller punctures than do relatively softer objects, such as trees. The ionized sheath around the tip of the bright leader stroke has never been measured but is estimated to be 3 to 20 m (10 to 66 feet) in diameter.

The temperature of the lightning stroke varies with the diameter of the stroke and has been calculated to be about 8000° C (14,432° F). Others estimate the temperature to be as high as 50,000° C (90,032° F). In a few milliseconds the temperature falls to 2000° to 3000° C (3632° to 5432° F), that of a normal high-voltage electric arc.

Forms of Lightning

Lightning occurs in many forms. As described previously, the most common is streak lightning ([Figure 3-10](#)). Sheet lightning is a shapeless flash of light that represents lightning discharges within and between clouds. Sheet lightning may also be seen when lightning occurs over the horizon. Ribbon lightning is streak lightning driven by winds of the thunderstorm; the ionized air channel moves so rapidly across the earth that the successive secondary or return strokes seem to parallel one another. Bead lightning occurs when different areas of ionization and charge persist, lending a beadlike appearance to the afterstrokes. Another possible explanation of bead lightning may be

perception of the bright end-on appearance of portions of a very jagged stroke.

The most unusual, least understood, and least predictable type of lightning is ball lightning. Ball lightning is usually described as a softball-sized orange to white globe. It may enter a plane, ship, or house, travel down the hallway, injure some people and objects and not others that it encounters, and exit out another door, chimney, or window, explode with a loud bang, or exhibit other bizarre behavior. ^[9] ^[16]

Figure 3-10 Example of classic streak lightning.

Lightning may be either positive or negative in charge. Negative lightning is the more common. Positive lightning tends to occur during the winter, at the beginning of very violent thunderstorms, and with tornadoes, and may have a very different injury profile from negative lightning. Positive lightning may be more likely to occur when there is particulate matter in the air.

Thunder

Thunder is formed when shock waves result from the almost explosive expansion of air heated and ionized by the lightning stroke. ^[52] ^[114] The following are accepted statements:

1. Cloud-to-ground lightning flashes produce the loudest thunder.
2. Thunder is seldom heard over distances greater than 10 miles (16 km).
3. The time interval between the perception of lightning and the first sound of thunder can be used to estimate distance from the lightning stroke.
4. Atmospheric turbulence reduces audibility of the thunder.
5. The intensity of a pattern of thunder in one geographic location appears different from the pattern in another location.
6. The pitch of thunder deepens as the rumble persists.

The thunder clap from a lightning flash that is close by is heard as a sharp crack. Distant thunder rumbles as the sound waves are refracted and modified by the thunderstorm's turbulence. ^[114] Using the difference in speeds between light and sound gives an estimate of the distance to the lightning stroke. To obtain the approximate distance to the flash in miles, a person can take the difference in seconds between the perception

MECHANISMS OF INJURY BY LIGHTNING^[8] ^[9] ^[17] ^[34]

Lightning is directly dangerous for three reasons: electrical effects, heat production, and concussive force. In addition, lightning may injure indirectly via forest fires, house fires, and explosions or by felling objects such as trees onto occupied homes and automobiles. Only injuries directly caused by lightning are discussed here: direct hit, splash, contact, step voltage, blunt trauma,^[34] and the newly described upward streamer.^[1]

A direct strike is most likely to hit a person in the open who has been unable to find a safe location.

A more frequent cause of injury is a splash. Splash injuries occur when lightning that has hit a tree or building splashes onto a victim who may have found shelter nearby.^[53] The current, seeking the path of least resistance, may jump to a person whose body has less resistance than the tree or object that the lightning had initially contacted. There are multiple reports of side flashes indoors from metal objects, including plumbing and telephones.^[1A] ^[105] ^[110] Splashes may also occur from person to person when several people are standing close together. On occasion, splashes occur from a fence or other long conductive object that was hit by lightning some distance away. Groups of animals have been killed as they stood near a fence or sought shelter under trees.^[53]

Contact injury occurs when the person is holding onto an object that is either directly hit or splashed by lightning.

Step voltage, also called stride voltage or ground current, is produced when lightning hits the ground or an object nearby.^[10] The current spreads like a wave in a pond, diminishing as the radius from the strike increases. Contrary to the public's belief that the Earth's surface is a decent "ground" (a good absorber of electrical energy), in reality, it is an excellent resistor of electrical energy. As walking bags of saltwater, animals and humans often have less resistance than the ground. If a person has one foot closer to the strike and one foot further away, a large potential difference may exist between them. Often the current will pass up and through the lower resistance circuit made by the victim's legs and body rather than stay in the ground. Swimmers may also be affected by this mechanism as the current passes through them in the water. Four-legged animals with longer distances between their front and back legs are at even greater risk.

Although ground current is less likely to produce fatalities than are direct hits or splashes, multiple victims and injuries are frequent. Large groups have been injured on

baseball fields, at racetracks, while hiking, and during military maneuvers.^[16]

Persons may suffer blunt injury either by being close to the concussive force of the shock wave produced as lightning strikes nearby or if ground current or some other mechanism induces an opisthotonic contraction. Victims have been witnessed to have been thrown tens of yards by either mechanism. In addition, some have theorized that the person who is struck by lightning may suffer from explosive and implosive forces created by the thunderclap, with resulting contusions and pressure injuries, including tympanic membrane rupture.

Injury caused by being the conduit for an upward leader, even though it may not contact a downward leader to complete a lightning pathway, has recently been described.^[35A]

PATHOPHYSIOLOGY OF LIGHTNING INJURY*

It is necessary to distinguish between lightning and generator-produced high-voltage electrical injuries, since there are significant differences between the mechanisms of injuries and their treatment. Although lightning is an electrical phenomenon and is governed by the laws of physics, it accounts for a unique spectrum of induced diseases that are best understood relative to specific physical properties of lightning.

Kouwenhoven determined six factors that affect the type and severity of injury encountered with electrical accidents ([Box 3-1](#)): frequency, duration of exposure, voltage, amperage, resistance of the tissues, and pathway of the current. The factor that seems most important in distinguishing lightning from high-voltage electric injuries is the duration of exposure to the current.

Frequency

Lightning is neither a direct nor an alternating current. At best, lightning is a unidirectional massive current impulse. The cloud-to-ground impulse results from breakdown of a large electric field between cloud and ground, measured in millions of volts. Once connection is made with the ground, the voltage difference between cloud and ground disappears and a large current flows impulsively in a very short time. The study of massive electrical discharges of such short duration, particularly their effects on the human body, is not well

*References ^[7] ^[9] ^[30] ^[31] ^[34] ^[70] ^[76] ^[77] .

advanced. Lightning is said to be a "current" phenomenon rather than a "voltage" phenomenon.

Box 3-1. FACTORS AFFECTING SEVERITY OF ELECTRICAL BURNS

Frequency

Voltage

Amperage

Resistance

Pathway

Duration

Voltage, Amperage, and Resistance

Lightning, being a current phenomenon, is not easily considered in terms of Ohm's law ($V = I \times R$) and power calculation ($P = V \times I$) terms. Because the voltage between cloud and ground disappears after lightning attachment, examining the particular voltage in these equations becomes difficult. Thus we must resort to alternative formulations of the equations.

The energy dissipated in a given tissue is determined by the current flowing through the tissue and its resistance by:

$$\text{Energy (heat)} = \text{Current}^2 \times \text{Resistance} \times \text{Time}$$

where a current flows through a resistance for time t.

As resistance goes up, so does the heat generated by passage of the current. In humans when low energy levels are encountered, much of the electric energy may be dissipated by the skin, so that superficial burns are often not accompanied by internal injuries.

Although lightning occasionally creates discrete entry and exit wounds, these are rare. Lightning more commonly causes only superficial streaking burns. The exception to this is when "hot lightning," or long continuous current (LCC), occurs. LCC is a prolonged stroke lasting up to 0.5 second that delivers a tremendous amount of energy, capable of exploding trees, setting fires, and acting like high-voltage electricity to produce injuries. Other factors not understood may contribute to the formation of deep burns, although deep burns similar to those of high-voltage electric injuries generally are quite rare with lightning.

Pathway, Duration of Current, and Flashover Effect

It takes a finite amount of time for the skin to break down when exposed to heat or energy. Generally, lightning is not around long enough to cause this skin breakdown. Probably a large portion travels along the outside of the skin as "flashover."^[100] There is some experimental evidence that a portion of the current may enter the cranial orifices—eyes, ears, nose, and mouth.^{[2] [3] [7]} This pathway would help explain the myriad eye and ear symptoms that have been reported with lightning injury.

Andrews^[2] further examined the functional consequences of lightning on cardiorespiratory function and concluded that entry of current into cranial orifices leads to passage of current directly to the brainstem. In a sheep study, he was able to demonstrate specific damage to neurons at the floor of the fourth ventricle in the location of the medullary cardiorespiratory control centers. It is postulated that current travels from there caudad via cerebrospinal fluid (CSF) and blood vessel pathways to impinge directly on the myocardium. Andrews^[2] also showed histologic damage to the myocardium, consistent with a number of autopsy reports of inferior myocardial necrosis.^[6]

An alternative hypothesis can be tested with mathematical modeling.^{[2] [9]} Certain assumptions are made in any model, usually based on principles accepted in the literature.^{[11] [76]} [Figure 3-11, A](#), shows a model for skin resistance, and its connection to the internal body milieu is shown in [Figure 3-11, B](#). It will be noted that the internal body structures are regarded as purely resistive, whereas the skin contains significant elements of capacitance.^{[11] [76]}

The sequence of events during the strike started with the postulate that the stroke attached initially to the head of the victim. For a small fraction of time, current flowed internally as the skin capacitance elements became charged. At a voltage taken as 5 kV, the skin was assumed to break down. It is worth noting in the context of time scale that a lightning stroke is modeled as a current wave building to a maximum value in around 8 msec, although this may be "modulated lightning"—lightning that has passed through other structures, such as wiring. Others have measured the rise time of direct lightning as 1.2 to 1.5 msec. Once the internal current increased, the voltage across the body to earth built up, and external flashover across the body occurred when the field reached the breakdown strength of air.

The results of mathematical modeling of these events are shown in [Figure 3-12](#), and the relative magnitudes of the various voltage components can be seen with their time scale. On this time scale the times to breakdown are short and most events occur early in the course of the stroke. In summary, in this model, lightning applies a current to the human body. This current initially is transmitted internally, following which skin breaks down. Ultimately, external flashover occurs. Andrews^[2] draws support for this model from measurements made in the experimental application of lightning impulses to sheep. Further modeling of step voltage injury verified that for the erect human, this mechanism is less dangerous than is a direct strike.

Experimental evidence suggests that "a fast flashover appreciably diminishes the energy dissipation within the body and results in survival."^[100] In addition, Ishikawa obtained experimental results with rabbits similar to the human data found by Cooper's study.^[29] Cooper^[38] ^[39] has carried her studies to animals in developing an animal model of lightning injury and has successfully shown primary cardiac arrhythmias, prolonged ventilatory arrest, secondary cardiac arrest, keraunographic skin changes, and temporary lower extremity paralysis.

As current flashes over the outside of the body, it may vaporize moisture on the skin and blast apart

90

Figure 3-11 A, Electrical model for human skin impedance. **B**, Model of human body for the purposes of examination of currents flowing during lightning strike.

clothes and shoes, leaving the victim nearly naked, as noted by Hegner^[58] in 1917:

The clothing may not be affected in any way. It may be stripped or burned in part or entirely shredded to ribbons. Either warp or wool may be destroyed leaving the outer garments and the skin intact.... Metallic objects in or on the clothing are bent, broken, more or less fused or not affected. The shoes most constantly show the effects of the current. People are usually standing when struck, the current then enters or leaves the body through the feet. The shoes, especially when dry or only partially damp, interpose a substance of increased resistance. One or both shoes may be affected. They may be gently removed, or violently thrown many feet, be punctured or have a large hole torn in any part, shredded, split, reduced to lint or disappear entirely. The soles may disappear with or without the heels. Any of the foregoing may occur and the person not injured or only slightly shocked.

91

Figure 3-12 Model of human body adapted for the circumstance of direct lightning strike. Responses of the body model are shown for cases of direct strike with and without subsequent flashover.

The amount of damage to clothing or to the surface of the body is not an index to the severity of injuries sustained within a human. Either may be disproportionately great or small. However, in unwitnessed situations, the first author (MAC) and others have found that forensic evidence of damage to shoes and clothing may be the most important and reliable indicator in determining if lightning caused a person's death.^[72]

Behavior of Current in Tissue

High- or low-voltage electric current may be carried through tissue in a direct conduction fashion, obeying simple linear equations such as Ohm's law. The result is heating of tissues under Joule's law, with thermally induced cellular death and dysfunction. Simple passage of current may interfere with neural and muscular function.^[76]

Earlier in the previous century, electric injury was thought to occur not only because of thermal effects but

also because of some mysterious cellular effects.^{[10] [70]} Unfortunately, the technology was not available to investigate these effects and this idea was largely forgotten. In the last few years, the theory of electroporation has been proposed. Cell wall integrity, enzyme reactions, protein shape and structure, and cell membrane "gates" and pumps operate by changes on the order of microvolts. It is not beyond the realm of imagination that passage of an electric current too small to produce significant thermal damage still may cause irreversible changes in these functions, leading to cell death or dysfunction.^[76] Induction of electric charges by external electromagnetic fields has been shown to force water molecules into cell walls, causing the occurrence of fatal "pores."

Magnetic Field Effects

Some persons contend that the injurious effects of lightning can in part be magnetically mediated.^[24] The case cited in support of this contention was a golfer under a tree in company with three other persons. It was stated that death occurred without evidence of current entering or leaving the index case. On the other hand, one accompanying golfer showed evidence of current traversal but survived. It is stated that three methods of

shock exist—direct strike, side flash, and ground potential—but no evidence of any was seen. It was apparently considered that contact potential was not relevant, and this may have been historically so. In this case, with persons under a tree, it would seem possible to explain deleterious effects without resort to a magnetic hypothesis, but nonetheless the hypothesis bears examination, since it is a recurrent question.

In the case under consideration, the stroke was considered a line current 1 m distant from the victim, and calculation of peak fields and their effects were given. It is useful to consider the stroke as a single line current as referenced; however, we must also gain a feeling for how far from a victim such a stroke will act. If the stroke is close to a victim, then attachment to the victim will take place and electrical effects will apply. If further away, the magnetic field will be operative without attachment and magnetic effects need to be examined. Ground potential at this distance will also exist.

To determine the magnitude of this effect, it is necessary to find the minimum distance away from a victim that a stroke reaches ground without attachment to the victim, to give the worst-case distance from (that closest to) a victim at which pure magnetic field acts.

The standard striking distance formula gives such a distance. ^[42] The formula is:

$$d_s = 10I^{0.65}$$

where d_s (m) is the striking distance and I is the stroke current in kA. This represents the distance at the last turn of the downward stepped leader, such that if an object lies inside this distance, attachment of the leader to the object will take place.

For illustrative purposes, let a stroke have a peak current of 20,000 A. This gives d_s of 70.09 m (230 feet). Pure magnetic effects are applicable at this distance and beyond. Inside this distance, the victim will be subject to electrical current effects. By comparison, the ground potential between two points 1 m (3 feet) apart at 60 m (197 feet) from a stroke of 20 kA is about 60 volts, assuming earth resistivity of 100 ohm-meters.

In examining the magnetic fields involved at this distance, assume a 20 kA stroke at 70 m distance from an individual. The peak magnetic B field (the "magnetic induction," formally quantifying the force on a moving charge in its influence) is:

$$B = \mu_0 I / 2\pi d_s = 57 \times 10^{-6}$$

$$w/m^2 = 57 \mu T$$

For comparison, the earth's magnetic field is about 1 μT , and the magnetic fields causing concern for power line fields are around the 1 to 100 μT range. The magnetic fields used in magnetic resonance imaging (MRI) scanning are around 2,000,000 to 5,000,000 times these levels. Thus, if concern is realistically held for power line fields in terms of field level, then the field of a lightning stroke must be regarded as dangerous.

However, magnetic problems of the acute kind are not seen in this circumstance, and the major concern (if any exists) would only be in terms of chronic exposure. Similarly, if one is concerned about a lightning stroke magnetic field, he or she should be entirely concerned about MRI fields. Again, the concern is not seen in the same terms.

Certainly, the time varying nature of any B field is important, both in terms of the rate of change of the field and of movement of a conductor within this field. If one assumes that the above B field is generated in about 2 μsec , then the time rate of change for the B field is about 30 T/sec. Suppose this is applied to an aorta of cross section 8 cm^2 ($8 \times 10^{-4} \text{ m}^2$). Then the magnitude of the induced electric field in this region is approximately 0.024 V/m. If the resistivity of blood is taken as 1 ohm-meter, then the current induced in the aorta has density of 0.024 A/m². The corresponding current is therefore approximately 20 μA in the cross section under consideration. It is stated elsewhere that the blood vessels represent the most likely conducting medium in the body, and the most likely danger of arrhythmia exists in the current-passing media around the heart, the ventricle being of the same order in dimension as the aorta. This current in the aorta broadly approximates that within the ventricle.

This current is calculated under quite ideal circumstances, and if myocardial effects are to occur, then the current must penetrate into a tissue of considerably higher resistivity with good coupling. This is unlikely,

and the current in itself is of arguable danger in any case.

One therefore concludes that magnetic field danger in normal circumstances is slight. Certainly special circumstances might exist, such as the presence of a pacemaker or the presence of an arrhythmic pathway, but in normal terms, magnetic effects would not seem to be clinically significant during occurrences of lightning strike.

INJURIES FROM LIGHTNING

Severity of Injury

Some of the most common signs and symptoms are listed in [Box 3-2](#). Lightning is almost instantaneous in its action and seemingly unpredictable in its physical effects. Each case report of lightning injury has unique characteristics, and symptoms may vary from trivial to fatal. For prognostic purposes, victims generally can be placed in one of three groups.

Minor Injury.

These victims are awake and may report dysesthesia in the affected extremity from a lightning splash or, in more serious strokes, a feeling of having been hit on the head or having been in an explosion. They may or may not have perceived lightning or thunder. They often suffer confusion, amnesia, temporary deafness or blindness, or temporary unconsciousness at the scene.^[16] They seldom demonstrate cutaneous burns or paralysis but may complain of paresthesias, muscular pain, confusion, and amnesia lasting from hours to days. Victims may suffer tympanic membrane rupture from the explosive force of the lightning shock wave. Vital signs are usually stable, although occasional victims demonstrate transient mild hypertension. Recovery is usually gradual and may or may not be complete. Permanent neurocognitive damage may occur.

Box 3-2. LIGHTNING INJURIES

IMMEDIATE

Neurologic signs

Seizures

Deafness

Confusion, amnesia

Blindness

Contusion from shock wave

Chest pain, muscle aches

Tympanic membrane rupture

DELAYED

Dysesthesias, peripheral neuropathy

Neuropsychologic changes

Moderate Injury.

Moderately injured victims may be disoriented, combative, or comatose. They frequently exhibit motor paralysis, particularly of the lower extremities, with mottled skin and diminished or absent pulses. Nonpalpable peripheral pulses may indicate arterial spasm and sympathetic instability, which should be differentiated from hypotension. If true hypotension occurs and persists, the victim should be scrutinized for fractures and other signs of blunt injury. Spinal shock from cervical or other spinal fractures, although rare with lightning, also may account for hypotension.

Occasionally, victims have suffered temporary cardiopulmonary standstill, although it is seldom documented. Spontaneous recovery of the pulse is attributed to the heart's inherent automaticity. However, respiratory arrest that often occurs with lightning injury

may be prolonged and lead to secondary cardiac arrest from hypoxia or some other yet-to-be-elucidated cause. Seizures may also occur.

First- and second-degree burns not prominent on admission may evolve over the first several hours. Rarely, third-degree burns may occur. Tympanic membrane rupture should be anticipated^[44] and, along with hemotympanum, may indicate a basilar skull fracture.

Whereas the clinical condition often improves within the first few hours, victims are prone to have permanent sequelae, such as sleep disorders, irritability, difficulty with fine psychomotor functions, paresthesias, generalized weakness, sympathetic nervous system dysfunction, and sometimes posttraumatic stress syndrome. A few cases of atrophic spinal paralysis have been reported.

Severe Injury.

Victims with severe injury may be in cardiac arrest with either ventricular standstill or fibrillation when first examined. Cardiac resuscitation may not be successful if the victim has suffered a prolonged period of cardiac and central nervous system (CNS) ischemia. Direct brain damage may occur from the lightning strike or blast effect. Tympanic membrane rupture with hemotympanum and CSF otorrhea is common in this group.

Victims with other signs of blunt trauma are likely to have endured direct hits, although sometimes no burns are noted.

The prognosis is usually poor in the severely injured group because of direct lightning damage, often complicated by a delay in initiating cardiopulmonary resuscitation with resultant anoxic injury to the brain and other organ systems.

Differences between Injuries from High-Voltage Electricity and Lightning^{[9] [34]}

There are marked differences in injuries caused by high-voltage electric accidents and lightning ([Table 3-3](#)). Lightning contact with the body is almost instantaneous, often leading to flashover. Exposure to high-voltage

TABLE 3-3 -- Lightning Injuries

FACTOR	LIGHTNING	HIGH VOLTAGE
Energy level	30 million volts, 50,000 Å	Usually much lower
Time of exposure	Brief, instantaneous	Prolonged

Pathway	Flashover, orifice	Deep, internal
Burns	Superficial, minor	Deep, major injury
Cardiac	Primary and secondary arrest, asystole	Fibrillation
Renal	Rare myoglobinuria or hemoglobinuria	Myoglobinuric renal failure common
Fasciotomy	Rarely if ever necessary	Common, early, and extensive
Blunt injury	Explosive thunder effect	Falls, being thrown

generated electricity tends to be more prolonged because the victim often freezes to the circuit. With skin breakdown, electric energy surges through the tissues with little resistance to flow, causing massive internal thermal injury that sometimes necessitates major amputations. Myoglobin release may be pronounced, and renal failure may occur. In addition, compartment syndromes requiring fasciotomy may occur. This is not the case with lightning injuries, in which burns and deep injury are uncommon and fluid restriction and expectant care are usually the rule.

Cardiopulmonary Arrest

The most common cause of death in a lightning victim is cardiopulmonary arrest. In fact, a victim is highly unlikely ($p < .0001$) to die unless cardiopulmonary arrest is suffered as an immediate effect of the strike.^[29] In the past, nearly 75% of those who suffered cardiopulmonary arrest from lightning injuries died, many because cardiopulmonary resuscitation was not attempted.

Primary and secondary cardiac arrests had previously been hypothesized and were recently confirmed in animal studies.^{[2] [6] [7] [34] [113]} Injury first occurs with immediate asystolic cardiac arrest and respiratory standstill. Because of the heart's automaticity, an organized series of contractions generally resumes within a short time. Unfortunately, respiratory arrest caused by paralysis of the medullary respiratory center may last far longer than cardiac arrest. Unless the victim receives immediate ventilatory assistance, attendant hypoxia may induce arrhythmias and secondary cardiac arrest. Alternatively, the respiratory arrest and secondary cardiac arrest may be from more severe injury and not cause and effect.

The course has been verified experimentally in sheep, with initial asystole, followed by resumption of a short run of bradycardia, then tachycardia, followed by an eventual block or bradycardia, and finally with second asystolic arrest.^[2] [Figure 3-13](#) shows the result on respiratory rhythm of an impulse applied to the cranium of a sheep. Initial muscle spasm is seen, followed by cessation of natural rhythm. [Figure 3-14](#) shows the progress of myocardial activity of another sheep, from impulse through asystole to secondary arrest. Prolonged respiratory arrest has also been confirmed in hairless rats by the first author (unpublished report).

Both asystole and ventricular fibrillation^[3] have been reported with lightning strike. As

noted in the animal work, asystole seems to be both the first and last response to the strike, as the secondary arrest rhythm of ventricular fibrillation deteriorates.^[2] Premature ventricular contractions, ventricular tachycardia, and atrial fibrillation have been reported.^[79]

It is not uncommon to find electrocardiographic (ECG) ST changes consistent with ischemia and damage in subepicardial, posterior, inferior, or anterior patterns.^[6] ^[79] Creatine phosphokinase MB isoenzyme elevation has been reported. Documentation of troponin levels in lightning patients has not been published. Elevations of serum glutamic oxaloacetic transaminase and lactate dehydrogenase may reflect concomitant trauma to other tissues.

ECG changes may not occur until the second day, making the initial ECG a poor screening tool for ischemia. In addition, several authors stress that cardiac symptomatology may be inapparent on initial presentation. Premature ventricular contractions were reported to begin in one patient nearly 1 week after presentation. Whereas most ECG changes resolve within a few days, some may persist for months.^[10]

The QT interval may be prolonged following lightning strike.^[4] This has been verified in animal experiments ([Figure 3-15](#)) in which the ischemic form of the ECG complexes gave way to normalization of morphology, followed by prolongation of the QT interval at 270 seconds after lightning strike in sheep that did not suffer respiratory arrest. Another hypothesis is that QT prolongation may have implications for the cessation of metabolism hypothesis if torsades des pointes is involved.^[4]

Some authors have theorized that vascular spasm is a cause of cardiac damage.¹⁶¹ However, ECG changes are not always consistent with cardiac vascular supply patterns.^[83] Areas of focal cardiac necrosis have been reported

Figure 3-13 Respiratory activity tracing in sheep struck by laboratory-generated lightning. *Top*, Where respiratory arrest did not occur. *Bottom*, Where respiratory muscle spasm occurred followed by respiratory arrest.

in autopsies, and histologic changes have been shown in sheep hearts.^[2]

Pulmonary edema may accompany severe cardiac damage. Pulmonary contusion, with severe hemoptysis and pulmonary hemorrhage, may result from blunt injury or direct

lung damage.^[112]

Neurologic Injuries

Although cardiac arrest may be the only immediate cause of death, lightning is primarily a neurologic insult with damage possible to central, peripheral, and sympathetic nervous systems. Injury to the nervous system far and away causes the greatest number of long-term problems to survivors. Tools commonly used in evaluation and treatment include functional scans, such as single photon emission computed tomography (SPECT) (often positive); anatomic scans, such as computed tomography (CT) and MRI (usually negative); neuropsychologic assessment and tracking; cognitive retraining; pharmacotherapy as already mentioned; psychotherapy; and computed body tomography (CBT). Electroencephalography (EEG) is often mentioned in other literature but is of variable utility and may be normal.^{[6] [34]}

Central Nervous System Injury.

When current traverses the brain, there can be coagulation of brain substance, formation of epidural and subdural hematomas, paralysis of the respiratory center, and intraventricular hemorrhage. Autopsy findings include meningeal and parenchymal blood extravasation, petechiae, dural tears, scalp hematomas, and skull fractures. CT of the brain may show diffuse edema or intracranial hemorrhage but is more commonly normal.^{[20] [21] [22]} Direct brain damage from blunt head injury occurs in a limited number of victims, particularly those whose mental status deteriorates over time.^{[20] [22]} There have been reports of MRI findings in a few acutely injured victims.^[21] Unfortunately, for victims with more chronic complaints, CT and MRI examinations are usually unremarkable.^{[6] [34]} Transient elevation of creatine phosphokinase BB has been reported.

Direct cellular damage to the respiratory and cardiac centers in the fourth ventricle, as well as the anterior surface of the brainstem, has been shown in animals.^[2] If current enters through the orifices of the head, passes through the area of the pituitary and hypothalamus, and through the CSF into the retropharyngeal area, it is reasonable to expect signs and symptoms consistent with damage to these areas, including endocrine dysfunction, respiratory or cardiac arrest, and sleep disturbances.

Seizures may accompany initial cardiorespiratory arrest as a result of hypoxia or intracranial damage.

Figure 3-14 Cardiac response in sheep (nonstandard leads) subjected to laboratory-generated lightning strike. **A**, Baseline. **B**, Initial morphology change, followed by, **C** to **E**, normalization of morphology, **C** and **D**, tachycardia, **E** and **F**, bradycardia, and, **F**, hypoxic secondary arrest. A short period of asystole was initially seen before tracing **B**.

97

Figure 3-15 Electrocardiogram (nonstandard leads) for sheep struck by laboratory-generated lightning. Asystolic arrest did not occur. QT was prolonged by 270 seconds after the strike

These are usually transient but may continue for the first few days.

EEG changes may isolate an epileptogenic focus in the acute phase in many lightning victims. These patterns may be focal or diffuse, varying with the site and type of injury. Many patients do not experience seizures during hospitalization, and most usually have normalization of their EEG within a few months. Other victims, including children, develop delayed seizures, some of which present as "absence spells," memory losses, or blackouts that are often diagnosed as "pseudoseizures." One severely injured patient was reported to have continued seizures after discharge to a nursing home.^[95]

Obviously, if the victim has prolonged cardiopulmonary arrest, there may be anoxic brain injury that is not specific to lightning injury.

In Cooper's study^[29] of severely injured victims, nearly two thirds had some degree of lower extremity paralysis (keraunoparalysis), usually demarcating around the waist or pelvis. Almost one third of victims incur upper extremity paralysis.^[29] The affected extremities appear cold, clammy, mottled, insensate, and pulseless.^[9] This is the result of sympathetic instability and intense vascular spasm, which has been likened to Raynaud's phenomenon in appearance, and which usually clears after several hours.^[9]^[34] Fasciotomies are almost never indicated for lightning injuries, since any signs of compartment syndrome or distal ischemia usually clear with patient observation. Pulses can sometimes be elicited with a Doppler examination. Atrophic spinal paralysis has

been reported, as have persistent paresis, paresthesias, incoordination, delayed and acute cerebellar ataxia, hemiplegia, and aphasia. There is one report of quadriplegia developing 36 hours after injury and one of progressive muscle atrophy of the upper extremities.

Nearly 72% of the victims in Cooper's study suffered loss of consciousness,^[29] which may be an ominous sign, since nearly three fourths of these persons also suffered a cardiopulmonary arrest.^[29] Those with cranial burns are two to three times more likely to suffer immediate cardiopulmonary arrest and have a three to four times greater probability of death.^[29] Persons who are stunned or lose consciousness without cardiopulmonary arrest are highly unlikely to die,^[29] although they may still suffer serious sequelae.

Whether or not victims have suffered loss of consciousness, they almost universally demonstrate anterograde amnesia and confusion, which may last for several days. Retrograde amnesia is less common. Often, the victim appears to be well oriented and remembers his or her actions before the strike but may not be able to assimilate new experiences for several days, even when there is no external evidence of lightning burns on the head or neck. Victims often act like persons who have experienced electroconvulsive therapy.^[36]

Survivors may have persistent sleep disturbances, difficulty with fine mental and motor functions, dysesthesias, headaches, mood abnormalities, emotional lability, storm phobias, decreased exercise tolerance, and posttraumatic stress disorder.^[36] ^[110]

The basal ganglia and cerebellum may also be affected.^[21] ^[22] This agrees with older reports of localization. CNS damage may also eventually present as parkinsonism or an extrapyramidal syndrome, signs of intracranial hematoma and hemorrhage, infarction, hypoxia, edema, cerebellar signs of infarction, dysfunction and atrophy, and centrally derived pain and psychologic syndromes.^[19]

Peripheral Injury.

The peripheral nervous system is often affected. Pain and paresthesias are prominent features of the injury, particularly in the line of the current passage. It would seem that the majority of ongoing pain and dysfunction may be explained in peripheral terms. On the other hand, much of the ongoing psychologic disturbance may be seen in central terms.

There is some suspicion that the peripheral nerves may be preferentially injured because of their lower resistance to electricity, although this may be more important in electrical than lightning injuries.^[122] There may also be possible mechanical damage to the nerves from electroporation.^[76] ^[77] Certainly, damage is noted by threshold alteration in chronic injury, which although usually reversible, can become persistent.

Symptoms may be delayed by weeks to years. Paraesthesias are frequently seen, often

area of keraunoparalysis. There is also evidence of autonomic neuropathy.

Autonomic Dystrophy.

Chronic pain syndromes may occur. Autonomic dystrophy, also called sympathetic dystrophy or sympathetically mediated pain syndrome (SMPS), may occur. The victim may exhibit perfusion alterations in affected limbs, altered temperature control, and altered skin appearance and reactions, most commonly in the path of the current, although these may later extend to other areas of the body. Autonomic dystrophies may have associated pain and movement disorders.

Reflex sympathetic dystrophy (RSD), a deep peripheral nerve disorder caused by injury to nerve, is a long-term neural sequela to damage characterized by pain, edema, autonomic dysfunction, and movement disorder. Schwartzman^[108] and Hendler^[59] provide equally excellent reviews with good summaries and useful diagnostic testing protocols,^[6] although the diagnosis is primarily clinical.

Damage to injured nerves containing sympathetic components is likely to yield an "injury picture." A partial nerve injury presents as "causalgia." Causalgia does not follow complete nerve transection and requires some form of intact, while damaged, sympathetic function.

There are three stages of RSD. The diagnosis is clinical; certain aspects of the stages may overlap or never appear. Much of the pain in lightning injury fits variants of these patterns, and the autonomic component cannot be ignored. In the first stage, the condition is sympathetically maintained. The second stage becomes independent. The third stage can involve spread to initially uninjured tissue, as well as to contralateral areas. Early in its course (first stage), induced sympathetic blockade will be diagnostic and may effectively break the pain cycle. Testing with local anesthetic blockade or intravenous phentolamine can be used as a screening test. Cure can sometimes be effected at the early stage, and sympathectomy may be considered.

Clinically, stage 1 follows quickly after injury, sometimes in a matter of hours. Autonomic instability may precede the picture and continue through this stage. The pain is described as burning, diffuse, deep, and usually distal. It is exacerbated by movement, emotion, and dependency. There may also be hyperalgesia, allodynia, and hyperpathia. Adrenergic blockade can relieve the syndrome. This stage is also characterized by edema, nail and hair growth, and temperature change with or without hyperemia. The stage may last up to about 6 months after injury.

In stage 2 (the dystrophic stage), pain spreads and has significant psychologic overtones. Whereas stage 1 requires maintenance by the sympathetic nervous system,

stage 2 becomes independent of it. Edema becomes indurated, and cool hyperhidrosis is present. Cystic bone change may be seen, and hair and nail loss often develops. Cyanotic change may be seen secondary to autonomic vascular alterations.

In stage 3, pain spreads further and becomes dominant, with the pathologic changes of allodynia, hyperalgesia, and hyperpathia. Reversed plantar reflexes are seen, and small finger flexion is tight. Movement disorder is marked and often ascribed to hysteria. This stage includes initiation difficulty, weakness, spasms, tremor, and dystonia.

Posttraumatic Headache.^[30]

Many victims of lightning injury exhibit severe, unrelenting headaches for the first several months after lightning injury. The first author (MAC) has found acupuncture to be effective for at least some of the headaches. Many victims complain of nausea and unexpected, frequent vomiting spells early on in their recovery period. Dizziness and tinnitus are also common complaints, especially with telephone-transmitted lightning strikes.

Burns

Most people assume that, because of the tremendous energy discharge involved, a lightning victim will be flash cooked.^[16] ^[35] Fortunately, the flashover effect saves most victims from more than minor burns. Although extensive third- and fourth-degree burns may occur in combination with skeletal disruption, these are quite rare. Often there are no burns, especially with ground current effects.

As shown in mathematical models, a portion of the lightning current may travel through the tissues.^[2] If the electric field in the tissue becomes too large, electrons can be freed from their atoms. Referred to as *dielectric breakdown*,^[76] this can cause a large increase in the flow of current and become manifest as an electric arc. This may occur internal to the body or external to the body when the breakdown strength of air (2×10^6 V/m) is exceeded. Arclike burns can result. This happens more often with high-voltage electrical injury but may also occasionally occur with lightning.

Discrete entry and exit points are rare with lightning. The burns most commonly seen may be divided into five categories: linear burns; punctate, full-thickness burns; feathering or flowers; thermal burns from ignited clothing or heated metal; and combinations.

Linear burns ([Figure 3-16](#)) often begin at the victim's head and progress down the chest, where they split and continue down both legs. The burns generally are 1 to 4 cm wide and tend to follow areas of heavy sweat concentration, such as beneath breasts, down the midchest, and in the midaxillary line.^[9] ^[34] Linear burns are usually first- and second-degree burns that may be present initially or develop as late as several hours after the lightning strike. They are probably not primary lightning injuries but are steam burns secondary to vaporization of sweat or rainwater on the victim's skin.

Figure 3-16 Linear burns from lightning injury.

Punctate burns ([Figure 3-17](#)) are multiple, closely spaced, and discrete circular burns that individually range from a few millimeters to a centimeter in diameter. They may be full thickness and resemble cigarette burns but are usually too small to require grafting.

Feathering burns ([Figure 3-18](#)) are pathognomonic of lightning and known by such names as Lichtenberg's flowers, filigree burns, arborescent burns, ferning, and keraunographic markings. [53] [62] There are references to these markings in the Bible, where they were described to represent photographic imprints of vegetation surrounding the victim. These markings are not true burns but appear as usually transient pink to brownish, sometimes lightly palpable, arborescent marks that follow neither the vascular pattern nor the nerve pathways. The pattern found is similar to that on a photographic plate exposed to a strong electric field and has been compared to fractals. Sometimes the most superficial skin over the areas will slough or flake off after a few days. Although many pictures exist of these marks, they have never been described histologically. They may represent blood cells extravasated into the superficial layers of the skin from capillaries. At least experimentally, they follow the current lines seen in flash-over in Cooper's animal model. [38] [39]

On rare occasions, clothing is ignited by lightning, causing severe thermal burns. [9] [34] A victim wearing metal, such as a necklace or belt buckle, or carrying coins in his or her pocket may suffer second- and third-degree burns to adjacent skin as the objects become heated by the electric energy. [Figure 3-19](#) shows the burn resulting from a metal belt buckle or athletic supporter worn by a young man who was struck while playing softball.

Victims of lightning may exhibit a combination of burns.

One author has related the prognosis of the victim

Figure 3-17 Punctate burns from lightning injury. (Courtesy Art Kahn, M.D.)

Figure 3-19 Burn resulting from metal belt buckle or athletic supporter worn by a man struck by lightning.

to the location of the burns.^[29] Persons who suffer cranial burns are four times more likely to die than those who do not have cranial burns ($p < .25$). Victims with cranial burns are two and a half times more likely to have a cardiopulmonary arrest than those who do not

100

exhibit burns around the head and neck ($p < .025$).^[29] Persons with leg burns are five times more likely to die than those who have no leg burns, perhaps because of a ground current etiology ($p < .05$).^[29]

Blunt and Explosive Injuries

The recipient of a lightning strike may be injured directly from the explosive force of lightning or from a fall (as from a horse or mountain ledge, out of a vehicle, or being hurled by endogenous opisthotonic force). Lightning victims incur a variety of fractures, including skull, ribs, extremities, and spine. Rarely, a burst-like injury of soft tissue occurs and discloses extensive underlying injuries, especially in the feet, where boots or socks may come apart ([Figure 3-20](#)).

Hemoglobinuria and myoglobinuria are seldom reported. When they occur, they are usually transient. Myoglobinuric renal failure has not yet been reported, although one case has been verbally relayed to the first author.

Persistent hypotension should alert the physician to blunt injuries to the chest, spine,

lungs, heart, and intestines, which may lead to complications of prolonged coma, pulmonary contusions,^[112] heart failure, and ischemic bowel.

Several victims have complained of jaw pain. At least one was found to have a styloid process fracture. Many recovering victims believe that premature arthritis may be a result of their injury, although this has never been proven.

Figure 3-20 Socks blown off during explosive lightning stroke.

Eye Injuries*

Ocular injuries may occur in as many as 55% of persons struck by lightning and may be due to direct thermal or electrical damage, intense light, contusion from the shock wave, or combinations of these factors.

Although cataracts most commonly develop within the first few days, they may occur as late as 2 years after the strike and are often bilateral.^{[15] [43]} Whereas the cataracts may be the typical anterior midperipheral type, posterior subcapsular opacities and vacuolization seem to occur more often with lightning injuries.^[15] Corneal lesions, hyphema, uveitis, iridocyclitis, and vitreous hemorrhage occur with greater frequency than do choroidal rupture, chorioretinitis, retinal detachment, macular degeneration, and optic atrophy.^[15] Diplopia, loss of accommodation, and decreased color sense have also been reported.

Autonomic disturbances of the eye, including mydriasis, Horner's syndrome, anisocoria, and loss of light reflexes, may be transient or permanent. Transient bilateral blindness of unknown etiology is not uncommon. Intense photophobia may be present as the victim recovers.

Dilated or unreactive pupils should never be used as a prognostic sign or as a criterion for brain death in a lightning victim until all anatomic and functional lesions have been ruled out.^[18]

Ear Injuries^{[56] [94] [99] [105]}

Temporary deafness is not uncommon.^[71] It has been postulated that the intense noise and shock wave accompanying thunder may be responsible for sensorineural hearing loss. Newer work shows that entry of lightning current through cranial orifices could also account for some of the injuries.^{[2] [7]} Telephone-transmitted lightning strikes may also

account for otologic damage.^[1A] ^[6]

Between 30% and 50% of lightning victims have rupture of one or both tympanic membranes, which may be from the shock wave effect, concomitant basilar skull fracture, or direct burn damage because of current flow into this orifice. ^[29] CSF otorrhea or hemotympanum may occur. Disruption of the ossicles and mastoid has been reported. Many cases of permanent deafness are noted in older literature. Facial palsies, both acute and delayed, may occur from direct nerve damage by lightning. Nystagmus, vertigo, tinnitus, and ataxia may follow otologic damage.

Fetal Survival

The fetus of a pregnant woman who has been struck by lightning has an unpredictable prognosis.^[29] Of 11 cases reported, nearly one half of the pregnancies ended in full-term live births, with no recognizable abnormality in the child. Approximately one fourth resulted in live births with subsequent neonatal death; the remainder

*References ^[43] ^[54] ^[56] ^[57] ^[71] ^[97]

were stillbirths or deaths in utero. There has been one report of ruptured uterus after lightning strike.

Hematologic Abnormalities

Several unusual hematologic complications have been attributed to lightning injuries. These include disseminated intravascular coagulation, transiently positive Coombs' test, and Di Guglielmo's syndrome, a type of erythroleukemia characterized by erythroblastosis, thrombocytopenia, and hepatosplenomegaly. There have been anecdotal reports of increased hypersensitivity, development of allergies, and increased risk of cancer in lightning victims, perhaps indicating an immunologic component to lightning injury, although this has not been studied.

Endocrine and Sexual Dysfunction

One 32-year-old victim reported amenorrhea and premature menopause as a result of her injury. Others have reported menstrual irregularities lasting for 1 to 2 years. Impotence and decreased libido are common complaints. A report of male hypersexuality after a lightning strike has not been authenticated.

Psychologic Dysfunction

It is not uncommon for a person hit by lightning to rest at home for a few days, assuming that he or she is supposed to feel "bad" after being hit by lightning. The victim may not see a physician until family members insist or symptoms do not abate. Often,

the person will attempt to return to work after the injury, but because of decreased work tolerance, short-term memory problems, and difficulty assimilating new information, he or she will be unable to continue in the prestrike occupation. Neurocognitive deficits may not become apparent until a victim attempts skilled mental functions.

Although some medical authors were historically suspicious of victims' complaints of psychologic and neurocognitive dysfunction, evaluation of many such patients appears to have confirmed a vast commonality of psychologic symptomatology. This should begin to reverse a regrettable tendency, both medically and legally, to discount complaints as evidence of malingering, excessive reaction, conversion reaction, personality problems, or manifestations of "weak" coping strategies.

The syndrome is described first from a clinical viewpoint and then discussed in light of the extant literature.

The experience of the authors demonstrates the following components of the syndrome:
Functional Issues

1. *Memory disturbance.* Individuals show marked diminution of short-term memory ability. They require shopping lists and reminder lists. Memory for recent names and places is diminished to the point of disability. In consequence, individuals do not mix socially or go into new circumstances. Study becomes impossible, and retraining for new facets of employment is difficult.
2. *Concentration disturbance.* Individuals are unable to focus attention for more than a short period and are easily distracted. In particular, reading and understanding are poor. Job training is detrimentally affected. This is coupled with sleep disturbance, indicated below.
3. *Cognitive powers.* Individuals report diminished ability with mental agility. The keeping of accounts is a noteworthy example. Calculation and estimation become erratic and affect work performance. Ability at mental manipulation and problem solving is markedly decreased.
4. *Higher executive functioning.* Individuals are neither able to coordinate multiple tasks simultaneously nor to follow orders for complex tasks they used to perform easily before the injury. One victim described it as if "the office manager of my brain had quit."

Behavioral Issues

1. *Emotional lability and aggression.* Individuals find that they are more aggressive than before. They are liable to outbursts and uncontrolled displays of temper and are easily frustrated. They state they hurt the people who they love and who provide care for "no good reason." The strains on a partnership are significant, and marital and relationship dysfunction are common. An increased state of arousal and anxiety may further complicate distractibility, as well as the proper recognition and assimilation of new learning.
2. *Sleep disturbance.* Extreme fatigue, sleep disturbance, or hypersomnolence is common and may last for years. Flashbacks and nightmares may be experienced.

3. *Phobic behavior.* Avoidance of the precipitant circumstances is demonstrated, in some cases to phobic proportion tantamount to posttraumatic stress disorder.

Depression is almost always present in quite classical biologic form and should be anticipated. Although the above symptoms can certainly arise secondary to a depressive state, it would also be quite reasonable for a victim to react with depression to the decrements in work power and lifestyle engendered by chronic pain or decreased personal performance. A third reasonable possibility is concurrent neuropsychologic syndrome and biologic endogeneous depression. It is the view of the authors that the psychologic disturbance exists as an organic entity, and that part of that syndrome is also depressive as a primary organic entity. Both elements "feed" each other, compounding to a mixed picture.

Antidepressant medication is useful, reinforcing the view that a biologic component is present. Formal neuropsychologic

testing is used to attempt to establish the injury pattern and quantify a functional baseline. Very few studies have formally examined the syndrome.^{[102] [103] [115]} Primeau et al point to research difficulties, including sample bias and heterogeneity, methodology (cross-sectional rather than longitudinal or prospective), and the essential difficulties of determining premorbid status or current independent psychiatric status. It is also noted that the magnitude of insult does not correlate with psychologic disability. Duration, type, and severity of the syndrome are therefore unpredictable.

Disturbances of verbal memory, attention, concentration, and new learning are very frequently identified.^[102] This commonality among victims is noteworthy.

Primeau et al also draw attention to the similarity of some facets of the disorder and that in other etiologies. They generally find the head injury model a useful one that can guide treatment. Other syndromes of which the lightning and electrical injury syndrome shows similarities include PTSD. They also examine depression, anxiety, obsessional, and adjustment disorders. Features of these are seen to be present, although the disorder is not simply an example of these dysfunctions per se.

We have considered somatoform disorders as a cause, noting the tendency to be preoccupied with the injury and to overattribute subsequent symptoms to the lightning injury. This may be due, in part, to the general lack of knowledge by physicians of the problems and likely outcomes of the injury, so that victims do not know what to expect in the future.

Conversion reaction may also be considered, although it cannot account for the symptomatology of lightning and electrical disability. Good neuropsychologic testing can detect this facet. One difficulty with neurocognitive testing is the use and interpretation of the Minnesota Multiphasic Personality Inventory (MMPI), which, although it was not

developed to characterize patients with chronic problems, has been applied to them, often resulting in erroneous conclusion of conversion reaction or preoccupation with physical complaints. It should be a surprise to no one that anyone who has chronic pain and neurologic injury hampering their normal preinjury activities will rank higher on the "preoccupation with physical complaints" and "conversion" scales than uninjured normal individuals.

Ultimately the authors conclude that a prototype of the disorder does not exist. It seems that a description, such as "postelectric shock syndrome," is warranted. Andrews et al^[5] recognized three postinjury syndromes and correlated these with the postinjury periods of 1 week, 1 week to 3 months, and 3 months to 3 years. Primeau et al^[102] add a fourth—those persons experiencing longer and perhaps lifetime dysfunction. ^[56]

The first 12 months after injury are crucial to recovery. It is in this period that the most recovery is seen, with possible mild improvement up to 3 years after injury. Beyond this time, chronic dysfunction may be assumed.

Van Zomeren et al^[115] provide one of the few thorough examinations of the syndrome in lightning-injured patients. Fatigue and energy loss were the main complaints; poor concentration, irritability, and emotional lability were other common themes. Impairment of memory, attention, and visual reaction times were documented. Depression and "convincing signs of PTSD" were seen. The syndrome was highly differentiable from normal ($p < .001$) and no parallel model was available for comparison. They stated that the lasting complaints and mild cognitive impairments could not be explained on the basis of anxiety reactions or depression. They summarized their findings under the heading of "vegetative dystonia."

RECOGNITION AND TREATMENT OF LIGHTNING INJURIES

Diagnosis

The diagnosis of lightning injury may be difficult. A history of a thunderstorm, witnesses who can report having seen the strike, and typical physical findings in the victim make diagnosis easier.

However, lightning can strike on a relatively sunny day, or thunder may not be appreciated. If the victim is struck while working alone in a field, the diagnosis may be initially confused with other entities ([Box 3-3](#)). In the past, persons have been suspected to have been the victims of assault because of the disarray of clothing and belongings.

A diligent historical effort and careful physical examination at the earliest opportunity may help determine the true cause. Any person found with linear burns and clothes exploded off should be treated as a victim of lightning strike. Feathering marks are pathognomonic of lightning strike and occur in no other type

of injury. Unfortunately, burns of any kind are not always present.

**Box 3-3. DIFFERENTIAL DIAGNOSIS
OF LIGHTNING INJURY**

Cerebrovascular accident
 Subarachnoid hemorrhage
 Intraventricular hemorrhage
 Stroke
Seizure disorder
Spinal cord injury
Closed head injury
Hypertensive encephalopathy
Cardiac arrhythmia
Myocardial infarction
Toxic ingestion (heavy metals)
Malingering, conversion reaction

Another sign/symptom complex that is diagnostic of lightning strike includes linear or punctate burns, tympanic membrane rupture, confusion, and outdoor location, whether or not there is history of a thunderstorm. Because there have been several cases of lightning sideflashes from indoor plumbing and telephones, the physician should suspect lightning strike in persons found confused and unconscious indoors after or during a thunderstorm.^{[1A] [5] [9] [34]}

Initial First Aid and Triage of Victims^{[9] [34]}

As in any other emergency, the first steps are the ABCs: airway, breathing, and circulation. If the victim has suffered a cardiac arrest, cardiopulmonary resuscitation should be started immediately and a rescue vehicle called for transportation.

If the strike occurs far from civilization and evacuation is improbable, the victim will probably die unless pulse and respirations resume spontaneously in a short period of time. The heart may resume activity but may slip into secondary arrest. It is unknown whether the secondary cardiac arrest is due to primary brain damage, hypoxia from

prolonged respiratory arrest, primary cardiac damage, or autonomic nervous system damage. If the rescuer is successful in obtaining a pulse with cardiopulmonary resuscitation, ventilation should be continued until spontaneous adequate respirations resume, the victim is pronounced dead, continued resuscitation is deemed unfeasible owing to rescuers' exhaustion, or there is danger to rescuers' survival.

When lightning strike involves multiple victims, resources and rescuers may not meet the demand and triage must be instituted. Normally the rules of triage in multiple-casualty situations dictate bypassing dead persons for those who are moderately or severely injured and can benefit from resuscitation efforts. However, "resuscitate the dead" is the rule in lightning incidents, since victims who show some return of consciousness or who have spontaneous breathing are already on the way to recovery. Survivors should be routinely stabilized and transported to the hospital for more thorough evaluation. In the field, the most vigorous attempts at cardiopulmonary resuscitation should be directed to the victims who appear to be dead because they may ultimately recover if properly resuscitated.

The probability that lightning victims can recover after prolonged cardiopulmonary resuscitation (several hours) is not high. Other than for a few anecdotal reports, there is no reason to believe that these victims will respond to prolonged efforts. If the victim has not regained a pulse after 20 to 30 minutes of resuscitation, the chances of recovery are slim and the rescuer should not feel guilty about stopping resuscitation. Often in a remote setting, the rescuer is emotionally tied to the victim by age and friendship and may tend to continue resuscitation past the point of futility. In pronouncing a victim dead, the rescuer must be sure that other problems, such as hypothermia, are not clouding the victim's response to resuscitation efforts.

Other stabilization procedures, including splinting of fractures, endotracheal intubation, spinal precautions, and institution of intravenous fluids and oxygen, should be accomplished whenever indicated and feasible before transport.

History and Physical Examination

An eyewitness report is helpful, since victims are often confused and amnesic. The history should include a description of the event and the victim's behavior following the strike.

Like any other trauma victim, the victim must be completely undressed to facilitate examination. Special note should be taken of the vital signs, temperature, and level of consciousness. Because many victims are struck during a thunderstorm, they may be wet and cold. Hypothermia should be anticipated and treated appropriately (see [Chapter 6](#)).

The awake patient should be assessed for orientation and short-term memory. A cursory mental status examination of the lightning victim may reveal good ability to carry on a "social conversation" that easily hides deficits in fine neurocognitive skills. It is easy to discover deficits when they are so severe that the victim cannot assimilate information, perseverates, or asks repetitive questions. Continuing confusion or a

deteriorating level of consciousness mandates CT of the head to rule out an intracranial injury.

Examination of the victim's eyes is essential to establish pupillary reactivity and ocular injury. Tympanic membrane rupture is an important indicator of lightning strike. Ossicular disruption may be one explanation for a victim's lack of appropriate response to verbal stimuli.

Although the pulmonary system may be affected by cardiac arrest, pulmonary edema, or adult respiratory distress syndrome, it is uncommon to witness these initially. The cardiovascular examination should include distal pulses in all extremities, appreciation of arrhythmias, and evaluation of cardiac damage, including isoenzymatic and ECG changes.

The victim's abdominal examination occasionally demonstrates absent bowel sounds, which suggests ileus or indicates acute traumatic injury, such as contusion of the liver, bowel, or spleen.

The examiner should document any skin changes. The victim's skin may show mottling, especially below the waist. Burns are not universally present or may take a period of hours to evolve. Notation of pulses, color, and movement and sensory examination of the victim's extremities are important.

The physical findings and mental state of minimally and moderately injured victims tend to change considerably over the first few hours; careful observation and documentation delineate the course so that therapy can be appropriate. The minimally injured victim can almost always be discharged to a responsible person or require only overnight observation, whereas the severely injured person may require intensive care with mechanical ventilation, antiarrhythmic medications, and invasive interventions and monitoring techniques.

Laboratory and X-ray Tests

Minimum laboratory examinations include complete blood cell count and urinalysis (including a test for myoglobin on fresh urine). Blood tests indicated for the more severely injured victim include electrolyte screen, blood urea nitrogen (BUN), and creatinine. Serial cardiac enzymes, isoenzyme tests, and troponin may be indicated in some cases. If the victim is to be placed on a ventilator, arterial blood gases will be necessary; if intracranial pressure monitoring is used, serum osmolality may be required.

An ECG is essential for all lightning victims and frequently shows QT prolongation, even

when otherwise normal.

Radiographs and other imaging studies may be obtained, depending on the presentation and history. Cervical spine imaging should occur if there is any evidence of cranial burns, contusions, loss of consciousness, or change in mentation that would make the physical examination unreliable, or if there are other historical considerations, such as a fall. The victim who is unconscious, confused, or has a deteriorating level of consciousness requires a CT or MRI scan of the brain to identify trauma or ischemic injury. X-ray studies to rule out fractures, dislocations, and other bony injuries are ordered as indicated.

Treatment

Fluid Therapy.

An intravenous lifeline is mandatory for the victim who shows unstable vital signs, unconsciousness, or disorientation. If the victim is hypotensive, fluid resuscitation with normal saline or Ringer's lactate solution is required, with the caution that significant cerebral edema may develop. Fluid restriction in normotensive or hypertensive victims is recommended because of this risk.

Arterial and/or central venous pressure monitoring may be indicated. Careful intake and output measurement is necessary in the severely injured patient and requires placement of an indwelling urinary catheter. Myoglobinuria is rare and usually transient, so that the mannitol diuresis, alkalization, and aggressive fluid loading used with high-voltage electric injuries are rarely necessary. However, if burns are severe and extensive, which is rarely the case, resuscitation such as is necessary for high-voltage electrical injuries may be required.

Fasciotomy.

The presence of keraunoparalysis, paralyzed and pulseless extremities seen with lightning injuries, should not be treated like similar-appearing traumatized extremities caused by high-voltage electric injury. Intense vascular spasm with lightning usually is caused by sympathetic instability. The victim's extremities should be treated expectantly.^[9] ^[34] ^[91] Steady improvement in the mottled, cool extremity, with return of pulses in a few hours, is the rule rather than the exception. Fasciotomies are rarely indicated unless the extremity shows no signs of recovery and raised intracompartmental tissue pressures are documented. Only one case necessitating fasciotomy has been reported as of this writing.

Antibiotics and Tetanus Prophylaxis.

Prophylactic antibiotics are not indicated. Standard therapy should follow culture and identification of pathogens. Exceptions to this rule include open extremity fracture or cranial fracture that violates the dura. In the latter situation, many neurosurgeons recommend antibiotic prophylaxis. Appropriate tetanus prophylaxis is mandatory if burns

or lacerations are present.

Cardiovascular Therapy.

Management of cardiac arrest is standard. In the victim who is not in a state of cardiac arrest, vasospasm may still make peripheral pulses difficult to palpate. Usually, femoral, brachial, or carotid pulses may be appreciated. A Doppler examination may be necessary to locate peripheral pulses and record blood pressure.

If a victim remains hypotensive on Doppler examination, fluid resuscitation may be necessary to establish adequate blood pressure and tissue perfusion. Causes of hypotension include major fractures, blood loss from abdominal or chest injuries, spinal shock, cardiogenic shock, and occasionally deep burns similar to high-voltage electric burns. As soon as an adequate central blood pressure is obtained, fluids should probably be restricted because of the high incidence of cranial injuries and cerebral edema.

The victim who is without spontaneous or adequate respirations should be mechanically ventilated until brain death is declared, he resumes adequate ventilation, or the physician and family decide to cease efforts.

All lightning victims, regardless of their condition, should have an ECG. Cardiac monitoring, serial isoenzyme, and troponin measurements are indicated if there is any sign of ischemia or arrhythmia or if the victim complains of chest pain. Injury patterns, as well as arrhythmias, have been reported.^[34] The indications for antiarrhythmic drugs and pressor agents are the same as for a suspected myocardial infarction.^[34]

Prolongation of the QT interval has been proposed, when part of a torsades des pointes phenomenon, as a possible explanation for the reports of suspended animation with recovery.^[4]

Transient hypertension may be so short-lived as to require no acute therapy. However, several cases of hypertension have occurred 12 to 72 hours after lightning strike and seemed to respond well to β -blockers and other antihypertensive medications. Use of newer antihypertensive agents with lightning injuries has not been reported but would probably be equally effective.

Central Nervous System Injury.*

Every lightning victim should have a complete neurologic examination. If there is a history of loss of consciousness or if the victim exhibits confusion, hospital admission is necessary. The victim with tympanic membrane rupture, cranial burns, or loss of consciousness, or who shows a decreasing level of consciousness, should undergo

cervical spine imaging, brain CT, and possibly brain MRI. Serial CT scans may be useful in assessing ventricular hemorrhage and edema.

In the victim with persistent loss of consciousness, slight hyperventilation may be useful to control cerebral edema. If there are no other contraindications, the head should be elevated.

Intracranial pressure monitoring may be a useful adjunct in persons with elevated intracranial pressure.^[78] Cerebral edema may be managed with mannitol, furosemide, fluid restriction, and other standard therapies.^[78] Although hypothermia was reported to contribute to complete recovery in one victim with prolonged cardiac arrest before resuscitation efforts, there is no firm evidence that this would benefit all victims.

Early seizures are probably due to anoxia. If there is evidence of CNS damage or if seizures continue after adequate oxygenation and perfusion have been restored, standard pharmacologic intervention with diazepam, phenytoin, or phenobarbital should be considered.

If paralysis does not improve, causes other than lightning, including blunt injury from a fall, may be responsible. In addition, spinal artery syndrome has been reported, perhaps caused by arterial spasm. A physical therapy program should be initiated before discharge. Unfortunately, in a number of patients, peripheral neuropathies develop with continuing dysesthesias and weakness. These may respond to chronic pain management techniques, including combinations of nonsteroidal antiinflammatory drugs, carbamazepine, and tricyclic antidepressants.^{[5] [9] [47] [110]}

In recent years, neuropsychologic deficits from lightning have become better appreciated.^{[36] [102] [103] [115]} Heightened anxiety states, hyperirritability, memory deficits, aphasia, sleep disturbance, posttraumatic stress disorder, and other evidence of brain damage should be assessed.^{[5] [47]} Some of these deficits are much like those suffered by victims of blunt head trauma. A rehabilitation program should be instituted early for these patients to return them to as functional a state as possible.

Often, the victim's family and co-workers have difficulty understanding the change in personality that affects many of these victims. Neuropsychologic testing with appropriate therapy may be necessary. Certain personality types may predispose victims to more pronounced neuropsychologic symptoms.

The feeling of isolation and change that victims sometimes experience may lead to depression, substance abuse, and thoughts of suicide. Because of unfamiliarity with lightning injuries and their sequelae, many physicians are ill equipped to manage long-term care of lightning victims, leading the victim and the family to become angry.

Referral to Support Groups and Other Information Sources.

Referral to Lightning Strike and Electric Shock Survivors International (LSESSI), a support group founded in the late 1980s, can be of substantial help to victims and

families. LSESSI is located at PO Box 1156, Jacksonville, NC 28541-1156, telephone 910346-4708, E-mail lightning@nternet.net, <http://lightningstrike.home.mindspring.com>. Some local chapters have been formed in areas with a high incidence of lightning strikes. Other useful websites are <http://www.uic.edu/labs/lightninginjury> and <http://www.thehub.com.au/~candy/rsch.htm>.

Burns.

Lightning burns may be apparent at the time of admission but more commonly develop within the first few hours. They are generally superficial, unlike high-voltage electrical burns, and seldom cause massive muscle destruction. Vigorous fluid therapy and mannitol diuresis are not indicated. The patient's urine should be tested for myoglobin, although it is infrequently seen. In the rare instance of myoglobinuria, intravenous mannitol and alkalization of the urine with bicarbonate may be used. Overhydration with resultant cerebral edema probably has killed more lightning victims than has myoglobinuric renal failure.

Lightning burns are generally so superficial that they do not require treatment with topical agents. In the unusual instance of deep injury, topical therapy should be standard. The findings that lightning burns are superficial and do not require active surgical intervention is reinforced by Matthews et al.^[91] Their paper provides a useful guide to the remote need for surgical intervention in lightning injury.

Eye Injuries.^[43] ^[99]

Visual acuity should be measured and the victim's eyes thoroughly examined. Cataracts are not uncommon. Eye injuries should be treated in

*References ^[9] ^[19] ^[21] ^[22] ^[23] ^[34] ^[78] ^[123] .

standard fashion and may require referral to an ophthalmologist. Dinakaran et al ^[43] report a case in which cataract can be ascribed to a telephone-transmitted lightning strike.

Ear Injuries.^[56] ^[94] ^[99]

Simple tympanic membrane rupture is usually handled conservatively with observation until the victim's tissues heal. Sensorineural damage to the auditory nerve and facial nerve palsies are not uncommon. Loss of hearing mandates otologic evaluation. Ossicular disruption or more severe damage may necessitate surgical repair. Otorrhea and hemotympanum are not uncommon and suggest basilar skull fracture. Complaints of pain around the angle of the victim's jaw should lead the physician to a search for occult fracture of the styloid process and other musculoskeletal damage. Gordon et al^[54] hypothesize that the injury must include components other than blast and consider

burns the most likely. The present authors concur and cite the possibility of the cranial orifices being portals of entry for current.^[3] Mora-Magana et al^[93] provide a review of the otic effects of lightning.

Pregnant Victims.

If a pregnant woman is struck, fetal viability must be assessed, including fetal heart tones and ultrasonography to observe fetal activity. Fetal death is treated with evacuation of the uterus.

Other Considerations.

Gastric irritation is occasionally seen. Histamine-2 antagonists or antacid therapy may be indicated. A nasogastric tube is appropriate if ileus or hematemesis occurs. An abdominal CT scan may be indicated in comatose patients who remain hypotensive, since intestinal contusions and hemorrhage have been reported.

Endocrine dysfunction, perhaps as a result of pituitary or hypothalamic damage, including amenorrhea, impotence, and decreased libido, has occurred in some victims.

Pronouncing the Victim Dead.^[14] ^[18]

The question of when to declare a lightning victim dead has always been controversial. Dilated pupils should not be taken as a sign of brain death in the lightning victim. It is always necessary to exclude other causes of dysfunction and eliminate them before death is declared. Hypothermia with lightning injury is possible, so normothermia should first be established if possible. Charleton^[18] states that lightning injury carries a high survival, so persistence in resuscitation should be the norm. His notion seems sensible, but his statement has drawn substantial correspondence. Campbell-Hewson et al,^[14] for example, raise the notion that it is a falsehood to claim that resuscitation after prolonged arrest is more likely with lightning-induced arrest. We entirely agree with this and agree that the notion arose from one misreported case.

PRECAUTIONS FOR AVOIDING LIGHTNING INJURY^[37] ^[74] ^[96] ^[117]

A multidisciplinary group of internationally recognized lightning experts met and reviewed new safety guidelines, which, along with the names of the participants, are available at <http://www.uic.edu/labs/lightninginjury>. These guidelines are the first to address different size groups and evacuation times. Most lightning accidents are isolated events. It is impractical for the National Weather Service to warn of every potentially dangerous lightning event, so the key to safety is individual education and responsibility.

The exceptions to this are when adults are in charge of groups of children and for large planned events, such as professional sporting or entertainment events.^[96] In the former, the adult must assume responsibility for the children and have a plan for evacuation. A simple motto to teach children is, "If you see it, *flee* it; if you *hear* it, *clear* it."

Promoters of large events carry the responsibility to be aware of threatening weather, determine when events should be cancelled, and have a plan of action that includes proper warning, shelter guidelines, and all-clear signals.

Everyone should be aware of weather predictions and conditions before undertaking excursions or working in the open. If a person cannot avoid being outdoors, he or she should carry a small radio to monitor weather reports. Be prepared to seek a safe location if a severe thunderstorm watch or warning is announced. If bad weather is expected, someone should appoint a spotter whose duty it is to watch the weather and provide appropriate warning.

Based on new meteorologic data, the "30-30 rule" states that when the time between seeing lightning and hearing the thunder is 30 seconds or shorter (the first 30 of the 30-30 rule), persons are in danger and should be seeking shelter. Persons who have a long evacuation time, such as those on golf courses or who are responsible for many others, should use an even longer count. It is not uncommon for a portion of the sky to be blue when lightning hits, and at least 10% of lightning strikes occur with no rain at the site of the strike, so that people should not delay until the rain sets in. Lightning often hits more than one spot on the ground.

It is easy to underestimate the danger at the end of a storm. Outdoor activities should not be resumed until at least 30 minutes (the second 30 in the 30-30 rule) after the last lightning is seen or the last thunder heard. Although there is still risk after the 30 minutes, this measure offers about a 90% chance of safety from lightning injury.

If a storm strikes, seek safety in a substantial building or in an all-metal vehicle, such as

a car, but avoid convertibles. Small buildings, such as golf shelters, bus shelters, and rain shelters, may actually increase the person's

risk, depending on the size and height of the building, since side flashes can occur to the occupants. Tents offer little protection because the metal support poles actually may act as lightning rods. Occupants of the tents should stay as far away from the poles and wet cloth as possible. Ground pads seem to offer increased protection against ground potential but are not foolproof.

All-metal vehicles (not a cloth-top convertible or Jeep) provide a safe haven because the automobile will diffuse the current around the occupants to the ground. It is a myth that rubber tires provide insulation, but it is true that the metal body generally affords protection. Golf tournament promoters often place a number of rented school buses around the course for lightning protection. A series of minivans around a soccer field can provide the same type of safety to a more limited number of people. Another alternative is to assure access to public buildings where the playing fields are located. If a safe location is not available and a group of people is exposed, they should spread out and stay several yards apart, so that in the event of a strike, the fewest number is injured seriously by ground current and by side flashes between persons.

All of the recommendations of decisions about "safer places" that follow should not be necessary if you have taken the proper initial precautions: known the weather, had an evacuation-safety plan, and followed the plan. Those persons who are "caught" by a storm have usually not used appropriate prudence and have already made too many bad decisions to remedy in any substantial way with the following advice.

Stay away from metal objects, such as motorcycles, tractors, fences, and bicycles, and any that are taller than you. Avoid areas near power lines, pipelines, fences, ski lifts, and other structural steel fabrications. If you are wearing a backpack that protrudes above your head, increasing your height and risk, it may be worth the time to shed it, if only because you can run faster to a safer area. Otherwise, throwing off metal wastes time and is useless because it is a myth that wearing metal attracts lightning.

If you are unable to find a safe location, do not stand near tall, isolated trees, on hilltops, or at a lookout or other exposed area. In a forest, seek a low area under a thick growth of saplings or small trees. Seeking a clearing to avoid trees makes a person the tallest object in the clearing and more likely to be struck. Avoid cornstalks, haystacks, or other objects that project above the ground. Caves of substantial size, ditches, and valleys may provide some protection unless they are saturated with water, which may conduct current. Sheltering under a small outcropping or overhang may actually increase a person's risk of injury, since lightning energy that has hit a hill tends to flow through the heavy downpour and literally "drip" onto the person with the rain.

If you are totally in the open, stay far away from single trees to avoid lightning splashes.

The "lightning position," recommended by the Lightning Safety Group, requires squatting with both feet close together and the ears covered by the hands to avoid acoustic trauma. This position minimizes a person's height, the area touching the ground, and the possibility of ground current effect. However, it is difficult for anyone over 35 years of age to achieve this position or for anyone to hold it for more than a few minutes. It is our best educated guess without scientific evidence that it is also acceptable to kneel on the ground or sit cross-legged, positions that are both much easier to achieve and maintain, and that increase the ground contact only minimally. One of these positions also puts the person in the position of supplication to a Higher Authority for Divine Intervention, which is highly recommended by all of the authors at this point.

If indoors during a thunderstorm, avoid open doors and windows, fireplaces, and metal objects, such as pipes, sinks, radiators, and plug-in electrical appliances. Avoid using the telephone or computer. Clothesline poles and fences may act as lightning rods and transmit lightning along the line or wire.

If you are on the water, seek the shore. Avoid swimming, boating, or being the tallest object near a large, open body of water. Lightning will usually preferentially strike the metal masts or other objects projecting above the surface of the water and flows well through the water to injure swimmers, on the same principle as ground current injuries. Moving under a bridge or cliff while in the boat may provide some protection. Sailboats and powerboats should be protected with lightning rods and grounding equipment attached to a metal keel or understructure of the boat.

INDUSTRIAL ELECTRICAL INJURIES

Direct current (DC) causes only one third as much damage as alternating current (AC) of the same voltage and amperage. High-voltage commercial electricity usually alternates at about 60 cycles per second, just the right frequency to cause muscle tetany. Because the victim is often working with the electrical source, the hands are the most frequently injured part of the body. The tetanic force triggered by the electricity causes the hand to freeze to the circuit, since the flexors of the forearm are stronger than the extensors. The current also arcs across flexed joints, producing kissing burns at each flexion point, including the wrist, elbow, and axilla.

The presence of water or sweat on the skin can lower resistance as much as 25 to 100 times. When the resistance of the dermis is lowered by moisture or diminished thickness, the applied energy preferentially courses through the inside of the body via lower resistance tissues. As a result, high-voltage electrical burns are characterized by deep muscle, nerve, and vascular damage, with variable overlying skin damage.

Both entry and exit wounds are usually seen with high-voltage electrical injuries, with diffuse, unpredictable

damage occurring in between, similar to that of gunshot wounds.

**Box 3-4. PRECAUTIONS WHEN
WORKING WITH ELECTRICAL
EQUIPMENT**

Do not work on live apparatus unless absolutely necessary.

If dealing with live equipment is unavoidable, work only in company, using appropriate safety dress (gloves, clothing, mats, etc.) and tools.

Wear clothing that leaves the minimum of bare flesh exposed. Do not wear metal components, such as belt buckles, or open footwear.

Near electrical fires, use fire extinguishers designed specifically for that task.

Do not use metal tools, such as metal tapes and poles, particularly if they are long and flexible.

BEFORE BEGINNING WORK

Determine which switch or circuit breaker controls the item on which you will work.

Open the switch or circuit breaker, or remove the fuse.

Firmly affix **Danger** signs to advise against reconnection by another party.

Test the apparatus to ensure that it is deenergized.

Test the testing device on a live circuit, after using it on the circuit on which you will work.

If possible, short to earth (ground) the active conductors after deenergization.

after using it on the circuit on which you will work.

If possible, short to earth (ground) the active conductors after deenergization.

Once again, never work alone on electrical apparatus.

If, as often happens, the victim clasps the current source in his or her hand, the exposure becomes prolonged and the victim's skin breaks down, allowing the current to pass internally through the excellent electrolyte media of the blood and muscles. The external wound may appear fairly benign, hiding the extensive damage that may have occurred in deeper structures. After high-voltage injuries, fasciotomies may be needed to maintain the circulation and viability of distal structures. Extensive amputations are not infrequent with high-voltage electrical injuries. Fluid loading, mannitol diuresis, and alkalization may be necessary to prevent myoglobinuric renal failure.

PRECAUTIONS FOR AVOIDING ELECTRICAL INJURY

Protection against the effects of electric current appears easy. Prevention is better than cure, and contact with any conductor should be avoided at all costs, on the assumption that the conductor is live. In the wilderness, high-voltage transmission lines are more likely to be encountered, with attendant increased danger. All intentional contact with conductors should be avoided. Persons should not climb pylons, swing from lines, or otherwise touch power lines. Insulation of electrical lines is for the sole protection of the lines from the weather and should not be assumed to be adequate to protect living things that touch or grab the line.

Nonetheless, nonintentional contact with electrical conductors can occur. They may be hidden from view; insulation on normally touched apparatus may have been damaged or have aged; lines may have fallen; and any one of many other scenarios of accidental contact may occur. As a general principle, any item unidentifiable from a safe distance should be assumed harmful and not investigated until safety is ensured. This applies no less to electrical objects.

Persons working on electrical equipment should follow the procedures in [Box 3-4](#) .

Residual current devices (RCDs), also known as ground fault circuit interrupters, sense any difference between current entering and leaving the line to which they are connected. Any difference must represent current conducted to the earth, and the circuit is immediately deenergized on the assumption the leak may be through a person. Because roughly 80% of accidents occur in this way, the RCD's importance is notable. RCDs are now required by code in new installations, particularly domestic ones, but they may be absent in older construction.

Part 2 - Cold and Heat

112

Chapter 4 - Thermoregulation

Larry I. Crawshaw
Richard N. Rausch
Helen L. Wallace

A warm body has long been recognized as a primary condition for and sign of life. Faced with primitive circumstances, maintaining body temperature can require both ingenuity and physiologic knowledge. Three thousand years ago, an aged King David suffered hypothermia. Ministrations included covering him with clothes and finding a "fair damsel" to keep him warm. Unfortunately, these attempts to achieve a positive heat balance were unsuccessful.^[56] More recently, the efficacy of body-to-body contact was assessed quantitatively when immersion hypothermia "victims" were placed in a sleeping bag alone or with male or female "heat donors." Surprisingly, the "victims" who were supplied with "donors" exhibited a blunted shivering thermogenesis and rewarmed at a lower rate.^[40]

Because the thermal environment can be extremely complicated and the human thermoregulatory system is similarly complex and only partially understood, decisions about body temperature maintenance in the field can be difficult. This chapter is designed to aid the decision process by providing a basic understanding of the relationships among the ambient thermal environment, the body's thermal characteristics, and the thermoregulatory system. First, the heat balance equation is used to quantify the thermal relationship between the body and the environment. Second, peripheral neuronal inputs, the nature of the central regulator, and methods for assessing core temperature are elucidated. Third, the various organ systems that the body uses as effectors to regulate body temperature are outlined. Finally, a number of

special circumstances that affect temperature regulation are noted.

PHYSICAL FACTORS GOVERNING HEAT EXCHANGE—THE HEAT BALANCE EQUATION^{[23] [48] [86] [93] [108]}

The physical laws governing heat transfer determine the net energy flux into or out of the body. The heat balance equation is a convenient method for partitioning and quantifying the flow of energy between the environment and the body. A high rate of metabolic heat production is critical for maintaining a constant body temperature in mammals. This is represented by total heat production (H_{tot}) on the left side of the equation. For a person whose body is at thermal equilibrium,

$$H_{\text{tot}} = \pm H_d \pm H_c \pm H_r \pm H_e$$

where

H_{tot} = total metabolic heat production

H_d = conductive heat exchange

H_c = convective heat exchange

H_r = radiative heat exchange

H_e = evaporative heat exchange

H_{tot} is always positive, although the various channels of heat exchange can be positive or negative, depending on the situation. Positive values refer to net heat loss from the body. If the sum of the net heat exchange through the various channels exceeds H_{tot} , heat content of the body will decrease and mean body temperature will fall. On the other hand, if H_{tot} is greater than the net heat exchange, heat content of the body will increase and mean body temperature will rise.

Conductive Heat Exchange (H_d)

Heat transfer between objects in direct contact is termed *conduction*. The direction of heat flow is always from the higher to the lower temperature. Since conduction involves a direct interaction between molecules (contact), this type of heat transfer is minimal except under certain circumstances, such as sitting on a cold rock with little insulation. Under these conditions, the heat loss to the rock would be similar to that lost from the

remainder of the body surface by radiation and convection.^[85] The equation governing heat exchange by conduction is

$$H_d = \frac{kA(T_{sk} - T_a)}{1}$$

where

k = thermal conductivity

A = area of contact

T_{sk} = skin temperature

T_a = ambient temperature

1 = distance between the two surfaces

The thermal conductivity of a number of substances is given in [Table 4-1](#) . Note that water has 25 times the conductivity of air, but only one fifth that of granite. Muscle tissue has about twice the conductivity of fat. The conduction of heat through a tissue is termed *thermal diffusivity*. This expression is obtained by dividing the thermal conductivity by the product of the density and the

TABLE 4-1 -- Thermal Characteristics of Selected Substances

SUBSTANCE	CONDUCTIVITY (cal·s⁻¹·cm⁻¹·°C⁻¹)	SPECIFIC HEAT (cal·g⁻¹·°C⁻¹)	VOLUMETRIC HEAT CAPACITY (cal·l⁻¹·°C⁻¹)
Air	0.000057	0.24	0.29
Water	0.0014	1.0	1000
Granite	0.007	0.2	540
Muscle tissue	0.0011	0.8	850
Fat	0.00051	0.5	460

specific heat. The specific heat of various substances is also given in [Table 4-1](#) . Water and muscle tissue (mostly water) have particularly high values. Specific heats can be misleading, however, so the volumetric heat capacities are also listed in [Table 4-1](#) . Although the specific heat of water is four times that of air, it takes about 3500 times as much heat to raise the temperature of a given volume of water by 1° C (1.8° F) as it does to accomplish the same feat with a similar volume of air. For someone in the water, the consequence of these properties is that skin temperature is within 1° C of water temperature, and heat transfer to or from the environment is greatly facilitated. In cool water, during rest, skin blood flow will be minimized because of peripheral vasoconstriction. Heat loss will, importantly, be determined by the subcutaneous fat layer; an average-sized fat person (36% body fat by weight) will begin shivering at a water temperature of about 27° C (81° F), whereas a lean person (below 10% body fat) will start shivering at about 33° C (91° F).^[92]

Convective Heat Exchange (H_c)

Convection can be seen as a facilitation of conduction caused by the movement of molecules in a gas or liquid. This movement decreases the functional value of 1, the denominator in the conduction equation. Convection can be either forced or natural (free). Forced convection results from gas or liquid movement caused by the application of an external force, such as the movement of a fan or the pumping of a heart. Natural convection results from density changes that are produced by heating or cooling molecules adjacent to the body. These density changes cause the molecules to move with respect to the body surface. For humans, natural convection predominates at air speeds below 0.2 m sec⁻¹ , whereas forced convection is more important at air speeds above this level.^[86]

The relationships defining heat exchange as a result of convection can be complicated and depend on surface temperature profiles, surface shape, flow dynamics, density, conductivity, and specific heat. Any factor that impedes movement of the boundary layer (the molecules immediately adjacent to the body) greatly retards convective heat transfer.

Brengelmann and Brown^[8] have noted that under relatively neutral conditions ($T_a = 29^\circ$ C [84.2° F], wind velocity = 0.9 msec⁻¹), about 40% of the heat loss from a nude human is mediated by convection. Increases in air or fluid velocity greatly increase convective heat transfer.

Radiative Heat Exchange (H_r)

All objects at temperatures above absolute zero emit electromagnetic radiation. This

energy transfer occurs through space and does not require an intervening medium. In any given situation, the object is both transmitting and receiving infrared thermal radiation. In some cases, the object also receives solar radiation. The net heat transfer depends on the absolute temperatures, the nature of the surfaces involved, and solar input. Surfaces that are effective absorbers of radiation are also effective emitters of radiation. The idealized "black body" illustrates this property; such bodies absorb all and reflect none of the incident radiation. Conversely, poor absorbers (such as a polished silver surface) are also poor emitters. Heat transfer resulting from infrared (first-term) and solar (second-term) radiation is given by the following equations:

$$H_r = se_{sk} e_a (T_{sk}^4 - T_a^4) + a(1 + r)s$$

where

s = Stefan-Boltzmann proportionality constant

e_{sk} = emissivity of the skin

e_a = emissivity of the environment

T_{sk} = skin temperature (K)

T_a = ambient temperature (K)

a = absorptance

r = reflectance

s = solar radiation

For temperatures in the physiologic range, and where $(T_{sk} - T_a)$ is less than 20° C (36° F), several authors have

noted that infrared radiation heat exchange is roughly proportional to $T_{sk} - T_a$.^{[9] [108]} Also of note is that the spectrum of emitted radiation depends on the temperature of the object. At physiologic temperatures, the wavelengths of emitted radiation are longer (infrared), whereas at higher temperatures, like that of the sun's surface, the wavelengths are shorter (visible radiation) and can be detected by the human eye. This difference leads to some important consequences. The middle infrared radiation that is emitted by mammals is maximal regardless of skin pigmentation or the color of clothing. Solar radiation, however, peaks in the visible portion of the spectrum and is absorbed to a significantly greater extent by darker clothes or skin.

Incident radiation can vary drastically under different environmental conditions and may severely tax the body's ability to respond. Heat input from solar radiation on a cloudless day may exceed by several times the heat produced by basal metabolism; on a cloudless night there is a significant net loss of radiation to the sky. Under the relatively thermoneutral conditions noted earlier by Brengelmann and Brown,^[8] radiant heat loss accounted for about 45% of the total.

Evaporative Heat Exchange (H_e)

When water changes state, a large amount of energy is either absorbed or given off. Evaporation of 1 g of water at 35° C (95° F), the usual skin temperature of a person sweating,^[108] requires the input of 0.58 kcal of thermal energy. In a neutral thermal environment, sweating does not occur and evaporation accounts for only 15% of the total heat loss. Of this, slightly more than half is due to evaporation from the respiratory tract, with the remainder coming from water that passively diffuses through the skin and evaporates.^[8]

Although it is unusual, the evaporation term (H_e) of the heat balance equation can become negative (meaning that heat is being introduced into the body). This occurs during airway rewarming when water-saturated oxygen is introduced into the respiratory system at about 43° C (109° F). Since the victim's body is considerably colder than 43° C, water condenses in the airways. For every gram of liquid water that is formed, the body heat content increases by 0.58 kcal.

THERMOREGULATORY NETWORK

A regulatory system requires sensing the controlled variable, comparing it with an ideal value, and producing an appropriate output signal. In this section, the role of the nervous system in the maintenance of a stable body temperature is outlined.

Peripheral Thermal Sensors

The entire outer surface of the body is well supplied with sensitive thermoreceptive structures. Because one destination of information from these receptors is the sensory cortex, many properties of the receptors can be gleaned from direct experience. Afferent thermal information produces both hot and cold sensations and is particularly rate sensitive. In addition to cortical input that arrives via the medial lemniscus and ventrobasal thalamus, the brain receives a large amount of thermal information from pathways that synapse in the reticular area.^[13] Although cortical thermal input is part of the sensory information used to reconstruct the external thermal environment, reticular inputs are more important in behavioral and autonomic regulation of body temperature.^[27] This distinction was pointed out by Cabanac,^[17] who found that internal body temperature determined whether a particular surface temperature was perceived as pleasant or unpleasant. However, altered body temperature did not affect the discriminative (cortically mediated) aspects of the thermal stimulus; subjects had no problem correctly identifying the actual peripheral temperature. This study also confirms the intimate relationship between the thermoregulatory network and the pleasure-pain system.^[96]

Although the structure, location, and properties of peripheral thermoreceptors are well documented, the transduction mechanism is poorly understood. Thermal sensors are free nerve endings and are categorized as either warm or cold. Cold receptors are found immediately beneath the epidermis, whereas warm receptors are located slightly deeper in the dermis. The hallmark of both types of receptors is their extremely high rate sensitivity ([Figure 4-1](#)).^[51] Although the static firing rate of cold receptors is usually less than 10 impulses per second, firing rates are often an order of magnitude higher under conditions of rapid temperature change. Cold receptors are excited by cooling, inhibited by warming, and have static maxima at about 25° C (77° F). These receptors are active from about 10° to 40° C (50° to 104° F). Warm receptors are excited by warming, inhibited by cooling, and have static maxima above 40° C. They are active from about 30° to 45° C (86° to 113° F).^[50] Studies on the mechanism underlying peripheral cold sensitivity have implicated thermal effects on the electrogenic Na⁺ /K⁺ pump.^[6]

Psychophysical and physiologic studies indicate that thermal receptors are not uniformly distributed across the body surface and that there are far more cold receptors.^[50] Since

peripheral thermal input is intimately involved in the regulation of body temperature, which body site is heated or cooled can have a definite effect on the magnitude of the response produced. In one study, for example, cooling the forehead was more than three times as effective (per unit area) in decreasing ongoing sweating as was cooling the lower leg.^[26] A separate study evaluated regional trunk and appendage sensitivity to cooling by assessing the magnitude of the gasping response that occurs at the onset of immersion.

Figure 4-1 Impulses from a recording of peripheral neurons that includes a single warm fiber and a single cold fiber. In recording **A**, a shield was periodically placed in front of and then moved away from the skin site that was innervated by the warm fiber. The discharge stops immediately when the skin is shielded from the radiation source. In recording **B**, the shield was simultaneously placed in front of the skin site innervated by both the warm fiber and the cold fiber. This caused excitation of the cold fiber and inhibition of the warm fiber. (From Hensel H, Kenshalo DR: *J Physiol [Lond]* 204:99, 1969.)

In this case, exposing various parts of the body to 15° C (59° F) water indicated that the upper torso had the greatest cold receptor density or sensitivity, or both. The lower torso was somewhat less sensitive, with the arms and legs exhibiting similar but considerably lower sensitivity.^[16]

The extremes of the thermal spectrum are sensed by a separate set of receptors, the hot-pain and cold-pain endings.^[44] Evidence provided by intradermal and intravenous temperature profiles, as well as intravenous nerve block, indicates that cold-pain receptors may be the nociceptors of the cutaneous veins.^[70]

Central Thermal Sensors

Many sites within the body are capable of eliciting generalized thermoregulatory responses. Such areas include the abdominal viscera, spinal cord, hypothalamus, and lower portions of the brainstem.^[6]^[48] The genesis of input to the regulator resulting from heating or cooling these areas is poorly understood. Some of the effects may be due to modulation of synaptic connections, rather than stimulation of specific thermodetectors per se. Input from central detectors is not rate sensitive but is rather a direct reflection of the absolute temperature. The area with the highest thermal sensitivity, and that has received the greatest amount of experimental attention, is the preoptic nucleus-anterior hypothalamic area (PO/AH). Heating or cooling this portion of the brainstem elicits the entire array of autonomic and behavioral heat loss and heat gain responses, respectively.^[45] Neurons in this portion of the brain exhibit both warm sensitivity and cold sensitivity.^[6] Recent work on hypothalamic slice preparations using synaptic blockers has indicated that warm sensitivity may be an inherent property of some of the PO/AH

neurons, whereas cold sensitivity in this area of the brain requires synaptic input.^{[6] [28]} [Figure 4-2](#) illustrates the effect of temperature on firing rates of three representative types of hypothalamic neurons. The high level of temperature sensitivity shown by one of the cells (labeled C) is due to the temperature-dependent characteristic of the prepotential. Voltage clamp experiments indicate that the altered rate of depolarization is most likely due to an effect on hyperpolarizing (K^+) conductances.^[42] Work using hypothalamic slices has also established that about half of the thermosensitive neurons also respond to nonthermal stimuli, such as osmotic pressure, glucose concentration, or steroid hormone

116

Figure 4-2 Effect of temperature on intracellular activity of three different types of hypothalamic neurons. Each vertical column represents the same neuron at the three temperatures shown. **A**, Low-slope temperature-insensitive neuron; **B**, moderate-slope temperature-insensitive neuron; **C**, warm-sensitive neuron. The thermosensitivity in each case was 0.06 (**A**), 0.5 (**B**), and 1.1 impulses $s^{-1} \text{ } ^\circ C^{-1}$ (**C**). All three types of neurons displayed depolarizing prepotentials, and action potentials occurred when the prepotentials reached threshold. As exemplified in **C**, putative postsynaptic potentials (especially IPSPs) were often observed in all neuronal types. (From Griffin JD, Kaple ML, Chow AR, Boulant JA: *J Physiol* 492:231, 1996.)

Figure 4-3 The response of a warm-sensitive preoptic nucleus-anterior hypothalamic area neuron to changes in temperature, glucose concentration, and osmotic pressure. The large downward arrows indicate changes in the media bathing the neurons. (From Boulant JA, Silva NL: *Brain Res Bull* 20:871, 1988.)

concentration. Such neurons could form the basis for the interactions between homeostatic systems described subsequently. [Figure 4-3](#) illustrates the response of a warm-sensitive PO/AH neuron in a slice preparation. This cell is excited by increased temperature, low glucose, or increased osmotic pressure.^[7]

Regulator

The neuroanatomic structures that establish the regulated body temperature include portions of the spinal cord, lower brainstem, hypothalamus, and septum. The PO/AH and the caudal hypothalamus, in particular, are recognized as important integrating

areas.^[47] The PO/AH has been assigned a unique role as the center of central nervous thermosensitivity and thermointegration,^[45] but other sites are also involved. As noted by Blatteis,^[5]

Autonomic thermoregulatory functions may be attributed to brain areas outside of the PO/AH. These mechanisms appear to be subsidiary controls, may have their own (direct?) links to thermoeffectors, and are capable of operating independently of the PO/AH, although they normally may be influenced by it through ascending and/or descending connections. Thus, the role of the PO/AH in temperature regulation may be seen as not essential, but nevertheless pre-eminent in the control of appropriate, coordinated, and low-threshold thermoregulatory responses. In this role, it receives afferent information from thermosensitive regions throughout the body, and is connected with all the thermoeffectors.

117

Figure 4-4 A schematic diagram denoting a suggested neuronal network to account for thermoregulation. **A**, The peripheral inputs and the site of the preoptic nucleus-anterior hypothalamic area (PO/AH)—the rectangle. **B**, Neuronal connections in the PO/AH. **C**, The firing rates of the warm-sensitive (*W*) and cold-sensitive (*C*) PO/AH neurons at different body (brain) temperatures. Synapses not shown as inhibitory are assumed to be excitatory. Details about the functioning of this system are in the text. *AC*, Anterior commissure; *CC*, corpus callosum; *Cer*, cerebellum; *C*, relays input from peripheral cold receptor; *NRM*, nucleus raphe magnus; *OC*, optic chiasm; *Pit*, pituitary; *SR*, subceruleus region; *W*, relays input from peripheral warm receptor. (*Concepts and information for this figure from Boulant JA, Curras MC, Dean JB: Neurophysiological aspects of thermoregulation. In Wang LCH, editor: Advances in comparative and environmental physiology, vol 4, Berlin, 1989, Springer-Verlag; Brück K, Hinckel P: Thermoafferent networks and their adaptive modifications. In Schönbaum E, Lomax P, editors: Thermoregulation: physiology and biochemistry, New York, 1990, Pergamon Press; and Hammel HT: Annu Rev Physiol 30:641, 1968.*)

A model for the regulation of body temperature is depicted in [Figure 4-4](#). Such models have the advantage of clearly depicting how the regulatory system could work, but, as has been emphasized,^[125] they greatly oversimplify the complexity and dynamic balance of the elements of the system. Some of the many inputs to this system include those illustrated in [Figure 4-3](#) (glucose concentration and osmotic pressure), as well as factors covered later in this chapter (e.g., time of

118

day, hormone levels, pyrogen titer, and oxygen concentration in the blood).

The network in [Figure 4-4](#) is based on the work of Hammel^[45] but also incorporates other sources.^{[6] [13]} This system depends on input from peripheral warm and cold receptors and central thermodetectors. Input arising from cold-sensitive peripheral neurons impinges on cells that excite noradrenergic neurons in the subceruleus region projecting to cold-sensitive neurons in the PO/AH. Peripheral warm-sensitive neurons provide input to serotonergic cells in the nucleus raphe magnus, which project to warm-sensitive cells in the PO/AH. The warm-sensitive (*W* in [Figure 4-4](#)) and cold-sensitive (*C* in [Figure 4-4](#)) neurons of the PO/AH provide reciprocal innervation that forms the basis for the thermostat. In this scheme, central cold sensitivity is postulated to be derived from inhibitory input via inherently warm-sensitive PO/AH cells. The interconnections of these neurons are shown in [Figure 4-4, B](#).

The firing characteristics of the warm (*W*) and cold (*C*) cells are illustrated in [Figure 4-4, C](#). At 37° C (98.6° F), the firing rates of warm and cold cells are balanced and there is no net output to either the heat loss or the heat gain effectors. If internal temperature increases, the warm cells fire faster, and vasodilation, sweating, and seeking of a cool environment are stimulated. On the other hand, if the internal temperature falls below 37° C, cold cells predominate, and vasoconstriction, shivering, and seeking of a warm environment are stimulated.

Without the aforementioned peripheral input, body temperature would have to change considerably to create the error signal needed to compensate for varying ambient thermal conditions. This does not occur; core temperature remains remarkably constant under most climatic conditions. This is accomplished by incorporating information from the peripheral thermodetectors. As illustrated in [Figure 4-4, C](#), if an animal moves into a cold environment, peripheral cold receptors are stimulated and peripheral warm receptors are inhibited. This produces the altered firing rates shown by the *W'* and *C'* curves. Now, even though body temperature is still 37° C, hypothalamic cold cells are firing faster than hypothalamic warm cells. This leads to activation of the heat gain effectors. If the system is properly designed (it is), augmentation of vasoconstriction and metabolism is just sufficient to match increased heat loss caused by the new, cooler thermal environment. The reverse occurs when a warmer environment is encountered. Peripheral warm receptors are stimulated and peripheral cold receptors are inhibited; the greater firing rate of the hypothalamic warm cells initiates sweating and vasodilation even though body temperature remains at 37° C. In this way, the regulator can maintain a remarkably constant internal temperature despite wide variations in ambient temperature.

Assessing the System

Overall status of the thermoregulatory system is determined by measuring the core temperature. This can be done at a number of sites with several types of instruments (thermometers). In this section, the relative merits of locations and instruments are discussed, and an overview of the causes of altered body temperatures and the consequences of abnormally high and low tissue temperatures are given.

Monitoring Core Temperature.

A recent history of clinical thermometry is available,^[80] as are good overviews of the assessment of core temperature.^{[4] [20] [124]} Minimally invasive measurement sites include the axilla, oral cavity, rectum, tympanum, and forehead. There is no clear-cut best site to monitor; particular situations demand different techniques. Thermometers used clinically include mercury-in-glass, electronic, tympanic radiation, and liquid crystal thermometers. Whatever instrument is used should have an accuracy of $\pm 0.1^{\circ}\text{C}$ (0.18°F). The handheld electronic thermometer is a good choice for field emergencies.

MEASURING INSTRUMENTS.

Clinical mercury-in-glass thermometers are widely available and easily used, but they have a number of disadvantages. In some situations, breakage can pose a problem, and the equilibration time is at least 3 minutes. These thermometers read the maximum temperature. It is therefore important that they be shaken down fully, or a core temperature below the initial reading will be missed. In addition, the lowest reading on the typical clinical mercury-in-glass thermometer (34.5°C [94.1°F]) is insufficient when hypothermia is a possibility.^{[4] [78]} Although typically accurate when new, mercury thermometers may lose precision over time. In one evaluation, after 10 months, 24% of the thermometers failed to meet the accuracy standard referred to above.^[20]

The handheld electronic thermometer has replaced the mercury-in-glass thermometer in many applications. These instruments can use either thermistors or thermocouples as sensors, have the requisite degree of accuracy, and are very flexible in application. Although an equilibration time of 1 minute is specified for the typical probe, this is due largely to the need for a stiff casing for ease of insertion. Smaller probes are available that can equilibrate in seconds. The digital display of these instruments reduces errors, and the probes can be left in place for continuous monitoring. A quality instrument with a wide range of interchangeable probes is important. Even then, these devices are subject to the usual problems inherent with electronic instruments. A mercury thermometer for backup and calibration, an alternate probe, and a spare battery are essential.

Tympanic infrared radiometers are often used in hospital settings, but even in this relatively predictable

environment, controversy exists over their ability to accurately assess core temperature. These instruments monitor electromagnetic radiation emanating from the ear canal, and various manufacturers use different, complicated electronic circuitry to produce a temperature display. An advantage is that the reading takes only a few seconds.^[20] Questions still remain, however, about the overall accuracy of the measurement displayed. In a laboratory situation in which the auditory canal is plugged with a sponge

and the probe measures only radiation emanating from the tympanum, infrared tympanic thermometry provides an excellent estimate of the core temperature.^[115] In clinical settings, however, the results are less consistent. In one study, infrared tympanic thermometry produced core temperatures that were much more variable than rectal temperatures. Even after correcting for the higher rectal values (0.5° C [0.9° F]), tympanic measurements still inaccurately displayed one third of the temperatures above 37.7° C (99.° F). An extended training program did not significantly alter the accuracy of the readings.^[98]

In one instance, a child arriving at an emergency department presented with tachycardia and skin vasoconstriction. Separate tympanic infrared thermometers gave core temperatures of 36.4° and 37.6° C (97.5° and 99.7° F). The rectal temperature was determined to be 42.2° C (108° F).^[103] On the other hand, in a hospital setting with a trained operator and immobile patients, two brands of infrared tympanic thermometers produced readings that were closer to pulmonary artery readings than were those of the axilla or rectum.^[102]

The potential benefits of a continuous, easily applied core temperature monitor has led to repeated attempts to validate liquid-crystal thermometers, typically placed on the head or neck surface. Unfortunately, the temperature readings produced by this methodology are not reliable.^{[4] [80]} Since these measurements are compromised by thermoregulatory vascular changes associated with heat conservation and heat dissipation, as well by as changes in ambient temperature,^[58] they are particularly unsuited for field emergency measurements.

MEASUREMENT SITES.

Although the deep internal temperatures of normothermic humans are reasonably similar, no specific anatomic site represents *the* core temperature. The temperature at each location is a consequence of a combination of local metabolic rate, local perfusion rate, proximity to the outer shell, and proximity to other locations with differing rates of metabolism and perfusion. Nevertheless, because of the generally high overall rates of tissue perfusion in mammals, deep core temperatures rarely differ by more than 0.5° C (0.9° F). The temperature of the pulmonary artery is a good reference temperature for the overall status of the thermal core. At steady state, accepted sites for assessing core temperature differ in varying amounts from this temperature. Esophageal and tympanic temperatures are essentially the same as the temperature of the pulmonary artery,^[102]^[106] whereas rectal temperature averages about 0.4° C (0.7° F) higher and axillary and oral temperatures about 0.2° and 0.4° C (0.4° and 0.7° F) lower, respectively.^{[4] [78] [102]}

Although the esophageal temperature is somewhat difficult to obtain, this is the site most likely to accurately reflect the temperature of the pulmonary artery. Measurement at this location accurately follows changes in core temperature and is reasonably noninvasive. For placement, the probe is lubricated and a small amount of local anesthetic is applied. It is then passed via a nasal passage into the distal portion of the esophagus at the level of the heart. The probe can be moved up and down slightly to obtain the highest temperature. Although somewhat unpleasant for conscious persons, this procedure is routinely used in physiology experiments. Esophageal temperature is

transiently (30 sec) affected by swallowing.

Tympanic temperature as an estimation of core temperature has long been controversial. Since the tympanic membrane is highly vascular and supplied by branches of the external and internal carotid arteries, it should be an ideal site. Nevertheless, many studies have indicated that tympanic temperature is affected by ambient temperature and local facial cooling.^[106] The conditions under which these complications can be avoided have now been clarified. If (1) the ear canal is insulated, (2) the thermocouple is made of fine wire and insulated except at the active junction, and (3) the thermocouple is in direct contact with the tympanum (which causes the subject to "hear" a continuous low-pitched sound), then alterations in core temperature are detected more rapidly than by an esophageal probe, are not affected by facial skin temperature, and are otherwise identical to esophageal temperature.^[106] Very similar results were obtained when an insulated probe was used in conjunction with an optical sensor to detect infrared radiation from the tympanum.^[115] Whether the conditions met in these two carefully controlled studies can be duplicated in the field is doubtful.

In steady-state conditions, rectal temperature is a good index of core temperature. However, when the heat content of the body or of the internal thermal compartments is in flux, rectal temperature changes more slowly than temperatures measured in other commonly used sites.^[102] There is a thermal gradient along the rectum, so all measurements should be made at a standard depth; 4 cm is recommended.^[4] The higher temperatures recorded in this region may be due to a combination of low perfusion rates, digestive reactions, and bacterial activity, but there is no clear evidence in this regard.^[79]

Oral temperature is an excellent index of core temperature, provided the mouth is kept closed. The sublingual pocket is well perfused and responds quite

rapidly to alterations in core temperature. Mastication, smoking, fluid intake, and mouth breathing can affect sublingual temperature and should be avoided in the period immediately preceding measurement.^[4] ^[78] ^[79] Use of an electronic thermometer with a rapidly responding sensor will make this measurement considerably more accurate and rapid than when performed with a mercury-in-glass thermometer.

Although axillary temperature reflects core temperature, it has a number of negative characteristics and should be used only as a last resort. The axillary temperature is affected by local blood flow, as well as by thermal and nonthermal sweating.^[4] Changes in core temperature are slow to affect the axillary temperature, and there is high interpatient variability.^[102] This measurement, however, has proven particularly useful for assessing core temperature in infants.^[4] ^[79]

Heterothermy.

Core temperature, as assessed in the previous section, provides a good estimate of the temperature of critical internal organs. This temperature is vigorously defended by the body. At low temperatures, regional heterothermy resulting from peripheral vasoconstriction forms an important aspect of this defense, increasing insulation by decreasing skin temperature. This decreases the thermal gradient for heat loss from the skin to the environment. Thus, at cooler temperatures, there can be a large amount of tissue that is well below core temperature, and as a consequence, the overall heat content of the body is greatly decreased. A nude human resting at 35° C (95° F) or 20° C (68° F) will exhibit similar temperatures at various locations within the core. However, because of decreased temperatures in the outer shell, the same person resting at 20° C will have a total heat content that is about 200 kcal lower than the same person resting at 35° C.^[108] If the peripheral vessels were suddenly dilated, an immediate drop in core temperature of about 3.5° C (6.3° F) would result. In a hypothermic individual, the discrepancy between core and shell temperatures could be considerably greater. The temperature of the outer shell can be estimated by measuring skin temperature at a number of sites, with the sensor in contact with the skin on one side and insulated on the other.^[4] An equation has been developed to estimate the mean temperature of the body using measurements of ambient temperature, several skin temperatures, and core temperature.^[38] Although this approach is not feasible in the field, several measurements along the distal extremities give an estimate of outer shell cooling.

A different type of heterothermy may be present in hyperthermic humans. As the brain temperature reaches high levels, blood flow that is normally outward from the intracranium to the face via the ophthalmic vein is redirected and flows from the face inward.^[54] This results in the brain being cooler than the remainder of the core. Although brain cooling is clearly documented and accepted in many mammals,^[3] it remains controversial in humans.^{[10] [18]} Nevertheless, the head is an extremely important area for heat loss.^{[10] [18]} Thus, for hyperthermic patients, it is important to optimize the heat loss from that region and, when necessary, to augment cranial heat dissipation by fanning and moistening.

Reasons for Altered Core Temperature.

Various conditions can lead to an abnormal core temperature. Under some circumstances, the regulator may be defending an altered core temperature for reasons to be described. Alternatively, the thermal load posed by the environment or by heavy exercise may be too great for the capacity of the effectors. Finally, the regulator could be deranged as a result of substance abuse, extreme temperatures, side effects of prescription drugs, or other factors. When interpreting a particular core temperature, it is important to evaluate all of the above alternatives.

Consequences of Altered Body Temperatures.

When tissue temperatures change, there are immediate and important effects on metabolism, as well as on other physiologic mechanisms. With a 10° C (18° F) increase in temperature, the typical human tissue increases metabolism by a factor (the Q_{10}) of about 2.7. The metabolic rate of the entire organism (apart from thermoregulatory

responses) responds similarly. Within the normal range of body temperatures, higher temperatures favor speed at the expense of tissue resources, whereas lower temperatures conserve resources. Although both high and low temperature extremes pose a threat to humans, increased temperatures greatly accelerate the development of serious complications and pose a much more immediate danger. Although a deviation of about 2° C (3.6° F) above or below the normal core temperature is well tolerated by the various regulatory systems of the body, a discrepancy of about 3° C (5.4° F) begins to disrupt these systems, including those involved in temperature regulation. At this level of deviation, if there is no intervention, physiologic problems compound very rapidly.

EFFECTOR RESPONSES

This section examines the properties of the response systems that heat or cool the body according to the output demands of the regulator. These effectors are influenced both by the output of the thermoregulatory network and by the temperature of the effector organ itself. Since patients away from medical facilities often exhibit whole body or regional hyperthermia or hypothermia, both central outputs and local effects are relevant; these factors are discussed separately.

121

Vascular Adjustments

Excellent overviews on the role of the vasculature in coping with thermal stresses are available.^[41]^[62] One function of the circulatory system is to maintain a relatively homogeneous internal body temperature. Heat from metabolically active organs is convectively distributed to portions of the body where less heat is produced. More commonly appreciated are the alterations of blood flow patterns that increase or decrease the body's overall thermal conductivity during exposure to hot or cold environments, respectively. Some of these alterations in conductivity result from preferentially shunting peripheral blood flow superficial or deep to the subcutaneous fat layer. Indeed, fat has about half the tissue conductivity of muscle. Nevertheless, shunting of blood away from major portions of the body is at least as important in determining overall conductivity as is the conductive property of the tissue itself. For example, during immersion in cold water, muscle accounts for about 90% of the total tissue insulation of the forearm.^[30] Thus directing blood away from poorly insulated (more highly conductive) regions reduces heat loss and preserves core temperature.

In addition to capillaries, microcirculatory units contain arterioles, metarterioles, and arteriovenous anastomoses. Flow through all of these vessels is under the control of smooth muscle. The smooth muscle of precapillary sphincters is largely influenced by local factors, whereas the other vessels are well supplied with receptors that respond to both neuronal and endocrine inputs. Active vasoconstrictor and vasodilator systems are both present. The vasoconstrictor system acts primarily through α_1 and α_2 adrenoceptors,^[67] whereas the active vasodilator system appears to use both acetylcholine and nitric oxide. About 90% of the elevation in skin blood flow during heat stress is due to input from the active vasodilator system.^[66] Thermoregulatory skin blood flow can reach up to 8 L per minute and involve 60% of cardiac output.^[67]

Operation of the vasomotor effector system is affected by excessive exposure to ultraviolet B radiation. A moderate sunburn impairs the vasoconstrictor response to cold; an associated, uncontrolled increase in thermal conduction is still present 1 week after exposure, although the original erythema has disappeared.^[95]

Central Signal.

Vascular changes are bioenergetically the least costly thermoregulatory autonomic effector responses. Because of the vasomotor system's high sensitivity, ambient temperatures between the thresholds for sweating and shivering are often referred to as being in the zone of vasomotor regulation. If a particular vascular bed is kept at a relatively constant temperature, output from the central nervous regulator can be assessed. Under these conditions, in dogs, manipulations of hypothalamic temperature confirm a high level of vasomotor activity between the thresholds for the activation of panting and shivering.^[49] In humans, forearm blood flow increases rapidly as core temperature rises; a sixfold increase in blood flow can occur with a core temperature that has risen to only 38° C (100.4° F).^[121] Within the vasomotor zone (skin temperatures of 33° to 35° C [91.4° to 95° F]), core and skin temperatures linearly combine to control skin blood flow. Skin blood flow responds very accurately and rapidly to changes in skin temperature, which leads to a very stable core temperature.^[11]

Although most peripheral arterioles are well supplied with adrenergic receptors, output from the thermoregulatory centers is not homogeneously distributed. Extensive nervous inputs from the thermoregulatory centers occur only in the lips, ears, and distal extremities. Thus immersing the feet in cold water leads to marked vasoconstriction in the hands and forearms but not in the abdomen or upper arms.^[41]

Local Modulation.

Local temperature has a great effect on the vasomotor status of peripheral vessels, and in some cases it may be largely responsible for the observed thermal conductivities. Although heat is generally considered a vasodilator,^[41] this is true only for cutaneous vascular beds; many other vascular beds dilate when cooled.^[33] The specific response to cold shown by cutaneous vessels follows from the observed distribution and properties of the α -adrenergic vascular receptors. Although in most of the vasculature α_1 receptors predominate, in the superficial cutaneous areas α_2 receptors constitute a clear majority. The usual predominance of α_1 receptors is found in the deeper blood vessels. Local temperature affects α_2 and α_1 receptors in a reciprocal manner. Although cooling augments the response of α_2 receptors, it either inhibits or does not affect the response of α_1 receptors. Cooling the skin, then, not only constricts the superficial vessels but also concomitantly dilates many underlying vessels. The ensuing flow pattern increases tissue insulation and augments countercurrent exchange between incoming cool blood and outgoing warm blood.^{[33] [34]} Although initial work was done on canine vessels, subsequent studies using α -adrenergic agonists and antagonists have

demonstrated that a similar mechanism exists in human fingers.^[31] ^[36]

Evaporative Responses

At high workloads and at environmental temperatures approaching 37° C (98.6° F), the only way to maintain thermal balance is to augment evaporative cooling by mobilizing the eccrine sweat glands. This sympathetic, cholinergically innervated organ system is spread over the entire body surface but is more profuse in some areas than in others. High rates of sweating occur on the forehead, neck, anterior and posterior portions of the

trunk, and the dorsal surfaces of the hand and forearm. Low rates occur on the medial femoral regions, lateral trunk areas, palms, and soles.^[91] Sweat is secreted in these latter two areas in response to emotional but not thermal inputs.^[8] Sweat gland activity interacts with the regional vasculature; both cholinergic receptors on local vessels and metabolic products of active sweat glands increase blood flow in areas of active sweating.^[41]

Central Signal.

By controlling the local milieu at different skin sites, it has been possible to separate the central thermoregulatory drive to sweat glands from local effects on the glands themselves. The central thermoregulatory system provides proportional output that is influenced by both internal and whole body skin temperatures. Per degree increase above thermoneutral values, internal temperature is about 10 times as important as mean skin temperature in eliciting an output to the sweat glands.^[87] ^[89]

Local Modulation.

Local effects are important in determining the output of sweat glands. Temperature exerts a multiplicative effect on sweat secretion; the Q_{10} for this augmentation is about 3.70. Skin wetness also has an important local effect on sweat glands. The wetter the skin, the greater the suppression of sweating.^[88]

A moderate sunburn disrupts evaporative cooling. This effect is locally mediated and involves decreases in both the responsiveness and the capacity of the sweat glands.^[94]

Metabolic Responses

Heat is an inevitable by-product of the inefficiencies in the body's metabolic reactions. In oxidizing foodstuffs to carbon dioxide and water during adenosine triphosphate (ATP) production and transferring the ATP produced to the functional systems of the cells, about 75% of the original chemical potential energy appears as heat. Excepting that

energy excreted or used to perform physical work, the remaining 25% of the original energy is also converted to heat when ATP is used in the body's numerous metabolic reactions.^[109] Mammals, relative to poikilotherms such as reptiles or fish, use much more ATP to maintain ionic and electrochemical balance of the cells,^[117] as well as for many other functions. This leads to greatly increased metabolic heat production, which forms the basis for homeothermy. It also creates the need to maintain a substantial thermal gradient between the body and the environment to dissipate the high levels of heat that are produced.

An increased rate of metabolism above basal levels is critical for maintenance of body temperature in cold environments. Elevated heat production is derived largely from simultaneous rhythmic excitation of agonistic and antagonistic skeletal muscles (shivering), but other domains, such as the gastrointestinal tract or adipose tissue,^{[41] [116]} may be involved to some degree. There is evidence that both epinephrine and thyroid hormones are released in humans after cold exposure.^[37] Since these hormones augment overall tissue metabolism, they are components of the response to cold environments.

Central Signal.

Of the various thermoregulatory outputs, metabolism is the easiest to evaluate quantitatively. The most complete documentation is available for this response, and most models of the thermoregulatory system are based on this information. Experiments on medium-sized mammals have allowed separate thermal manipulation of various parts of the brain, body core, and skin. This work has made it clear that the thermoregulatory centers act as proportional controllers and that skin temperature provides a feedforward input to the system.^{[45] [60]} Thus greater decreases in either core or skin temperature, or both, below neutral values elicit proportionally larger compensatory increases in metabolism.

Evidence indicates that humans have a similar control system. In a summary of their data and of that collected previously, Hong and Nadel^[57] noted that the central output for shivering is augmented by an increased rate of skin cooling. They also concluded that a given decrease in core temperature elicits 10 to 20 times the metabolic response of an equivalent decrease in mean skin temperature. Exercise is not incompatible with shivering, but increased levels of exercise exert increasing degrees of suppression on the shivering response, possibly as a consequence of an increased arousal response.^[57]

Hypothyroid states are associated with impaired metabolic thermogenesis. It has recently been shown that hypothyroidism (in rats) leads to a decrease in regulated core temperature of about 1° C (1.8° F).^[123]

Local Modulation.

Although the central and local effects of decreased core temperature on shivering have not been directly partitioned, both inputs are important. Slight decreases in core temperature create large compensatory responses, as delineated previously. However, even moderate hypothermia decreases the metabolic response to cold, and at about

30° C (86° F), the shivering response is lost.^[9] This decrement must involve nervous system malfunction, since the muscles themselves are quite responsive below 30° C. For example, limb muscles and diaphragm muscles develop peak tensions that are not greatly affected by temperatures down to 25° C (77° F), and fatigue resistance is considerably increased at 25° C.^{[99] [110]}

Behavioral Responses

In most wilderness situations, various ambient temperatures are available, and external insulation is easily

123

adjusted. Under these conditions, the choice of thermal microenvironment and clothing provides a far higher gain than do any of the autonomic effector systems discussed previously. Whole body adjustments are achieved by all motile animals and are particularly well developed in vertebrates.^[24] In addition to moving the body, the somatic effectors are important for optimizing the autonomic responses to thermal stress. Thus spreading out the arms and legs during heat stress increases the surface area available for autonomic augmentation of conductive, convective, evaporative, and radiative heat losses.

Central Signal.

Available evidence indicates that behavioral responses are elicited by the thermoregulatory controller through outputs similar to those delivered to the autonomic effector organs.^{[24] [27]} Severe deviations of core temperature disrupt this system; when this occurs, the person no longer feels too hot or too cold and the desire to take corrective action is lost.

Local Modulation.

As with shivering, most problems involving behavioral temperature regulation probably emanate from disruption of the centrally generated output. The muscles used to move the body are fairly resistant to thermal incapacitation (see previous discussion), but if this occurs, a major disruption of the body's thermal defenses ensues.

IMPORTANT MODIFICATIONS OF THERMOREGULATORY RESPONSES

Core temperature measurements typically provide information about whether body temperature is within the range for optimal physiologic function. Monitoring body temperature also provides a significant diagnostic indicator for many pathologic conditions. Whether the goal is to stabilize or to monitor body temperature, it is necessary to understand the many conditions that affect both the regulated temperature and the effectiveness of the thermoregulatory system. In this section, these circumstances are elucidated.

Normal Variation in the Regulated Temperature and in the Ability to Maintain Body Temperature

The same body temperature can represent a different state of affairs even under regularly encountered circumstances. Some of these conditions are noted in the following paragraphs.

Level of Activity.

Activity normally leads to increases in body temperature. Unlike peripheral temperature, the level of activity does not appear to provide direct input to the regulator of body temperature. Rather, the magnitude of the error signal for increased heat dissipation is determined simply by the increase in body temperature.^[118] Thus someone exercising heavily (or having just exercised) in a neutral environment has an unusually high body temperature, whereas someone sleeping or resting quietly has a relatively low body temperature. At a given level of exercise, core temperature will plateau 30 to 40 minutes after the exercise is initiated; higher levels of exercise will result in higher plateau levels of core temperature. For someone working at 50% of their maximal aerobic capacity, the increase in core temperature will be about 1° C (1.8° F).^[92]

Circadian Changes.

Body temperature shows cyclic changes throughout the day. Some of this variation is due to the daily cycle of activity, as described previously. However, there also exists a circadian rhythm for the body temperature set point. This sinusoidal rhythm accounts for much of the observed variation in body temperature. In a study involving 700 observations on 148 healthy individuals, the daily mean oral reading was 36.8° C (98.2° F). However, this was only a midpoint; the mean early morning low was 36.4° C (97.6° F) and the mean late afternoon high was 36.9° C (98.4° F).^[81] These diurnal changes

definitely reflect alterations in the controller, since the body temperature thresholds for eliciting sweating and peripheral vasodilation are significantly lower in the early morning than in the afternoon or evening, while the sensitivities and maximal response levels remain unchanged.^[1] ^[2] Melatonin may be an important factor in the rhythm of body temperature; light exposure produces similar shifts in both temperature and melatonin rhythms,^[114] and artificial reductions in melatonin levels attenuate the circadian decline in body temperature.^[19] A thorough, current review of body temperature cycles is available.^[101]

Interindividual Differences.

Normally, there is surprisingly little interindividual variability in core body temperature. In the study involving 700 observations described earlier, 90% of the early morning values were between 36.0° and 37.1° C (96.9° and 98.9° F); corresponding values for the late afternoon were 36.3° and 37.4° C (97.4° and 99.4° F). Based on these interindividual differences, as well as the diurnal changes described above, it has been suggested that the upper limit for a normal oral temperature should be 37.2° C (98.9° F) in early morning, increase gradually to 37.8° C (99.9° F) by early afternoon, and remain at that level until the early evening.^[81] These values delineate the 99th percentile for body temperature observed during the respective time periods.

On the other hand, it is important to be aware that the normal body temperature of some individuals will fall outside of population norms. In one person we encountered, core temperature was consistently 35.5° to 36° C (95.9° to 96.8° F). He mentioned that on one occasion

he had felt chills and malaise but was told by his physician that his temperature of 37° C (98.6° F) was normal. It was not; for this person a core temperature of 37° C represented a febrile state. Many individuals with atypical body temperatures are aware of their condition; it is prudent to ask about this possibility.

Age.

The circadian rhythm of body temperature develops soon after birth. Although newborns display small-amplitude rhythms, the patterns are not circadian. Circadian rhythmicity begins to develop during the second and third weeks of life, and after progressive increases in amplitude, typical adult temperature rhythms are reached at 2 years of age.^[101] Under thermoneutral conditions, rectal temperatures for the elderly are similar to those of younger people, whereas oral and axillary temperatures are slightly lower.^[65]

Of the major regulatory systems, temperature regulation is unique in the extent to which effector organs are "borrowed" from other systems. This makes developmental assessments difficult, since functional changes may be secondary to changes in primary systems, such as skeletal muscles or blood vessels. Other difficulties, detailed by

Cooper,^[22] include inconsistencies between chronologic age and physiologic viability, and the increased incidence of interfering disease states and cerebral microinfarcts as aging progresses.

Thermoregulatory capacities of the young show progressive increases but are not fully developed until after puberty. Effectors more important to infants than adults include certain behavioral responses (call for help) and the ability to activate thermogenic brown adipose tissue. Although brown adipose tissue is of little consequence in adults, it may aid in the production of heat in infants; adults may have the capacity to develop brown adipose tissue if subjected to chronic cold stress.^[53] Shivering is not present in infants and develops fully only after several years as the nervous system matures. Metabolism in infants is increased to some degree by an increase in motor activity, which accompanies cold stress.^[69]

Sweating is present and effective in children, but increases in sweat gland output during puberty lead to the typical high capacity for evaporative heat loss present in adults.^[32] For the adult years, factors affecting the loss of body heat during cold stress have been investigated by using a multiple regression analysis to evaluate fitness, fatness, and age (from the twenties to the early fifties). Fitness has no effect, whereas fatness retards heat loss. Aging during this period is correlated with a progressive weakening of the vasoconstrictor response to cold.^[14]

Individuals in their late sixties and beyond have a definite decrease in thermoregulatory capacity. Sweating is lessened in response to passive heating,^[59] vascular responses to heating and cooling are significantly reduced,^[67]^[68] and a distinct shivering tremor is rarely observed.^[69]

Gender.

Although less work has been done on thermoregulation in females, evidence indicates that their thermoregulatory responses are qualitatively similar to those of males.^[43] Taken as a group, females have a number of physiologic and morphologic characteristics that produce subtle differences in the regulation of body temperature. Such attributes include smaller blood volume, lower hemoglobin concentration, smaller heart, smaller lean body mass, greater percent of subcutaneous and total body fat, greater surface area-to-mass ratio, higher set point for cutaneous vasodilation and sweating onset, greater resting vasoconstriction in hands and feet, geometrically thinner extremities, and cyclic hormonal changes.^[83]

When age, thermal acclimation, body size, maximal aerobic capacity, and relative workload are matched, thermoregulatory gender differences are negligible. Nevertheless, in situations such as those encountered in the U.S. Navy, men and women do not tend to be matched for such nonthermoregulatory factors, and different thermal exposure standards may be required for the genders.^[43]

The menstrual cycle, menopause, and pregnancy are all associated with important effects on the thermoregulatory system. Relative to the early follicular phase of the menstrual cycle, core temperature is typically 0.3° C (0.5° F) higher in the late follicular

phase and 0.7° C (1.3° F) higher in the luteal phase.^[74] Postmenopausal hot flashes are experienced by most women and involve increases in sweating, vasodilation, and heart rate. Heat and exercise may be particularly stressful during and after these episodes. The proximate mechanism appears to involve central noradrenergic activation.^[35] Some information about hormonal effects on thermoregulation has been gained by studying postmenopausal women undergoing hormone replacement therapy. Administered estrogen acts to lower the core temperature at which heat loss effector mechanisms are activated and results in a lowered core temperature. The addition of exogenous progestins blocks these effects.^[12]

During pregnancy, the thermoregulatory system is far more sensitive to the heat produced by continuous exercise. The effector responses are initiated sooner and are more vigorous, so that toward the end of pregnancy, the steady-state core temperature during exercise is about 1° C (1.8° F) lower than before conception. This adjustment is seen as an adaptation that reduces possible thermal stress on the embryo and fetus.^[21]

Induced Alterations of the Regulated Temperature

The optimal body temperature is not always the same. In certain conditions of stress or vulnerability, the regulated temperature of the body may be altered. This is often an adaptive response to a particular physiologic crisis. Some of these situations are delineated in the following

paragraphs. In such circumstances, altered body temperature may be beneficial and should not necessarily be manipulated until the underlying condition is improved.

Fever.

Increased body temperatures have been associated with illness for thousands of years. Based on the population data presented previously, febrile body temperatures for resting, young adults would include morning temperatures equal to or exceeding 37.3° C (99.2° F), increasing gradually to 37.8° C (100° F) for early afternoon and evening. Such elevated temperatures would need to reflect a regulated increase to be considered a true fever. Pathogens and cancers are the usual causes of such increases in regulated temperature but are not directly responsible for increased body temperature. Rather, they interact with components of the immune system, such as macrophages, T cells, monocytes, and Kupffer's cells, as well as with glial, epithelial, and many other types of cells. This interaction stimulates the cells to produce pyrogenic cytokines.^[81] Such cytokines include interleukin-1, interleukin-6, and macrophage inflammatory protein-1. Cytokines act on cells in the vicinity of the anterior hypothalamus, inducing them to release prostaglandin E₂, which leads to an increase in the regulated temperature.^[73] Important avenues by which cytokine-mediated pyrogenic signals reach the brain include peripheral inputs from the abdominal vagus nerve^[105] and central inputs via the subfornical organs.^[119] Aspirin and related drugs block fever by inhibiting

prostaglandin synthesis.^[73] Interleukin-1 and other cytokines have many effects in addition to causing fever. These include decreased appetite, hypoferrremia, activation of B and T lymphocytes, and increased slow-wave sleep.^[71]

The increase in body temperature during fever aids many immune functions: neutrophil migration, antibacterial chemical secretion, and interferon production. It has been suggested that the most important aspect of fever is to greatly increase the temperatures of the peripheral tissues via selection of a warmer microclimate, increased insulation, and postural changes. As temperatures increase from typical peripheral tissue temperatures (29° to 33° C [84.2° to 91.4° F]) to those approximating core temperature, activation, proliferation, and effector production in cells involved in cell-mediated and humoral immunity show temperature coefficients (calculated for a 10° C [18° F] interval) of 100 to 1000. In contrast, the temperature coefficients for the effectiveness of the newly created effectors themselves, as well as for antigen-nonspecific defense systems, are much lower—about 1.5 to 5.36.

The presence and beneficial effects of fever have been documented in a variety of cold- and warm-blooded vertebrates, and even in some invertebrates. Under most conditions it is probably not advisable to alleviate a fever. Obvious exceptions include malignant hyperthermia, particularly high fevers during pregnancy, and any situation in which weakness makes the thermally induced increase in metabolic demands dangerous.^[71] ^[72]

Alcohol, Anesthetics, and Toxins.

Increases in the blood concentrations of ethanol, anesthetics, and a number of toxic substances lead to substantial decreases in body temperature.^[25] ^[112] In many cases, this fall is due to a decrease in the regulated temperature. In the case of high concentrations of alcohol and certain toxins, the reduction appears to be an adaptive adjustment that promotes survival. These chemicals disrupt protein structures within the cell membrane, an effect that is counteracted by a lower temperature.^[25] Indeed, studies of mice have shown that decreased body temperature counteracts ethanol toxicity.^[82] However, the lower blood ethanol levels associated with moderate consumption in humans, although causing some increase in vasodilation, have minimal, inconsistent effects on thermal balance of the whole body.^[29] ^[63]

Excellent overviews of the effects of general anesthetics on perioperative thermoregulation are available.^[111] ^[113] In anesthetic doses, many of these substances (halothane, fentanyl-nitrous oxide, enflurane, and isoflurane) act in a similar manner. Heat loss thresholds are increased by about 1° C (1.8° F), and heat maintenance thresholds are lowered by approximately 2.5° C (4.5° F). Interestingly, in the typical clinical dose range, the gain (sensitivity) of the effector responses is nearly normal. In the conditions under which general anesthetics are normally administered, body temperature decreases significantly. An initial rapid drop is due to redistribution of heat; cool blood from the periphery lowers central core temperature. A second, slower decrease results from a fall in body heat content. Finally, a plateau is reached, either because heat production and heat loss are passively balanced or because heat maintenance thresholds are reached. During postanesthetic recovery, there is vigorous shivering. Cutaneous warming before and during anesthesia prevents development of

hypothermia and decreases the incidence of infectious complications.^{[75] [111]}

Severe Hypoxia and Endotoxin Shock.

When inspired oxygen concentration falls to 10% to 12%, a substantial decrease in the regulated temperature occurs. This reaction has been documented, using behavioral responses, in fish, amphibians, reptiles, and mammals.^{[39] [122]} For humans exercising in 28° C (82.4° F) water under eucapnic conditions, decreasing inspired oxygen to 12% lowers core temperature thresholds for vasoconstriction and shivering and increases the rate of core cooling by 33%.^[64] The value of the resultant lowered body temperature is clear: the affinity of hemoglobin for oxygen is increased and overall metabolic rate is decreased. The mechanism underlying the

change in the regulated temperature may involve differential sensitivities of central neurons; hypoxia specifically increases activity of the warm-sensitive neurons (denoted by *W* in [Figure 4-4](#)) in the PO/AH.^[120]

A somewhat similar regulated hypothermic response occurs when an animal is exposed to very high levels of pyrogens; the same response occurs under less extreme conditions in weak or malnourished animals. The lowered body temperature may serve to decrease the energetic costs of maintaining a high body temperature for a severely compromised animal.^[103]

Altered System Responsiveness

A number of situations alter responsiveness of the thermoregulatory system. An awareness of these conditions is important in assessing the thermoregulatory capabilities of a particular person and in determining possible causes for hyperthermia or hypothermia.

Thermal Acclimation.

Thermoregulation is affected by chronic exposure to very cold environments, as well as by chronic exercise in cool or warm environments. Such exercise in a cool environment greatly increases responsiveness of the sweat glands; if exercise is in the heat, the central temperature at which sweating is initiated is also lowered. The net consequence of these adjustments is that a heat- and exercise-acclimated individual can work at a given level with far less increase in core temperature.^[90] Exercise in humid heat appears to decrease resting core temperature in acclimated individuals.^[15] Physical training also increases skin blood flow at any given increase in core temperature.^[61] Increases in both core and skin temperatures contribute to various changes involved in heat acclimation.^[100]

Conversely, repeated exposure to very cold environments (for example, 80 30-minute sessions at 5° C [41° F]) decreases the metabolic response to a standard cold air test, often leading to lower internal temperatures in cold-acclimated individuals.^[52]

Competition with Other Homeostatic Systems.

In addition to a constant core temperature, the body has many other requirements. When certain of these other needs are not met, thermoregulatory response can be compromised. For heat production and heat conservation, an adequate energy supply, patent nervous system, and functional effector organs are critical. Hypoglycemia decreases the core temperature at which shivering is initiated while leaving the thresholds for sweating and vasodilation unaffected.^[97] For maintaining exercise performance and body temperature in a warm environment, body water status is critical.^{[84] [107]} It is common for a person working in the heat to lose 1 L of water per hour, and even when fluids are readily available, maintaining a euhydrated state may be difficult. For hypohydration during activity, each percent decrease in body weight leads to a core temperature increase of about 0.15° C (0.27° F). This decreased heat dissipation is mediated by two mechanisms. At a given core temperature, hypertonicity decreases the sweating response and hypovolemia reduces skin blood flow.^[107] Hyperhydration has no effect on thermoregulation during compensable exercise-heat stress.^[76] During uncompensable exercise-heat stress, hyperhydration slightly increases the time to exhaustion, but only by delaying hypohydration; thermoregulation is not affected.^[77]

Alcohol, Drugs, Anesthetics, and Toxins.

Although moderate doses of many substances elicit adaptive changes in the regulated body temperature, elevated doses impair or abolish both autonomic and behavioral aspects of thermoregulation. Body temperature then changes passively, depending on the thermal environment. This can be particularly dangerous when elevated levels of alcohol or similar substances are combined with heat stress. An impaired ability to dissipate heat is then combined with the enhanced toxicity of increased tissue temperature.

ACKNOWLEDGMENTS

During the preparation of this chapter, the first author was partially supported by NIAAA Grant P50-AA10760. Helpful suggestions were made by Dr. Stanley Hillman, Dr. Randy Zelik, and Mark Haffner. Jackie Parker, Kim-Dung Tran, and Mirella Henderson are thanked for their work on the manuscript.

Chapter 5 - Nonfreezing Cold Injuries

Murray P. Hamlet

Nonfreezing cold injuries have a military origin. Although they have probably always occurred in civilians as well, they have not been documented in that population in sufficient numbers or severity to warrant interest. Armies, however, have suffered extensive injuries with significant impact on specific battles and campaigns. Several armies have been decimated by cold, wet conditions. Because of this epidemiology, there is usually a flurry of interest in these injuries immediately after wars. The interest is short-lived, however, probably because little impact has been shown on treatment of the injury. Interest in prevention with new clothing and footwear also flourishes, but it takes another military campaign to prove if the effort was successful. As we become more of an outdoor population, there is a high likelihood that civilians will put themselves in threatening environments more often and for longer times. Two particular groups appear to be producing injuries consistently. One is snowmakers at recreational ski facilities, and the second is rafting crews. The term "river rot" from the rafting community clearly refers to a trench foot injury. This chapter touches on the history, epidemiology, pathophysiology, clinical treatment, and postinjury sequelae of nonfreezing cold injury. Although many references and other sources of information are old, their observations still have significant value in understanding the injuries.

EPIDEMIOLOGY

Production of nonfreezing cold injuries involves having cold, wet extremities for an extended period. Historically, most injuries have been produced at just above the freezing temperature of human tissue. The most challenging condition involves fluctuations of temperatures above and immediately below freezing with wet socks and boots. Standing or sitting for a prolonged period with stagnation of circulation in the extremities and tight, constrictive footwear are major contributing factors. Blunt trauma of marching on cold, wet feet also adds to the severity.

Wetness increases conductive heat loss. Wetness with maceration of skin may contribute to the severity of the injury, but in animal models the injury can be produced with dry, cold air. This probably does not occur in a natural situation. This is because in the military context, the soldier is often unable to do anything to get his or her feet or boots dry because of the combat setting and urgency of the battle. Even if he or she knows what to do, the soldier does not have the time or the ability to attain an appropriate remedy. When the battle is over and the victim has time to warm and dry the feet, they become hot, swollen, and extremely painful. If the extremities are repeatedly exposed to injurious cold, the damage is compounded.

PERNIO

The civilian setting (e.g., rafting, snowmaking, winter hiking) often involves consecutive days of wearing wet boot liners and socks from hiking in wet weather or having wet feet from water immersion in a boat or life raft. Long canoe outings and sea kayaking trips lend themselves to this injury. The duration of exposure is important in determining the potential severity. Between 3 and 6 hours of cold and moisture produce swelling and tenderness with little or no residual consequences. Subcutaneous vesicles may be present, with or without blue discoloration and tenderness. This is termed *chilblain*. Between 6 and 12 hours of exposure produces more lasting swelling with some pain and deep ache. There is often scaling and desquamation but no deep tissue damage. There may be deep tissue sensitivity to pressure and subsequent resistance to wearing boots or shoes for a few days. After 12 hours to 3 days of being cold and wet, there may be deep pain and thin, partial-thickness skin eschars that form on the dorsum of the hands and feet. The eschars will slough without scarring but create persistent pain. This condition is termed *pernio*. The acute nature of the symptomatology is an early warning for the long-term sequelae of pernio. Although healing appears to occur as the edema subsides and the plaques slough, the pain persists and there may be later symptoms of tingling, paresthesia, skin scaling, and edema, even from mild cold exposure. Walking may be difficult, and shoes may cause enough constant pain that the individual has to go shoeless most of the day. This injury is seen in schoolchildren with tight, cold, and wet footwear who repeatedly walk home in slush without caring for their feet. It is seen in mild cold settings, such as logging, snowmaking, and kayaking, where the feet are cold and wet and the acute symptoms do not provoke the individual to protect the feet. In a battle setting, soldiers are often unable to take care of their feet, and their footwear is often poor. Prisoners of war often have pernio or trench foot from forced marches in cold and wet conditions.

One histopathologic study of nine victims of pernio noted a unique lymphocytic vasculitis. Edema of the papillary dermis was a variable feature, as was perivascular lymphocytic infiltration (characteristic of systemic lupus erythematosus, erythema multiforme, or drug eruption). In all likelihood, trench foot and chilblains share a common pathophysiology that includes sympathetic instability and vascular hypersensitivity to cold, with microvascular stasis and thrombosis.

Prevention is paramount for this injury. Awareness of the threat and training on keeping the feet dry, changing socks, massaging feet, and emergency care are essential. Preexposure training and daily foot checks are essential. A few minutes of scrutiny can

prevent serious damage and decrease the likelihood of requiring medical assistance. Leaders in summer camps and outdoor training must be constantly aware of foot care.

The treatment for pernio is simply to dry and massage the feet. Active, gentle warming above 30° C (86° F) as for frostbite usually produces significant pain and discomfort. Elevation is helpful to treat edema. Nonsteroidal antiinflammatory medication may be beneficial empirically but has not been studied in a randomized, prospective manner. Pain on warming may not respond to narcotics. Ketorolac tromethamine (Toradol) might be used, but there is no reference for its success.^[10] Topical substances do not appear to have any beneficial effects, although an antiinflammatory topical may be tried.

Sequelae of Pernio

Pernio produces long-term sequelae of pain, numbness, and paresthesia even with mild cooling. On occasion, healing is followed by hyperpigmentation. The victim is prone to recurrences on lesser exposure. Pain from pressure may limit the victim to loose-fitting footwear. Some relief can be had by resting feet on a brushlike surface, such as Astroturf. Sandals that support on points or small knobs seem to give relief and promote gradual desensitization to pain and pressure in the feet.

TRENCH FOOT (IMMERSION FOOT)

An excellent historical review of nonfreezing cold injury was offered by T.J.R. Francis in 1984.^[5] The term *trench foot* derives from World War I, when troops would stand in water-filled trenches for days and acquire this injury, severely limiting available manpower. There are earlier descriptions of cold, wet injuries. Critchie^[3] found references in 1727 describing the injury in shipyard workers and explorers. There is little doubt that Napoleon's surgeon Baron Larrey's description of cold "conjulgation" involved many nonfreezing cold injuries along with true frostbite. In the Crimean War (1845–1855), when British troops were poorly equipped and deployed in winter and were wracked with dysentery, there were 1924 reported injuries. Regimental medical officer B. Hughes first described the three stages of trench foot, the tenets of drying and massaging the feet, and the notion that dry socks and rubber overboots were responsible for a significant decrease in injury. After Smith, Ritchie, and Dawson's experimental work and observation,^[12] there were general orders issued to commanders to take steps to prevent the injury. These procedures carried over to the British troops in World War II, where few nonfreezing cold injuries occurred. Unfortunately, the American army suffered 4560 cold injuries in 2 ½ months in 1943–1944. Significant medical research and description of nonfreezing cold injury was performed by Ungley.^{[14] [15] [16]} He first recognized the similarities between trench foot and immersion foot symptoms and pathology from individuals in life rafts immersed in water. These descriptions of the pathophysiology are still the most detailed and useful. Nonfreezing cold injury was rarely reported in the Korean War. Postwar interviews with veterans indicate a high incidence of frostbite and some trench foot. British exposure in the Falklands Campaign defined a significant number of injuries with no amputations, but which required dismissal of many soldiers from military service. The Argentines suffered 274 amputation injuries from trench foot.

When one looks at the circumstances that have produced large numbers of nonfreezing cold injury in military operations, it is easy to transfer them to the civilian wilderness medicine setting. Poorly trained, tired, frightened, and dehydrated soldiers with thin socks and tight-fitting boots who are deployed in a cold and wet environment are unable to maintain foot care because of the battle setting. After several days of exposure, they are able to rest in a warm tent and remove their boots, where they begin to manifest the first stages of trench foot. Civilians in an outdoor setting who are similarly cold, wet, exhausted, and dehydrated are unwilling or unable to take the time and effort to care for themselves. Many are unaware of the threat and simply go to bed with wet feet or continue to put on wet socks and boots day after day. Uninformed outdoors-persons are simply naïve about the role of wet feet in producing trench foot.

The linchpin to disaster in a cold, wet environment is a pair of tight-fitting boots. Wetness increases conductive heat loss caused by the footwear. The cold produces

peripheral constriction, and the tight boots add to tissue ischemia. Reduced blood flow from sympathetic nervous system-mediated vasoconstriction along with dehydration leads to sluggish or nonexistent blood flow to the foot. Tissue anoxia leads to cellular compromise and death.

At the cellular level, there appears to be a hierarchy of sensitivity, with neurons, muscle cells, and endothelial cells being the most susceptible. The ischemic injury

131

to different cell types determines eventual outcome. With damage to neurons and their axons, there is paresthesia, pain, and muscle atrophy. With damage to sympathetic nerves, the result is hyperhidrosis and cold sensitivity. With damage to muscle and fat cells, there is atrophy and replacement with fibrous connective tissue, along with cramping and muscle spasms. Bone injury leads to bone infarcts and lysis, effects similar to osteoporosis, and subsequent arthritic changes. If one understands the cellular pathology, it is easy to envision the etiology of postinjury sequelae.

SIGNS AND SYMPTOMS

Trench foot and immersion foot are essentially the same injury. Both are produced by long-term cooling of the extremities. Trench foot occurs from wearing wet boots and socks, whereas immersion foot involves immersion of the feet in water, such as in a life raft or boat. Water temperature associated with trench foot is often 0° to 10° C (32° to 50° F). The pathogenesis of the injuries appears to be the same, but trench foot may include the blunt trauma of marching, which adds to the severity of the injury. Also, immersion foot is generally a single experience, whereas trench foot often involves repeated injury to the feet.

These injuries are vasomotor in the sense that the end result combines with damage to small blood vessels, peripheral nerves, and adjacent dermal organs; sympathetic, motor, and sensory nerves are affected. Symptomatology reflects injury to these nerves and damage to sweat glands, blood vessels, nail beds, muscle, cartilage, and bone.

Prehyperemic Phase

When one observes the limb immediately after exposure, it appears blanched, yellowish-white, and cold to touch. "Cold and numb" are the most common descriptions of the prehyperemic phase. The distal vessels may be pulseless for some time after admission. The victim describes "walking on wooden limbs," "walking on wool," or "walking in someone else's feet." Balance is impaired, and there is a shuffling gait.

Hyperemic Phase

The hyperemic phase lasts 6 to 10 weeks. Shortly after warming, the feet become hot, painful, red, dry, and swollen ([Figure 5-1](#)). This often occurs before medical management. Pain can be excruciating and is described as a deep, burning ache with throbbing. Definitive medical care is often sought at this time. Approximately 7 to 10 days later, shooting or stabbing pains occur down the foot, across the arch, out to the toes, and up the limb. Victims cannot tolerate even light pressure on their feet, and the bedsheets must be tented to prevent touching them at night. Nerve damage is evident

Figure 5-1 Moderate trench foot. No amputation. (Courtesy M.P. Hamlet.)

Figure 5-2 Immersion injury from a life raft. Note pressure necrosis from the shoes. This severe injury resulted in the amputation of all toes but the great toe. (Courtesy M.P. Hamlet.)

by loss of sensation and motor control, tingling pain, and paresthesias. Paresthesias and alternating pain and numbness increase with warming and dependency of the limb. Throbbing, pulsatile pain may last for weeks. Vibratory sensation is also diminished or lost. Hyperhidrosis occurs from nerve damage and local injury to sweat glands.

Vascular injury is reflected in the reactivity of the vessels. If the limb is elevated, it blanches. When lowered, it becomes blue or deep purple-red. Swelling occurs rapidly when the limb is warmed. Blisters may form with clear fluid or be hemorrhagic, indicating more severe injury.

The skin thins, indurates, and scales. Circular ulcerations may be superficial or deep. Black eschar forms and later sloughs, leaving pink, sensitive skin. Nails slough ([Figure 5-2](#)) without pain and continue to do so intermittently for years. Distal gangrene may be dry and mummifying or, more consistently, moist and liquefied. This often requires early surgical debridement.

Muscle is damaged with loss of muscle mass and strength. Electromyography shows slowing, deep tendon reflexes are sluggish or absent, and deep pain often results from muscle activity. A wasting deformity ("hollowing") of the sole of the foot occurs from loss of intrinsic muscles. Bone lesions representing decalcification of phalanges and periarticular lysis and loss of joint integrity occur.

Posthyperemic Phase

Swelling, hyperhidrosis, alternating pain and numbness, Raynaud's phenomenon, and cold sensitivity comprise the postinjury picture. Muscle wasting causes weakness and cramping when the victim attempts to stand. Neurologic damage with loss of proprioception and motor control leads to gait abnormalities that can last a lifetime. Wasting of intrinsic muscles results in claw defects of the toes. Areas that were formerly

hot and painful now become cold and cold-sensitive. They show pallor and cyanosis and are slow to rewarm. Affected areas become hyperhidrotic, may become swollen, and may harbor shooting pains, as well as intermittent return of the dull ache.

PATHOGENESIS

Ungley^[15] wrote that this injury should be described as a "peripheral vasoneuropathy after chilling," which in consideration leads to a sound understanding of trench foot. Although there has been significant effort to define the pathogenesis, the precise cause remains somewhat elusive. Reviewing past research and pathology information leads to the possibility of trench foot being a reperfusion injury. Green^[6] wrote that there was little damage while tissue was cold and that injury occurred upon rewarming. He believed that as tissue warmed, there was a mismatch between the nutrients and oxygen delivered during a state of vasoconstriction and the increased metabolic demands of cells. If the limb was warmed slowly, then there was less symptomatology and less damage. However, Smith, Rickles, and Dawson^[12] and Blackwood^[4] believed that cold itself damaged different cell types, although they had difficulty differentiating the effects of ischemia from the direct effect of cold on these cells.

Nerve damage was first thought to occur to small A and C fibers because pain was the predominant feature. It was later found that large myelinated fibers were also damaged but not as early. Small peripheral nerve endings are perhaps the most sensitive, but a precise hierarchy of injury has not been defined. Hyaline degeneration, swelling and disruption of neurolemmal sheaths, and precipitation of neural proteins appear in all nerves to some degree, depending on the severity and duration of the insult. Damage to autonomic nerve fibers is extensive and equates with the symptomatology at different stages. During the hyperemic stage, there is redness, swelling, and pain, along with anhidrosis. This is replaced in the posthyperemic phase with cold sensitivity, hyperhidrosis, and cooling of the limb.^[4] Although some regeneration of partially damaged neurons is possible, this ability appears limited, and long-term neurologic symptomatology is common.

Fibrous connective tissue deposits in vessel walls render them less compliant or rigid. Fat cells in muscle appear to be damaged early. Muscle cells show degeneration, swelling, loss of structure, hyaline degeneration, and complete loss of internal material. Muscle cells shrink and become fibrotic and nonfunctional.

Skin atrophy and thinning occur, and dry, scaly patches develop. In abraded areas, such as the bottom of the foot, the skin thickens and cornifies with thick calluses. Skin on the upper part of the foot becomes thin, friable, and very sensitive to pressure. There are collagen deposits around damaged nerve endings, small blood vessels, and damaged sweat glands. Hyperhidrosis may be from damage to autonomic innervation or from the direct effect of cold. Nerve endings in the skin send mixed messages. Pain vs. numbness and hot vs. cold all emanate from skin late in the posthyperemic phase.

Blisters followed by ulceration and subsequent eschar formation indicate local ischemia. Dry, mummifying gangrene may form tight, shieldlike eschars over toes and metatarsal areas. Demarcation may take weeks, but early infection, liquefaction, fever, and elevated muscle enzymes call for surgical intervention.

CLINICAL EVALUATION

Early clinical evaluation does not alter initial management. An accurate history of the duration and severity of cold exposure is the essential starting point to estimate severity of the injury later. Late evaluations of cold sensitivity, thermal threshold analysis,^[10] and infrared thermography after mild cold exposure have proven to be most useful in defining severity of injury. They are particularly important in the determination of the degree of disability for compensation or for continued military assignment.

TREATMENT

Drying and slight elevation of the feet with passive rewarming from core heat are indicated. Cool fanning of the feet at 20° C (68° F) may help minimize pain. There is no "silver bullet" for treatment; free radical scavengers and cytokine-blocking agents have the most potential for future investigation. Pain relief is not effective because nonsteroidal antiinflammatory agents and narcotics do not alleviate the different kinds of pain produced.

133

Oakley^[10] described the use of amitriptyline (50 to 150 mg at night) as somewhat beneficial. Patients should not be allowed to traumatize their feet during the hyperemic and early posthyperemic phase. Walking can be so painful that patients will refuse even mild physical therapy. Other medications, such as nifedipine and thymoxamine, were at first thought to offer some relief but have not been proven effective.^[10] Later, the feet should be kept warm and dry with thick socks and loose-fitting shoes. Avoidance of cold exposure is essential to prevent painful episodes. The remainder of treatment is symptomatic and often fairly nonproductive.

SEQUELAE OF TRENCH FOOT

Although the acute injury is difficult, long-term sequelae are the real problems with nonfreezing cold injury. Relatively minor injuries often produce clinically significant problems years later. With minor injury, short-term pain and dysfunction can be expected for days to weeks until recovery. There is often persistent mild cold sensitivity, but this is minor and quite tolerable. Years later, paresthesias, Raynaud's syndrome, chronic fungal infections, swelling, and alternating pain and numbness develop. Gait changes from pain avoidance and loss of proprioception include widened stance, shortened stride, and shuffling gait. Hyperhidrosis leads to chronic paronychia fungal infections that are refractory to treatment. Thick, deformed nails require professional podiatry care.

The more severe the acute injury, the quicker and more intense the sequelae. Moderate to severe injury often leads to symptoms early after acute recovery. Scaling, ulceration, and nail loss occur intermittently throughout life with no apparent precipitating events. Injured individuals are extremely cold sensitive, often requiring changes in job or residence. A complete lifestyle change may be required to tolerate symptomatology.

Individuals with severe injuries (e.g., necrosis and amputation) are never symptom free. There is a long healing time for ulcerations and amputation stumps. During this time, severe symptoms often occur proximal to the amputation site. Muscle atrophy that occurs proximal to the injury site often limits joint motion and flexibility. Cramping is common. Deep muscle aching while standing or even sitting for extended periods is also common.

There is a psychologic component to this injury. Because treatment for relief of symptoms is not very productive, patients become frustrated. The changes in lifestyle are significant. Victims may become depressed and home-ridden. Alcohol abuse is not uncommon. Because other vascular and neurologic conditions affect the lower extremities with aging, the combination with cold injury sequelae is often confusing to the examining physician.

CRYOGLOBULINS

Cold-induced precipitation of serum proteins was first reported in a patient with multiple myeloma by Wintrobe and Buell.^[18] Subsequently, the term *cryoglobulin* was introduced to denote a group of serum proteins that have the common property of reversibly precipitating or gelling in the cold.^[8] The vast majority of cryoglobulins are either intact monoclonal immunoglobulins (IgGs) or immunoglobulin complexes (that is, mixed cryoglobulins) in which one component, usually IgM, is directed against IgG.^[7] Symptoms directly attributable to monoclonal cryoglobulins are quite variable and include cold intolerance with typical Raynaud's phenomenon, dependent purpura, cutaneous vasculitis with ulceration, retinal hemorrhages, coagulopathies, and cerebral thrombosis. In many cases, only inexact correlations exist among the concentration of the cryoglobulin, the temperature of cryoformation, and the presence of symptoms.^[7] Of clinical relevance is the composition of the cryoprecipitate. Since acral temperatures of 30° C (86° F) are present in the hands and feet,^[2] in vivo cryoprecipitation may directly contribute to impaired capillary blood flow in the extremities; this has been demonstrated by biomicroscopy of conjunctival and nail bed capillaries.^[11] In patients with monoclonal cryo IgM, the higher intrinsic viscosity of IgM compared with IgG is greatly amplified and attendant symptoms can often be directly related to hyperviscosity.^[7]

In a large clinical series, only two thirds of the patients had skin lesions or vasomotor attack at initial examination.^[2] Cold sensitivity was apparent in less than half of these patients. Less common early symptoms were renal failure, mucosal bleeding, visual disturbance, and abdominal pain. In cryoglobulinemia without severe symptoms and in the absence of an underlying disease requiring active treatment, the decisions for treatment and type of treatment are difficult. Primary treatment should be directed toward minimizing cold exposure. Cyproheptadine (Periactin) 4 mg three or four times daily for approximately 1 to 2 weeks is useful when urticaria occurs.^[17] This is probably due to its antihistamine and antikinin activity. Avoidance of prolonged standing is important in patients to prevent dependent purpura. With severe manifestations, plasmapheresis may be required for emergency treatment.

COLD URTICARIA

Cold urticaria is a fairly common form of physical urticaria.^[9] It is characterized by local or generalized wheals, either on continuous cold exposure or on rewarming of sites previously exposed to cold. Local symptoms include redness, itching, wheals, and edema in cold-exposed skin. Systemic symptoms include fatigue,

134

headache, dyspnea, tachycardia, and rare anaphylactic shock. Usually the diagnosis is made by an ice cube or ice water immersion test, in which a wheal reaction appears in the exposed skin within 20 minutes. Primary acquired cold urticaria is the most common form. It occurs at any age, has an equal male/female incidence, and tends to be self-limited, although it may become chronic. Secondary acquired cold urticaria is associated with an underlying disorder, such as cold agglutinins or paroxysmal hemoglobinuria. Familial cold urticaria is rare.

The cause of cold urticaria is unknown. It has been reported to be mediated by IgE and IgM and to involve the release of histamine or other inflammatory mediators.^{[9] [17] [18]} Avoidance of cold is not always effective in preventing cold urticaria, since the rate of cooling and not absolute temperature appears to be the principal stimulus. Desensitization may achieve only short-term benefit. Cyproheptadine has been the most successful drug, but doxepin, hydroxyzine, and ketotifen have also been shown to be effective.^{[9] [13] [17] [18]}

Chapter 6 - Accidental Hypothermia

Daniel F. Danzl

Although used for medical purposes for millennia, cold modalities were not scientifically evaluated until the eighteenth century. The hemostatic, analgesic, and therapeutic effects of cold on various conditions were well known. Biblical references cite truncal rewarming of King David by a damsel; various remedies were mentioned by Hippocrates, Aristotle, and Galen.^[214]

The effects of cold on human performance are perhaps best documented in military history. Frosty conditions have decided many battles.^[116] Most cold injuries encountered today affect the urban destitute and wilderness and sports enthusiasts, such as skiers, hunters, sailors, climbers, and swimmers.^{[133] [234]} The popularity of Arctic and mountain expeditions has increased the number of persons at risk. Among those challenging the environment are climbers of Mt. Everest, Mt. Hood, and Mt. McKinley.^[108]

EPIDEMIOLOGY

In most countries, primary hypothermia deaths are considered violent and are classified as accidental, homicidal, or suicidal.^[32] Deaths from secondary hypothermia are usually considered natural complications of systemic disorders, including trauma, carcinoma, and sepsis. The true incidence of secondary hypothermia throughout the world is unknown because hypothermic persons found indoors usually have other serious and diverting secondary medical illnesses. In addition, delays are common between hospital admission and death, so secondary hypothermia is significantly underreported. In contrast, death certificate data more accurately quantify primary hypothermia.

Hypothermia occurs in various locations and in all seasons.^{[180] [196] [278]} In a multicenter North American survey of 428 cases of civilian accidental hypothermia, 69 occurred in Florida.^[49] Urban settings account for the majority of cases in most of the industrialized countries.^{[51] [137] [257]} During 1979–1995, there was an annual average of 723 deaths attributed to hypothermia in the United States. Around half of these fatalities were patients over age 65.^[33]

Classifications

Accidental hypothermia is best defined as the unintentional decrease of around 2° C (3.6° F) in the "normal" core temperature of 37.2° to 37.7° C (98.9° to 99.9° F) without disease in the preoptic and anterior hypothalamic nuclei ([Table 6-1](#)).^[182] Classically, hypothermia is defined as a core temperature below 35° C (95° F). Hypothermia is both a symptom and a clinical disease entity. When sufficient heat cannot be generated to maintain homeostasis and the core temperature drops below 30° C (86° F), the patient becomes poikilothermic and cools to the ambient temperature.

Among the clinical classifications, the most practical division includes healthy patients with simple environmental exposure (primary), those with specific diseases producing hypothermia (secondary), and those with predisposing conditions. Other divisions reflect the etiology of hypothermia and include immersion vs. nonimmersion and acute vs. chronic heat loss.^{[183] [199]}

Various physiologic stressors and other factors can impair thermoregulation. Age extremes, the state of health and nutrition, the type of exposure, and a multitude of intoxicants or medications can jeopardize thermostability by decreasing heat production or increasing heat loss. Physiologic stressors also include dehydration, sleep deprivation, and fatigue. These challenges increase heat loss via evaporation, radiation, conduction, and convection, and compensatory responses often fail.^[183] The resulting mortality rates range from the highly suspicious zero to well over 50% in many clinical

series, depending largely on the severity of risk factors and on patient selection criteria.^[51] ^[196] ^[278]

For safety, experimental investigations of induced hypothermia in human volunteers usually terminate cooling at about 35° C (95° F). Naturally this precludes analysis of some of the more significant pathophysiologic features of moderate or severe hypothermia. Design limitations also occur in studies of anesthetized animals, since the results of these experiments require variable degrees of extrapolation to humans. For example, large differences exist both in the cardiovascular responses to interventions and in the amounts of peripheral musculature that are present, particularly in nonporcine animal models. As a result, clinical treatment recommendations must be predicated on the degree and duration of hypothermia and on the predisposing factors that are subsequently identified.^[106]

NORMAL PHYSIOLOGY OF TEMPERATURE REGULATION

Warm-blooded animals maintain a precariously dynamic equilibrium between heat production and heat loss.^{[135] [136]} The normal diurnal variation in humans is

only 1° C (1.8° F). Since physiologic changes occurring in humans are modified by predisposing or contributory factors, the normal responses to severe temperature depression require significant extrapolation.^[203]

Basal heat production usually averages 40 to 60 kcal/m² body surface area per hour. It increases with shivering thermogenesis,^[194] ^[195] food ingestion, fever, activity, and cold stress. Normal thermoregulation in vertebrates involves transmitting cold sensation to hypothalamic neurons via the lateral spinothalamic tracts and the thalamus ([Figure 6-1](#)). The physiologic characteristics of the four zones of hypothermia appear in [Table 6-2](#) . A complete discussion of the physiology of cold exposure and thermoregulation is presented in [Chapter 4](#) .

TABLE 6-2 -- Characteristics of the Four Zones of Hypothermia

STAGE	CORE TEMPERATURE		CHARACTERISTICS
	° C	° F	
Mild	37.6	99.6 ± 1	Normal rectal temperature
	37.0	98.6 ± 1	Normal oral temperature
	36.0	96.8	Increase in metabolic rate and blood pressure and prshivering muscle tone
	35.0	95.0	Urine temperature 34.8° C; maximum shivering thermogenesis
	34.0	93.2	Amnesia, dysarthria, and poor judgment develop; maladaptive behavior; normal blood pressure; maximum respiratory stimulation; tachycardia, then progressive bradycardia
Moderate	33.30	91.4	Ataxia and apathy develop; linear depression of cerebral metabolism; tachypnea, then progressive decrease in respiratory minute volume; cold diuresis
	32.0	89.6	Stupor; 25% decrease in oxygen consumption
	31.0	87.8	Extinguished shivering thermogenesis
	30.0	86.0	Atrial fibrillation and other arrhythmias develop; poikilothermia; pupils and cardiac output two thirds of normal; insulin ineffective
Severe	29.0	85.2	Progressive decrease in level of consciousness, pulse, and respiration; pupils dilated; paradoxical undressing
	28.0	82.4	Decreased ventricular fibrillation threshold; 50% decrease in oxygen consumption and pulse; hypoventilation
	27.0	80.6	Loss of reflexes and voluntary motion
	26.0	78.8	Major acid-base disturbances; no reflexes or response to pain
	25.0	77.0	Cerebral blood flow one third of normal; loss of cerebrovascular autoregulation; cardiac output 45% of normal; pulmonary edema may develop
	24.0	75.2	Significant hypotension and bradycardia
	23.0	73.4	No corneal or oculocephalic reflexes; areflexia
22.0	71.6	Maximum risk of ventricular fibrillation; 75% decrease in oxygen consumption	

Profound	20.0	68.0	Lowest resumption of cardiac electromechanical activity; pulse 20% of normal
	19.0	66.2	Electroencephalographic silencing
	18.0	64.4	Asystole
	13.7	56.8	Lowest adult accidental hypothermia survival ^[91A]
	15.0	59.2	Lowest infant accidental hypothermia survival ^[208]
	10.0	50.0	92% decrease in oxygen consumption
	9.0	48.2	Lowest therapeutic hypothermia survival ^[203]

PATHOPHYSIOLOGY

Nervous System

Numbing cold depresses the central nervous system, producing impaired memory and judgment, slurred speech, and decreased consciousness. Temperature-dependent enzyme systems in the brain do not function properly at cold temperatures that are well tolerated by the kidneys.^[94] As a result, most patients are comatose below 30° C (86° F), although some remain amazingly alert.

Neurons are initially stimulated by a 1° C (1.8° F) drop in temperature, but the brain does not always cool uniformly during accidental hypothermia. After the initial increase, there is a linear decrease in cerebral metabolism by 6% to 10% per degree Centigrade from 35° C (95° F) to 25° C (77° F). Hypothermia affords cerebral protection because of the diminished cerebral metabolic requirements of oxygen.^[86] ^[93]

The electroencephalogram is abnormal below 33.5° C (92.3° F) and becomes silent at 19° to 20° C (66.2° to 68° F). The triphasic waves commonly noted in hypothermia are also observed in various metabolic, toxic, and diffuse encephalopathies. Visual evoked potentials, another objective measure of cerebral function, become smaller as the mercury drops. After cerebral cortical function becomes impaired, lower brainstem functions are also deranged.

Cerebrovascular autoregulation is protectively intact until the temperature drops below 25° C (77° F). Although vascular resistance is increased, blood flow is disproportionately redistributed to the brain. In canine studies, blood flow in the brain, muscle, kidney, and myocardium recovers quickly to control levels after rewarming. Flow deficits in the pulmonary, digestive, and endocrine systems persist for up to 2 hours after rewarming.^[49]

Chilling the peripheral nervous system increases muscle tension and preshivering tone, eventually leading to shivering. Shivering, which is also centrally controlled, is a much more efficient heat producer than voluntary muscle contractions of the extremities.

Cardiovascular System

Many cardiovascular responses caused by or associated with hypothermia are well

described but not well understood.^{[160] [161]} Cold stress increases the consumption of myocardial oxygen. Autonomic nervous system stimulation causes tachycardia and peripheral vasoconstriction, both of which increase systemic blood pressure and cardiac afterload.

After premonitory tachycardia, decremental bradycardia produces a 50% decrease in heart rate at 28° C (82.4° F). Since this bradycardia is caused by decreased spontaneous depolarization of the pacemaker cells, it is refractory to atropinization. If there is a "relative" tachycardia not consistent with the degree of hypothermia, the clinician should be concerned. Associated conditions include occult trauma with hypovolemia, drug ingestion, and hypoglycemia.

During hypothermic bradycardia, unlike normothermia, systole is prolonged longer than diastole. In addition, the conduction system is much more sensitive to cold than is the myocardium, so the cardiac cycle is lengthened. Cold-induced changes in pH, oxygen, electrolytes, and nutrients also alter electrical conduction.^[179]

Hypothermia progressively decreases the mean arterial pressure and cardiac index. Cardiac output drops to about 45% of normal at 25° C (77° F). Systemic arterial resistance, determined by invasive hemodynamic monitoring, is increased. Even after rewarming, cardiovascular function may remain temporarily depressed, with impaired myocardial contractility, metabolism, and peripheral vascular function.^[262]

Figure 6-2 The J or Osborn wave of hypothermia.

Mild, steady hypothermia in patients with poikilothermic thermoregulatory disorders causes electrocardiographic (ECG) alterations and conduction abnormalities.^[181] First the PR, then the QRS, and most characteristically the QTc intervals are prolonged. Clinically invisible increased prshivering muscle tone can obscure the P waves; ST segment and T wave abnormalities are inconsistent.

The J wave (Osborn wave or hypothermic hump; [Figure 6-2](#)), first described by Tomaszewski in 1938,^[261] occurs at the junction of the QRS complex and ST segment. It is not prognostic but is potentially diagnostic.^[210] J waves occur at any temperature below 32.2° C (90° F) and are most frequently seen in leads II and V₆. When the core temperature falls below 25° C (77° F), J waves are found in the precordial leads (especially V₃ or V₄). The size of the J waves also increases with temperature depression but is unrelated to arterial pH. J waves are usually upright in aV_L, aV_F, and the left precordial leads.

J waves may represent hypothermia-induced ion fluxes, resulting in delayed

depolarization or early repolarization of the left ventricle, or there may be an unidentified hypothalamic or neurogenic factor. J waves are *not* pathognomonic of hypothermia but also occur with central nervous system lesions, focal cardiac ischemia, and sepsis. They may also be present in young, healthy persons. When pronounced, J waveform abnormalities can simulate a myocardial infarction. Computer software is not widely available that can successfully recognize and suggest the diagnosis of hypothermia.

Such a capability can be important in rural and wilderness settings, since prehospital thrombolytic therapy will expand as the role of the field 12-lead ECG is refined.^[46] Thrombolysis is unstudied in hypothermia but would be expected to exacerbate coagulopathies.^[95]

Below 32.2° C (90° F), all types of atrial and ventricular arrhythmias are encountered.^[64] The His-Purkinje system is more sensitive to cold than is the myocardium. As a result, conduction velocity decreases and electrical signals can disperse. Since conduction time is prolonged more than the absolute refractory period, reentry currents can produce circus rhythms that initiate ventricular fibrillation (VF).

In addition to causing bradycardia, widening the QRS complex, and prolonging the QT interval, hypothermia increases the duration of action potentials ([Figure 6-3](#)).^[15] ^[16] During rewarming, nonuniform myocardial temperatures can disperse conduction and further increase the action potential duration, another mechanism to develop the unidirectional blocks that facilitate reentrant arrhythmias. At temperatures between 25° and 20° C (77° and 68° F), myocardial conduction time is prolonged further than the absolute refractory period. Another arrhythmogenic mechanism is development of independent electrical foci that precipitate arrhythmias.

Selection of the class III antiarrhythmic drug *d*-sotalol may be problematic.^[16] It has temperature-dependent effectiveness and lengthens prolonged action potentials more efficiently at long pacing cycle lengths. Various electrolyte abnormalities can further complicate the situation during hypothermic conditions, since they exacerbate the effects of prolonged action potentials. Most conspicuously, hypothermia-induced cellular calcium loading mimics digitalis toxicity and may predispose to a forme fruste of torsades de pointes.

Hypothermia-induced VF and asystole often occur spontaneously below 25° C (77° F). The VF threshold and the transmembrane resting potential are decreased. Since

Figure 6-3 Example of the effects of temperature on action potentials in cardiac

cells.

the heart is cold, the conduction delay is facilitated by the large dispersion of repolarization, and the action potential is prolonged. The increased temporal dispersion of the recovery of excitability is linked to VF. In a way, nature's model of resistance to VF is the heart of hibernating animals during rewarming.^[132] Animals with this capacity seem to be protected by a shortened QT duration and a calcium channel handling system that prevents intracellular calcium overload.

Asystole may be the more common on initial examination, and VF may be iatrogenic. Both rhythms may result from hypovolemia, tissue hypoxia, therapeutic manipulations, acid-base fluxes, autonomic dysfunction, and coronary vasoconstriction coupled with increased blood viscosity.^[49]

Core Temperature Afterdrop

Core temperature afterdrop refers to the continued decline in a hypothermic patient's temperature after removal from the cold (see also [Chapter 8](#)). Contributing to afterdrop is the simple temperature equilibration between the warmer core and the cooler periphery. Circulatory changes account for another set of observations. The countercurrent cooling of blood that perfuses cold extremities results in a core temperature decline until the existing temperature gradient is eliminated. In cold-water immersion, postrescue collapse may also result from abrupt hypotension after loss of the hydrostatic squeeze in the water.

The incidence and magnitude of core temperature afterdrop vary widely in clinical experiments and in surgically induced hypothermia.^{[88] [89] [91] [106]} Hayward^[109] measured his own esophageal, rectal, tympanic, and cardiac temperatures (via flotation tip catheter) during rewarming after being cooled in 10° C (50° F) water. On 3 different days, rewarming was achieved via shivering thermogenesis, heated humidified inhalation, and warm bath immersion. Coincident with a 0.3° C (0.5° F) afterdrop during warm bath immersion, Hayward's mean arterial pressure fell 30% and his peripheral vascular resistance fell 50%. These results provide impressive support for the circulatory hypothesis as one of the contributors to afterdrop.

Another study of peripheral blood flow during rewarming from mild hypothermia in humans suggests that minimal skin blood flow changes can lead to afterdrop ([Figure 6-4](#)). Harnett, Pruitt, and Sias^[106] precipitated the largest core temperature afterdrops when their subjects were rewarmed with plumbed garments and heating pads.

In summary, core temperature afterdrop appears to become most clinically relevant when a large temperature gradient exists between the periphery and the core, particularly in dehydrated, chronically cold patients. Both conductive and convective mechanisms are responsible for afterdrop.^{[86] [89]} Stimulating peripheral

Figure 6-4 Infrared scan of the palmar hand surface. Blue color = 43° C (109.4° F); red color = 68° C (154.4° F). **A**, At room temperature. **B**, After 5 minutes in a cold room, with evidence of vasoconstriction. (Courtesy Naval Health Research Center, San Diego, Calif.)

blood flow can increase afterdrop. Major afterdrops are also observed when frostbitten extremities are thawed before thermal stabilization of the core temperature.

Respiratory System

Any exposure to a big chill initially stimulates respiratory drive, followed by progressive depression of respiratory minute volume as cellular metabolism is depressed.

Respiratory rate often falls to 5 to 10/min below 30° C (86° F), and ultimately brainstem neurocontrol of ventilation fails. Carbon dioxide production drops 50% for each 8° C (14° F) fall in temperature. In severe hypothermia, carbon dioxide retention and respiratory acidosis reflect the aberrant responses to normothermic respiratory stimuli.^[85]

Other pathophysiologic factors contributing to a ventilation-perfusion mismatch include decreased ciliary motility, increased quantity and viscosity of secretions, hypothermic respiratory distress syndrome, and noncardiogenic pulmonary edema. The thorax loses elasticity while pulmonary compliance drops. The respiratory "bellows" stiffen and fail because the contractile efficiency of the intercostal muscles and diaphragms declines.

Pertinent potentially protective or detrimental factors that affect tissue oxygenation in endothermic humans are listed in [Box 6-1](#) .

Renal System

The kidneys respond briskly to hypothermia-induced changes in the vascular tree's capacitance. Peripheral vasoconstriction can result in a relative central hypervolemia, producing diuresis, even with mild dehydration. In addition, renal blood flow is depressed by 50% at 27° to 30° C (80.6° to 86° F), which decreases glomerular filtration rate. Nevertheless, there is an initial large diuresis of this dilute glomerular filtrate, which does not efficiently clear nitrogenous wastes.

**Box 6-1. OXYGENATION
CONSIDERATIONS DURING
HYPOTHERMIA**

DETRIMENTAL FACTORS

Oxygen consumption increases with rise in temperature; caution if rapid rewarming; shivering also increases demand

Decreased temperature shifts oxyhemoglobin dissociation curve to the left

Ventilation-perfusion mismatch; atelectasis; decreased respiratory minute volume; bronchorrhea; decreased protective airway reflexes

Decreased tissue perfusion from vasoconstriction; increased viscosity

"Functional hemoglobin" concept: capability of hemoglobin to unload oxygen is lowered

Decreased thoracic elasticity and pulmonary compliance

PROTECTIVE FACTORS

Reduction of oxygen consumption:
50% at 28° C (82.4° F); 75% at 22° C
(71.6° F); 92% at 10° C (50° F)

Increased oxygen solubility in plasma

Decreased pH and increased P_{aCO_2} shift oxyhemoglobin dissociation curve to right

The multifactorial etiology of the cold diuresis is still debated. [98] [99] Some of the suggested mechanisms include inhibition of antidiuretic hormone (ADH) release and decreased renal tubular function. Neither hydration nor ADH infusions seem to influence the diuretic response, which appears to be an attempt to compensate for initial relative central hypervolemia caused by vasoconstrictive overload of capacitance vessels.

The diuresis may be pressure related caused by impaired autoregulation in the kidney. Cold diuresis has circadian rhythmicity and correlates with periods of shivering. Cold water immersion increases urinary output 3.5 times, and the presence of ethanol impressively doubles that diuresis. [49]

Coagulation

The significant effects of temperature on coagulation continue to be investigated. [249] Coagulopathies often develop in hypothermic patients because the enzymatic nature of the activated clotting factors is depressed by cold. [72] [224] In vivo, prolonged clotting is proportional to the number of steps in the cascade. For example, at 29° C (84.2° F) a 50% to 60% increase in the partial thromboplastin time (PTT) would be expected. Kinetic tests of coagulation, however, are normally performed in the laboratory at 37° C (98.6° F). As the blood warms in the machine, the enzymes between each factor in the

cascade are activated. The sample of warmed in vitro blood will then clot normally.

The reversible hemostatic defect created by hypothermia may not be reflected by the "normal" prothrombin time (PT) or PTT. [229] This coagulopathy is basically independent of clotting factor levels and cannot be confirmed by laboratory studies performed at 37° C. Treatment is rewarming and not simply administration of clotting factors. [225]

Thrombocytopenia as a cause of bleeding becomes progressively significant in severe hypothermia. Proposed mechanisms include direct bone marrow suppression and splenic or hepatic sequestration. Thromboxane B₂ production by platelets is also temperature dependent, so cooling skin temperature in baboons produces reversible platelet dysfunction. Thrombocytopenia is a common but poorly recognized corollary of hypothermia in the elderly and neonates.

Coagulopathy in trauma patients is attributed to enzyme inhibition, platelet alteration, and fibrinolysis. The critical temperature at which enzyme activity slows significantly is 34° C (93.2° F). [273] In addition, clot strength weakens as a result of platelet malfunction. Fibrinolysis was not significantly affected at any temperature in the range measured (33° to 37° C [91.4° to 98.6° F]) (also see Trauma).

Physiologic hypercoagulability develops during hypothermia, with a sequence similar to

that seen in disseminated intravascular coagulation (DIC). This produces a higher incidence of thromboembolism during hypothermia. Causes include thromboplastin release from cold tissue, simple circulatory collapse, and release of catecholamines and steroids. Since fibrin split product levels can be normal, bleeding is not always considered a hematologic manifestation of DIC. One distinctive hypothermic hematologic picture includes thrombocytopenia, sideroblastic anemia, and erythroid hypoplasia.^[49]

Whole blood viscosity increases with the hemoconcentration seen after diuresis and the shift of fluid out of vascular compartments. Red blood cells (RBCs) simply stiffen and have diminished cellular deformity when chilled.^[217] The elevated viscosity of hypothermia is also exacerbated with cryoglobulinemia. Cryofibrinogen is a cold-precipitated fibrinogen occasionally seen with carcinoma, sepsis, and collagen vascular diseases. Blood viscosity is also increased by the transient increase in platelet and RBC counts seen with mild surface cooling. This could explain the increased mortality from coronary and cerebral thromboses that occur in winter.^[183]

PREDISPOSING FACTORS

The factors that predispose to hypothermia can be separated into those that decrease heat production, increase heat loss, or impair thermoregulation. ^[183] There is significant overlap among these groups ([Box 6-2](#)).

Decreased Heat Production

Thermogenesis is decreased at both extremes of age. In the elderly, neuromuscular inefficiency and decreased physical activity impair shivering. Aging progressively diminishes homeostatic and cold adaptive capabilities. Although most elderly persons have normal thermoregulation, they tend to develop conditions that impair heat conservation.

The elderly are physiologically less adept at increasing heat production and the respiratory quotient (the ratio of the volume of carbon dioxide produced to the volume of oxygen consumed per unit of time). Impaired thermal perception, possibly caused by decreased resting peripheral blood flow, leads to poor adaptive behavior. Metabolic studies also demonstrate that in severely hypothermic elderly persons, lipolysis occurs in preference to glucose consumption. ^[172]

Neonates have a large surface area/mass ratio, a relatively deficient subcutaneous tissue layer, and virtually no behavioral defense mechanisms. ^[131] Newborn "unadapted" infants attempt to thermoregulate with initial vasoconstriction and acceleration of metabolic rate. In contrast, "adapted" infants who are older than 5 days of age can increase lipolysis immediately and burn oxidative brown adipose tissue.

No cause-effect relationship has been found between hypothermia and the mortality rate of premature infants. ^[110] ^[237] Although the smaller infants in a neonatal intensive care unit are at the greatest risk of hypothermia, mortality is related to hypothermia only in larger neonates.

Emergency deliveries and resuscitations are responsible for most acute neonatal hypothermia. Other common risk factors are prematurity, low birth weight, inexperienced mother, perinatal morbidity, and low socioeconomic status. In more chronically induced subacute hypothermia, lethargy, a weak cry, and failure to thrive are common. ^[259]

Many cold infants have "paradoxical rosy cheeks," looking surprisingly healthy. After the first few days of life, hypothermia frequently indicates septicemia and carries a high mortality rate. ^[44] Low weight and malnutrition are common. Hypothermia in a low-birthweight neonate should suggest the possibility of intracranial hemorrhage;

hypothermia is also observed in shaken baby syndrome.

Endocrinologic failure, including hypopituitarism, hypoadrenalism, and myxedema, commonly decreases heat production. Interestingly, congenital adrenal hyperplasia with mineralocorticoid insufficiency is more common in cold climates, possibly an adaptive response to prolonged exposure to cold temperatures, since "normal" cold diuresis is reduced in these patients.

Hypothyroidism is often occult, with no history of cold intolerance, dry skin, lassitude, or arthralgias. The physician should check for a thyroid scar or any history of thyroid hormone replacement. The degree of temperature depression correlates fairly directly with mortality. Eighty percent of patients in myxedema coma, which is several times more common in females, are hypothermic.

The effects of insufficient nutrition extend from hypoglycemia to marasmus to kwashiorkor. Kwashiorkor is less often associated with hypothermia than is marasmus because of the insulating effect of hypoproteinemic edema. Central neuroglycopenia distorts hypothalamic function. Many alcoholic patients with hypothermia are hypoglycemic. Malnutrition decreases insulative subcutaneous fat and directly alters thermoregulation. In 744 elderly women with femoral neck fractures, poor nutrition predisposed to hypothermia and its attendant clumsiness.^[11] Partly because of fuel depletion, hypothermia is as great a threat as hyperthermia in marathon races run

in cool climates. Among 62 runners, participants slowing from fatigue or injury late in a race were at serious risk of hypothermia.^[189]

Increased Heat Loss

Poorly acclimated and insulated individuals often have high diaphoretic, convective, and evaporative heat losses during exposure to cold. Because the skin functions as a radiator, any dermatologic malfunction increases heat loss. Such erythrodermas include psoriasis, exfoliative dermatitis, and toxic epidermal necrolysis.^[171] Hypothermia with hypernatremic dehydration is also seen in congenital lamellar ichthyosis.

Burns and inappropriate burn treatment cause excessive heat loss, as do other iatrogenic factors, including massive cold intravenous infusions and overcooling heatstroke victims.^[151] When carbon dioxide is used for abdominal insufflation before laparoscopy, warming the gas before administration helps prevent hypothermia. Environmental immersion exposure is discussed in detail in [Chapter 8](#).^[87]

Many pharmacologic and toxicologic agents both increase heat loss and impair thermoregulation.^[135] The most common is ethanol, which interacts with every thermoregulatory neurotransmitter. Although ingestion of ethanol produces a feeling of warmth and perhaps visible flushing, it is the major cause of urban hypothermia.^[51]^[196] In fatal cases of accidental hypothermia, many victims are under the influence of ethanol. In children with ethanol intoxication, hypothermia is common.

Ethanol is also a poikilothermia-producing agent that directly impairs thermoregulation at high or low temperatures.^[1]^[134] Body temperature is lowered both from cutaneous vasodilation with radiative heat loss and from impaired shivering thermogenesis. Chronic ethanol ingestion damages the mamillary bodies and posterior hypothalamus, which modulates shivering thermogenesis.^[218] Ethanol also increases the risk of being exposed to the environment by modifying protective adaptive behavior. The ultimate example is paradoxical undressing, or removal of clothing in response to a cold stress. As an organic solvent, ethanol confers a few theoretically redeeming qualities in freezing cold injuries by lowering the cellular freezing point.^[98]^[99]

The neurophysiologic effects of ethanol are modified by duration and intensity of exercise, food consumption, and applied cold stress.^[78] Aging increases sensitivity to the hypothermic actions of ethanol in some primate experiments. Chronic ingestion yields tolerance to its hypothermic effects, and rebound hyperthermia may be seen during withdrawal. Conditions associated with ethanol ingestion that adversely affect heat balance include immobility and hypoglycemia.

Inhibited hepatic gluconeogenesis coexists with malnutrition. Hypothermic alcoholic ketoacidosis is reported.^[278] Intravenous thiamine is diagnostic and therapeutic for Wernicke's encephalopathy, another cause of reversible hypothermia. The acute triad of

global confusion, ophthalmoplegia, and truncal ataxia is often masked by hypothermia, and temperature depression may persist for weeks.

Impaired Thermoregulation

Various conditions that impair thermoregulation can be considered as having central, peripheral, metabolic, pharmacologic, or toxicologic effects.

Central.

Central conditions may directly affect hypothalamic function and mediate vasodilation. Traumatic lesions include skull fractures, especially basilar, and intracerebral hemorrhages, most commonly chronic subdural hematomas. Pathologic lesions include neoplasms, congenital anomalies, and Parkinson's disease. Patients with Parkinson's disease or Alzheimer's disease, because of global neurologic impairment, are particularly at behavioral risk. Finally, cerebellar lesions also impede heat production because of inefficient choreiform shivering.

Hypothermia can occur with Reye's syndrome. In Hodgkin's disease, hypothermia is seen only in previously febrile patients with advanced disease, independent of cell type. This seems to be a disease-associated functional disorder of thermoregulation, similar to that seen in anorexia nervosa. Centrally induced hypothermia is completely antagonized with thyrotropin-releasing hormone.

Peripheral.

Peripheral thermoregulation fails after acute spinal cord transection. Victims are functionally poikilothermic as soon as peripheral vasoconstriction is extinguished.^[193] Other peripheral impediments to thermostability include neuropathies and diabetes mellitus. Hypothermia is more common in elderly diabetics than in the general population, even after excluding patients with diabetic metabolic emergencies. The common denominator in metabolic derangements may be abnormal plasma osmolality that interferes with hypothalamic function. Similar causes of hypothermia include hypoglycemia, diabetic ketoacidosis, and uremia. Remarkably, the pH was 6.67 in one hypothermic survivor with lactic acidosis and 6.41 in another.^[201]

Pharmacologic/Toxicologic.

Numerous medications and toxins in therapeutic or toxic doses impair centrally mediated thermoregulation and vasoconstriction.^[215] ^[287] Of 103 critically ill patients with overdoses, 27 were hypothermic.^[141] The usual offenders are barbiturates, benzodiazepines, phenothiazines, and the tricyclic antidepressants. Reduced core temperature may be a prodrome of lithium poisoning. Organophosphates, narcotics, glutethimide, bromocriptine, erythromycin,

clonidine, fluphenazine, bethanechol, atropine, acetaminophen, and carbon monoxide all cause hypothermia.^[17] In experimental studies, hypothermia after acute carbon monoxide poisoning is associated with increased mortality.

Recurrent Hypothermia

Recurrent and episodic hypothermia are widely reported. The recurrent variety is more common and is usually secondary to ethanol abuse, with one person having survived 12 episodes. Severe, recurrent presentations are also caused by self-poisoning and anorexia nervosa.^[49]

Persons with episodic hypothermia can be divided into two groups, albeit with significant overlap, as follows:

Group 1: Diaphoretic episodes precede the temperature decline, which lasts several hours; includes those with hypothalamic lesions and agenesis of the corpus callosum (Shapiro's syndrome) and persons with spontaneous periodic hyperthermia. Resultant hyperhidrosis and hypothermia are successfully treated with clonidine, a centrally acting α -adrenergic agonist. The hypothermia of corpus callosum agenesis is also seen with hypercalcemia and status epilepticus; since no hypothermia results from experimental sectioning of the corpus callosum, associated lesions, including lipomas, probably cause thermoinstability. Spontaneous periodic hyperthermia may reflect a diencephalic autonomic seizure disorder and can accompany paroxysmal hypertension. Vasomotor and thermoregulatory mechanisms are successfully treated with anticonvulsants. Florid psychiatric symptoms often mask these intermittent hypothermic episodes.

Group 2: Consists of persons who remain cold for days to weeks, rather than hours; these have more seizure disorders, and the central hypothalamic thermostat is set abnormally low.

Patients with intermittent hypothermia usually show some characteristics from both groups.^[183] Circadian rhythm disturbances are also seen in persons with neurologic disorders who have chronic hypothermia.

Predisposing Infections/Conditions

Among the infestations and infections that not only elevate but often depress core temperature are septicemia, pneumonia, peritonitis, meningitis, encephalitis, bacterial endocarditis, typhoid, miliary tuberculosis, syphilis, brucellosis, and trypanosomiasis.^[168] Other diseases, in addition to cerebrovascular and cardiopulmonary disorders, that produce secondary hypothermia include lupus, carcinomatosis, pancreatitis, and multiple sclerosis. Hypothalamic demyelination may explain the episodic hypothermia

observed in some patients with multiple sclerosis.

Hypothermia can also result from low cardiac output after a major myocardial infarction, which can be reversed by intraaortic balloon counterpulsation. Finally, causes include vascular insufficiency, giant cell arteritis, uremia, sickle cell anemia, Paget's disease, sarcoidosis, and sudden infant death syndrome. Magnesium sulfate infusion during preterm labor has produced hypothermia with fetal and maternal bradycardia, and hypothyroidism can be manifested as hypothermia after preeclampsia (see [Box 6-2](#)).

Trauma

The relationship of hypothermia to trauma is still being actively investigated.^[83] Hypothermia protects the brain from ischemia but can result in arrhythmias, acidosis, and coagulopathies, and it can exact a high metabolic cost during rewarming. Hypothermia hinders the protective physiologic responses to acute trauma and affects the pharmacologic and therapeutic maneuvers necessary to treat the injuries.^[11]

There is usually an inverse relationship between the injury severity score and the core temperature of traumatized patients on arrival in the emergency department (ED). This observation does not settle whether hypothermia is just another risk factor for increased mortality or reflects the fact that the most severely injured patients are in hemorrhagic shock.

One study assesses the impact of hypothermia as an independent variable during resuscitation from major trauma.^[83] Patients not aggressively rewarmed with continuous arteriovenous rewarming (CAVR) had increased fluid requirements, increased lactate levels, and increased acute mortality.

Of the clinical entities associated with hypothermia, traumatic conditions causing hypotension and hypovolemia most dramatically jeopardize thermostability.^[139] Hypothermia is often obscured by obvious hemorrhaging and injuries. Conversely, traumatic neurologic deficits, including paresis and areflexia, can be misattributed to hypothermia. In trauma patients requiring surgery, the mean temperature loss was greater in the ED than in the operating room.^[101] Thermal insults are often added during a trauma resuscitation. The patient is completely exposed for examination, and resuscitative procedures cause further heat loss.

In a study stratifying subjects with the anatomic Injury Severity Scale (ISS), hypothermic patients had a higher mortality rate than did similarly injured patients who remained normothermic.^[140] Another study did not corroborate this finding,^[251] but those investigators stratified using Trauma Revised Injury Severity Scale (TRISS) methodology, which is probably less valid during hypothermia because its physiologic components overestimate injury severity. To illustrate this point, some component of hypotension is normal for a given degree of hypothermia.

Various adverse physiologic events accompany hypothermia with trauma.^[190] Decreased skin and core temperatures without compensatory shivering thermogenesis are reported in patients with major trauma as defined by the ISS.

Hypothermia directly causes coagulopathies in trauma patients through at least three avenues (see Coagulopathy).^[26] The cascade of enzymatic reactions is impaired and plasma fibrinolytic activity is enhanced, producing a clinical presentation similar to DIC. Also, platelets are poorly functional and become sequestered.

Hypothermia protects only when induced before shock occurs. This reduces adenosine triphosphate (ATP) utilization while ATP stores are still normal, as during elective surgery. ATP stores in traumatized patients are already depleted. Hypothermia worsens the effects of endotoxins on clotting time in vitro and may synergistically exacerbate the coagulopathy seen in trauma.^[73] The average temperature of 123 initially normothermic trauma patients in whom lethal coagulopathies developed was 31.2° C (88.2° F).^[144] In another study, postinjury life-threatening coagulopathy in the seriously injured who require massive transfusion is predicted by persistent hypothermia and progressive metabolic acidosis.^[41]

The appropriate target core temperature for a hypothermic patient with an isolated severe head injury may be 32° to 33° C (89.6° to 91.4° F). This target temperature balances neuroprotection against the adverse hematologic and physiologic consequences of hypothermia.^{[185] [186] [285]}

PRESENTATION

The patient's history may suggest hypothermia.^[26] Diagnosis becomes fairly simple when exposure is obvious, as with avalanche victims. Subtle presentations, however, predominate in urban settings. Victims often complain only of vague symptoms, including hunger, nausea, fatigue, and dizziness. Predisposing underlying illness or ethanol ingestion is also common, as are major trauma, immersion, overdose, cerebrovascular accidents, and psychiatric emergencies ([Box 6-3](#)).

During the head, eye, ear, nose, and throat examination, abnormal findings can include decreased corneal reflexes, mydriasis, strabismus, flushing, erythrospia, facial edema, rhinorrhea, and epistaxis. Mild hypothermia usually does not depress pupillary light reflex. Cardiovascular findings after initial tachycardia include bradyarrhythmias and hypotension. Heart sounds may be muffled and distant.

Tachypnea, an early respiratory finding, is usually followed by progressive hypoventilation with bronchorrhea and adventitious sounds. Because the gastrointestinal tract is depressed, abdominal distention or rigidity, ileus, obstipation, and poor rectal tone are often present. Gastric dilation is common in neonates and myxedematous adults. Genitourinary output ranges from initial polyuria resulting from cold diuresis to anuria. Interestingly, the incidence of testicular torsion reportedly increases because of cremasteric contractions.

Diffuse neurologic abnormalities vary widely. Some persons can still converse at 32° C (89.6° F) and are normoreflexic. The level of consciousness generally declines proportionate to the degree of hypothermia. The presence of ataxia and dysarthria may mimic a cerebrovascular accident. Speed of reasoning and memory registration are also impaired. Amnesia, antinociception, anesthesia, or hypesthesia can develop. Cranial nerve signs are present after bulbar damage from central pontine myelinolysis. These extraocular muscle movement abnormalities, similar to extensor plantar responses, do not directly correlate with the degree of hypothermia.^[75]

Hyperreflexia predominates from 35° to 32.2° C (95° to 90° F) and is followed by hyporeflexia. The plantar response remains flexor until 26° C (78.8° F), when areflexia develops. The knee jerk is usually the last reflex to disappear and the first to reappear during rewarming. From 30° to 26° C (86° to 78.8° F), both contraction and relaxation phases of reflexes are prolonged equally. In myxedema, however, the relaxation phase of the ankle reflex is more prolonged than is the contraction phase.^[183] Most importantly, spinal cord and other central nervous system lesions may be obscured by depressive neurologic changes that normally accompany hypothermia.^[75]

Psychiatric presentations and suicide attempts associated with hypothermia are commonly misdiagnosed initially. Preexistent psychiatric disorders can blossom in the cold, even if they were stabilized in temperate climates. Mental status alterations include anxiety, impaired judgment, perseveration, neurosis, and psychosis. Leaders of expeditions can become moody, apathetic, uncooperative, and risk taking. Elderly patients often withdraw in confusion, become silent, and display lassitude and poor judgment. A peculiar flat affect is common, and psychomotor impairment can resemble an organic brain syndrome.

Early in hypothermia, simply losing effective use of the hands can be devastating. Appropriate behavior adapted to the cold, such as seeking a heat source, is often lacking. An extreme example is paradoxical undressing.^[149] The clothing is removed in a preterminal effort to address impending thermoregulatory collapse, and many persons have been mistakenly identified as sexual assault victims. This phenomenon is also seen in hypothermic children.

Musculoskeletal posturing can extend to pseudo-rigor mortis. Preshivering muscle tone is increased before core temperature drops to 35° C (95° F), and muscular rigidity, paravertebral spasm, and even opisthotonos

may occur. Extremity compartment syndromes often develop because of associated conditions causing prolonged compression and immobility, in addition to compartment hypertension seen during reperfusion of frostbitten extremities.

LABORATORY EVALUATION

Acid-Base Balance

The strategy for achieving and maintaining acid-base balance in hypothermia differs from that of normothermia.^[57]^[107]^[126] After initial respiratory alkalosis from hyperventilation when a person first becomes chilled, a common underlying disturbance is mixed acidosis. The respiratory component of the acidosis is caused mainly by direct respiratory depression. In addition, as the temperature decreases, solubility of carbon dioxide in the blood increases. Further contributors to the metabolic component of this acidosis include impaired hepatic metabolism and acid excretion, lactate generation from shivering, and decreased tissue perfusion.^[113] Nevertheless, reliable clinical prediction of the acid-base status in accidental hypothermia is not possible. In one series of 135 cases, 30% were acidotic and 25% alkalotic.^[196]

Circulatory changes also prevent adequate mobilization and delivery of organic acids to buffer systems. As in normothermia, mixed venous blood may best reflect acid-base status during resuscitation.^[255] Despite flow changes in a moderately hypothermic canine model, a significant correlation persists between arterial and mixed venous pH. The arteriovenous change in pH is ± 0.03 to 0.04 pH unit. The buffering capacity of cold blood is also markedly impaired. In normothermia, when the P_{aCO_2} increases 10 mm Hg, a decrease in pH of 0.08 unit occurs. At 28° C (82.4° F), the decrease in pH doubles to 0.16.

The optimal strategy to maintain acid-base homeostasis during treatment of accidental hypothermia has changed from earlier days.^[230] The accepted earlier assumption was that 7.42 was the ideal "corrected" patient pH at all temperatures and that therapy should be directed at maintenance of the corrected arterial pH at 7.42.^[277] A better intracellular pH reference is electrochemical neutrality, at which pH equals pOH. Since the neutral point of water at 37° C (98.6° F) is pH 6.8, Rahn^[219] has hypothesized that this normal 0.6 unit pH offset in body fluids should be maintained at all temperatures.^[223] Because the neutral pH rises with cooling, so should blood pH ([Figure 6-5](#)).

Relative alkalinity of tissues makes physiologic sense. Intracellular electrochemical neutrality ensures optimal function of the enzyme systems and transport proteins at all temperatures and allows excretion of the neutral intracellular waste product urea.^[9]

Depressed metabolism and carbon dioxide generation are the physiologic responses to temperature depression, since each temperature has its associated metabolic rate. Ventilation is intrinsically adjusted to maintain a net charge on the defended parameter,

the peptide-linked histidine imidazole buffering system.

One homeostatic approach to maintain a steady pH is to keep the bicarbonate content constant. This is

Figure 6-5 Neutrality is the pH of water at any given temperature. At 25° C (77° F) the neutral pH of water is 7.0; at 37° C (98.6° F) it is 6.8. Ectotherm's physiologic 0.6 pH offset from neutral water progressively diminishes if the arterial blood gases are temperature corrected. After the in vitro sample is warmed in the analyzer to 37° C, do not mathematically correct the reported values to reflect the in vivo temperature.

achievable only if the total blood carbon dioxide content does not change. Since carbon dioxide solubility increases with temperature depression, alveolar ventilation must increase to compensate by lowering the P_{aCO_2} . The active ectotherms exhibit this respiratory adaptation and do not depress their respiratory minute volume when cold. This response, termed the *ectothermic*, or *alpha-stat*, *strategy*, allows them to maintain total bicarbonate and carbon dioxide content while increasing pH.^[213] Hibernating mammals are far more acidic and use an acid-base strategy that suppresses metabolism, termed the *endothermic*, or *pH stat*, *strategy*.

In summary, accidental hypothermia in a human should not be considered a protective form of "hibernation." The endothermic strategy using arterial blood gas values that are mathematically "corrected" after the values are determined by the analyzer is dangerous.^[13] The ectothermic approach assures adequate alveolar ventilation and acid-base balance at any temperature when the uncorrected pH is 7.4 and the uncorrected P_{aCO_2} is 40 mm Hg.

Hematologic Evaluation

The severity of blood loss is easily underestimated. Hematocrit value increases because of a decline in plasma volume and a 2% increase per 1° C (1.8° F) fall in temperature. In addition, total RBC mass might already be low because of preexisting anemia, malnutrition, leukemia, uremia, or neoplasm.

White blood cell count is frequently normal or low, even if sepsis is present. As a result, systemic leukopenia does not imply absence of infection, especially if the patient is at either age extreme, debilitated, intoxicated,

myxedematous, or has secondary hypothermia.^[168] Leukocyte count also drops during hypothermia because of direct bone marrow depression and hepatic, splenic, and splanchnic sequestration.

Serum electrolyte levels must be continuously monitored and rechecked during warming. There are no safe predictors of electrolyte values.^[49] ^[106] Serum electrolytes fluctuate with temperature, duration of exposure, and rewarming technique selected. Both membrane permeability and sodium-potassium pump efficiency also change with temperature. Isolated temperature depression per se has no consistent effect on sodium and chloride levels until well below 25° C (77° F). Plasma electrolyte levels are also affected by ongoing fluid shifts, prehydration, rehydration, and endocrine or gastrointestinal dysfunction.

Plasma potassium level is independent of temperature. Empirical potassium supplementation during hypothermia often results in normothermic toxicity. From a clinical perspective, hypokalemia occurs as potassium moves into the musculature and not simply out of the body through kaliuresis. The physiologically illogical discrepancy of decreasing potassium level with decreasing pH results from greater intracellular than extracellular pH changes. Hypokalemia is much more common in prolonged or chronically induced hypothermia.

Systemic potassium deficiencies can also be exacerbated by prior diuretic therapy, alcoholism, diabetic ketoacidosis, hypopituitarism, and inappropriate antidiuretic hormone secretion. Hypokalemic digitalis sensitivity can be masked by hypothermia, and gradual correction of persistent and severe hypokalemia during rewarming is necessary for optimal cardiac and gastrointestinal function.

When hyperkalemia is identified, the physician should search for other causes of metabolic acidosis, crush injury or rhabdomyolysis, renal failure, postsubmersion hemolysis, or hypoaldosteronism. Temperature depression can increase hyperkalemic cardiac toxicity. The well-known diagnostic ECG changes are often obscured, and VF can occur with serum potassium levels below 7 mEq/L.

Hypothermia has no consistent effect on magnesium or calcium levels. Severe hypophosphatemia is reported during treatment of profound hypothermia. Although increases in serum enzyme levels are not seen in mild experimental hypothermia, numerous serum enzymes are elevated when diffuse intracellular structural damage occurs in severe accidental hypothermia. Creatine kinase (CK) levels over 200,000 IU are observed, and rhabdomyolysis is often present in these instances.^[49]

Inhibition of cellular membrane transport decreases glucose utilization. In addition, insulin release and activity are markedly reduced below 30° C (86° F). Because target cells are insulin resistant, hyperglycemia is commonly seen initially. Markedly elevated glucose levels often correlate with hyperamylasemia and increased cortisol

secretion.^[278]

Acute hypothermia initially elevates serum glucose level through catecholamine-induced glycogenolysis. However, chronic exposure after exhaustion and glycogen depletion leads to hypoglycemia. The symptoms often resemble those of hypothermia. Cold-induced renal glycosuria is common and does not imply normoglycemia or hyperglycemia. When hypoglycemia and central neuroglycopenia are present, correction improves level of consciousness only to that expected for the current core temperature. Cholesterol and triglyceride levels are also often below normal.

Hyperglycemia that persists during and after rewarming should suggest diabetic ketoacidosis or hemorrhagic pancreatitis. Insulin is ineffective until core temperature is well above 30° to 32° C (86° to 89.6° F) and therefore should be withheld to avoid iatrogenic hypoglycemia after rewarming. Although prior renal disease should be a consideration, blood urea nitrogen (BUN) and creatinine concentrations are often elevated because of decreased nitrogenous waste clearance by cold diuresis. Because of ongoing fluid shifts, BUN is a poor reflector of circulatory volume status.

The relationship between primary accidental hypothermia and hyperamylasemia appears to correlate with the severity of temperature depression, but preexisting or hypothermia-induced pancreatitis is present in up to 50% of patients in some urban series. Since the abdominal examination is frequently unreliable, amylase and lipase levels should be measured, except in minor cases. Ischemic pancreatitis is attributable to microcirculatory collapse in hypothermia. Decreased pancreatic blood flow activates many proteolytic enzymes. The extent of hyperamylasemia can correlate with mortality rates. Hypothermia with hypothalamic astrocytoma and pancreatitis also occurs.^[49]

TREATMENT

Prehospital Management

The combination of cold and exhaustion is a common cause of hypothermia in the field.^[197] The individual's cold tolerance depends on temperature, wind, clothing worn, and wetness. It does not take an extremely cold temperature to produce hypothermia after energy depletion. As mental function decreases, the victim cannot respond to the rising threat. Judgment is impaired, and the victim seldom takes necessary precautions to prevent further disaster.^[21]

Field presentation of victims who are awake covers a wide spectrum. Some persons are obtunded but conscious. The British term for this is the "stumbling slobbers" because of the incoordination. Victims may or may not be shivering and often have a distant gaze and slurred speech.

149

Comatose victims require careful handling because they are extremely sensitive to VF and asystole. Rough handling causes VF ([Figure 6-6](#)). Gurneys should be carried or rolled slowly to avoid jostling, and "code 3 full lights and sirens" transport should be avoided if victims are perfusing adequately.

The initial rescuer and first responder often encounter obstacles to preventing further heat loss.^[198] Because cold, stiff, and cyanotic patients with fixed and dilated pupils have been "reanimated," the treatment dictum for prehospital personnel remains, "No one is dead until warm and dead."^[6] A succinct summary of prehospital care of the hypothermic patient is rescue, examine, insulate, and transport.

In certain imposing geographic settings, treatment protocols are helpful to standardize treatment while tacitly acknowledging that available health care facilities may offer limited expertise and equipment.^[231] Aeromedical transport is often ideal in these circumstances.^[282] In difficult environments, proper protocols with rehearsal and critique of mass casualty plans in the cold are far more important than similar adjuncts in flat and consistently sunny terrain.

The history obtained at the scene helps determine optimal treatment. The pertinent past medical history regarding prior cardiopulmonary, endocrinologic, or neurologic conditions is particularly helpful. The circumstances of discovery, duration of exposure,

associated injuries or frostbite, and obvious predisposing conditions should be recorded, as should the Glasgow Coma Scale score, although not predictive. No prognostic neurologic scale during hypothermia is valid, but trends are often useful.

Accurate field measurement of core temperature is generally impractical. Low-reading glass oral thermometers that record down to 25° C (77° F) give a rough estimate of the temperature in cooperative persons who are not tachypneic, but these thermometers are often unreliable outdoors in cold ambient conditions. The failure to consider accidental hypothermia in the differential diagnosis can present unforeseen problems.

Prolonged field treatment should be avoided whenever possible, although the rescuer must attempt to prevent further heat loss ([Box 6-4](#)). The rescuer should

Figure 6-6 In this patient, ventricular fibrillation developed during a code 3 transport by emergency medical services to the emergency department. Note the pronounced J wave after the QRS complex.

anticipate the presence of an irritable myocardium, hypovolemia, and a large temperature gradient between the periphery and the core.

Passive external rewarming with dry insulating materials minimizes conductive, convective, evaporative, and radiant heat losses. Remove any wet clothing from awake victims and insulate them with sleeping bags, insulated pads, bubble wrap, blankets, or even newspaper. In a survey of common field rewarming methods used by Mountain Rescue teams, the most common techniques include chemical pads, sleeping bags, and hot water bottles.^[104]

If extrication will be delayed, it may be safe to give warm, sweet drinks, warm gelatin (Jell-O), Tang, juice, tea, or cocoa. Avoid heavily caffeinated drinks. Because

a significant diuresis is usually associated with the cooling process, the victim's fluid balance must be assessed. Once mildly hypothermic victims are well hydrated, they can be walked out to safety.

Box 6-4. PREPARING HYPOTHERMIC PATIENTS FOR TRANSPORT

1. The patient must be dry. Gently remove or cut off wet clothing and replace it with dry clothing or a dry insulation system. Keep the patient horizontal, and do not allow exertion or massage of the extremities.
2. Stabilize injuries (i.e., the spine; place fractures in the correct anatomic position). Open wounds should be covered before packaging.
3. Initiate intravenous infusions (IVs) if feasible; bags can be placed under the patient's buttocks or in a compressor system. Administer a fluid challenge.
4. Active rewarming should be limited to heated inhalation and truncal heat. Insulate hot water bottles in stockings or mittens and then place them in the patient's axillae and groin.
5. The patient should be wrapped. The wrap starts with a large plastic sheet, on which is placed an insulated sleeping pad. A layer of blankets, a sleeping bag, or bubble wrap insulating material is laid over the sleeping bag; the patient is placed on the insulation; the heating bottles are put in place along with IVs, and the entire package is wrapped layer over layer. The plastic is the final closure. The face should be partially covered, but a tunnel should be created to allow access for breathing and monitoring of the patient.

Handle severely hypothermic victims gently, immobilizing them to prevent exertion. Although exercise can rewarm a person more rapidly than shivering, it also markedly increases afterdrop.^[88] ^[89] Because of autonomic dysfunction, victims should be kept in a horizontal position whenever possible to minimize orthostatic hypotension. Vigorously

massaging cold extremities is also contraindicated, since skin rubbing, like ethanol, suppresses shivering thermogenesis and increases cutaneous vasodilation.

Field management of the comatose victim first involves ventilation to raise oxygen saturation. Mouth-to-mouth or mouth-to-nose rescue breathing is appropriate but may be difficult because of chest stiffness and significant resistance to diaphragmatic motion. Forced ventilation increases oxygenation, which helps stabilize the heart electrically. The single greatest factor in maintaining perfusion is oxygenation provided during severe hypothermia.

During a storm, prolonged field rewarming may be the only viable option until meteorologic conditions become more favorable for land or, preferably, aeromedical evacuation.^[282] Many prehospital medications freeze in solution. If this occurs, their pharmacologic activity after thawing is indeterminate (see [Appendix](#) at end of this book). When available, consider whether administration of 50% dextrose or naloxone is indicated.

Give an intravenous (IV) fluid challenge with 250 to 500 ml heated (37° to 41° C [98.6° to 105.8° F]) 5% dextrose in normal saline solution. If that is unavailable, any crystalloid infusion with dextrose can be used. Improvisation during transport is often helpful. For example, a plastic IV container can be placed under the patient's back, shoulders, or buttocks to add warmth and infusion pressure. Taping heat-producing packets to IV bags is another option. These heating agents may be chemical packets or phase change crystals, which produce heat for up to several hours. IV fluid compressors are bulb-inflating cuffs that surround IV pouches to maintain flow. The Israeli army has a spring steel compressor system for IV bags.

Peripheral vessels may be difficult to locate, and IV lines are hard to maintain during transport. Ideally, IV fluids should be warmed to body temperature or slightly higher, but total body warming is not accomplished with IV fluids in the field. Using intraosseous infusions may provide a reasonable pathway for fluid replacement in the field when peripheral vessels have collapsed and cannot be entered.

The methods selected to stabilize core temperature should be tailored to the severity of hypothermia and the field circumstances. Gently removing or cutting off wet clothing while the patient remains prone may be the best option to limit heat loss and prevent orthostasis. Passive external rewarming with waterproof insulation suffices for mild chronic hypothermia. In their series of patients requiring cardiopulmonary bypass (CPB), Walpoth^[269] ^[270] "maintained" hypothermia during transport. Whether supplemental active field rewarming should be initiated en route to the ED, and in which subsets of patients, is not definitively established. Intentionally maintaining hypothermia during transport seems wise only for patients with an isolated closed head injury.

"Field rewarming" is a misnomer, since adding much heat to a hypothermic patient in the field is extremely difficult.^[68] Warmed IV solutions, heated sarongs, or heated humidified oxygen can provide only a small amount of heat input. Hot water bottles or heat packs can be placed in the axillae, in the groin, and around the neck. Casualty evacuation bags are available in many models and designs. Some have more insulation

than others, and some have specialized zippers and openings that allow access to the victim during transport. Most bags are windproof and waterproof.

Inhalation therapy is safe for active rewarming of victims with profound hypothermia in the field.^[106] It helps prevent respiratory heat loss, which represents an important percentage of heat production when the core temperature is below 32° C (89.6° F). Technical difficulties experienced while using inhalation rewarming devices in volunteers suggest the importance of proper instruction for the rescuer.^[253]

The current rewarming device weighs 3 kg, including oxygen tank, and consists of an oxygen cylinder, demand valve, 2-L reservoir bag, soda lime, and pediatric water canister. An in-line thermometer measures mean air temperature at the face mask. In the field, heat and moisture exchangers are practical, light, and inexpensive. They are, however, less efficient than active humidifiers.^{[173] [175]}

The Res-Q-Air (CF Electronics, Inc., Commack, N.Y.) is a lightweight, portable first-aid device that delivers heated humidified air or oxygen at temperatures ranging from 42° to 44° C (107.6° to 111.2° F) down to ambient conditions of -20° C (-4° F). This system consists of a heating chamber connected via a corrugated hose to a one-way flow valve and an oronasal mask. The temperature is controlled by a transducer in the one-way flow valve that provides feedback to the electronic control circuits. Supplemental oxygen and bag adaptation are possible.

Although surface rewarming suppresses shivering, it may be the only option when the victim is isolated from medical care. Active external rewarming options include radiant heat, warmed objects placed on the patient, and body-to-body contact.^[90] Care must be exercised

not to burn victims with hot objects, including commercially produced "hot packs." Total body contact rewarming may carry some risk,^{[90] [106]} but logistical impediments limit the use of this method unless extrication will be significantly delayed.

A hydraulic sarong or vest, in which heated water is circulated via hand pump, is also used occasionally.^[104] Immersion rewarming is dangerous in the field because monitoring and resuscitation capabilities are limited.

The Norwegian Personal Heater Heat Pac may be a useful device for field transport of hypothermic patients. This device uses a single "D" battery and burns 30 hours on a single charcoal block. It is durable, lightweight (1 kg), efficient, and effective. It circulates hot air within a blanket or sleeping bag and provides a comfortable, warm and dry environment for transporting victims. In a human model with shivering inhibited by meperidine, the rate of rewarming with passive external rewarming over 150 minutes is not improved with inhalation rewarming.^[96]

Another option under development is the use of a modified forced-air warming system for field use.^{[62] [63] [88]} The Portable Rigid Forced-Air Cover is heated with a Bair Hugger 505 Heater/Blower (Augustine Medical, Inc., Eden Prairie, Minn.). It covers the patient's trunk and thighs and can adapt to various transport vehicle power sources.

Figure 6-7 Prehospital life support. *PEA*, Pulseless electrical activity.

Prehospital Life Support ([Figure 6-7](#))

A patent airway and the presence of respirations must be established. The victim may appear apneic if respiratory minute ventilation is significantly depressed. A common error in tracheally intubated patients is overzealous assistance of ventilation, which can induce hypocapnic ventricular irritability. The indications for prehospital endotracheal intubation are identical to those under normothermic conditions. Appropriate ventilation with 100% oxygen may protect the heart during extrication and transport. Avoid overinflation of the tracheal cuff with frigid ambient air. As the victim warms, air in the cuff can expand and kink the tube. Careful protection and fixation of the tubing of the cuff port during extremely cold conditions are necessary to prevent breakage and cuff leak.

Palpation of peripheral pulses is often difficult in vasoconstricted and bradycardic patients. Apparent cardiovascular collapse may actually reflect depressed cardiac output just sufficient to meet minimal metabolic demands. The rescuer should auscultate and palpate for at least 1 minute to find pulses. Iatrogenic VF can easily result from unindicated chest compressions.

If a cardiac monitor is available, use maximal amplification to search for QRS complexes. If the victim is in VF, the rescuer should attempt defibrillation initially with 2 watt sec/kg up to 200 watt sec. If the second and

third attempts at 360 watt sec are unsuccessful, assume that the victim must be rewarmed before further attempts. Do not perform defibrillation if electrical complexes are seen on the monitor. Most monitors and defibrillators have not been tested for operation at temperatures below 15.5° C (59.9° F). Standard monitor leads do not always stick well to cold skin, so benzoin may be useful. If this fails, needle electrodes may be necessary. Another option is to puncture the gel foam conventional monitor pad with a small-gauge injection needle.^[274]

Carefully assess unresponsive victims for a central pulse before assuming they have pulseless electrical activity (PEA). The lowest temperature at which mechanical reestablishment of cardiac activity has been successful is 20° C (68° F),^[54] and defibrillation attempts rarely succeed below 30° C (86° F). If resuscitation in

TABLE 6-3 -- Core Temperature Measurements

TYPE	ADVANTAGES	CONSIDERATIONS
Rectal	Convenient	Insert 15 cm

Management in the Emergency Department

The history obtained from a hypothermic patient is often unreliable; therefore it is prudent to confirm hypothermia and monitor with continuous core temperature measurements. Diagnostic errors in the ED usually result from incomplete monitoring of vital signs. Doppler ultrasound may be necessary to locate a pulse and should be supported by continuous ECG monitoring. The physician should also address the requirements for resuscitation and initiate advanced life support when necessary ([Box 6-5](#)).

Temperature Measurement.

Some hospitals lack adequate equipment for accurate core temperature measurement.^[204] Rectal measurements are most practical clinically but may not reflect cardiac or brain temperatures.^[112] An indwelling thermistor probe placed to a depth of 15 cm is fairly reliable unless adjacent to cold feces. Rectal temperature lags behind core temperature fluctuations and is also affected by lower extremity temperatures^[280] ([Table 6-3](#)).

Simultaneous esophageal temperature measurements may be helpful when airway protection is provided with endotracheal intubation. Esophageal temperature approximates cardiac temperature. Since the upper third of the esophagus is near the trachea, the probe may read falsely high during heated inhalation therapy. The probe should be placed 24 cm below the larynx. The greatest discordance between rectal and esophageal temperatures is noted during the transition phase between cooling and rewarming. Correct selection, accuracy, and use of devices that measure urine

temperature are debated. Crystalloid resuscitation and cold-induced diuresis both produce erratic readings.

Tympanic temperature theoretically approximates hypothalamic temperature and can be accurately measured with thermometers in contact with the tympanic membrane. Since these are impractical except in anesthetized patients, external auditory canal thermometers that measure infrared emission from the tympanic membrane have been developed. These are not actually "tympanic" thermometers, but this term is used extensively.^[288]

External auditory canal thermometers are poorly sensitive for fever when used in clinical settings. Tympanic thermometers alone in patients with suspected hypothermia may also be very insensitive. Although bladder temperature measurement devices can be incorporated into the urinary drainage catheter, the readings are frequently unreliable. They will be falsely elevated with peritoneal lavage and, more commonly, low as a result of cold-induced diuresis.

Initial Stabilization.

After core temperature measurement, all clothing should be gently removed or cut off with minimal patient manipulation.^[212] Immediately insulate the patient with dry blankets. Apply a cardiac monitor, and insert intravenous catheters as needed. Arterial catheter insertion may help in managing selected profoundly hypothermic patients. Pulmonary artery catheters can precipitate cardiac arrhythmias and should be reserved for complex cases. Insertion of pulmonary artery catheters into cold vessels may perforate the pulmonary artery.^[39] Do not use central venous catheters in the right atrium, since this could precipitate arrhythmias.^[244]

Accuracy of pulse oximetry during conditions of poor perfusion is unclear. In one study of hypothermic patients on CPB, the finger probes were inaccurate.^[36] The probe may be fairly reliable if a vasodilating cream is applied first. The value of end-tidal carbon dioxide measurements to assess adequacy of tissue perfusion and tracheal tube placement has been established at normal temperatures. Most of these devices, however, only measure the carbon dioxide content of dehumidified air and thus cannot be used during airway rewarming.

Laboratory evaluations to be considered, except in some cases of mild hypothermia, include blood sugar, arterial blood gases, complete blood cell count, electrolytes, BUN, creatinine, serum calcium, serum magnesium, serum amylase and lipase, PT, PTT, international normalized ratio (INR), platelet count, and fibrinogen level. A toxicologic screen should be considered if the level of consciousness does not correlate with the degree of hypothermia. Selective studies of thyroid function, cardiac isoenzyme levels, and serum cortisol levels are indicated.

The indications for radiography should be liberalized from normothermia. Radiologic evaluation of poorly responsive patients must include cervical and other spine films to detect occult trauma. Chest radiographs may predict collapse during rewarming when cardiomegaly and redistribution of vascularity are already present. Abdominal films should be obtained when the physical examination is unreliable. Bowel sounds are usually diminished or absent in severe hypothermia, and rectus muscle rigidity is frequently present. Pneumoperitoneum, pancreatic calcifications, or hemoperitoneum may be noted. Small bowel dilation is associated with cold-induced mesenteric vascular occlusion, and colonic dilation is often present in conjunction with myxedema coma. The use of focused abdominal sonography may be helpful.

Nasogastric tube insertion should be performed after endotracheal intubation in moderate or severe hypothermia, since gastric dilation and poor gastrointestinal motility are common. Indwelling bladder catheters with urine meters are needed to monitor urine output and the cold diuresis.

FLUID RESUSCITATION

Most fluid shifts are reversed by rewarming, and mild hypothermia usually requires only an IV lifeline. In more severe cases, volume shifts and elevated blood viscosity from hemoconcentration, lowered temperature, increased vascular permeability, and low flow state mandate aggressive fluid resuscitation. The viscosity of blood increases 2% per degree Centigrade drop in temperature; therefore hematocrit values over 50% are commonly seen. Low circulatory plasma volume is often coupled with elevated total plasma volume during rewarming. Hemodilution is usually not a problem, seen only during massive crystalloid resuscitation of actively hemorrhaging patients. ^[49]

Assume that patients will be significantly dehydrated, with free water depletion elevating serum sodium concentration and osmolality. During the descent into a hypothermic state, normal physiologic cues for thirst become inactive and access to water is often difficult. Since hypothermia results in natriuresis, saline depletion may be present. Further causes of sodium losses include prior diuretic therapy and gastrointestinal losses. Preexisting total body sodium excess is seen with congestive heart failure, cirrhosis, and nephrosis. In these cases serum sodium and osmolality values are often normal. Rarely, serum sodium level is low because of free water excess. Other causes include myxedema, panhypopituitarism, and inappropriate antidiuretic hormone secretion. ^[49]

Most patients with core temperature below 32.2° C (90° F) should receive an initial fluid challenge with 250 to 500 ml of 5% dextrose in warmed normal saline

solution. Theoretically, Ringer's lactate solution should be avoided because a cold liver cannot metabolize lactate. Any potential advantages of colloids over crystalloids remain uncertain. Some clinicians administer colloids to patients who are not responding to crystalloids.

Monitor the victim for standard clinical signs of fluid overload, including rales, jugular venous distention, hepatojugular reflux, and S₃ cardiac gallop. Persistent cardiovascular instability often reflects inadequate intravascular volume. In this case, a properly placed central venous pressure catheter that does not enter and irritate the right atrium has a role. Pulmonary wedge pressure measurements should generally be deferred until after rewarming. The need for RBC transfusions is determined by the corrected hematocrit;

blood dilution with warmed infusate does not cause significant hemolysis.

In many cases, rapid volume expansion is critical. Circulatory volume is decreased, and peripheral vascular resistance is increased. In neonates, adequate fluid resuscitation markedly decreases mortality. Adults receiving hemodynamic monitoring have shown improvement of cardiovascular efficiency during crystalloid administration. VF immediately after rescue has been attributed to both core temperature afterdrop and vascular imbalance in patients who are moved from a horizontal supine position.^[174] The fluxing relationship between active vascular capacity and circulating fluid volume depends not only on the mechanism of cooling but also on the method of rewarming.

The safety and efficacy of the pneumatic antishock garment in hypothermia are unknown. Application presents several theoretic circulatory and limb hazards. Since the vasculature is already maximally vasoconstricted, provision of more peripheral vascular resistance by the garment will not be significant. Hypothermic patients, particularly those with frostbite, are at high risk for extremity compartment syndromes and rhabdomyolysis. Pneumatic trousers should be considered only to temporarily stabilize coexistent exsanguinating major pelvic fractures.

REWARMING OPTIONS

Passive External Rewarming

Because hypothermia is an extremely heterogenous condition and no controlled studies exist, rigid treatment protocols are not suggested.^{[231] [235] [289]} A versatile approach to rewarming can be developed after careful consideration of the observations from animal experiments, human experiments on mild hypothermia, and various clinical reports^[102] ([Box 6-6](#)).

The initial key treatment decision is whether to use active or passive rewarming ([Box 6-7](#)). Noninvasive passive external rewarming (PER) is ideal for most previously healthy patients with mild hypothermia. The patient is covered with dry insulating materials in a warm environment to minimize the normal mechanisms of heat loss. When the wind is blocked, less heat escapes via radiation, convection, and conduction. Conditions with higher ambient humidities slightly limit respiratory heat loss.

Box 6-7. INDICATIONS FOR ACTIVE REWARMING

Cardiovascular instability

Moderate or severe hypothermia (<32.2° C [90° F]) (poikilothermia)

Inadequate rate or failure to rewarm

Endocrinologic insufficiency

Traumatic or toxicologic peripheral vasodilation

Secondary hypothermia impairing thermoregulation

Identification of predisposing factors (see [Box 6-2](#))

Aluminized body covers significantly reduce heat loss.^{[69] [120]} Nevertheless, endogenous thermogenesis must generate an acceptable rate of rewarming for PER to be effective.^[205] Humans are functionally poikilothermic below 30° C (86° F), and metabolic heat production is less than 50% of normal below 28° C (82.4° F). Shivering thermogenesis is also extinguished below 32° C (89.6° F). This thermoregulatory neuromuscular response

Figure 6-8 First-hour rewarming rates from a large multicenter survey. ACR,

Active core rewarming; *AER*, active external rewarming; *ET*, endotracheal tube; *GBC*, gastric-bladder-colon lavage; *IV*, intravenous; *NT*, nasotracheal tube; *P*, peritoneal lavage; *PER*, passive external rewarming. (Data from Danzl DF et al: *Ann Emerg Med* 16:1042, 1987.)

to cold normally increases heat production from 250 to 1000 kcal/hr unless glycogen is depleted during cooling.

Elderly patients in whom mild hypothermia develops gradually are acceptable candidates for *PER*. Peripheral vasoconstriction is maintained, which minimizes the circulatory component of core temperature afterdrop. When rewarming times are markedly prolonged (over 12 hours), complications tend to increase.

Patients who are centrally hypovolemic, glycogen depleted, and without normal cardiovascular responses should be stabilized and rewarmed at a conservative rate. In a multicenter survey the first ($0.75^{\circ}\text{C} \pm 1.16$), second ($1.17^{\circ}\text{C} \pm 1.17$), and third ($1.26^{\circ}\text{C} \pm 1.28$) hour rewarming rates for the elderly far exceeded 0.5°C per hour with no increase in mortality rate ([Figure 6-8](#)).^[51]

Active Rewarming

Active rewarming, which is the direct transfer of exogenous heat to a patient, is usually required with temperatures below 32°C (89.6°F).^[162] Rapid identification of any impediment to normal thermoregulation, such as cardiovascular instability or endocrinologic insufficiency, is essential.^[163]^[196] Intrinsic thermogenesis may also be insufficient after traumatic spinal cord transection or pharmacologically induced peripheral vasodilation. Some patient populations generally require active rewarming.^[154] For example, aggressive rewarming of infants minimizes energy expenditure and decreases mortality.^[284] In these circumstances, vigorous monitoring for respiratory, hematologic, metabolic, and infectious complications is essential.

When active rewarming is needed, heat can be delivered externally or to the core. Active external rewarming (*AER*) techniques deliver heat directly to the skin. Examples include forced air rewarming, immersion, arteriovenous anastomoses rewarming, plumbed garments, hot water bottles, heating pads and blankets, and radiant heat sources.

Active External Rewarming.

The interpretation of survival rates with *AER* is affected by various risk factors and patient selection criteria. In some reports, "active" is an artificial description, since rewarming required more than 24 hours. One author reported a 100% success rate with immersion rewarming.^[77]

Some experimental and clinical reports link *AER* with peripheral vasodilation, hypotension, and core temperature afterdrop, but previously healthy, young, acutely hypothermic victims are usually safe candidates for *AER*.^[25] Heat application confined to the thorax may mitigate many of the physiologic concerns pertaining to the depressed cardiovascular and metabolic systems, which are unable to meet accelerated peripheral

demands. Combining truncal AER with active core rewarming may further avert many potential side effects.

FORCED AIR REWARMING.

Forced air warming systems efficiently transfer heat.^{[7] [88] [130]} The Bair Hugger (Augustine Medical, Inc.) uses hot forced air circulated through a blanket. The air exits apertures on the patient side of the cover, permitting the convective transfer of heat.^{[191] [240]} In one study that rewarmed accidental hypothermia victims in the ED, rewarming shock and core temperature afterdrop were not noted^[250] with the use of heated inhalation and warmed IV fluids. A group also treated with a convective cover inflated at 43° C (109.4° F) rewarmed 1° C (1.8° F) per hour faster than a group covered with a cotton blanket (1.4° C [2.5° F] per hour).

A study of full-body forced air warming compared a commercially available convective blanket with simple

air delivery beneath bed sheets.^[148] Directed 38° C (100.4° F) warm air under the sheets warmed standardized thermal bodies containing water very efficiently.

The use of forced air warming systems is most practical in the ED.^{[153] [158] [165]} Although these devices decrease shivering thermogenesis, afterdrop is minimized and heat transfer can be significant. Thermal injury to poorly perfused, vasoconstricted skin using some of the other external heat application techniques is a hazard in both adults and children.^{[104] [151]}

IMMERSION.

Immersion in a 40° C (104° F) circulating bath presents difficulties in monitoring, resuscitation, treatment of injuries, and maintenance of extremity vasoconstriction to prevent core temperature afterdrop. "Bobbing" CPR is impossible in the tub. In normothermic men with coronary artery disease, the cardiovascular stress and arrhythmogenic response to immersion in a hot tub are mild, less than those induced by exercise.^[2] In contrast, placing the hands and feet in warm water theoretically opens arteriovenous shunts and accelerates rewarming in acute hypothermia. The attraction to Scandinavian palmar heat packs may reflect this physiology.

ARTERIOVENOUS ANASTOMOSES REWARMING.

The original description of this noninvasive AER technique was by Vangaard^[264] in 1979. Exogenous heat is provided by immersion of the lower parts of the extremities (hands, forearms, feet, calves) in 44° to 45° C (111.2° to 113° F) water. The heat opens arteriovenous anastomoses (AVAs). These organs are 1 mm below the epidermal

surface in the digits. ^[14] ^[61] ^[195] As a result, there is increased flow of warmed venous subcutaneous blood returning directly to the heart. Countercurrent heat loss is minimized because the superficial veins are not close to the arterial tree.

To be efficacious, the cutaneous heat exchange area must include the lower legs and forearms, and the water must be 44° to 45° C. Reported advantages with AVA rewarming include patient comfort and decreased postcooling afterdrop.

A permutation of AVA rewarming is negative pressure rewarming. Under hypothermic conditions, the AVAs remain closed during peripheral vasoconstriction. In combination with localized heat application, application of subatmospheric pressure theoretically distends the venous rate and increases flow through the AVAs.

To initiate negative pressure rewarming, the forearm is inserted through an acrylic tubing sleeve device fitted with a neoprene collar. This allows an airtight seal to form around the forearm. After -40 mm Hg vacuum pressure is created, heat is applied over the dilated AVAs. ^[247] The thermal load can be provided via an exothermic chemical reaction or via a heated perfusion blanket.

The clinical efficacy and safety of AVA rewarming in accidental hypothermia remains to be determined. Studies concluding that heat exchange is ineffectual used cooler water applied only on the hands and feet. ^[30] ^[43] The potential for superficial burns of anesthetic, vasoconstricted skin is a consideration. Another caveat is hypotension precipitated in hypovolemic patients who remain semi-upright with this technique.

Active Core Rewarming.

Various techniques can effectively deliver heat to the core, ^[228] ^[239] ^[264] including heated inhalation, heated infusion, diathermy, lavage (gastric, colonic, mediastinal, thoracic, peritoneal), hemodialysis, and venovenous and continuous arteriovenous rewarming. Formal CPB is the definitive core rewarming technique. Average first-hour rewarming rates reported with some of these techniques in one multicenter study are listed in [Figure 6-8](#).

AIRWAY REWARMING.

Heated, humidified oxygen inhalation has been studied extensively for both prehospital and ED rewarming. ^[173] The effectiveness of the respiratory tract as a heat exchanger varies with technique and ambient conditions. ^[192] Since dry air has low thermal conductivity, complete humidification coupled with inhaled temperature of 40° to 45° C (104° to 113° F) is required. ^[222] The main benefit of airway rewarming is prevention of respiratory heat loss. Heat yield can represent 10% to 30% of the hypothermic patient's heat production when respiratory minute volume is adequate. ^[23]

The rate of rewarming is greater using an endotracheal tube (ETT) than by mask. In one series, the reported rewarming rate with 40° C aerosol was 0.74° C (1.33° F) per hour via mask and 1.22° C (2.2° F) per hour via ETT. ^[196] In the multicenter survey the

average first- and second-hour rewarming rates in severe cases were 1.5° to 2° C (2.7° to 3.6° F) per hour. Because of the decremental efficiency at higher temperatures, the rate is slower in mild cases.^[51]

Thermal countercurrent exchange in the cerebrovascular bed of humans^[56] affects the efficiency and influence of heated mask ventilation during hypothermia. Known as the *rete mirabile*, this system could preferentially rewarm the brainstem. Heated inhalation via face mask continuous positive airway pressure (CPAP) has been successfully used and may correct the ventilation-perfusion mismatch.^[31] Heated humidified oxygen via face mask may not be feasible in some patients with coexistent midface trauma.

Heat liberated during airway rewarming is produced mainly from condensation of water vapor. The latent heat of vaporization of water in the lung is slightly lower than 540 kcal/g H₂O. This is multiplied by the liters per minute ventilation to calculate the quantity of heat transfer. When core temperature is 28° C (82.4° F), the rate of rewarming with heated ventilation

157

at 42° C (107.6° F) equals endogenous heat production. Although the effect on overall thermal balance can be minimal, there may be preferential rewarming of thermoregulatory control centers.

Heated humidified inhalation ensures adequate oxygenation, stimulates pulmonary cilia, and reduces the amount and viscosity of cold-induced bronchorrhea. Although preexisting premature ventricular contractions (PVCs) may reappear during rewarming, there is no evidence that inhalation rewarming precipitates new, clinically significant ventricular arrhythmias.^[50] Vapor absorption does not increase pulmonary congestion or wash out surfactant. When the pulmonary vasculature is heated, warmed oxygenated blood that returns to the myocardium could attenuate intermittent temperature gradients. The amplitude of shivering is also lowered, an advantage in more severe cases. In theory, this suppression could decrease heat production in mild hypothermia, although experimentally the core temperature continues to rise.^[43]

There are numerous oxygenation considerations in hypothermia (see [Box 6-1](#)). The "functional" value of hemoglobin at 28° C (82.4° F) has been calculated to be 4.2 g/10 g in patients on CPB.^[76] The oxyhemoglobin dissociation curve also shifts to the left ([Figure 6-9](#)). This impairs release of oxygen from hemoglobin into the tissues. Although some patients can self-adjust their respiratory minute volume (RMV) for current carbon dioxide production, this may not be possible if there are additional toxins or metabolic depressants.

Most humidifiers are manufactured in accordance with International Standards Organization (ISO) regulations. The humidifier will not exceed 41° C (105.8° F) close to the patient outlet with a 6-foot tubing length.^[268] If the decision to alter the equipment is made, carefully monitor the temperature and do not exceed 45° C (113° F). The only

report of thermal airway injury was in a patient ventilated via endotracheal tube for 11 hours with 80° C (176° F) inhalant.

Figure 6-9 Oxyhemoglobin dissociation curve at 37° C (98.6° F). At colder temperatures the curve shifts to the left.

Strategies to circumvent the 41° C ceiling include reduction of tubing length, adding additional heat sources, disabling the humidifier safety system, and placing the temperature probe outside the patient circuit.^[268] Label all modified equipment to avoid routine use. A volume ventilator with a heated cascade humidifier can also deliver CPAP or positive end-expiratory pressure (PEEP) if needed during rewarming. The airway rewarming rates clinically range from 1° to 2.5° C (1.8° to 4.5° F) per hour.^[51]

Heat and moisture exchangers function like artificial nares by trapping exhaled moisture and then returning it. They provide inadequate humidification to treat accidental hypothermia. With prolonged use, ETT occlusion and atelectasis are both problems.^[38]^[97] In the field, heat and moisture exchangers are practical, lightweight, and inexpensive, although less efficient than active humidifiers.^[173]

Airway rewarming is indicated in the field when the equipment is available and in the ED when core temperature is lower than 32.2° C (90° F) on arrival. Although airway rewarming provides less heat than other forms of active core warming, it prevents normal respiratory heat and moisture loss and is safe, fairly noninvasive, and practical in all settings.

HEATED INFUSIONS.

Cold fluid resuscitation of hypovolemic patients can induce hypothermia. In one series of previously normothermic patients with major abdominal vascular trauma, the average postresuscitation temperature was 31.2° C (88.2° F) in those with refractory coagulopathies.^[144] IV fluids are heated to 40° to 42° C (104° to 107.6° F), although some authors suggest higher temperatures may be safe. The amount of heat provided by solutions becomes significant during massive volume resuscitations.^[245] One liter of fluid at 42° C provides 14 kcal to a 70-kg patient at 28° C (82.4° F), elevating the core temperature almost 0.33° C (0.6° F).

Microwave heating of IV fluids in flexible plastic bags is a widely available option.^[238] The plasticizer in the polyvinyl chloride containers is stable to microwave heating. Thermal packs, jackets, or insulation on IV bags also help preserve heat.^[20] Heating times should average 2 minutes at high power for a 1-L bag of crystalloid. The fluid should be thoroughly mixed before administration, since "hot spots" are common in ovens. Fresh

frozen plasma can also be thawed in under 5 minutes.

Significant conductive heat loss occurs through IV tubing, so long lengths of IV tubing increase heat loss, especially at slow flow rates.^[70] There are various methods to achieve and maintain ideal delivery temperature of IV and lavage fluids in hypothermia but no standardized approach.^[105]

Blood preheated to 38° C (100.4° F) in a standard warmer is useful, but clotting and shortened RBC life are hazards with blood-warming packs. Local microwave

overheating hemolyzes blood. An alternative is to dilute packed RBCs with warm calcium-free crystalloid. The Level 1 Fluid Warmer (Life Systems, Inc., Southfield, Mich.) warms cold crystalloid and blood from 10° C to 35° C (50° F to 95° F) via a heat exchanger at flow rates of up to 500 ml/min.

Rapid administration of fluid into the right atrium at a temperature significantly different from that of circulating blood may produce myocardial thermal gradients.^[244] In one study, heated IV fluid, up to 550 ml/min, was administered through the internal jugular vein without complication. In an experimental canine model with adequate cardiac output, central infusion of extremely hot (65° C [149° F]) IV fluids was reported to accelerate rewarming without hemolysis.^{[74] [241]}

Using amino acid infusions may accelerate energy metabolism. Fever is common in patients receiving hyperalimentation. In patients recovering from elective surgery, however, amino acids have had no significant thermogenic effect.^[117] The results might differ in energy-depleted patients with chronically induced accidental hypothermia.

In summary, intravenous solutions and blood are routinely heated during hypothermia resuscitations. Various blood warmers are available commercially, but countercurrent in-line warmers and rapid warm saline admixture are the most efficient techniques.^[128]

HEATED IRRIGATION

Gastrointestinal irrigation.

Heat transfer from irrigation fluids is usually limited by the available surface area, so do not use irrigation as the sole rewarming technique. Direct gastrointestinal irrigation is less desirable than irrigation via intragastric or intracolonic balloons because of induced fluid and electrolyte fluxes. Exceeding 200- to 300-ml aliquots may force fluid into the duodenum; therefore frequent fluid removal via gravity drainage minimizes "lost" fluid. A log of input and output is essential. This facilitates estimation of fluid balance during resuscitation and helps determine if irrigation should be abandoned in anticipation of

dilutional electrolyte disturbances.

To avoid these limitations, a double-lumen esophageal tube has been investigated, as have other modified Sengstaken tubes.^[155] Patients should be tracheally intubated before gastric lavage. Because of the proximity of an irritable heart, overly vigorous placement of a large gastric tube seems ill advised. In the multicenter survey, gastric, bladder, and colon lavage rewarmed severely hypothermic patients at 1° to 1.5° C (1.8° to 2.7° F) for the first hour and 1.5° to 2° C (2.7° to 3.6° F) for the second hour.^[51]

Commercially available kits designed for gastric decontamination are convenient ([Figure 6-10](#)). The use of a Y connector and clamp simplifies the exchanges. Ideal dwell times for thermal exchange depend on flow rates

Figure 6-10 Gastric lavage.

and may average several minutes. In direct gastric lavage, warmed electrolyte solutions, such as normal saline or Ringer's lactate, are administered via nasogastric tube.^[167] After 15 minutes the solution is aspirated and replaced with warm fluids. Disadvantages include the small surface area available for heat exchange and the large amount of fluid escaping into the duodenum.^[28] Regurgitation is common, and the technique must be terminated during CPR. Some authors continue to support the concept of esophageal heat exchange, but clinical success is limited.^{[157] [221] [274] [275]}

Bladder irrigation should be limited to around 200- to 300-ml aliquots to prevent bladder distention. A number of aesthetic obstacles must be overcome to maintain successful colonic irrigation.

Mediastinal irrigation.

Mediastinal irrigation and direct myocardial lavage are alternatives in patients lacking spontaneous perfusion. A standard left thoracotomy is performed while CPR is continued. Opening the pericardium is unnecessary unless an effusion or tamponade is present. The physician bathes the heart for several minutes in 1 to 2 L of an isotonic electrolyte solution heated to 40° C (104° F), then performs suction and replacement of warm fluids.^[29]

The physician may attempt internal defibrillation after myocardial temperature reaches 26° to 28° C (78.8 to 82.4° F). Unless a perfusing rhythm is achieved, lavage is continued until myocardial temperature exceeds 32° to 33° C (89.6° to 91.4° F). A standard post-thoracotomy tube in the left side of the chest could provide an avenue for continued rewarming via thoracic irrigation.

A median sternotomy also allows ventricular decompression and direct defibrillation.^[166] One potential disadvantage of both these techniques is that open cardiac massage of a cold, rigid contracted heart may not generate flow.^[3] ^[45] Unless immediate CPB is an option, mediastinal irrigation and direct myocardial lavage are indicated only if cardiac arrest has occurred. In this circumstance, personnel skilled in the technique should also initiate all other available rewarming modalities.

Closed thoracic lavage.

Irrigation of the hemithoraces is a valuable rewarming adjunct.^[10] ^[29] ^[272] Two large-bore thoracostomy tubes (36 to 40 Fr in adults; 14 to 24 Fr, ages 1 to 3; 20 to 32 Fr, ages 4 to 7) are inserted in one or both of the hemithoraces. One is placed anteriorly in the second to third intercostal space at the midclavicular line, and the other in the posterior axillary line at the fifth to sixth intercostal space. Normal saline heated to 40° to 42° C (104° to 107.6° F) is then infused via a nonrecycled sterile system ([Figure 6-11, A](#)). Hypothermic coagulopathies in extreme situations might necessitate the use of cautery at the incision sites.

A high-flow countercurrent fluid infuser (Level 1 Fluid Warmer)^[27] heats to 40° C and delivers normal saline in 1-L or preferably 3-L bags into the afferent chest tube.^[27] ^[246] I prefer connecting into the Level 1 tubing with standard 3/16-inch-internal-diameter suction connection tubing and a sterilized plastic graduated two-way connector, since this facilitates adaptation to any size chest tube ([Figure 6-11, A](#)). The effluent is then collected in a thoracostomy drainage set. The reservoir must be emptied frequently. Alternatively, when a single chest tube is used, 200- to 300-ml aliquots are used for irrigation, and suctioning is achieved through a Y connector. The Y connector is also useful for irrigating both hemithoraces with a single fluid warmer ([Figure 6-11, B](#)).

The clinical experience reported with closed thoracic lavage remains limited.^[142] ^[281] Fluid has been infused into the anterior higher chest tube (afferent limb) and suctioned or gravity drained out the lower posterior tube (efferent limb) into a water seal chest drain.^[103] Infusion inferoposteriorly with suction anteriorly can increase dwell times.^[129] The efficiency of thermal transfer varies with flow rates and dwell times. If the patient has been successfully rewarmed, the upper tube should be removed and the lower one left in place to allow residual drainage.

Closed sterile thoracic lavage seems a natural choice in the ED during cardiac arrest resuscitations. In patients who are perfusing, this technique should be considered hazardous unless extracorporeal rewarming capability is immediately available. Many

hypothermic trauma patients have been irrigated successfully in the operating room.

The clinically reported rates range from 180 to 550 ml/min. The overall rate of rewarming should easily equal or exceed that achievable with peritoneal lavage and is often 3° to 6° C (5.4° to 10.8° F) per hour. An added benefit is preferential mediastinal rewarming. In addition, closed chest compressions during cardiac arrest can maintain perfusion. Open cardiac massage of a rigid, contracted heart may not be possible in severe cases before bypass, which is a problem with mediastinal irrigation.^[3] ^[45] ^[47]

Various complications should be considered. Left-sided thoracostomy tube insertion into patients who are perfusing could easily induce VF. Patients with pleural adhesions have poor infusion rates, and subcutaneous edema may develop. If the fluids are infused under pressure without adequate drainage, intrathoracic hypertension or even a tension hydrothorax could develop and cause the expected adverse cardiovascular effects. Insufficient data are available to assess the effects on pulmonary ventilation and perfusion.

Peritoneal lavage.

Heated peritoneal lavage is a technique available in most facilities ([Figure 6-12](#)). Heat is conducted intraperitoneally via isotonic dialysate delivered at 40° to 45° C (104° to 113° F).^[265] This technique is not a practical option in the field.

Before lavage is initiated, chest and abdominal radiographs should be obtained because subsequent films may reveal subdiaphragmatic air introduced during the procedure. The bladder and stomach must be emptied before insertion of the catheter. The two common techniques for introducing fluid into the peritoneal cavity are the minilaparotomy and the percutaneous puncture.

The "minilap" requires an infraumbilical incision through the linea alba. A supraumbilical approach is necessary if previous surgical scars, a gravid uterus, or pelvic trauma is identified. The peritoneum is punctured under direct visualization and dialysis catheter(s) inserted. A much simpler and more rapid technique is the guidewire, or Seldinger's, variation of the percutaneous puncture. The site is infiltrated if necessary with lidocaine and a small stab incision is made. An 18- to 20-gauge needle penetrates the peritoneum, and a guidewire is introduced. Entry into the peritoneum is usually recognizable by a distinct "pop." A disposable kit is available (Arrow Peritoneal Lavage Kit [AK-0900], Arrow International Inc., Reading, Pa.). The 8-Fr lavage

161

Figure 6-12 Peritoneal lavage. **A**, Minilaparotomy for peritoneal lavage. **B**, The catheter in place with the needle removed and the wire introduced. **C**, An 8-Fr catheter is introduced over the wire, and the wire is then removed.

162

catheter is inserted over the wire and advanced into one of the pelvic gutters. Double-catheter systems with outflow suction speed rewarming.

Normal saline, lactated Ringer's solution, or standard 1.5% dextrose dialysate solution with optional potassium supplementation can be used.^[246] Isotonic dialysate is heated to 40° to 45° C. Up to 2 L is then infused (10 to 20 ml/kg), retained for 20 to 30 minutes, and aspirated. The usual clinical exchange rate is 6 L/hr, which yields rewarming rates of 1° to 3° C (1.8° to 5.4° F) per hour. An alternative for severe cases is a larger catheter, as found in cavity drainage kits (Arrow 14 Fr [AK-01601]) ([Figure 6-13](#)). The catheter can be placed with Seldinger's technique. The higher drainage capability markedly increases exchange rates and minimizes dwell times necessary for maximal thermal transfer. The flow rate via gravity through regular tubing is approximately 500 ml/min, which can be tripled under infusion pressure.

A unique advantage of peritoneal dialysis is drug overdose and rhabdomyolysis detoxification when hemodialysis is unavailable. In addition, direct hepatic rewarming reactivates detoxification and conversion enzymes. Peritoneal dialysis worsens preexisting hypokalemia. Vigilant electrolyte monitoring is essential before empirical modification of the dialysate. The presence of adhesions from previous abdominal

surgery increases the complication rate and minimizes heat exchange.

Peritoneal dialysis during standard mechanical CPR is as effective as partial cardiac bypass in resuscitating severely hypothermic dogs. Unlike the group of dogs receiving AER, peritoneal lavage rewarming did not require significantly greater quantities of crystalloids and bicarbonate. In another canine study, peritoneal dialysis at a rate of 12 L/hr rewarmed dogs more rapidly than did heated, humidified inhalation.^[279] This exchange rate is rarely possible in humans. Bowel infarction may be a concern when using prolonged warm peritoneal dialysis in severe hypothermia with inadequate visceral perfusion during CPR.^[12]

Peritoneal lavage is invasive and should not be routinely used in treating stable, mildly hypothermic patients. Extracorporeal rewarming should be available in case of rare major complications, including VF. This technique is indicated in combination with all available rewarming techniques in cardiac arrest patients.

EXTRACORPOREAL BLOOD REWARMING

Cardiopulmonary bypass.

Partial or complete CPB should be considered in severely hypothermic patients.^[100] ^[227] Favorable considerations include absence of severe head injury or a history of asphyxia. Some centers only initiate CPB if the presenting arterial pH is above 6.5, serum potassium is below 10 mmol/L, and core temperature is above 12° C (53.6° F).^[55] ^[119] ^[260] ^[270] A major advantage of CPB is preservation of oxygenated

Figure 6-13 Peritoneal lavage. A 14-Fr catheter is of greater caliber and can infuse fluids more rapidly.

flow if mechanical cardiac activity is lost during rewarming.^[60] ^[125] ^[127] ^[187] CPB is three to four times faster at rewarming than other active core rewarming (ACR) techniques and reduces the high blood viscosity associated with severe cases. CPB should also be considered when severe cases do not respond to less invasive rewarming techniques, in patients with completely frozen extremities, and when rhabdomyolysis is accompanied by major electrolyte disturbances.^[138]

Various extracorporeal rewarming (ECR) techniques can be lifesaving in selected profound cases of hypothermia.^[48] ^[108] Althaus^[3] describes complete recovery in three severely hypothermic tourists after prolonged periods of cardiac arrest and CPR. In another review of 17 cases, there were 13 survivors.^[248] Walpoth^[269] ^[270] reports

rewarming 32 patients with CPB, of which 15 are long-term survivors. The average age was 25.2 years. Their mean presenting T_{esoph} was 21.8° C (71.2° F), and the mean interval between discovery and CPB was 141 minutes.

The standard femoral-femoral circuit includes arterial and venous catheters, a mechanical pump, a membrane or bubble oxygenator, and a heat exchanger ([Figure 6-14](#)). A 16- to 30-Fr venous cannula is inserted via the femoral vein to the right atrium/inferior vena cava junction. The tip of the shorter 16- to 20-Fr arterial cannula is inserted 5 cm or proximal to the aortic bifurcation. Antretter^[5] uses 32-Fr venous and 28-Fr arterial cannulas with the open surgical technique, and 21-Fr venous and 19-Fr arterial cannulas if inserted percutaneously. Closed chest compressions can be maintained

163

Figure 6-14 Femoral-femoral bypass.

during percutaneous or open surgical technique insertion and may help decompress the dilated nonbeating heart. Transesophageal echocardiography can help evaluate ventricular load and valve function.

Techniques have been developed to decrease the need for IV anticoagulation with heparin, which previously limited clinical applicability.^[271] Heparin-coated perfusion equipment was used successfully without systemic heparinization in a patient with hypothermic cardiac arrest (23.3° C [73.9° F]) and intracranial trauma.^[266] The use of nonthrombogenic pumps, coupled with enhanced physiologic fibrinolysis seen in the first hour of CPB, also has succeeded experimentally.^[58]

Heated, oxygenated blood is returned via the femoral artery. Femoral flow rates of 2 to 3 L/min can elevate core temperature 1° to 2° C (1.8° to 3.6° F) every 3 to 5 minutes. In Splittgerber's review,^[248] the mean CPB temperature increase was 9.5° C (17.1° F) per hour. Most pumps can generate full flow rates up to 7 L/min. Long^[178] recommends considering the use of vasodilator therapy with IV nitroglycerin to facilitate perfusion. He initiates bypass flow rates at about 2 L/min and gradually increases to 4 to 5 L/min. Vasoactive agents may be needed to maintain the cardiac index at 30 or more and for a (low) systemic vascular resistance of 1000 or less.

The optimal temperature gradient and bypass rewarming rates are unknown. One study of rewarming via CPB in a swine model cooled to 23° C (73.4° F) addresses this concern. An excessive temperature gradient between brain tissue and circulant adversely affected electroencephalography (EEG) regeneration.^[226] The other theoretical

concern is the possibility of increased bubbling if high perfusate temperature gradients are used. Most current investigators use 5° C (9° F) gradients^[18] or 10° C (18° F) gradients.^[19] Eventually, neuromonitoring during rewarming will provide some answers. In severe cases, evoked cerebral responses before EEG regeneration could help assess the recovering brain.

Complications with the standard technique include vessel damage, air embolism, hemolysis, DIC, and pulmonary edema ([Box 6-8](#)). Endothelial leakage increases compartment pressures and exacerbates frostbite. If adequate flow rates of 3 to 4 L/min (50 to 60 ml/kg/min) cannot be maintained, thoracotomy or a venous catheter with side holes, augmenting intravascular volume, should be considered.

Arteriovenous rewarming.

CAVR involves the use of percutaneously inserted femoral arterial and contralateral femoral venous catheters.^{[80] [81] [82] [84]} This technique requires a blood pressure of at least 60 mm Hg. Seldinger's technique is used to insert 8.5-Fr catheters. Heparin-bonded tubing circuits obviate the need for

Figure 6-15 CAVR schematic.

systemic anticoagulation. CAVR has principally been performed on traumatized patients ([Figure 6-15](#)).

CONTRAINDICATIONS

CPR is contraindicated (see [Box 6-9](#))

Lack of venous return

Intravascular clots or slush

Complete heparinization would be
hazardous*

*Unless with athrombogenic tubing or adequate
physiologic fibrinolysis.

The blood pressure of spontaneously perfusing traumatized hypothermic patients creates a functional arteriovenous fistula by diverting part of the cardiac output out the femoral artery through a countercurrent heat exchanger (e.g., Level 1; Flo Temp-IIe). The heated blood is then returned with admixed heated crystalloids via the femoral vein. The additional fluids are titrated and infused by piggyback until hypotension is corrected.

The rate of rewarming exceeds hemodialysis. CAVR does not require the specialized equipment and perfusionist necessary for CPB.^[79] The average flow rates are 225 to

375 ml/min, resulting in a rate of rewarming of 3° to 4° C (5.4° to 7.2° F) per hour. Since the catheters are 8.5 Fr, the patient must weigh at least 40 kg. Coagulation begins to appear in the heparinized circuits at around 3 hours.

Venovenous rewarming.

In extracorporeal venovenous rewarming, blood is removed, usually from a central venous catheter, heated to 40° C (104° F), and returned via a second central or large peripheral venous catheter. Flow rates of 150 to 400 ml/min have been achieved.^[100] ^[111]

The circuit is not complex and is more efficient than many other nonbypass modalities. There is no oxygenator, and since the method does not provide full circulatory

support, volume infusion is the only option to augment inadequate cardiac output.

In another variation of the extracorporeal venovenous circuit, blood is removed from the femoral vein, heparinized, and sent through a blood warmer via an infusion pump accelerator. It is neutralized with protamine before reinjection into the subclavian or internal jugular vein, which would preferentially rewarm the heart.

Hemodialysis.

Standard hemodialysis is widely available, practical, portable, efficient, and should be strongly considered in patients with electrolyte abnormalities, renal failure, or intoxication with a dialyzable substance.^[202] Two-way flow catheters allow cannulation of a single vessel.^[159] A Drake-Willock single-needle dialysis catheter can be used with a portable hemodialysis machine and external warmer. After central venous cannulation, exchange cycle volumes of 200 to 250 ml/min are possible.

Although heat exchange is less than with standard two-vessel hemodialysis, the ease of percutaneous subclavian vein placement is a major advantage. Hemodialysis via two separate single-lumen catheters placed in the femoral vein can achieve continuous blood flow at 450 to 500 ml/minute.^[114] ^[115] In-line hemodialysis also simplifies correction of electrolyte abnormalities. Local vascular complications, including thrombosis of vessels and hemorrhage secondary to anticoagulation, may occur.

With all of these techniques there is no proof that rapid acceleration of the rate of rewarming improves survival rates in perfusing patients. Potential complications of uncontrolled rapid rewarming in severe hypothermia include DIC, pulmonary edema, hemolysis, and acute tubular necrosis.

In hypothermic cardiac arrest, rewarming should be attempted via CPB and hemodialysis when CPR is not contraindicated ([Box 6-9](#)), unless frozen intravascular

contents prevent flow. Clotted atrial blood or failure to obtain venous return also cause these techniques to fail. If experienced personnel and necessary equipment are unavailable, all other rewarming techniques should be used in combination.^[18] ^[282]

DIATHERMY.

Diathermy, the transmission of heat by conversion of energy, has been evaluated as a rewarming adjunct in accidental hypothermia.^[118] ^[176] Large amounts of heat can be delivered to deep tissues with ultrasonic (0.8 to 1 MHz) and low-frequency (915 to 2450 MHz) microwave radiation. Short-wave (13.56 to 40.68 MHz) modalities are high frequency and do not penetrate deeply. Contraindications include frostbite, burns, significant edema, and all types of metallic implants and pacemakers.

Under ideal conditions in a laboratory study, radiowave frequency (13.56 MHz) electromagnetic regional heating of hypothermic dogs after immersion did not damage tissue at 4 to 6 watts/kg and rapidly elevated the core temperature.^[280] Zhong^[290] successfully rewarmed 16 piglets with microwave irradiation "until they squealed and suckled." Subsequently, 20 of 28 human infants who were rewarmed with microwave irradiation at 90 to 100 watts survived. The temperature rose an average 1° C (1.8° F) after 6 to 7 minutes, and the average infant required 45 minutes to achieve a rectal temperature of 36° C (96.8° F). In an experimental study of men cooled to 35° C (95° F), warm water immersion rewarming was more rapid than radiowave rewarming with 2.5 watts/kg.^[146]

**Box 6-9. CONTRAINDICATIONS TO
CARDIOPULMONARY RESUSCITATION
IN ACCIDENTAL HYPOTHERMIA**

Do-not-resuscitate status is documented and verified.

Obviously lethal injuries are present.

Chest wall depression is impossible.

Any signs of life are present.

Rescuers are endangered by evacuation delays or altered triage conditions.

From Danzl DF et al: Ann Emerg Med 16:1042, 1987. Developed in conjunction with the Wilderness Medical Society.

Both ultrasonic and low-frequency microwave diathermy can deliver large quantities of heat below the skin. As dosimetry guidelines are developed, potential complications and ideal application sites for this experimental technique deserve further study in the hospital. In the field setting, potential problems with power supply and electronic and navigational interference have compounded the physiologic problems.

CARDIOPULMONARY RESUSCITATION

Basic and advanced life support recommendations in hypothermia continue to evolve ([Figure 6-16](#)). ^[252] Cardiac output generated with closed chest compressions maintains viability in selected patients with hypothermia. ^[254] The optimal rate and technique are unknown. Definitive prehospital determination of cardiac activity requires a cardiac monitor, since misdiagnosis of cardiac arrest is a hazard. Peripheral pulses are difficult to palpate when extreme bradycardia is present with peripheral vasoconstriction.

Some authors contend that asystole is a more common presenting rhythm than is VF. In the field, differentiating VF from asystole may be impractical. Possible causes of VF include acid-base fluxes, hypoxia, and coronary vasoconstriction with increased blood viscosity. Chest compressions and various therapeutic interventions are also implicated. The role of acid-base

Figure 6-16 Emergency department algorithm. *ACR*, Active core rewarming; *AER*, active external rewarming; *CPB*, cardiopulmonary bypass; *PEA*, pulseless electrical activity; *PER*, passive external rewarming.

fluxes is not clear. Mild alkalosis appears somewhat protective against VF during controlled, induced hypothermia. ^[156]

Blood Flow During Chest Compressions

During normothermic conditions, blood flow partially results from phasic alterations in intrathoracic pressure and not just from direct cardiac compression. Niemann ^[206] demonstrated that antegrade flow occurs without left ventricular compression in a normothermic canine model. Closed chest compressions increase intrathoracic pressure. When thoracic inlet venous valves are competent, the resultant pressure gradient between arterial and venous compartments generates supradiaphragmatic

antegrade flow.

Some clinical observations challenge the supremacy of the "cardiac pump" model. This model is predicated on closure of the mitral valve and opening of the aortic valve during chest compression. This allows a forward stroke volume. During release of compression, transmitral flow can fill the left ventricle. Optimal cardiac output is thus generated by achieving the maximal compression rate, which allows maximal left ventricular end diastolic filling. Interestingly, transesophageal echocardiography in a canine model demonstrates mitral valve closure during chest compression except during low-impulse (downstroke momentum) compressions. Compression of a cold, stiff chest wall may be equivalent to low impulse.^[45]

In hypothermia the role of a "thoracic pump" with the heart as a passive conduit is an attractive hypothesis. The phasic alterations in intrathoracic pressure generated by compressions are equally applied to all of the cardiac chambers and thoracic vessels. The mitral valve remains open during compression, and blood continues to circulate through the left side of the heart.

Myocardial compliance can be severely reduced in hypothermia. Althaus^[3] noted in one of three hypothermia survivors at thoracotomy that "the heart was found to be hard as stone and it is hardly conceivable how effective external cardiac massage could have been." Chest wall elasticity is also decreased with cold,

as is pulmonary compliance. Lastly, more force is needed to depress the chest wall sufficiently to generate intrathoracic vascular compartment pressure gradients. Despite these potential physiologic explanations, a large number of neurologically intact survivors remain after prolonged closed chest compressions. The explanation lies in measuring intrathoracic pressures during hypothermic closed chest compressions.

Perfusion enhancement maneuvers remain largely unstudied in hypothermia. Ancillary abdominal binding, as with the abdominal compartment of antishock trousers, might favorably inhibit paradoxical diaphragmatic motion.^[45] ^[206] Simultaneous compression and ventilation can increase flow in the heart's left side. Ventilation with the proper carbogen concentration also allows high ventilatory rates while maintaining uncorrected PaCO₂ at 40 mm Hg. Placement of a counterpulsation intraaortic balloon is another option. Mechanical thoracic compression devices could be useful during prolonged resuscitations with limited availability of personnel and no bypass capabilities.

During hypothermic cardiac arrest in swine, the cardiac output, cerebral blood flow, and myocardial blood flow averaged 50%, 55%, and 31%, respectively, of those achieved during normothermic closed chest compressions.^[184] Blood flow to these areas did not decrease with time, unlike in the normothermic group. No significant difference in flow generated appeared between normothermic and hypothermic swine at 20 minutes. Hypothermic rheologic changes, including increased viscosity, also affect flow.

Peripheral vascular resistance is expected to increase during vasoconstriction, but in the swine there was no difference in systemic and organ vascular resistance between normothermic and hypothermic CPR.^[184]

In a multicenter survey of 428 cases, 9 of the 27 patients receiving CPR initiated in the field survived, as did 6 of 14 patients with emergency department-initiated CPR.^[49] Based on these cases and a literature review, refinements of the American Heart Association's CPR standards in hypothermia have been proposed (see [Box 6-9](#)).^[67]

Since cardiac output is the product of heart rate and stroke volume, the optimal closed chest compression rate should be the fastest rate allowing optimal ventricular filling. Many patients have recovered neurologically following slow compression rates. One recovered after 220 minutes at half the normal compression rate.^[207] The optimal rate probably has a direct linear relationship with the degree of hypothermia.^[45]

Tissue decomposition, apparent rigor mortis, dependent lividity, and fixed, dilated pupils are not reliable criteria for withholding CPR. In addition, intermittent flow may provide adequate support during evacuation. Therefore CPR should not be withheld only because continuous chest compressions cannot be ensured.^[35] The lowest temperature documented in an infant survivor of accidental hypothermia is 15.2° C (59.4° F), in an adult is 13.7° C (56.8° F),^[91A] and in induced hypothermia is 9° C (48.2° F).^{[42] [54] [203] [208]} One patient recovered after 6 ½ hours of closed chest compressions.^[169] In Saskatchewan in 1994 a 2-year-old child reportedly recovered from a core temperature of 13.9° C (57° F).

Respiratory Considerations

When cardiopulmonary arrest develops during resuscitation, noncardiac causes are often pulmonary emboli or progressive respiratory insufficiency. Provision of adequate oxygen supply is essential during rapid rewarming. For each 1° C (1.8° F) rise in temperature, oxygen consumption increases up to three times^[76] (see [Box 6-1](#)).

Endotracheal intubation and ventilation decrease atelectasis and ventilation-perfusion mismatch. Complete airway protection averts aspiration, which is otherwise common in depressed airway reflexes, bronchorrhea, and ileus. Carbon dioxide production also drops by half with an 8° C (14.4° F) fall in the temperature. During induced hypothermia, carbogen (1% to 5% carbon dioxide added to oxygen) facilitates acid-base management by allowing adjustment of the fractional inspired CO₂ concentration (Fico₂) while adjusting the ventilation.^[188]

Past controversy regarding the hazards of endotracheal intubation reflected coincidental episodes and a miscitation by Fell^[71] of a series of hypothermic overdoses by Lee and Ames.^[164] Fell stated that "endotracheal intubation was followed by cardiac arrest in a large proportion of cases," whereas Lee and Ames merely cautioned of that possibility. In a multicenter survey, endotracheal intubation was performed on 117 patients by multiple operators in various settings.^[51] No induced arrhythmias were recognized, which is consistent with several reports. Danzl and Miller^{[46] [196]} also nasotracheally

intubated 40 hypothermic patients without incident, and Ledingham and Mone^[163] did not note arrhythmias in their series of 44 cases. Potential arrhythmogenic factors include hypoxia, mechanical jostling, and acid-base or electrolyte fluctuations.

The indications for endotracheal intubation in hypothermia are identical to those in normothermia.^{[48] [52] [92]} It is required unless the patient possesses intact protective airway reflexes. Ciliary activity is depressed in hypothermia, frothy sputum produces chest congestion, and bronchorrhea resembles pulmonary edema. Fiberoptic or blind nasotracheal intubation is preferable to cricothyroidotomy when cold-induced trismus or potential cervical spine trauma is present. Oral rather than nasal intubation is advisable in coagulopathic patients to avoid causing major epistaxis.

As expected, hypothermia prolongs the duration of neuromuscular blockade. With pancuronium the block

is prolonged because metabolism into inactive metabolites is markedly decreased. Neuromuscular blockade is also prolonged with vecuronium and atracurium.

RESUSCITATION PHARMACOLOGY

The pharmacologic effects of medications are temperature dependent. The lower the temperature, the greater the degree of protein binding. Enterohepatic circulation and renal excretion are also altered, so abnormal physiologic drug responses should be anticipated. The usual clinical scenario consists of substandard therapeutic activity while the patient is severely hypothermic, progressing to toxicity after rewarming.^[193] Medications are not given orally because of decreased gastrointestinal function, and intramuscular medications are avoided because they may be erratically absorbed from vasoconstricted sites.

The pharmacologic manipulation of respiratory drive, pulse, and blood pressure is generally not indicated. When relative tachycardia is not consistent with temperature depression, the possibility of hypovolemia, hypoglycemia, or a toxic ingestion should be considered. Vasopressors are potentially arrhythmogenic, lower VF threshold, and cannot increase peripheral vascular resistance if the vasculature is already maximally constricted.^[163] Vasodilators can precipitate core temperature afterdrop.

If intraarterial pressure is not consistent with the degree of hypothermia, judicious use of inotropic agents may be necessary.^[211] Dopamine can be a successful adjunctive treatment.^[236] Dopamine reverses cardiovascular depression under hypothermic conditions equivalent to up to 5° C (9° F) rewarming. Dopamine decreases systemic vascular resistance at low infusion doses and increases it at high infusion rates.^[211]

There is conflicting evidence regarding cardiovascular function after rewarming. In some studies, there was complete reversal of cold-induced changes, whereas in another, the physiologic response to norepinephrine was paradoxical.^[276]

Patients with profound hypothermia after ethanol ingestion have been resuscitated with low-dose dopamine support. In frostbite victims, however, the use of catecholamines may jeopardize the extremities.^[178] Catecholamines also exacerbate preexistent occult hypokalemia.

The effect of temperature depression on the autonomic nervous system is still being investigated. In primates, cooling produces a biphasic response in plasma catecholamine concentrations. After an initial increase, the autonomic nervous system switches off at 29° C (84.2° F),^[34] suggesting that catecholamine support might be useful below that temperature. The initial rise in catecholamine levels could also be caused by acute respiratory acidosis, which stimulates the sympathetic nervous system.^[24] Low-dose dopamine (1 to 5 mg/kg/min) or other catecholamine infusions are generally reserved for severely hypotensive patients who do not respond to crystalloid

resuscitation and rewarming.

Thyroid

The most dramatic "Rip Van Winkle" rude awakening from hypothermic myxedema coma was Dr. Richard Asher's patient in the 1950s. He was successfully metabolically aroused from a 7-year 30° C (86° F) slumber. Ironically, so was a quiescent oat cell carcinoma.

Cold induces stimulation of the hypothalamic-pituitary-thyroid axis. Unless myxedema is suspected, empirical therapy is not recommended. A history of neck irradiation, radioactive iodine, Hashimoto's thyroiditis, or surgical treatment of hyperthyroidism should heighten the clinician's suspicion of myxedema. Failure to rewarm despite an appropriate course of therapy is a further clue.^[183]

Myxedema coma is usually precipitated in elderly patients with chronic hypothyroidism who are stressed by trauma, infection, anesthesia, or medication ingestion. Typical nonspecific laboratory abnormalities include hyponatremia, anemia, and liver enzyme and lipid elevations. If myxedema coma is suspected, thyroid function studies, including serum thyroxine (T_4) by radioimmunoassay, triiodothyronine (T_3) resin uptake, and thyroid-stimulating hormone, should be obtained and serum cortisol level measured.

Given the appropriate index of suspicion, the physician should administer 250 to 500 μ g levothyroxine (T_4) intravenously over several minutes without waiting for confirmatory laboratory results. Daily injections of 100 μ g are required for 5 to 7 days. It is appropriate to consider adding at least 100 to 250 mg of hydrocortisone to the first 3 L of intravenous fluid. Absorption of T_4 is erratic if the drug is given orally or intramuscularly. The onset of action of T_3 is more rapid, which jeopardizes cardiovascular stability; therefore T_3 is avoided in acute replacement therapy. The onset of action of T_4 is 6 to 12 hours, evidenced by continuous improvement of the vital signs during rewarming. Up to one half of the T_4 is eventually converted by the peripheral tissues into T_3 .^[49]

Steroids

Acute cold stress and many coexisting disease processes stimulate cortisol secretion. The free active fraction of cortisol decreases as the temperature drops because of increased protein binding, and cortisol utilization is similarly decreased. The increase in adrenocorticotrophic hormone (ACTH) and adrenal steroid secretion may also be a neurogenic or emotional response in the conscious subject to an unpleasant environment. In rodents, inhibition of ACTH secretion during hypothermia is mediated by decreased hypothalamic

secretion of arginine vasopressin and oxytocin. This decreases pituitary responsiveness to corticotropin-releasing factor, inhibiting corticotropin release. Thus exogenous arginine vasopressin could prove helpful during rewarming.

Cold exposure also induces adrenal unresponsiveness to ACTH. As a result, false diagnosis of decreased adrenal reserve is possible and does not represent functional adrenal insufficiency, since ACTH levels return to normal after rewarming. Serum cortisol levels are commonly elevated. Secondary adrenal insufficiency resulting from panhypopituitarism may also coexist with myxedema. Empirical administration of steroids is not indicated unless hypoadrenocorticism is suspected based on a previous history of steroid dependence, suggestive physical findings, or an inexplicable failure to rewarm. The use of narcotic antagonists in hypothermia is reported. Naloxone may reduce the severity of hypothermia in drug overdoses and in spinal shock and appears to have activity at the mu receptor sites.^[49]

RESUSCITATION COMPLICATIONS

Atrial Arrhythmias

All atrial arrhythmias, including atrial fibrillation, should have a slow ventricular response with the temperature depression. Atrial fibrillation is commonly noted below 32° C (89.6° F) in accidental hypothermia victims. ^[278] Atrial fibrillation usually converts spontaneously during rewarming, and digitalization is not warranted. Electrophysiologic studies show that the interval prolongation present on His bundle electrocardiography is unresponsive to atropine. Mesenteric embolization is a potential hazard when the rhythm converts back to sinus rhythm.

Hypothermia renders the negative inotropic effects of calcium channel blockers redundant. Although verapamil has been used to resuscitate a profoundly hypothermic patient after near drowning, any additional cerebral protective effects are speculative. In summary, all new atrial arrhythmias usually convert spontaneously during rewarming and should be considered innocent. Attention is directed toward correcting acid-base, fluid, and electrolyte imbalances while avoiding administration of atrial antiarrhythmics.

Ventricular Arrhythmias

Since preexisting chronic ventricular ectopy may be suppressed in a cold heart, the physician noting ectopy during rewarming is placed in a quandary. The history from the hypothermic patient may be unproductive, and the past cardiac history is often unavailable.

Transient ventricular arrhythmias are generally to be ignored. In one study of 22 continuously monitored patients with hypothermia, supraventricular arrhythmias were common (nine cases) and benign. ^[220] Ventricular extrasystoles developed in 10 patients, but none experienced ventricular tachycardia (VT) or VF during rewarming. The terminal rhythm in the eight who died while being monitored was asystole and not VF. The energetics of the fibrillating hypothermic ventricle are under investigation because asystole may consume less energy and be more protective.

Pharmacologic options are limited, since hypothermia induces complex physiologic changes that result in abnormal responses. ^[283] Drug metabolism and excretion are both progressively decreased. In normothermia, class IA ventricular antiarrhythmics have negative inotropic and indirect anticholinergic effects, and moderately decrease conduction velocity ([Box 6-10](#)). Procainamide increases the incidence of VF during hypothermia. Quinidine has been useful during induced profound hypothermia, preventing VF during cardiac manipulation at 25° to 30° C (77° to 86° F). No reports

detail the effects of disopyramide. In class IB, lidocaine is yet to be proven effective for prophylaxis and is ineffective in facilitating defibrillation. In animal studies, lidocaine and propranolol have

minimal hemodynamic effects in hypothermia. If normothermic effects persisted during hypothermia, the class IB agents would appear attractive because they minimally slow conduction while shortening the action potential duration (APD).

Box 6-10. ANTIARRHYTHMIC AGENTS

Conduction and depolarization markedly slowed APD and repolarization prolonged

Encainide

Flecainide

Class II. β -Adrenergic blockers

<p>re-polarization prolonged</p> <p>Encainide</p> <p>Flecainide</p> <p>Class II. β-Adrenergic blockers</p> <p>Class III. Antifibrillatory properties APD prolonged</p> <p>Amiodarone</p> <p>Bretylum</p> <p><i>d</i>-Sotalol</p> <p>Class IV. Calcium channel blockers</p> <p>Diltiazem</p> <p>Verapamil</p> <p>Unclassified</p> <p>Adenosine</p> <p>Magnesium sulfate</p>

The class III agent bretylium tosylate, a unique bromobenzyl quaternary ammonium compound, has been extremely effective in several animal studies.^[65] This class of agents seems most ideal pharmacologically because it possesses direct antifibrillatory properties. The ability to prolong the action potential duration is temperature dependent. Ideally, a drug would lengthen the APD only in warmer regions to reduce dispersion. (See [Box 6-11](#) .)

Bretylium causes chemical sympathectomy and is both an antiarrhythmic and antifibrillatory agent. Bretylium increases the VF threshold, APD, and effective refractory period. Interestingly, at least at normal temperatures, antifibrillatory effects occur more acutely than do antiarrhythmic effects.

In the first study to evaluate the effects of bretylium administered after induction of hypothermia, Murphy^[200] noted that only one of 11 dogs given bretylium (mean 40.5 mg/kg) before five invasive maneuvers developed VF. No dog, including control subjects, showed fibrillation during endotracheal intubation. Of note during discussions regarding prophylaxis, three of the 11 dogs converted to VF during the drug infusion. The effect of bretylium on plasma catecholamines and electrically induced arrhythmias has also been studied. Since catecholamine levels increase during cooling, the demonstrated protection appears to result from alteration of electrophysiologic properties of the cardiac tissues.^[209] Amiodarone, another class III drug that possesses direct antifibrillatory activity, would be an interesting agent to study during hypothermic

conditions. Also of note, magnesium sulfate at a dose of 100 mg/kg IV can spontaneously defibrillate most patients on CPB at 30° C (86° F) with induced hypothermia.

Emergency transvenous intracardiac pacing of bradyarrhythmias is extremely risky with cold hearts because it commonly precipitates VF. New arrhythmias that develop after rewarming may require pacing on rare occasions. Transcutaneous pacing (TCP) with low-resistance electrodes seems far preferable before stabilization. In a canine model, TCP restored and maintained hemodynamic stability and rewarmed hypothermic animals twice as rapidly as it did the controls.^[59]

Box 6-11. ANTIARRHYTHMIC CHARACTERISTICS

The ideal ventricular antiarrhythmic would:

1. Cause no further decrease in conduction velocity
2. Shorten action potential duration (APD)
3. Only lengthen the APD in warmer regions of the myocardium to reduce dispersion
4. Possess direct antifibrillatory properties

In summary, bretylium is the only agent shown to have antiarrhythmic activity during hypothermic conditions. Two cases of chemical ventricular defibrillation after infusion of bretylium 10 mg/kg in accidental hypothermia are reported.^{[47] [152]} Bretylium appears to be the agent of choice for VF in hypothermia. Bretylium prophylaxis is investigational because toxicity, optimal dosage, and particularly the ideal rate of infusion are unknown.

Sepsis

Our knowledge of the pathophysiology of sepsis in hypothermia continues to improve.^[37] Classic signs of infection, including erythema and fever, are absent. Rigors and shakes resemble shivering. The initial history, physical, and laboratory data are often unreliable, so repeated evaluations and comprehensive culturing are mandatory in the ED. The 10% subset of patients with sepsis syndrome who manifest a hypothermic response have a significantly increased frequency of shock and death, and this secondary hypothermia does not appear to be protective.

Hypothermia compromises host defenses and results in serious bacterial infections.

These significant infections can be accompanied by minimal inflammatory response. Some common etiologic organisms include gram-negative bacteria, gram-positive cocci, oral anaerobes, and Enterobacteriaceae.^[168]

The core endotoxin components of gram-negative bacteria normally signal macrophages. At a normal or elevated temperature, active cytokine triggers include tumor necrosis factor, interleukin-1, and interleukin-6. The potential role of antiendotoxin monoclonal antibodies in patients with accidental but not cytokine-induced hypothermia is unresolved. Bone marrow release and circulation of neutrophils are compromised for up to 12 hours. In addition, human and porcine neutrophils are susceptible to hypothermia. In vitro, neutrophil migration and bacterial phagocytosis are reduced at 29° C (84.2° F). Neutrophilic extermination of various bacteria, including *Staphylococcus aureus* and *Streptococcus faecalis*, is also impaired.

Acquired neutrophil dysfunction is also identified. In addition, hypothermia was associated with decreased neutrophil levels in 40 near-drowned children. As a clinical demonstration of the importance of these factors, therapeutic maintenance of hypothermia to control cerebral edema in near drowning has been abandoned because of the substantial incidence of infectious complications.^[49]

The reported incidence of infection varies dramatically with the victim's age and the clinical series reported.^{[168] [278]}

In one group of 51 infants, 27 had sepsis.^[44] Although there were no reliable indicators of infection, some suggestive clues were present. Serum glucose and leukocyte abnormalities, anemia, uremia, and bradycardia were often identified. In addition to *Staphylococcus* and *Streptococcus*, the predominant organisms were *Haemophilus* and Enterobacteriaceae.

Lung infections, usually in the right upper lobe, were reported in 80 of 138 hypothermic infants by El-Radhi et al.^[66] Evaluation of the gastric aspirate was another diagnostic predictor of sepsis in 36 of 44 infected infants. In several studies, sepsis was found in 8% to 74% of hypothermic infants.^[44] In this age group, empirical broad-spectrum antibiotics are warranted.

In adults the incidence of infection ranges from less than 1% to over 40%, depending on patient selection criteria.^{[51] [168] [278]} In Lewin's series,^[168] serious soft tissue or pulmonary infections were present in 24 of 59 patients and in nine the infection was undiagnosed when the patient was admitted from the ED. Occult bacteremia was present in less than 1% of White's series^[278] of 102 patients, and results were negative in all of the 46 lumbar punctures. In other studies of hypothermic elderly patients admitted to hospitals, most have had evidence of probable or definite infections.^[53]

Invasive hemodynamic monitoring, although risky, may suggest an infection. Before

patients are rewarmed, the combination of an elevated cardiac index and decreased systemic vascular resistance should suggest bacteremia. Right heart catheterization is more hazardous in hypothermia than during normothermia.

In summary, unlike children and the elderly, most previously healthy young adults do not need empirical antibiotic prophylaxis. Nevertheless, treatment indications should be liberalized from normothermia. They should include failure to rewarm or any suspicion or evidence of aspiration, myositis, chest x-ray infiltrate, bacteriuria, or persistent altered mental status. In choosing broad-spectrum coverage, the physician should consider altered drug interactions, volumes of distribution, protein binding, hepatic metabolism, and renal excretion. The combination of an aminoglycoside with a broad-spectrum β -lactam antibiotic is often appropriate.

FORENSIC PATHOLOGY

Macromorphologic and micromorphologic lesions are variable and nonspecific in hypothermia, and there is no single pathognomonic finding at autopsy. ^[170] Establishing hypothermia as the primary cause of death requires an adequate history of exposure and the absence of other lethal findings at necropsy. ^[4] For example, unnatural deaths in nursing home patients may be significantly underreported for these reasons. ^[40]

Macroscopic skin changes can suggest the diagnosis. Hyperemia of the dorsa of the hands and knees is commonly found. Nonpathognomonic findings have been identified in the pancreas, lungs, and heart. ^[116] Pancreatic findings include fat necrosis, aseptic pancreatitis, and hemorrhage. Pulmonary changes consist of intraalveolar, interstitial, and intrabronchial hemorrhages.

An eye that has been directly exposed to the environment could be a chemical indicator of both the environmental and victim temperature at the time of death. Vitreous humor chemistry profiles at autopsy can reveal that glucose concentration and total carbon dioxide content vary inversely with temperature, with values significantly higher in the winter. An elevated vitreous glucose in a nondiabetic victim should suggest hypothermia.

The total urinary catecholamine content, particularly epinephrine, was high in one group of casualties known to be hypothermic. Erosions of the gastric mucosa, termed *Wischnewsky spots*, are also frequently found. ^[256] In addition, exposure to extreme cold should be suspected when unusual intravascular hemolysis, which is seen after freezing of blood, is observed in a corpse. ^[150]

PREVENTION

To function optimally "as the water stiffens" requires an understanding of the principles of heat conservation and loss.^[143] Well-trained and educated urban adults can participate in prolonged Arctic maneuvers safely.^{[242] [243] [258]} To maintain core temperature in the narrow band necessary for peak functioning in cold environments, appropriate adaptive behavioral responses are essential.^[121] Autonomic and endocrinologic mechanisms are only supplemental.

Studies of human cold adaptation have reached highly variable conclusions. Explanations for these discrepancies include changes in core and shell temperatures and in metabolic rates before and after cold adaptation. Some observations indicate hypothermic insulative isometabolic cold adaptation associated with local cold adaptation of the extremities.^[232]

Excellent physical conditioning with adequate rest and nutrition is paramount.^[22] Hikers and skiers must be accompanied by a partner and should wear effective thermal insulation. Wet inner garments must be changed promptly. Persons who exert themselves, including long-distance skiers, should switch garments depending on current exertional heat production.^{[122] [123] [124]} Since dehydration must be avoided, drinking from a cold stream is preferable to snow ingestion. Significant energy is needed to convert ice at 0° C (32° F) into water at 0° C.

All areas with a large surface area/volume ratio should be well insulated.^[286] The uncovered head can lose a large percentage of the body's total heat production. Of note, adrenergic vasoconstriction does not occur

effectively in the head and neck region,^[99] which is why a nightcap (not originally Kentucky bourbon) is effective when worn to bed. Excellent synthetic insulating materials include Gore-Tex, Thinsulate, and taslanized nylon.

Flectalon, a web of aluminized polyvinyl chloride fibers, is also a good insulating material. In comparing its insulating efficacy with that of other materials, the "critical" temperature was determined. This is defined as the lowest environmental temperature at which the core temperature can be maintained without increased oxygen consumption. Flectalon lowers the critical temperature more than Thinsulate and may

prove useful as an insulator to prevent and treat hypothermia.

Under certain circumstances, insidious hypothermia may develop during exposure to cold water because of the effects of increased insulation on compensatory physiologic events.^{[8] [145]} The army mnemonic "COLD," in reference to insulation with clothing, is *clean*, *open* during exercise to avoid sweating, *loose* layers to retain heat, and *dry* to limit conductive heat losses. For a complete discussion of preventive measures, refer to [Chapter 9](#) and [Chapter 71](#) .

Prevention of urban accidental hypothermia requires continuous public education. For example, the optimal safe indoor temperature recommendation for the elderly has risen to 21.1° C (70° F).^[172] Energy assistance and temporary sheltering are effective measures, and selective heating of sleeping quarters and use of electric blankets are economical suggestions. Prewarming bed and bedroom at night may be the best overall advice to the elderly.

OUTCOME

Even during normothermia, there is often no consensus regarding for how long to continue resuscitative efforts. Partially because of the dramatic reports of reanimations, the standard of care has been that "no one is dead until they are warm and dead." In reality, some victims are clearly dead when they are cold and dead, and it would be useful to safely identify them.^[6]

Survival is difficult to predict because human physiologic responses to temperature depression vary so widely.^[216] The type and severity of the underlying or precipitating disease process are two determinants. Age extremes, although not statistically correlated with survival, are commonly associated with severe illnesses. In a multicenter survey, however, there were no significant age differences in mortality.

Gender, trauma, infection, and toxin ingestions affected survival differently in multiple, uncontrolled clinical studies. There were no clinically significant differences in male vs. female profiles in the multicenter survey.^[51] From a large hypothermia database, a hypothermia outcome score has been developed that could enable multiple observers at differing sites to assess treatment modalities and outcome predictors. Prehospital cardiac arrest, low or absent blood pressure, elevated BUN, and the need for either endotracheal or nasogastric intubation in the ED were significant predictors of outcome after multivariate analysis.^{[52] [147] [233]}

In a multiple regression analysis of 234 cases in Swiss clinics,^[177] the biggest negative survival factors were asphyxia, slow rate of cooling, invasive rewarming, asystole, and development of pulmonary edema or adult respiratory distress syndrome. Positive predictors of survival include rapid cooling rate, presence of VF during cardiac arrest, and narcotic or ethanol intoxication. In a study of 29 patients below 30° C (86° F), mode of cooling was the only independent risk factor.^[216]

In a study of CPB survivors, 15 of the 32 patients are long-term survivors.^[270] Their neuropsychologic functioning after prolonged prehospital circulatory arrest is very encouraging. These patients were not asphyxiated before becoming hypothermic. Vretnar^[267] reviewed the literature regarding the outcomes of 68 other patients resuscitated with CPB. The survival rate was 60%, and the coldest survivor was 15° C (59° F).

There is need for a valid triage marker of death, since vital organ damage is difficult to predict. In one retrospective analysis of primarily avalanche burial victims, extreme hyperkalemia was noted on initial examination and resuscitation proved fruitless.^[233] In the Mt. Hood tragedy the nonsurvivors also were hyperkalemic (serum potassium

greater than 10 mmol/L).^[108] In both of these reports, asphyxia and compression injury may have been contributory. Other indicators of a grave prognosis include a core temperature below 12° C (53.6° F), arterial pH below 6.5, or evidence of intravascular thrombosis (direct visualization; fibrinogen below 50 mg %).

Chapter 7 - Frostbite

Robert L. McCauley
David J. Smith
Martin C. Robson
John P. Heggors

Cold-induced injuries are almost exclusively a result of humans' inability to properly protect themselves from the environment. Cold injuries may be either systemic or localized, depending on the temperature and length of exposure. Systemic injury is hypothermia (see [Chapter 6](#)), whereas localized injury is frostbite. Although much confusion exists in the literature regarding the myriad of clinical terms used to describe localized injury, the correct term is frostbite.

HISTORICAL ASPECTS

Numerous historical accounts discuss armies exposed to cold sustaining large numbers of cold-induced casualties. Although Hippocrates described some of the symptoms and sequelae of frostbite, cold injuries were probably not prevalent in ancient Greece. In 218 BC, Hannibal lost nearly half of his army of 46,000 to cold injuries in only 15 days when they crossed the Pyrenean Alps. In 210 BC, Xenophon described cold injuries suffered by Spartan soldiers during a retreat across the Carduchion mountains after leaving Alexander's armies. In 1778, Dr. James Thatcher wrote that 10% of George Washington's army had been left to perish in the winter cold during his campaign against the British soldiers.^[70]

Despite these accounts, it was not until 1805 that the first official report was published on the effect of cold injury.^[88] The first authoritative account of mass casualties was the description by Baron de Larrey, surgeon-in-chief of Napoleon's army during the invasion of Russia in the winter of 1812–1813.^[34] Larrey wrote, "When some external part of the body is caught by cold, instead of submitting it to heat, which provides gangrene, it is necessary to rub the affected part with substances containing very little calorick—for it is well known that the effect of calorick on an organized part that is almost deprived of life is marked by an acceleration of fermentation and putrefaction."^[34]

Larrey introduced the concept of friction massage with ice or snow, the avoidance of heat in thawing, and the idea that cold injuries were similar to burn injuries. These concepts are better understood against the background as viewed by Larrey.^[34] Soldiers with cold injuries rapidly rewarmed their extremities over roaring fires of 66° to 77° C (150° to 170° F) after long marches, only to renew the trek and refreeze their extremities the next day. Larrey recognized that warming was good but cautioned against the use of excessive heat and ultimately recognized the freeze-thaw-freeze cycle. Napoleon left France with 250,000 men and returned 6 months later with only 350 effective soldiers. The remainder were casualties to cold or starvation.^[34]

During the Crimean War (1854–1856), 300,000 French troops sustained 5000 cases of frostbite and 1000 deaths. During World War I (1917–1918), World War II (1941–1945), and the Korean conflict (1950–1953), at least 1 million cases of frostbite occurred.^{[59] [60] [78] [80]} In November and December 1942, the Germans performed 15,000 amputations for cold injuries.^{[78] [79]} High-altitude frostbite, first described in 1943, was recognized from the treatment of aviators in World War II.^[80] The most prevalent form of this injury was seen in B-17 and B-24 crews flying between 25,000 and 35,000 feet in temperatures of -32° to -43° C (-25° to -45° F). When attacked, the only way the waist gunners of the aircraft could operate their machine guns was to open the large waist pots through which the guns were fired. The gunners often took off their bulky mittens

and jackets to improve the dexterity they felt was crucial to saving their lives.^[80]

Until the 1950s, treatment of cold injuries basically followed Larrey's guidelines. In 1956, experimental laboratory work by Merryman encouraged Hamill, the Public Health Service district medical officer in Tanana, Alaska, to try rapid rewarming at 38° C (100° F) on a patient with frostbite and hypothermia.^[9]^[49] This was the genesis and has become the cornerstone of the method currently used in Alaska and popularized by Mills.^[49]

TEMPERATURE HOMEOSTASIS IN HUMANS

No comprehensive statistical data are available on the incidence of frostbite. The Royal College of Physicians in London estimated that 10% of elderly British home dwellers were hypothermic, but no comparable data were available for frostbite.^[15] Frostbite is much more prevalent during military campaigns and is a known hazard for mountain climbers and explorers. In the nonadventurer civilian population, Mills collected 500 cases in Alaska by 1963; Cook County Hospital in Chicago recorded 843 cases from 1962–1972; Maria Hospital in Helsinki, Finland, reported 110 cases in 1968; and Detroit Receiving Hospital reported on 154 patients treated from 1982 to 1985.^{[4] [22] [32] [50]}

Physiologically, humans are tropical beings, better suited to losing heat than retaining it. When naked and at rest, a person's neutral environmental temperature is 28° C (82° F); with an environmental drop of only

8° C (14.5° F), the metabolic rate must double to avoid a lowering of body temperature. In comparison, the Arctic fox can maintain a steady thermal state within an external temperature of -40° C (-40° F) and by doubling its metabolic rate could cope with an outside temperature of -120° C (-184° F).

Putting on clothes in response to cold is not a reflex but requires a conscious decision. When the ability to decide or to act is impaired, there is a risk of cold-induced injury.^[11] Alcohol has been implicated in many cases of frostbite.^{[27] [28]} Alcohol- or drug-intoxicated persons whose consciousness, judgment, or self-protective instincts are depressed often expose themselves to dangerous environmental hazards. Knize^[28] noted that alcohol intake or mental instability led directly to cold injury in 50% of their patients. Once the injury had occurred, alcohol intake probably did not significantly alter the course of events. Barillo et al^[11] experimentally demonstrated increased mortality and a detrimental effect of ethanol on tissue perfusion associated with severe murine frostbite. Alcohol consumption promotes peripheral vascular dilation and increases heat loss. This may make an exposed part more susceptible to frostbite.

The type and duration of cold contact are the two most important factors in determining the extent of frostbite injury.^{[80] [81] [82]} Touching cold wood or fabric is not nearly as dangerous as direct contact with metal, particularly by wet or even damp hands. Air alone is a poor thermal conductor. Cold alone is not nearly as dangerous a freezing factor as a combination of wind and cold.^[87] Wind velocity in combination with temperature establishes the windchill index. For example, an ambient temperature of

-6.7° C (20° F) with a 45 mph wind has the same cooling effect as -40° C (-40° F) temperature with a 2 mph breeze. ^[80] ^[81] ^[82] Thus it is important to think in terms of heat loss, not cold gain. Frostbite occurs when the body is unable to conserve heat or protect against heat loss.

Because many serious cases of frostbite originate at high altitude, it has been assumed that physiologic changes occurring with increased altitude make persons more prone to frostbite. However, present data suggest that reduction in atmospheric pressure has little or no effect on susceptibility to frostbite. Increased red blood cell concentration does not increase blood viscosity, impede capillary circulation, or have any other apparent bearing on cold injury. ^[80] ^[81] ^[82] On the other hand, deep, loose snow, which traditionally has been thought to insulate from the cold, may actually contribute to frostbite. Temperature measured beneath deep snow is frequently much lower than that on the surface. Washburn^[82] recounts one expedition to Mt. McKinley, Alaska, when members of his party found it extremely difficult to keep their feet warm, despite a clear, sunny, -16° C (3° F) day with little wind. One member inadvertently dropped a thermometer in the snow and noted that it registered -25.6° C (-14° F). Feet must be dressed for the temperature at their level, not for surface temperature protection. ^[82]

Development of frostbite does not depend simply on ambient temperature and duration of exposure. Along with wind chill, humidity and wetness also predispose to frostbite. Skin wetting adds an increment of heat transfer through evaporation and causes wet skin to cool faster than dry skin. ^[56] More important, water in the stratum corneum can terminate supercooling by triggering water crystallization not only in this layer but also in the underlying tissue. Skin wetness is therefore conducive to frostbite because it allows crystallization to terminate supercooling after approximately half of the exposure time required by dry skin. This substantiates the clinical observation that "it has been found that supercooling displays itself in greater degree in skin that remains unwashed. Washing the skin encourages freezing, while rubbing the skin with spirit and anointing it with oil discourages it. The capacity to supercool greatly would seem to be connected with relative dryness of the horny layers of the skin. It is well known that Arctic explorers leave their skins unwashed." ^[36]

The degree of inadequacy of protective clothing varies with conditions and may contribute to insufficient conservation of body heat. Tight-fitting clothing may produce constriction, which hinders blood circulation and lessens the benefit of heat-retaining air insulation. Wet clothing transmits heat from the body into the environment because water is a thermal conductor superior to air by a factor of about 25. ^[27] Clothing that transmits moisture away from the body may be protective if an outer wind-resistant layer decreases heat loss. However, this wind-resistant layer must retain the same transmission capabilities; otherwise, clothing will still become moist. Clothes that decrease the amount of surface area may decrease frostbite risk. Mittens are more protective than gloves, since gloves have greater surface area and prevent air from circulating between fingers. Eighty percent of total body heat loss can occur through exposed head and neck areas. Poorly fitted boots notoriously generate frostbite injuries.

During World War II and the Korean conflict, clinical studies indicated that cold injuries occurred with higher frequency among soldiers in retreat. ^[59] ^[60] ^[86] Fatigue and apathy

also increase the incidence of cold injury. When warfare is proceeding toward defeat or in conditions of starvation, soldiers often become indifferent to personal hygiene and clothing and the frequency of frostbite increases.^[26] Overexertion increases heat loss. A large amount of body heat can be expended by panting, and perspiration further compounds the problem of chilling.^{[80] [81] [82]} Both panting and sweating consume energy, which compounds the fatigue factor.

Impaired local circulation is a primary contributor to frostbite. Cigarette smoking causes vasoconstriction,

decreased cutaneous blood flow, and tissue loss in random skin flaps.^[35] Reus et al^[67] documented that smoking induced arteriolar vasoconstriction and decreased blood flow in a nude model. Although red blood cell velocity increased, the net effect was a decrease in blood flow in the cutaneous microcirculation during and immediately after smoking. Curiously, habitual heavy smokers do not appear to be more prone to frostbite. Other drugs known to have vasoactive properties may also predispose to or compound a frostbite injury. Disease states that alter tissue perfusion, such as atherosclerosis or arteritis, predispose to frostbite.

Based on clinical observations, an individual who has experienced prior cold injury is placed in a high-risk category during subsequent cold exposure.^{[53] [86]} For undefined reasons, cold injury sensitizes an individual so that subsequent cold exposure, even of a lesser degree, produces more rapid tissue damage.^[27] Military studies emphasize that long periods of immobility contribute to the extent of cold injury.^{[27] [28]} Motion produces body heat and improves circulation, especially in endangered limbs.

Civilian clinical studies are inadequate for statistical evaluation of factors such as race and previous climatic environmental exposure.^{[27] [44]} Military studies suggest that dark-skinned soldiers are more susceptible than whites to cold injury under the same combat conditions.^[87] Individuals from warmer climatic regions within the United States tend to be more susceptible.^[86] There are no data to suggest influence of age or gender in the incidence of frostbite.

THE SKIN

The skin is an individual's interface with the environment, serving as an organ of protection. It controls the invasion of microorganisms, maintains fluid balance, regulates temperature, protects against injury from radiation and electricity, and provides immunologic surveillance. Each function is specifically related to a cell or area within the skin.^[24]

The skin is a highly specialized bilaminar structure resting on a subcutaneous layer of padding. Generally, the skin is about 1 to 2 mm in thickness, but it varies between 0.5 and 6 mm. The highly cellular epidermis and underlying dermis are in contact by multiple interpapillary ridges and grooves. The outermost layer of the epidermis, the stratum corneum, functions for protection. The innermost layer, the stratum germinativum, or basal layer, contains the only proliferating cells within the epidermis. Between these two layers are keratinocytes in various stages of differentiation. Other cells derived from the neural crest (melanocytes) and mesenchyme (Langerhans' cells), as well as cells of unknown etiology (Merkel's cells), migrate into the epidermis and become organized in specific association with certain keratinocytes.

The dermal-epidermal junctions undulate in most areas of the body, increasing surface contact between the two layers to provide resistance to shearing. The dermal-epidermal junction is a complex of structures referred to as the basement membrane zone, which functions as a filter to inhibit or prevent passage of molecules greater than 40 kD.

The dermis, or deeper layer of skin, is 20 to 30 times thicker than the epidermis. It contains nervous, vascular, lymphatic, and supporting structures for the epidermis and harbors the epidermal appendages. Regions of the dermis differ in structural organization and biochemistry, and each responds uniquely to systemic disease, genetic disease, and environmental assault. The papillary dermis and reticular dermis compose the two main dermal zones. The dermis contains fibrous and nonfibrous matrix molecules. Fibrous proteins, primarily collagen, impart bulk, density, and tensile properties to skin but also allow compliance and elasticity. Nonfibrous matrix molecules, glycosaminoglycans and glycoproteins, form ground substance that influences the osmotic properties of skin, permits cellular migration in a more fluid milieu, and serves as an integrative, continuous medium for all of the other structural elements.^[23]

The papillary dermis is only slightly thicker than the overlying epidermis. It is separated from the underlying reticular dermis by a horizontal plexus of vessels. This plexus provides the overlying papillary dermis with a rich blood supply. The papillary dermis is more commonly altered in environmentally induced skin lesions (such as actinic damage) than in systemic disease or inherited diseases of connective tissue

metabolism.

The majority of dermis is reticular dermis. Epidermal appendages either terminate in the lower levels of the reticular dermis or penetrate even deeper into the subcutaneous tissue. Blood vessels pierce the dermis, yielding branches to hair follicles and sweat glands.

Thermoregulation is one body function in which the stratum corneum is not important. The rate at which heat is lost by radiation is a function of the temperature of the cutaneous surface, which in turn is a function primarily of the rate of blood flow through the skin. Heat is poorly conducted from warmer internal tissue to the cutaneous surface because adipose tissue is a good heat insulator.

Thus cutaneous circulation is key to the genesis of frostbite. Because of its role in thermoregulation, the normal blood flow of skin far exceeds its nutritional obligation. The skin holds a complex system of capillary loops that empty into a large subcapillary venous plexus containing the majority of the cutaneous blood volume. Under normothermic conditions, 80% of an extremity's blood volume is in the skin and muscle veins. Skin blood volume depends in part on the tone in the resistance and capacitance vessels, and tone in turn depends largely on ambient and body temperature. Under basal conditions, a 70-kg human has a total cutaneous

blood flow of 200 to 500 ml/min. With external heating to maintain skin temperature at 41° C (105.8° F), this may increase to 7000 to 8000 ml/min, whereas cooling the skin to 14° C (57° F) may diminish it to 20 to 50 ml/min.

Blood flow through apical structures, such as the nose, ears, hands, and feet, varies most markedly because of richly innervated arteriovenous connections. Blood flow to hand skin can be increased from a basal rate of 3 to 10 ml/min/100 g of tissue to a maximum of 180 ml/min/100 g of tissue. This cutaneous vascular tone is controlled by both direct local and reflex effects. Indirect heating (warming a distant part of the body) results in reflex-mediated cutaneous vasodilation, whereas direct warming results in vasodilation dominated by local effects. When both types (central and peripheral) of heating or cooling are present, their effects are additive.

Cutaneous vessels are controlled by sympathetic adrenergic vasoconstrictor fibers. Vascular smooth muscles have both α - and β -receptors, although the significance of the β -receptors is yet to be defined. Vasodilation in the hands and feet is passive, so maximal reflex vasodilation occurs after sympathectomy. After sympathectomy, residual local control of vascular tone persists so that direct heat or cold continues to alter blood flow.

When the hand or foot is cooled to 15° C (59° F), maximal vasoconstriction and minimal blood flow occur. If cooling continues to 10° C (50° F), vasoconstriction is interrupted by

periods of vasodilation and an associated increase in blood and heat flow. This cold-induced vasodilation (CIVD), or "hunting response," recurs in 5- to 10-minute cycles to provide some protection from the cold. There is considerable individual variation in the amount of CIVD, which might explain some of the variation in susceptibility to frostbite. Prolonged repeated exposure to cold will increase CIVD and offer some degree of acclimatization. Eskimos, Lapps, and Nordic fishermen have a very strong CIVD response and very short intervals between dilations, which may contribute to maintenance of hand function in the cold environment. ^[19]

There is little evidence that humans have any significant physiologic adaptation to cold. They remain homeothermic, warm weather, tropical animals who neither tolerate nor adapt well to the cold. They must find a well-defined microclimate to keep skin temperature close to 32.8° C (91° F). Normal skin maturation and tissue function rely on the maintenance of permeability and integrity of all tissue membranes. A steady rate relationship of prostaglandins, particularly prostaglandin E₂ (PGE₂; vasodilator) and PGF_{2a} (vasoconstrictor), is crucial for normal skin function. An imbalance may disrupt cell membrane equilibrium. This relationship is controlled through PGE₂-9-ketoreductase and nicotinamide adenine dinucleotide phosphate (NADPH). Low concentrations of PGE₂-9-ketoreductase found in normal skin emphasize an active biologic presence.

FROSTBITE INJURY

The frostbite injury has classically been divided into four pathologic phases^[31] :

1. Prefreeze phase. This is secondary to chilling and before ice crystal formation. Changes are caused by vasospasticity and transendothelial plasma leakage. Tissue temperature ranges from 3° to 10°C (37° to 50° F). Cutaneous sensation is generally abolished at 10° C (50° F).
2. Freeze-thaw phase. This is caused by actual ice crystal formation. Tissue temperature drops below the freezing point as the ambient environmental temperature dips below -15° to -6° C (5° to 21° F). Because of the underlying radiation of heat energy, skin must be supercooled to -4° C (24.8° F) to freeze. With no circulation, skin temperature may drop at a rate in excess of 0.5° C (0.9° F) per minute. After it is completely frozen, the tissue rapidly exhibits poikilothermy. The susceptibility of tissue to freezing varies, with endothelium, bone marrow, and nerve tissue more sensitive than muscle, bone, and cartilage.
3. Vascular stasis phase. This involves changes in blood vessels, including spasticity and dilation, and includes plasma leakage, stasis coagulation, and shunting.
4. Late ischemic phase. This is a result of thrombosis and arteriovenous shunting, ischemia, gangrene, and autonomic dysfunction.

Overlap occurs among these phases.^[30] The changes during each phase vary with rapidity of freezing and duration and extent of injury. It is therefore conceptually clearer to divide pathologic changes occurring in frostbite into those resulting from direct cellular injury and those from indirect cellular effects. Changes caused by direct injury include the following^[89] :

1. Extracellular ice formation
2. Intracellular ice formation
3. Cell dehydration and shrinkage
4. Abnormal intracellular electrolyte concentrations
5. Thermal shock
6. Denaturation of lipid-protein complexes

Cells subjected to a slow rate of cooling (hours) develop ice crystals extracellularly in the cellular interspaces. Rapid cooling (seconds to minutes) produces intracellular ice crystals, which are more lethal to the cell and less favorable for cell survival. In a clinical cold injury, the slower rate of freezing does not produce intracellular crystals^[46] ; however, the extracellular ice formed is not innocuous. It draws water across the cell membrane, contributing to intracellular dehydration. The theory of cellular dehydration

was originally proposed by Moran^[57] in 1929 and subsequently supported

by Merryman's study of "ice-crystal nucleation."^{[45] [46] [47]} Cellular dehydration produces modification of protein structure by high electrolyte concentration, alteration of membrane lipids, alteration of cellular pH, and imbalance of chemical activity.^{[41] [42] [47]} This phenomenon subsequently permits a marked and toxic increase of electrolytes within the cell, leading to partial shrinkage and collapse of its vital cell membrane. These events are incompatible with cell survival.

Not all the water within a cell is freezable. A small amount of unfrozen water, "bound water," constitutes up to 10% of the total water content and is held tightly in the protein complex within the cell. No matter how rapid or marked the cold injury, this bound water remains liquid. At temperatures below -20° C (-4° F), approximately 90% of available water is frozen.^[87] Although the theory of ice crystal disruption of cell structure is attractive, it has yet to be conclusively proven.

Thermal shock defines the phenomenon of sudden and profound temperature change in a biologic system.^[18] Precipitous chilling has been theorized to be incompatible with life, but the severity of this phenomenon is debatable. Another poorly understood concept is the manner in which subzero temperatures produce denaturation of lipid-protein complexes. One theory hypothesizes detachment of lipids and lipid-protein from cell membranes as a consequence of the solvent action of a toxic electrolyte concentration within a cell.^{[37] [38]} There is no direct evidence supporting an alteration of enzyme activity during freezing, but deoxyribonucleic acid (DNA) synthesis is inhibited.^[25] On the other hand, there is indirect evidence of ox liver catalase inactivation caused by denaturation and structural alteration of lactic acid dehydrogenase after freezing and thawing.^{[39] [77]}

Indirect cellular damage secondary to progressive microvascular insults is more severe than the direct cellular effect. This is supported by the observation that skin tissue subjected to a standard freeze-thaw injury, which consistently produced necrosis *in vivo*, survived as a full-thickness skin graft when transplanted to an uninjured recipient site.^[83] Conversely, uninjured full-thickness skin did not survive when transferred to a recipient area pretreated with the same freezing injury. Thus direct skin injury is reversible. The progressive nature of injury is probably secondary to microvascular changes.

Approximately 60% of skin capillary circulation ceases in the temperature range of 3° to 11° C (37.4° to 51.8° F), whereas 35% and 40% of blood flow ceases in arterioles and venules, respectively.^[68] Capillary patency is initially restored in thawed tissue, but blood flow declines 3 to 5 minutes later. Three nearly simultaneous phenomena occur after thawing: momentary and initial vasoconstriction of arterioles and venules, resumption of capillary circulation and blood flow, and showers of emboli coursing through microvessels.^[89] Ultimately, there is progressive tissue loss caused by progressive thrombosis and hypoxia. This is similar to tissue loss seen in the distal dying random flap and the no reflow phenomenon. For both of these, in addition to the effect of

arachidonic acid metabolites, oxygen free radicals have been shown to be detrimental and contribute to tissue loss. This may be the case in the frostbite injury.^[8]

Considerable evidence points to the primary alteration of the cold injury being injury to vascular endothelium.^[89] Seventy-two hours after a freeze-thaw injury, there is loss of vascular endothelium in the capillary walls, accompanied by significant fibrin deposition. The endothelium may be totally destroyed, and fibrin may saturate the arteriole walls.^[89] Ultrastructural derangement of endothelial cells after the thaw period has been observed by electron microscopy in capillaries of the hamster cheek pouch after subzero temperatures.^[65] The endothelial injury was confirmed by demonstrating fluid extravasation from vessels almost immediately after thawing.^[89] As in other forms of trauma, vascular endothelial cells swell and protrude inward into the lumen until they lyse.

Venules appear more sensitive to cold injury than are other vascular structures, partly because of lower flow rates. Arterioles, with a rate of flow almost twice that of venules, are less damaged by freezing and develop stasis later than venules. Capillaries manifest the fewest direct effects of cold injury, but their flow is quickly arrested as a result of their position between arterioles and venules. Generalized stasis and cessation of flow are noted at the point of injury within 20 minutes after freeze and thaw. "White thrombi" (blood cells and fibrin) follow platelet thrombi as blood flow progressively slows. Sludging and stasis result in ultimate thrombosis. Microangiography after cold injury shows that, although spasm of the arterioles and venules exists, it is not marked enough to completely account for the decreased flow of progressive microvascular collapse.^[2] It has been postulated that defects seen in angiograms are caused by local factors, possibly thrombi. It has also been observed that vascular thrombosis after cold injury advances from the capillary level to that of the large vessels and ultimately results in ischemic death of progressively larger areas.^[29] ^[31] Viable dermal cells may be observed histologically in cold-injured tissues for up to 8 days or until occlusion of local vessels occurs. This emphasizes that a major role is played by vascular insufficiency, and that direct injury to cellular structures and mechanisms may be reversible.

Because Cohnheim had shown changes in cold injury to be similar to changes seen in other inflammatory states, Robson and Heggors^[69] postulated that progressive ischemia seen in frostbite might be due to the same inflammatory mediators responsible for progressive dermal ischemia in the burn wound. They evaluated

blister fluid from victims with hand frostbite, measuring levels of PGE₂, PGF_{2a}, and thromboxane B₂ (TxB₂). Levels of the vasoconstricting, platelet-aggregating, and leukocyte-sticking prostanoids (PGF_{2a} and TxA₂) were markedly elevated. The investigators postulated that massive edema after cold injury was due either to leakage of proteins caused by release of these prostanoids or to leukocyte sludging in the capillaries and increased hydrostatic pressure. Recent studies have confirmed the similarity between cold injury and the burn wound.^[8]

Severe endothelial damage was observed by researchers studying a minimal cold injury model in the hairless mouse.^[5] In addition, the sequence of endothelial damage, vascular dilation, vascular incompetence, and erythrocyte extravasation was confirmed. This led to speculation that arachidonic acid metabolites, which may originate from severely damaged endothelial cells, are important in progressive tissue loss. Significantly absent from in vivo and microscopic observations were vascular spasm, thrombosis, and fibrin deposition, all of which have previously been implicated as pathophysiologic mechanisms. A rabbit ear model demonstrated increased tissue survival after blockade of the arachidonic acid cascade at all levels.^[66] The most marked tissue salvage resulted when specific TxA₂ inhibitors were used. This has now been shown to be effective in clinical situations.^[22]

Skin Changes in Response to Frostbite

Reports in the 1940s documenting the histopathology of frostbite injury to the skin have been scarce and incomplete. Historically, studies by several investigators have been limited to skin biopsies without documentation of location, exposure time, temperature, or post injury intervals.^[72] More recently, experimental studies have been able to document the histopathology of skin changes under controlled conditions.

In 1988, Schoning and Hamlet^[74] ^[75] used a Hanford miniature swine model for frostbite injury (-75° C [-103° F] exposure for up to 20 minutes) to note progressive epithelial damage. Early changes included vacuolization of keratinocytes, with loss of intercellular attachments and pyknosis over a period of 1 week or more. This subsequently progressed to advanced cellular degeneration and the formation of microabscesses at the dermoepidermal junction. Later changes include epithelial necrosis and regeneration, both separately or together within the same tissue. Such histopathologic data favor the current standard of conservative management of frostbite injury.

However, Marzella et al.^[40] used a New Zealand white rabbit ear model of frostbite injury and proposed that the skin necrosis induced by frostbite injury was merely a reflection of damage to the target cell: the endothelial cell. After submersion of a shaved rabbit ear in 60% ethyl alcohol at -21° C (-5.8° F) for 60 seconds, the entire microvasculature demonstrated endothelial damage within 1 hour; erythrocyte extravasation occurred within 6 hours. These early vascular changes in the rabbit ear model are in contradistinction to the timing of vascular changes in the Hanford miniature swine model reported by Schoning et al.^[75] These authors performed biopsies on animals exposed to frostbite injury (-75° C for up to 20 minutes) and evaluated the specimens for vascular inflammation, medial degeneration, and thrombosis. The earliest change documented both grossly and microscopically was hyperemia. Within 6 to 24 hours, leukocyte migration and vasculitis were noted. However, the most severe vascular changes of thrombosis and medial degeneration were not documented for 1 to 2 weeks after the injury.

Whether or not the changes in the epidermis are primary or secondary to damage to the underlying endothelial cells, it is clear that these tissues have a potential, although limited, capacity for regeneration. This further supports a conservative approach to the

management of frostbite injury.

Clinical Presentation

Classically, frostbite has been described by its clinical presentation. Initially, it is difficult to predict the extent of frostbite damage.^[28]^[52] Mills^[51] favors the use of two simple classifications: mild (without tissue loss) and severe (with tissue loss). Historically, frostbite has been divided into "degrees of injury" based on acute physical findings after freezing and rewarming. First-degree injury shows numbness and erythema. There is a white or yellowish, firm plaque in the area of injury. There is no tissue loss, although edema is common. Second-degree injury results in superficial skin vesiculation ([Figure 7-1](#) , [Figure 7-2](#) , [Figure 7-3](#)). A clear or milky fluid is present within the blisters, surrounded by erythema and

Figure 7-1 Vesiculation of right ear with clear fluid characteristic of second-degree frostbite.

edema. Third-degree injury shows deeper blisters, characterized by purple, blood-containing fluid ([Figure 7-4](#) and [Figure 7-5](#)). This indicates that the injury is into

the reticular dermis and beneath the dermal vascular plexus. Fourth-degree injury is completely through the dermis and involves the relatively avascular subcuticular tissues ([Figure 7-6](#) and [Figure 7-7](#)). This tends to cause mummification ([Figure 7-8](#) and [Figure 7-9](#)), with muscle and bone involvement. Less severe bone injury in children may affect the growth plate and result in developmental digital deformities.^{[7] [10]}

Frostbite Symptoms

The severity of frostbite symptoms generally parallels the severity of the injury. In the civilian population,

Figure 7-4 Edema and blister formation 24 hours after frostbite injury occurring in an area covered by a tightly fitting boot. (Courtesy Cameron Bangs, MD.)

Figure 7-5 Deep second and third degree frostbite with hemorrhagic blebs. One day postthaw. (Photo by Murray P. Hamlet, DVM.)

frostbite most frequently occurs on the extremities, with the lower extremity being far more common. It can also appear on the nose or ears and has been reported on the scrotum and penis in joggers.^[82]

Mere numbness followed by tingling after rewarming does not constitute bona fide frostbite. Even in its mildest form, true frostbite damages the affected tissue. In most victims the initial clinical observation is coldness of the involved extremity, with numbness present in more than three fourths of victims. This ultimately causes the involved

Figure 7-7 Fourth-degree frostbite. Note sharp line of demarcation under eschar, depigmentation of third degree skin proximally and indurated distal fingertips. Fingertips will autoamputate. Four weeks postthaw. (Photo by Murray P. Hamlet, DVM.)

part to feel clumsy or absent and has been attributed to ischemia after intense vasoconstriction. When numbness is initially present, it frequently is followed by extreme pain (76% of victims) during rewarming. Throbbing pain begins 2 to 3 days after rewarming and continues for a variable period, even after the tissue becomes demarcated (22 to 45 days). After about a week, the victim usually notices a residual tingling sensation, probably caused by ischemic neuritis. For this reason, this sensation tends to persist longer than do other symptoms. The severity of the injury usually defines the extent of neuropathologic

Figure 7-9 Fourth-degree frostbite. Fingertips will autoamputate. Note dried or absent bleb surface. Depigmentation and flexure contractures. Five weeks postthaw. (Photo by Murray P. Hamlet, DVM.)

damage. There may be a great deal of variation in symptoms, with some victims never noticing pain at the onset of the injury. In victims without tissue loss, symptoms usually subside within 1 month, whereas in those with tissue loss, disablement may exceed 6 months. In all cases, symptoms are intensified by a warm environment. Other sensory deficits include spontaneous burning and electric current-like sensations. The burning sensation, which is frequently early in presentation, subsides within 2 to 3 weeks. This sensation is not present in victims with tissue loss. In victims without tissue loss, it may resume on wearing shoes or increasing activity. The electric current-like shock is almost universal (97%) in victims with tissue loss. It usually begins 2 days after injury, lasts for about 6 weeks, and is particularly unpleasant at night. All frostbite victims experience some degree of sensory loss for at least 4 years after injury and perhaps indefinitely.

The clinical appearance of frostbite may be deceiving.^[4] ^[59] Only a few victims arrive with tissue still frozen. Originally the extremity appears yellowish white or mottled blue. It may be insensate and may appear frozen solid. Regardless of the depth of the injury, the extremity may have the appearance of being frozen. With rapid rewarming there is almost immediate hyperemia, even with the most severe injury. Sensation returns after thawing and persists until blebs appear. At this point, some effort may be made to assess the severity of the injury. Although "degrees" of injury have been defined, one usually differentiates between superficial (first- or second-degree) and deep (third- or fourth-degree) injuries. Even these distinctions are somewhat artificial, since the initial treatment of frostbite is identical. The degree system may have some importance in retrospective analysis of cases.

After the extremity is rewarmed, edema appears within 3 hours and lasts 5 days or longer, depending

186

Figure 7-10 Frostbitten toes demarcate three weeks after injury. Note the cotton padding between the toes. Minimal tissue loss occurred. (Photo by Paul Auerbach, MD.)

on the severity of the case.^[59] Vesicles, or bullae, form 6 to 24 hours after rapid rewarming.^[46] ^[60] During the first 9 to 15 days, severely frostbitten skin forms a black, hard, and usually dry eschar whether vesicles are present or not ([Figure 7-10](#)).^[60] Mummification forms an apparent line of demarcation in 22 to 45 days.^[59]

Favorable prognostic signs include sensation to pinprick; normal color; warmth; and large, clear blebs that appear early and tend to extend to tips of the digits. Unfavorable signs include small, dark blebs that appear late and do not extend to the digit tips; the absence of edema; and the presence of cyanosis that does not blanch with pressure.^[51]

Techniques that have been used to estimate the extent of injury and to predict ultimate tissue loss include intravenous radioisotope scanning (¹³¹ I RISA, ¹³³ Xe, ^{99m} Tc MDP, ⁹⁹ Tc stannous pyrophosphate), angiography, routine roentgenography, and digital plethysmography. These modalities have also been recommended for estimating the vascular response to vasodilators and identifying tissue boundaries for surgical management. No prognostic technique is absolutely accurate in the immediate postthaw period; a delay of 2 to 3 weeks is necessary to exceed the period of transitory vascular instability.

Ophthalmic Injuries

Ophthalmic injuries, particularly freezing of corneas, occur in individuals who try to force their eyes open in high windchill situations. Snowmobilers and crosscountry skiers are particularly susceptible. Blurred vision, photophobia, blepharospasm, tearing, and pain on rewarming suggest such an injury. Rapid rewarming and patching are the only effective treatments. Corticosteroids are contraindicated. Corneal transplantation may be required if keratitis and corneal opacification are irreversible and debilitating. Snow-blindness caused by ultraviolet exposure is discussed in [Chapter 14](#).

Management

In 1947, Hurley stated, "Tissue cells can be affected by freezing in three different ways: 1) a certain number of cells are killed; 2) a certain number remain unaffected; and 3) a large number are injured but may recover and survive under the right circumstances."^[24] Obviously the major treatment effort must be to salvage as many cells in category 3 as possible.

Frostbite treatment is directed separately at the prethaw and postthaw intervals. If a victim is referred from a nearby location, no attempt at field rewarming may be indicated. Vigorous rubbing is ineffective and potentially harmful. The extremity should not be intentionally rewarmed during transport and should be protected against slow partial rewarming by keeping the victim away from intense campfires and car heaters. All constrictive and wet clothing should be replaced by dry, loose wraps or garments. The extremity is padded and splinted for protection, but no other treatment is initiated. Although there is a correlation between the length of time tissue is frozen and the amount of time required to thaw that tissue, there is no direct correlation between the length of time tissue is frozen and subsequent tissue damage. Therefore rapid transport of frostbite victims (within 2 hours) is appropriate. Otherwise, rapid rewarming should be instituted and the victim transported with protective dressings to prevent refreezing. Blisters should be left intact. Victims with long transport times are at greater risk for recurrent injury. All efforts should prevent subsequent refreezing, since this creates an infinitely worse result than does delayed thawing. A victim who must walk through snow should do so before thawing frostbitten feet. During transport, the extremities should be elevated and tobacco smoking prohibited.^[50] Alcohol ingestion is contraindicated.

Once in the emergency department, rapid rewarming should be started immediately. Associated traumatic injuries or medical conditions should be identified. Systemic hypothermia should be corrected to a core temperature of at least 34° C (93° F) before frostbite management is attempted. Fluid resuscitation is usually not a problem with frostbite injuries, although one case of rhabdomyolysis and acute renal failure has been reported.^[71]

Treatment is directed at the specific pathophysiologic effects of the frostbite injury, either blocking direct cellular damage or preventing progressive microvascular thrombosis and tissue loss. Direct cellular damage is treated by rapid thawing of all degrees of frostbite with immersion in gently circulating water warmed to between 40°

and 42° C (104° and 108° F) ([Figure 7-11](#)).^[27] Adherence to this narrow temperature range is important, since rewarming at lower temperatures is less beneficial for tissue survival,^[16] ^[22] and rewarming at higher temperatures may compound the injury by producing a burn wound.^[54] Heated tap water

Figure 7-11 Technique to rapidly warm all four extremities simultaneously. The water is 40° to 42° C (104° to 108° F), monitored by a thermometer, and circulated manually. Thawing is usually complete in 30 minutes, when the extremities are pliable and color and sensation have returned.

(50° to 60° C [122° to 140° F]) is too hot and will cause profound discomfort and possible tissue damage. Frozen extremities should be rewarmed until the involved skin becomes pliable and erythematous at the most distal parts of the frostbite injury. This usually takes less than 30 minutes. Active motion during rewarming is helpful, but massage may compound the injury. Extreme pain may be experienced during thawing, and unless otherwise contraindicated, parenteral analgesics are administered. Rapid return of skin warmth and sensation with the presence of an erythematous color is a favorable sign, whereas the persistence of cold, anesthetic, and pale skin is unfavorable.

Rapid rewarming reverses the direct injury of ice crystal formation in the tissue. However, it does not prevent the progressive phase of the injury. McCauley et al^[43] ^[44] have designed a protocol based on the pathophysiology of progressive dermal ischemia that has been quite successful in minimizing the production of local and systemic thromboxane by injured tissues ([Box 7-1](#)). All but the most minor frostbite cases should be admitted to the hospital. Victims with minor injuries should be admitted if, after rapid rewarming, a warm environment cannot be ensured for the victim. No patient should ever be discharged into subfreezing weather. Even with a warm car waiting, the patient should be allowed to leave only with proper clothing (such as stocking cap, wool mittens, and wool socks). Since the majority of frostbite injuries necessitate admission to the hospital, a discussion of the protocol is warranted. White or clear blisters, which represent more superficial injury, are debrided to prevent further contact of PGF_{2a} or TxA₂ with the damaged underlying tissues. Unlike the clear blisters, hemorrhagic blisters reflect structural damage to the subdermal plexus. It may be worthwhile to aspirate the thromboxane-containing fluid out of these blisters, but debridement may allow desiccation of the deep dermis and allow conversion of the injury to full thickness. Therefore hemorrhagic blisters are left intact. A specific thromboxane inhibitor is placed on the wounds to prevent further formation of this vasoconstricting mediator ([Figure 7-12](#)). Aspirin was originally given systemically to block production of PGF_{2a} and TxA₂ . Since the correct dose of aspirin is not known, aspirin has been replaced by

ibuprofen.^[80] Ibuprofen not only inhibits the arachidonic acid cascade but also has the additional benefit of fibrinolysis. Elevation of the extremity minimizes dependent edema. Since edema inactivates the normal streptococcioid properties of the skin, parenteral penicillin is administered during the edema phase of the injury.^[11] Antitetanus prophylaxis is given if indicated by the patient's immunization history.^[12] Tetanus killed thousands of Napoleon's soldiers in the Russian campaign. There was a report as recently as April 1985 documenting tetanus associated with a frostbite injury. Since frostbite generally involves injuries to the extremities, appropriate physical and occupational therapy should be initiated early. Daily hydrotherapy for active and passive range of motion is extremely valuable in the preservation of function.^[14]

Between 1982 and 1985, 56 patients were treated with the previous frostbite protocol and 98 were treated by other "standard" methods. Of the 56 patients treated with the protocol, 18 were admitted with first-degree frostbite, 25 with second-degree frostbite, and 13 with third-degree frostbite. Thirty-two suffered acute frostbite, and 24 had subacute (presenting for treatment more than 24 hours after injury). The mean length of hospital stay for the acute protocol patients was 8.5 days and for the subacute group, 14.9 days. Overall, 67.9% of the protocol group healed without tissue loss, 25% healed with some tissue loss, and 7% required amputation. Of the nonprotocol patients, 11 were admitted with first-degree frostbite, 51 with second-degree frostbite, and 36 with third-degree frostbite. Fifty-six were acute cases, and 42 were subacute. The mean length of hospital stay was 17.5 days for the acute, nonprotocol patients and 19 days for the subacute group. Of this group, 32.7% healed without tissue loss, 34.6% healed with tissue loss, and 32.7% required amputation ($p < .001$; includes all groups of protocol-treated patients). These data indicate therapeutic efficacy of the protocol by virtue of less tissue loss, lower amputation rate, and significantly shorter hospital stay.^[22]

Other Therapies

A number of other therapeutic modalities have attempted to prevent progressive thrombosis and tissue loss. Most were proposed before the pathophysiology of the injury was found to be related to inflammatory

mediators. These therapeutic attempts deserve comment. It has been observed that cold-injured vessels, shortly after thawing, became dilated and filled with clumps of erythrocytes. These clumps can be easily dislodged by gentle manipulation and do not represent true thrombosis. Although the mechanism that leads to erythrocyte clumping is not completely understood, it may reflect a cold-induced increase in blood viscosity. This suggests that the use of low-molecular-weight dextran may be of benefit in the early treatment of frostbite. Although no controlled clinical trial of low-molecular-weight dextran has been reported, there has been experimental evidence to support its use. Weatherly-White, Sjostrom, and Paton^[83] demonstrated that the use of low-molecular-weight dextran, 1 g/kg/day, protected against tissue loss in the rabbit ear model. This led to the suggestion that the use of 1 L of 6% dextran intravenously on the day of injury, followed by 500 ml on each of 5 successive days, might be of benefit.^[70]

With our present understanding of the etiology of frostbite, there appear to be few instances when it may be used and have demonstrable benefit.

Box 7-1. PROTOCOL FOR RAPID REWARMING

1. Admit frostbite patients to a specialized unit if possible.
2. Do not discharge or transfer to another facility victims of acute frostbite requiring hospitalization unless it is necessary for specialized care. Transfer arrangements must protect the victim from cold exposure.
3. On admission, rapidly rewarm the affected areas in warm water at 40° to 42° C (104° to 108° F), usually for 15 to 30 minutes or until thawing is complete.
4. Upon completion of rewarming, treat the affected parts as follows:
 - a. Debride white blisters and institute topical treatment with aloe vera (Dermaide aloe) every six hours.
 - b. Leave hemorrhagic blisters intact and institute topical aloe vera (Dermaide aloe) every six hours.
 - c. Elevate the affected part(s) with splinting as indicated.
 - d. Administer antitetanus prophylaxis.
 - e. For analgesia, administer morphine or meperidine (Demerol) intravenously or intramuscularly as indicated.
 - f. Administer ibuprofen 400 mg orally every 12 hours.
 - g. Administer penicillin G 500,000 units intravenously every six hours for 48 to 72 hours.
 - h. Perform hydrotherapy daily for 30 to 45 minutes at 40° C (104° F). The solution should meet the following specifications:
 1. Large tank capacity—425 gallons

Fill level estimate—285 gallons

Sodium chloride—9.7 kg

Calcium hypochlorite solution—95 ml

2. Medium tank capacity—270 gallons

Fill level estimate—108 gallons

Sodium chloride—3.7 kg

Calcium hypochlorite solution—36 ml

3. Small tank capacity—95 gallons

Fill level estimate—72 gallons

Sodium chloride—2.5 kg

3. Small tank capacity—95 gallons

Fill level estimate—72 gallons

Sodium chloride—2.5 kg

Potassium chloride—71 g

Calcium hypochlorite solution—24 ml

5. For documentation obtain photographs on admission, at 24 hours, and serially every two to three days until discharge.
6. Discharge patients with specific instructions for protection of the injured areas to avoid reinjury and follow up weekly until wounds are stable. If the patient is being discharged with no open lesions, instruct him or her to use wool socks, wear a hat, and use mittens instead of gloves to decrease the loss of heat between the fingers. Explain to patients that they are more susceptible to refreezing, so they should avoid exposure to cold and should wear warm clothing and shoes or boots if going outside is necessary. Give similar instructions to patients who are discharged with open lesions. Also instruct these patients to keep the affected extremity elevated and to take ibuprofen 400 mg orally every 12 hours. Aloe vera should be applied to the involved areas, or scarlet red ointment used if the open areas are small.

Although true thrombi are not present in dilated, erythrocyte-filled vessels immediately after thawing, they form over the next few days. Heparin has been suggested as a possible treatment for frostbite. Lange and Loewe^[33] demonstrated its usefulness in experimental frostbite. Subsequent investigations have been unable to substantiate these findings, and at the present time there is no evidence that heparin alters the natural history of the frostbite.^[76]

Intraarterial reserpine has also been shown experimentally to be of use in frostbite. Porter et al^[62] reported its clinical use in five patients. Three of the patients were treated within 2 weeks of injury. Angiography of the involved extremities was performed before and after injection ([Figure 7-13](#)). Reserpine appeared to be effective in relieving vasospasm. However, treatment did not retard progression of tissue loss. A multiarmed clinical study compared slow rewarming combined with

Figure 7-12 A, Acute frostbite injury with clear fluid in superficial blisters. **B**, Blisters before treatment but after debridement. **C**, After 48 hours of therapy with topical aloe vera

(Dermaide aloe). **D**, Sixteen days after injury.

Figure 7-13 Angiograms of the left foot of a 30-year-old man with cold injury. **A**, Initial angiogram. **B**, Angiogram taken 2 days after intraarterial injection of reserpine. (From Galino BJ, Porter JM, Rosch J: *Radiology* 19:301, 1976.)

intravenous dextran, intraarterial tolazoline, intraarterial reserpine, and various combinations of these drugs.^[79] All of the drug treatments were superior to simple slow rewarming. However, rapid rewarming was as effective as any of the drug treatments. Therefore reserpine might be effective when patients are brought for treatment late and have not been rapidly rewarmed. To date, no anticoagulant or vasodilation treatment has proved useful in controlled clinical trials.

Several reports from Europe and the United States after World War II supported the use of sympathetic block and sympathectomy.^[6] However, this remains controversial. If the sympathetic nervous system is involved, it seems reasonable that early sympathectomy would be beneficial. However, experimental evidence indicates that sympathectomy performed within the first few hours of injury increases edema formation and accelerates the pathologic process of tissue destruction.^{[17] [83]} On the other hand, sympathectomy performed 24 to 48 hours after thawing seems to hasten resolution of edema and decrease tissue loss.^[17] The role of sympathectomy will not become clear until there is a verifiable clinical rating to evaluate results.^[13] Similar problems exist in evaluation of the use of hyperbaric oxygen. Although some experimental data support its use, only occasional anecdotal cases are reported.^[58] Furthermore, its use is predicated on the original theory of the frostbite injury and not the most recent experimental data.

Early surgical intervention has no role in the acute care of frostbite, unless there is ischemia from a constricting eschar or subeschar infection that cannot be controlled by topical antimicrobials. Decompressing escharotomy incisions are rarely necessary to increase the distal circulation. If such escharotomies are necessary to decompress digits and facilitate joint motion, incisions along the transaxial line are best. It is important that incisions avoid injury to the underlying structures. If uncontrolled infection is present early, escharotomy may be necessary. However, this is rare with the use of penetrating antibacterial agents, such as mafenide acetate.

Surgical intervention is properly reserved for late treatment of frostbite. This is most often necessary if frostbite is very severe or if treatment has been delayed. Normally, aggressive therapeutic measures can prevent progressive injury and gangrene. If gangrene ensues, amputation or debridement with resurfacing may be necessary (

[Figure 7-14](#)).

This should be accomplished only after the area is well demarcated, which generally requires 3 to 4 weeks. Historically, aggressive early debridement and attempted salvage have been thought to jeopardize recovering tissue and add to tissue loss. Gottlieb, Zachary, and Krizek^[18] have taken a more aggressive approach to coverage of severe frostbite injury. Using technetium phosphate and bone scans, they identify nonperfused tissue by the tenth day after injury and surgically remove necrotic tissue. The remaining nonvascularized, nonviable, yet nonnecrotic and noninfected, tissue is salvaged by early coverage with well-vascularized tissue. Theoretically, if nonvascularized tissue has not undergone autolysis and is not infected, it should behave as a composite graft. Preliminary reports are promising.^[18]

Late Sequelae

Until 1957, little was recorded about the long-term sequelae of frostbite injuries. Blair, Schatzki, and Orr^[3] studied 100 veterans of the Korean conflict 4 years after their injuries. In order of decreasing frequency, the victims reported excessive sweating, pain, coldness, numbness, abnormal skin color, and stiffness of the joints. In addition, the investigators noted frequent asymptomatic abnormalities of the nails, including ridges and inward curving of the edges. In general, the degree of long-term disability was related to the severity of the original injury. Symptoms were worse in cold than in warm weather. This is attributed to the fact that vessels do not react as well to stress.^[78] Previously injured blood vessels do not constrict when exposed to cold as effectively as do normal vessels, and they do not dilate as effectively when vasoconstriction is blocked.

Hyperhidrosis is probably both a cause and a result of frostbite. Hyperhidrosis suggests the presence of an abnormal sympathetic nervous response induced by cold injury and is abolished by sympathetic denervation. Sensitivity to cold and predisposition to recurrent cold injury should suggest hyperhidrosis. Blanching and pain on subsequent cold exposure may be a nuisance or may be dramatic enough to suggest a diagnosis of Raynaud's phenomenon. Almost without exception a painful, shiny, cyanotic, and sweaty limb becomes warm, dry, and useful with sympathetic interruption.^{[74] [75]} Schoning^[73] examined the changes in the sweat glands of Hanford miniature swine after experimental frostbite injury to determine the etiology of hyperhidrosis. She noted that severe sweat gland changes were of two types: degeneration with necrosis and squamous metaplasia. Clearly, if hypohidrosis were a sequela of frostbite injury, morphologically normal and active sweat glands would be an expected finding. We may conclude that hyperhidrosis may lack histologic documentation.

The late abnormalities of change in skin color, including depigmentation of dark skin and appearance resembling erythrocyanosis in light skin, are most likely the result of ischemia.^[3] Similarly, the nail abnormality is comparable with that seen with ischemia. Neither of these sequelae usually requires treatment.

Late symptoms of joint stiffness and pain on motion are relatively common and

undoubtedly are related to the underlying scars and mechanical problems occasioned

Figure 7-14 A, Gangrene from third-degree frostbite. **B**, Treated with partial hand amputation in preparation for toe-to-hand transfer.

by the variety of amputations. "Punched-out" defects in subchondral bone of involved limbs have been noted. These localized areas of bone resorption generally appear within 5 to 10 months after injury and may heal spontaneously. Vascular occlusion is the probable cause of these lesions. Such bone involvement in close proximity to joint surfaces may help explain joint symptoms.

The effects of frostbite on premature closure of epiphyses in the growing hand have recently been reemphasized.^[85] The extent of premature closure has been correlated with the severity of the frostbite and noted in partial-thickness injuries. In the digits, premature closure is more frequent from a distal to proximal direction (distal interphalangeal greater than proximal interphalangeal greater than metacarpophalangeal). The thumb has been less often involved. In only 2% of cases does partial epiphyseal closure cause angular deformity.

One of the characteristic features of frostbite is the surprising salvage possible in an apparently badly injured extremity. Amputation should therefore be performed with great conservatism and as late as possible. The line of demarcation may not be decided definitively for weeks or months after injury. As long as secondary sepsis does not intervene, patience often rewards both the patient and surgeon with maximal length of the useful limb. This is particularly true in the upper extremities.

Conditioning and Prevention

Frostbite can usually be prevented by experienced leadership, good physical condition, adequate food, and intelligently used equipment. Probably the two most important basic factors in prevention of frostbite are the heat-producing capacity of the body and the effectiveness of measures to conserve heat once it has been produced. The most fundamental defense against frostbite is a healthy body.

As previously noted, there are no data to support the belief that high altitude increases susceptibility based on changes in blood viscosity. On the other hand, living conditions at high altitude may contribute to increasing danger from frostbite. Cold becomes more intense, as do the violence and severity of storms. Shelter is less appealing and protective. Loss of sleep, inadequate diet, altered digestion, and nervous tension all contribute to a greater degree of fatigue than normally experienced at lower heights. Hypoxia reduces reasoning powers and leads to a tendency to laziness, carelessness,

indecision, and lack of normal insight and judgment.^[82]

The body requires the same amount of oxygen for various tasks regardless of the altitude. At higher altitudes, however, the body must process more air to gain that same amount of oxygen. Individuals must carefully regulate their activity; otherwise, they will not only exhaust the body but will also cool it. Large quantities of heat can be lost through the lungs by panting and overexertion,^[63] which also adds to fatigue.

At higher altitudes, the natural protective mechanism of shivering is impaired and heat production during rest can be significantly reduced. If an individual becomes unable to exercise, the body cannot maintain adequate heat production. The body reduces blood flow to its surface and extremities in an effort to maintain core temperature. In such a situation, no amount of insulation can prevent frostbite and nothing but vigorous warming and administration of oxygen can avert serious results. Since the use of auxiliary oxygen was introduced in mountaineering, frostbite has become less common.

192

Cold weather increases caloric needs, and variations in diet can have an effect on tolerance.^[55] In the cold, cooking, dishwashing, thawing food, and melting water are arduous tasks. Fluid requirements far exceed what is empirically thought to be necessary.

Frostbite is rarely experienced by healthy individuals who are standing still and adequately clothed. It seems to be related almost always to factors such as fatigue, a sudden storm, an accident, or combinations of these. Alcohol intoxication is a frequent forerunner of frostbite. Injury to any part of the body, combined with fear or panic, can allow frostbite in a situation where climatic effects alone would not cause trouble to a seasoned, uninjured person.^[82]

Because impaired local circulation is the primary cause of frostbite, anything with even a mildly adverse effect on normal peripheral circulation, such as tobacco or alcohol, should be avoided. Smoking results in varying degrees of diffuse vascular spasm, reducing normal peripheral circulation. Alcohol is not recommended at any time on the trail.^[21]

Previous frostbite injury usually results in a prolonged reduction in tolerance to cold by the injured part. Conversely, the concept of physiologic adaptation to cold is extremely controversial. There can be no argument that Eskimos and Tibetans in cold, rugged climates "feel" cold much less than do non-natives. They certainly seem to resist cold more than others and obviously tolerate cold better than those who live in temperate and tropical climates. However, many medical experts allege that this "resistance" is really no more than the result of experience in Arctic survival and day-to-day living. Furthermore, Eskimos, even though they do not feel cold as fast, freeze just as fast and badly as others, given the same actual contact situation. There is increasing evidence that tolerance exists, but even if it is proved, it may be of only academic interest. The

basic reason most outdoorspeople are not frostbitten is that they tend to be in good physical condition and know how to act and dress properly.

Many physicians enjoy mountain climbing. Those involved in the Everest exploration wrote about the effects of cold and how to protect against it. ^[44] ^[82] They suggested that overall physical well-being, good clothing, and intelligent operations in the field were by far the best insurance against frostbite. When a person is exhausted, hungry, ill, injured, or hypoxic, the chances for frostbite injury are increased. ^[21]

The following measures for frostbite protection are based on Washburn's recommendations^[82] :

1. Dress to maintain general body warmth. In cold, windy weather the face, head, and neck must be protected, since enormous amounts of body heat can be lost through these parts.
2. Eat plenty of appetizing food to produce maximum output of body heat. Diet in cold weather at low altitude should tend toward fats, with carbohydrates intermediate and proteins least important. As altitude increases above 3048 m (10,000 feet), carbohydrates become most important and proteins remain least important.
3. Do not climb under extreme weather conditions, particularly at high altitudes on exposed terrain, or get too early a start in cold weather. The configuration of a mountain can help the climber find maximum shelter and solar warmth.
4. Avoid tight, snug-fitted clothing, particularly on the hands and feet. Socks and boots should fit closely, with no points of tightness or pressure. In putting on socks and boots, a person should carefully eliminate all wrinkles in socks. Old matted insoles are to be avoided.
5. Avoid perspiration under conditions of extreme cold; clothing that is adequately ventilated should be worn. If perspiring, remove some clothing or slow down.
6. Keep the feet and hands dry. Even with vapor-barrier boots, socks must not become too wet. All types of boots must be worn with great care during periods of inactivity, especially after exercise has resulted in damp socks or insoles. Wet socks in any type of boot soften the feet and make the skin more tender, greatly lowering resistance to cold and simultaneously increasing the danger of other foot injuries, such as blistering. Extra socks and insoles should always be carried. Light, smooth, dry, clean socks should be worn next to the skin, followed by one or two heavier outer pairs.
7. Wear mittens instead of gloves in extreme cold, except for specialized work, such as photography or surveying, in which great manual dexterity is required for short intervals. In these situations, a mitten should be worn on one hand and a glove temporarily on the other. If bare finger dexterity is required, silk or rayon gloves should be worn, or a metal part that must be touched frequently covered with adhesive tape. The thumbs should be removed and fists held in the palm of mittens occasionally to regain warmth of the entire hand.
8. Be careful while loading cameras, taking pictures, or handling stoves and fuel. The freezing point of gasoline (-57° C [-70° F]) and its rapid rate of evaporation make it very dangerous. Metal objects should never be touched with bare hands in extreme cold or in moderate cold when the hands are moist.
9. Mitten shells and gloves worn in extreme cold should be made of soft, flexible,

dry-tanned deer-skin, moose, elk, or caribou hide. Horsehide is less favorable because it dries stiffly after

193

- wetting. Removable mitten inserts or glove linings should be of soft wool.
10. Mittens should be tied together on a string hung around the neck or tied to the ends of parka sleeves. Oiled or greased leather gloves, boots, or clothing should never be used in cold weather operations.
 11. Keep toenails and fingernails trimmed.
 12. Hands, face, and feet should not be washed too thoroughly or too frequently under rough weather conditions. Tough, weather-beaten face and hands resist frostbite most effectively.
 13. Wind and high altitude should always be approached with respect. They can produce dramatic results when combined with cold. Exercise should not be too strenuous in extreme cold, particularly at high altitude, where undue exertion results in panting or very deep breathing. Cold inspired air will chill the whole body and under extreme conditions may damage lung tissue and cause internal hemorrhage.^[82]
 14. When a person becomes thoroughly chilled, it takes several hours of warmth and rest to return to normal, regardless of superficial feelings of comfort. A person recovering from an emergency cold situation should not venture out again into extreme cold too soon.
 15. Avoid tobacco or alcohol at high altitudes and under conditions of frostbite danger.
 16. A person who is frostbitten or otherwise injured in the field must remain calm. Panic or fear results in perspiration, which evaporates and causes further chilling.
 17. Tetanus immunity should be current.
-

FROSTNIP

Frostnip is superficial and reversible ice crystal formation associated with intense vasoconstriction. Chilblains result from chronic intermittent exposure to environmental conditions of high humidity and ambient temperature above freezing, without the development of tissue freezing. Frostnip is characterized by discomfort in the involved parts. The symptoms usually resolve spontaneously, and no tissue is lost. There is some question whether this qualifies as cold-induced injury, since neither frozen extracellular water nor progressive tissue loss is routinely demonstrated.

THE FROSTBITE UPDATE

Animal Studies

Recent animal studies by Miller and Koltai^[48] and Ozyazgan et al^[61] suggest that pentoxifylline with *aloe vera* cream, or defibrotide alone, is beneficial in the treatment of frostbite. Miller and Koltai used the Weatherly-White rabbit model^[83] to examine the therapeutic efficacy of pentoxifylline and Dermaide aloe, both alone and in combination.^[48] They concluded that, although Dermaide aloe and pentoxifylline were comparable in tissue survival, combining these two therapeutic drugs created a synergistic response when compared with untreated controls ([Figure 7-15](#)). All three treated groups were significantly different from the control ($p < .05$). This substantiates earlier animal and human studies conducted by Raine et al,^[66] McCauley et al,^[43] and Heggors et al,^[22] using the thromboxane inhibitor Dermaide aloe.

Ozyazgan et al^[61] believed that the events occurring in frostbite were not completely elucidated but suggested that inflammatory mediators, such as PGI_2 and TxA_2 , may be the major factors in tissue damage resulting from frostbite coupled with reperfusion injury. Using the Weatherly-White rabbit model for frostbite injury, they established three groups: without freezing, with freezing but no treatment, and with freezing and treated with defibrotide, a polideoxyribonucleotidenaturium-salt that protects endothelium and is also antithrombolytic, anti-polymorphoneutrophilic (PMN), and anti-mast cell (MC). They treated the frostbitten rabbits with defibrotide with a 40mg/kg/day dose twice a day intraperitoneally for 3 days. The frostbitten control received saline, while the nonfrozen control remained untreated.

By measuring PGI_2 and TxA_2 levels and making histologic assessments of PMNs and MCs, it was noted that a significant decrease in these cells did not cause a decrease in tissue survival. It was also noted that PGI_2 was significantly higher than TxA_2 in the treated group when compared with the remaining two groups, which suggests that previous investigators were correct in

Figure 7-15 Percent tissue survival: Group 4, treatment group with both drugs; Group 2, treatment group with Dermaide aloe alone; Group 3, treatment with pentoxifylline; and Group 1, untreated controls. (Modified from Miller MB, Koltai PJ: *Arch Otolaryngol Head Neck Surg* 121:678,

TABLE 7-1 -- Tissue Survival of Patients Treated with Cook County, Illinois, Formula for Frostbite

PATIENT	INJURY	RESULTS
1	Feet bilateral digits 1 week postinjury	Partial amputation proximal interphalangeal joint 2 to 4 digits right; total amputation of digits 1 to 5 left
2	Feet bilateral digits 24 hours postinjury	Partial amputation of the proximal interphalangeal joints 2 to 5 right and 4 to 5 digits left, with total amputation of digits 1 to 3 left; nonambulatory
3	Feet, ankles, legs bilateral 24 hours postinjury	Bilateral open through-the-knee amputation; wheelchair-bound
4	Right foot wet, 6 hours in freezer, 3 days postinjury	Healed with cold sensitivity
5	Feet bilateral 5 hours exposure	Bilateral transmetatarsal amputation; ambulates independently

From Pulla RJ, Pickard LJ, Carnett TS: J Foot Ankle Surg 33:53, 1994.

NOTE: All patients were treated with povidone-iodine wet-to-dry dressings.

Figure 7-16 Algorithm for treatment of frostbite. Clinical determination of depth forms the first decision tree. Superficial injuries are treated according to standard protocol: aspiration of blisters and delayed debridement. Deep injuries are assessed for suitability of salvage. Salvage attempts follow protocol using triple-phase scanning. Scanning can also be used in the nonsalvage candidate if early debridement is planned. (Modified from Greenwald D et al: *Plast Reconstr Surg* 102:1069, 1998)

their hypothesis that TxA₂ was the major cause of tissue ischemia in the frostbite injury.^{[22] [43] [66]}

Human Studies

In recent human frostbite literature, Pulla et al^[64] presented five case studies of frostbite injury. Their treatment protocol was based on the McCauley et al^[43] frostbite treatment plan (see [Box 7-1](#)); however, reserpine and phenoxybenzamine hydrochloride were used to decrease the incidence of vasospasm. Dermaide aloe and/or silver sulfadiazine were used when available. When rapid rewarming was recommended, a solution of hexachlorophene, povidone iodine, or plain water was used as a wet-to-dry dressing between daily debridements.

Surgical intervention was based on technetium 99m pertechnate scintigraphy, which can assess viable tissue.

It was suggested that the scan be performed within 24 to 48 hours after injury and repeated between 7 to 19 days after. Four of the five patients treated required amputation ([Table 7-1](#)).

Consequently they reported 80% morbidity compared with the 7% morbidity reported in the study by Heggors et al.^[22] Using antivasospasm therapy and povidine-iodine wet-to-dry dressings may have been detrimental. Povidine-iodine is toxic to debrided tissue and might have precipitated further tissue ischemia.

Greenwald et al^[20] developed an innovative approach to determining the amount of tissue damage caused by frostbite, thus circumventing the traditional approach of the victim being treated with expectant observation. (With the exception of early blister aspiration, tissues are usually allowed to demarcate before definitive debridement is undertaken.) They used triple-phase bone scanning to define the extent of lethally injured tissues in an endeavor to allow early debridement, wound closure, and aggressive salvage of the extremities with flap reconstruction. Tendon, ligament, bone, and nerve were preserved and covered with vascularized tissue before the first indication of frank necrosis. Postoperative scans revealed revascularization of these tissues. Based on these findings, the authors developed an algorithm for the assessment and treatment of frostbite ([Figure 7-16](#)).

ACKNOWLEDGMENTS

The authors are indebted to Ms. Cassie Maness for her care in the preparation of the manuscript. We also compliment Mr. Lewis Milutin, Ms. Tina Garcia, and Ms. Sandra Baxter for their photography and artwork.

Chapter 8 - Immersion into Cold Water

Alan M. Steinman
Gordon G. Giesbrecht

Immersion in cold water is a hazard for anyone who participates in recreational, commercial, or military activities in the oceans, lakes, and streams of all but the tropical regions of the world. Recreational aquatic activities include swimming, fishing, sailing, power-boating, ocean kayaking, white-water rafting, canoeing, ocean-surfing, windsurfing, waterskiing, diving, hunting, and the use of personal watercraft. In addition, use of a snowmobile, although not technically a water sport, can involve cold water exposure resulting from accidental entry into lakes and streams. ^[1] Commercial activities involving water include fishing, shipping, offshore oil drilling, and diving. Military operations over cold water include Coast Guard, Navy, and Marine Corps missions; Army, Air Force, and Marine Corps forces, as well, may encounter cold water exposure during winter operations on land.

The definition of cold water is variable. The temperature of thermally neutral water, in which heat loss balances heat production for a nude subject at rest (i.e., not shivering), is approximately 33° to 35° C (91° to 95° F).^{[16] [17]} Hypothermia eventually results from immersion in water below this temperature. For practical purposes, significant risk of immersion hypothermia usually begins in water colder than 25° C (77° F).^{[104] [153] [154]} [Table 8-1](#) shows the variation of water temperatures throughout the year at various sites in North America,^[170] and [Figure 8-1](#) shows typical worldwide sea-surface temperatures for April.^[119] Using 25° C as the definition of cold water, the risk of immersion hypothermia in North America is nearly universal during most of the year.

Cold water immersion is associated with two significant medical emergencies: near drowning and hypothermia. This chapter discusses the physiologic responses to and treatment of immersion hypothermia. In addition, this chapter discusses the risk of near drowning with respect to the physiologic consequences of sudden immersion in cold water and the problems of survival in rough seas. [Chapter 6](#) discusses land-based hypothermia, [Chapter 56](#) provides a more complete discussion of drowning, and [Chapter 57](#) discusses diving injuries.

HISTORICAL AND STATISTICAL ASPECTS

The history of human association with the sea and with inland waters provides abundant examples of the effects of accidental cold water immersion. The following case studies demonstrate the scope of the problem:

Perhaps the most famous occurrence was the sinking of the *Titanic* in 1912. After striking an iceberg at approximately 11:40 PM on April 14, the ship sank in calm seas. Water temperature was near 0°C (32° F). Of the 2201 people on board, only 712 were rescued, all from the ship's lifeboats. The remaining 1489 people died in the water, despite the arrival of a rescue vessel within 2 hours. Nearly all of these people were wearing "life preservers," yet the cause of death was officially listed as drowning.^[112] More likely the cause of death was immersion hypothermia.^{[95] [102]}

In 1963 the cruise ship *Lakonia* caught fire and sank in approximately 18° C (64° F) water off the coast of Madeira in fairly calm seas. Two hundred people abandoned ship into the sea; all wore self-righting life jackets, but 120 died. The cause of death for most victims was hypothermia. Since rescuers reported that small waves washed over the faces of unconscious people, drowning was probably the terminal event.^[94]

Numerous examples of maritime occupational accidents exist. In 1982 the offshore mobile oil-drilling platform *Ocean Ranger* collapsed in mountainous seas near Newfoundland, Canada. Water temperature was -1° C (30.2° F). Eighty-four workers were plunged into the water, and despite the presence of a rescue vessel, all died. Immersion hypothermia was a significant factor in these deaths, although the inability of the workers to combat the rough seas and maintain airway freeboard (the distance between the water surface and the mouth) was also a major problem.^[106]

Fishing vessel mishaps are a common cause of immersion hypothermia. The following cases illustrate the problems facing the commercial fishing industry:

In 1983 the fishing vessels *Altair* and *Americus* capsized and sank in the Bering Sea in 1° C (33.8° F) water. Fourteen fishermen lost their lives, making it the worst commercial fishing accident in American history. A Coast Guard investigation found vessel over-loading, stability, and crew training and experience as possible factors in the mishaps.^{[29] [171]}

In September 1988 the *Cougar*, a Coast Guard-inspected passenger vessel used for fishing, sank with nine persons on board in 13° C (55.4° F) water 45 miles off the Oregon coast. Four occupants died from immersion hypothermia. The five survivors were rescued after spending 17 hours in the sea. Most of the survivors were severely

hypothermic, with core temperatures as low as 25° C (77° F). One of the survivors, remarkably, did not require hospitalization; before rescue,

he managed to get out of the water and spend most of the time sitting atop a buoyant life-float.^[107]

The best-selling book *The Perfect Storm: A True Story of Men Against the Sea* (made into the feature film *The Perfect Storm*) documents the tragic sinking of the fishing vessel *Andrea Gail* in October 1991. Six fishermen lost their lives in this accident, in which their vessel was caught in an intense Atlantic storm with hurricane-force winds

and seas running to 100 feet.^[89]

In January 1999 the fishing vessel *Beth Dee Bob*, with a crew of four, sank 13 miles off the New Jersey coast in rough seas. A Coast Guard helicopter responded to the vessel's distress call and arrived on-scene in about an hour. The rescue crew found two empty life rafts and only one crew member alive. He was floating in a life preserver in the 4° C (39.2° F) water while holding onto a strobe light. Unfortunately, he died of hypothermia after transport to a nearby hospital.^[171]

In January 1999 the *Kavkaz*, a fishing vessel from Homer, Alaska, capsized in rough seas, trapping two fishermen underneath the boat for 24 hours. Both men wore insulated dry suits (survival suits). However, the zipper on one of the suits was broken, destroying the integrity of the suit and allowing cold water to contact the fisherman's body. He did not survive the ordeal. The other fisherman survived but was moderately hypothermic with a core temperature of 30.5° C (86.9° F).^[33]

A 1999 U.S. Coast Guard Fishing Vessel Casualty Task Force Report^[171] found that in just 2 months (December 1998–January 1999), 20 commercial fishing vessels were lost at sea. In these mishaps, 21 persons on board died, mainly from exposure to cold water resulting from vessel sinking, capsizing, or the persons falling overboard. From 1994 through January 1999, U.S. Coast Guard statistics show that 396 fishermen lost their lives while fishing. Of these, 298 died from cold water immersion secondary to falling overboard or to the vessel sinking, capsizing, or flooding. In 1998 the death rate for fishermen was 179 per 100,000 workers, a rate 16 times higher than that for firefighters or for police officers.

Recreational aquatic activities are another major source of immersion incidents. In 1997, Coast Guard statistics show that there were 8047 recreational boating accidents producing 821 deaths, 4555 injuries, and over \$29 million in property damage. Over two thirds of these recreational boating fatalities involved exposure of the occupants to water through falling overboard or through vessel capsizing, flooding, swamping, or sinking. Hypothermia or drowning accounted for 74.3% of these fatalities.^[172] The following cases illustrate the potential problems with immersion hypothermia in recreational boating and other activities:

In December 1996, three young adults died from hypothermia after their boat sank in 7.3° C (45.1° F) water off East Moriches, New York. The three were experienced boaters and well-versed in cold water survival and safety. Unfortunately, because the weather was unusual for a winter's day in the Northeast (calm winds and seas with an air temperature of 7.3° C), the three left their safety gear and protective clothing at home. When they ended up in the cold seas, their lack of immersion-protective clothing led to death from hypothermia.^[8]

In October 1997, three persons died of immersion hypothermia when their 15-foot bass boat was swamped by the wakes of passing boats in Lake Mille Lacs, Minnesota. The four-person crew was forced to spend the night hanging onto their overturned boat in 15.5° C (59.9° F) water. They did not have a radio to call for assistance. Although they were wearing life jackets, they did not have immersion-protective clothing for insulation

against hypothermia.^[124]

In the winter of 1997–1998, four people died when their snowmobile broke through the thin ice of Lake Scugog, near Toronto, Ontario, Canada. The deaths occurred, ironically, during Snowmobile Safety Week in North America. The Canadian Safety Council reported that in 1997, 101 people were killed in snowmobile

199

Figure 8-1 Worldwide sea surface temperatures for April 1999. (From Space Science and Engineering Center, University of Wisconsin, http://www.ssec.wisc.edu/data/sst/latest_sst.gif, 1999. Data provided by National Center for Environmental Prediction.)

200

mishaps, the majority of them from drowning and hypothermia after crashing through ice on frozen rivers and lakes.^[4]

In the winter of 1988, two men died of hypothermia when their nine-man rowing scull sank in a winter storm on a small lake in western Canada. The nine rowers were immersed in 4° C (39.2° F) water, struggling to hang onto their overturned vessel in 0.6- to 1-m (2- to 3-foot) waves and 30 km/hr winds for over 50 minutes before rescuers could reach them. One man drowned just before rescue; the others were all conscious when pulled from the water. However, during the 13-minute boat transport to shore, three of the thinnest victims lost consciousness and one of these men suffered cardiopulmonary arrest. His core temperature in hospital, 44 minutes after rescue, was 23.4° C (74.1° F); subsequent resuscitation efforts were unsuccessful. The remaining seven survivors were resuscitated from core temperatures as low as 25° C (77° F). This case illustrates the rapidity of onset of immersion hypothermia in lean subjects, and the potentially serious consequences of cardiovascular instability, circum-rescue collapse, and postrescue core temperature afterdrop in immersion hypothermia.^[77]

The extensive use of combat ships and aircraft in World War II, particularly in the north Pacific and north Atlantic oceans, provided many examples of accidental immersion in cold water. Molnar reviewed several hundred of these cases.^[117] Among them was the following:

"A ship was rammed, and it sank in 3 minutes. Thirty survivors were picked up from rafts after exposure of 1.5 to 4 hours. Some drowned and others died of exposure because the water was 4° C with high seas and a wind

velocity of scale 7. Some of the survivors who held on to ropes couldn't let go and rescuers had to cut frozen rope to release them. It appears miraculous how the survivors could have endured such cold water. Most of those who were rescued were in an unconscious state and, when they became conscious complained of numbness of extremities and hands."

The Falklands War in 1982 provided further examples of immersion hypothermia related to naval combat. The Argentine cruiser *General Belgrano* sank in approximately 5° C (41° F) water, resulting in the deaths of many sailors. Some of the deaths from cold occurred even after the sailors had managed to emerge from the water into life rafts.

Maritime military operations are not the only source of hypothermia casualties in the armed forces; land operations, either in combat or in training, also have immersion hypothermia risks. In March 1995, four U.S. Army Rangers died and four others were hospitalized during a training mission in a Florida swamp. The water at the exercise site was deeper and colder than was customary for this exercise. Consequently the Rangers were forced to spend more than 6 hours in cold, wet conditions, much of the time partially immersed in 15° C (59° F) water. Night conditions and difficulties encountered in the medical evacuation of the accident victims contributed to the hypothermia deaths.^[67]

The relatively high fatality rate from accidental immersion in cold water in various military, commercial, and recreational settings has stimulated technologic advances in protective clothing and rescue devices. Current availability of commonplace items of survival equipment (such as wet suits, dry suits, survival suits, and inflatable life rafts) is primarily a response to the needs of people who work in cold water environments. The value of various types of protective clothing is examined later in this chapter.

In summary, numerous case histories and statistical evidence document the significance of cold water immersion as a cause of the environmental emergencies of drowning and hypothermia. Although drowning is relatively easy to prevent (e.g., through the use of personal flotation devices, water safety training, or restriction of alcohol use), hypothermia is not. Hypothermia is now more widely recognized than in the past, but prevention of immersion hypothermia is still a difficult and often expensive proposition. Therefore, in regions of cold water, which include most of the North American continent, cold water safety, knowledge of cold water risks, and use of appropriate flotation and protective clothing are essential.

PHYSIOLOGIC RESPONSES TO COLD WATER IMMERSION

The primary pathophysiologic effects of hypothermia are decrease in tissue metabolism and gradual inhibition of neural transmission and control. However, in the *initial* stages of cooling of an intact, conscious victim, secondary responses to skin temperature cooling predominate. Sudden immersion in cold water results in immediate decline in skin temperature, which in turn initiates shivering thermogenesis with increases in metabolism (V_{O_2}), ventilation (V_E), heart rate (HR), cardiac output (CO), and mean arterial pressure (MAP). As body temperature declines and shivering ceases, V_{O_2} , HR, MAP, and CO decrease proportionally with the fall in core temperature while hematocrit and total peripheral resistance increase. Renal diuresis and extravascular fluid shifts can lead to a considerable loss of intravascular volume, thus decreasing systemic perfusion. A more detailed description of the pathophysiologic effects of systemic hypothermia is provided in [Chapter 6](#). This section describes the pragmatic effects of the pathophysiologic changes accompanying cold water immersion and their impact on survival.

The body's responses to cold water immersion can be divided into three phases: (1) initial immersion and the cold shock response; (2) short-term immersion and loss of performance; and (3) long-term immersion and the onset of hypothermia. Each phase is accompanied by specific survival hazards for the immersion victim

201

from a variety of pathophysiologic mechanisms. Deaths have occurred in all three phases of the immersion response.

Phase 1: Initial Immersion and the Cold Shock Response

The cold shock response occurs within the first 1 to 4 minutes of cold water immersion and depends on the extent and rate of skin cooling. The responses are generally those affecting the respiratory system and those affecting the heart and the body's metabolism ([Figure 8-2](#)).^{[34] [156]} Rapid skin cooling initiates an immediate gasp

Figure 8-2 Possible cold shock responses. ↑, Increase; ↓, decrease. (From Edmonds C, Lowry C, Pennefather J: *Cold and hypothermia. In Diving and subaquatic medicine, Oxford, UK, 1992, Butterworth-Heinemann.*)

response, the inability to breath-hold, and hyperventilation. The gasp response may cause drowning if the head is submersed during the initial entry into cold water. Subsequent inability to breath-hold may further potentiate drowning in high seas. Finally, hyperventilation causes arterial hypocapnia, which leads to decreased brain blood flow and oxygen supply. This may lead to disorientation, loss of consciousness, and drowning.

Skin cooling also initiates peripheral vasoconstriction, as well as increased CO, HR, and arterial blood pressure. Increased workload on the heart may lead to

myocardial ischemia and arrhythmias, including ventricular fibrillation (VF). Thus sudden death can occur either immediately or within a matter of minutes after immersion (i.e., resulting from syncope or convulsions leading to drowning, vagal arrest of the heart, and VF) in susceptible individuals.^{[21] [42] [96] [111] [158]}

Phase 2: Short-Term Immersion and Loss of Performance

For those surviving the cold shock response, significant cooling of peripheral tissues, especially in the extremities, continues, with most of the effect occurring over the first 30 minutes of immersion. This cooling has a direct deleterious effect on neuromuscular activity.^[173] This effect is especially significant in the hands, where blood circulation is negligible,^[30] leading to finger stiffness, poor coordination of gross and fine motor activity, and loss of power.^{[38] [45] [125] [126] [177]} It has been shown that this effect is primarily due to peripheral and not central cooling.^[53] Loss of motor control makes it difficult, if not impossible, to execute survival procedures, such as grasping a rescue line or hoist. Thus the ultimate cause of death is drowning, either through a failure to initiate or maintain survival performance (e.g., keeping afloat, swimming, grasping onto a life raft) or excessive inhalation of water under turbulent conditions.

These phenomena have obvious survival implications. It is, of course, advisable to avoid cold water exposure completely. However, if cold water immersion occurs, it is best to quickly determine and execute a plan of action: (1) try to enter the water without submersing the head; (2) escape (i.e., pull oneself out of the water, inflate and board a

life raft); (3) minimize exposure (i.e., get as much of one's body as possible out of the water and onto a floating object); (4) ensure flotation if one must remain in the water (i.e., don or inflate a personal flotation device); and (5) call for assistance (i.e., activate signaling devices). It may be difficult to execute these actions while the cold shock responses predominate. However, once the respiratory effects are under control, immediate action should be taken. If self-rescue is not possible, actions to minimize heat loss should be initiated by remaining as still as possible in the heat escape lessening position (HELP), where arms are pressed against the chest and legs are pressed together, or huddling with other survivors ([Figure 8-3](#)).^[79] Drawstrings should be tightened in clothing to decrease the flow of cold water within clothing layers.

Phase 3: Long-Term Immersion and the Onset of Hypothermia

Most cold water deaths likely result from drowning during the first two phases of cold water immersion, as discussed earlier and during the introduction to this chapter. In general, true hypothermia usually only becomes a significant contributor to death if immersion lasts more

Figure 8-3 **A**, Heat escape lessening posture (HELP) and **B**, huddle techniques for decreasing cooling rates of survivors in cold water. (From Hayward JS, Eckerson JD, Collis ML: *J Appl Physiol* 38:1073, 1975.)

than 30 minutes. The individual who survives the immediate and short-term phases of cold water immersion faces the possible onset of hypothermia because continuous heat loss from the body eventually decreases core temperature (T_c). Many predictive models to determine the T_c response to cooling are based on the relationships among body composition, thermoregulatory response (i.e., shivering thermogenesis), clothing/insulation, water temperature, and sea conditions.^{[83] [154] [182] [186] [190]} These variables and their impact on survival time are discussed in more detail in the Cold Water Survival section of this chapter.

Body Core Cooling

Normal body T_c fluctuates around 37° C (98.6° F). The clinical definition of hypothermia is a T_c of 35° C (95° F) or lower; however, any exposure to cold that lowers the temperature below normal levels results in the body becoming hypothermic. Although various temperatures and terms have been used to classify different levels of hypothermia, the following classifications are used here and in [Chapter 6](#) . In mild hypothermia ($T_c = 32°$ to 35° C [89.6° to 95° F]), thermoregulatory mechanisms continue

to operate fully, but ataxia, dysarthria,

Figure 8-4 (Figure Not Available) The relationship between water temperature and the mean rectal temperature cooling rate in lightly clothed, nonexercising men and women during immersion in seawater. (From Hayward JS: *The physiology of immersion hypothermia*. In Pozos RS, Wittmers LE, editors: *The nature and treatment of hypothermia*, Minneapolis, 1983, University of Minnesota Press.)

apathy, and even amnesia are likely. In moderate hypothermia ($T_c = 28^\circ$ to 32° C [82.4° to 89.6° F]), effectiveness of the thermoregulatory system (i.e., shivering thermogenesis) diminishes until it fails, there is continued decrease in level of consciousness, and cardiac arrhythmias may also occur. In severe hypothermia ($T_c < 28^\circ$ C), consciousness is lost, shivering is absent, acid-base disturbances develop, and the heart is susceptible to VF or asystole. Death from hypothermia is generally from cardiorespiratory failure.

The rate of body core cooling during cold water immersion depends on the following variables:

1. Water temperature and sea state
2. Clothing
3. Body morphology
4. Amount of the body immersed in water
5. Behavior (e.g., excessive movement) and posture (e.g. HELP, huddle) of the body in the water
6. Shivering thermogenesis
7. Other nonthermal factors

Water Temperature, Sea State, and Clothing Insulation.

These variables are all critically important to intensity of the cold shock response, onset of physical and mental impairment, and rate of core cooling. Figure 8-4 (Figure Not Available) graphically illustrates the inverse linear relationship between water temperature and T_c cooling

Figure 8-5 The relationship between subcutaneous fat thickness in 10 men and the decline in rectal temperature during 30-minute immersions in stirred water at 15° C (59° F). Skinfold thickness is mean of readings at biceps, abdomen, subscapular, and subcostal sites. T_{re} , rectal

temperature. (From Keatinge WR: *Survival in cold water*, Oxford, UK, 1969, Blackwell Press.)

rate.^[74] Water has a specific heat 4000 times that of air and a thermal conductivity approximately 25 times greater.^[118] Immersion in cold water is thus associated with a high rate of heat transfer from skin to water, at least 100 times greater than in air of the same temperature.^[118] Sea state and clothing insulation are discussed in more detail in the Cold Water Survival section of this chapter.

Body Morphology (Size and Composition).

Children cool faster than do adults because children have a greater surface area-to-mass ratio. Cooling rate is generally proportional to surface area, whereas the amount of heat that can be lost is proportional to mass. Thus a large surface area-to-mass ratio favors cooling. Similarly, smaller adults generally cool faster than do larger adults, and tall, lanky individuals cool faster than do short, stout individuals. Body composition is also important. Subcutaneous fat is a very efficient insulator against heat loss, and cooling rate is inversely related to skinfold thickness. For example, subjects in the 10th percentile for skinfold thickness wearing light clothing in 5° C (41° F) water have nine times the cooling rate of 90th percentile subjects.^[123] Figure 8-5 shows the linear relationship between change in T_c and mean skinfold thickness.^[95] Shivering, which is a primary defense against core cooling, also varies with skinfold thickness.

At a given skin temperature, the shivering response is less in humans with greater amounts of subcutaneous fat.^[99] In moderately cold water temperatures (18° to 26° C [64.4° to 78.8° F]), core cooling has been shown to proceed at the same rate in high- and low-fat individuals because of the greater shivering thermogenesis in the low-fat subjects. However, at colder water temperatures (8° C [46.4° F]), core cooling is attenuated by greater amounts of subcutaneous fat and body mass resulting from increased insulation.^[46]

In general, for a survivor immersed in cold water, the core cooling rate is fairly linear once T_c begins to decline. This has been shown to be true for mildly hypothermic experimental subjects. The only data that exist for severely hypothermic humans are those from the infamous Dachau concentration camp atrocities, in which conscious victims, who were cooled to death in ice water, had linear cooling rates.^[2] Since these unfortunate victims were emaciated and ill, these data may not apply to healthy cold water immersion subjects.

Amount of Body Immersed.

Because of the difference in thermal conductivity between air and water (discussed above), heat loss from body surfaces immersed in cold water is far greater than from body surfaces exposed to cold air, even considering the effect of windchill. Thus immersed victims should attempt to get as much of their bodies out of the water as

possible. This issue is discussed in greater detail in the Cold Water Survival section of this chapter.

Behavior and Posture of the Body in Cold Water.

Behavioral variables also affect the core cooling rate. Hayward et al used infrared thermography to demonstrate that, despite marked peripheral vasoconstriction, heat losses are high in the groin, lateral and central thorax, and neck.^[73] In the groin and neck, regions with a relatively thin layer of peripheral soft tissue, blood flow through the large, relatively superficial femoral vessels, carotid arteries, and jugular veins potentiates heat flow to the cold water. In the lateral and central thorax, the relative absence of tissue insulation (muscle and subcutaneous fat), combined with high thermal conductivity of rib bone, potentiates heat loss from relatively warm lungs to the cold environment. Furthermore, exercise or excessive movement in the water greatly increases heat loss from active musculature.

The effect of activity on total heat balance depends on the balance among the many factors illustrated in [Figure 8-6](#) . In normothermic circumstances, heat produced locally in peripheral muscles is transferred to the core via venous return. In cold water immersion, by contrast, physical activity may actually increase heat loss through increased blood flow to the periphery. This is especially true when immersed victims engage in excessive movement in the water (e.g., swimming or vigorous

Figure 8-6 Factors influencing total thermal balance during increases in metabolic heat production (e.g., voluntary exercise and involuntary shivering).

extremity movements necessary to maintain airway freeboard in rough seas).

Hayward et al^[79] demonstrated that minimizing both voluntary activity and the exposure of major heat loss areas of the skin to cold water is the most effective way to minimize the decline in T_c . They showed that treading water and drownproofing significantly increased the cooling rate. In spite of increased metabolic heat production during exercise, increased surface heat loss resulted in faster core cooling during exercise in cold water. They also developed two well-known cold-water survival techniques: HELP and the group huddle (see [Figure 8-3](#)). These adaptive behaviors reduce core cooling by 69% and 66% that of control conditions, respectively.^[74] In conditions in which the sea is not calm, it may be difficult to perform the group huddle with complete thermal efficiency. However, other advantages of this position include maintenance of group contact and morale. Sagawa et al concluded that the lowest water temperature in which humans could maintain normal T_c by generating body heat through muscular activity is

25° C (77° F), although there may be individual variation in absolute water temperature.^[137]

Shivering.

Shivering is a thermoregulatory function in which involuntary muscle contraction increases heat production in an effort to prevent or minimize body core cooling. Shivering intensity increases as core and skin temperatures decrease. Generally, shivering intensity

205

Figure 8-7 Effectiveness of shivering heat production in preventing onset of hypothermia during exposure to **A**, 10° C (50° F) air; **B**, 15° C (59° F) water; **C**, 28° C (82.4° F) water; and **D**, 8° C (46.4° F) water. *T_{es}*, esophageal temperature.

is maximal at $T_c = 32^\circ$ to 33° C (89.6° to 91.4° F) and $T_{skin} = \sim 20^\circ$ C (68° F); however, shivering heat production is lower, at any given skin temperature, in individuals with higher levels of subcutaneous fat.^{[99] [184]}

Thermal balance during shivering depends on the same factors as during voluntary activity (see [Figure 8-6](#)). [Figure 8-7](#) illustrates how shivering heat production can maintain T_c in cold air and can arrest the fall in T_c in both warm and cool water. In colder water, the combination of shivering thermogenesis and body insulation (resulting from peripheral vasoconstriction) may result in maintenance of a steady-state T_c , albeit below normothermic levels. At even lower water temperatures, T_c will continue to decrease, and this decrease will accelerate when shivering thermogenesis eventually stops because of hypothermia-induced thermoregulatory impairment (below $\sim T_c = 30^\circ$ C [86° F]). The power of shivering is especially important in the consideration of the clinical classification of hypothermia and rewarming therapies, since this valuable heat source is an efficient mechanism for rewarming the core during postimmersion recovery and resuscitation. This is discussed in more detail in the Rescue and Management section of this chapter.

206

Nonthermal Factors.

Underwater divers often experience "symptomless," or "undetected," hypothermia. Several factors contribute to increased cooling. First, heat is lost through direct conduction to cold water and through breathing compressed air. Breathing compressed air at depth also alters human thermoregulation. Mekjavic et al studied the effects of hyperbaric nitrogen at 6 atm^[110]; these researchers also simulated inert gas or "nitrogen" narcosis with inhalation of 30% nitrous oxide.^[129] They demonstrated a decrease in the T_c threshold for shivering and an increase in the rate of core cooling of up to twofold under these conditions. In a separate study, Mekjavic et al demonstrated qualitatively similar effects of insulin-induced hypoglycemia.

Hypercapnia and hypoxia may also be present in various underwater scenarios. Hypercapnia has been shown to lower the shivering threshold^[88] and transiently inhibit shivering itself.^[103] Both hypercapnia^[88] and hypoxia^[87] have also been shown to accelerate core cooling.

Alcohol consumption is frequently associated with immersion hypothermia, since ethanol impairment of mental and motor performance is often the cause of accidental immersion. Social drinking can result in carelessness. Intoxicated mariners or others near water often fall from a boat, ship, gangway, wharf, or bridge into the water. Drunken drivers capsize or collide. On the basis of frequency of occurrence alone, the consequences of alcohol ingestion warrant special considerations.

Studies on the effect of moderate doses of ethanol (blood alcohol levels of 50 to 100 mg/dl, the range associated with legal impairment) on cold stress have established the following:

1. Rate of heat loss is not significantly increased. Alcohol has a primary vasodilatory effect under normothermic conditions.^{[37] [84] [101]} Under hypothermic conditions, where vasoconstriction predominates, alcohol lowers the vasoconstriction threshold during a moderate cold stress of 28° C (82.4° F) water immersion but does not affect the shivering threshold or rate of core cooling.^[86]
2. Rate of heat production is slightly decreased. For immersion in water colder than 28° C, a moderate ethanol dose inhibits the metabolic response to cold.^{[40] [108]} Shivering thermogenesis is reduced in cold water by approximately 10% to 20%.
3. Cooling rate is not significantly increased.^{[40] [86] [108]} Because the body's cooling rate in cold water is influenced more by rate of heat loss than by rate of heat production, the slight reduction in shivering thermogenesis induced by moderate ethanol ingestion is outweighed by factors affecting heat loss (e.g., peripheral vasoconstriction and body fat). Since these do not vary with alcohol use when the person is cold stressed, cooling rate does not change.
4. Fatigue potentiates thermoregulatory impairment by alcohol. Exhaustive exercise leading to fatigue (characterized by hypoglycemia and depletion of glycogen reserves), combined with a moderate dose of ethanol, significantly reduces resistance to cold.^{[70] [95]} Alcohol inhibits gluconeogenesis^{[68] [90]} so that the ability to provide glucose to maintain shivering is reduced. If a person enters cold water in

- this condition, cooling rate is likely to be greater than in the absence of ethanol.
5. Perception of cold is diminished. Experimental studies of humans in cold water show that moderate alcohol dosage to some extent relieves feelings of intense cold.^{[40] [95]} This cognitive alteration may be functionally related to reduced shivering response.
 6. Cold-induced diuresis is increased. Alcohol inhibition of antidiuretic hormone augments immersion diuresis.^[24] During the first hour of cold water immersion, urine flow rate can be more than six times normal (approximately 8 ml/min). For longer immersions, alcohol potentiates the development of dehydration and hypovolemia.

For most humans, high doses of alcohol (blood levels greater than 200 mg/dl) have an anesthetic effect. Major impairment of mental, motor, and involuntary function (including thermoregulation) occurs. Alcoholics who "pass out" in cold locations ("urban hypothermia") rapidly and passively become hypothermic (see [Chapter 6](#) for a complete discussion of hypothermia).^{[27] [114]} When highly intoxicated persons enter cold water (usually by falling in), hypothermia is seldom a problem because such persons usually drown quickly.

Cold Water Submersion

Cold water submersion, or near drowning, is covered in detail in [Chapter 55](#). However, a brief discussion is included here to provide a more complete discussion of cold water immersion. There have been several recent advances in our understanding of why individuals can survive cold water submersion for as long as 66 minutes^[9] with full or partial neurologic recovery (cold water near drowning). The most important factor in these unusual cases is the low water temperature and subsequent brain cooling. This principle has been used in clinical practice for years. For example, cardiopulmonary bypass was used to cool neurosurgical patients to a $T_c \sim 9^\circ \text{C}$ (48.2°F) to arrest brain blood flow for at least 55 minutes with full neurologic recovery.^[128] The full explanation for these recoveries relates to both (1) the mechanisms for, and amounts of, brain/body cooling that occurs, and (2) the mechanisms for the protective effect of this cooling.

Mechanisms for Brain/Body Cooling

Children have an advantage in cold water submersion incidents because their greater surface area-to-mass ratio

allows faster conductive cooling, which provides cerebral protection based on decreased cerebral metabolic requirements of oxygen (CMR_{O_2}). The mammalian dive reflex, which initiates intense bradycardia and shunts blood flow to important core organs, such as the heart and brain, has also been implicated. A third factor that has recently been explored is the possibility that cold water ventilation may result in rapid and extensive cooling during submersion (see below).

The effectiveness of the human dive reflex, especially the breath-hold response, is controversial. Nemiroff, who has one of the largest series of successful resuscitations of near-drowning victims, believes that the dive reflex plays an important role, particularly in children and infants, and especially in neonates.^{[120] [121]} Hayward et al^{[82] [131]} think that the enhanced success in resuscitation associated with cold water near drowning is more due to hypothermia than to the dive reflex.

It is important to note that the protective effect of cooling depends on the T_c at cessation of oxygen delivery and the subsequent rate and extent of the decrease of T_c . Since T_c is likely to be near normal at the onset of an accidental submersion, rapid cooling after onset of ischemia is important for survival. Conduction alone probably cannot account for the rapid decrease in T_c that occurs in cold water submersion incidents. Conn et al^[20] studied cold water (4° C [39.2° F]) drowning in shaved, anesthetized dogs. They found that submerged dogs continued to breathe the cold water for an extended period of time. T_c decreased 11° C (19.8° F) in 4 minutes in the completely submerged dogs compared with only 3° C (5.4° F) in the control (immersed with head out) dogs who did not breathe cold water. It is likely that rapid cooling was due to convective heat exchange in the lung compared with only surface conduction in the control dogs. The general conclusion that brain cooling is accelerated considerably by respiration of cold water has been proposed by others^{[47] [61] [65]} and mathematically predicted by Xu et al.^[189] Although breath holding may occur during submersion, a physiologic break point occurs where involuntary breathing movements predominate.^[3] This factor, coupled with unconsciousness, could reasonably be expected to result in respiration of water under at least some circumstances. Experimental and anecdotal evidence in humans is rare. However, one helicopter crash survivor reported that, after being trapped underwater for some time, he recalled feeling he was about to die and that he was breathing water in and out just before escaping the cockpit.^[12]

Mechanisms for the Protective Effect of Brain Cooling.

Hypothermia provides an advantage during anoxic periods, such as cold water submersion, because of what is known as the "metabolic ice-box." Whole body, or focal, hypothermia has long been used to extend biologic survival time during surgery under ischemic conditions. Cerebral protection under hypothermic conditions has commonly been attributed to decreased cerebral metabolic requirements for oxygen according to the Q_{10} principle. Although the Q_{10} of the whole body is about 2, the Q_{10} of the brain increases from ~3 between 27° and 37° C (80.6° and 98.6° F) to 4.8 between 18° and 27° C (64.4° and 80.6° F).^[113] Based on these values, if the brain could survive an ischemic insult for 5 minutes at 37° C, cooling to 27° C or to 17° C would provide 15- and 72-minute protection, respectively, based solely on decreased CMR_{O_2} ([Figure 8-8](#)). Although long survival times at brain temperatures below 20° C (68° F) may be predicted on the basis of increasing Q_{10} and diminishing CMR_{O_2} , some additional mechanism(s) may be required to explain intact survival after prolonged submersion in which reported core temperatures are often above 30° C (86° F; these factors are schematically shown in [Figure 8-9](#)). Over the past decade, several studies, directed mainly towards protection of the brain during or after cerebral ischemic events, have

demonstrated that even moderate brain cooling of 3° to 5° C (5.4° to 9° F) provides substantial cerebral protection from ischemic insult.*

Submersion likely promotes cerebral death as tissue ischemia depletes high-energy phosphates and leads to membrane depolarization. This stimulates release, into the extracellular space, of excitatory neurotransmitters, such as glutamate and dopamine, which mediate post-synaptic depolarization, causing calcium entry into the cell. Calcium influx mediates the production of oxygen and hydroxyl free radicals (which may be involved in reperfusion injury), and release of free fatty acids, resulting

Figure 8-8 Schematic presentation of survival time at different core/brain temperatures. Bottom line, prediction based on a Q_{10} of 2. Middle line, prediction based on the Q_{10} of 3. Top line, prediction based on the Q_{10} effect plus other factors, such as changes in neurotransmitter release (i.e., glutamate and dopamine). Actual survival times are from both neurosurgical and accidental hypothermia cases. Most of these cases fall outside the range predicted based on Q_{10} alone; thus some other factors must also contribute to survival.

*References [14] [15] [55] [105] [116] [138] [188] .

Figure 8-9 Schematic representation of theoretic times to cerebral injury and/or death after sudden onset of anoxia. Examples include anoxia induced by myocardial infarction at normal core temperatures, hypothermia-induced cardiac arrest during immersion hypothermia, ischemia-induced cardiac arrest after cold water near drowning (CWND), and electrically induced arrest after protective cooling for neurosurgery. Note that the times shown are representational; actual survival times may vary.

in eicosanoid synthesis.^[167] Various animal studies have shown that cooling the brain by only 3° to 5° C before ischemia delays terminal depolarization and reduces the initial rate of rise of extracellular potassium,^[91] results in complete suppression of glutamate release and 60% reduction in the peak release of dopamine,^[15] attenuates ischemia-induced damage to endothelial cells,^[28] reduces hydroxyl radical production,^[57] and improves postischemia glucose utilization.^[55] These results relate to mechanisms other than decreased CMR_{O_2} , which may explain cerebral protection during cold water near drowning.

In summary, these findings indicate that: (1) if the brain cools even by only 3° to 5° C, it is protected in excess of what would be predicted from decreased CMR_{O_2} alone; (2) protection results from additional protective mechanism(s) of cooling related to neurotransmitter release, calcium flux, eicosanoid synthesis, etc.; (3) the mammalian dive reflex may result in some cold-induced circulatory adjustments that favor conservation of oxygen for the heart and brain; and (4) any cold water ventilation may accelerate brain cooling and provide further protection.

Implications for Survival

The paradox of whether core cooling is an advantage or a disadvantage depends on whether there is cessation of oxygen delivery, and if so, the value of T_c when anoxia occurs and how much T_c subsequently declines. These factors are schematically illustrated in [Figure 8-9](#). If oxygen delivery is not compromised (e.g., immersion hypothermia), then core cooling will eventually lead to death from cardiac arrest. However, if oxygen delivery is compromised (e.g., submersion hypothermia and cold water near drowning), core/brain cooling will prolong survival compared with a condition in which core cooling does not occur (e.g., myocardial infarction). These factors are important in understanding whether children have a survival advantage over adults during cold stress. Because children cool faster, their body size would be an advantage when oxygen supply is compromised during cold water submersion. However, when the oxygen supply is uninterrupted in head-out immersion or in cold air, the small body size becomes a disadvantage because the onset of severe hypothermia will be faster.

Afterdrop and Circum-Rescue Collapse

Anecdotal cases of fatalities among immersion hypothermia victims have been noted in the immediate prerescue and postrescue periods despite the survivors being recovered in an apparently stable and conscious condition. These events are often referred to as cases of "rewarming shock" or "postrescue collapse." Golden et al^[64] have noted that deaths can occur either shortly before rescue, during rescue, or after rescue, and they have used the term *circum-rescue collapse* to describe these events. Deaths have occurred within minutes before rescue, while climbing out of the water, while being hoisted to a helicopter, within a few minutes after entering a warm compartment of a rescue vessel, 20 to 90 minutes after rescue, in hospital after transport, and during the 24-hour period postrescue.^{[59] [64] [94] [109]} Three causes of circum-rescue collapse have been proposed: (1) afterdrop—a continued drop in T_c after recovery; (2) collapse of arterial pressure; and (3) factors that potentiate the risk of VF (e.g., hypoxia, acidosis, rapid changes in pH). Each of these causes is discussed below.

Afterdrop is a well-known phenomenon that occurs after removal of a victim from cold water immersion. T_c continues to decline (i.e., afterdrop) in both animate and inanimate objects, even though cold water immersion has ended.* Afterdrop of as much as 5° to 6° C (9° to 10.8° F) has been observed in humans.^{[6] [41] [152]} This afterdrop was long proposed as the major cause of postrescue death because further cooling of the heart

might result in a temperature at which VF or cardiac arrest could occur.^[13]

Golden et al^[64] discount the importance of this phenomenon and propose collapse of arterial pressure as the cause of death during rescue. They correctly point out that an afterdrop occurring in victims who were hypothermic, yet warm enough to climb on board a ship without assistance, would be unlikely to cause enough myocardial cooling to result in cardiac arrest or VF.

*References ^[2] ^[13] ^[18] ^[54] ^[63] ^[133] ^[139] ^[179] .

Rather, Golden et al propose that removal from cold water results in a precipitous fall in blood pressure, inadequate coronary blood flow, and myocardial ischemia, possibly precipitating VF. This mechanism is likely the main factor in collapse before and during rescue. The fall in blood pressure *before* removal from the water may be due to reduced sympathetic tone or catecholamine secretion when rescue is imminent. Finally, hypotension *during* and shortly *after* rescue may be due to the sudden decrease in hydrostatic pressure on the body (i.e., removal of the "hydrostatic squeeze" of water pressure during immersion), hypovolemia, and/or impaired baroreceptor reflexes. However, this mechanism cannot fully account for all other postrescue deaths occurring 20 minutes to 24 hours postrescue.

The importance of continued myocardial cooling cannot be discounted. Fibrillation of a cold heart can be initiated by mechanical stimuli,^[127] hypoxia and acidosis,^[122] and by rapid changes in pH.^[95] In dogs, myocardial cooling from 30° C to 22° C (86° F to 71.6° F) has been shown to cause a fivefold decrease in the electrical threshold for fibrillation.^[23] It is also likely that an increase in the *rate* of myocardial cooling may stimulate fibrillation. Based on the large afterdrop values described above, it is plausible that continued core cooling in significantly hypothermic victims could result in VF, either primarily caused by spontaneous fibrillation of the cold myocardium, or secondarily caused by cold-induced increase in sensitivity to other fibrillation stimuli.

RESCUE AND MANAGEMENT

This section describes prehospital management of hypothermia with specific reference to immersion pathophysiology. Hospital management of both accidental immersion and land-based hypothermia is described in [Chapter 6](#) . Prehospital management of hypothermia patients, both in the field and during transportation to a site of definitive medical care, varies with the victim's level of hypothermia, with the rescuer's level of training, with the resuscitative equipment available, with the type of transportation, and with the time required for delivery to definitive care. Medical personnel must exercise good clinical judgment in balancing all these factors to select appropriate therapeutic modalities.

The primary goals in prehospital management of victims of accidental immersion hypothermia are prevention of cardiopulmonary arrest, prevention of continued T_c decline, moderate core rewarming if practicable, and transportation to a site of definitive medical care.^{[71] [148]} Aggressive rewarming in the field is usually contraindicated, since the means to either diagnose or manage the many potential complications of severe hypothermia are unavailable in this setting.^[115] In unusual circumstances, when transportation to a site of definitive care is impossible, definitive rewarming in the field, using the principles and techniques of management described in the following paragraphs, may be appropriate.

Rescue

Retrieval of a victim from cold water immersion must be performed with caution. Sudden reduction of the "hydrostatic squeeze" applied to tissues below the water's surface may potentiate hypotension, especially orthostatic hypotension.^[64] Since a hypothermic patient's normal cardiovascular defenses are impaired, the cold myocardium may be incapable of increasing cardiac output in response to a hypotensive stimulus. Putting a victim into vertical posture may also potentiate hypotension. Hypovolemia, secondary to combined cold-and immersion-induced diuresis, and increased blood viscosity potentiate these effects.^[25] Peripheral vascular resistance may also be incapable of increasing, since vasoconstriction is already maximal because of cold stress. The net result of sudden removal of a hypothermic patient from the water is similar to sudden deflation of antishock trousers worn by a patient in hypovolemic shock: abrupt hypotension. This has been demonstrated experimentally in mildly hypothermic human volunteers^[60] and has been suspected as a cause of postrescue death in many immersion hypothermia victims.^{[64] [148]} Accordingly, rescuers should attempt to maintain hypothermic patients in a horizontal position during retrieval from the water and aboard the rescue vehicle ([Figure 8-10](#) and [Figure 8-11](#)).^{[64] [143] [148]} If rescuers cannot recover the patient horizontally, they should place the victim in a supine posture as quickly as

possible after removal from cold water.^[148]

The victim's T_c may continue to decline (depending on the quality of insulation provided, the victim's endogenous heat production, active or passive manipulation of extremities, and the site of T_c measurement) even after he or she has been rescued, because of the physiologic processes described earlier for "afterdrop." To diminish this effect, the victim's physical activity must be minimized. Conscious persons should not be required to assist in their own rescue (e.g., by climbing up a scramble net or ship's ladder) or to ambulate once out of the water (as by walking to a waiting ambulance or helicopter).^[43]^[115]^[148] Physical activity increases afterdrop, presumably by increasing perfusion of cold muscle tissue with relatively warm blood.^[11]^[44]^[46]^[48] As this blood is cooled, venous return (the circulatory component to afterdrop) contributes to a decline in myocardial temperature, increasing the risk of VF.^[80] Experiments on moderately hypothermic volunteers (esophageal temperature 33° C) demonstrated a threefold greater afterdrop during treadmill walking than while lying still.^[10]^[51] Such exercise-induced enhancement of afterdrop could precipitate postrescue collapse. Throughout the rescue procedures and during subsequent management, hypothermic

210

Figure 8-10 U.S. Coast Guard crew keep a hypothermia victim in a horizontal posture during rescue operations.

Figure 8-11 Immersion hypothermia victim in a semihorizontal posture during helicopter basket hoist.

victims must be handled gently.^[69]^[115]^[143] Excessive mechanical stimulation of the cold myocardium is another suspected cause of deaths after rescue.^[102]^[178]

Examination and Life Support

Since hypothermia affects virtually every physiologic process, rescuers should manage a severely hypothermic patient as they would a victim of multiple trauma.^[147]^[148]

Rescuers should not focus solely on T_c to the exclusion of other potentially life-threatening problems. Conversely, when the incident includes cold exposure, care

must be taken to not focus solely on trauma injuries. Several victims have died of hypothermia when treatment focused only on non-life-threatening physical injuries. Figure 8-12 (Figure Not Available) shows a recommended algorithm for treatment of hypothermia. In accordance with standard emergency medical procedures, the ABCs (airway, breathing, and circulation) of first aid are essential.^{[143] [148]} Rescuers should ensure an open airway and confirm the presence of adequate ventilation and circulation. If the patient is severely hypothermic, respiration and pulse may be slow, shallow, and difficult to detect.^{[143] [147]} Therefore rescuers should take 30 to 45 seconds to assess these vital signs.^[143] If neither pulse nor breathing is detectable, rescuers should commence CPR in accordance with normal basic life support protocols.^{[143] [147]}

Cardiac rhythm should be carefully monitored, if possible. Percutaneous electrodes may be required to overcome interference from muscle fasciculation or shivering.^[143] Endotracheal intubation and the administration of heated, humidified air or oxygen are useful in the management of apnea or hypoventilation and in reducing further respiratory heat loss.^[143] Mouth-to-mouth or mouth-to-mask ventilation also provides heated, humidified air. If oxygen is available, it may supplement mouth-to-mouth or mouth-to-mask ventilation. Mouth-to-mouth or mouth-to-mask ventilation has the added advantage of providing a small amount of carbon dioxide to the patient's inspired gases. This may be useful in preventing hypocapnia secondary to relative hyperventilation in a severely hypothermic victim whose metabolic production of CO₂ is diminished.^[27] This is important because hypocapnia may decrease the threshold for VF.

Hypothermic patients with *any* detectable pulse or respiration do not require the chest compressions of cardiopulmonary resuscitation (CPR), even though severe bradycardia and bradypnea may be present.^{[143] [147]} This differs from normothermic CPR protocols, where chest compressions may be indicated if bradycardia fails to provide sufficient cardiac output or systolic pressure.^[143] Since the metabolic requirements of hypothermic patients are reduced, the observed bradycardia and bradypnea may still meet tissue oxygen requirements.^{[26] [43]} Inappropriate administration of chest compressions in an attempt to augment cardiac output may precipitate VF from mechanical stimulation of the irritable myocardium.^[26]

If a victim of immersion in cold water is found floating face down, near drowning should be suspected and managed accordingly (see [Chapter 56](#)). In this case, correction of anoxia is paramount, and consideration of hypothermia is of secondary importance.^[121]^[143] Normal advanced cardiac life support (ACLS) protocols should not routinely be applied to severely hypothermic patients in cardiac arrest, since management beyond basic life support differs from that used in normothermia.^{[26] [143]} Defibrillation and pharmacologic interventions are usually ineffective for myocardial temperatures below 30° C (86° F).^{[7] [26] [143]} Furthermore, repeated defibrillatory shocks may damage the myocardium.^{[143] [147]} Defibrillation should be limited to three shocks at 200 joules (J), 300 J, and 360 J, consecutively, in patients colder than 30° C.^[143] Administered medications are not only ineffective but may accumulate to toxic levels, since drug metabolism

Figure 8-12 (Figure Not Available) Algorithm for treatment of hypothermia. (*Adapted from Standards and guidelines for cardiopulmonary resuscitation and emergency cardiac care, JAMA 268:2172, 1992.*)

by the hypothermic liver and kidneys is reduced.^[26] ^[181] For hypothermic patients with a T_c greater than 30°C , normal ACLS protocols may be used.^[143] All intravenous (IV) fluids should be warmed before administration. However, it may be necessary to extend the recommended interval for IV medications because of the patient's reduced metabolic rate.

For the unconscious hypothermic patient who is not in cardiopulmonary arrest, endotracheal or nasotracheal intubation should be performed gently. Insertion of pacemaker wires and central venous catheters has been suspected of precipitating VF, but prior ventilation with 100% oxygen has been associated with decreased risk for this complication.^[25] ^[27] Rescuers should not withhold intubation, if indicated, for fear of precipitating VF.^[143]

If the patient does not require immediate life support intervention, a thorough and systematic examination must be performed as quickly as possible before initiation of hypothermia therapy. Since severely hypothermic patients may have markedly depressed mental status, they may not respond normally to painful stimuli. Victims of immersion hypothermia may have suffered trauma before entering or while in the water. Central nervous system, skeletal, and soft tissue injuries may be overlooked without careful examination.

Attention should be paid to the patient's mental status and other central nervous system signs. Rescuers should evaluate level of consciousness, presence or absence of shivering, and pupillary size and light reflex. Pupils may appear fixed and dilated in an unconscious, severely hypothermic patient, simulating the appearance of death. The diagnosis of death should not be made in a hypothermic patient, particularly in a field setting, unless resuscitation efforts fail after adequate rewarming efforts.

Vital signs should be carefully measured, with particular attention to T_c . A low-reading thermometer (capable of recording down to 20°C [68°F]) is required. Esophageal temperature (at the level of the atria) is the most clinically useful T_c obtainable, since this site most closely parallels cardiac temperature.^[51] ^[80] However, most rescue personnel are not equipped to measure esophageal temperature. Rectal temperature is the most easily obtained T_c , yet rescuers often show reluctance to obtain a recording from this site in the field, and incorrect thermometer placement may cause an erroneous reading. If neither esophageal nor rectal temperature is taken, oral or axillary temperature may be of value. Neither of these will be an accurate reflection of T_c in a

victim of immersion hypothermia. Facial cooling affects oral temperature, and cold skin temperature affects axillary recordings. However, the victim's true temperature will not be lower than indicated by an oral or axillary recording. Thus rescuers can use even superficial temperatures in a limited way to monitor the patient's status, although this is not ideal.

Hemorrhage should be controlled in the usual manner. However, antishock trousers are normally contraindicated because they are likely to be ineffective in the face of maximal vasoconstriction already present in a severely hypothermic patient.^[26] Since hypothermia itself can cause hypotension without massive fluid losses, antishock trousers should be used only if the victim's hypotension is severe and secondary to hemorrhage, or if required for temporary stabilization of major pelvic fractures.^[26]

Insulation, Stabilization, and Rewarming

After recovery of the victim from the water, and after management of immediate life-threatening emergencies, the next objectives are prevention of further heat loss and efforts at moderate rewarming (i.e., 1° to 2° C/hr [1.8° to 3.6° F/hr]). Strategies for moderate rewarming in the field vary with equipment available, training of rescue personnel, environmental conditions, and length of time required for transport to a site of definitive care. Maximum insulation of the whole body from any further cooling by the environment is an obvious first requirement. The main goal for rescue personnel is to maintain or improve cardiorespiratory stability and to minimize T_c afterdrop, which can depress cardiac temperature and potentiate VF, as previously discussed. All sources of heat loss (evaporation, conduction, convection, respiration, and radiation) should be controlled. Rescuers should maintain the victim in a horizontal posture to prevent hypotension, as discussed above. Movement of the victim must be kept to a minimum; clothing should be cut away if it is wet. The victim's skin should be dried, and he or she should be protected by dry, insulative clothing and blankets, sleeping bag, or specialized rescue bag. This protection must include the head and neck. Incorporation of a windproof and waterproof layer is of obvious value in preventing convective and evaporative heat loss. This is particularly important for victims requiring helicopter evacuation, since downwash from helicopter rotor blades can reach wind speeds in excess of 160 km/hour (100 mph), thus potentiating significant heat loss from windchill.^[148]

Spontaneous Rewarming.

Patients who are only mildly hypothermic (exposed to cold water for a relatively short time, fully conscious, and vigorously shivering with a T_c greater than 32° to 33° C [89.6° to 91.4° F]) are usually capable of rewarming themselves without difficulty. Heat production from shivering can reach levels five to six times that of resting metabolic rate.^[36] Shivering is thus a highly effective means of rewarming, particularly if rescuers insulate the patient's head and body with vapor barrier garments to minimize evaporative heat loss.^[51] Vigorous shivering has been shown to be capable of producing rewarming rates as high as 3° to 4° C/hr (5.4° to 7.2° F).^{[43] [51] [52]} Victims who are

conscious and vigorously shivering are generally not a medical emergency and

usually do not require immediate transportation for definitive care. However, rescuers should be aware that prolonged periods of shivering consume the patient's endogenous energy reserves. Thus rescuers should administer oral glucose-containing fluids to conscious persons who have adequate cough and gag reflexes. Attention to energy reserves in unconscious, severely hypothermic victims is also important. Warmed IV glucose solutions are useful in these persons as part of definitive resuscitative and rewarming protocols (see below).^[26] ^[143] Alcoholic beverages are contraindicated in all cases.

Inhalation Warming.

Rescuers should attempt to minimize respiratory heat losses. Hypothermic patients lose up to 11 to 13 kcal/hr through the inhalation of relatively cold, dry air and through the exhalation of water-saturated air at near T_c .^[185] Administration of heated, humidified air or oxygen at approximately 42° to 46° C (107.6° to 114.8° F) can result in a net positive gain of 17.1 kcal/hr.^[185] Although this is a relatively small amount of heat compared with the total kilocalories required to completely rewarm the hypothermic patient, heated and humidified ventilation is of value in insulating the airway from further evaporative heat loss. Some studies have shown, however, that inhalation rewarming reduces metabolic heat production through shivering.^[47] In experimental subjects whose shivering was pharmacologically inhibited, inhalation warming did not appear to provide any advantage over spontaneous rewarming.^[58] Other suggested benefits of inhalation warming include rehydration, stimulation of mucociliary activity in the respiratory tract, and direct heat transfer from the upper airways to the hypothalamus, brainstem, and other brain structures. Any resultant warming of the respiratory, cardiovascular, or thermoregulatory centers could be of benefit. While research continues on the efficacy of airway rewarming, most hypothermia treatment protocols continue to recommend inhalation warming as an adjunct to overall rewarming strategies.*

Warmed IV Fluids.

Administration of warmed IV fluids is beneficial in reversing hypothermia-induced dehydration and hypovolemia.^[26] ^[147] Replacement of fluids before rewarming has been shown in dogs to augment cardiac output.^[132] Dextrose 5% in water or normal saline, or normal saline alone, is preferable to lactated Ringer's solution, since a hypothermic liver may be unable to metabolize lactate normally.^[148] Administration of 300 to 500 ml should be given fairly rapidly, with the remainder of the liter administered over the next hour.^[5] In no case should cold IV fluids be administered. Plastic IV bags can be easily carried inside a rescuer's clothing (preferably next to the skin) to keep the fluids warm and to supply some perfusion pressure.

Body-to-Body Rewarming.

Body-to-body warming of the patient has long been advocated as an acceptable field treatment of the hypothermic patient. Sir John Franklin, in his 1823 text, *Narrative of a Journey to the Shores of the Polar Sea in the Years 1819, 20, 21*, describes this technique for resuscitation of an expedition member recovered from ice water.^[39] When wrapped together in a blanket or sleeping bag, a rescuer can donate body heat to a hypothermic patient. Experimental studies on human volunteers, however, have failed to demonstrate a rewarming advantage of this technique in shivering individuals. When subjects were cooled to an average core temperature (T_{es}) of 34.6° C (94.3° F), body-to-body rewarming proved no better than shivering alone.^[52] In this study, the heat donated by the "rescuers" was only sufficient to offset the heat lost by inhibition of shivering. Several theoretic arguments mediate against routine use of body-to-body rewarming in shivering victims in the field: (1) the large heat loss of an immersion hypothermic victim (e.g., 300 kcal in cooling an average normothermic adult to a T_c of 33° C [91.4° F]) is unlikely to be reversed by the relatively small amount of heat provided by the donor (e.g., a resting, nonshivering adult produces only about 100 kcal/hr)^[52]; (2) rescuers provide a relatively small surface area in direct contact with the hypothermic victim through which to donate heat; (3) peripheral vasoconstriction in the victim will limit heat flow to the core^[35]; and (4) external heat from body-to-body contact will inhibit the hypothermic victim's endogenous heat production through shivering.^[51] However, in severely hypothermic, nonshivering victims, or in victims whose shivering thermogenesis is inhibited by alcohol, medications, age, etc., body-to-body rewarming may be indicated. Furthermore, body-to-body rewarming may provide important psychologic support to the patient. For these reasons, rescuers should weigh response implications against the advantages and disadvantages of body-to-body rewarming in devising a field rewarming strategy for any particular hypothermic patient.

Heating Pads.

Application of external moderate heat sources to hypothermic patients has been a traditional method of field rewarming. Particularly when applied to the patient's neck, thorax, and groin (areas with high potential for conductive heat transfer),^[78] hot water bottles, chemical or charcoal heat packs, heating pads, or other warmed objects have been used in an attempt to stabilize the patient's T_c . Experimental evidence is lacking, however, to demonstrate the efficacy of this treatment modality over spontaneous shivering thermogenesis alone.^{[19] [51] [72] [151]} Only when combined with a source of heated, humidified ventilation has a heating pad been experimentally shown (on mildly hypothermic, shivering volunteers) to be marginally effective in shivering subjects.^[130] For more severely hypothermic patients who are not shivering, these types of external

*References ^[25] ^[26] ^[43] ^[143] ^[148] ^[180] .

heat sources may be indicated in helping stabilize the patient's T_c . Indeed, a recent study has demonstrated that charcoal heating provides a significant rewarming advantage in hypothermic subjects when shivering was pharmacologically inhibited.^[85]

Rescuers should be aware of several potential hazards with this rewarming technique. Hypothermic skin is very sensitive to heat and easily injured. All sources of external heat must be separated from direct contact with the victim's skin to prevent severe thermal burns.^[147] Third-degree burns have resulted from application of a lukewarm hot-water bottle directly to a hypothermic child's skin.^[120] Furthermore, heatpacks that use burning charcoal as a heat source can create a carbon monoxide hazard within an enclosed space.^[151]

Arteriovenous Anastomoses Rewarming.

This technique relies on the physiologic arteriovenous anastomoses (AVAs) that exist in human digits and on the superficial venous rete in the forearms and lower legs. Warming these areas opens the AVA and increases superficial venous return via the rete. Warmed venous blood thus reaches the core without excessive countercurrent heat loss to cold arteries (i.e., superficial veins are not in close contact with arteries). Because of the pioneering work of Vanggaard and Gjerloff,^[175] who proposed AVA rewarming, the Royal Danish Navy has been using this technique since 1970.^[174] Recent experimental studies have confirmed the efficacy of this technique.^[176] Mildly hypothermic subjects ($T_{es} = 34.2^\circ \text{C}$ [93.6°F]) whose hands, forearms, feet, and lower legs were immersed in either 42°C or 45°C (107.6°F or 113°F) water, had a smaller postcooling afterdrop than from shivering alone (0.4°C [0.72°F] compared with 0.6°C [1.08°F]) and a significantly faster rate of rewarming (6.6°C/hr and 9.9°C/hr [11.88°F/hr and 17.82°F/hr]) compared with shivering alone (3.4°C/hr [6.12°F/hr]). Although this technique may be difficult to implement in some field settings, it may be practical in mildly hypothermic victims on rescue vessels or other vehicles where a source of warm water is available. As with heating pads and other sources of external heat, however, rescuers should be concerned about the possibility of thermal burns. In the above study, no burns were observed in the experimental subjects, even when their extremities were immersed in 45°C (113°F) water, although some subjects complained of initial discomfort at this temperature. Rescuers opting to use AVA rewarming should perhaps start with a 42°C (107.6°F) water temperature and gradually raise the temperature to 44°C (111.2°F).^[176]

Another concern with AVA rewarming concerns potential cardiovascular instability. Hypotension may occur secondary to increase in peripheral blood flow in a hypovolemic patient. If the victim is required to be in a semiupright posture to receive AVA rewarming, orthostatic hypotension could potentially add to cardiovascular instability. No experimental data support these potential cardiovascular problems, but studies on AVA rewarming have only been performed on mildly hypothermic subjects.^[176] Further research is required to evaluate the efficacy and safety of AVA warming on severely hypothermic patients.

Forced Air Warming.

Forced air warming (FAW) is a technique derived from a treatment modality used to prevent or reverse hypothermia in surgical patients.^[98] ^[140] Convective heat transfer is provided by warm air blown into warming covers over the patient's body. Both experimental and clinical data support the efficacy of this technique on mild to moderate and on severely hypothermic patients. In mildly hypothermic experimental subjects, FAW was associated with a 30% smaller afterdrop than that found with shivering alone. Furthermore, in the initial 35 minutes of rewarming, shivering patients experienced a net heat loss of 30 to 50W, compared to a net heat gain from FAW of 163 to 237W.^[50] In moderately to severely hypothermic patients (mean $T_{re} = 28.5^{\circ} \text{C}$ [83.3°F]) treated in an emergency room, FAW (when used in conjunction with warmed IV fluids and inhalation warming) achieved a rewarming rate (2.4°C/hr [4.32°F/hr]) nearly twice that of patients treated only with warmed IV fluids and inhalation warming (1.4°C/hr [2.52°F/hr]).^[144]

In another series of experiments using human subjects, a FAW device designed for field use was associated with a significantly higher core rewarming rate (5.8°C/hr [$10.44^{\circ} \text{F/hr}$]) than that of shivering alone (3.4°C/hr [6.12°F/hr]) but showed no advantage over shivering in decreasing afterdrop.^[31] When shivering was inhibited with meperidine in human volunteers,^[54] FAW was associated with a 50% decrease in afterdrop and a 600% increase in rewarming rate compared with spontaneous rewarming alone.^[58] A different prototype FAW device, using a collapsible rigid patient cover and evaluated experimentally on nonshivering human volunteers, was associated with a smaller afterdrop and faster rewarming rate than spontaneous rewarming alone.^[49]

In summary, FAW has shown significant promise as both a field and hospital treatment modality. It is a safe, noninvasive technique that can both decrease afterdrop and increase core warming rate of immersion hypothermia patients. [Figure 8-13](#) schematically illustrates T_c responses to various rewarming methodologies under mild (shivering intact) and severe (shivering absent) hypothermic conditions.

Transportation

Stabilization, insulation, and rewarming of the hypothermic victim should be started during transport to an appropriate medical center for definitive rewarming. If possible, the receiving facility should be selected

Figure 8-13 Schematic illustration of the effectiveness of various rewarming techniques under shivering and nonshivering hypothermic conditions. Dashed line (at 30° C) indicates approximate core temperature at which shivering is spontaneously abolished. *Ex*, External rewarming.

on the basis of knowledge and experience in managing hypothermic patients. In the same manner that victims of multiple trauma are most appropriately managed in trauma centers, severely hypothermic patients are best managed in hospitals equipped to handle potential complications and to provide core rewarming therapies. For example, a hospital with cardiac bypass rewarming capabilities may be a better choice for managing a severely hypothermic patient than a hospital without such qualifications, even though the former may require a longer transport time.

During transport to a site for definitive medical care, emergency medical personnel should frequently monitor the patient's T_c and other vital signs. In addition, they should attach an electrocardiogram (ECG) monitor; continue administration of warmed IV fluids and heated, humidified air or oxygen; and continue other rewarming efforts discussed above. Rescuers should maintain the hypothermic victim in a supine posture and should restrict the voluntary movements of conscious individuals. At the receiving facility, rescuers should ensure that the patient is carried, and not allowed to walk, to the treatment location.

COLD WATER SURVIVAL

Cold water survival depends on avoidance of drowning and hypothermia and on the many factors related to these risks^{[145] [146] [149]} :

1. Ability to swim
2. Ability to keep the head out of the water (even without flotation aids)
3. Ability to avoid panic
4. Sea state
5. Availability and type of personal flotation device (PFD)
6. Availability of a life raft
7. Availability of other floating objects to increase buoyancy (such as a capsized boat)
8. Water temperature
9. Physical characteristics of the survivor
10. Type of protective clothing worn against immersion hypothermia and initial immersion cold shock
11. Behavior of the survivor in the water
12. Availability of signaling devices (whistles, flares, strobe lights, radios, and mirrors) and the ability to use these devices
13. Proximity of rescue personnel

Drowning is the most immediate survival problem following water entry. To maintain airway freeboard and to avoid drowning, a survivor must possess the physical skills and psychologic aptitude to combat the effects of wave action.^{[146] [160]} Although a PFD assists in maintenance of airway freeboard, waves can still submerge a survivor's head, even in moderately calm seas.^{[56] [145] [168]} To reduce the risk of drowning in rough seas, a survivor can increase effective airway freeboard by partially exiting the water (e.g., clinging to an overturned vessel or other debris floating in the water) or by climbing totally out of the water into a life raft or onto a capsized vessel. In both these environments, the survivor may still have to cope with the effects of cold wind, spray, and waves.

As previously discussed, sudden immersion in cold water initiates a cardiorespiratory cold shock response that significantly potentiates the risk of drowning. These reflexes and the resulting incapacitation that can accompany them have been suspected as the primary cause of drowning after short-term (<10 minutes) immersion in cold water.^[156] Abrupt tachycardia and hypertension induced by sudden immersion in cold water can produce incapacitating cardiac arrhythmias in susceptible individuals and myocardial infarction or cerebrovascular accident in persons with arterial disease or hypertension.^[156] In addition, reflex gasp and hyperventilation^{[156] [163]} significantly shorten breath-holding duration.^{[76] [82] [156]} **Figure 8-14** illustrates this phenomenon. Loss of

breath-holding capacity can have severe consequences for survivors attempting underwater egress from a submerged vehicle, capsized vessel, or aircraft or for survivors simply trying to maintain airway freeboard in a rough sea or white-water river.^{[82] [136] [160]}

The respiratory difficulties induced by the cold-shock reflexes makes breathing while swimming extremely difficult. Golden and Hardcastle^[62] have demonstrated a "swim stroke/respiration asynchrony" leading to water inhalation and swimming failure, and Golden et al^[66] have shown that even persons who are considered good swimmers (at least in warm water) can only swim in cold water for a few minutes. Swimming ability and survival time in cold water is further diminished by

Figure 8-14 Effect of water temperature on maximum breath-hold duration in young, physically fit human subjects (80 men and 80 women). First submersion was sudden after sitting comfortably in air at a mean temperature of 11.3° C (52.34° F). Second submersion followed 2 minutes of acclimatization to the water. The last 10 seconds of the acclimatization was accompanied by 10 seconds of hyperventilation. (From Hayward JS et al: *J Appl Physiol* 56:202, 1984.)

subjective perception of shortness of breath and by panic reactions from unexpected cold water immersion.^[156] The work required to swim in cold water is greater than that in warm water because of the former's higher viscosity (e.g., water at 4.7° C [40.5° F] has a viscosity 67% higher than water at 23.7° C [74.7° F]).^[97] The increased work of swimming in cold water potentiates the onset of fatigue. The combination of all these factors may incapacitate even physically fit, capable swimmers. Keatinge et al^[97] observed sudden incapacitation in two experimental subjects (who were good swimmers) immersed in 4.7° C water. One inhaled water from respiratory difficulty and fatigue after swimming for 7 ½ minutes and had to be pulled out of the water. The second subject lasted only 1 ½ minutes before he "floundered and sank without managing to reach the side of the pool, which was about 1 meter from his head, and had to be pulled" out of the water.^[97] The observed frequency of such swimming failures and unexpected submersions has led the U.S. Coast Guard to coin the term *sudden disappearance syndrome* to describe the phenomenon.^[168]

The magnitude of the cold shock response can be attenuated through habituation to cold immersion. Tipton et al demonstrated that habituating subjects to 10° C (50° F) water resulted in 16% reduction in respiratory rate during the first 30 seconds of immersion in 10° C water and 26% reduction in respiratory rate during the 30-second to

180-second interval after immersion in 10° C water. Tidal volume and heart rate response showed similar declines in habituated subjects. [161] Habituation through cold water survival training may thus be an important safety measure for workers in cold water environments.

Protective clothing also diminishes the cold shock response from initial immersion in cold water. Clothing that limits the amount and ingress velocity of water reaching a subject's skin (e.g., well-fitted wet suits and dry suits with adequate seals) significantly decreases the cardiorespiratory reflex responses to sudden immersion. [111] [162] [164] [165] Furthermore, Tipton and Golden demonstrated that subjects wearing a wet suit that protected the torso but left the limbs exposed had a significantly reduced respiratory reflex response but not a reduced heart rate response compared with control subjects with neither torso nor limbs protected. They concluded that the limbs may be more important than the torso in the cardiac response to sudden cold water immersion. [165] Tipton et al [162] also demonstrated that even loose-fitting, poorly insulated clothing can attenuate the magnitude of the cold shock response compared with immersion in swimming trunks only. When volunteers were immersed in 10° C (50° F) water wearing either conventional clothing or conventional clothing plus windproof/showerproof foul-weather clothing, cardiopulmonary and thermal responses were significantly less than those found with swimming trunks alone.

If a victim of cold water immersion can avoid drowning during the initial few minutes after water entry, prevention of hypothermia becomes an important problem. Survival time in cold water, based on the pathophysiological effects of decreasing T_c , is not a precise calculation. Large individual variations among survivors in body morphology and state of health and fitness, combined with many exogenous variables affecting cooling rate (e.g., clothing, water temperature, sea state, flotation, and behavior), preclude exact predictions of survival time. However, sufficient experimental data and case history findings exist to allow generalizations. At a T_c of 34° C (93.2° F), there is a significant deleterious effect on manual dexterity and "useful function" in cold water. [22] [123] If a survivor is trying to combat rough seas, this level of dysfunction may potentiate drowning. At a T_c of 30° C (86° F), unconsciousness

is probable. [17] [26] [149] [150] [154] Even if a survivor is wearing a self-righting PFD designed to maintain airway freeboard in an unconscious person, drowning is probable at this T_c in all but the calmest seas. At T_c below 25° C (77° F), VF or asystole often occur spontaneously. [26] Of these three core temperatures, 30° C is the most practical for defining the limits of survival in cold water.

For immersion hypothermia, the most important variables affecting cooling rates in cold water are:

1. Water temperature

2. Survivor's height, weight, and percent body fat
3. Type of protective clothing worn by the survivor
4. Sea state
5. Survivor's behavior in the water
6. Amount of the survivor's body immersed in the water
7. Metabolic heat production

The advantage of body fat as an insulator against cold has been discussed previously in the Body Morphology (Size and Composition) section covering pathophysiology and cooling rates. Using an extrapolation of linear cooling rate to 30° C (86° F), [Figure 8-15](#) shows predicted *calm water* survival times of lightly clothed, nonexercising humans in cold water. The graph shows a line for the average expectancy and a broad zone that indicates the large amount of individual variability associated with different body size, build, and degree of fatness. The zone would include approximately 95% of the variation expected for adult and teenage humans under the conditions specified. In the zone where death from hypothermia is highly improbable, cold water still potentiates death from drowning from "cold shock" (as discussed above) in the first few minutes of immersion, especially for those not wearing personal flotation devices. It is important to note that [Figure 8-15](#) discusses only calm water survival times. Since rough water conditions decrease survival times, as discussed below, [Figure 8-15](#) may be useful for estimating *maximum* survival times for an individual immersed in cold water. Search and rescue organizations might find such a maximum survival time helpful, since they often use the longest possible survival time in deciding when to terminate a search effort.

A large number of studies over the past few decades have evaluated the relationship of different types of protective clothing to heat loss and cooling rates.³ Nearly all of these studies have been conducted in calm water or in laboratory settings. As illustrated by the cooling rate data in [Table 8-2](#) and [Table 8-3](#), such studies have generally shown that in calm water, intact, "dry," insulated garments provide better protection than do "wet" insulated garments, and well-insulated garments

Figure 8-15 Predicted calm water survival time (defined as the time required to cool to 30° C [86° F]) in lightly clothed, nonexercising humans in cold water. The graph shows a line for the average expectancy and a broad zone that indicates the large amount of individual variability associated with different body size, build, fatness, physical fitness, and state of health. The zone would include approximately 95% of the variation expected for adult and teenage humans under the conditions specified. The zone would be shifted downward by physical activity (e.g., swimming) and upward slightly for heavy clothing or protective behaviors (e.g., huddling with other survivors or adopting a fetal position in the water). Specialized insulated protective clothing (e.g., survival suits, wet suits) is capable of increasing survival time from 2 to 10 times (or more) the basic duration shown here. In the zone where death from hypothermia is highly improbable, cold shock on initial immersion can potentiate death from drowning, particularly for those not wearing flotation devices. (From *US Coast Guard: Addendum to the National Search and Rescue (SAR) Manual, COMDTINST M16120.5 and COMDTINST M16120.6*,

1995.)

provide significantly better protection than do poorly insulated garments. [Figure 8-16](#) shows various types of cold water protective garments.

Although calm water studies have value in comparing the relative degree of protection afforded by different types of protective clothing, many immersion accidents occur in rough water.^{[135] [159] [160]} In this environment, a survivor's cooling rate may be affected by swimming to maintain airway freeboard, passive body movements caused by waves, flushing of cold water through "wet" suits, and leakage of cold water into "dry" suits. For example, subjects in a wave tank demonstrate higher energy expenditure and faster cooling rates than do subjects in calm water.^[73] Several experimental studies have demonstrated significantly faster cooling rates for human volunteers wearing "wet" protective garments in rough or turbulent water^{[134] [150] [187]} than for persons in calm water. Even "dry" suits have shown degradation of protection in rough water. In a recent study of dry immersion suits in 16° C water, Ducharme and Brooks^[32] found that wave heights up to 70 cm resulted in a 14% decrease in total suit insulation and an

Figure 8-16b **C**, Boat crew coveralls or snowmobile suit. **D**, Short wet suit worn as an undergarment. **E**, Full wet suit with personal flotation device. **F**, Insulated dry suit. **G**, Immersion suit. Garments **A** to **C** are loose-fitting, closed-cell foam-insulated wet suits; garments **D** and **E** are tight-fitting closed-cell foam-insulated wet suits; garments **F** and **G** are closed-cell foam-insulated dry suits.

average 45% decrease in thermal resistance at the head and trunk regions of the suits.

[Figure 8-17](#) shows a comparison of cooling rates for lean males dressed in the various types of protective clothing shown in [Figure 8-16](#) in both calm and rough water at approximately 10° C (50° F).^[150] The most dramatic differences occurred in the loose-fitted, "wet" protective clothing (such as the float coat and insulated coveralls), where cooling rates nearly doubled in rough seas over those in calm seas. This was primarily due to flushing of cold water through the garments. However, even the tight-fitted, full "wet" suit allowed a 30% faster cooling rate in rough water over that in calm water. The "dry" suit, which did not leak, showed no significant difference between calm and rough seas.

Estimated survival times in rough seas, based on experimental data, were published for thin men wearing different types of protective clothing in 6° C (42.8° F)

Figure 8-17 A comparison of mean rectal temperature cooling rates in lean male subjects in calm vs. rough seas at 10.7° C (51.26° F). The flight suit, used as a control garment, is equivalent to light clothing. (From Steinman AM et al: *Aviat Space Environ Med* 58:550, 1987.)

water.^[149] [Table 8-4](#) shows these times for three different levels of survival. The following assumptions underlie these estimations:

1. Cooling rates are linear.^{[81] [149] [150] [154]}
2. Initial T_c is 37.5° C (99.5° F).
3. Survivors are able to maintain airway freeboard until unconsciousness occurs at a rectal temperature of 30° C (86° F).
4. Self-righting flotation maintains airway freeboard when survivors are unconscious.

In comparing these estimated survival times with those of [Figure 8-15](#) (calm water survival times), the reader must recall that [Figure 8-15](#) concerns only survival to a T_c of 30° C. Furthermore, the zone in the graph must be adjusted downward for rough seas and for survivors wearing only light clothing, and upward for survivors wearing insulated clothing. For 6° C (42.8° F) water, the survival times (to a T_c of 30° C) correlate well between [Figure 8-15](#) and [Table 8-4](#) . We must emphasize that the estimates in [Table 8-4](#) pertain to lean individuals with a mean body fat of only 11.1%. Since many populations of adults (such as offshore oil workers) in the 30- to 50-year-old age range average 25% to 30% body fat, the estimates of "time to unconsciousness" and "time to cardiac arrest" must be considered conservative for a broader spectrum of adults.

Survivor location also has a significant effect on T_c cooling rate and survival time. The U.S. Coast Guard and other rescue organizations recommend that a survivor of a maritime accident in cold seas get as much of the body out of the water as possible to minimize cooling rate and maximize survival time.^{[149] [168]} This recommendation derives from the higher thermal conductivity of water compared with air at the same temperature. However, survivors exposed to cold air are still at risk from hypothermia secondary to convective, evaporative, and radiant heat losses. In a rough sea environment, wind increases the magnitude of convective heat loss, and spray and periodic wetting from breaking waves result in conductive heat loss.^{[153] [155]} Steinman et al^[149] confirmed the above observations. The cooling rates of thin male subjects, wearing different types of protective clothing, were compared for three survival situations:

1. Immersion in 6° C (42.8° F) water with 1.5-m (5-foot) breaking waves
2. Exposure to 7.7° C (45.9° F) air, continuous water spray at 6° C, continuous 28 to 33 km/hr wind, and occasional breaking waves while sitting atop an overturned boat
3. Exposure to 7.7° C air and occasional breaking waves while sitting in an open, one-person life raft

The results of the study are shown in [Figure 8-18](#) . For each type of garment worn, cooling rates were considerably faster in the water than atop the boat (despite the effects of wind, spray, and breaking waves) or within the raft.

Survivors should therefore attempt to get as much of their bodies out of the water as possible, even if it means exposure to cold wind and spray. Even rescue and medical personnel who frequently work in wilderness environments poorly understand this recommendation. A widespread misunderstanding of the concept of "windchill" causes many to conclude that survivors have higher heat losses if they are exposed to wind, especially if they are wet, than if they are immersed in water.^[149] Windchill (a term originally used by Siple and Passel^[142] to describe the increase in heat loss from unprotected skin exposed to wind) is frequently used in the communication media without regard to the difference between exposed and unexposed skin. This misleads many to believe that the windchill temperature applies to both clothed and unclothed areas of the body. Furthermore, common experiences during recreational activities at the beach, lake, or swimming pool, where people subjectively feel colder after leaving the water (because of evaporative heat loss from the skin) than they do while swimming, reinforce the misunderstanding. This has occasionally led survivors to abandon a position of relative safety atop a capsized vessel and reenter the water, usually with tragic results. The sensation of coldness (which is skin dependent) does not reliably convey information about rate of heat loss when two radically different environments such as air and water are compared.

Tikuisis^{[153] [154]} recently devised a more sophisticated set of survival time estimates for individuals immersed in cold, rough seas and for survivors partially immersed and/or exposed to cold wind under wet conditions. Using

Figure 8-18 Mean linear cooling rates ($^{\circ}\text{C/hr}$) for lean men in three survival environments: *water* = immersion in 6.1°C (42.98°F) breaking waves; *boat* = 5 minutes immersion in 6.1°C water followed by exposure to 7.7°C (45.86°F) air atop an overturned boat with continuous 28- to 33-km/hr wind, water spray, and occasional breaking waves; *raft* = exposure to 7.7°C air in an open, one-person life raft, preceded by 5-minute immersion in 6.1°C water. *AC*, Air crew coveralls; *BC*, boat crew coveralls; *FS*, flight suit (lightweight clothing); *NI*, intact, non-foam-insulated "dry" coveralls; *NX*, NI with a 5-cm tear in the left shoulder, thus permitting water to leak into the suit and degrade its insulation; *WS*, wet suit. Blank squares indicate combinations of garment and environment that were not tested. (From Steinman AM, Kubilis P: *Survival at sea: the effects of protective clothing and survivor location on core and skin temperature*, USCG Rep No. CG-D-26-86, Springfield, 1986, Va, National Technical Information Service.)

TABLE 8-4 -- Estimated Survival Times for Lean Subjects (Mean Body Fat = 11.1%) Wearing Various Types of Protective Clothing in Rough Seas

CLOTHING TYPE	ESTIMATED SURVIVAL TIME (HR) (95% CONFIDENCE RANGE)		
	TIME TO INCAPACITY (T = 34°C)	TIME TO UNCONSCIOUSNESS (T = 30°C)	TIME TO CARDIAC ARREST (T = 25°C)
Control (lightweight clothing)	0.4–1.3	0.8–2.6	1.3–4.3
Torn, non-foam-insulated dry coverall (2-inch tear in left shoulder)	0.9–2.7	1.6–5.2	2.5–8.4
Closed-cell foam-insulated, wet coverall (3.2-mm thick insulation in a loose fitted coverall)	1–2.9	1.9–6	3–9.9
Closed-cell foam-insulated, custom-fitted wet suit (4.8-mm thick insulation; tight-fitted)	1.6–4.7	3.1–9.9	4.9–16.2
Intact, non-foam-insulated dry coverall (watertight shell over thick, fiberfill, insulated underwear)	2.9–8.8	5.7–18.2	9.1–30

computer modeling of human cooling physiology and the experimental data of Steinman et al^[149] ^[150] shown above, he developed a series of survival time charts for a range of individual body morphologies while wearing various degrees of protective clothing.^[153] **Figure 8-19** shows his estimates for lean, average, and fat individuals wearing a loose-fitted, insulated coverall (boatcrew coverall, snowmobile suit, etc.; see **Fig 8-16**). Tikuisis defined the lean, average, and fat survivors as having the following morphologic characteristics: height = 1.77 m (5 feet 9 ½ inches); weight = 66.3, 73.9, and 88.2 kg, respectively, for lean, average, and fat; body fat = 11.2%, 17.7%, and 28.6%, respectively, for lean, average, and fat. Note that the lean definitions fit the experimental

Figure 8-19 Predicted survival time for individuals wearing the boatcrew coverall (see **Figure 8-16**) for **A**, immersion in rough seas vs. water temperature; and **B**, exposure to air at 20 km/hr under wet conditions (clothing wetness of 1550 g/m²) vs. air temperature. The lower and upper boundaries of the shaded regions represent predictions for lean and fat individuals, respectively. (From Tikuisis P: *Aviat Space Environ Med* 68:441, 1997.)

subjects used by Steinman et al^[149] (see **Table 8-4**). Tikuisis also published a series of survival time charts for the "average" individual (defined above) wearing various types of clothing protection. **Figure 8-20** shows his results for low insulation clothing (nude, float coats, average clothing, boatcrew coveralls, leaky "dry" suits), medium insulation clothing (partial or full wet suits), and high insulation clothing (dry, insulated coveralls and survival suits). Both the Canadian and United States Coast Guard in their search and rescue missions are now using these survival charts.

Figure 8-20 Prediction of survival time for an average individual under various degrees of clothing protection (See **Figure 8-16**). **A**, Immersion in rough seas vs. water temperature; *low* = nude,

flight suit, float coat, aviation coverall, boat crew coverall, torn coverall; *medium* = short wet suit, full wet suit; and *high* = dry coverall, dry suit. **B**, Exposure to air at 20 km/hr under wet conditions vs. air temperature; *low* = nude, flight suit, aviation coverall; *medium* = float coat, boat crew coverall, short wet suit, full wet suit, dry coverall, torn coverall; and *high* = dry suit. (From Tikuisis P: *Aviat Space Environ Med* 68:441, 1997.)

Chapter 9 - Polar Medicine

Betty Carlisle
Bern Shen

Like much of wilderness medicine, polar medicine's identity derives to a large extent from its setting. "Polar," however, can be defined in several different ways.^[33] Geographically, the Arctic and Antarctic circles, at latitudes 66°33' north and south, delimit areas in which the sun does not rise or set on at least 1 day of the year. A more functional definition is the 10° isotherm, which joins those areas in which the average temperature in the warmest month of the year is 10° C (50° F); this correlates roughly with the tree line. Still other definitions or subdivisions are based on the extent of permafrost, tundra, or sea ice.

For medical purposes, the definition of "polar" is more complex. Although climate and geography are clearly important, the salient features of polar medicine are logistic and experiential. Unlike high-altitude medicine or hyperbaric medicine, for example, polar medicine is not unified by an underlying pathophysiology. Although fields such as the former are medicine *because of* the environment's effect on the human organism, polar medicine is largely medical practice *within* the setting.

Medical practice in spite of isolated settings is paradigmatic of wilderness medicine; the patient population is essentially if not literally a small demographic island. A provisional definition of polar medicine, then, could be formulated as "the practice of medicine in isolated settings"; to borrow an anthropologic term describing isolated "island" communities, it could be called Fourth World medicine.^{[56] [120] [165]}

DISTINCTION BETWEEN ARCTIC AND ANTARCTIC MEDICINE

Although the Polar Regions share the predominant attributes of cold and isolation, they display many important contrasts. The Arctic has been described as a sea nearly surrounded by land, whereas Antarctica is a land and ice mass circumscribed by ocean. The moderating effect of the North Polar waters compared with the elevation (2835 m [9302 feet]) of the South Polar plateau accounts for the roughly 40° C (72° F) differences in wintertime low temperatures. On a plot of temperature vs. humidity, the South Pole is more similar to Mars than to the rest of the earth.

Such environmental contrasts are reflected in population density and diversity of flora and fauna. In contrast to the Arctic's boreal forest, tundra, and growing population of over 2 million, Antarctica is a high, dry, icy desert continent with almost nonexistent flora and fauna, no indigenous population, and transient influxes of a few thousand people each summer and merely a few hundred in winter.

The differences in population patterns mark an important north-south disjunction in polar studies in general,^[44] and in polar medicine in particular.^[187] There are actually two overlapping but distinct spectra of medical problems—those of indigenous Arctic people and those of visitors to either polar region. As we shall see, many of the medical problems among the Inuit, Sami, Chukchi, Nenet, and other northern groups are those of populations making the often Faustian demographic and cultural transition to a Western industrialized society. Thus medical practice among these groups is similar to that among many other displaced aboriginal populations.

In contrast, medical problems among the usually young and fit scientific, commercial, tourist, or expedition personnel are often related to trauma and the environment and thus fall more appropriately under the purview of travel or expedition medicine. In a sense, the current illnesses and health risks of the indigenous Arctic populations are the result of too much contact with other cultures, whereas those of the sojourners to either polar region are largely the result of too little connection with the culture and medical facilities of home.

The indigenous vs. sojourner or essentially north-south disjunction in polar medicine poses a challenge to a meaningful synthesis. In the spirit of a trend in travel medicine,^[72] I recognize that it makes sense to focus not only on the health of elite visitors to remote areas but also on the health problems surrounding and sometimes even caused by them.

A rigorous discussion of health risks, practices, and outcomes ultimately depends on much finer resolution of local climate, culture, and occupational conditions. Even among

the remarkably consistent linguistic cultures of the Arctic, there are clearly confounding variables in trying to metaanalyze, for example, health studies among reindeer herders in an isolated Sami village in northern Finland, Inuit apartment block dwellers in Nuuk, Greenland, and Alaskan pipeline workers on the North Slope. Likewise, in the Antarctic there are important differences among the living conditions and health determinants of a marine biologist on the Antarctic Peninsula, a geologist in the Dry Valleys, and a power plant mechanic at the South Pole Station.

IMPORTANCE OF POLAR MEDICINE

Increase in Tourism and Expeditions

The combined geographic polar regions cover about one sixth of the world's surface,^[158] and their territory in the imagination has been enlarged by several remarkable expeditions and recent popular magazine articles and books.[‡] Despite, or perhaps because of, the forbidding environment, tourism of various sorts to polar regions is increasing.^{[13] [89] [109] [177]} Junkets "to the North Pole" are popular, despite being costly. Antarctica has become a trendy destination for adventure seekers. Even though no permanent settlement is there, roughly 100,000 tourists a year visit Nordkapp on the tip of Norway.^[107] At the other end of the globe, in 1980 it was estimated that 31,000 paying tourists, adventurers, or guests of national scientific expeditions had visited Antarctica.^[133] More recently, the number of tourists has increased 33% per year since 1990–1991, when roughly 3200 tourists a year visited "the Ice." In 1998, there were 11,200 tourist visits, not including researchers and support personnel. Even further increases are anticipated in the new millennium.^[10] Commercial tourists have even been brought to the South Pole, including one ill-fated sky diving venture with the death of three of the four participants.

Geopolitical Concerns

The interest of governments in polar regions has not lagged behind that of tourists.^{[57] [63] [80] [176] [192]} Political and territorial concerns have been important in both polar regions; with increasing exploration of mineral and oil reserves^[86] and fishing potential, migrating humans will bring medical problems with them. Although the Antarctic Treaty of 1959 prohibits territorial or commercial claims, a number of nations have made sectoral claims on the continent. Some countries encourage couples to give birth to a child during their tour in Antarctica and thus claim true Antarctic "citizens."^[180] Concern about the environmental impact of increasing human activity in polar regions[‡] seems to be tempering the pace of development, but it appears likely that the pool of potential civilian and military patients in polar regions will increase.^[170]

Increasing Research Activities

Scientific research has been a part of polar exploration throughout this century.[‡] There are scientific and medical journals devoted to the polar regions, and thousands of articles are indexed each year in the Antarctic Bibliography alone.^[64] A 45,000-square-foot science facility has been completed at McMurdo,^[55] and the replacement of the current South Pole Station is expected to be completed by the year 2005.^[121] The Australian Stations have completed expansion and updating of research

and medical facilities.^[94] The Australian program also requires that the physicians undergo rigorous training before deployment.

Here as well, some observers have discerned a north-south split, perceiving research in Antarctica as having more of a political motivation, and that in the Arctic as more practical in orientation.^[41] For both scientific and political reasons, an important part of the scientific research in polar regions concerns environmental issues.^{[30] [79]} The remoteness of these regions enhances their value as a benchmark for studies of pollution. Studies have revealed several worrisome facts about the contamination of the formerly pristine wilderness, such as the prolonged effective half-life of radioactive fallout deposits^[171] and the increased chemical contamination, particularly in animals high on the food chain, with persistent organic compounds (POCs), heavy metals, and other contaminants. ^{[4] [30] [61] [171]} As occupational and environmental health issues draw more attention in the next few years, this aspect of polar medicine will assume greater importance.

Interest in Analogies to Space Missions

Several articles and conferences have explored analogies between isolated and confined environments of polar research stations and space stations.^{*} Data from polar (primarily Antarctic) stations tend to be more available and recent than from other space station analogs, such as nuclear submarines.^[181] International cooperation in polar health care and human research is coordinated by the Scientific Committee on Antarctic Research (SCAR).^[94] It is just a matter of time before long-distance human spaceflight begins, so polar studies may give planners more information of relevance to these future space missions. ^[117]

BRIEF HISTORY OF HUMAN HABITATION IN POLAR REGIONS

A perspective on the contrasts between Arctic and Antarctic medicine may be sharpened by review of an extremely brief summary of human habitation in the polar areas.

Humans are known to have inhabited Arctic regions for at least 4500 years. Anthropologists have uncovered evidence for several waves of population migration from Siberia through northern Canada to Greenland. Each of these migrations was probably linked to climatic conditions, and each resulted in a distinct set of cultures. The general pattern was of a nomadic life with population

*References ^[9] ^[84] ^[90] ^[101] ^[109] ^[127] ^[130] ^[158] .

†References ^[13] ^[60] ^[103] ^[113] ^[116] ^[177] .

‡References ^[6] ^[7] ^[8] ^[44] ^[155] ^[157] ^[178] .

densities of approximately 1 person per 400 km².^[73] ^[164] In more recent times, this long-established and remarkable adaptation to a hostile environment has been disturbed. The pace of cultural change increased dramatically during the second half of the nineteenth century, when the whaling industry moved into Hudson Bay, leading to sustained contact between Europeans and Inuit. In the early part of the twentieth century, religious missions, trading company posts, government stations, and eventually medical clinics and schools began to encourage permanent settlements, roughly quadrupling the population density.^[73] This change in population distribution and the contact, and sometimes conflict, between the indigenous and European cultures had medical consequences.

In contrast to the Arctic, the known history of human exploration of the Antarctic is quite recent. Recorded sightings of the continent date only to around 1800, and "winter-over" sojourns did not occur for another century. One can also construct waves of settlement in Antarctica: sealing in the early nineteenth century, whaling in the early twentieth, and scientific since the mid-twentieth.^[164] The heroic era of Antarctic exploration occupied the early years of the twentieth century, with exploits such as the highly publicized race for the South Pole between Roald Amundsen and Robert Scott in 1911, and the extraordinary survival of the crew of the 1914 *Endurance* expedition, led by Ernest Shackleton.^[84] Perhaps because of these and other dramatic events, and perhaps because of the absence of an indigenous population and the scarcity of easily exploited resources, human activities in the Antarctic have retained a somewhat more expeditionary flavor than in the Arctic. This has helped shape the contrasts in medical

practice between North and South Polar Regions.

ARCTIC MEDICAL PROBLEMS

Somatic Health Problems

Effects of Cultural and Demographic Transition.

Medical problems among indigenous populations in the Arctic are characteristic of those of displaced aboriginal people elsewhere in the world. On the one hand, recent episodes, such as the 1987 trichinosis outbreak in Salluit,^[96]^[97] the 1980 rabies outbreak in the Svalbard Islands,^[131] and continued problems with diphyllbothriasis^[31] and toxoplasmosis,^[100] reflect diseases characteristic of nonindustrial lifestyles. On the other hand, increased contact with industrialized cultures has brought problems, as well as benefits. For many years, health care has lagged behind national norms, with infant mortality in the Canadian Arctic greater than 10%, life expectancy in 1970 only 60% of the national average, and widely prevalent tuberculosis, alcoholism, and tobacco use.^[105]^[106]^[164]^[185] Despite dedicated individual efforts, catastrophes such as the 1948 outbreaks of influenza originating at Cambridge Bay,^[71] the 1949 polio epidemic among Hudson Bay Inuit,^[71]^[108] and widespread tooth decay and even malnutrition with the introduction of new foods^[71]^[72] have demonstrated negative medical consequences of cultural contact.

As indigenous Arctic populations and their environment make the cultural and demographic transition to a Western industrialized way of life, the spectrum of medical problems has shifted. Even isolated mining villages in Greenland no longer exhibit traditional patterns of illness.^[51] Changing social patterns have resulted in disturbing trends; more than half the births in Greenland in the 1970s were to unwed mothers,^[143] and the prevalence of gonorrhea and syphilis among Greenlanders is one in three,^[56] raising concerns about other transmissible diseases, such as viral hepatitis and acquired immunodeficiency syndrome (AIDS).^[154]

Environmental and Occupational Health Problems.

A consequence of the transition to industrialized life is a change in environmental health risks.^[3] Popular attention has been focused by such recent catastrophes as the Severomorsk submarine base explosion in May 1984 and the *Exxon Valdez* accident in Prince William Sound. The nuclear accident at Chernobyl in May 1986 led to cesium 134 and 137 levels in reindeer meat 50 to 100 times those considered safe, forcing destruction of the Sami reindeer herds. During that same time, lake fishing and berry picking were curtailed because of contamination.^[56] Industrial emissions from neighboring regions, including an estimated 100 million tons of sulfur dioxide, have led to the phenomenon of the "Arctic haze," a gradual whitening of the historically deep blue

Arctic sky.^[56]

Environmental impacts have direct health consequences.^{[32] [120] [137]} During the last 500 years, industrial pollution has led to a sevenfold increase in lead levels in human tissues in the Arctic.^[56] Another survey found blood mercury levels above the normative limit in over 10% of Sami reindeer herders in northern Finland, an index of ocean contamination and concentration of heavy metals in fish.^[95] Further contamination of the food chain with long-lasting POCs, including polychlorinated biphenyls (PCBs) and many organic pesticides, is increasingly identified. The long-term consequences of these environmental pollutants on the health of the Arctic dwellers is just recently being studied.^[4]

Nontoxicologic factors also make important contributions to Arctic morbidity and mortality. It is striking that Alaska's occupational death rate is five times that of the U.S. national average of 7.6 deaths per 100,000 workers.^[142] This reflects in part inherently hazardous working conditions and occupations^[17] and possible demographic biases of a young population.^{[85] [147]} Other factors, however, may play a role. Recently, aircraft safety has attracted increasing attention.^{[29] [147]} Since aircraft are

a predominant mode of transportation in polar regions, it is perhaps not surprising that Alaska accounted for almost one fourth of the fatal or serious commuter air crashes in the United States in a recent 5-year review.^[142] Nonscheduled or commuter plane (less than 30 seats) flights commonly used in isolated areas may pose a sixfold risk of a fatal crash relative to scheduled airliner flights,^{[12] [183]} a figure not surprising given the often extremely challenging flying conditions ([Figure 9-1](#)).

Psychosocial Health Problems

With social disruption and increased environmental and occupational health risks, it comes as no surprise that psychologic problems in the Arctic have achieved higher visibility in recent years. For a variety of reasons, stress seems to be higher in winter^[58] ; seasonal affective disorder (SAD) is discussed below. One survey of over 7000 adults living north of the Arctic Circle found a prevalence of midwinter mental distress of 14% in men and 19% in women ^[58] ; most other studies suggest that this figure may be low. Depression, suicidality, and domestic violence are prominent reasons for visits to the Baffin Consultation Service,^{[1] [191]} as well as for consultations in other communities. ^[38] Studies among scientific staff at research stations are relatively uncommon but show patterns of sleep disturbances, depression, and alcohol use reminiscent of those in Antarctic stations.^[27]

The double apparent risk factors of high latitude and being a displaced aboriginal population have made alcohol abuse and concomitant violence a serious problem in the Arctic. In Greenland, one in three Inuit dies a violent death, and roughly 25,000 adults consume 28 million cans of beer a year, one of the highest per capita consumptions of

alcohol in the world.^[56] Accidents are the leading cause of death in Greenland, and

Figure 9-1 Polar air travel is fraught with the ever-present danger of a crash. Sudden and unpredictable weather changes, lack of navigational aids and extreme cold add to the extremely challenging flying conditions. (Courtesy Stephen Warren.)

one third of these are estimated to be alcohol related, as are most of the crimes and domestic violence.^[143] Similarly, in the Canadian Arctic, alcohol consumption is one and a half times the national average, and Inuit and Indians between 15 and 24 years have a suicide rate six times the national average.^[56]

Current and Future Trends

Fortunately, there are encouraging signs related to Arctic health care. The incidence of low birth weight, 5.5% in the central Canadian Arctic, is low compared with many other populations,^[40] although it is higher than the non-Arctic dwellers.^[4] ^[144] Tuberculosis, which incapacitated up to 20% of the Canadian Inuit by 1950, has been largely brought under control.^[73] Perhaps most surprisingly, the age-standardized prevalence of diagnosed diabetes among circumpolar indigenous populations in Russia, Alaska, and Canada is low compared with the U.S. all-race prevalence of 23.5 per 1000, and quite low compared with the presumably genetically similar North American Indian groups.^[193]

An important development in recent years has been the institution of trauma registries to track and target significant causes of morbidity and mortality.^[47] A recent excerpt from Alaska's trauma registry reports that the leading category of death was firearms related (32%), whereas that of injury was falls (19%).^[75] Recent research has increasingly emphasized that injury prevention is not solely a function of safer design of equipment but a complex interplay of environment, activity, and people, notably including personal risk-taking behavior.^[81] If current trends toward greater economic independence and education of Arctic peoples continue, such potentially modifiable health behaviors may recede in importance in coming years.

ANTARCTIC MEDICAL PROBLEMS

Medical practice, problems, and their study in the Antarctic are somewhat different from those in the Arctic. After a description of the U.S. medical stations in Antarctica, some highlights of health problems as a spectrum from primarily somatic to primarily psychologic are mentioned.

Medical Stations in Antarctica

The medical facilities in the Antarctic polar regions can be conveniently divided into permanent and expeditionary facilities. As a result of community expectations and the long-term commitment to research in Antarctica, a notable shift has occurred in many of the Antarctic programs, "from an expeditionary, to an operational attitude." [\[94\]](#) [\[145\]](#) Although I describe facilities in the United States program, other nations have similar facilities. The United States maintains several small summer camps and three larger year-round stations: McMurdo

(77°53'S, 166°40'E) on the Ross Ice Shelf, Palmer (64°46'S, 64°03'W) on the Antarctic Peninsula, and Amundsen-Scott (90°S) at the geographic South Pole. There are 40 other stations, mostly coastal, that are maintained by more than a dozen other countries.

McMurdo on Ross Island is the largest settlement and major staging area for U.S. Antarctic activities. The summer population is about 1500 and the winter population is about 200. Monthly mean temperatures vary from -3° C (26.6° F) in summer to -22° C (-7.6° F) in midwinter; cold weather limits aircraft operations and physically isolates McMurdo from late February to late August. The medical facilities consist of a well-equipped infirmary staffed during the summer by two physicians, a nurse practitioner, and several technicians. During the winter, staffing contracts to one physician, a nurse practitioner, and a technician. The vast majority of patient visits are for routine minor medical problems. The rare patient requiring medical evacuation can be flown to Christchurch, New Zealand, during the summer. Unfortunately, the logistically difficult winter evacuation has been required several times. These have primarily been for medical emergencies. The most recent occurred in 1999, when a participant at the South Pole was evacuated in the late spring because of cancer.

Palmer Station on Anvers Island in the Antarctic Peninsula has summer and winter

populations of about 44 and 10, respectively. With monthly mean temperatures between -10°C and 2°C (14°F and 35.6°F), it is a popular Antarctic destination for cruise ships. Because of over a thousand visitors a year, there has been active debate regarding the proper role of station personnel in receiving commercial tourists.^[145] This issue was highlighted during the 1992 season when a tourist suffered an apparent myocardial infarction and required evacuation. The infirmary has been recently reorganized to facilitate rapid access to emergency medications and equipment.^[83]

In contrast to McMurdo and Palmer, Amundsen-Scott South Pole Station at 90°S is at an altitude of 2835 m (9302 feet) on the polar plateau and has monthly mean temperatures of -28°C (-18.4°F) in December and -60°C (-76°F) in July. Its summer and winter populations are roughly 120 and 25, respectively. However, with the recent building of a new station, the population has increased to 250 in summer and 45 in winter. One physician staffs the medical facility. It has a fairly well-stocked pharmacy, dental equipment, x-ray, darkroom, laboratory, bathtub for hypothermia, and a treatment/crash room that can be used for simple operations. In addition, there are two holding beds. Station personnel have undergone training in cardiopulmonary resuscitation and "trauma team" drills ^[21] ^[35] ^[67] ^[146] ([Figure 9-2](#)). There have been recent cases of pulmonary edema and carbon monoxide poisoning, high-altitude

Figure 9-2 Trauma and rescue teams are frequently composed of volunteers and at least one experienced and trained individual. This rescuer is practicing for possible extrication of a victim from a crevasse. (Courtesy Betty Carlisle, MD.)

illness, preinfarction syndrome, complex dislocation of a thumb requiring open reduction, and cancer. Fortunately, no deaths have occurred in station personnel since a cervical spine fracture in 1980. However, there were three fatalities in a tragic tourism sky diving event in 1997.

Somatic Health Problems

Many of the primarily somatic health problems in Antarctica have to do with cold, altitude, and trauma and are thoroughly covered in the chapters on those topics. In a midwinter setting where a tossed mug of coffee freezes before the liquid hits the ground, the dangers of frostbite are obvious. Anyone gasping for breath on "Heart Attack Hill" at the South Pole, or losing 5 kg in the first 2 weeks from resting tachycardia and tachypnea, can appreciate the physiologic stresses of rapid ascent to an equivalent of 3200 m (10,499 feet). Likewise, the dangers of ultraviolet exposure at altitude with an ozone hole and snow surface reflectance of 80% to 90% can become painfully evident

to the unwary visitor.^[148] A few points, however, deserve further mention.

Cold-Related Problems.

Cold, of course, is a dominant factor in polar medicine. It can be a source of humor, such as the infamous "300 Degree Club" at the South Pole, for which membership requires sprinting from a 200° F (93.3° C) sauna to the Pole at -100° F (-73.3° C) while somewhat less than completely clothed. Similarly,

the quintessential polar first-aid story involves creative solutions to the problem of finding warm fluids,^[2] but it would be reckless to forget the ever-present danger of such a hostile environment. Wind chill commonly drops far below -72° C (-100° F). It has been estimated that under the most severe winter conditions, an inactive person in full polar clothing would undergo a life-threatening drop in core temperature to 27° C (80.6° F) in only 20 minutes.^[46] Airplane refueling crews and others working with liquids at ambient temperatures are constantly reminded that even a small splash can mean instant frostbite.

Rescue and treatment are complicated by the additional need for both victim and rescuer to avoid hypothermia and frostbite.^[74] Disorientation and confusion from hypothermia, clumsiness from bulky clothing, and degraded performance characteristics of equipment and intravenous (IV) fluids can complicate otherwise straightforward procedures. A recent case report describes almost immediate freezing of fluid in IV lines and shattering of the plastic IV tubing despite vigorous attempts to warm them.^[74] Simple devices commonly used in warmer settings, such as air splints and pneumatic antishock garments, would be similarly unusable. In more sophisticated equipment, batteries would rapidly fail, unwinterized mechanical moving parts would seize, and metal objects would become dangerous sources of frostbite.

Clothing, not normally considered a medical topic, assumes special importance in the polar environment.^{[65] [66] [69]} Although the clothing used for many polar research programs in the summer seems adequate, a strong argument can be made for specialized winter gear, possibly adapted from the space program, that would allow relatively delicate manipulation of scientific equipment while offering protection from the cold ([Figure 9-3](#)). In fact, at temperatures below even that of most military specifications, material properties of equipment, including plastic electrical insulation, create unexpected and novel occupational hazards. Fortunately, the importance of ergonomic issues in the design of machinery and clothing for polar conditions is receiving increased attention.^{[40] [175]}

Nutrition Studies.

Nutrition has occupied a key niche throughout the history of polar expeditions.^[42] Early expeditions in both polar regions provided several examples of nutritional illnesses,

including scurvy and possible hypervitaminosis A and lead poisoning.^{[9] [179]} More sophisticated nutritional analyses have been possible in recent expeditions,^{[149] [160]} and advances continue to be made in development of lightweight but nutritionally dense rations.^[39]

During the Canadian-Soviet transpolar ski trek, participants skiing some 20 km/day at a speed of about 3.5 km/hr while carrying 37- to 45-kg packs showed increased

Figure 9-3 Clothing is an important topic in polar medicine. A researcher prepares to go out for extended period in ambient temperature of -56.7°C (-70°F). Total weight of clothes 25 lbs. Notice multiple layers for each area of the body. (Courtesy Stephen Warren.)

strength, decreased body fat, and increased high-density lipoprotein (HDL) cholesterol. However, a paradoxical drop in aerobic power was noticed, perhaps because of intensive pretraining and conditioning, as well as the increased efficiency of skiing as the trip progressed.^[148] Monika Christensen's expedition reported a daily expenditure of roughly 3000 kcal but noted that the men on the expedition consumed up to 6000 kcal/day by the end of the 2 ½-month trip, possibly related to the drop in temperature from -5°C to -40°C (23°F to -40°F).^[25] Although strenuous expedition activities can require caloric intake of up to 7000 kcal/day,^{[101] [161]} the applicability of these figures to more sedentary polar sojourners is probably limited.

Infection and Epidemiology.

With particular reference to analogs in space colonies, a number of studies have taken advantage of the physical isolation of Antarctic stations as a natural laboratory for infectious disease epidemiology.^[28] For example, transmission of *Escherichia coli* has been shown to correlate with population structure.^[174] Since microorganisms are thought not to survive the cold long enough to be carried in by winds, midwinter respiratory tract infection outbreaks caused by parainfluenza viruses 1 and 3 and a rhinovirus in the absence of outside contacts have suggested that such organisms could persist in clothing or other fomites.^[128] A similar study using swabs of 28 men isolated for a year demonstrated that *Staphylococcus aureus*

could be temporarily suppressed but not permanently eradicated by antibacterial agents.^[82]

Despite a widely reported leukopenia and decrease in cell-mediated immunity during the isolation of over-wintering,^[184] it is not clear whether persons emerging from Antarctic stations are more susceptible to infection. One study of 125 new and 75 winter-over crew at McMurdo during a 1977 outbreak of adenovirus type 21 showed that during a further 5-week isolation period, 89% of the population were susceptible but only 15% were infected (much less than in usual outbreaks). No significant difference was found between winter-over crew and newcomers.^[150]

Circadian Rhythms, Endocrine Studies, and Sleep Research.

Pioneering studies of Natani^[111] and Shurley^[152] on sleep electroencephalograms at the old South Pole station demonstrated clear patterns of sleep disturbances and "free cycling" of the sleep-activity cycle. Some of these findings have been extended in more recent studies. For example, among four subjects at a small winter-over camp, summer sleep cycles synchronized within the group and with clock time. During 126 days of sunless winter, rhythms free cycled in all four people, and then resynchronized with reappearance of the sun.^[78] The degree of synchrony vs. free cycling appears to depend on a number of factors, notably zeitgeber strength, although the number of subjects studied has not been large.^[48]

A number of studies have examined the effect of prolonged polar residence on diurnal variations in the level of melatonin. Its important role in free radical scavenging and sleep regulation is beginning to be elucidated.^[122] Therapy with full-spectrum bright light (greater than 2500 lux) seems to facilitate daily resetting of the melatonin cycle.^[104] Other endocrine fluctuations also appear to be correlated with the length of the day.^[173]

Other endocrine studies have examined effects of prolonged residence in polar regions with a longer than diurnal time constant. Twenty-four-hour urinary excretion of catecholamines increases in the cold, but social stresses appear to overwhelm climatic determinants of catecholamine metabolism, correlating with increases in diastolic blood pressure and pulse during the year.^[14] A more consistent pattern of decreased free thyroid hormones after several months has been demonstrated by several groups.^[54] ^[134]

There has even been identified a pattern of increased pituitary release of thyroid-stimulating hormone in response to IV thyrotropin releasing hormone and increased serum clearance of orally administered triiodothyronine (T_3), dubbed the "polar T_3 syndrome,"^[135] but the clinical significance of these findings remains unclear.

Environmental Health Issues.

Because of Antarctica's isolation, it seems a particularly disturbing site for litter and pollution. As in the Arctic, events such as the early problems with a nuclear reactor at McMurdo (since removed) and the 1989 oil spill from the *Bahia Paraiso* near Palmer Station,^[115] and studies by groups such as Greenpeace, have focused attention on environmental health risks in the Antarctic.^[19] ^[113] Environmental inspections at a broad range of Antarctic stations have raised concern about toxic effluents and heavy metal residues,^[129] as well as radioisotopes used for research.^[145] In an attempt to address

these issues, a number of countries have begun to implement more responsible waste management policies.

Occupational Health and Injury Prevention.

Rigorous studies of risk are important for injury prevention. ^[49] Unfortunately, they are complex and often bedeviled by challenges, including controversial data, multiple variables, imprecise heuristics, and biases. For example, for purposes of occupational epidemiology, it may ultimately prove useful to stratify the Antarctic sojourner population into groups such as sport expeditions, military, commercial, and scientific, but the health behaviors of these groups overlap, and currently few studies have gone beyond aggregate descriptive statistics.

Even from these broad statistics, however, some figures emerge that may be useful cognitive anchors. Forty-five percent of medical cases in the Davis 1982 expedition were related to accidents. ^[34] A larger study of 1301 injuries among Australian expedition members found that 93% were minor, 3% were major, and 4% were environmental, working out to roughly one injury per person per year. ^[92] About 7% of the injuries were thought to be alcohol related. There were 16 fatalities from 1947 to 1999, but only one fatality in the past 10 years in the Australian Antarctic Program. Among 3500 scientists and support personnel (2000 person years), there were four medical deaths, two myocardial infarctions, one case of appendicitis, one perforated gastric ulcer, and one cerebral hemorrhage. The remainder of events were accidents involving falls, head injuries, hypothermia, drowning, crush injury, and burns. ^[98] There have been 57 deaths ^[93] in the U.S. Antarctic Program since 1946. Relative rankings by cause are aviation 61%, vehicles 11%, ships 7%, recreational 7%, station/industrial 5%, field activities 5%, and other 4%. ^[102] ^[144] ^[145] Other reports describe overuse, repetitive work syndromes, and noise pollution. ^[22] ^[68] Often, it is more difficult to adhere to standard occupational safety practices when in a remote location. ^[146] Environmentally related dermatologic problems may have an incidence of up to 40%. ^[91] ^[136] A recent report highlights the use of cyanoacrylate glue to hasten healing of disabling fingertip fissures. ^[11]

Fire Safety.

In the face of extreme cold, it is somewhat counterintuitive that fire has been labeled as "the major concern and principal danger at all Antarctic stations." ^[45] ^[114]

This initially surprising assessment rests on a number of factors. Cold temperatures severely limit the utility of water for fire suppression. Firefighting equipment may become inoperative in extreme cold, and frequent high winds can fan fires. The extremely low absolute humidity in many polar regions results in an even lower relative humidity when outside air is warmed in station dwellings. This in turn leads to an increase in static electricity and dryness of combustibles, already at risk from frequent

use of space heaters. Finally, alternative food and shelter are limited or nonexistent.

Elaborate predeployment training, frequent on-site drills, and a keen awareness of potential fire hazards have correlated with a satisfactory fire safety record to date, but this good fortune cannot be taken for granted. At least four major fires have occurred in Antarctica in the last 15 years.^[145] Fortunately, only one person died, but there were several injuries, and the Soviet Vostok winter crew had to endure 8 months without a power plant to supply heat.

Tourist Safety.

Polar regions are imbued with a sense of the exotic, conjuring up "images of hardship, personal valor, danger, adventure, and of course, the hero."^[145] As transportation increasingly opens up previously inaccessible areas, this image attracts growing tourist traffic and, with it, hot debate from both legal and environmental viewpoints.^[19]

The essential medicolegal issue is the extent of governmental organizations' responsibility for medical care of participants in nongovernmental activities, whether scientific, political, or commercial.^[145] When a tourist group requires aid beyond its own capabilities, whose responsibility is it? To what extent should a research station with limited medical supplies be required to divert some of those supplies to an individual who presumably bears responsibility for planning his or her own medical coverage?

Although the ethical course of action seems clear in the preceding scenarios, there is still uncertainty in our litigious society regarding the relative strengths of the Good Samaritan principle and the doctrine of assumed risk.^[62] Perhaps eventually there will be a mandatory rescue insurance policy for tourists similar to the one currently being adopted in Mt. Rainier and Denali National Parks^[166] ([Figure 9-4](#)).

Air Safety.

As in the Arctic, reliance on aircraft for transportation has highlighted the critical importance of air safety. The worst Antarctic air accident was the crash of an Air New Zealand tourist "flightseeing" DC-10 on Mt. Erebus in November 1979. This accident killed all 257 people aboard and effectively ended such flights, which had flown an estimated 11,000 tourists in the previous 2 years.^[9] There have been 35 air-related fatalities

Figure 9-4 Increased numbers of nongovernmental Antarctic expeditions have created increased awareness of the continent, as well as occasional requests for assistance. A lone traveler departs from South Pole in an attempt to do a solo traverse of Antarctica. (Courtesy Betty

Carlisle, MD.)

in the U.S. Antarctic Program since 1946 from crashes related to either fixed-wing or rotor aircraft.^{[102] [145]} A ski-equipped LC-130 Hercules crashed at the remote D-59 camp in 1971. Fortunately, none of the 10-crew members aboard were injured, but during a salvage operation in 1987 another LC-130 bringing supplies to D-59 crashed nearby, killing two and injuring nine.

Psychosocial Health Problems

For many polar living arrangements, psychosocial issues may be more important than strictly medical or environmental factors.^{*} Psychiatric problems are mentioned even in reports of early expeditions,^{[9] [168]} and almost any participant in expeditions will recognize Thor Heyerdahl's observation^[168] :

The most insidious danger on any expedition where men [sic] have to rub shoulders for weeks is a mental sickness that might be called "expedition fever"—a psychological condition which makes even the most peaceful person irritable, angry, furious, absolutely desperate because his perceptive capacity gradually shrinks until he sees only his companions' faults while their good qualities are no longer recorded by his grey matter.

In fact, as Shurley notes, "minor mental troubles are both common and temporary."^[151] This is particularly important because there is growing evidence that psychologic and somatic health issues are linked.^{[81] [125]} Stress can lead to increased risk of accidents, and conversely, the fear of medical emergencies can lead to increased stress.^[162] Confidence in the medical staff and facilities in isolated polar settings is a key factor in countering the concerns arising from isolation. In addition,

*References ^{[27] [37] [52] [136] [148] [159]} .

appropriate exercise facilities, opportunities for quality mental stimulation, and frequent contact with friends and family via the Internet and telephone can help maintain stability. However, data from the Australian National Antarctic Research Expedition (ANARE) do not suggest a higher incidence of psychiatric problems in Antarctica. In fact, "except for insomnia, which is perhaps endemic, it is lower than expected in the overall population."^[94]

Alcohol Abuse.

Adjustment to psychosocial stresses in polar communities depends on a complex array of sociocultural factors.^{[124] [163]} One coping mechanism is alcohol use. As in many isolated communities at high latitudes, alcohol use can disrupt and lubricate social interactions. At one station, annual per capita absolute alcohol consumption was

calculated at 16.9 L.^[184] At another, a summer support staff member had to be terminated because of alcohol abuse and two winter-over staff had to be prohibited from purchasing alcohol from the station store; one of these actually required disulfiram to ensure abstinence.

At many Antarctic stations, alcohol is easily available and may be subsidized. In some stations, rations can be excessive or nonexistent. Although relatively few serious incidents involving intoxicated staff have been reported, the potential for serious accidents remains real, particularly during winter when medical evacuation flights are impossible. Recommendations have called for routine monitoring of alcohol levels of anyone involved in an accident^[145] or even prohibition of alcohol at Antarctic stations.^[37] However, as with prohibition in other countries, this might create more problems than it might solve.

Psychoneuroimmunology.

The concept of psychologic or meteorologic modulation of immune function and other physiologic responses is gradually gaining some credence and remains largely unexplored. For example, perhaps an alternative explanation for leukopenia during winters is not absence of antigenic stimulation, as previously thought, but increased stress from interpersonal interactions.^[16] In the last few years, SAD has been largely accepted as a useful construct, and it will be intriguing to see if related findings, particularly by ex-Soviet station scientists, on weather-related pathophysiology are confirmed.

Psychologic stress at research stations may arise from several sources.^[5] ^[140] One is the environment itself; environmental severity has been found to be an independent predictor of hostility and anxiety after wintering over.^[124] Perhaps more important is the perception of the environment. Newcomers to the South Pole station are usually observed wearing a full 12-kg polar outfit at -20° C (-4° F) for several weeks after arrival. By midwinter, the same individuals may eventually think little of walking from the gym to their rooms dressed only in running shorts and T-shirt at -60° C (-76° F).

Stress can also result from disjunction between a person's original motivation for joining the program and realities of life in the station. Studies suggest that people who go to Antarctic stations to seek thrills or to challenge themselves often have more difficulty sustaining their motivation and performance than those who go to accomplish a scientific mission or even those primarily motivated to earn money. In general, older individuals who are somewhat introverted are able to set work goals and work toward them, and persons who have broadly defined hobby interests seem to cope better with the social isolation and dynamics of wintering over.^[37]

Small Group Dynamics.

In addition to external climate and internal motivational factors, stress can arise from interpersonal interactions. Although there are many exceptions, participants in the Antarctic program often speak of a tendency for personnel to form cliques or microcultures. People may cluster according to ordinary personal chemistry, along lines

of OAE (Old Antarctic Explorer) vs. novice, winter-over vs. summer status, or according to scientific, civilian, or military affiliation.^[39] With time, such social clusters can be a source of support or of friction. Nuances of body language and proximity can take on heightened significance,^[156] conferring a premium on social adaptability and compatibility. In an attempt to unify the core group, winter-overs participate in a mini Outward Bound type of group bonding experience before deployment.

Social isolation is of course an important factor in polar communities. Although this isolation has been lessened by modern communications and transportation, polar communities resemble in many ways the "asylums" studied by Goffman, "a place of residence and work where a large number of like-situated individuals, cut off from the wider society for an appreciable period of time, together lead an enclosed, formally administered round of life."^[50]

A number of studies have drawn parallels between group processes in polar stations and those in other isolated and confined environments, such as submarines or in space.^{[77] [112] [118] [181]} Unfortunately, much of the submarine data are a decade or more old, raising questions of temporal drift and external validity, and the astronaut programs seem to have had little real interest in psychologic issues and so have missed some opportunities for research in this field.^[168]

Winter-Over Syndrome.

Stressors such as those mentioned previously can result in what has been termed the winter-over syndrome. The historically oftmentioned

"Big Eye" or "20-foot stare in a 10-foot room" seems to be less common now, perhaps because the stations are increasingly comfortable and stimulating environments, but the constellation of depression, hostility, sleep disturbances, and impaired cognition seems to be both common and underreported.^[162]

The winter-over syndrome is not a static condition but a time- and individual-dependent process. At the South Pole research station, for example, winter-over staff characteristically report a recognizable pattern of fluctuating activity and mood. There is often a mixture of relief, pride, and fearful anticipation as the last LC-130 flight departs in mid-February, followed by a period of frenetic activity to beat inventory deadlines, file resupply orders, launch projects, and prepare the station for winter. As work and recreation routines develop, mood generally drops with the setting sun and increasing anticipation develops around the upcoming midwinter airdrop of "freshies" (fruits and vegetables), mail, and supplies. However, since the 1995-1996 season, regular airdrops have not been scheduled because of budgetary constraints. A possible benefit of the canceling of the midwinter airdrop may be a less severe August nadir that occurred after the excitement surrounding the airdrop faded. Finally, a rise in mood generally occurs toward the end of the year, although studies at the Australian stations at Mawson and

Macquarie Island suggest that the influx of new staff at station opening may actually be associated with increased depression.^[184] As usual, the convenience of a descriptive label does not guarantee explanatory or predictive power or validity.

Seasonal Affective Disorder.

A probable contributor to and confounder of the winter-over syndrome is the apparently fairly consistent exacerbation of stress and depression under conditions of winter or night. The term *seasonal affective disorder* was first used in 1984 by Rosenthal et al^[138]^[139] to describe the annual recurrence of bipolar affective disorder, hypersomnia, and overeating, which was alleviated by daily exposure to bright (2500 lux) light. Although correlations with melatonin levels have been demonstrated, the detailed pathophysiology of SAD remains an active area of inquiry and may involve retinal signal transduction, as well as timing of light intensity.* Sunlamps have been used informally in some Antarctic stations for years, and full-spectrum lighting has been installed in many public areas since 1987. Given the current indoor lighting and self-selection of winter-overs, SAD may be no more prevalent in Antarctica than at lower latitudes.

Beneficial Effects of Isolation.

An interesting point is that isolation may have positive and negative effects.^[67] Isolation is not synonymous with loneliness and depression, as Amundsen reported from his sojourn at Framheim.^[153] In one study it was found that, except for insomnia, the more severe the environment, the less severe the symptoms of depression, hostility, and anxiety.^[126] In fact, a subset of "professional isolates" may actually prefer polar stations to "normal" society.^[167]

Reentry.

An important issue familiar to many travelers and expedition members is that of reentry or social reintegration on return from a polar sojourn.^[140] Although several studies suggest that personality traits are fairly stable during a polar stay, station personnel often require 6 months or more to normalize after returning from Antarctica.^[168]

A question that has not been answered fully is whether subtle long-term disabilities might be induced by prolonged isolation at polar stations. Although there have been impressions of cognitive and sensory decrements after wintering over, these have not been confirmed in a number of studies.^[168] As for somatic complaints, a study of enlisted Navy personnel who wintered over between 1963 and 1973 found fewer hospitalizations for medical problems on follow-up than among a similar cohort who qualified for wintering over but did not actually go.^[6]

Screening and Selection.

Based on the preceding findings, several attempts have been made to refine the selection and screening process for successful polar sojourners.^[188] These efforts have used a number of methods and instruments to cope with the methodologic constraints

common to many studies of complex human systems.^[23] ^[53] ^[136] ^[168] Perhaps unsurprisingly, previous successful polar experience seems to be among the best predictors of subsequent high performance. In general, biographic data, peer ratings, psychometric testing, and interviews all seem helpful in selection, although each has weaknesses and inconsistencies.

Early studies led to the tripartite "ability, stability, compatibility" criteria for successful participation in the Antarctic programs.^[53] This simple but useful scheme recognizes that technical skill, emotional equilibrium, and interpersonal skills all play important roles in an individual's performance and internal satisfaction. It would be desirable to improve measurement and predictive usefulness of these factors; such studies remain an active frontier for Antarctic research.

OVERVIEW AND FUTURE DEVELOPMENTS

A point made early in this chapter was the challenge inherent in meaningfully synthesizing Arctic and Antarctic medicine. Reflection on some of the issues raised previously suggests several common areas of linkage and directions for future work.

Issues of Methodology and Medical Epistemology

The state of knowledge about the Arctic and the Antarctic is still rudimentary. Studies in polar settings are often handicapped by extremely difficult research conditions and may never achieve the statistical power and validity expected of counterparts in more forgiving climes. Commonly encountered methodologic problems include most notably small sample sizes, unknown effect sizes, measurement of proxy variables, and multiple confounders.

In one study, cold tolerance of five Antarctic divers and five nondivers at the station were compared during the year, using finger immersion tests with measurements of index finger pulp temperature, onset of cold-induced vasodilation, and pain scores.^[18] No difference was found between the groups, perhaps, as the authors suggest, because of either whole body cooling or insufficient cold exposure during dives. In another review, it was pointed out that simplifying assumptions of laboratory studies of cold adaptation may overlook the intermittent pattern of chilling and overheating under actual field conditions.^[20] In yet another report, cardiac and respiratory functions were measured in Antarctic expedition members during a 3-month summer sojourn, and no persistent changes were noted; the authors suggest that the degree and duration of cold exposure may have been inadequate to produce notable changes.^[189]

The preceding examples are offered not to level specific criticism; in fact, the studies were carefully performed and analyzed. As the authors themselves point out, however, inherent difficulties of research under polar conditions weaken the conclusions derived from it. Methodologic issues are perhaps even more complex in studies of social phenomena, such as group dynamics, task performance, or depression. In these situations, it may prove necessary to use multiple triangulating techniques of observational, qualitative, quasiexperimental, and experimental designs.^[26] ^[99] ^[168] Given the high cost of supporting studies in a polar setting,^[141] a major challenge is to design

studies that can uncover meaningful results despite limited resources.

Fourth World Medical Decision Making

Given the relative paucity of rigorous studies on polar medical phenomena, a second challenge is to optimally design polar medical practice. Polar medical lore is replete with stories such as that of the physician of the 6th Soviet Antarctic Expedition who performed an appendectomy on himself^[36] or those of retrospectively humorous cold-related injuries.^[111] Although the basic principles of emergency medicine, epidemiology, occupational health, psychology, and other disciplines still apply in polar settings,^[70] the spectrum of health problems and some important aspects of their management are undoubtedly skewed.^[132] As with attempts to improve health care in the so-called developing countries, wholesale transplantation of the U.S. model of medicine may prove inappropriate. As polar medicine continues to evolve,^[119] it will need to adapt the Western industrialized model to local conditions.

Fourth World medicine requires distillation of medical practice into a compact yet comprehensive package that will be robust enough to travel well. Novel constraints and the inherently unpredictable nature of a hostile environment further stretch the usual, already tentative rules and thresholds of medical decision making. Perhaps to a greater extent than in most settings, prevention and preparation are paramount in polar medicine. As might be imagined, the risks from even minor mishaps are exacerbated by cold and its effects on both humans and equipment, by altitude and impaired tissue oxygenation and wound healing, and by restricted dexterity and vision from bulky clothing. Isolation from medical facilities exerts a multiplier effect on these risks^[147]; a victim extrication and resuscitation that would be routine in most urban or suburban settings presents an overwhelming challenge in polar settings.

With lives at stake, arguments have been made for planning for worst-case scenarios rather than only for likely situations.^{[145] [146]} On the other hand, a realistic balance point on the cost/utility curve must be set for each situation based on estimated risks. As polar health care workers have strived to build facilities and offer care of the highest quality, there have even been proposals for such luxuries as anesthesiologist-staffed helicopters and regionalized extracorporeal circulation equipment for rewarming hypothermic patients.^[186] Such suggestions, although in line with the polar paradigm of projecting expertise into isolated regions, perhaps overemphasize therapeutic rather than preventive priorities. Given existing fiscal and logistic constraints, preventive measures should take priority over higher-cost options.

A recurrent medical issue in polar stations involves contingency planning and the optimum level of inventory. This question applies equally to drugs, equipment, training, and personnel and is faced immediately by any incoming physician. Given finite (even scarce) resources, space, and resupply, does the physician have enough X on station, has he or she completed enough training to handle Y, is there enough help available to take care of Z? "Just in time" principles of inventory management are not likely to be appropriate. This issue is well illustrated by the recurrent debate over whether to maintain a frozen blood bank at polar stations.^{[22] [67] [145] [146]}

A promising tool for both improved data gathering and medical diagnosis and treatment is informatics. When combined with improved communications systems, the computer offers a flexible and powerful solution to the problems of isolation.^[24] Telemedicine embraces

237

a broad range of possible activities. The advantages of rapid access to organized databases and remote consultations for radiology and other specialties via video are promising. Telemedicine is already in place and functioning in some northern Arctic regions. The Australian Antarctic Program has been using it successfully for a number of years.^[92] Physiologic, psychologic,^[169] and occupational health data^[120] can be monitored or retrieved, ultimately linking geography and information flow.

Chapter 10 - Pathophysiology of Heat-Related Illnesses

Stephen L. Gaffin
Daniel S. Moran

Since the publication of the third edition of this text in 1995, developments in immunology, molecular biology, and systemic and cell physiology have broadened the understanding of heat-related illnesses. A brief outline of a few advances that are opening new avenues of investigation serves as introduction to a more detailed discussion.

Systemic mechanisms underlying heatstroke based on recent studies of induced cellular tolerance to heat,^[233] organ blood flow,^[205] and hemodynamics in heatstroke^[269] are presented. New explanations of the causes and consequences of voluntary dehydration^[240] are explored along with the expected impact of water and salt depletion on normal physiology and exercise performance.

The demonstration that strenuous exercise can produce systemic endotoxemia^[52] ^[64] and that endotoxins and the cytokine cascade have been implicated in acute heatstroke^[56] and in other stressors, such as fear and even depressed mood,^[276] may open new avenues of diagnosis and treatment. We present an update to the classic systemic approach to understanding the physiologic dysfunction in heatstroke and, where possible, relate it to emerging shock models involving bacterial toxins and cytokines, such as tumor necrosis factor.

OVERVIEW OF HEAT ILLNESS

A characteristic property of warm-blooded animals is the ability to raise body temperatures greater than ambient temperature (T_{amb}). However, this property is not limited to vertebrates. For instance, eastern tent caterpillars can raise their body temperatures above T_{amb} by 30°C (86°F) or more, using solar radiation.^[100] Certain plants even produce heat; a philodendron flower may have a temperature as high as 46°C (115°F) at T_{amb} of 4°C (39.2°F).^[450]

Accidental overheating is a danger in all organisms, but sometimes in nature, overheating is intentional and used as a weapon. Hornets occasionally attack the hives of Japanese honeybees. In response, scores of bees crowd closely around the invading hornet to form a "ball of bees" several layers thick. The bees vibrate their muscles rapidly, raising their own core temperature (T_c), which in turn heats the hornet to approximately 43.3°C (110°F). The hornet dies of "heatstroke"; the bees are relatively heat-tolerant and survive.

In humans and probably most animals, hyperthermia is not always painful and may even induce euphoria. It is this lack of a pain warning that is the major facilitator of heat illnesses. As a result, an athlete or soldier may choose to continue performing severe exercise in the heat, even as the risk of heat injury increases.

It is convenient to classify the more familiar heat disorders such as heat syncope, heat exhaustion (including that induced by exertion, and water or salt depletion), heat cramps, and classic and exertional heatstroke (EHS) into separate, well-defined categories. Even so, the symptoms often overlap.

HEAT STRESS AND THERMOREGULATION

Mechanisms of Heat Transfer

The human body obeys the laws of thermodynamics, as heat is transferred from a higher to a lower temperature. Applying these principles, Santee and Gonzalez^[433] and Gonzalez^[193] provide excellent discourse on characteristics of the thermal environment, the biophysics of heat transfer, the heat balance equation, and clothing considerations. When environmental temperature is higher than skin temperature, the body gains heat; when it is lower, the body loses heat. As a result, elevated environmental temperature adds to the heat burden of the body and interferes with heat dissipation. There are four mechanisms of heat transfer: conduction, convection, radiation, and evaporation. The environmental parameters that determine the potential for heat exchange constitute the thermal environment, which has been defined as "a biophysical aggregate of air temperature, wind speed, relative humidity, and radiation."^[492]

Conduction.

Conduction is heat exchange between two surfaces in direct contact. Since the areas are usually small (feet in contact with the ground) during the day in most mammals, conduction is generally the least important in quantitative terms, and behavioral thermoregulation generally intervenes (e.g., wearing of insulated boots while walking on hot desert sand). However, lying uninsulated while sleeping on either hot or cold ground can result in significant heat exchange, especially in a person under the influence of vasodilating drugs or alcohol. A person can usually hold the handle of a very hot cooking pot with a dry towel (containing

a large number of tiny cells filled with air) without discomfort. However, if the towel is wet (the cells are filled with water), it rapidly heats up because conduction of heat through water is much faster (32 times) than through air. Within a few seconds the pot becomes too hot to hold.

Convection.

Convective heat exchange refers to heat transferred from a surface to a gas or fluid, usually air or water. It is a more complex process than conduction because the medium of heat transfer (air or water) is usually moving. The rate of heat exchange by

convection depends on many variables, including the density of the fluid (e.g., water vs. air), the temperature gradient, the surface area exposed, and the flow rate of the fluid. Heat loss during cold water immersion is faster than standing nude in air because of the high thermal capacity of water, the greater body surface exposed, and the greater thermal conductivity of water.^[400] ^[406] Convective heat exchange varies with velocity of air movement. As T_{amb} rises to approach skin temperature (T_{sk}), heat loss becomes minimal. Once air temperature exceeds mean skin temperature, heat is gained by the body. Loose-fitting clothing maximizes convective and evaporative heat loss. By the same token, body motion alters heat exchange by convection both within (the air pocket between the skin surface and fabric) and on the surface of clothing.

Radiation.

Radiation refers to the transfer of heat between the body and its surroundings by electromagnetic waves. All matter absorbs and emits thermal radiation,^[471] which is the "radiant energy emitted by a medium that is due solely to the temperature of the medium." Clothing reduces the radiant heat impinging on the skin from industrial sources (e.g., boilers and motors), as well as the solar load in broad daylight. Solar load is a major source of heat gain in hot climates—up to 250 kcal/hr in a seminude man^[185] (approximately the same as walking; see later discussion) and 100 kcal/hr in a clothed man. The amount varies with the angle of the sun, season, clouds, and other factors. Concurrently, clothing affects the evaporative process.

Highly pigmented skin is protected from ultraviolet radiation, but it absorbs approximately 20% more heat than does nonpigmented or relatively nonpigmented skin.^[274] Increasing blood flow to the skin (BF_{sk} , at $T_{sk} > T_{amb}$) maximizes heat loss from the skin^[219] ^[420] by convection and radiation. Although heat is carried by convection and conduction from the body core to the skin, the main role of elevated BF_{sk} in a warm environment is to deliver the heat necessary to vaporize sweat.^[189]

Evaporative Cooling.

Evaporative, "wet," or insensible heat exchange is usually a one-way heat flow from a body surface to the environment. The heat of vaporization (2.45 J/kg) is "absorbed" slowly with an undetectable change in temperature of the skin or blood. As water is converted from a liquid to a gaseous state in insensible heat exchange, the rate of evaporation of water from the skin, and hence the cooling effect, is proportional to the difference between vapor pressures of water in sweat on the skin surface and that of the surrounding air. A lowered NaCl concentration in sweat increases this difference, hence increasing the rate of evaporation. Since acclimatization leads to lower sweat NaCl concentrations, this increases the sweat evaporation rate.^[231]

If the body is unable to maintain thermal equilibrium by radiation, convection, and conduction and core temperature rises, sweating must occur to permit heat loss by vaporization of water.^[189] Evaporative heat loss is accompanied by the loss of 580 kcal/L of water evaporated or heat loss of approximately 1 kcal/1.7 ml of sweat vaporized.

Since rates of gastric emptying and delivery of water to the intestines can exceed 1 L/hr, a 1 L/hr sweat rate appears sustainable without significant dehydration if fluid is consumed. Higher sweat rates (e.g., 1500 ml/hr) could theoretically achieve greater rates of heat loss (1500 ml/1.7 ml/kcal = 882 kcal) but are almost never achieved because some of the sweat drips off the skin and thus has no cooling effect. Moreover, these high sweat rates are often at the expense of total body water, since gastric emptying does not keep pace. Knochel^[288] has estimated that 650 kcal/hr is a more reasonable figure for an upper limit of heat dissipation.

Certain parts of the body surface are more important than others in providing cooling through sweating. The scalp, face, and upper torso are most important. Only about 25% of total sweat is produced by the lower limbs.^[512] Therefore, although wearing a shirt may be critical in the development of heat illness, wearing long or short pants is much less important. The wearing of protective headgear may be most important in the development of heat illness, as shown by a training exercise. In bareheaded persons, the exercise was merely grueling, but 33% of those wearing hats suffered heat illness casualties,^[224] as cited in Porter.^[397]

The maximum rate of sweat vaporization depends on air dryness and movement. In a hot climate, the limit to heat dissipation is a function of sweat rate and the "atmospheric cooling power," or maximal evaporative cooling capacity of the environment.^{[190] [440]} The environment's capacity to vaporize sweat varies primarily with humidity and also with wind velocity. As humidity approaches 100%, evaporative heat loss is minimized. The major effect of wind occurs in humid environments at a velocity between 0.5 and 5 m/sec.^[141] Sweat that drips from the body provides no cooling, and sweat evaporated from clothing is considerably less efficient than sweat evaporated directly from

skin.^[141] Risk of hyperthermia increases with air temperature and humidity. As a result, military trainers and coaches tend to conduct early morning runs to avoid high T_{amb} and the increased incidence of heat illness in humid climates, despite the lower dry bulb temperatures (T_{db}). Sutton^[482] pointed out that EHS is reported with increasing frequency during "fun runs" and marathons when the temperature is not particularly hot. This reinforces the simple definition that exertion-induced heatstroke occurs whenever the rate of heat production of an exercising individual exceeds the rate of heat loss, causing body temperature to rise to critical levels.

Heat Stress Indexes.

The ability to work in a hot environment is inversely related to the prevailing heat stress level; the higher the heat stress level, the shorter the ability to carry out work and the greater the risk of heat illness. Safety in a hostile environment depends on following strict rules and limitations concerning exposure time and work intensity. The need for a quantitative index that combines environmental heat stress factors to provide a reliable

and consistent correlation with the induced physiologic strain was recognized 100 years ago.^[203]

In 1905, Haldane suggested the use of wet bulb temperature (T_w) as an index of the severity of a warm environment in Cornish tin mines.^[203] T_w is lower than T_{db} because of the cooling effect of evaporation of water from the thermometer, which in turn, varies inversely with relative humidity (RH). However, the relationship between T_w and physiologic strain (rises in T_c , HR, respiratory rate, etc.) was not valid at high-humidity levels and in hot-dry climates.^[33] In 1923, Houghten and Yaglou^[238] developed the effective temperature (ET) index to define thermal comfort limits. This index was a combination of T_w , T_{amb} , and wind velocity (Va), and produced an equivalent thermal sensation. However, several deficiencies were recognized, including overestimation of the effects of T_{amb} at high temperatures and underestimation of Va in hot-wet climates.^[33]

In 1957, Yaglou and Minard^[535] suggested the wet bulb globe temperature (WBGT) index, which consisted of combining T_{amb} , T_w , and black globe temperature (T_g) according to unequal weights:

For outdoor use: $WBGT = 0.7T_w + 0.2T_g + 0.1T_{amb}$

For indoor use: $WBGT = 0.7T_w + 0.3T_{amb}$

However, calculation of WBGT involves measuring T_g from a thermometer surrounded by a 6-inch blackened sphere, which is inconvenient and not practical under many circumstances. Nevertheless, the WBGT index is the most widely used index to describe environmental heat stress for outdoor and indoor use and is used for setting limits of U.S. military training exercises in hot weather.^{[69] [117]} It is also used to set limits in industrial plants,^[369] by sports associations as guidance to prevent heat injury,^{[33] [337]} and by workers in different occupations as a safety index.^{[83] [164] [202] [463]} However, WBGT is limited for two main reasons: (1) it cannot be applied to persons wearing different types of clothing (e.g., protective clothing), and (2) measuring T_g is inconvenient.

Wearing protective clothing imposes a higher heat stress equivalent to adding 6° to 11° C (10.8° to 19.8° F) to the WBGT index.^[392] As a result, for WBGT to accurately reflect environmental stress, corrections and adjustments must be made for the type of clothing worn and the metabolic rate.^{[228] [271]}

Thus attempts were made to develop alternatives to WBGT. In 1971, Botsford^[53] suggested the wet globe thermometer (WGT), known also as the Botsball, which combined measuring T_{amb} , T_w , and radiation into a single reading. Unfortunately, the WGT index did not provide adequate precision values for hot climates, and its readings were significantly lower than the WBGT index.^[335]

In 1962, Sohar et al^[470] suggested the discomfort index (DI), using a combination of T_{amb} and T_w , which has been used extensively in Israel. However, a recently modified DI

(MDI) suggested altering constants to the parameters T_{amb} and T_w to achieve a better correlation with the WBGT index.^[349] However, uncertainties in the radiation component in any heat stress index would limit its assessment (e.g., solar radiation measurement for the shade vs. open sky). The most widely used WBGT index is computed from three separate environmental measurements, and the equipment to measure this index is cumbersome and more suited to a fixed-site station than a mobile situation. Furthermore, measuring T_g by a black globe thermometer requires about 30 minutes for the instrument to reach equilibrium. Thus the need for a reliable portable field instrument for measurement of this heat stress index in a mobile situation (e.g., training in the field) is essential.

In a Marine training base with 17,000 to 25,000 recruits per year, clinical studies from the 1950s reported a large number of heat casualties occurring upon strenuous physical exercise when the WBGT was higher than 26.7° C (80° F).^[344] As a result, new regulations and guidelines were implemented for different heat categories, which reduced the numbers of casualties. However, Kark et al.^[266] reported 1425 cases of exertional heat illness during the period of 1982–1991 and showed that 25% of the cases occurred between 7:00 to 9:00 AM at WBGT level of 26.7° C. These cases occurred in spite of the preventive measures taken on Parris Island, South Carolina, which involved rescheduling of training and physical activity according to newly categorized WBGT values. In addition, further attention was given to clothing, equipment, workloads, and hydration. Exertional heat illnesses continue to be a common problem during training in a warm environment despite preventive

measures taken.^[266] The WBGT index provides for measurement of heat load, but its practical application in current army doctrine is limited. If the "weather station" was alongside the trainees at the training site and the environmental measurements were taken continuously and not every hour, this might help in preventing some of the heat casualties.

Work and sports in a hot environment require a fairly accurate measurement of the stress index to prevent heat illnesses and to determine safety behavior patterns (e.g., water consumption rates and work/rest cycles). To implement the current guidelines and limitations for exercise in a hot climate, there is great need for development of an accurate, portable heat stress measurement device. We suggest that current technology, including very small electronic sensors to measure T_{amb} and RH, a miniature display, and a miniature programmable microprocessor for calculating and storing the MDI index, in a wristwatch format are already available to devise a new portable heat stress monitor. Such a tool could help in the decision-making process relating to permissible strain when working in a hostile environment, for use by medical monitors, leaders, or others directly exposed to heat stress. These measures would clearly help prevent heat illnesses and would decrease the dependency on weather station reports.

Temperature Regulation (See Also [Chapter 11](#) and [Box 10-1](#))

To prevent or appropriately manage heat illness, the clinician must understand thermal stress^[161] and human thermoregulation.^{[189] [214] [480]} Temperature regulation refers to both behavioral and autonomic thermoregulatory processes that modify the rates of heat production by shivering and variations in basal metabolism, and heat loss by sweating and peripheral vasomotor tone.^[189] These processes act to maintain the temperature of the body within a restricted range with a variable internal or external heat load. The regulated temperature is generally considered that of the "body core," or T_c .

Behavioral Thermoregulation.

Hyperthermia appears to represent a more serious problem than hypothermia, since humans have developed a greater capacity for heat elimination (vasodilation, sweating) than for heat conservation (vasoconstriction).^{[159] [214]} To live, work, and reproduce successfully in arid or tropical climates, humans depend not only on physiologic mechanisms to acclimatize to heat but also on behavioral responses to assist temperature regulation. Thus humans possess two control systems (behavioral and physiologic) to regulate body temperature.

Although behavioral responses augmenting shivering seem obvious in a cold environment (e.g., seeking shelter, wearing clothes, and building fires), behavioral factors for thermoregulation in the heat (resting in the heat of the day, seeking shade or water when thirsty) are also important. Behavioral responses are conscious actions, and therefore the subjective sensations of thermal discomfort inducing the behavior anticipate actual changes in T_c .^[102]

**Box 10-1. COMMONLY HELD
FALLACIES REGARDING HEAT
ILLNESS***

1. The sine qua non for diagnosis of heatstroke includes hot, dry skin; temperature greater than 42° C; and coma.
2. Unlimited access to fluids allows the exercising individual to maintain adequate hydration despite heat stress.
3. Development of salt depletion heat exhaustion requires 4 to 5 days of exposure to marked heat stress.
4. Consumption of commercially available electrolyte-containing beverages during exercise in the heat tends to return plasma potassium levels to resting values.
5. The primary underlying mechanisms for the development of heat cramps are hypokalemia and hypovolemia.
6. Consumption of excessive volumes of fluid to the point of development of nausea promotes the maximal clearance of free water by the kidneys.
7. When the patient is evaluated in the emergency department, a normal body temperature when combined with normal serum transaminases precludes the diagnosis of heatstroke.
8. The most physiologically appropriate method to achieve rapid reduction in body temperature from hyperthermia is the use of warm air spray.
9. The risk of dilutional hyponatremia should preclude consumption of fluids in the absence of thirst.
10. Endotoxemia is a rare complication of ultramarathon running in the heat.
11. Review of the medical literature reveals that an individual sustaining a single episode of heatstroke remains at increased risk for future heat injury.
12. A high degree of aerobic

11. Review of the medical literature reveals that an individual sustaining a single episode of heatstroke remains at increased risk for future heat injury.
12. A high degree of aerobic conditioning, when combined with an appropriate period of heat acclimation, prevents the development of heat illness.
13. Adherence to published guidelines using wet bulb globe temperature to modify physical activity in the heat prevents the development of heat illness.
14. Carpopedal spasm is a relatively rare complication of exercise-induced heat exhaustion.
15. Violent shivering is a common complication in response to whole body cooling of patients with heat exhaustion.

*These fallacies are discussed in greater detail later in the chapter.

Heat Production.

The basal metabolic rate of the average (70 kg) man in a sitting position amounts to approximately 50 to 60 kcal/hr/m² of body surface area or 100 kcal/hr.^[292] With increased activity, metabolic heat production increases significantly (walking produces

244

250 to 300 kcal/hr; walking rapidly with a load, up to 400 to 450 kcal/hr) and may reach 20 times baseline level with strenuous exertion. Depending on the exercise task, usually 70% to 85% of the metabolic rate is released as heat that must be dissipated to maintain thermal balance. If there were no means to dissipate heat, the addition of 70 kcal to a 70-kg person would theoretically be able to increase core temperature approximately 0.8° C (1.4° F), assuming the average specific heat of the human body is 0.8 (kcal/kg/° C). Cellular metabolism increases 13% for each 1° C (1.8° F) rise in temperature until the body approaches heatstroke temperature; at that point, cellular metabolism increases more rapidly. It is 50% above normal at 40.6° C (105.1° F).^[71]

Body Temperature Ranges.

Normal internal temperatures range from 36° to 38° C (96.8° to 100.4° F), whereas the limits of body temperature for efficient thermoregulation are 35° to 40° C (95° to 104° F).^[479] However, during athletic events, T_c increases to 40° to 42° C (104° to 107.6°

F).^[120] ^[356] ^[532] One marathoner was able to maintain a T_c greater than 41.5°C (106.7°F) for at least 44 minutes during a race.^[329] Survival limits of body temperatures are exceptions to these ranges. For example, one heatstroke victim survived a measured T_c of 46.5°C (115.7°F).^[466]

Sensing, Relaying, and Central Integration Functions.

Physiologic temperature regulation involves detecting changes in body temperature by sensory mechanisms and relaying thermal signals from central and peripheral locations to a central integrative area. This directs effector organs to increase or decrease heat storage appropriately^[189] and is mediated by the autonomic nervous system. Sensitive nerve endings within the hypothalamus and near the skin surface of most of the body act as thermoreceptors^[224] ^[361] to monitor T_c and T_{sk} .

The primary means of regulating T_c are (1) vasomotor alterations in blood flow and its distribution, (2) shivering, and (3) sweating. The threshold temperatures for sweating, BF_{sk} , and forearm venous volume depend on both T_c and T_{sk} . Heating the skin lowers these threshold temperatures.^[94] ^[438] ^[517] At any given T_c heating the skin increases the effector response. Mathematical modeling suggests that T_c is nine times as important as T_{sk} in the reflex control of BF_{sk} .^[436] However, the importance of T_{sk} should not be minimized; whereas T_c varies over a narrow range of 7°C (12.6°F), the variation in T_{sk} is threefold to fourfold as great, enabling the system to accommodate to a wide range of environmental temperatures.

During exercise, an increase in T_c elicits an effector response (sweating) with only a minimal change in T_{sk} . The rise in body temperature is proportional to the increased metabolic rate and does not depend on T_{amb} over a wide range.^[368] However, as anyone who has experienced heat exhaustion knows, this relationship does not hold under extremely hot or humid conditions or conditions of maximum effort. This disparity between theory and common experience gave rise to the concept of "prescriptive zone," or a set of conditions in which the magnitude of the core temperature response for everyday work was independent of the environmental temperature.^[314]

The preoptic area of the anterior hypothalamus of the brain is generally believed to be the primary site for integration and generation of a "thermal command signal." This area contains many neurons that alter their firing rate in response to warming or cooling.^[57] The brain is well perfused relative to its mass and responds rapidly to only a few tenths of 1°C (1.8°F) change in blood temperature.^[40] ^[41]

Sweating and skin vasodilation increased linearly above a "set point" temperature of approximately 37°C (98.6°F).^[40] ^[41] Local heating accelerates sweating. Thus central and peripheral mechanisms cause sweating when skin temperature is elevated. Local heating may result in a greater release of neurotransmitter for a given sudomotor signal,^[137] or heating increases the sensitivity of the gland to a given dose of neurotransmitter.^[376] Conversely, lower skin temperatures may inhibit sweating during

exercise.^[40] Since sweating is not completely abolished by cervical cord transection, spinal centers for temperature regulation appear to contribute.^[491]

Set Point Hypothesis.

The concept that the central nervous system is a functional interface ("central integrative area") between the thermosensors and thermoregulatory effectors is not accepted by all physiologists.^[461] However, it provides a rationale for envisioning a thermostat, or "set point," that shifts all effector thresholds in the same direction.^[189] This concept of a central thermostat provides a conceptual framework that fits a variety of situations.

The principal mechanisms involved in temperature regulation during exercise in the heat are venodilation, increased BF_{sk} , and sweating. Dilation of superficial veins increases the efficiency of heat flow from the core to skin and increases the time available for heat transfer between the blood and skin. The cutaneous vasculature is therefore an effector system in thermoregulation because BF_{sk} controls the rate of heat transfer between the body core and surface.^[189] ^[420] Unless the rate of heat storage exceeds the capacity of the thermoregulatory system (e.g., a breakdown of heat dissipation mechanisms), effector responses will increase until heat balance is restored.

Vasomotor System.

The term vasomotor system refers only to the arterioles that control organ blood flow, vascular resistance, and arterial blood pressure.^[420] Since arterioles

and the heart together regulate blood pressure, a change in blood pressure is corrected by changes in vascular resistance or cardiac output (CO).^[189] ^[215] ^[420] Vasomotor adjustments optimize and regulate the distribution of CO within and between different organ systems. Central thermal receptors alter vasomotor outflow to redirect blood flow to the skin. BF_{sk} in humans exposed to cold can be reduced to 1 ml/100g skin/min and can increase during maximal heat stress to 150 ml/100g skin/min, greater in the extremities than in the trunk.^[231]

Blood flow to the skin is under dual vasomotor control. In the cold, adrenergic vasoconstrictor fibers reduce skin blood flow.^[160] However, during heat exposure, blood flow increases to the hands, lips, nose, and ears as a result of vasodilation, largely because of the withdrawal of vasoconstrictor tone.^[160] Active sympathetic vasodilation over most of the skin area^[421] reduces vascular resistance below basal tone. There is a relationship between active sympathetic vasodilation and sweating, perhaps through the release of vasoactive intestinal polypeptide (VIP).^[498] The simultaneous release of both transmitters (VIP and acetylcholine) could help explain the apparent relationship

between eccrine sweat secretion and cutaneous vasodilation.^[320]

Venomotor System.

The venomotor system controls the veins; it should be noted, however, that there is a dual venous drainage of the limbs. The deep veins draining mainly from the muscles have relatively poor sympathetic innervation,^[510] whereas the superficial veins draining the skin are richly innervated. Although venodilation and increased BF_{sk} enhance heat transfer,^[192] they increase the amount of blood pooled in compliant peripheral vessels. As a consequence, filling of these veins reduces central blood volume; at some point, the redistribution of blood could compromise venous return and cardiac filling.^{[420] [421]} This system may be altered by fundamental changes in the smooth muscles of the various vessels. Heat increases the speed and extent of contraction of femoral arteries to K^+ and catecholamines (i.e., increases vascular resistance) and may therefore inappropriately slow blood flow to and from the extremities.^[382]

CLASSIC HEATSTROKE

The pathologic features of heatstroke are similar irrespective of the cause of the heat illness and are manifested by swelling and degeneration of tissue and cell structures, and widespread microscopic to massive hemorrhages. ^[456] Most organs are congested, with increased masses and swollen cells. In the gastrointestinal tract, postmortem examination often shows massive ulcerations, hemorrhages, and engorged intestinal vessels. ^[456] A discussion of the gut is important in any discussion of heat illness for two reasons: (1) its function determines whether ingested fluid and solutes are delivered to the systemic circulation to correct losses and thereby attenuate hyperthermia, dehydration, and reductions in splanchnic blood flow and gut distress; and (2) heatstroke may result from or be exacerbated by gastrointestinal dysfunction, leading to "leakage" of gut-derived endotoxin into the circulation, endotoxemia, and circulatory collapse. There is an equivalence between the rehydration demand, the capacity of the stomach to deliver water (gastric emptying under optimal conditions can provide 1.8 L/hr) and the intestine to absorb (1.4 to 2.2 L/hr) ingested fluids.

Classic heatstroke occurs when environmental heat stress is maximal. ^[134] ^[216] ^[476] Populations at risk include the elderly, the poor (who lack adequate air conditioning), those who suffer from malnutrition, and those who have chronic diseases or substance addiction. ^[216] In classic heatstroke, in contrast to EHS, physical effort is *not* a primary determinant of excessive heat storage and therefore the onset of classic heatstroke is slower. Predisposing factors commonly intervene over days rather than minutes or hours. As a result, there is often ample time for fluid and electrolyte imbalances to develop.

Under some circumstances, passive hyperthermia can develop rapidly in extremely hot environments, such as when infants and small children are left in locked vehicles in the summer heat. This is also true for adults who are passengers in improperly ventilated or non-air-conditioned vehicles. Within minutes under desert conditions, cabins and cargo spaces of vehicles can reach 54° to 60° C (129.2° to 140° F), depending on environmental temperature (T_{amb}) and solar radiation. ^[242] Similar high temperatures may occur in closed or confined spaces, such as enclosed attics, or in places where there is a high radiant load from machinery or power plants, such as boiler rooms. ^[292] Individuals who depend on others for fluid intake because of age (the very young or the elderly) or illness are at risk of involuntary dehydration. Infants are more heat labile because of their immature thermoregulatory systems. ^[442] (See later discussion of thermoregulation in children.)

Epidemiology—Heat Waves

When environmental heat stress is maximal, strenuous exercise is not necessary to produce heat illness.^{[134] [195] [216] [476]} In Peking in 1743, a heat wave reportedly caused 11,000 deaths^[456] ; 411 cases of severe heatstroke in Nanjing were reported.^[326] During the July 1996 Atlanta Olympics there were 1059 heat casualties reported, of which 88.9% were spectators and volunteers.^[520] In a separate heat wave,^[150] 42 of 44 cases occurred within 8 consecutive days during which the maximum ambient temperature varied from 38.9° to 41.1° C (102° to 106° F). The patients' local environment temperatures were probably much higher, since air conditioning was not widely available at the time.

Only 7 of 44 persons were less than 50 years of age, and the greatest frequency of age distribution was in the range of 60 to 70 years.

In Boulder City, Nevada, July 8 to 18, 1936, T_{amb} reached higher than 38.3° C (100.9° F) daily. Forty-four heatstroke victims were admitted to the Boulder City Hospital with progressively increasing daily admission rates during that period.^[119] The increasing number of admissions over time suggests that there is a progressive deterioration of the body with prolonged hot weather. This may be related to elevated cytokine levels. In a different heat wave near Dallas, Texas, lasting 26 days, the first case occurred on day 10 of the heat wave and the last case occurred 10 days after the end of the heat wave, with half the cases (14 of 28) occurring over a 3-day period on days 20 to 22. Age was a factor in both heat waves, with 8 of 72 victims above 80 years of age, and a mean age of 59 years in Boulder City and 70.5 years in Dallas. Alcoholism and degenerative diseases were contributing factors in both waves. The victims characteristically had a high rectal temperature (T_{re}) and dry skin, and half of the Boulder City patients and 24 of 28 Dallas patients were comatose. Of the 44 Boulder City patients, 23 showed a fiery red skin rash over the body, particularly over the chest, abdomen, and back.^[119] The most common presentation in Dallas patients was that of respiratory alkalosis, often accompanied by metabolic acidosis.^[216] All Dallas patients with blood lactate greater than only 3.3 mMol/L (normal range 0.6 to 1.8 mMol/L) suffered a poor outcome, whereas those with initial lactate less than 3 mMol/L did well. That is, what in exercise studies would be only modest elevations in blood lactate become adverse prognostic indicators in classical heatstroke. Furthermore, 9 of 28 classic heatstroke patients arriving with normal serum potassium subsequently became hypokalemic, and all victims were hypokalemic at some point in their course.^[216]

A heat wave in Chicago in July 1995 resulted in more than 600 deaths, and more than 3300 emergency department visits and intensive care unit admissions for near-fatal heatstroke. In a group of 58 of these victims with classic heatstroke, 100% experienced multiorgan dysfunction with neurologic impairment, 52% showed moderate to severe renal insufficiency, 45% had disseminated intravascular coagulopathy, and 10% had acute respiratory distress syndrome. Fifty-seven percent of the victims had infections on

admission. In-hospital mortality was 21%.^[112]

During a July 1988 heat wave in Nanjing, at least 4500 cases of heat illness cases were treated, with 411 of them classified severe.^[538] (See [Table 10-1](#) and [Box 10-2](#).) The mean age for males and females was 69.5 and 75.6 years, respectively, and persons over 60 years of age accounted for 77.4% of total deaths. Interestingly, some of these victims showed severe *overhydration*,

TABLE 10-1 -- Core Temperature of Heatstroke Victims in Nanjing, July 1988

T_c ON ADMISSION (° C)	DEATH RATE (%)	NUMBER OF DEATHS*
<39	11.5	52
39–39.9	13.4	112
40–40.9	31.0	126
41–41.9	40.0	85
>42	83.3	36

Data from Zhi-cheng M, Yi-tang W: Chinese Med J 104:256, 1991.

*Overall deaths = 124/411 (30.2%). Victims older than 60 years accounted for 77.4% of all deaths.

with electrolyte values falling to as low as Na⁺ 98, K⁺ 2.1, Ca²⁺ 1.52, and Cl⁻ 97.4 mMol/L.

During 5 heat wave years (1952–1955 and 1966) the average number of heatstroke or heat exhaustion deaths in the United States jumped from 179 to 820 deaths per year.^[138]^[139] In addition, the number of deaths classified as heat-precipitated was more than 8000 during heat wave years. There appears to be a reluctance to

certify heatstroke or heat exhaustion as a cause of death, and epidemiologic estimates of the incidence are probably conservative.^[456] As an example, heat-related death rates in the Chicago July 1995 heat wave were calculated by two methods: classification of heat-related deaths by the Cook County Medical Examiner's Office (CCMEO) and the excess mortality rates based on total mortality differentials during and before the heat wave. This analysis showed an underestimation of heat-related deaths in areas with high death rates. These results indicate that current practice does not adequately measure actual heat-related deaths. Nevertheless, those numbers may still be practical to use as an indicator to target specific communities for prevention and relief efforts.^[455]

Hyperthermia commonly occurs in the presence of numerous and varied host factors.^[27]^[242] These include many that affect thermoregulation through altering heat loss mechanisms (e.g., lack of acclimatization, fatigue, lack of sleep, dehydration, skin disorders), whereas others contribute to heat production (e.g., obesity, lack of physical fitness, dehydration, febrile illness, sustained exercise).

Classic heatstroke tends to be a disease of the elderly, the alcoholic, and the infirm. EHS is different, typically affecting young, healthy, and even euhydrated men and women during exercise, and is a syndrome involving hyperventilation and respiratory alkalosis.^[59]

EXERTIONAL HEATSTROKE

Physical training increases heat tolerance, whereas a sedentary lifestyle decreases it. A sedentary lifestyle leads to a loss of muscle protein and strength and gain of fat. As a result, more energy is required to carry out any given physical task per gram of body mass, consequently increasing metabolic heat production. Physical training improves tolerance to heat mainly by improving efficiency of the cardiovascular system, increasing the rate of sweat production, and reducing the threshold T_c at which cooling mechanisms are activated. ^[16]

Within certain body temperature limits, normal thermoregulatory mechanisms are capable of restoring T_c to 37° C (98.6° F) from either hyperthermia or hypothermia. However, if T_c rises to approximately 42° C (107.6° F), then metabolic pathways may be so altered that inappropriate physiologic responses occur. Vascular collapse, shock, and death can follow unless countermeasures such as cooling and volume therapy are initiated. It is not certain whether there is a single critical intracellular derangement occurring at 42° C that ultimately leads to the activation of many harmful metabolic pathways and heatstroke death, or if several harmful pathways become established independently at about the same time in response to the given T_c .

EHS often affects fit and highly motivated individuals participating in sporting events or undergoing performance tests, such as those for military recruits and firefighter and police officer candidates. There will be increases in exertional heat illness because of the increased numbers of individuals participating in sports ^[216] ^[288] ^[289] and fitness activities, such as jogging, ^[212] fun-running, ^[246] ^[367] ^[408] ^[483] bicycling, ^[456] and long-distance sporting events. ^[215] ^[532] For example, an estimated 25 million Americans and 1 million Canadians participate in organized road races annually. ^[216]

EHS has been reported during every season, even in winter. During a winter night a father totally covered his 9-month-old infant with a blanket and a thick quilt because its crying disturbed his sleep. In the morning the child was found dead with many petechial hemorrhages in the upper chest and thoracic viscera, the blood was concentrated (indicating dehydration), and the bedclothes were extremely wet with sweat. This was listed as an accidental death resulting from exertional self-overheating in bed. ^[539]

Heat Storage Rate

A temperature of 40.4° C (104.7° F) represents a threshold hyperthermia above which heatstroke mortalities occur in exercised, heat-stressed rats. ^[244] ^[245] The increase in an individual's heat storage, as shown by a rise in T_c , may be rapid (minutes to hours) and

metabolic in origin because of overloaded heat loss mechanisms. For brief periods of intense effort, heat production may exceed 1000 kcal/hr.^[390] An Olympic marathoner produced metabolic heat in excess of 1400 kcal/hr.^[17] Under conditions that limit heat dissipation, such as high humidity or impermeable clothing, this rate of heat storage would cause body temperature to rise approximate 0.5° C/min (0.9° F/min) and produce heatstroke within 10 to 12 minutes. Even under a moderate workload (300 kcal/hr), a person who cannot sweat effectively and thereby dissipate heat can experience a rise in T_c of 5° C/hr (9° F/hr).^{[356] [390]}

Others at increased risk of exertional heat illness because of occupation include miners,^[531] heavy industry workers,^{[123] [129]} and individuals in the military.^{[70] [322] [323] [344]} The yearly pilgrimage to Mecca has resulted in hundreds of fatalities from heat illness.^[277] Wearing impermeable garments during physical activity leads to rapid loss of sweat, overload of heat loss mechanisms, and hyperthermia. These events may occur voluntarily (e.g., dieters, wrestlers) or by occupation (e.g., firefighters, hazardous waste handlers). Some cases of EHS have a genetic component.^[381]

Failed thermoregulation can have its origin in the dysfunction of either central (hypothalamic) control or peripheral responses of heat loss mechanisms (sweating and vasodilation). A variety of drugs and toxins can produce hyperthermia and are implicated in some cases of severe heat illness.^{[4] [5]}

Individuals at Higher Risk

To preserve body temperature in its optimal range of 36.5° to 38.5° C (97.7° to 101.3° F), and to prevent an increase above 40.5° C (104.9° F), it is essential that the body delicately balance metabolic heat production, dry heat exchange, and evaporative heat dissipation. This requires highly developed and effective mechanisms of thermoregulation and temperature sensation. Heatstroke can be completely prevented by providing proper health education and following some simple regulations.^{[451] [452]} Prompt recognition, attention, and treatment usually result in complete recovery from heatstroke.

Preventive measures include acclimation to environmental conditions, adjusting physical efforts to match physical fitness, scheduling training to avoid the warmer hours of the day, establishing regulations to induce proper rehydration, and commanding adequate rest periods during activity. The medical team supervising the event should play a major role in preventing exertional heat illness during strenuous physical activity. It should also have the authority to cancel any strenuous activity whenever weather conditions are adverse. Before exercise, medical personnel must examine and evaluate each subject predisposed to heatstroke and, if necessary, exclude him or her from the activity. These measures were successfully implemented in the Israeli Defense Forces (IDF) and have been in practice there for many years. Recently these criteria also became an official

position offered by the American College of Sports Medicine.^[8]

Heat-susceptible persons include those who are obese, unfit, dehydrated, unacclimated; (perhaps) those with a previous history of heatstroke; and those who suffer from acute febrile illness, diarrhea, or chronic disturbances of the sweating mechanism. These persons carry risk factors for heat illnesses and should be prevented from participating in strenuous exercise, particularly in hot environments.^[142] Prescription drugs or drug abuse are among the acquired factors that underlie heat intolerance and may predispose individuals to excessive heat strain by altering thermoregulatory functions physiologically or behaviorally. Potentially harmful drugs include diuretics, anticholinergics, vasodilators, antihistamines, central nervous system inhibitors, muscle relaxants, tranquilizers and sedatives, β -blockers, amphetamines, and tricyclic antidepressants.^[380]

Box 10-3. EXERTIONAL HEATSTROKE IN THE FIELD

The following historical narrative from the middle of the nineteenth century describes vividly the devastating impact of heat and dehydration on a military unit in Texas during the Indian Wars, excerpted from "A Cavalry Detachment Three and a Half days Without Water" by CPT J.H.T. King, Assistant Surgeon, U.S. Army Post Surgeon, Fort Concho, Texas:

... The next day found them still marching onwards, and the mid-day tropical heat causing great suffering. The desire for water now became uncontrollable. The most loathsome fluid would now have been accepted to moisten their swollen tongues and supply their inward craving. The salivary and mucous secretions had long been absent, their mouths and throats were so parched that they could not swallow the Government hard bread ... Vertigo and dimness of vision affected all; they had difficulty in speaking, voices weak and strange sounding, and they were troubled with deafness, appearing stupid to each other, questions having to be repeated several times before they could be understood; they were also very feeble and had a tottering gait. Many were delirious ... As the horses gave out they cut them open and drank their blood ... (which) was thick and coagulated instantly on exposure; nevertheless, at the time it appeared more delicious than anything they had ever tasted. This horse blood quickly developed into diarrhea, passing through the bowels almost as soon as taken; their own urine which was very scanty and deep colored, they drank thankfully, first sweetening it with sugar. The inclination to urinate was absent and micturition performed with difficulty. A few drank the horses' urine, although at times it was caught in cups and given to the animals themselves. They became oppressed with dyspnea and a feeling of suffocation as though the sides of the trachea were adhering ... prolonging the intervals between each inspiration as much as possible, ... their lips ... were ... covered with a whitish, dry froth and had a ghostly, pale, lifeless appearance as though they would never be opened again. Their fingers and the palm of their hands looked shriveled and pale; some

animals themselves. They became oppressed with dyspnea and a feeling of suffocation as though the sides of the trachea were adhering ... prolonging the intervals between each inspiration as much as possible, ... their lips ... were ... covered with a whitish, dry froth and had a ghostly, pale, lifeless appearance as though they would never be opened again. Their fingers and the palm of their hands looked shriveled and pale; some who had removed their boots suffered from swollen feet and legs.

Most EHS victims are highly motivated, young, healthy individuals who exert themselves beyond their physiologic capacity ([Box 10-3](#)). In a recent review of 82 cases of EHS in soldiers,^[143] it was found that most cases occurred during basic training (57%) and an additional 21% occurred during screening tests for special forces—in which motivation is a key issue. Most of the EHS cases occurred in highly motivated but relatively unfit soldiers. Overmotivated soldiers misinformed the medical team regarding various issues that otherwise would have prevented their participation in the activity and therefore resulted in heatstroke.^[451] Shapiro and Moran^[451] concluded that in the young, active population, physiologic maladaptation is associated mainly with lack of acclimatization, dehydration, presence of infectious diseases or skin disorders, fatigue, and overweight. Although an internal "alarm system" should warn the human body to cease physical activity, during thermoregulatory maladaptation, it fails in the individual

who is overmotivated and/or under peer pressure. The most common underlying factors for heat sensitivity that may lead to heatstroke are summarized in [Box 10-4](#).

Mechanisms of temperature regulation have close functional relationships with other homeostatic mechanisms, that is, regulation of blood pressure, body fluid volumes, electrolytes, and acid-base balance.^[451] When these are intact, the thermoregulatory system has the physiologic potential to cope appropriately with any strain resulting from exercise-induced metabolic heat production. This will protect the body from the hazards involved with excessive heat accumulation and elevated body temperature. The defense from the threatening combination of intense physical effort (high metabolic rate) and low environmental potential to evaporate sweat (high humidity) is expressed by several body alarms that ultimately should result with cessation of physical activity. The subjective "alarm" may be caused by the thermoregulatory system and expressed by elevated body temperature or by the cardiovascular system and manifested by elevated HR.^[451] Heatstroke is a maladaptive state whereby the body temperature exceeds a temperature of 40.5° C (104.9° F) or greater, depending upon the severity of any recent exercise, as a result of the mismatch between heat production and heat dissipation.

PSYCHOLOGIC STRESS

Overmotivation
Peer pressure

Imbalances in fluids and electrolytes are common during hot spells, especially when salt losses in sweat are compounded by loss of appetite. Fluid and electrolyte losses resulting from illness (diarrhea or vomiting) often contribute to heat illness. In some cases, dehydration is the primary cause of death.^[456]

Sleep deprivation has an insidious effect. Prolonged sleep deprivation is fatal in animals, leading to immunosuppression and a sepsis-like death. That is, sleep is essential for optimal immune function.^[38] During hyperthermia, sleep deprivation increases the T_c threshold for the onset of sweating and, in women, reduces BF_{sk} .^[118]^[303] During moderate-intensity exercise, this delayed sweating onset reduced BF_{sk} in the heat, decreased total body sweat rate, reduced evaporative and dry heat loss, and led to elevated T_c .^[435] On the other hand, hyperthermia may disrupt the sleep-state pattern, decreasing the duration of rapid eye movement (REM) episodes, thereby degrading the quality of sleep and imposing a psychologic stress.^[175]

Combinations of factors that create a threat may be subtle. The presence of air

conditioning in the home, workplace, and transportation may decrease the risk for the development of classic heatstroke. However, by diminishing the state of heat acclimatization and respect for the environment, air conditioning may increase a person's risk for developing EHS. Intense and prolonged exposure during weekends and holidays accounts for many cases of sunburn and heat illness.

Military Training

From 1942 to 1944, there were at least 198 deaths from heat illness during military training in the United States.^[440] Gardener et al^[177] recently studied exertional heat illnesses in Marine recruits at Parris Island. During 12-week basic training of Marine recruits, the rate of exertional heat illness depended upon fitness. These rates correlated with body mass index (BMI) and time-to-complete a 1 ½-mile run during the first week of the training. Those recruits with a BMI greater than $22 \text{ kg} \times \text{m}^{-2}$ and a run-time greater than 12 minutes had eight times the risk for developing heat illness than those with lower values.^[177] In this study of 217,000 Marine recruits (90% male, 80% age 18–20 years), there were 1454 cases of exertional heat illness, with 89%

250

men and 11% women,^[177] and with a peak rate of 2% of recruits in summer. The frequency of reported cases closely correlated with daily heat load (a combination of T_w , T_{db} , and solar radiation) but did not correlate well with T_{amb} . Most cases occurred between 7:00 and 9:00 AM, during training that would have been restricted at elevated T_{amb} later in the day. During those hours, the rate of heat casualties increased substantially as WBGT increased, beginning at levels as low as 18.3° C (65° F). At WBGT of 23.9° to 26.7° C (75° to 80° F), heat illness rates increased 26-fold (over baseline rates at $T_{amb} < 18.3^\circ \text{ C}$ [65° F]) and 39-fold for the day before exercise. Exposure to WBGT of greater than 80° F was infrequent (25%) among the early morning cases at the time of illness. However, a fascinating observation was made: on the day before illness, high T_{amb} was common (87%), suggesting a prolonged biochemical/physiologic effect of heat exposure.^[266] Regardless of the current temperature, if the day before was cool, the frequency of heat cases was low; if it was hot, the frequency was high. Since the recruits were forced to drink large amounts of water, enough to keep them urinating during the night, elevated rate of heat casualties could not have been related to an accumulated dehydration from the day before. *The presence of a high environmental temperature caused an unspecified physiologic predisposition to heatstroke lasting for at least a day.*

Thus even following widely published guidelines based on WBGT for physical activity does not preclude risks. Perhaps a better index should be developed. High rates of metabolic heat production (e.g., running) combined with conditions that limit evaporative heat loss (e.g., high relative humidity, impermeable garments) appear to present a significant risk regardless of T_{db} . Furthermore, prevention is complicated by the

observation that conditions on the prior day contribute to the current risk of heatstroke.

Gender differences were found for the incidence of heat illnesses. Female rates were higher during the early hot season (May) and male rates were higher than those for females in the late hot season (September). Although May was cooler than September, there was a higher overall rate in May, probably reflecting less acclimatization in the spring. Comparing the days of the week, only 1.1% of casualties occurred on Sundays, reflecting decreased physical activity. In another study, obesity increased the risk of heat disorders in soldiers training in a hot and humid environment (Singapore).^[89]

In the IDF, 82 cases (of 150 suspected) were positively diagnosed as EHS from 1988 to 1996.^[143] More than 50% of these cases occurred during the first 6 months in service, mainly in summer (June–September), but 30% of the cases occurred during the spring, and some cases occurred during the winter season. EHS was not related to time of the day. Many cases occurred during the night or early morning, even under mild heat load. Interestingly, evaluated by the heat load index,^[470] 40% of the cases occurred during very short activities, whereas 60% occurred within the first 2 hours of exercise. The temperature regulation mechanism is efficient and the potential core-to-periphery conductance and sweating rate in the 82 heatstroke victims were higher than needed. Therefore EHS is more likely to occur when there is a severe thermal imbalance as a consequence of disturbance in the homeostatic mechanism aggravated by one or more predisposing factors^[451] (see [Box 10-4](#)).

Although heatstroke may be due to accident, lack of knowledge, poor judgment, or neglect, it is a preventable illness. Therefore cases of fatal heatstroke should be investigated for criminal intent. For instance, in the IDF, almost all cases of EHS occurred when regulations were not strictly followed.^[143] In a most unusual incident, an herbalist was convicted of manslaughter in Australia^[338] because he "treated" a young boy by immersing him for 40 minutes in a heap of fermenting horse manure, and the boy died of heatstroke. Educational efforts by both the media and the health care community aimed at parents of small children during heat waves should be made with the same enthusiasm as public service announcements of windchill factors during subzero temperatures. If participants develop heat injuries during sporting events that occur in hot weather outside the heat stress guidelines, coaches and organizers of the event should be held legally responsible. The military has long recognized the preventable nature of heat injuries that result from the intense physical activity in hot weather; a passage in the June 10, 1865 *Lancet* reads: "Commanding Officers of volunteers are very apt to err in this particular; and the spirit of their men is such that they shrink from complaint and persevere in efforts which may easily, under a burning sun, become dangerous to life."

Sports

EHS is a true sports emergency. There are several reports each year of heat illnesses with some fatal results, especially in competitive games. Incidence and mortality statistics for athletes are difficult to ascertain, but some have been reported. Undoubtedly, the incidences of unreported nonfatal heatstrokes are higher. From 1990 to 1995, there were 84 reported deaths resulting from heatstroke in athletes

participating in American football.^[399] In 1995, five American high school football players were reported to have died of heatstroke.^[432] Interior linemen are at higher risk because of their large muscle bulk. The uniform worn by football players covers almost the entire body and adds to heat load. In a 10-year study, 10% of 136 American high school and college athlete deaths were caused by EHS.^[500] In the Falmouth, Massachusetts, road race, there are between 10 and 15 heatstroke victims every year.^[432] Cyclists

and tennis players, in particular, tend to have great problems with dehydration, the cyclists because their sweat evaporates rapidly as they ride causing them to underestimate their fluid loss.^[222] In tennis, the duration of the game varies considerably and drinking is permitted only during changeover. The players' sweating rates can reach 2 L/hr, which presents a practical challenge for adequate fluid volume replacement.^[43] In soccer, 4.5% of injuries in 480 games were related to heat illnesses.^[279] Marathon runners thermoregulate at elevated core temperature ($\sim 40^\circ\text{C}$ [104°F]) during a run, and approximately 0.6% of the runners suffer from heat illnesses.^[396]

Training Injuries

Although it is clear that the rate of heat illnesses is greater in summer than in winter, the development of musculoskeletal and other injuries is a less obvious consequence of seasonal variations in climate. During basic military training, the incidence of musculoskeletal injuries severe enough to cause a time loss is higher in summer than in fall.^[286] That is, the injury rate increases with temperature and at $T_{\text{amb}} = 33.3^\circ\text{C}$ (92°F) is 2.6 times as high as that at $T_{\text{amb}} = 16.7^\circ\text{C}$ (61°F) for men and 1.8 times as high for women. This effect is also seen in elite athletes^[296] and in British professional rugby players, with summer seasons showing almost double the injury rate of winter (696.8/1000 hours and 363.6/1000 hours, respectively).^[393] In various studies, women had 1.5 to 3 times the injury rate of men.^[287] Risk factors for injury are poor physical fitness, cigarette smoking, physical inactivity, longer running distances, and use of old running shoes (those 6 months to 1 year old more than doubled the injury rate).^[176] Other risk factors for injury include older age, high-arched feet, and being "knock-kneed."^[286]

Heat Strain Indexes

How can one best quantify the dyshomeostasis and body injury, or the inability to maintain T_c at the level prescribed by the thermoregulatory center,^[203] resulting from exercise and heat? Heat strain is not simply a matter of T_c alone because heatstroke and other heat illnesses could occur at T_c less than 41°C (105.8°F). During the last century, environmental parameters and physiologic variables were combined to develop a unified heat strain index. Although more than 20 heat strain indexes have been described, none are accepted as a universal physiologic strain index. The main reasons for their lack of generality are related to the number and complexity of the

interactions among recognized determining factors and their limited validity.

The existing indexes can be divided into two main categories: (1) "effective" temperature (ET) scales^[238] based on meteorologic parameters only (e.g., ambient temperature, T_w , and T_g) and in which the WBGT index is derived^[535]; and (2) "rational" heat scales that include a combination of environmental and physiologic parameters (e.g., radiative and convective heat transfer, evaporative capacity of the environment, and rate of metabolic heat production). ET indexes have been widely applied to both assess and predict heat strain but cannot accurately account for different levels of metabolic rate, and different types of clothing (e.g., encapsulating).^{[271] [392]}

In 1937 the operative temperature index was developed,^[527] which combined the rates of metabolic heat production (M), heat transfer between the body and the environment (H_{r+c}) and the evaporative capacity of the environment to dissipate heat (E_{max}).^[34] Its best known modification is the Heat Strain Index (HSI), which relates total evaporation required (E_{req} , the sum of M and H_{r+c}) to E_{max} . HSI is widely accepted because it combines environmental variables and body activity. However, in certain situations, the heat strain was seriously in error and further modifications have not been fully satisfactory.^{[34] [228]} HSIs based on physiologic parameters were also suggested but found unsatisfactory.^[304] Collectively, although many HSIs were developed, some simple to apply, others highly complex, all were found to be valid only under certain specific conditions.

Recently, Moran et al^[350] introduced a new physiologic strain index (PSI) based upon adding equally-weighted the individual strains of T_{re} and heart rate (HR), which represent the combined strains of thermoregulatory and cardiovascular systems. Each strain system was scaled 0 to 5. Thus the PSI is scaled 0 to 10 and can be calculated continuously on-line or during data analysis. The PSI can be applied at any time whenever T_c and HR are measured, including during rest or recovery periods, unlike some of the other indexes.^[350] In a recent series of studies, PSI successfully evaluated the strains generated by different clothing ensembles, climatic conditions, different levels of hydration, and exercise intensity for gender during heat stress, for different age groups during acclimatization, and during acute exercise heat stress.^{[348] [351]} Furthermore, this index, when adjusted for animal values, successfully rated and correctly discriminated between trained and acclimated rats exposed to exercise heat stress.^[352]

PSI differs from previous indexes. It is easier to interpret and use than other indexes available and includes the ability to assess rest and recovery periods. PSI overcomes the shortcomings of previously described indexes and can be used over a wide range of conditions.

Heat strain is well known to correlate with environmental heat load and metabolic heat production, resulting in higher values of T_{re} , HR, and T_{sk} , and a reduced ability to maintain exercise. Various types of clothing with different degrees of water permeation

create microclimates differing from that of the environment

and lead to higher strains. The combination of different climates, impermeable garments, and hydration levels during different exercise intensities is a challenge for assessment of the individual physiologic strain. However, in two recent studies when different HSIs were applied to quantify the heat strain, PSI was successful at all levels of heat exposure while the other indexes were limited in their abilities.^[350] The applicability of PSI was further successfully shown for various sweat rates and relative exercise intensities in different climates and for exercise heat stress and gender at different combinations of exercise intensity and climate.^[348]

Gender

In many experiments, women exposed to acute heat stress and exercise thermoregulated less effectively than did men, resulting in the general conclusion that women are less heat-tolerant than are men.^{[340] [453] [459]} However, in most studies, women generally had lower cardiorespiratory fitness, higher percentage of body fat, lower body weight, lower body surface area, and higher surface area-to-mass ratio than men.^{[316] [387] [391]} Those physiologic differences are probably not intrinsically gender-specific but result from inequalities in fitness and acclimatization attributable to differences in lifestyle.^[372] When such variables were controlled, most of the physiologic differences were narrowed, although mean sweat rate (msw) still remained lower for women.^{[10] [186] [340] [533]} Stephenson and Kolka^[474] suggested that the apparent physiologic differences in msw were based on comparing unmatched genders, mainly aerobically fit men to relatively unfit women. They argued that most of the studies comparing responses of men and women were not controlled for menstrual cycle phase and thus were limited in their conclusions. Furthermore, Sawka et al^[437] concluded that when men and women were matched for aerobic fitness, they then had similar heat tolerances and body temperature responses during exercise in the heat. For instance, acclimatized men and women have comparable responses to rest and exercise in a desert environment.^[514] However, hormonal fluctuations of estrogen and progesterone concentrations associated with the menstrual cycle may alter women's performance and tolerance to exertional heat stress.^[316] In a recent study, Moran et al^[351] applied the PSI in three climates to evaluate the strain of men and women who were matched for maximal aerobic power ($ApV_{O_2 \max}$) and intensity for 60 minutes. All subjects underwent a matrix of nine experimental combinations of three different exercises.^{[23] [260] [437]} The PSI confirmed previous studies that when men and women were matched for $ApV_{O_2 \max}$ and selected physiologic parameters, there is no difference in strain between the two groups.

For middle-aged women, the effects of hormone replacement therapies on the thermoregulatory system were studied.^{[65] [66] [186] [489]} The luteal phase, with its increased progesterone-to-estrogen ratio, was associated with an elevated T_c , whereas elevated levels of unopposed estrogen were associated with a lower T_c at rest and during

exercise heat stress.^[489]

In summary, although mean physiologic responses to exercise heat stress suggest poorer thermoregulation for women, this is not necessarily an intrinsic gender difference but reflects a combination of social factors serving to reduce fitness in women.

Aging

In general, middle-aged and older men and women are less tolerant to heat and exercise, suffering more physiologic strain than younger individuals.^[237]^[505] They developed higher HR, T_{sk} , and T_c and lower msw than younger men and women during exercise heat stress. However, it is uncertain whether this is related to age per se or to other factors, such as disease states, decreased physical activity, and lowered aerobic fitness.^[386]

A subgroup of middle-aged men who were "habitually active" displayed the same strains to acute exercise heat tolerance and acclimated to heat at about the same rate and degree as when they were younger.^[414] Some studies on aging emphasize the importance of aerobic fitness and physical characteristics, such as body fat and body weight in maintaining work heat tolerance. In one study, old and young men and women were matched for $\dot{V}O_2$ max, surface area, and surface area-to-mass ratio but differed in age by 35 years.^[272] During 75 minutes of light exercise at 37° C (98.6° F) and 60% RH, all groups showed the same degree of physiologic strain. In 1988, Pandolf et al^[388] compared responses to acute heat tolerance between young and middle-aged men who were matched for $\dot{V}O_2$ max and morphologic factors. The middle-aged men's tolerance times were actually half an hour longer than the younger men's during the first day of acclimation (49° C [120.2° F], 20% RH) and they were also at a thermoregulatory advantage during the few days of heat acclimation, although both groups eventually acclimated to the same absolute degree. However, in these studies the middle-aged men were more chronically active than the younger men before heat acclimation. Under different environmental conditions, such as 30° C (86° F) with 80% RH and 40° C (104° F) with 20% RH, no differences were seen between the two groups.^[467] In summary, when properly matched subjects are studied, heat stress of middle-aged men resulted in either the same or reduced physiologic strain as that of younger men.

CELLULAR HEATSTROKE

Whatever physiologic derangements occur in the whole body as a result of overheating, some primary derangements must first occur in individual cells.

253

Subcellular Disruption

Heating alters subcellular structures in many cell types, including detachment of cortical microfilaments from the plasma membrane,^{[99] [133]} collapse of the cytoskeleton, swelling of the mitochondria and the endoplasmic reticulum,^[50] and disaggregation of polyribosomes and nucleoli.^{[80] [339]} Furthermore, heating increases membrane fluidity, grossly distorting the plasma membranes and forming bulges known as "blebs."^{[30] [113] [402]} Blebs alter membrane function,^[13] increasing membrane permeability^[494] with solute leakage.^{[404] [424]} Such changes are not necessarily lethal; up to a point, the bleb formation may be adaptive, increasing cell survival.^{[51] [261]} Red blood cells undergo rearrangements in their cytoskeleton with heat, but rather than forming blebs, they form spheroids at elevated temperatures.^[206] These enlarged spherically shaped cells are much less efficient at gas exchange than are normal red blood cells and probably contribute to reduced P_O₂ in the tissues at elevated temperatures. Spheroid formation has been found in athletes during long-distance running and may contribute to their physical collapse during exercise.^[206]

Apoptosis

Cells are destroyed within the body by the processes of apoptosis and necrosis. In apoptosis, certain individual cells within the body are genetically programmed to die. In this process, cells are broken into small vesicles containing condensed chromatin surrounded by intact cell membranes and are phagocytosed by neighboring cells. During necrosis, a variety of factors, including inflammation, cause swelling, destruction of the plasma membrane, and spewing of cell contents into the environment.^[332] Apoptosis may be induced by a variety of stressors, including hyperthermia, aging, and certain toxins (*Pseudomonas* endotoxin, diphtheria toxin, and ricin).^[131] A few minutes' exposure to temperatures of 41.5° to 42° C (106.7° to 107.6° F) triggers apoptosis in both cultured mammalian cells and experimental animals by activating Jun N-terminal kinase (JNK).^{[101] [428]} The organs producing the greatest number of apoptotic cells from whole body hyperthermia are the thymus, spleen, lymph nodes, and mucosa of the small intestine. The heat shock protein HSP-70 (see below) prevents this activation and

contributes to acquired thermotolerance in mammalian cells.^[166]

Ionic Changes

Ions do not readily cross lipid bilayers despite their large concentration gradients across plasma membranes. In general, they require specialized channels or carriers to do so. Membrane channels are proteins that contain hydrophilic "pores" penetrating the lipid bilayer, permitting the diffusion of specific ions down their electrochemical gradients to enter or leave cells.^[528] Cotransporters are fundamentally different types of pathways that move ions across the cell membranes up their electrochemical gradients by coupling the translocation of at least two ions (e.g., K^+ and Cl^-) using the energy stored in adenosine triphosphate (ATP)-dependent preformed chemical gradients, such as those of H^+ or Na^+ (rather than the concentration gradients of the transported ions).^[528]

Potassium ions enter cells by at least two pumping mechanisms, the membrane $Na^+ K^+$ ATPase pump and the "ouabain-resistant pump."^[207]^[537] K^+ exits cells through several types of membrane channels, including voltage-gated, ATP-gated, arachidonic acid-gated, and "leak" channels.^[281]^[364]^[473] Although the rate of K^+ transport by each pathway varies with temperature, during heating, the overall resultant flux is a net loss of intracellular K^+ and a primary rise in plasma K^+ .^[174]^[168]^[425]^[475]

Hyperthermia increases the rate of Na^+ influx, leading to a net rise in intracellular sodium (Na_i) that is prolonged and not rapidly reversed by cooling. At a sufficiently high temperature, the Na transport mechanisms become denatured and, because of the increased "leakiness" of the plasma membrane and the transmembrane Na concentration gradient, Na_i progressively rises until death.^[171] Acidifying cells leads to an explosive influx of Na^+ upon heating. Hyperthermia leads to at least mild cytoplasmic acidification,^[523] and therefore the combined stresses of heating and acidification lead to increased intracellular Na^+ .

Moderate heat activates a Ca^{2+} ATPase pump to temporarily lower intracellular calcium (Ca_i). However, severe heating causes a net rise in Ca^{2+} through the activation of at least two transport systems and therefore is expected to alter a number of metabolic pathways.^[294] Depending on the temperature, Ca^{2+} enters the cell from the extracellular fluid by means of the "reversed mode" of the plasma membrane Ca^{2+} -ATPase pump and enters the cytoplasm from intracellular Ca^{2+} stores.

Some ionic changes in mammalian cells induced by heating, for example, in Ca^{2+} and Na^+ , are mediated by inhibition of the Na - H exchanger, activation of $Na^+ K^+$ ATPase, and changes of membrane conductance for ions.^[465] See Gaffin^[168] for a review of these mechanisms.

Although heating acts directly on the rates of fundamental cell processes, heat also has indirect effects by causing the release of a variety of hormones. These hormones, singly or in combination, further alter the activities of virtually all the ionic pathways. For instance, catecholamines stimulate the muscle membrane $Na^+ K^+$ ATPase (by

approximately 100% in rat soleus), increasing both the intracellular K^+ concentration (Ki)^[92] and membrane potential.^[67] Epinephrine in the presence of insulin stimulates active Na^+ /K^+ transport and hyperpolarizes membrane potential in muscle.^[156] This effect may be so powerful that, for a time, it "masks" the primary decremting effect of the heat-induced hyperkalemia on performance.

254

In addition to the effect of heat on pathway activities, the rise in activity of the various ion pumps provides more metabolic heat, which, near the limit of sweat secretion, increases body temperature still more.

Increased membrane permeability from hyperthermia leads to rises in circulating enzymes. Creatine kinase is the first enzyme detected at T_c as low as $39.5^\circ C$ ($103.1^\circ F$) in monkeys (S. Constable and S.L. Gaffin, unpublished observations), and $42.5^\circ C$ ($108.5^\circ F$) in rats, followed by lactate dehydrogenase.^[324]

Stress Pathways

Early unicellular forms of life were preyed upon by their neighbors and, over geologic time, they developed an immune system for protection. This is a nonspecific immunity and is basic to all phyla today. The original mechanism destroyed the invader's cytoplasm by active oxygen species, including free radicals, produced by the host. In modern mammalian species, specialized inflammatory cells, such as macrophages and

Figure 10-1 Stress and the hypothalamic-pituitary-adrenal axis. Under basal conditions (1) the anterior pituitary secretes the immunostimulants prolactin, growth hormone, thyroid-stimulating hormone (TSH), and gonadotropin-releasing hormone, leading to the secretion of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and testosterone. Severe stress (2) acts on the paraventricular nucleus in the hypothalamus, producing CRF (3), downregulating the secretion of the immunostimulants and gonadal hormones, and (4, 5) upregulating the secretion of the immunosuppressors β -endorphin, α -melanocyte-stimulating hormone, and ACTH, the latter of which upregulates the secretion of the immunosuppressor cortisol. Stress also (6) activates the sympathetic nervous system, and catecholamines are secreted. These further downregulate the production of immunostimulants and (7) may reduce splanchnic blood flow sufficiently to cause ischemia of the intestinal vascular bed, local damage to the gut wall, and the leakage of lipopolysaccharide (LPS) into the circulation. LPS in turn (8) causes the production of the powerful immunosuppressors TNF and IL-1. TNF and IL-1 are also secreted within the hypothalamus in direct response to stress, leading to their participation (9) in a positive feedback loop, augmenting the secretion of CRF and resulting in even greater immunosuppression. NOTE: Moderate stress may have the opposite effect and increase the secretion of immunostimulants. (From Gaffin SL, Hubbar RW: *Wilderness Environ Med* 4:312, 1996.)

natural killer (NK) cells, are especially enriched in those enzymes and chemical

pathways producing the toxic free radicals. They also contain additional pathways that allow these cells to recognize invaders and penetrate tight epithelia so that they may easily reach and destroy them. The immune cells are activated by means of circulating and locally produced cytokines, such as tumor necrosis factor (TNF) and interleukin-1 (IL-1), as part of a stress reaction mediated by the hypothalamus. Thus there exists a common stress reaction in vertebrates that is activated by stresses other than infections, such as hyperthermia, and that activates pathways producing toxic species, which may now be inappropriate and toxic to the organism.^[169]

Severe hyperthermia in mammals leads to a common response pathway involving the secretion of corticotrophin releasing factor (CRF, also called corticotropin releasing hormone [CRH]) by parvocellular neurons of the paraventricular nucleus of the hypothalamus,^{[31] [497]} activation of the sympathetic nervous

system, and secretion of cortisol and catecholamines ([Figure 10-1](#)). CRF is directly transported via the hypothalamo-hypophyseal portal system to the anterior pituitary, where it has two important effects: (1) it downregulates eosinophilic cells that secrete the immunostimulants (growth hormone, prolactin, gonadotropin stimulating hormone, luteinizing hormone, and follicular stimulating hormone),^{[15] [127]} and (2) it upregulates the pro-opiomelanocortin (POMC) gene in basophilic cells, leading to the secretion of immunosuppressors (β -endorphin, α -melanocyte stimulating hormone, and adrenocorticotrophic hormone [ACTH], in turn leading to the secretion of the immunosuppressor cortisol) (see [Figure 10-1](#)). A rise in IL-1 is part of a positive feedback loop, causing a further rise in CRF and ACTH.^{[249] [257]}

These are not just theoretic predictions based on animal studies. In human subjects, circulating levels of CRF, ACTH, cortisol, and arginine vasopressin (AVP) rose during graded work rates until exhaustion. It appears that high-intensity exercise favors AVP release, whereas prolonged duration favors CRF release.^[250]

Energy-Depletion Model

During hyperthermia and continued heat stress, cellular Na^+ K^+ ATPase pumps operate at elevated rates, hydrolyzing ATP more rapidly and liberating waste heat into the body faster. If the body cannot dissipate this heat through radiation, conduction, convection, and sweat evaporation, then according to the laws of thermodynamics, T_c must rise further, leading to still greater rates of the Na^+ K^+ ATPase pumps—an ominous positive feedback loop. The amount of energy available to a cell is limited. Therefore, at a certain elevated temperature, ATP utilized by the activated Na^+ K^+ ATPase pump can no longer be resynthesized sufficiently rapidly to be available for normal cellular processes and the cell becomes "energy-depleted." Experimental support for this concept is the presence of swollen cells (implying a slowing of ion pumps, which affect water transport) and the rapid development of rigor mortis (caused by depletion of ATP) at the end stage of heatstroke pathophysiology. Persons exercising in the heat develop

lethal heatstroke at lower T_c than do those at rest. This can be explained by the concept that exercise lowers ATP stores (i.e., creatine phosphate) and therefore less is available for other important cellular processes.^[241]

CARDIOVASCULAR STRAIN AND EXERCISE

Severe heat illness involves every system and affects the regulatory (cardiovascular), the integrative (neuroendocrine), and ultimately the basic cellular systems of the body. Probably no greater strain is put on the human body than heavy physical exertion in the heat. This impact of heat stress on the cardiovascular system represents the strain resulting from increased demand for cardiac output to transfer heat and water to the skin for evaporative cooling.

Severe and prolonged exercise leads to changes in body compartments and the cardiovascular system, persisting for hours to days. For instance, a group of men carrying 20-kg backpacks during a 110-km march under warm conditions, eating and drinking ad lib, lost 3.4% of body weight and their plasma volume (PV) fell by 6.1%. However, the next day their PV *dropped still further* to -8.4%, even though they were not exercising. During the following day, PV rose to +3.7% above baseline and remained elevated 4 days after the march.^[21]

The hemodynamic displacement of blood to the periphery is aggravated by gravitational displacement of blood volume resulting from upright posture. In an upright human, about 70% of the blood volume is below heart level. Venous pooling of blood in the skin and in the great veins below the level of the heart leads to reduced venous return to the heart and consequent reduced cardiac filling.^[421] If active skeletal muscle then vasodilates to supply the increased demands for blood flow in support of muscle metabolism, the competing demands for blood flow between vascular beds translate into a major regulatory problem.^[420]

The potential conductance of the vasculature (skin 8 L/min⁻¹, viscera 3 L/min⁻¹, and muscle 65 to 70 L/min⁻¹) is enormous and far exceeds the pumping capacity of the normal human heart (about 22 L/min⁻¹).^[255]^[422] Since the combined blood flow requirements of these vascular beds cannot be met, an inherent competition takes place between the mechanisms that maintain blood pressure and those that maintain blood flow to support metabolism and thermoregulation.^[243]

The existence of a variety of types of heat illnesses suggests: (1) the physiologic strain resulting in homeostatic failure produces heat illness; (2) a certain biologic variability is expressed in the response to heat and exercise; (3) hemodynamic stability often takes precedence over thermoregulation; (4) volitional behavior, expressed as exercise performance, is often maintained even as the risk of heat injury increases; and (5) the onset and increase in hyperthermia are not painful.^[242] Not surprisingly, the physiologic threat to homeostasis is worsened when accompanied by fluid/electrolyte imbalance.^[240]^[383] Treatment is then directed at the major sources of homeostatic failure: cease the

activity, lie down, cool down, and rehydrate. Sometimes the cause of collapse or the other symptoms involved (such as headache, nausea, vomiting, and vertigo) is obvious; sometimes, it is not readily appreciated.

Sweating

Although human eccrine sweat glands generally behave physiologically and pharmacologically as if under parasympathetic or cholinergic control, they also

256

respond to adrenergic stimulation.^[434] There are 2 to 3 million sweat glands distributed with decreasing density in the skin of the palms and soles, head, trunk, and extremities, with an average density of about 100 to 200/cm². One g of sweat glands can secrete up to 250 g of sweat per day. Eccrine sweat is always hypotonic, contains variable concentrations of sodium, and is generally 99.5% water by weight.^[141] That 0.5% of sweat solids is important, since 1 L of 0.5% sodium chloride contains 5 g of salt, a potential cause of serious salt depletion.

The process of sweat secretion and sweat rate depend on activation of the sweat center in the hypothalamus, which discharges over the cholinergic fibers of the sympathetic nervous system. Rising blood temperatures increase both the number and the rate of sweat glands responding, until the body reaches a thermal equilibrium or the maximum sweat rate occurs.^[189] Dehydration and hyperosmolality each leads to reduced sweat rates,^[439] with hyperosmolality the more effective ([Figure 10-2](#)).

One of the highest sweat rates ever recorded in a human was in a world-class Olympic runner.^[17] He produced

Figure 10-2 Effect of reduced plasma volume or increased osmolarity on sweat rates in six individuals. (Modified from Sawka MN et al: *J Appl Physiol* 59:1394, 1985.)

sweat at a rate of 3.71 L/hr after 19 days of heat acclimation training. Because the maximum rate of gastric emptying is much less than the maximum sweat rate (1.2 vs. 3.7 L/hr), rehydration cannot keep pace with sweat losses under those conditions^[18] and an athlete faces significant risk of dehydration despite frequent drinking.^{[19] [20] [243]} Since rates of gastric emptying can exceed 1 L/hr, as a rule of thumb, a 1 L/hr sweat rate appears sustainable without significant dehydration.

Fluid and Electrolyte Imbalance

Heatstroke Model.

Determining the time courses of changes in various physiologic and biochemical parameters caused by heatstroke is difficult or impossible in humans for ethical considerations. Use of rodents precludes the determining of many parameters simultaneously because of lack of blood volume. Miniswine have been used as models because of their considerable physiologic similarities to humans and their practical size. When anesthetized miniswine were passively heated to $T_{amb} = 43^{\circ} \text{C}$ (109.4°F), HR and mean arterial pressure (MAP) rose only slightly until T_c reached 42°C (107.6°F) ([Figure 10-3, A](#)). At this T_c , the HR rose to a

257

Figure 10-3 A, Effect of hyperthermia on mean arterial pressure (MAP) and heart rate (HR) in anesthetized miniswine. After 1-hour baseline, environmental temperature was raised to 42° to 43°C (107.6° to 109.4°F). * = $P < 0.05$ compared with controls; # = $P < 0.05$ compared with own baseline values. **B**, Effect of hyperthermia on respiratory rate (resp rate), P_{CO_2} , and arterial pH in anesthetized miniswine. Changes from baseline levels. * = $P < 0.05$ compared with controls; # = $P < 0.05$ compared with own baseline values. **C**, Effect of hyperthermia on renal function. Percent baseline level. * = $P < 0.05$ compared with controls; # = $P < 0.05$ compared with own baseline values. **D**, Effect of hyperthermia on arterial potassium, calcium, and inorganic phosphate in anesthetized miniswine. * = $P < 0.05$ compared with controls; # = $P < 0.05$ compared with own baseline values. (From Gaffin LS et al: *J Thermal Biol* 23:341, 1998.)

258

peak and rapidly fell until death while MAP gradually fell until death but with a shoulder corresponding to the HR peak. The respiratory rate rose, peaking at approximately 42°C , and then continuously fell until death ([Figure 10-3, B](#)). Because of the increased ventilation, P_{CO_2} fell until shortly before death, but then rose to very high levels. As ventilation increased, plasma pH rose, but gradually fell as ventilation fell and CO_2 rose. Renal function was stable until 41° to 42°C (105.8° to 107.6°F), the same T_c that reduced MAP ([Figure 10-3, C](#)). Serum K^+ continuously rose with T_c ([Figure 10-3, D](#)).

A schematic model of normal thermoregulation and pathophysiology of heat stress and heatstroke (based on most of the preceding considerations) is shown in [Figure 10-4](#). Core temperature has been divided into two regions to clarify physiologic mechanisms.

NORMAL THERMOREGULATION.

Under a moderate heat load, as skin or core temperature (or both) rises, thermoreceptors (1) increase skin blood flow and (2) cause the secretion of sweat to (3) result in evaporative cooling. To prevent a drop in blood pressure (4), blood flow to the splanchnic regions and to muscle is reduced and (5) stroke volume and then (6) heart rate are increased. Then (7) catecholamines are secreted, followed by corticotropin-releasing factor (CRF), which lead to the secretion of adrenocorticotropic hormone followed by (8) cortisol. Catecholamines (9) cause leukocytosis, while cortisol (10) causes leukopenia, leading to (11) changes in amounts of subsets of leukocytes. If the heart stress is prolonged and severe, the immunosuppression could (12) lead to subsequent increased susceptibility to infections and decremented physical and mental performance. As temperature rises, (13) the respiratory rate increases. As a result of sweating, (14) plasma volume decreases and (15) hematocrit and (16) plasma osmolality rise, leading to (17, 18) the sensation of thirst and ADH release. Reduced plasma volume (14), together with (4) reduced renal blood flow, leads to (19) rises in water-sparing hormones and reduced kidney function.

IMPAIRED HOMEOSTASIS.

As temperature continues to rise above approximately 40° C (104° F), direct hyperthermic damage (A1) to cells commences with increases in membrane fluidity and permeability, increases in metabolic rate, including the activity of the Na⁺, K⁺-ATPase, increases in a variety of metabolites, and decreases in cellular ATP content. At about the same time the reduction in intestinal blood flow (4) becomes more severe, leading (A4) to ischemic injury of the gut wall. This in turn leads to rises in (A5) circulating lipopolysaccharide (LPS) and (A6) cytokines. By activating a blood factor (A7), LPS causes (A8) disseminated intravascular coagulation and a consequent rise in blood viscosity. Thermal injury of endothelia (A3) together with (A6) cytokines leads to (A9) enhanced metabolism of ω-6 fatty acids, including (A10) the production of thromboxanes and leukotrienes, (A11) oxygen free radicals and further (A12) cellular injury, the probable production of the highly toxic nitric oxide, and (A13) increased vascular permeability. This leads to the loss of fluids into the tissues, and thus (A14) reduced venous return and (A15) consequent reduced central venous pressure. Through Starling's law of the heart (A16), cardiac output begins to fall. This is made more serious (A17) by electrolyte changes in the blood. Eventually (A18) blood pressure falls, leading (A19) to reduced tissue perfusion. In the case of the lung (A20), reduced perfusion leads to (A21) systemic hypoxemia and eventually (A22) ischemia of various tissues and organs and its consequent (A23) contribution to further cellular damage. (A24) Reduced blood flow to the brain (A25), as well as (A26) probable direct thermal denaturation, leads to damage of centrally mediated homeostatic mechanisms, (A27, A28) reduced skin blood flow and drop in cooling rate, and eventually (A29) a fall in respiration. In a separate pathway, cardiac output is also depressed as a result of (A30) a too rapid

pulse rate causing (A31) incomplete cardiac filling. Electrolyte derangements are made more severe by (A32) an increased metabolic rate and (A33) reductions of renal blood flow in the kidney.

Hydration.

"Water discipline," meaning fluid deprivation, is an attempt to reduce the body's water requirements during activities in the desert or jungle. However, it is an outdated, incorrect, and dangerous concept. Voluntarily or involuntarily withholding water from persons in the heat, in the face of severe thirst, leads to unnecessary deaths and permanent neurologic damage in the survivors of heatstroke. ^[390A]

If an athlete is hypohydrated when commencing strenuous physical exercise in the heat, he or she will be at a disadvantage compared with a euhydrated person. He overheats earlier, physical and mental performance decrements sooner, and the victim is more susceptible to hemorrhage and trauma. Frequent spitting and withholding water are often done by collegiate wrestlers to qualify for a lower weight class. This behavior must be regarded as a serious risk for developing heat illnesses.

With normal nutrition, ingesting commercial electrolyte/carbohydrate-containing beverages offers no advantage over water in maintaining PV or electrolyte concentration or in improving intestinal absorption. However, under conditions of caloric restriction or repeated days of sustained sweat losses, there might be a benefit to consuming an electrolyte-containing beverage. For athletes, use of glucose polymer solutions may be considered. For the vast majority of individuals, however, the primary advantage of using

259

Figure 10-4 Model of the physiology and pathophysiology of heat stress and heatstroke. See text for description. (From Hubbard RW, Gaffin SL, Squire DL: *Heat-related illnesses*. In Auerbach PS: *Wilderness medicine: management of wilderness and environmental emergencies*, ed 3, St Louis, 1995, Mosby.)

260

electrolyte- or carbohydrate-containing drinks appears to simply improve taste, thereby enhancing voluntary consumption of fluids. This factor could become important if regulated intake is impossible.

Dehydration, as a dynamic change from euhydration to hypohydration, reduces or compromises the physiologic advantages of physical training or heat acclimation. Involuntary dehydration can produce serious water deficits, such as found in persons cast adrift on tropical seas or stranded in the desert without water. Survival under these conditions requires knowledge of the trade-offs between the benefits of increased physical activity to obtain water and the consequences of increased sweat and dehydration. Adolph et al.^[1] described both the symptoms and the expected dehydration rates under these circumstances.

The *minimum* unavoidable daily water loss approximates 1.5 L or about 2% of body weight as body water.^[330] Although hard work in the heat can elicit this sweat loss in 1 hour (1.5 L/hr), resting in the shade can reduce sweat losses to minimum values (50 to 300 ml/hr at air temperatures from 26.7° to 37.8° C [80° to 100° F]). Assuming that a 12% body weight loss as a water loss produces shock, then survival time could vary between 1 and 5 days. *In the desert, for every 20 miles walked at night, one should carry 1 gallon of water and, during the day, 2 gallons.*^[1]

Normal oxidation of carbohydrates produces a small amount of metabolic water that may have survival value. Approximately 500 ml may be produced per day, which represents 30% of the daily obligate water loss at rest. However, as running time in the heat, this represents only about 20 minutes.

Thirst and Voluntary Dehydration.

The sensation of thirst does not become prominent until osmotic dehydration exceeds the renal capacity to deal with it physiologically.^[240] Therefore inadequate fluid intake also can occur where drinking is possible. That is, the delay in thirst is a manifestation of the body's osmotic control. Although there is wide variation in the individual thirst threshold, it has an average value close to the upper normal value of 295 mOsm/kg H₂O (normal range = 280–295 mOsm/kg H₂O).^{[328] [411] [413]}

The most potent stimulator of both thirst and antidiuretic hormone (ADH) is dehydration.^[121] Within any one individual, the plasma vasopressin response (ADH release) is linearly related to plasma osmolality^[413] and therefore to plasma sodium. For example, at an osmolality of 280 mOsm/kg H₂O, ADH release is almost completely inhibited and the osmolality of the urine is minimal (<100 mOsm/kg H₂O). As dehydration occurs, Na rises, causing a rise in plasma ADH concentration (0.5 to 5 pg/ml). ADH causes conservation of water by increasing renal reabsorption of solute-free water.^[412] This action increases the concentration of urine (a rise in plasma by 1 mOsm increases urine osmolality by almost 100 mOsm/kg) and decreases its flow. At the thirst threshold of 295 mOsm/kg H₂O, urine flow is reduced tenfold to twentyfold.^[328]

In summary, for most people, small osmolality rises resulting from water loss do not normally initiate the sensation of thirst. During work in the heat, *men never voluntarily drink as much water as they lose*, and they usually replace only two thirds of the net

water loss. [394] Adolph and co-workers[418] called this phenomenon "voluntary dehydration" and found that it increases with elevated sweat rate induced by higher T_{amb} or work rate, by inadequate time allowed for rehydration, and by greater effort involved in acquiring water. *All persons in the heat should be considered dehydrated* (except immediately after a meal), unless they have recently been forced to drink more water than they desired. Consequently, in the past, heatstroke was almost always accompanied by some degree of dehydration.

However, in the past decade or so, medical authorities have fairly successfully educated athletes to drink adequate amounts of fluids during physical exercise in the heat, even if they are not thirsty. This has led to the routine establishment of water stations along marathon routes for participants to obtain drinks on the run and to drinking "on command" in the military. In a small number of cases, however, too much water was ingested, leading to overhydration, hyponatremia, physical collapse, and even deaths.[178] The administration of intravenous (IV) infusions to all collapsed marathon runners must be recorded, and all subsequent medical teams must be notified about the infusion. Since most collapsed athletes superficially appear similar, Noakes[370] emphasized that there is a significant danger of overhydrating persons who collapsed in the heat. Therefore it is essential to determine the patient's hydration status unless one is certain that the victim has not ingested adequate water.

Chronic Hypohydration.

The significant delay between the threshold for ADH release (>280 mOsm) and the thirst threshold (>295 mOsm) is important. It frees the individual from being "forced" to drink immediately in response to changes in osmolality. On the other hand, certain individuals and groups[240] maintain a chronic state of hypohydration just below the thirst threshold (294 mOsm/kg), which represents a deficit of some 2L in total body water (TBW), according to the following example:

It is assumed that the total body water (TBW) in the idealized 70-kg person is 42 L (about 60% of body mass), and that two thirds of this water (28 L) is intracellular and one third is extracellular (3.5 L of plasma and 10.5 L of interstitial fluid). By calculation,[148] the intravascular or PV is equivalent to one twelfth of the total body water (42 L TBW/12 = 3.5 L PV). It is further assumed that there is no salt loss.

Therefore TBW at the thirst threshold, compared with euhydration, is calculated by:

Normal TBW × normal plasma osm = thirst TBW × thirst plasma osm

42 L × 280 mOsm/kg = ? L × 295 mOsm/kg

11,760 mOsm/295 mOsm/kg = 39.9 L

That is, TBW at the thirst threshold is 39.9 L.

Therefore the actual water loss to reach threshold is 42 L - 39.9 L = 2.1 L, which represents nearly 3% of body weight ($[2.1 \text{ kg}/70 \text{ kg}] \times 100$). By exercising in the heat for only about 2 hours, one can incur an additional water loss of 2.1 L (= 4.2 L total), which then results in a water deficit equivalent to 6% of body mass. This 6% TBW deficit decrements performance and increases risk of heat illness. The relationship between hydration state, rise in T_c , and physical performance decrement is best shown in a classic work by Montain et al,^[346] who measured performance at three work rates and in three states of hydration. See [Figure 10-5](#).

Primary Water Depletion.

Hypohydration caused by primary water depletion and increased fluid losses is characterized by thirst and oliguria and is completely relieved by drinking pure water.^[355]
Sample calculations

Figure 10-5 Influence of hydration level and exercise intensity on esophageal temperature. *BWL*, Body weight loss; *Ap?Vo₂ max*, maximal O₂ uptake. (Data from Montain SJ, Latzka WA, Sawka MN: *J Appl Physiol* 79:1434, 1995.)

based on some commonly accepted estimates highlight the role of reduced water intake vs. missed meals and sweat (water and salt) losses in the dehydration process. In the absence of sweating, a pure water deficit caused by inadequate fluid intake slowly raises plasma Na⁺ and can eventually lead to symptoms of circulatory shock. Clinical shock from pure water deficit generally coincides with a sodium concentration above 170 mEq/L (normal range 135–145 mEq/L, mean 140 mEq/L).^[148] The water deficit vs. euhydration for an assumed plasma Na⁺ = 175 mEq/L can be estimated using the following formula:

$$\text{TBW}_{\text{normal}} \times \text{Na}^{\text{plus}}_{\text{normal}} = \text{TBW}_{\text{dehydrated}} \times \text{Na}^{\text{+}}_{\text{dehydrated}}$$

$$42 \text{ L (see above)} \times 140 \text{ mEq/L} = ? \text{ TBW} \times 175 \text{ mEq/L}$$

Then TBW for this dehydrated state = 33.6 L. Therefore the water deficit in TBW = 42 L - 33.6 L = 8.4 L.

Thus it is calculated that a loss of 8.4 L of body water or 12% of body mass in a 70-kg person produces shock. At minimal rates of water loss (1.5 to 2.0 L/24 hours), this could be produced in 4 to 5 days.

Therefore, by definition, if a pure water loss occurs (no salt loss), the loss would be apportioned over all the fluid spaces, with two thirds of the loss from the intracellular

water (8.4 L × ? = 5.6 L), one third from the extracellular water (8.4 L/3 = 2.8 L), and one twelfth

TABLE 10-2 -- Effect of Sweat Losses (Salt and Water) on Plasma Volume and Osmolality

		HYPOTONIC SWEAT (PERCENT × 280 mOsm)

from the plasma space (8.4 L/12 = 700 ml). This loss represents approximately 20% of the PV. In practice, usually less than one twelfth of the water loss comes from the plasma space because of its increased plasma protein oncotic pressure.

Sweat Salt Losses.

In contrast to the above loss of water only is the situation in which an unacclimatized individual has skipped a prior meal and is losing salt as well as water by producing hypotonic sweat assumed to be 0.41% NaCl = 140 mOsm/Kg = 0.5 × normal plasma osmolality. He is assumed to be euhydrated before commencing exercise in the heat for a 2- to 3-hour period, losing 6% of body mass (4.2 L) as sweat. Since this 4.2 L is at 0.5 × normal osmolality, it is equivalent to a loss of half that volume (2.1 L) of normal saline (280 mOsm/kg) and half (2.1 L) of pure water. That is, the extracellular space (3.5 L [plasma] + 10.5 L [interstitial] = 14 L; the sodium space) would lose 2.1 L of isotonic saline, of which the plasma contributes one fourth (3.5 L/14 L = 1/4). This is equivalent

to 525 ml (2.1 L/4) of PV.

In addition, the plasma would contribute one twelfth of the pure water deficit (2.1 L), or 175 ml (2.1 L/12). If these PV losses are added (525 ml + 175 ml = 700 ml), the plasma could lose 20% of its volume ($[100 \text{ ml}/3500 \text{ ml}] \times 100$), which is close to the shock threshold ([Table 10-2](#)).

This means a 4.2 L loss of sweat has theoretically as much impact on the PV (20%) as *twice* the volume (8.4 L) of pure water loss (20%). In this example, however, inadequate salt and water intake (skipped meals, no drinking) has a role, as does the rapidity of sweat losses (hours vs. days).

ACCLIMATIZATION

Prior heat exposure enhances heat tolerance by expanding circulating PV; increasing the maximum capacity of cutaneous vasodilatation and sweating; and reducing the threshold temperature for increased BF_{sk} and sweating, that is, commencing cooling mechanisms at lower temperatures.^{[187] [516]} An acclimatized person shows a lower T_c , T_{sk} , and HR and a higher msw in response to a standard heat stress. A further important benefit of heat acclimation is reduced loss of sodium (both urinary and in sweat) and therefore a reduced likelihood of developing salt-depletion heat illnesses from high sweat losses. When these physiologic adjustments occur in response to heat exposure in a controlled laboratory setting, they are termed *acclimation*, and if induced by the natural environment, *acclimatization*. The physiologic adaptations in the acclimation to heat and to severe physical exercise (training) are very similar; acclimation to one partly but not completely acclimates to the other.

The process of human acclimatization to heat produces both short-term and long-term changes in thermoregulatory responses involving sweating, skin circulation, and thermoregulatory set point. For instance, in some studies, short-term heat adapted people sweated more rapidly, whereas those who were long-term adapted sweated more slowly.^[231] Other equally impressive changes, but not specifically thermoregulatory, include cardiovascular alterations (HR, stroke volume, and PV) and endocrine adjustments. In the acclimatized state, a given heat and/or exercise load leads to reduced physiologic responses, for example, lowered T_c , lowered HR, elevated cardiovascular reserve, and increased cooling capacity through a reduced threshold for vasodilation.

Importantly, the rates of heat and exercise acclimatization are not uniform within a body but vary from tissue to tissue. As a result, there are periods when compensation processes in different organs are out of phase with one another and the overall effect may be negative.^[448] For example, in rats, the immediate heat adaptation response of both the salivary glands and heart is a temporary period of decreased sensitivity of those organs to their respective neurotransmitters, causing a reduced intrinsic secretion of saliva and HR. These intrinsic failures may be "masked" during the acclimation processes by overstimulating those organs through especially high autonomic activities.

Over time, different genes are activated within each organ, leading to the replacement of certain metabolic enzymes with isoforms more appropriate to elevated temperatures. These new isoforms have improved thermostability, altered reaction rates, and specificities, leading to the development of more efficient dynamic processes with reduced heat absorption by the body. In the final adaptive state, these altered enzymes

have improved cellular performance, even with normal autonomic activities.^{[152] [235] [309]}

Depending on a given individual's constitution, state of physical fitness, and thermal history, a specific thermal stress and intensity of exercise will produce some degree of thermal strain. However, each person acclimatizes heat stress in his or her own way, with considerable variation in indexes of heat strain (e.g., weakness, rapid pulse, narrow pulse pressure, flushing of the face and neck, headache, shortness of breath, dizziness, cramps, nausea, and vomiting).^[448] Many early studies have been shown to be unreliable because of small sample sizes, incomplete acclimation, or inappropriate measurements. Furthermore, Pandolf^[385] has noted that more is known about the time course for the acquisition of acclimation than its decay or loss. Recently, the use of sophisticated molecular biology techniques indicating the participation of heat shock proteins^[233] has shed new light on the fundamental processes involved in acclimation.

What is the fundamental event during exercise heat stress that causes the biochemical and physiologic alterations

264

in the body that ultimately result in heat tolerance? At the moment this is unknown. In humans, exercise in the heat causes a rise in aldosterone concentration within a few minutes. An elevated aldosterone concentration increases the number of Na⁺ K⁺ ATPase pumps on plasma membranes.^[162] Simply stimulating rabbit muscle over several days increased the number of Na⁺ K⁺ pumps on the sarcolemma^[197] and exercise training in humans raised the number of Na⁺ K⁺ ATPase pumps on sarcolemma within 1 week. As a result, severe exercise no longer caused a normal rise in plasma K⁺, probably because the increased number of Na⁺ K⁺ pumps attenuated the loss of K⁺ from working muscle.^[197]

Physiologic Changes

One benefit of adaptation is clearly shown by the incidence of heat syncope among persons suddenly exposed to living in a hot environment ([Figure 10-6](#)). Syncope, as described below, is caused by reduced cerebral blood flow resulting from a combination of peripheral blood pooling, reduced CO, and orthostatic hypotension. Syncope peaks on the first day of heat exposure and falls to zero by day 5. Although persons can acclimate to hot environments over a period of 1 to 2 weeks, they also deacclimate over approximately the same period of time.

Figure 10-6 Incidence of syncope among 45 subjects living in a hot environment for 24 hours each day and undergoing exercise trials. (Modified from Bean WB, Eichna LW: *Fed Proc* 2:144, 1943, by Hubbard RW, Armstrong LE. In Pandolph KB et al: *Human performance: physiology and environmental medicine at terrestrial extremes*, Indianapolis, 1988, Benchmark Press.)

In general, symptoms lessen as acclimation progresses. Nearly complete acclimation to a given level of daily exercise and heat stress can be achieved in 7 to 10 days ([Figure 10-7](#)).^[385] The physiologic changes produced by heat or physical training include a lowered threshold temperature for the onset of BF_{sk} , sweating (see [Figure 10-7](#)),^[410] increased PV, increased stroke volume, decreased HR, decreased skin temperature, decreased T_{re} , and increased $Ap?V_{O_2}$ max.^[16] Physical training also increases aerobic capacity. Practically, this means that a fit but untrained person who runs a 500-m race and develops a T_{re} of 40° to 43° C (104° to 109.4° F) could, after acclimation, run the same race under the same environmental conditions and have a T_{re} of only 37.5° C (99.5° F).^[288]

Although many controversial issues remain, a general rule is that either strenuous interval training or continuous exercise at an intensity greater than 50% $Ap?V_{O_2}$ max accounts for about 50% of the improvements found with classic acclimation procedures.^[188] This may be important to the individual who wants to

Figure 10-7 Effect of 10 days' acclimation on heart rate and rectal and skin temperatures during a standard exercise (five 10-minute periods of treadmill, separated by 2-minute rests) in dry heat. Large circles show values before start of the first exercise period each day, with small circles showing successive values. Squares show the final values each day. Controls of exercise in cool environment before and after acclimation. (Modified from Eichna LW et al: *Am J Physiol* 163:585, 1950.)

prepare for an acute change in thermal climate but does not have the means to safely elevate his or her core temperature in the heat.

The primary mechanism of the heat acclimation process is to raise internal body temperature sufficiently to induce moderate sweating. This can be achieved with moderate exercise in the heat or by wearing more clothing in a cooler environment. In the unacclimated individual, usually an hour per day of exercise in the heat is sufficient to produce an effect over days of exposure. As a rule, 10 days of successive treadmill walks in dry heat lower final exercise HRs by about 40 beats/min; lower rectal and skin temperatures by 1° and 1.5° C (1.8° and 2.7° F), respectively; and increase sweat production by about 10%.^[135] Generally, the degree of acclimation is related to the daily heat stress; that is, daily 100-minute bouts in the heat conferred more acclimation after 9 days than did 50-minute bouts.^[315] Most of the improvement in HR occurs in 4 to 5 days, and the improvement is nearly complete after 7 days (see [Figure 10-7](#)). As heat acclimation progresses, the onset of thermal sweating occurs at lower core temperatures and the peak sweat rate is higher or even doubled (1.5 to 3 L/hr). Furthermore, the ability to sustain sweating for prolonged periods improves, along with the ability to increase sweating in skin areas that sweated the least before acclimation. Acclimation tends to make the sweating response over different skin areas more uniform.

These effects result, in part, from central mechanisms, as well as from intrinsic fundamental changes in the pharmacologic activity of the sweat glands.^[96] Heat acclimation increases the sweat glands' capacity to reabsorb sweat sodium at any given sweat rate.^[6] Depending on the state of acclimation, the sodium concentration in sweat varies between approximately 5 and 60 mEq/L (10 to 20 mOsm/kg H₂O) (see [Table 10-2](#)) and increases with sweat rate but declines with the state of acclimation. The salt-sparing effect of acclimation seems to depend on the secretion of aldosterone, triggered by the combined effects of sodium depletion and heat stress.^[295]

Skin vasodilation, especially in the forearm where it can be measured, occurs at a lower core temperature after acclimation ([Figure 10-8](#)). Since these changes parallel the threshold T_c for sweating, they suggest that alterations are occurring in skin blood vessels at the same time as those in skin sweat glands.^[161] During acclimatization, despite the vasodilation of skin in the heat, BP is maintained for a long period and without reducing splanchnic blood flow (BF_{spl}). Improved vascular contraction results from improved responsiveness of α adrenoreceptors and decrease in β receptors.

Changes in HR and PV decrease in parallel during the first week of acclimation.^[448] The decrease in HR and increase in stroke volume may begin as early as the second day of work in the heat.^[534] These changes are nearly complete by day 5, whereas final rectal temperatures are still declining with subsequent exposures. Many authors have reported that PV increases with the days of heat exposure. However, the mechanisms involved, including salt retention, addition of protein to the vascular space, and fluid shifts between compartments, are unclear.^[447] What is interesting, however, is a return of PV to baseline levels after about 2 weeks without apparent thermoregulatory impairment.^[29] Horowitz et al^[236] have shown that long-term acclimation increased the compliance of rat ventricles in isolated hearts, resulting in a greater diastolic volume at any end-diastolic pressure, hence greater Starling contractility. This promising model has produced recent

insights described below.

Climatic Effects

There is a seasonal effect on the threshold temperature (T_{th}) for the onset of sweating; T_{th} is highest in winter and lowest in summer. Therefore, for a given heat stress, BF_{sk} and sweat rate are highest in summer and lowest in winter.^[358] Rapid air travel to a desert or jungle climate leads to incomplete acclimatization, or to none at all, and a very much increased rate of heat illnesses. For instance, military personnel have higher heat illness rates in summer than in winter in a number of locations.^[63]^[300] In a 4-year period, there were 10 severe heat casualties among soldiers visiting Cyprus during military

Figure 10-8 Effect of acclimation on forearm blood flow vs. esophageal temperature in one subject. (Modified from Roberts MF et al: *J Appl Physiol* 43:133, 1977.)

266

training, largely because of incomplete acclimatization. The rate was highest during summer months when the WBGT was 26° to 29° C (78.8° to 84.2° F).^[63]

The time course of acclimation is similar in hot climates that are equivalent in WBGT. Acclimation to a defined hot environment confers equal acclimation to any other equivalent climate.^[200] In groups of unacclimated healthy men subjected to heat for 9 days, those exercising under humid conditions produced better and more complete acclimatization than those exercising under dry conditions at similar WBGTs. Practically, when training at any given T_{amb} , a humid environment—and consequent higher heat load—leads to a more rapid acclimatization than training in a dry environment.^[357]

Athletes have thinner skinfold thickness than do nonathletes. This leads to an increased rate of heat loss from the core, across the skin barrier into air by radiation, convection, and conduction. Exercise training improves heat dissipation not only by the reflex physiologic changes previously described but also by causing a reduction in the thickness of subcutaneous fat. Importantly, skinfold thickness is thinner in summer than in winter, thereby improving heat dissipation when it is most needed.^[231]

Biochemical Changes

Heat Shock Proteins.

The metabolic heat produced by severe exercise can raise the temperature of exercising human muscle to 45° C (113° F), and T_c up to 44° C (111.2° F). These temperatures can damage muscle mitochondria so that they generate O_2^- and H_2O_2 , causing oxidative damage in addition to thermal stress.^[430]

All cells have the potential of being stressed by heat and other stressors. To survive they have developed the ability to rapidly synthesize specialized proteins known collectively as *heat shock proteins* (HSPs), which protect them against ordinarily lethal conditions. Many cell types are ordinarily destroyed by 5 minutes at $T_{amb} = 49° C$ (120.2° F). However, if they are first heated to 42° C (107.6° F) for 15 minutes, protective HSPs are induced within the cells so that they can survive $T_{amb} = 49° C$.^[427] HSPs refold denatured proteins into their normal conformation and stabilize normal proteins against thermal injury. The binding of HSPs to denatured proteins does not cause immediate global conformational change of the unfolded proteins; rather, HSPs act locally on small regions of exposed hydrophobic amino acids through repeated cycles of binding, folding, and release reactions that are energized by the hydrolysis of ATP.^[68] HSPs are produced as a general response to all known stresses, if sufficiently intense, including hypoxia; free radicals; cold, acidic environment; starvation; ionizing radiation; a variety of chemical toxins; and even electromagnetic fields.^{[68] [147] [313] [271]} Furthermore, HSPs may protect parasites against host defenses.^[441] Heat shocking a variety of cells and animals increased HSP content and protected them against not only heat but apoptosis, ischemia/reperfusion injury to the mucosa, and ionizing radiation.^{[354] [378] [431] [477]} Overall, in mammalian tissues, heat shock appears to provide a protective advantage of at least 2° C (3.6° F) against morbidity and mortality caused by high temperatures.^[333]

HSPs are induced not only by physical and chemical stresses, including sepsis, cocaine, and tobacco smoke,^{[45] [111] [503]} but apparently even by psychologic stresses, such as loud noise, isolation in darkness, restraint, water immersion, inescapable irritation, seizures, and sleep deprivation.^{[86] [165] [218] [226] [239]} Indications of elevated levels of HSP-60 were found in one small study of schizophrenics.^[444]

The production of high levels of HSPs is not without cost, otherwise they would be present in cells all the time. HSPs may interfere with the spontaneous folding of new proteins, and the stresses sufficient to induce HSPs redirect cellular machinery to produce HSPs at the expense of producing other proteins. This would be particularly damaging to rapidly growing cells, such as during fetal maturation.^[147]

HSPs are grouped into a series of families based upon their molecular masses; for example, the most important HSP-70 family contains several proteins of 68-75 kDa. In each cell, certain HSPs from each family are normally present and increase only moderately following heat, for example, HSP-73, which is sometimes referred to as "constitutive HSP-70." Other HSPs are normally absent from the cell or present in only very low amounts but are rapidly induced by heat ($T_{amb} > 41° C$ [105.8° F]) to become

the most common protein in the cell, for example, HSP-72. The widely used, but ambiguous, term *HSP-70* refers to any or all members of the family.

The threshold temperature for the induction of HSPs depends upon the species and cell type but is approximately 4° C (7.2° F) above the normal environmental temperature encountered by the cell. A temperature as low as 5° C (41° F) induces HSPs in Antarctic algae, which normally live at -1° to 1° C (32° to 33.8° F).^[502] Most investigators suggest that the threshold in mammalian cells is approximately 41° C (105.8° F), although temperatures as low as 39° C (102.2° F) have been reported.^[90]

The rate of heating may also be an important factor in thermal injury, since the production of HSPs and cell survival also depend upon the rate of heating.^[46]^[225] HSP production is also organ-dependent. In heat-shocked rats (42° C [107.6° F]), HSP-72 was produced in the order of liver >> small intestine > kidney, quadriceps > brain.^[155] In rat brain, lung, and skin, HSP-70 concentration peaked at 1 hour and returned to baseline at 3 hours poststress. In liver, however, HSP-70 peaked 6 hours poststress.^[46] The determination of HSP-72 may be useful as a diagnostic probe of recent heat injury when a rapid assay is developed.^[61]

Most studies on HSPs have been carried out in isolated cells and in rodent models. In humans, the threshold T_c and duration for a single heat shock to induce HSPs is not certain. Cells could survive very brief exposures (1 second) to temperatures as high as 60° C (140° F) because they induced HSPs that rendered them thermotolerant.^[58] Following a single heat shock in human peripheral blood mononuclear cells, HSP-72 concentration is unchanged for 1 to 2 hours, then rises rapidly to plateau at 4 hours and gradually falls after 12 to 18 hours, but remains above baseline at 24 hours (Gaffin, unpublished observations). Overall, however, upon a single supra-threshold stress, HSPs probably rise within an hour or two of the stress and remain elevated for 12 to 48 hours and possibly for as long as a week.^[211] During sport or exercise in summer, however, elevations in T_c would be repeated, and multiple stimuli may have profound effects on the time course of HSP elevation and protection.^[233]

This *temporary* thermoprotection by HSPs to heat and exercise is not "acclimatization." Acclimatization is a different process, although it may in part involve HSPs. It develops over a period of several days in response to several periods of moderate heat and may persist for weeks.

In the work of Horowitz et al,^[233] acclimatization involves alterations in autonomic, cellular, and molecular responses to heat, varying in their intensities and interrelationships over time. Some studies suggest that increased HSP-72 during rigorous exercise is one of the adaptive mechanisms to cope with increased stress.^[234]^[311] Rats run on a treadmill for 30 minutes per day at 75% $A_p V_{O_2}$ max showed increases in HSP-72 within 10 weeks.^[116] Endurance exercise-trained rats had higher levels of HSP-72, as well as lower levels of lipid peroxidation in their ventricles, and

could develop higher systolic pressures. [115] [398]

The presence of HSPs is extremely important, since during exercise in moderate and warm temperatures or at rest in tropical or desert heat, T_c may rise to levels that severely decrement performance or may lead to heatstroke, collapse, and even death. A better understanding of the role of HSPs may ultimately lead to methods for faster acclimatization to heat. The ability to produce HSPs may depend upon the diet, since vitamin D-deficient animals showed reduced HSP production. [270]

PROTECTION.

HSPs appear to be beneficial to membranes, cells, tissue, and organs. HSP-70 elevated by a variety of stresses (heat shock, brief cyanide, arsenite, peroxide, hypoxia, and toxins) protected cells and their ultrastructure against these or other stressors. [9] [49] [278] [507] HSPs protect against membrane damage caused by toxins (ionomycin) and cytokines. [201] [301] Well-healing wounds show high levels of hsp70mRNA, whereas poorly healing wounds have lower levels. [375] Overexpression of HSP-70 in transgenic mice rendered their hearts more resistant to ischemic injury. [327] Those human cell types normally exhibiting great resistance to hypoxia (proximal tubular epithelia) also contain high basal levels of HSP-70. [495] Elevated HSP-72 (by heat shock or arsenite) protected rats against heatstroke morbidity and mortality. [536]

Elevated HSP-72 blunted the liberation of inflammatory mediators (interleukin-6 and thromboxane B_2) in lipopolysaccharide (LPS)-challenged swine and improved the course of hemodynamic variables (decreased peak pulmonary artery pressure and pulmonary vascular resistance index values, increased systemic artery pressure and systemic vascular resistance index values, and favorably altered hypodynamic/hyperdynamic CO). [283] Elevated HSP-70 (by heat shock) protected rat intestine against toxin (ricin)-induced acute intestinal inflammation, with reduced generation of leukotriene B_4 and neutrophilic infiltrate in their ileums. [478] Monocytes and granulocytes constitutively express more HSP-70 and are more heat-resistant than lymphocytes. LPS raises HSP-70 content even more and may be the reason that those cells can survive and function in hostile inflammatory microenvironments. [153]

Not only is raising HSP levels protective against heat, but reducing them is damaging during stress. For example, reducing HSP-72 induction by 40% (by a specific toxin) rendered cardiac myocytes more susceptible to hypoxic injury. [359]

In principle, it may be possible in humans and experimental models to elevate HSPs by one stress (e.g., temporary hypoxia) to render athletes more tolerant to heat, cold, or toxins. This would benefit not only athletes but also soldiers deployed to hot climates and patients soon to undergo surgery.

AGE.

In normal adult rats, heat and exercise can each induce HSP-72. However, in aged rats, only exercise could induce HSP-72 [299]; that is, aging caused them to lose their ability to

induce HSPs by heat. In humans, the elderly have lower levels of HSP-70 in their peripheral blood mononuclear cells (PBMCs) than do the young.^[109] This loss of HSP protection may in part account for increased susceptibility of the aged to classical heatstroke, as is seen in heat waves.

RACE.

HSP production may be race-related. In one study, heat-induced HSP levels were very intense in cells isolated from native Turkish men living in the hot desert of middle Asia but very weak in Russians living in moderate climatic regions of European Russia. At the same time, those cells isolated from Turkish men better survived heat stress.^[253] Not surprisingly, organisms living many generations in hot climates become better adapted to it over time. No systematic study of racial influences on HSPs has been reported.

TRAINING.

Long-term exercise training in the heat induced HSPs. In one study of rat brains, HSP-70 content rose only if the exercising rats became hyperthermic, whereas exercise alone did not induce central HSP-70 expression.^[506] On the other hand, in spleen cells, peripheral lymphocytes, and soleus muscles, exercise alone induced HSP-60, HSP-70, HSP-90, and HSP-100.^[319] In male rowers in training, the HSP-70 content in an active muscle rose each week (181%, 405%, 456%, and 363%) with maximum HSP production at the end of the second training week.^[521] In humans walking 30 minutes on a treadmill at their individual anaerobic thresholds, messenger ribonucleic acid (mRNA) for HSP-70 rose but not the HSP-70 protein itself. That is, a single bout of exercise in humans may not be sufficient to induce HSP-70.^[401]

Combined stressors may be additive or synergistic in their effect. Exposure of cells to either a moderately elevated temperature or to a low level of ethanol do not induce HSPs. However, when the two stresses were applied at the same time, the cells induced large amounts of HSPs. Thus hyperthermia and ethanol acted synergistically to increase HSP gene expression.^[415] Practically, that implies that HSPs may be induced by overlapping periods of exercise, heat, hypoxia, and/or sleep deprivation.

CONSEQUENCES.

There is a downside to the production of HSPs during stress injury: the cell ceases or slows production of many other proteins. As a result, in cells at normal temperatures, the synthesis of HSPs (induced by a short heat stress) retards cell growth^[146] even as it protects against subsequent heat injury. Not only is growth retarded; heat-shocked immune cells secreted reduced amounts of cytokines in response to LPS.^[407] Therefore, persons with elevated HSPs may have reduced or inappropriately altered immune function. Clearly, the potential benefits of deliberately inducing HSPs, with presumed improved resistance to heat, hypoxia, and certain chemicals and toxins, must be

weighed against the potentially decremented ability to resist infections. More research in the field is necessary for the required quantitative data.

Thyroid Hormone and Protein Isoforms.

Recent studies indicate that thyroid gland function is an important component of heat acclimation. IL-1 reduces the release of thyroid hormone from the thyroid gland.^[103]^[127] Since IL-1 becomes elevated in response to many stresses (see [Figure 10-1](#)),^[170] its ability to lower thyroid hormone release may be part of the overall protective mechanisms and responses to stress.^[267]

Alterations in thyroid hormone concentrations have a number of physiologic and biochemical consequences. Deficiency of thyroid hormone has a negative cardiac chronotropic effect, reducing cardiac contractility and increasing systemic vascular resistance.^[62] The basal metabolic rate (BMR) falls with thyroxine deficiency, and since its secretion rate is lower in summer and higher in winter, there is a corresponding seasonal alteration in the BMR and all other processes influenced by thyroxine concentrations.^[231] One component of heat acclimatization is a reduction in BMR.^[231] Chronic heat stress decreases blood flow to the thyroid^[204] and reduces the production rate of thyroid hormone, leading to decreased food intake, growth rate, and oxygen consumption, and lower BMR.^[419] The consequences of deficiency in thyroid hormone during acute stress may be fatal. A young woman was discovered unconscious in a sauna and later died with a diagnosis of heatstroke. On autopsy, preexisting Hashimoto's thyroiditis was found.^[460]

Muscle contains characteristic isoforms of myosin, each with differing intrinsic metabolic activities, such as the rate of its actin-activated ATPases. Myosin molecules are composed of heavy and light subunits that associate in a specific manner, each of which is specific to muscle type during development and maturation; that is, ventricular myosin of a fetal heart is different from that of an adult heart.^[82] In some muscles, acclimation leads to a higher proportion of "slow" myosin ATPase, such as the replacement of myosin heavy chain type IIb (MHCIIb) with type IIx.^[124]^[236] Hearts isolated from heat-acclimated rats became more efficient in terms of amount of oxygen required per unit force time per gram of tissue,^[232] due presumably to the presence of altered isoforms of contractile proteins. Between 30 and 90 minutes of daily exercise for 10 weeks reduced the percentage of MHCIIb fibers in rats and increased the slower, but more efficient, MHCIIa fibers in rat hind limb muscle. That is, increasing the training duration increases the fast-to-slow shift in myosin isoforms.^[114] Excess thyroid hormone increases the amount of the myosin isozyme V1 with its high rate of ATPase and contractile speed, at the expense of the normal V3 isozyme, leading to greater speed and strength but reduced efficiency. In the case of sweat secretion, upon acclimation, there is intrinsically a greater secretion rate of sweat along the secretory tubules because of isoform alterations.

The administration of thyroid hormone to neonatal rats rapidly replaces fetal cardiac ventricular myosin with its adult isoform. On the other hand, if the synthesis of thyroid hormone is suppressed, then the slower, fetal isoform predominates;^[62] that is, thyroid hormone concentration regulates protein isoforms, activities, and therefore the output of

metabolic heat. [88]

The speed and extent of contractility of heart muscle depend upon the number of the Ca release channels in the sarcoplasmic reticulum (more channels permit faster Ca^{2+} entry into the cytoplasm and faster contraction), and the rate of Ca uptake by the sarcoplasmic reticulum (SR; faster uptake means faster relaxation). In ventricles, low thyroid hormone levels reduce the number

269

of Ca release channels, which depresses contractility. In the atria, low thyroid hormone also increases the density of muscarinic receptors, rendering them more sensitive to negative chronotropic agents. In summary, low thyroid hormone levels depress cardiac function and render the heart more sensitive to agents that decrease atrial contraction and less sensitive to agents that increase HR and contraction. [14] [282] [298] [416]

Acclimation occurs under conditions of relative or actual hypothyroidism. As a result, the acclimated heart shows altered myosin isoforms and increased phospholamban content but lowered contractile velocity, rate of Ca ATPase Ca uptake by the SR, and relative oxygen consumption. These changes increase overall efficiency of the heart at the expense of contractile velocity. [75] [345]

Thyroid hormone increases the number of $\text{Na}^+ \text{K}^+$ ATPase pumps [91] and decreases the density of voltage-dependent calcium channels on plasma membranes (leading to a reduced intracellular Ca^{2+} content). [149] Thyroid hormone and sustained aldosterone, such as from excess sweat loss and elevated Na, also alter metabolic processes and electrical activity of cells by regulating intracellular Na and K concentrations. In the short term, they increase the number of functional $\text{Na}^+ \text{K}^+$ ATPase pumps by recruiting preformed but inactive pumps and their subunits to the plasma membrane. In the long term, they induce the synthesis of new pump subunits. [91] [144] Therefore the prolonged reduced levels of thyroid hormone seen during acclimatization decrease the number of those pumps, hence reducing metabolic activity. [449]

Almost any traumatic insult to the body alters hormonal levels. It decreases thyroid hormone, gonadotropin, and gonadal steroid concentrations and increases ACTH, cortisol, growth hormone (GH), and prolactin levels [44] (see [Figure 10-1](#)). The reduction in thyroid hormone concentration commences within a few hours, may be maximal after 1 to 4 days, and persists for the duration of the illness. [529] Among heatstroke victims, the decreases in serum thyroid hormone correlated with severity of the heatstroke, according to peak T_c . [84] After the patients completely recovered, the thyroid function tests returned to normal. That is, the severity of heatstroke was related to the depression of thyroid function. The hypothyroid state may be protective by preventing undesirable catabolic effects. Therefore replacement therapy is not currently recommended. [84]

In summary, long-term acclimatization to heat and exercise involves changes on a

molecular level, including alterations in intracellular HSP concentrations, increased IL-1, reduced thyroid hormone, increased aldosterone, increased number of Na⁺ K⁺ ATPase membrane pumps, alterations in protein isoforms, altogether contributing to the physiologic adaptations in organ function.^[232]

IMMUNE SYSTEM

In the processes of digestion and absorption of ingested food, chyme remains in the intestines for hours to days. Although we receive a large share of the nutrients, bacteria present in the gut lumen also absorb nutrients from the chyme and reproduce rapidly, reaching concentrations of 10^9 to 10^{12} organisms/g.^[181] Dead gram-negative bacteria slough off into their milieu large amounts of the highly toxic cell wall component (endotoxin), which may reach concentrations of 1 mg/g in feces.

As long as LPS remains within the intestines, it is not harmful. Small amounts that "leak out" into the circulation are rapidly inactivated by several mechanisms: some LPS is phagocytosed by bound Kupffer's cells within the liver reticuloendothelial system (RES), where it is partly detoxified and then bound by hepatocytes for further degrading^[493]; some LPS binds to circulating antilipoplysaccharide antibodies^[167]; some binds to high-density lipoprotein (HDL)^[496]; and some binds to LPS-binding protein (LBP).^[530]

However, large amounts of LPS rapidly entering the circulation would overwhelm the protective systems, allowing LPS to express its toxic effects rapidly. At plasma concentrations between approximately 10 and 100 pg/ml, LPS initiates a cascade of molecular events, leading to nausea, vomiting, diarrhea, fever, and headache.^[42] Higher concentrations can lead to conditions identical to those of gram-negative bacteremia, including vascular collapse, shock, and death.^[76] In fact, at the time of death from gram-negative bacteremia, there may be no live bacteria in the plasma, and the circulating LPS appears to be the immediate cause of septic shock.^[519]

Intestinal Ischemia and Lipopolysaccharide Release

During exercise, blood flow to muscle may rise from a resting value of 1 to 2 ml/100 g/min to as high as 300 ml/100 g/min to provide oxygen and nutrients. As T_c rises, blood flow to the skin also rises to provide cooling. This strains the cardiovascular system's ability to maintain blood flow to the heart, brain, and liver.^[291]^[334] It is important that blood flow to the liver be maintained during heavy exercise to remove lactate and other metabolites from the blood and to provide glucose for energy.^[291]

To maintain blood pressure under still more intense exercise and thermal stress, blood flow is reduced to the less immediately critical organs, the intestines and kidneys. If splanchnic blood flow drops sufficiently, it causes regions of local ischemia and transitory gut wall damage. If this is prolonged, there may be permanent ischemic injury to the gut wall.^[400]^[403] Furthermore, several transitory bouts of local hypoxia and

stress in splanchnic tissues may generate free radicals, exacerbating ischemic injury. [208] Exercise at 80% $\dot{V}O_2$ max for 30 minutes at 22° C (71.6° F) increased the permeability of human intestines to small molecules. [384] Ischemic injury of the intestines causes the diarrhea or water intoxication occasionally encountered during a marathon run as a consequence of the inability to reabsorb water ingested during the race. [291] For example, in one extreme case, Fogoros [158] reported that after winning a marathon in 1979, Derek Clayton stated that "two hours later ... I was urinating quite large clots of blood, and I was vomiting black mucus and had a lot of black diarrhea." Intense and prolonged running is a common cause of gastrointestinal bleeding; up to 85% of ultramarathoners demonstrate guaiac-positive stools from a 100-km race. [28] The ultimate consequences of reduced gut blood flow—endotoxemia—may be severe.

Because of the high LPS gradient across the gut wall, almost any insult to the integrity of the gut wall leads to a rise in plasma LPS. Hemorrhage to 45 mm Hg reduces splanchnic blood flow and therefore reduces oxygen delivery to the walls of the stomach, small intestine, and sigmoid colon. [347] This has led to local elevations in the permeability barrier of the gut wall and caused endotoxemia. [172] In a swine model, blood flow through the superior mesenteric artery was progressively occluded, leading to progressive tissue hypoxia and a local shift to anaerobic metabolism, producing lactate and a fall in the pH of the gut wall. [154] At about the same time, LPS entered the circulation. This may lead to an ominous positive feedback loop, since infusing LPS causes hypotension, reduced splanchnic blood flow, and an increase in gut permeability so severe that bacteria can be translocated into the circulation. [154] [515]

The size of putative "holes" in the gut wall accounting for the rise in LPS permeability depends on the duration of the ischemia. When the superior mesenteric artery of canines was occluded, LPS (molecular or micellar) leaked out into the circulation within 20 minutes, but the appearance in the circulation of whole live bacteria (several orders of magnitude larger) required 6 hours of occlusion. [389] In other species, these times may be much shorter. [110]

In a different model, nonhuman primates breathed a hypoxic gas mixture for an hour. [173] The resultant hypoxemia rapidly initiated a reflex response designed to maintain oxygenation of the heart and brain at the expense of the rest of the body. This reflex caused intestinal blood flow to fall and was so intense that it resulted in transient ischemic injury to the gut wall and translocation of LPS into the circulation within only 5 to 10 minutes of hypoxia. When the immune system was suppressed by radiation, hypoxia caused LPS to rise to higher levels and persist in the blood for a longer period. On the other hand, when the gut flora had been reduced by administration of nonabsorbable antibiotics, there was no detectable translocation of LPS and bacteria by hypoxia. [110] [181]

There is a fitness component to alterations in splanchnic blood flow. When experimental animals were heat stressed, the fit ones with their greater cardiovascular capacity maintained BF_{spl} better, had reduced amounts of ischemic damage to the gut wall, and reduced quantities of LPS translocated into the circulation than did sedentary animals.^[429] That is, fitness may reduce the LPS load during severe exercise.

Such studies show that the permeability barrier in the gut wall is rapidly damaged by hypotension, reduced blood flow, and hypoxia, thus permitting LPS to enter the portal and systemic circulations at a high rate.

The development of secondary fever and infection with a high death rate is common after the cooling of patients with heatstroke.^[458] The susceptibility of such patients to infections^[458] may be due to a combination of changes in lymphocyte subpopulations, together with the increase in gut wall permeability to LPS and bacteria caused by hyperthermia and associated hypotension.^[110]

Cytokines and Shock

Cytokines are a class of protein cell regulators produced by a wide variety of cell types throughout the body. They control the timing, amplitude, and duration of the immune response.^[93] They are relatively low-molecular-weight proteins (<80 kDa), usually act at short range in a paracrine or autocrine manner rather than as circulating hormones,^[122] and interact with high-affinity cell surface receptors regulating the transcription of several cellular genes, resulting in changes in cell behavior.^[24] The various cytokines are extraordinarily active, have overlapping and important activities and may induce each other so that it is difficult to establish which cytokine has what critical function. The local concentration probably determines which regulatory influence a cytokine has at a particular time. After induction by a single stress, various cytokines may be present for hours to days.

Cytokines are usually grouped into two families, proinflammatory and antiinflammatory. The proinflammatory family cytokines are largely cytotoxic. They destroy invading microorganisms and loosen contacts between adjacent cells in a tissue to increase permeability and permit the entry of macrophages into the tissue. Antiinflammatory cytokines facilitate B-cell activation and production of antibodies.

LPS causes septic shock, but LPS itself is not a contact poison. Rather, LPS present in the bloodstream is first bound by LPB to form a complex, which circulates until it encounters a specific high-affinity LPS receptor, CD-14, on a macrophage.^[445] Binding of CD-14 by the LPS-LBP complex initiates a cascade of reactions within the macrophage involving hypersecretion of cytokines. Because of their inappropriate and excessive local concentrations, cytokines become highly toxic. Although the correlation between mortality and plasma concentration of any single cytokine is low in persons with

sepsis, mortality correlates closely ($p < .001$) with a "score" consisting of a summation of the concentrations of individual cytokines. [79]

Most of the symptoms of gram-negative bacterial shock can be induced by injection of some of the purified cytokines alone. The first two (and most important) cytokines induced by LPS are TNF and IL-1. [342] TNF administration to humans causes fever, tachycardia, increase in stress hormones, and leukocytosis, [342] with the intensity of symptoms closely correlating with peak concentrations of TNF.

TNF rapidly induces IL-1, which causes fever, sleep, anorexia, and hypotension. [325] IL-1 acts directly on vascular endothelium (which would be an organ the size of the liver if concentrated in one place) to increase local concentrations of nitric oxide and to raise circulating prostaglandin concentrations, ultimately resulting in vasodilation, hypotension, and, possibly, shock. [122] IL-1 may also have a more subtle effect. IL-1 changes the norepinephrine responses of arteries in different vascular beds. [395] It decreases norepinephrine-induced contraction by about 50% in the aorta, carotid, and pulmonary arteries but increases contraction in femoral arteries. By so doing, IL-1 may cause abnormalities in regional blood flow during sepsis. [409] Heatstroke raises circulating catecholamine concentrations, which in the presence of IL-1 may redirect blood flow inappropriately. [3]

In Marine recruits, the frequency of heat illnesses during training increases with the highest temperature on the previous day. [266] That is, high T_{amb} may lead to a prolonged rise in cytokines within the body, which in turn may lower the threshold for developing exertional heat illness (EHI) during exercise the following day. High T_{amb} leads to elevated T_c with apoptosis of "inappropriate" cells, including intestinal mucosal cells, over the next several hours, permitting leakage of toxic bacterial contents from the lumen into the circulation, rendering the person at risk from exercise.

Possible New Therapy.

A single injection of IL-1 receptor antagonist (IL-1ra) immediately after the onset of heatstroke in rats blunted the hypotension response to heat; they survived much longer (91 minutes vs. 17 minutes) than did controls. [87] However, with continuous perfusion of IL-1ra, the survival time increased to 10 hours from the onset of heatstroke. Currently, the beneficial effects of IL-1ra have not been proved in humans, and we do not recommend such therapy. However, if clinical trials should prove its effectiveness, then after initiating cooling procedures, volume therapy and transportation to a hospital, administration of IL-1ra may become part of heatstroke therapy. [87]

Arachidonic Acid, Leukotrienes, and Prostaglandins.

At the biochemical level, binding of IL-1 to its specific membrane receptor activates G

protein, which increases intracellular cyclic adenosine monophosphate (cAMP) concentration, which in turn activates membrane phospholipases. Activation of the phospholipases ultimately leads to cell damage and organism pathophysiology.^{[81] [191]} The phospholipases hydrolyze phospholipid esters of fatty acids, which in Western diets are largely the ω -6 fatty acids.^{[252] [305]} ω -6 fatty acids are hydrolyzed into the key metabolite, arachidonic acid.

Cells contain two major enzyme classes that can act on arachidonic acid: lipoxygenases and cyclooxygenases. Lipoxygenase acts on arachidonic acid to enter a pathway, forming 5-hydroperoxyeicosatetraenoic acid (5-HPETE) and a series of toxic leukotrienes. Of them, LTB_4 , LTC_4 , and LTD_4 are the most important. LTB_4 induces inflammation, increases capillary leakage, and causes leukocytes to aggregate. LTC_4 and LTD_4 are the strong bronchoconstrictors involved in asthma.^{[97] [210]} Cyclooxygenase converts arachidonic acid into prostaglandin G_2 (PGG_2), which is converted into PGH_2 with the formation of toxic free radicals. PGH_2 is a central metabolite on which a variety of enzymes act to form mainly toxic products, such as thromboxane A_2 (TxA_2) and many different prostaglandins, including the toxic PGD_2 . TxA_2 causes platelets to aggregate, is a strong vasoconstrictor, and increases capillary leakage. To a person in shock or with another circulatory disorder, such agents could convert a severe but treatable condition into a lethal one. In summary, eating a normal Western diet results in the presence of large amounts of ω -6 fatty acids in phospholipid cell membranes, predisposing to the formation of arachidonic acid and a large number of its toxic metabolites. For a review of prostaglandin and thromboxane biochemistry, see Oates et al^{[373] [374]} and Bottoms and Adams.^[54]

However, in fish-enriched diets laden with ω -3 fatty acids, a high proportion of the ω -6 fatty acids in plasma membranes are replaced by the ω -3 fatty acids, phospholipases hydrolyze the phospholipids into eicosapentaenoic acid, and no arachidonic acid is produced. Therefore no strongly toxic thromboxanes, prostaglandins, and leukotrienes are produced. Instead, only slightly toxic leukotriene B_5 is formed.

Dietary fish oil (rich in ω -3 fatty acids) dramatically downregulates key immunoregulatory cytokines involved in an autoimmune disease.^[256] Mice fed fish oil for 6 weeks showed reduced fever and weight loss caused by LPS injection and did not have the rise in PGE_2 that normally results from LPS activity. These changes suggest that, indeed, the pathophysiology induced by toxic arachidonic acid metabolites can be reduced or prevented by dietary replacement of ω -6 fatty acids with ω -3 fatty acids.^[297] However, there was an exaggerated rise in TNF- α , a toxin in itself, possibly because of the lack of the negative feedback from PGE_2 . Therefore, although these studies appear promising, they must be interpreted with extreme caution and are not recommended to guide a prophylaxis for heatstroke. There has not yet appeared a clinical study

showing that injection or ingestion of ω -3 fatty acids protects humans against heat illnesses. However, supplementing a normal Western diet with fish oil capsules replaces a significant proportion of ω -6 fatty acids by ω -3 fatty acids in human cell membranes within 6 weeks, and possibly much less.^[140]

Fever.

Fever, in contrast to exercise hyperthermia, represents a physiologic state in which the "thermostat" has been reset above 37° C (98.6° F) by exogenous pyrogens released by bacteria or viruses^[121] or from IL-1,^[138] IL-2,^[258] IL-6,^[353] and interferon- α and interferon- β .^[48]

Cytokines may be responsible in part for other clinical symptoms of fever, including fatigue, malaise, and edema. α -Melanocyte stimulating hormone inhibits IL-1-induced fever and the acute phase response.^[318] Interestingly, neutralizing antibodies to IL-1 and TNF have been found in the sera of both normal and sick individuals and may play a role in their regulation.^[485] Current evidence suggests that aspirin-like cyclooxygenase inhibitors interfere with IL-1-induced fever or shock responses by inhibiting prostaglandin synthesis.^[379]

Defervation.

Circulating LPS reaches the thermoregulatory control center in the anterior hypothalamus, activates cyclooxygenase, and induces prostaglandins.^[229] LPS also is bound by the liver, where it stimulates the vagus nerve to signal the hypothalamus to produce prostaglandins.^[417] At the onset of a fever, a patient often feels "chilled" and shivers to elevate T_c by additional metabolic heat. A new, higher preferred ambient temperature is behaviorally established.^[376] The physiologic change is even more important. Once this new set point temperature is established, the thermoregulatory center uses all available thermoregulatory mechanisms to maintain it. As a result, attempts at whole body cooling are met with sensations of extreme discomfort and violent shivering. Thus unsuccessful attempts to cool patients with suspected heat illness that results in chills and violent shivering suggest coexistent infection or disease.

This prostaglandin-mediated pathway may be responsible for fever, for normal circadian temperature variation, for pathologic temperature elevations, and for temperature elevations related to stress.^[39] Although there may be pyrogens that do not act via prostaglandins,^[105] treatment, if necessary, should be directed at agents that block the action of the pyrogen at the hypothalamic receptor sites.

The external application of cold to reduce true fever is illogical^[481] and often ineffective, even after antipyretic therapy.^[25] The body defends the higher temperature set point against environmental cooling. Therapy for fever that uses agents to block the causative molecular interaction is the most rational and clinically effective approach. Aspirin and other antipyretic agents, such as acetaminophen, indomethacin, ibuprofen, and other newer nonsteroidal antiinflammatory compounds, are effective and act either directly or indirectly through inhibition of the prostaglandin mechanism.^[107]

Fever and Resistance to Infections.

In simple heat stress or mild hyperthermia produced by passive heat exposure or an exercise-induced increase in metabolism, body temperature will usually fall spontaneously toward normal levels.^[353] The normal febrile response is generally self-limited in both magnitude and duration.^[518] Vasopressin^[504] and melanotropin^[362] appear to act centrally to suppress temperature elevation and may be important in preventing extreme hyperthermia.

Should Antipyretic Therapy Be Routine?

High temperatures enhance resistance to viral infections in experimental animals.^[37]^[77]^[151] For example, replication of deoxyribonucleic acid (DNA) viruses is inhibited by mild hyperthermia,^[184]^[227]^[321] and measles virus membrane protein is selectively blocked by heating cultures to 39° C (102.2° F).^[377] Some host defense functions^[423]^[501] that become more effective at 40° C (104° F) than at 37° C (98.6° F) level off or diminish at 42° or 43° C (107.6° or 109.4° F).^[481] Although fever has long been recognized as a manifestation of disease^[22] and may be identified as a debilitating problem even in the absence of other signs or symptoms,^[513] antipyretic therapy should not be instituted routinely for every febrile episode.^[157]^[196] Furthermore, although administration of aspirin lowers fever by altering the thermoregulatory set point in the hypothalamus, it also leads to a greater rise in T_c in response to a standardized heat stress and therefore is not a universal temperature-lowering agent.^[145]

In summary, at T_c up to approximately 40° C (104° F), the febrile process has a role in host defense and routine antipyretic therapy for fever is generally unnecessary and conceivably harmful,^[481] especially with a link between aspirin and Reye's syndrome.^[481] Instead, treatment should be based on evaluation of relative risks^[47]^[128]^[284] in the individual case and reassessed if the anticipated benefits are not achieved.^[481]

Role of Lipopolysaccharide in Heatstroke Pathophysiology

Heatstroke temperatures greater than 43° C (109.4° F) caused a large increase in permeability of isolated rat intestinal walls to LPS and persisted even after the temperature was reduced to 37° C (98.6° F).^[365] This suggests a direct thermal injury of the gut wall. The time course of the movement of LPS through the intestinal wall into the circulation resulting from hypoxia, ischemia, and ionizing radiation was determined in nonhuman primates^[363] and compared with hyperthermia ($T_{amb} = 41° C [105.8° F]$, RH = 100%, 3 to 4 hours).^[310] As T_c rose, the

plasma LPS concentration remained low until 42° to 43° C (107.6° to 109.4° F) (Figure 10-9 (Figure Not Available)). At this temperature, there was a sudden rise in LPS

concentration, first in the portal vein, and 10 to 15 minutes later in the systemic circulation. This sequence appears to be the main route of LPS: out of the lumen of the intestines, through the portal vein and liver, and into the vena cava as a result of intestinal ischemia and heatstroke. ^[182]

In a previous study of infection by injecting live gram-negative bacteria, Gaffin and coworkers^[519] noted that when the concentration of live gram-negative bacteria or LPS rose, the concentration of measurable circulating LPS-specific antibodies fell because they bound to circulating LPS and were "consumed" and no longer detectable by an immunoassay.^[519] It had been expected therefore that in the heatstroke experiments the concentration of "natural" anti-LPS antibodies would also immediately fall at 42° to 43° C (107.6° to 109.4° F). Contrary to expectations, natural anti-LPS began to decline at temperatures as low as 39° to 40° C (102.2° to 104° F) (see Figure 10-9 (Figure Not Available)).^[182] This suggests that as T_c rose to only 39° to 40° C, LPS actually commenced to leak into the circulation at a slow rate, gradually consuming the anti-LPS antibodies. As T_c continued to rise, at a certain point massive damage to the gut wall occurred, leading to rapid leakage of LPS into the portal vein. Currently it is not clear how much of this damage is caused by reduced oxygen delivery from reduced intestinal blood flow, how much by direct thermal damage of the gut wall, and how much by other causes.

Anti-LPS antibodies were protective against heatstroke in vervet monkeys up to a T_c of 43.5° C (110.3° F),

Figure 10-9 (Figure Not Available) Endotoxemia caused by heatstroke in anesthetized nonhuman primates. At T_{re} of 42° to 43° C (107.6° to 109.4° F), plasma lipopolysaccharide (LPS) concentration rose first in the hepatic portal vein and 10 to 15 minutes later in the systemic circulation. However, a decline in "consumed" anti-LPS antibodies occurred at temperatures as low as 39° to 40° C (102.2° to 104° F). (Modified from Gathiram P et al: *Circ Shock* 25:223, 1988.)

but no higher.^[180] This suggests that LPS-induced toxicity is important in the pathophysiology of heatstroke death only up to 43.5° C (108.5° F). Above this temperature, other mechanisms are more important, such as direct thermal damage to nervous tissue.

LPS had previously been implicated as a factor in heatstroke death by indirect observations. Injection of very low doses of LPS leads to rapid "tolerance" to ordinarily lethal doses of LPS.^{[126] [198]} Administration of low doses of LPS protected rats against heatstroke. When the activity of the reticuloendothelial system (the main mechanism for removal of LPS from the circulation) was reduced, the mortality of heatstroke increased.^[125] Ryan et al^[426] found the inverse effect. Rats were heated to T_c of 42.5° C (108.5° F) and then were passively cooled. The next day they were challenged with a lethal dose of LPS, and the mortality rate dropped from 71% in the control rats to zero in the previously heat-stressed rats.

The importance of LPS in heatstroke death was confirmed in a canine model of heatstroke.^[220] T_c was raised to 42.5° C (108.5° F) for 3 hours and then cooled to 38° C

(100.4° F). Deaths occurred only if the animals had rises in plasma LPS concentration.

Exertional Heatstroke.

Several studies support the idea that the immune system and LPS are involved in the pathophysiology of heatstroke. Leukocytosis is a general response to most forms of stress, including muscular activity,^[179] administration of epinephrine or glucocorticoid, and excitement. Prolonged or severe exercise initiates mobilization and activation of neutrophils and causes proteolysis of skeletal muscle and production of acute phase proteins by the liver.^[72] Exercise leads to local disruption of tissues and sloughing of tissue fragments that circulate and activate the complement system. This activation primes monocytes for further activation by LPS or by fragments of tissue subsequently damaged.^[74]

Severe exercise impaired renal function, causing a 100-fold increase in urinary excretion of proteins so profound that it led to an actual depletion of circulating proteins.^[395] Although it is well known that hyperthermia in humans results in a reduction in splanchnic blood flow,^[400] only recently has sufficient evidence accumulated to provide a mechanism of how this may contribute to the pathophysiology of heatstroke. To consider the relationship of this evidence to heatstroke it is necessary to consider the contents of the intestinal lumen and the likely results of their leakage into the systemic circulation.

It was first reported that many of the clinical signs in a heatstroke victim, including blood clotting disturbances, were similar to those seen in septic shock cases.^[194] LPS activates a blood factor leading to disseminated intravascular coagulation,^[336] ^[540] a common complication

of septic shock. The authors therefore suggested that LPS participates in the pathophysiology of heatstroke. Similarities between heatstroke and septic shock are described in [Box 10-5](#).

Since core temperatures of long-distance runners may rise above 40° C (104° F), we examined runners who collapsed during an ultramarathon (89.5 km) on a warm day^[64] and who reached or were carried into the medical tent at the finish line. Blood samples were taken from 98 patients before therapy. Eighty of 98 had plasma LPS levels raised above normal values, including two in the 1 ng/ml lethal range! It should be noted that the body can tolerate short periods of much higher concentrations, and the lethal concentration usually given as of 1 ng/ml refers to a long-term level, after detoxifying mechanisms come into play.^[519] Although hypovolemia and hemoconcentration resulting from sweating may have caused a few "high normals" to cross into the elevated range, this was not the case of the majority. Of those who finished the race, the smaller group with the normal, low LPS levels finished faster. Furthermore, this normal group had higher levels of "natural" anti-LPS in their plasma; that is, the presence of high levels of

anti-LPS antibodies correlated with low levels of LPS and better performance. This low LPS and high anti-LPS group also had reduced indexes of nausea, vomiting, and headache and recovered faster (within 2 hours) than did the larger high LPS and low anti-LPS group (up to 2 days).

LPS elevated

In triathlon participants, the concentrations of anti-LPS antibodies fell and LPS rose at the end of the third race.^[52] Some athletes had higher levels of "natural" anti-LPS antibodies than did others. When individuals were questioned about their training regimen, it became clear that those who trained the hardest (miles swum, bicycled, and run the 3 weeks before the triathlon) had the highest levels of anti-LPS. It may be that one component of the benefit of physical training is the increase in levels of natural anti-LPS antibodies. We proposed that as a result of severe training, temporary periods of intestinal ischemia occurred, leading to the entry of low to moderate levels of LPS into the circulation, which was enough to stimulate the immune system and induce anti-LPS antibodies. When a marathon was run on a cold day, no elevations in plasma LPS were seen (T. Noakes and S. Gaffin, unpublished observations). At present, it is not clear what combinations of heat load and exertional factors are required to decrease BF_{spl} sufficiently to damage the gut wall for translocation of LPS into the circulation.

Classic Heatstroke.

The survival of hospitalized heatstroke patients depends in large part on the rapidity of cooling on entry to a hospital intensive care unit. This time factor may be important because of the time required for the production of cytokines, which is in the range of minutes to hours. Seventeen Hadj patients with classic (nonexertional) heatstroke were admitted to a hospital an average of 2 hours after the onset of heatstroke.^[56] Each victim's T_c was greater than 40.1° C (104.2° F). They suffered from delirium, convulsions, and coma. Their plasma LPS concentrations ranged from 8 to 12 ng/ml, that is, extremely high and in the potentially lethal range.^[508] Furthermore, their TNF and IL-1 concentrations were also very high. The authors suggested that those cytokines exacerbated the hyperthermia of heatstroke through the induction of prostaglandins.

Nine of eleven heatstroke patients showed a marked leukocytosis resulting from a large increase in the number of T suppressor cytotoxic cells (CD8) and NK cells (CD16/CD56).^[55] This leukocytosis increased with increasing T_c . There were also substantial decreases in T helper cells (CD4) and B cells (CD19) as a result of heatstroke. Heatstroke is known to elevate catecholamine levels.^[3] Since epinephrine

causes leukocytosis with an increase in NK and T suppressor/cytotoxic cells, these authors suggested that heatstroke raised catecholamines, which in turn altered the lymphocyte subpopulations.

On the other hand, hyperthermia causes elevated cortisol^[264] ^[265] and cortisol causes lymphocytopenia.^[55] In the preceding study, 2 of the 11 heatstroke patients had a decreased number of lymphocytes. To account for the reduction in lymphocytes, the authors suggested that

in those two patients the effects of cortisol, rather than of catecholamines, were dominant. That is, changes in subpopulations of lymphocytes in heatstroke may depend (on an individual basis) on the relative rises in concentration of catecholamines and cortisol, as well as on individual sensitivities to them. However, this is not yet clearly established.

Adaptation and the Immune System.

Activity of the immune system through cytokine expression not only alters susceptibility to heat illnesses but determines the winners and losers of athletic competitions or battles as much as skill, strength, and speed. A sick athlete or professional soldier may be defeated by an inferior but healthy opponent. Through appropriate training an athlete may reach his or her peak muscular strength, cardiovascular capacity, coordination, and maximal oxygen consumption. However, at the same time, other environmental, psychologic, or nutritional factors may degrade the immune system, such that he or she becomes more susceptible to an opportunistic infection, very rapidly becomes unfit for competition, and is at risk for heat illnesses.

Mammals possess a programmed universal response to various stressors known as the *general adaptation syndrome*. This includes responses to heat, trauma, hemorrhage, toxins, cold, infections, and nervous irritation. ^[446] Prolonged heat provokes the general adaptation syndrome, leading to shrinkage of immune tissues and organs with a decrease in immune function.^[163] Among various lymphoid subclasses, human NK cells and their precursors are especially sensitive to heat and are completely inactivated by $T_{amb} = 42^{\circ} \text{C}$ (107.6°F) for 60 minutes.^[259]

There are relatively few published studies of cytokine secretion following exercise and heat. A new journal, *Exercise Immunology Review*, was established to promote this kind of investigation. Early studies may have been hampered by problems in sampling tissue. Urine samples taken after a race showed large increases in interferon, TNF, IL-1, IL-6, and soluble IL-2r. ^[472] Failure to detect changes in plasma cytokine concentrations may have been due to rapid renal clearance from the circulation. Rises in IL-1 were observed in human skeletal muscle after muscle-damaging eccentric exercise.^[73] Ingestion of vitamin E prevented a rise in IL-1 in vitro from leukocytes obtained from persons subjected to severe exercise.^[74] IL-1 causes muscle proteolysis by inducing

branched chain keto acid dehydrogenase. This is a rate-limiting enzyme for the oxidation of amino acids in skeletal muscle. As this enzyme increases in concentration, amino acids are progressively oxidized, leading to muscle protein breakdown. Severe exercise suppressed mouse lung macrophages and increased their susceptibility to infections, with greater morbidity and mortality than in moderately exercised mice.^[106]

Fourteen consecutive heatstroke patients were found immunosuppressed at admission from depressions in the number of T and T helper cells, CD11a, CD11c, CD44, CD56, and CD54 and rises in T suppressor/cytotoxic T cells. (The many subpopulations of immune cells are usually defined by CD markers.) Cooling led to partial or complete normalization, further derangements, or overcorrection.^[209] After a marathon race, leukocyte levels approximately tripled and cortisol concentration rose approximately fivefold.^[213] The concentrations of NK cells and B cells fell, although no changes occurred in number of lymphocytes.

Adequate lymphocyte activity is required for normal muscle function. Overtraining may be harmful. A combination of intense physical training and the stress of competition makes some athletes immunosuppressed and more susceptible to infection. One possible mechanism of overtraining muscle injury is that glutamine induces HSPs that protect muscle cells, and overtraining reduces the amount of glutamine available for normal lymphocyte function.^[454] There may be a point at which laboratory techniques can quantitatively determine that the disadvantage of immunosuppression is greater than any benefit from exercise training, and that exercise should be curtailed.^[213]

HEAT-RELATED ILLNESSES—VARIANTS OF HEATSTROKE

A number of clinical situations arise in which hyperthermia develops that is sufficiently severe ($>40^{\circ}\text{C}$ [104°F]) that it be included as a subgroup of EHS. Neuroleptic seizures and overdose of recreational drugs share with EHS the features of massive muscle contractions (with consequent overuse of high-energy compounds) and rhabdomyolysis.^[290] Since the use of recreational drugs is not expected to decline and the number of persons using neuroleptic drugs is probably on the increase, the involvement of heatstroke pathophysiology should be considered in treating those cases. In an unusual situation during mountaineering in summer, two persons died of heatstroke and acute rhabdomyolysis. Both patients had received treatment with antipsychotic drugs, including phenothiazine.^[293] In summary, heatstroke in a summertime vacation area might be complicated by the use of therapeutic or recreational drugs.

Malignant Hyperthermia

Malignant hyperthermia is a rare life-threatening disorder involving hypermetabolism, rapid rise in body temperature, and rigidity of skeletal muscle. It is induced by exposure to volatile anesthetics during surgical procedures in affected patients. In about half these patients, mutations were seen in the gene for the Ca^{2+} release channel (RyR).^[98]^[306]^[511] The anesthetic binds to

276

RyR and activates the Ca^{++} release channel, causing massive calcium entry into the cytoplasm. This activates contractile proteins, calmodulin, and a variety of calcium-sensitive enzymes, which leads to muscle rigidity, hypercatabolism, fulminating hyperthermia, and metabolic acidosis.^[98]

Rhabdomyolysis, hyperkalemia, and myoglobinemia^[443] are commonly associated with malignant hyperthermia, with plasma K^{+} rising as high as 10 mmol/L .^[341] Underlying illnesses in five cases of rhabdomyolysis included heatstroke, high fever, and grand mal seizures with associated hyperthermia. Nevertheless, there were multiple factors responsible for rhabdomyolysis in each case, such as hypokalemia, hypophosphatemia, shock, and arteriosclerosis.^[360] A 41-year-old man susceptible to malignant hyperthermia developed an infection and self-medicated with a cold medicine. He presented with high fever, dysarthria, dysphagia, and progressive weakness of his muscles and developed

massive rhabdomyolysis with acute renal failure.^[268]

Neuroleptic Seizure

The treatment of psychiatric patients with neuroleptic drugs, as well as with antidepressants, antiemetics, and others,^[130] may lead to the uncommon but often fatal neuroleptic malignant syndrome, characterized by hyperthermia as high as 42° C (107.6° F),^[7] "lead pipe" (skeletal muscle) rigidity, dyspnea, coma, extrapyramidal syndrome, rhabdomyolysis, severe metabolic acidosis, leukocytosis, and elevated creatine phosphokinase.^{[221] [258] [488]} A number of factors predispose to neuroleptic seizure, including dehydration, exhaustion, aggression, and restraints^[254]; high environmental temperature; high doses of neuroleptics; abrupt discontinuation of antiparkinsonism agents; and administration of lithium.^[130] Successful treatment of these cases includes immediate withdrawal of the drug, administration of dantrolene, and either oral bromocriptine or the combination of levodopa and carbidopa.^[130]

Drug Overdose

Although the toxicity of drug overdose is well recognized, it is not often appreciated that the hyperthermia attained can be in the range reported for heatstroke. Such hyperthermia has been induced with cocaine^[120] and amphetamine derivatives, such as 3,4-methylenedioxymethamphetamine (MDMA, "ecstasy") and 3,4-methylenedioxyethamphetamine (MDEA, "Eve").^[490] Other components of this syndrome include hyperkalemia, rhabdomyolysis,^[462] sympathetic hyperactivity, convulsions, rectorrhagia, psychosis, disseminated intravascular coagulation in the absence of positive blood cultures, and acute renal failure.^[223]

Susceptibility to Heatstroke

There may be an inherited susceptibility to EHS. Muscle biopsy specimens taken from two men in military service who had recovered from EHS had abnormal responses to halothane, a well-known cause of malignant hyperthermia.^[511] Furthermore, muscles from members of their families had abnormal responses to halothane or ryanodine, a drug that binds to the Ca²⁺ release channels of the sarcoplasmic reticulum.^[230] A ryanodine contracture test has been proposed as an in vitro diagnostic test to screen for surgical patients susceptible to malignant hyperthermia.^[230] This test might be useful in identifying, retrospectively, a possible subgroup of patients with EHS.

Changes in Cognitive Function

Changes in cognitive function appear to occur before the development of the physical symptoms associated with heat stress.^[78] Typically, heat stress causes distortion of the sense of time,^{[35] [36] [104]} memory impairment,^[525] deterioration in attention, and decreased ability to calculate mathematical problems.^{[85] [199] [524]} Health care personnel should be trained to recognize that confusion, changes in affect, and impaired ability to function in the work environment can be early signs of heat injury under heat stress conditions.^[78]

Vasovagal Syncope.

Syncope is the cause of about 3% of emergency department visits and 6% of hospital admissions.^[183] Vasovagal syncope is responsible for 28% to 38% of syncope patients aged 35 to 39 years.^[108] ^[263] ^[331] Benign presyncope or syncope may result from diminished venous return to the heart because of blood pooling in the peripheral circulation. Syncope encompasses psychologic disturbances activating an autonomic vasodilation response; reflex syncope caused by heavy coughing, micturition, and pressure on an irritable carotid sinus; or reduced vasomotor tone caused by hypotensive drugs or alcohol.^[132]

Interestingly, the frequency of vasovagal syncope is greater in the young than in the elderly, whereas orthostatic hypotension is more common in older persons.^[317] Propranolol does not prevent the vasovagal reaction in response to head-up tilt.^[317] Therefore, after the age of 40, presyncope may suggest a more serious condition, such as gastrointestinal bleeding, myocardial or valvular heart disease, or severe anemia. Cardiovascular syncope resulting from arrhythmia carries a 1-year mortality rate of about 30%.^[262]

Hyperventilation Dizziness.

A slight but prolonged increase in respiratory rate or tidal volume may accompany an increase in anxiety.^[132] This can lead to increased blood oxygen content and decreased P_{CO_2} , with accompanying alkalosis. Altogether, these lead to generalized cerebrovascular vasoconstriction with ischemia and dizziness.

Heat-Induced Syncope.

The associated clinical syndromes vary in severity depending on the cause of the

hyperthermia and therefore so does the duration of central nervous system (CNS) dysfunction. Transient or temporary loss of consciousness associated with a mild form of heat syncope has its origins primarily in the cardiovascular system. It is a consequence of a reduced "effective" blood volume rather than an actual loss of volume.

In an upright and stationary person, blood volume is displaced into the dependent limbs by gravity. If that person is also heat stressed, more blood is displaced into the peripheral circulation to support heat transfer at the body surface. These combined reductions in the effective blood volume can temporarily compromise venous return, CO, and cerebral perfusion. Patients are usually erect at the outset and sometimes report prodromal symptoms of restlessness, nausea, sighing, yawning, and

dysphoria.^[280] Hypotension results predominantly from vasodilation and bradycardia. This systemic disorder is self-limited because when the person faints and assumes a horizontal position, central blood volume is restored, cardiac filling rises, blood pressure is restored, and the problem remedied.

Fainting is usually brief and responds to horizontal positioning and improved venous return. The patient should be allowed to rest in cooler, shadier surroundings and be offered cool water. The patient should be cautioned against protracted standing in hot environments, advised to flex leg muscles repeatedly while standing to enhance venous return, and warned to assume a sitting or horizontal position at the onset of warning signs or symptoms, such as vertigo, nausea, or weakness. Normally, muscles in the legs act as a "second heart" and in concert with venous valves promote venous return, thereby counteracting orthostatic

TABLE 10-3 -- Clinical Data in 17 Patients with Heat Exhaustion

Abd, Abdomen; *RR*, respiratory rate.

pooling and the predisposition to syncope. Consistent with this, nonfainters have higher

intramuscular pressure than fainters.

The transient loss of consciousness in syncope has a metabolic basis within ischemic cells of the brain. Despite this, the effects, although startling to onlookers and frightening to the patient, appear readily reversible. There is no risk of direct thermal injury to brain cells complicating the circulatory origin of this sudden decline in effective arterial volume.

The incidence of syncopal attacks falls rapidly with increasing days of work in the heat (see [Figure 10-6](#)), suggesting the importance of salt and water retention in preventing this disorder.^[242] Thus individuals medicated with diuretics would be at high risk. Furthermore, potassium depletion and hypokalemia may lower blood pressure and blunt cardiovascular responsiveness.^[292] In stark contrast to simple syncope is the profound CNS dysfunction dominating the early course of heatstroke. Thus, if a person faints in a setting where hyperthermia is possible and does *not* rapidly return to consciousness, heatstroke should be suspected and body temperature measured.

Exertion-Induced Syncope, Cramps, and Respiratory Alkalosis.

During basic military training, a cluster of 17 syncopal episodes was associated with a seldom-described form of heat exhaustion^[247] ([Table 10-3](#)). In contrast to hypovolemic salt depletion, this heat exhaustion was characterized by hyperventilation, respiratory alkalosis, syncope, and tetany. Most victims also experienced abdominal cramps, yet this was independent of lactic acidosis and hyponatremia. These descriptions were unique in that the heat syncope episodes were not

those classically described as the venous pooling or postural hypotension variety.^{[32] [368]} The incapacitated trainees arrived at a heat ward within 10 to 30 minutes of the onset of symptoms and blood samples were drawn immediately on admission. They exhibited a moderate to marked respiratory alkalosis, but only two appeared to be severely dehydrated; nearly all (16 of 17 patients) had severe cramps of the abdominal or extremity muscles.

Clinical data recorded on admission are shown in [Table 10-3](#). Almost all the casualties occurred in the afternoon during July 1971 at Fort Polk, Louisiana. All were diagnosed as heat exhaustion resulting from training in the field (12 of 17 while speed marching). Rectal temperatures on admission were elevated, even though most of the victims had been doused with water before evacuation. Serum electrolytes were in the normal range in the majority of the victims. However, hemoconcentration with elevated serum sodium level was observed in four patients. Only 1 of 17 patients had a low serum sodium level and also experienced severe muscle cramps.

The majority of these patients were not water or salt depleted, and 15 of the 16 remaining patients with cramps had normal to elevated serum sodium and chloride

levels (not shown). The mean arterial pH for this group of patients was 7.62 ± 0.03 (SEM), and 5 had a pH of 7.67 or greater. Arterial P_{CO_2} was reduced to a mean value of 23.5 ± 2 mm Hg. Thus all patients had moderate to marked respiratory alkalosis, and nine had obvious tetany with carpopedal spasm.^[60] The presence of carpopedal spasm and paresthesias in the distal extremities and perioral area helps distinguish this form of cramps from the classic variety.

These data associate exertion-induced heat exhaustion with a form of respiratory alkalosis characterized by syncope, tetany, and muscle cramps and may possibly be the result of "an exaggeration of the normal physiological ventilatory response to thermal extremes."^[60] Hyperventilation with its resulting decrease in cerebral blood flow^[275] ^[457] ^[509] could account for a significant number of cases of exercise-induced heat syncope. Recumbency, rest, and oral replacement of fluid and electrolyte deficits are usual recommendations. Rebreathing of expired air is directed at alleviating carpopedal spasms but should be done with extreme caution because of its hypoxemic effect.

Classic syncope is usually associated with postural hypotension, whereas heat exhaustion and heat cramps are usually associated with water and electrolyte imbalance. Most literature suggests that unacclimated workers have higher salt losses in the heat than those who are acclimated.^[302] ^[308] Thus this series is a good example of the real world with a "mixed bag" of heat illness symptoms. To explain these clinical results, one should recall that acclimated individuals have higher sweat rates (2.5 L/hr vs. 1.5 L/hr) than do nonacclimated persons but also have increased tolerance to exercise. If both groups voluntarily work at maximum sweat rates for any given task, those who are heat-acclimated could produce higher salt losses, despite their reduced sweat sodium concentrations. Under such a scenario, the acclimated individuals would be predicted to be the more prone to heat cramps.^[11] However, [Table 10-2](#) indicates that there are higher salt losses for unacclimated individuals at any given sweat rate or volume of sweat lost. The differential diagnosis of heat cramps should also include exercise-induced peritonitis.^[484]

Heat-Induced Tetany

It has long been known that in excessively hot environments, men at rest hyperventilate.^[203] Adolph and Fulton^[2] described dyspnea and tingling in the hands and feet of men being dehydrated in the heat. In 1941, during a voyage through the intense heat of the Persian Gulf, a ship's engineer was reported experiencing spontaneous hyperventilation and attacks of tetany.^[526] He could reproduce these symptoms simply by deliberately overbreathing. This appeared to be the first clinical description of heat-induced hyperventilation tetany.

The exposure of male test subjects to hot, wet conditions led to physiologic changes and onset of symptoms ranging from slight tingling of the feet and hands to more severe carpopedal spasms.^[247] ^[248] The frequency and severity of symptoms were apparently not related to the absolute change in the four measured parameters (P_{CO_2} , CO_2 , pH, and T_{re}) but rather to the rate of change as depicted in [Figure 10-10](#). There was a direct relationship between the rate of change of the four parameters and the incidence of symptoms. When the subject's tolerance time was short, changes occurred rapidly

and the incidence of symptoms was high; conversely, when the tolerance time was long, the same degree of change occurred but the incidence of symptoms was low. It was suggested that rapid changes lead to imbalance between intracellular and extracellular compartments and that this imbalance may be one of the factors inducing symptoms. Again, treatment consists of rest, cooling, and rebreathing expired air.

Heat Cramps

Heat cramps typically occur in conditioned athletes who compete for hours in the sun. They can be prevented by increasing dietary salt and staying hydrated.^[136] Heat cramps are brief, intermittent, and often excruciating muscle contractions and are a frequent complication of heat exhaustion and occurred in about 60% of 969 cases of heat exhaustion.^{[95] [308] [479]} The term "heat cramps" is a misnomer because heat itself does not cause them; rather, they occur in muscles subjected to intense activity and fatigue. The victim with salt depletion

279

Figure 10-10 Comparison of absolute change and rate of change of P_{CO_2} , CO_2 , pH, and T_{re} with incidence of heat-induced tetany. Rate of change values were obtained by dividing the absolute change during exposure by the exposure time in minutes and multiplying by 60. (From Iampietro PF: *Fed Proc* 22:884, 1963.)

at the time of heat exhaustion is obviously ill and has numerous symptoms other than cramps. Furthermore, fatigue, giddiness, nausea, and vomiting are common and may occur before and more prominently than cramps. Sometimes, heat cramps occur as the only complaint with minimal systemic symptoms. Furthermore, there is a difficulty in distinguishing abdominal heat cramps from gastrointestinal upset.

During the 1930s, steel workers, coal miners, sugar cane cutters, and boiler operators were among the most common victims of classic heat cramps.^{[486] [487]} Three factors common to most reports are that cramps are preceded by several hours of sustained effort, are accompanied with heavy sweating in hot surroundings, and are combined with the ingestion of large volumes of water. A fourth factor (see later discussion) may be cooling of the muscles. Serum Na^+ levels ranged from 121 to 140 mEq/L (normal 135 to 145 mEq/L).^[487] Diagnostic of heat cramps are hyponatremia and hypochloremia that might be due to salt deficit or some degree of water intoxication.^[292] If overdrinking causes gastric distention, nausea^[405] could trigger vasopressin release and contribute to renal water retention. In an industrial setting, heat cramps occur most commonly late in

the day, and after physical activity has ceased; they sometimes occur while a person is showering and occasionally occur in the evening.^[308]

Classic heat cramps are distinguished from hyperventilation-induced tetany in that they are limited to contractions of those voluntary skeletal muscle subjected to prior exertion and usually affect only a few muscle bundles at a time. As one bundle relaxes, an adjacent bundle contracts for 1 to 3 minutes. The cramp thus appears to wander over the affected muscle, but the pain can be excruciating in severe cases. Three precipitating conditions (exhaustive work, hemodilution, and cooling the muscle) can each depolarize the muscle cell.^[292] This could explain the association of cramps with showering in cool water, since cooling slows sodium transport and depolarizes the cell and may thus reach excitation threshold.^[464] The low incidence of heat cramps within the Indian Armed Forces^[323] and the fact that Shibolet observed no cases within IDF suggest that heat-acclimated individuals are less likely to experience them. This is consistent with the observation that the incidence was greatest during the first few days of a heat wave.^[487]

Heat cramps generally respond rapidly to salt solutions. Mild cases may be treated orally with 0.1% to 0.2% salt solutions (2 to 4 10-grain salt tablets [56 to 112 mEq] or ¼ to ½ teaspoon table salt dissolved in a quart of water). Cooling and flavoring enhance its palatability. Oral salt tablets are gastric irritants and are not recommended. In severe cases, IV isotonic saline (0.9% NaCl) or small amounts of hypertonic saline (3% NaCl) are administered by physicians for rapid relief.

Heat Exhaustion

Classic heat exhaustion is a manifestation of cardiovascular strain resulting from maintaining normothermia. The symptoms of heat exhaustion include various combinations of headache, dizziness, fatigue, hyperirritability, anxiety, piloerection, chills, nausea, vomiting, heat cramps, and heat sensations in the head and upper torso.^{[16] [19] [242]} Clinical descriptions include tachycardia, hyperventilation, hypotension, and syncope. Although

the boundary between heat exhaustion and heatstroke is usually defined as 39.4° to 40° C (102.9° to 104° F), the differential diagnosis is often tenuous^[217] or even considered artificial.^[456] The victim may collapse with either a normal or an elevated temperature (severe cases around 40° C), usually with profuse sweating. Spontaneous body cooling can occur, which is not prominent in severe heatstroke. The clinical determination of heat exhaustion is primarily a diagnosis of exclusion.

Classic heat exhaustion, like classic heatstroke, tends to develop over several days or longer and presents ample opportunity for the occurrence of electrolyte and water imbalance. The hyponatremia and hypochloremia of patients with either heat cramps or salt depletion heat exhaustion often develop over 3 to 5 days^[307] and usually in the

unacclimatized individual who has not fully developed his or her salt-conserving mechanisms.^{[468] [469]} In salt depletion heat exhaustion, muscle cramps, nausea, and vomiting may be intense, but victims do not feel very thirsty.^{[242] [383]} The major route of fluid and electrolyte imbalance (salt depletion, water depletion, water intoxication) involved in a particular heat exhaustion case can be discovered from the events surrounding the collapse and a careful history.^{[71] [292] [308] [499]}

The alternate forms of heat exhaustion are characterized by the type of fluid or electrolyte deficit (primarily pure water or salt deficiency), their underlying causes (prolonged heat exposure vs. intense, short-term exertion), the intensity of the hyperthermia, and the absence or form of CNS disturbance. For example, [Table 10-4](#) is a theoretic demonstration of the impact of body weight loss as either pure water or sweat of varying salt concentrations. If external cooling does not rapidly lower T_c to normal or, conversely, precipitates severe

TABLE 10-4 -- Signs and Symptoms of Salt and Water Depletion Heat Exhaustion

SIGNS AND SYMPTOMS	SALT DEPLETION HEAT EXHAUSTION	WATER DEPLETION HEAT EXHAUSTION	DILUTIONAL HYPONATREMIA*

shivering, intercurrent illness is suspected. Anecdotal experience that in the field suggests that approximately 20% of persons with suspected heat exhaustion have some form of viral or bacterial gastroenteritis. This is especially true if untreated (nonchlorinated) water or ice is available.

At any given loss of body weight (see [Table 10-4](#)) the decrement in PV increases with the salt content of sweat. This would be the case for relatively unacclimated individuals. On the other hand, the more dilute the sweat (approaching a pure water deficit) and therefore the greater the retention of salt the greater the increase in osmolality, plasma, sodium, and thirst. [Table 10-4](#) attempts to compare and contrast the various signs and symptoms of salt and water depletion heat exhaustion with dilutional hyponatremia. It is clear that at some point both syndromes share many symptoms. Vomiting and cramps appear to signal a significant sodium deficit, in addition to some degree of water deficit.

Heat Illness and Coexistent Disease

It has long been known that coexistent illness or infection predisposes an individual to heatstroke.^[185] In one study of heat illnesses, 11.2% of patients^[522] also had gastrointestinal (choleraic) illness.^[522] The reverse is also true: heat waves produce excess deaths from all categories of disease. For example, in one heat wave week in New York in the late summer of 1948, deaths from diseases of the heart and arteries and from diabetes more than doubled (1364 vs. 585), and pneumonia deaths tripled.^[139]

Infection predisposes to heat illness and heat stress exacerbates infections, leading to greater morbidity and

mortality.^[312] Relatively few studies have been reported on the susceptibility to infection during heat exposure, or the influence of infection on heat tolerance, and there is a need for further research into the effects of diseases on thermoregulation.^[273]

ACKNOWLEDGMENT

This chapter is, in part, a revision of Gaffin SL, Hubbard RW, Squires DL: Heat-related illnesses. In Auerbach P, editor: *Wilderness medicine*, St Louis, 1995, Mosby, pp 167–212, and Dr. Hubbard's original contribution to this chapter is recognized.

The opinions or assertions contained herein are the private views of the authors and should not be construed as official or reflecting the views of the United States Army or Department of Defense. Citations of commercial organizations and trade names in this report do not constitute an official Department of the Army endorsement or approval of the products or services of these organizations. Human subjects participated in these studies after giving their free and informed voluntary consent. Approved for public release; distribution is unlimited.

Chapter 11 - Clinical Management of Heat-Related Illnesses

Daniel S. Moran
Stephen L. Gaffin

This chapter discusses clinical observations of heatstroke victims, management of heat-related illnesses, and consequences of different levels of hydration on heat illnesses. In heatstroke, the most severe heat illness, early clinical signs are nonspecific. A common picture of heatstroke is sudden collapse of an individual during physical activity carried out in a warm environment. This is usually followed by loss of consciousness with elevated core temperature (T_c) greater than 40°C (104°F), rapid heart rate (HR), tachypnea, hypotension, and, possibly, shock. The severity of heat illness depends on the degree of elevation in T_c and its duration. Therefore, to prevent and minimize complications and save lives, proper management and clinical care are essential.

This chapter focuses on the three different phases of heatstroke (acute, hematologic and enzymatic, and late), problems with recognition of heat illnesses, diagnosis and complications of heatstroke, treatment, and awareness of risk factors. Updated descriptions of issues related to dehydration, hypohydration, hyperhydration, and rehydration are also presented.

CLINICAL AND LABORATORY OBSERVATIONS IN HEATSTROKE

The clinical manifestations of heatstroke vary, depending on whether the victim suffers from classic heatstroke or exertional heatstroke (EHS) ([Table 11-1](#)). Some overlap in presentation may occur; treatment with a medication that places an elderly person at risk for classic heatstroke also places an exercising individual at risk for EHS. The clinical picture of heatstroke usually follows a distinct pattern of events in three phases.^[76]

Acute Phase

The acute phase is characterized by central nervous system (CNS) disturbances. Since brain function is very sensitive to hyperthermia, this phase presents in all heatstroke patients. Signs of depression of the CNS often appear almost simultaneously in the form of irritability, aggressiveness, stupor, delirium, and coma.^{[3] [37] [214]} Seizures occur in 60% to 70% of heatstroke cases. After a return to normothermia, the persistence of coma is a poor prognostic sign.^{[126] [214]} Other symptoms include fecal incontinence, flaccidity, and hemiplegia. Cerebellar symptoms, including ataxia and dysarthria, are prominent and may persist.^{[153] [214] [242]} In over 60% of heatstroke cases, pupils were constricted to pinpoint size.^{[126] [243]} Papilledema was found to present in cases of cerebral edema. However, cerebrospinal fluid and pressure were usually within normal values.^{[3] [126] [214]}

Other common disturbances for the acute phase occur in the gastrointestinal and respiratory systems. Gastrointestinal dysfunction, including diarrhea and vomiting, often occurs. The latter, however, may reflect translocation of toxic gram-negative bacterial lipopolysaccharide (LPS) from the lumen of the intestines because of poor splanchnic perfusion, as well as from CNS impairment.^{[34] [94] [214]} Hyperventilation and elevation of T_c primarily lead to respiratory alkalosis, which in EHS may be masked by metabolic acidosis as a result of increased glycolysis and the development of hyperlactemia.^{[39] [172]} Hypoxemia may be present in cases of respiratory complications.^{[44] [172] [222]}

Hematologic and Enzymatic Phase

In the hematologic and enzymatic phase of heatstroke, hematologic, enzymatic, and other blood parameters are altered. In humans and experimental animals, hyperthermia results in temporary leukocytosis^[107] and changes in lymphocyte subpopulations—both in absolute numbers and in percentages.^[1] Leukocytes may range from 20 to 30 × 10³ /mm⁻³ and higher.^{[21] [110]} In one study, all fatal cases of exertional heatstroke had disturbances in the blood coagulation system.^{[215] [216]} Prothrombin time, partial thromboplastin time and the level of fibrin split products increased with a fall in

thrombocytes.^[76] Clotting dysfunction peaked 18 to 36 hours after the acute phase of heatstroke, and 2 to 3 days after heatstroke prothrombin levels fell to 17 to 45% of normal. Depending on the severity of heatstroke, thrombocyte values range between $110 \times 10^3 / \text{mm}^{-3}$ and zero.^[215] ^[216] These clotting disturbances resemble those of gram-negative bacterial sepsis, and it has been suggested that LPS participates in the pathophysiology of heatstroke.^[101]

Significant lay interest, scientific research, and commercial product development and marketing have focused on electrolyte abnormalities associated with physical exertion under various conditions. The marked variability in electrolyte content of sweat and intensity

TABLE 11-1 -- Comparison of Classic and Exertional Heatstroke

	CLASSIC	EXERTIONAL
Age group	Elderly	Men (15–45 yr)
Health status	Chronically ill	Healthy
Concurrent activity	Sedentary	Strenuous exercise
Drug use	Diuretics, antidepressants, antihypertensives, anticholinergics, antipsychotics	Usually none
Sweating	May be absent	Usually present
Lactic acidosis	Usually absent; poor prognosis if present	Common
Hyperkalemia	Usually absent	Often present
Hypocalcemia	Uncommon	Frequent
Hypoglycemia	Uncommon	Common
Creatine phosphokinase/aldolase	Mildly elevated	Markedly elevated
Rhabdomyolysis	Unusual	Frequently severe
Hyperuricemia	Mild	Severe
Acute renal failure	<5% of patients	25% to 30% of patients
Disseminated intravascular coagulation	Mild	Marked; poor prognosis

Mechanism	Poor dissipation of environmental heat	Excessive endogenous heat production and overwhelming of heat loss mechanisms
-----------	--	---

Modified from Knochel JP, Reed G: Disorders of heat regulation. In Kleeman CR, Maxwell MH, Narin RG, editors: Clinical disorders of fluid and electrolyte metabolism, New York, 1987, McGraw-Hill.

of physical activity, along with ambient temperature (T_{amb}), humidity, and the preexisting state of hydration in the individual, all contribute to the degree of electrolyte abnormalities observed in plasma and sweat.

Plasma Volume Changes.

Physical exertion alters plasma volume (PV), depending on several factors: environmental conditions, intensity and duration of exercise, preexisting and coexisting state of hydration, and level of heat acclimatization. In a cool environment, PV is maintained or even increased with exercise. However, in the heat, a few minutes' burst of supramaximal exercise causes a biphasic reduction in PV. [24] During severe exercise, there is rapid efflux of K^+ and metabolites from contracting muscles, causing a local rise in osmotic pressure in the interstitial fluid. As a result, by Starling's law, fluid is initially drawn across capillary walls from the circulation into the extravascular space. This increases the transcapillary osmotic gradient, leading to the observed secondary reduction in PV. The combined processes result in overall sustained reduction of PV by 10% to 15% within 30 seconds.

The volume of sweat lost associated with intense physical activity of 30 minutes or more decreases total body water; if these fluid losses are not replaced, a further reduction in PV results.

Potassium.

The literature is contradictory regarding the effect of heat stress on plasma potassium concentration. Generally, most classic heatstroke patients appear to have normal serum K^+ levels at admission, whereas EHS patients often show hyperkalemia and rhabdomyolysis, but may range from hypokalemia to hyperkalemia. [216]

MECHANISMS.

Early studies suggested that hypokalemia predisposes to heatstroke [85] [119] and the subsequent resultant cellular damage with its elevated K^+ efflux would raise plasma values back to near normal or above.

Only about 2% of total body K^+ is extracellular, and the intracellular environment behaves as a large K^+ reservoir. K^+ passively diffuses out of the cells, down its concentration gradient through K^+ "leak" channels in the plasma membrane. It requires

a significant amount of adenosine triphosphate (ATP) to pump it back into the cell. Agents that act on K^+ transport system can cause rapid changes in plasma K^+ concentrations. Elevated extracellular K^+ concentrations depolarize excitable cell membranes. During hyperthermia in several animal models, ranging from crustaceans to miniswine, serum K^+ rose substantially.^{[14] [32] [83] [130]} In some, the higher the K^+ , the shorter was the survival time. If the animals had been heat acclimated, the rise in K^+ was blunted.

During prolonged exercise, elevated serum K^+ is usually seen.^[204] In some human subjects, serum K^+ levels rose during heat and exercise.^{[84] [183]} This would be expected to cause vasodilation of terminal blood vessels within active skeletal muscles. Several days' training

lowered this increase in extracellular K^+ for a given workload and improved cardiovascular stability and the ability to dissipate heat. An increase in serum K^+ from exercise may be due in part to the large number of depolarizations of muscle membranes. This elevated K^+ concentration was reduced by insulin injection, but performance was not improved.^[147]

In the early stage of heatstroke, victims arriving at a hospital may present with hypokalemia, normokalemia, or hyperkalemia. Rhabdomyolysis, cellular damage, and decreased renal perfusion may in part account for hyperkalemia.²

The loss of K^+ in sweat usually cannot account for hypokalemia in EHS because the normal K^+ of 4 to 5 mmol/L is not significantly affected by prolonged sweating, heat acclimation, or dietary intake of potassium.^[52] However, earlier studies suggested that repeated bouts of intense exercise in the heat lead to K^+ deficiency resulting from sweat loss.^[135] More recent reports under similar conditions, however, demonstrate normal K^+ levels in plasma and muscles, associated with reduced urinary K^+ excretion. Development of hyperkalemia in heatstroke victims appears to be a consequence of increased K^+ permeability, resulting from failure of the $Na^+ K^+$ ATPase pump at the cell membrane level, as described in [Chapter 10](#).

One group concluded that hyperthermia in humans leads first to hypokalemia, probably because of respiratory alkalosis, increased renal secretion, and loss in sweat.^[205] This would be followed by metabolic acidosis and hyperkalemia when a potential combination of impaired renal function and general cellular damage develops. Most heatstroke patients admitted during the Hadj exhibited normokalemia or hypokalemia, with concentrations as low as 2 mEq/L or less.^[129] Furthermore, once the characteristic hypovolemia had been corrected, serum K^+ fell still further. During exercise in the heat, humans can lose K^+ in an amount of 0.225 mEq/100 g body mass (70% into urine and 30% into saliva).^[166] Those differences are not simply a matter of experimental error. Gaffin et al^[90] explained these discrepancies in a miniswine model described in [Chapter](#)

Sodium.

Failure to maintain normal salt intake can suppress triggering of the thirst mechanism, thereby reducing voluntary rehydration. Model experiments indicate that, unlike K^+ , intracellular Na^+ content does not change significantly in response to heat treatment until a few minutes before death, at which point there was a small rise. [234] [244] However, in some clinical cases serum Na^+ levels were low, reflecting a state of hyperhydration or rhabdomyolysis. [91] [106]

The concentration of sodium chloride in sweat may range from 10 to 60 mEq/L, depending on physical activity, heat exposure, the state of heat acclimatization, and the amount of salt ingested. [189] Whereas gender does not affect Na^+ in sweat, children show lower concentrations than adults. [14] [66] Values rarely reach 40 mEq/L in prepubertal boys. The average American diet contains about 170 mEq of Na^+ per day, an amount usually adequate to replace all Na^+ lost through sweating by the trained athlete. However, an athlete with an inadequate caloric intake may suffer from dietary salt deficiencies and soldiers in combat usually have insufficient food intake. In such cases, supplementation may be required after moderate sweat losses.

EFFECT OF PHYSICAL ACTIVITY ON SODIUM SWEAT CONCENTRATION.

A sudden increase in exercise intensity rapidly increases the electrolyte concentrations of sweat and more slowly increases electrolytes in serum. [29] [78] [139] The electrolyte concentration of sweat is highest immediately after commencing physical activity and gradually decreases with prolonged exercise, possibly as a passive result of falling body salt content.

Thermal stress alone raises Na^+ and Cl^- concentrations less than those induced by running. [88] In a variety of sports (yachting, rowing, handball, and cycling), initial sweat electrolyte concentrations were dependent on type of sport, duration of performance, and level of training in elite athletes. [29] Cyclists and rowers, whose sports produce high-endurance capability, had significantly lower sweat Na^+ content than did yachtsmen. In addition, participation in an intensive training program led to a further reduction in sweat electrolyte concentration.

The sweat of a trained athlete may show a Na^+ content as low as 17 mmol/L (34 mOsm/kg), a level one third that of a person who is untrained and unacclimated to the heat. Conversely, the untrained, unacclimatized "weekend warrior" or vacationer is at greatest risk for significant Na^+ losses when exercising in the heat (see [Table 10-2](#)).

EFFECT OF HEAT EXPOSURE ON RENAL ABSORPTION OF SODIUM.

After repeated days of exercise in the heat, there is an increased production of aldosterone with consequent enhanced renal reabsorption of Na^+ ; thus Na^+ is

progressively conserved. After prolonged strenuous exercise and sweating, urinary excretion of Na⁺ may almost cease temporarily.^[51]

SODIUM DEFICIENCY.

In temperate thermal environments, a Na⁺ deficit due to exercise is unlikely to be so severe as to require Na⁺ supplementation of the normal diet. Similarly, a brief (<2 hours) episode of moderate exercise in the heat rarely causes clinically significant hyponatremia upon voluntary rehydration. However, when sweat loss exceeds 5 L/day, hyponatremia may develop upon rehydration and occur during the initial

*References ^[22] ^[56] ^[109] ^[136] ^[214] ^[216] .

stage of acclimation to heat, during prolonged and repeated exercise in the heat (training camps), or during ultra-endurance events, such as marathons, 50-mile runs, or triathlons.^[170]

In one report, four athletes developed hyponatremia and water intoxication during endurance events lasting more than 7 hours.^[177] The cause was thought to be voluntary hyperhydration with hypotonic solutions, combined with moderate losses of Na⁺ and Cl⁻ in sweat. These athletes were slower runners who competed at a lower intensity than did the top finishers.

An interesting case of symptomatic hyponatremia resulting from excessive voluntary intake of water showed paradoxical secretion of antidiuretic hormone (ADH) leading to renal shutdown instead of increased output of urine.^[4] Ordinarily, ADH is secreted in response to dehydration but not hyponatremia. However, volume overload of the stomach is known to cause nausea, which is a strong stimulus for production of ADH.

Calcium.

In isolated cultured cells, heating may lead to increased permeability of the plasma membrane^[234] and an increase (~0.1 μM) in cytoplasmic Ca²⁺ concentration.^[85] It is unclear if the rise in Ca²⁺ contributes to the pathophysiology of heatstroke, since elevating the total cell content of Ca²⁺ sixfold had no effects on survivability at 45° C (113° F).^[234]

Several studies suggest that hyperthermia leads to a reduction in serum Ca²⁺ as a result of deposition of Ca²⁺ phosphates and Ca²⁺ carbonates in injured skeletal muscles.^[205] Other studies, however, indicate that high temperatures may cause acute renal failure or rhabdomyolysis, which in turn releases Ca²⁺ into serum.^[134] Moreover, in microswine with heatstroke, we reported a biphasic reduction in Ca²⁺ concentration.^[14] At approximately 41° C (105.8° F), Ca²⁺ concentration declined, reaching a minimum at

44° C (111.2° F), and then rapidly rose to near baseline levels. This may account for both the rises and falls in serum Ca^{2+} reported for heatstroke victims.

Fluorescence imaging^[138A] and tracer techniques^[234] show that heating cultured cells raises cytoplasmic Ca^{2+} concentration.

Magnesium.

Concentrations of magnesium in sweat vary from 0.02 to 5 mmol/L and might be expected to cause hypomagnesemia during prolonged exercise in the heat. ^[47] ^[48] ^[54] ^[231] Significant loss of total body magnesium is prevented, however, because there is a concomitant rapid decrease in renal magnesium excretion. ^[52] ^[231] Losses during endurance exercise have been estimated to be about 1% of total body magnesium content. ^[54] Occasionally, an acute fall in serum magnesium occurs following prolonged intense exercise, ^[25] ^[190] which may be caused by a temporary uptake of Mg^{2+} by erythrocytes, ^[186] mononuclear cells, ^[207] and actively contracting muscle, ^[49] in addition to the losses in sweat. ^[51] Although some studies suggest that these losses are severe enough to cause symptoms, the consensus is that the development of clinical hypomagnesemia secondary to losses in sweat is unlikely. ^[146]

Phosphate.

Hypophosphatemia is frequently seen in EHS. ^[31] Heat stress often causes respiratory alkalosis, which increases the rate of cellular uptake of phosphate and reduces its excretion. ^[168] Other studies suggested that hypophosphatemia was caused by increased renal clearance of phosphorus with a decreased renal threshold, plus contributions from metabolic acidosis and increased uptake of phosphorus by cells. ^[205] However, hypophosphatemia is not always reported in humans or animal models, and respiratory alkalosis does not always occur at the same time as hypophosphatemia.

Enzymes.

One of the prominent and almost pathognomonic characteristics of EHS is the appearance of exceptionally high levels of certain cellular enzymes, implying cell damage or death. Most EHS patients show elevation of serum creatine phosphokinase (CPK) activity and myoglobinuria, suggesting damage of skeletal muscles. ^[77] CPK activity in the range of 10^3 to 10^4 IU/L was commonly found, with peak values 24 to 48 hours after collapse. ^[63] ^[206] At T_c of 41.8° to 42.2° C (107.24° to 74.2° F), aspartate aminotransferase (AST) and alanine aminotransferase (ALT) concentrations rose by factors of 25 and 8, respectively, and bilirubin concentration approximately doubled to 1.56 mg/dl. ^[183]

These rises in enzyme levels are related to tissue damage, which in turn depends upon both T_c and its rate of rise and its duration. ^[151] CPK, an indicator of skeletal and cardiac muscle damage, was the most sensitive to increases in T_c , followed by lactate dehydrogenase, an index of generalized tissue damage. In microswine with heatstroke,

however, we found rises in CPK and lactate dehydrogenase (LDH) only about 20 minutes before death and a rise in AST about an hour before death, but no change in ALT concentration.^[90]

In 26 heatstroke victims during the 1994 Hadj, at admission to the heatstroke treatment unit, CPK, AST, ALT, and LDH were elevated in heatstroke victims and remained high after 24 hours. Those who died had higher enzyme levels than the survivors. LDH concentration was useful in distinguishing between those who died and those who had a rapid recovery. The enzymes were better prognostic indicators than T_c , anion gap, and serum K^+ .^[9]

Glucose.

The stress hormones catecholamines and cortisol are secreted during heatstroke, stimulate glycogenolysis, and raise plasma glucose concentrations.^[2] Thus classic heatstroke patients are usually hyperglycemic.^[31]^[103] Approximately half of miniswine with

heatstroke studied also developed hyperglycemia, but 20 to 30 minutes after a rise in circulating insulin, glucose concentrations sharply declined. In accordance with these observations, patients suffering from heat exhaustion were normoglycemic, but some of those with heatstroke were hypoglycemic.^[56]

Late Phase

The late phase of heatstroke is characterized by disturbances in renal and hepatic functions. High bilirubin levels, which may last for several days, reflect both hepatic dysfunction and hemolysis.

Acute renal failure is a common complication of severe cases and occurs in approximately 25% to 30% of EHS patients.^[136]^[150]^[216] Oliguria and anuria are characteristic features. At this phase, urine has been described as appearing like "machine oil," with a low specific gravity.^[182]^[185]^[202]^[216] Usually present in the urine are red and white cells, hyaline and granular casts, and mild to moderate proteinuria.^[202] The etiology is of multiple causes,^[182] but a major cause is reduced renal blood flow subsequent to heat-induced hypotension, hypohydration, and peripheral vasodilatation. Furthermore, direct thermal injury may also lead to widespread damage of renal tissue.^[202] Myoglobinuria and elevated blood viscosity resulting from disseminated intravascular coagulation (DIC) may further contribute to acute oliguric renal failure.^[185]^[202]^[221]^[232]

Recovery

CNS dysfunction becomes increasingly severe with prolonged duration of hyperthermia and its associated circulatory failure. Nevertheless, coma persisting for 24 hours, even with subsequent seizures, is usually followed by complete recovery without evidence of mental or neurologic impairment.^{[3] [191]} Chronic disability may prevail for several weeks or months in the form of cerebellar deficits, hemiparesis, aphasia, and mental deficiency.^{[3] [136] [191]} Only in exceptional cases, when coma persists for more than 24 hours, mental and neurologic impairment may become chronic and prevail for some years.^[5] However, in one study of classic heatstroke, 78% of patients had minimal to severe neurologic impairment.^[63] Shapiro and Moran^[206] studied 82 cases of EHS in Israeli soldiers and concluded that associated with each case was at least one factor predisposing to heatstroke (e.g., diarrhea, lack of acclimatization, poor fitness). Correcting those individual risk factors should lead to strategies capable of preventing heatstroke. Indeed, in more than 90% of the victims in whom predisposing background factors were identified and eliminated, and after waiting 6 to 8 weeks to ensure full recovery, the patients were permitted to return to their routine training schedule.

Heat Tolerance Test.

In the Israeli Defense Forces, all heatstroke victims must undergo an exercise-heat tolerance test after recovery, in order to rule out any effect of concurrent disease and abnormality in thermoregulation.^[75] The patients schedule the test 6 to 8 weeks after the collapse, and before taking the test they are not permitted any activity related to heat stress until they have taken the test. During the test, the individuals wear only shorts and sport shoes. After 10 minutes of rest, they walk on a treadmill at 1.34 m/sec^{-1} at a 2% grade in a hot/dry environment (40° C [104° F], 40% RH) for 120 minutes.^[6] Analysis of multiple physiologic variables during the test helps to diagnose any congenital or acquired factors that might compromise body temperature regulation.^[75]

CLINICAL MANAGEMENT OF HEAT-RELATED ILLNESS

Heat-Related Illnesses

Classic heatstroke occurs when environmental heat load is very high.^{[69] [109] [223]} Usually it develops over a few days (e.g., during a heat wave) and affects mainly the elderly, especially those with underlying infection, liver disease, or/and limited access to air conditioning. In classic heatstroke, physical effort is not the primary cause and in most cases is accompanied by dehydration. However, there are many similarities in the pathology of different heat illnesses (classic or EHS, heat exhaustion, etc.), irrespective of the cause of the heat illness (see [Chapter 10](#)).

As previously discussed, individuals exercising in the heat develop a spectrum of clinical illnesses ranging from syncope to heatstroke. Further discussion of the clinical management of heat illness focuses on heat exhaustion and heatstroke. The distinction between these two clinical diagnoses is somewhat artificial and may be difficult to establish in the field or at the medical facility.

Exertional Heat Illness.

A universal feature of heatstroke is a state of collapse. This puts an abrupt end to the physical effort; activity ceases, body temperature falls, and the victim may spontaneously regain consciousness.

Although strenuous physical exercise (e.g., athletic events, military training, hard labor) in the heat has been notorious in causing heatstroke, it has also occurred at relatively low T_{amb} .^[12] In principle, diagnosing exertional heat illness (EHI) is clear: if a previously healthy individual collapses while exercising in a warm environment for more than 1 hour with rectal temperature (T_{re}) greater than 40.5° C (104.9° F), the diagnosis of heatstroke is virtually certain.^{[44] [96] [120] [144] [220]} Although EHI might be diagnosed immediately, EHI and its severity can also be diagnosed retrospectively from clinical laboratory data after proper clinical management.^{[28] [65] [108] [181]} Occasionally, T_{re} less than 40° C (104° F) has been seen in cases diagnosed as heatstroke, and later confirmed by blood chemistry.

The presentation of heatstroke is usually acute, with approximately 25% of all casualties

exhibiting prodromal symptoms lasting minutes to hours. These include dizziness, weakness, nausea, confusion, disorientation, drowsiness, and irrational behavior. Failure to recognize the first signs of disability, and in some cases an assumption that the subject is malingering, has led to incorrect assessment of true physiologic status. Because of delay in transportation, a heatstroke victim is likely to arrive at the emergency room with T_c lower than that at the site of collapse and partially rehydrated, thus showing only mild CNS disturbances. Therefore a correct diagnosis of heatstroke depends on understanding the entire clinical and pathologic picture (see [Chapter 10](#)).

At the time of heatstroke collapse, sweat glands are usually still active and profuse sweating is usually present, in contrast to earlier beliefs about heatstroke.^{[55] [120] [144] [220]} The appearance of dry skin mainly occurs in a very dry climate where sweat evaporates very rapidly or dehydration has become so severe that secretion of sweat is depressed^[122]; it is most often seen in classic heatstroke rather than EHS.

It is essential to determine body temperature as soon as possible after collapse, bearing in mind that intense hyperthermia occurs immediately after exercise. Heatstroke has been misdiagnosed from adherence to certain conventional criteria, such as a warm climate, very high body temperature, and lack of sweating. The widely held criterion that T_{re} must be high is incorrect. At the moment of collapse, body temperature probably does exceed a certain critical temperature that usually leads to heatstroke. However, delaying the first measurement of body temperature may provide misleading lower temperatures. In one instance, during transportation between the site of collapse and the hospital emergency room, body temperature dropped from $41.1^\circ\text{C} \pm 0.8$ to $37.8^\circ\text{C} \pm 1.2^\circ$, a fall of 3.3°C (6.4°F).^[226] Furthermore, temperatures may be taken by untrained individuals or measured incorrectly.^{[121] [136] [226]}

Heat Exhaustion.

Heat exhaustion occurs in individuals who sweat profusely while participating in an endurance event or while engaging in repeated bouts of exercise. This results in significant and unreplaced sweat losses. Prolonged insensible sweat losses, such as occur while sitting in the sun in a moderate breeze, predispose to heat exhaustion if fluid and electrolyte losses are significant.

PROBLEMS WITH RECOGNITION.

The early symptoms of heat illnesses are often unrecognized or mistaken for malingering. Failure to attend to these symptoms puts the individual at risk of significant thermal injury. Headache, confusion, drowsiness, and even euphoria may be important warning signals. Individuals who anticipate exposure to hot environmental conditions should be thoroughly versed in the manifestations of heat illness.

The victim of heat exhaustion may arrive at the medical facility with nausea and visual disturbances that mimic the prodrome of a migraine headache. Dizziness or syncope may mistakenly suggest arrhythmia or seizure. Symptoms of chilling, piloerection, sweating, and moderately elevated temperature may suggest an infectious process.

Development of altered mental status or ataxia raises the possibility of meningitis, encephalitis, or drug intoxication.

TREATMENT.

Treatment is based on symptoms and focuses on both rehydration and reduction in temperature. The victim must immediately cease exercising. Although this appears to be intuitively obvious, some persons develop euphoria and may resist this measure. Furthermore, later return to physical activity on the same day is contraindicated. When possible, the victim should be removed from direct sunlight (which could have a heat load of hundreds of kCal/hr) and restrictive clothing should be loosened. If the victim is unconscious or the T_{re} is greater than 39° C (102.2° F), he or she should be treated as an incipient heatstroke victim and immediately evacuated to a medical facility following the guidelines below.

Body temperature may be lowered by a variety of means. When available, *immersion in ice water facilitates the most rapid drop in body temperature.*^{[55] [89]} Alternative measures in the field include sprinkling with water and fanning, or placing ice bags over the superficial great vessels (axillae and groin) and fanning.^[46] Periodic toweling of the skin renews the evaporative surface and facilitates evaporative cooling. See [Box 11-1](#) .

If the patient is alert, oral rehydration can be instituted with cold water or a fluid replacement beverage; the concentration of carbohydrates in such a beverage should not exceed 6%, otherwise gastric emptying and fluid absorption by the intestines may be delayed. An initial target intake of 1 to 2 L over 2 to 4 hours is reasonable; a greater rate results in limited absorption with inappropriate diuresis. The victim should continue to rest and drink over the next 24 hours. As a general rule, for every pound of weight lost by sweating, one pint (2 cups or 500 ml) of fluid should be consumed. It may require 36 hours to completely restore lost electrolytes and fluid volume to all body compartments via oral intake.

After the acute episode the medical care provider should determine any possible host risk factors for heat illness and review with the victim signs of heat illness and preventive measures.

Heatstroke

Heatstroke is a true medical emergency; before 1950, the mortality rate was 40% to 75%.^{[13] [73]} Long-term survival is directly related to rapidly instituting resuscitative measures.

Box 11-1. CURRENT COOLING METHOD FOR EXERTIONAL HEATSTROKE

At the USMC training base at Parris Island, SC, victims of exertional heatstroke are routinely cooled using the following procedures. *NB: These victims are young men and women who are otherwise healthy.* Victims of *classic* heatstroke are usually elderly and with concurrent diseases, and those factors must be taken into consideration.

1. During physical training, the clinic routinely maintains a dedicated room with two bathtubs full of cold water and ice.
2. In the field, the blouse and pants are removed from a collapsed suspected heatstroke patient, leaving on the shorts and T-shirt. Rectal temperature is measured, ice is packed around the groin/axillary areas, and the patient is immediately transported to the clinic on a stretcher. Upon arrival, the stretcher is placed on top of the iced bathtub above the water and ice, with the carrying handles sticking out at both ends.
3. Mental status and other vital signs are assessed and blood drawn for laboratory analyses.
4. One liter of normal saline is administered as a bolus.
5. Sheets are dipped into the tub's icy water and are used to cover and drench the patient. Copious ice is added to the top of the sheet to cool still further, and the skin is massaged to improve skin blood flow. The sheets are frequently rewetted with the icy water.
6. Concurrently, the head is constantly irrigated with more ice water and a fan is directed at the patient.

The victim is not routinely immediately

rewetted with the icy water.

6. Concurrently, the head is constantly irrigated with more ice water and a fan is directed at the patient.

The victim is not routinely immediately immersed in the ice water in case cardiopulmonary resuscitation becomes necessary. However, if rectal temperature is not lowered sufficiently, then the victim is immersed directly into the ice and water. With this procedure, rectal temperature usually falls to 39.5° C (102.5° F) within 15 to 20 min and the patient is removed from the stretcher, rinsed, and placed on a gurney, and IV fluids and laboratory studies are reviewed.^[89]

From Gaffin SL, Gardner J, Flinn S: Ann Intern Med 132:678, 2000.

Problems with Recognition.

Earlier diagnosis of heatstroke required three signs: severe hyperthermia ($T_c > 41^\circ \text{C}$ [105.8° F]), CNS disturbance, and cessation of sweating.^[43] This symptom complex represents the extreme or full-blown heatstroke presentation and is now recognized to be *too rigid* and possibly delaying institution of critical interventional measures. We consider each of these criteria in turn.

- The body temperatures reported in heatstroke victims *in the field* may be significantly higher (41.1° C [106.9° F] vs. 37.8° C [100° F]) than those documented in the hospital emergency department.^[213] Failure to obtain or record on-site rectal temperatures may hinder prompt diagnosis; similarly, documentation of only mild elevation in body temperature should *not* preclude the diagnosis of heatstroke.
- The victim's altered mental status may adversely affect the ability of emergency department personnel to obtain a detailed history regarding precipitating events. Lack of such information may also delay diagnosis. Emergency medical transport personnel should attempt to obtain this history before evacuating the victim and communicate the information to the appropriate medical staff.
- Recent investigations have shown that cessation of sweating is a late phenomenon of heatstroke.^{[187] [216]} *At the time of collapse, most heatstroke victims continue to sweat profusely.* Failure to consider the diagnosis of heatstroke in a diaphoretic patient could be fatal.
- Unless an alternative cause is obvious, the previously healthy individual who collapses after physical exertion in hot weather should be considered to have EHS.^{[41] [214]}

Diagnosis.

Shibolet^[213] noted that a delay in measurement of T_c or inaccurate methodology in obtaining initial temperature values often led to inappropriately low initial temperature determinations when compared with actual T_c at the time of collapse. Loss of consciousness is an unvarying feature of heatstroke. With cessation of physical activity, the rate of metabolic heat production markedly decreases and T_c will fall if skin temperature (T_{sk}) is greater than T_{amb} and sweating persists. Shapiro and Seidman^[210] proposed that the diagnosis of heatstroke should be considered in any person who has lost consciousness during exertion and demonstrates clinical and laboratory signs of heatstroke, even if body temperature was not markedly elevated several hours after collapse. A history of prodromal symptoms as described for heat exhaustion should markedly increase the suspicion for heatstroke.

CNS disturbances (coma, convulsions, confusion, or agitation) accompanying hyperthermia may also be due to CNS infections, sepsis, or other disease processes. Evaluation for these disorders should proceed only after the diagnosis of heatstroke is ruled out. Markedly elevated levels of AST, ALT, and LDH may help in differential diagnosis.^[123] However, the clinician should bear in mind that elevation of these enzymes may not occur for 24 to 48 hours after heat injury.^[214]

Complications.

Observed complications of heatstroke reflect the results of both direct thermal injury and cardiovascular collapse. Autopsy of persons with EHS showed multiple hemorrhages, congestion, and cellular degeneration in most or all of the organs examined.^[216] In EHS in particular, rhabdomyolysis is usually present.^[137] A brief overview of the specific pathology found should provide a framework for discussion

of the therapeutic and supportive management of heatstroke.

CENTRAL NERVOUS SYSTEM.

The brain is particularly susceptible to thermal injury. CNS dysfunction is directly related to the duration of hyperthermia and to circulatory failure. The underlying pathology observed on autopsy is brain edema and congestion, with petechial hemorrhage and neuronal degeneration.^[150] Cerebrospinal fluid pressure and hematologic features are normal.^[214] In Shibolet's study,^[213] all patients presented with confusion or agitation or both and 72% had convulsions, but all eventually became comatose. Agitation, delirium, and hallucinations reflect CNS hyperirritability. Pupillary constriction was present in 66% of cases.^[127] Seizures occur in approximately 50% of cases.^[127] Decerebrate rigidity, oculogyric crisis, and opisthotonos may develop; other findings may include loss of rectal sphincter tone, loss of skeletal muscle tone, and hemiplegia.^[214] Cerebellar

findings of dysarthria and ataxia are common.

Complete recovery occurs in most cases. However, chronic disability may develop in the form of mental deficiency, dysarthria, ataxia, aphasia, and hemiparesis.

CARDIOVASCULAR SYSTEM.

Hypotension does not always occur in heatstroke but is usually present in fatal or severe cases.^[216] This hypotension, which may persist even after large volumes of fluid therapy along with vasopressors, is an ominous late feature of heatstroke and may reflect failure of compensatory vasoconstriction of mesenteric blood vessels. As vital organs are hypoperfused, shock develops. Left ventricular subendocardial hemorrhage and focal necrosis of cardiac muscle fibers are commonly found on autopsy.^{[150] [214]}

The extreme stress placed on the cardiovascular system of victims with heatstroke results in a universal finding of sinus tachycardia, often with rates exceeding 140 beats/min.^[216] Pulse pressure is elevated in the face of low cardiac output (CO) and low diastolic blood pressure.^[214] Electrocardiographic findings include ST segment and T wave abnormalities and conduction disturbances.^[56] In microswine and monkeys, during heating, HR rose to a plateau shortly after heating and commenced to rise still further at T_c of 41° C (105.8° F), peaking a few minutes before death. Blood pressure was stable or even rose until HR peaked at T_c of 41° C and then declined until death.^[90]

PULMONARY SYSTEM.

Hyperventilation is a common finding, particularly in EHI. Persistent hyperventilation may lead to respiratory alkalosis and tetany. Coma or seizures may predispose to pulmonary aspiration with consequent lung injury.^[214] Pulmonary edema may become severe or fatal; DIC may lead to adult respiratory distress syndrome.^[72] Pulmonary infarctions have been found on autopsy.^[150]

RENAL SYSTEM.

Acute renal failure develops in approximately 25% of heatstroke victims.^[133] Hypotension and resultant decreased renal blood flow constitute the primary underlying etiology. As in the CNS, thermal injury may cause direct cellular damage.^[202] DIC and myoglobinuria exacerbate the insult to renal tissue. Hematuria, pyuria, proteinuria, and hyaline and granular casts are seen on urinalysis. Eventually, oliguria and anuria may develop.

HEPATIC SYSTEM.

Within 12 to 24 hours after heatstroke collapse, elevated AST, ALT, and serum bilirubin levels can be detected.^[125] Levels of AST greater than 1000 U/ml are commonly seen in severe heatstroke.^[233] Prothrombin level reaches its nadir 48 to 72 hours after heat injury.^[201] Cholestasis and hepatocellular necrosis may develop.

GASTROINTESTINAL SYSTEM.

Vomiting and diarrhea are common symptoms of heatstroke. Compensatory mesenteric vascular constriction may produce localized areas of gut ischemia and mucosal injury with consequent breakdown of its permeability barrier and translocation of LPS into the circulation.^[93] Direct thermal damage to the gut wall may also contribute to gut wall pathophysiology. As previously discussed, the subsequent increase in serum LPS and its role as inducer of potentially damaging cytokines may play a critical part in both the morbidity and potential therapy of heatstroke. In the presence of DIC, hematemesis and melena may develop.^[214]

HEMATOLOGIC SYSTEM.

White blood cell counts may be elevated to as high as 20,000 to 30,000/ml. Platelet count is depressed, as are levels of clotting factors V and VIII. The commonly seen bleeding diathesis may be manifested as conjunctival hemorrhage, melena, purpura, or hematuria.^[214] The primary causes of this coagulopathy are believed to be release of thromboplastic substances secondary to endothelial damage, and endotoxemia resulting in intravascular thrombosis and secondary fibrinolysis.^[213] Other contributing factors include direct inactivation of clotting factors by thermal injury, decreased hepatic production of clotting factors, and decreased production of platelets secondary to thermal injury to marrow megakaryocytes. Low levels of fibrinogen and elevated levels of fibrin split products, in the presence of thrombocytopenia, herald the onset of DIC. Clotting abnormalities most often peak 18 to 36 hours after acute heat injury.^[213]

ACID-BASE AND ELECTROLYTE ABNORMALITIES.

Early in the course of heatstroke, respiratory alkalosis secondary to hyperventilation may be present. As anaerobic or even aerobic glycolysis increases, serum lactate levels rise, generating metabolic acidosis.

Hypernatremia reflects associated dehydration common in heatstroke; however, Na⁺ levels may appear normal. In the face of dietary deficiency of Na⁺ or profuse sweat losses, initial normonatremia may develop into hyponatremia upon rehydration. Potassium levels may be low or elevated, with hyperkalemia associated with tissue damage and renal compromise. Hypocalcemia, hypomagnesemia, and hypophosphatemia may also occur. Although hypoglycemia may develop in cases of EHS, hyperglycemia secondary to elevated catecholamine release may also be seen.

ON-SITE EMERGENCY MEDICAL TREATMENT

Heatstroke is a medical emergency. Rapid reduction of elevated body temperature is the keystone of management of heatstroke; *duration* of hyperthermia may be the primary determinant of outcome.^{[133] [216]} Nevertheless, it is important to follow the ABCs of stabilization while cooling efforts are initiated. See [Box 11-2](#) for basic first aid.

Early diagnosis of heat exhaustion can be vital. Early warning signs include flushed face, hyperventilation, headache, dizziness, nausea, tingling arms, piloerection, chilliness, incoordination, and confusion.^[71] Pitfalls in the diagnosis of heat illness include *confusion, preventing self-diagnosis*.^[71] Mainstays of therapy include emergency on-site cooling, intravenous (IV) fluids, treating hypoglycemia as needed, IV diazepam for seizures or severe cramping or shivering, and hospitalization if response to therapy is slow or atypical.^{[71] [138]}

Cooling should be energetically initiated immediately upon collapse and minimally delayed only for vital resuscitation measures in order to prevent or minimize expected complications. In the field, the sick individual should be placed in the shade and any restrictive clothing removed. The victim's skin should be kept wet by applying large quantities of tap water or water from any source and his or her body constantly fanned. However, it is of utmost importance that these measures do not delay evacuation of the victim to a hospital or the closest medical facility.

In a comatose victim, airway control should be established by insertion of a cuffed endotracheal tube. When available, administration of supplemental oxygen may help meet increased metabolic demands and treat hypoxia commonly associated with aspiration, pulmonary hemorrhage, pulmonary infarction, pneumonitis, or pulmonary edema.^{[72] [150]} Positive-pressure ventilation is indicated if hypoxia persists despite supplemental oxygen administration (Figure 11-1 (Figure Not Available)).

As discussed previously, resuscitative measures may rapidly lower body temperature. Monitoring and recording rectal temperature on site may be important for the correct diagnosis of heatstroke. Vital signs should be monitored, with attention to blood pressure and pulse. Although normotension should not be taken as a reassuring sign, *hypotension should be recognized for the ominous sign it always represents*. If possible, urine and blood samples should be obtained for evaluation before fluid infusion.

Box 11-2. BASIC FIRST AID FOR HEAT ILLNESSES

1. Place the victim in the shade.
2. Remove restrictive clothing.
3. Apply large amount of water on the victim and keep his or her skin wet.
4. Improvise a fan and cool the victim.
5. Measure rectal temperature to confirm diagnosis.
6. Evacuate to the nearest medical facility.

Vascular access should be established without delay by insertion of a large-gauge IV catheter. Administration of normal saline or lactated Ringer's solution should be begun. Recommendations regarding the rate of administration of fluids vary. Some authors advise a rate of 1200 ml over 4 hours,^[180] but we consider this to be too conservative. Others encourage a 2-L bolus over the first hour and an additional liter of fluid per hour for the next 3 hours.^[210] However, vigorous fluid resuscitation may precipitate the development of pulmonary edema, so careful monitoring is indicated. *Ideally, 1 to 2 L of fluid should be administered during the first hour after collapse and additional fluids administered according to the level of hydration.*^[76]

Cooling measures should be initiated immediately. However, cooling techniques are ineffective when the victim suffers seizures that increase storage of body heat. Therefore convulsions should be controlled by IV administration of 5 to 10 mg of diazepam, as necessary.

As a result of drastic cooling, skin temperature may decrease enough to cause shivering. IV administration of chlorpromazine (50 mg)^[124] or diazepam are effective to suppress shivering and prevent an additional rise in body temperature from metabolic heat production.

Cooling Methods

Much debate exists in the literature regarding the best approach to cooling heatstroke victims.^{[46] [55] [102] [219] [239]} Morbidity and mortality are directly related to duration and intensity of elevated T_c . Therefore the rate at which any given method lowers body temperature is extremely important. Another consideration in choosing a cooling modality is the need for access to the victim for continuous monitoring.

Khogali and co-workers^[239] developed a body cooling unit designed to maximize evaporative cooling by maintaining cutaneous vasodilation and minimizing

Figure 11-1 (Figure Not Available) Flow chart for on-site emergency medical treatment of exertional heat illnesses. *DD*, Differential diagnosis. (Modified from Shapiro Y, Seidman DS: *Med Sci Sports Exerc* 22:6, 1990).

shivering. The patient is suspended on a net and sprayed from all sides with water at 15° C (59° F). Warm air (45° to 48° C [113° to 118.4° F]) is blown over the victim. Cooling rates of 0.06° C/min (0.11° F/min) have been obtained. Although this method is widely recommended as the treatment of choice, the rate of cooling is actually much less than that accomplished by ice water immersion.

Although not always available, *ice water or cold water immersion is an effective and easily available method of rapidly lowering core body temperature*. However, its use is one of the more hotly debated topics in the heatstroke literature. In most cases, the increased thermal conductivity of water results in reduction of T_c to less than 39° C (102.2° F) in 10 to 40 minutes.^[56] This reflects a mean rate of cooling of 0.13° C/min (0.23° F/min), that is, *twice* the rate of the body cooling unit. Use of cold water rather than ice water resulted in a similar rate of cooling of 0.13° C/min.^[180] Cold water immersion is less uncomfortable for the victim than immersion in ice water. In *hundreds* of EHS victims in a military population, there were no fatalities or permanent sequelae after treatment with ice water immersion.^{[55] [56] [179]} Although other cooling methods reduce the rate of mortality, none has been as successful as ice water-soaked sheets or immersion.^[89]

In discussing an alternative cooling method, Khogali^{[128] [239]} summarizes the most commonly offered criticisms of ice water immersion:

- Exposure to severely cold temperatures may cause peripheral vasoconstriction with shunting of blood away from the skin, resulting in a paradoxical rise in core temperature.
- Induction of shivering (in response to the cold) may cause additional elevation in temperature.
- Exposure to ice water causes marked patient discomfort.
- Working in ice water is uncomfortable for medical attendants.
- Access to the patient for monitoring of vital signs or administration of cardiopulmonary resuscitation is more difficult.
- There is difficulty maintaining sanitary conditions should vomiting or diarrhea develop.

Although the first two criticisms may appear physiologically appropriate, review of the medical literature fails to provide documentation for a rise in body temperature following ice water immersion or shivering as a problem.^[56] In fact, vascular resistance decreased

during ice bath cooling and persisted until normothermia.^[180] This is an expected observation. The hypothalamic set point for temperature regulation is not raised during heatstroke (unlike during febrile illness), and brain temperature accounts for approximately 90% of the thermoregulatory response, compared with the skin's 10%.^[196] The shivering response should only occur if body temperature is allowed to fall below normal. When shivering occurred, chlorpromazine treatment (25 to 50 mg intravenously) was effective.^[117] Heatstroke victims rarely require cardiopulmonary resuscitation, so this concern should not preclude the use of ice baths to treat heatstroke. The documented efficacy of ice water immersion in rapidly reducing body temperature, and therefore morbidity and mortality, overrides any consideration of transient personal discomfort for the patient or medical attendants.

If other methods are used initially, any victim whose core temperature does not reach 38.9° C (102.2° F) within 30 minutes after beginning treatment should be placed in a tub containing ice water or on a stretcher above the tub and covered with ice water-drenched sheets and massaged.^[89] The tub should be deep enough for submersion of the neck and torso.^[188] Rapidly falling core temperature may not be accurately reflected by measured rectal temperature,^[44] so with any cooling technique, active cooling should be discontinued when core body temperature falls to 39° C to prevent inducing hypothermia.

In summary, ice water treatment cools EHS patients fastest, can be easily set up with little training, is available in most hospitals without purchasing capital equipment, and may also be used on classic heatstroke victims. However, in treating elderly classic heatstroke patients, a case-by-case judgment call should be made deciding whether the risk of a theoretic, but never-shown, harmful stress by ice water treatment is worth the clear benefit of rapid cooling. Otherwise, cold water or ice water cooling is the method of choice.

Various ancillary modalities have been proposed to facilitate cooling, including administration of cold IV fluids, gastric lavage with cold fluids, and inhaling cooled air. Although these therapies lower body temperature, their effects are minimal compared with ice water immersion. Cooling blankets are ineffective in inducing the rapid lowering of body temperature required in treatment of heatstroke. Use of antipyretics is inappropriate and potentially harmful in heatstroke victims. Aspirin and acetaminophen lower temperature by normalizing the elevated hypothalamic set point caused by pyrogens; in heatstroke, the set point is normal, with temperature elevation reflecting failure of normal cooling mechanisms. Furthermore, acetaminophen may induce additional hepatic damage, and administration of aspirin may aggravate bleeding tendencies. Alcohol sponge baths are inappropriate under any circumstances, since absorption of alcohol may lead to poisoning and coma.

HOSPITAL EMERGENCY MEDICAL TREATMENT

If airway control has not been previously established, a cuffed endotracheal tube should be inserted to protect against aspiration of oral secretions (Figure 11-2 (Figure Not Available)). Supplemental oxygen and, when necessary, positive-pressure ventilation should be provided. Temperature should be continually monitored (at 5-minute intervals) by means of an esophageal or rectal probe. Cooling measures should be maintained for T_c greater than 38°C (100.4°F).

IV access should be obtained as quickly as possible. In the emergency room, IV fluid should be administered to EHS victims as a bolus of 1 L. Additional fluid should be based on the clinical situation after laboratory results are obtained to support the circulatory system without risk of inducing pulmonary or cerebral edema. Most heatstroke victims arrive with high cardiac index, low peripheral vascular resistance, and mild right-sided heart failure with elevated central venous pressure. Only moderate fluid replacement is indicated if effective cooling results in vasoconstriction and increased blood pressure. A Swan-Ganz pulmonary artery catheter may be necessary to assess appropriate fluid supplementation. Some victims have low cardiac index, hypotension, and elevated central venous pressure. These persons have been successfully treated with an isoproterenol drip (1 mg/min).^[180] Patients with a low cardiac index, low central venous pressure, hypotension, and low pulmonary capillary wedge pressure should receive fluid.

Figure 11-2 (Figure Not Available) Flow chart for hospital medical treatment of exertional heat illnesses. (Modified from Shapiro Y, Seidman DS: *Med Sci Sports Exerc* 22:6, 1990.)

Cardiac monitoring should be maintained during at least the first 24 hours of hospitalization. Use of norepinephrine and other α -adrenergic drugs should be avoided because they cause vasoconstriction, thereby reducing heat exchange through the skin. Anticholinergic drugs that inhibit sweating, such as atropine, should also be avoided.

As previously discussed, chlorpromazine may be used to treat uncontrollable shivering that might lead to rising body temperature. However, chlorpromazine should be used advisedly because it may cause hypotension or seizures and its anticholinergic effects may interfere with sweating. For these reasons, some physicians prefer to use diazepam to control shivering.

A Foley catheter should be placed to monitor urinary output. Myoglobinuria and hyperuricemia can be prevented by promoting renal blood flow by administering IV mannitol (0.25 mg/kg) or furosemide (1 mg/kg).^[210] Early dialysis should be considered if anuria, uremia, or hyperkalemia develops.

Cooling and hydration usually correct any acid-base abnormality; however, serum electrolytes should be monitored and appropriate modifications of IV fluids made. Glucose should be monitored repeatedly because both hypoglycemia and hyperglycemia may occur after heatstroke.^[205]

Oral and gastric secretions are evacuated via nasogastric tube connected to continuous low suction. Although

antacids and histamine H₂ blockers have been used to prevent gastrointestinal bleeding, no studies to date demonstrate their efficacy in heatstroke victims.

As previously discussed, clotting disturbances peak 18 to 36 hours after onset of heat injury.^[214] Coagulation tests (platelet count, prothrombin time, fibrinogen levels, fibrin split products) should be obtained on admission and after 24 hours. DIC may develop 24 to 72 hours after admission and is marked by acute onset of bleeding from venipuncture sites, gingivae, nasal mucosae, lungs, and/or the gastrointestinal tract. DIC is best prevented by rapid cooling of initial hyperthermia and replacement of clotting factors and platelets by transfusion of fresh frozen plasma and platelets.

Acute hepatic dysfunction is exhibited by elevated levels of aminotransferases and bilirubin. The peak levels are seen 36 to 72 hours after collapse. These high levels may last for several days.^{[76] [159] [216]} Muscle damage is displayed primarily by marked elevation of serum CPK activity levels, which peak 24 to 48 hours after collapse and usually return to normal spontaneously within 5 days. Muscle and liver enzymes and bilirubin values should be carefully followed, but drastic interventions (e.g., liver transplant) are rarely necessary.

Prognosis

Rapid reduction of body temperature, control of seizures, proper rehydration, and prompt evacuation to an emergency medical facility currently result in a 90% survival rate in heatstroke victims, with morbidity directly related to duration of hyperthermia.^[209] A poor prognosis is associated with T_c greater than 41° C (105.8° F), prolonged duration of hyperthermia, hyperkalemia, acute renal failure, and elevated serum levels of liver enzymes. Full recovery without evidence of neurologic impairment has been achieved even after coma of 24 hours' duration and subsequent seizures.^[216] The persistence of coma after return to normothermia is a poor prognostic sign.^[214] In a few victims, some

neurologic deficits may persist, but usually for a limited period of 12 to 24 months, and only rarely for a longer period.^[5] However, one recent study of classic heatstroke reported that 33% of patients left the hospital with some neurologic impairment.^[63]

Dantrolene

Dantrolene has been used very successfully in the treatment of several hypercatabolic syndromes, such as malignant hyperthermia, neuroleptic malignant syndrome, and other conditions characterized by muscular rigidity or spasticity.^[224]^[236] Dantrolene stabilizes the Ca^{2+} release channel in muscle cells, reducing the amount of Ca^{2+} released from the cellular calcium stores. This lowers intracellular Ca^{2+} concentrations, muscle metabolic activity, and muscle tone, and thus heat production.^[40]^[175] In some studies, dantrolene was claimed effective in treating heatstroke, whereas in others it neither improved the rate of cooling nor improved survival.^[38]^[64]^[148]^[228] In six rhabdomyolysis patients, intramuscular Ca^{2+} concentrations were 11 times higher than in controls and dantrolene successfully lowered this elevated Ca^{2+} .^[145] Collectively, the limited data available are at best inconsistent. In spite of growing evidence for a possible benefit of dantrolene treatment in heatstroke, justification for its routine use in such cases is not proved, although future clinical trials may change this assessment.^[30]^[112]^[141]^[184]

Recently, Moran et al^[164] studied dantrolene in a hyperthermic rat model. They found it effective as a prophylactic agent in sedentary animals only. Dantrolene induced more rapid cooling by depressing Ca^{2+} entry into the sarcoplasm. This led to relaxation of peripheral blood vessels with attenuated production of metabolic heat. Dantrolene also may be effective in treating heatstroke by increasing the cooling rate. However, in other animal models, dantrolene was not superior to conventional cooling methods.^[245]

Prevention

Prevention of heat illness relies upon awareness of host risk factors, altering behavior and physical activity to match these risk factors and environmental conditions, and a requirement for appropriate hydration during physical exercise in the heat. More aggressive educational activity of the media explaining heat illness and its prevention to the public are to be strongly promoted. Primary care physicians should incorporate this information in the anticipatory guidance of routine health assessment. Despite a wealth of medical literature on heat injury, some athletic coaches continue to use physical or psychologic methods to force athletes to compete or run under intolerably hot conditions. This practice should be viewed as irresponsible, dangerous, and possibly criminally negligent.

AWARENESS OF HOST RISK FACTORS

Risk Factors

Any underlying condition that causes dehydration or increased heat production, or decreased dissipation of heat, interferes with normal thermoregulatory mechanisms and predisposes an individual to heat injury. Older individuals are less heat tolerant than are younger persons to EHI and more susceptible to classic heatstroke because of decreased secretory ability of sweat glands and decreased ability of the cardiovascular system to increase blood flow to the skin (BF_{sk}). When healthy young adults exercise strenuously in the heat, EHS may occur, despite the absence of host risk factors. In particular, persons with type II muscle fiber predominance are more susceptible to EHS because these fibers are "faster" but less efficient than other

303

fiber types.^[115] In principle, since women have a thicker subcutaneous fat layer and a T_c 0.4° to 0.5° C (0.7° to 0.9° F) higher during the luteal phase than in the follicular phase, they may be at greater risk for heat injury during the luteal phase, but this has not been documented in controlled studies.^{[183A] [223A]}

BMR-to-surface area ratios of children are higher than those of adults. As a result, the child's T_{sk} is higher. Although the secretory rates of sweat glands are lower in children, they have greater numbers of active sweat glands per area of skin than do adults and overall greater sweat rates per unit area.^[113] Any reduction in sweat rates would therefore put children especially at risk.

Endocrine abnormalities, such as hyperthyroidism and pheochromocytoma, cause a marked increase in heat production. Acute febrile illness, by virtue of the elevated hypothalamic set point caused by pyrogens, also leads to increased heat production. Muscular activity associated with uncontrolled gross motor seizures or delirium tremens also releases significant metabolic heat.

The primary means of heat dissipation is production and evaporation of sweat. Any condition that reduces this process places the individual at risk for thermal injury. Poor physical conditioning, fatigue, cardiovascular disease, and lack of acclimation all limit the cardiovascular response to heat stress. Obesity places an individual at risk from reduced CO , increased energy cost of moving extra mass, increased thermal insulation, and altered distribution of heat-activated sweat glands.^[161] The elderly and the young

show decreased efficiency of thermoregulatory functions and increased risk of heat injury.

Several congenital or acquired abnormalities affect sweat production and evaporation. Ectodermal dysplasia is the most common form of congenital anhidrosis. Widespread psoriasis, scleroderma, miliaria rubra ("prickly heat" caused by plugging of the sweat ducts with keratin), or deep burns may also limit sweat production.

Dehydration affects both central thermoregulation and sweating. A mere 2% decrease in body mass through fluid loss produces an increase in HR, increase in T_c , and a decrease in PV. In an otherwise healthy adult, gastrointestinal infection with vomiting and diarrhea may cause sufficient dehydration to place the individual at risk for EHS. Chronic conditions that may contribute to dehydration include diabetes mellitus, diabetes insipidus, eating disorders (especially bulimia), and mental retardation. Alcoholism and illicit drug use are among the 10 major risk factors for heatstroke in the general population.^[131] An important effect of alcohol consumption is inhibition of ADH secretion, leading to relative dehydration.

Despite evidence that hypohydration limits physical performance, voluntary dehydration continues to be routine in certain athletic arenas.^{[15] [36] [112] [230]} Wrestlers, jockeys, boxers, and bodybuilders commonly lose 3% to 5% of their body mass 1 to 2 days before competition. In addition to restricting fluid and food, they also use other pathogenic weight control measures, such as self-induced vomiting, laxatives and diuretics, and exposure to heat (saunas and hot tubs or "sauna suits"). Athletes undergoing rapid dehydration are at risk not only for heat injury but also for other serious medical conditions, such as pulmonary embolism.^[60]

[Box 11-3](#) highlights some of the common medications that interfere with thermoregulation. Special attention should be paid to the role of antihistamines in reducing sweating. This class of medications is commonly obtained over the counter, and the general population should be warned of the dangers of exercising in the heat when taking antihistamines.

Although it has been widely believed that sustaining an episode of heatstroke predisposes the individual to future heat injury, this has been refuted in a recent study of heatstroke victims.^[16] Ten heatstroke patients were tested for their ability to acclimate to heat; by definition, the ability to acclimate to heat indicates heat tolerance. Nine of these patients demonstrated heat tolerance within 3 months after the heatstroke episode; the remaining patient acclimated to heat a year after his heat injury. In no case was heat intolerance permanent. Although individuals may show transient heat intolerance after thermal injury, evidence for permanent susceptibility to thermal injury is lacking.

Adaptation to Environmental Conditions

Appropriate adaptation to hot environmental conditions encompasses many forms of behavior, including modification of clothing, degree of physical activity, searching for

shade, anticipatory enhancement of physical

304

conditioning, acclimation to heat stress, and attention to hydration.

**Box 11-3. DRUGS THAT INTERFERE
WITH THERMOREGULATION**

***DRUGS THAT INCREASE HEAT
PRODUCTION***

Thyroid hormone

Amphetamines

Tricyclic antidepressants

Lysergic acid diethylamide (LSD)

Haloperidol

DRUGS THAT DECREASE SWEATING

Antihistamines (diphenhydramine)

Anticholinergics

Phenothiazines

Benztropine mesylate

Clothing.

Different regions of the body are not equivalent in their sweat production.^[111] The face and scalp account for 50% of total sweat production, whereas the lower extremities contribute only 25%. When exercising under conditions of high heat load, maximal evaporation of sweat is facilitated by maximum exposure of skin. Clothing should be lightweight and absorbent. Although significant improvement has been made in the fabrication of athletic uniforms, the uniforms and protective gear required by certain branches of the military and public safety officers continue to add to the risk of heat injury. Development of protective clothing that will also permit more effective heat dissipation is indicated.

Activity.

Behavioral actions can effectively minimize the occurrence of classic heatstroke. Lack of residential air conditioning places indigent persons at risk during heat waves. By sitting in a cool or tepid bath periodically throughout the day, the individual can decrease the heat stress and thereby prevent heat injury.

Modification of physical activity should not be based solely on any individual parameter of T_{amb} , wet bulb temperature or relative humidity (RH), or solar radiation, since all of these contribute to heat load. The wet bulb globe temperature (WBGT) is an index of heat stress that incorporates all three factors. This value may be calculated ([Table 11-2](#)) or obtained directly from portable heat stress monitors that measure all three parameters simultaneously and compute the WBGT. Alternatively, the heat index may be obtained from national weather stations. Current recommendations for prevention of thermal injuries during distance running from the American College of Sports Medicine (ACSM) are based on WBGT.^[10] It is stated that "distance races (=16 km or 10 miles) should not be conducted when the WBGT exceeds 28° C (82.4° F). During periods of the year when the daylight T_{amb} often exceeds 27° C (80° F), distance races should be conducted in the early morning or in the evening to minimize the heat load from T_{amb} and solar radiation."^[10] In the British Army, the strenuous Combat Fitness Test (CFT) occasionally leads to heat casualties. To prevent a mean rise in T_c of 0.7° C (1.26° F) and minimize heat illnesses, calculations indicate that CFT should not be undertaken when the end WBGT is expected to be greater than 25° C (77° F).^[33]

[Table 11-3](#) presents a suggested modification of sports activity that is also based on the WBGT. Although ACSM guidelines for summer indicate that vigorous physical activity should be scheduled in the mornings or in the evenings, it should be cautioned that *the highest humidity of the day is usually early morning*. Recently, Montain et al^[157] updated the replacement guidelines for warm weather training ([Table 11-4](#)). It is

TABLE 11-2 -- Wet Bulb Globe Temperature (WBGT) Heat Index

TEMPERATURE (° F)	EXAMPLE
Wet bulb × 0.7 =	78 × 0.7 = 54.6
Dry bulb × 0.1 =	80 × 0.1 = 8.0

Black globe × 0.2 =	100 × 0.2 = 20.0
HEAT INDEX	82.6

Wet bulb reflects humidity. Dry bulb reflects ambient air temperature. Black globe reflects radiant heat load. Alternative equation: WBGT = (.567) Dry bulb temperature + (.393) Environmental water vapor pressure + 3.94.

TABLE 11-3 -- Modification of Sports Activity Using Wet Bulb Globe Temperature

INDEX (° F)	LIMITATION
<50	Low risk for hyperthermia but possible risk for hypothermia
<65	Low risk for heat illness
65–73	Moderate risk toward end of workout
73–82	Those at high risk for heat injury should not continue to train; practice in shorts and T-shirts during the first week of training
82–84	Care should be taken by all athletes to maintain adequate hydration
85–87.9	Unacclimated persons should stop training; all outdoor drills in heavy uniforms should be canceled
88–89.9	Acclimated athletes should exercise caution and continue workouts only at a reduced intensity; light clothing only
90 or above	Stop all training

important to note that compliance with these recommendations does not remove all risk of heat injury. Developing another index of heat stress that provides a better basis for prevention of EHS is indicated. Recently, a new user-friendly miniaturized (2-inch × 1-inch × 0.5-inch) device based on measuring T_{amb} and RH with microsensors was developed for assessment of heat stress. ^[162] However, further miniaturization and evaluations of this device are required.

Conditioning.

The contribution of cardiovascular conditioning to thermoregulation is discussed in [Chapter 10](#). Ideally, before exercising in the heat, an individual should train under temperate or thermoneutral conditions. For the previously sedentary individual, an exercise regimen incorporating 20 to 30 minutes of aerobic activity 3 to 4 days a week will improve cardiovascular function after 8 weeks.

It is important to remember that even physically active individuals may lack physical conditioning relative

BDU, Battle dress uniform; NL, no limit to work time per hour.

The work/rest times and fluid replacement volumes will sustain performance and hydration for at least 4 hours of work in the specified heat category.

Individual water needs will vary \pm ¼ quart/hr.

Rest means minimal physical activity (sitting or standing), accomplished in shade if possible.

CAUTION: Hourly fluid intake should not exceed 1 ½ quarts.

Daily fluid intake *should not exceed 12 quarts.*

Wearing body armor: add 5° F to WBGT index.

Wearing mission-oriented protective posture (MOPP, chemical protection) overgarment: add 10° F to WBGT index.

EASY WORK: Weapon maintenance; walking hard surface at 2.5 mph, = 30 lb load; manual handling of arms; marksmanship training; drill and ceremony.

MODERATE WORK: Walking loose sand at 2.5 mph, no load; walking hard surface at 3.5 mph, = 40 lb load; calisthenics; patrolling; individual movement techniques, e.g., low crawl, high crawl; defensive position construction; field assaults.

HARD WORK: Walking hard surface at 3.5 mph, = 40 lb load; walking loose sand at 2.5 mph with load.

to a particularly stressful competition or activity. Heat illness in runners commonly occurs when novices exceed their training effort during races or when well-trained athletes increase their pace above normal during long-distance events.

Acclimatization.

On initial exposure to a hot environment, workouts should be moderate in intensity and duration. A gradual increase in the time and intensity of physical exertion over 8 to 10 days should allow optimal acclimatization^[70]; children require 10 to 14 days to achieve a similar response. Acclimation can be induced by simulating hot environmental conditions indoors. If symptoms of heat illness develop during the acclimation period, all physical activity should be stopped and appropriate interventions begun. Acclimation is not facilitated by restricting fluid intake; in fact, conscious attention to fluid intake is required to prevent dehydration. As with physical conditioning, there are limits to the degree of protection that acclimation provides from heat stress. Given a sufficiently hot and humid environment, no one is immune to heat injury.

HYDRATION

Replacement of fluid loss during exercise preserves muscle function. Even after the loss of a large volume of sweat, a well-rehydrated cardiovascular system can maintain CO and blood pressure despite increased BF_{sk} and continued sweating necessary for optimal temperature regulation.^[171]

Throughout this chapter, *euhydration* refers to the idealized "normal" body water content based upon measurements of mass, electrolytes, urine specific gravity, and hematocrit, taken daily for at least 3 days after the first urination of the day and breakfast.

Dehydration refers to loss of body fluids relative to euhydration, *rehydration* refers to replacement of body fluids, *hypohydration* refers to body fluids debt, and *hyperhydration* refers to excess body fluids.

Dehydration

Under neutral T_{amb} , a person at rest dissipates heat by transitory increases in BF_{sk} to accelerate heat losses by radiation, conduction and convection. When T_{amb} is greater than T_{sk} , exercise generates the need for additional mechanisms to dissipate heat. Evaporation of sweat is the only effective cooling mechanism, but this also causes loss of body fluid. Dripping sweat has no cooling effect and is especially prominent in a hot/wet climate. Under those conditions, the sweat rate (\dot{m}_{sw}) will be higher but will not be able to adequately dissipate body heat and lower T_c .^[61] Fluid losses through sweating may exceed 2 L/h and up to 15 L/day.^{[162] [196]} As a consequence, insufficient drinking for sweat loss may rapidly lead to dehydration, compounding the cardiovascular and metabolic stresses already present.^[53]

Blood flow to exercising muscles declines in parallel with dehydration.^[97] The combined stresses of dehydration

MEAN DIFFERENCE IN PERFORMANCE BETWEEN WINNING AND LOSING: 0.32%

and hyperthermia during exercise in the heat may exceed the body's ability to maintain CO and blood pressure. This renders the dehydrated sportsman less able to cope with hyperthermia.^[99]

In a number of studies, 1.9% to 6% dehydration decremented performance in various tasks by 6% to 57% in athletes ([Table 11-6](#)).^{*} Among elite athletes, the mean time difference between first and second place in international competitions was 0.32% (range: 0% to 0.83%) ([Table 11-5](#)). That is, a small degree of hypohydration may lead to a large decrement in performance among athletes. A dehydrated top-rated athlete can be defeated by a euhydrated but inferior opponent, particularly in endurance events.

Physical and cognitive performance is decremented by 1% dehydration (600 to 800 ml body fluid loss [BFL]), and the decrement becomes more severe with increasing BFL.^[100]
^[140] At 7% BFL there is evidence of exhaustion, and collapse is imminent.

Females were thought to be at higher risk for dehydration than males because females have less total body water, comparatively less lean body mass, and proportionately more adipose tissue than do their male counterparts of similar mass.^[26] No gender differences were observed in \dot{m}_{sw} , but for similar \dot{m}_{sw} , females had higher T_{re} , suggesting that females have a less efficient process of evaporating sweat.^[211] A larger surface area-to-mass ratio should promote more effective thermoregulation, but nonetheless, if fluid replacement is not sufficient, females may have higher risk for heat illnesses.

How Much to Drink?

The individual should be well hydrated before commencing physical activity in the heat; hypohydration for any reason should preclude physical activity while the individual is heat stressed. The ACSM guidelines recommend that individuals drink 500 ml of fluid about 2 hours before exercise to promote adequate hydration and allow time for excretion of excess water. In general, dehydration can be prevented by replacing body fluid losses through drinking. However, reliance on voluntary fluid intake through the sensation of thirst results in significant dehydration. Ten to 15 minutes before commencing physical activity, 8 oz. (½ cup) of water or appropriate fluid replacement beverage should be ingested. Continued intake of 8 to 12 oz. of fluid every 20 to 30 minutes during exercise should be enforced, or

urine color should be monitored (when the color becomes darker, it is time to drink more).^[17] See [Box 11-4](#) .

Box 11-4. FINDING WATER IN THE DESERT

Persons traveling in hot climates should be prepared for strandings that might lead to death resulting from heat and dehydration. These have included the deaths of large numbers of Egyptian soldiers in the Sinai. The deaths could have been prevented had the soldiers known about subsurface "sweet" water. Another man in the desert who did not drink his car's cooling water also did not lie in the shade below his car and instead wandered off into the desert, where it took a long time to find his body. A woman alone for 2 days in the desert knew enough to stay in the shadow of a cliff. She benefited from the fact that maximal physical activity in the desert may cause a loss of 4 L of water per hour, whereas minimum activity in shade loses approximately 2.5 L per day.

1. Sources of water in the desert: Look for green plants.
2. Near the seashore, drinkable water, usually originating from rain, may be found below a sandy/gravel surface, and above any seawater because of its lower density. Particular plants may use this water and show greenery against a gray/brown substrate.
3. Water for drinking may be found at the foot of cliffs that become waterfalls only during a flood. Below these cliffs, pounding water and gravel may have carved a depression in the rocky floor that becomes filled in with gravel saturated with water. At the top of the saturated gravel, evaporation may render the surface dry and hot. However, much of the water often remains in pools or below the soil surface. Green plants often inhabit these areas and are markers for water. Such natural reservoirs retain water for a long time.
4. In wadis, after heavy rain, depressions filled with gravel and rocks become filled with water, with plants surrounding them.

Sweat rate is a function of individual metabolic rate, clothing, and climatic conditions. During mild work and while wearing cotton clothes, \dot{m}_{sw} ranged between 0.3 and 1.2 L/hr. Performing the same activity but wearing nonpermeable clothing, \dot{m}_{sw} rose to 1 to 2 L/hr. Likewise, during high exercise intensity in a hot climate, an athlete often has \dot{m}_{sw} of 1 to 2.5 L/hr.^[195] A high \dot{m}_{sw} of 3.7 L/hr was reported in a marathon runner in the 1984 Olympics.^[18] Voluntary matching of fluid consumption to sweat loss is a serious issue because thirst provides a poor index of body water needs.^[194] As a result, individuals can dehydrate by 2% to 8% of their body mass during prolonged high sweat rate *even though water may be readily available*.^[104] Since about 60% of body mass is water, dehydration of 2% to 8% is equivalent to a loss of 1 to 4 L of body fluids for a person of 75 kg body mass.^[194]

The most widely used guideline for fluid replacement was suggested by Shapiro et

al.^[208] It is based on a mathematical sweat prediction model and is in use by the U.S. Army, as well as by other organizations. Recently, Montain et al^[155] adjusted those guidelines for different U.S. Army activities (see [Table 11-4](#)).

The color of urine has been suggested as a way to monitor hydration status. This method is based on a color-coding key in which persons pay attention to the color of their urine; darker urine color indicates a higher level of hypohydration. Thus, if urine is strongly yellow-colored, the person is hypohydrated and must drink more water. If urine is clear, he is adequately hydrated. This method is practical for determining moderate degrees of hypohydration and is more sensitive than those based on blood measurements.^[20]

The measurements of preexercise and postexercise nude dry weights can also be used as a guide for the need to drink more fluid. For every pound of weight lost during activity, the individual should consume 1 pint (2 cups) of fluid. Fluid loss should be replaced before return to activity in the heat; if a loss greater than 2% of body mass persists, the individual should be withheld from activity. Prehydration slows development of dehydration and temporarily enhances performance.

For assessment of day-to-day hydration status in athletes in the field, Shirreffs and Maughan^[217] recently suggested a new method based on a standardized procedure for measuring osmolality of the first urine sample of the day. Urine is collected after waking and before breakfast to allow day-to-day comparisons of individuals. After analyzing data from 29 athletes, they concluded that their method is reliable for individual hydration status and is a quick and easy method to achieve an approximation of day-to-day hydration status. However, we believe that a better method to evaluate hydration status that is noninvasive, rapidly responsive, and user friendly should be developed.

Advances in biosensor technology and microminiaturization have reduced commercial devices for measuring blood parameters to 2 inches × 6 inches × 1 inch (i-STAT Corporation, Princeton, N.J.), with results as accurate as those obtained from full-sized hospital automated blood chemistry analyzers. The i-STAT analyzer is portable enough to be useful in field scenarios for emergency diagnoses.^[138]

The traditional rules of some sports (e.g., field hockey, soccer, tennis, rugby) unintentionally limit opportunities for hydration by failing to provide for timeouts and incorporating brief halftimes. During extremely hot and humid weather, team physicians, trainers, coaches, and officials should work together to incorporate additional breaks (quarters rather than halves) and provide unlimited access to fluids on the sidelines.

Hypohydration

Hypohydration leads to reduced ability to dissipate metabolic heat, rapid elevation in T_c , and more rapid exhaustion. Heat exhaustion occurs at relatively low T_c because blood volume displacement to the skin causes marked cardiovascular strain and instability.^[156]

[199]

The impact of different levels of hypohydration on heat tolerance while wearing clothing was studied under various heat loads.^{[199] [201]} Under severe heat stress and wearing impermeable clothing, tolerance time was shortened by hypohydration before commencing the exercise, and the rate of rise in T_c during exercise increased with the degree of hypohydration.^[152] The main contributor to excessive rise in T_c was believed to be decreased sweat rate.^[104] In warm environments, increased levels of hypohydration result in increased threshold temperature for the onset of sweating and decreased sweat rate at each work rate during exercise.^[154]

Hydration status may affect thermoregulatory or cardiovascular responses to exercise via alterations of body fluid volumes or osmolality. Hypovolemia and hyperosmolality, individually or acting synergistically, impair heat loss by elevating threshold T_c for the onset of both peripheral vasodilation and sweating, and possibly by decreasing the gain of these responses.^{[81] [82] [174]} Hypohydration may also directly impair sweat gland function.^[229] Hypohydration of 1.9% (by 24 hours of fluid restriction) increases T_c and serum osmolality during cycling exercise, and decreases blood flow to nonexercising muscles (e.g., forearm) in a normothermic environment.^[227] Increasing levels of hypohydration and plasma osmolality, and decreases in PV, cardiac filling, and stroke volume, lead to progressively decremented CO and thermoregulation.^[201] During exercise in the heat, each 1% increase in hypohydration levels raised T_c 0.1° to 0.5° C (0.18° to 0.9° F) and increased HR by 4 bpm.^{[95] [104]} HR is elevated to compensate for decreased stroke volume presumably caused by reduced central venous pressure and end-diastolic ventricular volume, both consequences of decreased blood volume^[98] (see [Chapter 10](#)).

When required evaporative heat loss is less than maximal capacity of the environment to support evaporative heat loss ($E_{req} < E_{max}$), then the heat stress is described as "compensable"; if, however, $E_{req} > E_{max}$, it is "uncompensable." At an uncompensable heat load, minor levels of hypohydration impair exercise tolerance, even at lower metabolic rates. The impairment becomes evident as the duration of the exercise increases at lower metabolic rates. Hypohydration decreases PV and increases plasma osmolality and inhibits peripheral blood flow and the sweating response, resulting in increased rate of rise in T_c .

The effects of hypohydration on heat strain are well documented. The new physiologic strain index (PSI) showed high correlation between strain and losses of

body mass through sweating^{[160] [161] [163]} (see [Chapter 10](#)). However, the effects on skeletal muscle performance and metabolism are less well known.^{[154] [198] [199] [201]} Some studies indicated that hypohydration reduces muscle endurance,^{[27] [77] [165]} whereas others found no difference.^{[4] [79] [114]} Recently, Montain et al^[157] reported that moderate

hypohydration (4% body mass) decreased skeletal muscle performance by 15%. This disagreement with previous studies was explained by inadequate control of prior exercise, heat exposure, and caloric intake in previous studies.^[157]

Physiologic Consequences of Hypohydration.

Hyperosmolality per se, even without a fall in blood volume, increases the threshold temperatures for onset of skin vasodilation and sweating during exercise in the heat.^[57] These effects may be neurally mediated, since preoptic anterior hypothalamic neurons are osmosensitive.^[218] Moreover, hypovolemia reduces the rate of sweating during exercise in the heat.^[80]^[201] Decreased PV as a result of lost water and salt, concomitant with increased distribution of blood volume to skin vascular beds, can reduce venous return, central venous pressure,

Figure 11-3 Decrements of cardiac performance with 3% and 5% body weight loss. (From Montain SJ et al: *Int J Sports Med* 19:87–91, 1998.)

cardiac filling pressure, stroke volume, and CO.^[132]^[173] This would be followed by compensatory increases in HR^[158] (**Figure 11-3**). In addition, increases in plasma hematocrit and viscosity further reduce cardiac filling pressure as a result of increased resistance. In one series of patients with EHS,^[213] 35% were hypotensive with systolic blood pressure below 90 torr. Similar findings have been reported for classic heatstroke.^[103]

Sinus tachycardia in response to excessive circulatory requirements is consistently present in heatstroke victims.^[210] CO and diastolic blood pressure are low, while pulse pressure is high.^[214] Depending on the degree of hypoperfusion of vital organs, shock may ensue.^[133] Hypohydration compromises thermoregulation,^[214] with linear increases in T_c of about 0.15°C (0.27°F) for each 1% decrease in body mass during exercise in the heat.^[201] Additionally, hypohydration negates most of the thermoregulatory advantages conferred by high aerobic fitness and heat acclimatization,^[35] increasing the risk of heat illness.^[214] Sawka et al^[199] reported that exhaustion from heat strain occurred at higher T_{re} for euhydrated than for hypohydrated subjects during uncompensable exercise heat stress.

Some athletes use diuretics to reduce body weight to compete in a lower weight

category. Diuretics increase the rate of urine formation and generally result in loss of solute and volume.^[238] Relatively less intracellular water (approximately 65% of total body fluid) is lost after using diuretics because there is no excess of extracellular solute to stimulate redistribution of body water. Unlike either exercise or heat-induced hypohydration, diuretic-induced hypohydration generally results in isoosmotic hypovolemia, since there is a greater ratio of plasma loss to body water loss.^[116] Among the common diuretics in use are thiazide, furosemide, and carbonic anhydrase inhibitors.

Hyperhydration

It had been hypothesized that consuming excess water before activity would improve performance during heat stress by expanding blood volume and reducing blood osmolality, thereby reducing cardiovascular and thermal strain during exercise.^{[86] [197]} Earlier studies^{[105] [149] [167] [176]} suggested that hyperhydration lowered HR and T_c compared with euhydration. Hyperhydration is usually achieved by drinking water in excess but can also be achieved by ingesting glycerol, since glycerol reduces free water clearance through the kidneys, thereby increasing retention of fluid.^[86] In one study, glycerol/water ingestion improved thermoregulation during exercise heat stress.^[149] The rise in T_{re} was attenuated by 0.7° C (1.26° F) and the sweat rate was elevated by ~300 to 400 ml/hr above control levels.

More recently, Latzka et al^{[142] [143]} studied hyperhydration induced by drinking either water or a water/glycerol mixture during compensable and uncompensable exercise heat stress. Surprisingly, compared with euhydration, hyperhydration did *not* alter T_c , T_{sk} , whole body sweating rate, local sweating rate, sweating threshold temperature, sweating sensitivity, or HR responses. Furthermore, there were no differences in physiologic variables between those achieving hyperhydration with water or by water/glycerol. These data demonstrate that hyperhydration provides no thermoregulatory or cardiovascular advantages over the maintenance of euhydration during compensable or uncompensable exercise heat stress.

Exercise and heat stress each reduce renal blood flow and free water clearance. Therefore the effectiveness of glycerol relative to water as a hyperhydrating agent may be masked. Latzka et al^[143] concluded that hyperhydration per se only provides an advantage (over euhydration) in delaying hypohydration during either compensable or uncompensable exercise heat stress. Furthermore, glycerol ingestion caused nausea and headaches on several occasions. The reasons for the conflicting results with previous studies are uncertain but may be due to differences in experimental design. For example, Latzka et al carefully controlled for the initial baseline hydration status for both treatments, whereas earlier studies did not address this important independent variable.

Hyponatremia.

Symptomatic hyponatremia is diagnosed when serum Na^+ is less than 130 mEq/L and is generally caused by hypervolemia secondary to drinking large volumes of water or

markedly hypoosmotic fluids. This illness has been reported in psychiatric patients and in cases of water overload. However, nonpsychiatric cases are usually associated with enforced water drinking to prevent EHI or with being "too conscientious" in drinking at water stations during a marathon run. There have been several cases of hyponatremia from excessive fluid intake during prolonged exertion in the heat, especially in events such as ultramarathons, triathlons, and recreational hiking, as well as in military training.^{[23] [68] [87]} Hyponatremia subsequent to water overload is potentially a cause of fatal cerebral and pulmonary edema.^{[92] [178]} During the development of hyponatremia, ingested water is absorbed from the gut lumen, diluted blood circulates to the brain, and water enters relatively hypertonic brain tissue by osmosis. Since the brain is enclosed by bone, it cannot swell and intracranial pressure increases. This essentially "squeezes" the cerebrovascular system, reducing intracranial blood flow and occasionally leading to ischemic damage and regulatory collapse. Immediate medical treatment is required.

In the U.S. Army, 125 cases of documented hypoosmolality/hyponatremia were reported over a 7-year epidemiologic study.^[67] Many of these cases were associated with excessive water intakes relative to sweat loss, with average serum Na⁺ of 121 mEq/L (116 to 133 mEq/L). Such low serum Na⁺ values imply that total body water increased by 3 to 5 L.^[155] As a result of this report, Montain et al.^[155] recently revised the U.S. Army fluid replacement guidelines, emphasizing on one hand the need for sufficient fluid replacement during heat stress, while on the other, concern for the danger of overhydration and water intoxication. To achieve an accurate guideline for fluid replacement during heat stress, a two-phase study was carried out by Shapiro et al.,^[208] who developed a computer model to predict sweating loss ($m\dot{V}_{sw}$) during different exercise intensities, followed by validation in a laboratory study. The fluid replacement guidelines presented in [Table 11-4](#) were designed to be a simple and practical tool. These recommendations specify an upper limit for hourly and daily water intake, which safeguards against overdrinking and water intoxication.

TREATMENT OF HYPONATREMIA.

It is critical to differentiate between water intoxication and heat exhaustion/heatstroke because the treatments are very different. In the field, discriminating between hyponatremia and

certain heat illnesses may be difficult because of considerable overlap of symptoms.^[92] A major difference between water intoxication and heat illnesses would probably be in T_c . In heat illnesses, T_c is generally greater than 39° C (102.2° F), whereas in hyponatremia, T_c is usually normal or close to normal.^{[23] [92]} Heat illnesses are treated by cooling and sufficient rehydration, whereas hyponatremia is treated by restricting fluids and gradually correcting Na⁺ concentration by infusion of hypertonic NaCl solution. Too rapid a correction of hyponatremia can cause the demyelinating syndrome known as pontine myelinolysis.

Rehydration

Optimal performance is attainable only with sufficient drinking during exercise to minimize dehydration. It is beyond dispute that even low levels of dehydration (1% loss of body mass) impair cardiovascular and thermoregulatory responses and reduce capacity for exercise.^[171] Fluid replacement reduces the risk of heat illness and improves exercise performance by preventing or reducing dehydration. Consuming fluids in amounts directly proportional to sweat loss maintains optimal physiologic functions and significantly improves exercise performance, even with exercise lasting 1 hour. However, it is recommended that ingested fluid be cooler than T_{amb} (15° to 25° C [59° to 72° F]) and flavored to enhance palatability and promote fluid replacement.^[11]

Once heat injury has progressed to the point of heatstroke, *IV replacement of fluid losses is required. Normal saline solution is the initial IV fluid of choice*, providing excellent expansion of intravascular volume without risking too rapid a correction of undiagnosed hyponatremia. The rate of fluid administration should reflect preexisting or coexisting medical conditions. An initial rate of 1200 ml over 4 hours has been proposed.^[180] *Supplemental potassium should be withheld until serum electrolyte levels are known.* This is important because some commercial beverages previously ingested by the victim contain additional K^+ . Future choice of fluids should reflect the individual's electrolyte status and cardiac and renal function.

Recommendations for maintaining oral hydration (or, more accurately, minimizing dehydration) are presented in the Prevention section. *The inability to rely on the thirst mechanism to prevent dehydration cannot be overemphasized.* Simple provision of fluids at the sideline during athletic practices and competitions and military training scenarios is not sufficient. Scheduled breaks in activity (every 20 to 30 minutes depending on the degree of heat stress) for required consumption of fluids should become more commonplace.

Rehydration with and without Acclimatization.

Sweating and normal thermoregulation have another impact on the predisposition to clinical states that is widely unappreciated by trainers, coaches, and team physicians. In unacclimatized individuals, sweat salt losses can theoretically produce solute deficits having a profound impact on thirst and therefore on potential rehydration rates.

On average, 60% of body mass is water, so that a 70-kg adult contains $0.6 \times 70 \text{ kg} = 42$ L of total body water (TBW). If he now loses 6% of body mass by hypothetically sweating pure water, then he has lost a volume of $0.06 \times 70 \text{ kg} = 4.2$ L, or $(4.2 \text{ L}/42 \text{ L}) = 10\%$ of TBW. Thus TBW has been reduced by 4.2 L to 37.8 L.

Since, in this example, all salts are retained within the body, plasma Na^+ rises in proportion to the ratio of euhydrated volume to the new dehydrated volume, $(42 \text{ L} \div 37.8 \text{ L}) \times 140 \text{ mEq/L}$; *Na^+ has risen to 155 mEq/L*, (assuming two osmotically active particles

per NaCl molecule) and 310 mOsm/L.

If, however, that same sweat volume contained NaCl at a concentration of half the normal euhydrated value ($0.5 \times 140 \text{ mEq/L} = 70 \text{ mEq/L}$), then there was a sweat loss of $70 \text{ mEq/L} \times 4.2 \text{ L} = 294 \text{ mEq Na}^+$, as well as the 4.2 L of water. Since the normal euhydrated plasma Na^+ concentration is 140 mEq/L, crude calculations indicate that the total amount of Na^+ present is $42 \text{ L} \times 140 \text{ mEq/L} = 5880 \text{ mEq}$. To calculate the crude final Na^+ concentration, the original total amount of Na^+ must be reduced ($5880 - 294 \text{ mEq} = 5586 \text{ mEq}$) by the 294 mEq lost in sweat, and therefore the *final Na^+ concentration* ($5586 \text{ mEq} \div 37.8 \text{ L}$) becomes 148 mEq/L and 296 mOsm/L. This is high enough to reach the thirst threshold (295 mOsm), so the person feels moderately thirsty and will "desire" to consume only 80 ml of water (vs. 1270 ml; see later discussion) before osmolality is reduced to the thirst threshold. This represents only 1.9% ($80 \text{ ml}/4200 \text{ ml} \times 100$) deficit of the water. Consumption of a solute-rich meal or a fluid-replacement beverage about 2 hours before exercise potentially counteracts the salt loss in sweat of a nonacclimatized individual. This probably also explains, by and large, why water balance is often not fully restored until mealtime in sweating, nonacclimatized individuals.

Another clinically and physiologically relevant aspect of this calculation should be emphasized. It is generally appreciated that fully acclimatized subjects, compared with nonacclimatized ones, sweat sooner (at lower T_c and T_{sk}), with lower sweat salt concentration and in larger volume. That is, acclimated persons sweat more and require larger volumes of replacement fluids than do unacclimatized ones for the same activity.

If this sweat were to contain a Na^+ concentration as low as 0.17% NaCl, the solute loss would be reduced to 235 mOsm, compared with 588 mOsm (see earlier discussion). The dehydrated plasma osmolality would be 305 mOsm/kg, and the thirsty subject would have to consume 1270 ml (a sixteenfold increase) to lower the

osmolality to the thirst threshold (30.2% of the water deficit vs. 1.9% above). Although this theoretically important aspect of acclimation on thirst and rehydration volumes has not been experimentally verified, it could significantly improve resistance to heat illness by maintaining more adequate body water stores.

Fluid Replacement Beverages.

A more widely investigated and hotly debated topic is appropriate fluid replacement during physical activity in the heat. Confusion has arisen over a need for replacing electrolyte losses, as well as the advantages of carbohydrate supplementation. The benefits of fluid replacement with electrolyte-carbohydrate-containing beverages vs. water was studied in athletes with 1.9% and 3.5% electrolyte losses. ^[241] No significant difference was found in the maintenance of PV between trials with water and the

experimental formulations. During intense exercise lasting longer than 1 hour, the ACSM guidelines for exercise and fluid replacement recommend that carbohydrates be ingested at the rate of 30 to 60 g/hr to maintain oxidation of carbohydrates and delay fatigue.^[11]

Early investigators promoted consumption of Na⁺-containing fluid to prevent development of hyponatremia during exercise. The rehydration effectiveness of three commercial sports drinks was compared during 4 hours of physical activity.^[118] The beverages consisted of prepared solutions containing component individual minerals and glucose. All solutions proved equally effective in maintaining water and electrolyte balance during moderate physical performance. A benefit of ingesting commercial sports drinks appears to be enhanced palatability that increases voluntary fluid consumption, thereby reducing dehydration.^[170]

The rate of rehydrating various body compartments depends on the rates of gastric emptying of ingested fluid and the intestinal absorption of water. Gastric emptying is the slower rate-limiting step and depends principally on osmolality and caloric content of the fluid.^[74] Which factor predominates depends on physical activity and the temperature and volume of the beverage. Earlier studies suggested that there was a delay in gastric emptying and increased rehydration time when the beverage contained more than 2.5% glucose, sucrose, or fructose. However, more recent studies have reported that there is in fact little or no difference in gastric emptying rates between water and carbohydrate solutions as high as 7%.^[62]^[203] Other investigators have confirmed that under exercise conditions, 5% glucose polymer solutions show a gastric emptying rate similar to water.

A frequent argument for including Na⁺ in fluid replacement beverages is to enhance intestinal water absorption, since Na⁺ transport is the major determinant of water absorption in the proximal small bowel. Active coupled transport of Na⁺ and glucose creates an osmotic gradient that pulls water from the lumen into epithelial cells. However, the rate of intestinal absorption of carbohydrate-electrolyte solutions is equal to, but not faster than, absorption of water.^[170]^[240]

Cold fluids increase the motility of smooth muscles in the gastric wall, thereby speeding gastric emptying more rapidly than do warm drinks. The commonly held belief that consumption of cold water results in stomach cramps has not been confirmed. Such a phenomenon, if it occurs, is more likely related to the volume of the beverage than to its temperature.^[50]

Gastric emptying is speeded by stretching the gastric wall. Therefore large volumes of liquid empty from the stomach more rapidly than do small quantities. Athletes, however, are uncomfortable exercising with a nearly full stomach. Indeed, although there may be a benefit to rapid oral rehydration, if the nausea threshold is reached, a secondary increase in ADH secretion may impair the kidneys' ability to excrete excess fluid volume and result in hyponatremia and water intoxication.^[19] By drinking smaller volumes (150 to 250 ml) at 15- to 20-minute intervals, athletes can maintain adequate hydration while minimizing gastric distension.

A sports drink should contain 5% to 10% carbohydrate in the form of glucose or sucrose

to enhance endurance.^[58] However, many athletes suffer cramps, nausea, and diarrhea after drinking a 10% glucose solution. An isocaloric glucose-polymer solution has only one fifth the osmotic pressure. Its lower osmolality allows an increase in the carbohydrate content of a sports drink without risking the gastrointestinal side effects of a high osmolar drink. Several commercial polymer solutions are available.

Carbohydrate feeding during prolonged exercise enhances performance, whether assessed by time to exhaustion or by time to complete a predetermined exercise task.^[45]^[170] Glucose polymer solutions given before and during a soccer game sustained blood glucose concentration and improved performance, although no difference in perceived exertion was found.^[212] However, dehydrated soldiers who ingested fluids during exercise in the heat reduced their strain and the intensity of perceived exertion.^[169] Whether use of these beverages spares muscle glycogen is a matter of current debate.

A potential problem in using carbohydrate-rich beverages is that they may attract bees and yellow jackets into the vicinity of the athletes, placing them at risk for sting-induced allergic or anaphylactic reactions.

Under normal conditions, use of electrolyte-carbohydrate-containing beverages offers little advantage over water in maintaining PV or electrolyte concentration or in improving intestinal absorption. Consumption of an electrolyte-containing beverage may be indicated under conditions of caloric restriction, prolonged exercise, or repeated days of sustained sweat losses. Drinking carbohydrate solutions during prolonged exercise

may enhance performance; athletes who might benefit are those involved in soccer, field hockey, rugby, and tennis. For these athletes, use of glucose polymer solutions may be considered. Under no circumstances should carbohydrate-containing beverages be placed into canteens, since microbial contamination would be unavoidable and subsequent sterilization required.

For the vast majority of individuals, however, the primary advantage of using electrolyte- or carbohydrate-containing drinks appears to enhance voluntary consumption. This factor should not be considered insignificant if regulated intake is impossible.

318

Chapter 12 - Wildland Fires: Dangers and Survival

Kathleen Mary Davis
Robert W. Mutch

It is hard to know what to do with all the detail that rises out of fire. It rises out of a fire as thick as smoke and threatens to blot out everything. Some of it is true but doesn't make any difference. Some of it is just plain wrong. And some doesn't even exist, except in your mind, as you slowly discover long afterwards. Some of it, though, is true—and makes all the difference.
Norman Maclean, *Young Men and Fire*, 1992

Describing the 13 fatalities in the Mann Gulch fire near Helena, Montana, in 1949, Norman Maclean wrote, "They were still so young they hadn't learned to count the odds and to sense they might owe the universe a tragedy." The Mann Gulch fire has been called "the race that couldn't be won."^[27] Although the crew increased their pace ahead of the fire, the fire accelerated faster than they did until fire and people converged at the end of a race the firefighters could not win. Miraculously, three persons survived the fire. The foreman ignited an escape fire into which he tried to move the crew; two of the smoke jumpers found a route to safety. Many improvements in a person's odds of surviving an encounter with a wildland fire have occurred since 1949. These advances include improved understanding of fire behavior, increased emphasis on fire safety and fire training, and development of personal protective equipment. However, as events such as the Colorado fires of 1994 showed, tragedies continue to occur.

Whether the Mann Gulch fire, the 1871 Peshtigo fire in Wisconsin that killed 1150 people, the Great Idaho fire of 1910 that left 85 dead ([Figure 12-1](#)), the 1947 Maine

fires that produced 16 victims, or the 1991 Oakland fire that killed 25 people, wildland fires are as much a threat to human life, property, and natural resources on the North American continent as are hurricanes, tornadoes, floods, and earthquakes. This chapter describes the current look of this historical force and discusses new federal fire management policies, the nature and scope of wildland fire hazards, behavior of fires, typical injuries, summary of fatalities (1990–1998), and survival techniques.

WILDLAND FIRE MANAGEMENT AND TECHNOLOGY

Programs for dealing with the overall spectrum of fire are collectively termed *fire management*.^[1] They are based on the concept that fire and the complex interrelated factors that influence fire phenomena can and should be managed. The scientifically sound fire management programs that respond to the needs of people and natural environments must also maintain full respect for the power of fire.^[1]

Since the early 1900s, federal, state, and local fire protection agencies have routinely extinguished wildland fires to protect watershed, range, and timber values, as well as human lives and property. Fire detection, fire danger rating systems, and fire suppression methods have been developed by fire science laboratories and two equipment development centers maintained by the U.S. Department of Agriculture (USDA) Forest Service. Patrol planes, some with infrared heat scanners, and other aircraft can deliver firefighters, equipment, and fire-retarding chemicals to the most remote fire. These firefighting resources are organized under an Incident Command System that can easily manage simple to complex operational, logistical, planning, and fiscal functions associated with wildfire suppression actions.^[3]

Modern fire suppression technology, however, cannot indefinitely reduce the number of hectares burned, as demonstrated by several large fires in recent years: the Greater Yellowstone Area fires in 1988; Mack Lake fire in Michigan in 1980; Foothills fire near Boise, Idaho, in 1992; Silver Complex in Oregon in 1987; and Stanislaus Complex in California in 1989. The hard lesson learned from these fires and others is that wildfires are inevitable. Several factors have coincided to produce massive forest mortality, including drought, epidemic levels of insects and diseases,^[21] and unnatural accumulations of fuels as a result of fire exclusion. Many agencies are now using prescribed fire more frequently, deliberately burning under predetermined conditions to reduce accumulations of fuels and to protect human life and property.

Research has indicated that fires are not categorically bad. In fact, many plant communities in North America are highly flammable during certain periods in their life cycles. For example, annual grasses, ponderosa pine, and chaparral plant communities are flammable almost every dry season. Other communities, such as jack pine or lodgepole pine forests, although fire resistant during much of their life cycle, eventually become fire prone when killed by insects, diseases, and other natural causes. The spread of nonnative grasses, such as cheat-grass and red brome, in the arid West has increased the frequency of fires in desert shrublands.

Wildland fires can benefit plant and animal communities. Evolutionary development

produces plant species

319

Figure 12-1 Burned ruins of the foundry in Wallace, Idaho, furnish mute testimony to the destructive force of the 1910 fires. The cottage on the terrace was the only one left standing in that part of town. (Courtesy the USDA Forest Service. Photo by R.H. McKay.)

well adapted to recurrent fires. Fire tends to recycle ecosystems and maintain diversity. ^[15] Thus there is growing consensus that fire should be returned to wildland ecosystems where appropriate to perpetuate desirable fire-adapted plant and animal communities and to reduce fuel accumulations.

A landmark report in 1963 to the National Park Service by the Advisory Board on Wildlife Management^[14] described how the western slope of the Sierra Nevada had been transformed by fire protection:

When the forty-niners poured over the Sierra Nevada into California, those that kept diaries spoke almost to a man of the wide-spaced columns of mature trees that grew on the lower western slope in gigantic magnificence. Today much of the west slope is a dog-hair thicket of young pines, white fir, incense-cedar, and mature brush—a direct function of over- protection from natural ground fires. Not only is this accu- mulation of fuel dangerous to the giant sequoias and other mature trees, but the animal life is meager, wildflowers are sparse, and, to some at least, the vegetative tangle is depress- ing, not uplifting.

The board recommended that the Park Service recognize in management programs the importance of the natural role of fire in shaping plant communities.

Federal Wildland Fire Management Policy

Recent tragedies in the West focused attention on the need to reduce hazardous fuel accumulations. The events of 1994 created a renewed awareness and concern among federal land management agencies about wildfire impacts, leading to a combined review of fire policies and programs. The result was the enactment of a new interagency federal wildland fire management policy, which provided a common approach to wildland fire among federal agencies and called for close cooperation with tribal, state, and other jurisdictions.^[37] The principal points of the new federal wildland fire policies

are as follows:

1. Firefighter and public safety remains the first priority in wildland fire management. Protection of natural and cultural resources and property is the second priority.
2. Wildland fire, as a critical natural process, must be reintroduced into the ecosystem, accomplished across agency boundaries, and based on the best available science.
3. Where wildland fire cannot be safely reintroduced because of hazardous fuel accumulations, pretreatment must be considered, particularly in the wildland-urban interface.
4. Wildland fire management decisions and resource management decisions are connected and based on approved plans. Agencies must be able to choose from the full spectrum of actions—from prompt suppression to allowing fire to have an ecologic function.
5. All aspects of wildland fire management will involve all partners and have compatible programs, activities, and processes.
6. The role of federal agencies in the wildland-urban interface includes firefighting, hazardous fuel reduction, cooperative prevention and education, and technical assistance. Ultimately, the primary responsibility rests at the state and local levels.
7. Structural fire protection in the wildland-urban interface is the responsibility of tribal, state, and local governments.
8. Federal agencies must better educate internal and external audiences about how and why we use and manage wildland fire.

Prescribed Fire and Fire Use

Prescribed fire, the intentional ignition of grass, shrub, or forest fuels for specific purposes according to predetermined conditions, is a recognized land management practice. The objectives of such burning vary: to reduce fire hazards after logging, expose mineral soil for seedbeds, regulate insects and diseases, perpetuate natural ecosystems, and improve range forage and wildlife habitat. In some areas managed by the National Park Service, USDA Forest Service, and Bureau of Land Management, naturally ignited fires may be allowed to burn according to approved prescriptions; fire management areas have been established in national parks and wildernesses from the Florida Everglades to the Sierra Nevada in California ([Figure 12-2](#)). Visitors are increasingly aware that wildland fires can provide an important environment for the enjoyment of park and wilderness experiences.

Figure 12-2 Some lightning fires in wildernesses and national parks are now allowed to burn under observation to perpetuate natural ecosystems. (*Courtesy the USDA Forest Service.*)

WILDLAND-URBAN INTERFACE: NEW LOOK OF A HISTORICAL PROBLEM

Just as resource agencies are attempting to provide a more natural role for fire in wildland ecosystems, the general public is increasingly living and seeking recreation in many of these areas. However, past fire exclusion practices have allowed abnormal fuel accumulations, and this fact has combined with the sacrifice of relatively safe perimeter fire suppression strategies in favor of directly protecting people and their possessions.^[42]

Direct suppression actions *within* the fire's perimeter place firefighters at a greater disadvantage from a safety standpoint. The new interagency policy that emphasizes firefighter and public safety as the first priority will result in less effort to save structures in dangerous situations. What is known of fire behavior and fire survival principles must be readily available to emergency medical personnel, wildland dwellers, and recreationists. In fact, fire protection agencies have been making such information more available to the general public.

Nature of the Problem

Hot, dry, windy conditions annually produce high-intensity fires that threaten or burn homes where wildland and urban areas converge. Can the historical levels

Figure 12-3 These burned-over and wind-thrown trees resulted from the intense behavior of the 1910 forest fire near Falcon, Idaho. (Courtesy the USDA Forest Service. Photo by J.B. Halm.)

of destruction, injury, and fatality be repeated today in the face of modern fire suppression technology? The answer requires an analysis of the conditions that created high-intensity fire behavior in the forests of Idaho and Montana in 1910 ([Figure 12-3](#)). The Peshtigo, Michigan, Hinckley, Yacoult, and Maine fires burned hundreds of thousands of hectares and killed more than 2000 people between 1871 and 1947.

On October 8, 1871, the same day that fire wiped out the town of Peshtigo, Wisconsin, the great Chicago fire devastated urban Chicago. Comparative statistics for those two

fires highlight the destructive potential of wildland fires. The Peshtigo fire covered 518,016 hectares (1,280,000 acres) and killed 1150 people, whereas 860 hectares (2124 acres) burned and 300 lives were lost as a result of the Chicago fire.^[41] The 1910 wildland fires had several common elements: many uncontrolled fires burning at one time; prolonged drought, high temperatures, and moderate to strong winds; and mixed conifer and hardwood fuels with slash from logging and land clearing. These large fires occurred primarily in conifer forests north of the 42nd meridian, or roughly across the northern quarter of the contiguous United States.^[2] One of these critical elements that is not as likely to occur today as formerly is the simultaneous presence of many uncontrolled fires. The effectiveness of modern fire suppression organizations reaches the most remote wildland

locations. High-velocity winds and more than 1600 individual fires contributed to the spread of the 1910 fires; it is unlikely that a multifire situation of that magnitude would occur today. Prolonged drought, high winds, and flammable fuel types, however, remain significant to the behavior of high-intensity fires.

Some of the fires most potentially damaging to human lives and property occur in areas rich in chaparral shrub fuel in California. Wilson^[42] described the severe 1970 fire year in California, in which official estimates showed that 97% of 1260 fires occurring between September 15 and November 15 were held to less than 121 hectares (300 acres). The other 3% of the fires, fueled by a prolonged drought and fanned by strong Santa Ana winds, produced 14 deaths, destroyed 885 homes, and burned more than 242,820 hectares (600,000 acres). Ten years later the situation recurred over 28,330 hectares (70,000 acres) in southern California, resulting in the deaths of 5 persons and loss of more than 400 structures.

More recently, on October 20, 1992, a devastating fire occurred in the hills above Oakland and Berkeley, California. Burning embers carried by high winds from the perimeter of a small fire resulted in a major wildland-urban interface conflagration that killed 25 people, including a police officer and a firefighter, injured 150 others, destroyed nearly 2449 single-family dwellings and 437 apartment and condominium units, burned over 648 hectares (1600 acres), and did an estimated \$1.5 billion in damage.^[23] The scenario for disaster included a 5-year drought that had dried out overgrown grass, shrubs, and trees, making them readily ignitable. Other factors included untreated wood shingles, unprotected wooden decks that projected out over steep terrain, low relative humidity, high temperatures, and strong winds that averaged 32 km per hour (20 mph) and gusted up to 56 to 80 km per hour (35 to 50 mph). These severe conditions produced a voracious fire that consumed 790 homes in the first hour. Winds lessened to 8 km per hour (5 mph) by the first evening, and firefighters had the situation under control by the fourth day, but not before they had an awful glimpse of what future fires will be.

Wildland fires that threaten human lives and property are not exclusively located in southern California, since the exodus to wildland regions has become a national

phenomenon. Fires burned more than 80,940 hectares (200,000 acres) in Maine in October 1947, killing 16 people; another 80,940 hectares (200,000 acres) burned in New Jersey in 1963. On July 16, 1977, the Pattee Canyon fire in Missoula, Montana, destroyed 6 homes and charred 486 hectares (1200 acres) of forests and grasslands in only a few hours.^[7] Fires at the wildland-urban interface also have increased internationally. For example, the Ash Wednesday fire disaster in 1983 burned more than 340,000 hectares (840,000 acres) of urban, forested, and pastoral lands in Victoria and South Australia, killing 77 persons, injuring 3500 persons, and destroying 2528 homes.^[36] A May 1987 wildfire in northern China added a new perspective regarding the devastating impact wildland fires may have on human lives, property, and natural resources. This fire reportedly burned over 404,700 hectares (1 million acres), killed almost 200 persons, seriously injured another 200, destroyed or damaged 12,000 houses, and forced nearly 60,000 people to evacuate their homes—clearly it was a disaster of major proportions. Protecting lives and property from wildfires at the wildland-urban interface presents one of the greatest challenges faced by wildfire protection agencies.

Large forest fires around the world during the intense El Niño drought conditions of 1997–1998 focused public and media attention once again on the need to evaluate public policies and practices in the forestry and nonforestry sectors that directly or indirectly contribute to the impact of forest fires. The size and damage attributed to these fires was so immense that the *Christian Science Monitor* termed 1998 "the Year the Earth Caught Fire." At times that seemed to be literally true as smoke palls blanketed large regional areas, disrupting air and sea navigation and causing serious public health threats. Seventy people were killed in Mexico alone as a result of the fires, and ecosystems that generally are not subjected to fires, such as the Amazon rain forest and the cloud forest of Chiapas, Mexico, sustained considerable damage. A global fire conference sponsored by the Food and Agricultural Organization of the United Nations (October 1998) brought together specialists from 33 countries to review the serious nature of worldwide fires. Participants at the conference in Rome concluded that governments needed to enact more sustainable land use policies and practices to reduce the impacts of wildfires on people and natural resources. More recently, as of the end of September, 2000, nearly 7 million acres had been scorched by approximately 80,000 fires in the United States.

It is becoming increasingly rare to have a wildland fire situation that does not involve people. However, people are not fully aware of the fire risks and hazards of living and traveling in or near wildlands. *Risk*, in the jargon of the wildland fire specialist, is the probability that a fire will occur. *Hazard* is the likelihood that a fire, once started, will cause unwanted results. Risk deals with causative agents; hazard deals with the fuel complex.^[9] The results of two surveys indicated a general feeling of overconfidence by most residents toward the potential danger of forest fire. Eighty percent of Seeley Lake, Montana forest residents who were interviewed thought that the forest fire hazard was low to moderate in their area.^[8] Seventy-five percent of Colorado residents interviewed thought that the forest fire hazard was low or moderate in mountain subdivisions of their state.^[13] Forest fire hazards in these two areas were much

higher than the public estimates. There is a growing need for the general public, emergency medical personnel, and fire suppression organizations to be well prepared to deal with wildland fire encounters ([Box 12-1](#)).

Box 12-1. RECOMMENDATIONS TO REDUCE LOSS OF LIFE AND PROPERTY IN THE WILDLAND-URBAN INTERFACE

FIRE PROTECTION SERVICES

Remember that firefighter and public safety is the first priority in every fire management activity.

Ensure that all personnel receive regular cross-training in fighting wildfires and structural fires.

In urban departments, in particular, recognize the need to extinguish fires in wildland fuels by using thorough mop-up procedures.

Recognize the need for close coordination of response efforts among neighboring departments or agencies.

Develop specific mutual aid plans for coordinating resources to attack fires in the wildland-urban interface.

Schedule and conduct regular mutual aid training exercises.

Regularly schedule and conduct fire prevention and fire preparedness education programs for the general public and homeowners.

Conduct an assessment of fire risks and prepare a strategic plan to reduce these risks.

Work effectively with lawmakers and other government officials to help prevent unsafe residential and business development.

LEGISLATORS

Examine existing laws, regulations, and standards of other jurisdictions that are applicable for local use in mitigating hazards associated with wildland fires.

Adopt National Fire Protection Association Standard 299 for the Protection of Life and Property from Wildfire. (The purpose of this standard is to provide criteria for

Examine existing laws, regulations, and standards of other jurisdictions that are applicable for local use in mitigating hazards associated with wildland fires.

Adopt National Fire Protection Association Standard 299 for the Protection of Life and Property from Wildfire. (The purpose of this standard is to provide criteria for fire agencies, land use planners, architects, developers, and local government for fire-safe development in areas that may be threatened by wildfire.)

Provide strong building regulations that restrict untreated wood shingle roofs and other practices known to decrease the fire safety of a structure in the wildlands.

PLANNERS AND DEVELOPERS

Create a map of potential problem areas based on fuel type and known fire behavior.

Evaluate all existing or planned housing developments to determine relative wildland fire protection ratings and advise property owners of conditions and responsibilities.

Ensure that all developments have more than one ingress-egress route.

Offer options for fire-safe buildings.

Provide appropriate fuel breaks or green belts in developments.

Ensure that adequate water supplies exist in developments.

Follow specifications in NFPA Standard 299 for the Protection of Life and Property from Wildfire.

PUBLIC AND HOMEOWNERS

Determine the wildfire hazard potential of the immediate area before buying or moving into any home.

Contact federal, state, and local fire services for educational programs and materials regarding fire protection.

Provide a defensible space around structures to help protect them.

Design and build nonflammable homes.

Urge lawmakers to respond with legislative assistance to require appropriate fire safety measures for communities.

Wildland Lessons

Recommendations to reduce the loss of life and property in the wildland-urban interface will be useless unless they are implemented at the grassroots level by all stakeholders. An excellent example of a community-based program is one implemented at Incline Village and Crystal Bay in the Lake Tahoe basin.^[32] The objective of this program is to "reduce the potential for natural resource, property, and human life losses due to wildfire by empowering the communities' residents with the knowledge to address the hazard, providing the resources necessary to correct the problem, and encouraging the cooperative efforts of appropriate agencies." The three major components of this defensible-space program include neighborhood leader volunteers, a slash removal project, and agency coordination. The key to protecting life and property in the wildland-urban interface is property owners' realization that they have a serious problem and that their actions embody a significant part of the solution. In the Incline Village/Crystal Bay Plan, neighborhood leader volunteers are trained in defensible-space techniques and are expected to teach these techniques to their neighbors and to coordinate neighborhood efforts. Such concerted community action will greatly minimize the threats from Oakland-type "fires of the future."

It is also wise to have sensible land development practices, since tragedies arise not only from ignorance of fuels and fire behavior but also from a greater concern

323

for the esthetics of a homesite than for fire safety. Several aspects of development detract from fire safety in the wildland-urban interface.^[6] ^[7] :

1. Lack of access to adequate water sources
2. Firewood stacked next to houses
3. Slash (i.e., branches, stumps, logs, and other vegetative residues) piled on homesites or along access roads
4. Structures built on slopes with unenclosed stilt foundations
5. Trees and shrubs growing next to structures, under eaves, and among stilt foundations
6. Roads that are steep, narrow, winding, unmapped, unsigned, unnamed, and bordered by slash or dense vegetation that makes them impossible to drive on during a fire
7. Subdivisions on sites without two or more access roads for simultaneous ingress and egress
8. Roads and bridges without the grade, design, and width to permit simultaneous evacuation by residents and access by firefighters, emergency medical personnel, and equipment
9. Excessive slopes, heavy fuels, structures built in box canyons, and other hazardous situations
10. Lack of fuel breaks around homesites and in subdivisions

11. Living fuels that have not been modified by thinning, landscaping, or other methods to reduce vegetation and litter that contribute to fire intensity
 12. Homes constructed with flammable building materials (wooden shakes, shingles)
-
-

FIRE BEHAVIOR

Urban and Wildland Fire Threats

Safety precautions for wildland firefighting crews are continually upgraded as new knowledge is gained about fire behavior. Fire sites where people were injured or killed are visited afterward to assess fuel conditions, terrain features, probable wind movements at the time of the fire, and actions of firefighters ([Figure 12-4](#)). This information, as well as data about hazards in the wildland-urban interface, is not included in training programs and safety briefings.

In reviewing fire tragedies, a sobering observation is that crew members are almost always experienced and well-equipped firefighters, trained to anticipate "blowup" fire conditions. However, when visibility is lowered to 6 m (20 feet), noise levels preclude voice communication, eyes fill with tears, and wind blows debris in all directions, a person's judgment is badly impaired. Previous training can give way to panic, leading to decisions that result in serious injury or death. This scenario is most evident in urban fires; the pattern of hysteria affecting persons trapped in burning

Figure 12-4 In an attempt to avoid the intense heat of this brush fire in southwestern Colorado, four firefighters took refuge in the fireline, in the foreground at point *A*. Affected by intense convective and radiant heat and dense smoke, one individual ran into the fire and died at point *B*. Another individual ran approximately 1000 feet down the ridge, where his body was found at point *C*. The third fatality was a person who remained at point *A*; he died a short time after this position was overrun by fire. The only survivor also remained in a prone position at point *A* with his face pressed to the ground. At one point he reached back and threw dirt on his burning pants legs. The survivor sustained severe burns to the back of his legs, buttocks, and arms. The deaths of the other three individuals were attributed to asphyxiation. (Courtesy the USDA Forest Service.)

buildings is familiar to fire chiefs. The way fire kills in the urban setting can be compared with wildland fires, as shown here^[24] :

Heat rises rapidly to upper stories when a fire starts in the basement or on the ground floor. Toxic gases and smoke rise to the ceiling and work their way down to the victim—a vital lesson for families planning protective measures. Smoke poses the double problem of obscuring exit routes and contributing to pulmonary injury and oxygen deprivation. As the fire

consumes oxygen, the ambient oxygen content drops, impairing neuromuscular activity. When the oxygen content drops below 16%, death by asphyxiation will ensue unless the victim is promptly evacuated. Asphyxiation, not fire itself, is the leading cause of fire deaths. Ambient temperatures may rise extremely rapidly from even small fires. Temperatures of 149° C (300° F) will cause rapid loss of consciousness and, along with toxic gases, will severely damage lung tissues. Warning devices may offer the only possibility for survival due to the rapid onset of debilitating symptoms.

Obvious similarities and differences are seen:

1. Smoke, heat, and gases are not as concentrated in wildland situations as in the confined quarters of urban fires.
 2. Flames are not a leading killer in either the urban or wildland situation.
 3. Although oxygen levels may be reduced near wildland fires, there is usually sufficient replenishment
-

324

of oxygen in the outdoor environment to minimize deprivation. Asphyxiation, however, can also be an important cause of death in wildland fires.

4. Inhalation of superheated gases poses as serious a threat to life in wildland fires as in urban fires.
5. Wildland smoke does not contain toxic compounds produced by combustion of plastics and other household materials, but it does impair visibility, contain carbon monoxide, and have suspended particulates that cause severe physical irritation of the lungs.
6. Automatic early-warning devices and sprinkler systems may protect people from serious injury or death in the urban environment, but in the wildland environment people must rely on their senses, knowledge, and skills to provide early warning of an impending threat to life.

Fire Behavior Knowledge: A Wildland Early-Warning System

The science of fire behavior describes and predicts the performance of wildland fires in terms of rates of spread, intensity levels, ignition probabilities, spotting, and crowning potentials. *Spotting* is a fire spread mechanism resulting from airborne firebrands or embers. *Crowning* is a fire spread mechanism that moves horizontally through the canopies of shrubs or trees. Knowledge of current and predicted weather information and fire danger ratings can be obtained from local wildland fire protection agencies. Experienced firefighters routinely assess the probable behavior of fires using current and expected weather conditions in relation to local fuel and topographic conditions. The emergency medical person, backcountry recreationist, and wildland homeowner must also understand basic fire behavior principles to provide for adequate personal safety. A cardinal rule is to base all actions on current and expected fire behavior. Attention to simple principles, indicators, and rules should enable wildland users to

anticipate and avoid fire threats.

Heat, oxygen, and fuel are required in proper combination before ignition and combustion will occur ([Figure 12-5](#)).¹¹ If any one of the three is absent, or if the three elements are out of balance, there will be no fire. Fire control actions are directed at disrupting one or more elements of this basic fire triangle.

Physical Principles of Heat Transfer.

Heat energy is transferred by conduction, convection, radiation, and spotting, but generally only the last three processes are significant in a wildland setting. Although conduction through solid objects is important in the burning of logs, this process does not transfer much heat outward from a flaming front.

Convection, or the movement of hot masses of air, accounts for most of the heat transfer outward from the

Figure 12-5 Combustion is a process involving the combination of heat, oxygen, and fuel. An understanding of the variation of these three factors is fundamental to an understanding of fire behavior.

fire. Convective currents usually move vertically unless a wind or slope generates lateral movement. Convection preheats fuels upslope and in shrub and tree canopies, which contributes further to a fire's spread and the onset of crown fires.

Via radiation, heat energy is emitted in direct lines of rays; about 25% of combustion energy is transmitted in this manner. The amount of radiant heat transferred decreases inversely with the square of the distance from a point source. More radiant heat is emitted from a line of fire than from a point source. Radiant heat travels in straight lines, does not penetrate solid objects, and is easily reflected. It accounts for most of the preheating of surface fuel ahead of the fire front and poses a direct threat to people who are too close to the fire ([Figure 12-6](#)). Many organized fire crew members carry aluminized fire shelters in belt pouches so that they can deploy them quickly when escape is not possible ([Figure 12-7](#)). These shelters are used as a last resort to protect from radiant heat.

Spotting is a mass transfer mechanism by which wind currents carry burning or glowing embers beyond the main fire to start new fires ([Figure 12-8](#)). In this manner, fire spread may accelerate, unexpected fires occur, and fire intensity and indraft winds may

increase.

Factors in Wildland Fire Behavior.

A wildland fire behaves according to variations in fuel, weather, and topography. Early warning factors that signal the onset of hotter and faster burning conditions appear in [Box 12-2](#) .

When a person encounters a wildland fire, the first

325

Figure 12-6 Fuels and people upslope or downwind from a fire receive more radiant heat than on the downslope or upwind side.

Figure 12-7 An aluminized fire shelter, carried in a waist pouch, is deployed by firefighters as a last resort to provide protection from radiant heat and superheated air. (Courtesy the USDA Forest Service.)

step should be to review the principles and indicators of fire behavior, sizing up the situation in terms of fuel, weather, topographic factors, and observed fire behavior. After the fire's probable direction and rate of spread are estimated, travel routes that avoid life hazards can be planned ([Figure 12-9](#)). The direction of the main body of smoke is often a good indicator of the direction the fire will take.

FUEL.

The more fuel that is burning, the hotter the fire will be. Certain types of fuel, such as chaparral, pine, and eucalyptus, burn more intensely because of their fine foliage that contains flammable oils. The size and

Figure 12-8 Fuels and people on the slope opposite a fire in a narrow canyon are subject to intense heat and spot fires from airborne embers.

326

Figure 12-9 The parts of a fire are described in terms of its left flank, right flank, head, and rear. There may also be unburned islands within the fire and spot fires ahead of the fire. The safest travel routes generally involve lateral movement on contours away from the fire's flank or movement toward the rear of the fire. Moving in front of a headfire should be avoided. The burned area inside the fire's perimeter can offer a safe haven, if the flaming perimeter can be safely penetrated by an individual.

arrangement of fuel also influence fire behavior. Small, loosely compacted fuel beds, such as dead grass, long pine needles, and shrubs, burn more rapidly than does tightly compacted fuel. Large fuels burn best when they are arranged so that they are closely spaced, such as logs in a fireplace. Scattered logs with no small or intermediate fuel nearby seldom burn unless they are old and rotten.

**Box 12-2. EARLY WARNING SIGNALS
FOR HOTTER, FASTER BURNING
CONDITIONS**

FUEL

More fuel; drier fuel; dead fuel; flashy fuel (dead grass, pine needles, and shrubs); aerial fuel (combustible material suspended in crowns of high shrubs and trees, such as branches, needles, lichens, and mosses).

WEATHER

Faster winds; unstable atmosphere (indicators: gusty winds, dust devils, and good visibility); downdraft winds from dry thunderstorms and towering cumulus clouds (erratic and strong winds); higher temperatures, drought conditions, and lower humidities.

TOPOGRAPHY

Steeper slopes; south- and southwest-facing slopes; gaps or saddles; chimneys and narrow canyons ([Figure 12-11](#)).

FIRE BEHAVIOR

Rolling and burning pine cones, agaves, logs, hot rocks, and other debris igniting fuel downslope; spot fires that occur ahead of the main fire; individual trees that torch out, or areas of shrubs and trees that burn in a continuous crown fire; fires that smolder over a large area; many fires that start simultaneously; fire whirls

debris igniting fuel downslope, spot fires that occur ahead of the main fire; individual trees that torch out, or areas of shrubs and trees that burn in a continuous crown fire; fires that smolder over a large area; many fires that start simultaneously; fire whirls that cause spot fires and erratic burning; intense burning with flame lengths greater than 1.2 m (4 feet); dark, massive smoke columns with rolling, boiling vertical development; lateral movement of fire near the base of a steep slope.

WEATHER.

The greater the wind, the more rapid the spread of fire. Drier air and higher temperatures cause fuel to dry out more quickly; fire burns more intensely because drying creates more fuel. Prolonged drought makes more fuel available. Fires tend to burn more vigorously when atmospheric conditions are unstable.

The North American continent has been classified into 15 fire climate regions based on geographic and climatic factors ([Figure 12-10](#)).^[29] Major fire seasons, or periods of peak fire activity, can be used to warn emergency medical personnel and wildland users of the most probable times for life-threatening situations. Although the fire season for the southern Pacific coast is shown as June through September, critical fire weather can occur year round in the most southerly portion. Fire seasons are most active during spring and fall in the Great Plains, Great Lakes, and North Atlantic regions.

TOPOGRAPHY.

The steeper the slope, the more rapid the spread of fire. Fire usually burns uphill, especially in daytime. Changes in topography cause changes in fire behavior ([Figure 12-11](#)). On steep terrain, rolling firebrands may cause a fire to spread *downhill*.

Extreme Fire Behavior.

Several years of drought combined with a national forest health issue that has produced many dead and dying forests has set the stage for extreme fire behavior conditions that threaten people, property, and natural and cultural resources. Protection from these conditions requires an understanding of the crown fire process. As the name implies, a crown fire is carried through the crowns, or foliage, of a forest or shrubland.

Rothermel^[26] described the conditions that produce a crown fire:

1. Dry fuels
2. Low humidity and high temperatures
3. Heavy accumulations of dead and downed fuels
4. Small trees in the understory, or "ladder fuels"
5. Steep slope

6. Strong winds
7. Unstable atmosphere
8. Continuous crown layer

The two most prominent behavior patterns of crown fires are wind-driven fires and plume-dominated fires. Each type of crown fire poses a distinct set of threats to people. Fires are seldom uniform and well behaved, so these descriptions of wind-driven and plume-dominated fire behavior may not be readily apparent. The behavior of these types of fires can be expected to

327

Figure 12-10 Fire climate regions of North America, based on geographic and climatic factors, are as follows: (1) interior Alaska and the Yukon, (2) north Pacific Coast, (3) south Pacific Coast, (4) Great Basin, (5) northern Rocky Mountains, (6) southern Rocky Mountains, (7) Southwest (including adjacent Mexico), (8) Great Plains, (9) central and northwest Canada, (10) sub-Arctic and tundra, (11) Great Lakes, (12) Central States, (13) North Atlantic, (14) Southern States, and (15) Mexican central plateau. The bar graphs show the monthly and annual precipitation for a representative station in each of the fire climate regions. Months on the map indicate fire seasons. (From Schroeder MJ, Buck CC: *Fire weather, Agricultural Handbook 360, 1970, USDA Forest Service.*)

change rapidly as environmental, fuel, and topographic conditions change.^[26]

WIND-DRIVEN FIRE.

A running crown fire can develop when winds increase with increasing elevation above the ground, driving flames from crown to crown ([Figure 12-12](#)). Steep slopes can produce the same effect. Spread rates can vary from 1.6 to 11 km per hour (1 to 7 mph) and possibly faster in mountainous terrain.^[26] A running crown fire is accompanied by showers of firebrands downwind, fire whirls, smoke, and the rapid development of a titled convection column. As long as

328

Figure 12-11 Chutes, chimneys, and box canyons created by sharp ridges provide avenues for intense updrafts (like a fire in a stove) and rapid rates of spread. People should avoid being caught above a fire under these topographic conditions.

Figure 12-12 Cross-sectional view of a wind-driven crown fire. People are most at risk on the downwind side of a wind-driven fire. This type of fire is caused by winds that increase in velocity with increasing elevation above the ground.

329

the wind remains fairly constant from one direction, the flanks of the fire can remain relatively safe. The greatest threat is to people who are at the head, or downwind, side of the fire, although long-distance spot fires that ignite from flying embers as far as 1.6 km (1 mile) ahead of the main fire front also pose a risk.

PLUME-DOMINATED FIRE.

An alternative form of crown fire develops with relatively low windspeeds or when windspeed decreases with elevation above the ground. This type of crown fire is called a plume-dominated fire because it is characterized by a towering convection column that stands vertically over the fire ([Figure 12-13](#)). This type of fire poses a unique threat to people because it can produce spot fires in any direction around its perimeter. It can also spread rapidly as the combustion rate accelerates.

Figure 12-13 Cross-sectional view of a plume-dominated crown fire. People are at risk around the complete perimeter of this type of fire because the fire can spread intensely or spot in any direction. This form of crown fire develops when wind velocities are relatively low or when velocities decrease with elevation above the ground. The convection plume above this type of fire may rise to 7600 to 9100 m (25,000 to 30,000 feet) above the ground.

One form of a plume-dominated fire can be especially dangerous when a downburst of

wind blows outward near the ground from the bottom of a convection cell. These winds can be extremely strong^[12] and can greatly accelerate a fire. This type of wind occurred during the Dude fire north of Phoenix, Arizona, on June 26, 1990, when six firefighters were killed.

Some indicators help signal the onset of a downburst from a plume-dominated fire. The surest indicator is the occurrence of precipitation of any amount, even a light sprinkle, or the appearance of virga (evaporating rain) below a convective cell.^[26] Another indicator is the rapid development of a strong convection column above the fire, or nearby thunder cells. A third and very short warning is the calm that develops when the indraft winds stop before the turnabout and outflow of wind from the cell. This brief period of calm may be accompanied by a humming sound just before the reversing wind flow arrives. If any of these indicators is present, the area should quickly be evacuated. The downburst may also break or uproot trees, creating an additional hazard for people.

FIRE-RELATED INJURIES AND FATALITIES

Most fatalities in wildland fires occur on days of extreme fire danger when people are exposed to abnormally high heat stress caused by weather or proximity to fires. Loss of life is dramatically highlighted under extreme burning conditions; however, many more people are injured than are killed by fires.

One of the worst fire disasters in Australia occurred on February 7, 1967, when 62 persons died in Tasmania.^[17] Analysis of location and age of 53 individuals at the time of death is instructive ([Table 12-1](#) and [Table 12-2](#)). Most people whose bodies were found within or near houses were old, infirm, or physically disabled. More than half of the houses vacated by the 11 people who traveled some distance before being killed were not burned. Most of these victims would probably have

survived if they had remained in their homes. Most of the 11 firefighters who died were inexperienced. Many might have survived if they had observed fire behavior and safety rules.

A review of USDA Forest Service records between 1926 and 1976 shows that 145 men died in 41 fires from fire-induced injuries.^[42] Large losses occurred in the Blackwater fire in Wyoming in 1937 (15 deaths), in the Rattlesnake fire in California in 1953 (15 deaths), and in the 1933 Griffith Park fire in southern California (25 fatalities and 128 injuries). Wilson's analysis of people lost to fires in areas protected by other federal, state, county, and private agencies indicated 77 fire-induced fatalities in 26 fires. Wilson^[42] identified some common features connecting these fatal fires:

1. Relatively small fires or isolated sectors within larger fires seemed associated with most fatal incidents.
2. Flare-ups of presumed controlled fires were particularly hazardous. Fatalities occurred in the mop-up stage.
3. Unexpected shifts in wind direction or speed occasionally caused flare-ups in deceptively light fuels.
4. Gullies, chimneys, and steep slopes directed fires to run uphill.
5. The violent wind vortices left by helicopters and air tankers may have caused flare-ups in previously controlled areas.

Wilson concluded that the hairline difference between fatal fires and near-fatal fires was determined by the individual's reaction to a suddenly critical situation. Escapes were due to luck, circumstances, advance planning, a person's ability to avoid panic, or a combination of these factors. Frequently, poor visibility and absence of concise fire information threatened survival opportunities by creating confusion and panic.

Nature of Injuries and Fatalities

Fire-related injuries and fatalities are a direct consequence of heat, flames, smoke, critical gas levels, or indirect injuries ([Figure 12-14](#)). Injuries and fatalities associated

Figure 12-14 The annual death toll for persons who died from all causes while

involved in fighting wildland fires from 1990 to 1998 (133 total deaths).

with wildland fires fall into categories of heat (direct thermal injury, inhalation, and heat stress disorders), flames (direct thermal injury and inhalation), smoke (inhalation and mucous membrane irritation), critical gas levels (oxygen, carbon monoxide, and carbon dioxide), and indirect effects (acute and chronic medical disability and trauma).

Intense fires that produce very high temperatures generally last for only a short time. The duration of intense heat increases with fuel load, being greater in a forest fire where heavy fuels are burning than in a grass or shrub fire. Temperatures near the ground are lower because radiant heat is offset somewhat by inflow of fresh air and the fact that gases of combustion rise and are carried away by convection.^[4] Close to the ground, within a few meters of flames reaching up to 11 m (36 feet), air temperatures may be less than 15° C (59° F) above ambient temperature. The breathing of heated air can be tolerated for 30 minutes at 93° C (199° F) and for 3 minutes at 250° C (482° F).^[16] Death or severe pulmonary injury occurs when these limits are exceeded. Thermal injuries of the respiratory tract frequently contribute to the clinical picture of smoke inhalation. Persons trapped in a fire may have no choice but to breathe flame or very hot gases. This usually injures the tissues of the upper airway and respiratory tract, most commonly the nose, nasopharynx, mouth, oropharynx, hypopharynx, larynx, and upper trachea. These injuries may result in edema that obstructs the airway and produces asphyxia or that causes tracheitis and mediastinitis.

Signs of thermal injury to the airway include thermal injuries to the head, face, and neck; singed facial hair; burns of the nasal, oral, or pharyngeal mucosa; and stridor or dysphonia.^{[19] [33] [45]} Associated with a history of exposure to flame and hot gases in a closed space, these clinical findings strongly suggest the presence of a thermal injury to the airway. With the potential for acute airway obstruction, there is obvious urgency in establishing this diagnosis. Most experts who treat thermal injuries of the tracheobronchial tree advocate early visualization of the vocal cords by laryngoscopy and bronchoscopy.^[20] Bronchoscopy is a useful

predictor of the clinical course and urgency of intensive care unit intervention. In addition, one report shows a significantly greater incidence of pneumonia and late mortality in persons with facial burns than in those without them.^[43]

Burns of the lower trachea are rarely reported. In fact, injuries to and beyond the carina are difficult to produce when the trachea is cannulated and hot gases are delivered in the anesthetized dog.^{[18] [44]} Air has a very low specific heat and is therefore a poor conductor of thermal energy. In addition, the thermal exchange systems of the upper airway are quite efficient. The hot gas or flame is cooled sufficiently in the upper airway so that it does not burn the bronchi or more distal structures. However, although water or steam in the hot gas mixture is probably rare, it is a far more efficient conductor of

heat and permits significant thermal injury to the lower trachea and bronchi.

A delayed onset (2 to 24 hours after smoke inhalation) of pulmonary edema and adult respiratory distress syndrome is widely reported and should be anticipated. Whether this results from direct injury to alveoli, prolonged hypotension, or cerebral hypoxia and cerebral edema is unclear.

Heat stress^[30] occurs when air temperature, humidity, radiant heat, and poor air movement combine with strenuous work and insulative clothing to raise body temperature beyond safe limits. Sweating cools the body as moisture evaporates. When water lost through sweating is not replaced, physiologic heat controls can deregulate and body temperature may rise, leading to heat exhaustion or heatstroke (see [Chapter 10](#)).

Direct contact with flames causes thermal injury, and death is inevitable with exposure for long periods. Burns may be superficial, partial, or full thickness (see [Chapter 13](#)). Immediate death results from hypotension, hyperthermia, respiratory failure, and frank incineration.

The common cause of asphyxia in wildland fire is smoke. Danger increases where smoke accumulates because of poor ventilation, as in caves, box canyons, narrow valleys, and gullies.

Dense, acrid smoke is particularly irritating to the respiratory system and eyes. Excessive coughing induces pharyngitis and vomiting. Keratitis, conjunctivitis, and chemosis may make it impossible to keep the eyes open.

There are concerns about the levels of oxygen, carbon monoxide, and carbon dioxide associated with fire. Critical levels readily occur in a closed space and near burning or smoldering heavy fuels, but the open space of a wildland fire usually contributes to continual mixing of air. Misconceptions about lack of oxygen or excessive carbon monoxide and carbon dioxide in a wildland fire abound in the lay literature.

Flaming combustion can be maintained only at oxygen

Figure 12-15 Ranger Pulaski led 42 men and 2 horses to this mine tunnel near Placer Creek in northern Idaho to seek refuge from the 1910 fire. One man who failed to get into the tunnel was burned beyond recognition. All the men in the tunnel evidently were unconscious for a period of time. Five men died inside the tunnel, apparently from suffocation. The remainder of the crew was evacuated to the

hospital in Wallace, where all recovered. (Courtesy the USDA Forest Service. Photo by J.B. Halm.)

levels that exceed 12%, a level at which life can also be supported.^[4] ^[16] With continued indrafts of air that feed the flames, a fresh source of oxygen is usually present. Even mass fires, in which large tracts of land are burning, rarely reduce oxygen to hazardous levels. Low oxygen levels may occur, however, where there is little air movement, such as in caves ([Figure 12-15](#)) or in burned-over land that continues to smoke from smoldering fuels.

Concentrations of carbon monoxide exceeding 800 parts per million (ppm) can cause death within hours. Most fires produce small quantities, but atmospheric concentrations rarely reach lethal levels because of air movement. High concentrations appear to be associated with smoldering combustion of heavy fuels, such as fallen trees or slash piles, and carbon monoxide may also collect in low-lying areas or underground shelters.^[5] Outdoors, the danger lies in continual exposure to low concentrations that can increase blood carboxyhemoglobin levels. Prolonged exposure affects the central nervous system, resulting in headache, impaired judgment, progressive lethargy, decreased vision, and other psychomotor deficits.^[42]

Carbon monoxide levels of 50 ppm were measured close to a prescribed burn in grass.^[9] In another estimate, concentrations of 30 ppm were found roughly 61 m (200 feet) from the fire front. Studies on the 1974 Deadline

and Outlaw forest fires in Idaho showed that firefighters were exposed to levels above the standards proposed by the National Institute of Occupational Safety and Health (35 ppm over an 8-hour period).^[34]

Decreased ambient oxygen may contribute to hypoxia and the overall picture of smoke inhalation ([Table 12-3](#)). This mechanism is at least variably operant. When standing gasoline was ignited in a closed bunker, the fire self-extinguished, while the ambient oxygen level remained at 14%, a survivable level.^[18] Injecting burning gasoline or napalm into bunkers produced nearly complete and prolonged exhaustion of ambient oxygen. Conflicting data make it difficult to classify definitively situations in which decreased ambient oxygen and subsequent hypoxia of exposed individuals contribute to the clinical picture of smoke inhalation. Studies in which ambient oxygen was measured by scientists did not show significant depletion of the scene of the fire.^[11]

Few data are available on levels of carbon dioxide around wildland fires. Although it may be produced in large quantities, it apparently never reaches hazardous concentrations, even in severe fire situations.^[4] ^[16]

The quantity of burning fuel and the type of topography affect levels of oxygen and toxic gases. Danger is greater in forest fires where heavy fuels burn over long periods of time than in quick-moving grass and shrub fires. Topography has a major influence; caves,

box canyons, narrow canyons, gulches, and other terrain features can trap toxic gases or hinder ventilation, thereby preventing an inflow of fresh air. Although most fatalities result from encounters with smoke, flames, and heat, critical gas levels can induce handicaps sufficient to render the victim more vulnerable to other hazards.

Wildland Fires, Air Toxins, and Human Health

In the United States about 80,000 firefighters are involved with suppression activities on 70,000 wildland

TABLE 12-3 -- Human Response to Decreased Ambient Oxygen at Sea Level

AMBIENT OXYGEN (%)	HUMAN RESPONSE
20.9	Normal function
16–18	Decreased stamina and capacity for work
12–15	Dyspnea with walking; impaired coordination; variable impaired judgment
10–12	Dyspnea at rest; consciousness preserved; impaired judgment, coordination, and concentration
6–8	Loss of consciousness; death without prompt reversal
<6	Death in 6 to 10 minutes

fires that burn an average of over 0.8 million hectares (2 million acres) each year. In 1988 over 2 million hectares (5 million acres) of land were burned, with a total combined suppression cost exceeding \$600 million. The firefighting effort has another cost that has not been quantified: the effect of smoke on firefighter health and productivity. Over the 4 months of the Greater Yellowstone Area fires, approximately 40% of the 30,000 medical visits made by wildland firefighters were for respiratory problems. More than 600 firefighters required subsequent medical care. In the Happy Camp area during the Klamath fire complex in California in 1987, ambient concentrations of carbon monoxide measured as high as 54 ppm on a volume basis.^[36] A better understanding of the effects of wildland fire smoke on people is clearly needed. The combustion products of concern include these classes of materials:

1. Particulate matter
2. Polynuclear aromatic hydrocarbons
3. Carbon monoxide
4. Aldehydes
5. Organic acids
6. Semivolatile and volatile organic compounds
7. Free radicals
8. Ozone
9. Inorganic fraction of particles

Large variances are associated with the development of smoke combustion products and exposure to the materials of concern.^[38] Ward et al^[39] indicated that the toxicity of the combination of combustion products depends on the relative concentrations of the individual compounds, as well as the overall concentration and length of exposure. Individual toxicities are associated with many of the compounds found in smoke. The combined toxicity of these substances is not known. A detailed set of studies is being carried out to provide answers so that risk management options can be exercised. One of these studies suggested that wildland firefighters experience a small cross-seasonal decline in pulmonary function and an increase in several respiratory symptoms.^[28] Eye irritation, nose irritation, and wheezing were associated with recent firefighting.

The strenuous work of fighting or escaping a fire magnifies chronic illnesses, age disabilities, exhaustion, and cardiovascular instability. Common trauma is induced by falling trees or limbs, rolling logs or rocks, vehicular accidents, poor visibility, panic, falling asleep in unburned fuels that later ignite, and leaving the safety of buildings and vehicles. Cuts, scrapes, scratches, lacerations, fractures, and eye injuries (foreign particles, smoke irritation, sharp objects) are other common afflictions. Poison oak, poison ivy, stinging insects, and poisonous snakes are additional sources of trauma during wildland fires. To avoid fire-related injuries and fatalities, a person must keep attuned to mental and

physical stress levels and be aware of cumulative effects.^[30] *Ignorance of this simple principle is disastrous.*

WILDLAND-URBAN INTERFACE FIRE SURVIVAL PRINCIPLES AND TECHNIQUES

History has demonstrated repeatedly that individuals simply were not prepared to make correct choices of survival alternatives under stressful situations. Overconfidence, ignorance, bad habits, lack of preparation, and panic quickly lead to improper and unsafe actions during fire emergencies.^[42] "Learning from mistakes" in these settings is not a reasonable education strategy; second chances are frequently unavailable.

The USDA Forest Service organized a task force in 1957 to "study how we might strengthen our ways and means of preventing firefighting fatalities." A major recommendation was to adopt service-wide standard firefighting orders. Ten standard firefighting orders summarize the fundamental principles of safety on the fireline ([Box 12-3](#)). Although these were written for firefighters, they apply to all people working, living, or traveling near wildland fires and are adapted here to remind emergency medical personnel, wildland homeowners, and recreationists of safety precautions.

Box 12-3. TEN STANDARD FIREFIGHTING ORDERS

1. Keep informed of fire weather conditions, changes, and forecasts and how they may affect the area where you are located.
2. Know what the fire is doing at all times through personal observations, communication systems, or scouts.
3. Base all actions on current and expected behavior of the fire.
4. Determine escape routes and plans for everyone at risk and make certain that everyone understands routes and plans.
5. Post lookouts to watch the fire if you think there is any danger of being trapped, of increased fire activity, or of erratic fire behavior.
6. Be alert, keep calm, think clearly, and act decisively to avoid panic reactions.
7. Maintain prompt and clear communication with your group, firefighting forces, and command/communication centers.
8. Give clear, concise instructions and be sure that they are understood.
9. Maintain control of the people in your group at all times.
10. Fight fire aggressively, but provide for safety first. (Nonqualified and improperly equipped persons should fight fire only when it is necessary to assist injured persons.)

LCES: The Key to Safe Procedures

LCES stands for lookouts, communications, escape routes, and safety zones.^[10] These variables are key components in evaluating a fire hazard and determining the best course of action. The wildland fire environment's basic hazards are lightning, volcanoes, fire-weakened trees, rolling rocks and logs, entrapment by running fires, respirable particulates, air toxins, and heat stress. When these hazards exist, there are two

options:

1. Do not enter the environment.
2. Adhere to safe procedures according to LCES.

LCES should be viewed from a "systems" point of view, stressing their interdependence. For example, the best safety zone is worthless if the escape route does not offer access at the point of need. People must be familiar with the LCES plan well before it is needed. In addition, the nature of wildland fires dictates that LCES be redefined in pace with changing conditions.

The LCES system is implemented as follows:

1. *Lookouts*. Fixed lookouts or roving lookouts must be where both the hazard and the people can be seen. Lookouts are trained to observe the wildland fire environment and to recognize and anticipate fire behavior changes. When the hazard becomes a danger, the lookout relays this information so people can depart for the safety zone.
2. *Communications*. Communications refers to alerting people to the approaching hazard. Promptness and clarity are essential.
3. *Escape routes*. These paths lead from a currently threatened position to an area free from danger. More than one escape route must be available. Escape routes are probably the most elusive component of LCES, since they change continuously. Timely access to safety zones is the most important component.
4. *Safety zones*. In safety zones those threatened find adequate refuge from danger. The size of the safety zone must provide protection from flames, radiant heat, convective heat, and falling trees and will vary with changes in fuels, topography, wind conditions, and fire intensity.

Eighteen Watch-Out Situations in the Wildland

The following 18 watch-out situations are of particular relevance to emergency medical personnel and wildland users:

1. You are moving downhill toward a fire, but must be aware that fire can move swiftly and suddenly uphill. Constantly observe fire behavior, fuels, and escape routes, assessing the fire's potential to run uphill.
-

2. You are on a hillside where rolling, burning material can ignite fuel from below. When below a fire, watch for burning materials, especially cones and logs, that can roll downhill and ignite a fire beneath you, trapping you between two coalescing fires.
3. Wind begins to blow, increase, or change direction. Wind strongly influences fire behavior, so be prepared to respond to sudden changes.
4. The weather becomes hotter and drier. Fire activity increases, and its behavior

changes more rapidly as ambient temperature rises and relative humidity decreases.

5. Dense vegetation with unburned fuel is between you and the fire. The danger in this situation is that unburned fuels can ignite. If the fire is moving away from you, be alert for wind changes or spot fires that may ignite fuels near you. Do not be overconfident if the area has burned once because it can reignite if sufficient fuel remains.
6. You are in an unburned area near the fire where terrain and cover make travel difficult. The combination of fuel and difficult escape makes this dangerous.
7. Travel or work is in an area you have not seen in daylight. Darkness and unfamiliarity are a dangerous combination.
8. You are unfamiliar with local factors influencing fire behavior. When possible, seek information on what to expect from knowledgeable people, especially those from the area.
9. By necessity, you have to make a frontal assault on a fire with tankers. Any encounter with an active line of fire is dangerous because of proximity to intense heat, smoke, and flames, along with limited escape opportunities.
10. Spot fires occur frequently across the fireline. Generally, increased spotting indicates increased fire activity and intensity. The danger is that of entrapment between coalescing fires.
11. The main fire cannot be seen, and you are not in communication with anyone who can see it. If you do not know the location, size, and behavior of the main fire, planning becomes guesswork, which is an unfavorable response.
12. An unclear assignment or confusing instructions have been received. Make sure that all assignments and instructions are fully understood.
13. You are drowsy and feel like resting or sleeping near the fireline in unburned fuel. This may lead to fire entrapment. *No one should sleep near a wildland fire.* If resting is absolutely necessary, choose a burned area that is safe from rolling material, smoke, reburn, and other dangers or seek a wide area of bare ground or rock.
14. Fire has not been scouted and sized up.
15. Safety zones and escape routes have not been identified.
16. You are uninformed on strategy, tactics, and hazards.
17. No communication link with crew members or supervisor has been established.
18. A line has been constructed without a safe anchor point.

Fifteen Structural Watch-Out Situations for the Wildland-Urban Interface

Because fires occur more often in the wildland-urban interface, these 15 structural watch-out situations have been defined to increase awareness of structural fire dangers^[35] :

1. Access is poor (for example, narrow roads, twisting, single lane with inadequate turning).
2. Load limits of local bridges are light or unknown; the bridges are narrow.
3. Winds are strong, and erratic fire behavior is occurring.
4. The area contains garages with closed, locked doors.
5. You have an inadequate water supply to attack the fire.
6. Structure windows are black or smoked over.

7. There are septic tanks and leach lines. (These are found in most rural situations.)
8. A house or structure is burning with puffing rather than steady smoke.
9. Inside and outside construction of structures is wood with shake shingle roofs.
10. Natural fuels occur within 9 m (30 feet) of the structures.
11. Known or suspected panicked persons are in the vicinity.
12. Structure windows are bulging, and the roof has not been vented.
13. Additional fuels can be found in open crawl spaces beneath the structures.
14. Firefighting is taking place in or near chimney or canyon situations.
15. Elevated fuel or propane tanks are present.

Refuge in Vehicles, Buildings, and Fire Shelters

The radiant energy of a fire, although highly intense at a given location, typically lasts for only a short time. Because radiant heat travels in straight lines, does not penetrate solid substances, and is easily reflected, seeking refuge in vehicles, buildings, or fire shelters is often lifesaving.

Vehicles.

In the United States, firefighters have survived severe fire storms or the passage of fire fronts by taking refuge in vehicles. The following case histories

335

serve as examples of intense burning situations where lives were saved because people stayed inside vehicles when the fire passed^[31] :

In 1958 a veteran Field Section Fire Warden and two young men were fighting forest fires that burned in heavy fuels near the Bass River State Forest in southern New Jersey. A 90 degree wind shift transformed the flank fire into a broad headfire, with advancing flames up to 12 m (40 feet). The men entered their vehicle, a Dodge W300 Power Wagon, which stood in the middle of a sand road 4 m (12 feet) wide. Simultaneously the engine and radio failed. The Fire Warden repeatedly admonished the crewmen, who wished to flee, to stay in the truck. Subsequently the truck was rocked violently by convection currents and microclimatic changes generated by the flames. The men could neither see nor breathe because of smoke, and the cab began to fill with sparks that ignited the seat. The men stayed with the truck for only 3 or 4 minutes during the passage of the headfire, but they indicated later that the interval involved seemed more like 3 or 4 hours. At the first opportunity all of them left the vehicle on the upwind side and crouched beside it to escape the searing heat and burning seats. The warden proceeded to burn his hand severely while disposing of a flaming gas can in the truck bed. While the young men escaped virtually unscathed, the older man suffered lung damage and remained on limited duty for 5 years. He has since recovered completely and retired. In 1976 a firefighter

died while fighting a grass fire near Buhler, Kansas, in Reno County. A flashover occurred from a buildup of gases on the lee side of a windbreak. A fire truck was caught in the flashover, and the firefighter working from the back of the vehicle ran and was killed. Although the truck burned, the driver was not seriously hurt. In a 1962 California Division of Forestry fire in Fresno County, three men, followed by a flank fire that had turned into a headfire, raced back to their truck only a few feet ahead of the flames. The truck would not restart. After the main body of flames passed over the vehicle, the men jumped out in order to breathe, since the truck was burning. Almost completely blinded by smoke and heat, they stumbled headlong into matted fuels, and two received first- and second-degree burns. One man was not burned but had to be treated for smoke inhalation. The truck was a loss.

Sitting in a vehicle during a passing fire front is often perilous, but when a person is trapped, it is almost certain doom to attempt escape by running from the fire. The preceding case histories illustrate a few facts that, if remembered, may prevent panic:

1. The engine may stall and not restart.
2. The vehicle may be rocked by convection currents.
3. Smoke and sparks may enter the cab.
4. The interior, engine, or tires may ignite.
5. Temperatures increase inside the cab because the heat is radiated through the windows.
6. Metal gas tanks and containers rarely explode.
7. If it is necessary to leave the cab after the fire has passed, keep the vehicle between you and the fire.

The type of vehicle determines the amount of protection afforded. Two travelers died in a fire in 1967 in Tasmania, Australia, when they were caught in a canvas-topped vehicle.^[19] A later fire in Australia led to further research on various vehicles' protection and the explosiveness of gasoline tanks. In 1969 at Lara, Victoria, Australia, a fast-moving grass fire crossed a four-lane expressway. Several cars stopped in the confusion of smoke and flames. Seventeen people left the safety of their cars and perished. Six people stayed inside their vehicles and survived, even though one car ignited.

Investigations were carried out by the Forest Research Institute (now the Commonwealth Scientific and Industrial Research Organization [CSIRO], Division of Forest Research) in Canberra, Australia, to collect accurate data and dispel the misconceptions that make persons flee a safe refuge if trapped by fire.^[4] Cars were placed between two burning piles of logging slash to study a car's ability to shield against radiation. The test was a hotter, longer fire than normally encountered.

Car bodies halved the external radiation transmitted at the peak of the fire, but a person inside would have suffered severe burns to bare skin. Although air temperatures inside the car did not reach hazardous levels until well after the peak radiation had passed, smoke from smoldering plastic and rubber materials would have caused discomfort and made the car uninhabitable. In this study, metal gasoline tanks did not explode, whether

intact on cars or separated and placed on a burning pile of slash. Apparently, when tanks are sealed, the space above the liquid contains a mixture too deficient in oxygen vapor to support an explosion.

Cheney^[4] ^[5] offered the following advice for survival when in a car and trapped by fire:

1. If smoke obstructs visibility, turn on the headlights and drive to the side of the road away from the leading edge of the fire. Try to select an area of sparse vegetation offering the least combustible material.
 2. Attempt to shield your body from radiant heat energy by rolling up the windows and covering up with floor mats or hiding beneath the dashboard. Cover as much skin as possible.
 3. Stay in the vehicle as long as possible. Unruptured gas tanks rarely explode, and vehicles usually take several minutes to ignite.
 4. Grass fires create about 30 seconds of flame exposure, and chances for survival in a vehicle are good. Forest fires create higher-intensity flames lasting 3 to 4 minutes and lowering chances for survival. Staying in a vehicle improves chances for surviving a forest fire. Remain calm.
 5. A strong, acrid smell usually results from burning paint and plastic materials, caused by small quantities of hydrogen chloride released from breakdown of polyvinyl chloride. Hydrogen chloride is water soluble, and discomfort can be relieved by
-

336

breathing through a damp cloth. Urine is mostly water and can be used in emergencies.

Buildings.

The decision to evacuate a house or remain and defend it is not easy. Fire services generally prefer that residents evacuate the threatened area so that agencies can concentrate on protecting structures. Authorities also agree that evacuation of elderly, very young, infirm, and fearful people is usually a good idea. People should evacuate only if it can be accomplished safely, well in advance of any danger. Several principles should guide the evacuation decision^[40] :

1. A fire within sight or smell is a fire that endangers you.
2. More unattended houses burn down.
3. Evacuation when fire is close is too late; evacuation must be done well before danger is apparent.
4. More people are injured and killed in the open than in houses.
5. Learn beforehand about community refuges.
6. Evacuate only to a known safe refuge.

Whether people can find refuge in buildings depends on construction materials and amount of preparation in reducing fuels around the structure. If a home is constructed

amid flammable vegetation, plans and procedures to safeguard the home and its occupants are essential. A building usually offers protection while the fire passes even if it ignites later because it shields against radiant heat and smoke. After the fire passes, it may be necessary to exit if the building is burning.

Case histories from Australia demonstrate that homes provide safe havens.^[16] In 1967 in Tasmania, 21 people left their houses as fire approached. All died, and some were within a few meters of the buildings. Many houses did not burn and would have been refuges.

When taking refuge in a building, give people useful jobs, such as filling vessels with water, blocking cracks with wet blankets, and tightly closing windows and doors. If possible, assign lookouts to keep watch for spot fires on the outside of the building until the last minute. Before fire approaches the house, take the following precautions^[31] :

1. If you plan to stay, evacuate your pets and all family members not essential to protecting the home.
2. Be properly dressed to survive the fire. Cotton fabrics are preferable to synthetics. Wear long pants and boots, and carry for protection a long-sleeved shirt or jacket, gloves, a handkerchief to shield the face, water to wet it, and goggles.
3. Remove combustible items from around the house, including lawn and poolside furniture, umbrellas, and tarp coverings. If they catch fire, the added heat could ignite the house.
4. Close outside attic, eave, and basement vents to eliminate the possibility of sparks blowing into hidden areas within the house. Close window shutters.
5. Place large plastic trash cans or buckets around the outside of the house and fill them with water. Soak burlap sacks, small rugs, and large rags to use in beating out burning embers or small fires. Inside the house, fill bathtubs, sinks, and other containers with water. Toilet tanks and water heaters are an important water reservoir.
6. Place garden hoses so that they will reach any place on the house. Use the spray gun type of nozzle, adjusted to spray.
7. If you have portable gasoline-powered pumps to take water from a swimming pool or tank, make sure they are operating and in place.
8. Place a ladder against the roof of the house opposite the side of the approaching fire. If you have a combustible roof, wet it down or turn on any roof sprinklers. Turn on any special fire sprinklers installed to add protection. Do not waste water. Waste can drain the entire water system quickly.
9. Back your car into the garage and roll up the car windows. Disconnect the automatic garage door opener (in case of power failure, you cannot remove the car). Close all garage doors.
10. Place valuable papers and mementos inside the car in the garage for quick departure, if necessary. In addition, place all pets still with you in the car.
11. Close windows and doors to the house to prevent sparks from blowing inside. Close all doors inside the house to prevent drafts. Open the damper on your fireplace to help stabilize outside-inside pressure, but close the fireplace screen so that sparks will not ignite the room. Turn on a light in each room to make the house more visible in heavy smoke.
12. Turn off pilot lights.

13. If you have time, take down drapes and curtains. Close all venetian blinds or noncombustible window coverings to reduce the amount of heat radiating into the house. This provides added safety in case the windows give way because of heat or wind.
14. As the fire front approaches, go inside the house. Stay calm; you are in control of the situation.
15. After the fire passes, check the roof immediately. Extinguish any sparks or embers. Then check the attic for hidden burning sparks. If you have a fire, enlist your neighbors to help fight it. For several hours after the fire, recheck for smoke and sparks throughout the house.

Fire Shelters.

The fire shelter described earlier was developed by the Missoula Technology Development

337

Center to reduce the number of serious burn injuries and fatalities among firefighters who become trapped while fighting wildland fires. Shelters, designed in the shape of a pup tent, protect the firefighter by reflecting radiant heat. Constructed of an aluminum foil-fiberglass cloth laminate, the shelter reflects approximately 95% of the radiant heat emanating from a fire. The shelter is credited with saving more than 300 lives since its introduction in the 1960s.^[25] Why fire shelters work well was demonstrated dramatically on August 29, 1985, when 73 firefighters were forced to take refuge in their shelters for approximately 1 ½ hours while a severe crown fire burned over them.^[22] The incident took place during the Butte fire in the Salmon National Forest in Idaho. Observers described the crown fire that overran the firefighters as a standing wall of flame that reached 61 m (200 feet) above the treetops. Within the shelters, firefighters experienced extreme heat for as long as 10 minutes. Shelters were so hot that they could be handled only with gloves. After leaving the shelters, some firefighters showed symptoms of possible carbon monoxide poisoning, including vomiting, disorientation, and difficulty breathing. Emergency medical technicians administered oxygen to several individuals before evacuation. Five firefighters were hospitalized overnight for heat exhaustion, smoke inhalation, and dehydration. The consensus of those interviewed was that without the shelters, none would have survived.

Entrapment Procedures

Sometimes there may be no chance to escape a fire. When entrapment is imminent, injuries or death may be avoided by following entrapment procedures:

1. Do not panic. Most people are afraid when trapped by fire, so accept this fear as natural, so that clear thinking and intelligent decisions are possible. If fear overwhelms you, judgment is seriously impaired and survival a matter of chance.
2. Do not run blindly or needlessly. Unless a clear path of escape is indicated, do not

- run. Move downhill and away from the flank of the fire at a 45-degree angle where possible. Conserve your strength.
3. Enter the burned area. Particularly in grass, low shrubs, or other low fuels, do not delay if escape means passing through the flame front into the burned area. Move aggressively and parallel to the advancing fire front. Choose a place on the fire's edge where flames are less than 1 m (3 feet) deep and can be seen through clearly, and where the fuel supply behind the fire has been mostly consumed. Cover exposed skin and take several breaths, then move through the flame front as quickly as possible. If necessary, drop to the ground under the smoke for improved visibility and to obtain fresh air.
 4. Burn out. If you are in dead grass or low shrub fuels and the approaching flames are too high to run through, burn out as large an area as possible between you and the fire edge. Step into the burned area and cover as much of your exposed skin as possible. This requires time for fuels to be consumed and may not be effective as a last-ditch effort, nor does this work well in an intense forest fire.
 5. Regulate breathing. Avoid inhaling dense smoke. Keep your face near the ground, where there is usually less smoke. Hold a dampened handkerchief over the nose. Match your breathing with the availability of relatively fresh air. If there is a possibility of breathing superheated air, place a dry, not moist, cloth over the mouth. The lungs can withstand dry heat better than moist heat.
 6. Protect against radiation. Many victims of forest fires actually die before the flames reach them. Radiated heat quickly causes heatstroke, a state of complete exhaustion. Find shielding to reduce heat rays quickly in an area that will not burn, such as a shallow trench, crevice, large rock, running stream, large pond, vehicle, building, or the shore water of a lake. Do not seek refuge in an elevated water tank. Avoid wells and caves because oxygen may be used up quickly in these restricted places; consider them a last resort. To protect against radiation, cover the head and other exposed skin with clothing or dirt.
 7. Lie prone. In a critical situation, lie face down in an area that will not burn. Your chance of survival if the fire overtakes you is greater in this position than standing upright or kneeling.

Arnold "Smoke" Elser, an accomplished Montana outfitter, described how he helped guests avoid entrapment by a forest fire in this personal communication:

The fire began at the bottom of the canyon and proceeded up canyon as fires do. However, the wind currents carried the smoke to the east and not up the drainage to the north; therefore, we received no warning of the fire. The Monture Creek trail goes through some very old mature timber which was not burning as we approached. As my stock, the guests, and I arrived at the fire site and realized that we were in danger, we felt we should fall back and try to flank the fire to the east. Starting back toward this trail, we found a ground fire that made it very hazardous to travel in this direction. Because of my knowledge of the trail and terrain, I knew that our best bet would be to wet down the stock, guests, saddles and outer clothing and try to break through the head of the fire. We successfully did this, receiving only a few minor burns on the horses and the loss of some apparel tied to the backs of the saddles. Some lessons that I learned in this experience were that in handling livestock in a fire situation you must have a very close, firm hand on

them. It is also very important that no one panics or shows any excitement, as this alarms the livestock and begins the panic run that is so well known. I found that by talking in very low monotone, keeping the pack stock and saddle stock very close together (head to tail), and moving on a good trail, we were able to come through this fire with virtually no harm.

338

Figure 12-16 Protective clothing for a firefighter includes hard hat and safety goggles, fire-resistant shirt and trousers, leather boots and gloves, and fire shelter carried in a waist pouch. Firefighters also carry canteens to ensure an adequate water supply in a heat-stressed environment. (Courtesy the USDA Forest Service.)

Elser had these additional suggestions for wildland recreationists:

Campers, whether they be livestock oriented, hikers, or boaters, should know where to camp to provide adequate fire barriers around campsites. All campers should consider at least one, and preferably two, safe escape routes and havens (such as rock piles, rivers, and large green meadows) away from heavy fuel areas. Campers should be alert to canyon air current conditions in critical fire seasons. The safety of many recreationists is threatened by nylon and other synthetic fabrics used in the manufacture of most backpacking equipment. These materials melt upon contact with heat. The very nature of good horse packing equipment is a deterrent to fire; canvas mantles that cover the gear and the canvas pack saddles are easily wet down. Leather items such as chaps, good saddle bags, and western hats [that] can shield against heat blasts all provide important protection for the horse user.

Proper Clothing

Clothing protects against radiant heat, embers, and sparks, so it is sensible to dress appropriately ([Figure 12-16](#)). Closely woven material is more resistant to radiation and less likely to ignite than is open-weave material. Natural fibers are best. Wool is more flame resistant than cotton, although cotton can be improved by chemical treatment to retard flammability. Synthetic materials are a poor choice because they readily absorb heat, ignite, or melt.

Closely woven materials that provide protection also restrict airflow, so clothes should fit

loosely so that they do not interfere with dissipation of body heat. Cotton long johns or undergarments absorb sweat, aid evaporation, and do not melt. Wearing excessive layers of clothing generally contributes to heat stress.

As little skin as possible should be exposed to fire. Long trousers and a long-sleeved shirt should be worn. For maximum protection the shirt should be kept buttoned with sleeves rolled down.

Brightly colored (yellow or orange) coveralls or shirts are worn by organized firefighting crews. These colors improve safety and communications because they are visible in smoke, vegetation, and blackened landscapes.

Other essential apparel includes a safety helmet (hard hat), gloves (leather or natural fiber), leather work boots, woolen or cotton socks, a warm jacket for night wear, goggles, and a handkerchief. Clothing, backpacks, tents, and other camping equipment made of synthetics should be discarded when a person is close to a fire.

Water Intake (see [Chapter 11](#))

Sweating is the primary method for body cooling, although exhaling warm air and inhaling cooler air also decreases body temperature. Because the cooling effect of sweat evaporation is essential for thermoregulation, fluids lost during strenuous work must be replaced. In firefighting, water losses of 0.5 L/hr (1 pint/hr) are common, with losses of up to 2 L/hr (2 quarts/hr) under extreme conditions.^[16] Unless water is restored regularly, dehydration may contribute to heat stress disorders, reluctance to work, irritability, poor judgment, and impatience.

Thirst is not a good indicator of water requirements during strenuous work, so additional drinking of small quantities of water at regular intervals is recommended. A useful signal of dehydration is dark, scanty urine.

An excessive amount of electrolytes may be lost through sweating, leading to nausea, vomiting, and muscle cramps. When meals are missed or unseasoned foods are eaten, electrolyte supplements may be needed to replace lost salts. Sweetened drinks should be used as a source of energy if solid food is not available.

Personal Gear

Some rescue and medical missions take a few days. Therefore it is necessary to be prepared for extended periods and changing conditions in the backcountry ([Box 12-4](#)).

**Box 12-4. PERSONAL GEAR FOR
RESCUE MISSIONS**

1. Boots (leather, high-top, lace-up, nonslip soles, extra leather laces)
2. Socks (cotton or wool, at least two pairs)
3. Pants (natural fiber, flameproof, loose fitting, hems lower than boot tops)
4. Belt or suspenders
5. Shirt (natural fiber, flameproof, loose fitting, long sleeves)
6. Gloves (natural fiber or leather, extra pair)
7. Hat (hard hat and possibly a bandanna, stocking cap, or felt hat)
8. Jacket
9. Handkerchiefs or scarves
10. Goggles
11. Sleeping bag and ground cover
12. Map
13. Fire shelter
14. Food
15. Canteen
16. Radio (AM radio will receive better in rough terrain; FM is more line-of-sight; emergency personnel should have a two-way radio)
17. Bolt cutters (carried in vehicles to get through locked gates during escape from flare-ups or in the rescue of trapped people)
18. Miscellaneous items (mess kit, compass, flashlight, extra batteries, toilet paper, pencil, notepaper, flagging tape, flares, matches, can opener, wash cloth, toiletries, insect repellent, plastic bags, knife, first aid kit, and lip balm)

How to Report a Wildland Fire to Local Fire Protection Authorities

A caller should be prepared to provide the following information when reporting a fire:

1. Name of person giving the report
2. Where the person can be reached immediately
3. Where the person was at the time the fire was discovered
4. Location of the fire; orient the fire to prominent landmarks, such as roads, creeks, and mileposts on highways
5. Description of the fire: color and volume of the smoke, estimated size, and flame characteristics if visible
6. Whether anyone is fighting the fire at the time of the call

Portable Fire Extinguishers

People should know which extinguisher to select for a specific hazard in the home or recreational vehicle and be trained in its use. When a fire is discovered, first evacuate occupants to safety and promptly report the fire to appropriate authorities. If the fire is small and poses no direct threat, an extinguisher should be used to fight it.

The three major classes of fires are as follows:

Class A fires: Fueled by ordinary combustible materials, such as wood, paper, cloth, upholstery, and many plastics.

Class B fires: Fueled by flammable liquids and gases, such as kitchen greases, paints, oil, and gasoline.

Class C fires: Fueled by live electrical wires or equipment, such as motors, power tools, and appliances.

The right type of extinguisher must be used for each class of fire. Water extinguishers control Class A fires by cooling and soaking burning materials. Carbon dioxide or dry chemical extinguishers are used to control Class B fires by smothering flames. Multipurpose dry chemical or liquefied gas extinguishers control Class A, B, or C fires by a smothering action. Liquefied gas extinguishers also produce a cooling effect. A dry chemical or liquefied gas extinguisher is recommended for recreational vehicles.

Wildfire Fighting Training Course

"Wildfire Fighting," a self-contained 35 mm slide-audiocassette training program produced by the National Fire Protection Association, was designed to help paid and volunteer fire departments, forestry organizations, and individual volunteers prepare for emergencies and carry out effective wildfire fighting operations. It includes useful information on prefire planning, mutual aid, logistic support, safety, fire ground organization, equipment and apparatus, and other topics essential for the safe and successful control of wildfires. The "Wildfire Fighting" program (NFPA Catalog Number SL-104; Harry Abraham, editor) can be ordered from the National Fire Protection

Association, Batterymarch Park, Quincy, MA 02269.

"Lessons Learned: Fatality Fire Case Studies" (PMS 490) (1998) uses past fatality fires as a learning tool to help fireline tactical decision-makers avoid similar mistakes. It can be valuable information for emergency response personnel. The course is available from NWCG Publications Management System, National Interagency Fire Center, Attn: Great Basin Cache Supply Office, 3833 S. Development Avenue, Boise, ID 83705, phone 208-387-5104.

CONCLUSIONS

Fire suppression efforts in the late 1800s and early 1900s were largely ineffective because of limited access, absence of trained firefighting organizations, and lack of a fire detection network. During these times, many residents and numerous firefighters died in wildland fires in the United States and Canada. In the recent

340

past, firefighters were more vulnerable to injuries and fatalities from wildland fires than was the general public. Today, with many people living and seeking recreation in wildlands, the odds for serious fire encounters are shifting toward an inexperienced populace. Large property losses and direct injuries are being reported in increasing numbers in the wildland-urban interface. Although wildland fires have not yet posed a serious threat to backcountry recreationists in the United States, the prospect for such confrontations is growing.

Experience with wildland fires allows us to conclude the following:

1. Many indicators point to the fact that increases in investments for only emergency responses to wildfires will result in more damaging and expensive wildfire emergencies in the future. Public policies and public education that link sustainable land use practices with emergency preparedness are likely to be the most successful in the long run.
2. Residential shifts to the wildland-urban interface will increase exposures to life-threatening situations.
3. The expanded use of fire in managing national parks and wildernesses will increase the likelihood that people will encounter fires.
4. The general public tends to underestimate existing fire hazards and is usually not experienced in avoiding fire threats.
5. In some instances, past fire exclusion practices have contributed to the development of more wildland fuel, setting the stage for greater rates of spread and higher intensity levels in some plant communities. The national ecosystem health issue has compounded this problem by producing vast expanses of dead and dying forests, increasing the threat to people from fast-moving, high-intensity fires.
6. Knowledge of fire behavior principles and survival guidelines will prepare people to

take appropriate preventive measures in threatening situations.

The general public must share responsibility with suppression organizations to minimize fire hazards created by humans. Care with fire, proper cleanup of debris, fuel reduction efforts on wildland property, fire-safe construction guidelines, and the application of survival skills will minimize fire threats. Such precautions should become as commonplace in the wildland environment as smoke alarms and fire extinguishers have become in the home.

Wildland fire suppression agencies will continue to provide fast, safe, and energetic initial attack responses to protect human life, property, and natural resources. Under conditions of prolonged drought, strong winds, low humidities, and high temperatures, some fires will escape even the best initial attack efforts, directly threatening human life and property. Emergency medical personnel will probably have increasing exposure to wildland fires and will need to know more about fire-related injuries, fire safety, and fire survival.

Chapter 13 - Emergency Care of the Burned Victim

Roberta A. Mann
David Heimbach

EPIDEMIOLOGY

Each year in the United States approximately 2 million individuals are burned seriously enough to seek the care of a physician, and about 70,000 of these require hospitalization. Fortunately, the number of deaths attributable to burns decreased from 12,000 in 1979 to 6000 in 1990. Although treatment facilities would like to take credit for this decrease, the most likely factor responsible is the widespread use of smoke detectors in both public and private dwellings. It has been estimated that more than 90% of burns are preventable and that most are caused by carelessness or ignorance. During the next few years, the biggest contributions in decreasing burn mortality and morbidity may come not from medical scientists but rather from improved engineering design and more successful programs in teaching burn prevention to the public.

Like other forms of trauma, burns frequently affect children and young adults. The hospital expenses and the social costs related to time away from work or school are staggering. Although most burns are limited in extent, a significant burn of the hand or foot may prevent a manual laborer from working for a year or more and in some cases may permanently prevent a return to former activity. The eventual outcome for the burned victim is related to the severity of the injury, individual physical characteristics of the victim, motivation toward rehabilitation, and the quality of treatment of the acute burn.

Most persons with burns who are seen by physicians visit emergency departments, where judgment in triage, care plan for small burns, and initial management for major burns can influence survival of the victim and eventual cosmetic and functional results. Because most victims are young and about one third are children, they will live with the consequences of the acute treatment for an average of 50 years.

The decisions made at the initial contact with the victim require answers to the algorithm shown in [Figure 13-1](#). This chapter describes first responder care for major burns and

is organized to guide assessment of burn severity and initial management of the serious burns, as well as to provide an initial treatment plan for minor burns.

PHYSIOLOGY

For burns other than chemical burns, the primary events of injury occur during the time of heat contact. Coagulation necrosis takes place within cells, and denaturation of collagen occurs in the dermis. Either blood vessels are completely destroyed or the endothelium is damaged severely enough to cause clotting, which leads to ischemic necrosis of remaining viable cells. The burn wound is not static. Surrounding the "zone of coagulation" is a zone of capillary and small vessel stasis. Red cells form into rouleaux, platelet and white cell aggregates form, and the circulation becomes stagnant. Over the next hours or even days the ultimate fate of the burn wound depends on the resolution or progression of this zone of stasis. Cells and tissue stroma release mediators to initiate the inflammatory response. Histamine, serotonin, prostaglandin derivatives, and the complement cascade all have roles. In victims with burns of less than 10% of the total body surface area (TBSA), the actions of these mediators are generally limited to the burn site itself. Capillary permeability increases, neutrophils marginate, and additional inflammatory cells (monocytes, macrophages) are attracted by chemotaxis to the site of injury, initiating the healing process.

As burns approach 20% TBSA, the local response becomes systemic. The capillary leak, permitting loss of fluid and protein from the intravascular compartment into the extravascular compartment, becomes generalized. Cardiac output falls as a result of marked increased peripheral resistance, decreased intravascular fluid volume from the capillary leak, and the accompanying increase in blood viscosity. The decreased blood volume and cardiac output, accompanied by an intense sympathetic response, lead to decreased perfusion to the skin and viscera. Decreased flow to the skin can convert the zone of stasis to one of coagulation, increasing the depth of the burn. The capillary leak and depressed cardiac output lead to depressed central nervous system (CNS) function, and in extreme cases they result in severe cardiac depression with eventual cardiac failure in healthy patients or in myocardial infarction in patients with preexisting coronary artery disease. The first sign of CNS change is restlessness, followed by lethargy and finally coma. Without adequate resuscitation, burns of 30% TBSA frequently lead to acute renal failure, which in a victim with a severe burn almost invariably leads to a fatal outcome.

Cardiovascular changes begin immediately after a burn. The extent of these changes depends primarily on the size of the burn and to a lesser extent on the depth of the burn. Most victims with uncomplicated

Figure 13-1 Algorithm for decision making at the scene.

burns of less than 15% TBSA can undergo oral fluid resuscitation with some salt-containing solution. As the burn extent passes 20% TBSA, massive shifts of fluid and electrolytes occur from the intravascular into the extravascular (extracellular) space. Reversal of the shifts begins during the second postburn day, but normal extracellular volume is not completely restored until 7 to 10 days after the burn. Unless the intravascular volume is depleted, classic hypovolemic shock occurs. An untreated person will die of cardiovascular collapse; if treatment is poor, irreversible acute tubular necrosis and renal failure will develop.

TYPE OF BURNS

Scald Burns

In civilian practice, scalds, usually resulting from hot water, are the most common cause of burns. Water at 60° C (140° F) creates a deep partial-thickness or full-thickness burn in 3 seconds. At 68.9° C (156° F) the same burn occurs in 1 second. Freshly brewed coffee from an automatic percolator is generally about 82° C (180° F). Boiling water always causes deep burns, and soups and sauces, which are thicker in consistency, remain in contact longer with the skin and often cause deep burns. In general, exposed areas tend to be burned less deeply than areas covered with thin clothing. Clothing retains the heat and keeps the liquid in contact with the skin for a longer time.

Immersion scalds are deep and severe burns.^{[21] [31] [97]} Although the water may be cooler than with a spill scald, the duration of contact is longer and these burns frequently occur in small children or elderly victims with thin skin. Consequently, many states have passed legislation to set home and public hot water heaters to maximum temperatures well below 60° C (140° F).

Scald burns from grease or hot oil are generally deep partial thickness or full thickness. Cooking oil and grease, when hot enough to use for cooking, may be in the range of 204.4° C (400° F). Tar and asphalt burns are a special kind of scald. The "mother pot" at the back of the roofing truck maintains tar at a temperature of 204.4° to 260° C (400° to 500° F). Burns caused by tar directly from the mother pot are invariably full thickness. By the time the tar is spread on the roof, its temperature has decreased enough that most of the burns are deep partial thickness. Unfortunately, the initial evaluator cannot usually examine these burns because of the

adherent tar. The tar should be removed by application of a petroleum-based ointment (such as Vaseline) under a dressing. The dressing may be removed and the ointment reapplied every 2 to 4 hours until the tar has dissolved. Only then can the extent of the injury and the depth of the burn be accurately estimated.^{[43] [96]}

Flame Burns

Flame burns are the next most common burn injuries. Although injuries in house fires have decreased with the advent of smoke detectors, a significant number of burn

injuries still result from careless smoking, improper use of flammable liquids, automobile accidents, and clothing ignited from stoves or space heaters. Victims whose bedding or clothes have been on fire rarely escape without some full-thickness burns. Outdoor misadventures result from using cooking stoves fueled by white gasoline, taking lanterns into tents, smoking in a sleeping bag, and starting (or improving) charcoal fires with gasoline or kerosene.

Flash Burns

Flash burns are next in frequency. Explosions of natural gas, propane, gasoline, and other flammable liquids cause intense heat for a very brief time. For the most part, unignited clothing protects the skin in flash burns. Flash burns generally have a distribution over all exposed skin, with the deepest areas facing the source of ignition. Flash burns are partial thickness, with the depth dependent on the amount and kind of fuel that explodes. Although such burns generally heal without requiring extensive skin grafts, they may be very large and associated with significant thermal damage to the upper airway.

Contact Burns

Contact burns result from hot metals, plastic, glass, or hot coals. Such burns are usually limited in extent but deep. Victims involved in industrial accidents commonly have both severe contact burns and crush injuries, since these accidents often occur from presses or from hot, heavy objects. With the increased use of wood-burning stoves, an increasing number of toddlers are burned each year. The most common injuries are deep burns on the palms because the child falls with hands outstretched against the stove. Contact burns, especially in unconscious persons or those dealing with molten materials, are frequently fourth degree.^{[19] [56] [84]} In the wilderness setting the most common contact burn is from hot coals. Intoxicated campers dance around and then into the campfire, architects of "river saunas" mishandle hot rocks, children fall into fires, and beach walkers may sustain deep burns when coals are buried in sand overnight. Even though the injured areas may be small, they can be deep and devastating when the hiker must walk a considerable distance on burned feet.^[27]

Electrical Burns

Electrical burns are actually thermal burns from very high-intensity heat. As electricity meets the resistance of body tissues, it is converted to heat in direct proportion to the amperage of the current and the electrical resistance of the body parts through which it passes. The smaller the body part through which the electricity passes, the more intense the heat and the less it is dissipated. Therefore fingers, hands, forearms, feet, and lower legs are frequently totally destroyed, whereas larger-volume areas, such as the trunk, usually dissipate the current enough to prevent extensive damage to the viscera, unless the contact point is on the abdomen or chest. Although cutaneous manifestations may appear limited, massive underlying tissue destruction may be present.^{[18] [36] [37] [68]}

Arc burns occur when current takes the most direct path rather than the one of least

resistance. These deep and destructive wounds occur at joints that are in close apposition at the time of injury. Most common are burns of the forearm to the arm when the elbow is flexed and from the arm to the axilla if the shoulder is adducted when current passes from the upper extremity to the trunk.

Electrical burns cause a particular set of other injuries and complications that must be considered during the initial evaluation. As mentioned previously, injuries related to a fall are common. The intense associated muscle contractions may cause fractures of the lumbar vertebrae, humerus, or femur and may dislocate shoulders or hips.

Electrical cardiac damage may have symptoms like those of a myocardial contusion or infarction. Alternatively, the conduction system may be deranged. There can be actual rupture of the heart wall or of a papillary muscle leading to sudden valvular incompetence and refractory cardiac failure. Household current at 110 volts generally either does no damage or induces ventricular fibrillation. Alternating current is more likely to induce fibrillation than is direct current. If no cardiac abnormalities are present when a victim is first seen after shocks of 110 to 220 volts, the likelihood that they will appear later is small.

The nervous system is particularly sensitive to electricity. The most severe brain damage occurs when current passes through the head, but spinal cord damage is possible any time current passes from one side of the body to the other.^[47] ^[51] Myelin-producing cells are susceptible. The devastating effects of transverse myelitis may develop days or weeks after injury. Conduction remains normal through existing myelin, but as the old myelin wears out, it is not replaced and conduction stops. Peripheral nerves are commonly damaged and may demonstrate severe permanent functional impairment.^[23] ^[34] Every victim with an electrical injury must have a thorough neurologic examination as part of the

initial assessment. Myoglobinuria is a frequent accompaniment of severe electrical burns. Disruption of muscle cells releases cell fragments and myoglobin into the circulation to be filtered by the kidney. If untreated, this can lead to permanent renal failure.

Lightning strikes are discussed in [Chapter 3](#) . Several recent reviews are available.*

Chemical Burns

Chemical burns, usually caused by strong acids or alkalis, are most often the result of industrial accidents, home use of drain cleaners, assaults, and other improper use of harsh solvents.[†] In contrast to thermal burns, chemical burns cause progressive damage until the chemicals are inactivated by reaction with the tissue or dilution by flushing with water. Although individual circumstances vary, acid burns may be more self-limiting than are alkali burns. Acid tends to "tan" the skin, creating an impermeable

barrier that limits further penetration of the acid. Alkalis combine with cutaneous lipids and saponify the skin until they are neutralized. A full-thickness chemical burn may appear deceptively superficial, appearing as only a mild brownish surface discoloration. The skin may appear intact during the first few days after the burn and then begin to slough spontaneously. Unless the observer can be absolutely certain, chemical burns should be considered deep partial thickness or full thickness until proven otherwise.

CLINICAL PRESENTATION

Cutaneous burns are caused by the application of heat or caustic chemicals to the skin. When heat is applied to the skin, the depth of injury is proportional to the temperature applied, the duration of contact, and the thickness of the skin.

The severity of the burn injury is related to the size of the burn, the depth of the burn, and the part of the body that is burned.

Estimation of Burn Size

Burns are the only quantifiable form of trauma. The single most important feature in predicting mortality, need for specialized care, and the complications expected from the burn is the overall burn size in proportion to the victim's TBSA. Treatment plans, including initial resuscitation and subsequent nutritional requirements, are derived directly from the size of the burn.

A general idea of burn size is provided by the "rule of nines." Each upper extremity accounts for 9% of TBSA, each lower extremity accounts for 18%, the anterior and posterior trunk each account for 18%, the head and neck account for 9%, and the perineum accounts for 1% ([Figure 13-2](#)). Although the "rule of nines" provides a reasonably accurate estimate of burn size, a number of more precise charts have been developed. A diagram of the burn can be drawn on a chart so that a relatively precise calculation of burned area can be made from the accompanying TBSA estimates given. Children under 4 years of age have much larger heads and smaller thighs in proportion to body size than do adults. In an infant the head accounts for nearly 20% of the TBSA; body proportions do not fully reach adult percentages until adolescence. To further increase accuracy in burn size estimation, especially when burns are in scattered body areas, the observer might calculate the unburned areas on a separate diagram. If the calculations of the unburned areas and the burned areas do not add up to 100%, the observer should begin again with a new diagram to calculate the burned areas. For smaller burns an accurate assessment of burn size can be made by using the victim's hand. The hand amounts to 2.5% TBSA. The dorsal surface accounts for 1%, the palmar surface for 1%, and the vertical surface for 0.5%.

Depth of Burn

An understanding of burn depth requires an understanding of skin anatomy ([Figure 13-3](#)). The epidermis, an intensely active layer of epithelial cells under layers of dead keratinized cells, is superficial to the active structural framework of the skin, the dermis. Although metabolically very active, the dermis has no regenerative capacity, and

epithelial cells must eventually cover the surface of the dermis before the burn is healed. The skin appendages (hair follicles, sebaceous glands, and sweat glands) all contain an epithelial cell lining, so when the surface epidermis has been killed, epithelial covering must take place from overgrowth of the epithelial cells lining the skin appendages. As these cells reach the surface, they spread laterally to meet their neighbors, creating a new epithelial surface. As the burn extends deeper into the dermis, fewer and fewer appendages remain, and the epithelial remnants must travel farther to produce a new surface covering, sometimes taking many weeks to produce coverage. When the burn extends beyond the deepest layer of the skin appendages, the wound can heal only by epithelial ingrowth from the edges, by wound contraction, or by surgical transplantation of skin from a different site. The thickness of skin varies both with the age and gender of the individual and with the part of the body considered. Although the thickness of the living epidermis is relatively constant, keratinized epidermal cells may reach a height of 5 mm on palms of hands and soles of feet. The thickness of the dermis, on the other hand, may vary from less than 1 mm on eyelids and genitalia

Figure 13-3 Skin anatomy.

347

to more than 5 mm on the posterior trunk. Although the proportional thickness of skin in each body area is similar in children, infant skin thickness in each specific area may be less than half that of adult skin; the skin does not reach adult thickness until adolescence. Similarly, in patients over 50 years of age, dermal atrophy causes all areas of skin to become quite thin.

Burns are classified by increasing depth as first degree, superficial partial thickness, deep partial thickness, full thickness, and fourth degree.

First-Degree Burns.

First-degree burns involve only the epidermis. The prototype is mild sunburn. First-degree burns do not blister. They become erythematous because of dermal vasodilation and are quite painful, both spontaneously and when touched. The erythema and pain subside over 2 to 3 days. By the fourth day the injured epithelium desquamates in the phenomenon of "peeling."

Superficial Partial-Thickness Burns.

Superficial partial-thickness burns include the upper layers of dermis and characteristically form blisters with fluid collection at the interface of the epidermis and dermis. Blistering may not occur for some hours after injury. Burns initially thought to be first degree may therefore be diagnosed as superficial partial thickness by day 2. When blisters are removed, the wound is pink and wet and is quite painful as currents of air contact it. The wound is hypersensitive to touch and blanches with pressure, and blood flow to the dermis is increased over that of normal skin. If infection is prevented, superficial partial-thickness burns heal spontaneously within 3 weeks without functional impairment. They rarely cause hypertrophic scarring, but in pigmented individuals the healed burns may never completely match the color of the surrounding normal skin.

Deep Partial-Thickness Burns.

Deep partial-thickness burns also blister, but the wound surface is usually a mottled pink and white color immediately after the injury. The victim complains of discomfort rather than pain. When pressure is applied to the burn, capillary refill returns slowly or may be absent. The wound is often less sensitive to touch than is the surrounding normal skin. By the second day the wound may be white and is usually fairly dry. If infection is prevented, such burns heal in 3 to 9 weeks but invariably do so with considerable scar formation. Unless active physical therapy is continued throughout the healing process, joint function may be impaired and hypertrophic scarring, particularly in pigmented individuals and children, becomes inevitable.

Full-Thickness Burns.

Full-thickness burns involve all layers of the dermis and can heal only by wound contracture, epithelialization from the wound margin, or skin grafting. Full-thickness burns are classically described as leathery, firm, depressed when compared with the adjoining normal skin, and insensitive to light touch or pinprick. Unfortunately, the difference in depth between a deep partial-thickness burn and a full-thickness burn may be less than 1 mm. Full-thickness burns are easily misdiagnosed as deep partial-thickness burns, since the two types have many of the same clinical findings. For example, they may be mottled in appearance. They rarely blanch with pressure, and

they may have a dry, white appearance. The burn may be translucent with clotted vessels visible in the depths. Some full-thickness burns, particularly immersion scalds, have a red appearance and can be confused with superficial partial-thickness burns by the uninitiated. However, these red, full-thickness burns do not blanch with pressure. Full-thickness burns develop a classic burn eschar. An eschar represents the structurally intact but dead and denatured dermis that, over days to weeks, separates spontaneously from the underlying viable tissue.

Fourth-Degree Burns.

Fourth-degree burns involve not only all layers of the skin but also subcutaneous fat and deeper structures. These burns almost always have a charred appearance, and frequently only the cause of the burn gives a clue to the amount of underlying tissue destruction.

Although these descriptions appear to separate burns into clearly defined categories, many burns have a mixture of characteristics that give the observer an imprecise diagnostic ability. Considerable research is under way to devise instruments that will more precisely measure the depth of injury. Much of current burn treatment depends on knowledge of the depth of the burn.

TREATMENT

Care at the Scene

Flame Burns.

The first responder must remove the injured person from the source of heat. Because of the potential dangers of smoke inhalation in closed areas, the rescuer in a fire must take extreme caution not to become a victim. Persons with burning clothing should be prevented from running and should be made to lie down to keep flames and smoke away from the face. If water is not immediately available, the flames can be smothered with a coat or blanket. If nothing is available, the victim should be rolled slowly on the ground. Once the burning has stopped, the clothes should be removed; some fabrics will continue to smolder and synthetic fabrics may melt, leaving a hot adherent residue on the victim that will continue the burning process.

Scalds and Grease Burns.

The victim of a scald or grease burn must be removed from the source of heat.

348

Any wet clothing or wrap should be removed, since fabric retains moist heat and may continue to burn skin that is in contact with the hot material. Accidents resulting from cooking indoors with grease are particularly hazardous. The startle response to a grease splatter may cause the victim to drop a pan of grease onto the fire, starting a kitchen fire that can rapidly become a dwelling fire.

Airway.

Once flames are extinguished, primary attention must be directed to the airway. Any person rescued from a closed space or involved in a smoky fire should be considered at risk for smoke inhalation injury. If compressed oxygen is not available and the victim is coughing independently, he or she should be encouraged to continue to do so. If the victim is unconscious or the airway status is in question, the victim should be placed supine and the airway manipulated manually via the chin lift or jaw thrust maneuver. When possible, 100% oxygen should be administered by tight-fitting mask if smoke inhalation is suspected. If the victim is unconscious and if personnel are trained to insert an endotracheal tube, such a tube should be passed and attached to a source of 100%

oxygen. If the airway has to be supported by a tight mask, the rescuers must be aware of the significant danger of aspiration of gastric contents. Air forced into the stomach distends it and causes vomiting. The mask prevents expulsion of the fluid, and the victim rapidly aspirates vomitus into the tracheobronchial tree. No unconscious supine victim should ever be left unattended.

Other Injuries and Transport.

Once an airway is secured, the first responder should quickly assess the victim for other injuries and then transport him or her to the nearest hospital.^{[9] [23] [68]} Victims should be kept flat and warm and should be given nothing by mouth. Aside from establishment of an airway, further resuscitation is unnecessary if the victim will arrive at a hospital within 30 minutes. For transport the victim should be wrapped in a clean, dry sheet and blanket. Sterility is not required.

Cold Application.

Smaller burns, particularly scalds, may be treated with immediate application of cool water in hopes of limiting the extent of injury. The application of cold water is controversial, but immediate cooling does decrease the pain, possibly by a decrease in thromboxane production. By the time several minutes have passed, or after arrival in the emergency department, further cooling is not likely to alter the pathologic process. Ice water should not be used except on the smallest burns. Using ice on larger burns can easily induce systemic hypothermia and associated cutaneous vasoconstriction that can extend the thermal damage.

Swelling.

During transport, constricting clothing and jewelry should be removed from burned and distal parts, since local swelling begins almost immediately. Constricting objects increase the swelling, and the removal of tight jewelry in the presence of distal edema is time consuming once swelling has occurred.

Electrical Burns.

Electrical burns are particularly dangerous, both to the victim and to the rescuer. If the victim remains in contact with the source of electricity, the rescuer must avoid touching the victim until the current can be turned off or the wires cut with properly insulated wire cutters. Once the victim is removed from the source of current, airway, breathing, and circulation must be checked. Ventricular fibrillation or standstill is a common accompaniment to a major transthoracic current; cardiopulmonary resuscitation should be instituted if carotid or femoral pulses are not palpable. If pulses are present but the victim is apneic, mouth-to-mouth resuscitation alone may be lifesaving. Cardiopulmonary resuscitation should continue until a cardiac monitor can be obtained, which will direct treatment with epinephrine for cardiac standstill or defibrillation for ventricular fibrillation. Once an airway is established and pulses return, a careful search must be made for associated life-threatening injuries. Electrocuted victims frequently fall

from heights and may have serious head or neck injuries. The intense tetanic muscle contractions associated with electrocution may fracture vertebrae or cause major joint dislocations. Patients with high-voltage electrical injuries should be treated with spinal precautions, and splints if necessary, until fractures can be ruled out.

Chemical Burns.

Whenever possible, chemical burns should be thoroughly flushed with copious amounts of water at the scene of the accident. Chemicals will continue to burn until removed; washing for 5 to 10 minutes under a stream of running water may limit the overall severity of the burn. No thought should be given to searching for a specific neutralizing agent. Delay deepens the burn, and neutralizing agents may cause burns themselves; they frequently generate heat while neutralizing the offending agent, adding a thermal burn to the already potentially serious chemical burn.

First Aid at the Scene for Smaller Burns.

Not all burns need immediate medical attention. Burns less than 5% TBSA (excluding deep burns of the face, hands, feet, perineum, or circumferential extremity) can be treated successfully in a wilderness setting if adequate first-aid supplies are available and wound care is performed diligently. Except for the very shallow burn that heals within a few days, most burns should be seen by a physician within 3 to 5 days after injury.

Burns should be washed thoroughly with plain soap and water and dried with a clean towel. Any obviously dead skin should be peeled off (which may be painful) or trimmed with sharp manicure scissors (usually painless). Large (greater than 2.5 cm), thin, fluid-filled blisters should be drained and the dead skin trimmed away. Small, thick blisters may be left intact. If any blister begins to leak fluid, it should be drained and trimmed to prevent a potential closed-space infection. Deep burns, as from a flame, are firm and leathery and do not require immediate debridement. A small tube of silver sulfadiazine cream and tubes of antibiotic (such as bacitracin) ointment should be available in the first-aid kit. Either may be used and should be spread lightly over the wound. The wound may then be wrapped in dry, clean gauze, which does not have to be sterile. Simple dressings (one type of topical cream, plain gauze) are sufficient. Some patients prefer nonadherent dressings, such as Telfa, because they are less likely to stick to the wound during dressing changes. The same effect can be achieved by soaking (with water) a plain gauze dressing that appears stuck to the wound, waiting a few minutes, and then removing the dressing with additional water if necessary. Other dressings are available (antibiotic-impregnated silicone gel sheets, calcium aginate). Although patients may prefer one dressing over another for various reasons, no dressing has been shown conclusively to accelerate the healing of burn wounds. The first-aid kit should be stocked with general use supplies; soaps and dressings designed

specifically for burns are expensive and unnecessary.

Mobility of the wound area must be actively maintained, and concentrated efforts should be made to avoid dependent positioning, especially when the victim is resting or sleeping. Focal edema in a small burn wound can be painful and alarming and should be prevented with extremity elevation and active range-of-motion exercises several times a day. Wound care should be performed once a day if the dressing remains dry. A wet, sticky dressing needs more frequent wound care. If only the outer dressing is dirty, it be changed as needed. For the quickest healing of superficial burns, daily wound care should remove all exudate and crust, both of which significantly retard wound healing. Items for the first-aid kit include plain (not perfumed) soap, sharp scissors (large and small), a small tube of silver sulfadiazine, tube(s) of bacitracin ointment, cotton gauze, Band-Aids, tape, and acetaminophen.

Emergency Department Care

The primary rule for the emergency physician is to "forget about the burn." Although a burn is usually readily apparent and often a dramatic injury, a careful search for other life-threatening injuries must take priority. Only after an overall assessment of the victim's condition should attention be directed to the specific problem of the burns. Assessment of the non-thermally injured victim is presented in [Chapter 18](#) ; the following sections consider the specific problems encountered in the victim with burns.

Resuscitation

During the past 30 years more than a dozen resuscitation plans have been suggested. The goal of all resuscitation plans is to complete treatment with a living victim who has normally functioning kidneys and does not have cardiac failure or pulmonary edema. Nearly all of these plans use a combination of colloid and crystalloid solutions, but they vary considerably in the ratio of colloid to crystalloid, the timing of colloid administration, the sodium concentration of crystalloid solution, and to a much lesser extent the total volume of fluid given. Some require frequent changing of solutions, others require mixing of solutions, and some require careful monitoring of the victim's electrolytes. Intense controversy rages over the "best" resuscitation plan. The controversy, however, need not concern the physician without a special interest in burn physiology. There is general agreement on a few facts. A victim with very large burns will probably need both colloid and crystalloid. Initially, capillaries are permeable to both crystalloid and colloid solutions. The capillary leak to albumin and other large molecules repairs itself between hours 6 and 24.

The choice of formulas for initial resuscitation is probably of relatively little consequence as long as the rate of fluid administration is modified according to the victim's changing requirements as the hours pass. Because of its simplicity, ease of administration, and need for little blood chemistry monitoring, the formula developed by Baxter, known as the Baxter formula, or Parkland formula, has been adopted by most hospitals and has been recommended officially by the American College of Surgeons Committee on Trauma.

According to the Baxter formula, crystalloid is given during the first 24 hours while the capillaries are still permeable to albumin and then colloid is given during the second 24 hours when the capillary leak has presumably sealed. Rapid administration of crystalloid solution results in early expansion of depleted plasma volume, which will return cardiac output toward normal. Once the capillary leak has sealed, colloid (usually in the form of albumin) remains the most effective solution to maintain plasma volume without further increasing edema. The Baxter formula was derived to provide specific replacement of known deficits measured by simultaneous determinations of red blood cell volume, plasma volume, extracellular fluid volume, and cardiac output during burn shock.

*References [\[4\]](#) [\[16\]](#) [\[32\]](#) [\[35\]](#) [\[41\]](#) [\[59\]](#) [\[63\]](#) [\[65\]](#)

The first 24-hour and second 24-hour calculations are shown in [Box 13-1](#). The formula calls for the administration of lactated Ringer's solution, 4 ml/kg body weight/percent body surface burned during the first 24 hours after the injury. Half of this fluid should be given in the first 8 hours and the second half during the next 16 hours. Fluid therapy during the second 24 hours consists of the administration of free water in quantity sufficient to maintain a normal serum sodium concentration, as well as plasma (or other colloid) to maintain a normal plasma volume.

The adequacy of resuscitation can best be judged by frequent measurements of vital signs, central venous pressure, and urine output and by observation of general mental and physical responses. Despite myriad new monitoring devices, urine output remains one of the most sensitive and reliable assessments of fluid resuscitation. In the absence of myoglobinuria a urine output of 0.5 ml/kg/hr in adults and 1 ml/kg/hr in children less than 10 kg ensures that renal perfusion is adequate. The victim's sensorium gives an indication of the state of cerebral perfusion and oxygenation. The victim should be alert and cooperative; confusion and combativeness are signs of inadequate resuscitation or warn of other causes of hypoxia.

Victims with burns of less than 50% TBSA can usually be resuscitated with a single large-bore peripheral intravenous (IV) line. Because of the high incidence of septic thrombophlebitis, lower extremities should be avoided as IV portals. Upper extremities are preferable, even if the IV line must pass through burned skin. Victims with burns larger than 50% TBSA or who have associated medical problems, are at the extremes of age, or have concomitant smoke inhalation should have additional central venous pressure monitoring. Because of the extremely unstable state of the circulation in victims with burns over 65%, such victims should be monitored in an intensive care setting where a Swan-Ganz catheter for measuring pulmonary capillary wedge pressure and cardiac output is available.

**Box 13-1. BAXTER (PARKLAND)
FORMULA**

***FIRST 24 HOURS—RINGER'S
LACTATE***

4 ml/kg/% burn in 24 hours

One half in first 8 hours

One half in second 16 hours

Example: 70-kg man with 50% burn

4 ml × 50% × 70 kg = 14,000 ml in 24
hours

7000 ml hours 1–8

3500 ml hours 8–16

3500 ml hours 17–24

***SECOND 24 HOURS—ALBUMIN OR
PLASMA AT MAINTENANCE***

Maintain normal vital signs

Adequate urine output

Example: 70-kg man with 50% burn

250–500 ml plasma

2000–2500 ml D₅ W

The presence of myoglobinuria alters the resuscitation plan. Myoglobinuria results from the destruction of muscle cells with release of the red muscle pigment myoglobin. This is most often a problem in victims with associated crush injuries, electrical burns, or extremely deep thermal burns. Characteristic cola-colored urine is an indication to increase the amount of fluid given and to establish a diuresis of 70 to 100 ml urine per hour. An initial bolus of 12.5 g of mannitol with a repeat dose in 15 to 30 minutes should be considered.

Escharotomy

Careful monitoring of the peripheral circulation is required in victims with circumferential full-thickness burns of the extremities. The edema that forms beneath inelastic eschar increases tissue pressure to a point at which it exceeds lymphatic pressure, thereby further increasing edema. When the edema exceeds venous pressure and eventually approaches arterial pressure, it stops all circulation to the extremity distal to the constricted area.

The classic findings of a compartment syndrome, usually considered to be pain, paresthesias, pulselessness, and tense swelling, may or may not be present in the burned extremity. Therefore distal pulses should be carefully monitored with a Doppler ultrasound, and if any of the clinical signs mentioned above occur, or if Doppler signals disappear, an escharotomy should be performed immediately.

Escharotomy is performed as a ward procedure and does not require an anesthetic, since only insensate full-thickness burn is incised. An incision is made through the eschar into subcutaneous tissue, first along the lateral aspect of the extremity and, if symptoms or signs do not improve, along the medial aspect. The incisions need not be as deep as the investing muscle fascia, and bleeding can usually be easily controlled with an electrocautery and the use of topical clotting agents. If arrival to hospital will be within 6 hours, escharotomies should not be done in the field because the victim may bleed to death without proper equipment to control bleeding.

Circumferential full-thickness burns of the trunk in small children occasionally demand an escharotomy to improve pulmonary function. Chest wall escharotomies are made in the anterior axillary line bilaterally, extending from the clavicle to the costal margin. If the

abdomen is involved with the burn, the inferior margins of the escharotomy may be connected transversely.

Fasciotomies are rarely needed in victims with thermal burns. However, if distal pulses do not return after medial and lateral escharotomies, fasciotomy should be considered. On the other hand, victims with electrical injuries frequently need fasciotomy. Careful monitoring of all victims with electrical burns and with burns associated with soft tissue

trauma or fractures is mandatory. In these circumstances, loss of pulses is a strong indication for urgent fasciotomy under general anesthesia in the operating room.

The need for escharotomy in the burned hand is somewhat controversial. Fingers burned badly enough to require escharotomy are frequently mummified, and the lack of muscles in the fingers puts less tissue at ischemic risk. Escharotomy done in fingers that may not require it runs the risk of exposing the interphalangeal joints, leading to subsequent infection that may ultimately require joint fusion or finger amputation. Both the palmar arch and digital vessels should be monitored with Doppler ultrasound in any significant hand burn. If the signals disappear over the palmar arch or in the digital vessels, consideration should be given to performance of a dorsal interosseous fasciotomy.

Burn Wound Management

The burn wound should be cleansed initially with a surgical detergent. All loose, nonviable skin should be gently trimmed. Debridement should be done gently; small doses of IV narcotic are sufficient analgesia for this procedure. General anesthesia and operating room debridement should be avoided until resuscitation is complete, unless other surgical procedures are necessary.

Once the wound is cleansed, a topical chemotherapeutic agent should be applied. A detailed description of all the agents available is beyond the scope of this chapter, but those most commonly used in the United States and other industrialized countries contain silver sulfadiazine. It comes as a white cream, is soothing to the wound, has a good antimicrobial spectrum, and has almost no systemic absorption or toxicity.^{[7] [40] [81] [90]} The victim should be carefully questioned about allergy to sulfa drugs before their use, however, since allergic reactions are encountered in about 3% of patients. These reactions may be manifested clinically as pain after application rather than the soothing feeling that silver sulfadiazine usually provides. If an allergy is suspected (by history), a small (10 × 10 cm) patch of silver sulfadiazine should be applied as a test. The remainder of the wound can be dressed in bacitracin. If no local reaction occurs after 2 to 4 hours, an allergy is unlikely and silver sulfadiazine is the dressing of choice. If an allergy is confirmed, the victim should be referred to a burn center, where the next choice of topical antimicrobial would probably be silver nitrate solution.

Outpatient Burns

According to guidelines given above, the vast majority of victims with burns do not require hospitalization. In many cases, the burn, if merely kept clean, heals spontaneously in less than 3 weeks with acceptable cosmetic results and no functional impairment. Unfortunately, good results in treating superficial minor burns may entice the unwary physician to treat more complex burns by the same methods. For the victim, the consequences of such a mistake can be the need for subsequent hospitalization, joint dysfunction, and hypertrophic scarring that may be difficult to correct, as well as considerable loss of time from work or school.

First-Degree Burns

Although first-degree burns are very painful, victims rarely seek medical attention unless the area burned is extensive. These victims do not require hospitalization, but control of the pain is extremely important. Aspirin or codeine may be adequate for small injuries, but for large burns, liberal use of a more potent narcotic for 2 to 3 days is indicated.

For topical medication we recommend one of the many proprietary compounds containing extracts of the aloe vera plant in concentrations of at least 60%. Aloe vera has antimicrobial properties and is an effective analgesic.^[49]^[77] Anecdotal evidence suggests that it may decrease subsequent pruritus and peeling.

Burns from ultraviolet rays (sunlight, sunlamp) may initially appear to be only epidermal, but the injury may in fact be a superficial partial-thickness burn with blistering apparent only after 12 to 24 hours. Therefore the victim with such a burn should be cautioned about blisters and should be asked to return if they form, since wound management then becomes more important because of the potential for infection and subsequent scarring.

Superficial Partial-Thickness Burns

Treatment of superficial partial-thickness burns presents little problem. If the wound is kept clean, the victim is kept comfortable, and the joints are kept active, these wounds heal in less than 3 weeks with minimal scarring and no joint impairment.

Initially the wound should be cleansed and debrided as described previously. Small blisters may be left intact. Biochemical analysis of the protein-banding pattern of burn blister fluid, obtained by polyacrylamide gel electrophoresis, has shown it to be similar to that of serum.^[93] These authors suggest that the fluid is an exudate mainly from the vascular system, that it provides a good environment for the fibroblasts in the damaged

site, and that it facilitates the healing process. Larger blisters are difficult to protect, however, and blister fluid is a rich culture medium for bacteria that live in the skin appendages. Therefore large blisters and small blisters in large burns should usually be totally removed with forceps and scissors. In some instances the blister fluid can be aspirated with a large-bore needle, allowing the blistered epidermis to remain on the wound as a biologic dressing. This dead epidermis, however, is fragile, tends to contract, and rarely stays in place except over small areas.

After debridement these wounds can sometimes be managed with a biologic dressing, such as porcine xenograft.^[5]^[95] Pigskin is available in frozen or lyophilized forms. After a biologic dressing is applied, the burn pain is markedly diminished, and if the xenograft

"sticks," no further treatment is necessary except for a periodic wound check. When the burn reepithelizes, the xenograft desiccates and peels away from the new epidermis. Other synthetic dressings, such as those made from plastic film (Op-Site or Epigard) have achieved some popularity.^{[11] [69] [88]} We find that these dressings adhere poorly (a leaking dressing is not an occlusive one) and provide no advantage. The most commonly used treatment is wound coverage with silver sulfadiazine and application of a light dressing to promote active range of motion. Some very small burns do not require topical agents. For small facial burns, bacitracin ointment may be a better choice than silver sulfadiazine cream because it is less drying.

Pain is managed as for first-degree burns, and the patient usually should return every 2 to 3 days until the wound heals or the patient has demonstrated the ability to manage the wound without supervision.

One home treatment regimen is to have the patient cleanse the wound once daily with tap water and reapply the topical agent and light dressing. During dressing changes, and as often as possible, all involved joints should be put through a full range of motion. The dressing may be unnecessary while the patient is at home, but the patient should dress the wound before leaving the house. This method is highly successful, but it is inconvenient and fairly painful and requires good patient cooperation.

Another treatment regimen advocated by some physicians is a single initial debridement and application of a bulky dressing to be left in place for several days without intermediate cleansing or dressing change. This method reduces pain, but the patient must be careful of the bandage. If the bandage is allowed to become saturated with fluid draining from the wound or to become dirty, it may promote infection.

The "exposure" method has little to recommend it. This method involves leaving the wound open, allowing the wound drainage to desiccate and form a scab. Controlled studies in animals have shown that desiccation and crust formation interfere with wound healing. Our experience has also shown that crusts crack over joints, cause considerable discomfort, and can hide infection.

Deep Partial-Thickness and Full-Thickness Burns

Treatment of deep partial-thickness and full-thickness burns is a matter of grave concern. Full-thickness burns heal only by contraction and epithelialization from the periphery. Epithelium does not begin to migrate until the eschar is removed; the growth rate then is only about 1 mm/day. Thus healing of even a small full-thickness burn may involve many weeks of discomfort and disability.

Deep partial-thickness burns may take 4 to 8 weeks to heal and then leave an unacceptable scar. If a joint is involved, some loss of joint function is the rule. We have adopted a policy of early excision and grafting for such wounds.

Initial outpatient treatment can be followed by elective surgery as soon as it can be scheduled. Small wounds can be treated through day surgery; larger wounds located

over dynamically important areas can be closed with only a day or two of hospitalization. The excision and grafting procedures should be done by a surgeon experienced in tangential wound excision.

The advantages of this aggressive approach—a pain-free patient with normal joint function, a better cosmetic result, and a rapid return to work or school—more than compensate for the brief hospitalization and the very small risk associated with minor operation.

Should the excision and grafting plan be unacceptable to the patient or the treating physician, the standard method of daily cleansing and application of silver sulfadiazine cream is used. Most full-thickness burns need grafting at about 3 to 4 weeks after the injury. Deep dermal burns should be seen by the physician frequently during the healing process; active physical therapy is crucial to ensuring a successful outcome.

REHABILITATION

Physicians who regularly care for people with burn injuries recognize that treatment goals extend far beyond healing of the wounds and survival of the victim. We aim to return victims at least to their preburn functional status physically and to ensure a smooth and timely reentry into family and social situations, including work or school. Awareness that recovery from burn injury often depends on a number of nonphysician health care workers is essential. Depending on the severity of the burn and the associated social situation, participation of nurses, nutritionists, occupational therapists, physical therapists, recreational therapists, social workers, vocational rehabilitation counselors, psychologists,

353

pain management specialists, and clergy is commonly required.

Burn rehabilitation should be initiated by the first physician to see the victim. Once all systemic and wound issues have been addressed, proper positioning of wounded extremities or digits should be assessed by an occupational therapist who has been specially trained in burn management. Splints should be made immediately if deemed appropriate. Range-of-motion exercises should be started on the day of injury, and frequent follow-up by a physical therapist is essential. The best functional outcomes result from meticulous attention to early mobility. Patients almost universally choose not to move a burned body part, and an active ancillary burn staff is essential for satisfactory results. Burn scars require approximately a year to fade, soften, and mature. Physical therapy may be required throughout this time period or longer. Pressure garment therapy may be used in certain cases in an attempt to prevent the development of hypertrophic scars. The interested reader is referred to books dealing with acute burn care, reconstructive plastic surgery, and burn rehabilitation for further discussion.^[1] ^[8] ^[14]

INHALATION INJURY

Epidemiology

Of the nearly 500,000 fire victims admitted to hospitals each year, smoke or thermal damage to the respiratory tree may occur in as many as 30%.^[71] Carbon monoxide poisoning, smoke poisoning, and thermal injury are three distinctly separate aspects of clinical inhalation injury and are discussed as such. Inhalation injury rarely occurs in an outdoor setting.

Carbon Monoxide Poisoning

PATHOPHYSIOLOGY.

Carbon monoxide (CO) is a colorless, odorless, tasteless gas that has an affinity for hemoglobin 200 times greater than that of oxygen. The most simply explained mechanism of action of CO is reversible displacement of oxygen on the hemoglobin molecule. Although worsening hypoxia is important, and the percentage of carboxyhemoglobin in the blood represents in large measure the degree of victim hypoxia, this simple mechanism cannot account for all of the experimental and clinical findings seen with exposure to CO. For example, an experimental group of dogs was exchange-transfused with blood containing 80% carboxyhemoglobin (COHb). They showed no symptoms. In a control group with COHb levels of 80% produced by inhalation of CO, all animals died. Furthermore, the degree of enzyme and muscle impairment may not correlate accurately with the levels of blood COHb.^{[15] [20] [30] [50]}

In vitro, CO combines reversibly with cardiac muscle myoglobin and heme-containing enzymes, such as cytochrome oxidase a_3 .^[15] Despite its intense affinity, it readily dissociates according to the laws of mass action. The half-life of COHb in humans breathing room air is 4 to 5 hours. In humans breathing 100% oxygen, the half-life is reduced to 45 to 60 minutes.^[54] In a hyperbaric oxygen chamber at 2 PSI, the half-life is 30 minutes, and at 3 atmospheres in a chamber it is reduced to 15 to 20 minutes.^[92]

CLINICAL PRESENTATION.

Blood levels of COHb provide a laboratory measure to correlate with associated symptoms of CO poisoning. Levels less than 10% do not cause symptoms, although victims with exercise-induced angina may show decreased exercise tolerance. At levels of 20%, healthy persons complain of headache, nausea, vomiting, and loss of manual dexterity. At 30% they become confused and lethargic and may show depressed ST

segments on electrocardiogram. In a fire situation this level may lead to death as the victim loses both the interest and the ability to flee the smoke. At levels between 40% and 60% the victim lapses into coma, and levels much above 60% are usually fatal.

THERAPY.

Victims who have not been unconscious and who have a normal neurologic examination on admission almost always recover completely without treatment beyond administration of 100% oxygen. Victims who remain comatose once COHb levels have returned to normal have a poor prognosis, and in our experience they rarely awaken. Although enthusiasts for hyperbaric oxygen treatment (HBOT) consider it a standard of care for CO poisoning,^{[2] [3] [52] [61]} many physicians are skeptical.^[78] One controlled study indicated that hyperbaric oxygen made no difference for moderate poisoning, and multiple treatments were no better than a single treatment for victims with severe poisoning.^[72] Furthermore, when associated with a major burn, transport to a chamber delays definitive care and is associated with numerous complications, including emesis, seizures, eustachian tube occlusion, aspiration, hypocalcemia, agitation requiring restraints or sedation, arterial hypotension, tension pneumothorax, and cardiac arrhythmia or arrest.^{[33] [87]} The issue of whether, and at what time in the progression of CO poisoning, HBOT may be of value will undoubtedly be continued to be studied and debated.

Thermal Airway Injury

PATHOPHYSIOLOGY.

The term *pulmonary burn* is a misnomer. True thermal damage to the lower respiratory tract and lung parenchyma is extremely rare unless live steam or exploding gases are inhaled. The air temperature near the ceiling of a burning room may reach 540° C (1000° F) or more, but air has such poor heat-carrying capacity that most of the heat is dissipated in the nasopharynx and upper airway. The heat dissipation in the upper airway, however, may cause significant local thermal injury.

CLINICAL PRESENTATION.

Victims who have been in explosions (propane, natural gas, or gasoline) and have burns of the hands, face, and upper torso are particularly at risk for pharyngeal edema.

THERAPY.

Maintenance of the airway is the main concern with potential thermal airway injury. Victims injured in explosions should be examined for oropharyngeal erythema and edema. If these are present, the victim should be intubated for 24 to 72 hours until

edema subsides. A simple test to determine if intubation should continue is to see if the victim can breathe around the endotracheal tube when the cuff is deflated. If so, the airway edema has probably resolved and extubation should be safe. If doubt exists, extubation should be performed over a fiberoptic bronchoscope or nasogastric tube, which allows easy replacement of the endotracheal tube if necessary. Since this is not a pulmonary parenchymal injury, the purpose of intubation is to protect the airway and not necessarily to assist with ventilation. Ventilator settings should be adjusted accordingly, and vigorous pulmonary toilet should be instituted to prevent the pulmonary problems (atelectasis and pneumonia) commonly seen in intubated victims.

Smoke Poisoning

PATHOPHYSIOLOGY.

Some 280 separate toxic products have been identified in wood smoke. Modern petrochemical science has now produced a wealth of plastic materials in homes and automobiles that when burned produce nearly all of these and many other products not yet even characterized.^{[45] [66] [85] [99]} Prominent by-products of incomplete combustion are oxides of sulfur, nitrogen, and many aldehydes. One such aldehyde, acrolein, causes severe pulmonary irritation and edema in concentrations as low as 10 ppm. Although the chemical mechanisms of injury may be different with different toxic products, the overall end organ response is reasonably well defined.^{*} There is an immediate loss of bronchialepithelial cilia and decreased alveolar surfactant. Microatelectasis, and sometimes macroatelectasis, results and is compounded by mucosal edema in small airways. Wheezing and air hunger are common symptoms at this time. After a few hours, tracheal and bronchial epithelia begin to slough and hemorrhagic tracheobronchitis develops. In severe cases interstitial edema becomes prominent, resulting in a typical picture of the adult respiratory distress syndrome (ARDS). Pulmonary alveolar macrophages are poisoned, causing severe impairment of chemotaxis, which undoubtedly contributes to the high incidence of late pneumonia seen in victims with associated cutaneous burns. The activated neutrophils release superoxides and free radicals of oxygen, which together with other inflammatory mediators aggravate alveolar-capillary damage, leading to increased interstitial edema and impaired oxygenation.

CLINICAL PRESENTATION.

Any victim who has been indoors in a smoky fire and has a flame burn or was in an enclosed space should be assumed to have smoke poisoning until proven otherwise. The acrid smell of smoke on the victim's clothes should raise suspicion. Rescuers are often the most important historians and should be carefully questioned.

Careful inspection of the mouth and pharynx should be done early. Hoarseness and expiratory wheezes are signs of potentially serious airway edema or smoke poisoning. Copious mucus production and carbonaceous sputum are sure signs, but their absence should not raise false hopes that injury is absent. COHb levels should be obtained; elevated carboxyhemoglobin levels or any clinical symptoms of CO poisoning are presumptive evidence of associated smoke poisoning. In very smoky fires, COHb levels

of 40% to 50% may be reached after only 2 to 3 minutes of exposure. ^[92]

Anyone with suspected smoke poisoning should have a set of arterial blood gases drawn. One of the earliest indicators is an improper ratio (P/F ratio) of the arterial P_{AO_2} to the percent of inspired oxygen (F_{iO_2}). Normally the ratio is 400 to 500, whereas patients with impending pulmonary problems have a ratio of less than 300 (e.g., P_{AO_2} of less than 120 with an F_{iO_2} of 0.40). A ratio of less than 250 is an indication for vigorous pulmonary therapy and not an indication for merely increasing the inspired oxygen concentration.

A number of authorities suggest the routine use of fiberoptic bronchoscopy. ^{[12] [55] [74] [81]} It is inexpensive, quickly performed by an experienced clinician, and useful in accurately assessing edema of the upper airway. Aside from the presence of tracheal erythema, however, it does not materially influence the treatment for smoke poisoning. Therefore it should be used only when the diagnosis is in doubt or for experimental studies.

We have correlated by multivariate analysis a constellation of historical items, signs, and symptoms with bronchoscopic findings in 100 consecutive patients with suspected smoke inhalation admitted to the University of Washington Burn Center in Seattle. If the patient had the combination of history of closed space fire, carbonaceous sputum, and a COHb level greater than 10%, there was 96% correlation with positive bronchoscopy. Presence of two of the above features dropped correlation to 70%, and if only one was present, the correlation dropped to 36%. As discussed previously, upper airway edema was best correlated with an explosion (flash burn) that involved both the face and the upper torso. Nearly 50% of such victims had significant upper airway edema and underwent prophylactic airway intubation.

THErapy.

There is clear agreement that all victims burned in an enclosed space or having any suggestion of neurologic symptoms should be given 100% oxygen while awaiting measurement of COHb levels. This should be administered through a tight-fitting mask in the field. If the victim demonstrates labored breathing or if a prolonged transport time is anticipated, endotracheal intubation should be performed by trained personnel. One hundred percent oxygen can then be administered by ventilator.

Mucosal burns of the mouth, nasopharynx, and larynx respond with edema formation and may lead to upper airway obstruction at any time during the first 24 hours after the burn. Red or dry mucosa or small mucosal blisters should alert the observer to the possibility of subsequent airway obstruction; they also should raise suspicion that significant smoke inhalation may have occurred. Any victim with burns of the face should have a careful visual inspection of the mouth and pharynx; if abnormalities are

found, the larynx should be examined immediately on arrival at the hospital. The presence of significant intraoral and pharyngeal burns is a clear indication for early endotracheal intubation, since the progressive edema may make later emergency intubation extremely hazardous, if not impossible.

The mucosal burns themselves are rarely full thickness and can be successfully managed with good oral hygiene. Once inserted, the endotracheal tube should remain in place for 2 to 5 days until the edema subsides.

Pulmonary functions early in the course of smoke poisoning are variably affected. Typically there are decreased lung volume (functional residual capacity) and vital capacity, evidence of obstructive disease with reduction in flow rates, increased dead space, and rather rapid decrease in compliance. Surprisingly, much of the variability in pulmonary response appears to correlate with the severity of the associated cutaneous burn.^[14] Without associated burns the mortality from smoke poisoning is low, the disease rarely progresses to ARDS, and symptomatic treatment usually leads to complete resolution of symptoms in a few days. In the presence of burns, smoke poisoning appears to approximately double the rate of mortality from burns of any size. Pulmonary symptoms (hypoxia, rales, rhonchi, wheezes) are seldom present on admission but may appear 12 to 48 hours after exposure. In general, the earlier the onset of symptoms, the more severe the disease.^[9]

No standard treatment has evolved to ensure survival after smoke poisoning; each recommended treatment modality is tempered by opinion and the individual experience of the treating physician. In the presence of increasing laryngeal edema, nasotracheal or orotracheal intubation is indicated. A tracheostomy is never an emergency procedure and certainly should be avoided as initial airway management in victims with burns to the face and neck. A soft-cuffed endotracheal tube should be left in place for 3 to 5 days until the generalized oropharyngeal edema subsides.

Mild cases of smoke poisoning are treated with highly humidified air, vigorous pulmonary toilet, and bronchodilators as needed. Blood gases are drawn at least every 4 hours, and the P/F ratio is calculated. Worsening symptoms, difficulty in handling secretions, and a falling P/F ratio are all indications for intubation and respiratory assistance with a volume ventilator. If oxygenation is impaired (P/F ratio 250 or less), positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP) is initiated and increased by increments of 3 to 5 cm H₂O until no further improvement in the P/F ratio occurs or there is evidence of decreased cardiac output.

The physician must carefully search for other mechanical causes of poor ventilation (e.g., restricted chest wall motion from full-thickness burns, pneumothorax from high ventilator pressures, or mechanical difficulties with the endotracheal tube.)

Prophylactic antibiotics have no value in this chemical pneumonitis, and the subsequent burn management and treatment of eventual bacterial pneumonia can be made more difficult by the development of resistant organisms if antibiotics are used early.

Steroids are commonly used in victims with severe asthma. Clinicians dealing with

smoke poisoning often use them for their spasmolytic and antiinflammatory actions. Several authors have studied the use of steroids, but a most convincing study comes from Moylan, who showed in a prospective blinded study of patients with smoke poisoning and associated major burns that the rates of mortality and infectious complications were higher in the steroid-treated patients. In patients with associated burns, Robinson and Seward^[76] found that steroids did not alter the hospital course of patients admitted to the hospital after the MGM Grand and Hilton Hotel fires in Las Vegas in 1981.

The decision for hospital admission and the need for specialized care rest on the severity of symptoms from the smoke and the presence and magnitude of associated burns. Any victim who shows symptoms of smoke inhalation and has more than trivial burns should be admitted. If the burns are greater than 15% TBSA, the victim should probably be referred to a special care unit. In the absence of burns, admission depends on the severity of symptoms, presence of preexisting medical problems, and the social circumstances of the victim. Otherwise healthy victims with mild symptoms (only a few expiratory wheezes, minimal sputum production, COHb level less than 10%, and normal blood gas levels) can be watched for an hour or two and then discharged if they have a place to go and someone to stay with them. Victims with preexisting cardiovascular or

pulmonary disease should be admitted for observation if they have any symptoms related to the smoke. Victims with moderate symptoms (generalized wheezing, mild hoarseness, moderate sputum production, COHb levels 5% to 10%, and normal blood gas levels) may be admitted for close observation and treated as for asthma. Severe symptoms (air hunger, severe wheezing, and copious [usually carbonaceous] sputum) require immediate intubation and ventilatory support in an intensive care unit setting.

OTHER CONSIDERATIONS

Burns are tetanus-prone wounds. The need for tetanus prophylaxis is determined by the victim's current immunization status. The treating physician should follow the recommendations of the American College of Surgeons.

All victims undergoing IV resuscitation should have an indwelling urinary catheter placed for hourly monitoring of urine output. Arterial lines are useful in victims who need frequent assessment of blood gases or who will need repeated blood sampling. Necessary laboratory work during the resuscitation phase is relatively minimal. Baseline blood chemistries should be drawn. If major operative procedures, such as fasciotomy or multiple escharotomies, are expected, blood should be sent for type and crossmatching for several units of whole blood. Blood gases are mandatory in any victim with a suspected inhalation injury, and arterial pH measurement is useful as an assessment of the overall treatment of shock. If the Baxter formula is used for resuscitation, frequent electrolyte determinations are not necessary because levels will remain in the normal range. By 48 hours, however, careful monitoring of serum sodium and potassium becomes important. High levels of circulating aldosterone result in an increase in renal potassium excretion, and varying degrees of evaporative water loss through eschar dramatically increase the free water requirements of burned victims. Hemoglobin and hematocrit levels are initially high and remain high or normal until the third or fourth postburn day. The blood glucose level commonly is elevated because of the glycogenolytic effect of elevated catecholamines, the gluconeogenic effect of elevated glucocorticoid and glucagon levels, and relative insulin resistance.^{[44] [82] [94] [100]} This well-described "stress diabetes" can become a problem in normal patients if glucose-containing solutions are given during resuscitation and frequently is a serious problem in patients with preexisting diabetes. All diabetic patients require careful monitoring of blood and urine glucose, and most require supplemental insulin during resuscitation.

All medications during the shock phase of burn care should be given intravenously. Subcutaneous and intramuscular injections are unreliably absorbed systemically, and their use should be avoided. Pain control is best managed with small IV doses of morphine given until pain control is adequate without affecting blood pressure.

Before the discovery of penicillin, 30% of burn victims died during the first week after the injury from overwhelming β -hemolytic streptococcal sepsis. The availability of penicillin decreased streptococcal infections but had no influence on mortality or the incidence of bacterial sepsis. Victims then survived the first postburn week only to die of gram-negative penicillin-resistant bacterial sepsis during the second or third week after the burn. The advent of effective topical chemotherapeutic agents applied directly to the burn wounds made possible the control of streptococcal infection, obviating the need for

prophylactic penicillin. The use of prophylactic antibiotics in outpatient burns has not been carefully evaluated, so opinion is divided regarding its utility in victims not requiring hospitalization.

Stress ulceration of the stomach and duodenum was once a dread complication, occurring in nearly 30% of victims with burns. Protection of the gastric mucosa by immediate feeding through a small nasogastric tube or, failing that, with instillation of antacids or sucralfate has made stress ulcers rare. ^[48] ^[61] ^[70] ^[73] ^[89]

Psychosocial care should begin immediately. The victim and family must be comforted, and a realistic outlook regarding the prognosis of the burns should be given, at least to the victim's family. In house fires the victim's loved ones, pets, and many or all possessions may have been destroyed. If the family is not available, some member of the team, usually the social worker, should find out the extent of the damage in hopes of comforting the victim. If the victim is a child and the circumstances suggest that the burn may have been deliberately inflicted or resulted from negligence, physicians in most states are required by law to report their suspicion of child abuse to local authorities.

Burn Severity and Categorization

Severity of injury is proportionate to the size of the total burn, the depth of the burn, the age of the victim, and associated medical problems or injuries. Burns have been classified by the American Burn Association and the American College of Surgeons Committee on Trauma into categories of minor, moderate, and severe. ^[6] Moderate burns are defined as partial-thickness burns of 15% to 25% of TBSA in adults (10% to 20% in children); full-thickness burns of less than 10% of TBSA; and burns that do not involve the eyes, ears, face, hands, feet, or perineum. Because of the significant cosmetic and functional risk, all but very superficial burns of the face, hands, feet, and perineum should be treated by a physician with a special interest in burn care in a facility that is accustomed to dealing with such problems. Major burns as described previously, most full-thickness

burns in infants and elderly victims, and burns combined with diseases or injuries should also be treated in a specialized facility. Moderate burns can be treated in a community hospital by a knowledgeable physician as long as the other members of the health care team have the resources and knowledge to ensure a good result. Newer techniques of early wound closure have made burn care more complex, and an increasing number of victims with small but significant burns are being referred to specialized care facilities to take advantage of these concepts.

The criteria for admission to the hospital of victims with "minor" and "moderate" burns vary according to physician preference, the victim's social circumstances, and the ability to provide close follow-up. In some circumstances, superficial burns as large as 15% can be successfully managed on an outpatient basis. In other circumstances, burns as

small as 1% may require admission because of the victim's inability or unwillingness to care for the wound. In general, the threshold for admission of elderly victims and infants should be low. Any victim (child or adult) who the physician suspects of having been abused must be admitted.

Transport and Transfer Protocols

Once an airway is established and resuscitation is under way, burn victims are eminently suitable for transport.^{[9] [22] [46]} Resuscitation can continue en route, since for the most part patients remain stable for several days. This was well proven during the Vietnam War, when burn victims were transported from Vietnam to Japan and then from Japan to the military burn center in San Antonio, Texas. The transport was generally accomplished during the first 2 weeks after the burn, with few complications occurring in about 1000 patients transferred.

Hospitals without specialized burn care facilities should decide where they will refer patients and work out transfer agreements and treatment protocols with the chosen burn center well in advance of need. If this is done, definitive care can begin at the initial hospital and continue without interruption during transport and at the burn center. In general, transfer should be from physician to physician, and contact should be established between them as soon as the patient arrives at the initial hospital.

The mode of transport depends on vehicle availability, local terrain, weather, and the distances involved. For distances of less than 50 miles, ground ambulance is usually satisfactory. For distances between 50 and 150 miles, many people prefer helicopter transport. It should be noted, however, that monitoring, airway management, and any changes in therapy are more difficult to achieve in a helicopter. All victims transported by air should have a nasogastric tube inserted and be placed on dependent drainage, since nausea and vomiting usually result during the flight. Two large-bore IV lines should be functional in case one stops working.

For distances over 150 miles, fixed-wing aircraft are usually satisfactory. Modern air ambulances are completely equipped flying intensive care units, and the personnel are usually well trained for both critical care and the peculiarities of victim care during the flight (see [Chapter 27](#)).

The referring physicians must ensure that the victim's condition is suitable for a long transport and prepare the victim for the flight. The victim's airway must be secure. At 9144 m (30,000 feet), planes can be pressurized to an altitude of about 1676 m (5500 feet). Although supplemental oxygen can be given in flight, if the victim's oxygenation is marginal, performing intubation and starting mechanical ventilation before the transport may be preferable. Intubation is difficult en route, so if there is any question of upper airway edema, the victim should be intubated at the referring hospital. Burned victims have difficulty maintaining body temperature, and they should be wrapped warmly before transport. Bulky dressings, a blanket, and a Mylar sheet (usually available from the flight team) can help maintain body temperature. In case the victim has any cardiac irregularities, the plane must be equipped with electronic monitoring capability, since

noise and vibrations in flight make clinical monitoring difficult.

Only after all other assessments are complete should attention be directed to the burn itself. If the victim is to be transferred from the initial hospital to a definitive care center during the first postburn day, personnel at the referring hospital can leave the burn wounds alone, merely calculating the size of burn for resuscitation and monitoring pulses distal to circumferential full-thickness burns. The victim can be wrapped in a clean sheet and kept warm until arrival at the definitive care center.

Chapter 14 - Exposure to Radiation from the Sun

Lee A. Kaplan

Sun exposure, sun damage, and sun protection are increasingly the focus of medical, scientific, and public attention. Adverse effects of sunlight overexposure are well documented,^{[74] [118]} but the value and safety of sun-protective strategies are debated. These issues are of particular concern to wilderness enthusiasts who spend considerable time in the sun. Sun protection against acute phototrauma, especially sunburn, is more easily judged than protection against chronic phototrauma—photoaging, cataracts, and photocarcinogenesis. Yet these chronic effects are increasingly relevant to modern societies with demographically aging populations. The economic concerns are huge: billions of dollars are spent annually in the cosmetic and medical industries to repair photodamage, photoaging, and skin cancer. Consumer interest in photoprotection is rapidly expanding. With better sunscreens and, more recently, photoprotective clothing, still more attention and investment will be focused on sun protection.

SOLAR RADIATION

Electromagnetic Spectrum

The sun produces a continuous spectrum of electromagnetic radiation ([Figure 14-1](#)). The most energetic rays, those with wavelengths shorter than 10 nm (cosmic rays, gamma rays, x-rays) do not appreciably penetrate to Earth's surface. Phototrauma is primarily due to ultraviolet radiation (UVR). UVR (10 to 400 nm) accounts for about 10% of incident radiation at Earth's surface, visible light (400 to 760 nm) 50%, and infrared (IR; 760 to 1700 nm) 40%.^[74]

UVR has four components. Vacuum UVR (10 to 200 nm) is readily absorbed by air and does not penetrate Earth's atmosphere. UVC (200 to 290 nm) is almost entirely absorbed in the stratosphere, 15 to 50 km above Earth's surface, by oxygen and ozone. Man-made sources of UVC—germicidal lamps and arc welding devices—are rarely medically relevant. UVB (290 to 320 nm) is biologically quite active and is principally responsible for tanning, burning, and nonmelanoma skin cancer (NMSC) formation.^[74] ^[118] Beneficial effects of UVB include vitamin D production from cutaneous precursors. Approximately 90% of 25-hydroxy vitamin D is formed in this manner.^[184] Of the UVR that reaches Earth's surface, UVB accounts for roughly 10%, whereas UVA accounts for 90%, depending on the time of day and season. UVA is typically subdivided into "near" UVA, or UVA II (320 to 340 nm), and "far" UVA, or UVA I (340 to 400 nm). These subdivisions, although somewhat arbitrary, are based on photobiologic responses. UVA is also biologically active, contributing to tanning, burning, photoaging, and carcinogenesis. UVA penetrates the skin more deeply than does UVB, with less energy lost in the superficial layers of the stratum corneum and epidermis. UVA is the principal trigger for photodrug reactions. Visible light and IR may cause cutaneous phototrauma, albeit rarely. Solar urticaria has been reported to visible wavelengths. IR alone, and along with UVR, may produce epidermal and dermal alterations.^[123]

Environmental Influences on UVR Exposure

UVR intensity is substantially affected by latitude, altitude, season, time of day, surface reflection, atmospheric pollution, and ozone levels. Most UVR reaches Earth in midday; 80% between 9 AM and 3 PM, and 65% between 10 AM and 2 PM.^[74] UVB peaks at midday when the sun is at its zenith.^[144] UVB is absorbed, reflected, and scattered by the atmosphere; at midday it has less atmosphere to traverse. In early morning and late afternoon, when the sun nears the horizon, UVB decreases considerably. Latitude and season have similar effects; peak UVB exposure is approximately 100 times greater in June than December.^[144] For each degree of latitude away from the equator, UVB intensity decreases an average of 3%. UVA varies considerably less than UVB with

latitude, time of day, and season, as predicted by Rayleigh's law:

Atmospheric light scattering $\propto 1/\lambda^4$

where λ = wavelength

The shorter the wavelength the greater the atmospheric scattering, so UVB is scattered much more readily than UVA. Additionally, UVA but not UVB is transmitted through window glass, allowing indoor exposure to UVA but not UVB.

UVR may be increased by surface reflection. Water, surprisingly, is a relatively poor reflector. UVR at midday penetrates water up to 60 cm.^[144] Reflection from water may increase as the sun nears the horizon, but then there remains little UVB because of atmospheric attenuation. Ice and snow are considerably better reflectors. Clean snow may reflect up to 85% of UVR,^[144] accounting for oddly distributed sunburns in spring skiers. Sand, metal, concrete, and other surfaces may reflect UVR to varying degrees.

Clouds may attenuate UVR exposure. Absorption by clouds varies from 10% to 80% but rarely exceeds

361

Figure 14-1 Electromagnetic spectrum.

40%.^[118] Interestingly, polluted clouds—those containing the greatest concentration of hydrocarbons—are the most effective at absorbing UVR. Clouds are more effective at absorbing heat, in the form of infrared radiation, occasionally seducing hikers and bathers into excessively lengthy midday exposures.

Wind and water augment sunburn. In mice, exposure to wind plus UVR results in more erythema than UVR alone.^[177] In humans, wind may reduce heat perception, encouraging longer exposure. Water increases UVR exposure because moist skin reflects less UVR, resulting in greater absorption of UVB. Swimmers and hikers in humid environments may be at risk for increased UVR absorption.^[74]

Altitude profoundly influences UVB exposure. Until recently, it was generally accepted that UVB exposure rises 4% for each 305-m (1000-foot) rise above sea level. More recently, however, Rigel et al^[190] demonstrated an 8% to 10% increase in UVB for each 305-m rise above sea level. Beginning at the 3353-m (11,000-foot) summit of a ski run in Vail, Colorado, these investigators measured UVB readings every 152 m (500 feet) as they skied down to the base of the run at 2500 m (8200 feet). This study showed that UVB exposure in Vail at 2591 m (8500 feet) is similar to exposure levels in Orlando,

Florida, 775 miles further south.

Snow, wind, and altitude may act simultaneously to greatly augment UVB exposure for skiers and climbers. Singh et al^[210] reported that 36% (24/67) of climbers developed significant sunburns during three consecutive expeditions up to 7000 m (23,400 feet) in the western Himalayas, despite the application of sunscreen. These data emphasize the difficulties in providing appropriate UVR protection for high-altitude outdoor enthusiasts.

Ozone Depletion and UVR Exposure

Stratospheric ozone, 15 to 50 km above Earth's surface, provides a thin, fragile shield against UVR. The combination of ozone and oxygen absorbs virtually all of the incident UVC. Ozone attenuates UVB and modestly reduces UVA II but allows transmission of all UVA I.^[245] Ozone is continuously created and removed from the stratosphere by natural physicochemical processes that are in turn significantly affected by human-made pollution. Molina and Rowland^[164] first suggested that chlorofluorocarbons (CFCs) could cause ozone depletion. CFCs are organic chemicals containing carbon, chlorine, and fluorine, initially developed in the 1970s as refrigerants. Today, CFCs are used in several industrial processes: air conditioning systems, insulation, cleaning solvents, degreasing agents, and metered dose inhalers. Related compounds, halons, contain bromine and also deplete stratospheric ozone. Halons arise from seawater, fire extinguishers, and various industrial processes.^[106] CFCs and halons belong to the halocarbon group.

The remarkable stability of CFCs allows them to rise into the stratosphere, where, catalyzed by solar radiation,

362

they release Cl^\cdot and ClO^\cdot that in turn degrade ozone. One prominent chemical pathway by which CFCs deplete ozone is as follows^[106] :

Note that Cl^\cdot is preserved in this reaction. The half-life of Cl^\cdot is approximately 75 years,^[234] though CFCs may reside in the stratosphere for 50 to 200 years.^[106] During that time, each Cl^\cdot molecule may destroy 100,000 molecules of ozone.^[234] Over Antarctica, other ozone depletion mechanisms operate: molecular halogens coat the

surface of ice clouds, making them even more reactive and able to degrade ozone.^[106]

Ozone losses were first reported over Antarctica in 1985^[66] by the British Antarctic survey. Ozone showed large declines in the austral springtime (September/October), decreasing a total of 35% during springtimes 1975–1984.^[106] Ozone depletion is now documented at all latitudes except the equator. This depletion is uneven, with greater amounts at the poles and less at middle latitudes.^[234] Using NASA's Total Ozone Mapping Spectrometer (TOMS) in satellite orbit, ozone depletion has been documented over continental Europe, North and South America, South Africa, New Zealand, and Australia.^[136]

Significant increases in UVB have been documented, even in middle latitudes, because of ozone depletion. In Toronto from 1989 to 1993, Kerr and McElroy^[121] documented surface UVB increases of 35% per year in winter and 7% per year in summer, corresponding to ozone decreases of 4% per year and 1.8% per year, respectively. Their experimental design allowed the assignment of all of the UVB increase to ozone depletion rather than cloud coverage or pollution. Similar increases in ground level UVB, paralleling decreases in stratospheric ozone, have been documented in Scotland.^[168] Typically, in the northern hemisphere's middle latitudes, ozone losses are greater in winter (about 6% per decade) than in summer (3% per decade).^[106] Ironically, pollution—smog and particulates—may mitigate UVR increases by absorbing UVB.^[234]

The effects of ozone depletion on the biosphere and human skin cancer rates have been estimated. Although estimates vary, generally, for every 1% decrease in ozone, there is a corresponding 2% increase in the incidence of basal cell cancer (BCCa) and a 3% increase in the incidence of squamous cell cancer (SCCa).^[50] Melanoma incidence may increase 1%.^[234] However, even if UVB triples near the poles, as suggested in worst-case scenarios, polar areas will still receive less UVB than current equatorial levels.^[234] Ozone depletion may have its greatest effects on nonhuman biosystems. Plant and plankton yields may be diminished significantly, with uncertain, potentially severe, detriment to terrestrial and marine life.^[245]

To prevent ecologic disturbances and restore ozone levels, international agreements have been negotiated. The Vienna Convention in 1985 and the subsequent Montreal Protocol in 1987 were among the first and most notable. The Montreal Protocol, signed by 42 countries, agreed to limit, and then reduce, CFC production, leading to a 50% reduction by 1998.^[106] Three later amendments were made to accelerate progress in response to increasing awareness of ozone depletion in middle latitudes. The London Amendment in 1990 required complete phaseout of halocarbon production; and the Copenhagen Amendment in 1992 accelerated the timetable for complete phaseout, stopping production in developed countries by 1996 and undeveloped nations within 10 years. It also extended the protocol to include hydrochlorofluorocarbons. The Vienna Amendment in 1995 revised the phaseout schedule of hydrochlorofluorocarbons.^[106]^[211]

Although the Montreal Protocol is working—CFC production decreased 75% in the period 1986–1994—its modest limitations would allow continued stratospheric chlorine levels through most of the twenty-first century.^[106] In contrast, the stricter limitations of the Copenhagen Amendment will result in ozone levels rising again within the first

decade of the twenty-first century.^[211] Among the remaining sources of CFC production are metered dose inhalers and cleaning agents for rocket motor manufacturers.^[106] American factories may produce 53,500 tons of CFCs annually for export until the year 2005.^[20] CFC substitutes are more costly, leading to a black market in CFCs, with an estimated 22,000 tons produced in 1994.^[20] A significant portion of this black market is in Freon smuggled to auto air conditioner rechargers. In 1996, an estimated 10,000 tons of CFCs were smuggled into the United States from Mexico and elsewhere.^[73] Despite these black market sources, current projections suggest that atmospheric chlorine will begin to fall shortly after 2000. UVB will peak in the first decade of the twenty-first century and then gradually fall by 2050 to levels recorded in the 1950s.

ACUTE EFFECTS OF ULTRAVIOLET RADIATION ON SKIN: SUNBURN AND TANNING

The effects of UVR on skin depend primarily on wavelength, length of exposure, intensity of exposure, repetition of exposure, age at time of exposure, site of exposure, and genetic factors of the individual exposed. To have a biologic effect, UVR must be absorbed. Absorbing molecules are known as *chromophores*. Different

363

chromophores are in the skin for different wavelengths of UVR. Among these are nucleic acids, especially pyrimidine bases, various amino acids in cutaneous proteins, and lipoproteins in cell membranes. These chromophores are at various depths in the skin, accounting in part for the differing photobiologic responses to UVR. As of now, we have only imprecise knowledge of how a given photochemical reaction results in a specific biochemical product, leading to an observable clinical change.

UVC

UVC has no appreciable impact on human health, since it is effectively screened from Earth's surface by stratospheric ozone and oxygen. Even with continued ozone depletion, levels of UVC are not expected to rise. Human-made sources of UVC—germicidal lamps and arc welding devices—have been only rarely associated with cutaneous pathology, as might be predicted, since UVC is effectively absorbed by the stratum corneum, the outermost cutaneous layer.^[74]

UVB

UVB acutely induces a cutaneous inflammatory response that is at least partially definable clinically, histologically, and biochemically.^[113] Clinically, erythema, or sunburn, is the hallmark of acute overexposure to UVB. The action spectrum for erythema peaks in UVB.^[169] Generally, UVB is considered 1000-fold more effective than UVA at inducing erythema. In a human model, 300 nm UVB is 1280-fold more effective at inducing erythema than 360 nm UVA.^[246] We usually define erythemogenic doses as multiples of the minimal erythema dose (MED)—the lowest dose to elicit perceptible erythema. In a typical fair-skinned individual, the MED might range from 15 to 70 mJ/cm² for UVB and 20 to 80 J/cm² for UVA.

One MED of UVB for a typical fair-skinned individual would require 20 minutes of

midsummer exposure in San Diego, whereas an MED of UVA would require 2 to 3 hours of exposure. In a day's time, a person can receive 15 MEDs of UVB but only 2 to 4 MEDs of UVA.^[156] Consequently, although we are exposed to 10-fold to 100-fold more UVA than UVB, more than 90% of sunlight-induced erythema is attributable to UVB. The erythema action spectrum, which peaks in UVB, is remarkably similar to the absorption spectrum of deoxyribonucleic acid (DNA),^[169] suggesting that DNA is a principal target chromophore for UVB-induced erythema^[247] and pyrimidine dimer formation. Supporting this is the finding that pyrimidine dimer yields correlate with erythema.^[98]

Sunburn reflects a local vascular reaction. The causes are multifactorial; DNA damage, prostaglandin activation, cytotoxicity, and other mechanisms are implicated. UVB erythema has its onset 2 to 6 hours after exposure, peaks at 12 to 36 hours, and fades over 72 to 120 hours.^[74] ^[113] ^[118] Acute histologic changes accompanying UVB exposure include edema with vasodilation of upper dermal vasculature^[113] and endothelial cell swelling, likely caused by the release of vasoactive mediators.^[96] Delayed histologic changes include appearance of sunburn cells in as little as 30 minutes after exposure. These dyskeratotic cells have enlarged nuclei and vacuolated cytoplasm. Initially, sunburn cells are in the lower half of the epidermis but by 24 hours are also in the upper half. These sunburn cells may represent actively cycling, proliferating basal cells that cannot adequately repair UVR-induced DNA lysosomal damage.^[46] Beginning 1 hour after exposure, stainable Langerhans' cells are reduced by 25%, and by 72 hours after exposure only 10% remain.^[113] In mice exposed to repetitive suberythemogenic doses of UVB, normal numbers of Langerhans' cells return by 8 days after exposure.^[113] Vacuolization of melanocytes is seen after 1 hour, returning to normal 4 to 24 hours after exposure.^[113] Mast cells decrease in number and granularity within 1 hour, returning to normal in 12 to 72 hours.^[113] By 24 to 48 hours after exposure, there is increased melanin synthesis, epidermal proliferation, and thickening of the stratum corneum. Functionally, the epidermal permeability barrier diminishes after UVB exposure because of the altered kinetics of lamellar body-containing cells in the exposed epidermis.^[109]

Biochemical changes accompanying sunburn include increased levels of histamine,^[113] which return to normal within 74 hours. However, histamine is unlikely to be the sole or even principal mediator of vasodilation and erythema, since antihistamines are ineffective in preventing sunburn. UVR induces increased phospholipase activity, with accompanying increases in prostaglandins. PGD₂, PGE₂, PGF, and 12-hydroxyeicosatetraenoic acid (12-HETE) are increased in suction blister aspirates immediately after UVB, peaking in 18 to 24 hours.^[113] Topical and intradermal indomethacin, a prostaglandin inhibitor, blocks UVB-induced erythema for 24 hours after exposure,^[212] supporting the thesis that eicosanoids (prostaglandins and leukotrienes) are significant mediators of UVR-induced inflammation.^[129] UVB stimulates induction of proinflammatory and mutagenic cytokines tumor necrosis factor- α (TNF- α), interleukin-6 (IL-6), and IL-12.^[109] UVR generates free radicals in the skin that likely contribute to the sunburn reaction^[152] by causing peroxidative chromosomal, membrane, and protein damage.^[14] Topical antioxidants may mitigate sunburn when applied before but not after exposure. Melatonin^[14] and vitamin C^[48] act protectively by scavenging UVR-generated free radicals; neither absorbs UVR.

UVA

UVA penetrates more deeply into the skin than does UVB. Whereas 95% of incident UVB is reflected or absorbed

364

by the epidermis, nearly 50% of UVA reaches the dermis.^[65] UVA contributes modestly to sunburn and may cause clinical erythema. Prolonged daily UVA exposure can approach 125 J/cm^2 , significantly exceeding the threshold erythema dose of 20 to 80 J/cm^2 .^[214] Clinically, UVA erythema has an onset within 4 to 6 hours, peaks in 8 to 12 hours, and fades in 24 to 48 hours.^[113] ^[118] Erythema resulting from UVA may have a distinct pathophysiologic mechanism. UVA-induced erythema may be caused by keratinocyte cytotoxicity.^[113] Histologically, UVA erythema displays more epidermal spongiosis, fewer sunburn cells, and more dermal changes than does UVB-induced erythema, with a denser, deeper mononuclear cell infiltrate and more vascular damage.^[113]

Infrared

IR radiation plays a less well-defined role in photodamage. Near IR preirradiation prevents UVR-induced cytotoxicity,^[156] suggesting a possible evolutionary protective mechanism for IR is daily preparation of skin cells to resist UVR-induced damage. However, no data indicate whether IR protects against UVR's mutagenic and carcinogenic effects.

Sunburn Treatment

Sunburn is self-limited, and its treatment is largely symptomatic, involving local skin care, pain control, and antiinflammatory agents ([Box 14-1](#)).^[13] Cool water soaks or compresses may provide immediate relief, and topical anesthetics are sometimes useful. It is generally preferable to use the nonsensitizing anesthetics menthol, camphor, and pramoxine rather than potentially sensitizing anesthetics containing benzocaine and diphenhydramine. Refrigerating topical anesthetics before application provides added relief. A legion of topical remedies have been suggested anecdotally, including aloe, baking soda, and oatmeal, though controlled studies are lacking. Topical steroids may blanch the reddened skin. Oral nonsteroidal antiinflammatory drugs provide analgesia and may reduce sunburn erythema.^[74] Few published studies support the value of systemic steroids, but they enjoy considerable anecdotal support. Sadly, warnings regarding skin cancer are rarely given to sunburned patients seen in the emergency room.^[13]

Tanning

Tanning, like sunburning, is caused by UVR. Consequently, persons seeking tan risk sunburn. Tanning is biphasic. After sun exposure, there is immediate pigment darkening (IPD) within minutes, followed by delayed pigment darkening (DPD) in 3 days. IPD is predominantly due to the action of UVA on preformed melanin precursors and occurs in as little as 5 minutes after exposure, peaks in 60 to 90 minutes, and then fades quickly. However, DPD represents new melanin synthesis within melanocytes and the subsequent spread of the richly melanized melanosomes into surrounding

keratinocytes. After UVB exposure, DPD is notable by 72 hours, peaks in 5 to 10 days, and slowly fades. DPD is primarily a response to UVB. Most tanning studies have been performed with erythemal doses of UVR. However, multiple suberythemal exposures to UVA are significantly more melanogenic than similarly dosed UVB.^[17] The mechanism of DPD is uncertain but is likely multifactorial. UVB stimulates tyrosinase release and arachidonic acid metabolites and releases α -melanocyte-stimulating hormone (α -MSH) from keratinocytes.^[5] It also increases the binding affinity of melanocytes for MSH, resulting in increased melanocyte proliferation, melanization, and arborization.^[26] UVB increases melanocytes in both exposed and protected human skin,^[218] suggesting the possibility of a UVR-stimulated circulating factor that promotes melanocyte proliferation.

CHRONIC PHOTOTRAUMA

Natural Defenses and Skin Type

The absence of erythema does not preclude cutaneous photoreactions. Chronic exposure to UVR is accompanied by insidious cumulative biologic and clinical changes. Although some of these changes are due to broad-band UVR, UVA and UVB often have distinct and different effects on the epidermis, dermis, extracellular matrix, cytokines, and immune response.^[236] In response to UVB, the stratum corneum thickens^[95] and melanin increases, both protective mechanisms to mitigate further UVB photodamage. The stratum corneum,

365

the outermost layer of skin, is composed of flattened anucleate keratinocytes. It reflects, scatters, or absorbs up to 95% of incident UVB, depending largely on its thickness.^[102] With repeated exposure to UVB, the stratum corneum can increase its thickness up to sixfold.^[74] As a consequence, the stratum corneum is the main photoprotective factor in Caucasians.^[95] Repeated UVA exposures may cause some thickening,^[143] but to a much lesser degree. Consequently, UVA tans are not as photoprotective as UVB tans.

Melanin reflects, scatters, and absorbs throughout the UVR spectrum; acts as an antioxidant; and reduces UVR-induced photoproducts.^[126] Consequently, constitutive (racial) skin color is a principal determinant of an individual's erythematous response to UVR. Although blacks and whites have similar numbers of melanocytes, these pigment-forming cells are differently melanized and distributed in black and white skin. Increased melanin in blacks can decrease the dermal penetration of UVR up to fivefold^[43] and increase the MED up to thirtyfold. In contrast, tanning is much less protective. After an entire summer of tanning, the MED in whites increased only 2.3-fold.^[43] Clinically, these racial differences in melanization are reflected in lower rates of burning, photoaging, and skin cancer in blacks.

Susceptibility to photodamage is typically defined by six distinct skin types ([Box 14-2](#)). Racial pigmentation alone does not account for differences in skin type. Some redheads tan easily, whereas some blacks burn readily. Reporting errors, typically overstating sun tolerance, are common, further complicating the interpretation of skin types.^[185]

Skin type correlates well with MED. Additional factors that influence MED include age and anatomic site. Lower MEDs are recorded in the very young and the very old.^[118]

Differences in stratum corneum thickness and melanocyte concentration may account for body site-specific differences in MED. For example, the MED of the back is typically less than the MED of the lower leg.

Chronic suberythral UVA exposures also cause photodamage. Repetitive, low-dose exposures to UVA result in histologic changes,^[139] ^[143] including thickened stratum corneum, granular and stratified cell layers, decreased elastin, vascular dilation, and inflammation.

Box 14-2. SKIN TYPES

- II. Often burns. Tans minimally.
- III. Sometimes burns. Tans moderately.
- IV. Burns minimally. Tans well.
- V. Rarely burns. Tans deeply.
Moderately pigmented (brown).
- VI. Never burns. Deeply pigmented
(black).

Aside from stratum corneum thickening and increased pigmentation, intrinsic mechanisms of photoprotection include antioxidants, such as the glutathione peroxidase-reductase system, that mitigate damage from UVR-induced reactive oxygen species. DNA repair enzymes correct most UVR-induced mutations. Carotenoids stabilize biologic membranes from singlet oxygen attack. Urocanic acid absorbs some of the UVR that penetrates the stratum corneum.

Photoaging

Long-term repetitive exposures to sunlight result in photoaging.^[69] This process, known as *dermatoheliosis*, is distinctive clinically and histologically from chronologic aging; it is not merely accelerated chronoaging. Photoaged skin is characterized by dryness, roughness, mottling, wrinkling, atrophy, and pebbling and may be studded with precancers (actinic keratoses) or cancers ([Figure 14-2](#)). Most of what we consider "old-looking" skin is in fact the result of photoaging and not chronoaging. Although age can be estimated from observing sun-exposed sites, it cannot be estimated from photoprotected sites.^[232] The action spectrum for photoaging includes UVB, UVA, and infrared.^[143]

Chronically sun-exposed sites have fewer Langerhans' cells. Keratinocytes and fibroblasts from sun-damaged skin have diminished lifespans in culture.^[90] The most notable histologic change with chronic UVB exposure is deposition of thickened amorphous elastic fibers high in the dermis, demonstrable in photoexposed white skin

by age 30. In a transgenic mouse model, UVB but not UVA produces this solar elastosis.^[226] Another mouse model suggests that the action spectrum for "photosagging" peaks in UVA at 340 nm,^[101] and that this action spectrum is remarkably similar to that for the generation of singlet oxygen by excitation of trans-urocanic acid. These authors conclude that UVA causes photoaging because of its interaction with trans-urocanic acid, releasing reactive oxygen species.

With photoaging, elastin gene expression appears to be activated, although data are conflicting. Tropoelastin and fibrillin synthesis actually diminish with chronic UVB exposure.^[235] There is enhanced transcription of other extracellular matrix genes. In particular, photoaged skin demonstrates increased matrix metalloproteinases, potent mediators of connective tissue damage.^[69] These arise within hours of UVB exposure, even suberythral exposure.^[68] Interestingly, tretinoin inhibits induction of these UVB-induced proteinases,^[68] ^[69] perhaps explaining in part its clinical utility against photoaging.^[175] ^[233] Tretinoin also normalizes photoaltered epidermal differentiation and deposits new type I collagen in the upper dermis.^[97]

Ocular Effects

Acute overexposure to UVB may cause photokeratitis, especially in skiers and climbers ("snowblindness"),^[248] whereas chronic exposure to UVR may cause or contribute to pterygia, cataracts, and macular degeneration. A full discussion is presented in [Chapter 22](#).

Sun and Skin Cancer

Skin cancer, the most common of all cancers, is overwhelmingly caused by UVR exposure. In particular, UVR is the principal cause for NMSC—basal and squamous cell cancers. UVR also contributes significantly to melanoma but is not a sine qua non. The incidence of skin cancer is staggering. One in five Americans^[190] and two thirds of all Australians^[11] born today will develop skin cancer. In addition, the incidences of both NMSC^[93] and melanoma continue to increase.^[189] Three causative factors seem to

predominate:

1. Lifestyle trends, including sun exposure, sunbathing, and tanning bed use
2. Demographic aging of the population
3. Ozone depletion

Since the 1890s, epidemiologic evidence has accumulated linking sun exposure and NMSC in humans. The incidence of skin cancer increases with increasing proximity to the equator.^[45] NMSC has a far greater incidence

367

in whites than in blacks and occurs primarily on sun-exposed areas. The risk of NMSC increases with increasing sun exposure, and repeated sunburn is an independent risk factor.^[132] Adoption of a sun-protected lifestyle is associated with decreased risk.^[108] Patients with xeroderma pigmentosum (XP), with deficient ability to repair UVR-induced DNA damage, have a 1000-fold greater risk of developing NMSC, typically at a very early age.^[129]

In the 1920s, laboratory data confirmed that UVR induces and promotes NMSC in mammalian animal models.^[118] ^[222] UVC and UVB are effective inducers of SCCa in mice.^[113] Although UVB is primarily implicated, UVA augments UVB-induced carcinogenesis,^[222] but it is not clearly a carcinogen on its own.

Development of NMSC in humans is related to the time and intensity of exposure. Sun exposure in childhood and adolescence is more predictive of later BCCa.^[78] British immigrants to Australia assume the much higher Australian risk of NMSC only if they emigrate before age 18; after 18, immigrants retain the lower British risk.^[149] A separate study suggests the risk decreases after age 10.^[131] Gallagher et al^[78] found that BCCa is associated with sun exposure up to age 19 but not associated with mean annual cumulative summer sun exposure. In this study, risk for BCCa was also associated with fair complexion and freckling. Kricker et al^[132] suggest that intermittent, rather than continuous, sun exposure in poor tanners is the most important factor in the development of BCCa.

The relationship of photoexposure and SCCa is distinct and different from that of sun and BCCa. There is significantly increased risk of SCCa with chronic occupational exposure, especially in the 10 years before diagnosis.^[79] Although cumulative lifetime photoexposure and SCCa are not associated, risk factors include periodic recreational exposure, pale complexion, and red hair. Persons who develop SCCa seem phenotypically sensitive to UVR with chronic exposure as adults. Household and office exposure to nonsolar UVR does not increase the risk of BCCa and SCCa.^[12] In select mouse models, suberythemal UVR causes SCCa.^[169] In these models, gradual suberythemal exposures to UVR may be actually more carcinogenic than are erythemal doses.^[77] This may be relevant to humans and explain why persons without any prior

sunburns may develop SCCa.

Melanoma

Melanoma has a less well-defined relationship to sun exposure. Clearly, however, sun exposure plays a significant role in its development.^[4] The ultraviolet action spectrum for melanoma remains uncertain, with different results in different animal models. In *Monodelphis domestica*, a South American marsupial, both UVA and UVB are implicated^[54]; in *Xiphophorus* (platyfish and swordtails), UVA, UVB, and visible (blue) light are causative^[54]; and in transgenic mice Tyr-SV40E (C57BL/6 strain), UVB is the etiologic waveband.^[122] In humans with XP, the 1000-fold increased incidence of melanoma strongly supports UVB as a causative agent.^[130] A unique, recent, and elegant laboratory experiment documented that UVB induces melanocytic hyperplasia, atypia, and melanoma in newborn human foreskin xenografts on RAG-1 (immunodeficient) mice.^[5]

Melanoma incidence increases with proximity to the equator in white populations^[119] in the United States, Australia, and Scandinavia, as well as in the nonwhite population of India.^[135] Intermittent intense exposures pose a high risk for melanoma.^[61] Metaanalysis of 15/16 case-controlled studies supports a significantly increased risk of melanoma with a history of sunburn. By contrast, there is only a small increased risk for total exposure and a decreased risk with heavy occupational exposure.^[63] Patients with melanoma are twice as likely to relate a history of a prior sunburn and three times as likely to relate a history of multiple prior sunburns, compared with age-matched controls.^[63] Persons who tan poorly and burn readily are at higher risk for melanoma.^[145] The distribution of melanomas on the trunk (in both genders) and lower legs (in women) is consistent with the hypothesis that intermittent sun exposure is provocative. Note, however, that melanomas also arise in sun-protected sites, especially in nonwhite populations, suggesting an additional cause separate from sun exposure.

A high level of outdoor activity in college is associated with a fourfold risk of later melanoma.^[62] Servicemen who served in the Pacific theater during World War II have higher risks of melanoma than those who served in Europe.^[34] The incidence of melanoma is increased in indoor workers with higher socioeconomic status, again reflecting the role of intermittent intense sun exposure.^[119] Fluorescent light raises some concerns^[230] but does not significantly increase melanoma risk, especially when lights have covers or diffusers.^[110]

Sunburns in childhood may be particularly relevant to the later development of melanoma. Celtic migrants to Australia arriving before age 10 assume the high melanoma risk of native Australians; migrants older than 15 at arrival have only one-fourth that risk.^[200] Europeans who live more than 1 year in a sunny climate have an increased relative risk (RR = 2.7) of melanoma, and the risk increases substantially if they arrive before age 10 (RR = 4.3).^[8] However, a recent study suggests that childhood sun exposure contributes a serious risk only if there is subsequent and significant sun exposure as an adult.^[9]

This association of increased melanoma risk with youthful sun exposure may be in part

attributable to the effect of sun on the development of melanocytic nevi (moles) in children. Several studies confirm that the number of nevi in children increases with increasing

acute and chronic sun exposure.^{[33] [81] [82] [104]} In Australia, the number of nevi up to age 12 increases with increasing proximity to the equator.^[120] Queensland children have the highest number of nevi in the world, and, not surprisingly, Queensland has the highest incidence of melanoma in the world^[104] at 55.8/100,000 for males and 42.9/100,000 for females.^{[11] [23]} The number of nevi is a strong predictor of melanoma risk. Melanoma increases with increasing numbers of benign acquired nevi. In a large European case-controlled study, the most important risk factors for melanoma are the number of nevi and number of atypical nevi.^[82] Established nevi may develop histologic changes transiently, simulating melanoma after a single UVR exposure,^[225] and some recent data suggest that sunburn can induce malignant transformation in benign nevi.^[40]

In the United States, melanoma incidence has increased since records were first kept in the 1930s, rising 121% in the 20 years between 1973 and 1994.^[99] In 1999, there will have been 44,200 new cases of invasive melanoma.^[137] The lifetime risk of melanoma for a child born in the United States today is 1 in 87, and this is anticipated to rise to 1 in 75.^[99] Similarly large increases have been noted in Europe, Australia, and even Japan.^[119] However, melanoma incidence and death rates show signs of stabilizing and perhaps decreasing for younger cohorts,^{[92] [99] [119]} likely because of improving sun protective behaviors.

Significant national efforts have been made to educate and protect populations at risk. In Australia, taxes have been removed from sunscreen sales, hats are typically required for children in outdoor sports, and artificial shade is increasingly available in public parks. In addition to improved photoprotection, early detection has been widely promoted. The Skin Cancer Foundation encourages monthly self-examinations, with special attention to pigmented lesions displaying atypical clinical features, the so-called "ABCDs" of melanoma: *A*symmetry, *B*order irregularity, *C*olor variegation, and *D*iameter greater than 6 mm ([Figure 14-3](#)). Nevi (moles) with these clinical features, changing nevi, or nevi that bleed should be evaluated by a physician.

Molecular Basis of Photocarcinogenesis

Some photomolecular events are associated with NMSC. UVR causes characteristic photoincidents at sites of adjacent pyrimidines on DNA.^{[32] [166] [246]} UVR photons are absorbed at the 5-5 double bonds, resulting in cyclobutane dimers if both bonds open and 6-4 (pyrimidine-pyrimidone) photoproducts if a single bond opens.^[32] Cyclobutane dimers predominate 3:1, with thymine (T-T) dimers most common.^[129]

Suberythemal, as well as erythemal, doses of UVR can induce T-T dimers.^[247] Data suggest that cyclobutane dimers and 6-4 photoproducts produce the mutagenic^[138] and

carcinogenic^[129] properties of UVR. High-performance

Figure 14-3 Melanoma. Note the asymmetry, border irregularity, color variegation, and diameter greater than 6 mm.

liquid chromatography can now quantitatively measure UVB photoproducts.^[38] Such measurements indicate a thirtyfold interindividual variation in photoproduct yields.^[38]

Resultant UVR-induced mutations have a distinctive signature: two thirds display cytosine ? thymine (C ? T) substitutions at dipyrimidine sites; 10% show CC ? TT substitutions.^[32] These mutations are relatively unique to UVR damage and allow UVR-induced mutations to be distinguished from chemical mutations.^[32]

The most likely target for UVR-induced mutagenic initiation of skin cancer is p53, a tumor suppressor gene.^{[31] [111]} Mutations of p53 are the most common genetic alterations yet identified in cancers,^[111] found in nearly 50% of all human cancers.^{[32] [129]} Approximately 50% of BCCa, 60% of actinic keratoses, and 90% of SCCa contain p53 mutations.^{[32] [250]} Although p53 mutations may be found in non-sun-damaged skin with low frequency, 10^{-2} to 10^{-3} , mutations are much more common in sun-exposed sites.^[32]

Normal p53 protein is a transcription factor, regulating the cell cycle. DNA damage stimulates p53 protein production, which leads to cell cycle arrest in G1 (a premitotic phase), allowing time for DNA repair.^[32] Irreparable damage leads to apoptosis, or programmed cell death. Sunburn cells are examples of apoptotic cells.^[250] Cells with mutated p53 are more resistant to apoptosis with subsequent UVR exposures, explaining why p53 inactivation reduces sunburn cells in irradiated mouse skin.^[250]

Within the p53 gene there are "hot spots," codons where mutations frequently occur.^{[32] [37]} Most p53 mutations result in a single amino acid substitution, typically cytosine to thymine (C ? T).^[250] Although normal, wild-type p53 has a short half-life and is generally unstable and unstainable, mutated p53 is significantly more stable and consequently stainable by immunohistochemical techniques.^{[37] [190]} Both UVA and UVB upregulate p53

expression in human skin.^[39] After a single UVR exposure to the forearms, p53 protein expression peaks in 24 hours, returning to baseline after 360 hours.^[100]

Mutations in p53 occur as an early, initiating event in photocarcinogenesis.^[129] In actinic

keratoses, unique p53 mutations are present throughout the lesion,^[250] confirming that they occur before, not after, lesion formation. Different actinic keratoses display different p53 mutations, again supporting the role of p53 mutations as initial causative events, followed by clonal expansion of mutated cells to form clinically visible lesions of precancerous actinic keratosis.^[250] Altered p53 provides a survival advantage to mutated cells. In response to chronic UVR, neighboring nonmutated cells become apoptotic and die, allowing space for further expansion of the mutated clone with ongoing UVR exposure^[32] and ultimately resulting in the development of actinic keratosis or SCCa.

However, p53 mutations alone may be insufficient to produce NMSC. Patients with Li-Fraumeni syndrome, who inherit a mutated form of the p53 gene, have an increased incidence of sarcomas, adenocarcinomas, and melanomas but not NMSC.^[129] Consequently, other factors, such as decreased DNA repair and UVR-induced immunosuppression, must play a permissive role. In patients with XP, for example, there are increased numbers of p53 mutations,^[32] defective gene repair mechanisms, and greatly increased numbers of NMSC. DNA repair may also be defective in normal, nonsyndromic patients who develop BCCa at an early age^[231] and in elderly patients^[166] who have a higher incidence of NMSC.

Cutaneous lymphomas may also show a higher frequency of UVR signature p53 mutations.^[154] In mycosis fungoides, these mutations are found in the tumor stage but not the plaque stage,^[154] suggesting that UVR promotes the clinical progression of this lymphoma. These findings are particularly interesting in view of recent epidemiologic data demonstrating an increased incidence of non-Hodgkin's lymphoma as one moves closer to the equator.^[1]

Photoimmunology

UVR produces local and systemic immunosuppression.^[172] Locally, UVB depletes Langerhans' cells, which are immunocompetent antigen processing cells, for up to 2 weeks after exposure.^[160] In addition, UVB functionally alters Langerhans' cells, diminishing Th1 responses (which promote contact hypersensitivity) while preserving Th2 responses^[202] (which suppress contact hypersensitivity), effectively converting the remaining Langerhans' cell from immunogenic to tolerogenic. Antigen-specific suppressor T cells arise, their appearance possibly mediated by UVR-induced synthesis of IL-10 from keratinocytes.^[202] As a consequence, contact hypersensitivity and mixed lymphocyte reactions are diminished with UVR exposure. This may explain, at least partially, why UVR-induced skin cancers, which are antigenic, progress into clinical lesions. In mice, this UVR-induced immunosuppression can be transferred with irradiated T lymphocytes.^[172] Other proposed mediators of UVR-induced immunosuppression include cis-urocanic acid,^[49] TNF- α , prostaglandins,^[169] and DNA photoproducts.^[161]

Immunoregulatory failure contributes to skin cancer formation.^[133] Skin cancer is often more aggressive and occurs at an earlier age in immunosuppressed patients.^[64]^[176] In Australia, 45% of kidney transplant patients develop skin cancer within 11 years and 70% within 20 years.^[28] For heart transplant patients in Australia, the incidence of skin cancer is 31% at 5 years and 43% at 10 years, and skin cancer accounts for 27% of

patient deaths in this group after the fourth year post-transplant.^[176] In these patients, the ratio of SCCa:BCCa is 3:1, precisely opposite the ratio present in non-immunosuppressed patients. These figures are only unusual in that most studies suggest the risk of skin cancer is higher after heart transplant than kidney transplant because of higher doses of immunosuppressive drugs with the former. Chronic sun exposure and fair complexion further increase risks of skin cancer in transplant patients,^[176] possibly resulting from overexpression of p53.^[88]

PHOTOPROTECTION

Sunscreens

Chemical sunscreens were discovered in 1926. By 1928, the first commercial sunscreen, containing benzyl salicylate and benzyl cinnamate, was marketed in the United States.^[74] Subsequent sunscreen evolution was primarily directed toward UVB protection to mitigate the development of sunburn from overexposure to the sun. Paraaminobenzoic acid (PABA) was first advocated as a sunscreen in 1942, patented in 1943, and made commercially available in 1960. By then, national advertisements for sunscreens were blazing the message: tan without burning. Sun protection factor (SPF) 15 formulations only became available around 1980. More recently, as UVA photodamage has been appreciated, UVA sunscreens, such as avobenzone, have been introduced. Micronized preparations of titanium dioxide (TiO₂) and zinc oxide (ZnO) have become popular, providing broad-spectrum protection throughout the UVR range. Previously considered "physical" (reflective) as opposed to "chemical" (absorptive) sunscreens, these micronized preparations blur the traditional distinctions. Micronized TiO₂ and ZnO are largely transparent and absorb, reflect, and scatter UVR.^[127] Consequently, chemical and physical labels for sunscreens are of diminishing value and perhaps should be dropped.

In the United States, sunscreens are regulated over-the-counter (OTC) products. Until recently, the U.S. Food and Drug Administration (FDA) *Tentative Final Over-the-Counter Drug Products Monograph on Sunscreens*, published in 1993, established the allowable sunscreens, testing procedures, and labeling claims for efficacy, water resistance, and safety.^[71] This was superseded by the *Final Monograph*, published on May 21, 1999, in the *Federal Register*.^[72]

The current FDA-approved sunscreens are listed in [Table 14-1](#). PABA is an effective UVB absorber but has fallen out of favor. Poorly water soluble, PABA must be formulated in an alcohol vehicle. On the skin, it binds epidermal proteins, enhancing its resistance to water wash-off (substantivity), but provoking contact and photocontact dermatitis in approximately 4% of exposed subjects. Further limiting its acceptability, PABA can permanently stain fabrics a dull yellow color. As a consequence, PABA has been largely replaced by PABA esters—amyl dimethyl PABA (padimate A) and octyl dimethyl PABA (padimate O). These absorb well in UVB, are easier to formulate in

nonalcoholic vehicles, and are less staining and less allergenic.

TABLE 14-1 -- Sunscreening Agents Approved in the United States

SUNSCREEN	MAXIMUM %
Aminobenzoic acid	15
Avobenzene	3
Cinoxate	3
Diethanolamine methoxycinnamate*	10
Digalloyl trioleate†	5
Dioxybenzone	3
Ethyl 4- (bis [hydroxypropyl]) aminobenzoate†	5
Glyceryl aminobenzoate†	3
Homosalate	15
Lawsone with dihydroxyacetone*	0.25 with 3
Menthyl anthranilate	5
Octocrylene	10
Octyl methoxycinnamate	7.5
Octyl salicylate	5
Oxybenzone	6
Padimate O	8
Phenylbenzimidazolesulfonic acid	4
Red petrolatum†	100
Titanium dioxide	25
Trolamine salicylate	12
Zinc oxide	25

From Food and Drug Administration: Final Monograph, Rockville, Md, May 21, 1999.

*Reserved for inclusion if USP monograph established by May 21, 2001.

†Deleted from FDA *Final Monograph*. To be withdrawn by May 21, 2001.

Cinnamates are the next most potent UVB absorbers. They often replace PABA in "PABA-free" sunscreens, but octyl methoxycinnamate (Parsol MCX) is an order of magnitude less potent than padimate O.^[141] Cinnamates are poorly bound to the stratum

corneum and may cause contact dermatitis. Cinoxate is the most frequent contact sensitizer, with cross-sensitization to related cinnamates in coca leaves, balsam of Peru, and cinnamon oil.^[57]

Salicylates, including homosalate and octyl salicylate, are relatively weak absorbers of UVB and are consequently used in combination with other sunscreens. They have the advantage of being nonsensitizing and water insoluble, while helping to solubilize benzophenones in commercial products.^[74]

Anthranilates are similarly weak UVB absorbers that also filter UVA. They display peak absorption at 340 nm.^[141] Octocrylene is another weak UVB absorber that also absorbs modestly in UVA up to 360 nm. Phenylbenzimidazole sulfonic acid (PBSA) is a unique UVB absorber. Unlike other chemical absorbers, which solubilize in the oil phase of emulsion formulations, PBSA is water soluble. This physiochemical property has resulted in its increasing use in "oil-free" cosmetic sunscreens.^[141]

Benzophenones are broader-spectrum sunscreens, with good absorption in UVB and UVA up to 360 nm.^[141] The three benzophenones available in the U.S. market are oxybenzone, dioxybenzone, and sulisobenzene.

In the United States, dibenzoylmethanes are represented by a single agent—avobenzone (Parsol 1789, butyl methoxydibenzoylmethane). Among the chemical sunscreens, it is the most potent UVA absorber, with little or no absorption in UVB.^[141] Its absorption peak at 358 nm falls nearly to zero at 400 nm.^[197] Concerns have been raised that photodegradation may limit its effectiveness. Under solar simulated light, avobenzone can be degraded 36% in as little as 15 minutes.^[203] However, these data are disputed, and there is debate whether any significant decrease occurs with typical use, especially given the mitigating effect of combined sunscreens agents in commercially available preparations.^[203] Additionally, select stabilizing compounds, such as vitamin C, vitamin E, and iron chelators, may retard photodegradation.^[155]

Physical sunscreens traditionally refer to opaque agents that primarily reflect, scatter, and, to a lesser extent, absorb UVR. These include calamine, ichthammol, iron oxide, kaolin, red veterinary petroleum, starch, talc, TiO₂, and ZnO. In the wilderness, extemporaneous physical blockers can be made from ashes, mud, and leaves. A sunscreen with a physical filter typically protects throughout the UVR and visible spectra and may even protect against IR-induced erythema.^[178] However, classic physical blockers are messy, uncomfortable, and cosmetically undesirable.

In recent years, smaller (micronized or microfine) particle-sized preparations of TiO₂ and ZnO have been made available. Micronized TiO₂ and ZnO have particle size 0.015 to 0.035 μm,^[55] making them more soluble in their vehicle base and minimally reflective of visible light. This makes them transparent, or nearly so, in thin coats. ZnO has a lower

refractive index than TiO₂ in the visible range, making ZnO less white and more transparent.^[163] These micronized preparations significantly absorb UVR, providing broad-spectrum protection from UVB and UVA, blurring the distinction between chemical and physical sunscreens.^{[55] [141] [205]} TiO₂ and ZnO are sometimes marketed as "chemical-free" sunscreens, clearly a misnomer. Additionally, products containing "physical" sunscreens are often marketed as "sunblocks," a misleading term eliminated in the 1999 FDA *Final Monograph*.^[72]

Sunscreen Vehicles.

Sunscreen vehicles affect efficacy and acceptability. The ideal vehicle spreads easily, maximizes skin adherence, minimizes interaction with the active sunscreens, and is noncomedogenic, nonstinging, nonstaining, and inexpensive. In practice, the best vehicle is highly dependent on personal preference. Creams and lotions (emulsions) are most popular. Both are oil-in-water or water-in-oil preparations, although lotions spread more easily. Most sunscreens are lipid soluble, accounting for an objectionable, greasy feel. Increasingly popular "dry lotions" minimize the lipid component and often include at least one water-soluble sunscreening agent to reduce oiliness.^[141] In contrast, sunscreen oils contain only a lipid phase. Oils spread easily, but thinly, limiting the achievable concentration of active sunscreening agent and thereby limiting protectiveness. In addition, oils are oily and cosmetically less acceptable. Other anhydrous vehicles—ointments and waxes—may be desirable for climbers and winter campers, reducing the risks of chapping and frostbite. Gels are generally nongreasy but tend to wash or sweat off easily. In addition, gels seem to produce more stinging and irritation. Sticks typically incorporate sunscreening agents into wax bases, but application of stick preparations to larger areas is problematic. Aerosols are wasteful, with spray lost to the air, and usually form an uneven film.^[141] Increasingly, sunscreens are being incorporated into cosmetics, including foundations, lipsticks, and moisturizers.

Sun Protection Factor.

The ability of a sunscreen to protect the skin from UVR-induced erythema is measured by the SPF. The SPF is defined as the ratio of UVR required to produce minimal erythema (1 MED) in sunscreen protected as opposed to unprotected skin.^{[72] [118]} It can be represented by the following formula:

$$\text{SPF} = \frac{\text{MED of sunscreen protected skin}}{\text{MED of unprotected skin}}$$

Testing conditions are standardized by the FDA.^[72] The agent to be tested is applied at a standard concentration of 2 mg/cm². Testing is performed indoors with a solar simulator on the back between the beltline and scapulae. The SPF is typically determined on a panel of 20 (maximum 25) subjects with skin types I, II, or III. The

mean is then determined to be the approved SPF. Using indoor testing with a solar simulator, although more reproducible than outdoor natural sun exposure, may yield a falsely high SPF value. In outdoor testing of more than 30 sunscreens labeled SPF 15, none had SPFs greater than 12.^[180] Several factors are responsible: sweating, clothing or towel abrasion, and application variability. In addition, solar simulators generally have reduced outputs of UVA compared with sunlight.^[206]

SPF determinations use erythema as their measurable endpoint. Erythema is predominantly a result of UVB, not UVA, exposure. Consequently, SPF is *primarily* a measure of *UVB* protection. The relationship of SPF and UVB absorption is given in [Table 14-2](#).

How high an SPF is necessary? Given that SPF 15 blocks 93% of UVB, some argue that SPF 15 is sufficient^[148] and that higher labeling claims are misleading and costly for consumers. However, in several studies, higher SPF sunscreens confer clinical and histologic benefits. In children on Florida beaches, a single application of SPF 25 sunscreen protected just as well as multiple applications for up to 6 hours of exposure.^[173] Histologically, an SPF 30 sunscreen provides better protection against sunburn cell formation than does an SPF 15 sunscreen.^[116]

Sunscreen Application.

Perhaps the most persuasive argument in favor of higher SPF sunscreens derives from variations in application technique. In the real world, sunscreens are applied at much lower concentrations than the 2 mg/cm² at which they are tested. Used ad lib, sunscreens are typically applied in concentrations of 0.5 to 1 mg/cm².^{[18] [204]} The resultant SPF is considerably reduced, typically to about 50% of the labeled SPF for chemical sunscreens.^[35] Some suggest the reduction is even greater and that the actual SPF is only 20% to 50% of the labeled value.^[219] Physical sunscreens tend to be applied even more thinly, typically

TABLE 14-2 -- Skin Protection Factor and UVB Absorption

SPF	UVB ABSORPTION (%)
2	50
4	75
8	87.5
15	93.3
30	96.7
50	98

at two thirds the concentration of chemical sunscreens, likely because of their cosmetic visibility.^[53] For TiO₂ products, application concentrations of 0.65 mg/cm² result in SPF values of only 20% to 30% of the intended, labeled value.^[219] Not surprisingly, persons who burn more easily tend to apply thicker concentrations of sunscreen.^[53] There is no difference in the applied concentrations of higher vs. lower SPF formulations.

Uneven application further reduces sunscreen protection. Using a fluorescent dye, a pattern of spotty use emerges. Individuals typically cover the forehead adequately, but the temples, ears, and posterior neck are often undertreated or missed entirely.^[86] ^[142] ^[188] Newly available sunscreens that contain disappearing colorants are popular, allowing visible assurance of complete coverage. Adequate coverage of just the chronically exposed areas (face, ears, and dorsal hands) requires 2 to 3 g,^[141] requiring an 8-oz bottle of sunscreen every 80 to 120 days.

Application delay imposes a further decrease in protectiveness. In a study of families on Chicago beaches in summer,^[194] sunscreen was applied only after arriving at the beach in 98% of families. The median delay from arrival to application to the last family member was 51 minutes.

Underapplication, uneven application, and delayed application of sunscreens result in unnecessary photoexposure and photodamage. In addition, for hikers, the concomitant use of sunscreen and insect repellent containing diethyltoluamide (DEET) lowers the effective SPF by 34%.^[165] Balancing these issues with consumer concerns over SPF inflation, the FDA set a labeling limit of SPF 30+ in the 1999 *Final Monograph*,^[72] effective May 21, 2001. This was subsequently extended to December 31, 2002.

UVA Protection Factors.

With our increased understanding of UVA-induced photodamage and the recent addition of better UVA blocking agents (avobenzone and micronized TiO₂ and ZnO), more attention has been focused on measuring UVA protection. Several measures of UVA protectiveness have been suggested, but none have been widely accepted or used. Among them are the UVA protection factor (APF), analogous to the SPF.^[198] The principal drawback to APF determination regards the lengthy exposure times required to induce erythema. A second method, the phototoxic protection factor (PPF), shortens exposure times by sensitizing the skin to UVA with oral or topical psoralens. However, the relevance of PPF data to real-world conditions has been challenged. Other UVA protection factors involve measurement of UVA-induced immediate pigment darkening, suppression of UVA-induced sunburn cell formation in psoralen-treated skin, and UVA-induced photocurrent transmission through various media.^[74] In its 1999 *Final Monograph*, the FDA chose not to impose a specific UVA protection factor but allows a sunscreen to make UVA protection claims as long as it contains an approved UVA sunscreensing agent.^[72] However, Rosenstein et al^[200] found that sunscreens with a labeling claim of UVA protection allow transmission of 6% to 52% of UVA.

Substantivity.

The ability of a sunscreen to resist water wash-off is referred to as substantivity. "Water-resistant" sunscreens maintain their SPF after 40 minutes of immersion, "waterproof" sunscreens after 80 minutes. The 1999 FDA *Final Monograph*^[72] changes these labels to "water resistant" and "very water resistant," respectively, effective May 21, 2001. Select sunscreens agents, primarily PABA and PABA-esters, are intrinsically substantive resulting from bonding with stratum corneum proteins. Other sunscreens must be incorporated into vehicles that confer substantivity. By applying sunscreen 15 to 30 minutes before water exposure, substantivity can be increased. Reapplication after swimming or sweating helps ensure protection. Numerous high-SPF, waterproof sunscreens are commercially available ([Table 14-3](#)).

Conditions for testing substantivity are set by the FDA.^[72] Freshwater immersion is required in a pool, whirlpool, or Jacuzzi at 23° to 32° C (73.4° to 89.6° F). This raises some concerns regarding the relevance of substantivity labeling for saltwater ocean enthusiasts, including surfers, sailors, and scuba divers. The MED for skin bathed in salt water is less than the MED for skin bathed in fresh water, and both are lower than the MED of dry skin.^[80] Further, cold, churning water; sand abrasion; and toweling may add to sunscreen loss, begging the question of whether waterproof sunscreens are really surfproof. The concerns over saltwater substantivity, amplified by surfer folklore, have led to an almost cultish market of "surfshop" sunscreens, although few published data indicate whether these are more substantive in a saltwater environment.

Sunscreen Prevention of Chronic Photodamage.

Sunscreens not only prevent sunburns but also mitigate UVR-induced histologic damage, UVR-induced immunosuppression, photoaging, and photocarcinogenesis. Sunscreens reduce UVR-induced DNA damage,^[228] but not entirely.^[38] Reductions are seen in pyrimidine photoproducts in humans,^[38] as well as in UVR-induced p53 mutations and skin cancer in mice.^[3] Sunscreen nearly eliminates the overexpression of p53 in mice after acute^[183] and chronic^[80] UVR exposure. In humans, an SPF 15 sunscreen reduces p53+ cells by 33% after chronic UVR exposure.^[21]

The published effects of sunscreen on immunosuppression are contradictory, largely resulting from the complex relationships of UVR dosing and sensitivity in different experimental models. SPF is not a reliable

measure of a sunscreen's ability to block UVR-induced immunosuppression; two sunscreens with identical SPF values may vary considerably in their immunoprotectant effects. ^[191] Overall, sunscreens mitigate but do not abrogate UVR-induced immunosuppression. In mice, sunscreens prevent UVR-induced depletion of Langerhans' cells, with higher-SPF sunscreens conferring greater protection.^[16] However, earlier studies noted little or no beneficial effect from sunscreens.^[16] A broad-spectrum SPF 15 sunscreen prevents UVR-induced suppression of contact hypersensitivity to dinitrochlorobenzene (DNCB), a potent topical allergen, in humans.^[207] In C3H mice transplanted with NMSC, sunscreen blocks UVR-induced immunosuppression, allowing tumor rejection, again with increased protection with higher SPF values. ^[193] However, in susceptible mice injected with melanoma, sunscreens failed to adequately suppress UVB enhancement of melanoma growth. ^[238] This finding was overinterpreted and misinterpreted to support a peculiar antisunscreen stance. The most appropriate interpretation, however, is that sunscreens by themselves are not sufficient to prevent all of the immunosuppressive sequelae of UVR exposure, and that sunscreen should be used as part of a larger sun-protective strategy, including avoidance and clothing protection.

Sunscreens reduce sunburn cell formation and solar elastosis^[29] in humans. Histologic changes of photoaging in mice are prevented by pretreatment with SPF 15 sunscreen.^[124] In mice exposed to UVB for 10 to 20 weeks, subsequent sunscreen use prevents further photodamage and promotes repair of previous damage, even with continued exposure.^[125] Higher-SPF sunscreens provide increasing protection against UVB-induced wrinkling in mice.^[25] Similarly, histologic and clinical signs of UVA-induced photoaging are prevented by broad-spectrum sunscreens.^[103]

Sunscreen use reduces the formation of precancerous actinic keratoses^[170] ^[223] and promotes the resolution of preexisting lesions.^[223] In a 2-year trial of sunscreens in humans with actinic keratoses, subjects who benefited most had the greatest number of keratoses at enrollment,^[170] underscoring the value of continuing sunscreen use in adults. The daily use of SPF 15 sunscreen in adults reduces the incidence of SCCa but not BCCa.^[96A] Stern et al^[217] estimated that use of an SPF 15 sunscreen from birth until age 18 would reduce the lifetime risk of NMSC by 78%.

Liquid base makeup, even without sunscreen, provides an SPF of approximately 4 because of pigments in the foundation.^[141] For women who use lipstick, the incidence of SCCa is lower than in nonusers or men.^[182]

Sunscreens and Melanoma.

With melanoma incidence and sunscreen sales both rising over several decades, some have suggested that sunscreens cause melanoma. Garland et al^[83] ^[84] have put forth two possible mechanisms:

1. They suggest that sunscreens, by primarily blocking UVB and sunburn, seduce us into longer exposures to UVA in sunlight, and that this increased UVA exposure results in an increased incidence of melanoma.
2. Sunscreens, by blocking UVB, decrease vitamin D levels, which in turn favors melanoma development.

However, most modern sunscreens block substantial amounts of UVA, and recent data suggest that the action spectrum for melanoma in humans is in UVB.^[5] ^[122] In addition, vitamin D levels are not diminished in even the most rigorous sunscreen users.^[150] ^[213] Consequently, the rises in melanoma incidence and sunscreen use generally reflect increased recreational sun exposure.^[169]

Nonetheless, epidemiologic studies have generally failed to demonstrate decreased melanoma incidence with sunscreen use. Paradoxically, several studies have shown an increased risk of melanoma with sunscreen use.^[7] ^[54] In 1996, Donawho and Wolf^[54] reviewed retrospective studies evaluating melanoma risk in sunscreen users. Only one showed a decreased risk,^[110] whereas seven showed an increased risk. A more recent case control study in southern Spain showed a decreased melanoma risk with

sunscreen use.^[196] Confounding all of these studies, however, are the following:

1. Persons at highest risk for melanoma (those with fair complexion who burn easily) are precisely the same persons who use sunscreens.
2. Earlier sunscreen products generally had lower SPFs and narrower spectrums.
3. Since sun exposure in childhood appears most provocative for melanoma, surveying adults about sunscreen habits may be irrelevant and misleading.

Sunscreens and Herpes.

UVB is a potent stimulus for reactivation of herpes labialis in outdoor enthusiasts. Sunscreen, although ineffective at preventing recurrences in skiers on the slopes,^[159] is quite effective in preventing recurrences in the clinical laboratory.^[199] Further studies will hopefully resolve this issue.

Sunscreen Side Effects.

Sunscreen side effects are generally mild and limited. In a prospective study of 603 subjects who applied SPF 15 sunscreen or vehicle control,^[70] 19% in both groups had adverse reactions. Most reactions were irritant in nature, and fewer than 10% were allergic. More than half who developed irritation were atopic. These data support the notion that most contact irritant dermatitis to sunscreens is attributable to excipients. Similarly, allergic reactions to sunscreens are more often due to preservative and fragrances than to active sunscreens agents.^[57] As a consequence, and contrary to popular belief, higher-SPF sunscreens are not more irritating than lower-SPF sunscreens.^[208]

Nonetheless, most sunscreens agents can cause allergic or photoallergic contact dermatitis.^[118] For example, PABA is now rarely used because it sensitizes approximately 4% of exposed subjects. Once sensitized, cross sensitization may occur to thiazides, sulfonamides, benzocaine, and hair dyes containing paraphenylenediamine.^[192]

Paradoxically, sunscreens have become the leading cause of photoallergic contact dermatitis.^[224] Oxybenzone is the most commonly implicated. In 283 cases of photodermatitis, 35 were photoallergic to oxybenzone and 17 to PABA.^[221] In a separate study of 108 patients with photodermatitis, 4 were photoallergic to oxybenzone and 4 to other sunscreens agents.^[224]

Stinging or burning without accompanying erythema, scaling, or dermatitis is common, especially in periocular areas and particularly in patients with rosacea, although addition of skin "protectants" (dimethicone or cyclomethicone) to the sunscreen vehicle can mitigate this.^[171] Certain vehicles, such as alcoholic gels, may be more stinging. Even when periocular application is avoided, perspiration, water immersion, and rubbing may cause sunscreen to migrate, producing symptoms.

Comedogenicity is primarily related to ingredients in the vehicle base. Certain common excipients (almond oil, cocoa butter, isopropyl myristate, isopropyl palmitate, and olive oil) are possible comedogens.

TiO₂ and ZnO can generate reactive molecular species, called free radicals, with sun exposure.^[55] TiO₂ is more photoactive than is ZnO.^[163] Electromagnetic radiation with ? less than 412.5 nm has sufficient energy to excite TiO₂ electrons from the valence band to the conduction band.^[127] Photoactivated TiO₂ can damage DNA in vitro.^[107] In vivo, however, it is unlikely that TiO₂ particles penetrate the stratum corneum to reach underlying epidermal cells containing DNA. Transmission electron microscopy fails to demonstrate TiO₂ penetration of the stratum corneum.^[58] Data also demonstrate that ZnO is not absorbed, and Zn levels are unchanged after application.^[85] Coating TiO₂ or ZnO with silicone halts the photoproduction of reactive species.^[55] Still, some concerns have been raised regarding the use of these agents on broken skin.

Concerns regarding sunscreen-induced vitamin D depletion are generally not warranted. Although regular sunscreen use can decrease cutaneous synthesis of 25-hydroxyvitamin D,^[153] sunscreen users nonetheless maintain normal levels of vitamin D. One hundred thirteen subjects using an SPF 17 sunscreen throughout an Australian summer maintained adequate vitamin D levels,^[150] and 24 subjects using SPF 15 sunscreen for 2 years maintained normal parathyroid hormone levels and normal bone metabolic markers.^[67] Moreover, 8 patients with XP maintained normal vitamin D levels for the 6 years observed, despite rigorous photoprotection with sunscreens, clothing, and sun avoidance.^[213] Still, vitamin D supplementation should be considered for elderly patients who may have inadequate vitamin D dietary intake and who are especially at risk for osteopenia and fractures.^[94]

Clothing Protection

Clothing is a crucial part of sun protection, providing substantive coverage to broad surface areas. However, clothing varies considerably in its ability to block UVR. Robson and Diffey^[195] determined an SPF for 60 different clothing fabrics, ranging from 2 (polyester blouse) to 1000 (cotton twill jean). The single most important factor in determining SPF is the tightness of the weave,^[89] ^[144] ^[195] then the actual fabric. An extreme example of this is Lycra, which blocks nearly 100% of UVR when lax and only 2% when maximally stretched.^[144] Other determinants include wetness and color. Dry, dark fabrics have a higher SPF than otherwise identical wet, white fabrics.^[89] A typical dry, white cotton T-shirt has an SPF of 5 to 9.

Accumulating data show that clothing prevents chronic photodamage. In European children, clothing coverage is associated with fewer nevi.^[10] Blue denim reduces UVR-induced p53+ cells twice as effectively as an SPF 15 sunscreen.^[21] Denim greatly

reduces the formation of skin cancers in patients with XP.^[19]

Standardized testing of clothing fabrics has produced a new measure, the ultraviolet protection factor (UPF), analogous to the SPF for sunscreens. A collimated UVR source is passed through flat, tensionless, fabric, with resultant transmission measured by a spectroradiometer or broad-band sensor.^[89] ^[195] ^[249] The resultant UPF, however, is generally much lower than actual use values, since natural sunlight is scattered and reflected to a far greater extent than a collimated beam. ^[187]

In the United States, sun-protective clothing is regulated as a medical device ([Figure 14-4](#)). Several manufacturing strategies are used to achieve high SPFs. One approved product, Solumbra, is made of tightly woven nylon with an SPF of 30+. In hairless mice, this fabric is significantly better than cotton in reducing the formation of UVR-induced SCCa.^[157] By contrast, Solarknit uses chemically treated cotton and cotton-synthetic blends to achieve an SPF of 30+. Rayosan, a UVR-absorbing agent, bonds to various fabrics, increasing their SPF by up to 300%, and lasts through several washings.^[144] A new, unique chemical UVR protectant, Tinosorb FD, may be incorporated into detergents, increasing the SPF of clothing with each wash.

Ladies' hosiery provides a surprisingly low SPF; black hose has an SPF of 1.5 to 3.0 and beige hose has an SPF less than 2.^[209] Perhaps this explains in part why skin cancers are more common on the lower legs of women than on those of men.

Hats are also protective, with protection varying as a function of brim diameter and wearing style. Small-brimmed (<2.5 cm) hats adequately protect the forehead and upper nose; medium-brimmed (2.5 to 7.5 cm) and wide-brimmed (>7.5 cm) hats protect increasing proportions of the nose, cheeks, chin, and neck,^[52] with large-brimmed hats providing an equivalent SPF of 7 for the nose, 3 for the cheeks, and 2 for the chin. Baseball-style caps are especially useful as a part of an overall sun-protective strategy in children. Using hats to protect the forehead and periocular areas, sunscreen application may be limited to areas below the cheekbones, mitigating the risk of stinging near the eyes.

Glasses, contact lenses, and sunglasses protect the corneas from most UVB and variable amounts of UVA.^[201] Surprisingly, price is unrelated to protection.^[2] A complete discussion is contained in [Chapter 22](#) .

Sun Avoidance

An indoor lifestyle is protective but undesirable for most persons. More practical is the avoidance of excessive midday sun, from 10 AM to 3 PM, significantly reducing UVB exposure.^[144] Shade provides variable and often lesser protection than generally assumed. In one study, shade beneath leafy trees provided an SPF less

Figure 14-4 Photoprotective clothing. **A**, Solumbra hat, shirt, and pants. **B**, Long-sleeved 100% cotton Solarknit T-shirt. (**A** courtesy Sun Precautions, Inc.; **B** courtesy SunGrubbies.com.)

than 4.^[179] Shade cloths allow significantly more UVB exposure than clothing of the same fabrics, largely because of atmospheric scattering and surface reflection.^[239]

Automobile windshields typically block UVB and some UVA, whereas side windows block only UVB. This may explain why photodamage is more prominent on the left side of the face in Americans (and on the right side in Australians) who drive a lot.^[56] Transparent plastic films, meeting legal requirements in all 50 states, can be applied to block more than 99% of UVR (Llumar UV Shield, CPFilms, Martinsville, Va.).

Sunless Tanning

Bronzers.

Most artificial tanners and bronzers contain dihydroxyacetone (DHA, or $C_3H_6O_3$). DHA reacts with amino groups of keratin proteins via the Maillard reaction to form brown pigmented products known as melanoidins.^[140] With DHA, bronzing can occur in as little as 1 hour. Often, however, it requires multiple applications to achieve the desired depth of color. Maintaining this bronzed look requires reapplication every few days as the stained stratum corneum is shed from the skin surface. The depth of color is related to the thickness of the stratum corneum and the amount and frequency of application.^[141] Frequent cosmetic complaints with DHA include difficulty in obtaining an "even" tan and yellowing of the palms.

DHA + lawsone (a henna dye) is a sunscreensing agent. However, DHA alone is an inadequate sunscreen. It absorbs no UVB; rather, DHA absorbs higher-wavelength UVA I and lower-wavelength visible light,^[75] making it useful in select photosensitivity disorders, such as porphyrias and polymorphous light eruption. Some commercial bronzing products now contain sunscreen in addition to DHA. However, although the artificial tan in these combination products lasts for days, photoprotection lasts for only hours. Effective May 22, 2000, the FDA *Final Monograph* requires that bronzers without sunscreens display a warning that they do not protect against sunburn.

Certain other products to promote indoor tanning have been used, but few are safe and effective. Tan accelerators, containing melanin precursors such as tyrosine, have no discernible benefit.^[114] Sunscreen preparations containing psoralens, most commonly 5-methoxypsoralen (oil of bergamot), are available in Europe. Although these stimulate melanin synthesis, they are tumorigenic in mice.^[41] Psoriasis patients treated with

psoralen + UVA (PUVA) have a higher incidence of SCCa^[215] and, with prolonged use, melanoma.^[216] Users of psoralen-containing sunscreen have an increased risk of subsequent melanoma.^[7] Oral carotenoids, especially canthaxanthin, have been promoted as tanning pills but are potentially toxic and, consequently, not approved in the United States.

Tanning Salons.

Although precise data are lacking, approximately 25 million North Americans, many of them adolescents, use tanning salons each year.^[220] In a survey of high school students in St. Paul, Minnesota, 34% admitted to using tanning salons at least four times in the previous year.^[174] Until 1980, most sunlamps

emitted mostly UVB.^[7] Now tanning salons utilize high-output UVA tanning beds and market their services as a way to tan without burning with a subtle but incorrect message that such tans are safe. However, chronic suberythral UVA contributes to photoaging, immunosuppression, and carcinogenesis. In addition, there is significant variation in the radiation output of tanning beds. In a study of 50 tanning beds in England,^[241] UVA outputs varied by a factor of 3 and UVB output varied by a factor of 60. Typically, tanning bed outputs are contaminated with 2% to 10% UVB,^[229] more than the average UVB content of natural sunlight. In 38 Scottish tanning units, 10 minutes of exposure yielded the same carcinogenic risk as 30 minutes of peak summer sun at the same latitude.^[167]

Tanning bed exposure for 15 to 20 minutes induces DNA damage in fibroblasts.^[240] Several case-control studies document a positive association between tanning bed use and the later development of melanoma.^[6] ^[230] ^[237] In a Swedish study of 400 patients and 640 controls, persons who used sunbeds or sunlamps before age 30 had a 7.7-fold increased risk of melanoma.^[237] In 420 patients from Germany, France, and Belgium, melanoma risks increased 8.97-fold when sunlamps or sunbeds were used for tanning.^[6]

Ironically, UVA tans are less effective than natural tans in conferring protection against subsequent sunburn.^[117] In addition, maintenance of a yearlong tan provides no protection against subsequent melanoma development.^[110] Too often, tanning salons ignore photosensitizing risks in their patrons.^[36] Sadly, the damage from tanning salons is insidious. Public awareness and governmental regulation need to be heightened.

Melanin and Thymine Dimers.

Cyclobutane T-T dimers, produced by the action of UVR on skin, stimulate melanin synthesis and subsequent pigmentation.^[91] Eller et al^[60] exposed melanocyte cultures to synthetic T-T dimers and noted twofold to threefold increases in tyrosinase messenger ribonucleic acid (mRNA) and sevenfold increases in melanin production. Topical

application to guinea pigs increases pigmentation. This raises the question of whether induction of protective pigmentation in humans might be possible with T-T dimers, whether it is possible to induce a safe tan.

Unique Photoprotectants

Systemic Sunscreens.

Safe and effective oral sunscreens remain elusive. Clearly, these would have an advantage in convenience, coverage, and substantivity. Several oral agents have been evaluated, but none has a favorable risk/benefit ratio in normal individuals, although a few are used in patients with photosensitivity disorders. Betacarotene is helpful in erythropoietic protoporphyria, chloroquine in lupus erythematosus, and psoralens in polymorphous light eruption.

Antioxidants.

UVR exposure results in reactive oxygen species that contribute to DNA damage^[181] and the peroxidative destruction of membrane lipids.^[113] These effects contribute to DNA structural abnormalities, inflammation, and immune alterations. Protecting the skin from reactive species are various natural antioxidants (vitamins A, C, and E; reduced glutathione; urocanic acid; melanin) and enzymatic systems (catalase, superoxide dismutase).^[113] However, chronic exposure to UVR depletes the skin of these antioxidants.^[147]

Application of antioxidants before UVR exposure delays skin damage in hairless mice.^[24] Select forms of vitamin E, especially tocopherol sorbate, diminish photoinduced free radicals and skin wrinkling in mice.^[115] Topical application of vitamins C and E provide protection against the histopathologic changes of photodamage in swine skin.^[48] In this animal system, sunscreen plus vitamins C and E provide more protection than sunscreen alone.^[48] Although vitamin C does not act as a sunscreen—it does not absorb UVR—it protects against erythema and sunburn cell formation by quenching free radicals that are at least partially causative.^[47] Interestingly, the beneficial effect of topical vitamin C in swine skin persists for 72 hours after application, suggesting a potential strategy for longer-term photoprotection.

Topical antioxidants seem more effective than oral antioxidants in preventing photodamage. Orally, 2 g of vitamin C combined with 1000 IU of vitamin E for 8 days increases the MED only modestly.^[59] There are some concerns, however, about the routine use of topical antioxidants. For example, vitamin E may provoke contact sensitization and serve as a tumor promoter.^[162] Antioxidants might interfere with the normal functioning of p53 protein to produce apoptosis of photodamaged keratinocytes via oxidative enzymes.

Repair Enzyme: T4N5.

Recently there has been considerable interest in postexposure therapy for sunburn with

topical application of a DNA repair enzyme, T4 endonuclease V (T4N5). Applied in liposomes, it localizes in the epidermis and appendages,^[243] enhancing repair of UVR-induced DNA damage in mice and humans.^[242] T4N5 prevents UVR-induced immunosuppression^[134] and reduces UVR-induced skin cancer in mice.^[244] With these qualities, T4N5 may serve in the future as a "morning-after" cream.

PHOTOSENSITIVITY DISORDERS

Endogenous Photosensitivity Disorders

Sun protection is especially important for persons with endogenous photosensitizing disorders, persons who take photosensitizing medications ([Box 14-3](#)) and persons exposed to topical photosensitizers ([Box 14-4](#)). The most common endogenous photodermatosis is polymorphous

378

light eruption (PLE), affecting 10% to 14% of whites, predominantly females under age 30. Clinically this presents with pruritus, erythema, macules, papules, or vesicles on sun-exposed skin, arising 1 to 2 days after exposure and resolving spontaneously over the next 7 to 10 days. It is most common with initial sun exposures in spring or early summer; "hardening" of the skin may occur with subsequent exposures. The action spectrum is unclear, although it is most commonly 290 to 365 nm.^[74] Sunscreens are only sometimes helpful, although a broad-spectrum sunscreen containing padimate O and avobenzone was quite effective in one study.^[76] Sun avoidance and protective clothing are valuable. PUVA, oral antimalarials, and betacarotene have also been used with varying success.

Lupus erythematosus may be exacerbated by sunlight. Although UVB is typically causative, UVA can contribute in some patients. Consequently, broad-spectrum sunscreens, combined with sun avoidance and clothing protection, are most appropriate. A broad-spectrum sunscreen containing padimate O and avobenzone diminished the clinical severity in a 4-week study.^[44] Systemic antimalarials may also be used in more serious cases.

Porphyrias are due to inherited abnormalities in heme synthesis. Clinical manifestations vary with the genetic subtype, but photosensitivity is common to this group of disorders. Typically, the action spectrum is in the Soret band, 400 to 410 nm. Consequently, sunscreens other than "physical" blockers are generally inadequate,

although topical DHA and oral beta carotene may be useful adjuncts to sun avoidance and protective clothing.

Chronic actinic dermatitis presents as persistent macules and plaques, often infiltrated and lichenified, in chronically sun-exposed sites on older men. These patients may demonstrate dermatitic flares on involved areas with even modest photoexposure to UVR and shorter wavelength visible light. Histologically, the disorder can demonstrate progression from dermatitis to T cell lymphoma. Broad-spectrum sunscreens, sun avoidance, and clothing protection, including brimmed hats, are essential. For advanced cases, therapy with azathioprine, cyclosporine, PUVA, and retinoids has been used.

Persons with persistent light reaction (PLR) display a peculiar and persistent overreaction to sun from a prior topical photoallergy. Musk ambrette, found in many perfumes, has been reported to provoke PLR.^[192] UVB is most often causative, although UVA may be involved as well. Broad-spectrum sunscreens, sun avoidance, and clothing protection provide appropriate prophylaxis.

For disorders in which melanocytes are defective or absent, such as albinism and vitiligo, and disorders in which DNA repair mechanisms are deficient, such as xeroderma pigmentosum, the protective triad of sunscreens, sun avoidance, and clothing protection is required.

Phototoxicity

Most oral photodrug eruptions are phototoxic, clinically presenting as exaggerated

sunburn on exposed skin. Typically, there are sharp "cutoffs" at the V of the neck and short-sleeve line. Less commonly, there may be photoonycholysis, in which the distal fingernails separate from their underlying beds. Photodrug eruptions are usually triggered by UVA. The most common offending drugs are listed in [Box 14-3](#).

Topical photosensitizers may cause phototoxicity, photoallergy, or both. Phototoxicity results in an exaggerated sunburn, typically followed by postinflammatory pigmentation. Phototoxicity is nonimmunologic. The action spectrum for most topical phototoxic sensitizers is in UVR.

A surprisingly large number of plants contain photosensitizers that can produce phototoxic reactions in exposed human skin (see [Box 14-4](#)), resulting in a condition known as phytophotodermatitis. The most common chemical precipitants are furocoumarins, especially psoralens found in limes, lemons, and certain other plants. Phytophotodermatitis is common in farmworkers, bartenders, cannery packers, and vacationers to sunny climates. Oil of bergamot, containing 5-methoxypsoralen, is a frequent cause of phototoxicity in perfumes (berloque dermatitis). Streaks of erythema and subsequent pigmentation on exposed skin of the face, neck, and wrists typify this eruption. Meadow-grass dermatitis in hikers is another example of phytophotodermatitis. Various common weeds, including meadow parsnip, contain furocoumarins, causing whiplike erythematous streaks and pigment on skin after exposure to sunlight.

Psoralens have been incorporated into sunscreens in Europe to promote tanning, although their use is associated with increasing risks of burns and carcinogenicity.^[41] Psoralens, in combination with UVA (PUVA), are used therapeutically for psoriasis and select other dermatoses.

Photoallergy

Although phototoxic reactions may occur in anyone, photoallergic reactions occur only in previously sensitized individuals. Photoallergic reactions are uncommon. They are typically provoked by the interaction of UVA on a topical proallergen, resulting in contact dermatitis within 48 hours. Unlike phototoxic reactions, which are limited to exposed skin, photoallergic reactions can spread to sun-protected adjacent sites. Paradoxically, sunscreens are the current leading cause of photoallergy.^[51]^[112] In the 1970s, a fragrance, 6-methyl-coumarin, added to a suntanning product was responsible for a number of cases of photoallergy.^[192] In the 1960s, there was a virtual epidemic of photoallergic reactions resulting from antibacterial salicylanilides in soaps.^[192] Prevention requires excellent UVA protection, including broad-spectrum sunscreens.

CHANGING ATTITUDES TOWARD PHOTOPROTECTION

In the twentieth century, a tan has become desirable, equated with health, wealth, and stylishness. Characterizing the temper of the times is Coco Chanel's pronouncement in 1929 that "A golden tan is the index of chic." Sadly, this attitude led to dangerous behaviors, resulting in an epidemic of skin cancer.

Several studies document current attitudes toward photoprotection. In a study of Connecticut beachgoers, 70% were there to get or maintain a tan.^[252] College students questioned in North Carolina rarely, if ever, used sunscreens.^[227] In a U.S. study of 2459 Caucasians, 59% admitted to sunbathing and 25% to sunbathing more than 10 times in the preceding year.^[128] Among spring skiers, only two thirds used sunscreens, and, of those, one third were sunburned at the time of the survey.^[155] A survey in Leicester, England, found that half of all children sunburn at least once a year.^[27] Even patients with sun-related problems often do not adopt adequate sun protection habits. One study documented that patients with dysplastic nevus syndrome, who are at higher risk for melanoma, do not avoid sunburning.^[30] Among Israeli patients 1 year after treatment for BCCa, only 49%

wear hats or long sleeves in summer and 62% use less than two bottles of sunscreen per year.^[105]

Sunscreen use correlates with knowledge of the harmful effects of sun exposure and understanding of SPF values.^[22] In a survey of 1001 adults in the United States, only 42% were aware of the term *melanoma*, and only 34% knew it was some type of skin cancer.^[158] Many mistakenly use sunscreens in the belief that sunscreens will promote tanning. Clearly, more education is needed. In Australia, where a significant educational effort is underway, three fourths of adults visiting a family physician report using sunscreens.^[151] Increasingly, Australian fashion magazine models are less tan and feature more hats.^[42]

Photoprotection education needs to begin in childhood. Up to 80% of lifetime sun exposure occurs by age 18,^[217] and childhood exposure may be more significant than lifetime exposure in determining the subsequent risks of BCCa and melanoma. Children who use, or are compelled to use, sunscreens at an early age are more likely to use sunscreens as adolescents.^[15] This requires educating parents. Sadly, parents too often ignore, or are ignorant of, photoprotective measures. On beaches in Galveston, Texas, in midday July, only 42 of 82 parents interviewed applied sunscreen to their children.^[146]

Only a history of prior painful sunburns was correlated with sunscreen use, a finding documented in other studies as well.^[251] Hopefully, physicians can alter parental behavior through education, beginning with the first well-baby visit. In the Galveston study, photoprotection was discussed in only 18% of well-baby checkups. Sun avoidance and clothing protection should be advocated for infants under age 6 months, while sunscreen may be added to the photoprotective regimen for older toddlers and children. Consistent use of sun protection in childhood would not only decrease sunburns but would provide lifelong reductions in photoaging and NMSC.^[217]

Advertisers and the fashion industry continue to glorify tans with darkly tanned models. Even sunscreen advertisements seem to have a dual and medically incompatible message: tan beautifully while protecting your skin. No wonder the public is confused by oxymoronic enticements to a "healthy tan."^[186] Recently, in the United States, there is a glimmer of progress toward photoprotection education in the public media. In a review of models in six popular American fashion magazines, 1983-1993, there is a trend toward lighter tans, more sunscreens, and more sun awareness articles, although men's magazines did not show this trend.^[87]

CONCLUSION

Sun exposure is associated with deleterious sequelae, both acute and chronic. Sun protection significantly mitigates these sequelae. Effective sun-protective strategies include sun avoidance, clothing protection, and sunscreens. Sun protection should begin in infancy and continue throughout life; education of parents and children is key to its success. With the introduction of high-SPF, broad-spectrum, waterproof sunscreens and high-SPF clothing fabrics, the office worker and wilderness enthusiast alike can enjoy the outdoors more safely.

Part 4 - Injuries and Medical Interventions

386

Chapter 15 - Wilderness Injury Prevention

Ariel D. Marks

The feasibility of terrestrial and underwater wilderness exploration and the medical management of related emergencies have changed dramatically as the availability, performance, and distance capabilities of off-road vehicles, watercraft, and vertical-flying, long-range aircraft have allowed access to the most remote and extreme recesses of the planet's environment. Advances in mountain climbing, backpacking, and recreational scuba equipment; affordable cellular telephones; global positioning systems with satellite tracking; computer communications; infrared sensors; radio beacons; and night vision aids have made such exploration safer. Advances in water purification technology, food processing, and preservation techniques extend the potential duration and distance of expeditions. Armed with technologic innovations, novices, children, elders, and persons with disabilities or impaired health now venture into areas once explored only by skilled and experienced wilderness enthusiasts. Accompanying increased access is a rise in the number of associated injuries and fatalities.

CAUSES OF WILDERNESS INJURIES

Contrary to popular belief and media reports, most U.S. wilderness injuries are not due to exotic causes (e.g., wild animal attacks, rock climbing, hang gliding) but occur during common events, such as hiking, swimming, walking, skiing, and driving. Fighting and substance abuse accounted for more than 3 times as many wilderness injuries as did rock climbing,^[23] and purely environment-related activity fatalities (e.g., avalanche, shark attack, volcanic fume inhalation) accounted for less than 4% of all deaths.^[23] Surprisingly, suicide ranked fourth in a field of 12 activities leading to death.

In one study, researchers found that sprains, strains, and soft tissue injuries accounted for 80% of the injuries; 60% of illnesses were due to nonspecific viral illnesses or diarrhea; and 39% of injuries required evacuation. Researchers concluded that wilderness medical efforts should concentrate on wilderness hygiene and management of musculoskeletal injuries and soft tissue wounds.^[14]

MORBIDITY AND MORTALITY STATISTICS

Injury rates in traditional sporting activities are well studied, but wilderness-related injuries are not.^[14] In the United States, no general database tracks the incidence of wilderness-related morbidity and mortality. Thus only a sample of the total number of participants and injury rates can be examined. Data reveal that more than 11 million people participated in backpacking or wilderness camping in 1990. The morbidity and mortality figures from eight national parks in California between 1993 and 1995 reported 1708 injuries and 78 fatalities.^[23]

There are more than 5 million certified scuba (self-contained underwater breathing apparatus) divers in the United States, with approximately 650,000 annual certifications. The Divers Alert Network (DAN) at Duke University Medical Center, Durham, North Carolina, reported approximately 800 serious diving-related injuries and 80 to 90 diving-related fatalities each year between 1990 and 1993.^[10]

From 1990 through 1995 an estimated 32,954 persons were involved in injuries related to personal watercraft. No estimate of total participants has been recorded.^[5]

In western Washington, 40 pediatric wilderness-activity related deaths were recorded between 1987 and 1996.^[26] Ninety percent of the victims were male, and 83% were age 13 to 19 years. The most common cause of death was by drowning (55%), followed by closed head injury (26%). Injuries or mortalities resulted from lack of preparation, lack of training for wilderness activities, and inadequate basic safety equipment; alcohol use and rescue delays were contributing factors. Of note, the presence of adults did not appear to be significant in reducing the incidence of mortality among the pediatric population.

INJURY PREVENTION IN MEDICAL PRACTICE

Relatively few physicians recognize injury as a disease process with predictable patterns based on patient demographics, geographic locations, and temporal variation. Moreover, most physicians do not yet embrace injury prevention as a realistic dynamic of medical practice. Traditional medical training emphasizes intervention over prevention, and it does not often approach injury as a "preventable disease."

Minimizing the risks of wilderness environments and effectively evaluating and treating illnesses and injuries in remote settings constitute the central mission of wilderness medicine. Because wilderness injuries occur in remote settings, distant from usual sources of medical care, injury control is very important. This chapter distinguishes accidents from injuries, presents

387

the principles of wilderness injury prevention, examines equipment designed to protect or limit injury, lists injury prevention practices in wilderness settings, and identifies vehicular safety strategies.

ACCIDENTS VS. INJURIES

Accidents are defined as unpredictable acts of fate or chance events. *Injuries* are defined as corporeal damages resulting from such events.^[28] Injuries are prevented by stopping or reducing the number of accidents causing them. By applying this principle, practitioners of injury prevention estimate that 90% of all injuries are predictable and preventable. For example, by inspecting, testing, and replacing rappelling gear, mountain climbers consciously attempt to prevent accidents related to equipment failure. If equipment-related accidents do occur, mountain climbers then minimize injury by safeguarding their bodies through the use of protective devices, such as helmets, harnesses, and ropes.

Active vs. Passive Injury Prevention Strategies

Injury prevention strategies are either active or passive.^[28] Active injury prevention strategies require wilderness enthusiasts to change their behaviors when exposed to risks.^[33] For example, wilderness enthusiasts must be convinced that wearing seatbelts reduces the risk of injury when riding in off-road vehicles, then must take the action of buckling up every time they ride.

Passive injury prevention strategies require no action. Rollover bars on off-road vehicles are passive injury prevention devices because, unlike seatbelts, they do not rely on the beliefs or behaviors of passengers. Making off-road vehicles safer by equipping them with rollover bars has done more to decrease injuries from accidents than warnings to wear seatbelts.^[29] Another example of passive injury prevention would be to select a campsite well away from steep drops or water hazards to protect children from potential dangers.^[17] Passive injury prevention strategies are generally more likely to decrease injury rates than are active injury prevention strategies.^[19]

PRINCIPLES OF WILDERNESS INJURY PREVENTION

Planning, preparation, and problem anticipation are the three principles of wilderness injury prevention.

Planning

Careful planning builds the foundation for a safe wilderness outing. This multifaceted task includes thoroughly researching all aspects of the wilderness activity or destination. Today, critical and up-to-date information regarding weather, trail conditions, best times to travel, permit requirements, etc., can be easily and readily obtained. Planning includes developing a comprehensive equipment checklist, a realistic activity timeline, acceptable alternate plans, and emergency procedures. A critical determinant for trip planning is weather, but even the most recent detailed forecast can be wrong, so one must be prepared for unexpected weather.

Planning includes identifying and understanding the potential hazards and risks associated with a wilderness activity or destination. For example, the injury most often associated with kayaking is anterior shoulder dislocation caused by the "high brace" maneuver. Knowing this, kayakers can incorporate shoulder strengthening exercises into fitness regimens and practice "low brace" maneuvers that minimize the risk of shoulder dislocation when paddling in white water.

Planning for health and safety includes establishing limitations that directly minimize any known potentials for harm in specific wilderness activities. High-altitude mountain and rock climbers may plan to limit daily ascent rates not only to allow for acclimatization but also to avoid headaches, fatigue, and dizziness—symptoms of acute mountain sickness.^[16]

Preparation

When traveling, many people focus on the logistical aspects of a trip, taking health for granted and assuming standards of health and hygiene similar to those at home. They should be prepared for the worst possible eventuality and expect poor hygiene practices and substandard medical services when traveling to remote locations.

Physical Preparation.

Physical preparation includes maintaining excellent fitness and health in anticipation of the added stress of outdoor activities. Because wilderness activities take place in

remote settings, distant from usual sources of medical care, a much higher level of medical self-sufficiency is required. Reading a book is a far cry from actually performing these physical functions under duress and challenging environmental conditions, so it is a good idea to rehearse hands-on first-aid procedures.

Mental Preparation.

Mental preparation emphasizes being confident about the planned trip. Confidence is based on knowing that you have the skills and experience necessary to handle the situation and not exceeding your limits. Possible evacuation routes and emergency procedures should be established, and you must be aware of each participant's level of comfort with self-treatment and their specific abilities. Determine the location of and distance to known medical care facilities. Notify a friend or neighbor of your departure date, planned length of stay, and anticipated return date and time. Plan your trip, establish priorities, and carry out the plan. Be prepared to take charge in the event of an emergency situation.

Material Preparation.

Material preparation involves acquiring proper equipment, testing and organizing equipment, and having backup equipment should something fail. Have sufficient equipment to survive the night under the worst possible environmental conditions for that time of the year.

The wilderness explorer must have all equipment maintained regularly and inspected carefully before a trip. Have emergency bivouac equipment. Carry equipment (in excess of personal needs) that could be given to a person overcome by sudden illness or injury.

If traveling with partners, review what each person is responsible for bringing. Try to "streamline" the equipment so that it does not get caught on things, will be easier to handle, and will be maneuverable when traveling under windy conditions or in water.

Use battery-powered items that require the same size and type of batteries. Keep a gear checklist to avoid forgetting essential items. Depending on your wilderness activity, essential equipment may include an avalanche beacon, compass, duct tape, emergency blankets, emergency bag, extra clothing, extra food, fire-starter, first-aid kit, flashlight, ground insulation, knife, maps, matches, sunglasses, sunscreen, shelter (e.g., emergency tube tent), survival whistle, water, water disinfection system, and timepiece. If the risk of human immunodeficiency virus (HIV) or hepatitis B is great, carry a small kit containing sterile needles, syringes, intravenous catheters, and supplies for suturing.

Having adequate light on a trail is essential. Headlamps are particularly useful because

they free up the hands.

Problem Anticipation

Discuss and agree on a travel route. Choose a leader, and review each member's capabilities and what equipment and supplies are necessary. Bring adequate protection from environmental and recreational hazards. Be sure to have all the appropriate immunizations. Maintain safe drinking and food hygiene practices. Make sure you have a working knowledge of first aid relevant to the environment at hand.

If using specialized equipment, take a course in its proper use and maintenance. Specialty courses available through retail outlets, clubs, and wilderness organizations prepare and train you for most outdoor activities. For example, a course in avalanche safety will help if you plan to travel through avalanche areas.

INJURY PREVENTION

Scuba Diving and Snorkeling

DAN reported 1132 cases of decompression illness treated in hyperbaric chambers and 104 recreational dive facilities in 1995.^[11] Other data collected by DAN reveal approximately 800 serious scuba diving accidents per year and approximately 80 to 90 annual fatalities.^[10]

Common causes of injury while diving or snorkeling include drowning, barotrauma, environmental exposure, bites, and stings. Unique to diving are arterial gas embolism, decompression sickness, and nitrogen narcosis.

Preventing drowning includes always wearing a buoyancy control device and a quick-release weight belt, as well as not diving or snorkeling under hazardous weather conditions. Diving with a buddy ensures that you will have someone to assist you if a muscle cramp, exhaustion, entanglement, or other adverse situation occurs. Carrying an underwater knife helps in case of entanglement in monofilament fishing line or seaweed. Carrying a whistle, beacon, or other attention-getting device, such as an "emergency sausage" (a flexible plastic tube 6 feet long that can be filled with air), visible or audible from a great distance provides a help signal if ocean currents carry a person far from the point of entry.

Because of higher conductive heat loss in water, divers and snorkelers should wear insulating wet suits or dry suits. This outerwear also protects against scrapes, bites, and stings. Booties can protect the feet when walking along a rocky beach while carrying heavy scuba gear. When immersed for any length of time, the skin of the hands and feet becomes soft and more prone to injury. Gloves and booties guard these areas from cuts caused by rock or coral.

When in an underwater environment, pay attention to marine life that bites or stings. Avoid aggressive interactions with marine organisms because their aggressive behavior is generally made in self-defense.

Decompression sickness is prevented by following dive table guidelines to limit on-gassing of excessive nitrogen. Divers must attend a training course to understand how dive tables operate.

Preventing arterial gas embolism requires that divers breathe continuously when using compressed air. Persons with certain pulmonary contraindications, such as severe

asthma, are generally advised not to dive.

Nitrogen narcosis impairs judgment and can result in disorientation and drowning. Usually occurring at depths exceeding 30 m (100 feet) of salt water, nitrogen narcosis is rapidly reversible by swimming into shallower water. To prevent nitrogen narcosis, avoid diving to depths exceeding 100 feet.

The most common site of barotrauma is the tympanic membrane external to the middle ear space, resulting from inadequate equalization of pressure during descent. Preventing barotrauma is achieved by "equalizing" properly.

Injury prevention behaviors for diving include the following:

1. Breathe continuously. Never hold your breath.
 2. Clear your ears. Do not dive if your sinuses are congested. Do not dive if you have a medical contraindication to diving.
 3. Know how to use and follow the dive tables.
-

389

4. Dive with a buddy. Review underwater and topside communications.
5. Inspect your dive gear regularly.
6. Know your training and physical limitations.
7. Procure air refills from a reputable air station.
8. Get a pre-dive orientation. Learn about the environment and be prepared to abort a dive if conditions are hazardous.
9. Do not use drugs or alcohol before, immediately after, or when diving.
10. Leave your dive plan with a friend or neighbor so that rescue procedures can be initiated if you do not return when expected.

Kayaking, Canoeing, and Rafting

Kayaking, canoeing, and rafting have become the third largest outdoor recreational industry in the United States,^[15] with 76 million people participating in these activities. New equipment designs, such as self-bailing inflatable rafts and lightweight, plastic polymer kayaks, have opened up more remote and difficult waterways for exploration and commercial recreation. The American Canoe Association reports approximately 130 white-water fatalities each year, and the most common contributing factor is failure to wear a personal flotation device (PFD).^[31]

Exposure to cold water stimulates cardiorespiratory reflexes that make it difficult for submersed swimmers to keep their heads above water.^[20] The preferred type of PFD, therefore, when participating in kayaking, canoeing, or rafting, is a vest-type jacket (Coast Guard Type III PFD) that provides heads-up buoyancy. A PFD should fit snugly and not ride up over the head when the user is in the water. Some PFDs include crotch

straps as an added safety feature.

PFDs also provide some protection from hypothermia. Closed-cell foam flotation material also protects the thorax from impact injuries during falls on slippery rocks or when swimming rapids. A PFD can also be used as an improvised splint.

Helmets should also be worn by all white-water enthusiasts to protect against head trauma after capsizing. From 10% to 17% of all kayaking accidents involve head injury.^[21] ^[32] White-water rafting enthusiasts have used polypropylene helmets similar to those used by bicyclists, having foam liners, nylon chin straps, and drainage holes for head protection. The helmet should have a hard outer shell to protect the skull from impact with sharp rocks. The ears should always be covered and protected. Portholes that allow rapid exit of water from the inside of the helmet should be included so that the helmet does not become waterlogged and add to drag when submerged. The chinstrap should be secure and waterproof so that it does not stretch when wet. These brightly colored, highly visible helmets aid in locating an injured individual in the water.

An athlete is 60 times more likely to sustain a dental injury when not wearing a mouth guard.^[25] Mouth guards shield the teeth and protect the lips, cheek, tongue, mandible, neck, temporomandibular joint, and brain.^[34] Presently, three types of mouth guards exist—stock, mouth-formed, and custom models—with costs and protective benefits of each increasing, respectively. The American Dental Association currently "recognizes the preventing value of orofacial protectors and endorses the use of orofacial protectors by all participants in recreational sport activity." This endorsement includes recommendations for water sports, such as water skiing, surfing, and water polo.^[1] ^[15] In the future, this recommendation should be extended to include high-velocity water sports, such as operating a personal watercraft.

Rope should be readily accessible and secured so that it can be rapidly deployed without entanglement. The type of rope used should not absorb water and should stretch somewhat. Rope can be used to rescue a paddler who has fallen out of a vessel or thrown to a paddler who is pinned or broached.

Injury relating to kayaking, canoeing, and rafting commonly occurs when portaging vessels. If proper lifting techniques are not used, portaging a kayak or canoe can cause back strain. Careful attention to using leg muscles rather than those of the lower back can prevent lower back injury. Injuries resulting from poor conditioning, improper stroke technique, muscle overuse, shoulder dislocation, low back strain, tendonitis in the wrist, extensor tenosynovitis of the forearm, muscle strains, and sprains are relatively common. Prevention and correction involve maintaining physical fitness, engaging in a conditioning program, relaxing the grip on the oar, and taping the wrist in a neutral position. Blisters are also common and can be prevented by wearing properly fitted gloves. Warm-up exercises, including stretching, are beneficial.

All paddlers should watch where they step to avoid ankle sprains and fractures, especially when stepping out of vessels onto wet rocks. "Reef walkers" or neoprene booties with antiskid soles are helpful.

Enthusiasts should also apply sunscreen often, carry a first-aid kit, and avoid drinking river water and eating unrecognizable plants. They should watch the weather and modify activities accordingly. If paddling in cold water, paddlers should dress appropriately, wearing wet suits, gloves, booties, and woolen pullover hats to avoid hypothermia in case of capsizing. They should also avoid ingesting alcohol or illicit drugs, since these intoxicants impair judgment, balance, and heat production. (Alcohol is believed to be a contributing factor in as many as half of all drowning deaths.) Paddlers should apply insect repellent and keep tetanus immunization current.

Backpacking and Hiking

A common injury that occurs during hiking and backpacking is low back pain. It is frequently caused by carrying

390

excessive or poorly distributed loads. Several improvements in backpack design have been developed to prevent low back injury.

The two basic types of backpacks are those with external frames and those with internal frames. The frames are designed to transfer the weight of the backpack from the shoulders and back to the hips and legs. An ideal backpack weight distribution is 20% on the shoulders and 80% on the hips. This distribution lowers the body's center of gravity, making it more stable ([Figure 15-1](#)).

Backpacks with External Frames.

An external frame pack allows a larger amount of weight to be carried, using a ladderlike frame made of aluminum or plastic. A hip belt and shoulder strap are attached to the frame, usually with clevis pins and split rings. Some backpacks are adjustable to fit the length of the spine. Hikers should look for lumbar padding, a conical hip belt, recurved shoulder pads/straps, and a chest compression strap that improves distribution of weight and increases comfort.

A backpack with an external frame allows air space between the back and the pack, reducing sweating. With an external frame pack, the weight is carried

Figure 15-1 To prevent injuries, a backpacker should limit the contents of a backpack to 25% of body weight. (Courtesy Jandd Mountaineering.)

higher in the pack, allowing for a more upright posture. However, the pack frequently wobbles side to side during walking.

Backpacks with Internal Frames.

The internal frame backpack conforms more to the body, allowing for better balance, and can be worn comfortably for longer periods of time. However, back perspiration can be a problem. Since the bulk of the weight is carried lower, one must bend more, which in turn alters proper posture and can predispose to low back strain. Compression straps can compact the contents of the pack, keeping it more stable.

Backpack Considerations.

Backpack size is an important consideration for injury prevention. Hikers need to be sure that all the equipment necessary for the duration of the trip can be carried without putting excessive strain on the shoulders and back muscles. The amount of weight that can be carried in a backpack is determined by the size, body weight, and fitness level of the backpacker. For multiday trips, one should attempt to limit the contents to 25% of body weight. When loading the backpack, 50% of the weight should be in the upper third of the pack. To accomplish this distribution, lighter and bulkier items should be packed in the bottom and heavier items should be packed in the top. The heaviest items should be packed on the top, closest to the frame.

Backpack Lifting.

The least injurious method for donning a backpack is to have someone hold and stabilize the pack while the carrier slips his or her arms into the shoulder straps. If a second person is not available, the backpacker can lift and rest the backpack on an object that is waist high and slip into it.

If a backpack must be donned from the ground, it is not recommended that the carrier sit down, slip into the backpack, and stand up. Rather, he or she should lift the backpack onto a bent knee and slide one arm through the shoulder strap. After adjusting the strap so that the backpack rests on the shoulder, the carrier should lean forward and rotate the body slightly, allowing the free arm to slide through the other shoulder strap. While still leaning forward with bent knees, the backpacker adjusts the

second strap and hip belt.

To prevent low back strain, a backpacker should use the knees rather than the lower back to bend. Good abdominal muscle tone helps limit back strain.

Backpacks and Children.

Backpacks that carry small children can be dangerous. Risks include strangulation if a child becomes entangled in the carrier's harness and head and body injury if a child wiggles out of the harness and falls or is struck by an overhead obstruction, such as a tree branch. Be certain to use a well-structured

carrier with a design that restrains the ambitious, mobile child.

Hiking Footwear.

Blisters are a common backpacking and hiking injury, but careful selection of shoes and socks limits this problem. The purposes of footwear are protection, cushioning, support, and grip. Selecting, fitting, breaking in, and caring for footwear help them last a long time and maximize comfort. Size footwear in the afternoon, since feet swell during the day. Also, try footwear on both feet before purchase. If one foot is larger than the other, select the size where the larger foot has the best fit.

Size your feet using a Brannock device, which measures not only the length and width of a foot but also the ball-to-heel (arch) length. When selecting footwear, check the length first. If your toes touch the end, leaving no space for the heel, the shoe is too small. When you slide your foot forward into an unlaced shoe or boot, you should be able to insert a finger between the footwear and your heel. If you can't do this, the footwear is too short and will bruise your toes, especially on long downhill walks. When hiking, wear shoes that extend above the ankle to reduce the likelihood of an ankle sprain.

Footwear should fit comfortably with moderate tension on the laces so that they can be tightened or loosened as needed. To avoid blister formation, seams should not rub against any part of the foot. The tongue of the footwear should be aligned and laced properly; otherwise the tongue can slide into a bad position and cause blisters. Ankles should be comfortably supported by stiff heel counters or heel cups and should not slip with toe flexion, causing blisters because of repetitive rubbing. With the foot on the ground, there should be no more than 6 to 12 mm of heel lift.

The soles are protected with layers of cushioning thick enough to prevent bruising but pliable enough to allow natural heel-to-toe flexion. Thick soles insulate against cold and heat. The tread provides grip. Support comes from a fit that stops the foot from slipping

inside the shoe but that is not so tight that it prevents the foot from expanding when it swells.

Socks.

Many boots feature sock liners or booties made from vapor-permeable membranes, such as Gore-Tex and Sympatex, hung between the lining and outer aspect of the boot. These make boots waterproof when they are new, but most boots leak after a few weeks in wet weather. In addition, lack of breathability means that water vapor cannot penetrate the barrier, resulting in hot, sweaty feet. Socks cushion the feet, preventing abrasion. They also wick away moisture, keeping the feet at the right temperature and humidity. New synthetic materials, such as polypropylene, Capilene, and Thermax, wick away moisture quickly, making them good choices for an inner layer.^[13] Pile or fleece socks do not wick away moisture very well.

Wool offers many advantages. It is warm in winter, cool in summer, absorbs and wicks away sweat, and keeps the feet warm when wet. Furthermore, during long trips, it rinses well in cold stream water, can be worn for days at a time without wear, and does not mat down like cotton socks with terry loop liners.

It is worth the time to check socks for loose threads, knots, or harsh stitching that might cause blisters or sore spots. Flat seams at the toes are important. Bulky seams rub and cause blisters. Consider wearing one pair of fairly heavy socks (rag wool) and one pair of light liner socks next to your skin. With one sock, the boot and the outer sock tend to move as a unit. They rub against the heel and the top of the toes at the metatarsal heads. A lightweight liner sock tends to cling to the foot. As the boot moves, the socks rub against each other, not against foot skin.

Foot Hygiene.

Keep toenails short and cut them square. Keep feet dry to avoid skin softening. Immediately stop walking and attend to the first sign of a sore or "hotspot" to prevent further injury. Protect any reddened areas with moleskin, tape, or molefoam. Be sure that the covering extends beyond the reddened area.

Avoid getting blisters. Once formed, they must be protected to prevent rupture and infection. If a blister has already formed, relieve external pressure by applying a doughnut-shaped piece of molefoam. A blister should not be unroofed unless absolutely necessary. If this is required, wash the area with soap and water and insert a decontaminated needle ("sterilized" by a flame or with rubbing alcohol) into the edge of the blister. Gently press out the fluid. Apply a sterile dressing. If the blister has already broken, cleanse and cover the area. Topical antiseptic ointment may be beneficial.

Exposure.

Overexposure caused by inadequate skin covering results in several problems. An essential area to protect is the head. From preventing heat loss to blocking ultraviolet

(UV) exposure, hats are an integral component of the wilderness wardrobe. The uncovered head is a source of considerable heat loss, since it can dissipate up to 70% of total body heat production.^[4] Because there is no substantial decrease in blood flow to the head in cold conditions, hats should be worn to stay warm. Hats large enough to cover the ears, face masks, and neck warmers (gaiters) are popular among skiers. The preferred type of hat for wilderness expeditions is the stocking type.

In warm climates, hats with visors and brims provide considerable protection from UV exposure to the face, nose, and ears. Hats also provide some degree of insect protection, especially if sprayed with insect repellent, and reduce radiant heat exposure. They repel

light rain, keep leaves and twigs out of the hair, and hold a mosquito net in place. In addition, when worn in the jungle where larger arboreal animals reside, hats can protect the head and hair from airborne droppings. Hats should be lightweight, light colored, and preferably vented. It is helpful to have a retention neck or chin strap for windy days and to have snaps to fasten the brim up when traveling on a trail. Hats do not need to be waterproof. They should be loose fitting.

Eye protection is also essential. Sunglasses provide protection against injury caused by UV exposure, which can contribute to ocular complications, including photokeratitis (snowblindness), cataracts, pterygium, and macular degeneration ([Figure 15-2](#)).

The major variables to consider in selecting sunglasses are light transmission, coloration, polarization, and lens construction. Lenses for wilderness exposure should absorb 99% of UV radiation. If used in high solar reflection areas, lenses should also absorb 85% to 95% of visible light.

The preferred lens is made of glass or polycarbonate. Polycarbonate lenses are lightweight, scratch resistant, and shatterproof (a major consideration if impact is possible). Plastic lenses scratch easily and are generally not recommended.

When wearing dark lenses in a bright environment, the pupils dilate and allow more harmful radiation exposure to the retina. Photochromic lenses (those that darken with increasing sun intensity) are potentially dangerous when driving. If fully darkened in bright sunlight, photochromic lenses limit vision considerably when traveling through a tunnel. It is preferable to have a less dark pair of sunglasses for driving. Amber lenses or rose lenses enhance contrast. Polarization is particularly useful in reducing reflective solar glare from water, snow, and ice. UV-absorbing contact lenses do not provide adequate protection from UV radiation and should not be used as substitutes for sunglasses. Sunglasses are still needed to cover the entire eye area, including eyelids.

Choose sunglasses that are close-fitting and have larger lenses, or are of the wraparound variety to prevent UV rays from entering from the side. Children, including

infants, should wear sunglasses. Glasses should be secured with some type of strap. Commercial lens "defoggers" are available, although any surfactant, such as soap, rubbed or washed onto lenses will have the desired defogging effect.

In severe blizzard conditions, goggles improve visibility. The goggle's foam mesh vents help reduce fogging. A wide elasticized headband helps keep them in place. For protection from impacts and foreign bodies, safety glasses or goggles should be worn when traveling on bicycles, horses, or any off-road motorized vehicle without a windshield.

Figure 15-2 Sun protection for the eyes is critical in outdoor activities to prevent premature cataracts, photokeratitis, and other ocular injuries. (Courtesy Black Diamond Equipment.)

Hiking Accessories.

A useful injury prevention adjunct is a hiking pole or staff to provide stability on rough ground and diminish impact on knees and ankles. A staff can support a good walking rhythm and prevent imbalance when carrying a heavy load. Hiking poles allow for probing and identifying hidden rocks and deep spots and can hold back bushes, barbed wire, stinging plants, and other trail obstructions. They can even be used to fend off aggressive dogs or wildlife.

Using two staffs or poles takes the load off the legs and hips and redistributes part of the weight to the upper body musculature. On a steep area, hiking poles enable tripodding, or having three points of contact with the ground.

Injury Prevention for the Genitourinary Tract.

To prevent genitourinary infections during wilderness outings, enthusiasts should maintain superb genital hygiene and assure adequate hydration. To counteract the tendency to bathe less frequently during an extended outing, a shower should be part of the daily schedule ([Figure 15-3](#)).

Infections and irritation of the genitourinary tract are more common in women than in men, since the female urethra is shorter, leaving the bladder more predisposed to colonization by bacteria. Infrequent urination and urethral trauma from vigorous activity or bruising from a bike seat, saddle, or climbing harness are common contributing factors to urinary tract infections.

VAGINITIS.

Vaginitis can occur with increased stress, sweating, or strenuous and vigorous activities, as well as with changes in the environment, including heat and humidity. To avoid

vaginitis, women should keep themselves cool and dry by wearing loose-fitting clothing that maximizes air circulation and minimizes the optimal conditions for bacterial and fungal growth.

393

Figure 15-3 Several new and effective methods of transporting water into the wilderness have been developed. A biking hydration system can help prevent urinary tract infection by facilitating the opportunity for adequate hydration. (Courtesy Jandd Mountaineering.)

Avoid nylon undergarments because they retain humidity. Cotton underwear is preferable.

SANITARY PROTECTION FOR MENSTRUATION.

If menstruating while in the wilderness, women should change their tampons or sanitary napkins just as frequently as at home to avoid infection or toxic shock syndrome. Women who use tampons should make sure their hands are scrupulously clean before insertion. For environmental reasons, tampons with cardboard rather than plastic applicators should be used if wilderness disposal is a possibility.

PERIANAL HYGIENE.

Whenever possible, cleanse the anal area with fresh water. If pruritus ani develops, medicated wipes, such as witch hazel tucks or moisture-blocking ointments, have been shown to be beneficial for some individuals. "Porta-showers" or "sunshowers" are particularly helpful to maintain good anal hygiene. Baby wipes are often quite soothing.

For wilderness excursions, biodegradable toilet paper is recommended. Select toilet paper that is dye and perfume free. Use double zip-lock bags for packing to keep the toilet paper dry and clean. Burning toilet paper creates a fire hazard, so, ideally, it should be packed out. If buried, it should be placed 6 inches from the ground surface and at least 60 m (~200 feet) from any natural water supply. Toilet paper decomposes more rapidly if wet and not buried too deeply.

Trail Safety.

Finding one's way in the wilderness, sometimes in unfavorable and extreme weather conditions; negotiating cliffs, loose scree, uneven and hazardous terrain, including snow, ice, and mud; and facing other hazards, such as wild animals, can be challenging. Do not assume that because a trail is marked that it is safe, clear, and well maintained. Take a switchback route across slopes when possible. Utilize rest areas.

Balance is key to crossing rough terrain. Watch for unstable rocks and boulders. Keep body weight over feet, with knees bent, and do not lean backward. When traveling along scree, do not have anybody traveling directly below or above you because stones can dislodge and fall. If this occurs, shout a warning, but the person below should not look up. For rock climbers, do not climb what you cannot descend.

At altitude, strong winds can make walking impossible. Be prepared to descend early or take an alternate route if weather worsens. It may be necessary to "sit out" bad weather.

When fording rivers and streams, remember that water is very powerful. The use of safety ropes is recommended.

Hammock Safety.

Small, lightweight minihammocks are popular in camping and backpacking. These hammocks have no spreader bars and can be folded easily. The U.S. Consumer Product Safety Commission (CPSC) warns that children can become trapped and strangle on certain minihammocks; two deaths and one nonfatal incident have involved minihammocks or backpacker hammocks. If a hammock is rigged too high off the ground, a child will have difficulty climbing into it and may become trapped or entangled, leading to strangulation. To prevent injuries, install a minihammock near the ground.^[9]

Maps.

Knowing where you are is a key wilderness skill. Carry maps and know how to read them. Always establish entry, check, and exit points on your maps. Even on marked trails, an inadvertent turn can rapidly create confusion and allow you to become lost.

Two types of maps are available—planimetric (two dimensional) and topographic (three dimensional).

Planimetric maps identify features on the ground. Topographic maps provide information about the shape of the ground itself. Topographic maps use contour lines to identify points of equal elevation. The standard United States Geologic Survey 1:24000 maps have contour intervals of 40 feet. More recent Bureau of Land Management maps use a metric 50-m interval. The closer together the contour lines, the steeper the slope.

Global Positioning Devices (see [Chapter 73](#)).

The global positioning system (GPS) is a government-operated system consisting of approximately 28 satellites at 12,000 miles altitude. Each satellite orbits the earth twice a day, emitting continuous signals of time and position. By carrying a GPS receiver on the ground, your position can be triangulated.

Line of sight is required between the receiver and satellite. Therefore position determination may be impossible in dense forests, jungles, or below steep cliffs. Furthermore, electronic GPS receivers are sensitive to mishandling, extremes of temperature, and battery failure. They should be an addition to, and not a replacement for, traditional maps and compasses. Natural references, such as sun position, wind, and topography, can provide useful clues to your position.

Cellular Telephones.

Cellular telephones can provide ready access to the outside world, as well as an additional form of security when traveling in remote locations. They are sensitive to mishandling and have limited battery life. Since signal transmission relay stations are infrequent in the wilderness, there is a real chance of telephone failure.

If emergency assistance is needed during a wilderness activity, dialing 911 can connect you to a service that will assist with wilderness rescue. Calling the local National Park Service office, a search and rescue organization, or even the local sheriff's office may result in an earlier and more efficient rescue response.

Other Emergency Forms of Communication.

The international distress signal (SOS) consists of three short signals, followed by three long signals, and then three short signals, repeated at intervals. This signal can be transmitted with light, sound, or Morse code. Ground-to-air signals can be used with any material visible from the air.

Climbing

Common climbing injuries involve falls, often from great heights. One of the most critical pieces of safety equipment is a helmet, since the head is a major area of potential injury.

Helmet Composition and Fit.

The purpose of a helmet is to absorb the energy of an impact, minimizing or preventing head injury. Generally, crushable, expanded polystyrene foam is used for this purpose. Most helmets now have a hard outer shell to protect the head in a collision with a sharp object. It is prudent to wear a hard-shelled helmet when climbing because falling rocks

can cause significant damage. It is also beneficial to have a visor attached to the helmet to protect the face and eyes.

Helmets should have a snug, but comfortable, fit. Some helmets have varying thicknesses of internal padding to custom fit the helmet to the user. Ideally, helmets should be lightweight and have a buckle that stays securely fastened. No combination of twisting or pulling should remove the helmet from the head or loosen the buckle on the strap ([Figure 15-4](#)).

Additional guidelines for effective helmet wearing practices include the following:

1. Wear the helmet flat atop your head, not tilted back at an angle.
2. Make sure the helmet fits snugly and does not obstruct your field of vision.
3. Make sure the chin strap fits securely and the buckle stays fastened.

Climbing Equipment.

To prevent trauma to the torso when climbing, a harness should be worn. Harnesses secure the wearer's center of gravity to a safety line. If footing is lost, free-fall injuries are abated by the harness and safety line. To be effective, a harness must fit securely and be made of strong material with reinforced stitching. It should be inspected regularly for wear.

A useful accessory if climbing at altitude is an "AvaLung." The AvaLung is worn like a life jacket and can help keep a person alive in an avalanche (see [Chapter 2](#)). A victim buried in snow can breathe for approximately

Figure 15-4 Helmets should be worn by all wilderness enthusiasts involved in activities that might result in head injury. (Courtesy Black Diamond Equipment.)

10 minutes without and up to 1 hour with the AvaLung vest. The additional time is gained by increasing the surface area for air exchange, using the vest as a "breathing membrane" ([Figure 15-5](#)).

Knee guards, elbow guards, and wrist guards are useful protective devices when traveling with heavy packs or on slippery surfaces. Crampons are metal devices that

attach to the outside bottom of footwear to provide traction on ice. Although crampons allow the crossing of ice and hard snow without slipping, walking with them involves a change in gait. Because they have sharp metal serrated edges, stress injury to the medial aspect of the knee can occur unless a wider gait is maintained during walking.

Altitude.

Along with the limitation of oxygen because of reduced partial pressures, a major consideration at altitude is hypothermia. Hypothermia is prevented through proper exposure protection and common sense. Potential hypothermic situations must be managed before they become serious (see [Chapter 6](#)).

Recognize the environmental conditions that lead to hypothermia. Wear appropriate clothing for cold and wet conditions and always wear a hat. Use polypropylene underwear to wick water away from the skin. Wear multiple layers, including but not limited to wool, and a wind and waterproof covering.

Figure 15-5 The AvaLung is a life jacket worn by avalanche victims. It allows them to breathe while buried.

Physical fitness, continuous exercise, high-calorie food intake, and consumption of hot beverages will prevent the onset of mild hypothermia. Avoid exhaustion, panic, and energy-depleting activities. Carry fire-starting materials and some form of improvisation shelter. Pack a VHF radio and know how to use it. Learn to recognize warning signs of hypothermia.

An ice ax is imperative for traversing snow and ice at altitude. A walking staff or ski pole is entirely inadequate for crossing hard-packed snow or ice. On these surfaces, a slip can quickly become an out-of-control fall. Limiting this fall (self-arrest) involves proper use of an ice ax, which can also be used to cut steps into ice.

Boating (see [Chapter 56](#))

The single most useful injury prevention device for boating is the personal flotation device.^[3] A PFD or life jacket should be used when participating in any water-related activity, such as canoeing, kayaking, or jet skiing, but it is not a replacement for knowing how to swim. Brightly colored so that it can be seen at a distance, the PFD is designed to provide the wearer a stable, face-up position in calm water when the head is tilted back. However, most PFDs do not hold up the face of an unconscious wearer, although some newer models assure flotation even with an unconscious user. In rough water, the

wearer's face may often be covered by waves, since the PFD is not designed for extended survival in rough water. The styles that ensure face-up flotation and that are designed for the body habitus and the weight of the user are safest.

PFDs require routine minor maintenance. Check the PFD frequently for rips, tears, and holes. Confirm that the seams, fabric, straps, and hardware are in good working order. If caught in riptides, undertows, or strong currents, ride the current out and work your way back to the shore in the area adjacent to the current where the water is calmer.

Personal Watercraft

The use of personal watercraft (PWC), such as jetskis or waverunners, in water recreation has increased rapidly since 1990. Personal watercraft are less than 4 m (13 feet) in length and designed to be operated by persons sitting, standing, or kneeling on the craft, instead of within the confines of the hull.^[30] These watercraft allow swifter movement and attain faster speeds in less time than larger, motor-drive boats.

From 1990 through 1995, there were an estimated 33,000 injuries associated with PWC use. Injury rates increased fourfold from an estimated 2860 in 1990 to more than 12,000 in 1995. Injuries and deaths to both the watercraft drivers and bystanders occurred disproportionately among the very young or the intoxicated.^[18]

Almost 86% of injured persons were 15 to 44 years of age. The median age was 25 years. Of injured persons,

71% were male. An estimated 7% of the persons injured in the cited report were 14 years old or younger. The rate of injuries related to PWC treated in emergency departments was about 8.5 times higher than the rate of emergency department-treated injuries from motorboats. Kinetic energy is the pathogen of PWC injuries.^[29] Increased speed equals increased crash fatality risk and large increases in death tolls.^[27]

Given the fast speeds that can be achieved with PWCs, training requirements and enforcement may reduce the number of injuries considerably. Parental or adult supervision is recommended for minor children. Right-of-way guidelines currently in place for boat operators, including maintaining safe distances and reduced speeds, should be extended to PWC users. PWCs should not be used where others are swimming or wading. PWCs offer no protection from impact to the driver or the bystander. No federal laws govern the safe conduct of these vehicles, and many injuries involve swimmers and other unprotected water enthusiasts. The impact of a PWC on a swimmer can be equivalent to a pedestrian being hit by a small truck at high speed.

Hunting (see [Chapter 20](#))

Over 35,000 firearm fatalities have occurred in the United States each year since 1989, and it is estimated that there are three nonfatal firearm injuries for each death associated with a firearm.^[2] Hunter safety courses are available in every state and are a prerequisite in most states to obtaining a hunting license. Key recommendations include warning nonhunters of hunting season, limiting hunting to hunting areas, and wearing international orange clothing articles when traveling in areas frequented by hunters. Hunters should always be sure of their target before shooting. A safety harness should be worn when using a tree stand. Care should be taken to use appropriate techniques when cleaning game. Eye protection should always be worn with impact-resistant lenses to prevent injury from ricocheting fragments and shotgun pellets. Ammunition should always be stored separately from guns.

High-frequency hearing loss is common among hunters because of the loud report of the firearm. Earplugs and headsets, although impractical for most hunting situations, can provide good protection for the ears. In most scenarios, a single earplug for the ear closest to the muzzle will protect the ear most likely to be injured.

The greatest potential serious injury from hunting is a gunshot wound. Every effort should be made to ensure that inadvertent misfires do not occur. Most injuries relating to firearms occur during common gun-related activities, such as cleaning and inspection and are therefore self-inflicted. Further studies are needed to evaluate the efficacy of gun safety training courses and to assess the potential role of various gun safety devices, such as trigger locks and loading indicators.

Vehicular Safety

Off-road travel is challenging for both vehicle and driver. Off-road path conditions are usually poor, with deep potholes, large boulders, and mud that limit traction. Because of a lack of clearing and the absence of street lighting, visibility is usually low. There is also the chance of encountering wildlife, which may jump out in front of the vehicle.

Off-road four-wheel-drive vehicles have high centers of gravity to allow for ground clearance so that boulders and rocks do not damage the vehicle's underside. This means that the vehicles are top heavy and prone to tipping, especially when turning corners at high speeds. Care should be taken to travel slowly.

Since most four-wheel-drive vehicles have stiff suspensions (for better maneuverability), always wear a three-point harness and be cognizant of bumping and jarring that can injure the spine. Secure all equipment.

Many off-road vehicles have no air bags or cabs, and many only have lap-belt restraint systems. They often have thin-walled bodies and frames and are not well designed for impact.

Rollover protective structures (ROPS) are essential. These can be enclosed in the cab or unenclosed (resembling one or more exposed rollover bars). ROPS are structural

components attached to vehicles designed to protect the operator from being crushed if the vehicle overturns. Although ROPS offer some degree of protection, passengers must be securely fastened with seat belts so they are not ejected from their seats if the vehicle rolls over. Passengers must remain confined within the space protected by the ROPS.

All-terrain vehicles.

All-terrain vehicles (ATVs) are motorized recreational cycles with four (and sometimes three) large soft tires. These vehicles are designed for off-the-road use on various terrains.

ATVs have become enormously popular, particularly among the young, with approximately 2.5 million vehicles in use. Although ATVs give the appearance of stability, the three-wheeled design is unstable, especially on hard surfaces. Stability is further compromised by a high center of gravity. The hazard is compounded by the fact that all-terrain vehicles can achieve speeds up to 30 to 50 mph. Moreover, their use by youths has sometimes been promoted.^[29] Recent studies by the CPSC showed the risk of injury is 2.5 times higher when children younger than 16 years of age drive ATVs than for drivers 16 to 34 years of age, and 4.5 times higher than for drivers 35 to 54 years of age. Over 2400 deaths associated with three- and four-wheel ATVs occurred from 1982 to 1993.^[8]

The majority of injuries associated with ATVs occur when the driver loses control, the vehicle rolls over, the driver is thrown off the vehicle, or the driver collides with a fixed obstacle. Children are often injured when struck by a fence wire or tree branch while traveling at a high speed. In a recent study of three-wheeled ATVs in Alaska,^[12] risk factors were found to include intoxication with alcohol, excessive speed, lack of proper protective helmet usage, and rider inexperience.

ATVs should only be used in daylight or driven very slowly at night. These vehicles should never be used on unfamiliar terrain or on public roadways. ATVs should not carry more than one person at a time. Riders should always wear helmets, eye protection, and protective clothing, such as gloves and hand guards.

Drivers should always use the buddy system, driving with other ATVs. In case of injury in a remote area, a buddy ATV can go for help.

In 1982 an estimated 12,000 children 14 years of age and younger suffered motorized minibike- and trail-bike-related injuries.^[24]

All-terrain bikes and mountain bikes are a popular form of recreation for wilderness enthusiasts. The rider may be traveling on uneven trails with multiple obstacles, including logs, rocks, and streams. Falls usually cause the rider to lunge forward and

sustain concomitant injury to the face and head. Consequently, riders should wear full-face helmets with chin guards to limit maxillofacial injuries. Other forms of injury prevention gear include gloves and hand, elbow, knee, and shin guards. The rider should also wear eye protection if it is not a part of the helmet.

Snowmobiles.

In New Hampshire, between January 1989 and February 1992, there were 12 fatal and 165 nonfatal snowmobile injuries.^[6] None of the snowmobile drivers who died had taken an off-highway recreational vehicle (OHRV) course. Overall, 76% of the fatal incidents were associated with alcohol use and 67% with excessive speed. Of 165 persons nonfatally injured, 104 (63%) were reported to have been wearing helmets. Helmets were reported to have been worn by 31 (57%) of 54 persons with nonfatal head injuries, compared with four of six persons (67%) with fatal head injuries. In Maine, from fall of 1991 through spring of 1995, 25 (81%) of the 31 who died from snowmobile-related causes were wearing helmets at the time of the incident.^[7] The observation that a large percentage of deaths occurred in persons wearing helmets demonstrates that this behavior modification does not ensure survivability. Other contributing factors, such as excessive speed, alcohol, and lack of other corporeal protection, have significant impact on outcome.

In Alaska, between 1993 and 1994, injury, death, and hospitalization rates were greater for snowmobiles than for on-road motor vehicles.^[22] A total of 26 snowmobile injury deaths were reported. Seven decedents drowned after breaking through ice, and eight were ejected from vehicles. More than half (58%) of the snowmobile injury deaths involved a natural object, such as a boulder, ravine, or river. Of the 17 decedents for whom blood alcohol concentrations were available, 11 (65%) had blood alcohol concentrations greater than or equal to 100 mg/dl. Thus natural obstacles, excessive speed, and alcohol intoxication contribute to the high risk of injury death associated with snowmobile use.

Chapter 16 - Principles of Pain Management

Bryan L. Frank

Safe and effective pain management in the wilderness is subject to the effects of remote location, extrication considerations, and concomitant illness or injury on physical modalities, anesthetics, analgesics, and other pharmacologic agents. More adventurers with chronic pain syndromes are traveling into remote settings. World travelers are often exposed to various indigenous therapies for conditions, and many of these therapies are increasingly available to American wilderness travelers as "complementary and alternative" medicine. These therapies can be integrated with conventional medical therapies and may be superior to conventional approaches in treating acute or chronic pain in the wilderness.

The old adage "nobody ever died of pain" may be very inappropriate in a wilderness setting. Effective pain management can dramatically enhance a rescue effort and minimize morbidity and mortality. Pain management advances over the last decade that have dramatically altered care in hospitals and clinics also impact care in the wilderness.

PATHOPHYSIOLOGY OF PAIN

Perception of pain is critical for the survival of most organisms. Detection of tissue injury leads to a nociceptive response that initiates protective behavior. The simple response seen with acute injury becomes complex in chronic pain syndromes, where the original insult is long past. Numerous clinical pain entities have been recognized, including acute nociceptive pain (somatic and visceral), postoperative pain (posttraumatic), neuropathic pain, terminal pain, chronic pain, and psychogenic pain. Acute nociceptive pain and chronic pain can generally be managed effectively by the wilderness physician who is informed and prepared.

Acute Nociceptive Pain

Designed to protect us from danger, acute pain is critical to human survival and well-being. In acute trauma, the human peripheral nervous system receptors detect noxious events, peripheral transmission relays information centrally for processing, and the response apparatus is triggered.^[51]

Free nerve endings, commonly called *polymodal nociceptors*, respond to mechanical, thermal, and chemical stimuli. These nerve fibers are generally A-delta and unmyelinated C fibers and are most prevalent in the skin. Greater stimuli lead to greater frequency of action potentials. Acting as transducers, these nociceptors transmit their signals to the spinal cord via primary afferent nerve fibers.^{[52] [53]}

The peripheral nerve terminals experience a change in milieu after tissue damage and subsequent plasma extravasation resulting from increased capillary permeability. The result is a red flush at the site of trauma secondary to arteriolar dilation, local edema caused by increased capillary permeability, and primary and secondary hyperalgesia. There may also be pain from normally nonnoxious stimuli (allodynia), and an exaggerated response to noxious stimuli (hyperpathia). Tissue substances released in response to injury may magnify the body's nociceptive response. Histamine and serotonin further stimulate free nerve endings and produce vasodilation. Kinins, including bradykinin, are also released and stimulate free nerve endings, as can lipidic acids, cytokines, and various primary afferent peptides (calcitonin gene-related peptide, substance P, and others)^{[52] [53]} ([Box 16-1](#)).

In the dorsal horn of the spinal cord, connections are made from peripheral nerves to one of five zones, known as laminae I to V. Connections within these laminae differ based on cell type, interneural connections, and histochemistry. Neurochemicals within the dorsal horn include substance P, β -endorphin, enkephalins, dynorphin, serotonin, dopamine, norepinephrine, vasoactive intestinal peptide, γ -aminobutyric acid (GABA),

neurotensin, thyrotropin-releasing factor, and oxytocin.^[51] ^[53]

Somatic afferent fibers and large-diameter myelinated primary afferent axons, with cell bodies in the dorsal root ganglia, ascend within the spinal cord and terminate in the cuneate and gracile nuclei. Other branches terminate in the anterior horn of the spinal cord. The spinothalamic tracts (neo- and paleo-) ascend the anterolateral pathways after crossing from the contralateral dorsal horn. These fibers then terminate in the thalamic nuclei or with collateral connections in the brainstem and midbrain, where they may modulate sensory transmission.^[51]

Descending inhibitory pathways use enkephalins, serotonin, noradrenaline, and probably other neurotransmitters. Central structures include the somatosensory cortex, periventricular gray matter, periaqueductal gray matter, dorsal raphe nuclei, reticular formation, medulla, and nucleus raphe magnus.^[51] These mechanisms and others modulate the nociceptive experience.

Chronic Pain

With chronic pain, the sensation of pain no longer warns of trauma and danger. The initial stress response of acute pain is no longer present. Chronic pain is poorly defined through coinvolvement of peripheral and central mechanisms. The pain's duration is not what characterizes pain as "chronic." Rather, it is the prevalence of cognitive-behavioral aspects that supersede nociception. Prolonged pain that is traumatic, postoperative, neuropathic, or terminal is not "chronic" if the pathophysiologic and psychological

characteristics of acute pain are maintained. ^[51]

Psychologically, the chronic pain patient is commonly depressed. The sufferer may seek secondary gain and demonstrate psychosis, neurosis, or a premorbid personality. Pharmacologic interventions for chronic pain are often more challenging than in acute pain. Antiinflammatory agents, neural blockade, sedative-hypnotics, and narcotics are often ineffective or contraindicated, but antidepressants, cognitive coping strategies, and behavioral modification may be useful.

Recent therapies for chronic pain of use to wilderness travelers include implantable infusion pumps that deliver narcotic and nonnarcotic medications, dorsal column spinal stimulators, and transcutaneous electrical nerve stimulators (TENS).

GOALS OF WILDERNESS PAIN MANAGEMENT
