6.4
Palladium

N. M. KOSTIĆ and L.-M. DUTCĂ
Iowa State University, Ames, IA, USA

6.4.1 INTRODUCTION

6.4.1.1 Scope

In preparing this chapter, the authors surveyed a vast literature seeking studies with original findings, convincing explanations, and probable useful applications. Merely solid studies were downplayed, as their results are more or less predictable. Whenever possible, studies of palladium complexes were placed in their broader context, with minimal "dilution" of the content of this chapter.

Compounds containing multiple metal atoms, or mixed ligated atoms, or palladium atoms in different oxidation states, or more than one of these characteristics could be placed in different sections and subsections of the chapter, and so could reactions in which palladium-containing reactants and products differ greatly in properties. In very large clusters, which contain many metal atoms, oxidation states are nearly meaningless. In all of these cases, classification was made according to the feature of greatest interest or novelty. Certain "hot" areas of research, such as supramolecular assemblies, hydrolytic and similar reactions, and nanoparticles have subsections dedicated to them.

In view of an enormous number of publications on many diverse subjects, it was found both practical and prudent to rely on the supreme expertise of the authors of the source publications. While these sources were read critically, their authors' statements were borrowed or adapted, but these sources are always cited unambiguously.

6.4.1.2 Previous Reviews

A review[1] presents various palladium complexes with chiral ligands containing sulfenyl, sulfinyl, sulfoxamine, and selenenyl groups. Organosulfur functionalities, such as sulfenyl and sulfinyl groups, can serve as coordinating elements in ligands in Pd-catalyzed reactions, and normally they function as good π-acceptors. High enantioselectivity was obtained with chiral oxazoline, amidine, and imine ligands. Sulfinyl functionality serves as a slightly weaker coordinating element compared with sulfenyl function.

A review[2] describes the structural investigations of the compounds containing the direct Si—Pd bonds.

A review[3] with 57 references discusses the interaction of Pt^{II} and Pd^{II} with histidine and histidyl containing peptides. The coordinating behavior of histidyl containing peptides towards Pt^{II} and Pd^{II} depends on the histidyl position in the peptide sequence.

A review[4] with 40 references covers reactions of palladium(II) and platinum(II) complexes as synthetic peptidases, i.e., reagents that promote and, in some cases, catalyze hydrolytic cleavage of amide groups (peptide bonds) in peptides and proteins. Topics include general principles of reactivity and experimental methods for studying them; selective binding of these metal complexes to peptides and subsequent cleavage of these peptides; cleavage of proteins by these methods; and prospects for future developments.

Two reviews[5,6] with approximately 34 references discuss a coordination approach to three-dimensional assemblies via molecular paneling. Families of planar *exo*-multidentate organic ligands (molecular panels) assemble into large three-dimensional assemblies through metal-coordination. In particular, *cis*-protected square planar metals, $(en)Pd^{2+}$ or $(en)Pt^{2+}$ (en = ethylene-1,2-diamine), are very useful to panel the molecules. Metal-assembled cages, bowls, tubes, capsules, and polyhedra are efficiently constructed by this approach.

The quantum chemical studies of Pd and Pt molecular systems carried out since 1990 are reviewed[7] with 482 references to complement earlier comprehensive reviews. Topics covered include mononuclear systems, polynuclear systems, reactivity of Pd and Pt complexes, and catalytic cycles.

A review[8] with more than 186 references discusses the synthesis of Rh and Pd complexes with optically active P,N-bidentate ligands and their applications in homogeneous asymmetric catalysis. The effect of the nature of the P,N-bidentate compounds on the structure of the metal complexes and on enantioselectivity in catalysis was examined. Allylic substitution, cross-coupling, hydroboration and hydrosilylation catalyzed by Rh or Pd complexes with optically active P,N-bidentate ligands are considered.

A review[9] with more than 37 references includes an examination of symmetry groups and chirality conditions for C_{60} and C_{70} bonded to one or two metals in η^5 and/or η^6 fashion. Palladium and platinum η^2 complexes of C_{60} and C_{70} are described (novel synthesis, NMR spectra, electrochemistry) as well as first optically active organometallic fullerene derivatives.

A review[10] with eight references describes the photochemical reactions of the binuclear palladium(0) complex $[Pd_2(dppm)_3]$ (dppm = bis(diphenyl)phosphinomethane) with organic halides.

A review[11] with 123 references is given on amino acid bonding preferences in complexes of platinum and palladium. The preferences for a particular donor atom for Pd^{II} depends primarily on relative thermodynamic stabilities of the complexes formed. Sizes of potential chelate rings often play a crucial role in determining donor atom preferences.

A review[12] with 26 references of the biocoordination chemistry of Pd, Pt, and Ru and the discovery of a new type of immunomodulating activity of the Pd compounds is presented.

A review[13] with 53 references of the transition-metal mediated supramolecular self-assembly is presented. Focus is on the self-assembly of macrocycles, catenanes, and cages from $(en)Pd(NO_3)_2$ and pyridine-based bridging ligands.

A review[14] discusses palladium and the other noble metals forming a variety of complexes $M(P)LL'$ with tetrapyrrole ligands.

A review[15] with 90 references covers the coordination chemistry of palladium(0TO–+4) reported in 1992.

A review[16] with 89 references is given on the excited state properties of the low valent (0 and +1) bi- and trinuclear complexes of Pd and Pt. Physical characterization of the nature of the lowest energy excited states along with their photoinduced chemical reactivities toward oxidative additions is discussed.

A review[17] with 25 references of five-coordination in palladium(II) and platinum(II) chemistry is presented. The complexes have invariably a trigonal bipyramidal geometry with the bidentate ligand and the alkene in the equatorial plane.

Two reviews[18,19] with 20 references are presented. A series of Pd clusters containing from four to several hundred Pd atoms in the metal skeleton was prepared and characterized with structural data and by chemical properties including catalytic activity.

A review[20] with 101 references includes topics on coordination complexes of palladium and catalysis.

A review[21] with 45 references has topics on syntheses, characterization, structures, bonding, and reactivity of palladium cluster compounds.

A review[22] with 100 references, is given on the chemistry of coordinatively unsaturated tripalladium and triplatinum clusters and on the relation between this chemistry and that which occurs on a Pt surface during chemisorption and catalysis.

A review[23] with 1,160 references describes the chemistry of Pd and Pt complexes and cluster compounds, catalysis by Pd and Pt complexes, and nonstoichiometric binary and ternary compounds.

A review[24] with 15 references discusses the theoretical aspects of the coordination chemistry of palladium and platinum in relationship with their biological activity.

A review[25] with 20 references has information on the preparation and properties of such large clusters as $Pd_{561}(phen)_{36}O_{190-200}$ (phen = 1,10-phenanthroline).

A review[26] with 787 references on Pt and Pd salts and coordination compounds covering literature cited in *Chemical Abstracts*, Vol. 97 (issue 21) to Vol. 99 (issue 24) is presented.

A review[27] has 554 references, on palladium and platinum coordination compounds.

A review[28] describes compounds of the Pt-group metals including halide, oxide, sulfide, coordination compounds, organometallic compounds, and metal cluster compounds.

A review[29] with 59 references of the inorganic and coordination chemistry of palladium is presented.

6.4.2 OXIDATION STATES ALLEGEDLY HIGHER THAN +4

Chen *et al.*[30] synthesized two derivatives of an unprecedented trinuclear complex of palladium with ligands coordinated through silicon atoms. The qualitative discussion of bonding was based mostly on the crystallographic evidence, given below.

In Figure 1 the silicon atoms are considered parts of silyl ligands, and bonding of the central palladium atom to individual silicon atoms is emphasized. Because a silicon atom with only three substituents and an octet of valence electrons is nominally anionic, and because the compound as a whole is electroneutral, the central palladium atom appears to have the oxidation number VI. The authors noticed the relatively short Si3—Si6 and Si4—Si5 distances and acknowledged the alternative view of bonding, shown in Figure 2. They realized that this bonding mode, involving electron donation from two Si—Si σ-bonds and two silyl ligands to Pd^{II}, is also unprecedented. Still, the authors favored the former view of bonding and palladium(VI).

Aullon *et al.*[31] starkly contrasted the alternative views of bonding, and consequently the different oxidation states of the central palladium atom. They reinterpreted the experimental results by Chen *et al.* analyzed their original quantum-chemical calculations, and convincingly chose the oxidation state II. Aullon *et al.*[31] drew an apt analogy between the Si—Si single bond and the familiar H—H, Si—H, C—H, and other single bonds in saturated ligands, which are known to bond to transition-metal atoms in various complexes. They rightly stressed the

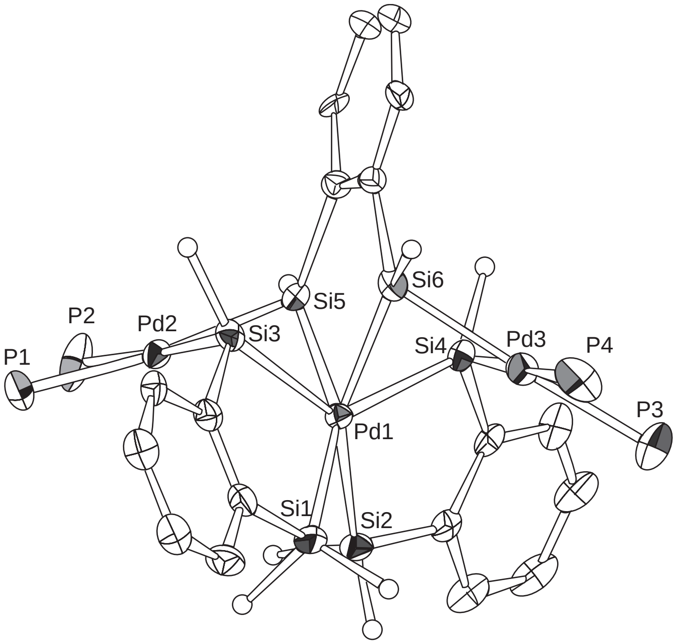

Figure 1 Trinuclear complex of palladium with ligands coordinated through silicon atoms.

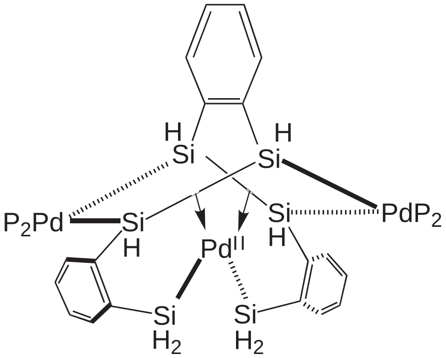

Figure 2 The alternative view of bonding for the trinuclear complex shown in Figure 1.

importance of the discovery by Chen *et al.* of the dihapto (η^2) coordination of disilane ligands to transition metals.

Sherer *et al.*[32] carried out systematic DFT calculations (DFT = density functional calculations) on the compound in question and on pertinent simpler compounds. They optimized the geometric structures and compared the computed bond lengths and bond orders. These authors, too, chose the oxidation state II for the central palladium atom.

This controversy is settled.[33]

6.4.3 PALLADIUM(IV)

6.4.3.1 Carbon

For the relatively new oxidation state IV for organopalladium chemistry,[34,35] there appear to be only two reports of intramolecular coordination, and in these cases unstable species were detected for which ^{1}H-NMR spectra are consistent with presence of Pd^{IV}.[36,37] Palladium(IV) complexes are usually synthesized from diorganopalladium(II) substrates via oxidative addition chemistry, and for organohalides this has been demonstrated to occur for C(sp^3)—X bonds including benzyl halides[38–42] and (halomethyl)naphthalenes.[34,35,38] Appropriate choice of intramolecular coordination system and synthetic strategy, based on C(sp^3)—Br oxidative addition to Pd^{II}, allowed the synthesis of stable Pd^{IV} complexes and the first structural analysis of an arylpalladium(IV) complex.[43] Synthesis and characterization of stable arylpalladium(IV) complexes indicates that species of this type are feasible as intermediates in organic synthesis, in particular where proposed for systems where the individual steps involving Pd^{IV} are supported by model reactions for these steps.[43] Representative examples of such syntheses and reports of model reactions for key steps include halogenation of azobenzenes,[37,44,45] the synthesis of 2,6-dialkyl-substituted arenes and vinylarenes,[34,35,41,42,46,47] and the acetoxylation of arenes.[48–50]

6.4.3.2 Phosphorus

There are several palladium catalyzed processes for which the involvement of palladium(IV) intermediates has amply been demonstrated.[51] There are reports of spectroscopic detection of unstable species $[PdMe_3(bipy)(L)]^+$ (L = PPh_3, $PMePh_2$ or PMe_2Ph) formed in equilibrium with $[PdIMe_3(bipy)]$ and formation of $[PdMe_3(bipy)(PPh_3)]^+$ (where bipy = 2,2-bipyridyl).[52] Trimethylpalladium(IV) complexes containing one phosphine donor interaction are stabilized in the coordination geometry *fac*-$[PdMe_3(N—N)(L)]^+$ (L = phosphine), and are sufficiently stable for isolation and structural analysis. Facile reductive elimination of ethane occurs in solution to form monomethylpalladium(II) complexes.[53]

6.4.3.3 Selenium

Recent development of organopalladium(IV) chemistry has provided new perspectives in d^6 chemistry.[34,35,41,54–58] $PdIMe_3(bpy)$ undergoes facile decomposition at ambient temperature in solution allowing detailed mechanistic studies of reductive elimination at a d^6 metal center.[59,60] There is a report of thiolate or selenolate complexes in organopalladium(IV) chemistry. Such complexes are formed via oxidation of palladium(II) reagents by $(ER)_2$. Both $(EPh)_2$ (E = S, Se) and $(O_2CPh)_2$ were used as oxidants.[49] The results reported illustrate several new phenomena in organopalladium(IV) chemistry: isolation of stable dimethylpalladium(IV) complexes and selenolate complexes and detection of unstable thiolate complexes; formation of C···O, C···S, and C···Se bonds on decomposition; and structural studies allowing detailed comparisons between palladium(IV) and platinum(IV).[49] The low stability of organopalladium(IV) complexes renders them ideal candidates for studies of decomposition at d^6 metal centers, and the dominance of C···C bond formation from triorganopalladium(IV) complexes is not reflected in diorganopalladium(IV) complexes in the presence of group 16 donor atoms (E) where C···E coupling becomes an important feature.[49] The observation of C···O coupling at palladium(IV) is relevant to the proposed catalytic role of palladium(IV) in the acetoxylation of arenes.[48,50]

6.4.3.4 Polynuclear Compounds and Polymers

Low-dimensional compounds have attracted much attention because they show very interesting physical properties such as Peierls transition, spin-Peierls transition, neutral-ionic transition, charge density wave (CDW) states, spin density wave (SDW) states, and superconductivities, etc. Among these compounds, quasi-one-dimensional halogen-bridged mixed-valence compounds (hereafter abbreviated as MX chains) have been extensively investigated during the last 20 years of the twentieth century, because of their interesting physical properties. In most MX chains, due to the strong electron–phonon interaction, the bridging halogens are distorted from the midpoints between the neighboring two metal atoms, giving CDW states or M^{II}–M^{IV} mixed-valence states ($\cdots M^{II}\cdots X—M^{IV}—X\cdots M^{II}\cdots$). Accordingly, the half-filled metallic band is split into the occupied valence band and the unoccupied conduction band with finite Peierls gaps. Therefore, these compounds belong to the class II of the Robin-Day classification for the mixed-valence complexes. These compounds are formulated as $[M^{II}(AA)_2]$ $[M^{IV}(AA)_2X_2]Y_4$ (M^{II}–M^{IV} = Pd^{II}–Pd^{IV}, Pd^{II}–Pt^{IV}; X = Cl, Br, I, and mixed halides; AA = ethylenediamine (en), cyclohexanediamine (chxn), etc.; Y = ClO_4, BF_4, X, etc.). These MX chains have two characteristic points compared with the inorganic semiconductors and organic conjugated polymer as follows. The magnitudes of the band gaps or CDW strengths can be tuned by varying chemical factors such as M, X, AA, and Y. Moreover, the interchain interaction can be controlled by using the intra- and interchain hydrogen bond networks between amino hydrogens and counteranions. Synthesis and the physical properties of a series of $Ni_{1-x}Pd_x(chxn)_2Br_3$ compounds with various mixing ratios, have been reported.[61] In the Ni—Pd mixed-metal compounds the electron correlation in Ni^{III} states (SDW) and the electron-phonon interaction in Pd^{II}—Pd^{IV} mixed-valence states (CDW) compete with each other. As a result, the Pd^{II}—Pd^{IV} mixed-valence states gradually approach the Pd^{III} state with the decrease of the Pd ratios influenced by the increase of the Ni^{III} states. This means that the electron–phonon interactions in the Pd^{II}—Pd^{IV} mixed-valence states are weakened by the strong electron correlation in the Ni^{III} states. In other words, the CDW strengths of Pd sites can be tuned by competition between the electron–phonon interaction of the Pd^{II}—Pd^{IV} states and the electron correlation of the Ni^{III} states in the Ni—Pd mixed-metal compounds $Ni_{1-x}Pd_x(chxn)_2Br_3$.[61]

6.4.4 PALLADIUM(III)

6.4.4.1 Mononuclear

6.4.4.1.1 Various donor atoms

Mononuclear palladium(III) complexes are relatively uncommon;[62] the two most well-characterized examples are $[Pd([9]aneS_3)_2]^{3+}$ ($[9]aneS_3$ = 1,4,7-trithiacyclononane)[63,64] and $[Pd([9]aneN_3)_2]^{3+}$ ($[9]aneN_3$ = 1,4,7-triazacyclononane),[65,66] for which X-ray structures have been determined. Several others have been generated electrochemically or otherwise studied *in situ*, but not isolated, including $[Pd(B_9C_2H_{11})_2]^-$ ($B_9C_2H_{11}{}^{2-}$ = 7,8-dicarbollide),[67] $[Pd(B_9C_2Me_2H_9)_2]_9{}^{2-}$ = 7,8-dimethyl-7,8-dicarbollide),[68] $[Pd(mnt)_2]^-$ (mnt = maleonitriledithiolate),[69] $[Pd(dmit)_2]^-$ (dmit = isotrithionedithiolate),[69] $[Pd(xdt)_2]^-$ (xdt = *o*-xylenedithiolate),[69] $[Pd([18]aneN_2S_4)]^{3+}$ ($[18]aneN_2S_4$ = 1,4,10,13-tetrathia-7,16-diazacyclooctadecane),[70,71] $[Pd([10]aneS_3)_2]^{3+}$ ($[10]aneS_3$ = 1,4,7-trithiacyclodecane),[72,73] and $[Pd([9]aneNS_2)_2]^{3+}$ ($[9]aneNS_2$ = 1,4-dithia-7-azacyclononane).[74]

6.4.4.1.2 Boron

The *nido*-borane cage ligand $[B_{11}H_{11}]^{4-}$ can support unusually high formal oxidation states of transition metals. An attempt to synthesize the closo anion $[(PMe_2Ph)_2Pd^{II}(B_{11}H_{11})]^{2-}$ from $[B_{11}H_{11}]^{4-}$ and $(PMe_2Ph)_2PdBr_2$, instead led to the synthesis, isolation, and characterization of an air-stable Pd^{III} complex which incorporates a B_{11} borane cage ligand.[75]

6.4.4.1.3 Nitrogen

In 1988 a powdered material believed to be $[PdL'_2](PF_6)_3$ (L′ = 1,4,7-triazacyclononane), which behaved electrochemically in accord with that formula, was prepared.[76]

6.4.4.1.4 Sulfur

Only in 1987 was the compound $(H_3O)[PdL_2](ClO_4)_4 \cdot 3H_2O$ (L = 1,4,7-trithiacyclononane) reported with a structure determination.[77] Since then there have been no others unambiguously established.

6.4.4.1.5 Halogens

The number of compounds of Pd^{III} that have been isolated and characterized is extremely limited. In the realm of aqueous chemistry there is no aqua ion nor any classical anionic complexes, PdX_6^{3-}; the latter have been made only in the solid state under strenuous conditions.[78] There are no binary compounds ("PdF_3" being a mixed Pd^{II}, Pd^{IV} compound).[79]

6.4.4.2 Polynuclear Compounds and Polymers

Three reported attempts to make and isolate dinuclear Pd^{III} complexes were unsuccessful. In Cotton's laboratory[80] $Pd_2(DTolF)_4$, $DTolF^- = [(p\text{-tolyl})NC(H)N(p\text{-tolyl})]^-$, was oxidized to $[Pd_2(DTolF)_4](PF_6)$ which was crystallographically characterized. In it, the Pd—Pd distance of 2.637(6) Å is little different from that, 2.622(3) Å, in the unoxidized starting material. No product containing a Pd_2^{6+} core could be isolated although a $Pd_2^{5+} \rightarrow Pd_2^{6+}$ oxidation wave was seen at +1.19 V, and the EPR spectrum of the Pd_2^{5+} compound was considered indicative of ligand rather than M_2 core oxidation. Contemporaneously, Bear and co-workers[81] prepared the similar *N*,*N*′-diphenylbenzamidinate compound. They saw only one oxidation wave, but from their EPR spectrum they concluded that a genuine $Pd_2^{4+} \rightarrow Pd_2^{5+}$ oxidation had occurred. Finally, attempts were made[82] to oxidize the $Pd_2(pyt)_4$ ($pyt^- = $ 2-thiopyridinate anion) molecule which appears to generate an unstable $Pd_2(pyt)_4X_2$ species during cyclic voltammetry, but no Pd_2^{5+} or Pd_2^{6+} products were actually isolated. Recently, use of the binitrogen-donor ligand hpp (the anion of 1,3,4,6,7,8-hexahydro-2H-pyrimido[1,2-*a*]pyrimidine) has proven to be effective in stabilizing metal–metal bonds in paddlewheel complexes for several transition metals. The first single bond between two trivalent palladium atoms has been reported.[83] A reaction of Pd^{II}acetate with Li(hpp) in THF produces the orange complex $Pd_2(hpp)_4$. Its cyclic voltammogram in CH_2Cl_2 showed a quasi-reversible oxidation at −0.12 V and an irreversible oxidation at +0.82 V, indicating that oxidation products obtained under these conditions are likely to be unstable. However, the two electron oxidation with $PhI \cdot Cl_2$ resulted in the formation of the dark complex $Pd_2(hpp)_4Cl_2$. Reproducibly a small amount of $Pd_2(hpp)_4Cl_2$ was obtained from several reactions, even when different temperatures, solvents, and oxidizing agents such as $NOPF_6$ and $NOBF_4$ were used. All invariably gave a mixture of products. Unfortunately, the only way to separate them was to hand-pick them. The presence of $Pd_2(hpp)_4Cl_2$ was confirmed in each case by checking the cell dimensions by X-ray diffraction.[83] The structures of both centrosymmetric complexes, $Pd_2(hpp)_4$ and $Pd_2(hpp)_4Cl_2$, are very similar; only the latter is shown in Figure 3. In each complex the two palladium atoms are bridged by four hpp ligands, resulting in a paddlewheel-type structure. Additionally, two axial chloride ions are present in the latter. There is formally no metal–metal bond in the former although the intermetallic separation is quite short (2.555(1) Å). In similar complexes containing binitrogen-donor ligands, the Pd—Pd separations are comparable although slightly longer.[83] The unprecedented Pd—Pd bond distance of 2.391(2) Å found in $Pd_2(hpp)_4Cl_2$ is 0.164 Å shorter than that in $Pd_2(hpp)_4$ and 0.097 Å shorter than the shortest Pd—Pd distance ever reported for any type of complex (in this case a Pd^I—Pd^I acetonitrile complex)[84]. It is also worth noting that the Pd—Pd single bond distance in $Pd_2(hpp)_4Cl_2$ is 0.36 Å shorter than the Pd—Pd distance in the metal itself. The magnitude of the shortening of the Pd—Pd distance provides strong evidence that the oxidation does occur in the dipalladium unit and that the electron-rich single bond configuration of $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*4}$ can be appropriately assigned to the metal–metal interaction.[83] A high-level calculation of the electronic structure of the $Pd_2(hpp)_4Cl_2$ molecule, in which the geometry was optimized, gave results in excellent agreement with experiment: Pd—Pd, 2.402 Å vs. 2.391 Å (obs) and for the torsion angle 22.6° vs. 24° (obs). The HOMO/LUMO gap is calculated to be 167 kcal mol^{-1}.[83]

6.4.5 PALLADIUM(II)

6.4.5.1 Carbon

The cyanide exchange on $[M(CN)_4]^{2-}$ with M = Pt, Pd, and Ni is a rare case in which mechanistic comparisons between 3*d*, 4*d*, and 5*d* transition-metal complexes. Surprisingly, the behavior of these metal square-planar centers leads to mechanistic diversity involving pentacoordinated species or transition states as well as protonated complexes. The reactivities of these species are strongly pH-dependent, covering 15 orders of magnitude in reaction rates.[85]

A variety of palladium(II) complexes with porphyrins,[86] heteroporphyrins,[87] and doubly-N-confused porphyrins[88] have been isolated and characterized. Importantly, the palladium(II) ion is susceptible to phenyl coordination in a cyclopalladation process.[89–91] Once the carbon donor is built into macrocylic or pincer ligands, the palladium(II) ion forms robust organometallic compounds.[92–94] Oxybenziporphyrin is conceptually derived from benziporphyrin, in which a benzene ring replaces one of the porphyrinic pyrroles leading to a structure devoid of macrocyclic aromaticity. A study of the synthesis and spectroscopic properties of oxybenziporphyrin complexes with Pd^{II} examined the effects of complexation and electrophile addition on the aromaticity of the ligand.[95]

Intramolecular π–π aromatic stacking interactions are rare, especially within ligands of transition metal compounds for which electrostatic interactions are likely to dominate over weak dispersion effects. Chiral Pd complexes, shown in Figure 4, present three pairs of aromatic ring systems that adopt almost parallel, stacked configurations. In the full QM-calculated models (a) PdBr(*p*-CNC_6H_4)({S}-MeO-Biphep); (b) PdBr(C_6F_5)({S}-MeO-Biphep) potential aromatic π–π stacking interactions are indicated by arrows.

Combined quantum mechanics/molecular mechanics studies have demonstrated that π–π stacking interactions are important in determining the structural features of polyarene transition metal compounds such as the two d^8 Pd complexes.[96]

Photorefractivity is a property exhibited by some materials in which the redistribution in space of photogenerated charges will induce a nonuniform electric space-charge field which can, in turn, affect the refractive index of the material. In a new material the active species is a highly efficient cyclopalladated molecule[97,98] shown in Figure 5. The palladium-bonded azobenzene molecule is conformationally locked, and gratings derived from *cis–trans* isomerizations can be safely excluded.

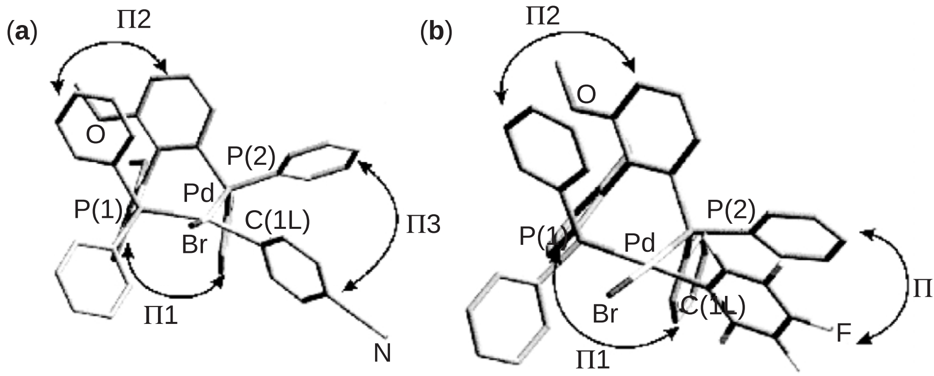

Figure 4 Chiral Pd complexes (a) PdBr(p-CNC_6H_4)({S}-MeO-Biphep); (b) PdBr(C_6F_5)({S}-MeO-Biphep). Potential aromatic π–π stacking interactions are indicated by arrows.

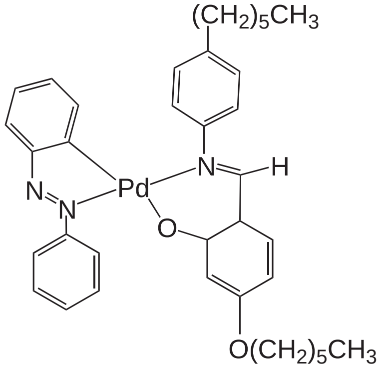

Figure 5 Palladium-bonded azobenzene molecule.

Lanthanides in combination with transition metals have been shown to have a positive effect in promoting heterogeneous catalytic reactions. The bimetallic Yb—Pd catalyst obtained from the precursor $\{(DMF)_{10}Yb_2[Pd(CN)_4]_3\}_\propto$ on a titania surface offers improved performance over a palladium-only catalyst for the reduction of NO by CH_4 in the presence of O_2.[99,100] The structure, shown in Figure 6, consists of two inverted parallel zigzag chains that are connected through the lanthanide atoms by *trans*-bridging $[Pd(CN)_4]^{2-}$ anions.[101]

The synthesis and structural characterization of luminescent di- and tri-nuclear organopalladium complexes with rigid conjugated alkynyl–aryl bridges and preliminary experiments on the formation of the first generation metallodendrimer using the trinuclear complex as the backbone were reported.[102]

Halo carbonyl complexes of palladium have been widely studied.[103–108] For homoleptic typical carbonyls and highly reduced carbonylates, the square planar coordination geometry was unknown. All known tetracarbonyl species are invariably tetrahedral, including $Pd(CO)_4$ which exists in inert gas matrices only.[109] A new synthetic methodology, the use of various superacids as reaction media in carbonylation and solvolysis reactions, provides a viable pathway to a wide range of homoleptic metal carbonyl cations, among them many superelectrophilic cations, with ionic charges of +2 and +3. This approach has been applied to the reductive carbonylation of $Pd[Pd(SO_3F)_6]$.[110,111] The solvated cation $[Pd(CO)_4]^{2+}{}_{(solv)}$ forms initially in HSO_3F, but the fluorosulfate *cis*-$Pd(CO)_2(SO_3F)_2$ is eventually isolated.[112] The molecular structure of *cis*-$Pd(CO)_2(SO_3F)_2$ is known.[113] In liquid SbF_5 in a CO atmosphere *cis*-$Pd(CO)_2(SO_3F)_2$ is easily converted to $[Pd(CO)_4][Sb_2F_{11}]_2$. The square planar coordination geometry of the cation is easily deduced from the vibrational spectra.[114] $Pd(CO)_4][Sb_2F_{11}]_2$[114] and the precursor *cis*-$Pd(CO)_2$-$(SO_3F)_2$[112,115] appear to be the only true cationic polycarbonyl derivatives of palladium(II),[105] with the possible exception of thermally unstable $Pd(CO)_2R_2$, $R = C_6F_5$, C_6Cl_5.[116] An early claim of the synthesis of *cis*-$Pd(CO)_2Cl_2$[117] has been repudiated,[118] and the reported crystal structure and spectroscopic properties of "$[Pd(\mu\text{-}Cl)(CO)_2]_2$"[119] are evidently identical in all respects to those of well-known $[Rh(\mu\text{-}Cl)(CO)_2]_2$.[120,121] A detailed study[122] reached the following goals: summarized

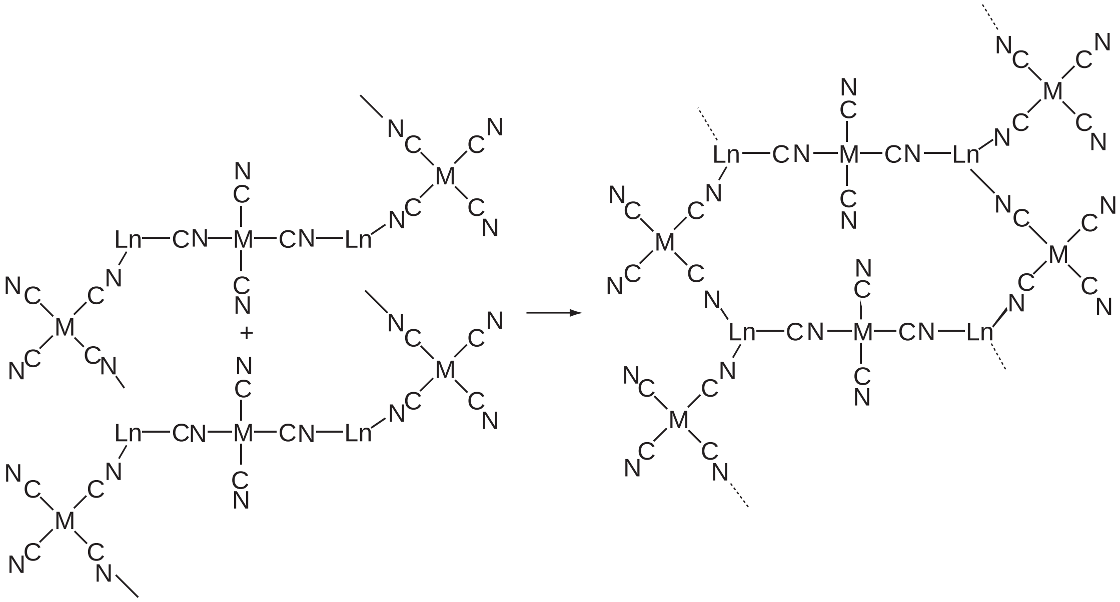

Figure 6 Bimetallic Yb—Pd catalyst obtained from the precursor $\{(DMF)_{10}Yb_2[Pd(CN)_4]_3\}_\infty$ on a titania surface and consisting of two inverted parallel zigzag chains that are connected through the lanthanide atoms by *trans*-bridging $[Pd(CN)_4]^{2-}$ anions.

and evaluated a number of alternative synthetic routes to $[Pd(CO)_4]^{2+}$,[123] investigated the thermal behavior of $[Pd(CO)_4][Sb_2F_{11}]_2$, and reported the crystal, molecular and extended structure of $[Pd(CO)_4][Sb_2F_{11}]_2$.[122]

The photophysics and photoreactivity of coordinatively unsaturated platinum(II) complexes[124–128] and their applications as luminescent sensors are areas of considerable interest in inorganic photochemistry. Rich and diverse low-energy excited states, including IL (intraligand: $\pi \rightarrow \pi^*$), MLCT (metal-to-ligand charge transfer) [$d\sigma^* \rightarrow p\sigma$], and [$d\sigma^* \rightarrow \pi^*$] (or MMLCT, metal–metal-to-ligand charge transfer), have been observed. Relatively scant attention has been focused upon the luminescent characteristics of palladium(II) complexes. Nevertheless, such investigations have been dominated by cyclometalated derivatives,[129–132] and reports comparing Pd^{II} and Pt^{II} analogues can yield information on electronic structures and excited states.[91,133–136] The ability of cyclometalated Pd^{II} complexes to effect DNA cleavage has been described.[137,138] Various aspects of luminescent cyclometalated Pt^{II} complexes bearing substituted 6-phenyl-2,2′-bipyridine ligands have been studied.[139–143] The preparation, crystal structures, and spectroscopic behavior of mono- and binuclear cyclometalated Pd^{II} derivatives are presented. The correlation between Pd^{II} and Pt^{II} congeners has enabled evaluation of metal–metal and ligand–ligand interactions in these systems and offered insight into their excited-state properties.[144]

Palladium(II) complexes containing orthometalated chiral amines such as those shown in Figure 7 are useful reagents:

(i) for the resolution of chiral phosphines and arsines,
(ii) for the determination of the optical purity of chiral phosphines by $^{31}P\{^1H\}$-NMR spectroscopy, and
(iii) as templates for the asymmetric syntheses of conformationally rigid bidentate ligands derived from metal-promoted intramolecular [4+2] Diels–Alder cycloadditions of 3,4-dimethyl-1-phenylphosphole (DMPP) with a variety of dienophilic ligands.

Complexes shown in Figure 7 undergo facile bridge-splitting reactions with a variety of two-electron donor ligands to give mononuclear species.[145]

The preparation of helically well-ordered polymers with stable screw-sense, which is able to be transmitted to newly formed polymer main-chains effectively, is highly desired for the development of new methodology for the synthesis of optically active helical polymers. An aromatizing polymerization of 1,2-diisocyanobenzenes is promoted by methylpalladium(II) complexes, producing poly(quinoxaline-2,3-diyl)s.[146–148] The polymerization proceeds with successive insertion of the two isocyano groups of the diisocyanobenzene to the carbon–palladium bond of

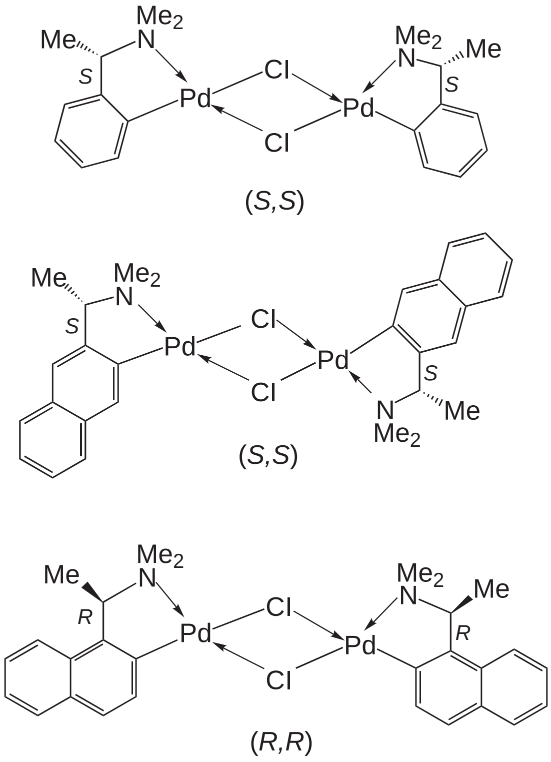

Figure 7 Palladium(II) complexes containing orthometalated chiral amines.

organopalladium complex to give 2-quinoxalinylpalladium complexes, whose carbon–palladium bond undergoes further successive insertion of the diisocyanobenzenes to provide the quinoxaline polymers. The poly(quinoxaline)s thus produced feature their rigid helical structures. The first attempt for the synthesis of optically active, helical poly(quinoxaline)s started with separation and isolation of two diastereomerically pure bromo[oligo(quinoxalinyl)]palladium(II)-L$^*_2$ (L* = di((*S*)-2-ethylbutyl)phenylphosphine) complexes, which were produced by the oligomerization of 3,6-di-*p*-tolyl-1,2-diisocyanobenzene with optically active *trans*-(bromo)methylpalladium(II)-L$^*_2$.[149–153] Right- and left-handed bromo(quinquequinoxalinyl)palladium(II)-L$^*_2$ thus prepared were subjected to ligand exchange reaction with a large excess of a chiral dimethylphenylphosphine. The enantiomerically pure right- and left-handed bromo(quinquequinoxalinyl)palladium(II) bis(dimethylphenylphosphine) complexes isolated were used as catalysts for polymerization of 1,2-diisocyanobenzenes, providing right- and left-handed helical poly(quinoxaline-2,3-diyl)s after removal of the palladium moiety with methylmagnesium bromide. The asymmetric polymerization of 1,2-diisocyanobenzenes is promoted by optically active iodo(1,1′-binaphth-2-yl)palladium(II) complexes as initiators. The axial chirality of the binaphthyl group, which becomes far from the living palladium terminus with propagation of the polymerization, successfully induced high screw-sense selectivity to provide optically pure, helical poly(quinoxaline-2,3-diyl)s.[154] The choice of substituents on the binaphthyl groups was crucially important to attain the high screw-sense selectivity. The highly effective control of the helical sense by the 7′-methoxy-1,1′-binaphthyl group at the initiation terminal of the polymer may arise from highly diastereoselective formation of the (terquinoxalinyl)palladium(II) intermediate, whose screw-sense was completely maintained for further propagation. The complete retention of the helical structure in the polymerization was demonstrated by the synthesis of optically pure polymers with varying molecular weights up to 100mer. The asymmetric polymerization has successfully been applied for the screw-sense selective synthesis of poly(quinoxaline-2,3-diyl)s having hydrophobic and/or hydrophilic side chains, by which the surface of the polymer is modifiable for new functional materials.[154]

Square-planar d^8 platinum complexes could perhaps be used as the chemically sensitive layer for a chemical sensor system. These complexes are robust and form colored solid-state materials that respond spectroscopically to a wide range of volatile organic compounds (VOCs); this process has been named vapochromism. The vapochromic shifts occur in the solid-state UV–vis, NIR, and IR spectra of [Pt(p-CN-C_6H_4-$C_{10}H_{21}$)$_4$][Pd(CN)$_4$].[155] These studies suggest that sorbed guest molecules capable of significant H-bonding interact with the cyanide ligands to produce shifts in the ν(CN) stretching frequencies that also correlate with the UV–vis changes. The synthesis and X-ray powder diffraction studies of a series of hydrated and solvated [Pt(CN-*iso*-C_3H_7)$_4$][Pd(CN)$_4$] complex were reported.[156] These studies show that vapochromism is accompanied by large reversible increases in the unit cell dimensions perpendicular to the Pt—Pd direction. The large (50–90%) unit cell increases allow the reversible inclusion of solvent molecules. Significant H-bonding interactions are present between the guest molecules and the cyanide ligands of the tetracyanometalate anions.[156]

6.4.5.2 Silicon and Tin

For trinuclear complexes that have a central Pd atom coordinated by six silyl groups, as shown in Figure 8, a highly unusual Pd^{VI} oxidation state has been assigned.[30] There are several reasons why the formulation of such a compound as a Pd^{II} center with two η^2-coordinated Si—Si single bonds is strongly favored, rather than as a Pd^{VI} center with six-coordinate silyl groups.[31–33] (see Section 6.4.2)

In a trinuclear complex two of the Pd atoms can be readily characterized as Pd^{II} centers but the nature of the third, central Pd atom is less clear.[30] While this Pd atom is considered as bonding directly to two Si atoms and further interacting with two Si—Si bonds, the interatomic distances from the X-ray crystal-structure data could also be interpreted to be consistent with an absence of Si—Si bonds and instead six Pd—Si bonds,[30] that is, the central metal would formally be Pd^{VI}. Both structures are without precedent in palladium coordination chemistry,[157,158] although compounds of the type [PdF_n] ($n = 2, 4, 6$),[159–162] have been reported where the extreme electronegativity of fluorine is exploited for the generation of higher oxidation states.[163] Assigning the central metal to be Pd^{VI} is not warranted, unless such an assignment is permitted to encompass the ambiguity of multicenter, delocalized bonding.[32] (see Section 6.4.2)

Complex (dippe = 1,2-bis(diisopropylphosphino)ethane)Pd(SiH_2Ph)$_2$ is a very rare example[164–168] of an isolated Pd^{II} *cis*-bis(silyl) complex.[169]

A bis(stannyl)bis(phosphine)palladium complex has a twisted square planar structure and shows facile unimolecular twist-rotation.[170]

6.4.5.3 Nitrogen

An analogue of 2,2′-bipyridine is capable of coordinating to *trans* metal binding sites. A ligand consisting of two 2-pyridyl moieties joined by a well-organized tether that orients the nitrogens at an appropriate distance affords exactly the required geometry.[171–174]

In a tetraazaporphyrin selective oxidative cleavage of one or more of the pyrrole rings yields secoporphyrazines. The new ligands and metal complexes derived thereof are of potential interest in areas such as nonlinear optics, electron transfer, and photodynamic therapy. Bis(dimethylamino)porphyrazines are versatile since they can be converted not only to seco analogues but also to new solitaire complexes upon peripheral metalation. The synthesis of the first macrocycles containing both an oxidatively cleaved pyrrole ring and a peripherally coordinated metal species has been reported.[175] The peripheral complexation and the oxidative cleavage of one of the pyrrole rings have a profound effect on the electronic properties of the porphyrazines.[175]

The incorporation of photoactive components into the molecular structure, which allows reversible switching of the output physical properties, such as light or redox potential, by an

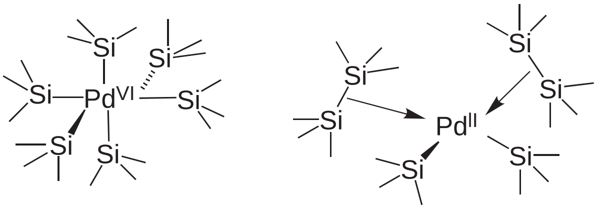

Figure 8 Trinuclear complexes that have a central Pd atom coordinated by six silyl groups.

external trigger, is promising in the development of molecular or supramolecular devices. The preparation and photochemistry of a series of self-assembly transition-metal-based macrocyclic compounds bridged by a photoisomerizable 4,4′-azopyridine or 1,2-bis(4-pyridyl)ethylene ligand was described.[176] The self-assembled Pd—Re and Pd tetranuclear squares can be photochemically converted to their corresponding dinuclear squares and thermally returned back to the tetranuclear squares.[176]

One of the chief defects of the phosphorus based pyrazolyl (PZ) ligands appears to be the hydrolytic sensitivity of the P—N bond particularly after interaction of the ligand with transition metal ions. The interactions of $PhP(O)(3,5\text{-}Me_2pz)_2$ and $Ph_2P(O)(3,5\text{-}Me_2pz)_2$ with Pd^{II} salts accelerates the P—N bond hydrolysis.[177]

Potentiometric and ^{1}H-NMR methods were combined in the studies of the interaction of $[Pd(en)(H_2O)_2]^{2+}$ and $[Pd(pic)(H_2O)_2]^{2+}$ (pic = 2-picolylamine) with monodentate ligands containing nitrogen or sulfur donor atoms. The ligands represent the side chain residues of nucleic acids and proteins.[178]

Metals are well known to induce conformational changes upon binding ligand systems. Upon removal of the metal ion the ligand usually "forgets" and reverts to its conformationally flexible state. Remarkably, a bis(pyridine) ligand can retain its metal-induced conformation even in the absence of the metal ion. At room temperature the ligand adopts one of two conformations: *syn*- or *anti*-. On heating in the presence of $[PdCl_2(PhCN)_2]$, the *syn*-isomer is preferred. On cooling this conformational preference is "locked-in" even on removal of the Pd^{II} ion (see Figure 9). The ligand can be programmed to adopt either a convergent *syn*-conformer that forms chelates or a divergent *anti*-conformer that forms coordination polymers.[179]

The octaethylporphyrin (OEP) complex cocrystalline with C_{60}, namely $Pd^{II}(OEP)\cdot C_{60}\cdot 1.5C_6H_6$ is one of the first examples of the *anti*-formed macrocyclic metal complexes of OEPs.[180,181]

In the ligand 1,2-bis-(2-pyridylethynyl)benzene the pyridyl N atoms easily attain the appropriate separation for *trans*-chelation of metal cations. The 1:1 complex of the ligand with palladium(II) chloride has been structurally characterized.[171,182]

The reactivity of a series of closely related substances can either be enhanced or inhibited depending on the type and extent of interaction with double-helical DNA. This was shown in a kinetic study of the substitution of ethylenediamine (en) or *N*,*N*′-dimethylethylenediamine (Me_2en) by thiourea in the palladium(II) complexes $[Pd(4,4'\text{-}R_2bpy)(en)](PF_6)_2$ (R = H or Me), $[Pd(en)_2](PF_6)_2$, and $[Pd(Me_2en)_2](PF_6)_2$, in water and in the presence of calf thymus DNA.[183]

"N-Confused porphyrin" (NCP) is a porphyrin isomer in which one of the pyrrolic rings is inverted. NCP can coordinate a metal in the porphyrin core by using the inner carbon and nitrogens. Owing to the outward pointing nitrogen, outer-N coordination is also conceivable. Two types of palladium-NCP complexes, inner-coordinated Pd^{II}-NCP and inner- and outer-N-coordinated, double-decker Pd complexes,[184] are reported (see Figure 10).[88] The latter Pd dimers are the first examples of the outer-N coordination in the NCP family.

Short peptides (fewer than 15 residues) are rarely helical in solution. A stable single α-helical turn in solution, a native pentapeptide, was constrained by a Pd^{II} clip to the shortest α-helix

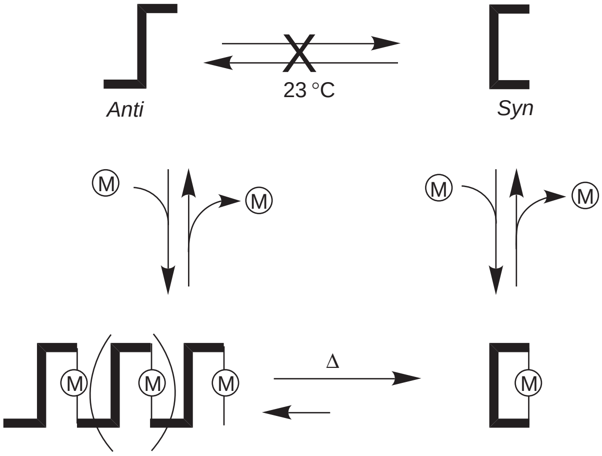

Figure 9 Retention of metal-induced conformation of a bis(pyridine) ligand by heating in the presence of $[PdCl_2(PhCN)_2]$.

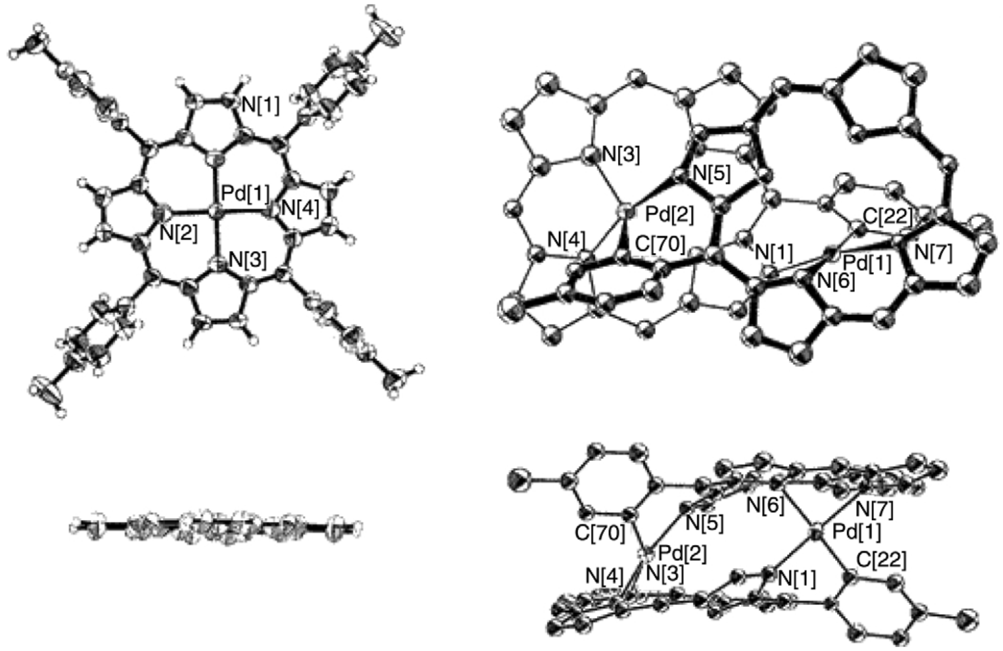

Figure 10 Two types of palladium-NCP complexes, inner-coordinated Pd^{II}-NCP and inner- and outer-N-coordinated, double-decker Pd complexes.

known, as shown in Figure 11.[185] This ion chelates two histidines (via N1 nitrogens) arranged at *i* and $i+4$ positions, inducing α-helicity even in a pentapeptide.

Novel cationic methyl and neutral methyl, chloro Pd^{II} complexes have been synthesized with various functionalized imidazole ligands. For the first time, structurally characterized examples of this type of Pd complex could be obtained. The chelate ligand is shown to adopt a boat conformation. Inversion of the chelate ring was established by NMR spectroscopy. Depending on electronic and steric features of the ligand, the complexes can act as catalysts in the CO/ethylene as well as the Heck reaction.[186]

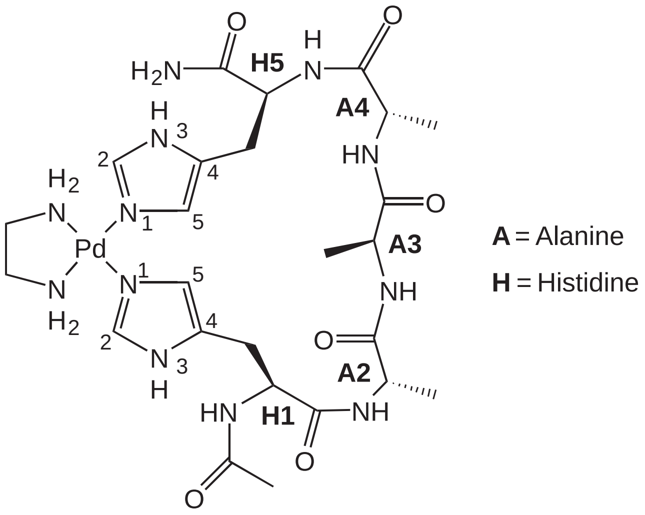

Figure 11 Pd^{II} chelates two histidines (via N1 nitrogens) arranged at *i* and $i+4$ positions, inducing α-helicity even in a pentapeptide.

Certain azacrown-appended cholesterol derivatives can form unique vesicular or lamellar structures in the absence and the presence of metal salts in aqueous solution.[187–190] These superstructures created from the azacrown-appended cholesterol derivatives are useful as a template for the transcription into the silica structure. Azacrown-appended cholesterol gelator creates the novel multilayered spherical structure in acetic acid, whereas this gelator results in the fluffy globular aggregates in the presence of $Pd(NO_3)_2$.[191]

AMTTO—a representative of 4-amino-6-alkyl-1,2,4-triazine-5-one—acts as a bidentate chelating ligand towards $PdCl_2$ in methanol/acetonitrile to give the air-stable palladacycle [(AMTTO) $PdCl_2$]·MeOH.[192] Its reactions with triphenylphosphane and sodium thiocyanate, led to the air-stable complexes [(AMTTO)Pd(PPh_3)Cl]Cl·MeOH and [(AMTTO)Pd($SCN)_2$]·MeOH, respectively.[193] Another paper reports the halide exchange reactions with sodium bromide and sodium iodide, as well as the reactions of the bromine and iodine palladacycles with triphenylphosphane.[194]

In order to anchor a metal ion firmly on a pyrazole derivative, polydentate ligands shown in Figure 12 can form stable chelates involving one soft ligating atom (P or S) and one pyrazole N, while leaving the other pyrazole N and its attached hydrogen available for donating a hydrogen bond or a proton to another ligand on the metal. In this study, a pyrazole substituent containing a ligating P or S atom must be attached to a *carbon* of the heterocycle. Four new ligands designed to form bidentate complexes using a soft donor atom and a pyrazole nitrogen have been synthesized and their corresponding *cis*-dichloropalladium(II) complexes prepared. In the solid state, the two palladium complexes with a pyrazole N—H group show intra- and intermolecular hydrogen bonding to the chloride ligands. The intramolecular distances between chloride and the NH proton are comparable to the closest intermolecular contacts found in the solid state structures. In contrast, isomeric complexes lacking an N—H group show no hydrogen bonding.[195]

The self-assembled membrane (SAM) technique has been much used as an effective method to organize the molecules on the solid surface with well-ordered structure and thickness for interfacial optical studies. Palladium porphyrins show strong room-temperature phosphorescence with high quantum yield and long lifetime. Therefore these compounds have been widely utilized as oxygen-sensitive dyes. There was a report previously on optical oxygen sensing using an SAM of palladium tetrakis(4-carboxyphenyl)porphyrin (PdTCPP) on an alumina surface, but a more sensitive oxygen sensing system and stable and highly ordered films are desired. Highly organized SAMs can be obtained using compounds with long hydrocarbon chains. An optical oxygen-sensing technique was established using a self-assembled film of Pd porphyrin with long alkyl chain, PdPC10COOH, on an alumina plate.[196]

Among luminescent dyes, palladium porphyrins display strong room-temperature phosphorescence with a high quantum yield and long lifetime. Therefore these compounds have been frequently utilized as oxygen-sensitive dyes. As palladium tetrakis(4-carboxyphenyl)porphyrin (PdTCPP) has a carboxyl group, a stable self-assembled PdTCPP film will be formed on an alumina surface. An optical oxygen sensor was prepared using PdTCPP self-assembled film on alumina plate. The film is highly sensitive to oxygen pressure and possesses good operational stability and a fast response.[197]

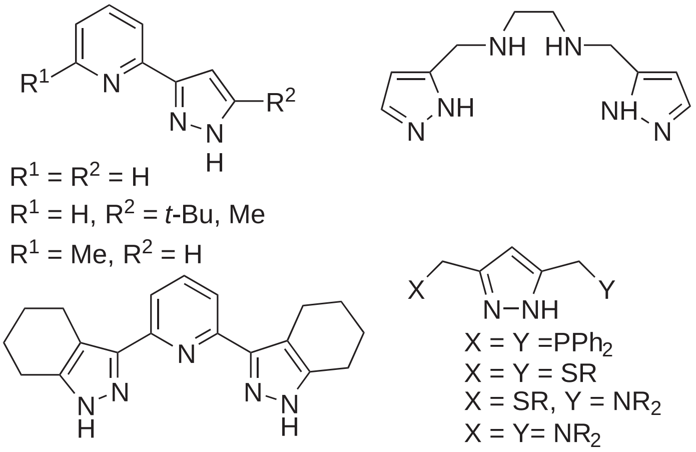

Figure 12 Polydentate ligands capable of anchoring a metal ion on a pyrazole derivative.

Traditionally, oxidations of alcohols are performed with stoichiometric amounts of inorganic oxidants, notably chromium(VI) reagents. These oxidants are not only relatively expensive, but they also generate copious amounts of heavy-metal waste. Moreover, the reactions are often performed in environmentally undesirable solvents, typically chlorinated hydrocarbons. In a constant search for cleaner ("greener") technologies, there is a definite need for catalytic oxidations that use dioxygen (O_2) or hydrogen peroxide as the stoichiometric oxidant. These oxidants are atom efficient and produce water as the only by-product. Supported noble metals, such as palladium or platinum on carbon, are known to catalyze the aerobic oxidation of alcohols in an aqueous medium, but the method is generally limited to water-soluble substrates, such as carbohydrates.[198] Moreover, primary alcohols are oxidized to carboxylic acids, and one equivalent of base is required. An extremely effective aerobic oxidation of alcohols, both of activated and nonactivated hydroxyl groups, was performed in water with a soluble catalyst.[199] The latter is a water-soluble palladium complex of bathophenanthroline disulfonate (PhenS*), see Figure 13.

A wide range of both primary and secondary allylic, benzylic, and aliphatic alcohols can be oxidized with high conversions and selectivities. Mechanistic studies[199] of olefin oxidations with this catalyst showed that, under neutral conditions, the catalyst precursor is a dimeric palladium species with two bridging hydroxy ligands.[200] Increasing the pH values up to pH ~10 yields a similar dimeric species with three bridging hydroxy ligands,[201] apparently without changing the rate equation. The addition of sodium acetate (NaOAc) further increases the reaction rate. The reaction may also be carried out at neutral pH at only marginally lower rates. Coordination of the alcohol to the metal center probably splits the dimeric precursor, see Scheme 1. Next, a base (B) abstracts a proton from the coordinated alcohol to form a palladium alcoholate species that subsequently undergoes β-hydride elimination to give the alkanone, water, and a zerovalent palladium species. Oxidation of the latter with O_2 gives a palladium peroxide. Reaction of this peroxide with one equivalent of zerovalent palladium yields the starting palladium dimer. Reoxidation of Pd^0 seems to be facilitated by NaOAc, which avoids the irreversible formation of a palladium mirror. A minimum of 1 mmole of NaOAc is recommended to avoid this palladium black formation.[199]

Octaethylbilindione (H_3OEB) is a convenient model for the bile pigment biliverdin IXα. Key redox states of this ligand as observed in its complexes are shown in Figure 14. The redox behavior of the palladium complex of octaethylbilindione was examined in order to determine the generality of the redox behavior of this group of transition metal complexes.[202] A preliminary report on the novel tetrameric $Pd_4(OEB)_2$, which contains palladium(I) ions π-bonded to C=C bonds of the tetrapyrrole ligand, and of $Pd^{II}(OEB\cdot)$ has appeared.[203]

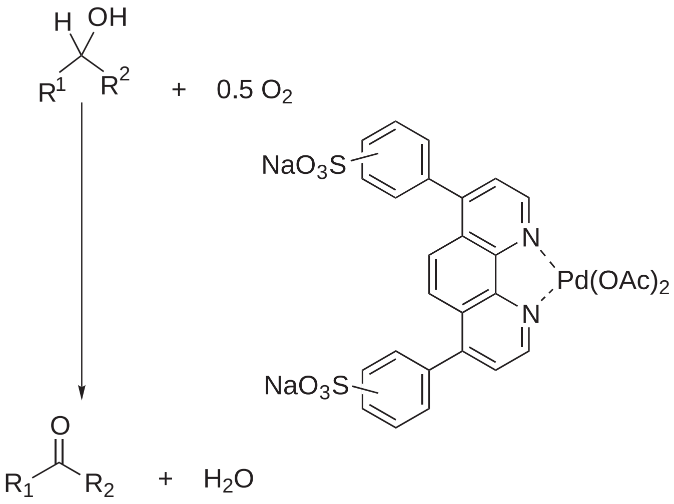

Figure 13 Aerobic oxidation of alcohols catalyzed by water-soluble PhenS*Pd(OAc)$_2$; R = alkyl, aryl.

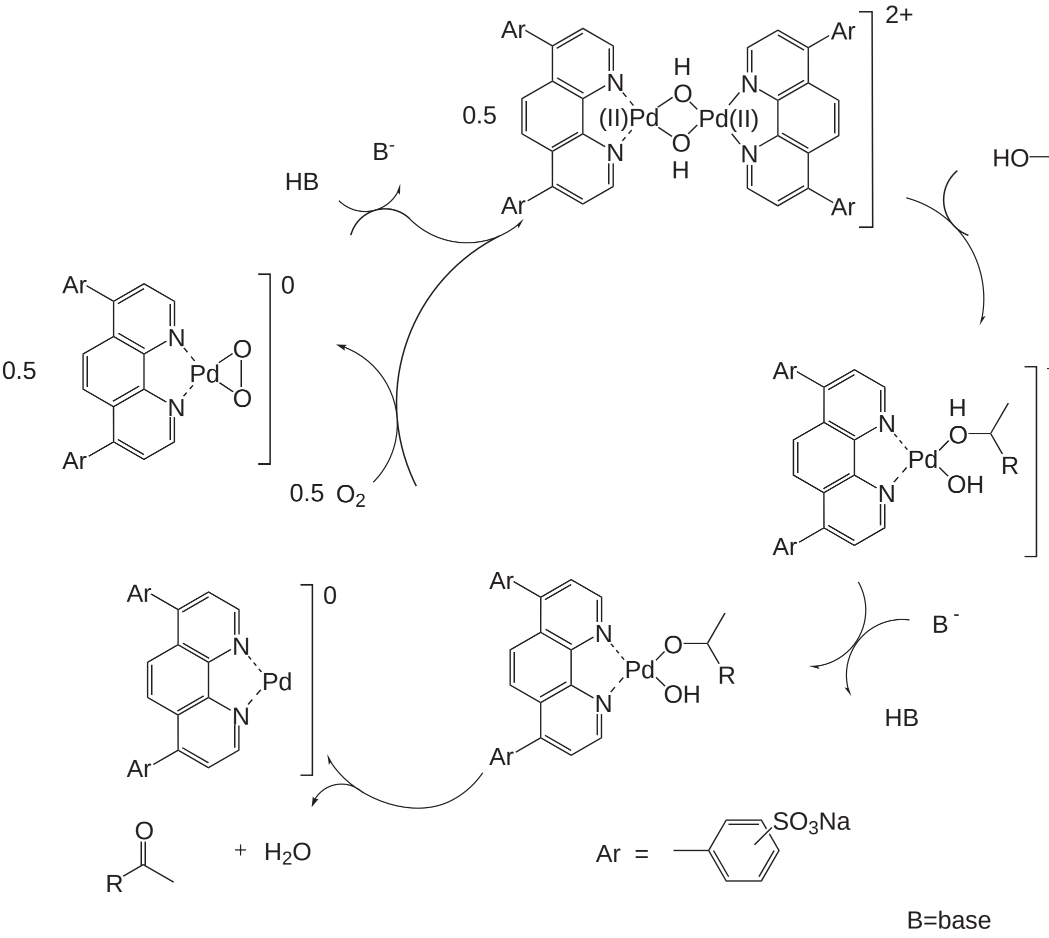

Scheme 1

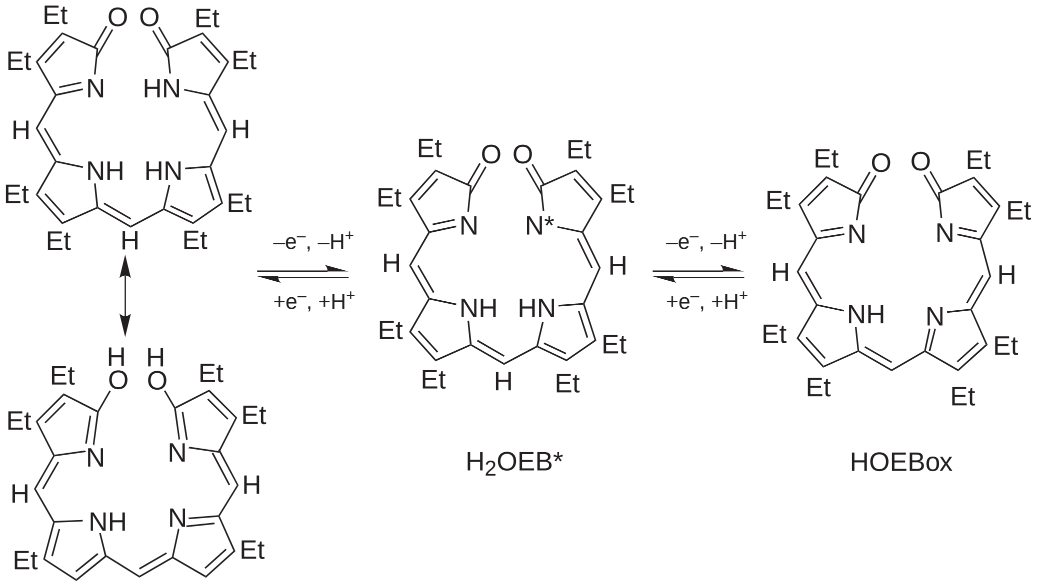

Figure 14 Redox behavior of octaethylbilindione.

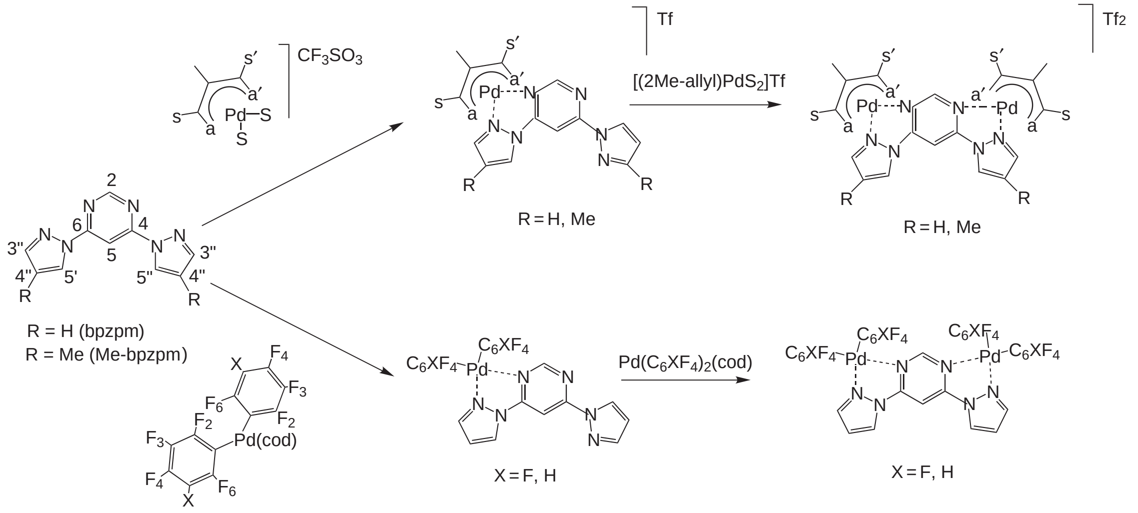
The fluxional behavior of new palladium and platinum derivatives containing 2,4,6-tris-(2-pyridyl)-1,3,5-triazine and 2,4,6-tris(2-pyridyl)pyrimidine ligands has been reported.[204,205] An intramolecular mechanism based on a 1,4-metallotropic shift coupled to the metal hurdling along the coordination positions of the N-donor ligand has been proposed. There has been some controversy about the mechanism of the 1,4-metallotropic shift process, and both associative[206] and dissociative[207] pathways have been proposed. An elegant study with asymmetric terpyridine ligands coordinated to palladium and platinum fragments, showed that the 1,4-metallotropic shift pursues an associative mechanism where the role of the N atom in the central pyridine ring is essential.[208] A study[209] reported the synthesis and the dynamic behavior of new allylpalladium derivatives coordinated to pyrazolyltriazine ligands where the metallic group interchanges between the different coordination positions of the ligand. As in aforementioned examples,[204,205] but with energy barriers low enough to observe several coalescences in the ^{1}H-NMR spectra, the authors measured two different free activation energies whose difference lies correctly with the expected strengths of the Pd—N bonds, which are necessarily broken in each step. This implies the existence of Pd—N bond rupture in the two processes. The N_5 atom of the triazine ring could assist the palladium group in the 1,4-metallotropic shift, making the process intramolecular. The role of the triazine central nitrogen atom, was evaluated with two similar ligands, 4,6-bis(pyrazol-1-yl)pyrimidine[210] (bpzpm) and 4,6-bis(4-methylpyrazol-1-yl)pyrimidine (Me-bpzpm) (see Scheme 2), that lack the N_5 atom, making impossible an intramolecular 1,4-metallotropic shift of the metal. Because these new ligands still possess two identical asymmetric chelating coordination sites, if the palladium fragments are able to jump from one position to the other, a different pathway must be involved.

Two processes have been detected in the complex: an intramolecular apparent allyl rotation and an intermolecular process of interconversion of the two pyrazolyl groups, with negative activation entropy, for which an associative mechanism is proposed. The existence of this latter process indicates that the presence of a nitrogen atom is not necessary in the 5-position of the central heterocycle of the ligands in order for an interconversion of the two pyrazolyl groups to take place. However, participation of a nitrogen atom in the 5-position cannot be excluded when it is present.[211] Another goal of this study[211] was to explore the possibility of synthesizing asymmetric dinuclear derivatives and to study the mutual influence of the two metallic groups through the ligand core. In this context different reactions have been performed with the bpzpm and Me-bpzpm ligands, with the metallic complex $Pd(C_6F_5)_2(COD)$ or $Pd(C_6HF_4)_2(COD)$ where COD = cyclooctadiene, and with the solvato $[Pd(^3\text{-}2\text{-}Me\text{-}C_3H_4)(S)_2]Tf(Tf = CF_3SO_3)$.



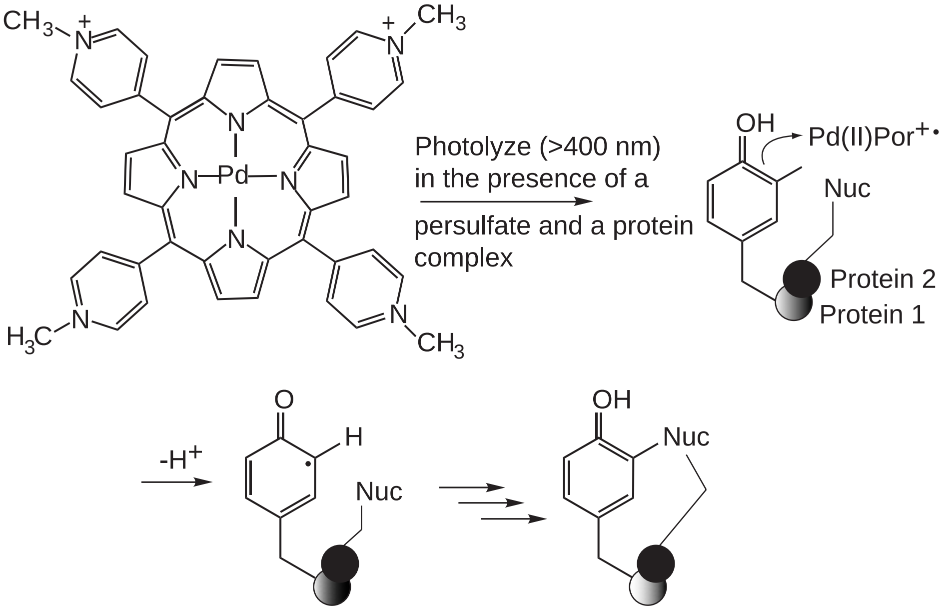
Scheme 2

Immobilized metal ion affinity chromatography (IMAC) is an important method for the separation of proteins having exposed histidine groups. Attachment of polyhistidine tails (His_n where $n = 2$–6) fused to a desired peptide or protein has been developed to enhance its affinity to the IMAC column. A peptide Ser-Pro-His-His-Gly-Gly (SPHHGG) has been bioengineered to select for high-affinity binding to of Cu^{II}-IMAC columns.[212,213] The diamagnetic, square-planar

[Pd^{II}(mida)] chelate (mida^{2-} = methyliminodiacetate) is used to approximate the distorted tetragonal Cu^{II}-IMAC sites in order to identify which amino acid groups or their side-chain donors of SPHHGG and HHHHHH become attached to the metal site.[214]

Chemical cross-linking is a useful method to probe protein–protein interactions in solution. A significant advance in this area would be to design chemical cross-linking reagents that could be activated efficiently with visible light and which would then mediate protein cross-linking very rapidly. A molecule that could be photoexcited to a state capable of oxidizing tyrosine might mediate protein cross-linking with the assistance of a hydrogen atom-abstracting agent (see Scheme 3).

The literature on Pd^{II} porphyrin photochemistry suggests that these agents might be useful in this regard.[215–217] To probe this point, glutathione S-transferase (GST), a native homodimer that can also associate into higher-order species, was photolyzed with visible light (>400 nm) in the presence of Pd^{II} 5,10,15,20-tetra(methylpyridinium)porphyrin (Pd^{II}TMPyP) and ammonium persulfate (APS), a good electron acceptor.[218] An approximately 50% yield of cross-linked products was produced after only a 10s irradiation using a 150 W xenon lamp and a 400 nm cutoff filter. Little or no cross-linking was observed when either light, APS, or Pd^{II} porphyrin was omitted from the solution or when free base porphyrin was substituted for the Pd^{II} derivative.[218] To probe the scope of this reaction, the Pd^{II} porphyrin/APS photomediated cross-linking of several proteins was examined.[218] A limitation of this reaction is the requirement for APS, which is cell-impermeable and can oxidize some cellular components directly. Therefore, it would be useful to find an APS substitute with more favorable properties. Co^{III} complexes are sometimes used to accept electrons from excited-state metal complexes. Unfortunately, much lower yields of cross-linked products were produced when Co^{III}(NH$_3$)$_5$Cl^{2+} was used in place of APS.[218]



Scheme 3

Mono- and dinuclear 2,2′:6′,2″-terpyridine (terpy) complexes of Pt^{II} and Pd^{II} have been the subject of numerous studies, e.g., with regard to photophysical[219–222] and electrochemical[223] properties as well as substitution-mechanistic aspects.[224] The mononuclear compounds have also been applied in biochemical and biochemistry related studies as DNA intercalators[225–227] or metal probes for the histidine[228–230] and arginine residues.[231] The interaction of [(terpy)PdCl] with model nucleobases such as 1-methylcytosine (Hmcyt) was studied.[232] Formation of mononuclear [(terpy)Pd(Hmcyt-N$_3$)]$^{2+}$ as well as dinuclear {(terpy)Pd}$_2$(mcyt-N$_3$, N$_4$)]$^{3+}$ was clearly evident from potentiometric and proton NMR studies, but there was contradicting evidence as to the spatial orientation of the two metal entities in the dinuclear complex. Mono- and dinuclear (terpy)M^{II} (M = Pd, Pt) complexes containing the model nucleobase 1-methylcytosine have been prepared, X-ray structurally characterized and their solution behavior studied by spectroscopy.[233] Evidence points to a stacked conformation rather than an *anti* orientation of the two (terpy)M entities, and the visible spectrum is likewise in agreement with such a structure. The solid state structures further confirm that a stacked conformation is possible, in principle.[233]

Recently, variably substituted oligonitriles became available for the first time in monodisperse, well-defined form. Although these substances are isoelectronic with polyacetylenes (polyenes), their structural and electronic properties are entirely different. Of special interest is their behavior in complexation and redox reactions as well as their electrical conductivity and the NLO (nonlinear optical) properties. The complexation ability of oligonitriles was studied using palladium(II) as the metal counterpart. Oligonitriles are expected to serve as potent polydentate ligands since each imine nitrogen atom is a potential σ donor. Furthermore, the numerous C=N bonds may give rise to π complexation. High molecular flexibility due to low barriers of rotation around the C—N single bonds is expected to facilitate complexation.[234]

The tetraazaporphyrin (porphyrazine) macrocycle is a structural template for rigid organization of the metal centers, with the potential to mediate electron transfer or magnetic exchange between metal ions. Peripherally functionalized porphyrazines are prepared by the template cyclization of maleonitrile derivatives and have the form $\mathrm{M[pz(\mathbf{A}_{\mathit{n}};\mathbf{B}_{4-\mathit{n}})]}$, where **A** and **B** symbolize functional groups fused directly to the β-positions of the pyrroles, and M represents a metal ion coordinated in the macrocyclic core. The peripheral **A** moieties generally involve heteroatoms (S, N, O) appended to the porphyrazine ring and can be designed to bind an exocyclic metal ion. The **B** groups can be designed to:

(i) optimize the yields;
(ii) introduce novel electronic, optical, or redox properties; or
(iii) to confer a desired solubility.

In octakis(dimethylamino)porphyrazine[235,236] the peripheral $(NMe_2)_2$ moiety is analogous to the metal-binding chelates tetramethylethylenediamine (tmen) and tetramethyl-*o*-phenylenediamine (tmopda). This new ligand will coordinate $PdCl_2$. The chlorine ligands were substituted by dithiolato ligands and the first stable heteroleptic bis(amine)dithiolene palladium(II) complex was synthesized and structurally characterized.[237] As a step toward the synthesis of metal-linked multiporphyrazine arrays, the bis(palladium)(btt)-bridged porphyrazine dimers were assembled (btt=1,2,4,5-tetra(benzylthio)benzene).[237] The heteroleptic palladium(II) complexes with electron rich dithiolene ligands were unstable toward disproportionation.[237]

Present methods for the cyclization of peptides generally require a completely protected peptide precursor, which is cyclized in solution or at a solid phase by using a coupling agent, as well as a strongly activated acyl component. A facile, metal-mediated synthesis of 12-, 14-, 16-, and 18-membered cyclic tetrapeptides or macrolactams is possible from readily accessible nonactivated dipeptide ester precursors. The reaction of Pd^{II} salts with two equivalents of dipeptide ester in methanol in the presence of NaOMe as base results in dianionic complexes, which can be isolated by precipitation with suitable cations (see Figure 15).[238]

The crucial step is the same as that assumed for the oligomerization of peptides at metal centers,[239–241] namely the nucleophilic attack of a coordinated terminal amino group on the carbonyl group of the neighboring *trans*-coordinated dipeptide ester.[238] The cyclic tetrapeptide is bound to the metal through the four deprotonated amide nitrogen atoms. The palladium center and the N atoms lie in a plane.[238] Tetrapeptide ester can be employed instead of two dipeptide esters (see Figure 16).[238] This synthesis of cyclotetrapeptides requires neither a protecting group nor an activated group or a coupling reagent. It can be performed as a one-pot process. High dilution of the reaction mixture is also not necessary (see Figure 16).[238]

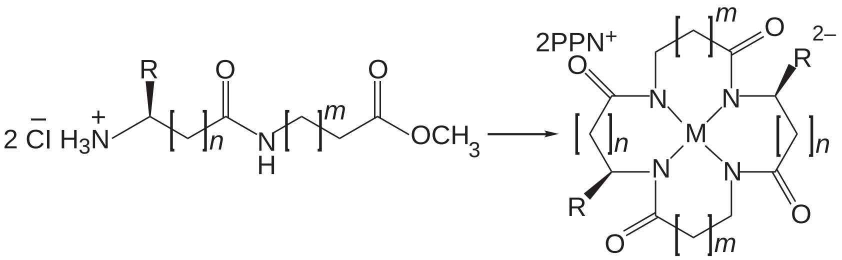


Figure 15 The reaction of Pd^{II} salts with two equivalents of dipeptide ester in methanol in the presence of NaOMe as base results in dianionic complexes, which can be isolated by precipitation with suitable cations.

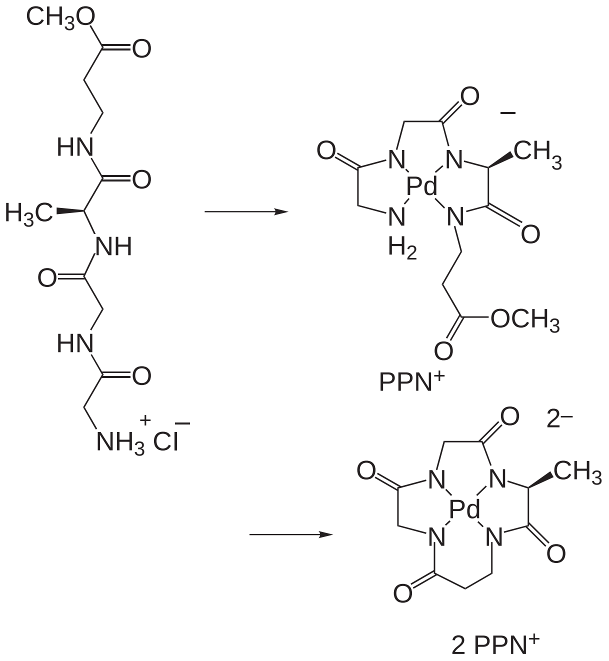

Figure 16 Synthesis of Pd^{II} cyclotetrapeptides.

6.4.6.4 Phosphorus

Several amphiphilic and water-soluble phosphine ligands have been reported with the aim of anchoring the metallic center to a surfactant molecule to obtain a microheterogeneous arrangement of the catalyst in the reaction media. A new water-soluble phosphine family with surfactant properties was synthesized; their complexing properties toward Pd^{II} and the aggregation properties of these ligands and their metallic complexes were studied.[242]

Calix[4]arenes possessing the P^{III} functionality are receiving considerable attention as the ligands of transition-metal complexes.[243] Matt and co-workers reported the preparation of calix[4]arene propyl ether having *two* diphenylphosphino groups at distal positions.[244] They studied its complexation with Pd^{II} and other transition metals to obtain the corresponding complexes with a *trans* configuration. A bis(diphenylphosphino)calix[4]arene ligand has the benzyl ether group[245] at the lower rim, which fixes the cone conformation.[245] Pt^{II} and Pd^{II} complexes bearing the bis(diphenylphosphino)calix[4]arene as a ligand involve *trans*-dinuclear and *cis*-mononuclear derivatives. Especially, the latter show unique fluxional behavior caused by two simultaneous motions.[246]

In-plane bis(dipolar) assemblies were synthesized by stereoselective coordination of P,N-chromophores on a d^8-square-planar Pd-center.[247] These are the first NLO-phores based on phosphole rings. *Trans*-effect offers a simple synthetic methodology for controlling the in-plane parallel arrangement of 1D-P,N-dipoles in a molecular assembly.

Phosphine ligands based on the ferrocene backbone are very efficient in many palladium-catalyzed reactions, e.g., cross-coupling reactions,[248] Heck reaction,[249] amination reaction,[250] and enantioselective synthesis.[251] A particularly interesting example of an unusual coordination mode of the 1,1′-bis(diphenylphosphino)ferrocene (dppf) ligand has been reported. Dicationic palladium(II) complexes, such as $[(dppf)Pd(PPh_3)]^{2+}[BF_4^-]_2$, were shown to contain a palladium–iron bond.[252,253] Palladium–iron bonds occur also in monocationic methyl and acylpalladium(II) complexes.[254] A palladium–iron interaction is favored by bulky alkyl substituents on phosphorus and a lower electron density at palladium.

The first catalytic dihydroamination of a phosphaalkyne was confirmed when the product diaminophosphine was formed, the complex *trans*-$[PdCl_2\{P(Pr^iNH)_2CH_2(Bu^t)\}_2]$.[255]

Palladium complexes of inexpensive, easily synthesized bis(phosphinite) "PCP"-pincer ligands show good activity in the Suzuki coupling of deactivated and sterically hindered aryl bromides.[256]

The first heterodifunctional ligand derived from a tetradentate phosphine was made in a study concerning synthesis and characterization of *cis,trans,cis*-1,3-bis(diphenylphosphino)-2,4-bis-(diphenylphosphinothioyl)cyclobutane and its complex with $PdCl_2$.[257]

Deprotonation of $[Pd(dppe)(Me)(PH_2Mes^*)][BF_4]$ (dppe = $Ph_2PCH_2CH_2PPh_2$, Mes* = 2,4,6-$(Bu^t)_3C_6H_2$) gave Pd(dppe)(Me)(PHMes*), which underwent reductive elimination to give PH(Me)(Mes*) and Pd^0. Since this type of P—C bond-forming step is important in Pd-catalyzed cross-coupling reactions used for synthesis of tertiary phosphines, the authors have investigated its generality and mechanism. Several complexes $[Pd(diphos)(R)(PR'_2H)]^+$ could be prepared by the reaction of Pd(diphos)(R)(X) (diphos = dppe or dcpe ($Cy_2PCH_2CH_2PCy_2$, Cy = cyclo-C_6H_{11}); R = Me, Ph, Mes (2,4,6-$Me_3C_6H_2$); R′ = Ph, Cy, Mes; X = Cl, Br, I) with Ag^+ and secondary phosphines.[258] However, attempts to extend these syntheses to complexes with diphosphines having different bite angles and/or steric bulk did not give analogous products.[259]

The susceptibility of phosphites to hydrolysis limits their application as ligands for homogeneous catalysis. The fused tricyclic monophosphites derived from calix[4]arenes[260–262] form coordination complexes with palladium.[263]

Very little work has been devoted to cholesteryl-derived phosphines. The cholesteryl fragment offers many advantages in terms of chirality, liquid crystalline behavior, lipophilicity, optical and molecular recognition. Novel optically pure cholesteryl-phosphine ligands (3α-PPh_2chol and 3β-PMe_2chol) have been synthesized and were shown to form stable and highly soluble Pd^{II} and Pt^{II} complexes; as revealed by an X-ray analysis, the (chol)-P···P(chol) fragment of the square planar *trans*-$[PtI_2(3\text{-}\beta\text{-}PMe_2chol)_2]$ complex adopts a staggered arrangement (V-shape), see Figure 17.[264]

Cocrystals composed of two different neutral molecules are very rare and most can be classified as those which have two or more very similar molecules, often differing in a substituent on a ligand or by the presence of slightly different ligand such as replacement of one halide for another. The reaction of $[Pd(cod)Cl_2]$ (cod = cycloocta-1,5-diene) with *rac*-diphenyl[2.2]paracyclophanylphosphine $PPh_2(C_{16}H_{15})$ affords *trans*-$[Pd\{PPh_2(C_{16}H_{15})\}_2Cl_2]$ and $[Pd\{PPh_2(C_{16}H_{15})\}Cl_2]_2$ in approximately equal yield which cocrystallize to form an unusual solid-state material.[265] The crystal is composed of alternating layers of the two complexes intercalated with dichloromethane solvent molecules (see Figure 18).[265]

The transformation of carbon dioxide into useful chemical derivatives is an attractive goal in chemistry. Electroreduction of $Pd_2(dppm)_2Cl_2$ and $Pd(dppm)Cl_2$ (dppm = bis(diphenylphosphino)-methane) in an aprotic medium under carbon dioxide produces $Pd_3(\mu_3\text{-}CO)(\mu\text{-}dppm)_3$.[266]

6.4.5.5 Oxygen

Cationic palladium(II) complexes are homogeneous catalysts for both intramolecular and intermolecular hydroamination reactions.[267] Palladium species immobilized on silica can be prepared by the simple addition of alkyl- or hydroxopalladium(II) complexes to partially dehydroxylated silica. The silica-bound species are more stable than their molecular precursors and are efficient catalysts for the cyclization of aminoalkynes.[268]

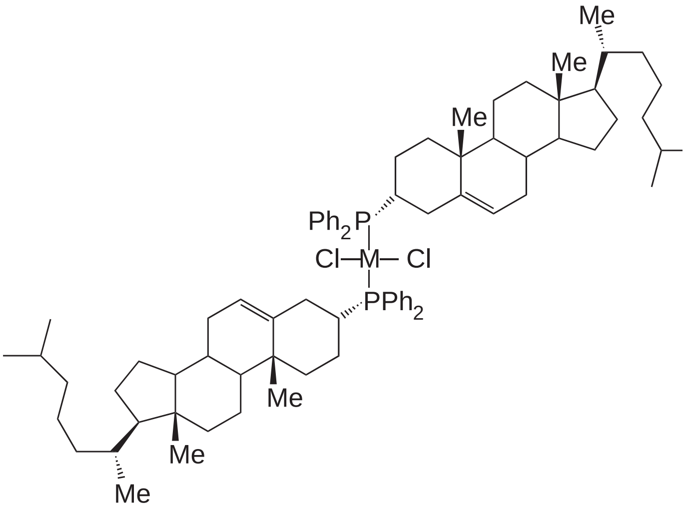

Figure 17 The (chol)-P···P(chol) fragment of the square planar *trans*-$[PtI_2(3\text{-}\beta\text{-}PMe_2chol)_2]$ complex adopts a staggered arrangement (V-shape).

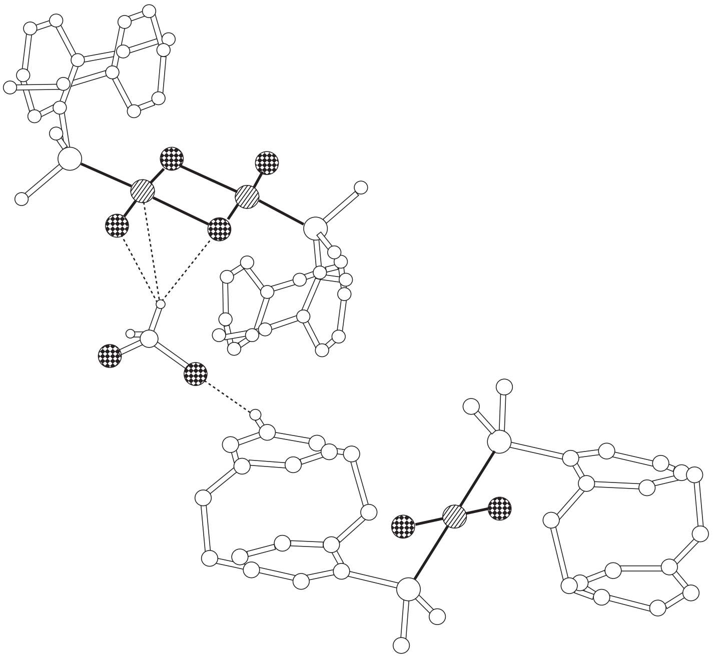

Figure 18 *trans*-[Pd{$PPh_2(C_{16}H_{15})$}$_2Cl_2$] and [Pd{$PPh_2(C_{16}H_{15})$}Cl_2]$_2$.

The majority of reported palladium hydroxo complexes are formed by the reaction of hydroxide with a metal–halide species by a simple metathesis reaction.[269] Direct observation of protonation of a hydrocarbyl ligand (M-R) on a d^8 square planar metal by water to form R-H and a M-OH species is extremely rare.[270–274] However, this type of protonation reaction with water has been proposed as the product release step in catalytic reactions that involve d^8 square planar hydroxo complexes.[275,276] Preparation of a new potentially tridentate ligand, *o,o′*-$Ph_2PC_6H_4C{=}NCH_2C_6H_4Br$ (PNC-Br), and a Pd^{II}-Br complex, (PNC)PdBr, of this new ligand were reported. Abstraction of a bromide ion from the complex with $AgBF_4$ in the presence of H_2O leads to protonation of the benzyl group of the PNC ligand, resulting in formation of a palladium bis-μ-hydroxo dimer, $[(PN)Pd(\mu\text{-}OH)]_2[BF_4]_2$.[277]

Dehydrative condensation of transition metal hydroxo complexes is a versatile synthetic method, when the conjugated acid of the incoming ligand (H-A) is a protic compound. There are reports of the synthesis of two types of square-planar hydroxopalladium complexes, mononuclear $[Tp^{iPr2,X}(L)Pd\text{-}OH]$ ($X = H$, Br) and dinuclear complexes $[Tp^{iPr2}Pd(H_2O)(\mu\text{-}OH)_2(H_2O)PdTp^{iPr2}]$ (Tp^{iPr2} = hydrotris(3,5-diisopropylpyrazolyl)borate), and some dehydrative condensations of them.[278]

Gas-phase photolysis of metal-containing molecules readily causes photofragmentation to produce metal atoms and ions. More recently it has been shown by luminescence spectroscopy that photolysis of these molecules also readily produces diatomic metal-containing molecules in the gas phase. These discoveries have assisted in the elucidation of the photolytic decomposition pathways relevant to laser-assisted chemical vapor deposition (LCVD). Both desired fragments and undesirable fragments containing heteroatoms that contaminate the final films have been identified. The fluorinated acetylacetonate ligands (1,1,1,5,5,5-hexafluoro-2-4-pentanedionate = hfac) that were used in the latter studies provide good precursor volatility and allow for facile transport in the gas phase, but they may also result in fluorine and/or carbon contamination of the final deposit. The formation of diatomic metal fluorides can be easily eliminated by removing the fluorine substituents from the precursor, but the carbon that leads to metal carbide molecules cannot be so easily eliminated. Studies of the gas-phase photolysis of $Pd(hfac)_2$, showed that PdC^+ is a common photoproduct over a wide range of irradiation wavelengths, but that the ratio of Pd^+ to PdC^+ is very sensitive to the wavelength. Changing the wavelength by a few angstroms can cause the formation of PdC^+ to decrease below the detection limit. The photoproducts are monitored by using time-of-flight mass spectroscopy.[279] The energy level diagram (Figure 19) illustrates the photochemical events leading to Pd^+ and PdC^+ formation.[279] These types of wavelength dependence studies of chemical vapor deposition precursors are leading to a

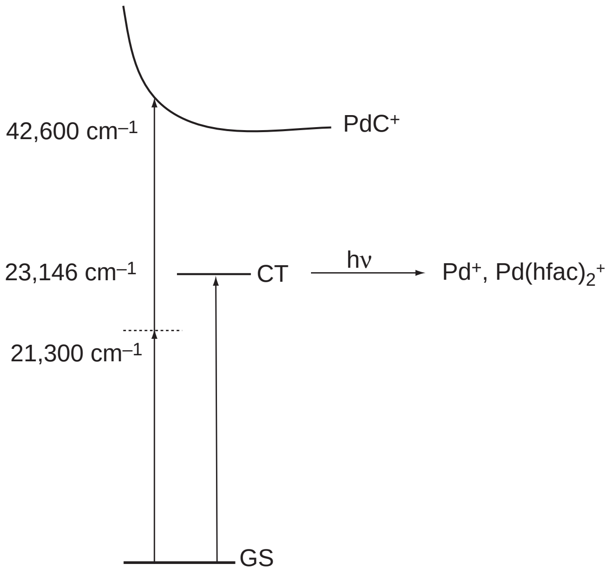

Figure 19 Energy level diagram illustrating the photochemical events leading to Pd^+ and PdC^+ formation.

fuller understanding of the gas-phase photochemical components of the LCVD process and may be helpful toward designing strategies for obtaining higher quality thin films.[279]

The coordination and catalytic chemistry of 1,1′-bis(diphenylphosphino) ferrocene (dppf) has been reviewed.[280,281] It can be readily oxidized to its mono- and di-oxide (dppfO2) forms. Interest in Pd^{II}–dppf chemistry stems from the rich catalytic activities shown by many dppf complexes of Pd^{II}.[282–286] Some of these complexes are susceptible to oxidation in solution and the decomposition product is generally assumed to be chiefly free dppfO2.[287] There is a report of the isolation of a simple Pd^{II}–dppfO2 complex with a rare mononuclear tetrahedral Pd^{II} center which, to our knowledge, has not previously been reported in the literature.[288] It is well known that d^8 platinum metals overwhelmingly favour square planar structures and only Ni^{II} forms a significant number of tetrahedral complexes. The magnetic moment ($2.48\,\mu_B$) is lower than that of a typical Ni^{II} tetrahedral complex (ca. $3.2\,\mu_B$) but still consistent with paramagnetic Pd^{II} with two unpaired electrons. The cyclic voltammogram shows a reversible one-electron couple.[288] Crystallographic analysis confirmed a mononuclear neutral complex with a chelating dppfO2 and two terminal chlorides (see Figure 20). The near-ideal tetrahedral geometry at the Pd^{II} center is exemplified by the large intra- and inter-ligand angles (O1—Pd1—O2, Cl1—Pd1—Cl2 and O—Pd—Cl angles of 104.3(3)°, 120.4(2)°, and 107.8° (av.), respectively).[288]

Reaction control with transition metal catalysis is largely underdeveloped in the carbohydrate field. One of the most important reasons for the limited use of metal catalysis is the lack of knowledge of the bonding mode of carbohydrates towards transition metal ions. An aqueous solution of *cis*-$[Pd(en)(OH)_2]$ is a versatile agent for the analysis of carbohydrate–metal interactions in alkaline aqueous media. In the presence of carbohydrate-based 1,2- and 1,3-diol groups, the hydroxo ligands of *cis*-$[Pd(en)(OH)_2]$, are replaced by a dianionic diolato ligand. The ligating alkoxo O atoms are acceptors in hydrogen bonds, which are established as intramolecular bonds whenever possible. Pd-en is a coordinating solvent for polysaccharides, including cellulose, which is molecularly dispersed to give entirely metallated single strands.[289]

A columnar mesophase consisting of chiral molecules tilted with respect to the column axis can be ferroelectrically switched. The possibility of achieving ferroelectric switching in a columnar liquid crystal comes from the appearance of a macroscopic polarization perpendicular to the column axis. Ferroelectric columnar metallomesogens can be designed by taking advantage of the possibility of obtaining disklike molecules by means of metal complexation, for metal bis(1,3-diphenyl-1,3-propanedionates) bearing 10 peripheral tails.[290] Two pentasubstituted 1,3-diphenylpropanedione ligands can be complexed to palladium(II), thus giving rise to a disklike core surrounded by 10 chiral tails derived from L-(−)-lactic acid. A combination of different characterization techniques—optical microscopy, differential scanning calorimetry, X-ray diffraction, circular dichroism, and dielectric spectroscopy—has allowed a rigorous analysis of the mesophase

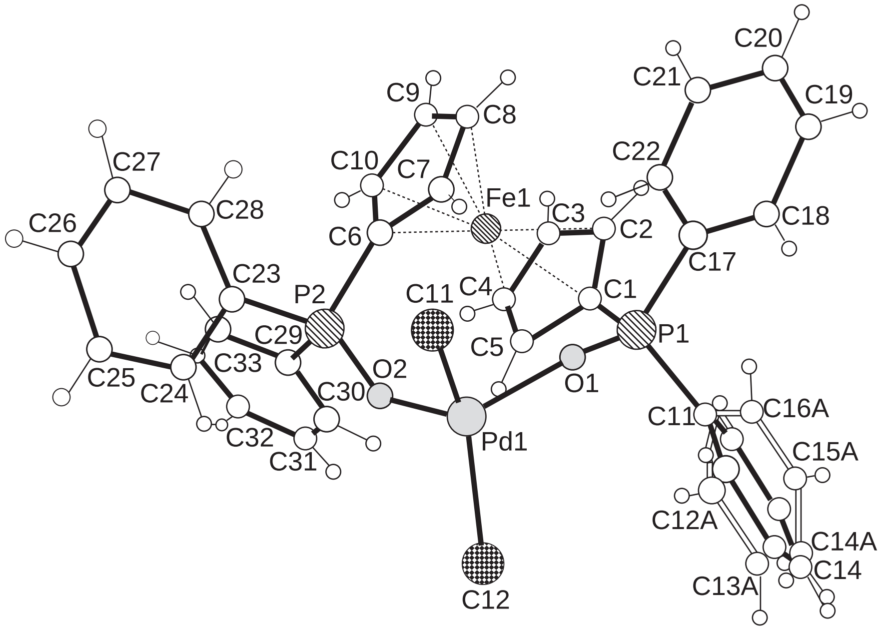

Figure 20 A mononuclear tetrahedral complex with a chelating dppfO2 and two terminal chlorides.

structure and the switching process of these compounds.[290] A single mesophase is stable at room temperature. The mesophase has been identified as rectangular columnar by X-ray diffraction. Circular dichroism has demonstrated the existence of helical order within the column. By application of an alternating electric field, an electrooptic effect was observed. The response of the material to the field is in accordance with a strong tilting of the molecules with respect to the column axis.[290]

6.4.5.6 Sulfur

Hydrosulfido palladium complexes are rare. Only some terminal hydrosulfido compounds of the type $[PdL_2(SH)_2]$ ($L_2 = 2$ PPh_3, 2 PEt_3, 2 PBu^i_3, or diphos) (diphos = [1,2 bis(diphenylphosphino)ethane]),[291–293] have been reported and no examples of bridging hydrosulfido ligands on palladium were known until recently. The μ-hydroxo complexes of palladium are excellent precursors in synthetic work.[294–296] Their reactions with H_2S gas gives the first bridging hydrosulfido palladium complexes. The mononuclear hydrosulfido complexes $[Pd(C_6F_5)_2(SH)(PPh_3)]^-$ prepared from the corresponding dimers by addition of PPh_3 in the molar ratio 1:2, can be used as metalloligands toward $M'(PPh_3)^+$ ($M' = Ag$ or Au), yielding heterobinuclear or heterotrinuclear complexes.[297]

Potentially coordinatively unsaturated dithiolene-metal complexes are rare,[298–306] and 1:1 dithiolene-transition-metal complexes with no other ligands are, to our knowledge, unprecedented.[307] The neutral complex $[PdS_2C_2(COOMe)_2]_6$,[308] is homoleptic containing one dithiolene unit for each palladium atom and no other ligands. Electrochemical reduction of the compound depicted in Figue 21 proceeds in four reversible steps.

As nucleobases can bind metal ions, base-pairing interactions can be used directly in their complexes. For the adenine–thymine (AT) pair, there are numerous possibilities for interactions which involve two hydrogen bonds. The thermodynamically favored arrangement is the Hoogsteen AT pattern, which involves A-N7. However, since this is also the preferred site for metal-ion binding, this pairing mode is often unavailable. The dithioether, shown in Figure 22, reacts with Pd^{II} to give cationic A-N3-bonded complex.[309] The dithioether group and the A-N3 site coordinate to the metal ion. The molecular structure of the complex cation is presented in Figure 23. There is Hoogsteen base pairing between complex cations. Infinite base-paired chains are formed by translational symmetry. The crystal symmetry produces antiparallel alignment of neighboring chains. Further interactions between the nucleobases involve dimers of stacked AT

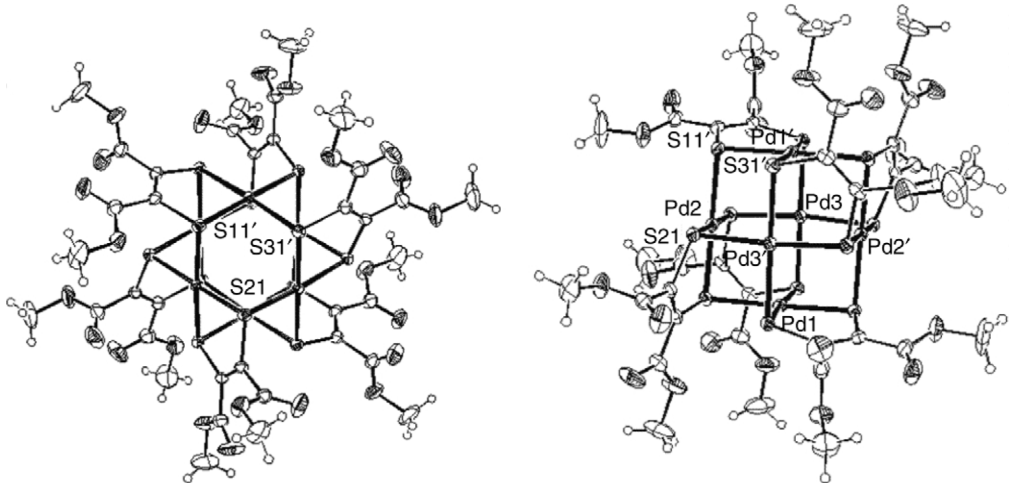

Figure 21 The neutral complex containing one dithiolene unit for each palladium atom and no other ligands.

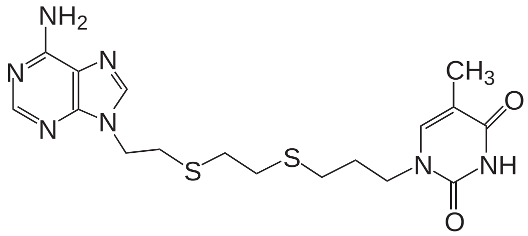

Figure 22 The dithioether that reacts with Pd^{II} to give cationic A-N3-bonded complex in Figure 23.

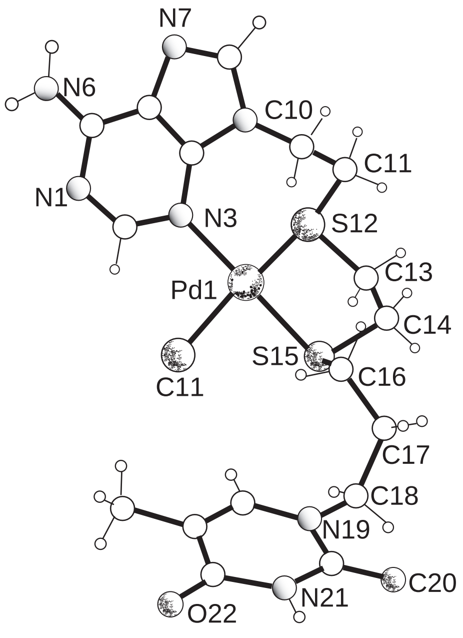

Figure 23 Molecular structure of the complex cation containing adenine and thymine.

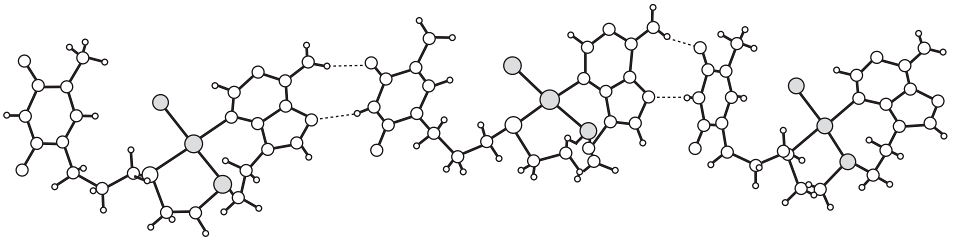

Figure 24 Interactions between the nucleobases involve dimers of stacked AT pairs that are slipped so as to form ATTA sequence.

pairs that are slipped so as to form ATTA sequence runs with typical separations for π–π stacking, as depicted in Figure 24. Evidently, controlling the metal ion nucleobase binding pattern by using a chelating group enables the synthesis of base-pairing complexes that assemble in a predictable arrangement.

Early/late heterobimetallics can be prepared from so-called metalloligands, in which a bifunctional ligand is coordinated to a transition metal. In a second step, a second transition metal is introduced. When the zirconocene metalloligand was treated with $[PdCl_2(PBu^n{}_3)_2]$, the octanuclear Zr^{IV}—Pd^{II} complex was formed unexpectedly, albeit in low yield (see Figure 25).[310] There is no Pd—Pd interaction [Pd1···Pd2 3.141(1) Å]. The cavity of the central 20-membered ring (Zr1—Pd1—Zr1a—Pd1a) is filled by the *n*-butyl groups of the phosphine ligands. Additionally, two 10-membered rings are formed by Zr_2, Pd_2, and the monodentate sulfidoacetato ligands. The formation of this unprecedented large ring-like molecule is apparently preferred over the formation of simple heterodinuclear complexes.

Palladium dimethylsilanedithiolato complex is a precursor for Ti—Pd and Ti—Pd_2 heterometallic complexes.[311] The bis-silyl sulfides $(R_3Si)_2S$ have been widely used to prepare a variety of metal sulfide clusters, because these reagents exploit the strength of the Si—O and Si—Cl bond to

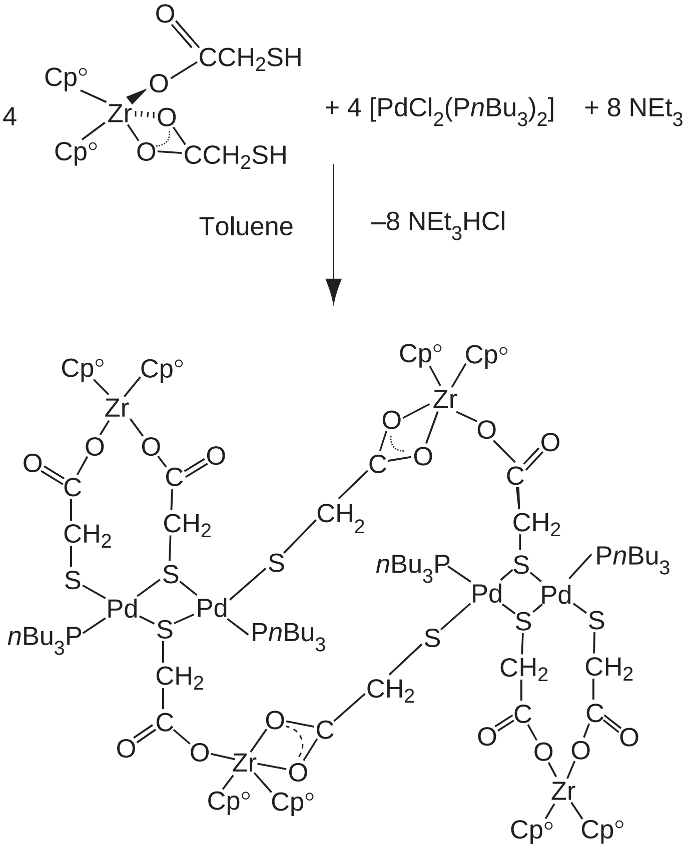

Figure 25 Formation of an octanuclear Zr^{IV}—Pd^{II} complex.

replace a halide, alkoxide, acetate, or oxide with a sulfido ligand under very mild and controlled conditions. Therefore, a metal–silanethiolato complex (e.g., M—SSiR$_3$) would be expected to serve as a synthetic precursor for homo- and hetero-metallic sulfido clusters.[312,313] The synthesis of a palladium dimethylsilanedithiolato complex and its cluster forming reactions with (C$_5$H$_5$)TiCl$_3$ and TiCl$_4$(THF)$_2$ are shown in Figure 26.[311]

The formation of mesogenic materials from functionalized macrocyclic ligands is the subject of considerable current interest. On complexation to Pd^{II}, the macrocyclic ring becomes conformationally locked and acts as a rigid spacer which couples the terminal mesogenic groups together.[314] This demonstrated the ability of a metal ion to induce mesomorphism (liquid crystallinity) in non-mesomorphic ligands, and thus to define a sensing function for the ligands.

Pelletier and Reber[315] present new luminescence and low-energy excitation spectra of Pd(SCN)$_4$$^{2-}$ in three different crystalline environments, K$_2$Pd(SCN)$_4$, [K(18-crown-6)]$_2$Pd(SCN)$_4$, and (2-diethylammonium *N*-(2,6-dimethylphenyl)acetamide)$_2$Pd(SCN)$_4$, and analyze the vibronic structure of the luminescence spectra, their intensities, and lifetimes as a function of temperature. The spectroscopic results are compared to the HOMO and LUMO orbitals obtained from density functional calculations to qualitatively illustrate the importance of the bending modes in the vibronic structure of the luminescence spectra.

The best known dithiolenes are those derived from the dmit ligand (dmit = C$_3$S$_5$$^{2-}$, 1,3-dithiole-2-thione-4,5-dithiolate) with d^8 transition-metal ions[316–325] because of their interesting electrical conduction properties. At present, several superconductors deriving from the dmit ligand, such as α-TTF[Pd(dmit)$_2$],[326] (TTF = tetrathiafulvalene) are known. Some neutral [Ni(S$_2$C$_2$R,R$'$)$_2$] dithiolenes could be used as Q-switching dyes for NIR-lasers because of their high photochemical stability and intense vis-NIR absorption.[327] This absorption, attributed to a π–π^* electronic transition between the HOMO and the LUMO, occurs at energy values depending on the nature of the R and R$'$ substituents. For the simplest dithiolenes (R = R$'$ = H, often reported as "parent dithiolenes") this absorption was observed at 785 nm for [Pd(S$_2$C$_2$H$_2$)$_2$].[328] The more recently reported [Pd(Et$_2$timdt)$_2$][329] shows the NIR absorption band at 1010 nm with a molar extinction coefficient of 70,000 M^{-1} cm^{-1}. The wavelength and the high intensity of the NIR absorption band also propose this new class of dithiolenes as candidates for Q-switching the Nd:YAG laser (excitation wavelength 1,064 nm). To obtain dithiolenes characterized by the NIR absorption as close as possible to the excitation wavelength of the Nd:YAG laser, the authors have systematically varied either the central metal or the substituents R and R$'$ in the [M(R,R$'$timdt)$_2$] dithiolene unit. Therefore, dithiolenes with M = Pd have been synthesized (see Scheme 4).[330]

The interaction of palladium(II) complexes with sulfur-containing peptides was studied by electrospray mass spectrometry.[331]

Ferrocene compounds containing heteroelements are versatile building blocks for polynuclear complexes. They possess electrochemically active iron centers as well as unique cylindrical shapes. An example of ferrocene-substituted thiolato ligands is 1,1$'$-ferrocenedithiolate (S$_2$fc). Its complex with Pd(II) lacks a Pd—Fe bond.

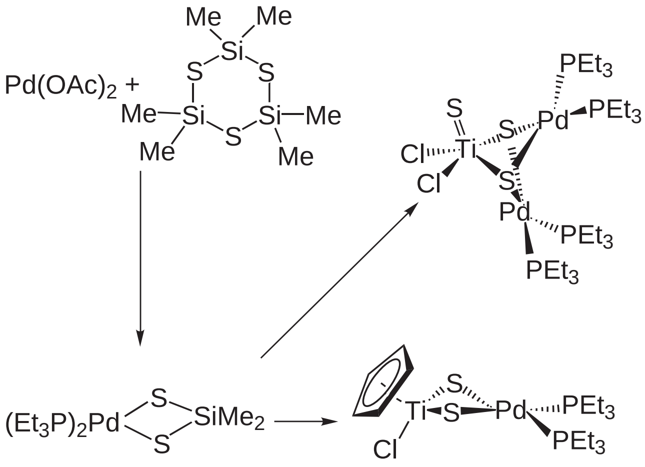

Figure 26 Synthesis of a palladium dimethylsilanedithiolato complex and its cluster forming reactions with (C$_5$H$_5$)TiCl$_3$ and TiCl$_4$(THF)$_2$.

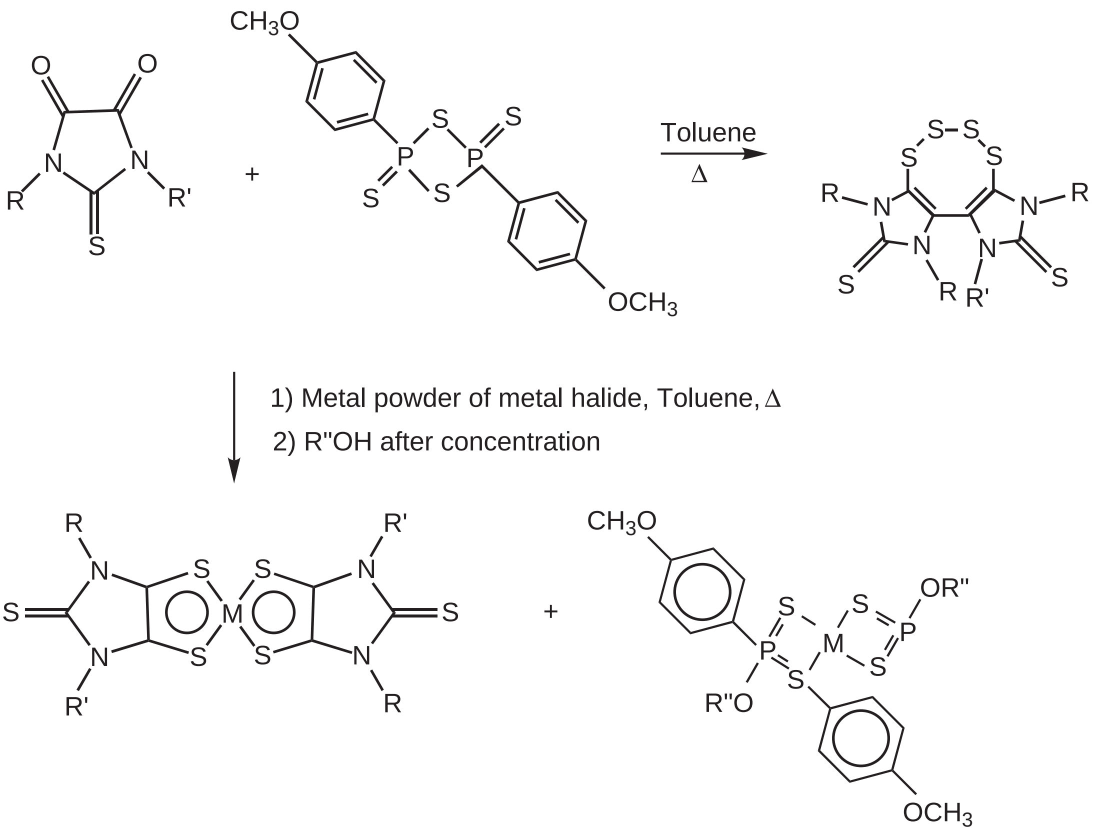

Scheme 4

Metal dithiolenes can exist in well defined oxidation states. The intense vis–NIR absorption is assigned to a $\pi \rightarrow \pi^*$ transition between HOMO and LUMO and depends on the nature of the substituents R^1 on the carbon atoms of the $[S_2C_2R^1{}_2\,]^{2-}$ moiety. Accepting substituents shift this absorption to lower energies. The aim is to prepare complexes of this class having the NIR absorption as close as possible to the Nd–YAG laser excitation energy. The first Pd complex belonging to this new class of dithiolenes, $[Pd(Et_2timdt)_2]$, is fully characterized.[329] In order to obtain mixed-valence compounds which might have interesting conducting properties, the authors treated it with diiodine in several molar ratios.[329]

6.4.5.7 Selenium and Tellurium

The preparation of transition metal complexes with organoselenide and -telluride ligands characteristically involves the oxidative addition of the organochalcogen compounds to low-valent transition metal centers most often resulting in the cleavage of the chalcogen–chalcogen bond and the formation of mono- or dinuclear complexes with anionic bridging or terminal RE^- ($E = Se$, Te) ligands, as shown in Figure 27.

It has, however, also been reported that the reaction of aryl ditellurides with Ni^0, Pd^0, and Pt^0 may result in the cleavage of the carbon–chalcogen bond.[332–335] The oxidative addition of organochalcogen compounds to low-valent transition metal centers is considered a key step in homogeneous catalysis.[336] Complex $[Pd_2(SePh)_4(PPh_3)_2]$ forms from Ph_2Se_2 and $[Pd(PPh_3)_4]$ in benzene.[337] Analogous dinuclear complexes in which two bridging RE^- ($E = S$, Se) ligands link two palladium centers together are exemplified by $[Pd_2(C_3H_5)_2\{Ph_2P(O)NP(Se)Ph_2Se\}_2]\cdot 2CHCl_3$,[338] $[Pd_2\{Se_2C_8H_{12}\}_2(PPh_3)_2]$,[339] and $[Pd_2Cl_2(SeMe)_2\{SeMe(C_4H_2O)\}_2CMe_2]$.[340] The oxidative addition of bis(thienyl) diselenide to $[Pd(PPh_3)_4]$ results in the cleavage of the Se—Se bond. The main products in the reaction of $[Pd(PPh_3)_4]$and Th_2Se_2 are dinuclear *cis*- and *trans*-$[Pd_2(SeTh)_4(PPh_3)_2]$, which could be identified by ^{31}P- and ^{77}Se-NMR spectroscopy.

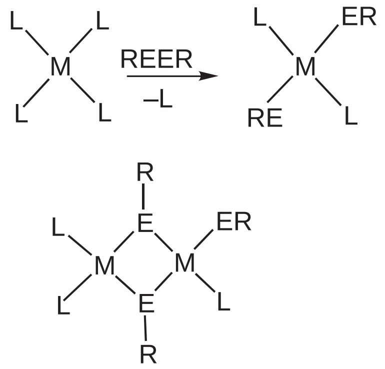

Figure 27 Oxidative addition of the organochalcogen compounds to low-valent transition metal centers most often resulting in the cleavage of the chalcogen–chalcogen bond and the formation of mono- or dinuclear complexes with anionic bridging or terminal RE^- (E = Se, Te) ligands.

Recrystallization afforded *trans*-$[Pd_2(SeTh)_4(PPh_3)_2]$, which could be characterized by X-ray crystallography. When the reaction is carried out in dichloromethane, a small amount of $[PdCl(Th)(PPh_3)_2]$ is formed. This implies that the solvent plays an active role in the reaction and that the cleavage of a C—Se bond may also occur during the oxidative addition.[341] The different behavior of analogous palladium and platinum complexes has been noted for the reactions of $[MCl_2(PhCN)_2]$ (M = Pd, Pt) with cyclohepteno-1,4-diselenin.[339,342] The reaction with $[PdCl_2(PhCN)_2]$ is a simple ligand substitution reaction whereas with $[PtCl_2(PhCN)_2]$ an oxidative addition of a C—Se bond to a Pt^{II} center takes place with the formation of a dinuclear platinum(IV) complex.[341] The oxidative addition reactions involving aromatic ditellurides are significantly more complicated than those involving diselenides. They also depend on the choice of the aromatic substituent, and are sensitive to the choice of the solvent.[341]

The complex bis(tetraphenylphosphonium)[bis(1,2-diselenosquarato)palladate(II)], $(Ph_4P)_2[Pd(dssq)_2]$, is the first coordination compound of the new ligand 1,2-diselenosquarate.[343]

6.4.5.8 Halogens

Neutral palladium(II) complexes containing carboxylic acid groups can give supramolecular structures through intermolecular hydrogen bonding, but in cationic complexes the desired hydrogen bonding between carboxylic acid groups did not occur because H-bonding of the carboxylic acid groups to the anions or to solvent molecules was generally preferred.[344,345] Amides form stronger hydrogen bonds. Both neutral and cationic palladium(II) complexes containing carboxamide groups are readily prepared, and they self-assemble to form interesting supramolecular arrays. The neutral complex *trans*-$[PdCl_2(NC_5H_4\text{-}3\text{-}CONHMe)_2]$ forms an infinite two-dimensional sheet structure in the solid state. The sheets are further connected by weaker Pd···Cl bonds and O···H—O hydrogen bonds to form a three-dimensional network.[346]

For halide ligands, a coordination number of four (μ_4-X) is rare. Self-assembly of d^8 metal centers and halides around a pyramidal halide gives tetrapalladium complexes. In this unprecedented case the metallamacrocycle owes its formation to the halide acting as a template.[347] The complexes $(PPN)[Pd_4(Fmes)_4]$ (Fmes = 2,4,6-tris(trisfluoromethyl)phenyl) display fluxional behavior in solution in noncoordinating solvents.[347]

Only eight transition-metal species containing a terminal FHF (FHF = Fluorine-Hydrogen-Fluorine) ligand have been described in the literature. Of those, only six have been isolated in pure form and only four have been structurally characterized. A palladium bifluoride complex, $[(Ph_3P)_2Pd(Ph)(FHF)]$, has been studied by X-ray diffraction, IR, and VT (variable temperature), ^{1}H-, ^{19}F-, and ^{31}P-NMR spectroscopy, and ^{19}F-NMR magnetization transfer.[349] The Pd bifluoride is fluxional in solution at room temperature due to F/F interchange. When the latter is frozen at $-60\,^\circ C$, the structure in solution is similar to the solid-state X-ray structure. Although all structural and spectroscopic data point to MF···HF rather than M···FHF character, ^{19}F-NMR magnetization transfer experiments have demonstrated a minor contribution of HF dissociation to the exchange. The main process that governs F/F exchange is intramolecular ($\Delta H^\ddagger = 33.7 \pm 2.1\ \mathrm{kJ\,mol^{-1}}$; $\Delta S^\ddagger = -56.1 \pm 9.6\ \mathrm{J\,mol^{-1}\,K^{-1}}$), which is proposed to occur via the pentacoordinate intermediate $[(Ph_3P)_2Pd(Ph)(\eta^2\text{-FHF})]$. DFT calculations for two model Pd bifluoride complexes $[(R_3P)_2Pd(Me)(FHF)]$ (R = H, Me) indicate virtually unrestricted rotation around the Pd-FHF bond.[349]

One way to investigate the effect of halide ions on the structure and reactivity of palladium(0) complexes in oxidative addition with aryl halides[350–353] was to generate them by electrochemical reduction of $PdX_2(PPh_3)_2$ in the presence of various amounts of halides X^- (X = Cl,[350,351] Br,[351] I[351]) in THF. Reinvestigation of this reaction led the authors to reject their first tentative hypothesis and to establish that reactions of halides X^- with $PdX_2(PPh_3)_2$ result in substitution of one phosphane ligand with formation of an anionic $PdX_3(PPh_3)^-$ species; this palladium(II) complex is more difficult to reduce. In other words, the two peaks represent the reduction of two different palladium(II) complexes. Halide ions can substitute a phosphane ligand in $PdX_2(PPh_3)_2$ complexes to afford anionic species $PdX_3(PPh_3)^-$ by an equilibrium. The phosphane substitution is easier for chloride ions which reveals the higher nucleophilic affinity of Cl^- for the palladium(II) center than that of Br^- or I^-. This can be understood as an interaction between "hard" Lewis acids and bases.[354] Conversely, we have reported that the affinity of Cl^- for palladium(0) centers is less than that of Br^- or I^- which can be rationalized as an interaction between "soft" centers.[351] Those results are evidence of the ability of halide ions to coordinate both palladium(0) and palladium(II) complexes. The ligation of palladium(0) complexes by halide[351–353] or acetate ions[353,355] affects the mechanism of palladium-catalyzed reactions. Although palladium(II) dihalide complexes are less involved as promoters of catalytic reactions than palladium(0) complexes, arylpalladium(II) halide complexes are postulated to be crucial intermediates in palladium(0) catalyzed reactions involving aryl halides. Reactions of halide ions X'^- with $ArPdX(PPh_3)_2$ complexes do not result in a substitution of one phosphane ligand but rather substitution of the halide X^- to form neutral $ArPdX'(PPh_3)_2$ complexes.[356] In fact, $ArPdX(PPh_3)_2$ complexes are not reactive intermediates in cross-coupling[351,353] or Heck[353,355] reactions, and the effect of chloride or acetate anions on the course of these reactions is to produce new anionic or neutral complexes such as $ArPdX(Cl)(PPh_3)_2{}^-$, $ArPdX(OAc)(PPh_3)_2{}^-$, $ArPd(OAc)(PPh_3)_2$, where the two phosphane ligands remain attached to the palladium(II) center.[354]

6.4.5.9 Hydrogen

Rate constants for H_2 activation vary with Pd_n cluster size.[357] This is in accord with theoretical studies, which have predicted that the minimum-energy structure is a side-bonded atom-molecule complex,[7,358–364] but that Pd_2 can form a stable ring $(PdH)_2$ species with no H—H bond.[13,14] Evidence for naked metal–H_2 complexes in a krypton and xenon matrix study with Pd was interpreted in terms of both end- and side-bonded complexes;[362,365] however, theoretical investigations find a stable minimum only for the side-bonded structure. The complete infrared spectrum of $Pd(H_2)$ in solid argon, is in very good agreement with the density functional theory (DFT) calculated vibrational spectrum. The novel bis- and tris-H_2 complexes, the related Pd—$Pd(H_2)$ complex, and the stable $(PdH)_2$ reaction product containing dissociated dihydrogen are identified.[366]

Many palladium-catalyzed reactions are initiated by the reaction of a palladium(0) complex with an acidic derivative.[367] The catalytic cycle is considered to be induced by a hydridopalladium complex. When the acidic derivatives are strong acids (e.g., HBF_4, HCl, CF_3CO_2H, HOTs), the hydridopalladium formation may be regarded as the protonation of basic Pd^0 to afford complexes $HPdL_3{}^+$[368–374] or $HPdL_2S^+$,[375] in which S = solvent (see Equation (1)):

$$\mathrm{H^+ + Pd^0L_{\mathit{n'}} \longrightarrow HPdL_{\mathit{n}}{}^+ + (\mathit{n'}-\mathit{n})L} \tag{1}$$

The palladium may then be considered as either Pd^0 ligated by a proton or as Pd^{II} ligated by a hydride,[376] albeit that the very negative shift of the ^{1}H-NMR signal is more indicative of a hydride linked to a palladium(II) center. This is why this reaction is also considered as an oxidative addition.[376] When weak carboxylic acids are involved (e.g., acetic acid, formic acid), the reaction is regarded as an oxidative addition, i.e., insertion of palladium(0) into the H—X bond (see Equation (2)):[367,376]

$$\mathrm{HX + Pd^0L_{\mathit{n'}} \longrightarrow HPd^{II}XL_{\mathit{n'}} + (\mathit{n'}-\mathit{n})L} \tag{2}$$

It is not clear whether the X anion remains ligated to the palladium(II) center. For example, for acetic acid, the palladium hydride was initially postulated as being $HPd(OAc)L_n$,[377,378] but more recently as $HPdL_n^+$.[367] To date, none of these complexes has been characterized.[367] Oxidative addition of acetic acid or formic acid to a palladium(0) complex in DMF affords a cationic palladium hydride *trans*-$HPd(PPh_3)_2(DMF)^+$, with an acetate or a formate counter-anion. Both reactions are reversible and involve an unfavorable equilibrium so that a large excess of acid is required for the quantitative formation of the palladium hydride complex.[379] This allows us to conclude that the catalytic reactions initiated by reaction of palladium(0) and acetic acid (or formic acid) proceed via a cationic palladium hydride *trans*-$HPd(PPh_3)_2(DMF)^+$, when they are performed in DMF.[379]

6.4.5.10 Mixed Donor Atoms

The palladium(II) chemistry of the tri-linked macrocycles of the type shown in Figure 28, parallels that of the related single ring macrocycles.[380]

There has been considerable interest in the study of multinuclear d^8 metal complexes with bridging sulfide ligands.[381] The first examples of *triangulo* palladium(II) are the complexes containing substituted 2,2′-bipyridine and triply bridging sulfide ligands, namely $[Pd_3(diimine)_3(\mu_3\text{-}S)_2][ClO_4]_2$.[382]

Carbon disulfide undergoes 1,3-dipolar cycloaddition to the coordinated azide in the cyclopalladated Pd^{II} complex.[383]

The authors synthesized three amino acid substituted calix[4]arenes and investigated their coordination reactions towards Pd^{II} using electrospray mass spectrometry.[384]

By linking metal-binding domains to estrogen through the 17α-position, strong affinity for the estrogen receptor is achieved. The palladium(II) metallo–estrogen shows transport and subsequent binding affinity that is of the same order as estradiol itself. Despite their monocationic nature, the palladium(II) complexes have exhibited similar (and even enhanced) receptor binding affinities compared to their corresponding neutral free ligands.[385]

Many bis-chelate Pd^{II} complexes possessing a *cis*-arrangement of the phosphinoalkylsilyl ligands have been synthesized,[386–389] but comparatively few *trans*-bis-chelates are known. The kinetic stability of *trans*-bis-chelates can be greatly enhanced by placing a bulky *o*-carborane unit in the ligand backbone.[390]

Hydrothermal synthesis using hard and soft acids and bases gave the metal hydroxide-based phases $M_3Pd_2(OH)_2[NC_5H_3(CO_2)_2\text{-}2,4]_4(H_2O)_4$ (M = Co, Ni, Zn).[391] A crystal structure is shown in Figure 29.

The C_2-symmetric 1,1-binaphthyl unit and tetradentate Schiff bases (salen) constitute two of the most important types of chiral auxiliaries in metal-mediated asymmetric catalysis. Their "hybridized" forms, i.e., binaphthyl Schiff bases, have been developed. One palladium(II) tetradentate Schiff base complex, characterized by X-ray crystallography, contains N_3O rather than N_2O_2 chelating atoms.[392] These ligands, shown in Figure 30, favor the nonplanar N_2O_2 arrangement in binding metal ions.

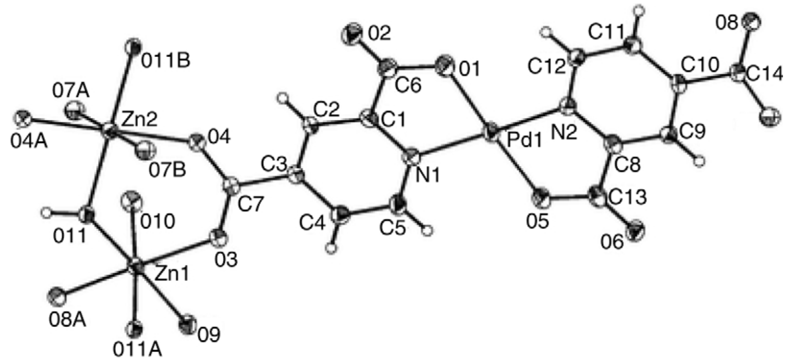

Figure 29 Crystal structure of the basic building block for $M_3Pd_2(OH)_2[NC_5H_3(CO_2)_2\text{-}2,4]_4(H_2O)_4$ (M = Co, Ni, Zn).

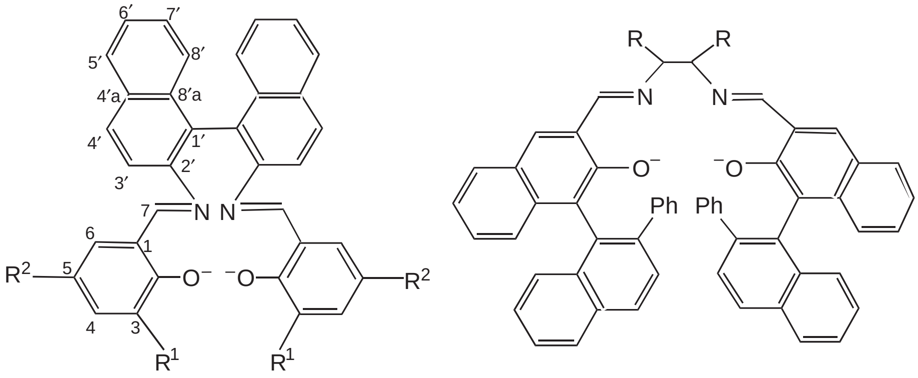

Figure 30 Schiff base binaphtyl ligands.

The synthesis, structure, and catalytic properties of a Pd^{II} complex with a partially hydrogenated ligand, shown in Figure 31, are described.[393] This study provides the first asymmetric epoxidation of alkenes catalyzed by a palladium complex.[393]

In many reactions catalyzed by late transition metals, the precatalyst is stabilized by ligands having phosphorus donor atoms which are compatible with a wide variety of metal oxidation

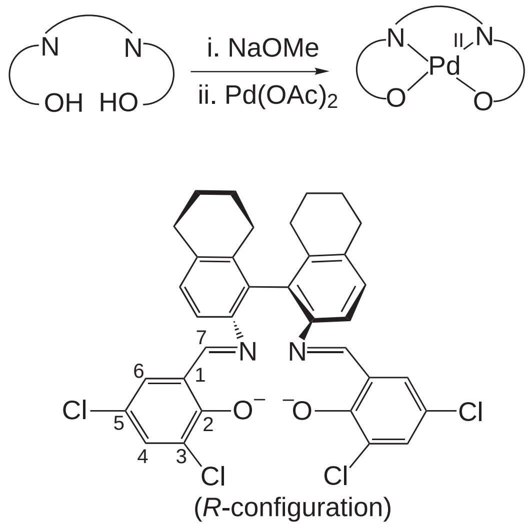

Figure 31 A Pd^{II} complex with a partially hydrogenated ligand acts as a catalyst for asymmetric epoxidation.

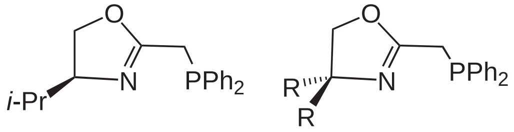

Figure 32 The first P,N-ligand shown in Figure 32 can form five-membered ring chelates, in allylic alkylation with Pd; the second is a chelating (phosphinomethyl)oxazoline P,N-type ligand, that catalyzes the copolymerization of ethylene/CO.

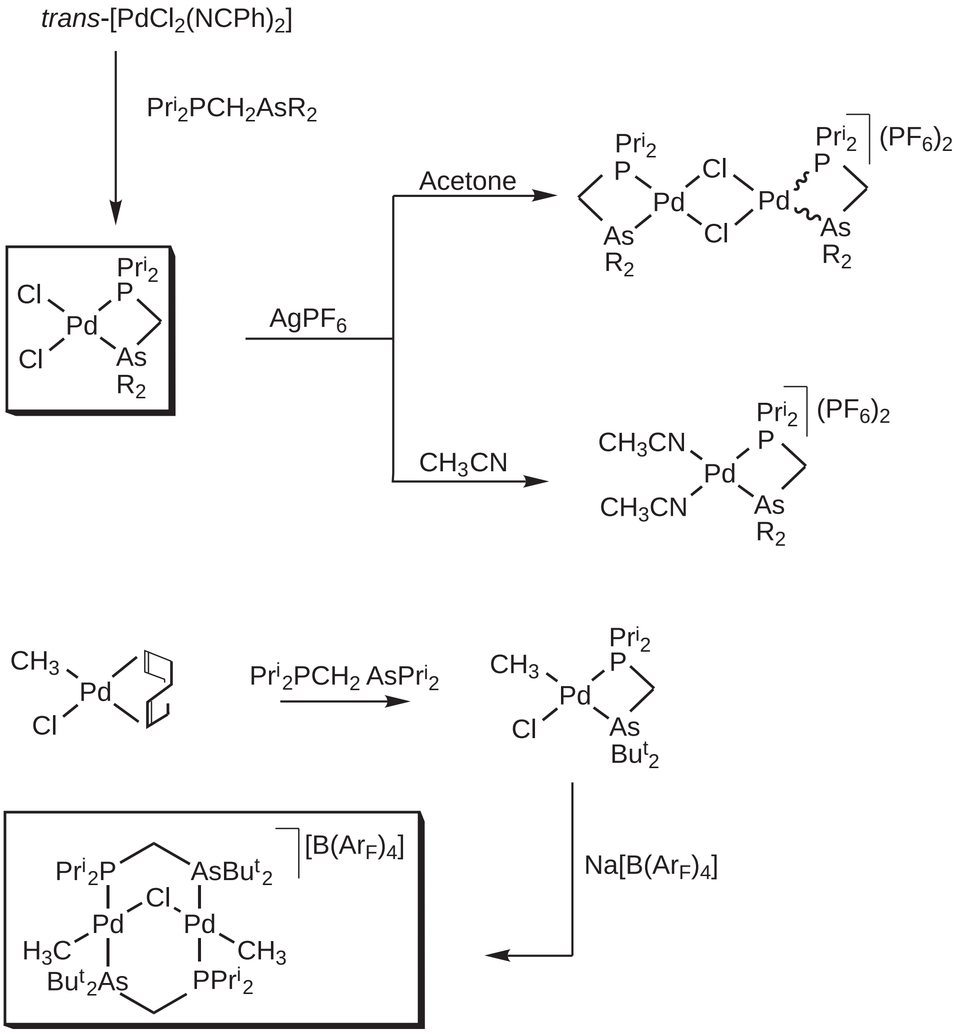
states and therefore with redox changes that may occur. Ligands which bear both phosphorus and nitrogen donors confer high reactivity and selectivity in some catalytic reactions. The first P,N ligand shown in Figure 32 can form five-membered ring chelates, in allylic alkylation with Pd.[394] A study reports the synthesis and structure of Pd^{II} complexes containing chelating (phosphinomethyl)oxazoline P,N-type ligands, the second shown in Figure 32. These complexes catalyze the copolymerization of ethylene/CO.[395]

The new arsino(phosphino)methanes with bulky substituents at the two donor centers can behave both as chelating and bridging ligands toward palladium(II). Besides neutral and mono- as well as di-nuclear cationic compounds, in which these ligands are bonded in a chelating fashion, a di-nuclear complex of the A-frame type could also be generated (see Scheme 5).[396]



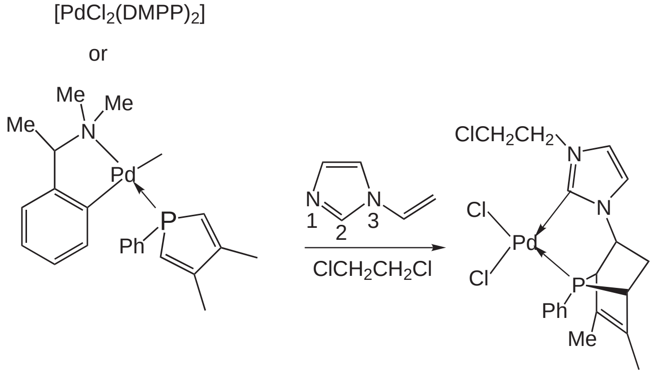
Scheme 5

An optical-microwave double resonance study[131] of a metal–organic chelate compound Pd(2-thpy)$_2$ ((2-thpy)$^-$ = 2-thienylpyridinate) in the lowest excited triplet state demonstrated the complementary nature of time-resolved emission spectroscopy and phosphorescence microwave double-resonance spectroscopy. Interestingly, both methods[131,397] can reveal a spin selectivity in the vibrational satellite lines of the emission spectrum. The complex Pd(qol)$_2$ (qol$^-$ = 8-quinolinolato-*N,O* = oxinate) is investigated by means of high-resolution and site-selective emission spectroscopy as well as by methods involving microwave double-resonance spectroscopy to develop a detailed understanding of the properties of the lowest excited states, presumably of the intraligand charge-transfer type.[398]

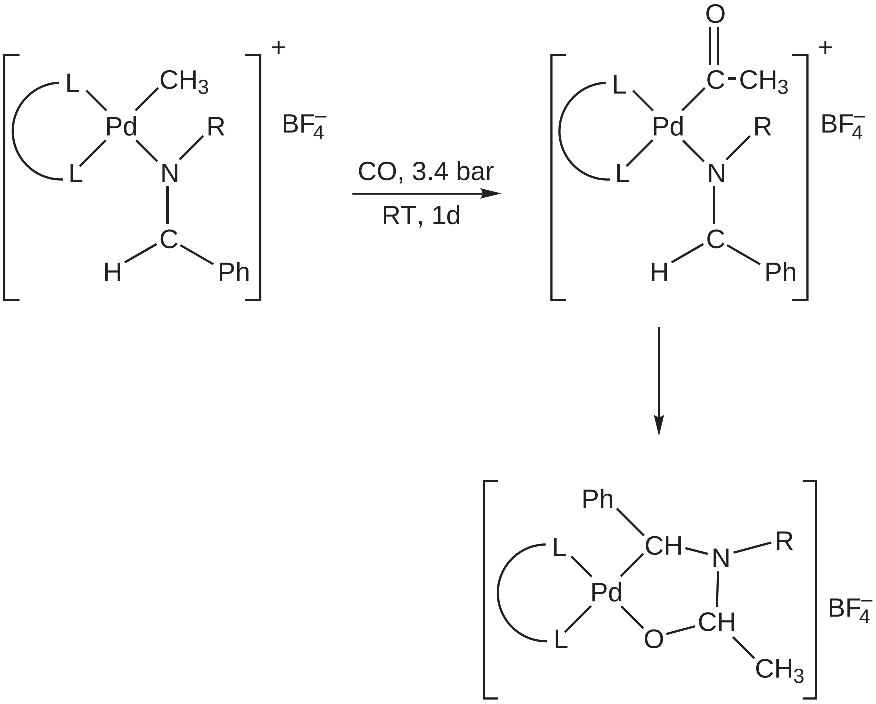
Phosphinothiolato chelate ligands place phosphorus and sulfur in a *cis* configuration, and this should imprint electronic asymmetry on the metal center to be transmitted to any *trans* groups. An important difference in bulk between coordinating atoms is also characteristic of this type of ligands. Asymmetry in size and electronic influence should be important to the stability of the key intermediates that control the stereochemistry of the products of interesting reactions that are thought to depend on two adjacent coordination sites, such as catalytic palladium mediated carbonylations. Furthermore, more recent reports point to the particular nature of catalytic carbonylation systems that incorporate thiolato ligands. Aminothiolato complexes of palladium with triphenylphosphine catalyze the conversion of styrene to 2-phenylpropionic acid in high yield and excellent regioselectivity.[399,400] While these systems could only be acting with an *open* P,S-coordination, phosphinothiolato complexes could act with a *closed* P,S-coordination. Synthetic routes were found to hitherto unknown stable compounds containing palladium(II), the simple phosphinothiolato ligands 2-(diphenylphosphino)ethanethiol ($HSCH_2CH_2PPh_2$, Hdppet) and 3-(diphenylphosphino)propanethiol ($HS(CH_2)_3PPh_2$, Hdpppt), and also triphenylphosphine in an effort to contain the tendency of thiolato ligands to form bridged species.[401] Complexes of the type [PdCl(S-E)(PPh$_3$)] with E = P, contain the chelating dppet and dpppt ligands. Mononuclear complexes of this class with E = N are the aminothiolato-*S,N* complexes [PdCl(S-N)(PPh$_3$)], where S-N are the ligands derived from cisteamine, cysteine ethyl ester, and penicillamine methyl ester.[399] Phosphinothiolato complexes of palladium have never been tested in any carbonylation reaction, and catalysis reports on open P,S-coordinated thiolato phosphine palladium systems are rare.[402] In phosphinothiolato complexes, the phosphorus side is bulkier, so that *trans* complexes are expected for the square planar coordination of d^8 ions. Complexes of palladium with the ligand *o*-(diphenylphosphino)benzenethiolato, such as *trans*-[Pd(SC$_6$H$_4$PPh$_2$)$_2$] and [Pd$_2$I$_2$(SC$_6$H$_4$PPh$_2$-*P*,μ-*S*)$_2$], have been obtained from the corresponding thioether complexes.[403–405] In a series of studies on the resolution of ligands with chirality at phosphorus involving metal complexation, a series of group 10 metal complexes with 2-(methylphenylphosphino)ethanethiol have been reported, including the palladium bischelate Pd(SC$_2$H$_4$PMePh)$_2$.[406–409] Palladium complexes with a ferrocenyl phosphinothiolato ligand[410] and with a phosphacyclic thiolato ligand[411] have been recently described. Curiously, the anion bis(ethane-1,2-dithiolato)palladate [Pd(edt)$_2$]$^{2-}$ [412] evolves into anionic [Pd$_2$(edt)$_3$]$^{2-}$. Structural diversity makes it difficult to predict the precise nature of dppet and dpppt palladium species of 1:1 stoichiometry.[401]

The imidazole unit coordinates to transition-metal ions, such as palladium(II) and platinum(II), predominantly via one of its nitrogen atoms. In some rare cases, however, the cyclic unit may also coordinate as a carbene or an amidine ligand via its C^2 carbon atom.[413] Palladium complexes containing C-bound imidazole ligands are efficient catalysts for cross-coupling reactions.[414] There is a report of the palladium-template synthesis of the first imidazole-substituted tertiary phosphine bidentate ligand in which the C^2 carbon of the imidazole unit is involved in metal chelation.[415] An organopalladium-complex-promoted Diels–Alder reaction between 1-phenyl-3,4-dimethylphosphole and 1-vinylimidazole gave a novel imidazole-substituted phosphanorbornene bidentate ligand which coordinated to the palladium template via the C^2 carbon atom of the imidazole group and the bridgehead phosphorus donor atom (see Scheme 6).[415]

The insertion of unsaturated molecules into metal–carbon bonds is a critically important step in many transition-metal catalyzed organic transformations. The difference in insertion propensity of carbon–carbon and carbon–nitrogen multiple bonds can be attributed to the coordination characteristics of the respective molecules. The difficulty in achieving σ to π isomerization may be the reason for the paucity of imine insertions. The synthesis of amides by the insertion of imines into palladium(II)-acyl bonds is the first direct observation of the insertion of imines into bonds between transition metals and carbon (see Scheme 7). The alternating copolymerization of imines with carbon monoxide (in which the insertion of the imine into palladium-acyl bonds would be the key step in the chain growth sequence), if successful, should constitute a new procedure for the synthesis of polypeptides (see Scheme 7).[348]

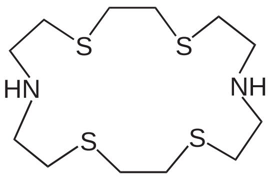


Scheme 6



Scheme 7

Anionic, nonzeolitic inorganic supramolecular architectures are very rare, and the only examples known involve iodine-rich compounds.[416–418] Reaction of the binuclear complex $[Pd_2Cl_2([18]ane\text{-}N_2S_4)](PF_6)_2$[70] with Bu^n_4NI and I_2 in a 1:2:4 molar ratio in acetonitrile, followed by several days of slow evaporation of the solvent, affords black prismatic crystals in 90% yield. The asymmetric unit consists of one I_5^- and two I_3^- ions and one and a half binuclear $[Pd_2Cl_2([18]aneN_2S_4)]^{2+}$ dications. The Pd^{II} ions are each coordinated to one N- and two S-donor atoms, and a Cl^- ligand completes the square-planar coordination. The two coordination planes lie parallel to each other but the overall binuclear dication adopts a stepped conformation in order to minimize steric interactions, see Figure 33.[419] The dications are linked pairwise by hydrogen bonds. The intracation Pd···Pd distances are 4.055(2) Å and 4.155(2) Å, while the Pd···Pd distances between adjacent cations are significantly shorter. The infinite chains of binuclear dications are embedded in a unique matrix of polyiodides whose fundamental units are one "L"-shaped I_5^- ion consisting of an asymmetric I_3^- ion interacting with a I_2 molecule and two slightly asymmetric I_3^- ions.[419] These results confirm the general principle of template



$[18]aneN_2S_4$

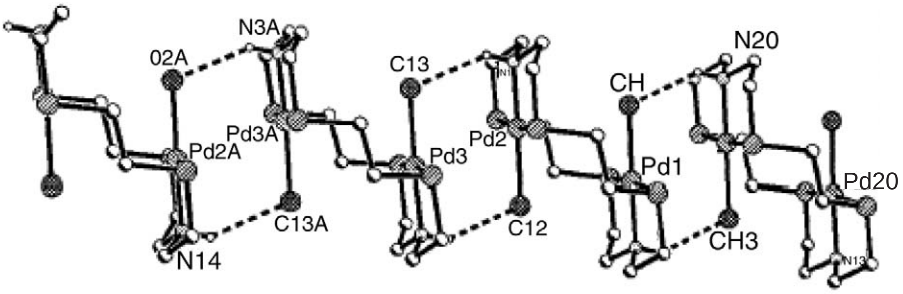


Figure 33 The two coordination planes lie parallel to each other but the overall binuclear dication adopts a stepped conformation in order to minimize steric interactions.

condensation of three-dimensional polyiodide networks at metal cations complexed by macrocycles. The formation of polyiodide architectures may be regarded as a template reaction in the second coordination sphere of complex cations in which the unique topology of the resultant polyanionic networks depends upon the shape and charge of the template cations.[419]

6.4.5.10.1 Promoters and catalysts for hydrolysis and related reactions

Complexes of palladium(II) can bind to the thioether group in methionine (Met) and to the imidazole group in histidine (His) residues. In the dipeptides of general formula Ac-His-Aa and Ac-Met-Aa (in which Ac is *N*-acetyl group and Aa is a leaving amino acid), the anchored Pd^{II} ion hydrolyzes the peptide bond involving the carboxylic group of the anchoring amino acid, that is, the first peptide bond downstream from the anchor.[4,420–425] The cleavage of dipeptides Ac-His-Aa is moderately catalytic;[423,425] a turnover as high as 14 was achieved with a binuclear Pd^{II} complex as a catalyst.[426]

Palladium(II) complexes act with different regioselectivity in cleaving dipeptides and proteins, as shown in Figure 34. The sites of cleavage are highlighted. The anchoring side chain is coordinated to the Pd^{II} ion via the group L; the remaining three ligands are not specified. The direction of the cleavage is defined with the anchor as the reference point. A study involving a histidine-containing 19-residue fragment of the protein myohemerythrin, which can exist as an

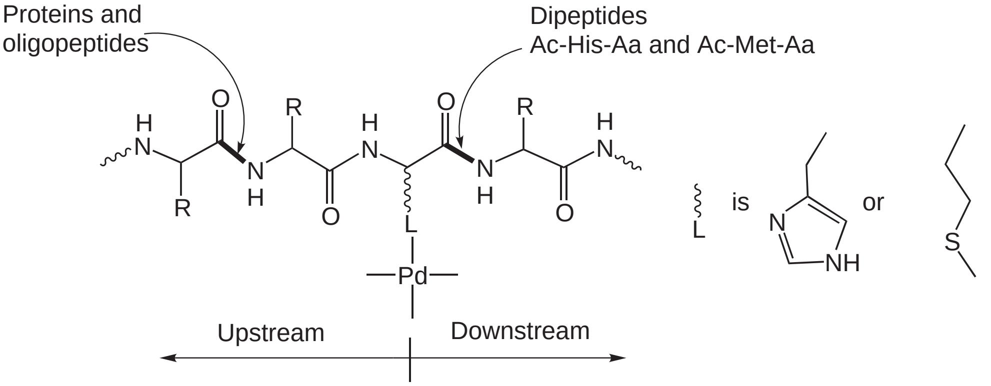

Figure 34 Palladium(II) complexes act with different regioselectivity in cleaving dipeptides and proteins.

α-helix or a random coil, showed that the regioselectivity and the rate of cleavage are independent of the overall conformation.[427] In this long substrate, the only cleaved site was the second peptide bond from the N-terminal side of one of the two histidine residues, that is, the second bond upstream from the anchor. Palladium(II) complexes proved remarkably effective in promoting fairly regioselective cleavage of cytochrome *c*,[428] myoglobin,[429] three albumins,[430] and several other proteins. Because histidine and methionine residues have a combined average abundance in proteins of only 5.5%, the cleavage usually will give large fragments, convenient for sequencing and other biochemical applications. Upon removal of Pd^{II} ions by precipitation or chelation, the peptides (protein fragments) should remain pristine and can be used further. Simple and readily available Pd^{II} complexes act with unprecedented and useful regioselectivity in promoting the hydrolytic cleavage of peptides and proteins. In acidic aqueous solution, these reagents hydrolyze the peptide bond involving the amino group of the residue preceding the methionine or histidine side chain in the sequence, that is, the second peptide bond upstream of these anchoring residues (see Figure 34).[431] The ability of Pd^{II} complexes to cleave proteins at relatively few sites, with explicable selectivity, and with good yields bodes well for their growing use in biochemical and bioanalytical practice.

Kostić *et al.* showed that palladium(II) complexes spontaneously bind to the side chains of methionine and histidine residues and effect hydrolytic cleavage of short peptides with half-lives that range from several hours to several minutes.[4,231,420–449] Because palladium(II) complexes are diamagnetic, kinetic experiments are easily done by ^{1}H-NMR spectroscopy. Because the cleavage reactions sometimes occur with turnover,[424–426] the simple palladium(II) complexes that catalyze them can be considered primitive artificial peptidases. The successes in selective cleavage of cytochrome *c*,[422] myoglobin,[429] and other proteins[4,431] bode well for the general applicability of these new reagents in biochemistry and allied disciplines. A study showed for the first time that peptide bonds can be cleaved with commercially available salts of $[PdCl_4]^{2-}$ anion; no chemical derivatization or modification of this simple complex is required. Aquation of this complex, however, causes a remarkable difference in reactivity; the complex $[Pd(H_2O)_4]^{2+}$ cleaves peptides more rapidly and with different regioselectivity than its chloro precursor does. Experimental kinetics and theoretical molecular dynamics were combined to study how simple substitution of ancillary ligands affects hydrolytic cleavage of peptides by palladium(II) complexes and to determine the stereochemical basis for the regioselectivity of cleavage.[444]

Palladium(II) complexes, as cleavage agents, differ from the well known complexes of other transition metals because their attachment to substrates is achieved simply by mixing; the hydrolysis reactions have half-lives as short as 15 min, and the complexes are easily removed from the cleaved substrates. Longer peptides and proteins are readily cleaved by Pd^{II} complexes, but with a different regioselectivity.[4,431] A better knowledge of the coordination chemistry of histidine-containing peptides with palladium(II) complexes is necessary for understanding the regioselectivity of peptide and protein cleavage promoted by such complexes. A paper reports an ^{1}H-NMR investigation of the hydrolysis reaction of a model histidine-containing dipeptide, *N*-acetylated L-histidylglycine, catalyzed by a series of palladium(II) complex cations of the type *cis*-$[Pd(L)(H_2O)_2]^{2+}$ in which L is a chelating diamine ligand, which differ in the number of methyl groups at the nitrogen or carbon atom, or *S,N*-coordinated amino acid. The observed rates of reaction are explained in terms of steric hindrance of the chelating ligand on the palladium(II) complexes.[447] The results of this study of dipeptides are not pertinent to study of cleavage of longer peptides and proteins by Pd^{II} complexes.

A monodentate palladium(II) complex *trans*-$[Pd(py)_2(H_2O_2)]^{2+}$ hydrolyzes Met-Aa amide bonds with a rate comparable with that promoted by $[Pd(H_2O)_3(OH)]^+$. Unlike $[Pd(H_2O)_3(OH)]^+$, *trans*-$[Pd(py)_2(H_2O_2)]^{2+}$ is relatively stable and easy to prepare. An N,N-chelated complex containing temed (*N*,*N*,*N*′,*N*′-tetramethylethylenediamine) hydrolyzes Met-Aa amide bonds with hydrolytic rate controlled by temed release. The action of the other two complexes, *cis*-[Pd(EDTA)Cl$_2$] (EDTA = ethylene diaminetetraacetic acid) and *cis*-1,2-bis(2-formylglycinebenzenesulfenyl)ethane Pd^{II} chloride differs from the action of similar complexes of *cis*-[Pd(en)Cl$_2$] and *cis*-[Pd(dtco-3-OH)Cl$_2$] (dtco-3-OH = 1,5-dithiacycooctan-3-ol).[448]

A promising method for protein cleavage consists of spontaneous attachment, without tethering, of preformed Pd^{II} complexes to nucleophilic side chains, followed by cleavage of proximate amide bonds. To investigate possible effects of the secondary structure (conformation) on the cleavage promoted by palladium(II) complexes, Kostić *et al.* compared the reactivity of the same nonadecapeptide in predominantly α-helical and essentially random-coil conformations. This study indicates that cleavage is probably unaffected by the overall conformation of the substrate, at least in the polypeptide examined.[427]

Most of the palladium hydrolysis reagents used to date must be applied in aqueous solution. This requirement is incompatible with the cleavage of lipophilic peptides and proteins, which are insoluble or sparingly soluble in water. During the hydrolysis of methionine-containing dipeptides the most active mononuclear complexes, $[Pd(OH_2)_4]^{2+}$ and *cis*-$[Pd(en)(OH_2)_2]^{2+}$, form dinuclear active species bridged by methionine side chains.[421,449,450] An important advantage of dimerization is the possibility of cooperation between metals. These considerations suggested to Kostić *et al.* that polynuclear complexes should be good reagents for peptide hydrolysis. The thiolate-bridged complex $(Me_4N)_2[Pd_2(\mu\text{-}SPh)_2Cl_4]$, is expected to be stable in solution. The bridging thiolate ligands should not be displaced by methionine side chains or other donor groups in peptides and proteins. In addition, the *trans* effect of the thiolate sulfur atoms should allow for especially weak and potentially reversible binding of methionine to palladium(II). Indeed, this complex is an effective catalyst for rapid cleavage of methionine-containing dipeptides in nonaqueous solvents.

Selective cleavage of peptides and proteins is an important procedure in biochemistry and molecular biology. The half-life for the uncatalyzed hydrolysis of amide bonds is 350–500 years at room temperature and pH 4–8. Clearly, efficient methods of cleavage are needed. Despite their great catalytic power and selectivity to sequence, proteinases have some disadvantages. Peptides [420,423,424,426] and proteins[428,429] can be hydrolytically cleaved near histidine and methionine residues with several palladium(II) aqua complexes, often with catalytic turnover.

Kostić *et al.* reported that palladium(II) complexes bind to *N*-acetylated tryptophan-containing peptides AcTrp-Ala, AcTrp-Val, and AcTrp-ValOMe in acetone solution and regioselectively cleave them upon addition of an equivalent of water.[436] Upon mixing of *N*-acetyl-L-tryptophanamide (AcTrp-NH_2) and *cis*-$[Pd(en)(sol)_2]^{2+}$ in acetone solution, the complex shown in Figure 35 appears.[436] In the presence of the palladium(II) complexes and one equivalent of water in an acetone-d_6 solution, peptides are completely cleaved in less than a day. The active intermediates are complexes of the type shown in Figure 35. As Scheme 8 shows, the products are the *C*-terminal amino acid and palladium(II) complex of *N*-acetyl-L-tryptophan. Acetic acid is not detected. In control experiments with AcAla-Trp, which lacks a *C*-terminal amide bond adjacent to the tryptophanyl residue, neither amide bond is cleaved. Evidently, palladium(II) regioselectively cleaves on the *C*-terminal side of tryptophan, not on the *N*-terminal side. In aqueous solution coordination of the tryptophanyl residue to palladium(II) completely ceases, and the peptides do not hydrolyze.[436]

Absence of aqua ligands in the hydrolytically active complexes of the type shown in Figure 35 rules out the internal attack of a Pd^{II}-bound nucleophile at the amide carbon. Coordination of the amide oxygen renders the amide carbon more electrophilic and susceptible to external attack of solvent water, which causes the hydrolytic cleavage on the *C*-terminal side of tryptophan (see Scheme (8)). There is no cleavage on the *N*-terminal side, presumably because that amide bond is not activated by the palladium(II) atom.[436] To our knowledge, this is the first report that coordination of the tryptophan side chain is followed by hydrolysis of a nearby peptide bond. Unlike methionine and histidine, which coordinate to palladium(II) in aqueous as well as acetone solutions,[420,423,424,426] tryptophan coordinates only in acetone solution.[436] Therefore, the overall selectivity of cleavage can be altered simply by changing the solvent or the concentration of the palladium(II) promoter. Cleavage will occur near histidine and methionine in aqueous solution, and near histidine, methionine, and tryptophan in acetone solution, if the promoter is present in excess. The fine selectivity, preference for the *C*-terminal over the *N*-terminal amide bond of tryptophan, is due to the stereochemistry of chelate rings. Further studies will show whether proteins and longer peptides are cleaved with the same regioselectivity. A prospect for cleaving hydrophobic or membrane-bound proteins in nonaqueous solutions, by palladium(II) complexes, has emerged.

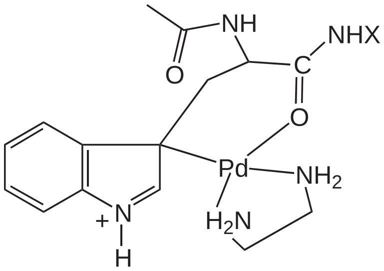

Figure 35 Complex formed by mixing *N*-acetyl-L-tryptophanamide (AcTrp-NH_2) and *cis*-$[Pd(en)(sol)_2]^{2+}$ in acetone solution.

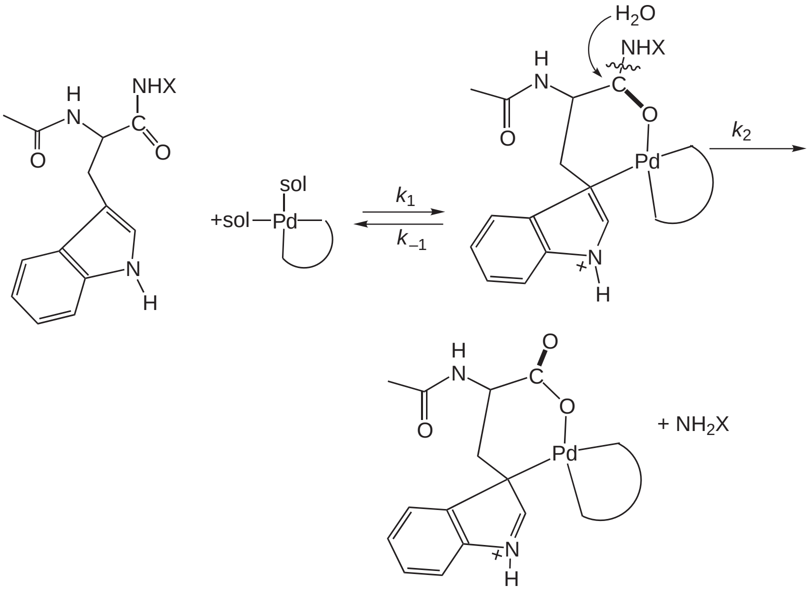
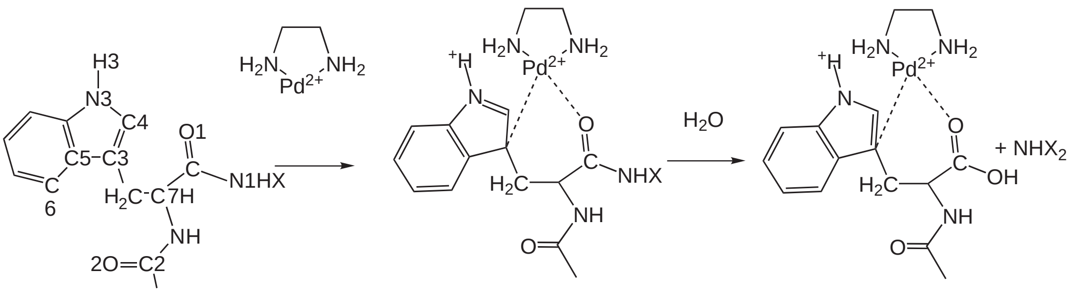


Scheme 8

Kostić *et al.* discovered that Pd^{II} complexes, when attached to tryptophan residues, can rapidly cleave peptides in acetone solutions to which a stoichiometric amount of water is added, for hydrolysis.[436] The indole tautomer in which a hydrogen has moved from the nitrogen to C(3) is named indolenine. Its palladium(II) complexes that are coordinated via the nitrogen atom have been characterized by X-ray crystallography and spectroscopic methods.[451] Binuclear dimeric complexes between palladium(II) and indole-3-acetate involve cyclopalladation.[452] Bidentate coordination to palladium(II) through the N(1) and the C(2) atoms occurs in binuclear complexes.[453] Reactions of palladium(II) complexes with indole-3-acetamide and its derivatives produced new complexes of unusual structure. Various NMR, UV, IR, and mass spectral analyses have revealed bidentate coordination via the indole carbon C(3) and the amide oxygen.[437]

Selective cleavage of peptides and proteins is one of the most common and most important procedures in biochemistry. The extreme inertness of the amide bond makes this reaction interesting from the chemical point of view. Several proteolytic enzymes are used for cleavage, but application of enzymes is limited by their rather narrow requirements for temperature and pH. Therefore, new methods for selective hydrolysis of peptides and proteins are required. Kostić and coworkers have shown that palladium(II)[420–424,432,438,440] aqua complexes are promising reagents for hydrolytic cleavage of peptides and proteins. These complexes bind to the heteroatom in the side-chain of methionine[420–422,432,438,440] or histidine[423,424,432,438,440] in dipeptides and promote cleavage of the amide bond involving the carboxylic group of this anchoring amino acid. This regioselectivity in the cleavage is clearly demonstrated in the reaction of *cis*-$[Pd(en)(H_2O)_2]^{2+}$ with a series of MeCO His-X dipeptides, in which X is Gly, Ala, Leu, Ser, Thr, Tyr or Phe.[424] In this reaction, the amide bond involving the carboxylic group of histidine is completely hydrolyzed at relatively mild and unrestrictive conditions (60 °C and $1.5 \leq pH \leq 2.5$) in less than two days, while the amide bond involving the amino group of histidine is not cleaved. It was found that only catalyst monodentally bound to the N-3 atom of imidazole can effect this reaction; none of the other modes of coordination is effective.[423,424] The reaction is unimolecular with respect to the palladium(II)–peptide complex. However, when the carboxylic group of histidine is free, as in MeCO-Gly-His, *cis*-$[Pd(en)(H_2O)_2]^{2+}$ does not effect hydrolysis. Another study dealt with stoichiometric hydrolysis of inactivated amide bonds in histidine-containing peptides promoted by *cis*-$[Pd(\text{L-Ala-}N,O)Cl_2]^-$ and *cis*-$[Pd(\text{L-Ala-}N,O)(H_2O)_2]^+$ complexes (L-Ala is amino acid alanine coordinated via N and O atoms). There are interesting differences between the active form of the palladium(II) complex and the reagent that is initially added.[454]

The highly regioselective hydrolysis of tryptophan-containing peptides with the $[Pd(en)]^{2+}$ ($en = H_2NC_2H_4NH_2$) complex has been reported by Kostić and co-workers.[436] The hydrolysis does not proceed without the palladium(II) complex. However, when equimolar amounts of a peptide and a palladium(II) complex are mixed in acetone solution at 50 °C with a stoichiometric amount of H_2O, the reaction is remarkably promoted and occurs selectively on the *N*-terminal side of the peptide, producing the *N*-terminal amino acid and the palladium(II) complex of *N*-acetyltryptophan, as shown in Scheme 9.



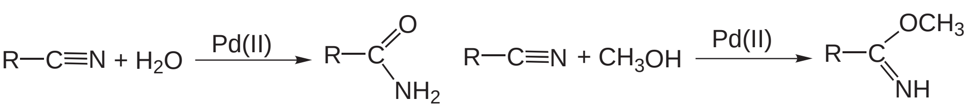
Scheme 9

The origin of the regioselectivity and the promotion effect of the palladium(II) complex $[Pd(en)]^{2+}$ on the hydrolysis of a tryptophan-containing peptide was theoretically examined by means of the density functional method B3LYP using the model peptide *N*-formyltryptophanamide.[455] The calculations confirmed the explanations by Kostić *et al.* The *N*-formyltryptophanamide easily binds to the $[Pd(en)]^{2+}$ complex to form the stereochemically stable compound with the six-membered ring, where not only the carbonyl oxygen but also the indole carbon interact with the Pd atom, and its binding is kept during the hydrolysis reaction, to stabilize the energy surface and reduce the energy barrier. The positive charge of the *N*-terminal amide carbon is remarkably enhanced by the formation of *cis*-$[Pd(en)$*C*,*O*-FmTrp-$NH_2)]^{2+}$, and thereby, the water oxygen selectively attacks the *N*-terminal amide carbon and the electron is transferred from the water to the electron acceptor $[Pd(en)]^{2+}$ complex along the O3(water)—C1—O1—Pd linkage. The largely positively charged water hydrogen migrates as a proton to the amide nitrogen to break the C—N bond of the amide. The good correlation found between the energy barrier and the strength of the electron donation of the ligand suggested that the ligand plays a key role in the reaction, and the less electron donative ligand is more efficient for the hydrolysis.[455]

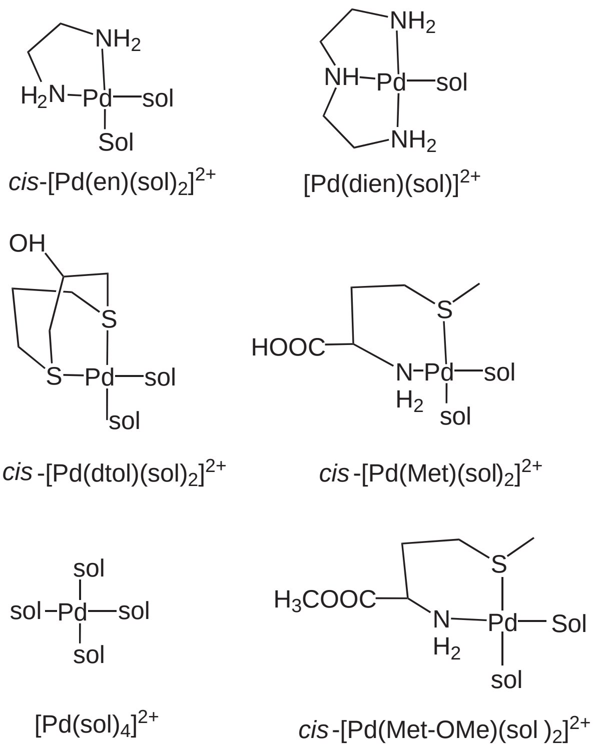
Kostić *et al.* reported the use of various palladium(II) aqua complexes as catalysts for the hydration and alcoholysis of nitriles,[435,456] decomposition of urea to carbon dioxide and ammonia, and alcoholysis of urea to ammonia and various carbamate esters.[457] Labile aqua or other solvent ligands can be displaced by a substrate. In many cases, the coordinated substrate thus becomes activated toward nucleophilic addition of water or alcohols.

Hydrolysis of oximes catalyzed by transition-metal complexes has not been studied prior to a report by Kostić *et al.* They have reported kinetics of hydrolysis of acetoxime to acetone catalyzed by two palladium(II) complexes, identified active species in the hydrolysis reaction, proposed a reaction mechanism, and fully characterized a bis(acetoxime) complex that is relatively stable toward hydrolysis.[458]

Kostić *et al.* recently reported the use of various palladium(II) aqua complexes as catalysts for the hydration of nitriles.[456] crossref:1.34 Reactivity of coordination These complexes, some of which are shown in Figure 36, also catalyze hydrolytic cleavage of peptides, decomposition of urea to carbon dioxide and ammonia, and alcoholysis of urea to ammonia and various carbamate esters.[420–424, 427,429,456,457] Clearly, palladium(II) aqua complexes are versatile catalysts for hydrolytic reactions. Their catalytic properties arise from the presence of labile water or other solvent ligands which can be displaced by a substrate. In many cases the coordinated substrate becomes activated toward nucleophilic additions of water/hydroxide or alcohols. New palladium(II) complexes *cis*-$[Pd(dtod)Cl_2]$ and *cis*-$[Pd(dtod)(sol)_2]^{2+}$ contain the bidentate ligand 3,6-dithiaoctane-1,8-diol (dtod) and unidentate ligands, chloride anions, or the solvent (sol) molecules. The latter complex is an efficient catalyst for the hydration and methanolysis of nitriles, reactions shown in Equation (3):[435]



$$R{-}C{\equiv}N + H_2O \xrightarrow{Pd(II)} R{-}C({=}O)NH_2 \qquad R{-}C{\equiv}N + CH_3OH \xrightarrow{Pd(II)} R{-}C(OCH_3){=}NH \tag{3}$$



cis-$[Pd(en)(sol)_2]^{2+}$ $[Pd(dien)(sol)]^{2+}$

cis-$[Pd(dtol)(sol)_2]^{2+}$ *cis*-$[Pd(Met)(sol)_2]^{2+}$

$[Pd(sol)_4]^{2+}$ *cis*-$[Pd(Met\text{-}OMe)(sol)_2]^{2+}$

Figure 36 Complexes catalyzing hydrolytic cleavage of peptides, hydrolysis and alcoholysis of nitriles, decomposition of urea to carbon dioxide and ammonia, and alcoholysis of urea to ammonia and various carbamate esters.

The complex *cis*-$[Pd(dtod)(sol)_2]^{2+}$ also promotes the stoichiometric alcoholysis of urea by the hydroxyl groups within the ligand dtod.[435]

6.4.5.11 Five-coordinate Complexes

Five-coordinate complexes of Pd^{II} are so distinctive that they are grouped together and not classified according to the ligand atoms.

Palladium(II) coordination and organometallic compounds usually are square-planar; five- and six-coordinate species are less common.[459] Cyclometalated palladium(II) complexes with mono- and diphosphine ligands invariably are square-planar.[460] Tri- and tetradentate polyphosphine ligands are known to promote the formation of stable complexes with uncommon coordination numbers and geometries. The first pentacoordinated cyclometalated palladium(II) complex was prepared by reaction of a monodentate Schiff base cyclometalated derivative and the triphosphine (triphos), in which the coordination geometry of the palladium atom is a distorted trigonal bipyramid.[461] The reaction of four cyclometalated Pd^{II} complexes with triphos gives four new pentacoordinated species, three of which have been characterized by X-ray crystallography.[462]

The stereochemistry of divalent palladium is characterized by the square-planar arrangement in the majority of its coordination and organometallic compounds. Coordination number six has been reported for a few unusual complexes whose structures have been investigated, generally showing two weaker interactions on the metal atom.[463,464] Five-coordinate Pd^{II} complexes have been more extensively investigated, probably due to the interest in clarifying the kinetic properties for substitution and exchange reactions for palladium complexes in solution and in biological systems.[465] Treatment of cyclometalated halide-bridged palladium(II) dimer complexes with tertiary mono- and diphosphines, gave only four-coordinate compounds with a square-planar environment for the palladium atom.[466–468] Polyphosphine ligands offer a number of special characteristics, among which are the formation of stable complexes with different oxidation states and coordination numbers and the stereoselective occupation of center of the cooordination polyhedron.[469–471] Five-coordinate cyclometalated palladium(II) compounds may be synthesized with ligands such as tridentate phosphines that control the geometry and coordination number at the metal center. This is the first example of a “true” five-coordinate example of its kind, by formation of three five-membered rings at palladium: two comprising the triphos ligand and the palladacycle from the *C,N*-bonded organic ligand.[461]

Palladium(II) pentacoordinate complexes[472–474] are mechanistically and synthetically relevant in organometallic chemistry. Complexes of substituted phenanthrolines with pentacoordinate palladium halides[475] and cyanide[476,477] were studied. They can be synthesized either by treating a four-coordinate complex with an olefin[478–480] or by oxidative addition of an alkyl halide to three-coordinate palladium(0) olefin complexes.[481] Steric hindrance of the N—N′ chelating ligand is a demanding requirement for the stabilization of five-coordinate palladium complexes.[482] The reaction of palladium 1,10-phenanthroline bis(carbomethoxy) complex $\mathrm{Pd(phen)(CO_2CH_3)_2}$, with HCl gave $\mathrm{Pd(phen)Cl(CO_2CH_3)}$. Surprisingly, the reaction with the nonconventional acid phenanthrolinium hexafluorophosphate gives the new five-coordinate complex $\mathrm{[Pd(phen)_2(CO_2CH_3)](PF_6)}$, whose structure is shown in Figure 37.[483]

6.4.5.12 Polynuclear Compounds

Metallodendrimers are emerging as efficient and recyclable catalysts in many chemical reactions.[484–486] Generally, metal centers involved in chemical reactions are placed either at the periphery or within the dendrimers. When the active site is located at the core, the dendritic superstructure around it can provide a shielding which generates a microenvironment reminiscent of those found in biological systems.[487,488] A series of dendritic pyridyl ligands, and the corresponding $\mathrm{Pd^{II}}$ complexes were synthesized.[489] Mechanistic studies on the reactivity of the η^3-allyl complexes containing such ligands toward amination with piperidine were reported.[490]

Dendrimers having nanoscopic dimensions can be molecularly dissolved. Thus, soluble dendrimers carrying a defined number of catalytic sites can be removed from homogeneous reaction mixtures by simple nanofiltration techniques. The combination of these properties makes them suitable to bridge the gap between homo- and heterogeneous catalysts. Moreover, the use of dendrimers instead of polymers for anchoring catalytic sites leads to well-defined nanosized species in which the number and location of the catalytic sites can be controlled. The synthesis of the compound depicted in Figure 38 and utilization of its aqua complexes as homogeneous catalysts for an aldol condensation reaction were presented.

Numerous dendrimers, which contain coordination sites on the outer surface, within the macrostructure throughout all layers, and at the inner core have been prepared. In contrast,

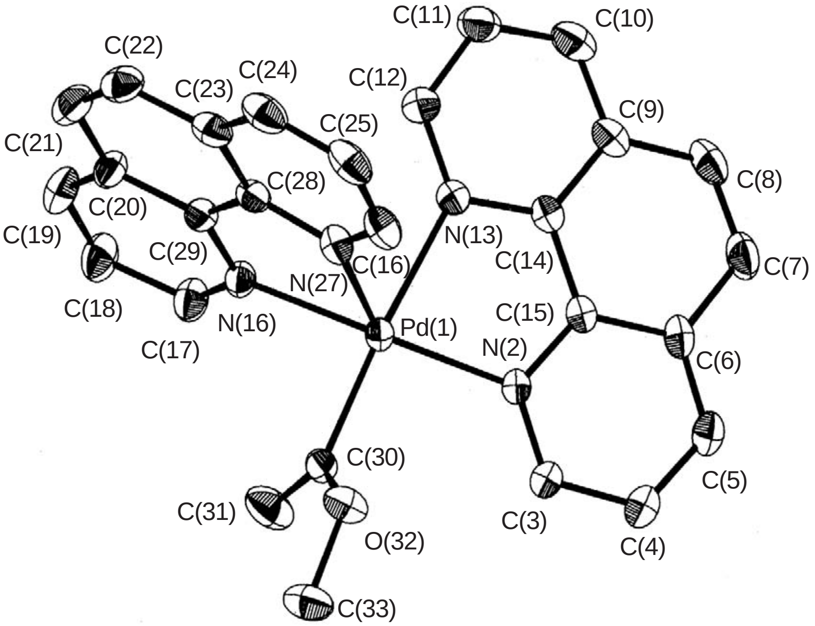


Figure 37 Structure of the five-coordinate complex $\mathrm{[Pd(phen)_2(CO_2CH_3)](PF_6)}$.

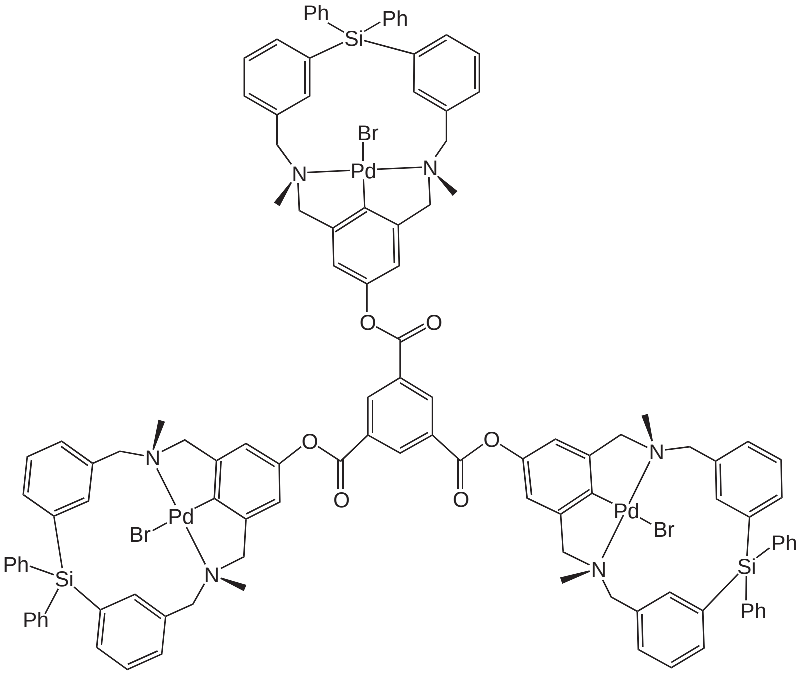

Figure 38 Pd dendrimer

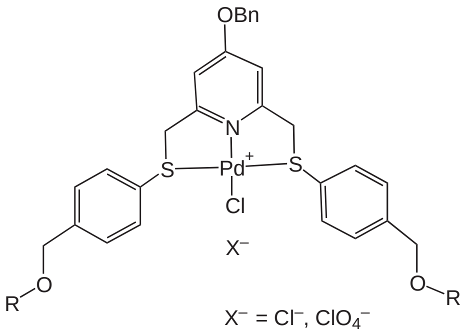
except for scant coordination studies, very little has been done about the construction of dendrimers with specific coordination centers within the dendritic wedges and their reaction with metal substrates. In particular, only one report has yet appeared on the synthesis of dendrimers with a pyridine based skeleton incorporating a specific coordination site for platinum-group metals.[489] The 2,6-di(thiomethyl)pyridine subunit, has been shown to form very stable Pd^{II} complexes.[492] The complexation of Pd^{II} with dendrons gives metallodendrons, shown in Figure 39.[489]

Dendrimers are attractive nanosize model compounds because of their globular architecture and their highly functionalized surface. These hyperbranched compounds are synthesized in a repetitive reaction sequence of nearly quantitative reactions. The synthetic route can either be divergent, starting from the nucleus toward the surface, or convergent, where "dendrons" or "wedges" are covalently linked to a polyfunctional nucleus. The number of metallodendrimers is still limited.[493–506]

Metallodendrimers can have a metal in the core, in every generation, or only at the outside. A noncovalent, divergent synthesis toward nanosize metallodendrimers has been developed.[507,508] The "controlled assembly" is based on the activation of the nucleus, containing three Pd—Cl pincer complexes, by removing the chloride ion with $AgBF_4$. Subsequent addition of three equivalents of nitrile-containing building blocks yields a first generation metallodendrimer by coordination of the nitrile ligands to the palladium centers. Using controlled assembly the authors were able to synthesize metallodendrimers up to generation five.[508] With the combination of two



$X^- = Cl^-, ClO_4^-$

Figure 39 A Pd metallodendron.

different ligands one can construct metallodendrimers not only via a divergent but also via a convergent route.[507] The combination of pyridine- with cyano-based building blocks allowed the assembly of dendrons up to the third generation. It has been possible to attach these dendrons to an activated nucleus. This is an example of the assembly of metallodendrimers via a convergent route.[507]

One of the main applications of dendrimers is in catalysis allowing easy recycling of the homogeneous catalyst by means of nanofiltration. Carbosilane dendrimers functionalized with diphenylphosphine groups at the periphery have been synthesized and characterized. Palladium complexes of these dendrimers have been used as catalysts in the allylic alkylation reaction. These dendrimeric catalysts can be used in a continuous process using a membrane reactor.[509]

Architectural control of transition metal-directed assembly to construct well-arranged metallomacrocycles is one of the current research areas to create organized nanostructures for advanced materials.[510–513]

A conjugated homobimetallic palladium(II) complex (see Figure 40) was formed by one-pot oxidative complexation of 1,4-phenylenediamine with a palladium(II) complex bearing the tridentate ligand shown. In the absence of 1,4-phenylenediamine this palladium(II) complex undergoes controlled formation of a macrocyclic tetramer *via* removal of a labile solvent ligand, as shown in Figure 41.[514]

It is possible to prepare coordination polymers not requiring the presence of counterions, if suitable negatively charged ligands (obtained from deprotonated stable polyazaheterocycles) are used with metal cations.[515] The synthesis of M(im)$_2$ species containing rigorously square-planar MN$_4$ systems, exploited the well-known tendency of group-10 metal ions (in their +2 oxidation state) to afford local D_{4h} symmetry. Hydrogen-bonded polymers of general M(Him)$_2$(im)$_2$ formula (M = Pd, Pt; Him = imidazole) were completely characterized.[516] The imidazole/imidazolate Pd and Pt derivatives sharing the same formula are not isostructural nor, obviously, isomorphous.

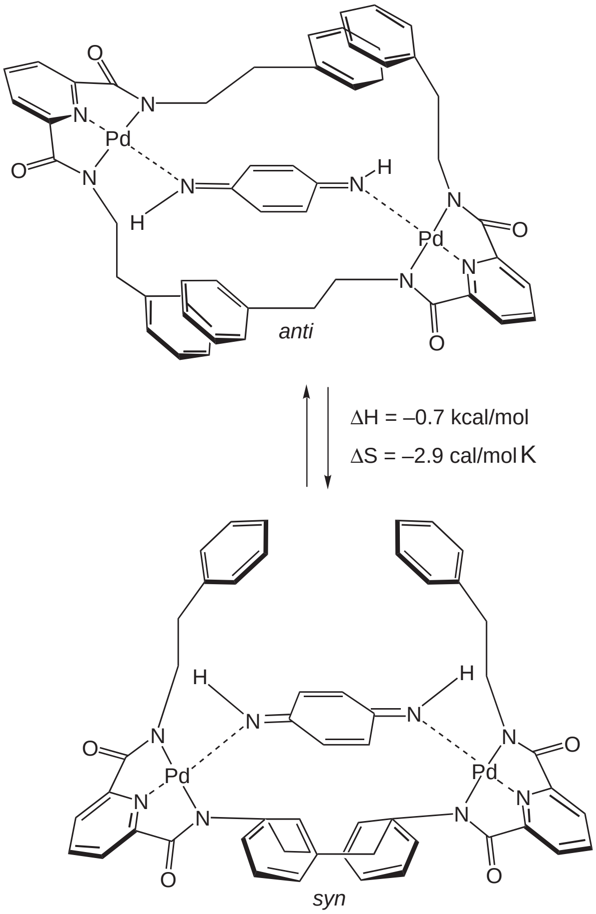


Figure 40 A conjugated homobimetallic palladium(II) complex, formed by one-pot oxidative complexation of 1,4-phenylenediamine with a palladium(II) complex bearing the tridentate ligand.

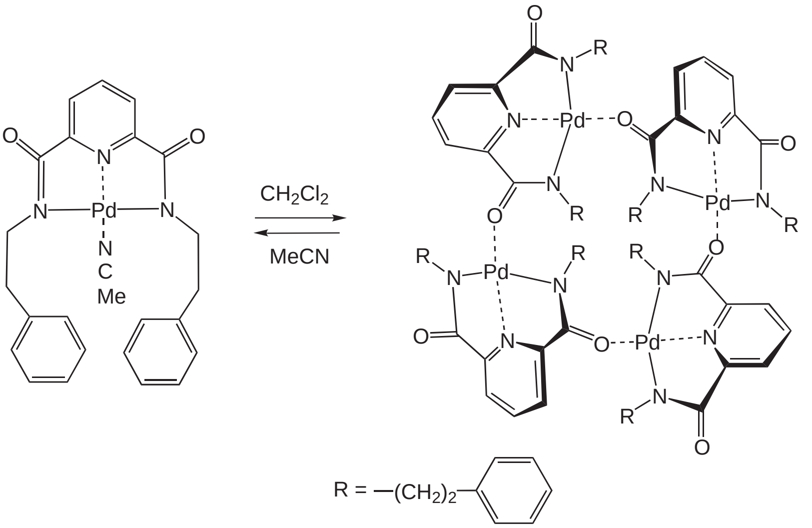

Figure 41 Controlled formation of a macrocyclic tetramer *via* removal of a labile solvent ligand.

Fullerenes are spontaneously attracted to porphyrins and metalloporphyrins. The palladium-linked *m*-pyridyl dimer (shown in Figure 42) has a high binding constant in solution. Addition of C_{60} or C_{70} to solutions of these palladium-linked bis-porphyrins gave complexes that were chromatographically distinct from their individual components. This indication of tight binding was also seen in MALDI mass spectra.[517]

Covalently linked multiporphyrin arrays are interesting because of their unique photoelectronic properties and potential applications as mimics of light-harvesting systems in photosynthesis and as electron transfer moieties in molecular wires. Among these, fused oligoporphyrins sharing a common extended π-electron network are of particular interest. The electrochemical oxidation of the Pd^{II} complex gave a meso-β-linked diporphyrin.[518] The reaction mechanism involves the reaction of a radical cation with a neutral metalloporphyrin. Oxidation reactions of metalloporphyrins with a strong oxidant tris(4-bromophenyl)ammonium hexachloroantimonate (BAHA) facilitated the instantaneous generation of a porphyrin radical cation.[519] Doubly meso-β-linked diporphyrin products were obtained in the reaction of Pd^{II}-porphyrin with 1.2 equivalents of BAHA (see Figure 43). Their most notable feature is a red-shifted, intense Q-band. The oxidation

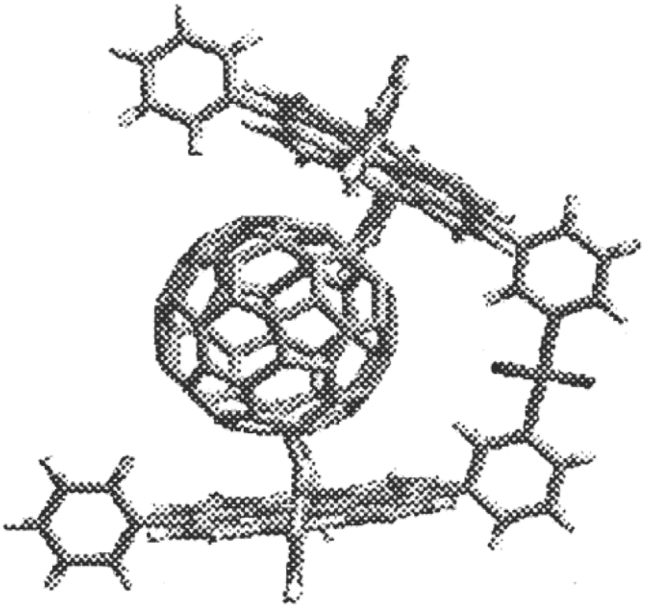

Figure 42 Palladium-linked *m*-pyridyl dimmer–C_{60} complex.

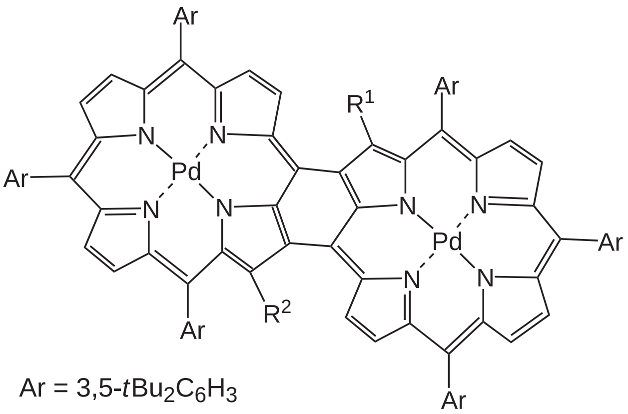

Figure 43 Doubly meso-β-linked diporphyrin products obtained in the reaction of Pd^{II}-porphyrin with 1.2 equivalents of BAHA.

of 5,10-diaryl- and 5,10,15-triaryl- Pd^{II}- porphyrins with BAHA constitutes a new, facile synthetic route to doubly meso-β-linked diporphyrins that exhibit unique optical and electrochemical properties stemming from their full π-conjugation. The lower oxidation potentials of the doubly meso-β-linked diporphyrins than that of the starting metalloporphyrin suggest an extension of this synthetic strategy to higher oligoporphyrins.[519]

A new type of tweezer complex involving a rhenium–rhenium multiple bond enforces an unusual structure in a dipalladium(II) unit. The coordination of the P atoms of *cis*-$Re_2(\mu$-$O_2CC_6H_4$-4-$PPh_2)_2Cl_2(\mu$-dppm$)_2$ to a $[Pd_2(\mu$-$Cl)_2Cl_2]$ unit creates a Re_2Pd_2 assembly in *cis*-$Re_2(\mu$-$O_2CC_6H_4$-4-$PPh_2)_2Cl_2(\mu$-dppm$)_2(Pd_2Cl_4)$ (shown in Figure 44).[520]

The structure of a non-hydrolyzed dimer, $\{cis$-[(2,2′-bipyridine)palladium(II)$]_2(\mu$-1,3-$NO_3)_2\}^{2+}$ is shown in Figure 45.[521] The dimerized *cis*-(2,2-bipyridine)Pd^{II} units aggregate into a dimer-to-dimer linear conformation through direct metal–-metal interaction[522] and π–π stacking.[523] Notably, the dimer was first reported to be linked by double nitrato-bridges (μ-1,3-$NO_3)_2$ in a cofacial

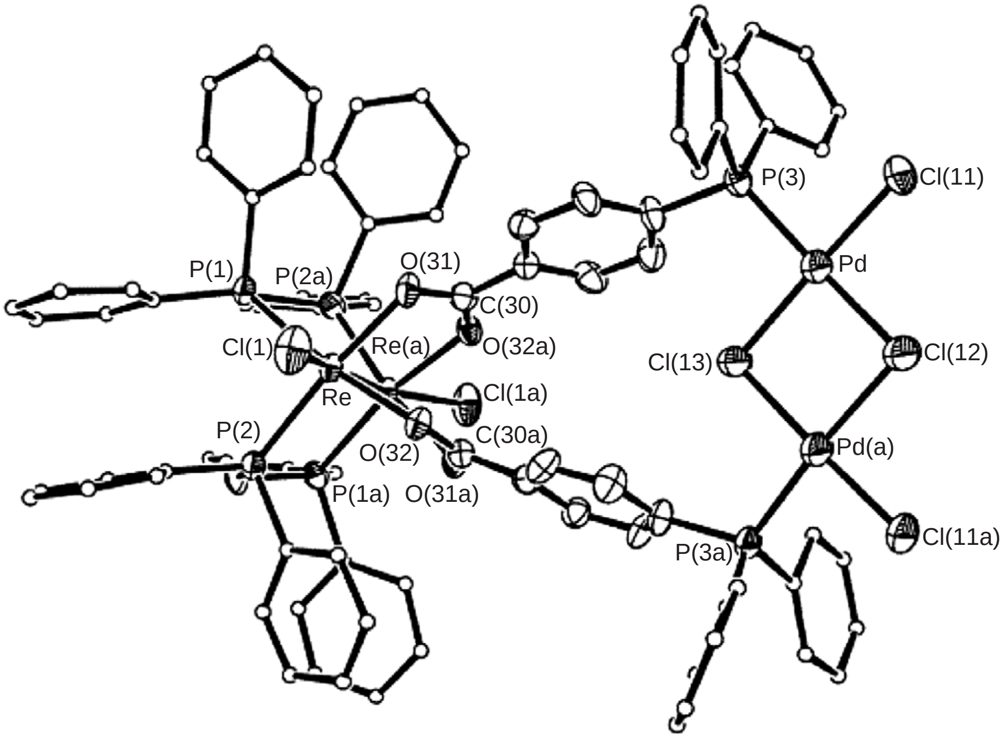

Figure 44 Structure of *cis*-$Re_2(\mu$-$O_2CC_6H_4$-4-$PPh_2)_2Cl_2(\mu$-dppm$)_2(Pd_2Cl_4)$.

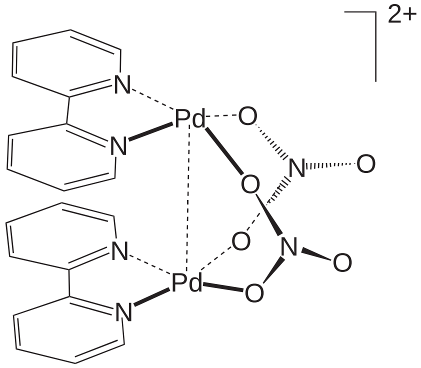

Figure 45 Structure of $\{cis\text{-}[(2,2\text{-bipyridine})\text{palladium(II)}]_2(\mu\text{-}1,3\text{-}NO_3)_2\}^{2+}$.

arrangement, similar to the amido- or carboxylato-bridged platinum blue-type dimeric or polymeric Pt and Pd complexes.[524–527] It has been mentioned that there is a coordination mode of (μ-1,3-$NO_3)_2$ bonded to two metals,[528] which is scarcely seen in platinum group metals.[524–529] The two dimers aggregate alternately along the linear chain consisting of the four Pd^{II} atoms with Pd···Pd distances of 2.848(3) Å (intradimer) and 3.117(3) Å (interdimer), showing quite strong metal–metal interactions.

Dithiolene complexes $[\{Pd(PPh_3)_2\}_n\{S_2C{=}CCHC(O)R\}]$ are mononuclear or homodinuclear derivatives of ferrocenyl-substituted dithiolene ligands.[530] 2,2-Diacetyl-1,1-ethylenedithiolato complexes of palladium can be used to prepare dinuclear PdAg and PdAu complexes.[531]

In a polythiophene derivative conjugated chains are linked by Pd bridges in which the metal is σ-bonded to a C of the backbone.[532] Interesting materials are formed by electropolymerization of Pd^{II} complexes containing phosphinoterthiophene ligands exhibiting several different bonding modes.[533] The largest degree of interaction between the dimethylterthienyl groups is seen in a complex where the metal is both P,C- and P,S-coordinated. The conductivity appears to involve a contribution from cross-metal delocalization.[533]

A dinuclear complex of Pd^{II} was obtained by the reactions of $[Pd(bpm)(H_2O)_2]^{2+}$ (bpm = bis (pyridine-2-yl)methane) with model nucleobases as constituents of DNA.[534]

In the homodinuclear complex $[\{Pd(dppp)\}_2(\mu\text{-biim})](OTf)_2$ (dppp = bis(diphenylphosphino)-propane, biim = 2,2′-biimidazole, OTf = OSO_2CF_3) a $biim^{2-}$ ligand spans the two palladium(II) centers.[535]

Many metal-containing liquid crystals (metallomesogens) contain coordination compounds; there are fewer liquid crystals of the organometallic type. Among the latter, there are many dinuclear and mononuclear orthometallated complexes. The dinuclear complexes $[Pd(\mu\text{-}X)L^n]_2$ permit one to induce thermotropic changes not only by modifying terminal alkyl or alkoxy chains in L^n,[536–539] but also by modifying the bridging system X, which can be bridging thiolates.[540,541] Reactions of dinuclear compounds $[Pd(\mu\text{-}OH)L^n]_2$ with protic substrates like amines, thiols, and carboxylic acids give other dinuclear complexes with double and mixed bridges: air stable amido–hydroxo, anilido–hydroxo, bis-amido, amido–thiolato, and amido–carboxylato complexes.[542] Noteworthy is the thermal stability of those with amido ligands containing β-hydrogens: the number of known dinuclear amido–bridged palladium complexes is limited[296,543–554,] and even fewer possess β-hydrogens,[543,544,547] because there is a strong tendency for the late transition metal amido complexes to undergo β-hydrogen elimination, usually followed by decomposition.

A trinuclear system, whose structure was published,[555] was formed in high yield by the cyclometalation of a 1,3-bis(alkylbenzimidazol-2-yl)benzene ligand, followed by the trimerization of the unit, which possesses a vacant coordination site on the palladium atom and a pendant noncoordinated benzimidazole moiety. The resulting product forms a cup-shaped trimer or tricorn, presented in Figure 46, that includes a molecule of acetonitrile in the crystal structure.[556]

Binuclear μ-hydroxo-μ-amido palladium(II) complexes of the type $[\{Pd(C_6F_5)(PPh_3)\}_2(\mu\text{-}OH)(\mu\text{-}NHC_6H_4X\text{-}p)]$ have been prepared by reaction of $[\{Pd(C_6F_5)(PPh_3)(\mu\text{-}OH)\}_2]$ with the corresponding aromatic amine, and the bis(amido) complexes $[\{Pd(C_6F_5)(Bu^tNC)(\mu\text{-}NHC_6H_4X\text{-}p)\}_2]$ by the reaction of $[\{Pd(C_6F_5)(Bu^tNC)(\mu\text{-}Cl)\}_2]$ with $[NBu_4]OH$ and the arylamine (1:2:2 mol ratio).[550] Although the reductive elimination chemistry of the mononuclear methyleneamido palladium complex $[(DPPF)Pd(C_6H_4)\text{-}Bu^t)(N{=}CPh_2)]$ (DPPF = (1,1′-diphenylphosphino)ferrocene), which contains one unsaturated nitrogen bound to palladium, has been reported,[557]

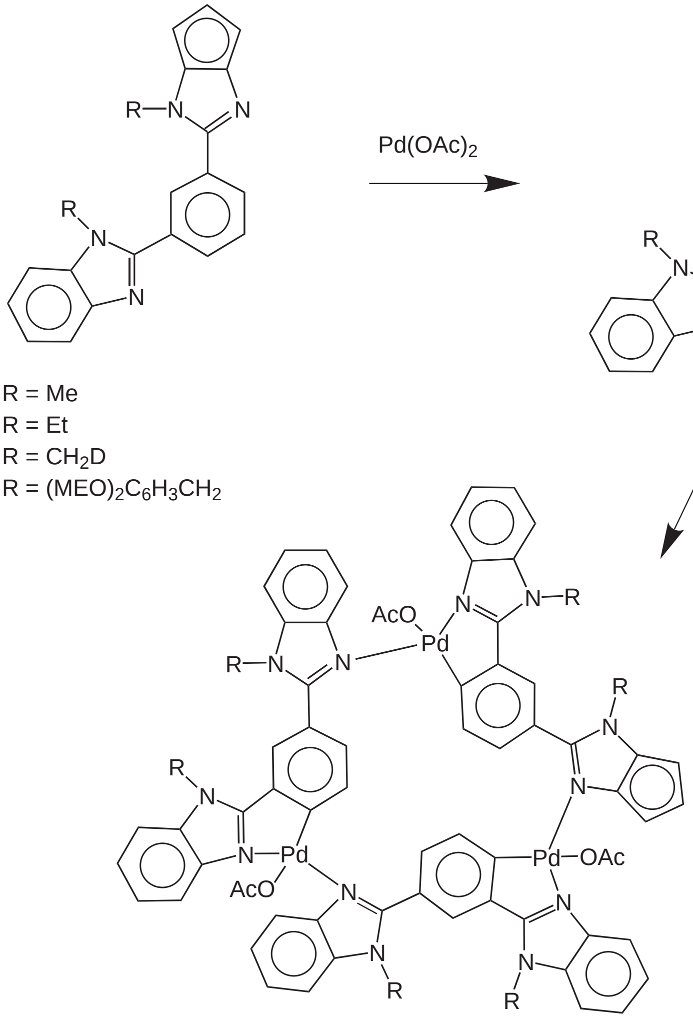

Figure 46 A trinuclear system, formed in high yield by the cyclometalation of a 1,3-bis(alkylbenzimidazol-2-yl)benzene ligand.

it could not be isolated. Little is known about methyleneamido (or azavinylidene)-bridged compounds. The first synthesis of a stable azavinylidene-bridged palladium complex, $[\{Pd(C_6F_5)(Bu^tNC)(\mu\text{-}N{=}CPh_2)\}_2]$, and its structural elucidation by an X-ray diffraction analysis have been reported.[558]

Trifluorophosphane can behave as a μ_3 donor towards a triangular palladium core.[559,560] The symmetrically bridging μ_2-coordination mode has little precedent for tertiary ligands based on Group 15 atoms. The synthesis of a Pd^I dimer featuring a strongly bonded symmetrically bridging μ_2-phosphole unit, which is the first example of this coordination mode for a tertiary phosphane, has been reported.[561]

Dinuclear Pd^I complexes involving six two-electron donors arranged about the Pd—Pd bond are well-known,[203,562] but the new complex, shown in Figure 47, exhibits two striking features: (i) In contrast to most Pd^I dimers,[203,562,563] the Pd_2^{2+} core has an edge-bridged planar structure imposed by the topology of ligand; and (ii) the phosphorus atoms of both coordinated phospholes bridge almost symmetrically the Pd—Pd vector (Pd—P: 2.349(2) Å and 2.358(2) Å).[561]

A possible way to achieve more robust coordination polymer frameworks is to put the powerfully stabilizing chelate effect to use in the bridging ligands. If appropriate donor centers are introduced into the three substituents on the CN$_3$ core, then it may be possible to chelate three metal centers strongly and symmetrically, in a roughly planar fashion, and providing a close metal–metal contact. Tris(2-hydroxybenzylidene)triaminoguanidine LH$_5$ is very easily made from triaminoguanidine and salicylaldehyde. Reaction of LH$_6$Cl with $(Et_4N)_2[PdCl_4]$ in acetonitrile in

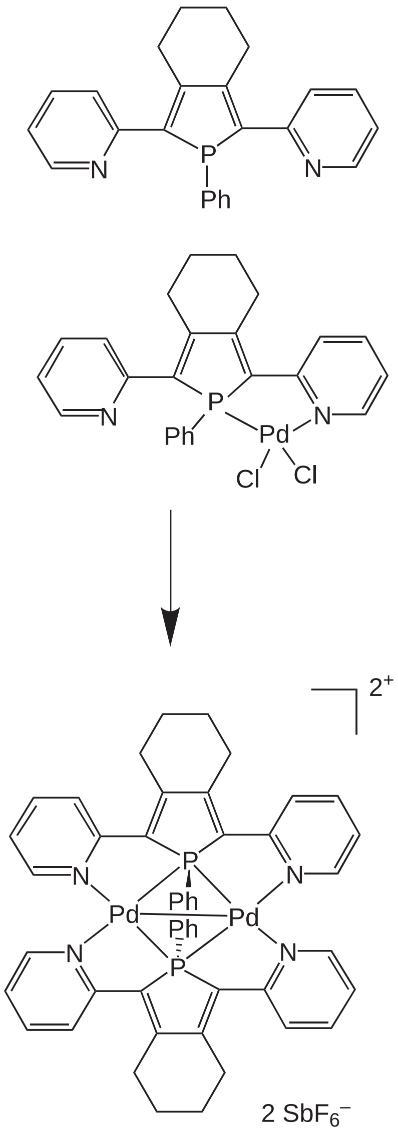

Figure 47 The new dinuclear Pd(I) complex.

the presence of Et_4NOH yielded dark red crystals of $(Et_4N)_2[LPd_3Cl_3]CH_3CN$. The chiral propeller-like structure of the $[LPd_3Cl_3]^{2-}$ ion is shown in Figure 48.[564] The wide scope offered by these types of LM_3 species as 3-connecting building blocks in the construction of networks is immediately apparent. One possibility would be to substitute the Cl ligands in the LPd_3 system by appropriate bridging ligands linking one LM_3 unit to another.[564]

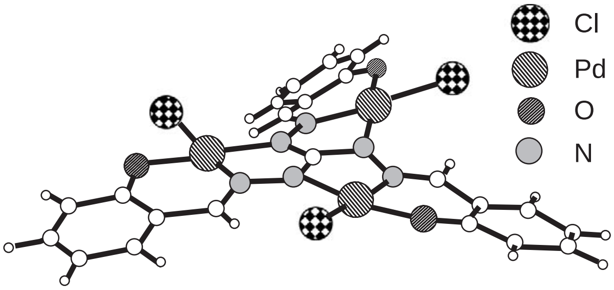

Figure 48 The chiral propeller-like structure of the $[LPd_3Cl_3]^{2-}$ion.

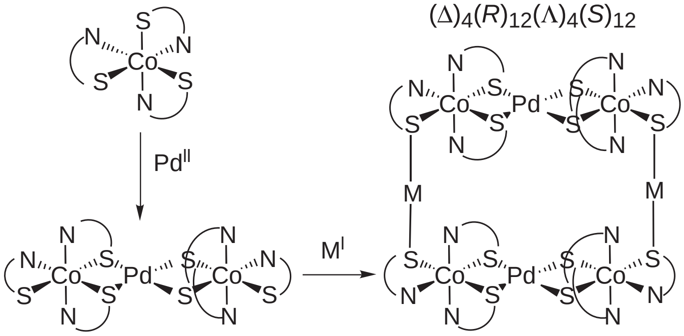

Figure 49 Cyclic sulfur-bridged octanuclear complexes $[M_2'\{Pd[Co(aet)_3]_2\}_2]^{6+}$.

Octahedral metal complexes assemble with simple thiolate ligands, such as 2-aminoethanethiolate (aet) and l-cysteinate (l-cys). The assembly of these types of complexes can be achieved by facile reactions with a variety of metal ions, M, which utilize the binding ability of a coordinated thiolato sulfur atom toward a second metal ion, M′. One way to do this is to introduce a four-coordinate metal ion, such as M′=Pd^{II}, Pt^{II}, at the center of the linear trinuclear structure in $[M'\{M(aet)_3\}_2]^{2+}$. The reaction of *fac*(*S*)-[Co(aet)$_3$] with $[PdCl_4]^{2-}$ in a 1:1 ratio produced a sulfur-bridged Co$_2$"Pd$_3$" pentanuclear complex, $[Pd_2\{Pd(aet)_2\}\{Co(aet)_3\}_2]^{4+}$, in which all of the eight thiolato sulfur atoms from two *fac*(*S*)-[Co(aet)$_3$] and one *cis*(*S*)-[Pd(aet)$_2$] units are bound to two square-planar Pd^{II} ions.[565] The corresponding 2:1 reaction under milder conditions gives the desired trinuclear complex $[Pd\{Co(aet)_3\}_2]^{2+}$, which readily reacts with Ag^{I} or Au^{I} as M′ to afford cyclic sulfur-bridged octanuclear complexes $[M_2'\{Pd[Co(aet)_3]_2\}_2]^{6+}$(see Figure 49). This is the first example of chiral metallacycles composed of three kinds of metal ions with different oxidation states and coordination geometries: octahedral Co^{III}, square-planar Pd^{II}, and linear Ag^{I} or Au^{I} ions.[566] Synthesis, reactivity, and X-ray crystallographic characterization of mono-, di-, and tetranuclear palladium(II)-metalated species were reported.[567]

The compound $\{Pd[\mu_2\text{-}(C_6H_4)PPh_2]Br\}_4$ has $[(C_6H_4)PPh_2]^-$ anions bridging two palladium atoms in a tetranuclear structure. This tetranuclear frame was cleaved with phosphines to form mononuclear compounds.[568] Intermediate products of the frame degradation were detected (see Figure 50).[567]

An example of the modified 7-azaindolyl ligands is the novel starburst molecule, 1,3,5-tris(7-azaindol-1-yl)benzene (tabH). The complex [Pd$_3$(tab)$_2$Cl$_4$] has three Pd^{II} ions in two different environments.[569] The tab ligand acts both as a chelating and a bridging ligand (see Figure 51).

Although two closed-shell metal cations with the same charge would normally be expected to repel each other, evidence has been obtained for an entire family of cation–cation interactions in d^{10} or s^2 systems.[570] This attraction is now shown to originate from dispersion (van der Waals)

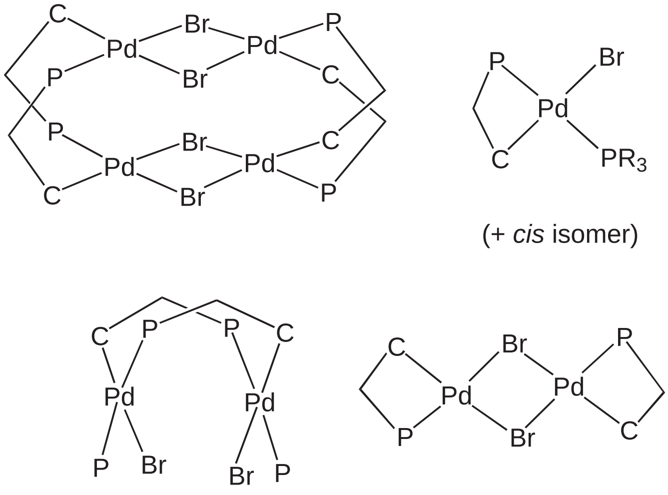

Figure 50 Intermediate products of the frame degradation of $\{Pd[\mu_2\text{-}(C_6H_4)PPh_2]Br\}_4$ after being cleaved with phosphines.

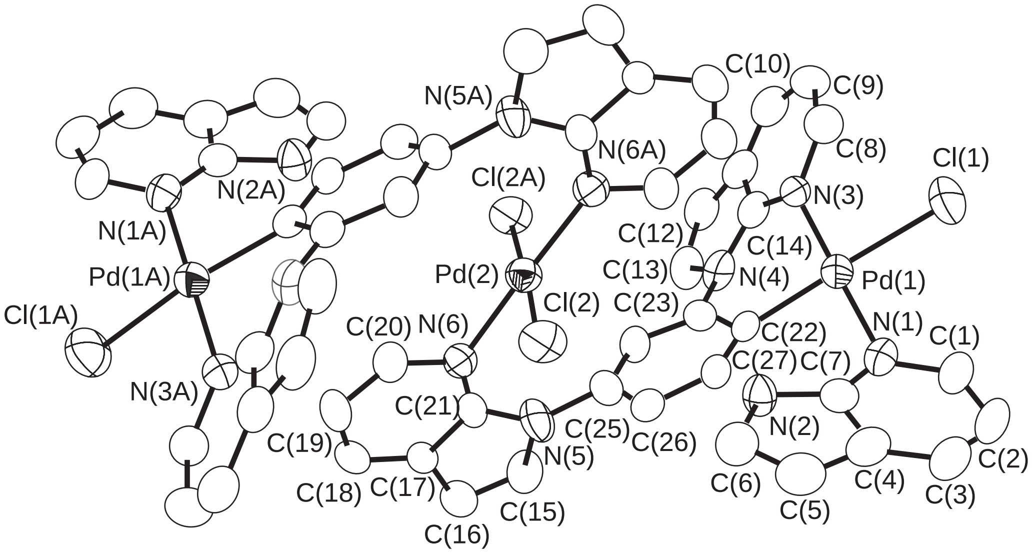

Figure 51 The complex $[Pd_3(tab)_2Cl_4]$.

interactions. It is comparable in strength with typical hydrogen bonds, and it is especially strengthened by relativistic effects for heavy elements such as gold.[571–573] Also, because of the large crystal-field splitting, d^8 ions are, in a sense, closed-shell atoms and can be involved in similar attractions. Regarding d^8-d^{10} systems, a number of structurally characterized complexes in which metallophilic attraction appears are known, but although heterometallic gold-palladium complexes have been characterized,[574] no examples of $Au^I\cdots Pd^{II}$ interactions seem to have been reported before year 2000.[575] The main contribution to the Pd^{II}–Au^I attraction is dispersion. Charge-transfer type contributions are about half as important, but the two contributions $Pd \rightarrow Au$ and $Au \rightarrow Pd$ are energetically comparable.[575]

Dinuclear complexes with bridging phosphido, hydrido, and diphosphine ligands were formed via some interesting transformations, such as P—C bond formation, P—H bond activation, and conversion of a chelate diphosphine to one bridging two metal centers.[259]

The 2,2′-bipyrazine (2,2′-bpz) complexes $[L_2Pd(2,2'\text{-bpz-}N^1,N^1)]^{2+}$ in which (L_2 = en and L = H_2O) represent useful angular units for the generation of larger cationic aggregates. There are two principal ways by which this can be achieved: (i) When additional metal ions M bind to the available N(4) positions of the chelating 2,2′-bpz ligand and cross-link to other cations, depending on the geometry of M′, flat triangles (M′ = *trans*-$(NH_3)_2Pt^{II}$),[576] loop structures (M′ = Ag^+), or hexanuclear vases (M′ = $enPd^{II}$)[577] can form. (ii) The aqua compound can likewise act as an angular unit upon substitution of the aqua ligands by other bridging ligands L. These may be small (OH^-) or large (4,4′-bpy) and may themselves be angular (OH^-) or linear units (4,4′-bpy). Of course, variations of these motifs are possible, e.g., upon use of M′—L—M′ fragments in (i) or L—M′—L linear units in (ii). Finally there is, in principle, also the possibility of combining (i) and (ii) in such a way as to use as a cross-element in molecular architecture (option (iii) in Figure 52).[578]

Owing to the high affinity of palladium for sulfur, the palladium complexes with phosphine ligands readily react with organosulfur compounds[579–587] to give very stable sulfide and thiolate complexes, which are probably responsible for the poisoning of palladium catalysts by organosulfur impurities in feedstocks. The palladium(II) complexes blending both phosphine and thiolate ligands have received attention only in the 1990s.[136,588–590] A tetranuclear complex $[Pd_4(\mu_3\text{-}Se)_2(\mu\text{-}SCH_2Ph)_2(\mu\text{-dppm})_2Cl_2]$ is formed via the reaction of $[Pd_2(\mu\text{-dppm})_2Cl_2]$ with selenium powder in the presence of $NaSCH_2Ph$ in DMF.[591] The features of this complex are its novel structure arising from the asymmetric coordination by phosphorus, selenium, sulfur, and chlorine atoms and its formation involving considerable rearrangement of the initial components. A study reports the condensation reactions of mononuclear palladium(II) complexes with mixed diphosphine and thiolate ligands, [Pd(dppp)(SRS)] (SRS^{2-} = edt^{2-} or propane-1,3-dithiolate), through oxidation of the ligands with oxygen or elemental Se, and the crystal structures of a series of polynuclear palladium complexes isolated from the condensation reactions along with their spectroscopic properties are presented.[592]

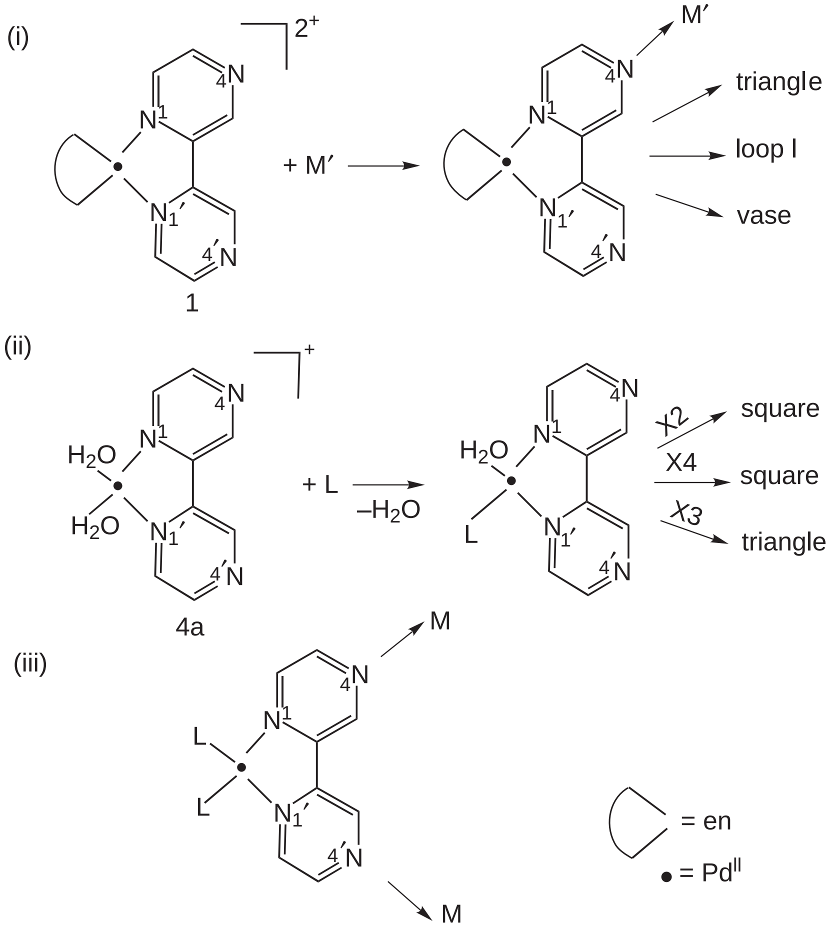

Figure 52 Use of the 2,2′-bipyrazine (2,2′-bpz) complexes $[L_2Pd(2,2'\text{-bpz-}N^1,N^{1'})]^{2+}$ in which (L_2 = en and L = H_2O) as angular units for the generation of larger cationic aggregates.

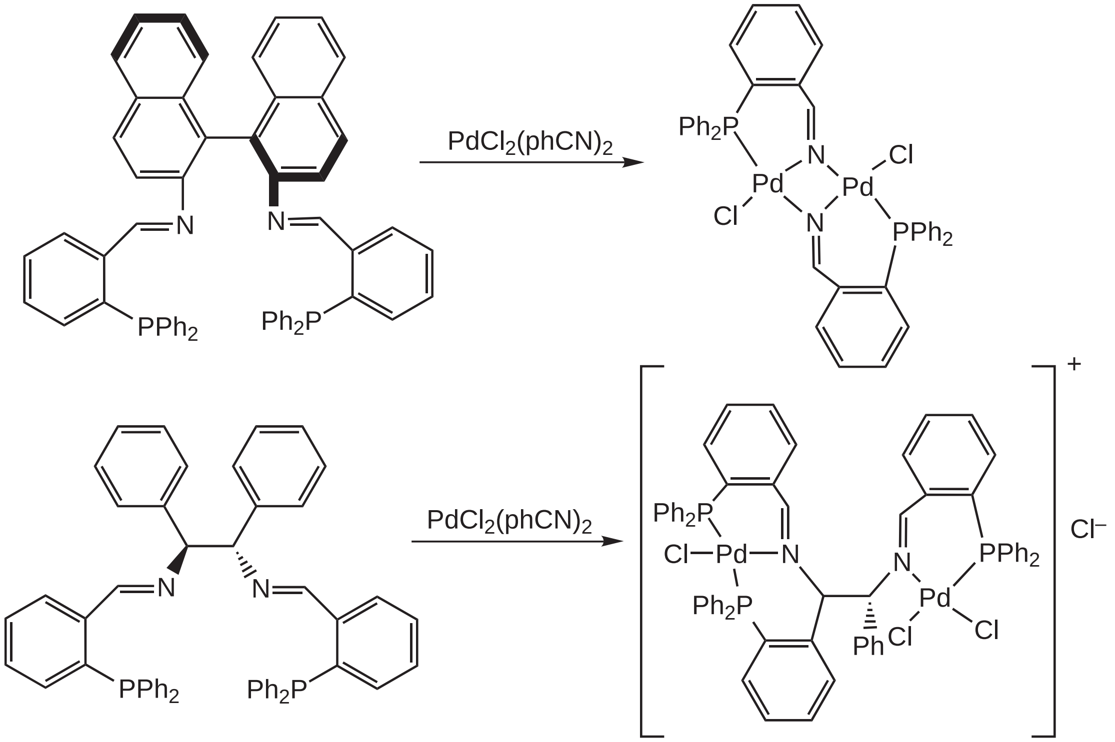
Reactions of $PdCl_2(PhCN)_2$ with (*S*)- *N*,*N*′-bis[2-(diphenylphosphino)benzylidene]-2,2′diimino-1,1′-binaphthylene and (*S*,*S*′)-*N*,*N*′-bis[2-(diphenylphosphino)benzylidene]-1,2-diimino-1,2-diphenylethane give unexpected results, as shown in Scheme 10:[593]

Palladium(II) complexes possessing bidentate ligands are known to efficiently catalyze the copolymerization of olefins with carbon monoxide to form polyketones.[594–596] Sulfur dioxide is an attractive monomer for catalytic copolymerizations with olefins since SO_2, like CO, is known to undergo facile insertion reactions into a variety of transition metal-alkyl bonds. Indeed, Drent has patented alternating copolymerization of ethylene with SO_2 using various palladium(II) complexes.[597] In 1998, Sen and coworkers also reported that $[(dppp)PdMe(NCMe)]BF_4$ was an effective catalyst for the copolymerization of SO_2 with ethylene, propylene, and cyclopentene.[598] There is a report of the insertion reactions of SO_2 into Pd^{II}-methyl bonds and the attempted spectroscopic detection of the copolymerization of ethylene and SO_2.[599]

The cationic 1,3-bis(diphenylphosphino)propane (dppp) palladium(II) complex (see Figure 53) can be prepared by the low temperature reaction of $(dppp)PdMe_2$ with $H(OEt_2)_2[BAr'_4]$ [$Ar' = C_6H_3(CF_3)_2$-3,5].[600] Reaction of this complex with an excess of SO_2 (~25 equivalents) at 193 K produces an unusual dinuclear complex, shown in Figure 54.[599] The eight-membered ring consists of a plane of palladium and oxygen atoms, with the sulfur atoms located above and below the plane. The six-membered rings formed by the dppp ligand are in the chair conformation.

The cyclooctapyrroles shown in Figure 55 appear predestined to form binuclear metal complexes since the loop-shaped conformation of these macrocycles exhibits two structurally identical, helical N_4 cavities. Enantiomers of such complexes, which are presumably generally very stable towards racemization owing to the rigidity of the molecule imposed by the incorporation of the metal, are of interest as possible models for binuclear metalloenzymes and as potential catalysts in asymmetric synthesis. The first two ligands as well as their recently obtained palladium complexes[601] were



Scheme 10

investigated as examples to effect enantiomeric separation.[601] The molecular frameworks of the cyclooctapyrroles show the figure eight conformation previously derived from the NMR studies.[601] The ability of the first two cyclooctapyrroles shown, to form binuclear chelates was confirmed by the preparation of the homobinuclear palladium(II) complexes.

X-ray structure analysis shows that on incorporation of two Pd^{II} ions into the two N_4 cavities the molecular symmetry remains unaffected, but there are marked conformational changes in the ligand framework, as shown in Figure 56. The intramolecular separations of the metal centers are not conducive to significant intermetal interactions. Figure eight cyclooctapyrroles and—presumably in general—their binuclear metal complexes are amenable to preparative enantiomeric separation by chromatography on suitable phases (here a CDMPC (CDMPC = cellulose tris(3,5-dimethylphenylcarbamate)) coated silica gel proved suitable). They hold promise for a symmetric catalysis.[601]

Many examples are known of edge-sharing square planar bimetallic complexes formed by d^8 transition-metal centers. A recent report tentatively classified the structures of such complexes bridged with two X ligands (X = halogen anion, RO^-, RS^-, S^{2-}, or R_2P^-) into two possible groups, that is, flat and bent forms (see Figure 57).[602] Of these two structures, the bent form is of interest, particularly because axial orbitals of the two metals are in close proximity under the hinged planes and interact cooperatively with a substrate. Such an interaction is expected to play a significant role in binding a substrate to a bimetallic complex. A study reports the preparation and X-ray structure of unprecedented linked-bisphosphido dipalladium-(II) complexes with a

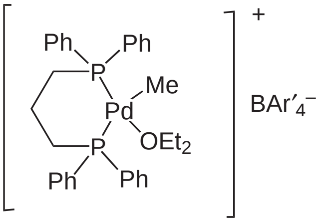


Figure 53 Cationic 1,3-bis(diphenylphosphino)propane (dppp) palladium(II) complex.

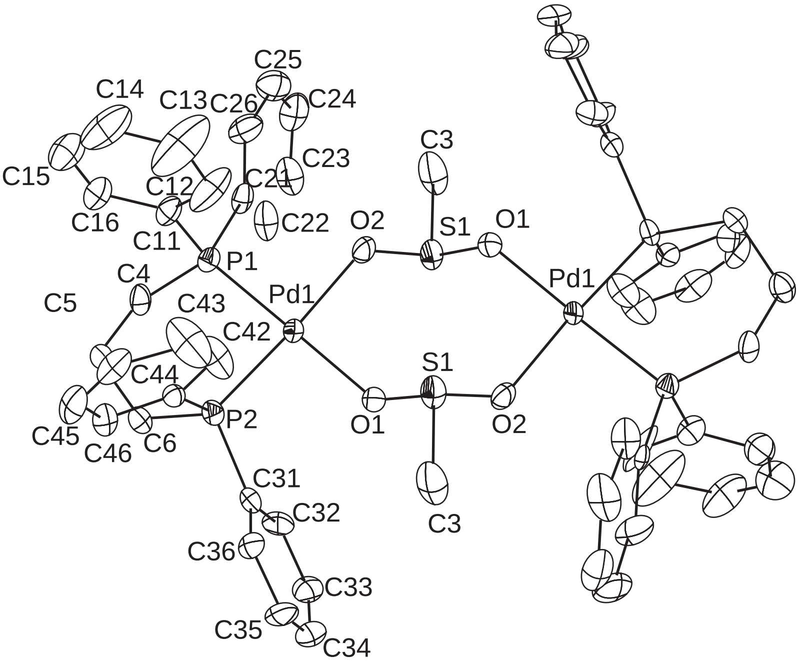

Figure 54 Product of the reaction of 1,3-bis(diphenylphosphino)propane (dppp) palladium(II) complex with an excess of SO_2.

formula $[Pd_2(\mu\text{-}RPCH_2CH_2PR)(DPPE)_2]Cl_2$ (R = Me and Ph), in which the linked-bisphosphido groups are employed as ligands to enforce them sterically to adopt a bent structure.[603]

Trinuclear clusters $[Pd_3(\mu_3\text{-}E)_2(L)_3]^{2+}$ (E = S, Se or Te; L = bis(diphenylphosphino)methane (dppm), 1,2-bis(diphenylphosphino)ethane (dppe), 1,3-bis(diphenylphosphino)propane (dppp) or 1,4-bis(diphenylphosphino)butane (dppb)) were made and studied by cyclic voltammetry. The extent of chemical reversibility of the reduction process clusters depends on the chelate ring size and varies in the order L = dppe > dppp > dppb = dppm for the clusters. For the $[Pd_3(\mu_3\text{-}E)_2(dppe)_3]^{2+}$ clusters, the extent of reversibility improves in the order Te > Se > S. The ease of reduction follows the order Te > Se > S regarding the chalcogenido ligands.[604–606] The ligand 1,2-bis(diphenylarsino)ethane (dpae) was used to synthesize trinuclear $[Pd_3(\mu_3\text{-}E)_2(dpae)_3]^{2+}$ (E = S, Se or Te) clusters. The dpae ligand chelates to a metal ion through its two arsenic atoms. The synthesis and cyclic voltammetry and X-ray structure of $[Pd_3(\mu_3\text{-}S)_2(dpae)_3][BPh_4]_2$ are described.[607]

Metallacrown ethers are a class of molecular receptors with both crown ether- and transition metal-receptor sites. The metallacrown ether $[PdCl_2\{PPh_2\text{-}(CH_2CH_2O)_4CH_2CH_2PPh_2\text{-}P,P'\}]_m$,[608] exhibits a unique mode of molecular recognition in which the metallacrown ether ring is expanded by the incorporation of a $PdCl_2$ moiety. The product of this reaction is the first reported example of a dimetallacrown ether, see Scheme 11.[609]

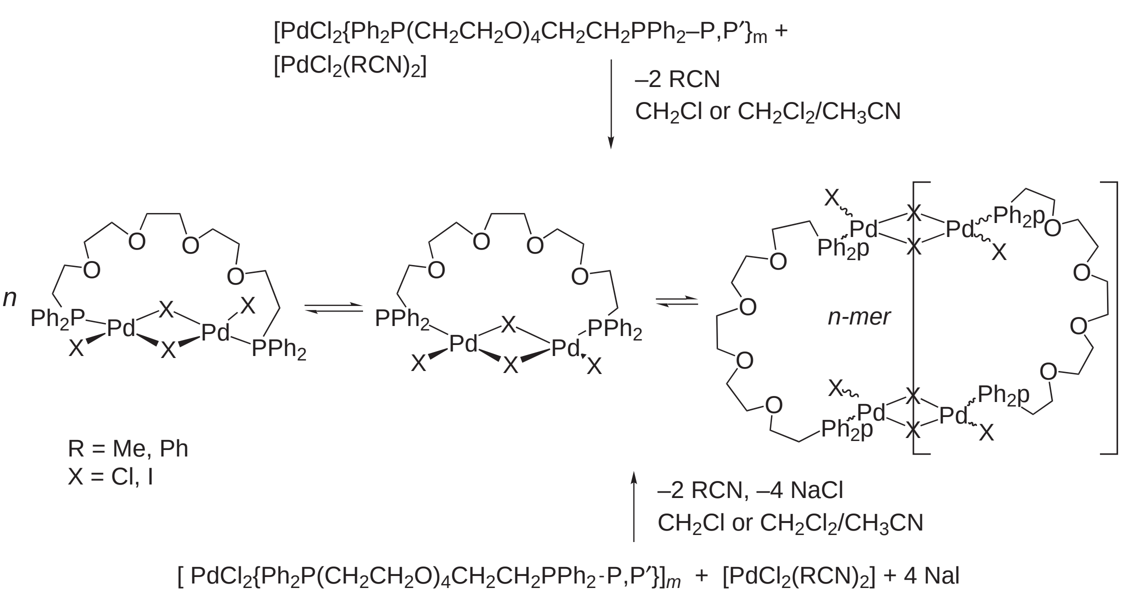

Scheme 11

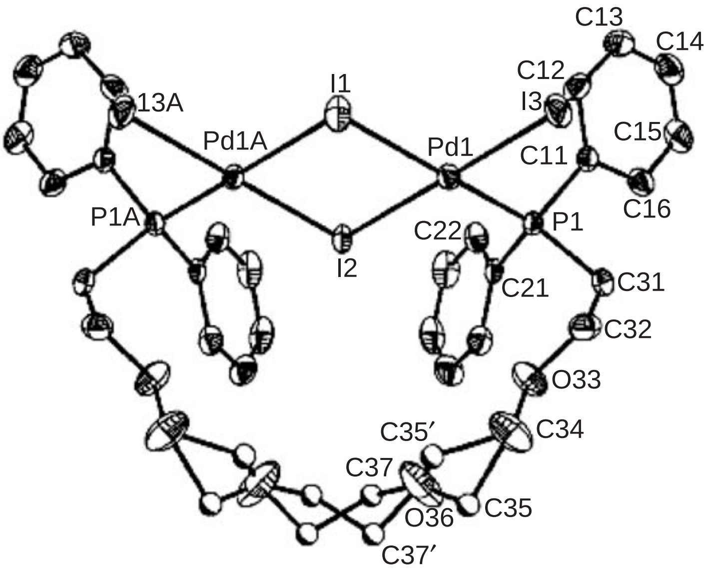

Figure 58 X-ray crystal structure of a dimetallacrown ether.

The X-ray crystal structure shown in Figure 58 suggests that this dimetallacrown ether could have quite different receptor properties from those of the previously reported metallacrown ethers. The average cross-ring oxygen–oxygen distance (O33–O36A and O33A–O36, 5.27 Å), provides a measure of the ring size.[609] A bifunctional molecule, such as CO, could easily coordinate to both the Pd and the alkali metal cation in the dimetallacrown ether.[609]

Syntheses and reactivities of noble metal-sulfur clusters are still poorly understood. The mixed-metal sulfido cluster containing a cubane-type $PdMo_3(\mu_3\text{-}S)_4$ core is capable of catalyzing the stereo- and regioselective addition of alcohols[611] or carboxylic acids[611] to the alkynes with electron-withdrawing substituents as well as the intramolecular cyclization of alkynoic acids.[612] Two versatile synthetic routes lead to metal sulfido clusters containing Pd. One involves the reactions of the hydrosulfido-bridged dinuclear complexes $[Cp^*MCl(\mu_2\text{-}SH)_2MCp^*Cl]$ ($Cp^* = \eta^5\text{-}C_5Me_5$; M = Ru, Rh, Ir) with various metal complexes affording an enormous body of $M_2M'(\mu_3\text{-}S)_2$ clusters,[613,614] while the other is the incorporation of one or two noble metals into the dinuclear complexes $[M_2S_2(\mu_2\text{-}S)_2(S_2CNEt_2)_2]$ (M = Mo, W) affording the mixed-metal clusters with the $M_2Pd(\mu_2\text{-}S)_4$ or $Mo_2Pd_2(\mu_3\text{-}S)_4$ core.[615] Most of the metal–sulfido cluster cores have been constructed by the use of self-assembly systems, and the rational and reliable methods to form the desired metal-sulfur frameworks in satisfactory yields are still rare.[615]

The ability to switch a molecular unit on and off is a key component of an efficient molecular device, since it allows modulation of the physical response of such a device by external physical or chemical triggers. A molecular device, based on a trinuclear metal complex, shown in Figure 59, functions as an electroswitchable-photoinduced-electron-transfer (ESPET) device.[616] Electrochemical switching of the redox state of a spacer intervening between a donor–acceptor pair can dictate the type of the observable charge separation and the lifetime of the resulting ion pair.[616]

The insertion of an S or Se bridge into $[Pd_2(\mu\text{-dppm})_2X_2]$ (X = halogen) to give rise to complexes $[Pd_2(\mu\text{-E})(\mu\text{-dppm})_2X_2]$ (E = S, Se) with a change of the oxidation state of palladium from +1 to +2 has been reported,[582,617,618] whilst reports on the palladium complexes with mixed thiolate and diphosphine ligands, especially those having a palladium formal oxidation state of +2 and containing both dppm and thiolate ligands, are very rare. A metal–thiolate–diphosphine

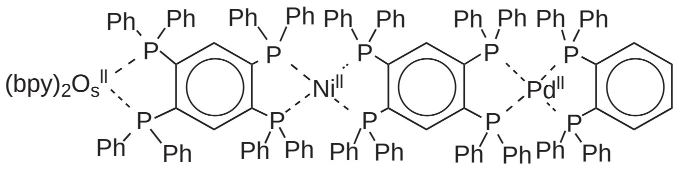

Figure 59 A trinuclear metal complex that functions as an electroswitchable-photoinduced-electron-transfer (ESPET) device.

complex $[Pd(SR)_2(dppx)]$ [dppx = $Ph_2PCH_2PPh_2$, $Ph2P(CH_2)_2PPh_2$][619–621] is known. The oxidation of $[Pd_2(dppm)_2Cl_2]$ with selenium in the presence of $NaSCH_2Ph$ in DMF (see Equation (4)) gives rise to a novel polynuclear complex $[Pd_4(\mu_3\text{-}Se)_2(\mu\text{-}SCH_2Ph)_2(\mu\text{-}dppm)_2Cl_2]$; all the palladium(II) atoms in the compound are tetracoordinated with distorted square-planar geometry, of which two are asymmetrically coordinated with selenium, sulfur, chlorine, and phosphorus atoms:[591]

$$[Pd_2(dppm)_2Cl_2] \xrightarrow{Se} [Pd_2Se(dppm)_2Cl_2] \xrightarrow[NaSCH_2Ph]{Se} [Pd_4Se_2(SCH_2Ph)_2(dppm)_2Cl_2] + dppmSe + NaCl \quad (4)$$

For heterobinuclear complexes which contain an early and a late transition metal and in which the metal centers can “communicate” with one another, interesting properties have been predicted, such as multifunctionality and cooperative effects. However, the problems encountered in the realization of the differing coordination chemical requirements of both metals in close proximity to one another are just as great as the expectations. There is a report on the synthesis and structure of heterobinuclear complexes in which interactions of palladium with a lanthanide (Nd) are possible.[622–624] A decisive factor for this enlargement of the class of “early-late heterobimetallics”(ELHB) is a novel ligand system incorporating bisaminopyridinato (bis(Ap)) ligands.[625] The Nd—Pd-alkyl complex is isolated as a light yellow powder. The molecular structure (see Figure 60) shows a planar coordination geometry, characteristic of Pd^{II} compounds, and a Nd—Pd distance of 3.0345(12) Å. The two metal centers are bridged by only one ligand.[625] Decisive for the preparation as well as the stabilization of the heterobimetallic compound is that

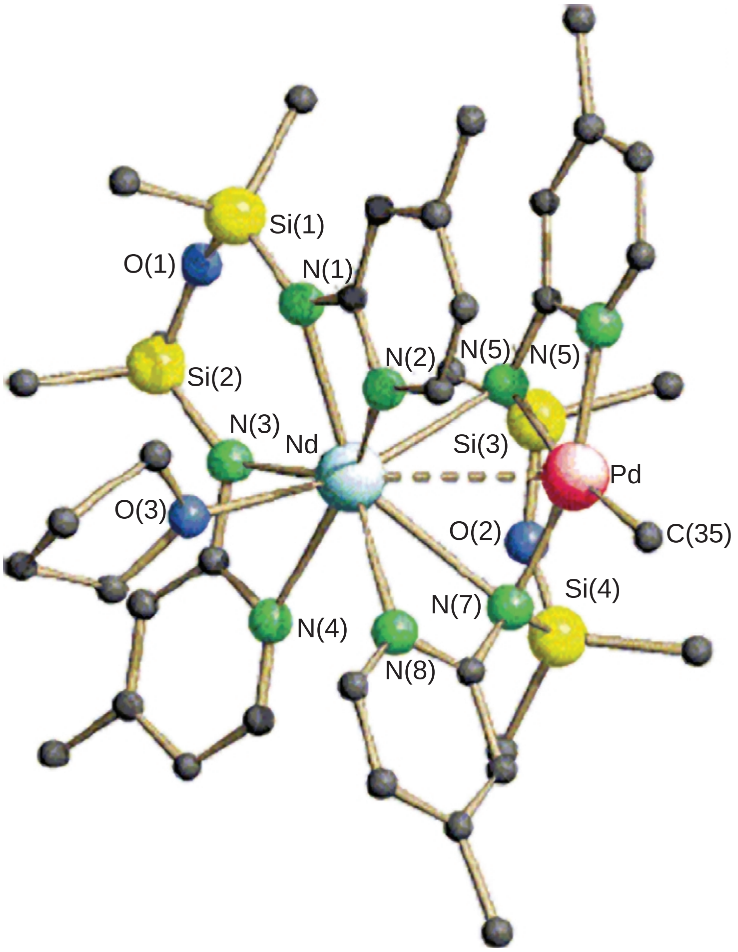

Figure 60 A novel complex incorporating bisaminopyridinato (bis(Ap)) ligands.

the lanthanide “ate” complexes react with chlorides of electron-rich transition metals, such as Pd by salt elimination and that bisaminopyridinato ligands can prevent the ligand transfer from early to late transition metals and thus the decomposition of the bimetallic complex. The flexible coordination mode of the bis(Ap) ligands allows a coordinative saturation of the lanthanide metal center, leaving two or three nitrogen donor groups for a square-planar coordination geometry at the late transition metal as well as an interaction between the two metals.[625]

6.4.5.12.1 Supramolecular assemblies (see Chapters 7.7 and 7.8)

A considerable variety of frequently predesigned molecular polygons and polyhedra have been established, and a methodology exists on how to combine angular and linear building blocks to generate a particular ensemble. As far as the smallest possible polygon, the triangle, is concerned, it should be formed most readily by combining three 60° angular fragments and three linear ones, see Figure 61.[626–628]

However, a triangle with a 60° turning angle at the metal was unknown because of the impossibility of generating such an angle in a metal fragment of common coordination numbers. Virtually all molecular triangles, with metal entities at the corners display 80–90° angles. It is the flexibility of the organic ligand, shown in Figure 62 that in essence enables formation of the triangle.

Complex formation of enPt^{II} with 2,2′-bipyrazine (bpz) leads in a kinetically controlled reaction and in reasonable yield to a cyclic trimer of composition $[\{\text{enPt(bpz-N4,N4}')\}_3]^{6+}$. Due to the low barrier of rotation about the central C2—C2′ bond of the bpz ligand and because of monodentate binding of each pyrazine half to the heavy metal, the molecular triangle is rather flexible.[577] It has been crystallized in two distinctly different forms, with an all-*trans* orientation of the two pyrazine entities (C_2 molecular symmetry) and an all-*cis* arrangement of the pyrazine rings (approximately C_3 symmetry). The trimer in its all-*cis* form behaves as an efficient ligand toward additional metal electrophiles such as enPd^{II}, affording highly charged multinuclear species of different topologies, with vases, a paddle wheel, and a barrel crystallographically characterized.[577] The building block $[\text{enPd(bpz-}N1, N1')]^{2+}$, is the starting material for another type of molecular triangles,[576] containing metal ions at the corners and at the centers of the sides.

Self-assembled metallomacrocycles have attracted a great amount of attention because of their shape- and size-selective encapsulating properties, with potential applications in catalysis, sensing devices, molecular electronics, and small molecule transport. For example, *cis*-blocked, square-planar palladium(II) and platinum(II) complexes with bidentate or tridentate pyridine-based ligands have been used to prepare molecular boxes and cages that are soluble in either water or organic solvents.[511,628–634] It is established that 4(3*H*)-pyrimidone is a versatile ligand, either in the neutral or deprotonated form. A neutral palladium(II) complex and cationic complexes with diphosphine ligands contain the neutral ligand while the cationic tripalladium complexes contain the deprotonated ligand acting as a bridging group. The Pd_3 complex can act as a host for anions.[635]

Construction of discrete and well-defined molecular architectures using organic ligands and metal ions through the self-assembly route has received much attention. A dinuclear Pd^{II} cage,[636] includes a hexafluorophosphate ion inside the cavity. Self-assembly of a novel macrotricyclic cage

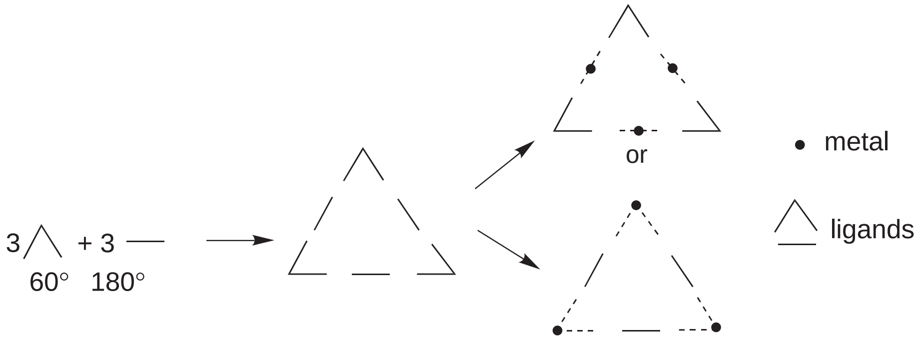

Figure 61 Formation of a triangle by combining three 60° angular fragments and three linear ones.

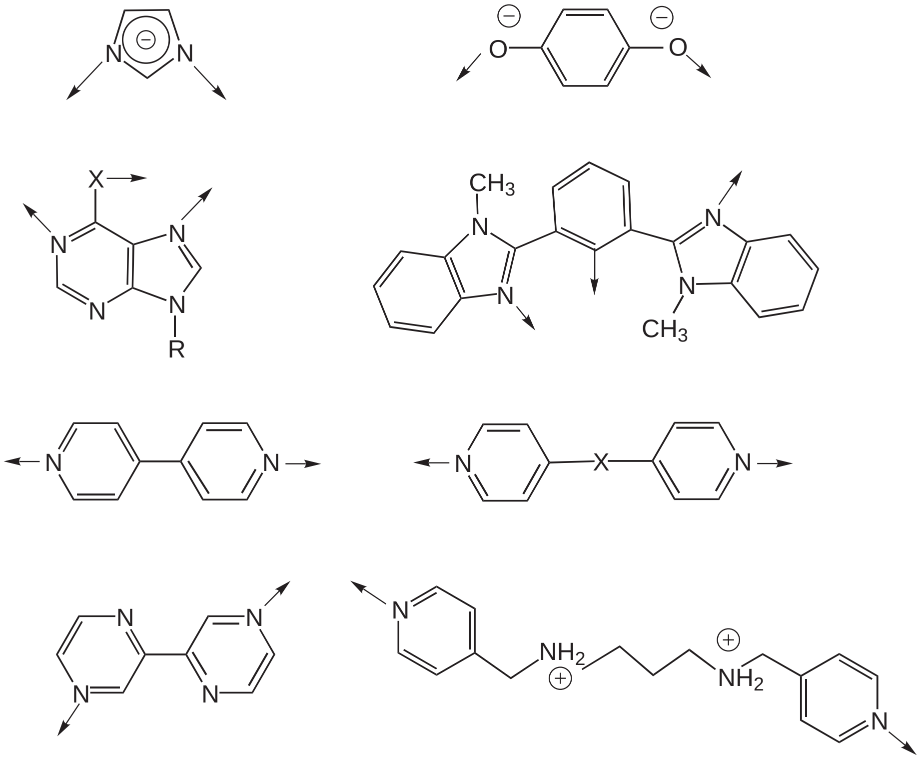

Figure 62 Flexible organic ligands.

molecule from the ligand and $Pd(NO_3)_2$, shown in Figure 63, was directly monitored using NMR spectroscopy.[513]

Capsules are instantly formed by simple addition of two equivalents of $Pd(dppp)(OTf)_2$ (dppp = 1,3-bis(diphenylphosphino)propane) to acetone, CH_2Cl_2 or $CHCl_3$ solutions of resorcin [4]arene derivatives having four pyridine units as pendent groups, see Figure 64.[637]

One of the most successful approaches to the synthesis of metalla-supramolecular systems has been by templated self-assembly processes. Most of the templating agents used by synthetic chemists are either cationic or neutral species. Anions, on the other hand, have only fairly recently been successfully utilized as templates. The new metalla-macrocycles $[Pd_2Ni_2(atu)_4(PPh_3)_4X]^{3+}$ (atu = deprotonated amidinothiourea, X = Cl, Br, I) have been prepared using anion templated syntheses. Only in the presence of each of these three halides are the metalla-macrocycles formed.[638]

Transition metal-directed self-assembly of macrocycles and cage compounds has received considerable attention lately, leading to more and more complex architectures.[511] Numerous examples for square structures but considerably less for triangular structures are given in the literature.[576,577,639–644] Equilibria between molecular squares and triangles have been reported.[13,517,577,645–648] One of the most useful corner units is *cis*-dpppPd^{II}.[649] These corners are reported to form almost exclusively molecular squares with linear diazaligands.[646,650] Self-assembly of substituted diazadibenzoperylene bridging ligands with Pd^{II}-phosphane corners resulted in unexpected equilibria between molecular triangles and molecular squares. Owing to complex dynamics on the NMR time scale, identification and characterization of the species could only be accomplished by a combination of variable-temperature ^{1}H-and ^{31}P{^{1}H}-NMR spectroscopy and ESI-FTICR mass spectrometry.[651]

Since the first self-assembly of a molecular square based on a labile Pd^{II} complex,[652] many self-assembly molecular squares utilizing Pd^{II} as corners have been reported.[511,512] Strategies of self-assembly and "complexes as ligands" were combined in the preparation of the octanuclear molecular square $\{(dppf)Pd[\mu\text{-}(pyterpy)_2Ru]\}_4(PF_6)_8(OTf)_8$, where pyterpy is 4′-(4‴-pyridyl)-2,2′:6′,2′-terpyridine and dppf = 1,1′-bis(diphenylphosphino)ferrocene. The dimensions of this large square are about 21.8 × 21.8 Å, probably the largest reported in the literature to 2003. The complex exhibits multielectron redox processes, indicating negligible electronic communications between the individual chromophores. The observed photophysical properties are

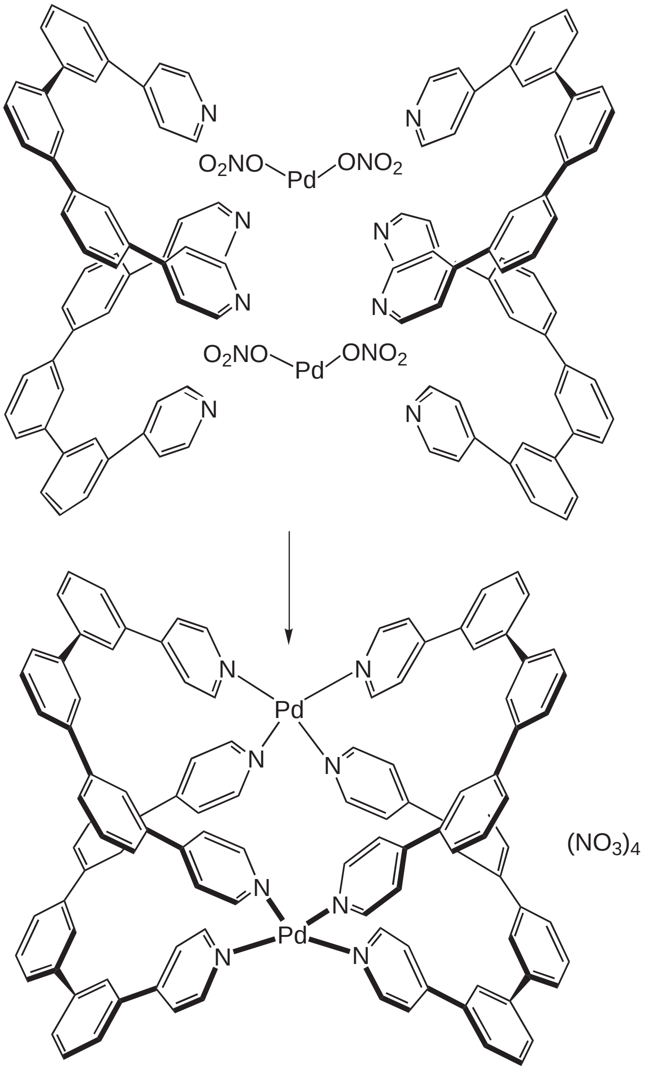

Figure 63 A dinuclear Pd^{II} cage.

dominated by the bridging metal–complex ligands with minimum influence from the corner chromophores.[653]

Two homooxacalix[3]arenes dimerize with three $Pd^{II}(Ph_2PCH_2CH_2CH_2PPh_2)\cdot(OTf^-)_2$ into a molecular capsule,[654,655] which can specifically include C_{60} fullerene, the selectivity of C_{60} fullerene versus C_{70} fullerene being nearly "perfect."[655,656] A new molecular capsule is composed of two homooxacalix[3]arene with 3-pyridyl substituents at the *para*-positions and three Pd^{II} complexes. According to computational studies and examination of CPK molecular models, this capsule should be "chirally" twisted into either a right-handed (*P*) or a left-handed (*M*) form because of the asymmetrical structural characteristic of the 3-pyridyl substituents, and the ratio should be controlled by "chiral" guest molecules included in the cavity.[657–660] Indeed this molecular capsule has a chiral factor and the (*P*) versus (*M*) equilibrium is readily controlled by the inclusion of Pirkle's reagent or chiral $R^*NH_3^+$ ions.[661]

The method developed by Fujita[662,663] and Stang[626,627] has proved to be remarkably successful in that predictable supramolecular structures are formed in essentially quantitative yield under thermodynamic control (see Figure 65). It employs a square-planar complex of Pd^{2+} or Pt^{2+} bearing an inert bidentate ligand and easily displaceable ligands, L, in the remaining *cis*-disposed coordination sites. If a linear linker, such as 4,4′-dipyridyl is used, a quantitative yield of the square is slowly formed.[652] In a similar way, by using, the Pd^{II} complex and the tripyridyl linker, the three-dimensional triangular structure is isolated.[664,665]

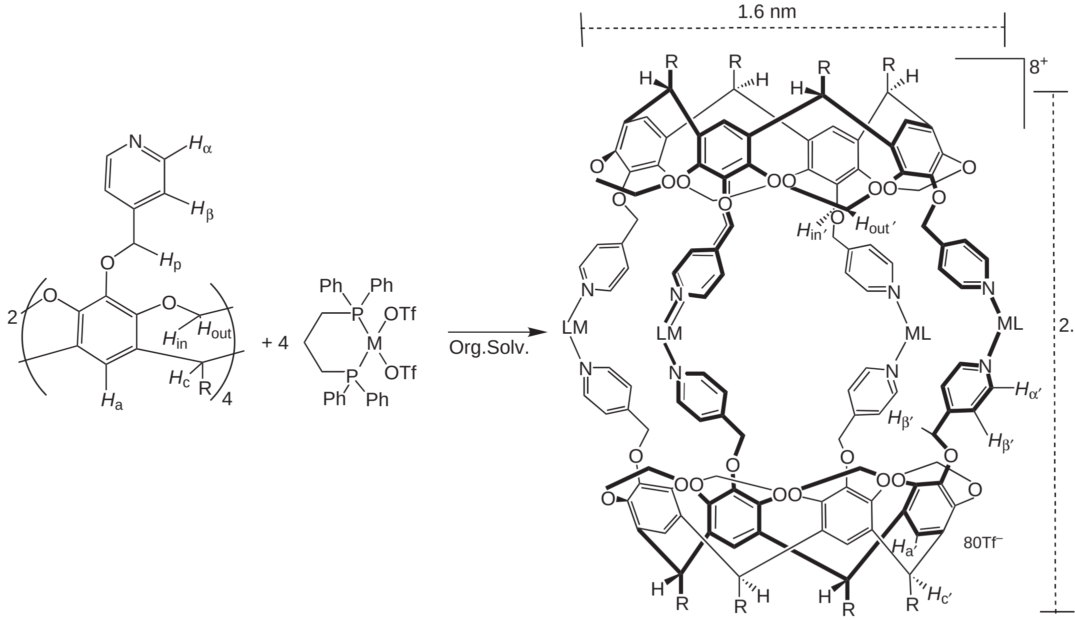

Figure 64 Synthesis of molecular capsules.

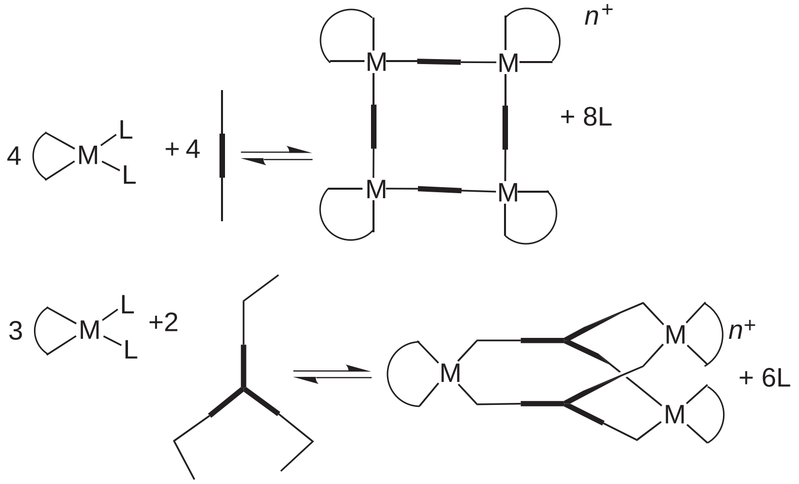

Figure 65 Preparation of supramolecular structures.

Many of the larger supramolecular structures have been shown to incarcerate multiple guest molecules.[662] Square planar d^8 transition metal complexes formed from planar aromatic ligands are known to form stacked crystal structures which have weak metal–metal bonding and attractive π–π-stacking.[125,219,666–669] The metal–metal separations are about 3.5 Å which is similar to the separation between stacked aromatic molecules. Consequently, to provide a receptor for square planar d^8 complexes with planar aromatic ligands and also purely organic aromatic molecules, a spacer-chelator molecule is required which holds the chelators cofacially at a separation of about 7 Å. Two cofacial tridentate chelators bound to a square planar metal are shown in Figure 66.

Provided the unidentate ligand, L, is a good leaving group, addition of a linear linker should generate the molecular rectangle. Similarly, a triangular linker should generate a molecular triangle, and so on. Because complexes may carry charge, the cofacial disposition of the metals should allow for the incorporation of negatively charged ligands and complexes into the molecular clefts as illustrated in Figure 67. The synthesis of a spacer-terpyridyl chelator, the formation of molecular rectangles with Pd$^{\mathrm{II}}$, and the stabilities of various guests in the cofacial molecular cleft have been reported.[670]

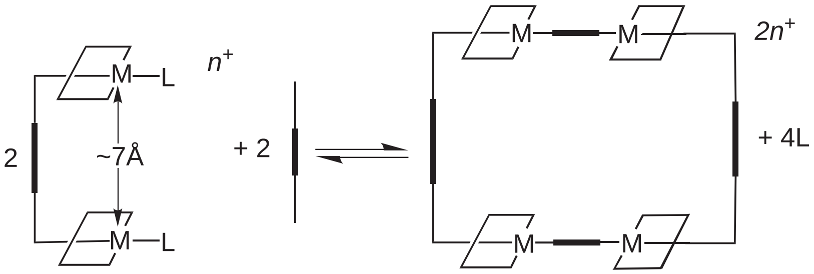

Figure 66 Two cofacial tridentate chelators bound to a square planar metal.

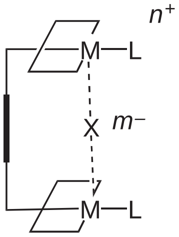

Figure 67 Cofacial disposition of the metals allowing for the incorporation of negatively charged ligands and complexes into the molecular clefts.

The simple combination of square-planar coordination geometry of Pd^{II} or Pt^{II} with pyridine-based ligands offers an efficient method for the self-assembly of nanometer-sized frameworks such as macrocycles, cages, catenanes, tubes, and capsules.[511,663,671] To expand the structures of pyridyl-coordinated Pd^{II} complexes into more rigid and bigger coordination frameworks, one can replace a mono-coordinating 4-pyridyl group by a doubly ligating 3,5-bis(3-pyridyl)phenyl unit. According to this idea, 4,4′-bipyridine, which is the simplest pyridine-based bridging ligand, is modified into a tetradentate ligand. This ligand is expected to take a panel-like conformation and, on complexation with $(en)Pd(NO_3)_2$, assemble into large discrete box structures in analogy to the assembly of trinuclear and tetranuclear cyclic complexes from $(en)Pd(NO_3)_2$ and 4,4′-bipyridine.[626,627,649,652,672–676] These expected box structures are efficiently formed in a *dynamic* fashion. Namely, the boxes are in equilibrium and smoothly interconvertable. Cold-spray ionization mass spectroscopy (CSI–MS)[677] is very effective to study both kinetic and thermodynamic products in the assembly process shown in Figure 68.[678]

The propeller-like $[M(L\text{-}L)_3]^{\pm z}$ structural motif in supramolecular chemistry has been exploited to introduce chirality at both the local and global structural level in these assemblies. Evidence is presented to support the self-assembly of molecular hexagons of large dimension (>5 nm).[679] Six inert, chiral transition metal complexes $[(bpy)Ru(tpphz)_2]^{2+}$ or $[(bpy)Os(tpphz)_2]^{2+}$ are joined by six labile Pd^{II} ions. The Ru_6Pd_6, Os_6Pd_6, and $Ru_3Os_3Pd_6$ structures (shown in Figure 69) form due to the torsional restraints imposed by the Ru or Os stereochemistry along with the entropic factors which favor rings systems over polymeric structures. The metals alternate in a Ru—Pd, Os—Pd, and Ru—Pd—Os—Pd fashion.[680]

A number of supramolecular aggregates of the cubic cluster Pd_6Cl_{12} with methylated benzenes (i.e., durene and mesitylene), the fullerene C_{60}, and polynuclear aromatic hydrocarbons (i.e., naphthalene and 1,2:5,6-dibenzanthracene) can be isolated in crystalline form.[681,682] Compounds of this type, which include $Pd_6Cl_{12}\cdot$(durene), $Pd_6Cl_{12}\cdot 1.5$(naphthalene), $Pd_6Cl_{12}\cdot 0.5C_{60}\cdot 1.5$(benzene), and $Pd_6Cl_{12}\cdot 0.5$(1,2:5,6-dibenzanthracene)$\cdot 0.5$(benzene), consist of individual molecules of Pd_6Cl_{12} and the flat aromatic molecules arranged in close, face-to-face proximity. These molecules are formed by simply mixing the appropriate hydrocarbon or fullerene (as a solution in benzene if it is not a liquid) with the labile complex, bis(benzonitrile)palladium(II) dichloride, and allowing the mixture to stand over a prolonged period. Eventually, deep red, air-stable crystals of the aggregates crystallize from solution. The Pd_6Cl_{12} cluster itself is soluble in aromatic solvents. Spectroscopic studies on solutions of Pd_6Cl_{12} in various methylated benzenes (i.e., mesitylene, xylene, and toluene) are consistent with charge-transfer interactions between the aromatic donors

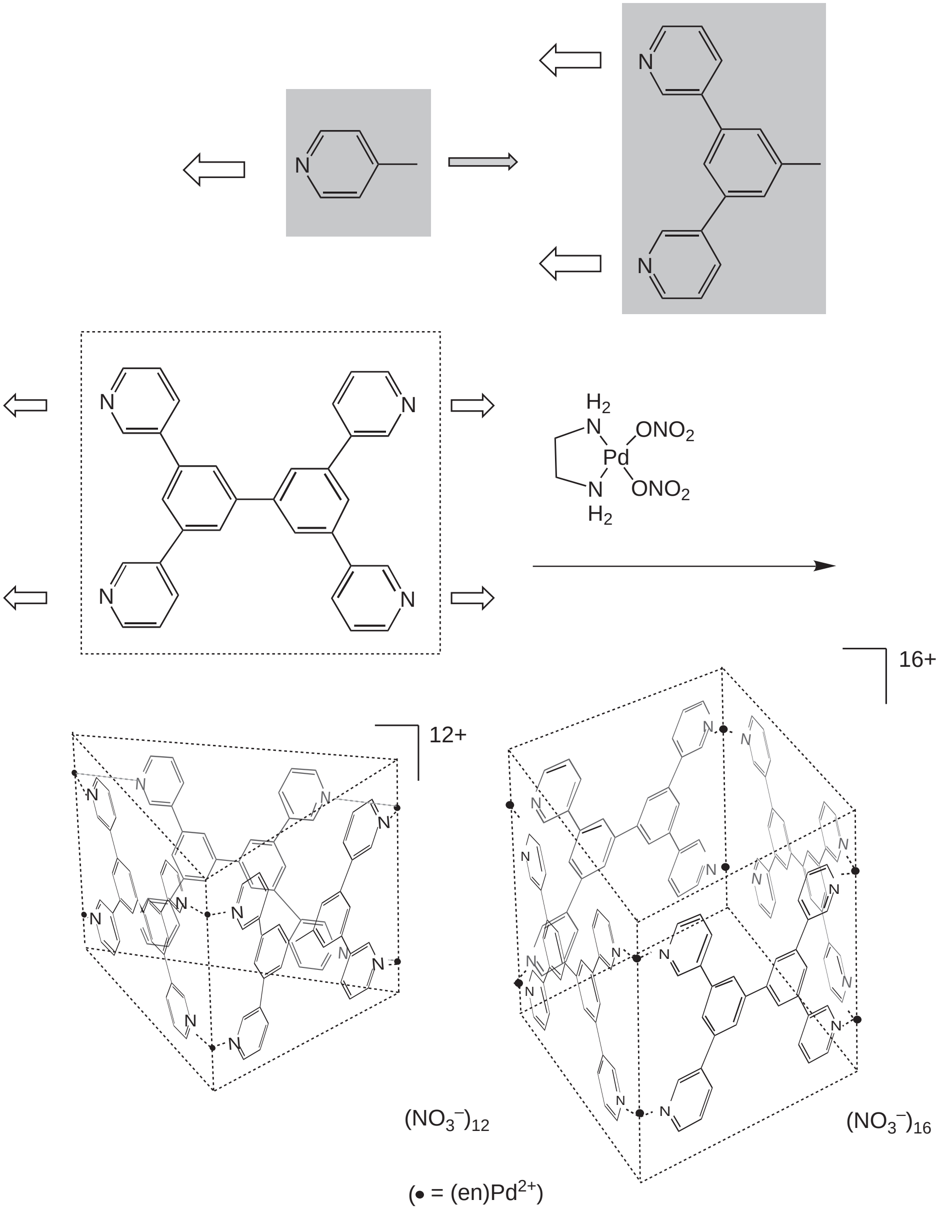

Figure 68 Self-assembly process of box structures.

and the palladium cluster. The new clusters Pd_6Br_{12} and Pd_6I_{12} are made from the corresponding bis(benzonitrile)palladium(II) dihalides. Additionally, two new compounds contain the Pd_6Cl_{12} cluster cocrystallized with its precursor, bis(benzonitrile)palladium(II) dichloride, and with a potential ligand, (*E*)-stilbene.[683]

A dynamic receptor library is an equilibrium mixture of several receptors from which the appropriate one is selected by an optimal guest. It is particularly important to study the dynamic features of guest–selected receptor formation from the library because the phenomenon is closely related to biological receptor systems. Shown in Figure 70 is the guest-controlled assembly of Pd^{II}-linked cage-like receptors from a dynamic library generated from a Pd^{II} complex and two different tridentate ligands. The library contains two classes of receptors: homoleptic and heteroleptic. The homoleptic receptor contains two identical ligands and, hence, is termed a "self-recognized" receptor while the heteroleptic receptor contains two different ligands and is termed "hetero-recognized." The equilibration between the receptors is very efficiently controlled by the addition of appropriate guests which selectively stabilize their optimal receptors.[684]

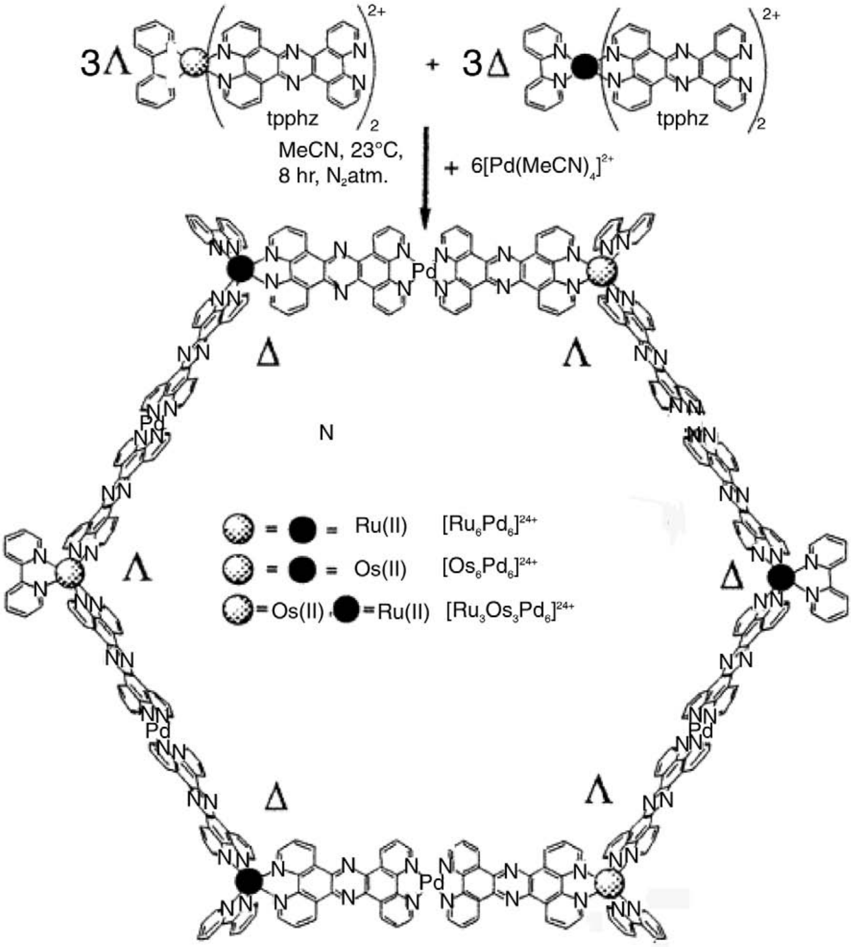

Figure 69 The molecular hexagons Ru_6Pd_6, Os_6Pd_6, and $Ru_3Os_3Pd_6$.

Triangular *exo*-polydentate ligands have been frequently employed for the metal-directed assembly of coordination polyhedra. By linking triangles at their corners or edges, a family of polyhedral structures can, in principle, be made. A triangular panel-like ligand was designed, with four donor sites on the two edges of the triangle (two donor sites on each edge); see the Figure 71. Having two-point binding sites on its two edges, this triangular unit is expected to assemble into edge-sharing polyhedral entity upon complexation with $(en)Pd(NO_3)_2$, which is a versatile 90° coordination unit for metal-directed assembly. Whereas previous triangular ligands all possess C_3 symmetry, this panel is C_2-symmetric and hence can be linked in two different ways: parallel and antiparallel links. Interestingly, these two options were perfectly controlled by the guests.[685] A new study showed that some large guests induce the parallel link of the triangles leading to open cone (tetragonal pyramidal) structure, whereas antiparallel link is selected by some small tetrahedral guests giving closed tetrahedron structure, see Figure 71. Both assemblies have the same M_8L_4 composition and, therefore, constitute a dynamic receptor library[646,657,658,664,686–692] from which each receptor is selected by its optimal guests.[693] The structure of the lower right complex was finally determined by an X-ray crystallographic analysis.

Several complexes were derived from $enPd^{II}$ and $enPt^{II}$ entities and the 2-hydroxypyrimidine ligand. By making use of a combination of 120° and 90° bond angles provided by the 2-hydroxypyrimidine ligand and enPd metal entities, respectively, the direct synthesis of metallacalix[4]arenes by a self-assembly process is possible. These compounds are analogous to classic organic calix[4]arenes in both their structure and conformational dynamics. Despite the positive charge of these metallacalix[4]arenes, interactions with positively charged species are possible. Multiple H-bonding interactions between metallacalix[4]arenes and guest molecules are the driving force in the molecular recognition process.[632]

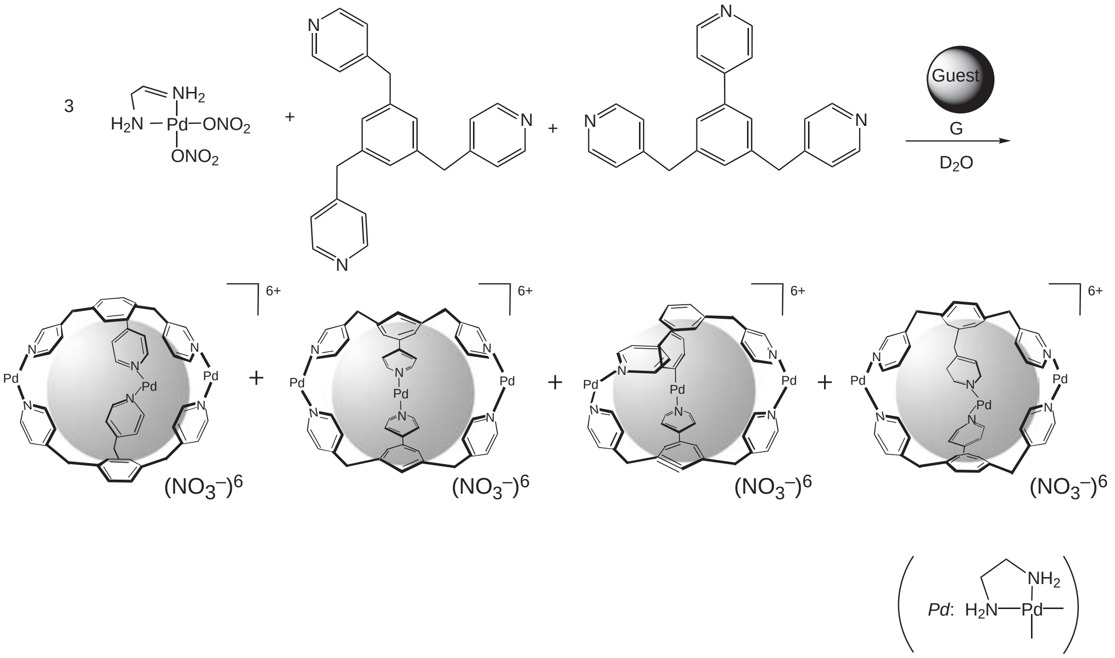

Figure 70 Guest-controlled assembly of Pd^{II}-linked cage-like receptors from a dynamic library generated from a Pd^{II} complex and two different tridentate ligands.

Cyclic frameworks of calixarenes associated with the presence of phenol oxygen atoms afford efficient complexing agents for metal ions, while their hydrophobic cavities allow the inclusion of guest molecules. Formation of analogous inorganic macrocycles, metallacalixarenes, can be achieved by combining 120° and 90° bond angles provided, respectively, by an appropriate ligand and a suitable metal entity.[632,672,694] Other angle combinations lead to molecular triangles,[576,643] squares,[652,695] and other structures of higher complexity.[696,697] Reaction of $[(en)Pd(H_2O)_2]^{2+}$ with 4,6-dimethyl-2-hydroxypyrimidine (Hdmpymo) generates the cyclic species $[(en)\text{-}Pd(dmpymo\text{-}N^1,N^3)\ ]_4^{4+}$, by a self-assembly process, shown in Figure 72.[698] The presence of four exocyclic oxygen atoms of the pyrimidine moieties, suggested the possible coordination of additional metal atoms. Lanthanide metal ions were thought to be ideally suited in terms of both size and oxygen affinity. Addition of an excess of $Gd(NO_3)_3{\cdot}6H_2O$ to an aqueous solution of the tetramer affords $\{Gd(NO_3)_2(H_2O)[(en)Pd(dmpymo)]_4\ \}^{5+}$ which has been structurally characterized and has been proved to be a metallacalix[4]arene of C_s symmetry, see Figure 73. The four Pd centers lie in a plane forming an almost perfect square with ca. 5.7 Å sides. The pyrimidine rings A, B and C, are not coplanar to the Pd_4 plane, which results in the formation of a molecular vase, see Figure 73.[699]

Self-assembly via dative bonding of bidentate nitrogen-containing ligands with transition metal complexes is a widely used methodology in supramolecular chemistry.[627,699,700] Such systems as helicates,[636] catenanes,[701] cylinders,[702] and other three-dimensional cage compounds[663] have been prepared. Much progress has been made in the design of molecules that can act as host molecules for organic guests,[663,703] and the physical basis of self-assembly macrocyclizations is the subject of current research.[704] Over the past few years, the synthesis of diverse molecular squares and rectangles has been reported,[663,705–709] but only a few publications show the design of parallelograms with other than 90° angles at the corners.[710–712] The synthesis of new silicon-containing pyridine-based linker units with tetrahedral angles of 109° may allow the self-assembly of hitherto unknown silicon-containing supramolecular parallelograms. The larger atomic size of silicon compared to carbon is especially important for the synthesis of cyclic compounds and possible host–guest chemistry within the cavities of these molecules. Cationic dinuclear rhomboids have been isolated via modular self-assembly of silicon- and carbon-based tectons with *cis* square-planar palladium bistriflate complexes. The versatility of the coordination paradigm was shown by the use of diverse angular linkers to form similar rhomboid-like systems.[713] Entropy plays an important role in the formation of these macrocyclic systems, favoring the formation of the smallest cycle even though the hydration is thermodynamically disfavored. X-ray crystal structure analysis showed planar rhomboids with small internal cavities of approximately 10 Å × 8 Å.[713]

Biological receptors modulate the shape and size of their recognition sites to bind substrate molecules, generating numerous receptor structures from which the most suitable one is selected (or induced-fit) by their substrates. Modeling such a system is particularly important to develop a new receptor design wherein artificial receptors are constructed through a selection process by their own guests. In Figure 74 Pd^{II}-linked cages, and some oligomeric compounds[658] accessible from the same components are in equilibrium. From this thermodynamic mixture, each cage structure is selected upon the addition of appropriate guest molecules. The phenomenon described herein is a prototype for a "dynamic receptor library," which represents one of the important goals in the field of molecular recognition.[658] An asymmetric cage complex was selectively formed from a mixture of oligomeric compounds upon the addition of 1,3,5-benzenetricarboxylic acid.

The selective formation of a symmetrical host was induced by the addition of spherical guests such as $CBrCl_3$ and CBr_4. Molecular modeling, refined by Cerius program, explains the origin of the selectivity in the formation of the two hosts shown in Figure 75. The host frameworks should be organized so that maximum hydrophobic interaction can be gained. Therefore, flat guests select the asymmetric host, whereas spherical guests prefer the symmetric host.[658]

Supermolecules consisting of interlinked ring-like molecules (catenanes)[714] are an interesting target for chemical synthesis both for their intrinsic interest as noncovalently bound but robust assemblies and because of the perspective they offer on materials chemistry.[715] Catenanes have been prepared by metal-ion templating[716,717] and self-assembly through other noncovalent interactions. Fujita *et al.* report the synthesis of a catenane composed not of two interlocking rings but of two cages.[665] This structure is prepared by metal-mediated self-assembly.[662,665,718] The

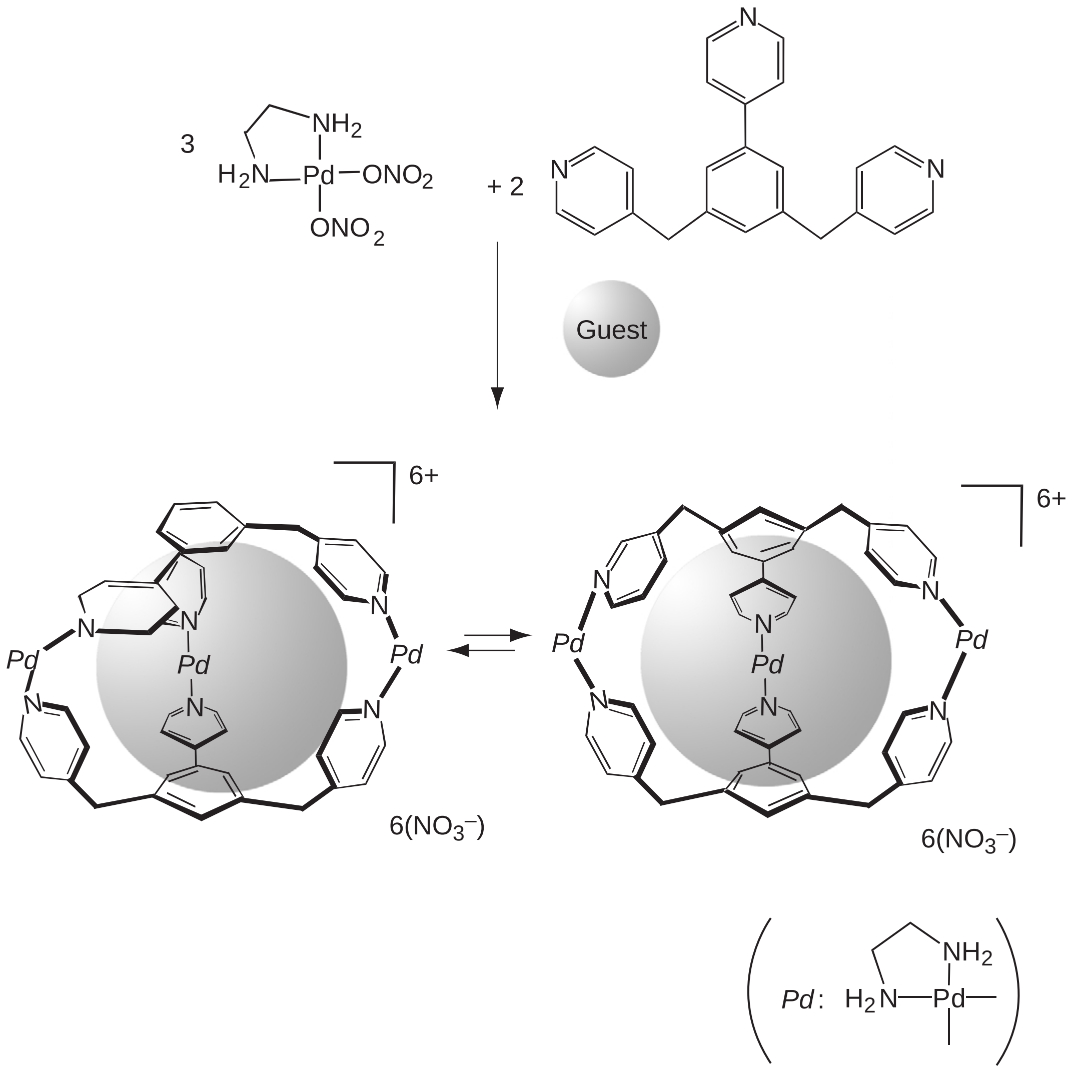

Figure 74 Pd^{II}-linked cages and some oligomeric compounds accessible from the same components are in equilibrium.

framework of each cage is assembled from five components: two tridentate ligands held together with three metal ions (see Figure 76). A cage-like complex is designed, in which the interplanar surface-to-surface distance between the "floor" and the "ceiling" is ~3.5 Å, an ideal distance for binding an aromatic ring. Because each cage framework can bind an aromatic ring, two cage units

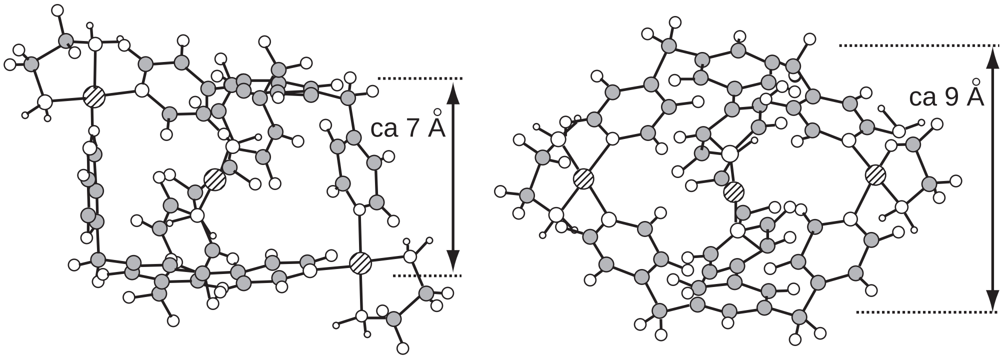

Figure 75 Selectivity in the formation of the two hosts. Flat guests select the asymmetric host, whereas spherical guests prefer the symmetric host.

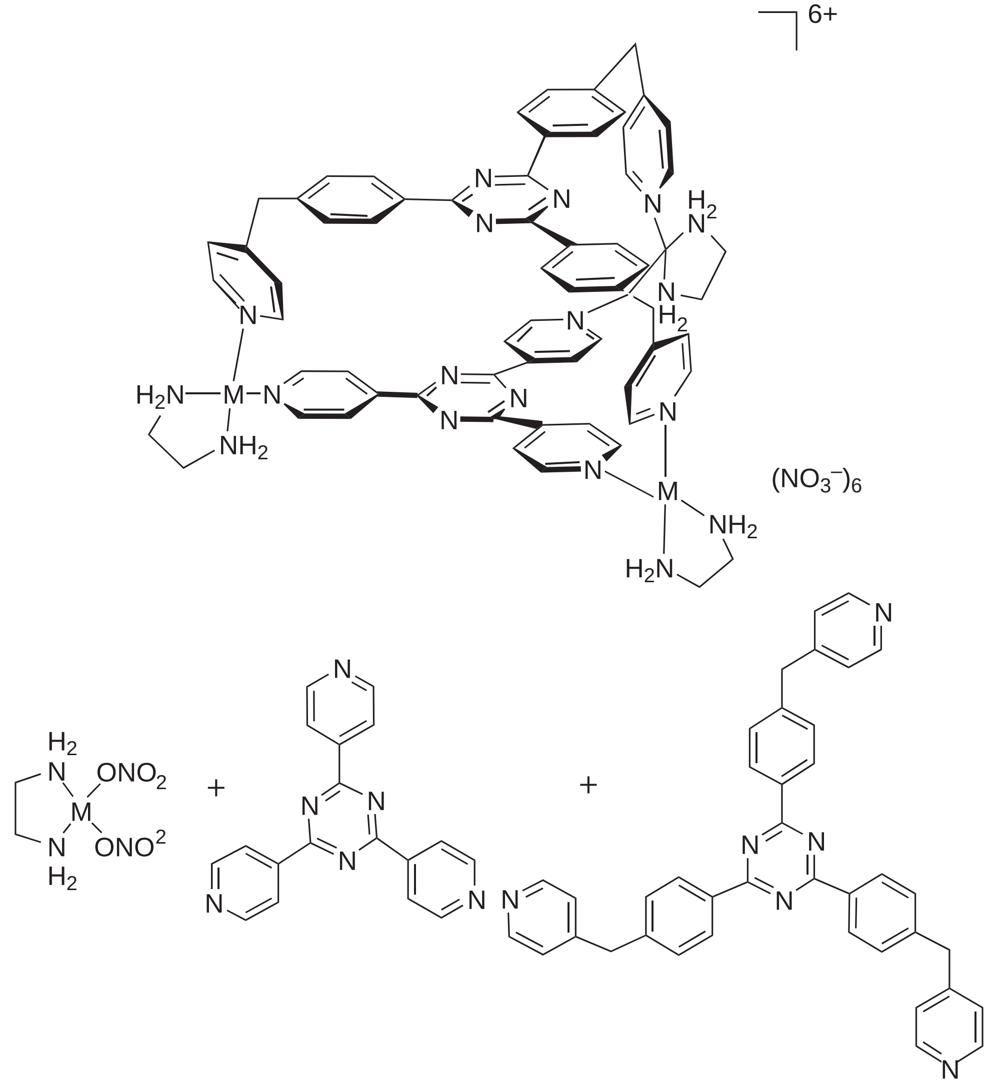

Figure 76 Framework of each cage is assembled from five components: two tridentate ligands held together with three metal ions.

will bind one another during their assembly process through the formation of a quadruple aromatic stack, giving rise to the ten-component interlocked supermolecule (see Figure 77).[665]

Rectangular molecular boxes with interplanar separation of ~3.5 Å were shown to effectively self-assemble into catenated dimers.[719] X-ray crystallographic analysis shows that the catenane consists of two identical cage frameworks interlocking with each other. From the side view the efficient quadruple stacking of aromatic rings is observed. This stacking makes the interlocked structure the most stable of any possible structures.[665] The interlocked cages are further stacked in an intermolecular fashion, leading to one-dimensional infinite stacking of triazine π-systems. The structure of the catenane in solution was determined by NMR studies. Both ^{1}H and ^{13}C NMR agree well with the structure.[665] A striking observation is that two preformed Pd^{II} cage compounds are reorganized into the three-dimensionally interlocked catenane in high yield when they are mixed in an aqueous solution (see Figure 78). The 12+ cage M_6L_4 type is a very stable cage compound which assembles from ten components. The 6+ cage is also found to assemble from five components. These cage compounds were independently prepared in D_2O and then combined in 1:2 ratio so that the component ratio became 6:2:2. After the solution was allowed to stand at room temperature, all components were completely reorganized into an interlocked-cage catenane compound. At an elevated temperature (80 °C), the reorganization was completed within 10 minutes.[665]

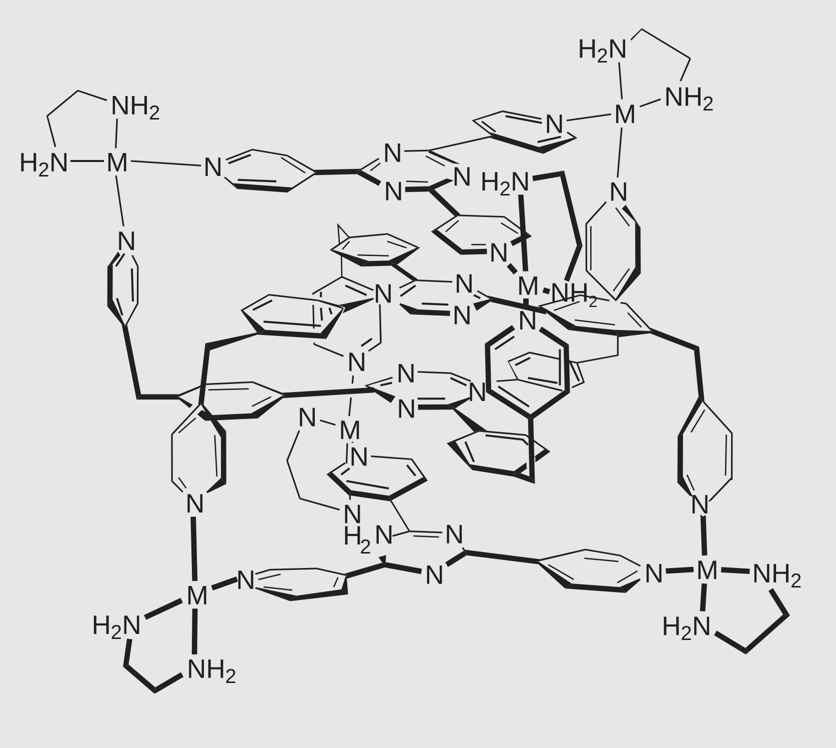

Figure 77 A ten-component interlocked supermolecule.

Molecular capsules consist of closed, hollow frameworks within which encapsulated molecules are isolated from interaction with external molecules. In this environment, otherwise reactive molecules can be stabilized. An *exo*-hexadentate ligand, 1,3,5-tris(3,5-pyrimidyl)benzene, is used as a triangular assembly unit. This ligand is an almost planar triangle and is expected to give edge-sharing polyhedra when its aromatic nitrogens are ligated at the *cis*-coordination site of a metal ion. A *cis*-protected palladium(II), $Pd(NO_3)_2(en)$, provides a 90° coordination angle, and has been shown to be useful for constructing well-defined discrete structures on complexation with a variety of *exo*-polydentate ligands.[13,652,720] Because the angles between the planes of tetra-, hexa-, and octahedra do not significantly deviate from 90°, the assembly of such a polyhedron was achieved on complexation of this ligand with Pd^{II} unit (see Figure 79).[630] Of the several possibilities, the assembly of a molecular hexahedron trigonal bipyramidal actually occurred.[630] The by-product formation was completely suppressed by employing a small excess amount of $Pd(NO_3)_2(en)$. The crystal structure shown in Figure 80 clearly demonstrates that the assembly is a trigonal bipyramidal coordination capsule with the chemical formula $C_{144}H_{216}N_{108}Pd_{18}$, a molecular mass of 7,103 Da, and a dimension of $3 \times 2.5 \times 2.5$ nm.[630] Each equatorial corner of the hexahedron is made up by the assembly of four triangle units, where a $(Pd^{II}\text{-pym})_4$ cyclic framework gives a small "pinhole" (2×2 Å). Through these holes, only small molecules such as water and molecular oxygen may pass, but ordinary organic molecules cannot enter or escape. Not even such a "pinhole" exists at the apical corners. The free volume inside the capsule, into which guests can be accommodated, is $\sim$900 Å^3, implying that the complex can host large molecules such as buckminsterfullerene, C_{60}.[630] The thermodynamic stability is explained by a strong positive cooperative effect of 36 Pd^{II}–pym coordination bonds involved in the framework. The metal-linked dimer and trimer (see Figure 81) may be involved as intermediates in the assembly process, because these species were observed when the triangular ligand was titrated with Pd^{II} complex.

These results complement Fujita's previous synthesis of a corner-sharing octahedron assembling from an *exo*-tridentate ligand, 1,3,5-tris(4-pyridyl)triazine, and the same Pd^{II} complex.[720,721] The framework of this octahedron complex has large windows and encloses large guest molecules (for example, as many as four carborane molecules) which can enter or exit through the openings. In contrast, the edge-sharing hexahedron complex has a closed shell structure, and it should be able to encage large molecules.[630]

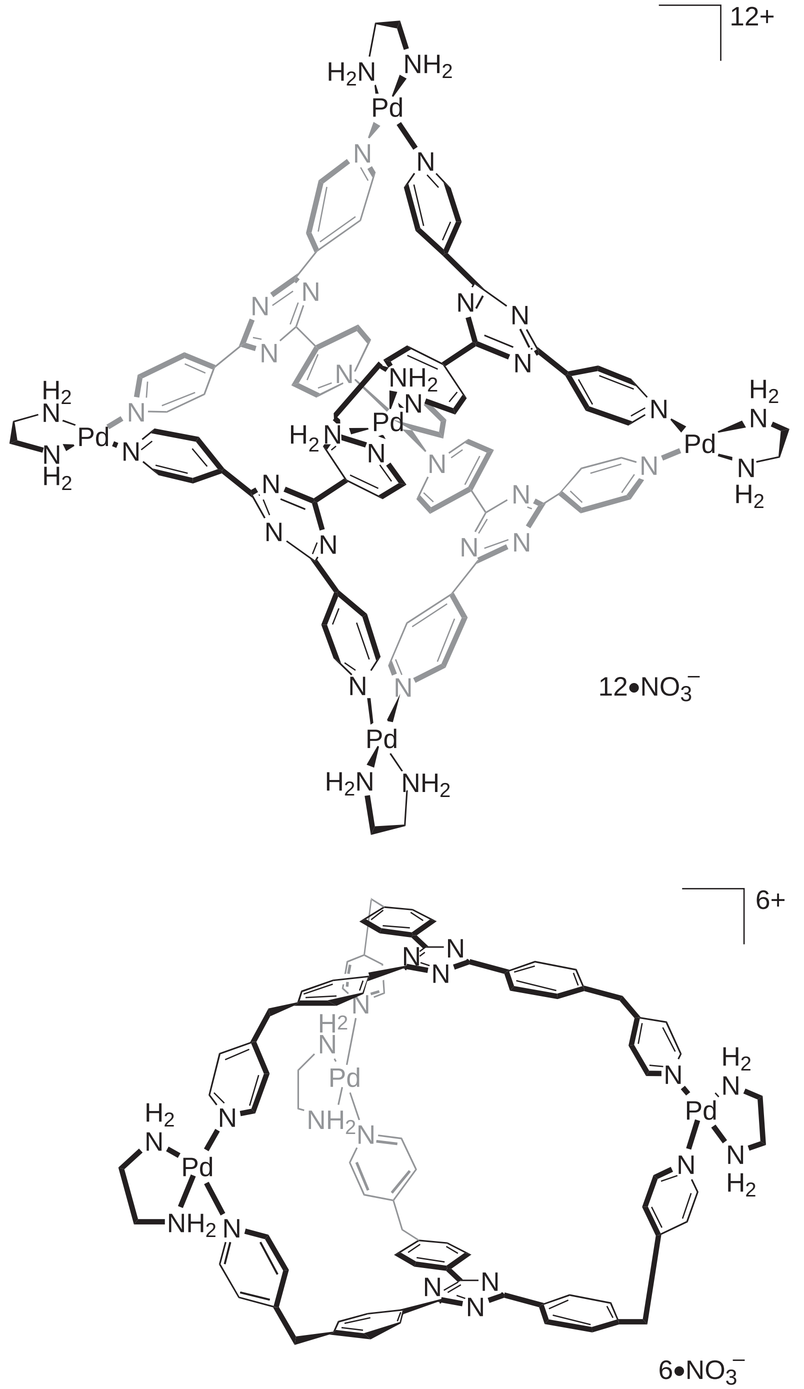

Figure 78 Two preformed Pd^{II} cage compounds that are reorganized into the three-dimensionally interlocked catenane in high yield when they are mixed in an aqueous solution.

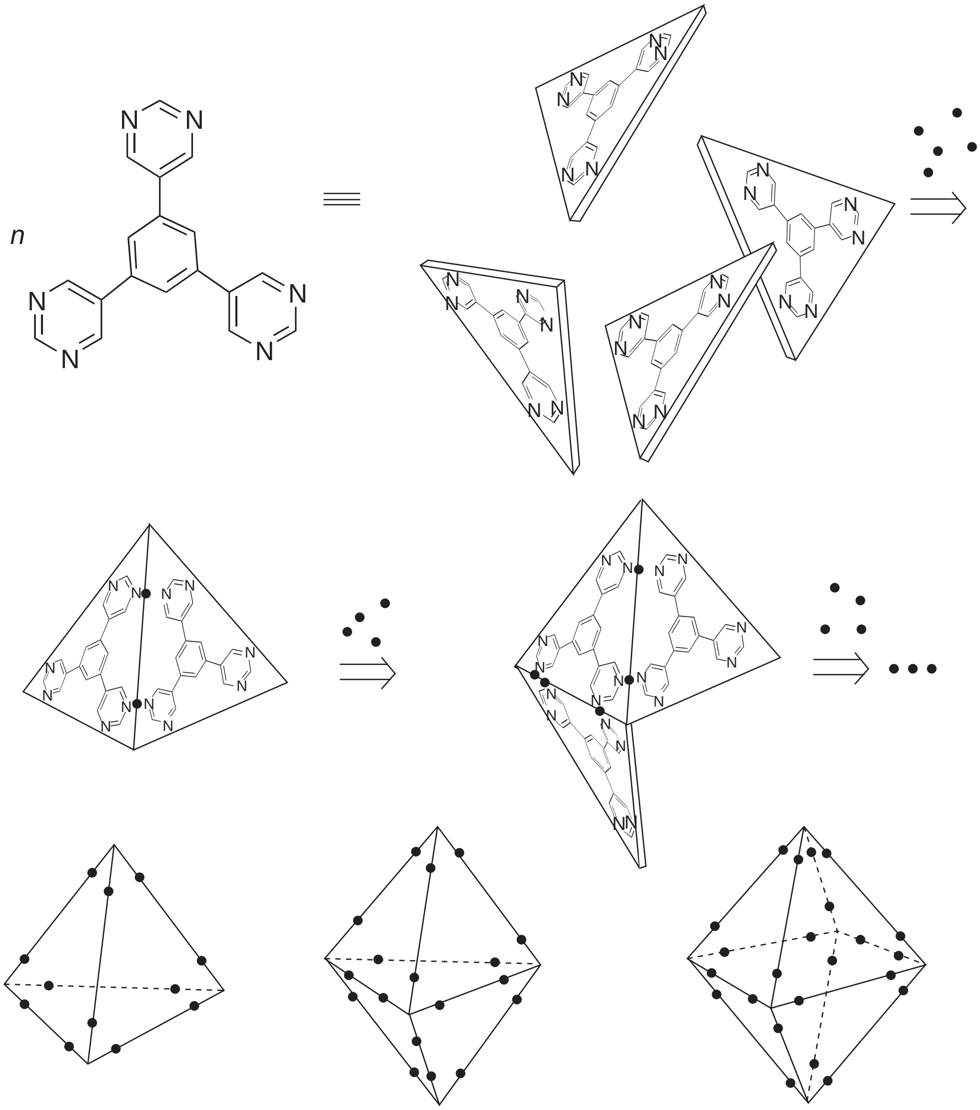
Various molecular devices based on oligoporphyrins have recently been engineered and prepared. The porphyrin oligomers have been synthesized by either covalent attachment of the monomers or methods of self-assembly. Porphyrin arrays consisting of up to nine units have been reported.[722] Preparation of the porphyrin arrays in high yields and significant quantities is still problematic. One of the major obstacles for synthesizing porphyrin derivatives is low solubility.[723] Macrocyclic assemblies, containing two or four porphyrin units, are readily obtained on a preparative scale via self-assembly with use of Pd^{II}- or Pt^{II}-containing auxiliary modules. The bisphosphine ligands coordinated to transition metals provide an enhanced solubility of



tetrahedron hexahedron octahedron

Figure 79 Assembly of a polyhedron achieved by complexation of 1,3,5-tris(3,5-pyrimidyl)benzene with $Pd(en)^{2+}$ groups.

macrocycles. The porphyrin cores are not coplanar when used as parts of the linear modules in the tetramers.[723] Chiral macrocycles are formed upon employment of the BINAP—Pd^{II} angular building block. The chiral tetramers have a puckered structure of D_2 symmetry at ambient temperature.[723] The high solubility and ease of synthesis of self-assembled porphyrin macrocycles, based on Pt^{II} and Pd^{II} phosphine bistriflates, provides tetramers that are excellent ensembles for the study of porphyrin exciton coupling interactions and induced circular dichroism.[723]

Rapid progress in molecular enclathration chemistry has been partly the result of the development of the facile preparation of cage compounds by noncovalent synthesis exploiting hydrogen and coordination bonds.[724–730] Transition metal-mediated self-assembly[720] has recently allowed the highly effective construction of hollow, nanosized coordination cage (shown in Figure 82), which enclathrates large neutral guest molecules at a fixed position of the cavity in a 1:4 host-guest ratio.[721] Fujita *et al.* report the remarkable ability of the cage for the selective enclathration of "C-shaped" molecules such as *cis*-azobenzene and *cis*-stilbene derivatives. These guest molecules are enclathrated in the cavity through the "ship-in-a-bottle" formation of a hydrophobic dimer of the guest, (see Figure 83). The hydrophobic dimer of azobenzene derivative is considerably stabilized and does not undergo *cis–trans* isomerization.[731]

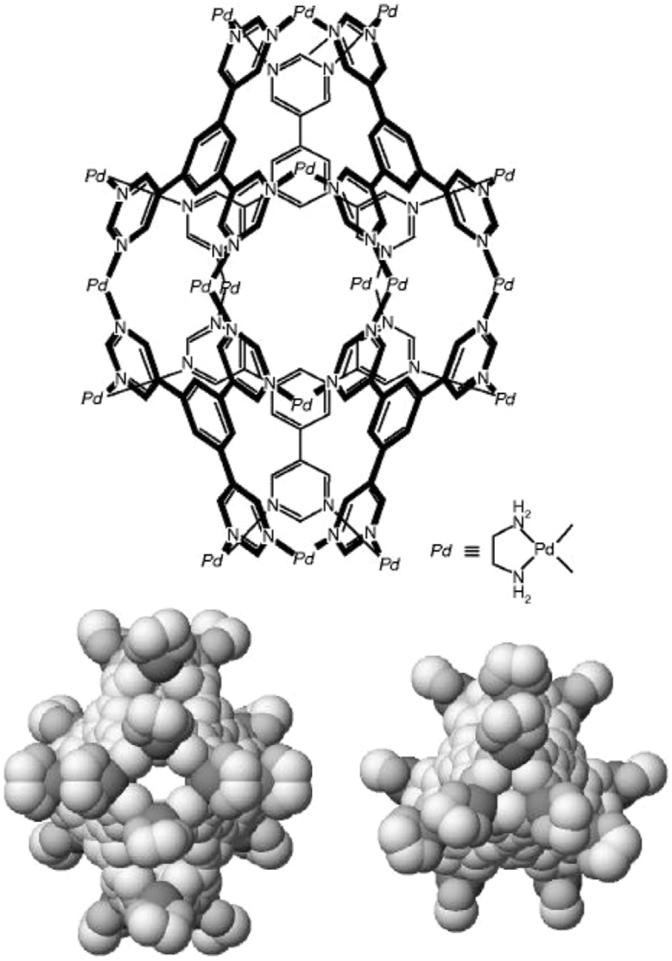


Figure 80 Trigonal bipyramidal coordination capsule with a chemical formula of $C_{144}H_{216}N_{108}Pd_{18}$, a molecular mass of 7,103 Da, and a dimension of 3 × 2.5 × 2.5 nm.

Transition-metal-mediated self-assembly and metal–ligand interactions are becoming increasingly popular in the construction of a variety of nanoscale-sized entities. The basic appeal of this method is in its highly convergent synthetic protocol, the fast and facile formation of the final product, as such metal–donor ligand interactions are established very rapidly, and most importantly, the great versatility of this method, as a large number of nanostructures can be prepared via the combination of a relatively small number of building blocks.[718,732] Among these assemblies, chiral structures (shown in Figure 84) occupy an important place, as they are the first examples of transition-metal-based discrete supramolecular assemblies with controlled stereochemistry. A first step in their study is the careful determination of rotational barriers and a detailed study of the fluxional behavior of various heteroaryl complexes of Pd^{II} and Pt^{II} bis(phosphanes), as they are directly responsible for the existence of different rotational isomers in these chiral assemblies.[733]

The interaction between chelated Pd^{II} triflates with various heteroaryl complexes results in the formation of diastereomeric, square-planar, cationic complexes. For reaction with $[Pd(R\text{-}(+)\text{-}BINAP)][OTf]_2$ (BINAP = 2,2′-Bis(Diphenylphosphino-)-1,1′-Binapthyl) and 2-bromo-5-methylpyridine the formation of a diastereoisomeric mixture of three rotamers and a complex with a single heteroaryl group is observed. Reaction of 3-methylisoquinoline with the above bis(triflates) also yielded similar results, whereas in the case of the more sterically demanding 2-methylquinoline, the mono(heteroaryl) complexes $[Pd(R\text{-}(+)\text{-}BINAP)(2\text{-}methylquinoline)][OTf]_2$ are observed exclusively. Steric effects of the substituents located in close proximity to the transition metal are responsible for such remarkable control of the stoichiometry of the products.[733] The restricted rotation about the metal–nitrogen heteroaryl bond in the complex $[Pd(R\text{-}(+)\text{-}BINAP)(3\text{-}picoline)_2][OTf]_2$ was investigated by temperature-dependent ^{1}H-NMR spectroscopy. The free energy of

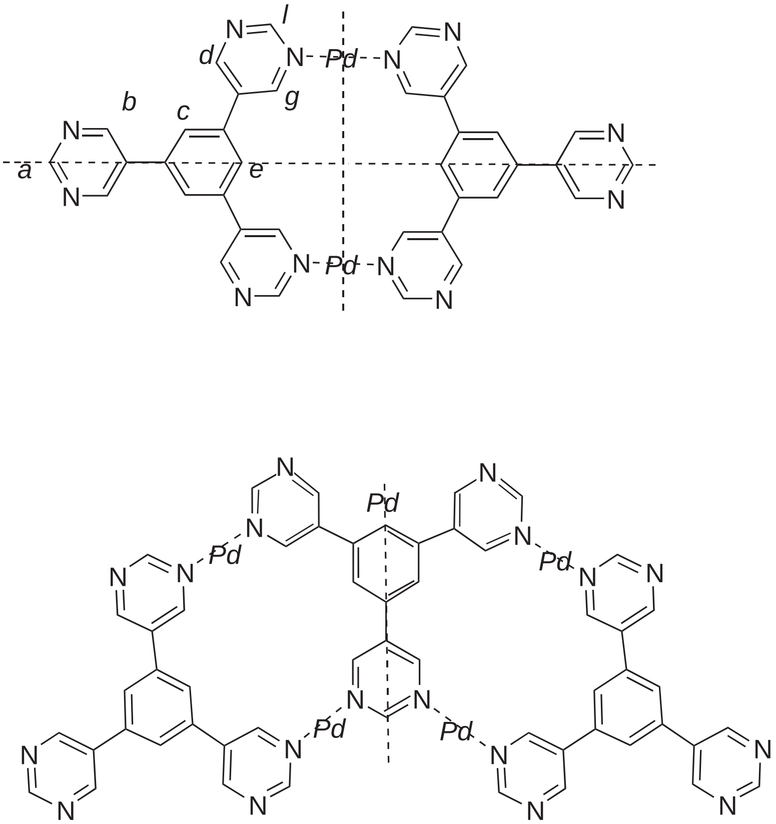

Figure 81 Metal-linked dimer and trimer.

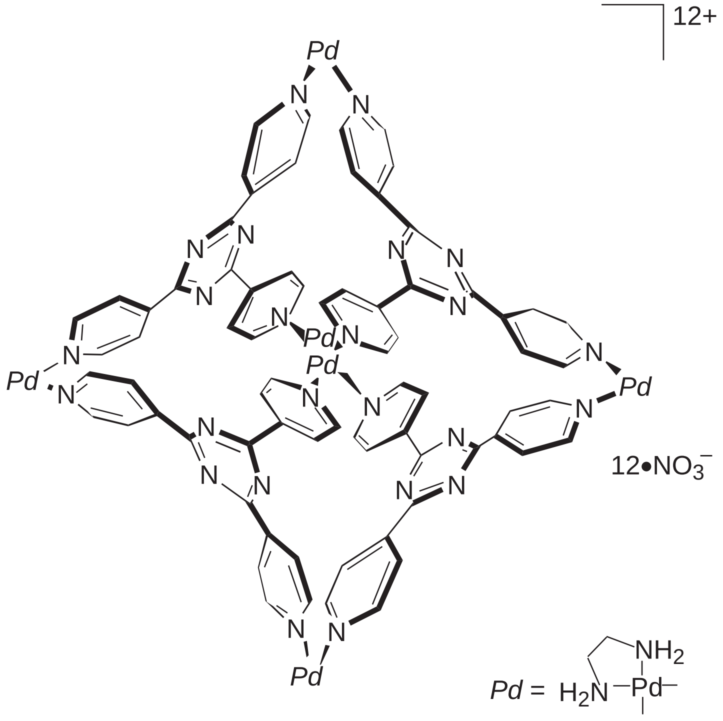

Figure 82 A hollow, nanosized coordination cage.

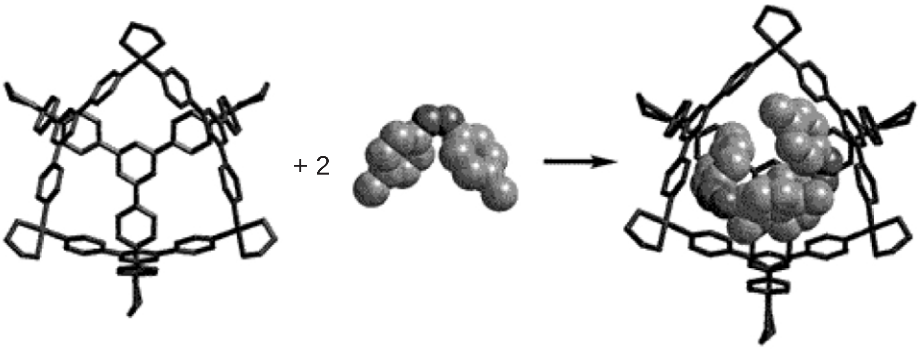

Figure 83 Guest molecules are enclathrated in the cavity through the "ship-in-a-bottle" formation of a hydrophobic dimer of the guest.

activation $\Delta G^{\ddagger}$ is $12 \pm 0.5\,\mathrm{kcal\,mol^{-1}}$ for the Pd complex.[733] *Ab initio* calculations (HF/lanl2dz) of model complex $[\mathrm{dpe}]\mathrm{Pd(HN{=}CH_2)_2}^{2+}$ (dpe = diphosphinoethylene) support the interpretation of experimental results.[733] The rotation of the heteroaryl ligand is hindered, therefore making these assemblies stable to interconversion even at elevated temperatures. Since these assemblies are formed in near-quantitative yield, probably there are some additional factors that influence the formation and high thermodynamic stability of these macrocycles besides their conformational rigidity and the lability of the metal-heteroaryl bond. There are indirect indications that the degree of π-stacking between the phenyl ring of the bis(phosphane) (BINAP) and the coordinated heteroaryl plays an important role in the stabilization of these assemblies.[733]

Although single-, double- and triple-stranded helicates have been well documented,[734–737] quadruply stranded helicates are rare. One type are pentanuclear metal complexes bridged by a pentadentate ligand.[738] These species contain metal–metal bonds with terminal ancillary ligands on octahedral metal centers and, as such, can be classified as unsaturated helicates.[734] It was predicted[734] that the synthesis of a saturated quadruply stranded helicate might be achieved by employing a combination of square-planar metal centers with oligomonodentate bridging ligands. There is a report on the successful realization of this challenge, with the synthesis and X-ray crystal structure of a quadruply stranded helicate that encapsulates a hexafluorophosphate anion.[636] Its synthesis is shown in Figure 85. The dimeric complexes contain $\mathrm{PPh_3}$ or pyridine as ligand. Diffusion of diethylether into an acetonitrile solution of the pyridine complex containing ammonium hexafluorophosphate resulted in a reorganization of the components and the assembly of a helicate species, which deposited from the solution as a tetrakis(hexafluorophosphate) salt and as a bis(acetonitrile) solvate. The compound contains a full $\mathrm{M_2L_4}$ helical cage that has each square-planar palladium atom coordinated to the four bridging ligands and within which resides a well-ordered $\mathrm{PF_6}^-$ ion (see Figure 86). External to the cage are three other $\mathrm{PF_6}^-$ anions and two acetonitrile solvate molecules. The dimensions of the cage are defined by the Pd···Pd separation (8.8402(8) Å) and the distance between the centroids of the cofacial benzene rings (8.849(7) Å and 8.925(7) Å).[636]

A remarkable feature of the stucture is the encapsulation of the hexafluorophosphate anion. In contrast to the many molecular hosts capable of recognizing and complexing cationic guests, the search for similar species capable of complexing anionic guests has proved considerably more difficult. Although $\mathrm{PF_6}^-$ ions normally act as noncoordinating anions, the encapsulated anion within cage makes weak contacts with the palladium centers (Pd1—F11 = 2.789(5) Å; Pd2—F12 = 2.911(5) Å). This structure is maintained in solution.[636]

A coordination cage, shown in Figure 87, with a diameter of approximately 2 nm was constructed through transition metal mediated self-assembly from six metal ions and four ligands.[720,739,740] The remarkable ability of this complex to encapsulate large, neutral molecules was explored.[721] It encapsulated four molecules of *o*-carborane, an icosahedral carbon–boron cage molecule with a diameter of 8 Å. This large, neutral molecule is nonpolar and immiscible with water. However, when a hexane solution of it was stirred with a $\mathrm{D_2O}$ solution of the cage, four equivalents were rapidly transferred into the aqueous phase and the stoichiometric formation of the complex was observed. Adamantane was also encapsulated by the cage to form a 1:4 complex.[721] The cage and the two guests are shown in Figure 87. When 1- or 2-adamantanol was employed as a guest, the formation of a stable 1:4 complex was again observed. The interior of the host is highly hydrophobic and the guest molecule is located in the cage such that the hydroxyl group is pointed outward. Significant

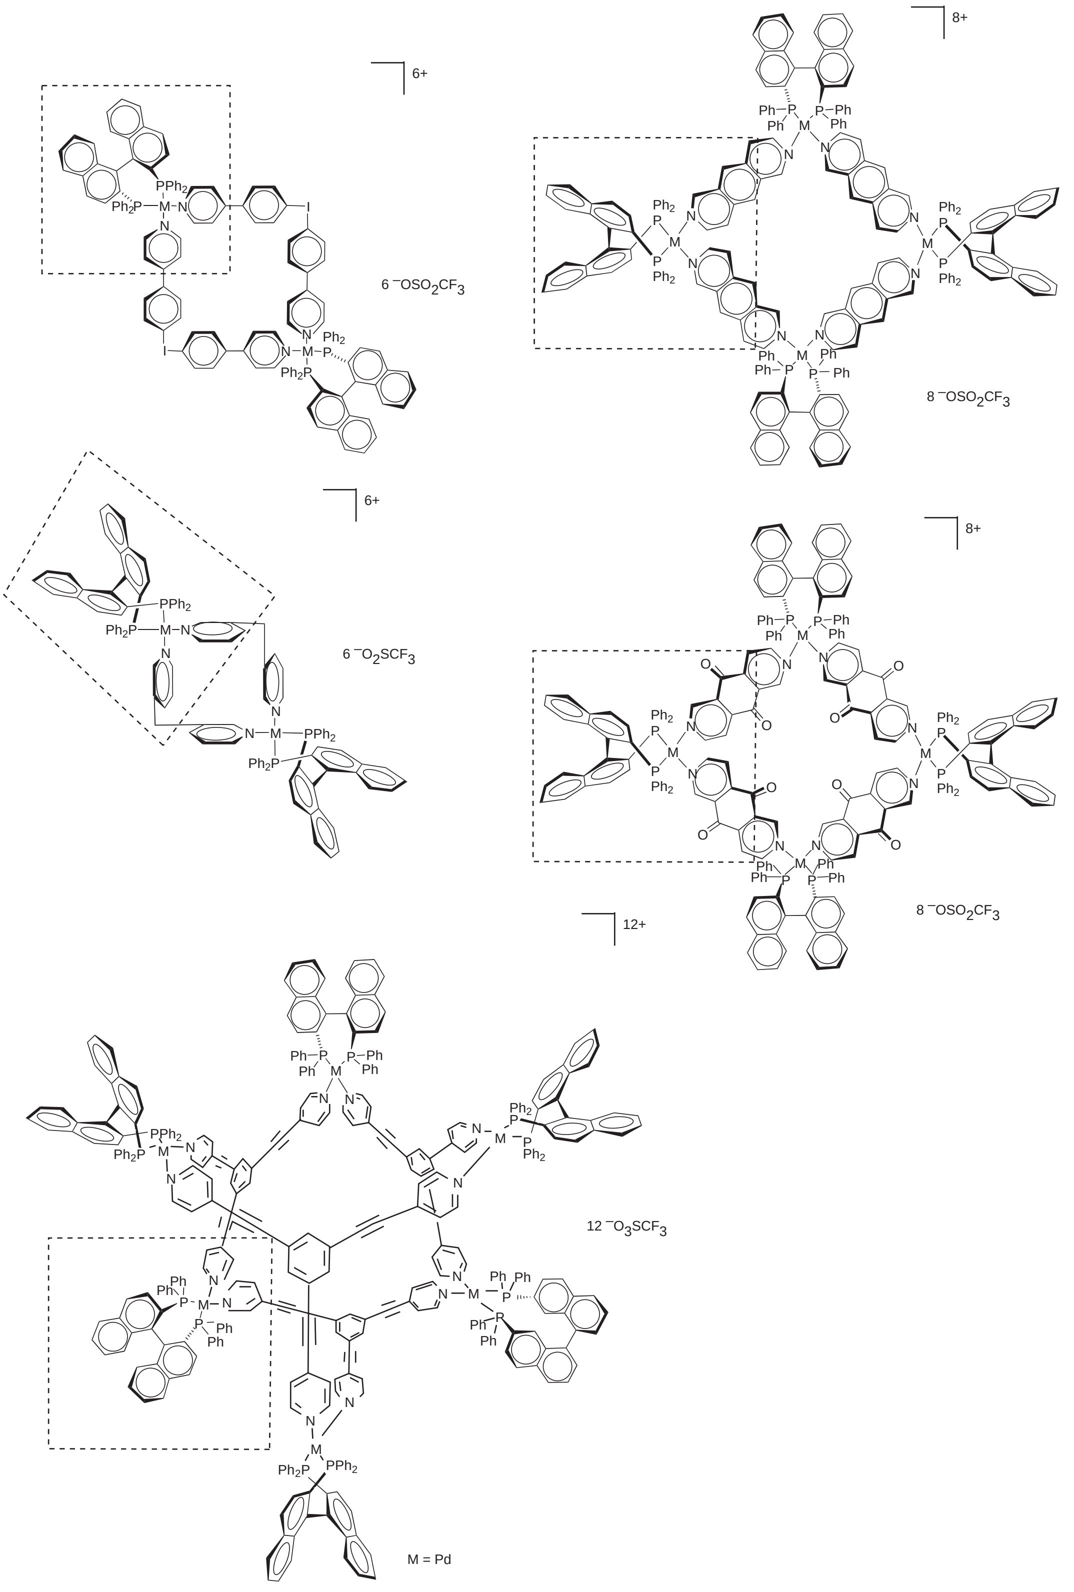

Figure 84 Chiral structures—the first examples of transition-metal-based discrete supramolecular assemblies with controlled stereochemistry.

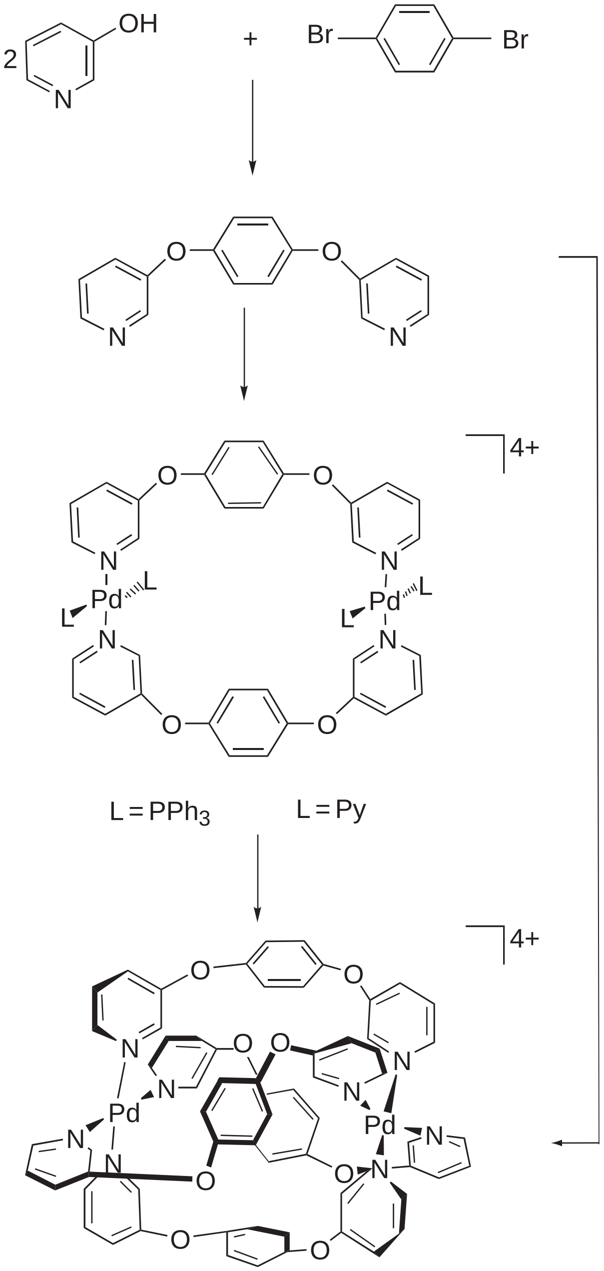

Figure 85 A quadruply stranded helicate that can encapsulate a hexafluorophosphate anion.

π-donor–acceptor interactions were observed when 1,3,5-trimethoxybenzene was employed as a guest.[721] The complexation is much faster when the guest molecules are smaller. Tri-*t*-butylbenzene, which is slightly larger than the portal of the cage, is very slowly encapsulated by the cage through thermally induced slippage at 80 °C. Once encapsulated, this oversized guest did not escape from the cavity within two hours at room temperature even when the solution was treated with an organic solvent.[721]

Organic and organometallic polynitriles are polytopic organic ligands for the self-assembly of coordination polymers and supramolecular metal complexes. Transition metal complexes of arylisocyanides bearing nitrile groups in peripheral locations can be employed in a similar fashion.[741] The solid formed from *trans*-diiodobis(4-isocyanobenzonitrile)palladium and two equivalents of bis(hexafluoroacetylacetonate)copper, was found to possess a one-dimensional structure, which can be described as a string of 20-membered rings, each consisting of two I–Pd–CN–C_6H_4–CN subunits that are joined by copper bridges, whereby the palladium atoms are

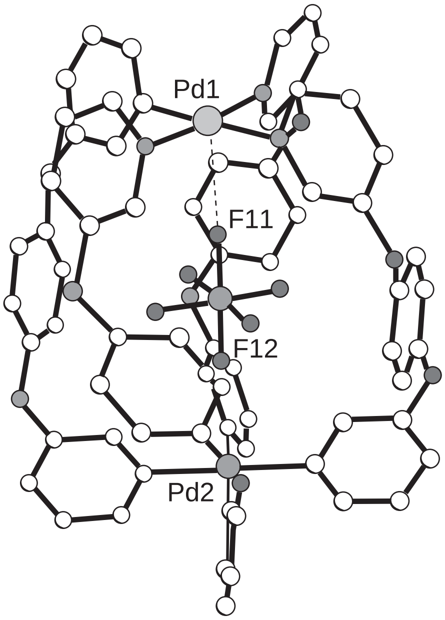

Figure 86 Compound containing a full M_2L_4 helical cage that has each square-planar palladium atom coordinated to the four bridging ligands and within which resides a well-ordered PF_6^- ion.

shared by adjacent rings. As a consequence of the linear nature of the Pd–CN–C_6H_4–CN– portion within the rings, the copper-nitrile linkages are strongly bent.[742] The analogous solid, formed from *trans*-diiodobis(3-isocyanobenzonitrile)palladium and bis(hexafluoroacetylacetonate)copper, contains the same type of rings but with linear copper–nitrile linkages. The observation of end-on- and side-on-bonded nitrile ligands in the two isomeric coordination polymers suggests that metal–nitrile bonds may not generally be relied upon as rigid structural links in coordination polymers.[742]

In the synthesis of discrete ordered arrays of covalently linked porphyrins, there now seems to be a practical limit of about 10 macrocycles. To create ever larger arrays in reasonable yields, a supramolecular approach has been employed to design a variety of discrete porphyrin arrays. The largest designed discrete assemblies containing six or more components have been squares made up of four porphyrins assembled by four transition metal ions,[743–746] and a rosette containing six porphyrins assembled by hydrogen bonding. A discrete supramolecular array of nine porphyrins has been made. Self-assembly is accomplished by coordination of exocyclic pyridyl groups on three different porphyrin derivatives to 12 palladium(II) dichloride units: Four different types of molecules self-assemble to a 21-membered array that is 25 nm^2 large.[722] These types of systems are expected to: further our understanding of photonic communication between chromophores mediated by noncovalent interactions; serve as guides for the formation of molecular channels or receptors; and be a foundation for the development of molecular photonic materials for use in nonlinear optics. The well-characterized photophysical behavior of these macrocycles provides a tool for the examination of the kinetics, mechanism, and thermodynamics of self-assembly. The nonameric arrays were designed by appropriate choice of *trans* coordination by the relatively labile square planar bis(benzonitrile)palladium(II) dichloride, the correct stoichiometries of the components, and the correct substitution patterns of three different porphyrins: one central X-shaped unit, four T-shaped units on the sides, and four L-shaped units in the corners (see Figure 88). The "molecular information" inherent in the individual molecules and the stoichiometry (12Pd, 1″X″, 4″L″, and 4″T″) favors the formation of the desired arrays, but the reversibility of pyridyl – palladium bond formation is also crucial for reaching what appears to be the thermodynamic product. Thus, the desired arrays are formed in approximately 90% yield at room temperature in less than 30 minutes.[722] There are three different porphyrins, so any combination of free base and metallo compounds may be used to make the supramolecular arrays. This results in arrays with metallo derivatives in predictable positions. Only the all-free base or all-zinc complexes are presented to avoid the kinetic and spectroscopic complications that arise from axial coordination by the pyridyl groups to other metalloporphyrins (homocoordination).[722]

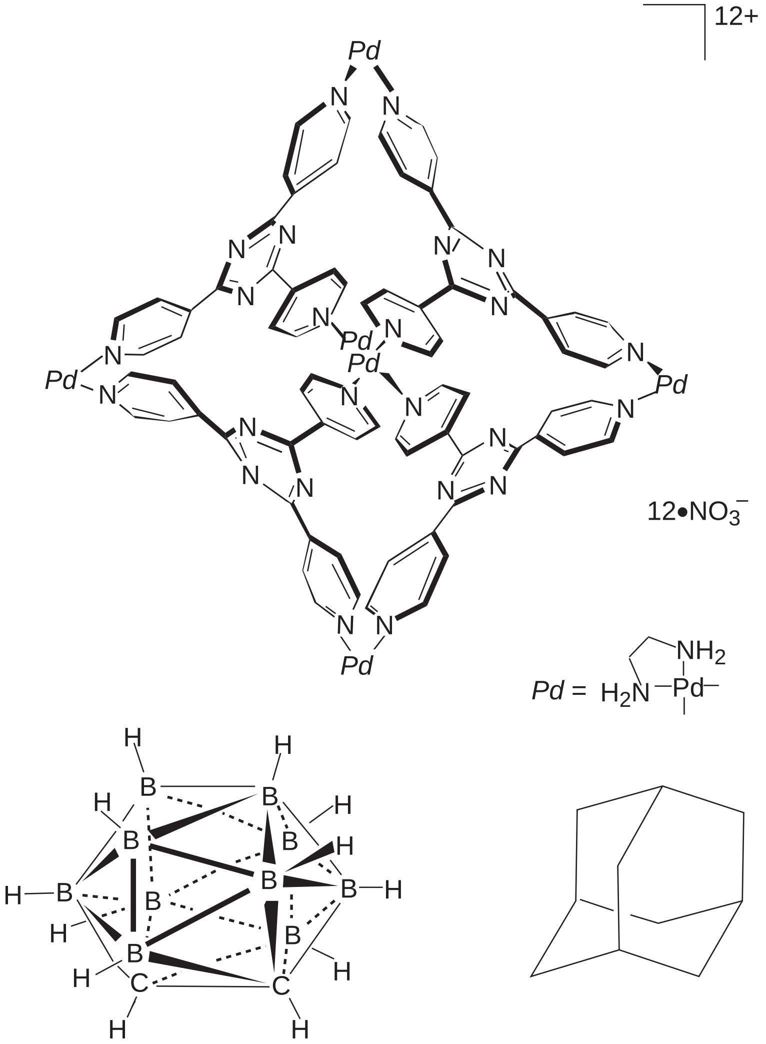

Figure 87 A host cage, constructed through transition metal mediated self-assembly from six metal ions and four ligands, and two guests.

Porphyrin tapes (see Figure 89) are made in a manner similar to that of the nonamers. For example, addition of two porphyrins (“O”) to two “I”-shaped porphyrins and two equivalents of [$PdCl_2(NCPh)_2$] results in the palladium-based tape as a mixture of the dimer, the trimer, and the tetramer in a ratio of about 3:8:2.[722] The substantial broadening, concomitant decrease in intensity, and red shift of the Soret band are typical for electronically coupled porphyrins. It is observed to a lesser extent for the Pd-mediated dimer and tetramer arrays and other squares.[743–746] There is a consistent red shift of about 2 nm (and broadening) per porphyrin. The excited state lifetime for a mixture of porphyrins in toluene at room temperature is 12 ns, and that of the array is less than 1 ns.[722] The substantial additional quenching for the arrays is likely due to energy transfer from one porphyrin moiety to another, and to some π stacking of the nonamers.[722] The ^{1}H-NMR titrations exhibit similar trends as those observed for other porphyrin squares,[743–746] namely, there is a highly characteristic shift in the pyridyl protons upon coordination of a metal ion.[722] Light-scattering results suggest that clusters with a radius of 5–7 nm are present in solution. Depending on solution conditions, deposition of nonameric arrays on polished glass substrates results in the formation of nanoparticle clusters. Characterization of the three-dimensional arrangement of these clusters by atomic force microscopy (AFM), shown in Figure 90, suggests that the nonameric arrays deposit as columnar structures on the glass surface, potentially as nanocrystals. The clusters range in height from 1.3 nm to 39 nm with over 75% between 4.5–6.5 nm, which is consistent with the light-scattering data.[722] Such sharp, clear images of the tip structure (shown in Figure 90) strongly suggest the nonamers deposit as stacks

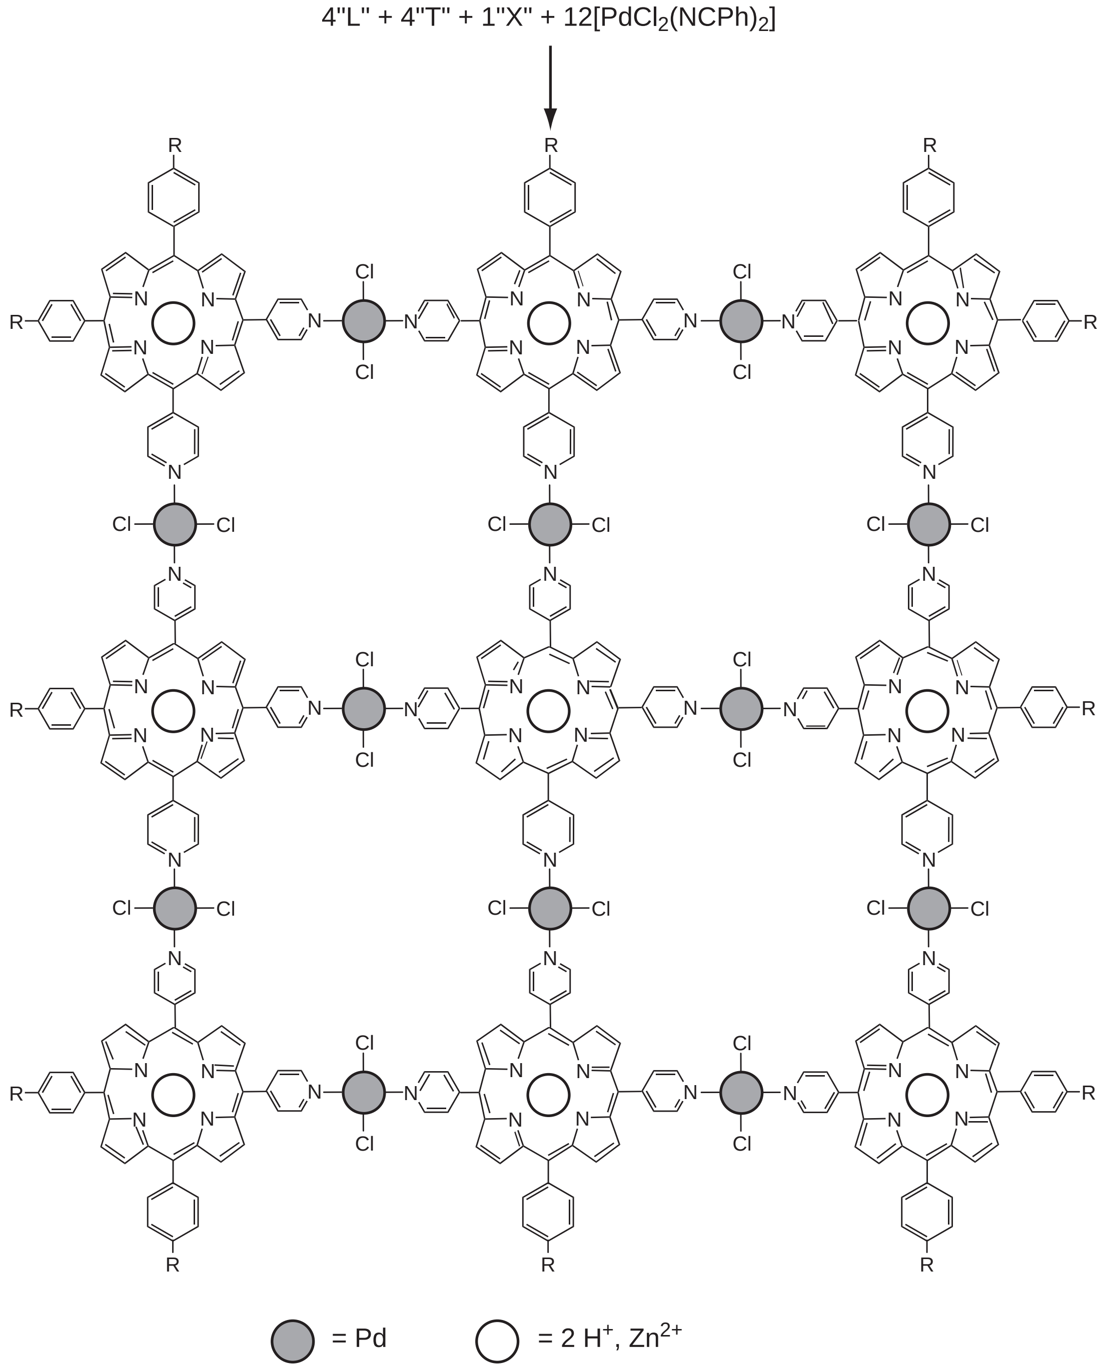

Figure 88 Nonameric arrays of porphyrins.

on the order of 5 × 5 × 5 nm^3. These arrangements are induced by a significant intermolecular π stacking energy per porphyrin face (~5 $\mathrm{kcal\,mol^{-1}}$) depending on solvent and concentration. Other evidence for the formation of the arrays and tapes comes from a variety of methods: dynamic light scattering and size-exclusion chromatography; ESMS; and vapor phase osmometry.[722] The data taken together indicate formation of nonamer arrays that are about 25 nm^2 large, objects that are between discrete chemical species and polymeric materials. This work demonstrates that it is possible to design and self-assemble large, complex arrays of rigid dye molecules such as porphyrins by choosing the appropriate geometry of the building blocks and metal ions.[722]

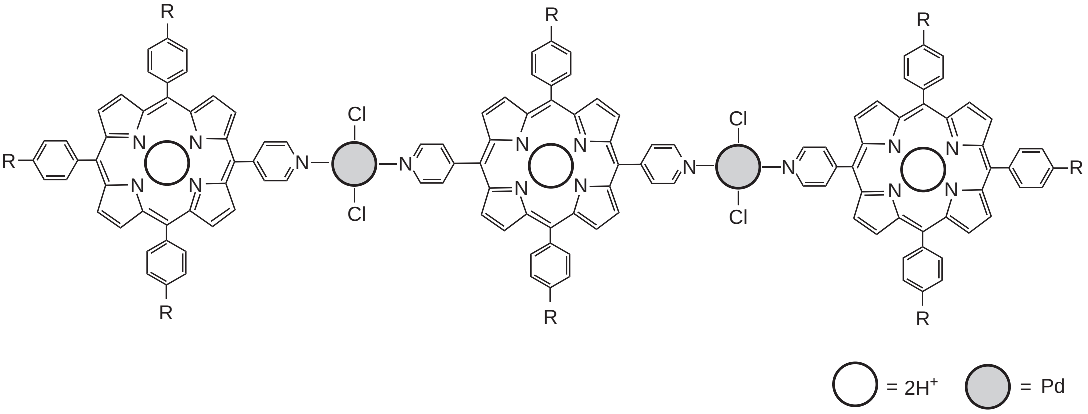

Figure 89 Porphyrin tapes.

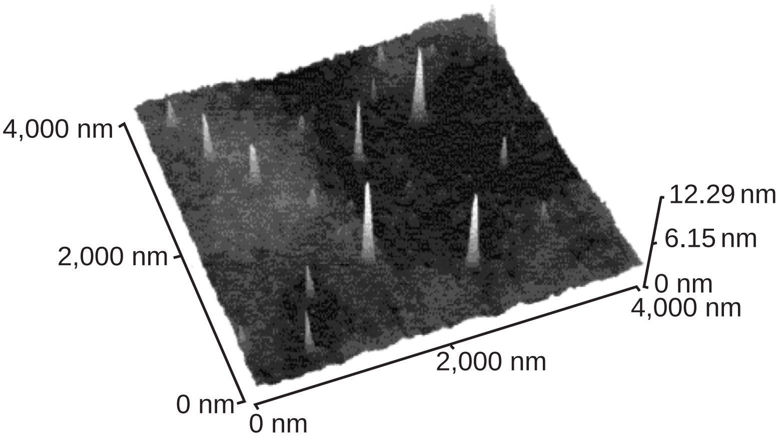

Figure 90 Characterization of the three-dimensional arrangement of porphyrin arrays by atomic force microscopy.

A number of chiral transition-metal-based infinite structures and smaller chiral systems, such as helices and helicates,[747–760] have been reported. It is important to understand the function of chiral elements in supramolecular structures in an effort to unravel the intricacies of biological systems and the subtle functions respective chiral components introduce.[761] Bisphosphines such as 2,2′-bis(diphenylphosphino)-1,1′-binaphthyl (BINAP) and its derivatives have been most extensively utilized as chiral transition-metal-chelating reagents. The BINAP Pd^{II} and Pt^{II} bistriflate complexes[762] are fairly pliant and have been shown to be suitable building blocks for the preparation of chiral macrocyclic molecular squares.[763] DIOP (2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphino)-butane) is also widely used. Stang *et al.* reported the preparation of all transition metal and mixed Pt and Pd-iodonium, fully charged, cationic systems and the asymmetric induction resulting in these complexes using metal centers with chiral chelating ligands and helicity.[763,764] A new chiral tetranuclear molecular Pt—Pd square was made using the simplest approach, that of a chiral chelating ligand, to access chirality. The resulting chiroptical properties of the chiral assemblies were studied. Optical rotation and CD spectra of the chiral starting material are reported; their set of intrinsic properties is being compared to those of the resulting macrocycles. The coordination of silver via π-interaction with the acetylenes is detected by CD, as well as the capture of neutral diheteroatomic aromatic guests by the resulting Lewis acid/base receptors.[761] NMR spectroscopy, circular dichroism (CD), and UV spectroscopy were used to observe tetramer formation, silver coordination, and guest inclusion. The DIOP moiety was most useful when used in conjuction with the achiral triethyl phosphine palladium bistriflate. However, the BINAP moiety allowed for the observation of larger Cotton effects, which proved particularly useful for monitoring the formation of the chiral tetramers as well as the inclusion of neutral guests.[761]

Rigid complexes can be synthesized in which the overall structure is dictated by a combination of the binding constraints of the ligand and the geometrical requirements of the metal ions. There is a report of the self-assembly of a rigid, cyclic structure that contains 4,7-phenanthroline and the linear organopalladium complex fragments, shown in Figure 91, as building blocks. Self-assembly of these complementary molecular building blocks with angular requirements of 60° and 180° results in a six-component [3 + 3] cyclic array.[639]

In attempts to observe intermediates in the self-assembly process, experiments involving stepwise addition of metal to ligand and ligand to metal were monitored by ^{1}H-NMR spectroscopy. In no case were species other than the cyclic product and the component in excess observed. This is consistent with rapid formation of the thermodynamically favored cyclic product. An X-ray structural study confirmed the postulated hexanuclear structure (see Figure 92).[639] 4,7-Phenanthroline is a simple, commercially available ligand that favors bridging over chelation and provides a rigid 60° corner for creating unique metal–ligand arrays. An advantage of employing the organopalladium complex fragments described here is the readily variable substituent on the sulfur atom, which allows the modification of the physical properties.[639]

6.4.6 PALLADIUM(I)

6.4.6.1 Carbon

Tetrapyrrole ligands, including porphyrins, porphyrinogens, and bilindiones, can coordinate metal ions in a π-fashion as well as in the usual σ-fashion through the nitrogen lone pairs. In $Pd_4(OEB)_2$, a $[Pd_2]^{2+}$ unit is bound in π-fashion to olefinic sites that are exocyclic to pyrrole rings of the octaethylbilindione (H_3OEB) ligand.[203] An unprecedented rearrangement of the framework of the bilindione occurs as a direct consequence of the π-coordination of the palladium. This complex, multistep process involves cleavage of the Pd—Pd and Pd—C bonds, oxidation of palladium, migration of the nitrogen atom from one carbon to another, and introduction of the oxygen atom via a hydrolytic process, not necessarily in this particular sequence.[765]

6.4.6.2 Phosphorus

Palladium triphenylphosphine complexes are important because of their numerous applications in organic synthesis and catalysis. A new binary palladium triphenylphosphine complex shows an unprecedented triphenylphosphine bonding mode.[766] Yellow $[(PPh_3)_2Pd(\mu\text{-}OH)]_2(BF_4)_2$[767] is only slightly soluble in CH_2Cl_2 but rapidly dissolves to give a red solution when ethanol is added. The $[Pd_3(PPh_3)_4]^{2+}$ cation consists of a Ph_3P—Pd—Pd—Pd—PPh_3 linear chain sandwiched by two head-to-tail Ph_2P–C_6H_6 groups each bonded through the P atom to one Pd atom and to two Pd atoms through a phenyl ring.[768] Although PPh_3 has been observed to bridge two metal centers through the P atom and a Ph ring,[769–777] a three-metal-center bridge is without precedent; see Figure 93.[766]

The arene rings bind to the Pd centers through four carbon atoms, bridging the two Pd atoms as μ-η^2:η^2-diene units. Arene bonding similar to that in the complex has been observed in Pd_2 complexes.[778–780] Pd oxidation states in the chain may be described as Pd^I—Pd^0—Pd^I.[766] The formation of this complex involves Pd^{II} reduction. The alcohol is the reducing agent and free PPh_3 is scavenged by air oxidation, thereby improving the yield of the new complex. The novel triphenylphosphine bridging to three metal centers is surprisingly robust and resists degradation at ambient temperatures. The low PPh_3/Pd ratio does, however, suggest that $[Pd_3(PPh_3)_4]^{2+}$ may be a useful precursor in stoichiometric and catalytic reactions.[766]

6.4.6.3 Hydrogen

Although a number of mono- and binuclear palladium hydrides have been successfully identified structurally and spectroscopically,[375,781–786] very rare are the hydrido polynuclear Pd complexes that have been convincingly characterized. To our knowledge there is no X-ray structure of

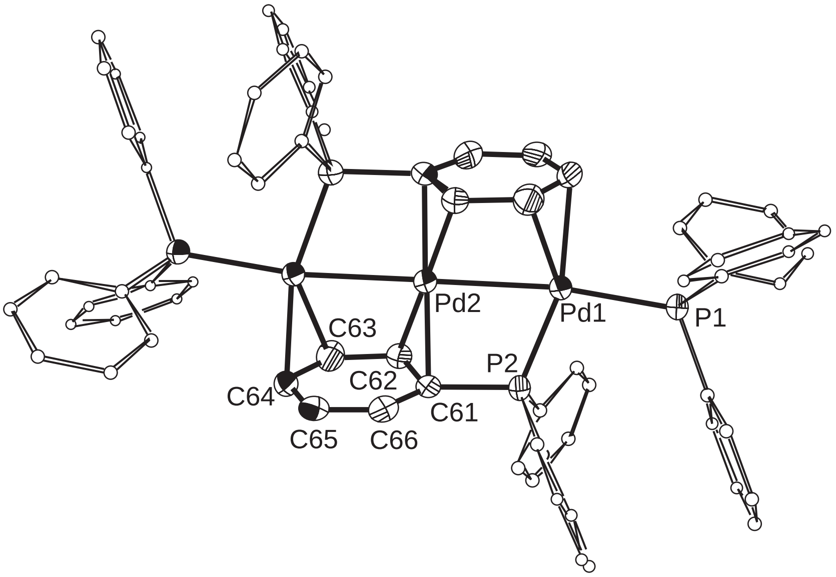

Figure 93 A three-metal-center bridge in $[Pd_3(PPh_3)_4]^{2+}$ ion.

$Pd_3(H)_x$ or of hydride Pd_n ($n \geq 4$) complexes in the literature. Puddephatt *et al.*[787,788] prepared the unstable compound $[Pd_3(dppm)_3(\mu^3\text{-S})(H)]PF_6$ which was characterized by NMR and IR and by comparison with the X-ray crystallographically characterized Pt analogue. Furthermore, attempts to prepare $[Pd_3(dppm)_3(\mu^3\text{-H})]^+$ were unsuccessful. One group studied the reaction between $Pd_2(dppm)_2Cl_2$ and $NaBH_4$ which produced putative "$Pd_2(dppm)_2(H)_x$."[789] Another group reinvestigated the reaction between $Pd_2(dppm)_2X_2$, where X = Cl, Br, or I, and $NaBH_4$ under the same experimental conditions. While no reaction is observed for the I derivative, they have obtained the same diamagnetic product according to color, spectra, and chemical behavior, except that both compounds contain halides (Cl or Br). They report the characterization of the first tetrapalladium hydride cluster, formulated as $[Pd_4(dppm)_4(H)_2]X_2$ (X = Cl, Br), along with some of its electrochemical properties in relation to electrocatalysis.[790]

6.4.6.4 Polynuclear Compounds and Polymers (see Chapter 7.6)

Homoleptic transition metal complexes containing weakly coordinated ligands have long been recognized as versatile sources of active catalysts or inorganic functional materials.[791,792] For example, the combination of an electrophilic Pd^{II} complex $[Pd(CH_3CN)_4][BF_4]_2$[793,794] and appropriate auxiliary ligands has been frequently used as a pre-catalyst for olefin oligomerization, aromatic substitution, Wacker type oxidation, or alkyne hydroamination reaction.[795–802] Preparation of the first homoleptic nitrile dipalladium(I) complex is shown in Figure 94.[803]

The dipalladium complex underwent facile ligand-substitution reaction with the Pd—Pd bond remaining *intact* under moderate conditions.[803] The reaction with two equivalents of bidentate phosphine, dppm (diphenylphosphinomethane), in CD_3CN afforded a known complex $[Pd_2(dppm)_2(CH_3CN)_2][BF_4]_2$[804] quantitatively. The reaction with two equivalents of 1,10-phenanthroline (phen) afforded $[Pd_2(phen)_2(CH_3CN)_2][BF_4]_2$.[805]

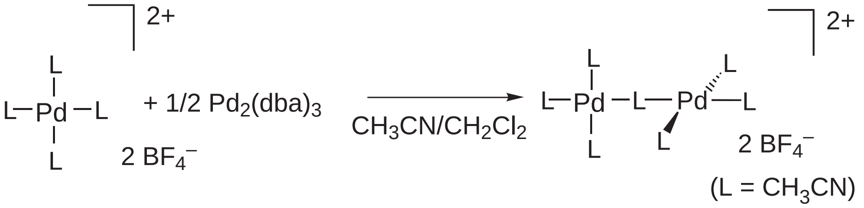

Figure 94 Preparation of the first homoleptic nitrile dipalladium(I) complex.

The design of efficient molecular catalysts for proton reduction to H_2 has recently become a subject of increasing interest.[806–809] The identification and electrochemical characterization of a tetrapalladium dihydride cluster $[Pd_4(dppm)_4(H)_2](X)_2$ ($X^- = Cl^-$, Br^-) was reported.[790] Because this cluster exhibits hydrides and an electrochemically reversible (two-electron) reduction system,[790] one can hope for hydrogen evolution electrocatalysis. Another work[810] reports the first homogeneous electrocatalytic hydrogen evolution reaction induced by a cluster compound. Experimental results indicate that the intermediate is another polyhydride species, $Pd_4(dppm)_4(H)_3^+$, that is relatively stable. This study[810] also reports the one electron electrocatalytic decomposition of the formate ion to CO_2 and $1/2H_2$ by this same intermediate. The dihydrido cluster can be prepared chemically and electrochemically by various methods using the starting $Pd_2(dppm)_2Cl_2$ material. The dihydrido cluster is sensitive to nucleophiles such as Cl^-, Br^-, and CN^-, but the $[Pd_4(dppm)_4(H)_2](X)_2$ salts ($X^- = BF_4^-$, PF_6^-, BPh_4^-) proved to be particularly stable, even for weeks in solution. Its preparation in two general ways is shown in Figure 95: The first being the addition of "H^+" to a chemically or electrochemically generated $Pd_2(dppm)_2$ species (d^{10}–d^{10}); and the second being the addition of "H^-" to $Pd_2(dppm)_2Cl_2$ (d^9–d^9).[810]

The studies on palladium-phosphine complexes, especially those with diphosphine ligands, have mainly been focused on the complexes of palladium in lower oxidation state of 0 and +1,[84,580,581,583,766,787,788,811–816] such as $[Pd_2(dppm)_2]^{2+}$, $[Pd_2(dppm)_3]$,[815] $[Pd_3(dppm)_3(\mu_3\text{-}S)H]PF_6$,[787,788] $[Pd_4(dppm)_4(H)_2]X_2$,[814] and $\{[Pd(\mu\text{-}SC_6F_5)(\mu\text{-dppm})Pd](\mu\text{-}SC_6F_5)\}_4$.[813]

Until recently, only a few examples of clusters containing $[MSe_4]^{2-}$ units and non-d^{10} metal atoms were known.[817,818] In order to obtain such a cluster, the reaction of palladium(I) complex $[Pd_2(\mu\text{-dppm})_2Cl_2]$[819] with $[Et_4N]_2[WSe_4]$ in a CH_2Cl_2–DMF mixture solvent was carried out. The neutral heterohexanuclear cluster $[(\mu_3\text{-}WSe_4)_2(Pd_2)_2(\mu\text{-dppm})_2]\cdot 2DMF$ was formed by displacement of two chlorides and one dppm ligand in the complex, with two $[WSe_4]^{2-}$ groups coordinated to the two $[Pd_2(dppm)]^{2+}$ species, see Figure 96.[820]

In this reaction, the $[WSe_4]^{2-}$ anion is employed as a tridentate ligand and resembles a triseleno acid or four electron ligand, thus the synthesis entails the metathetical reactions of palladium chlorides and $[WSe_4]^{2-}$ anion. Moreover, perhaps more significantly, electrically neutral polynuclear heterometallic clusters with an open d-shell metal center appear to be promising precursors to new inorganic solids. The synthesis, structural characterization, and spectroscopic properties of the hexanuclear W-Se-Pd cluster $[(\mu_3\text{-}WSe_4)_2(Pd_2)_2(\mu\text{-dppm})_2]\cdot 2DMF$ are presented, see Figure 97.[820]

The quadruply bonded dinuclear dimolybdenum(II) complex, $Mo_2(pyphos)_4$ (shown as the upper left structure in Figure 98(a)) (pyphos = 6-diphenylphosphino-2-pyridonate), binds two palladium(I) species at both of the axial positions of the Mo_2 core to form the metal–metal-bonded tetranuclear complex $Mo_2Pd_2Cl_2(pyphos)_4$ (shown as the middle structure in Figure 98(b)), which has two single Pd^I—Mo^{II} bonds and one triple Mo—Mo bond.[821,822] This reaction involves the coordination of two Pd^{II} at the axial positions of the Mo_2 core to form $Mo_2Pd_2Cl_4$

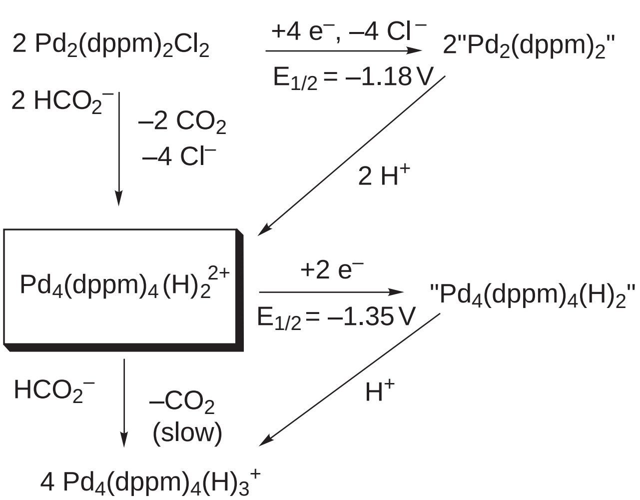

Figure 95 Preparation of $[Pd_4(dppm)_4(H)_2](X)_2$ salts ($X^- = BF_4^-$, PF_6^-, BPh_4^-) in two general ways.

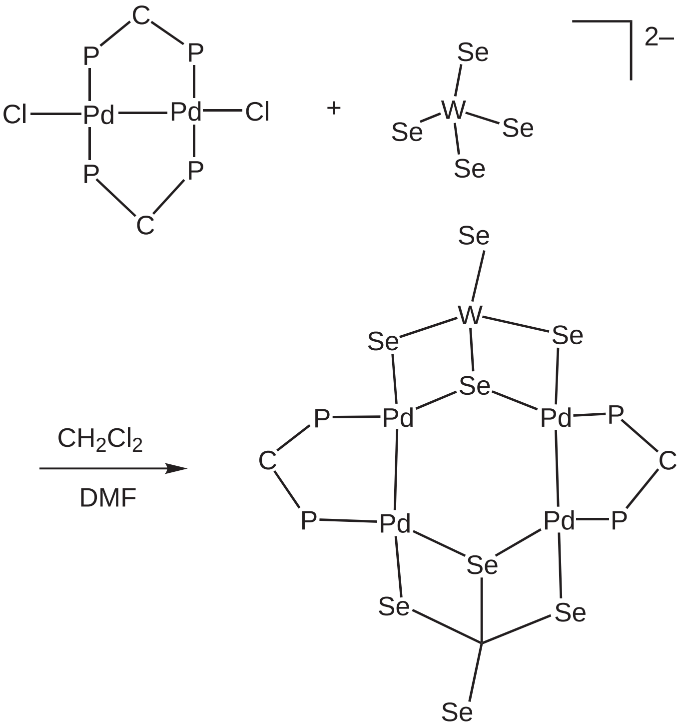

Figure 96 Preparation of neutral heterohexanuclear cluster $[(\mu_3\text{-WSe}_4)_2(\text{Pd}_2)_2(\mu\text{-dppm})_2]\cdot 2\text{DMF}$.

$(\text{pyphos})_4$ (shown as the upper right structure in Figure 98(c)) and then the reduction of Pd^{II} to Pd^{I} as a result of the formation of Mo—Pd σ bonds.

Bis(diphenylphosphine)methane (dppm), as a constraining ligand, prefers to lock two metal atoms together in close proximity and favors unusual oxidation states; thus, most palladium complexes containing dppm are binuclear complexes doubly bridged by dppm and related ligands, such as $[\text{Pd}_2(\mu\text{-dppm})_2\text{X}_2]$ (X = halogen),[579,580,583,823] and the oxidation state of palladium is mainly +1. Many studies have been carried out on the insertion of small molecules, such as CO, SO_2, RCN, etc., into the Pd—Pd bond in $[\text{Pd}_2(\mu\text{-dppm})_2\text{X}_2]$ to yield the so-called A-frame complexes with the maintenance of the oxidation state of palladium.[824–827] In the octanuclear $\{[\text{Pd}(\mu\text{-SC}_6\text{F}_5)(\mu\text{-dppm})\text{Pd}](\mu\text{-SC}_6\text{F}_5)\}_4$, the oxidation state of palladium remains +1.[828,829]

Up to a few years ago, a common viewpoint was that monodentate phosphines act exclusively as two-electron terminally bonded donors. The structure of $[\text{Pd}_2(\text{dppp})_2][\text{CF}_3\text{SO}_3]_2$ [dppp = 1,3-

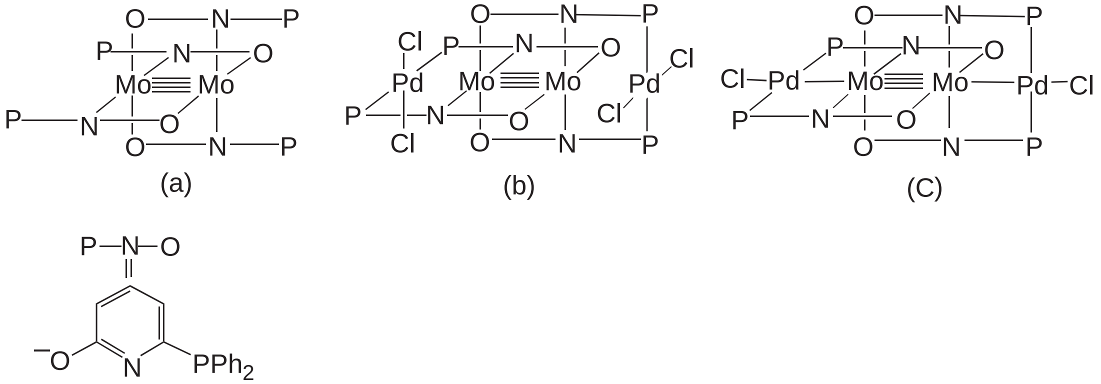

Figure 98 Quadruply bonded dinuclear dimolybdenum(II) complexes (a) $Mo_2(pyphos)_4$, (b) $Mo_2Pd_2Cl_2(pyphos)_4$, and (c) $Mo_2Pd_2Cl_4(pyphos)_4$.

bis(diphenylphosphino)propane][768] contains a dinuclear palladium(I) cation, surviving thanks to a metal–metal bonding interaction, and two bridging phosphines. The cation can in fact be viewed as the dimer of the bent $(dppp)Pd^+$ moiety; within each dppp molecule one phosphorus binds terminally one of the metals and the remaining one bridges the Pd—Pd bond, as shown in Figure 99.[768]

The complex $[Pd_2(\mu\text{-}PBu^t{}_2)(\mu\text{-}PBu^t{}_2H)(PBu^t{}_2H)_2]BF_4$[830] contains a secondary phosphine as bridging ligand, see Figure 100. With respect to most of the bridges described above, which involve orbitals centered on single phosphorus atoms, the bridging secondary phosphine differs substantially because of the active role played by the P—H σ-bond. This furnishes two extra electrons, involved in an unprecedented Pd–H–P agostic interaction, to the dimetallic system. The $PBu^t{}_2H$ molecule can therefore be formally considered as a four-electron donor, or, in other words, a bidentate ligand,[830] as for example the bridging diphenylvinylphosphine in the cation $[\{Pd[\mu\text{-}Ph_2(CH]]CH_2)][PPh_2(CH]]CH_2)]\}_2]^{2+}$, shown in Figure 101.[831]

The bridging $PBu^t{}_2H$ molecule is not as tightly bonded as other bridging bidentate ligands. This can easily be confirmed by comparing the reactivities of monodentate phosphines.[832] The strength of the overall $Pd_2(m\text{-}PBu^t{}_2H)$ interaction is greater than that of a terminal $Pd—Bu^t{}_2H$ bond.[832]

6.4.7 PALLADIUM(0)

6.4.7.1 Carbon

Many research groups have employed Pd catalysis to prepare a variety of covalently-linked multiporphyrin arrays. Couplings of the Heck, Suzuki, Sonogashira, and Stille types, amongst others, have so far been used.[833–841]. In couplings of the *meso*-haloporphyrin using Pd^0 and phosphines, an essential step is the oxidative addition to form a *meso*-η^1-palladioporphyrin.[839] Synthesis and spectra of peripherally-palladated porphyrins have been reported.[842]

Isolated mononuclear Pd^0–carbonyl complexes are rare. Examples include $(Ph_3P)_3Pd(CO)$, which on reversible phosphine dissociation gives rise to $(Ph_3P)_2Pd(CO)$, which itself has not been isolated,[843,844] $\{N(C_2H_4PPh_2)_3\}Pd(CO)$,[845] and $\{MeC(CH_2PPh_2)_3\}Pd(CO)$;[846] the last compound has been structurally characterized. Matrix isolation techniques have allowed the spectroscopic characterization of the highly unstable homoleptic complexes $Pd(CO)_n$ ($n = 1$–4).[847–849] The dinuclear Pd^0-carbonyl complexes $\{(bpy)Pd(\mu\text{-}CO)\}_2$ and $\{(o\text{-}phen)Pd(\mu\text{-}CO)\}_2$[850] and trinuclear clusters $L_nPd_3(CO)_3$ ($L = PPh_3$: $n = 3$, 4; $L = P^tBu_3$, PPh^tBu_2: $n = 3$)[851] have been reported, but without structural data. The molecular structures of larger clusters such as $(Ph_2MeP)_4Pd_4(\mu_2\text{-}CO)_5$,[852] $(Bu^n{}_3P)_4Pd_4(\mu_2\text{-}CO)_6$,[853] $(Me_3P)_7Pd_6(\mu_3\text{-}CO)_4$,[854] and $(Me_3P)_7Pd_7(\mu_2\text{-}CO)_3(\mu_3\text{-}CO)_4$[855] have, however, been established.[856] Dinuclear $Pd_2(\mu\text{-}CO)$ bonding has been suggested for adsorption of CO on a Pd(100) surface,[857,858] but interestingly no examples of dinuclear Pd^0-monocarbonyl complexes were known until recently.[859] The synthesis and properties of the novel mononuclear complexes $(R_2PC_2H_4PR_2)Pd(CO)_2$ ($R = Pr^i$, Bu^t), with terminal CO ligands, and the dinuclear $\{(d^tbpe)Pd\}_2(\mu\text{-}CO)$, containing a single CO bridge were reported.[859] It appears that for the Pd^0–CO system the $Pd_2(\mu\text{-}CO)$ entity is strongly favored over other possible coordination modes (e.g., Pd–σ-CO and $Pd_2(\mu\text{-}CO)_2$).[859]

There is a growing class of metal carbonyl compounds with unusually high ν(CO) values. These and other high ν(CO) values are due to greatly diminished π backbonding for late transition metal $[M(CO)_n]^{m+}$ species. A ν(CO) value greater than 2,143 cm^{-1} can occur for two distinguishable situations: (i) negligible or relatively minor $M \rightarrow CO$ π backbonding (i.e., nonclassical behavior) or (ii) π backbonding that is significant (i.e., classical behavior) but insufficient to lower ν (CO) below 2,143 cm^{-1}.[860] There is computational evidence that the metal-carbon bonds in the d^{10} $D_{\infty h}$ species such as $[Pd(CO)_2]$, are fundamentally different than the metal–carbon bonds in the isoelectronic, isoleptic, and isostructural species $[Ag(CO)_2]^+$, $[Zn(CO)_2]^{2+}$, $[Cd(CO)_2]^{2+}$, and $[Hg(CO)_2]^{2+}$.[861]

6.4.7.2 Nitrogen

The simplest carbohydrates are easily available, chiral, and may afford both lipo- and hydrosoluble ligands[862–867] depending on whether or not the hydroxyl groups are protected. There are new nitrogen chelates based on α-D-mannose and α-D-glucose, where the sugar residue was bound to the N-donor through the C6 atom. Their coordination properties were investigated by preparing lypo- and hydro-soluble complexes of Pd^0 with general formula $[Pd^0(N,N\text{-chelate})(\text{olefin})]$. A significant diastereoselectivity in the coordination of both dimethyl fumarate and fumarodinitrile (fdn) was obtained with ligands of the type shown in Figure 102.[868]

Improved *N*,*N*-ligands, shown in Figure 103, have a chiral carbon closer to the coordinating atoms, i.e., a linkage between the carbohydrate C1 carbon and the N donor. This feature enhances the ability of the ligands to induce enantioselective coordination of prochiral olefins.

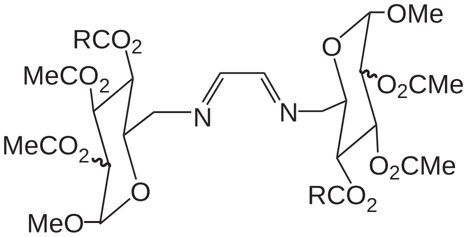

Figure 102 Chelating ligand that is derived from α-D-MANOSE.

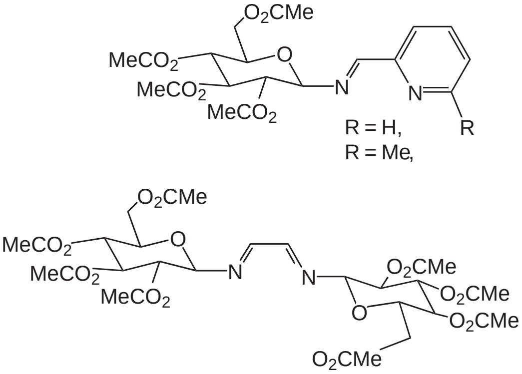

Figure 103 Improved N,N-ligands.

A new water soluble palladium(0) complex was also prepared. This compound and a previously reported related species were examined as catalysts in the hydrogenation of unsaturated nitriles in water. It was found that the pH of the solvent plays a crucial role in determining both yield and reaction course.[869]

6.4.7.3 Phosphorus

Determination of the rate constant of the oxidative addition of aryl halides with $Pd^0(PPh_3)_4$ or with the Pd^0 complexes generated from $Pd^0(dba)_2$ and one equivalent of dppp shows that the oxidative addition is slower for *ortho*-substituted aryl halides than for the corresponding non-substituted or *meta*-substituted aryl halides.[870]

Sources of catalytically active palladium(0) typically arise from ligand dissociation from coordinatively more saturated Pd^0 complexes[871–880] or from reduction of a Pd^{II} species.[353,881] Another route to catalytically active (P—P)Pd fragments is the dissociation of the dinuclear complexes $[(\mu\text{-P—P})Pd]_2$.[882] Complexes $[(\mu\text{-dcpm})Pd]_2$ and $[(\mu\text{-dtbpm})Pd]_2$ were obtained from the reductive elimination of ethane from dimethylpalladium(II) complexes (dippm = bis(diisopropylphosphino)methane; dcpm = bis(dicyclohexylphosphino)methane; dcpm = bis(di-*t*-butylphosphino)methane).[883]

During the 1990s the interest in the complexating properties of calixarenes shifted toward transition metal complexation. This shift has resulted in the synthesis of an appreciable number of phosphorus-containing calix[4]- and calix[6]arenes. Calix[4]arene diphosphite is shown in Figure 104. The ligand shows a tendency to form *cis*-coordinated complexes with palladium(II) in which it has an almost ideal bite angle of 94°. Furthermore it can stabilize palladium(0). The geometry of this complex is presumably a (distorted) tetrahedron. This complex is successful in palladium-catalyzed copolymerization of carbon monoxide and ethene.[884]

Tetracoordinate Pd^0–phosphine complexes are widely used as catalysts in organic synthesis. Interesting among the several routes to these compounds is the formation of a Pd^0 complex in quantitative conversion via a redox transmetalation involving Pd^{II} and Pt^0.[885] In more traditional preparations, Pd^{II}–halide complexes are reduced to the corresponding bis(diphosphine)Pd^0 or tetrakis(phosphine)Pd^0 analogues in the presence of the phosphine or diphosphine. In the redox reaction shown in Equation (5) Pd^{II} bis-phosphine complexes are reduced to tetrakis(phosphine)Pd^0

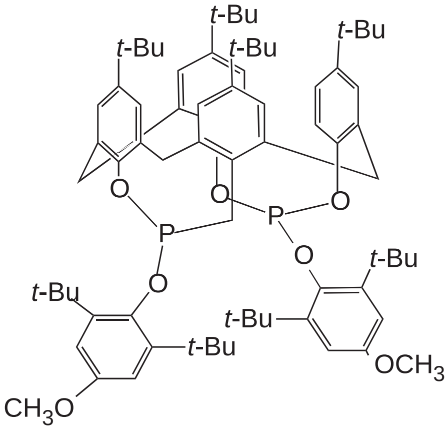

Figure 104 Calix[4]arene diphosphite.

complexes while part of the excess phosphine is oxidized to $R_3P{=}O$.[887] This reaction is catalytic in fluoride in the presence of very strong nonionic bases:[887]

$$\begin{array}{l}(R_3P)_2PdCl_2 + 2F^- + H_2O + 3PR_3 \longrightarrow \\ \qquad (R_3P)_4Pd + 2Cl^- + 2HF + R_3P{=}O\end{array} \tag{5}$$

6.4.7.4 Hydrogen

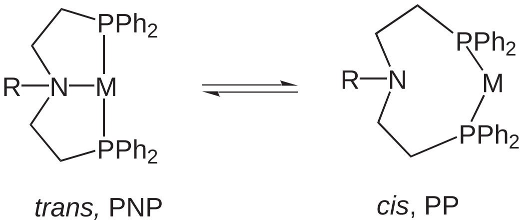
The family of solid-state hydrides now comprises the members $Li_2(PdH_2)$, $Na_2(PdH_2)$, $NaBa(PdH_3)$, $Sr_2(PdH_4)$, and $Ba_2(PdH_4)$.[888–891] Also these hydrides can be made fairly conveniently by hot sintering compacted powder mixtures of the binary alkali or alkaline earth hydrides with Pd in hydrogen. The existence of these complexes is interesting as such low oxidation states of the transition metal are usually associated with ligands having good electron-accepting properties. This conventional stabilization by "back-donation" to ligand orbitals is, however, not available in homoleptic hydrido complexes. Some of the hydrides show metallic electric conductivity, indicating that the cations are required to participate more in the bonding, beyond the role of a conventional undeformed cation. Thus it seems likely that a stabilization mechanism for these electron dense low formal oxidation states is to be found in the interaction of the hydrogen ligands with the cations surrounding the complexes. This could correspond to a somewhat indirect "back-bonding" mechanism where electron density from the *d*-orbitals of the transition metals are distributed to the cations via bonding with the hydrogen atoms. Such a mechanism could also be of interest for applications as it may offer a way to influence the stability of a complex and thus the hydrogen release pressure by manipulating the "electropositive matrix" surrounding the complexes. The stabilization of four palladium-hydrido complexes, a square-planar $[Pd^{II}H_4]^{2-}$, a linear $[Pd^0H_2]^{2-}$, a trigonal $[Pd^0H_3]^{3-}$, and a slightly distorted $[Pd^0H_4]^{4-}$, in the solid-state hydrides $K_2[Pd^{II}H_4]$, $Li_2[Pd^0H_2]$, $Na_2[Pd^0H_2]$, $NaBa[Pd^0H_3]$, and $Ba_2[Pd^0H_4]$ has been studied by investigating the palladium–hydrogen bond strength with inelastic neutron scattering and by performing self-consistent linear muffin-tin orbital calculations on the corresponding solid-state structures.[892] The capacity of the easily polarizable H^- ion for redistributing electron density has thus probably a somewhat neglected importance for complex chemistry in general, but the effect has not been elucidated until the work with homoleptic hydrido complexes.[892] In hydrides where the interactions between neighbors become so large that electrons become itinerant, we might further find new interesting electric phenomena relating conductivity with the crystal lattice modes.[892]

Metal hydrides containing transition metal (TM)–hydrogen complexes, with the transition metal in a formally low oxidation state, are of fundamental interest for clarifying how an electron-rich metal atom can be stabilized without access to the conventional mechanism for relieving the electron density by "back-donation" to suitable ligand orbitals. By reacting electropositive alkali or alkaline earth metals (*s*-elements) with group 7, 8, 9, and 10 transition metals in the presence of hydrogen, a large number of interesting ternary and quaternary complex transition metal hydrides have been synthesized. Although none of the transition metals form stable binary hydrides, except for palladium, the hydrides based on the hydrogen-rich TM complexes have a considerably higher storage capacity than the hydrogen storage alloys commercially available in the early twenty-first century. In the synthesis of these new hydrides, the electropositive *s*-elements are supplying their valence electrons to allow for the formation of usually 18-electron homoleptic TM-hydrogen complexes. A small number of electron-dense Pd–H complexes have already been found, namely Li_2PdH_2 and Na_2PdH_2.[889,890] The flexibility inherent in the polarizable TM—H bond and lattice-induced effect seems to offer enough relief of the high electron density in the d^{10} state of the central atom, helping to stabilize a formal oxidation state that is usually found only with good electron-accepting ligands. Palladium seems to even favor such a low oxidation state, as it has been found with a formal oxidation state of zero in two complexes: a linear PdH_2 complex in Li_2PdH_2 and Na_2PdH_2 and a planar trigonal PdH_3 complex in $NaBaPdH_3$.[891] For comparison, an assumedly more conventional square-planar $Pd^{II}H_4$ complex was synthesized in Na_2PdH_4, but at an extreme 2,000 bar H_2 pressure.[893] The addition of a third zerovalent-palladium hydrido complex in the series A_2PdH_2, namely A_2PdH_4 (A = Sr, Ba),[894] shows that hydrogen as a ligand can participate in the stabilization of such a formally low oxidation state, where one would only expect good electron accepting ligands to be involved. The large variation in hydrogen coordination numbers and geometries in response to the *s*-metal counter ion charge distribution implies that the unique chemical softness of H^- permits stabilization of a number of probably energetically similar structural configurations in these systems. It also indicates the need to consider the total metal lattice when explaining the stability of the different complexes.[894]

For the palladium hydrides, the formation of $[Pd^0H_2]$ complexes is favored over that of a more common square planar arrangement in $[Pd^{II}H_4]{\cdot}Na_2PdH_4$, containing the latter four-coordinated complex, has been synthesized but could only be obtained at an extreme 2 kbar H_2 pressure.[893] K_2PdH_4, containing the larger and more electropositive potassium ion, was synthesized at a more moderate pressure.[895] Both hydrides are nonmetallic, and the Pd—H distances are short, 1.61 Å and 1.63 Å, respectively, indicating more conventional covalent bonding than the longer Pd—H distances, 1.68 Å, in the metallic Li_2PdH_2 and Na_2PdH_2 hydrides. The quaternary hydride $NaBaPdH_3$, contains unprecedented 16-electron $[PdH_3]$ complexes that contain formally zerovalent palladium with planar trigonal D_{3h} symmetry. The crystal structure was determined and refined from single-crystal X-ray diffraction data and was verified by a neutron powder diffraction experiment on a deuterated sample.[896]

6.4.7.5 Mixed Donor Atoms

Ligands with mixed donor atoms have been the subject of many studies. Particularly interesting are the hemilabile ligands, in which "soft" and "hard" donor atoms are combined to give flexible coordination modes. This behavior has been exploited to maximize the stability of a metal complex and has been implicated in a number of catalytic reactions. Although the coordination chemistry of phosphorus–nitrogen–phosphorus donors (PNP ligands) to transition metals has been widely reported, their application to catalysis is fairly recent, where in most cases the nitrogen is used either as a means of tethering the ligand to solid supports, and chiral or hydrophilic groups. As nitrogen is inherently a weaker donor toward later transition metals than phosphines, it is conceivable that the complex could isomerize between *cis* and *trans* configurations as the ligand alters between the bi- and terdentate modes (see Equation (6)). As this isomerization process does not necessarily entail a cleavage of the M—P bond, it is envisaged that ligand dissociation and decomposition during a catalytic reaction should be minimized:[897]



(6)

General routes for the synthesis of a number of PNP ligands of the general formula $\mathrm{R\text{-}N(CH_2CH_2PPh_2)_2}$ (R = acyl, alkyl, aryl) have been developed. Their coordination chemistry with palladium has been explored and was found to be capable of PP–dimeric, PNP–monomeric, and PP–monomeric modes of coordination, depending on the substituents on palladium, as well as on the nature of the R group on the nitrogen donor. Different substitutions on nitrogen have an appreciable effect on the rates of the oxidative addition reaction on palladium(0).[897]

6.4.7.6 Polynuclear Compounds

Ruthenium–ruthenium bonds form adducts to the Lewis acid palladium grouping $\mathrm{Pd(PBu^t{}_3)}$.[898] The tripalladium complex $\mathrm{Ru_3(CO)_{12}[Pd(PBu^t{}_3)]_3}$, shown in Figure 105, was obtained from the reaction of $\mathrm{Pd(PBu^t{}_3)_2}$ with $\mathrm{Ru_3(CO)_{12}}$. The compound consists of a central triruthenium triangle with three Ru—Ru bonds. Each Ru—Ru bond contains a bridging $\mathrm{Pd(PBu^t{}_3)}$ grouping. Each palladium atom is bonded to two ruthenium atoms. The cluster of six metal atoms is not planar, but has a dish-like shape. The reaction of $\mathrm{Pd(PBu^t{}_3)_2}$ with $\mathrm{Ru_6(CO)_{17}(C)}$ yielded two isomers of the dipalladium complex $\mathrm{Ru_6(CO)_{17}(C)[Pd(PBu^t{}_3)]_2}$. In one isomer the $\mathrm{Pd(PBu^t{}_3)}$ groups bridge two edges of the $\mathrm{Ru_6}$ octahedron; in the other isomer, one $\mathrm{Pd(PBu^t{}_3)}$ group bridges an edge of the $\mathrm{Ru_6}$ octahedron while the other $\mathrm{Pd(PBu^t{}_3)}$ group serves as a triple bridge. The reaction of

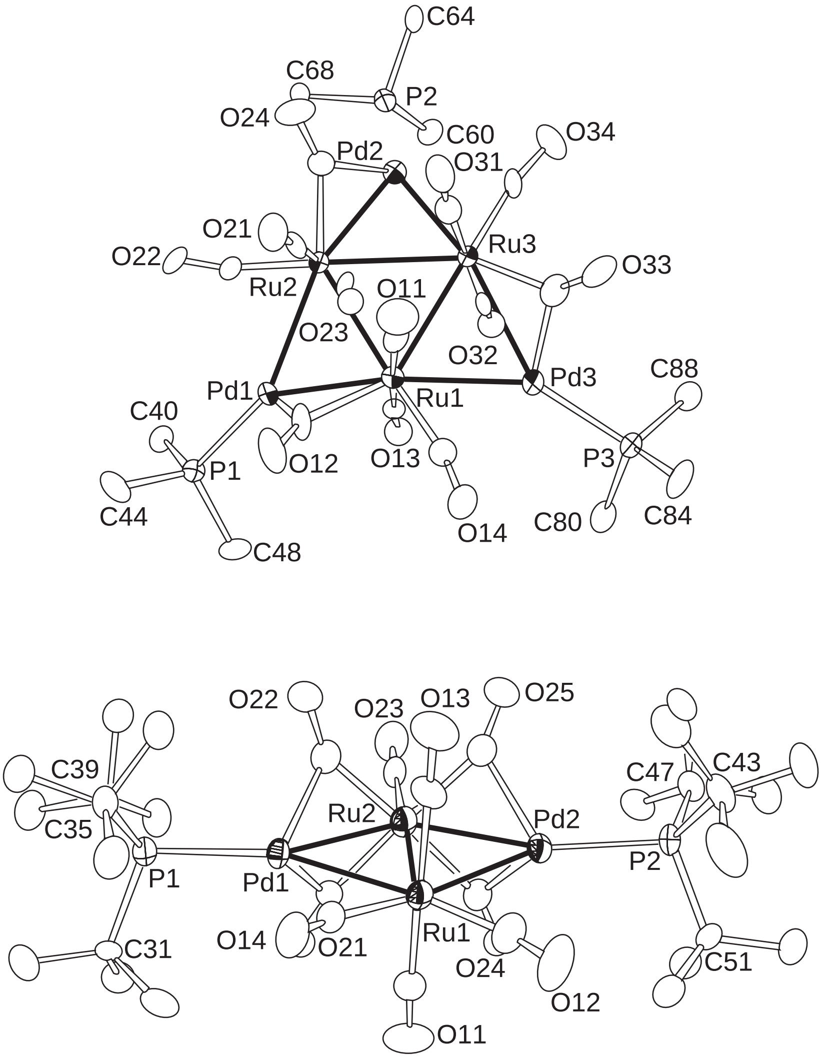


Figure 105 The structures of the complexes $\mathrm{Ru_3(CO)_{12}[Pd(PBu^t{}_3)]_3}$ (above) and $\mathrm{Ru_2(CO)_9[Pd(PBu^t{}_3)]_2}$ (below).

$Ru(CO)_5$ with $Pd(PBu^t_3)_2$ gives $Ru_2(CO)_9[Pd(PBu^t_3)]_2$, depicted in Figure 105, which can be viewed as a dipalladium adduct of the elusive compound $Ru_2(CO)_9$.

There has been great interest in the preparation of bimetallic transition metal cluster complexes containing palladium.[899–902] Bimetallic palladium–ruthenium clusters have been shown to be good precursors to supported bimetallic catalysts.[903,904]

Since the first report on the synthesis and characterization of the $Pd_3(dppm)_3(CO)^{2+}$ cluster (dppm = bis(diphenylphosphino)methane), by Puddephatt *et al.*[905,906] numerous and exhaustive works on its reactivity and properties have appeared.[22,907,908] This cluster exhibits a triangular Pd_3 frame with three dppm-supported M—M single bonds. While one M_3 face is capped by a CO group (see Figure 106), the other one is unsaturated, giving rise to rich coordination chemistry.[22,907–909] The dppm-phenyl groups form a cavity above this M_3 plane, limiting access to smaller substrates only.[907,908] The binding of halide ions onto this Pd_3^{2+} species leads to very stable architectures,[909] and the approximated binding constants indicate that the stability varies as $I \gg Br \gg Cl$.[910–912]

This cationic cluster exhibits a two-electron-reduction process, and depending upon the counter anion or the solvent, this event can appear either as a single two-electron step or two one-electron peaks on the cyclic voltammogram. The two-electron transfer reaction, which can be discriminated into its one-electron individual steps, has been the topic of many studies.[913,914] The electrochemically induced R—Br and R—I bond cleavage by the generated paramagnetic $Pd_3(dppm)_3(CO)^+$ intermediate cluster occurs by a pathway producing "R^+" and "X^-."[915] One of the driving forces of this reactivity is the great affinity of the unsaturated Pd_3^{2+} center toward Br^- and I^-, leading to the final inorganic products $Pd_3(dppm)_3(CO)(X)^+$ ($X = Br^-$, I^-).[916]

Relatively few investigations involving palladium carbonyl clusters have been carried out, partly because palladium *per se* does not form stable, discrete homometallic carbonyl clusters at room temperature in either solid or solution states.[114,917–922] Nevertheless, solution-phase palladium carbonyl complexes have been synthesized with other stabilizing ligands (e.g., phosphines),[105,923] and carbon monoxide readily absorbs on palladium surfaces.[924] Moreover, gas-phase $[Pd_3(CO)_n]^-$ anions ($n = 1$–6) have been generated and their binding energies determined via the collision-induced dissociation method.[925]

Many intriguing palladium carbonyl phosphine clusters have been prepared and their stereochemistry extensively investigated; however, the number of high-nuclearity homopalladium carbonyl clusters characterized by X-ray diffraction analysis is still limited: namely, $Pd_{10}(CO)_{14}(PBu^n_3)_4$,[926] $Pd_{10}(CO)_{12}(PBu^n_3)_6$,[927] $Pd_{12}(CO)_{12}(PBu^n_3)_6$,[928] $Pd_{16}(CO)_{13}(PEt_3)_9$,[929] $Pd_{23}(CO)_{22}(PEt_3)_{10}$,[930] $Pd_{23}(CO)_{20}(PEt_3)_8$,[931] $Pd_{34}(CO)_{24}(PEt_3)_{12}$,[932] and $Pd_{38}(CO)_{28}(PEt_3)_{12}$.[932,933] Synthetic pathways to these large clusters usually involve the elimination of ligands from smaller palladium clusters thereby resulting in aggregation. The products of such reactions are unpredictable, and consequently X-ray crystallography is normally utilized to establish the composition as well as atomic arrangement.

High-nuclearity homopalladium carbonyl clusters $Pd_{16}(CO)_{13}(PMe_3)_9$, $Pd_{35}(CO)_{23}(PMe_3)_{15}$, $Pd_{39}(CO)_{23}(PMe_3)_{16}$, and $Pd_{59}(CO)_{32}(PMe_3)_{21}$ were obtained in moderate yields from a highly reproducible synthesis involving the initial preparation of a heterometallic Pd—Ni carbonyl cluster without phosphine ligand followed by its reaction with PMe_3 under acidic conditions.[935]

Nanosized $Pd_{145}(CO)_x(PEt_3)_{30}$ contains a capped three-shell 145-atom metal-core geometry of pseudo icosahedral symmetry. The pseudo-I_h metal core (see Figure 107) consists of a central Pd atom surrounded by 12 Pd atoms (shell 1), which in turn are encapsulated by 42 Pd atoms (shell 2), which in turn are encapsulated by 60 Pd atoms (shell 3). Thirty additional Pd atoms cap the 30 square polygons of the third-shell polyhedron with a triethylphosphane ligand attached to each capping Pd atom. It is currently presumed that 60 CO groups (crystal-disordered) edge-bridge the 30 capping Pd atoms with one-half of the square basal Pd atoms. The diameter of the entire Pd_{145}

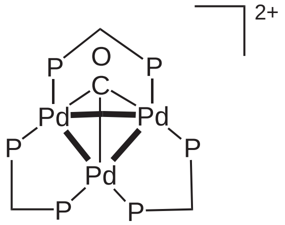

Figure 106 The complex ion $[Pd_3(dppm)_3(CO)]^{2+}$.

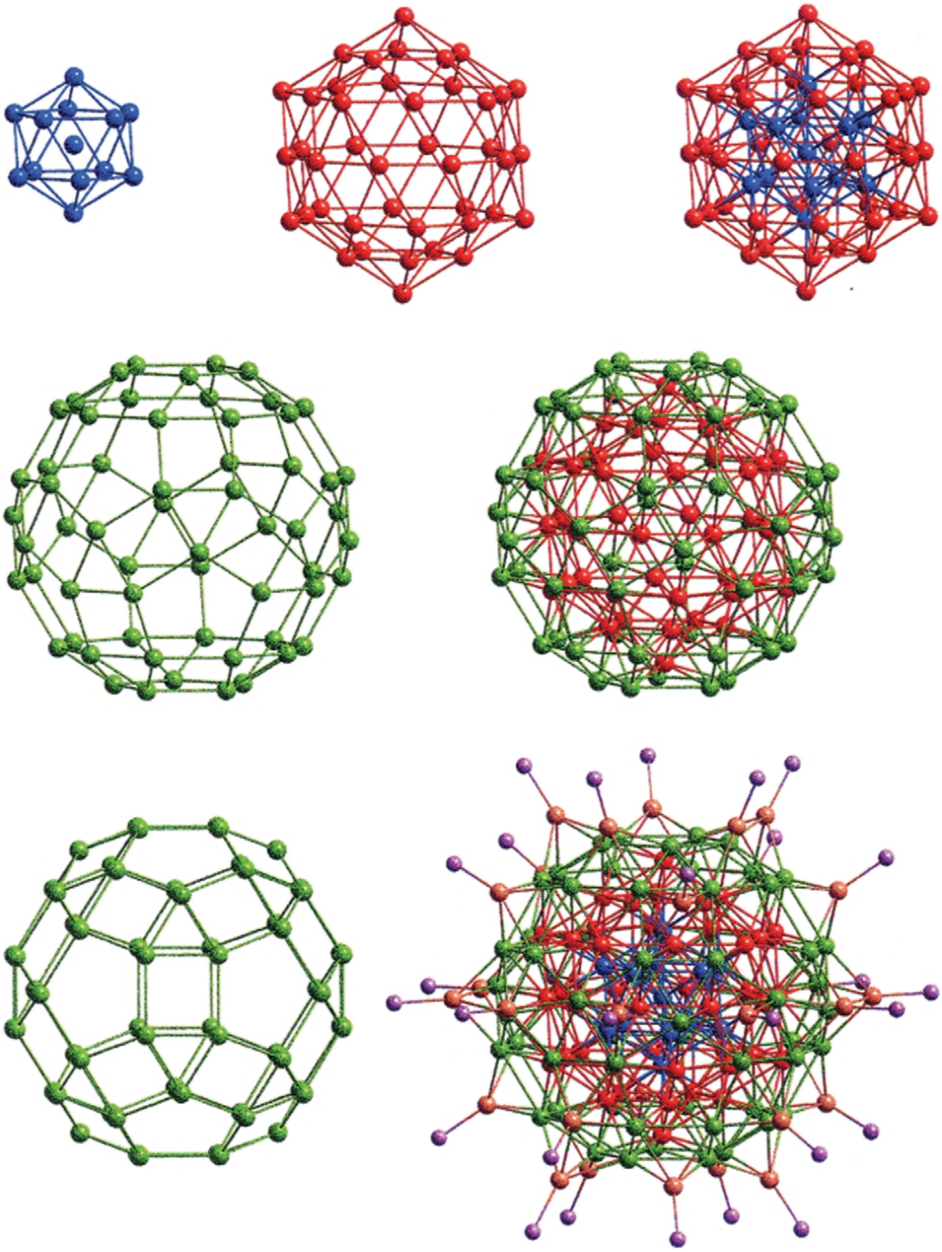

Figure 107 The pseudo-I_h metal core showing three shell layers and 145-atom metal-core geometry in $Pd_{145}(CO)_x(PEt_3)_{30}$.

core of is 1.65 nm; the geometry of the centered three-shell Pd_{115} kernel (that is, without the 30 capping Pd atoms) is spheroidal.[934]

This remarkable Pd_{145} nanocluster, whose metal-core geometry was unambiguously characterized, was isolated from the reduction of a monomeric square-planar palladium precursor, $[Pd(PEt_3)_2Cl_2]$.[934] A preliminary investigation has already indicated the existence of PMe_3 and PPh_3 analogues.[934]

Since the early 1980s a variety of high-nuclearity neutral homopalladium carbonyl phosphine clusters have been prepared and characterized from X-ray crystallography.[926,927,930,932] Analyses of the stereochemistry and prominent bonding features of several of these clusters have been presented.[21,936,937] Moreover, *N,O*-ligated palladium nanoclusters possessing idealized formulations based upon concentric closed-shell palladium cores have been reported, namely, five-shell Pd_{561} clusters[25,938–940] and mixtures of seven-shell Pd_{1415} and eight-shell Pd_{2057} clusters.[941]

Zero-valent Pd complexes in organic solutions (e.g., THF) decomposed under CO in the presence of PPh_3 to give novel PPh_3/CO-stabilized Pd particles which were studied by spectroscopic methods;[942] although the Pd particles were relatively unstable and were subject to size variations in solution, three distinct size-selected distributions were obtained with observed mean diameters determined from TEM to correspond to idealized two-shell Pd_{55}, three-shell Pd_{147}, and five-shell Pd_{561} cores.[942] The well-defined neutral cluster $Pd_{59}(CO)_{32}(PMe_3)$ possesses the largest crystallographically determined metal-atom core with direct metal–metal bonding. Furthermore, it contains a nanosized metal core with 11 interior atoms. The ellipsoidal-shaped architecture of its Pd_{59} core may be formally considered as a trigonal deformation of a spheroidal-like geometry.[856] The new cluster was obtained in moderate yields (~40%) from a highly reproducible synthesis involving the initial preparation of a heterometallic Pd—Ni carbonyl cluster (without phosphine ligands) followed by its reaction with PMe_3 under acidic conditions. Although it was presumed that the latter reaction would result in PMe_3 substitution for CO ligands and/or other large Pd—Ni carbonyl clusters via phosphine stabilization, the reaction instead gave rise to several new high-nuclearity homopalladium clusters with $Pd_{59}(CO)_{32}(PMe_3)$ as the major product.[856] The trimethyl phosphine ligands are distributed about the metal core as six Pd $(\mu_3\text{-CO})_2PMe_3$, nine $Pd(\mu_2\text{-CO})_2PMe_3$, and six $Pd(\mu_3\text{-CO})PMe_3$ moieties. The ^{1}H-NMR measurements showed no detectable high-field signals characteristic of hydride-like atoms.[856]

An efficient synthesis of the dinuclear palladium(0) complexes has been devised.[169]

The bonding interaction between closed-shell, heavy metal atoms or ions is gaining increasing attention.[570] The complex $[Pd(PPh_2py)_3Tl]^+$ (PPh_2py = diphenyl-2-pyridylphosphine) contains the first example of unsupported Pt^0—Tl^I bond.[943] *In situ* addition of Tl^I salts to some Pd^0-catalyzed reactions is an efficient method for controlling the regioselectivity and rate of catalysis.[944,945]

Catalano *et al*. reported the synthesis and characterization of a new series of Pd^0-based metallocrypates that bind Tl^I ion in the absence of attractive ligand interactions through metallophilic connections. The cationic species have been characterized by a variety of methods and have considerable stability. From the solid-state structural data it is apparent that interaction of the metal atoms with one another is the dominant bonding interaction within the metallocryptate cavity. The characterization of complexes supports the concept of "metallophilic" behavior as a fundamental component of bonding in closed-shell systems. These materials may ultimately serve as prototypical systems for detection of closed-shell ions.[946]

Synthesis and characterization of the Pd^0-based metallocryptates with exceptionally short Pd^0—Pb^{II} interactions has been reported. This seems to be the first report of an unsupported Pd^0—Pb^{II} bond.**[948]** Further, these metallocryptands represent a new type of host complex that employ attractive metallophilic interactions for metal ion binding rather than Lewis acid–base interactions. The deep green–brown, air-stable $[Pd_2(P_2phen)_3Pb](ClO_4)_2$ [P_2phen = 2,9-bis(diphenylphosphino)-1,10-phenanthroline], shown in Equation (7), is easily synthesized in good yield in acetonitrile. The Pb^{II} can be replaced by addition of an excess of Tl^I ion:

$$Pd_2(dba)_3{\cdot}CHCl_3 + 3\ P_2phen + Pb(ClO_4)_2 \longrightarrow [Pd_2(P_2phen)_3Pb](ClO_4)_2 + 3dba + CHCl_3 \quad (7)$$

The Pb atom resides in the center of the D_3 symmetric cavity formed by the P_2phen ligands coordinated to the two trigonal Pd^0 centers. The Pd(1)—Pb(1) and Pd(2)—Pb(1) separations are nearly identical, and a Pb center is nearly linearly bonded in Pd(1)—Pb(1)—Pd(2), indicating that the lone pair is stereochemically inactive (see Figure 108).

The attractive metal–metal interactions observed here can be rationalized by employing a qualitative MO diagram similar to that proposed by Balch *et al.*[948] by combining the filled d_{z^2} and empty p_z-orbitals on the transition metals with the filled Pb 6*s* and empty Pb $6p_z$-orbitals. Mixing between levels stabilizes the filled orbitals relative to their unfilled counterparts leading to an attractive interaction between these metals.[947] The compounds reported here are examples of a rapidly expanding class of easily synthesized inorganic host complexes that employ strong, closed-shell attractive interactions for metal ion binding. By eliminating ligand–ion interactions these metallocryptands provide a simple probe to the metal–metal bonding both in solution and in the solid state. Substitution of Pb^{II} for other heavy metal ions should provide numerous combinations of heavy metal interactions for further study.[947]

The $Ph_2P(CS_2Me)$ ligand can transfer between $[Pd(PPh_3)_4]$ and $[W(CO)_5[PPh_2(CS_2Me)]]$, forming *anti*-$[(Ph_3P)_2Pd[\mu\text{-}\eta^1,\eta^2\text{-}(CS_2Me)PPh_2]W(CO)_5]$ as an intermediate.[949] Next, the existence of configurational isomers in complexes between [diphenyl(dithioalkoxycarbonyl)phosphine]tungsten(0) compounds and $Pd(PPh_3)_4$ was studied.[950] $PPh_2(CS_2R)$ acts as a bridging ligand through phosphorus σ-bonding and C=S π-bonding and forms *syn*- and *anti*-configurational dimetallic complexes. The diphenyl(dithiomethoxycarbonyl)phosphine transfer reaction between $[Pd(PPh_3)_4]$ and $[W(CO)_5[PPh_2(CS_2Me)]]$ forms $[[(Ph_3P)Pd[\mu\text{-}\eta^1,\eta^2\text{-}(CS_2Me)PPh_2]]_2]$ as the ultimate product.

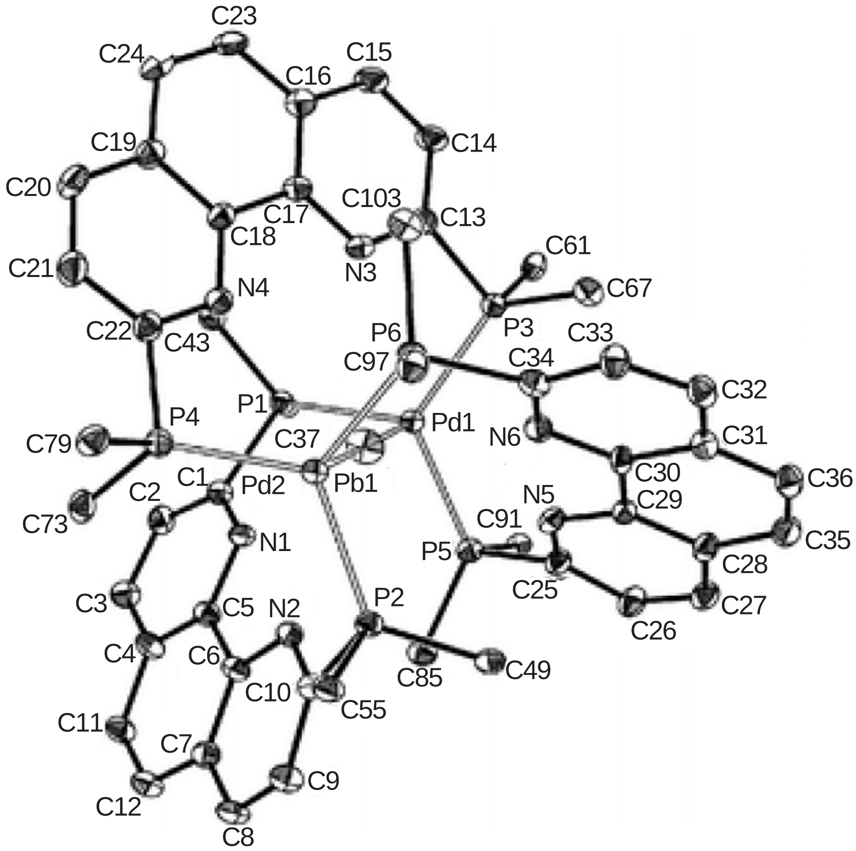

Figure 108 Structure of $[Pd_2(P_2phen)_3Pb](ClO_4)_2$.

The reaction proceeds via a η^2-coordination of the C=S fragment to Pd, giving *anti*-$[(Ph_3P)_2Pd[\mu\text{-}\eta^1,\eta^2\text{-}(CS_2Me)PPh_2]W(CO)_5]$ as an intermediate. Increased hindrance of the thioalkoxy groups exerts stereospecific control leading to the formation of *syn* configurational complexes. Useful $^{31}P\{^1H\}$-NMR patterns are able to differentiate configurational compounds.[950]

The reactions of cluster anions with cation or halide of Group 10 transition metals give clusters comprising two different transition metals, for example, $[Pd_{33}Ni_9(CO)_{41}(PPh_3)_6]^{4-}$[951] and $[Fe_6Pd_6(CO)_{24}H]^{3-}$.[952] In these examples, considerable fragmentation and recombination of the original cluster component appear to be the important factors. The coupling of ruthenium carbide carbonyl clusters through palladium species gives high-nuclearity Ru/Pd mixed-metal complexes of "sandwich cluster" type structure. Treatment of the pentanuclear ruthenium carbido anion $[Ru_5C(CO)_{14}]^{2-}$ (cation: PPN = $N(PPh_3)_2{}^+$) with two equivalents of $[Pd(C_3H_5)Cl]_2$ in THF at room temperature for 12 h gave dark red crystals of a neutral cluster with the composition $[Pd_8Ru_{10}C_2(CO)_{27}(C_3H_5)_4]$ in 52% yield. The molecule has two pseudomirror planes.[900] The Pd_8 core is flanked on each side by a squarepyramidal Ru_5 core (shown in Figure 109(a)). Refluxing $[PPN]_2[Ru_6C(CO)_{16}]$ in CH_2Cl_2 with about one equivalent of $[Pd(CH_3CN)_4][BF_4]_2$ for four hours under air and subsequent treatment with CH_2Cl_2/MeOH resulted in crystals of $[PPN]_2[Pd_2Ru_{12}C_2(CO)_{30}]$ (see Figure 109(b)) in 33% yield. Reaction of the same reactants in the same feeding ratio in THF at room temperature for 12 hours but under argon gave dark red crystals of the composition $[PPN]_2[Pd_4Ru_{12}C_2(CO)_{32}]$, shown in Figure 109(c). The yield of this reaction was 34% based on the starting ruthenium complex and 68% based on the palladium cation used.[900]

In the second cluster, the two Ru_6 octahedra are linked through two palladium atoms. The third cluster contains two additional palladium atoms. The Pd_4 skeleton adopts the form of a bent square. The two Ru_6 octahedra have local structures similar to those in the second cluster, but their relative orientation is now twisted. Apparently, formation of these heterometallic cluster complexes does not result from a simple combination reaction between cationic and anionic complexes but is accompanied by partial redox reactions.[900]

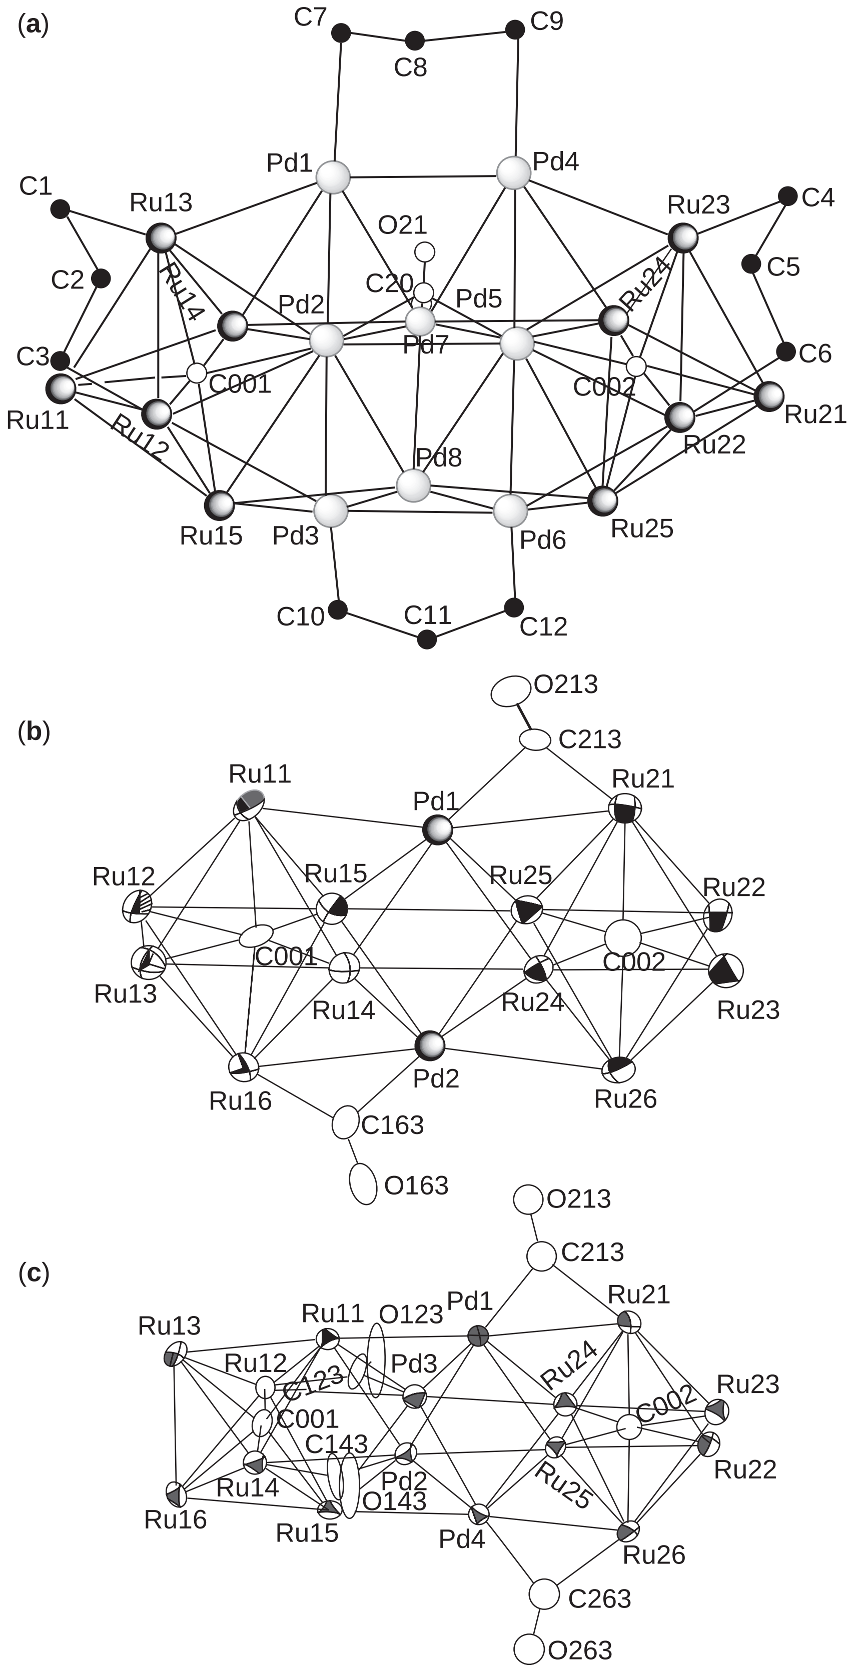

Figure 109 Structures of (a) $[Pd_8Ru_{10}C_2(CO)_{27}(C_3H_5)_4]$; (b) $[PPN]_2[Pd_2Ru_{12}C_2(CO)_{30}]$; and (c) $[PPN]_2[Pd_4Ru_{12}C_2(CO)_{32}]$.

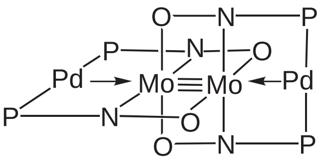

Figure 110 Tetrametal complex $Mo_2Pd_2(pyphos)_4$.

The short-bite ligand bis(diphenylphosphinoamine) ($Ph_2PNHPPh_2$, dppa) has received attention for assembling metal centers in bi- or polynuclear metal complexes owing to both its isoelectronic relationship with the more popular bis(diphenylphosphinomethane) ligand ($Ph_2PCH_2PPh_2$, dppm) and the increased reactivity of its N—H group compared with that of the CH_2 unit in dppm.[580,953–957] Thus, the greater acidity of the NH proton versus the CH_2 protons may facilitate subsequent functionalization reactions that would require too drastic conditions in the case of dppm. The synthesis of Co_2Pd and $MoPd_2$ mixed-metal clusters containing the dppa ligand[958] was reported. Heterometallic triangular clusters containing two dppa ligands or dppa and dppm (mixed ligand sets) have been prepared by direct incorporation of the second diphosphine ligand.[958]

The tetrametal complex $Mo_2Pd_2(pyphos)_4$ (pyphos = 6-diphenylphosphino-2-pyridonate), (see Figure 110), has a Pd^0—Mo^{II}—Mo^{II}—Pd^0 skeleton.[959]

The existence of a $Pd^0 \rightarrow Mo^{II}$ dative bond elongates the quadruple Mo_2 bond to some extent. This complex has two Pd^0 centers that can react with a variety of olefinic compounds, shown schematically in Figure 111; such reactions give $Mo_2Pd_2(pyphos)_4(L)_2$ [L = acrylonitrile, fumaronitrile, tetracyanoethylene] in moderate yields. Unlike the previous compounds which have a strictly *trans* arrangement of the P-donor atoms, the last compound has a *cis* arrangement and thus the four metals are not linear.[959]

The palladium(0) complex with dative $Pd^0 \rightarrow Mo^{II}$ bonds is very reactive toward oxidative addition reaction. Its treatment with dichloromethane at room temperature results in the formation of a palladium(II) complex, $Mo_2Pd_2Cl_2(CH_2Cl)_2(pyphos)_4$ (shown in Figure 112), which is a rare example of the oxidative addition of dichloromethane to a Pd^0 center, e.g., mononuclear Pd^0 complexes[960,961] and a dinuclear Pd^0 complex, $Pd_2(dpm)_3$ (dpm = bis(diphenylphosphino)methane).[585,781] The metal atoms, Pd, Mo, Mo, and Pd, are aligned linearly. Each of the palladium atoms is coordinated to a chlorine atom and a chloromethyl group in square-planar geometry.[959]

The palladium(I) complex $[Pd_2(\mu\text{-dppm})_2Cl_2]$ is used to generate mixed-metal systems. Most investigations have been concerned with the formation of A-frame complexes via insertion of small molecules, e.g., CO, SO_2, or RCN, into the M—M bond, or their reactivity towards nucleophilic metal reagents, such as carbonylmetalates.[824–827] For example, the reaction of $[Pd_2(\mu\text{-dppm})_2Cl_2]$ with the dianion $[Fe(CO)_4]^{2-}$ yielded the neutral heterotrinuclear complex $[Pd_2Fe(dppm)_2(CO)_4]$ by displacement of the two chloride ligands and the insertion of the iron group into one of the Pd—P bonds. Two Fe—Pd bonds were formed in the process.[827]

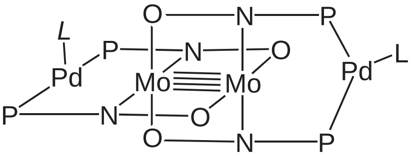

Figure 111 $Mo_2Pd_2(pyphos)_4(L)_2$ [L = acrylonitrile, fumaronitrile, tetracyanoethylene].

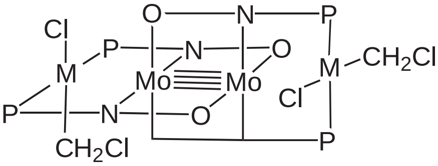

Figure 112 $Mo_2Pd_2Cl_2(CH_2Cl)_2(pyphos)_4$.

The reaction with $[Mn(CO)_5]_2$ or $[Co(CO)_4]_2$ also led to mixed-metal clusters.[962,963] Osmium–palladium mixed-metal carbonyl clusters were made using the unsaturated cluster $[Os_3(CO)_{10}(\mu\text{-}H)_2]$ and the carbido cluster $[Os_5(\mu_5\text{-}C)(CO)_{15}]$.[964–970] Treatment of $[Os_3(CO)_{10}(\mu\text{-}H)_2]$ with $[Pd_2(\mu\text{-dppm})_2Cl_2]$ afforded the novel high-nuclearity osmium–palladium mixed-metal carbonyl clusters $[Os_5Pd_6(CO)_{13}(\mu\text{-}CO)_5(\mu\text{-}H)_2(\mu\text{-dppm})_2]$, $[Os_5Pd_6(CO)_{13}(\mu\text{-}CO)_6(\mu\text{-dppm})_2]$, and $[Os_4Pd_6(CO)_8(\mu\text{-}CO)_8(\mu\text{-dppm})_2]$ in low yields, while the reaction of $[Os_5(\mu_5\text{-}C)(CO)_{15}]$ with $[Pd_2(\mu\text{-dppm})_2Cl_2]$ afforded $[Os_5Pd_4(\mu_6\text{-}C)(CO)_{12}(\mu\text{-}CO)_3(\mu\text{-dppm})_2]$ and $[Os_5(\mu_5\text{-}C)(CO)_{13}(\mu\text{-dppm})]$ in moderate yields.[289] The electron counts found in these osmium–palladium clusters do not always agree with those predicted by skeletal electron counting rules. This may simply be ascribed to the ability of Pd to be satisfied with both 16- and 18-electron counts.[289]

6.4.7.7 Nanoparticles

Transition metal nanoparticles have attracted a great deal of attention in the 1990s.[971–977] The method most generally used is the chemical or electrochemical reduction of a metal salt by a suitable reducing agent in the presence of stabilizers, which adsorb to the particle surface thus preventing agglomeration and controlling the particle size. Palladium nanoparticles were encapsulated in a dendrimer with a periphery featuring amino groups which interact with polyfluorinated carboxylic acids, the total architecture being soluble in perfluorinated phases.[978,979] These architectures catalyze the hydrogenation of alkenes.1,5-Bis(4,4′-bis(perfluorooctyl)-1,4-pentadien-3-one stabilizes palladium nanoparticles of 4–5 nanometers in diameter.[980] These nanoparticles are active in Heck and Suzuki reactions. Other compounds highly loaded with fluorine possess the same property.[981] In all cases a solution of $Na_2[Pd_2Cl_6]$ was reduced in methanol at 60 °C.

Giant noncrystalline *N*,*O*-ligated nanosized palladium clusters possess idealized formulations based upon concentric closed-shell metal cores: namely, five-shell Pd_{561} clusters[982–985] and mixtures of seven-shell Pd_{1415} and eight-shell Pd_{2057} clusters.[941] Zerovalent Pd complexes in organic solutions (e.g., THF) decompose under CO in the presence of PPh_3 to give PPh_3/CO-stabilized Pd nanosized particles that were investigated by spectroscopic methods; although the Pd particles were subject to size variations in solution, three distinct size-selected distributions were obtained with observed mean diameters determined from TEM indicating idealized two-shell Pd_{55}, three-shell Pd_{147}, and five-shell Pd_{561} cores.[942]

Metal nanowires have attracted much attention due to their potential magnetic, optical, electrical, and catalytic properties. The synthesis and characterization of novel necklace-shaped Pt—Pd nanowire in hybrid organic–inorganic mesoporous material was reported. The dry hybrid organic–inorganic mesoporous material was impregnated with an aqueous solution of $H_2PtCl_6{\cdot}6H_2O$ and H_2PdCl_4. The unique magnetic property of the Pt—Pd nanowires is also reported.[986]

Nanoparticles modified with organic monolayers may exhibit combined properties from their inorganic nuclei and their organic surfaces. The surface attachment of cyclodextrins (CDs) to palladium nanoparticles that catalyze the hydrogenation of allylamine has been reported. As opposed to classical Pd catalytic materials, these novel nanocomposites are soluble in aqueous media and can be easily recovered by precipitation with ethanol.[987] Solutions of $PdCl_4^{2-}$ sodium salts in DMSO–H_2O were readily reduced with BH_4^- in the presence of *per*-6-thio-β-cyclodextrin[988] (see Figure 113), leading to the isolation of dark precipitates. IR spectra show conversion of the H—S bonds in HS-β-CD to metal–thiolate bonds as the CD host chemisorbs on the surface of the metal nanoparticles. ^{1}H-NMR spectroscopy also provides experimental evidence that supports the presence of cyclodextrin in the dark precipitates.[987] TEM measurements verified

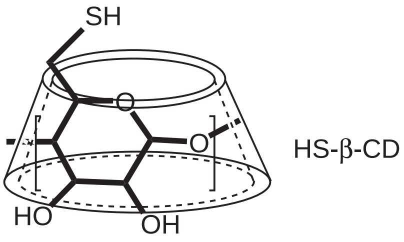

Figure 113 Structure of *per*-6-thio-β-cyclodextrin.

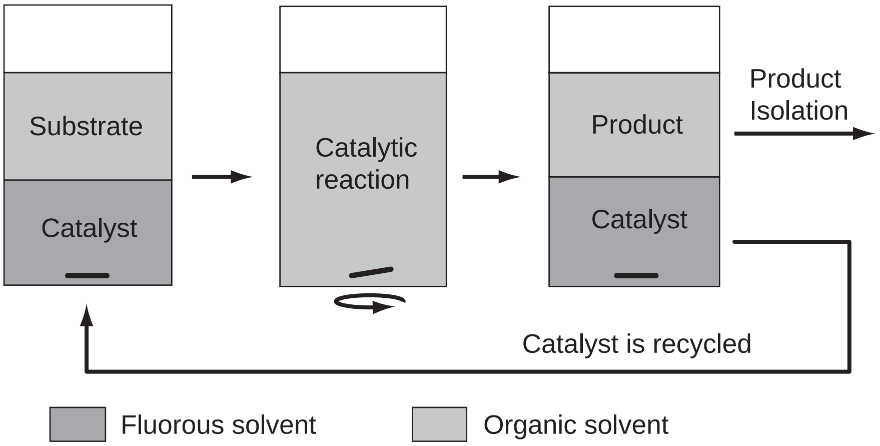

Figure 114 Biphasic catalysis in an organic/fluorous solvent system by Pd/dendrimer nanocomposites.

that these solid materials are composed of metal particles with dimensions in the nanometer range. The surface modified Pd colloidal particles reported in this work are active catalysts for the hydrogenation of allylamine in aqueous solution.[987]

The general approach to biphasic catalysis is illustrated in Figure 114.[989] The system consists of organic and fluorous layers. The catalyst is selectively soluble in the fluorous phase, while the reactants are preferentially soluble in the organic solvent. Stirring, sonicating, and/or heating of the mixture leads to formation of a fine emulsion and partial homogenization, and the catalytic reaction proceeds at the interface between the two liquids. When the reaction is over, the liquid phases are separated, the product is isolated from the organic phase, and the catalyst-containing fluorous layer is recycled. Many fluorous phase-soluble catalysts have been reported in the literature, including some based on metal complexes. Preparation of fluorous phase-soluble metal nanoparticles, however, has not been reported, prior to the study in reference.[978] Remarkably, the Pd/dendrimer nanocomposites are catalytically active in fluorous biphasic systems.[978] These new catalysts can be used for hydrogenation of a range of unsaturated compounds, and also for isomerization of terminal alkenes. The reaction selectivity resembles that of colloidal, rather than bulk, Pd catalysts.[978] The methodology is very simple to implement and the catalysts are easy to separate from the product and recycle. Taken together, these factors suggest that these materials are promising candidates for selective, environmentally friendly catalysis applications.[978]

6.4.8 PALLADIUM IN NEGATIVE AND FRACTIONAL OXIDATION STATES

6.4.8.1 Phosphorus

Balch *et al.*[560] prepared the cluster $[Pd_3(\mu\text{-dppm})_3(\mu_3\text{-I})(\mu_3\text{-PF}_3)]PF_6$ [dppm = bis-(diphenylphosphino)methane] (shown in Figure 115), which contains a PF_3 molecule triply bridging a central triangular Pd_3 core. However, exceptions are not limited to PF_3, an atypical phosphine often considered closer to carbon monoxide. For further examples, see the section on polynuclear Pd^I complexes.

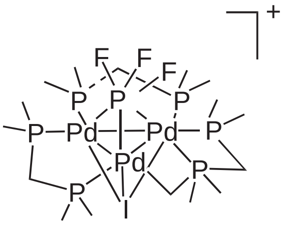

Figure 115 The cluster $[Pd_3(\mu\text{-dppm})_3(\mu_3\text{-I})(\mu_3\text{-PF}_3)]PF_6$ [dppm = bis-(diphenylphosphino)methane].

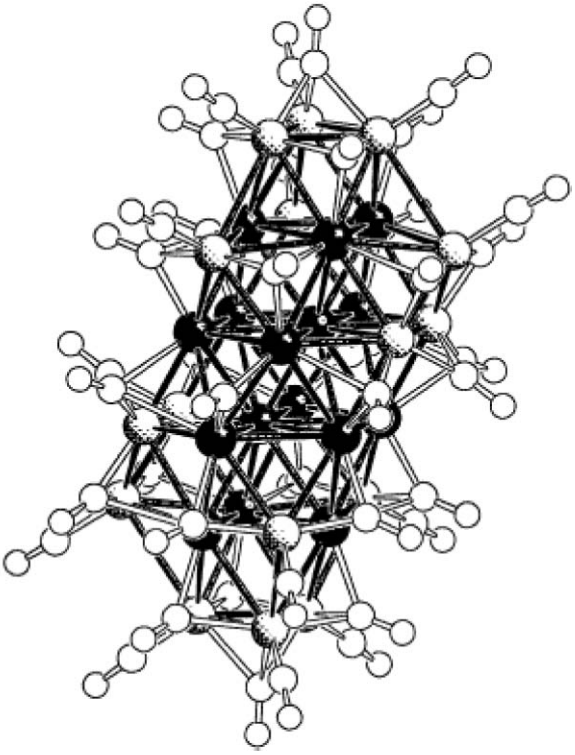

Figure 116 The structure of $[Ni_{16}Pd_{16}(CO)_{40}]^{4-}$.

6.4.8.2 Polynuclear Compounds and Polymers

Recent collision-induced dissociation studies on the gas phase $[Pd_3(CO)_6]^-$ cluster[925] supplement other experimental observations,[923,924,990–992] which seem to suggest the feasibility of derivatives. The synthesis of Ni—Pd homoleptic carbonyl bimetallic clusters (HCBCs) has been reported.[993] So far, only the related phosphane substituted derivative $[Ni_9Pd_{33}(CO)_{41}(PPh_3)_6]^{4-}$[951] and the trimetallic derivative $[Au_6Ni_6(Pd_{6-x}\,Ni_x)Ni_{20}(CO)_{44}]^{6-}$[994] have been reported. To our knowledge, the only Ni—Pd HCBC cited in the literature is the incompletely characterized $[Ni_{30\text{-}x}Pd_x(CO)_y]^{4-}$ ($x \approx 16$, $y \approx 36$) species, which has been used as a precursor for the synthesis of the giant complex $[Pd_{59}(CO)_{32}(PMe_3)_{21}]$.[856] Investigation of the reaction of $[Ni_6(CO)_{12}]^{2-}$ with Pd^{II} compounds in miscellaneous molar ratio and reaction solvents displayed the existence of wide series of Ni—Pd HCBCs. There is a report[993] on the synthesis, chemical properties, and X-ray structural characterization of the tetranion $[Ni_{16}Pd_{16}(CO)_{40}]^{4-}$, as well as preliminary details of the closely related hexaanion $[Ni_{26}Pd_{20}(CO)_{54}]^{6-}$. The structure of $[Ni_{16}Pd_{16}(CO)_{40}]^{4-}$ is shown in Figure 116. The black spheres represent the palladium atoms. The range of M—M bonds (Å) is: Ni—Ni 2.426(1)–2.473(1) Å, Ni—Pd 2.582(1)–2.825(1) Å, Pd—Pd 2.674(1)–2.930(1) Å. The Ni—Ni interlayer separations of the outer pair of layers are outside of the above range.[993]

6.5

Platinum

L. M. RENDINA and T. W. HAMBLEY
University of Sydney, NSW 2006, Australia

6.5.1 INTRODUCTION

The coordination chemistry of platinum is a massive field and a thorough survey of its coordination chemistry in a limited number of pages was simply impossible. Instead, what we have attempted to do is provide a flavor of this enormous range of chemistry.

6.5.2 PLATINUM(0)

The chemistry of platinum(0) is overwhelmingly dominated by phosphine complexes with the general formula $[Pt(PR_3)_n]$ ($n = 2$–4). These complexes undergo various types of oxidative addition reactions, activating a wide variety of bonds. The stability of the complexes depends on the steric bulk of the phosphine ligand with the bulkier ligands stabilizing the lower coordination numbers.

6.5.2.1 Platinum(0) Complexes with Phosphorus Donor Ligands

6.5.2.1.1 Synthesis

A variety of methods have been reported for synthesizing platinum(0) tertiary phosphine complexes and a range of standard methods have been described in a series of reports in

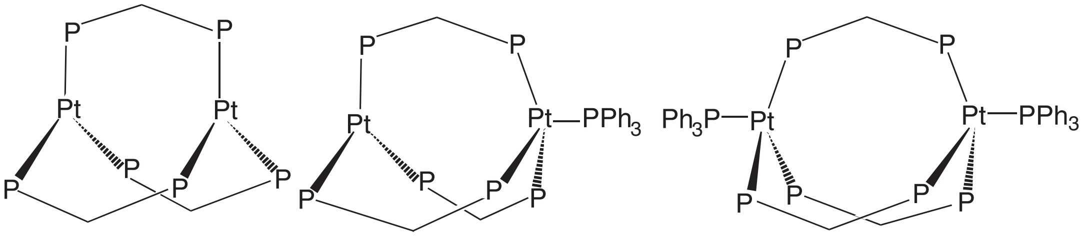
Inorganic Syntheses.[1–5] In addition, a number of novel methods have been reported for preparing such complexes, particularly those that are more unstable and cannot be prepared by the standard methods. For example, in contrast to bulkier analogues, the two-coordinate, 14-electron complex $[Pt(PPh_3)_2]$ is not stable, but can be prepared by bulk reductive electrolysis of *cis*-$[PtCl_2(PPh_3)_2]$.[6] The ethyl analogue $[Pt(PEt_3)_2]$ can also be produced by electrolysis.[7] These complexes are too reactive to be isolated, but they can be trapped by reaction with O_2, HCl,[8,9] MeI, PhCOCl, or alkynes.[7] $[Pt(PEt_3)_2]$ can also be prepared photochemically by UV irradiation of $[Pt(C_2O_4)(PEt_3)_2]$ via reductive elimination of oxalate as CO_2.[8,9] The generation of $[Pt(PPh_3)_2]$ under phase transfer conditions (benzene/60% KOH-18-crown-6) has been reported,[10] and its subsequent reaction with a variety of ligands ranging from CO, phosphines, and alkenes gives products in high yield.

6.5.2.1.2 Platinum(0) dimers

The characterization and crystal structure of the dimer $[Pt_2(\mu\text{-dppm})_3]$ (dppm = bis(diphenylphosphino)methane), first reported as a deep red complex in 1978, was described by Manojlović-Muir *et al.* in 1986.[11] The structure, the first of its type, is made up of two parallel and almost eclipsed trigonal-planar platinum moieties bridged by three diphosphine ligands. The Pt···Pt separation is 3.0225(3) Å, too long to be considered a bond.[11] $[Pt_2(\mu\text{-dppm})_3]$ catalyzes the hydrogenation/reduction of carbon dioxide with dimethylamine to give dimethylformamide[12] (Equation (1)) and the reverse reaction.[13]

$$CO_2 + H_2 + Me_2NH \rightleftharpoons HC(=O)NMe_2 \qquad (1)$$

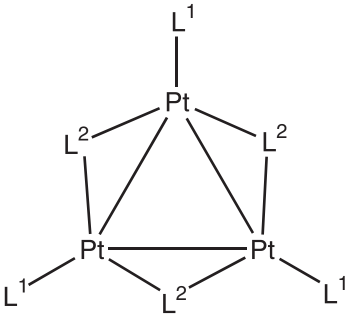
The characterization of two other types of novel platinum(0) dimer was reported at about the same time. Reaction of $[Pt(PPh_3)_3]$ with a bidentate diphosphine produced either $[Pt_2(\mu\text{-}R_2PCH_2PR_3)_3(PPh_3)]$ (R = Me or Et) or $[Pt_2(\mu\text{-}R_2PCH_2PR_3)_3(PPh_3)_2]$ (R = Ph or OEt).[14] Both structures can be thought of as deriving from the $[Pt_2(\mu\text{-dppm})_3]$ dimer by the addition of a PPh_3 to one or both platinum centers. Thus, one has one three-coordinate and one four-coordinate platinum and the other two four-coordinate platinum atoms (**1**).



(**1**)

6.5.2.1.3 Platinum(0) trimers

Numerous examples of 42-electron trinuclear platinum(0) clusters of the type $[Pt_3(\mu\text{-}L^2)_3L^1_3]$ (**2**) have been reported,[15,16] including recent examples with polyaromatic phosphine ligands incorporating naphthyl groups.[17] However, there have been few studies of their properties and reactions. Their electronic spectra are dominated by metal-to-ligand charge transfer (MLCT) transitions.[18] The terminal ligands in $[Pt_3(\mu\text{-CO})_3L_3]$ (L = bulky phosphine) undergo facile ligand exchange on a time scale of seconds to minutes.[19] Scrambling of the carbonyl ligands also occurs, but on a time scale of hours. Reaction with CS_2, OCS, and SO_2 results in fragmentation to dimeric species such as $[Pt_2(\mu\text{-}CS_2)_2(\text{phosphine})_2]$.[19] Reaction of $[Pt_3(\mu\text{-CO})_3(PCy_3)_3]$ with 3 or 5 mole-equivalents of 2,6-xylylisocyanide results in displacement of two or three of the bridging carbonyl ligands and one or two of the terminal phosphine ligands to give $[Pt_3(\mu\text{-CO})(\mu\text{-}CNC_8H_9)_2(CNC_8H_9)(PCy_3)_2]$ and $[Pt_3(\mu\text{-}CNC_8H_9)_2(CNC_8H_9)_2(PCy_3)]$.[20]



(**2**)

Reaction of $[Pt_3(\mu\text{-}SO_2)_3\{P(Cy)_3\}_3]$ with 2,6-xylyl isocyanide results in displacement of one or at most two of the SO_2 ligands by the isocyanide.[21] Similarly, carbon monoxide usually only partially displaces the SO_2, but the addition of trimethylamine *N*-oxide (Me_3NO) facilitates the substitution leading to formation of $[Pt_3(\mu\text{-}CO)_3\{P(Cy)_3\}_3]$.[22] Me_3NO also facilitates substitution of one SO_2 ligand by halides and azide.[22]

The propensity of $[Pt_3(\mu\text{-}CO)_3(CO)_3]$ clusters to oligomerize into chains of the type $[Pt_3(\mu\text{-}CO)_3(CO)_3]_n^{2-}$ ($n = 2$–6, 10) has been analyzed and the need for the additional two electrons is discussed in terms of the electronic structure of the oligomers.[23]

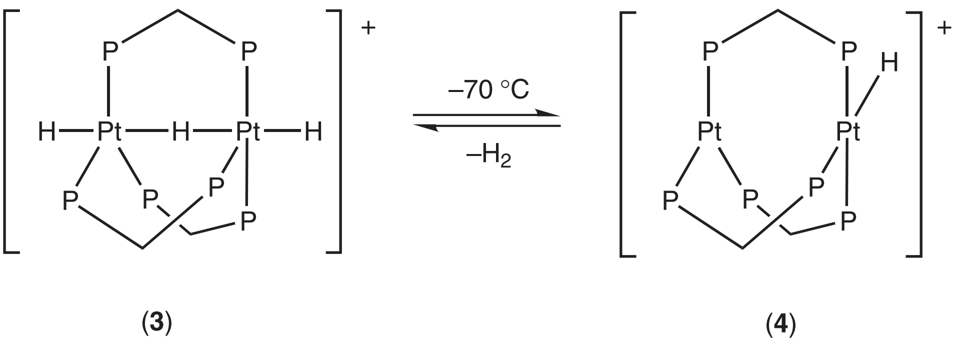
6.5.2.1.4 Hydrides

The $[Pt(PR_3)_n]$ ($n = 2$–4) complexes are quite basic and will react with protic acids, generally yielding platinum(II) hydride complexes. For example, $[Pt(PR_3)_2]$ ($R_3 = (Bu^t)_3$ and $(Bu^t)_2Ph$) react with the ammonium cation to give platinum(II) complexes *trans*-$[PtH(NH_3)(PR_3)_2]X$ ($X = PF_6^-$ or ClO_4^-).[24] Protonation of the dimeric platinum(0) complexes $[Pt_2(\mu\text{-}R_2PCH_2PR_2)_3(PPh_3)_n]$ ($n = 0$, R = Ph or Et; $n = 1$, R = Me; $n = 2$, R = EtO) gives rise to the dimeric platinum(I) species $[Pt_2H(\eta^1\text{-dppm})(\mu\text{-dppm})_2]$ when R is phenyl and different structural forms of the dimeric platinum(II) complexes $[Pt_2H_2(\mu\text{-}R_2PCH_2PR_2)_2]$ when R is one of the smaller groups, Me, Et, or EtO.[25] Reaction of $[Pt(Cy_2P(CH_2)_nPCy_2)]$ ($n = 2$–4) with hydrogen gives rise to complexes $[PtH_2(Cy_2P(CH_2)_nPCy_2)]$ that can be described as either *cis* platinum(II) dihydrides or platinum(0) η^2-dihydrogen complexes.[26] Interchange of the hydrogen atom positions and the ready loss of dihydrogen on heating are consistent with a dynamic process involving an exchange between these two alternatives. The dihydrides give rise to bridged platinum(I) species $[Pt(\mu\text{-}H_2)(Cy_2P(CH_2)_nPCy_2)]$ on standing.[26]

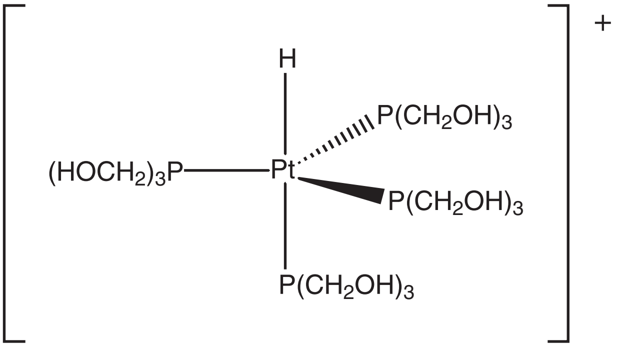
Protonation of $[Pt(PR_3)_3]$ complexes is known to be reversible because they have been used to activate H_2O for hydrogen–deuterium exchange. However, it has recently been shown that the protonation state and oxidation state can be readily controlled by adjusting the pH.[27] Thus, adding acid to a solution of the platinum(0) complex $[Pt(TPPTS)_3]$ ($TPPTS = P(m\text{-}C_6H_4SO_3Na)_3$) gives the platinum(II) hydride $[PtH(TPPTS)_3]$, and addition of base results in reversion to the platinum(0) complex. These reactions are slow indicating a substantial activation barrier, perhaps due to the energy needed to convert from the tetrahedral platinum(0) to the square-planar platinum(II).[27] A novel platinum(0)–platinum(II) hydride (**4**) has been reported to result from the reversible decomposition of the platinum(II) hydride (**3**) (Scheme 1).[28] (R_P)-phenylphosphinate adds to $[Pt(PEt_3)_4]$ to give the platinum(II) hydride $[PtH\{P(=O)Ph(OR)\}(PEt_3)_2]$ with retention of the configuration at the phosphorus.[29]

6.5.2.1.5 Unusual platinum(0) complexes

The first monometallic anionic platinum(0) complex, $[Pt(Me_2NCS_2)(PEt_3)]^-$ was prepared *in situ* by hydrogen abstraction from the platinum(II) hydride, $[PtH(Me_2NCS_2)(PEt_3)]$.[30] This complex has not been isolated, but it has been trapped by reaction with Ph_3SnCl, MeI, and I_2 giving a range of platinum(II) complexes.[30]



Scheme 1



(**4**)

The first platinum complex of buckminsterfullerene (C_{60}) was prepared by reacting the ethene complex $[Pt(\eta^2\text{-}C_2H_4)(PPh_3)_2]$ with C_{60} in toluene solution yielding black crystals of $[Pt(\eta^2\text{-}C_{60})(PPh_3)_2]$ in 2 hours.[31] Reaction of $[Pt(PEt_3)_4]$ with C_{60} in benzene yielded the hexasubstituted complex $[\{Pt(PEt_3)_2\}_6(\eta^2\text{-}C_{60})]$.[32] Reaction of $[Pt(\eta^2\text{-}C_2H_4)(PPh_3)_2]$ with C_{70} in benzene in appropriate ratios yielded mono-, di-, tri-, and tetra-substituted complexes, but higher levels of substitution could not be achieved.[33] In all complexes, the bonding between the platinum and the fullerene is very similar to that in platinum(0) ethene complexes. Coordination to platinum shifts the reduction potentials of the C_{60} to more negative potentials and the reduction is accompanied by loss of the diphosphineplatinum(0) moieties.[34] More recently, a platinum moiety with a chelating diphosphine ligand has been coordinated to C_{60} by first reacting the fullerene with $[Pt(COD)_2]$, giving $[PtC_{60}]$ in quantitative yield, and then reacting this species with the diphosphine.[35] $[PtC_{60}]$ had been reported previously, obtained by reaction of the fullerene with $[Pt(dba)_2]$ (dba = 1,5-diphenylpenta-1,4-dien-3-one).[36]

Platinum(0) complexes of monodentate and bidentate dendrimer–phosphine ligands were prepared by reaction with $[PtCl_2(COD)]$ (COD = cyclooctadienes) followed by borohydride reduction.[37] The monodentate ligands gave $[PtL_3]$ complexes and the bidentate $[Pt(L\text{-}L)_2]$. The former complexes readily underwent oxidative addition reactions indicating that the metal centers remained accessible in the dendrimeric structure. Molecular modeling of these complexes revealed nanoscale structures with approximate diameters of 4.4 nm.[37]

Tri-*n*-butylphosphite, tri-*n*-butylarsine, and tri-*n*-butylstibine complexes of platinum(0) have been prepared by the reaction of the ligand with $[Pt(COD)_2]$ or, in the case of the phosphite, by reaction with $[Pt(PPh_3)_4]$.[38] All form four-coordinate complexes when 4 mole-equivalents of ligand are used, but when 2 or 3 mole-equivalents of the phosphite ligand are used, mixtures of three- and four-coordinate complexes are observed.[38]

The first reported example of an η^2-bonded nitroso ligand was in the complex $[Pt(PPh_3)_2(PhNO)]$.[39]

6.5.2.1.6 Unusual phosphine ligands

The effectiveness of platinum(0) complexes of phosphines as catalysts has led to the synthesis of a wide variety of complexes with phosphines that confer solubility in a range of solvents or have unusual electronic properties. Water-soluble complexes are of particular interest because of their potential as immobilized homogeneous catalysts. Tris(hydroxymethyl)phosphine forms a water soluble platinum(0) complex, $[Pt\{P(CH_2OH)_3\}_4]$, which is a catalyst for the addition of PH_3 to formaldehyde.[40,41] In aqueous solution $[Pt\{P(CH_2OH)_3\}_4]$ exists in an equilibrium with a five-coordinate platinum(II) hydride (**4**). $[Pt\{P(CH_2OH)_3\}_4]$ can be formed by the reaction of these reagents with $K_2[PtCl_4]$ or $Na_2[PtCl_6]$ in a self-replicating reaction.[40] A similar example of self-replication has been reported for the synthesis of tris(cyanoethyl)phosphine (tcep) from PH_3 and $CH_2{=}CHCN$, catalyzed by $[Pt(tcep)_3]$.[42] The platinum complex is a more effective catalyst for this process than are either the nickel or palladium analogues.

The replacement of one or all of the phenyl groups in triphenylphosphine with pyridine confers water solubility on the platinum(0) complexes, but has interesting effects on their properties.[43] For instance, the trispyridylphosphine ligand forms the tetrakis complex $[Pt(Ppy_3)_4]$, but not the analogous tris complex. The reverse reaction is observed for the pyridyldiphenylphosphine ligand with only $[Pt(PPh_2py)_3]$ observed.[43] Both complexes undergo oxidative addition with MeI, but only the latter reacts with gaseous HCl.[43]

Phosphite complexes of platinum(0) have received substantially less attention than have phosphine complexes.[44] $[Pt\{P(OC_6H_4OMe\text{-}2)_3\}_3]$ can be prepared by reduction of the $[PtCl_2\{P(OC_6H_4OMe\text{-}2)_3\}_2]$ complex in the presence of the phosphite or by the reaction of the phosphite with tris(η^2-norbornene)platinum(II).[44] Alkene complexes of bis(phosphite)platinum(II) can be prepared in a similar manner to the analogous phosphine complexes.[44]

6.5.2.1.7 *Oxidative addition reactions of platinum(0) complexes*

Platinum(0) phosphine complexes undergo a variety of oxidative addition reactions with compounds containing Group 14 elements. These reactions are of widespread interest because similar processes are probably involved in the catalysis by platinum complexes of reactions such as the hydrosilation of alkenes and the disilylation of dienes and alkenes.

(i) Tellurides

Silyl, germyl, and stanyl tellurides, ($RTeMMe_3$), react readily with $[Pt(PEt_3)_3]$ in hexane at 25 °C to give *trans*-$[Pt(RTe)(MMe_3)(PEt_3)_2]$ ($M = Si$, Ge, Sn; $R = Ph$, 4-biphenyl, Bu, Me_3Sn).[45] A slower reaction was observed for the selenide (PhSeTMS), but no reaction was observed with the analogous sulfide.[45]

(ii) M—M (M = Si, Ge, Sn)

$[Pt(PEt_3)_3]$ cleaves the Si—Si bond in the halodisilanes, $XMe_2Si{-}SiMe_2Y$ (X, Y = F, F; Cl, Cl; Cl, Me; Br, Me), yielding *cis*-$[Pt(XMe_2Si)(YMe_2Si)(PEt_3)_2]$ whereas IMe_2Si—TMS oxidatively adds at the Si—I bond to give *trans*-$[PtI(TMS{-}SiMe_2)(PEt_3)_2]$.[46] The 1,2-dihydrosilane, $HMe_2Si{-}SiMe_2H$ similarly reacts with $[Pt(PEt_3)_3]$ to give *cis*-$[Pt(HMe_2Si)_2(PEt_3)_2]$ as well as oligosilanes.[47] HMe_2Si—TMS and TMS—TMS gave oligomeric species, but no silicon bonded Pt complexes.[47] The products of these reactions are probably the catalytically active intermediates in the addition of Si—Si bonds to unsaturated complexes.[48] Pham and West reported that platinum(0) diphosphines reacted with 1,2-dihydrosilanes to give disilene platinum complexes.[49,50]

The Ge—Ge bond in $ClMe_2Ge{-}GeMe_2Cl$ oxidatively adds to $[Pt(PEt_3)_3]$ to give *cis*- and *trans*-$[Pt(ClMe_2Ge)_2(PEt_3)_2]$.[51] Similarly, the organodistannane $Me_3Sn{-}SnMe_3$ reacts with $[Pt(PR_3)_4]$ to give *cis*- and *trans*-$[Pt(Me_3Sn)_2(PR_3)_2]$, $R_3 = Ph_3$, *p*-Tol_3, Ph_2Me.[52] The crystal structure of the complex with $R_3 = p\text{-}Tol_3$ reveals a highly twisted square-planar structure with the *cis* geometry, presumably brought about by the steric bulk of the ligands.[52]

The trimeric platinum(0) complex $[Pt_3(CNBu^t)_6]$ undergoes a double oxidative addition reaction with 2,2-bis(disilanyl)dithiane to give tetrakis(organosilyl)bis(*t*-butylisocyanide)platinum(IV) complexes.[53] The Si—Ge bonds in bis(silylgermyl)dithiane are also cleaved by $[Pt_3(CNBu^t)_6]$ giving analogous platinum(IV) complexes with Pt—Si and Pt—Ge bonds.[53]

(iii) Si=Si

Disilenes are generally unstable with respect to polymerization. However, if very bulky groups are attached to the silicon atoms then they can be obtained as stable compounds.[54] Such disilenes react with *in situ* generated [Pt(PR_3)$_2$] to give disilene complexes analogous to alkene complexes.[50]

(iv) M—X (M = Si, Ge, Sn, X = halide)

Early attempts at the oxidative addition of Si—X bonds to transition-metal complexes failed, but Tanaka and co-workers showed that when X = Br or I, the reactions are quite facile.[55,56] For instance, TMS–Br reacts with [Pt(PEt_3)$_3$] in benzene solution at 90 °C to give *trans*-[PtBr(TMS)(PEt_3)$_2$].[55] However, there is no reaction with [Pt(PPh_3)$_4$] nor do chlorosilanes react. In general, the order of reactivity for the silanes TMSX were X = Cl (no reaction) ≪ Br < I and for the platinum complexes [Pt(PPh_3)$_4$], [Pt(dppe)$_2$] (no reaction) ≪ [Pt(PMe_2Ph)$_4$] < [Pt(PMe_3)$_4$] < [Pt(PEt_3)$_3$].[56] As mentioned above (Section 6.5.2.1.7(ii)), cleavage of the Si—I bond is favored over cleavage of the Si—Si bond.[46] In contrast, the Ge—Cl bond in Me_2GeCl_2 is cleaved by [Pt(PEt_3)$_3$] to give *trans*-[PtCl($ClMe_2Ge$)(PEt_3)$_2$].[51]

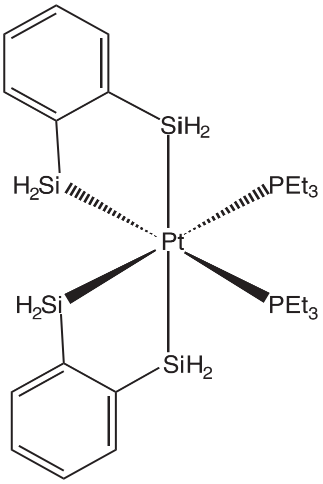
In alcohols, [Pt(PPh_3)$_4$] undergoes a double oxidative addition reaction with $SnCl_2{\cdot}2H_2O$ to give the octahedral platinum(IV) complex [PtCl(H)(OEt)($SnCl_3$)(PPh_3)$_2$].[57] When $SnCl_4{\cdot}5H_2O$ is used, a similar product, believed to be a different isomer, is observed. Similar reactions are also observed in 1-propanol and 1-butanol, but in isopropanol the product is a binuclear nonhydrido complex [PtCl(OPr^i)($SnCl_3$)$_2$(PPh_3)$_2$]$_2$ with bridging chloro ligands.[57]

6.5.2.1.8 Addition reactions of silanes

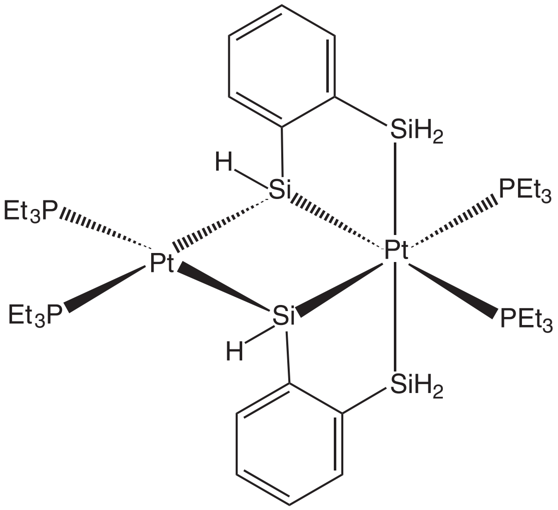
Many catalytic reactions involve the activation of Si—H bonds and consequently the reaction of silanes with platinum(0) has been studied extensively. The reactions of hydrosilanes with transition-metal complexes, including platinum, has been extensively reviewed by Corey and Braddock-Wilking.[58]

(i) $SiRH_3$

1,2-Disilylbenzene reacts with [Pt(PEt_3)$_3$] to give a tetrakis(silyl)platinum(IV) complex (**5a**), which when reacted with additional amounts of [Pt(PEt_3)$_3$], gave a novel platinum(II)/platinum(IV) complex (**5b**).[59] [Pt(PEt_3)$_3$] reacts with $SiArH_3$ (Ar = Ph, mesityl, *p*-toluene) in a 2:1 ratio to give the dimeric complex shown in (**6**) and in a 1:3 ratio to give monomeric *cis*-[Pt(SiH_2Ar)$_2$-

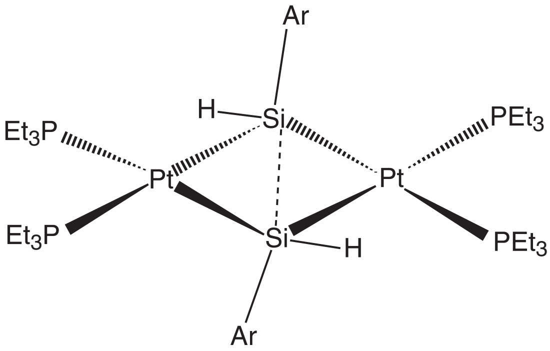


(**5a**)

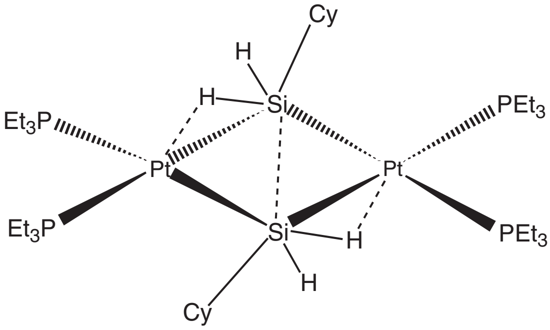


(**5b**)

$(PEt_3)_2]$.[60] When $[Pt(PEt_3)_3]$ or $[Pt(PPr_3)_3]$ reacts with the bulkier silane Si(*n*-hexyl)H_3, two dimeric products are observed, one with a short Si···Si contact analogous to that shown in (**6**) and the other with a short Pt···Pt contact (**7**).[61]



(**6**)

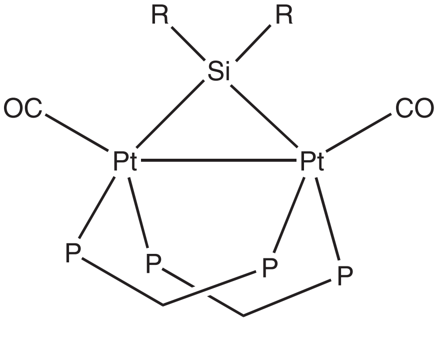


(**7**)

(ii) SiR_2H_2

Reaction of $SiAr_2H_2$ (Ar = Ph or *p*-C_6H_4F) with $[Pt(PEt_3)_4]$ yields *cis*-$[Pt(SiH_2Ar)_2(PEt_3)_2]$ in contrast to reaction with *cis*-$[PtEt_2(PMe_3)_2]$, which yields the unstable *trans* isomer.[62]

The dimeric complex $[Pt_2(\mu\text{-CO})(CO)_2(\mu\text{-dppm})_2]$ reacts with the secondary silanes $SiMe_2H_2$, $SiEt_2H_2$, $SiPh_2H_2$, and $SiMePhH_2$ to give complexes of the type $[Pt_2(\mu\text{-SiR}_2)(CO)_2(\mu\text{-dppm})_2]$ (**8**).[63]



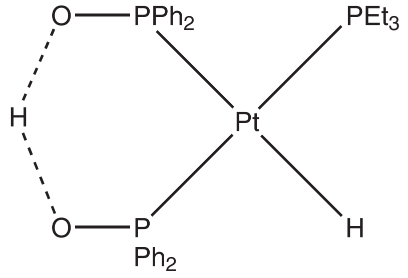
(**8**)

(iii) SiR_3H

There are relatively few examples of the reaction of platinum(0) with tertiary silanes. A novel example is the reaction of $[Pt(PEt_3)_4]$ with the rhodium complex $[RhCl(H)(SiAr_3)(P(Pr^i)_3)_2]$, which results in silane transfer to give the platinum(II) complex *cis*-$[PtH(SiAr_3)(P(Pr^i)_3)_2]$.[64]

6.5.2.1.9 Other reactions

The alkenylphosphine oxide $Ph_2P(O)H$ reacts with $[Pt(PEt)_3]$ at room temperature to give *cis*-$[PtH(P(O)Ph_2)(P(OH)Ph_2)(PEt_3)]$ (**9**), the crystal structure of which reveals a novel intramolecular hydrogen bond.[65]



(**9**)

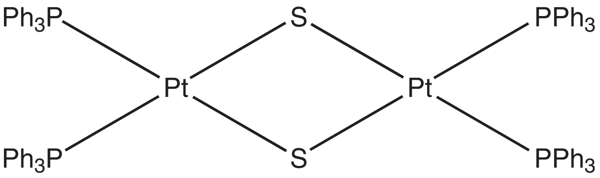
The complex, $[Pt(np_3)(PPh_3)]$ ($np_3 = N(CH_2CH_2PPh_2)_3$) with a tripodal ligand, dechlorinates $ClPEt_2$, undergoing oxidative addition to give a five-coordinate platinum(II) complex $[Pt(PEt_2)(np_3)]^+$.[66] The PEt_2 ligand in this complex can be protonated by HCl or methylated with methyl iodide to give $[Pt(PHEt_2)(np_3)]^{2+}$ or $[Pt(PMeEt_2)(np_3)]^{2+}$, respectively.[66]

The bis(β-diketone) 2,2,4,4-tetraacetyl-1,3-diselenetane reacts with $[Pt(PPh_3)_4]$, undergoing cleavage of the Se—Se bond to give the platinum(II) complex [Pt(2,4-pentanedione-3-selenolate)$(PPh_3)_2$].[67] $[Pt(PEt_3)_3]$ and $[Pt(PEt_3)_4]$ insert into the Te—C bond of Ph_2Te to give *trans*-$[PtPh(PhTe)(PEt_3)_2]$.[68] When mixed tellurides, R^1–Te–R^2, are used, mixtures of complexes are obtained with either R^1 or R^2 bound directly to the platinum.[68]

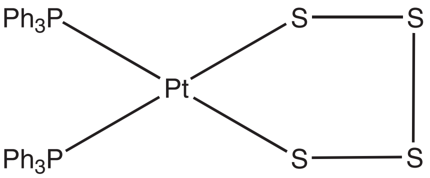
6.5.2.1.10 Reactions with chalcogens

Elemental sulfur reacts with $[Pt(PPh)_4]$ in ratios of three to six to give mixtures of $[Pt_2(\mu\text{-}S)_2(PPh)_4]$ (**10a**) and $[PtS_4(PPh_3)_2]$ (**10b**).[69] The former complex is alkylated at one bridging sulfido ligand by dichloromethane and chloroform to give $[Pt_2(\mu\text{-}S)(\mu\text{-}SR)(PPh)_4]$, $R = CH_2Cl$ and $CHCl_2$, respectively.[69]

Sulfur dioxide and carbon disulfide react with bis(bulky phosphine)platinum complexes to give monomeric trigonal planar $[Pt(PR_3)_2(SO_2)]$ and trimeric complexes such as $[Pt_3(\mu\text{-}SO_2)(PR_3)_2]$ and $[Pt_3(\mu\text{-}CS_2)(PR_3)_2]$ where R = Cy or Bu^t.[70,71]



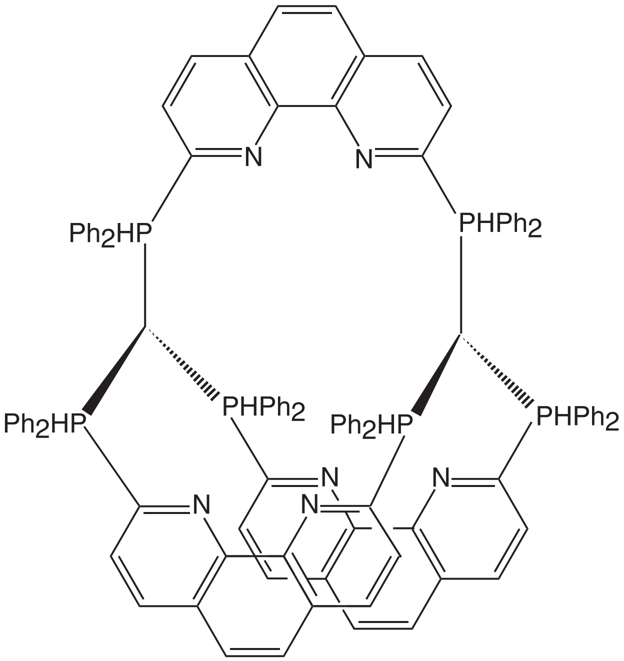
(**10a**)



(**10b**)

6.5.2.2 Platinum(0) Interactions with Other Metals

There are many examples of platinum(II) interacting with metals such as lead(II) or thallium(I) but few where the same metals interact with platinum(0). Catalano *et al.* have reported a series of metallocryptands such as the one shown in (**11**) that act as hosts for thallium(I)[72] and lead(II).[73] They have also reported an unsupported thallium(I) interaction with the platinum in $[Pt(PR_3)_3]$ (R = Ph or $R_3 = Ph_2py$).[74] The Pt···Tl separations in the cryptands (2.791–2.795 Å) are slightly shorter than those in the unsupported complexes (2.865–2.889 Å).[72,74]



(**11**)

6.5.2.3 Spectroscopy

The electronic absorption and MCD spectra of $[Pt(P(Bu^t_3)_2)]$ can be explained in terms of $5d \rightarrow 1\pi_u$ MLCT transitions.[75,76] The $5d_z$ orbital is not strongly involved in the P → M σ bonding. There is some M → P back bonding in these systems, but it does not add a lot to the stabilization. Thus, there is minimal 5*d* orbital involvement in the bonding and it mostly involves the 6*s* and $6p_z$ orbitals.[75,76]

The electronic absorption and emission bands of $[Pt_2(dppm)_2]$ are attributable to $d \rightarrow p\pi$ bonding.[77] The Pt–Pt stretching vibrations in the resonance Raman spectra are indicative of weak Pt—Pt bonds with a metal–metal separation of 3.024 Å and a force constant of 0.6 mdyne $Å^{-1}$.

6.5.2.3.1 Other platinum(0)complexes

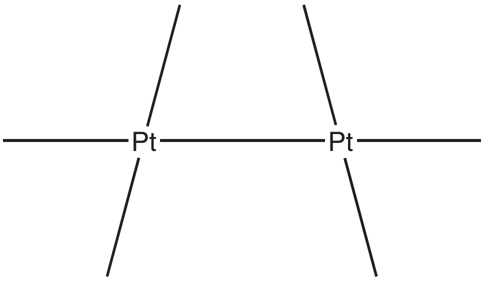
Bis(amido)-germylene and -stannylene react with $[Pt(COD)_2]$ to give the platinum(0) complexes $[Pt(M\{NTMS\}_2)_3]$, M = Ge or Sn.[78] The stannylene complex has a trigonal-planar structure with Pt—Sn bond lengths of 2.47–2.50 Å.[79]

6.5.3 PLATINUM(I)

The chemistry of platinum(I) is overwhelmingly dominated by the formation of Pt—Pt bonded dimers. In addition, there are mixed oxidation state clusters and these are dealt with in Section 6.5.6.

6.5.3.1 Unsupported Dimers

The great majority of platinum(I) complexes are binuclear with monofunctional or bifunctional bridging groups. However, there is also a series of unsupported dimers with the general structure shown in (**12**). These are generally stabilized by phosphine, carbonyl, and isocyanide ligands.[17] Dimeric hydride complexes can have terminal or bridging hydrides and these are discussed above in Section 6.5.2.1.4.

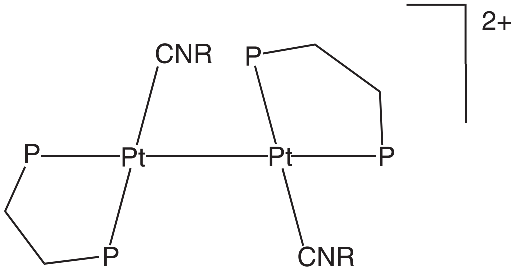


(**12**)

6.5.3.1.1 Preparations

Among the simplest of the unsupported dimers are the anions $[Pt_2X_4(CO)_2]^{2-}$ ($X = Cl^-$, Br^-, I^-). A high yielding method for preparing these complexes involves reaction of $[PtX_3(CO)]^-$ with controlled amounts of formic acid and NPr^i_3 in THF.[80] NMR studies revealed intramolecular exchange of CO and X, probably via a mechanism involving CO bridging. Asymmetrically bridging carbonyls have been reported in the structure of $[Pt_2Br_2(\mu\text{-CO})(PPh_3)_3]$, derived from $[Pt_2Br_4(CO)_2]^{2-}$ by reaction with PPh_3[81] and in the structure of the chloro analogue.[82]

The neutral dimer $[Pt_2Cl_2(RNC)_4]$, R = 2,4-Bu^t_2-6-MeC_6H_2, or 2,4,6-Bu^t_3-C_6H_2, has been prepared both by electrochemical reduction of *cis*-$[PtCl_2(RNC)_2]$ and by its reaction with zerovalent $[Pt_3(RNC)_6]$.[83,84] A similar reaction between divalent *cis*-$[Pt(C_6X_5)_2L_2]$ (X = F, L = CO, *p* = MeC_6H_4NC, $C_6H_{11}NC$, or Bu^tNC; X = Cl, L = CO or *p*–MeC_6H_4NC) and zerovalent $[Pt(\eta^2\text{-}C_2H_4)(PPh_3)_2]$ produced the platinum(I) complexes $[Pt_2(C_6X_5)_2L_2(PPh_3)_2]$.[85] Controlled potential electrolysis of $[Pt(2,6\text{-}Me_2C_6H_3NC)_4]$ gives dimeric $[Pt_2(2,6\text{-}Me_2C_6H_3NC)_6]$[86] and electrolysis of $[Pt(diphos)(RNC)_2](PF_6)_2$ (diphos = $Ph_2P\text{-}(CH_2)_n\text{-}PPh_2$ ($n = 2-4$) or $Bu^t_2P\text{-}(CH_2)_n\text{-}PBu^t_2$, R = 2,6-dimethylphenyl or 2,4,6-trimethylphenyl) gives dinuclear $[Pt_2(diphos)_2(RNC)_2](PF_6)_2$ (**13**).[87,88] Electrochemical reduction of $[Pt(RNC)_4]^{2+}$ (R = 2,6-$Me_2C_6H_3$, or 2,4-Bu^t_2-6-MeC_6H_2) and $[Pt(RNC)_2(dppm)]^{2+}$ (R = 2,6-$Me_2C_6H_3$) gives the cationic dimer $[Pt_2(RNC)_6]^{2+}$ along with trimeric and mixed metal complexes.[89]



(**13**)

Chemical reduction of $[PtCl_2(COD)]$ using $LiBHEt_3$ in the presence of CO and a phosphine yields $[Pt_2Cl_2(CO)_2(PR_3)_2]$ ($PR_3 = PNpPh_2$ and PFc_2Ph; Np = naphthyl, Fc = ferrocenyl).[17] The triflate complexes $[Pt(SO_3CF_3)_2(PP)]$ (PP = dppm or dppe; dppe = 1,2-bis(diphenylphosphino) ethane) are reduced in the presence of CO to give $[Pt_2(CO)_2(\mu\text{-dppm})_2]^{2+}$ or $[Pt_2(CO)_2(dppe)_2]^{2+}$.[90] Reaction of $[Pt_3(CO)_3(P\text{-}Bu^t_2Ph)_3]$ with HCl at −50 °C initially results in the formation of platinum(II) complexes, but these slowly convert to the dimeric platinum(I) complex $[Pt_2Cl_2(CO)_2(P\text{-}Bu^t{}_2Ph)_2]$.[91]

The first homoleptic, dinuclear platinum(I) carbonyl complex $[Pt_2(CO)_6]^{2+}$ has been prepared by dissolving PtO_2 in concentrated sulfuric acid under a CO atmosphere.[92,93] The structure is rigid on the NMR time scale at room temperature. DFT studies suggested a staggered structure for the dimer.[92,93]

6.5.3.1.2 *Reactions*

The hexakis(methyl isocyanide) dimers, $[Pt_2(CNMe)_6]$, undergo photolytic cleavage of the Pt—Pt bond to give 15-electron radicals, $Pt(CNMe)_3$.[94] Mixtures of platinum and palladium dimers give rise to heteronuclear complexes under photolytic conditions. Mixtures of normal and deuterium-labeled methyl isocyanide complexes reveal that the metal–ligand bonds undergo thermal redistribution.[94]

6.5.3.2 Hydride Complexes

6.5.3.2.1 *Structures*

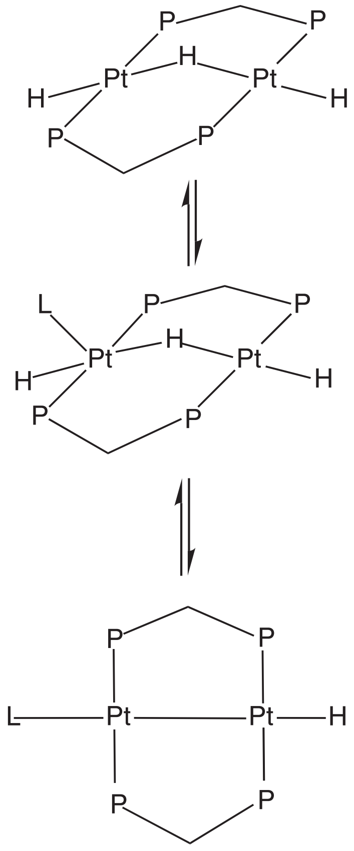
The hydride complexes of platinum(I) fall naturally between the supported and unsupported dimers because they range from one to the other. On going from nickel to platinum, there is a decreasing tendency for hydride ligands to bridge,[95] although there are examples of both bridging and terminal hydrides. *bis*Dihydride diphosphine platinum(II) complexes have a tendency to decompose to give dimeric platinum(I) complexes. For example, $[Pt(\mu\text{-}H)(Cy_2P(CH_2)_nPCy_2)]_2$ ($n = 2$–4) is formed from the *cis*-dihydride on standing.[26] It is also formed by reaction of the ethylene complex with hydrogen gas.[26] A similar complex, $[Pt(\mu\text{-}H)(dppe)]_2$ is obtained by reacting $[PtCl_2(dppe)]$ with $LiBEt_3H$, a reaction that proceeds via the *cis*-dihydride.[96] $[Pt(\mu\text{-}H)(dppe)]_2$ is a strong base and reacts with protic solvents such as methanol to give the hydride bridged platinum(II) complex ($[PtH(dppe)(\mu\text{-}H)_2Pt(dppe)]^+$.[96] Schwartz and Anderson similarly found that the *cis*-dihydrides $[PtH_2(PP)]$ ($PP = Pr^i{}_2P(CH_2)_2PPr^i{}_2$, $Cy_2P(CH_2)_2PCy_2$, or $Bu^t{}_2P(CH_2)_2PBu^t{}_2$) formed dimeric platinum(I) complexes in solution and established that the hydrides are terminal rather than bridging.[95] Fryzuk *et al.* also found terminal hydrides in the closely related complex $[PtH(PP)]_2$ ($PP = Pr^i{}_2P(CH_2)_3PPr^i{}_2$).[97] In contrast, Bennett and Roddick reported that the hydrides in $[PtH(dfepe)]_2$ are bridging and the Pt—Pt distances (2.7–2.8 Å) are more consistent with this description than those in the complexes mentioned above (2.5–2.6 Å).[98]

6.5.3.2.2 *Reactions*

The A-frame hydride $[Pt_2H_2(\mu\text{-}H)(\mu\text{-}dppm)_2]$ undergoes reductive elimination of H_2 in the presence of tertiary phosphine ligands, L, to give the platinum(I) dimer, $[Pt_2HL(\mu\text{-}dppm)_2]$. Hill and Puddephatt have shown that this occurs via the intermediate $[Pt_2H_2(\mu\text{-}H)L(\mu\text{-}dppm)_2]$ (**14**).[99] Carbon monoxide reacts rapidly and reversibly with $[PtH(\mu\text{-}PP)_2Pt(CO)]^+$, $PP = R_2P\text{–}CH_2\text{–}PR_2$, R = Et or Ph, to give $[PtH(\mu\text{-}PP)_2Pt(CO)_2]^+$ and $[PtH(CO)(\mu\text{-}PP)_2Pt(CO)_2]^+$, the first reported mixed valence, platinum(0)–platinum(II) complexes.[100]

6.5.3.3 Phosphine-bridged Dimers

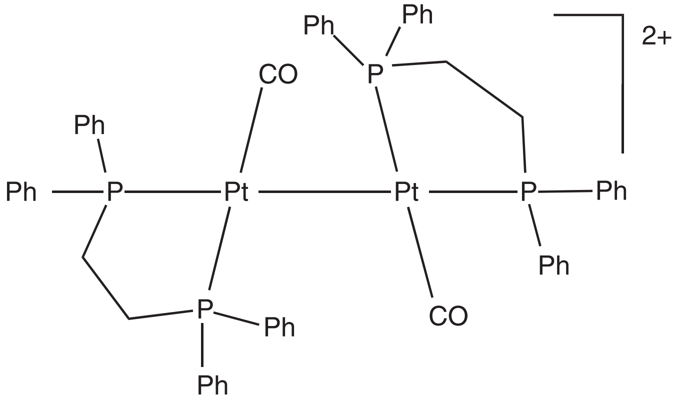
Phosphine-bridged dimers form the largest group of platinum(I) complexes. The most efficient bridging phosphines are those with a single central atom, $R_2P\text{–}CH_2\text{–}PR_2$ and the tendencies of these and longer chain phosphines are exemplified by the reactions of $[Pt(triflate)_2(PP)]$ ($PP = Ph_2P\text{–}(CH_2)_n\text{–}PPh_2$, $n = 1$ or 2) with carbon monoxide. When $n = 2$, the product is the unbridged complex, (**15a**), and when $n = 1$ it is the bridged complex, (**15b**).



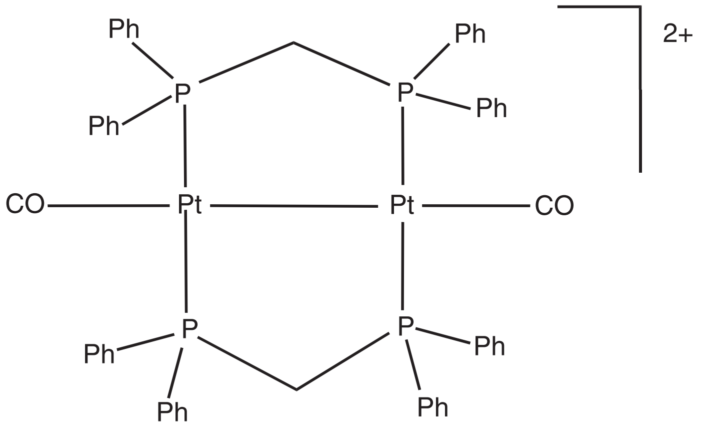
(**14**)

6.5.3.3.1 *Preparation of phosphine-bridged dimers*

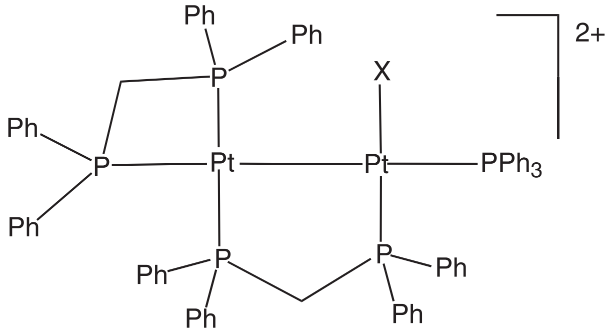
The asymmetric platinum(I) dimer $[Pt_2Cl(PPh_3)(\mu\text{-dppm})_2]^+$ is the only product of the reaction of $[Pt_2Cl_2(\mu\text{-dppm})_2]$ with PPh_3 in relatively nonpolar solvents.[101] Only in more polar solvents such as methanol are both chloro ligands replaced by the phosphine and the product, $[Pt_2(PPh_3)_2(\mu\text{-dppm})_2]^{2+}$, reacts with halides ($Cl^-$, Br^-, I^-) in dichloromethane to give the asymmetric dimer.[101] An intermediate in these processes is the complex shown in (**16**), which has both bridging and chelating dppm ligands. The X-ray crystal structure of the PF_6^- salt of the asymmetric dimer reveals that the PPh_3 coordinated platinum is tetrahedrally distorted as a result of steric clashes between the phosphine ligands.[102]



(**15a**)



(**15b**)



(**16**)

A mixed palladium/platinum dimer, [PtX(μ-dppm)$_2$Pd(C_6F_5)] (X = Cl, Br, or C_6F_5) has been prepared by the reaction of [PdX(C_6F_5)(η^1-dppm)$_2$] with [Pt(COD)$_2$] or [Pt(PPh_3)$_4$].[103]

6.5.3.3.2 Reactions of phosphine-bridged dimers

Bridged phosphine complexes of the type [Pt_2X_2(μ-dppm)$_2$] undergo reactions with a variety of substrates to give either the A-frame complexes [Pt_2X_2(μ-Y)(μ-dppm)$_2$]$^{n+}$, and/or the substituted platinum(I) dimers, [Pt_2XY(μ-dppm)$_2$]$^{n+}$ and [Pt_2Y_2(μ-dppm)$_2$]$^{n+}$, depending on the nature and proportion of the substrate used. Isocyanides in particular, give rise to a range of products. For instance, [Pt_2X_2(μ-dppm)$_2$] (X = Cl or I) reacts with *p*-tolylisocyanide (CNR) to give [Pt_2X_2-(μ-CNR)(μ-dppm)$_2$], [Pt_2X(CNR)(μ-dppm)$_2$]$^+$, and [Pt_2(CNR)$_2$(μ-dppm)$_2$]$^{2+}$.[104] Reaction of [Pt_2Cl_2(μ-dppm)$_2$] with NO^+ gives the stable cationic A-frame complex [Pt_2Cl_2(μ-NO)-(μ-dppm)$_2$]$^+$.[105] Similar reactions are observed for the bromo and iodo complexes. [$Pt_2(PPh_3)_2$(μ-dppm)$_2$]$^{2+}$ reacts with CH_2N_2, CO, S, and SO_2 in dichloromethane to give [$Pt_2(PPh_3)_2$(μ-Y)(μ-dppm)$_2$]$^{2+}$ (Y = CH_2, CO, S, and SO_2).[106] The reaction has pseudo first-order kinetics that are consistent with pre-association between the reactants or with formation of a common intermediate, probably one with a dangling dppm ligand.[106] The reaction of [Pt_2Cl_2(μ-dppm)$_2$] with S_8 is second-order, whereas that with SO_2 involves pre-association of the reactants.[107] When the chloro ligands are replaced by uncharged ligands such as pyridine, NH_3 or CO, the reactions are much slower.[107] The chloro ligand in the unsymmetrical complex [PtCl(μ-dppm)$_2$Pt(C_6F_5)] can be replaced by Br^-, SCN^-, PPh_3, $AsPh_3$, pyridine, or CO to give platinum(I) dimers.[108] Other agents such as alkynes, SO_2, [$N_2C_6H_4Me$-*p*]$^+$, and H^+ insert in the

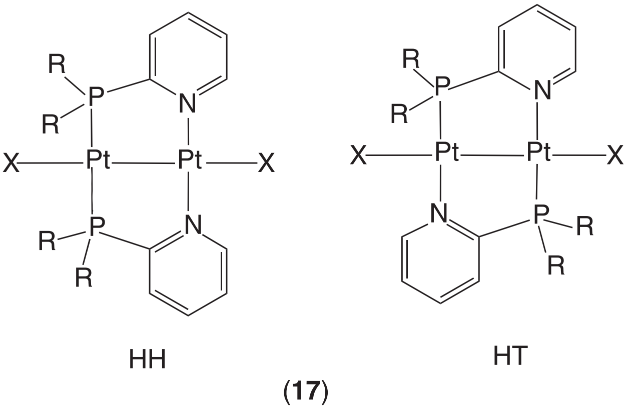
Pt—Pt bond to give A-frame complexes.[108] The related mixed-metal complex $[PtCl(\mu\text{-}dppm)_2Pd(C_6F_5)]$ also reacts with R_2N^+, SO_2, and alkynes to give A-frame complexes.

Both chloro ligands of $[Pt_2Cl_2(\mu\text{-}dppm)_2]$ are replaced by quinoline, 1-methylimidazole, and 4-*t*-butylpyridine, but only one is replaced by 2,4,6-trimethylpyridine.[109] All of these platinum(I) dimers and $[Pt_2(PPh_3)_2(\mu\text{-}dppm)_2]$ display solid-state luminescence at room temperature and long emission lifetimes at 77 K.[109]

The $[Pt_2L^1L^2(\mu\text{-}dppm)_2]$ series of complexes has been used to study the trans influence of the ligands L^1 and L^2 on both the Pt—Pt bond and on each other. Platinum(195)–^{31}P NMR coupling constants are influenced by the ligands and correlate with the Pt—P bond lengths in both platinum(I) dimers and platinum(II) complexes.[110] The Pt—Pt bond exerts *cis* and *trans* influences similar to those of a hydride ligand and the *cis* and *trans* coupling constants can be used to estimate the Pt—Pt bond length.[110] The ^{1}H and ^{31}P NMR spectra reveal that the ligands L^1 and L^2 primarily influence the Pt—Pt bond, but ligands that exert a very strong *trans* influence can also affect each other.[111] Two-dimensional ^{31}P COSY (Correlation Spectroscopy) spectroscopy can be used to determine the sign and magnitude of $^2J_{Pt-P}$ coupling constants that were unobtainable in complex spectra.[112]

6.5.3.4 Dimers Bridged by Unsymmetric Ligands

There is a range of complexes, analogous to the diphosphine-bridged dimers, in which one arm of the diphosphine is replaced by a nonphosphine donor. These complexes can exist as head-to-head (HH) or head-to-tail (HT) isomers as illustrated in (**17**) for the most widely studied group, where the bridging ligands are either 2-diphenyl- or 2-dimethyl-phosphinopyridine. The HT isomer is obtained only in the reactions of $[Pt(Ph_2Ppy)_2Cl_2]$ with either $[Pd_2(dba)_3]\cdot CHCl_3$ or $[Pt(dba)_3]$ to give $[PtPdCl_2(\mu\text{-}Ph_2Ppy)_2]$ and $[Pt_2Cl_2(\mu\text{-}Ph_2Ppy)_2]$, respectively.[113] In contrast, reaction of the iodo equivalent gives the HH isomer which undergoes isomerization on heating, the difference arising because $[Pt(Ph_2Ppy)_2Cl_2]$ exists as the *cis* isomer in solution whereas $[Pt(Ph_2Ppy)_2I_2]$ exists as the *trans* isomer.[113] Similar conproportionation reactions involving the less bulky 2-dimethylphosphinopyridine ligand and Cl^-, Br^-, or I^- also give the HH isomer followed by isomerization to the HT isomer.[114] The structures of these complexes and those of the diphenyl analogue were confirmed by X-ray crystallography,[115] and revealed Pt—Pt bonds ranging from 2.56 Å to 2.59 Å, significantly shorter than those found in diphosphine bridged complexes.



(**17**)

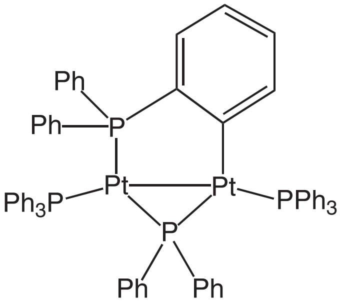
The diarsine and arsine/phosphine analogues of dppm have been used to prepare bridged diplatinum(I) complexes, in both cases with terminal chloro ligands.[116,117] Both complexes react with carbon monoxide to produce carbonyl-bridged species. The mixed thio/phosphine ligand Ph_2PCH_2SMe (PS) also forms a diplatinum(I) complex by conproportionation of its dichloroplatinum(II) complex with $[Pt(dba)_2]$.[118] This dimer reacts with carbon monoxide to produce an unsupported dimer $[PtCl(PS)(CO)]_2$ with the thioether arm of the Ph_2PCH_2SMe unbound.

6.5.3.5 Dimers Bridged by Monodentate Ligands

A number of complexes with carbonyl and hydride bridges have been discussed above and phosphido bridges are discussed below. The most common of the other bridges are sulfur and selenium, either in elemental form or as SR^- or CSR^-. For example, [Pt(CSE)(dppe)] (E = S or Se) reacts with $[Pt(PPh_3)_4]$ to give $[Pt_2(\mu\text{-}E)(dppe)(PPh_3)CS]$ as a result of cleavage of CS_2 or CSSe.[119] Addition of dppe or dpmb (dpmb = $Ph_2PCH_2\text{-}o\text{-}C_6H_4\text{-}CH_2PPh_2$) results in reformation of the CSE to give the bridged complex $[Pt_2(\eta^2\text{-}EC{=}S)(diphos)_2]$ (diphos = dppe or dpmb, E = S or Se).[119] A similar cleavage of CS_2 occurs on reaction of $[Pt(\eta^2\text{-}CS_2)(dppe)]$ with $[Pt(\eta^2\text{-}C_2H_4)(PPh_3)_2]$ to give $[Pt_2(\mu\text{-}S)(dppe)(PPh_3)CS]$.[120]

6.5.3.6 Phosphido-bridged Dimers

The trinuclear clusters $[Pt_3(\mu\text{-}X)(\mu\text{-}PPh_2)_2(PPh_3)_3]^{n+}$ (X = H, Cl, S, SR, PPh_2) react with dppm to give a dinuclear cation, $[Pt_2(\mu\text{-}PPh_2)(\mu\text{-}dppm)(PPh_3)_2]^+$, with bridging phosphido and dppm ligands.[121] Unlike its palladium analogue, the platinum(II) dihydride, $[Pt(\mu\text{-}PBu^t{}_2)(H)(PBu^t{}_2H)]_2$, does not undergo elimination of molecular hydrogen to give a platinum(I) dimer.[122] However, oxidant-induced hydride abstraction gives $[Pt_2(\mu\text{-}PBu^t{}_2)_2(H)(PBu^t{}_2H)_2]^+$ and this can be deprotonated with a strong base to give $[Pt(\mu\text{-}PBu^t{}_2)(PBu^t{}_2H)]_2$.[122] This complex reacts with CO, resulting in displacement of one of the phosphines to give the monocarbonyl complex, $[Pt_2(\mu\text{-}PBu^t{}_2)_2(PBu^t{}_2H)(CO)]$.[122] Thermally initiated degradation of a variety of platinum(0) complexes such as $[Pt(PPh_3)_2(C_2H_4)]$, $[Pt(PPh_3)_4]$ or $[Pt(PPh_3)_2(alkyne)]$ in toluene gives a platinum(I) dimer with bridging phosphido and deprotonated triphenylphosphine $[Pt_2(\mu\text{-}C_6H_4(PPh_2)(\mu\text{-}PPh_2)(PPh_3)_2]$ (**18**).[123] Reaction of *cis*-$[Pt(C_6F_5)_2(PPh_2H)_2]$, $[Pt(norbornene)_3]$, and PPh_3 in a 1:1:1 ratio results in platinum(II) dimers, but in 1:1:2 ratio results in the phosphido bridged platinum(I) dimer $[Pt(C_6F_5)(PPh_3)(\mu\text{-}PPh_2)Pt(PPh_3)_2]$.[124]



(**18**)

6.5.3.7 Electrochemical Reduction and Linear Chain Complexes

The reduction of $[Pt(bipy)_2]^{2+}$ in water by metallic iron or at a platinum electrode gives monomeric $[Pt(bipy)_2]NO_3{\cdot}2H_2O$ that forms as black–green needles.[125] The needles have a relatively high electrical conductivity and a Pt···Pt separation of 3.563(1) Å.[125] In contrast, reduction in aprotic solvents such as DMF or DMSO results in the formation of dimeric $[Pt_2(bipy)_2(\mu\text{-}bipy)]^{2+}$ (bipy = 2,2′-bipyridine) with a Pt···Pt separation of 2.527,2(5) Å.[126]

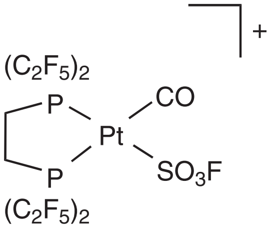
6.5.4 PLATINUM(II)

6.5.4.1 Platinum(II) Complexes with Carbonyl and Silicon-donor Ligands

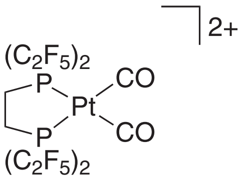
6.5.4.1.1 Carbonyl ligands

Platinum(II)–carbonyl complexes have a long history. Indeed, chloro derivatives such as *cis*-$[PtCl_2(CO)_2]$ were among the first transition metal carbonyl complexes to be prepared. Novel high-yielding, preparative routes to *cis*-$[PtCl_2(CO)_2]$ have been described, in addition to its X-ray structure.[127] Methods of synthesis have included the reaction of $[NBu_4]_2[PtCl_4]$ with 1 atm of CO in CH_2Cl_2 solution at room temperature in the presence of $AlCl_3$, which is added to the solution in order to scavenge free chloride. Another method involves the reaction of PtI_2 with 1 atm of CO to afford $[PtI_2(CO)_2]–[Pt_2I_4(CO)_2]$, which is then treated with SO_2Cl_2 under a CO atmosphere. The third method involves the treatment of anhydrous $PtCl_2$, suspended in CH_2Cl_2, with 1 atm of CO over a period of 2 d.

Highly electrophilic platinum(II) complexes containing the electron-poor perfluorinated phosphine ligand 1,2-bis(pentafluoroethylphosphino)ethane have been generated in superacidic media.[128] In polar aprotic solvents, the reaction of $[PtX_2(dfepe)]$ (X = OTf, SO_3F; dfepe= 1,2-bis(pentafluoroethylphosphino)ethane) with 1 atm of CO does not occur. In fluorosulfonic acid, however, the reaction proceeds smoothly to generate the monocarbonyl species $[Pt(SO_3F)(CO)(dfepe)]^+$ (**19**). At higher pressures of CO (>6 atm), the bis(carbonyl) derivative $[Pt(CO)_2(dfepe)]^{2+}$ (**20**) is obtained. When CF_3SO_3H is used as the solvent, only the monocarbonyl species $[Pt(CF_3SO_3)(CO)(dfepe)]^+$ was observed. Loss of CO from the complexes ensues after several days at room temperature in the absence of a CO atmosphere.



(**19**)



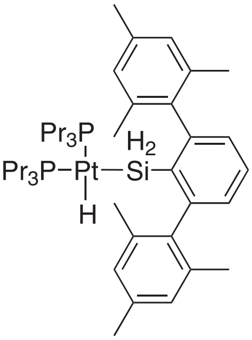
(**20**)

Treatment of the trinuclear cluster $[Pt_3(CO)_3(PBu^t_2Ph)_3]$ with HCl gas (or its $MeCONMe_2$ adduct) affords the mononuclear species $[Pt(H)Cl(CO)(PBu^t_2Ph)]$ in which the CO is located *trans* to the hydrido ligand.[91] The complex undergoes an isomerization reaction at elevated temperatures (>50 °C) to afford the thermodynamic product in which the CO ligand is located *trans* to the tertiary phosphine. Treatment of $[Pt_3(CO)_3(PBu^t_2Ph)_3]$ with an excess of Cl_2 affords $[PtCl_2(CO)(PBu^t_2Ph)]$, which is formed via the diplatinum(I) intermediate $[Pt_2Cl_2(CO)_2(PBu^t_2Ph)_2]$.

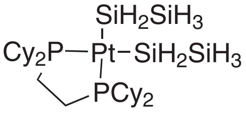
The bis(carbonyl)platinum(II) complex *cis*-$[Pt(SO_3F)_2(CO)_2]$ has been prepared by the reductive carbonylation of the platinum(IV) precursor $[Pt(SO_3F)_4]$ in fluorosulfuric acid,[129] and its structure has been determined by X-ray diffraction.[130] The key intermediate in this reaction is the mixed-valence salt $[Pt(CO)_4][Pt(SO_3F)_6]$.[131] Carbonylation of *cis*-$[Pt(SO_3F)_2(CO)_2]$ in liquid SbF_5 quantitatively affords the tetrakis(carbonyl)platinum(II) species $[Pt(CO)_4][Sb_2F_{11}]_2$, the structure of which was confirmed by X-ray crystallography.[132] An alternative route to this product is the reductive carbonylation of PtF_6 in SbF_5.[130] When HF is used as a solvent, $[Pt(CO)_4][PtF_6]$ is formed instead.

6.5.4.1.2 Si-Donor ligands

Mono- and bis(silyl)platinum(II) complexes are believed to play important catalytic roles in hydrosilylation, dehydrocoupling, and double silylation reactions with disilanes and hydrosilanes. A stable, mono(silyl)platinum(II) complex has been prepared by the oxidative addition reaction of the sterically hindered, primary arylsilane 2,6-$Mes_2C_6H_3SiH_3$ (Mes = 2,4,6-trimethylbenzene) to the platinum(0) species $[Pt(PPr_3)_3]$ in hexane solution at room temperature.[133] The colorless product *cis*-$[PtH(2,6-Mes_2C_6H_3(H)_2Si)(PPr_3)_2]$ (**21**) was isolated as the $OPPr_3$ adduct, and its

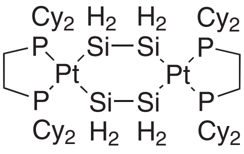


(**21**)

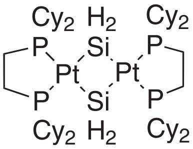


(**22**)

structure was determined by means of X-ray crystallography. The related species *trans*-[PtH(SiHMes$_2$)(PCy$_3$)$_2$] (Cy = cyclohexyl) has also been reported.[134]



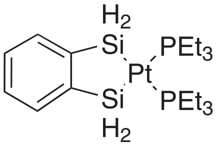
(23)



(24)

The reactions of the dihydrido complex [PtH$_2$(dcpe)] (dcpe = 1,2-bis(dicyclohexylphosphino) ethane) with silanes have been reported.[135] Treatment of [PtH$_2$(dcpe)] with H$_3$SiSiH$_3$ in toluene solution at room temperature rapidly leads to the formation of [Pt(SiH$_2$SiH$_3$)$_2$(dcpe)] (**22**) and the unusual dinuclear species [{Pt(dcpe)}$_2$(μ-SiH$_2$SiH$_2$)$_2$] (**23**), the ratio of which depends upon the rate of addition of the disilane to the platinum precursor. If the addition is carried out very slowly, however, another dinuclear species [{Pt(dcpe)}$_2$(μ-SiH$_2$)$_2$] (**24**) is also formed, probably via the bis(silyl) intermediate [Pt(SiH$_3$)$_2$(dcpe)]. Indeed, the use of one equivalent of the methyl-substituted disilane MeH$_2$SiSiH$_2$Me in the reaction with [PtH$_2$(dcpe)] affords the bis(silyl) analogue [Pt(SiH$_2$Me)$_2$(dcpe)] in quantitative yield; an analogous product is also obtained in the reaction of [Pt(PEt$_3$)$_3$] with PhH$_2$SiSiH$_2$Ph.[60] bis(silyl)platinum(II) complexes can also be formed by the hydrogenolysis of corresponding η^2-disilene complexes.[136] The complexes [Pt(SiH$_2$SiH$_3$)$_2$(dcpe)] and [{Pt(dcpe)}$_2$(μ-SiH$_2$SiH$_2$)$_2$] are the first isolated examples of platinum(II) complexes containing terminal and bridging disilanyl ligands, respectively. Even though both the mono- and dinuclear species can be isolated as white, crystalline solids, only the latter is stable to air both in solution and as a solid. The X-ray structures of both complexes were also determined, but only that of the dinuclear species was reported.

The preparation of various platinum–silyl complexes, including a platinum(II), platinum(IV), and mixed-valence platinum(II)–(IV) species, has been described.[59] The treatment of one equivalent of 1,2-disilylbenzene with [Pt(PEt$_3$)$_3$] in toluene solution at 0 °C affords [Pt(C$_6$H$_4$Si$_2$H$_4$)(PEt$_3$)$_2$] (**25**) as a white powder; the use of excess 1,2-disilylbenzene in the reaction leads to the formation of various platinum(IV) derivatives.



(25)

6.5.4.2 Platinum(II) Complexes with Nitrogen-donor Ligands

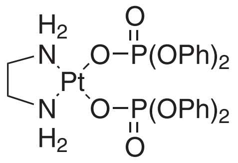
6.5.4.2.1 Ammine and alkylamine ligands

The affinity of platinum(II) for N-donor ligands is well established. There are numerous examples in the literature of mono-, di-, and trinuclear platinum(II)–ammine and alkylamine complexes, most of which are structural analogues of the anticancer agent, *cis*platin (*cis*-[PtCl$_2$(NH$_3$)$_2$]), and the corresponding *trans* isomer. Selected novel complexes and synthetic methods are presented below.

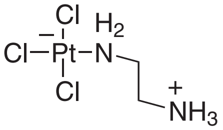
A ^{15}N and ^{195}Pt NMR study of the solution chemistry of *trans*-diammineplatinum(II) complexes containing water, chloro, nitrato, sulfato, acetato, and dihydrogenphosphato ligands has been described.[137] A convenient small-scale (0.1–5.0 g) preparation of *trans*-[PtCl$_2$(^{15}NH$_3$)$_2$] that involved the heating of anhydrous, solid [Pt(^{15}NH$_3$)$_4$]Cl$_2$ under vacuum for 5 h at 190–195 °C has also been reported.

A versatile synthesis of monoamine platinum(II) complexes of the type [PtCl$_3$(amine)]$^-$, where the nature of the amine ligand can be varied readily, involves treatment of the iodo-bridged dimer [PtI(μ-I)L]$_2$ (L = NH$_3$, methylamine, ethylamine, isopropylamine, cyclobutylamine, and cyclopentylamine) with an excess of $AgNO_3$.[138] Pt–I–Pt bridge cleavage and subsequent hydrolysis followed by the addition of chloride affords $[PtCl_3(amine)]^-$ in reasonable-to-high yields.

The preparation of the first phosphodiester complexes of platinum(II), in particular those containing the diphenylphosphato ligand, has been reported.[139] Treatment of $[PtCl_2(en)]$ with Ag_2O in DMF with two equivalents of diphenylphosphate gives $[Pt(dpp)_2(en)]$ ((**26**); dpp = diphenylphosphato, en = ethylene-1,2-diamine), the first example of a bis(phosphodiester) complex of platinum(II). The complex is stable as a monomer, and it does not undergo dimerization or oligomerization reactions.



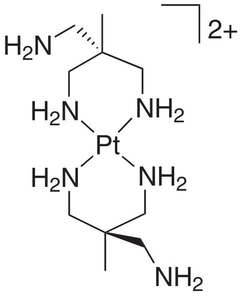
(26)



(27)

The reaction of $[PtCl(Me_2S)(en)]Cl$ with concentrated HCl results in the formation of the zwitterionic complex $[PtCl_3(enH)]$ (**27**), where the en no longer acts as a chelating ligand owing to protonation of one of the amine groups.[140] The X-ray structure of the complex confirms the unusual coordination mode of the en ligand.

Bulk electrochemical reduction of the platinum(IV) complex of the tridentate ligand 1,1,1-tris(aminomethyl)ethane(tame), $[Pt(tame)_2]^{4+}$, leads to the quantitative formation of $[Pt(tame)_2]^{2+}$ (**28**), in which one of the amine donor groups in tame remains noncoordinated.[141] The X-ray structure of the diprotonated complex $[Pt(Htame)_2]^{4+}$, as its tetrachlorozincate(II) salt, is also reported.



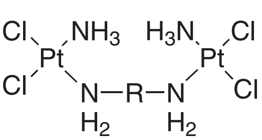
(28)

The synthesis and neutron diffraction study of the double-salt complex $[NPr^n{}_4]_2[PtCl_4]\cdot$*cis*-$[PtCl_2(NH_2Me)_2]$ at 20 K has been reported.[142,143] The molecular structure of the complex shows strong N—H···Pt and N—H···Cl hydrogen bonds that link the two platinum(II) complexes. The structure confirms that transition metal centers can act as H-bond acceptors, and that a new three-center, four-electron hydrogen bridge model best describes the N—H···Pt interaction.

The detailed photophysics have been reported for the 1:1 supramolecular complex of $[Pt(NH_3)_2(bipy)]^{2+}$ and a cylindrical macrocyclic receptor comprising of two [18]-N_2O_4 moieties linked to two 2,6-dimethylnaphthalene bridges.[144] The adduct is stabilized by the formation of an extensive network of H-bonds between the *O*-atoms of the macrocycles and the H-atoms of the ammine ligands. The electron-deficient bipy ligand and electron-rich naphthalene moieties also undergo π–π stacking interactions, allowing for facile charge-transfer interactions to occur.[145]

One of the most active research areas in bio-inorganic chemistry at the present time is the study of di- and trinuclear platinum complexes as potential anticancer drugs and as probes of DNA structure and function. Notably, a series of dinuclear complexes based on cisplatin and the corresponding *trans* isomer, linked by variable-length primary amines, have been studied in great detail by Farrell and co-workers.[146] The general formula of the complexes is $[\{PtCl_m(NH_3)_{3-m}\}\text{-}\mu\text{-}H_2N\text{–}R\text{–}NH_2\text{-}\{PtCl_n(NH_3)_{3-n}\}]^{\{(2-m)+(2-n)\}+}$($m$ and n = 0–3; R = linear or substituted aliphatic group). Spermine- and spermidine-bridged complexes have also been studied.[147,148]

The preparation of the dinuclear complexes is readily achieved by taking advantage of the well-established *trans* effect in square-planar complexes. For example, the treatment of two equivalents of $[PtCl_3(NH_3)]^-$ with 1,4-diaminobutane leads to the formation of the dinuclear species *cis*-$[\{PtCl_2(NH_3)\}_2\{\mu\text{-}H_2N(CH_2)_4NH_2\}]$ (**29**), in which the diaminoalkane acts as bridging bidentate ligand.[149] Tetraamine complexes of the type $[\{Pt(NH_3)_3\}_2\{\mu\text{-}H_2N\text{–}R\text{–}NH_2\}]^{4+}$(**30**) can be prepared by the reaction of *cis*-$[\{PtCl_2(NH_3)\}_2\{\mu\text{-}H_2N\text{–}R\text{–}NH_2\}]$ with aqueous ammonia. Another class of tetraamine complexes is prepared by the reaction of *cis*-$[PtCl_2(NH_3)_2]$ with the diaminoalkane to afford the doubly bridged species *cis*-$[\{Pt(NH_3)_2\}_2\{\mu\text{-}H_2N-R-NH_2\}_2]^{4+}$ (**31**). Further reaction of this species with aqueous HCl (6 M) affords *trans*-$[\{PtCl_2(NH_3)\}_2\ \{\mu\text{-}H_2N-R-NH_2\}]$ (**32**). The mononuclear species *trans*-$[PtCl_2(NH_3)\{H_2N-R-NH_3\}]^+$ (**33**), containing a dangling protonated amine, is also formed in the reaction mixture.[150] This species has proved to be very useful in the synthesis of the mixed *cis–trans* species $[\{cis\text{-}PtCl_2(NH_3)\}\ \mu\text{-}H_2N-R-NH_2\text{-}\{trans\text{-}PtCl_2(NH_3)\}]$ (**34**) upon reaction with $[PtCl_3(NH_3)]^-$.[151] The dinuclear trichloro species including $[\{trans\text{-}PtCl(NH_3)_2\}\mu\text{-}NH_2-R-NH_2\{cis\text{-}PtCl_2(NH_3)\}]^+$ (**35**) and $[\{cis\text{-}PtCl(NH_3)_2\}\mu\text{-}NH_2-R-NH_2\{cis\text{-}PtCl_2(NH_3)\}]^+$ (**36**) have also been reported,[152] as have related structural types,[153,154] including the first examples of platinum(II)–amine complexes containing a carborane (dicarba-*closo*-dodecaborane(12)) ligand (**37**) and (**38**).[155]



(**29**)

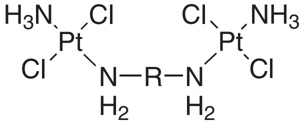
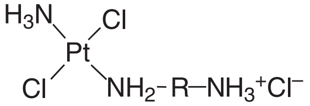
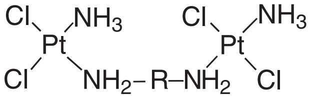
(**31**)



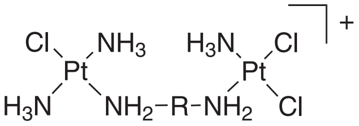
(**32**)



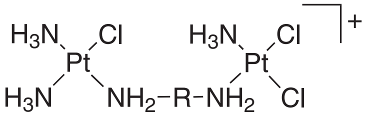
(**33**)



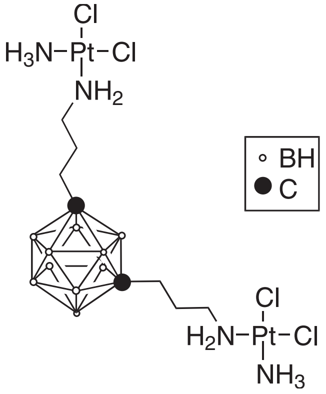
(**34**)



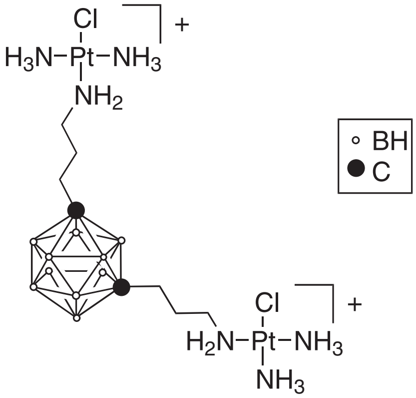
(**35**)



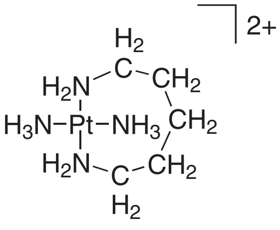
(**36**)



(**37**)



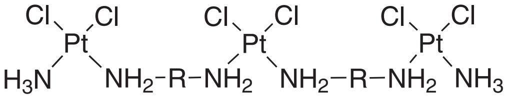
(**38**)



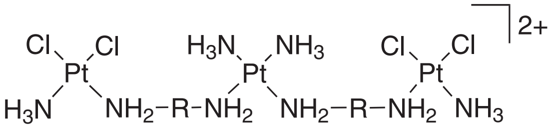
(**39**)

Farrell has noted that the types of products formed in the reaction of two equivalents of *trans*-$[PtCl_2(NH_3)_2]$ with diaminoalkanes of the type $NH_2(CH_2)_nNH_2$ ($n = 2$–8) depend on the polymethylene chain length.[156] For example, the use of amines with $n = 2$–4 affords the dinuclear complexes $[\{trans\text{-}[PtCl(NH_3)_2]\}_2\{\mu\text{-}NH_2(CH_2)_nNH_2\}]^{2+}$, even when the chelating en ligand is used. In contrast, when $n = 5$, the amine acts as a *trans*-chelating bidentate ligand and the resulting complex has the formulation *trans*-$[Pt(NH_3)_2\{NH_2(CH_2)_5NH_2\}]^{2+}$ (**39**). With longer chain length amines ($n = 6$–8), mixtures of products were observed, but the desired dinuclear complexes can be prepared in high yield and purity by the use of the labile species *trans*-$[PtCl(dmf)(NH_3)_2]^+$ instead of the corresponding dichloro precursor.

The chemistry of dinuclear platinum(II) species linked by bridging diaminoalkane ligands can also be extended to related trinuclear species.[157] In general, the synthesis of a suitable mononuclear precursor complex containing two monoprotected amine ligands (by means of an amine hydrochloride salt, or a suitable blocking agent such as *t*-butoxycarbonyl that is readily removed by the addition of strong acid) is used as a source for further reactions with two equivalents of an appropriate platinum(II) complex in the presence of base. For example, the trinuclear species $[\{cis\text{-}PtCl_2(NH_3)\}_2\{\mu\text{-}cis\text{-}PtCl_2(NH_2{-}R{-}NH_2)_2\}]$ (**40**) can be prepared in three steps. First, treatment of $[PtCl_4]^{2-}$ with two equivalents of a BOC-monoprotected diaminoalkane ligand affords *cis*-$[PtCl_2\{NH_2{-}R{-}NH(BOC)\}_2]$. Second, treatment of the *cis*-dichloro species with concentrated HCl affords the deprotected complex *cis*-$[PtCl_2(NH_2{-}R{-}NH_3)_2]^{2+}$. Finally, the triplatinum species is prepared by the reaction of the BOC deprotected *cis*-dichloro intermediate with two equivalents of $[PtCl_3(NH_3)]^-$ in the presence of base. More complicated complexes with two inequivalent coordination spheres can also be prepared as follows. First, treatment of *cis*-$[PtCl_2(NH_3)_2]$ with two equivalents of a BOC-monoprotected diaminoalkane ligand affords *cis*-$[Pt(NH_3)_2\{NH_2{-}R{-}NH(BOC)\}_2]^{2+}$. Second, treatment of the *cis*-dichloro species with concentrated HCl affords the deprotected complex *cis*-$[Pt(NH_3)_2(NH_2{-}R{-}NH_3)_2]^{4+}$. Finally, the triplatinum species $[\{cis\text{-}PtCl_2(NH_3)(\mu\text{-}NH_2{-}R{-}NH_2)\}_2\{cis\text{-}Pt(NH_3)_2\}]^{2+}$ (**41**) can be prepared by treatment of *cis*-$[Pt(NH_3)_2(NH_2{-}R{-}NH_3)_2]^{4+}$ with two equivalents of $[PtCl_3(NH_3)]^-$ in the presence of base.

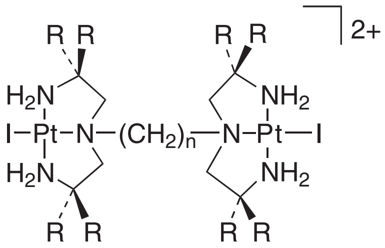


(**40**)



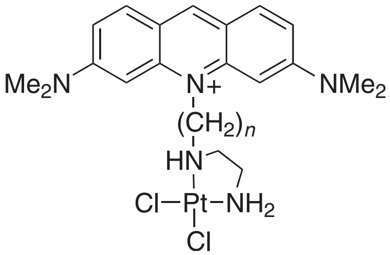
(**41**)

A comprehensive series of mono- and dinuclear iodoplatinum(II) complexes $[PtI(dien)]^+$ and $[\{PtI(dien)\}_2(\mu\text{-}CH_2)_n]$ (**42**) (dien = parent or substituted diethylenetriamine; $n = 2$–9), respectively, have been synthesized as potential probes of nucleic acid structure.[158] Both chiral and achiral species were prepared. In general, the complexes are synthesized by the reaction of *trans*-$[PtI_2(DMSO)_2]$ with the dien ligand in DMF solution.



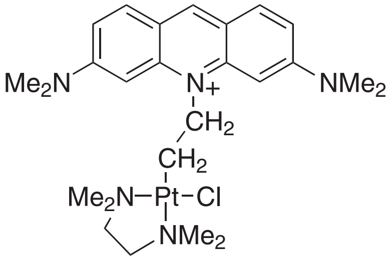
(42)

The synthesis and DNA-binding properties of a $[PtCl_2(en)]$ complex tethered to an intercalating acridine orange (3,6-bis(dimethylamino)acridine) via a polymethylene chain ($n = 3$ or 6; (**43**)) have been reported.[159,160] The solution aggregation behavior of these complexes was also studied in great detail. Both complexes are capable of binding to calf-thymus DNA, as determined by UV–visible spectroscopy. The hexamethylene-tethered complex is also capable of unwinding and rewinding supercoiled plasmid DNA. However, it does not shorten the DNA helix like its parent complex $[PtCl_2(en)]$, probably due to the inhibition of the platinum binding mode that is responsible for the shortening effect by the nearby intercalator. Upon irradiation with a visible-light source, photonicking of the DNA was observed.[159]



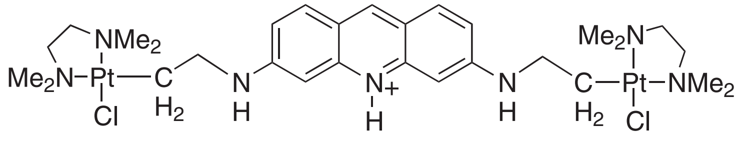
(43)

Chloroplatinum(II) complexes linked to DNA intercalators such as proflavine (3,6-diamino-acridine, dac) and 3,6-bis(dimethylamino)acridine (AO) may lead to enhanced DNA interactions when compared to cisplatin and other platinum drugs. Such complexes can be prepared by the direct reaction of the electrophilic coordinated alkene in $[PtCl(C_2H_4)(tmen)]^+$ (tmen = *N*,*N*,*N*′,*N*′-tetramethylethane-1,2-diamine) with the endocyclic *N*-atom or the exocyclic amino groups of the acridine.[161] The endocyclic *N*-atom of AO is involved in the reaction with the platinum(II) complex to afford the mononuclear species $[PtCl\{CH_2CH_2\text{-}AO\}(tmen)]^+$ (**44**), in which the platinum(II) moiety is linked to the AO via an ethylene chain; the product structure was confirmed by means of X-ray diffraction. In the case of proflavine, the two exocyclic amino groups react with $[PtCl(C_2H_4)(tmen)]$ to afford the dinuclear platinum(II) species $[\{PtCl(tmen)\}_2\{CH_2CH_2NH–C_{13}H_7NH–NHCH_2CH_2\}]^+$ (**45**).



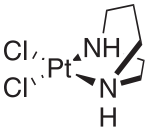
(44)

Hambley and co-workers have reported the synthesis, DNA cross-linking, and *in vitro* anti-cancer properties of a platinum(II) complex that was designed to bind the macromolecule in an interstrand rather than intrastrand manner,[162] the latter being the dominant mode of DNA-binding by platinum anticancer drugs such as cisplatin. The complex $[PtCl_2(hpip)]$ ((**46**);



(**45**)

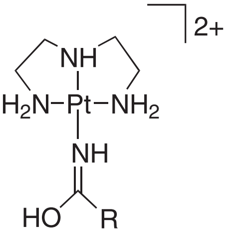
hpip = homopiperazine) was shown to cross-link linearized plasmid DNA in a bifunctional manner. Indeed, at low Pt/DNA nucleotide ratios, the complex was found to be equally effective at forming interstrand cross-links when compared to *cis*platin, but at higher Pt/DNA ratios cisplatin was found to be more effective. Furthermore, the complex proved to form very few intrastrand cross-links, but monofunctional adducts were clearly dominant, accounting for over 90% of the total DNA interactions. Studies of the interaction of [$PtCl_2$(hpip)] with a d(GpG) dinucleotide have also been reported.[163]



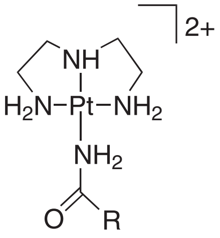
(**46**)

6.5.4.2.2 *Amide ligands*

The coordination modes of acetamide and formamide toward platinum(II) complexes containing diethylenetriamine have been reported.[164] The complexes were prepared by treatment of the labile aqua species [$Pt(OH_2)$(dien)]$^{2+}$ with the amide in acetone solution. In both cases, two linkage isomers were isolated, in which the amides are *O*- or *N*-bonded to the metal center. The latter was found to exist in solution as the imidol [Pt{NHC(OH)R}(dien)]$^{2+}$ (R = H, Me) (**47**) form instead of the tautomeric amide [Pt{NH_2COR}(dien)]$^{2+}$ (**48**) and, furthermore, it adopted only a *cis* geometry with respect to the C—N bond, which possesses restricted rotation. The *O*-bonded isomers are the kinetic products, and very slowly ($t_{1/2}$ = ca. 30 h at 293 K) convert to the thermodynamically favored *N*-bonded species in an intramolecular manner. Alternatively, base-catalyzed hydrolysis of the acetonitrile complex [Pt(MeCN)(dien)]$^{2+}$ in water leads to the *N*-bonded acetamide complex [Pt(NHCOMe)(dien)]$^{+}$, which can be protonated by strong Brönsted acids such as CF_3SO_3H to afford the iminol species [Pt{NHC(OH)Me}(dien)]$^{2+}$. The free-energy difference between the two isomeric forms was determined to be 8.3 kJ mol^{-1} in all cases. In a related study, the coordination chemistry of 1,1-dimethylurea in platinum(II)-dien complexes was also explored.[165] Once again, both *O*- and *N*-bound linkage isomers were isolated and characterized, with the latter being slightly thermodynamically favored ($K_{eq(N\text{-isomer}/O\text{-isomer})} \sim 3$). Interestingly, in the *N*-bound complex, the 1,1-dimethylurea exists in the amide rather than iminol tautomeric form.

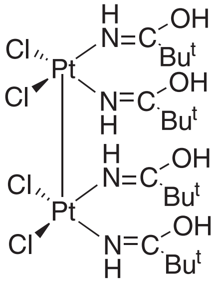


(**47**)

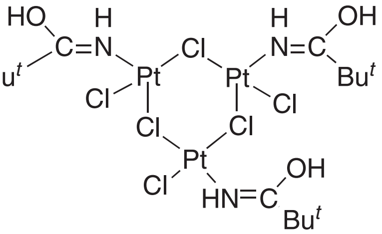


(**48**)

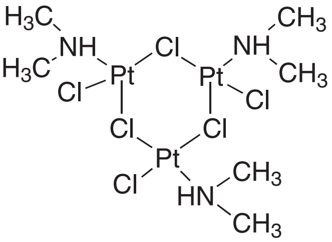
In a study of the hydrolysis of platinum(II)-nitrile complexes to afford the corresponding amides, the first well-characterized examples of platinum(II) complexes that dimerize spontaneously to form weakly bonded Pt–Pt dimers with an unsupported intermetallic bond have been described.[166] For example, treatment of *cis*-[$PtCl_2(NCBu^t)_2$] with excess KOH affords the amide species *cis*-[$PtCl_2\{HN{=}C(OH)Bu^t\}_2$], which exists as a dimer (**49**) both in solution and in the solid state, with a Pt–Pt bond length of 3.165(1) Å, as determined by X-ray crystallography. Four interfacial N—H···Cl. H-bonds are also evident in the dimeric structure. An intermediate complex *cis*-$[PtCl_2\{HN{=}C(OH)Bu^t\}_2\{H_2NC({=}O)Bu^t\}]$, containing three amide ligands, two of which are *N*-bonded and one *O*-bonded to the platinum(II) center, was also isolated from the reaction mixture. It also dimerizes spontaneously both in solution and in the solid state with the formation of a weak intermetallic bond (d(Pt—Pt) = 3.399(1) Å). The propensity of these complexes to form Pt–Pt dimers is reminiscent of the "aurophilic" interactions observed in many types of gold complexes, and it appears to stem from the intermetallic bonding that can result from the mixing of filled platinum $5d_z{}^2{-}5d_z{}^2$ orbitals with the higher-energy $6p_z{-}6p_z$ orbitals. The structural details of linear-chain complexes of the type $[PtX_2(NN)]$ (X = Cl, NN = 2,2′-bipyrimidine; X = CN, NN = 1,10-phenanthroline; X = NCS, NN = bipy) have also been reported, with weak intermetallic bonding (d(Pt–Pt) = 3.24–3.49 Å) playing an important role in the solid-state stacking of monomers.[167] Theoretical calculations on the nature of the intermetallic bonding in unsupported d^8 dimers have complemented these studies.



(49)



(50)

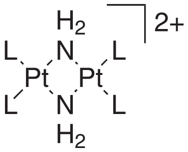


(51)

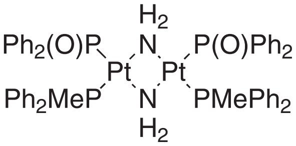
The dimer *cis*-$[\{PtCl_2\{HN{=}C(OH)Bu^t\}_2\}_2]$ (**49**) isomerizes to *trans*-$[PtCl_2\{HN{=}C(OH)Bu^t\}_2]$ in CH_2Cl_2 and other chlorinated solvents.[168] When large amounts of *n*-hexane are present in the solution, two products are formed. One product is formulated as the dimeric *cis*-$[PtCl_2\{HN{=}C(OH)Bu^t\}_2\{H_2NC({=}O)Bu^t\}]$ described above, and the other was identified by X-ray crystallography as the trinuclear species *cyclo*-$[(PtCl_2\{HN{=}C(OH)Bu^t\})_3]$ (**50**). In this unusual complex, each platinum atom is surrounded by two bridging chloro ligands in a *cis* geometry, with the *N*-bonded amide and terminal chloro ligands completing the coordination sphere around each platinum atom. Another trinuclear chloro-bridged complex, *cyclo*-$[(PtCl_2\{(Me)_2NH\})_3]$ (**51**), was prepared by the treatment of $[PtCl_3\{(Me)_2NH\}]^-$ with $HClO_4$.[169]

6.5.4.2.3 Amido, imido, and nitrido ligands

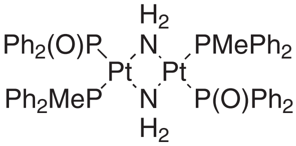
Amido complexes of platinum(II) are not easily prepared,[170,171] but the syntheses of the mono- and diplatinum(II) complexes *trans*-$[PtX(NH_2)(PCy_3)_2]$ (X = H, Me), $[Pt_2(\mu\text{-}NH_2)_2L_4]$ (L = PEt_3, PPh_2Me, PMe_2Ph, PMe_3) (**52**) and $[Pt_2H_2(\mu\text{-}NH_2)_2L_2]$ (L = PPh_3, PEt_3), respectively, have been described.[172–174] The dinuclear species *cis*- and *trans*-$[Pt_2(\mu\text{-}NH_2)_2(POPh_2)_2(PMePh_2)_2]$ ((**53**) and (**54**), respectively) can be obtained by the treatment of $[PtCl_2(dppm)]$ and NaOH in liquid or aqueous ammonia solution.[175] The authors proposed that the reaction proceeds via a μ-hydroxo intermediate. Indeed, the direct conversion of a μ-hydroxo ligand to an amido ligand was also reported for the first time. For example, treatment of $[Pt_2(\mu\text{-}OH)_2(PPh_3)_4]^{2+}$ with aqueous ammonia leads to the rapid and quantitative formation of $[Pt_2(\mu\text{-}NH_2)_2(PPh_3)_4]^{2+}$.



(52)

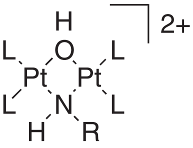


(53)

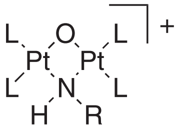


(54)

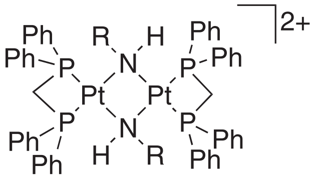
A comprehensive study of aminolysis reactions involving dinuclear platinum(II)–hydroxo complexes has been described.[176] Treatment of the di-μ-hydroxo complexes of the type $[Pt_2(\mu\text{-}OH)_2(L_2)_2]^{2+}$ with an excess of aryl amine RNH_2 (L = PPh_3, R = Ph, *p*-tolyl, *p*-$Bu^tC_6H_4$, *p*-$NO_2C_6H_4$; $L_2 = $ 1,3-bis(diphenylphosphino)propane (dppp), R = Ph, *p*-tolyl) affords the mixed hydroxo-amido species $[Pt_2(\mu\text{-}OH)(\mu\text{-}NHR)(L_2)_2]^{2+}$. In some cases, the di-$\mu$-amido complexes of the type $[Pt_2(\mu\text{-}NHR)_2(L_2)_2]^{2+}$ are obtained (R = H, L_2 = dppm, dppe, dppp, $2PMe_2Ph$; R = Ph, *p*-tolyl, L_2 = dppm, dppe; R = NH_2, L_2 = dppm, dppp, dppb). When the mixed hydroxo-amido species $[Pt_2(\mu\text{-}OH)(\mu\text{-}NHR)(L_2)_2]^{2+}$ (**55**) are treated with strong bases such as $LiNPr^i{}_2$, deprotonation of the bridging hydroxo group occurs exclusively to afford the mixed oxo-amido species of the type $[Pt_2(\mu\text{-}O)(\mu\text{-}NHR)(L_2)_2]^{+}$ (**56**), and deprotonation of the amido ligand is never observed. In the $[Pt_2(\mu\text{-}NHR)_2(dppm)_2]^{2+}$ (**57**) complexes, however, deprotonation of the dppm methylene group occurs with $LiN(TMS)_2$ to give complexes of the type $[Pt_2(\mu\text{-}NHR)_2(dppm\text{-}H)_2]$; R = H, NH_2, Ph, *p*-tolyl) (**58**); the di-μ-hydrazido complex was crystallized as the $[Li(THF)_2]$ adduct, in which the Li^+ ion is strongly associated with the two hydrazido NH_2 groups. In another study, Sharp and co-workers have reported several other examples of related μ-hydrazidodiplatinum(II) derivatives.[177] Finally, treatment of the di-μ-amido species of the type $[Pt_2(\mu\text{-}NHR)_2(dppm\text{-}H)_2]$ (R = H, Ph, *p*-tolyl) with strong bases such as MeLi results in the deprotonation of the amido ligands to afford the di-μ-imido complexes $[Pt_2(\mu\text{-}NR)_2(dppm\text{-}H)_2]^{2-}$ (**59**).[176]



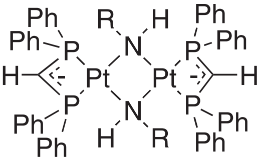
(**55**)



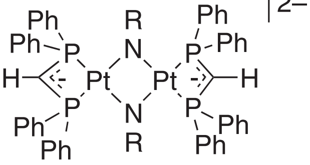
(**56**)



(**57**)



(**58**)



(**59**)

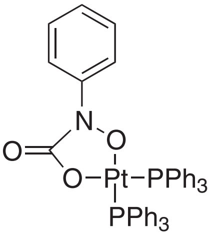
The phenylamidoplatinum(II) complex *trans*-$[PtH(NHPh)(PEt_3)_2]$ can be obtained by the reaction of *trans*-$[PtH(NO_3)(PEt_3)_2]$ with NaNHPh in C_6H_6/THF solution.[178] In the solid state, the complex is unstable and decomposes within a matter of hours at room temperature, but in solution it is stable for indefinite periods at ambient temperatures. Despite its instability in the solid state, the X-ray structure of the complex was determined at −100 °C. Addition of CO or PEt_3 to the complex results in the rapid formation of the platinum(0) species $[Pt(CO)_2(PEt_3)_2]$ or $[Pt(PEt_3)_4]$, respectively, by the reductive elimination of aniline. Treatment of the complex with H_2 gives $[PtH_2(PEt_3)_2]$ and aniline. The reaction of *trans*-$[PtH(NHPh)(PEt_3)_2]$ with acrylonitrile generates the hydrido(alkyl) species *trans*-$[PtH\{C(CN)CH_2NHPh\}(PEt_3)_2]$, formed by regioselective insertion of the activated alkene into the Pt—N bond, thus modeling one of the key steps that would be required in a catalytic cycle for alkene amination.[178,179] Other electrophilic substrates such as CO_2, COS, and PhNCO also insert into the Pt—N bond, with no insertion into the Pt—H bond ever observed. In a related reaction, *trans*-$[PtH(OPh)(PEt_3)_2]$ is prepared by the reaction of *trans*-$[PtH(NO_3)(PEt_3)_2]$ with NaOPh in C_6H_6/MeOH solution.[178] Its reactivity toward electrophilic substrates, for example, is similar to that of the amido analogue, although the reactions occur much more rapidly. The relative strength of the Pt—O bond vs. the Pt—N bond appears to govern the reactivity of the complexes.

Numerous sulfur nitrido derivatives of platinum(II) have been reported. Treatment of $(TMSN)_2S$ with the platinum(0) complex $[Pt(C_2H_4)(PPh_3)_2]$ affords *cis*-$[Pt(NSN\text{-}TMS)_2(PPh_3)_2]$ by oxidative addition, the first example of a metal complex containing the $RNSN^-$ ligand.[180] X-ray crystallography confirms that the ligand is σ-bonded to the platinum(II) center via the terminal *N*-atom. Disulfur dinitrido derivatives of platinum(II) have been prepared by the reaction of $Na(S_3N_3)$ with $[PtCl_2L_2]$ (L = PMe_3, PMe_2Ph, $PMePh_2$, PPh_3, PEt_3, $PPr^n{}_3$, $PBu^n{}_3$; L_2 = dppe) to afford complexes of the type $[Pt(S_2N_2)L_2]$.[181] The molecular structure of $[Pt(S_2N_2)(PMe_3)_2]$ was confirmed by X-ray crystallography. In a related study, treatment of *cis*-$[PtCl_2(PMe_3)_2]$ with

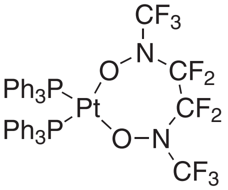
$[Me_2Sn(S_2N_2)]_2$ and NH_4PF_6 in CH_2Cl_2 solution affords the *N*-protonated metallacycle $[Pt(S_2N_2H)(PMe_3)_2]PF_6$ and Me_2SnCl_2.[182] Another method of preparation involves protonation of disulfur dinitride complexes with strong acids. For example, treatment of $[Pt(S_2N_2)(PMe_2Ph)_2]$ with HBF_4 affords $[Pt(S_2N_2H)(PMe_2Ph)_2]BF_4$. Treatment of $[Pt(S_2N_2H)L_2]^+$ (L = PMe_2Ph, PMe_3, PPr^n_3) with Br_2 gives the platinum(IV) complex *trans*-$[PtBr_2(S_2N_2H)L_2]^+$, which rapidly undergoes isomerization to the corresponding *cis* isomer, followed by an unusual reductive elimination reaction to give $[PtBr(S_2N_2H)L]$. The analogous iodo complex $[PtI(S_2N_2H)(PMe_2Ph)]$ can be prepared by the reaction of $[Pt(S_2N_2H)(PMe_2Ph)_2]^+$ with I_2.[183] The first example of a six-membered PtS_2N_3 metallacycle was prepared by the reaction of $[PtCl_2(PMe_2Ph)_2]$ with $S_4N_4O_2$ in liquid ammonia to afford $[Pt\{S_2N_3(SO_2)(NH_2)\}(PMe_2Ph)_2]$.[184] The X-ray structure of the product was also reported, confirming the puckered nature of the PtS_2N_3 ring. The complex *trans*-$[Pt(NSO)_2(PPh_3)_2]$ can be obtained by the reaction of the platinum(0) species $[Pt(C_2H_4)(PPh_3)_2]$ with $Hg(NSO)_2$.[185]

6.5.4.2.4 Nitroso ligands

The platinum(0) complex $[Pt(PhNO)(PPh_3)_2]$ reacts with CO_2 to afford the metallacyclic nitroso species $[Pt\{ON(Ph)C(O)O\}(PPh_3)_2]$ (**60**), the first example of insertion of CO_2 into a Pt—N bond.[186] Other unsaturated carbon compounds such as CS_2 and electrophilic alkenes and alkynes react similarly. The diradical perfluoro-*N*,*N*′-dimethylethane-1,2-bis(amino-oxyl) reacts readily by oxidative addition to the platinum(0) precursor $Pt(PPh_3)_4$ to afford the corresponding platinum(II)–nitroso complex containing a seven-membered chelate ring (**61**). The resulting complex is stable in air for several days at room temperature.[187]

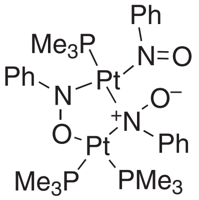


(**60**)



(**61**)

A dinuclear platinum(II) species containing three distinct linkage isomers of nitrosobenzene can be prepared by the treatment of $[PtH_2(PMe_3)_2]$ with a large excess of nitrobenzene to afford black crystals of $[Pt_2(PhNO)_3(PMe_3)_3]$ (**62**) in low yield.[188] The X-ray structure of the product shows that the two platinum(II) centers and two bridging, dianionic nitroso groups are arranged in a puckered five-membered ring, with one of the nitroso ligands bridging the two metal centers in a unusual η^2-manner and the other ligand bridging via the *N*-atom only. The third nitroso group acts as an uncharged N-donor ligand to one of the platinum atoms, formed by displacing one of the PMe_3 ligands.

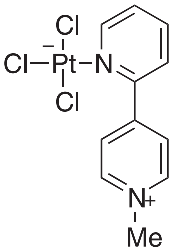


(**62**)

6.5.4.2.5 Heterocyclic N-donor ligands

Nitrogen heterocycles have a strong affinity for platinum(II), and complexes of these ligands, particularly pyridine and related diimines such as bipy, are ubiquitous.[189,190] The favorable electronic (strong σ-donor/weak π-acceptor) and steric properties of such ligands lead to the formation of many distinct classes of stable complexes, with many of these exhibiting strong luminescence owing to favorable MLCT processes.[191]

The cationic ligand 1′-methyl-2,4′-bipyridinium (mbpy) ion reacts with $[PtCl_4]^{2-}$ to afford the zwitterionic complex $[PtCl_3(mbpy)]$ (**63**) in which the mbpy ligand is coordinated to the metal center in a monodentate manner via the N-1 atom.[192] Refluxing the complex in water for several hours yields the cyclometallated species $[PtCl_2(mbpy)]$, in which the platinum(II) center is coordinated to the pyridyl N-1 and C-5′ atoms of the chelating mbpy ligand.



(**63**)

The orange–yellow complex $[Pt(CN)_2(5,5'\text{-}Me_2bipy)]$ is intensely luminescent in MeCN solution ($\lambda_{\text{emission}} = 502$ nm, with a lifetime (τ_0) of 6.3 μs) at room temperature.[193] The excited triplet state arising from a π–π* transition is a potent one-electron oxidizing agent and also a useful reductant, with numerous substrates such as alkyl iodides being able to quench the excited state. The intense solution and solid-state emission properties of related diimineplatinum(II) complexes of the type $[PtL_2(5,6\text{-}Me_2phen)]$[194] and $[Pt(CN)_2(NN)]$ (NN = 4,4′-dimethyl-2,2′-bipyridine; bipy; 1,10-phenanthroline),[195] respectively, have also been reported.

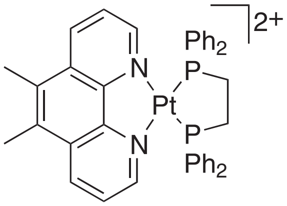
Herber and co-workers[198] have described the detailed FT-IR, UV–visible and EXAFS study into the origin of the polychromism of $[PtCl_2(bipy)]$ which is known to exist in both red and yellow crystalline forms.[196,197] The predominant difference between the two modifications is the considerable differences in the stacking interactions of the monomers in the solid state.[198] Temperature-dependent X-ray diffraction and emission spectroscopy studies of the red form have also been reported.[199] The related complexes $[Pt(CSN)_2(bipy)]$[200] and $[Pt(CSN)_2(4,4'\text{-}Me_2bipy)]$[201] were also studied. Both complexes display linkage isomerism where the thiocyanato ligand is coordinated to the metal center by either the *S*- or *N*-atom. Interestingly, the mixed linkage isomer $[Pt(SCN)(NCS)(4,4'\text{-}Me_2bipy)]$ can be isolated by the careful heating of solid $[Pt(SCN)_2(4,4'\text{-}Me_2bipy)]$ under vacuum.

Langmuir-Blodgett films of luminescent platinum(II) complexes such as $[Pt(dppe)(5,6\text{-}Me_2phen)]^{2+}$ ((**64**); phen = 1,10-phenanthroline) are of great interest.[202] Both monolayer and multilayer films can be prepared and manipulated on a water surface when the complexes are mixed with stearic acid in either a 1:1 or 1:2 ratio. The pressure–area isotherms of the films have been analyzed, and the monolayer-transferred films were studied by means of scanning tunneling microscopy. Luminescent Langmuir-Blodgett films of the amphiphilic complex $[PtClL]^+$ (L = 2,6-bis(1-octadecylbenzimidazol-2-yl)pyridine) have also been reported.[203]

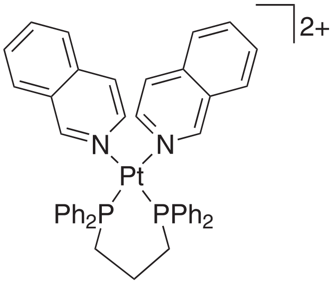
Platinum(II) complexes of the type $[PtI_2(2,9\text{-}Me_2phen)L]$; L = C_2H_4, CO, PPh_3, ONPh) can be prepared by the facile addition of L to $[PtI_2(2,9\text{-}Me_2phen)]$.[204,205] The X-ray structure for each of the complexes was determined. In the case of strong π-accepting ligands such as CO, the ground-state geometry of the complex is close to five-coordinate, but in the case of ONPh and PPh_3, the rigid 2,9-Me_2phen ligand becomes monodentate and the complex is four-coordinate. *Ab initio* Hartree-Fock SCF MO calculations were performed in order to rationalize this behavior. In later work, the synthesis and detailed dynamic behavior of complexes of the type *cis*- and *trans*-$[PtX_2(2,9\text{-}Me_2phen)(PPh_3)]$, *trans*-$[PtX(2,9\text{-}Me_2phen)(PPh_3)_2]^+$, and *trans*-$[PtX(2,9\text{-}Me_2phen)(PBu^n{}_3)_2]^+$ (X = Cl, Br, I), where the Me_2phen ligand acts as a monodentate ligand, were also reported.[206]

A series of diastereomeric platinum(II) complexes of the type *cis*-$[PtL_2Y_2]^{2+}$ (L = 3-bromopyridine, quinoline, isoquinoline; Y = PEt_3, Y_2 = dppp, (*R*)-(+)-2,2′-bis(diphenylphosphino)-1,1′-binaphthyl (*R*-(+)-binap)) have been prepared by the reaction of *cis*-$[PtY_2(OTf)_2]$ (OTf = tri-trifluoromethanesulfonate) with two equivalents of the N-donor ligand.[207] Related complexes have also been studied, for example when L = pyridine.[208] Restricted rotation about the Pt—N bonds in many of the complexes is usually detected by NMR spectroscopy, with only $[Pt(dppp)(isoquinoline)_2]^{2+}$ (**65**) exhibiting dynamic behavior at ambient temperatures. The PEt_3

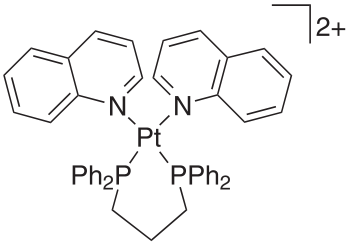
complexes are found to restrict the rotation of the N-donor ligand to the greatest extent, with the quinoline complexes undergoing the slowest interconversion. The X-ray structure of $[Pt(dppp)(quinoline)_2](OTf)_2$ (**66**) and its ^{31}P NMR solution spectrum confirm that the complex exists in the *syn* conformation. In contrast, the major rotamer of [Pt{(*R*)-(+)-binap}(isoquinoline)$_2$] (**67**) exists in one of the two *anti* (C2-symmetrical) forms.[207] In a related study, the Pt—N rotational barriers in complexes of the type [Pt{*R*-(+)-binap}L$_2$]$^{2+}$ (L = 3-picoline, 2-bromo-5-methylpyridine, 2-methylquinoline, 3-methylisoquinoline) were determined by means of variable-temperature NMR spectroscopy.[209]



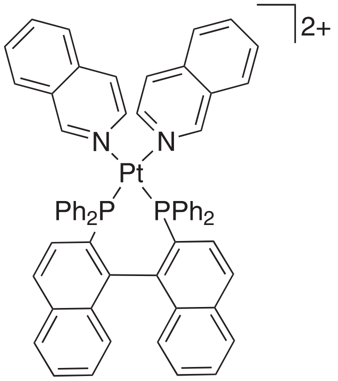
(**64**)



(**65**)

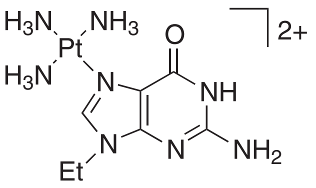


(**66**)

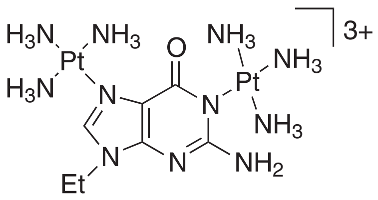


(**67**)

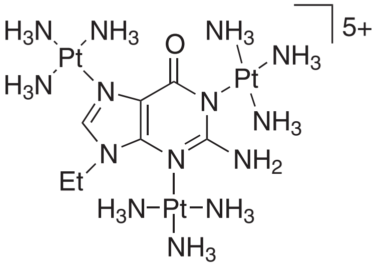
Platinum(II) complexes of 1-methyluracil, 9-ethylguanine, 9-methyladenine, and several other nucleobase derivatives have been reviewed extensively,[210,211] and the following examples serve to highlight this rich and diverse area of coordination chemistry. The molecular structure of *cis*-$[Pt(NH_3)_2(1\text{-}MeU)_2]\cdot 4H_2O$ has been determined by X-ray diffraction, confirming the coordination of 1-MeU to the metal center via N-3 of the pyrimidine base.[212] The reaction of $[Pt(NH_3)_3(H_2O)]^{2+}$ with 9-EtGH affords three products, the mononuclear species $[Pt(NH_3)_3(9\text{-}EtGH)]^{2+}$ (**68**) where the platinum(II) center is bonded to N-7, the dinuclear species $[Pt(NH_3)_3(9\text{-}EtG)\text{-}Pt(NH_3)_3]^{3+}$ (**69**) where one platinum(II) center is bonded to N-7, and the other bonded to (deprotonated) N-1 and, finally, the trinuclear species $[\{Pt(NH_3)_3\}_3(9\text{-}EtG)]^{5+}$ (**70**) where the sites of platination occur at (deprotonated) N-1, N-3, and N-7.[213] The triplatinated species is the first example of a guanine complex containing three metal centers. The synthesis and structure of a dinuclear platinum(II) derivative of 9-EtG bridged by pyrazolate (pz), *cis*-$[\{Pt(NH_3)_2(9\text{-}EtG)\}_2(\mu\text{-}pz)]^{3+}$ (**71**), has been reported.[214] The unusual but facile intramolecular migration of *trans*-diammineplatinum(II) from the endocyclic N-1 (or N-7) site to the exocyclic NH_2 group in 9-MeA has been demonstrated.[215,216] A platinum(II) derivative of 3′,5′-diacetylthymidine (Ac_2(dT)) has been prepared by the treatment of *cis*-$[PtCl_2(dppf)]$ (dppf = 1,1′-bis(diphenylphosphino)ferrocene-P^1,P^2) with Ac_2(dT) in dimethylsulfoxide or *N*,*N*-DMF solution to rapidly afford the species *cis*-[PtL{Ac_2(dT)}(dppf)] (L = DMSO, DMF). The Ac_2(dT) ligand is coordinated to the platinum(II) center via the (deprotonated) N-3 atom of thymidine.[217]



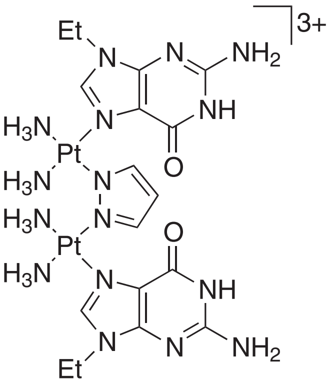
(**68**)



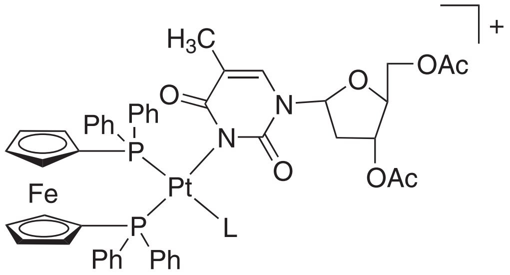
(**69**)



(**70**)

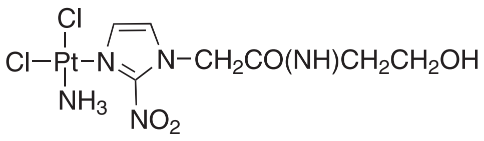


(**71**)



(**72**)

Farrell and Skov have reported the synthesis and properties of the two- and five-substituted nitroimidazole complexes *cis*- and *trans*-$[PtCl_2(NH_3)(ImNO_2)]$, which may be useful as potential radiosensitizers and hypoxic cytotoxins.[218,219] Treatment of $[PtCl_3(NH_3)]^-$ with one equivalent of the nitroimidazole derivatives etanidazole, misonidazole, and metronidazole affords the *cis* isomers. Heating the complexes for several hours leads to the formation of the corresponding *trans* isomers when misonidazole or metronidazole is used. The X-ray structure of *cis*-$[PtCl_2(NH_3)$(etanidazole)] (**73**) and the reduction potentials of all new complexes were also determined. Interestingly, the reduction potential of all nitroimidazole ligands increased by 0.15–0.25 V upon coordination to the metal. The complexes have also been shown to bind to DNA.[218]

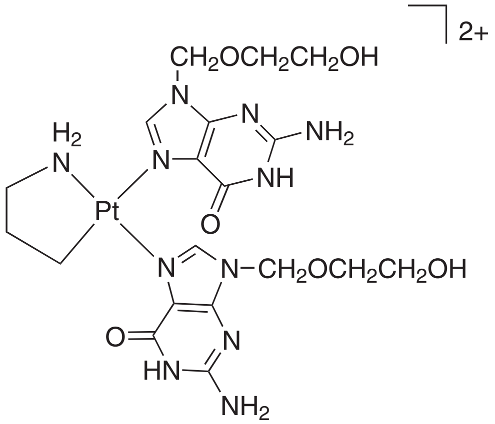


(**73**)

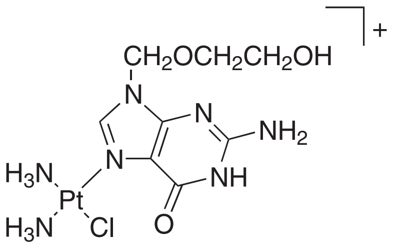
The preparation and DNA-binding properties of platinum(II) complexes of the type [Pt(bipy)(n-R-py)$_2$]$^{2+}$ (R = CN, Cl, H, Ph, Me, NH_2; $n = 2$–4), prepared by the reaction of excess pyridine with $[PtCl_2(bipy)]$, have been reported.[220] The related $[Pt(Ph_2bipy)(4\text{-}R\text{-}py)_2]^{2+}$ complexes were also studied.[221]

The synthesis and X-ray structure of a platinum(II) complex containing the well-known antiviral nucleoside acyclovir (9-(2-hydroxyethoxymethyl)guanine, acv) have been described.[222] Treatment of acyclovir with $[PtCl(DMSO)(en)]^+$ results in the formation of $[Pt(en)(acv)_2]^{2+}$ (**74**), whereby two acv molecules are coordinated to the platinum(II) center via their N-7 atoms. The related complex *cis*-$[PtCl(NH_3)_2(acv)]^+$ (**75**) has also been reported.[223]

Numerous examples of nucleophilic attack on coordinated nitrile ligands are found in the literature, particularly when the transition metal is platinum(II).[224] The nucleophilic attack of two equivalents of $ClCH_2CH_2O^-$ on the electrophilic nitrile carbon atoms of both nitrile ligands in *cis*- or *trans*-$[PtCl_2(RCN)_2]$ (R = Et, Pr^n, Pr^i, Bu^t, p-$CF_3C_6H_4$, p- and o-MeC_6H_4) affords the corresponding Δ^2-1,3-oxazoline complexes ((**76**) and (**77**), respectively), in which the heterocycle acts as a



(**74**)

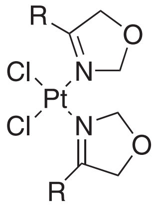


(**75**)

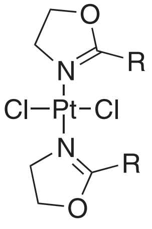
N-donor ligand. The reaction appears to proceed via an acyclic iminoplatinum(II) intermediate that undergoes a subsequent intramolecular cyclization. Some mechanistic aspects of this versatile reaction have been elucidated.[225,226] Δ^4-1,2,4-oxadiazolines have been prepared by the [2+3] cycloaddition of various nitrones to coordinated benzonitrile in *cis*-[$PtCl_2$(DMSO)(PhCN)] precursors.[227,228] Racemic and chiral [$PtCl_2$(PhMeSO)(PhCN)] complexes have also been used in order to introduce a degree of stereoselectivity into the reaction, resulting in the first enantioselective synthesis of Δ^4-1,2,4-oxadiazolines, which can be liberated from the complexes by the addition of excess ethane-1,2-diamine.

Liquid–crystalline complexes (metallomesogens) containing platinum(II) are new types of materials that have been the subject of several studies. These have largely included complexes of the type *trans*-[PtX_2L_2] (X = Cl, L = cyanobiphenyls;[229] X = Cl, carboxylate, L = 4-alkoxy-4′stilbazoles;[230] X = Cl, L = 2,4-, 3,4-, or 3,5-dialkoxystilbazoles, 2,3,4-, 2,4,5-, or 3,4,5-trialkoxystilbazoles).[231,232] Their liquid–crystalline properties have also been reported.

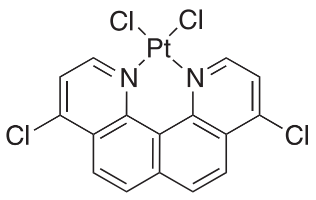
The first examples of transition metal complexes containing 4,9-dichloroquino[7,8-*h*]quinoline, also known as a "proton sponge", have been described.[233] Treatment of Zeise's dimer, [$Pt_2(C_2H_4)_2Cl_4$], with 4,9-dichloroquino[7,8-*h*]quinoline (dcqq) in CH_2Cl_2 solution leads to the formation of [$PtCl_2$(dcqq)] (**78**). The X-ray structure of the complex reveals a highly distorted aromatic system, with the platinum atom lying 1.43 Å out of an idealized square plane.



(**76**)



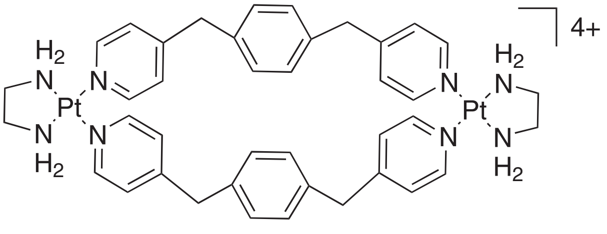
(**77**)



(**78**)

Fujita *et al.* have reported the synthesis of a remarkable "molecular lock" comprising of two dinuclear platinum(II) complexes that form a mechanically interlocked [2]-catenane structure.[234] Heating the monomeric platinum(II) species (**79**) in highly polar media such as a concentrated aqueous solution of $NaNO_3$ (5 M) results in the cleavage of at least one of the Pt—N bonds, and a subsequent equilibrium results between the monomer and catenated dimer, with the self-assembly of the latter favored under these conditions. Cooling and crystallization from the solution allowed the [2]-catenane species to be isolated, the structure of which was confirmed by X-ray diffraction. The mechanically interlocked species was stable to 100 °C in aqueous solution. This example is only one of several that have highlighted the great versatility of the Pt—N bond in the construction of nanomolecular polygons and polyhedra by self-assembly, an area that has been reviewed extensively.[235–249] Furthermore, supramolecular coordination chemistry is comprehensively reviewed in Volume 6 of *Comprehensive Coordination Chemistry II.* Two major classes of precursor platinum(II) complexes containing labile ligands have been utilized in these studies, namely the mononuclear complexes

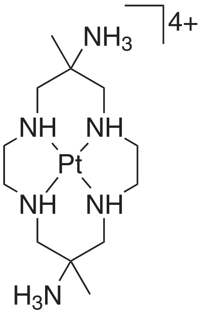
$[Pt(en)(NO_3)_2]$ and $[Pt(OTf)_2L_2]$ (L = mono- or 1/2 bidentate tertiary phosphine) or dinuclear complexes of the type $[Pt_2(OTf)_2(\mu\text{-}\sigma\text{-aryl})L_2]$ (L = monodentate tertiary phosphine; σ-aryl = 4,4′-biphenyl, *p*-terphenyl, 4,4′-benzophenone, etc.); other structural motifs employing platinum(II) have also been reported.[250] The addition of bridging, multidentate N-donor ligands of various shapes and sizes to the labile complexes in a suitable solvent system has afforded several classes of discrete, platinum(II)-containing polygons, polyhedra, and catenanes.



(**79**)

6.5.4.2.6 Macrocyclic N-donor ligands

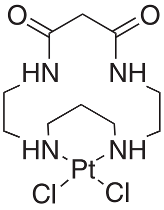
The first structurally characterized example of a platinum(II) derivative containing a saturated tetraamine macrocycle, 6,13-dimethyl-1,4,8,11-tetraazacyclotetradecane-6,13-diamine has been reported (**80**).[251] The species crystallizes as the colorless tetra-cationic complex from dilute $HClO_4$ solution by slow evaporation, where the two pendant primary amines are protonated. Other macrocyclic tetraamine complexes including $[Pt([14]aneN_4)]Cl_2$ have also been described.[252]



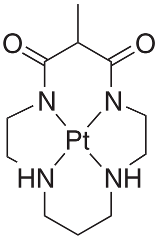
(**80**)

A lipophilic dioxocyclam derivative has proved to be very efficient at the selective extraction of platinum(II) from complexes such as *cis*-$[PtCl_2(NH_3)_2]$ or $[PtCl_4]^{2-}$ at pH > 3.[253] Addition of the reducing agent $S_2O_3^{2-}$ to the solution assists with metal complexation, possibly by reductive weakening of the Pt—X bond prior to complexation by the macrocycle. Indeed, the absence of a reducing agent leads to very little complexation. The macrocycle can also selectively remove platinum(II) from a mixture of metal ions including copper(II) and nickel(II). The method described in this work may have potential applicability in chelation therapy and in analytical and mineralogical systems. The first X-ray structures of dioxocyclam- and 6-methyldioxocyclam-platinum(II) complexes ((**81**) and (**82**), respectively) have also been reported.[254]

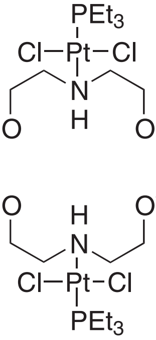
The reaction of *trans*-$[PtCl_2(NH_3)(PEt_3)]$ with the aza-crown ethers $[12]aneNO_3$, $[15]aneNO_4$, and $[18]aneNO_5$ in $CHCl_3$ solution has been reported.[255] Substitution of the ammine ligand by the secondary amine of the crown ether ensues to give complexes of the type *trans*-$[PtCl_2$(aza-crown)$(PEt_3)]$. When the 4,13-diaza[18]crown-6 ether $[18]aneN_2O_4$ is used, a dinuclear complex $[\{[PtCl_2(PEt_3)]\}_2([18]aneN_2O_4)]$ (**83**) is obtained. If equimolar amounts of *trans*-$[PtCl_2(NH_3)(PEt_3)]$ and *trans*-$[PtCl_2([18]aneNO_5)(PEt_3)]$ are allowed to crystallize from $CHCl_3$ solution then yellow crystals of the second-sphere adduct *trans*-$[PtCl_2(NH_3)(PEt_3)]\cdot[PtCl_2([18]aneNO_5)(PEt_3)]$ (**84**) are formed, the first example of a metalloreceptor in which *both* the host and guest are transition metal complexes. X-ray analysis of the adduct reveals extensive H-bonding interactions of the ammine ligand in the *trans*-$[PtCl_2(NH_3)(PEt_3)]$ guest with the crown ether *O*-atoms in the *trans*-$[PtCl_2([18]aneNO_5)(PEt_3)]$ host. The same authors have also reported that the dicationic tetrakis(*n*-butylnicotinamide)platinum(II) species is a useful receptor for oxoanions such as nitrate.[256]



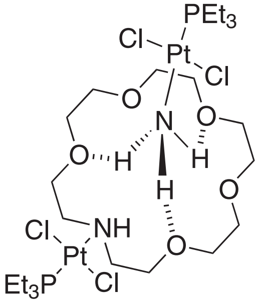
(**81**)



(**82**)



(**83**)



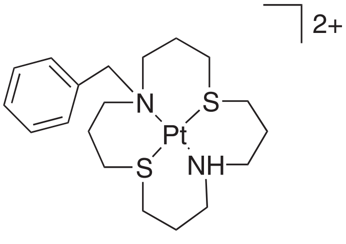
(**84**)

Platinum(II) derivatives of the mono- and trimacrocylic N_2S_2-donor ligands based upon 1,9-dithia-5,13-diazacyclohexadecane have been reported.[257] Treatment of the ligands with *cis*-$[PtCl_2(PhCN)_2]$ in MeCN solution under reflux conditions afforded the mono- and trinuclear complexes ((**85**) and (**86**), respectively) in good yield.

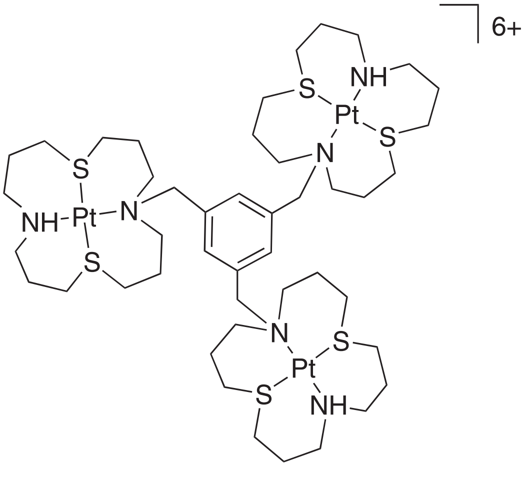
6.5.4.2.7 *Amino acid and peptide ligands*

The interaction of platinum(II) complexes with various amino acids and simple peptides is relevant to understanding the biological fate of platinum anticancer agents such as *cis*platin, and this area has been reviewed extensively.[258–261]

Treatment of the simplest amino acid glycine, with *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ in aqueous solution affords *cis*-$[Pt(NH_3)_2(O\text{-glyH})(H_2O)]^{2+}$ (**87**), in which the glycine is coordinated to the metal center via the *O*-atom only.[262] The product subsequently converts to the thermodynamically

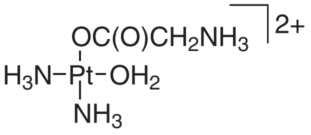


(**85**)

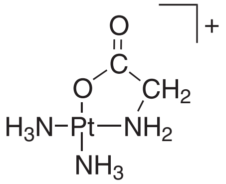


(**86**)

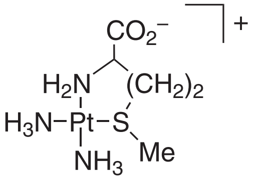
favored chelate complex $[Pt(NH_3)_2(N,O\text{-gly})]^+$ (**88**). The slow rate of the ring closure reaction is considerably enhanced if base is added to the solution in order to deprotonate the ammonium group of the glycine. Alternatively, gentle heating of the solution enhances the rate of ring closure also. Similar reactions were also observed with *N*-acetylglycine.[263] In a related study, treatment of *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ with L-methionine and *S*-methyl-L-cysteine at pH = 5 affords the chelate complexes $[Pt(NH_3)_2(N,S\text{-met})]^+$ (**89**) and $[Pt(NH_3)_2(N,S\text{-mecys})]^+$ (**90**), respectively, as slowly interconverting diastereomers owing to the different configurations about the sulfur atom.[264] At low pH values (≤0.5), the first product that is formed in the reaction with *S*-methyl-L-cysteine is the *O*-bonded chelate complex $[Pt(NH_3)_2(O,S\text{-mecysH})]^{2+}$ (**91**), which is slowly converted to the thermodynamically preferred *N*,*S*-chelate species (**92**). A similar type of reaction occurs with L-methionine, but *cis*-$[Pt(NH_3)_2(S\text{-metH})_2]^{2+}$ (**93**) is also formed in competition with *cis*-$[Pt(NH_3)_2(O,S\text{-metH})]^{2+}$ (**94**). Loss of ammonia occurs in all complexes upon standing, most probably due to the strong *trans*-effect of the S-donor ligand. In another study involving the reaction of *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ with the thiol-containing amino acids *N*-acetyl-L-cysteine, D,L-homocysteine and the peptide glutathione, a dinuclear complex containing a four-membered Pt_2S_2 ring is formed, with slow loss of ammonia from the complexes again being observed.[265] L-Cysteine affords a related complex in addition to two minor components, *cis*-$[Pt(NH_3)_2\{(SCH_2CH(NH_3)(CO_2H)\}_2]^{2+}$ and $[Pt(NH_3)_2(N,S\text{-cysH})]^+$. Finally, the use of D-penicillamine at low pH (<0.5) leads to the initial formation of a dinuclear platinum(II) species $[\{Pt(NH_3)_2\}_2(\text{penH})]^{3+}$ in which it appears that the two metal centers are bridged by both the sulfur atom and the carboxylato group. Within a few hours at room temperature, the complex converts to a new isomeric species in which the two metal centers are still bridged by the sulfur atom, but the D-penicillamine amino group is coordinated to one of the platinum(II) centers, and the carboxylate group is bound to the other metal center.



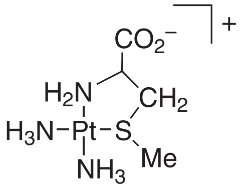
(**87**)



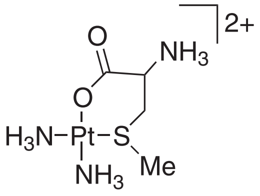
(**88**)



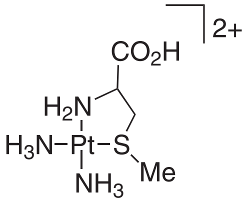
(**89**)



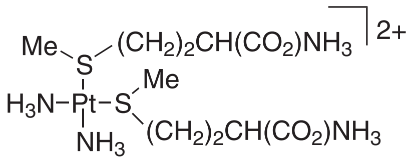
(**90**)



(**91**)

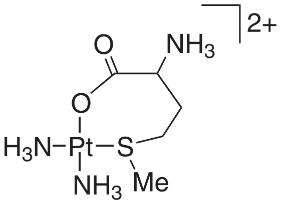


(**92**)

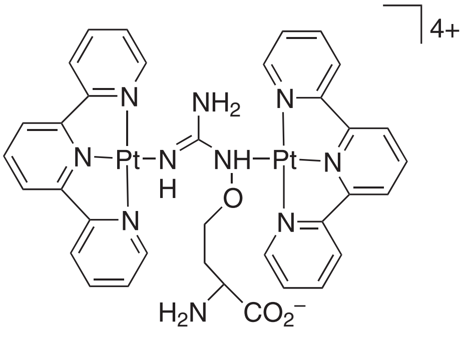


(**93**)

The use of luminescent complexes such as $[PtCl(\text{terpy})]^+$ (terpy = 2,2′:6′,2″-terpyridine) and its derivatives as reporter probes for biomolecules is now well-established.[266,267] As part of a number of studies involving the labeling of specific protein sites with metal complexes,[268–271] Kostic and co-workers have investigated the reactions of $[PtCl(\text{terpy})]^+$ with arginine, guanidine, *N*-acetylarginine, canavanine, and methylguanidine.[272] The platinum(II) precursor reacts with ArgH, CanH, and MeGua to afford the yellow, mononuclear species of the type $[PtL(\text{terpy})]^{2+}$ (L = ArgH, CanH, and MeGua, respectively). In these reactions, a red dinuclear species $[\{Pt(\text{terpy})\}_2L]^{4+}$ was also formed, and the two species were readily separated from each other by means of cation-exchange chromatography. In the mononuclear complexes, the guanidine ligand coordinates to the metal center by means of the trigonal imino-type N atom. In contrast, the guanidine ligand bridges two metal centers in the dinuclear complexes via the amino- and imino-type *N*-atoms. The X-ray structure of $[\{Pt(\text{terpy})\}_2(\text{Can})]^{4+}$ (**95**) confirms the unusual bonding mode of the guanidine ligand.

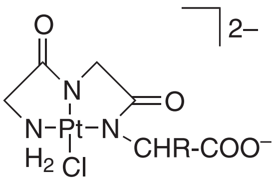


(94)

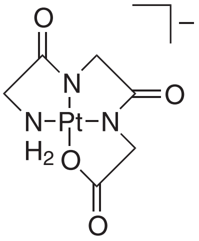


(95)

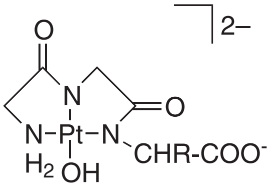
The ^1H, ^{13}C, and ^{195}Pt NMR and CD spectroscopic characterization of platinum(II) complexes containing the triglycine (trg) peptide has been reported. Treatment of triglycine with $[PtCl_4]^{2-}$ in aqueous solution (pH = 6–7) affords three distinct 1:1 peptide complexes, namely $[PtCl(trg)]^{2-}$ (**96**), $[Pt(trg)]^-$ (**97**), and $[Pt(OH)(trg)]^{2-}$ (**98**) with the chloro species present in greatest abundance (ca. 70% of total platinum). In all cases, two deprotonated *N*-peptide ligands are arranged in a *cis* geometry.[273]



(96)



(97)



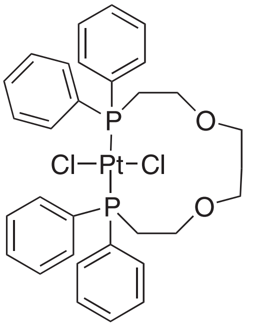
(98)

6.5.4.3 Platinum(II) Complexes with Phosphorus-, Arsenic-, and Antimony-donor Ligands

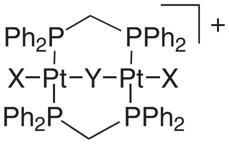
6.5.4.3.1 Mono-, bi-, and tridentate P-donor ligands

Studies of the conductivity behavior of $[Pt(dppm)_2]X_2$ (X = Cl, Br, I, PF_6, BF_4) in solution have been reported.[274] Both conductivity and NMR studies of the halide complexes are consistent with the five-coordinate adduct $[Pt(dppm)_2X]^+$ being present in chlorinated hydrocarbon and ethanenitrile solutions.

The various factors that influence the formation of *cis* and *trans* complexes of platinum(II) containing long-chain diphosphine ligands of the type $Ph_2P(CH_2)_nPPh_2$ (n = 2, 6–12, 16) have been investigated.[275] The formation of individual isomers appears to be highly dependent on the nature of the precursor complex. In the case of $[PtCl_4]^{2-}$, the *cis* isomer is formed exclusively, whereas the *trans* isomer is formed when $K[PtCl_3(C_2H_4)]\cdot H_2O$ (Zeise's salt) is employed in the synthesis. The thermodynamically more stable *cis* isomer is formed if a strong *trans*-labilizing ligand is not present in the precursor complex. Indeed, the *trans* isomer is readily converted to the *cis* form by the application of heat or the addition of excess phosphine ligand to the solution. The presence of bulky R groups on the phosphorus atoms is not a necessary criterion for the formation of the *trans* isomer. For the *cis* complexes, a dimeric form whereby the two phosphine ligands bridge two platinum(II) centers, is generally preferred over the monomeric, chelated species. A related study involving the 1,8-bis(diphenylphosphino)-3,6-dioxaoctane ligand involved parallel syntheses to those described above, with *cis*-$[Pt(dpdo)Cl_2]$ (dpdo = 1,8-bis(diphenylphosphino)-3,6-dioxaoctane) prepared from $[PtCl_4]^{2-}$ and the corresponding *trans* isomer (**99**) prepared from Zeise's salt.[276]



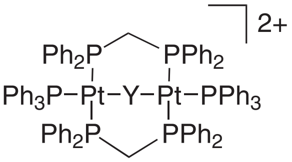
(99)



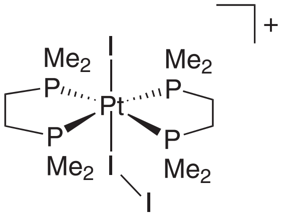
(100)

The mechanism of "A"-frame inversion for dinuclear platinum(II) complexes of the type $[Pt_2(\mu\text{-}Y)X_2(\mu\text{-dppm})_2]^+$ (Y = H, Cl, SMe, PPh_2; X = H, Cl, Me) (**100**) has been studied in great detail.[277] All of the complexes that undergo an inversion process on the NMR time scale possess a bridging hydrido ligand or are capable of rapidly isomerizing to a complex possessing a bridging hydride. The key step in the process appears to involve an intermediate with a linear Pt–H–Pt group. An elucidation of the mechanism and reaction energetics for the ligand-induced reductive elimination of H_2 from the parent "A"-frame species $[Pt_2(\mu\text{-H})H_2(\mu\text{-dppm})_2]^+$ by various tertiary phosphines to afford a species containing a Pt—Pt bond has also been reported.[99] In this process, the key intermediate $[Pt_2L(\mu\text{-H})H_2(\mu\text{-dppm})_2]^+$ (L = tertiary phosphine) is formed, and is followed by intramolecular loss of H_2.

The reactions of the dinuclear platinum(I) species $[Pt_2(PPh_3)_2(\mu\text{-dppm})_2]^{2+}$ with CH_2N_2, CO, SO_2, and S_8 to afford the corresponding "A"-frame complexes of the type $[Pt_2(PPh_3)_2(\mu\text{-}Y)(\mu\text{-dppm})_2]^{2+}$ (Y = CH_2, CO, SO_2, and S, respectively) (**101**) have been described.[106] The results of comprehensive kinetic experiments are consistent with the unimolecular formation of a common intermediate possessing a dangling dppm ligand, which is then attacked by the inserting reagent to form the final product.



(101)

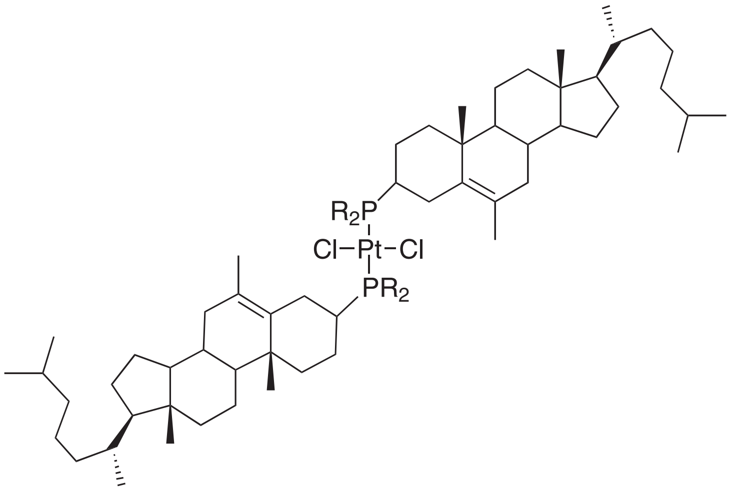


(102)

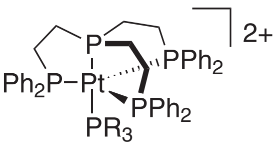
An extremely rare example of a six-coordinate platinum(II) complex has been prepared by the reaction of $[Pt(dmpe)_2]^{2+}$ with three equivalents of I_2 in H_2O/EtOH solution which affords black crystals of $[PtI(dmpe)_2(\kappa\text{-}I_2)]I_3$ (**102**). X-ray crystallography reveals a neutral I_2 ligand that is coordinated to the metal center through one of the iodine atoms.[278] XPS (X-ray photoelectron spectroscopy) measurements are consistent with the platinum center having a +2 oxidation state.

The coordination chemistry of tertiary phosphine-functionalized calix[4]arenes have been described.[279] Treatment of a bis(diphenylphosphino) or bis(dimethylphosphino) derivative of calix[4]arene with $[PtCl_2(COD)]$ leads to the formation of the corresponding dichloroplatinum(II) complex. The related diplatinum(II) species has also been reported with the tetrafunctionalized calix[4]arene.[280] The mononuclear derivative is susceptible to oligomerization if the two free phosphine ligands are not oxidized or complexed to another metal center such as gold(I).[279] The platinum(II) coordination chemistry of a mono-[281] and diphosphite[282] derived calix[*n*]arene (*n* = 4 and 6, respectively) has also been described.

The first examples of platinum(II) complexes of the steroid 5-cholestene have been reported.[283] Treatment of two equivalents of 5-cholestene-3*n*-diphenylphosphine (*n* = α) or -dimethylphosphine (*n* = β) with $[PtCl_2(PhCN)_2]$ or $[PtCl_2(SEt_2)_2]$, respectively, affords the corresponding *trans*-dichloroplatinum(II) derivatives (**103**) in high yield.



(103)

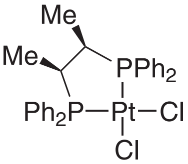


(104)

The first examples of five-coordinate platinum(II) complexes of the type $[Pt(PR_3)L]^{2+}$ (L = tris(2-(diphenylphosphino)ethyl)phosphine; R = Et, OMe, OEt) (**104**) containing only P-donor atoms have been prepared by the reaction of $[PtClL]^+$ with an appropriate monodentate tertiary phosphine or phosphite ligand.[284] Triaryl phosphines and phosphites do not react with the precursor complex, even at elevated temperatures, most probably due to the considerable steric interactions that would occur upon the approach of the P-donor ligand to the platinum(II) center.

A study of sequential Arbuzov-type demethylation reactions of the platinum(II)–phosphite complex $[Pt\{P(OMe)_3\}_4]^{2+}$, in which the phosphite ligands are converted to phosphonates, has been described.[285] Many of the products of the reaction were characterized by NMR spectroscopy and X-ray crystallography.[286] The X-ray structures are the first reported for trialkylphosphite complexes of platinum(II).

A rare example of the resolution of a planar-chiral platinum(II) complex has been described.[287] Treatment of the ligand with $[PtCl_2(COD)]$ in CH_2Cl_2 solution affords the *meso* complex $[PtCl_2$-(achiraphos)] (achiraphos = (R^*,S^*)-2,3-bis(diphenylphosphino)butane) (**105**) in high yield. The addition of one equivalent of Ag^+ to remove one of the two enantiotopic chloro ligands, followed by the addition of the homochiral resolving ligand *R*-diphenylmenthylphosphine (*R*-$PMenPh_2$) and NH_4PF_6 affords the diastereomeric complexes $[PtCl(R\text{-}PMenPh_2)(achiraphos)]PF_6$ in which the monodentate phosphine ligand is located *trans* to the diphenylphosphino group attached to either the *R* or *S* carbon atom of the chelating achiraphos. The homochiral epimer in which the *R*-$PMenPh_2$ ligand is bonded *trans* to the diphenylphosphino group attached to the *S* carbon atom of the achiraphos ligand is crystallized from the concentrated mother liquor containing a mixture of the two epimers. X-ray crystallography confirmed the structure of the planar-chiral complex.

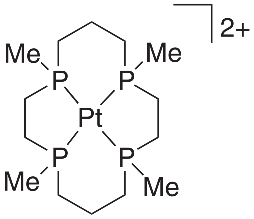


(105)

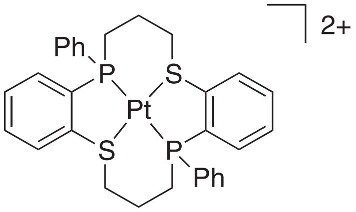
A variable-temperature ^{19}F NMR spectroscopic study of pentafluorophenylphosphine complexes of the type *trans*-$[PtCl_2(PEt_3)L]$ (L = $P(C_6F_5)_3$, $PPh(C_6F_5)_2$, $PPh_2(C_6F_5)$) has been reported.[288] Hindered rotation occurs about the P—C_6F_5 bonds in *trans*-$[PtCl_2(PEt_3)\{P(C_6F_5)_3\}]$, but no such phenomena were observed in the other complexes.

6.5.4.3.2 *Macrocyclic P-donor ligands*

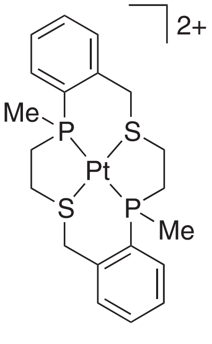
The synthesis and X-ray structure of the platinum(II) derivative of a tetradentate macrocycle $Me_4[14]aneP_4$ has been described.[289] The ligand is the phosphorus analogue of tetramethylcyclam, and it was prepared by means of a template reaction employing $[Pt(MeHPCH_2CH_2PHMe)_2]^{2+}$ and 1,3-dibromopropane in the presence of a weak base. The resulting complex $[Pt(Me_4[14]aneP_4)]^{2+}$ (**106**), with a trans III (*RRSS*) configuration of the four asymmetric P-atoms, was obtained in low yield.



(**106**)



(**107**)

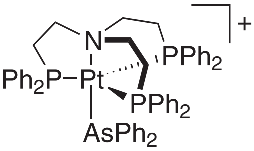


(**108**)

The platinum(II) derivative of a 14-membered P_2S_2-macrocycle containing the 1-thio-2-(phenylphosphino)benzene moiety (**107**) has been described.[290] X-ray crystallography confirms the square-planar geometry of the coordination sphere, with the Pt—S and Pt—P bond lengths being almost identical. The low-yielding metal-templated preparation of another 14-membered *trans*-P_2S_2 macrocycle has also been described.[291] Both the *R**,*R** and *R**,*S** forms of the macrocycle were isolated by the reaction of (±)-(2-thioethyl)(2-methoxybenzyl)methylphosphine with $[PtCl_4]^{2-}$ in the presence of base, followed by fractional crystallization of the mixture of *cis* and *trans* diastereomers, to afford *trans*-$[Pt(tmbmp)_2]$ (tmbmpH = (±)-(2-thioethyl)(2-methoxybenzyl)-methylphosphine) as lemon–yellow crystals. Treatment of the complex with BBr_3 allowed cyclization at sulfur to occur and thus generate the desired macrocyclic complex (**108**).

6.5.4.3.3 *As- and Sb-donor ligands*

In the first examples of terminal arsenido derivatives of platinum, treatment of $[Pt\{N(CH_2CH_2PPh_2)_3\}(PPh_3)]$ with one equivalent of R_2AsX (R = Me, X = I; R = Ph, X = Cl) in C_6H_6/EtOH solution affords the species $[Pt\{N(CH_2CH_2PPh_2)_3\}AsR_2]^+$ (**109**) in high yield. X-ray diffraction studies of the R = Ph derivative confirm that the platinum(II) center is five-coordinate.[292]



(**109**)

Wendt and co-workers have reported the synthesis of platinum(II) complexes of the type $[PtI_3(EPh_3)]^-$ (E = P, Sb, As).[293,294] A systematic mechanistic study demonstrated that the *trans* effect for the Group 15 ligands follows the order $Ph_3Sb > Ph_3P > Ph_3As$. From X-ray data, the *trans* influence of the ligands is found to follow the order $Ph_3P \geq Ph_3As > Ph_3Sb$.

6.5.4.4 Platinum(II) Complexes with Oxygen-donor Ligands

6.5.4.4.1 *Aqua, hydroxo, and oxo ligands*

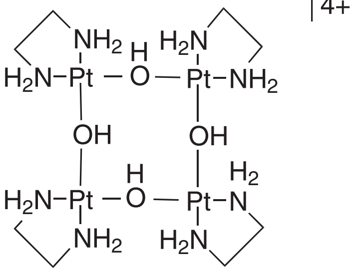
The reactions of the $[Pt(H_2O)_4]^{2+}$ ion with various anionic (A^{m-}) ligands have been studied by means of ^{195}Pt NMR spectroscopy.[295] The formation of complexes of the type

$[PtA_n(H_2O)_{4-n}]^{(2-mn)+}$ was reported for Cl^- ($n=1$–4), ONO_2^- ($n=1$–3), OSO_3^{2-} ($n=1$, 2), $OPO_3H_2^-$ ($n=1$–4), OH^- ($n=4$), and $MeCO_2^-$ ($n=1$). No evidence of a reaction with the weakly coordinating ClO_4^- was observed.

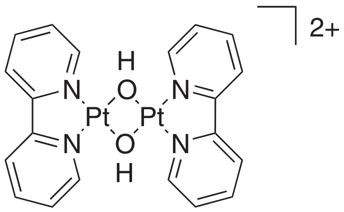
The original synthesis[296] of $[Pt(H_2O)(PEt_3)_3](PF_6)_2$ has been improved by the reaction of equimolar amounts of $[PtCl_2(PEt_3)_2]$ and Ag_2SO_4 to afford $[Pt(SO_4)(PEt_3)_2]$.[297] The addition of one equivalent of triethylphosphine to the sulfato complex in dilute H_2SO_4 solution results in the quantitative formation of $[Pt(H_2O)(PEt_3)_3]^{2+}$. FAB-MS evidence is consistent with the proposed structure of the complex. The labile aqua ligand can be displaced by a variety of other ligands, e.g., chloride, nitrate, perchlorate, acetate, and tertiary phosphines.[296] Furthermore, fluoride ion is abstracted from hexafluorophosphate in acetone solution to afford $[PtF(PEt_3)_3]^+$, a rare example of a fluoroplatinum(II) species.

The aqua-sulfato complex $[Pt(SO_4)(H_2O)(dmen)]$ (dmen = *N*,*N'*-dimethylethane-1,2-diamine) has been prepared by the reaction of $[PtI_2(dmen)]$ with Ag_2SO_4 in aqueous solution.[298] The complex is the first example of a platinum(II) species containing a monodentate sulfato ligand, as determined by X-ray diffraction. In a related study, treatment of $[PtCl_2(en)]$ with $AgNO_3$ in aqueous solution, followed by adjustment of the pH of the solution to 5.8 by the addition of 1 M NaOH affords crystals of the unusual tetranuclear complex *cyclo*-$[Pt_4(\mu\text{-}OH)_4(en)_4](NO_3)_4$ (**110**), the structure of which was confirmed by X-crystallography.[299]

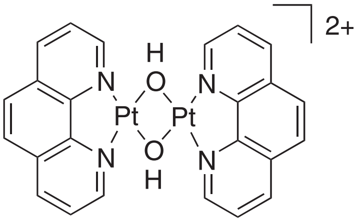
The yellow–orange, di-μ-hydroxo species $[(NN)Pt(\mu\text{-}OH)_2Pt(NN)]^{2+}$ (NN = bipy or phen) ((**111**) and (**112**), respectively) can either be prepared by the reaction of $[PtCl_2(NN)]$ with $AgNO_3$ in aqueous solution, or by the reaction of $[PtI_2(NN)]$ with $AgNO_3$ in acetone, followed by dissolution of the resulting nitrato species $[Pt(NO_3)_2(NN)]$ in water.[300] Treatment of the dinuclear products with one equivalent of hydroxide ion affords the stable, deep-red tri-μ-hydroxo species $[(NN)Pt(\mu\text{-}OH)_3Pt(NN)]^+$ ((**113**) and (**114**)). Alternatively, the reaction of $[Pt(OH)_2(NN)]$ with HX (X = ClO_4, NO_3) affords $[(NN)Pt(\mu\text{-}OH)_3Pt(NN)]^+$, $[(NN)Pt(\mu\text{-}OH)_2Pt(NN)]^{2+}$, and $[Pt(NO_3)_2(NN)]$ at pH 8, 4, and 1, respectively.



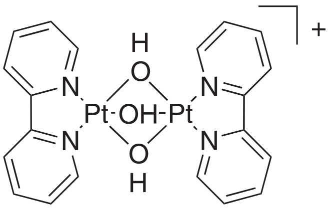
(**110**)



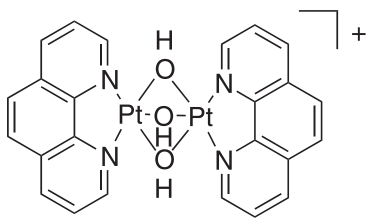
(**111**)



(**112**)



(**113**)



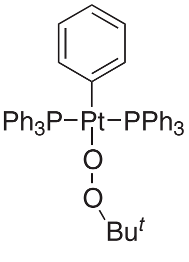
(**114**)

Platinum(II)–oxo intermediates have been implicated in the reactions of bis(alkoxo) and carbonato complexes with ligands such as CO and tertiary phosphines,[301] but there are few examples of stable platinum(II)–oxo species in the literature. Sharp and co-workers have reported the synthesis and characterization of several diplatinum(II)–hydroxo and –oxo complexes.[302–304] Treatment of $[PtCl_2L_2]$ (L_2 = dppm, dppe, dppp, dppb, $2PMe_2Ph$, 4,4'-Bu^t_2bipy) with $AgBF_4$ in the presence of small amounts of water affords $[Pt_2(\mu\text{-}OH)_2(L_2)_2]^{2+}$; the analogous $[Pt_2(\mu\text{-}OH)_2(PMe_3)_4]^{2+}$ species has also been reported.[305] Most of the reactions are sensitive to the nature of the solvent and the amount of water present. Addition of excess $LiN(TMS)_2$ to $[Pt_2(\mu\text{-}OH)_2(L_2)_2]^{2+}$ leads to the deprotonation of the bridging hydroxo groups to afford the corresponding di-μ-oxo species. In all cases, the platinum(II)–oxo complexes are strongly basic.

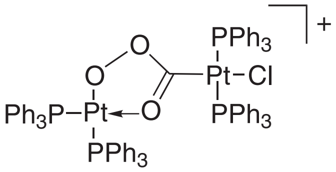
The triphenylphosphine derivative $[Pt_2(\mu\text{-}O)_2(PPh_3)_4]$ crystallizes with one equivalent of $LiBF_4$, in which the lithium ion of a $LiBF_4$ ion pair is strongly associated with both of the μ-oxo groups. The dppe, dppp, dppb, and $Bu^t{}_2$bipy complexes react similarly, but the resulting di-μ-oxo species crystallize with two equivalents of $LiBF_4$. In the case of $PMePh_2$, the deprotonation reaction is more complicated, as the initially formed $[Pt_2(\mu\text{-}O)_2(PMePh_2)_2]\cdot LiBF_4$ undergoes further reaction to afford the trinuclear di-μ_3-oxo species $[Pt_3(\mu_3\text{-}O)_2(PMePh_2)_6]^{2+}$. Interestingly, treatment of $LiN(TMS)_2$ with the dppm complex $[Pt_2(\mu\text{-}OH)_2(dppm)_2]^{2+}$ results in the deprotonation of the dppm methylene groups rather than the hydroxo ligands to afford $[Pt_2(\mu\text{-}OH)_2(dppm\text{-}H)_2]$. Further deprotonation occurs in THF solution to afford the anionic di-μ-oxo species $[Pt_2(\mu\text{-}O)_2(dppm\text{-}H)_2][Li(THF)_2]_2$.

6.5.4.4.2 Peroxo ligands

The preparation, characterization, and reactivity of novel platinum(II) complexes containing hydroperoxo and alkylperoxo ligands, $[PtR^1(OOR^2)L_2]$ ($L = $ monodentate phosphine, $L_2 = $ bidentate phosphine; $R^1 = CF_3$, CH_2CF_3, CH_2CN; $R^2 = H$, Bu^t) have been reported.[306] The complexes have been prepared by a condensation reaction of the corresponding hydroxo precursors $[PtR^1(OH)L_2]$ with R^2O_2H. The complexes are capable of acting as effective *O*-atom transfer reagents toward compounds such as CO, PPh_3, and NO. In related work, complexes of the type *trans*-$[PtR(OO\text{-}Bu^t)L_2]$ ($L = $ mono- or bidentate tertiary phosphine; $R = CF_3$, Ph-*o*-CN, Ph) have been prepared by a similar condensation route to that described above, and the X-ray structure of *trans*-$[PtPh(OO\text{-}Bu^t)(PPh_3)_2]$ (**115**) was reported. Most of the complexes are capable of stoichiometrically oxidizing 1-octene to 2-octanone under anhydrous conditions.[307] Interestingly, related complexes with a *cis* geometry and those with the hydroperoxo ligand are found to be incapable of the oxidation reaction. The epoxidation of 1-octene takes place in the presence of H_2O_2 and catalytic amounts of $[PtR(OH)L_2]$ when $L_2 = $ bidentate tertiary phosphine; the formation of the catalytically active hydroperoxo species $[PtR(OOH)L]$ was inferred.[308,309] Further kinetic studies of this reaction suggest a bimetallic mechanism in which the hydroperoxo complex interacts with a platinum(II)–alkene intermediate in the *O*-atom transfer step.[310]



(115)

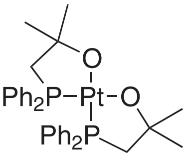


(116)

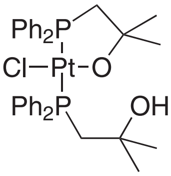
A rare example of the activation of O_2 and CO by platinum involves the treatment of the nucleophilic dioxygen species $[Pt(O_2)(PPh_3)_2]$ with the electrophilic carbonyl ligand in $[PtCl(CO)(PPh_3)_2]^+$ to afford a dinuclear cycloperoxycarbonyl adduct (**116**) in high yield.[311]

6.5.4.4.3 Alcohol, alkoxo, and ether ligands

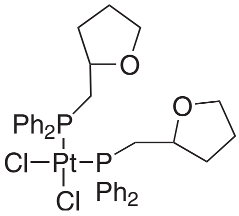
There are several studies describing the synthesis of stable alcohol, alkoxo, and ether complexes of platinum(II) that have the O-donor functionality incorporated into a phosphine ligand. The reaction of $Ph_2PCH_2CMe_2OH$ with $[PtCl_2(COD)]$ or Zeise's salt forms the *cis* and *trans* isomers of $[PtCl_2\{Ph_2PCH_2CMe_2OH\}_2]$, respectively, which can be readily interconverted.[312] The bis(alkoxo) chelate complex *cis*-$[Pt\{Ph_2PCH_2CMe_2O\}_2]$ (**117**) is formed upon the addition of a base such as NEt_3 or NaOH to the *cis*-dichloro species. Alternatively, treatment of the *trans*-dichloro species with NEt_3 affords the species *trans*-$[Pt\{Ph_2PCH_2CMe_2O\}\{Ph_2PCH_2CMe_2OH\}]$ (**118**), possessing one chelated alkoxo ligand and one dangling alcohol group; its conversion to the bis(alkoxo) chelate species is realized by the addition of NaOH in refluxing ethanol solution. A number of stable platinum(II)–alcohol intermediates were also characterized in this work, and the X-ray structure of the bis(alkoxo) chelate complex was determined. In a related study, the chelate-stabilized primary and secondary alcohol and alkoxo complexes containing the less bulky ligands Ph_2PCH_2CHROH (R = H or Me) were also studied.[313]



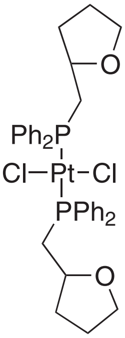
(117)



(118)

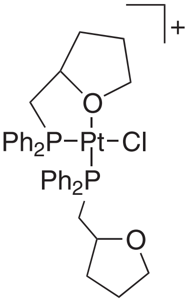


(119)

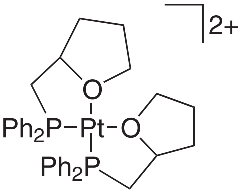


(120)

Treatment of the tetrahydrofuran phosphine ligand, $PPh_2CH_2C_4H_7O$, with $[PtCl_2(NCBu^t)_2]$ in acetone solution affords *cis*- and *trans*-$[PtCl_2(PPh_2CH_2C_4H_7O)_2]$ ((**119**) and (**120**), respectively).[314] Subsequent treatment of the *cis* isomer with KPF_6 in MeCN solution yields the chelate-stabilized THF complex *cis*-$[PtCl(PPh_2CH_2C_4H_7O)_2]PF_6$ (**121**), containing one pendant THF group and one THF group coordinated to the metal center through the *O*-atom. If $AgClO_4$ is used instead of KPF_6, then the bischelated THF product $[Pt(PPh_2CH_2C_4H_7O)_2](ClO_4)_2$ (**122**) is formed instead. The X-ray structure of the monochelate complex *cis*-$[PtCl(PPh_2CH_2C_4H_7O)_2]PF_6$ is consistent with its solution NMR structure, with no evidence of fluxionality observed in solution. From this and earlier data, the *trans* influence of neutral O-donor ligands was deduced to follow the order: alcohols > THF > alkyl ethers.[314] From ^{31}P NMR data, the *trans* influence of alkoxo ligands was found to follow the order: $3° > 2° > 1°$, even through the relative differences are quite small.[313] The isolation of air- and moisture-stable platinum(II)-alkoxo complexes supports the notion that the observed instability of several types of alkoxo complexes is probably the result of kinetic phenomena rather than inherently weak Pt—O bonds.[171]



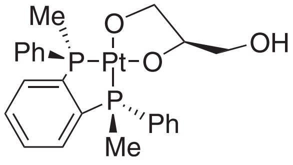
(121)



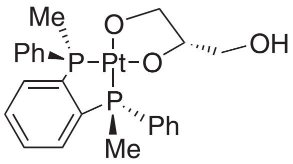
(122)

The use of a chiral platinum(II) auxiliary for the discrimination of the terminal hydroxy groups of glycerol in diastereomeric *O*,*O*-glycerolato chelate complexes has been described.[315] Treatment of (R^*,R^*)-(±)-$[Pt(OMe_2)\{1,2\text{-}C_6H_4(PMePh_2)_2\}]$ with glycerol in C_6H_6/MeOH solution affords a 3:2 equilibrium mixture of [(R^*,R^*),(R^*)]- and [(R^*,R^*),(S^*)]-(±)-$[PtOCH_2CH(O)CH_2OH\{1,2\text{-}C_6H_4(PMePh_2)_2\}]$ ((**123**) and (**124**)), respectively. The product [(R^*,R^*),(R^*)]-(±)-$[PtOCH_2CH(O)CH_2OH\{1,2\text{-}C_6H_4(PMePh_2)_2\}]\cdot 2MeOH$ crystallizes from CD_2Cl_2 solution as an (externally) H-bonded centrosymmetric dimer consisting of asymmetric monomers of opposite helicity.

Well-characterized transition metal complexes of vitamin C (ascorbic acid) are rare, and a select number of these exhibit anticancer properties. Hollis *et al.* have described the first examples to be fully characterized by X-ray crystallography.[316] Treatment of $[Pt(H_2O)_2L_2]^{2+}$ (L = NH_3, $MeNH_2$; L_2 = en, 1,2-chxn) with ascorbic acid gives either the mono- or bisascorbate species of the type *cis*-$[PtL_2(C^2,O^5\text{-ascorbate})]$ (e.g., (**125**)) or *cis*-$[PtL_2(C^2\text{-ascorbate})(O^3\text{-ascorbate})]$, respectively. Interestingly, in both types of complexes, platinum(II) forms a bond with the C-2 atom of ascorbic

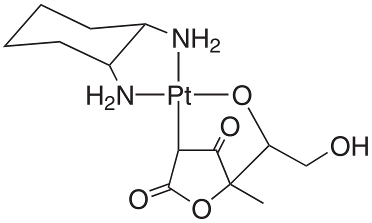


(**123**)

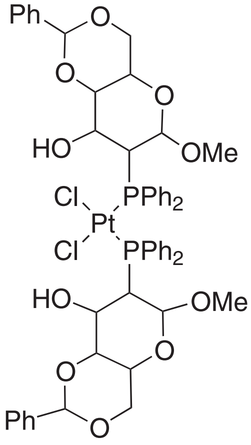


(**124**)

acid. NMR studies[317] of the solution chemistry of these complexes and the reaction chemistry of the chelate complexes in the presence of various protic acids have also been reported.[318] The phosphorus-containing chelate analogues [Pt(Asc-O^2,O^3)L_2] (L_2 = dppm, dppe, dppp) have also been described.[319] The reaction of $[Pt(H_2O)_2L_2]^{2+}$ (L_2 = en, dmen, tmen) with sodium ascorbate (AscH), results in the formation of mixtures containing ascorbate bound to platinum in several distinct modes.[319] The first involves monodentate coordination of one or two ascorbate ligands to the metal center via the O-3 atom to afford [Pt(HAsc-O^3)(H_2O)L_2]$^+$ or [Pt(HAsc-O^3)$_2$$L_2$], respectively. The ascorbate is also found to coordinate via the C-2 atom to give the mixed complex [Pt(HAsc-O^3)(HAsc-C^2)L_2]. Finally, the ascorbate can act as a chelating ligand to afford [Pt(Asc-O^2,O^3)L_2] and [Pt(Asc-C^2,O^5)L_2]; the structure of the latter (L_2 = en) was determined by X-ray diffraction. In all cases, the *O*-bound complexes are formed first and then slowly re-arrange to the *C*-bound ligand, with the relative rates of conversion dependent upon the degree of methyl substitution of the N-donor ligand. Indeed, the re-arrangement process was not observed for the bulky tmen ligand, in accordance with previous work.[320]



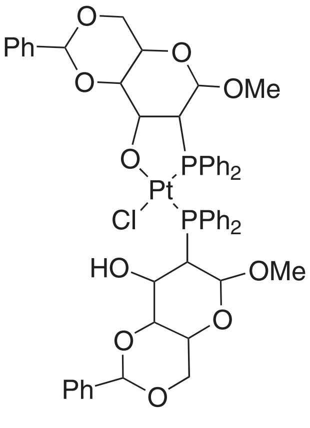
(**125**)



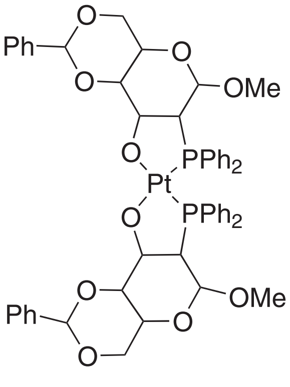
(**126**)

Carbohydrate derivatives of tertiary phosphine ligands have been prepared as new types of chiral ligands for transition metals such as platinum(II).[321] Treatment of [$PtCl_2$(COD)] with methyl-4,6-*O*-benzylidene-2-deoxy-2-(diphenylphosphino)-α-D-altropyranoside affords [$PtCl_2$(2-Hmbpa)$_2$] ((**126**); 2-Hmbpa = methyl-4,6-*O*-benzylidene-2-deoxy-2-(diphenylphosphino)-α-D-altropyranoside).[322] In the presence of NEt_3, *cis*-[PtCl(2-Hmbpa)(2-mbpa)] (**127**) is formed, in which two phosphine ligands and one deprotonated 3-OH group of the sugar moiety are coordinated to the platinum(II) center. Addition of NaOMe generates the *P*,*O*-chelated, bis(alkoxo) species *cis*-[Pt(2-mbpa)$_2$] (**128**), the structure of which was determined by X-ray crystallography. Finally, the 4,6-*O*-benzylidene groups can be removed from the sugar moieties by the addition of 5% $HClO_4$ solution to afford *cis*-[Pt(2-mpa)$_2$] (**129**) (mpa = methyl-2-deoxy-2-(diphenylphosphino)-α-D-altropyranoside).

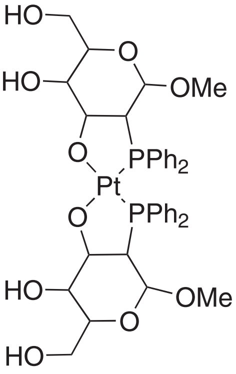
The reaction of [Pt(CO_3)(dppp)] with a modest excess of vicinal diols in CH_2Cl_2 solution affords the corresponding [Pt(α,β-diolato)(dppp)] species under equilibrium conditions, a reaction that is readily reversed by the addition of dry ice to the product. The reaction with triols such as glycerol and alditol carbohydrates also affords the corresponding diolato species, with the reaction exhibiting excellent equilibrium regioselectivities for a number of isomers, of which the γ, δ-*threo* diols are the most favored.



(127)



(128)

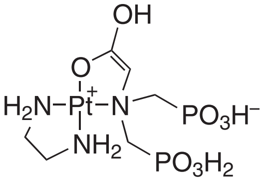


(129)

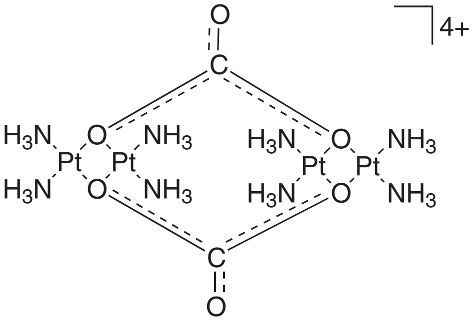
6.5.4.4.4 *Carboxylato and carbonato ligands*

A remarkably versatile synthesis of symmetrical and nonsymmetrical dicarboxylatoplatinum(II) complexes of the type $[Pt(O_2CRCO_2)L^1L^2]$ ($R = CH_2$, cyclobutyl; L^1 and L^2 = same or different amine) that allows one to systematically vary the nature of the amine ligands in a facile manner has been described.[323] This method greatly expands the number of potential third-generation platinum anticancer drugs that can be prepared and studied. In general, the method utilizes the dimethylsulfoxide precursor complexes $[Pt(O_2CRCO_2)(DMSO)_2]$, which are readily prepared from *cis*-$[PtCl_2(DMSO)_2]$ and the disilver salt of a dicarboxylic acid, e.g., malonic acid. If this precursor is treated with two equivalents of amine at 100 °C in aqueous solution, then the symmetrical complexes $[Pt(O_2CRCO_2)L_2]$ are prepared in high yields. Alternatively, the reaction of $[Pt(O_2CRCO_2)(DMSO)_2]$ with one equivalent of amine at 40 °C in water affords the monosulfoxide complex $[Pt(O_2CRCO_2)(DMSO)L^1]$. When this intermediate is treated with an equivalent of a different amine ligand L^2 at 100 °C, then the unsymmetrical mixed-amine complex $[Pt(O_2CRCO_2)L^1L^2]$ is conveniently generated in good yield.

The first example of a stable geminal enediol derivative of a carboxylic acid, isolated as its platinum(II) complex, has been reported.[324] Treatment of $[Pt(OH_2)_2(en)]^{2+}$ with *N*,*N*-bis(phosphonomethyl)aminoacetic acid yields zwitterionic [Pt(bpmaa)(en)] (bpmaaH = *N*,*N*-bis(phosphonomethyl)aminoacetic acid), which upon crystallization from water (pH 1) affords the corresponding enol tautomer (**130**), as determined by X-ray crystallography and IR spectroscopy.



(130)



(131)

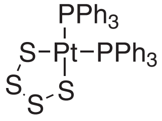
Stein and co-workers have reported the structure of an unusual tetranuclear platinum(II) complex possessing both ammine and carbonato ligands.[325] During a study of the reaction of cisplatin with Ag^+, followed by the addition of 2′-deoxyuridine to afford "platinum blue"-like products from aqueous solution ($pH < 2$), a colorless minor product was isolated from the reaction mixture. X-ray crystallography confirmed that the product was a *cyclo* tetra-cation consisting of four *cis*-diammineplatinum(II) units bridged by two μ_4-carbonato ligands, $[\{cis\text{-}Pt(NH_3)_2\}_4\{\mu_4\text{-}CO_3\}_2]^{4+}$ (**131**). The source of the carbonato ligand was probably adventitious CO_2 present in the original reaction mixture that was used to prepare the blue complexes.

New reproducible syntheses of platinum(II) carbonato complexes of the type $[Pt(CO_3)L_2]$ (L = mono- or bidentate tertiary phosphine) involve the reaction of Ag_2CO_3 with $[PtCl_2L_2]$ in water-saturated CH_2Cl_2 solution.[326] Other methods of preparation include the conversion of the dichloroplatinum(II) complexes to the corresponding bis(alkoxo)- or bis(phenoxo)-platinum(II) species, followed by hydrolysis in the presence of CO_2.

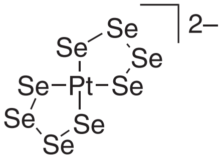
6.5.4.5 Platinum(II) Complexes with Sulfur- and Selenium-donor Ligands

6.5.4.5.1 S_n and Se_n ligands

The first X-ray and molecular structure of a metallacyclic platinum(II) complex containing a chelating S_4^{2-} ligand, $[Pt(S_4)(PPh_3)_2]$ (**132**), has been reported.[327] The complex can be prepared by treating the platinum(IV) species $[Pt(S_5)_3]^{2-}$ with an excess of PPh_3. The X-ray structure of the complex shows some notable features that are not apparent in other MS_4 (M = Mo, W) species, notably the absence of alternating S—S bond lengths and the asymmetric puckering of the PtS_4 ring, with one of the sulfur atoms lying significantly out of the plane of the remaining PtS_3 atoms.



(**132**)

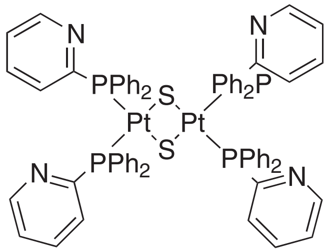


(**133**)

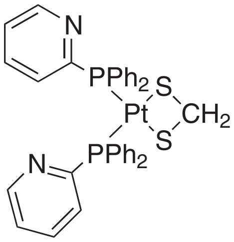
The $[Pt(Se_4)_2]^{2-}$ complex (**133**) has been prepared by the reduction of the platinum(IV) species $[Pt(Se_4)_3]^{2-}$ with excess borohydride.[328] The X-ray structure of the complex shows that each of the five-membered rings adopts a half-chair conformation, with the platinum coordination sphere exhibiting slight distortion from a square-planar geometry.[329]

The first examples of mononuclear disulfur and diselenium complexes of platinum have been described.[330] Reduction of the sterically hindered complex *trans*-$[PtCl_2(PMe_2Ar)_2]$ (Ar = 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl, 2,6-bis[bis(trimethylsilyl)-methyl]-4-[tris(trimethylsilyl) methyl]-phenyl) with lithium naphthalide in THF solution affords the platinum(0) species $[Pt(PMe_2Ar)_2]$. Oxidative addition of elemental sulfur or selenium yields the dichalcogenatoplatinum(II) complexes of the type $[PtE_2(PMe_2Ar)_2]$ (E = S, Se) containing a unique PtE_2 ring system. The complexes are stable to air in the solid state, but slowly decompose in solution after several days at room temperature.

The luminescent, dinuclear platinum(II) species $[Pt_2(\mu\text{-}S)_2(dppy)_4]$ (**134**) can be prepared by treating $[PtCl_2(dppy)_2]$ with NaSH in the presence of NEt_3 under anaerobic conditions.[331] When the complex is dissolved in CH_2Cl_2 solution, pale-yellow crystals of $[Pt(S_2CH_2)(dppy)_2]$ (**135**) are formed, the first example of a four-membered, saturated dithiolato platinacycle.



(**134**)



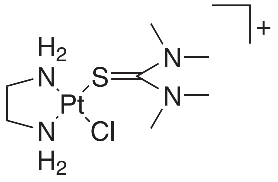
(**135**)

Treatment of $[PtCl_2L_2]$ ($L_2 = 4,4'$-Bu^t_2bipy, 4,4′-dmc_2bipy = 4,4′-dimethylcarboxylate-2,2′-bipyridine [dmc_2bipy], dppm) with Na_2S affords novel trinuclear platinum(II) complexes of the type *cyclo*-$[Pt_3L_2(\mu_3\text{-}S)_2]^{2+}$, with a triply bridging sulfido ligand.[332] The solid-state luminescence properties of the complexes and the X-ray structure of the Bu^t_2bipy complex have also been determined.

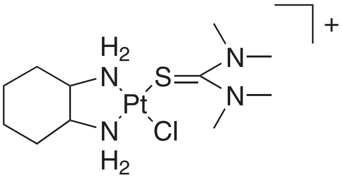
6.5.4.5.2 *Sulfoxide, thiourea, and thiolato ligands*

Numerous sulfoxide complexes of the type *trans*-$[PtCl(R^1R^2SO)L_2]^+$ ($L = NH_3$, pyridine, picoline; $R^1 = R^2 = Me$; $R^1 = Me$, $R^2 = Ph$; $R^1 = Me$, $R^2 =$ benzyl) and $[PtCl(R^1R^2SO)(NN)]^+$ (NN = cyclohexane-1,2-diamine [1,2-chxn], 1,1-bis(aminomethyl)cyclohexane [damch]; $R^1 = R^2 = Me$, Ph, benzyl; $R^1 = Me$, $R^2 = Ph$; $R^1 = Me$, $R^2 =$ benzyl) have been reported.[333,334] The preparation of the chelate complexes $[PtCl(R^1R^2SO)(NN)]^+$ is best accomplished by the addition of $[PtCl_2(NN)]$ to R^1R^2SO.[334] The preparation of *trans*-$[PtCl(R^1R^2SO)L_2]^+$ involves the treatment of *trans*-$[PtCl_2L_2]$ with Ag^+ in the presence of R^1R^2SO.[333]

The synthesis of mono- and dinuclear complexes containing thiourea derivatives have been described.[335] Treatment of $[PtCl_2(en)]$ or $[PtCl_2(1,2\text{-chxn})]$ with one equivalent of Ag^+ in DMF solution, followed by the addition of 1,1,3,3-tetramethylthiourea (tmtu) affords $[PtCl(en)(tmtu)]^+$ (**136**) and $[PtCl(1,2\text{-chxn})(tmtu)]^+$ (**137**), respectively, in which the tmtu ligand acts as a S-donor ligand. Dinuclear platinum(II) species containing the novel, bridging-bidentate thiourea derivatives $C_2H_4(NMeCSNMe_2)_2$ and $C_6H_{12}(NMeCSNMe_2)_2$ can also be prepared in a similar manner.



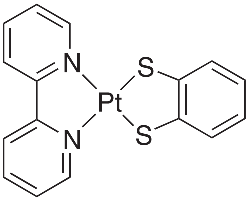
(136)



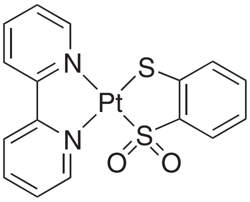
(137)

There are numerous examples of platinum(II)–dithiolato complexes that exhibit remarkable luminescence properties. Eisenberg and co-workers have reported a novel class of maleonitrile-dithiolato complexes of the type $[PtL_2(mnt)]$ ($L = P(OEt)_3$ and $P(OPh_3)_3$; $L_2 =$ COD and dppm; mnt = maleodinitriledithiolate) that exhibit luminescence in the solid-state and in rigid glasses at low temperature, with highly structured emission and excitation spectra.[336] The solvent and temperature dependence of the emission process for a series of related [Pt(NN)(SS)] (NN = 4,4′-dimethyl-2,2′-bipyridine, 4,7-diphenyl-1,10-phenanthroline; SS = 1-(ethoxycarbonyl)-1-cyanoethylene-2,2-dithiolate [ecda], 1-(*t*-butoxycarbonyl)-1-cyanoethylene-2,2-dithiolate) complexes was also reported.[337] Strong luminescence and solvatochromism were also observed at room temperature for related diimine complexes possessing a variety of chelating dithiocarbamato or dithiolato ligands,[338,339] and the luminescence properties of such complexes have been reviewed.[191,340] The analogous complexes $[PtL_2(SS)]$ ($L_2 =$ mono- or bidentate tertiary phosphine ligands; SS = mnt, ecda) have also been studied, with strong emissions being observed in the solid state and in rigid media at low temperature, with emission lifetimes for the latter being in the microsecond range.[341] The photooxidation reactions of [Pt(bdt)(bipy)] (bdt = 1,2-benzenedithiolate; (**138**)) have been reported.[342] The complex reacts with O_2 in the presence of light to form the mono- and disulfinated products $[Pt(bdtO_2)(bipy)]$ (**139**) and $[Pt(bdtO_4)(bipy)]$ (**140**), respectively. The oxidant is likely to be photogenerated singlet O_2. The photochemically stable platinum(II)–diimine complexes $[Pt(dip)(1\text{-}S\text{-}C_2B_{10}H_{11})_2]$ and $[Pt(dip)(1,2\text{-}S_2\text{-}C_2B_{10}H_{10})_2]$ (dip = 4,1-diphenyl-1,10-phemanthroline) containing the 1-thiolato-1,2-carborane and 1,2-dithiolato-1,2-carborane ligands, respectively, exhibit remarkable photoluminescence and excited-state oxidation characteristics.[343] The preparation of the orange $[Pt(pyridine\text{-}4\text{-}thiolato)_2(Bu^t_2bipy)]$ with two free pyridyl groups for further coordination to transition metals allows for the study of supramolecular materials containing a highly luminescent chromophore.[344]

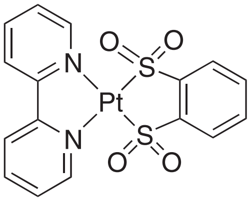
The donor-acceptor complex $(TTF)[Pt(dmit)_2]_3$ (dmit = 4,5-dimercapto-1,3-dithiol-2-thione) and its Group 10 congeners have been reported, and their electrical conductivities have been examined.[345] The platinum(II) complex is semi-conducting in the 100–300 K temperature range. Its X-ray structure shows aggregates of monomers and dimers (connected by a Pt—Pt bond) alternately stacked in columns, with an adjacent layer of TTF molecules. In related work, the electrochemical synthesis and characterization of a salt comprising of the bis(ethylenedithio)-tetrathiafulvalene (bedt-ttf$^+$) radical cation and the bis(dithiosquarato)platinate(II) (bis(3,4-dithio-1,2-cyclobutenedione)platinate(II)) complex has been described. Black hexagonal crystals of [bedt-ttf$^+$]$_2$[Pt($S_2C_4O_2$)$_2$] consist of bedt-ttf$^+$ dimers and complex anions alternating along one axis of the unit cell.[346]



(138)



(139)

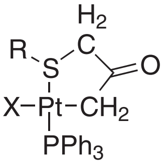


(140)

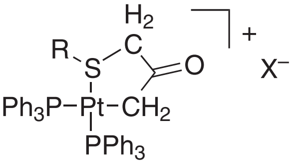
An unusal hexanuclear complex of platinum(II) has been isolated from the reaction of [$PtBr_2$(en)] with 2-aminoethanethiol under basic conditions.[347] The product [$Pt_6(SCH_2CH_2NH_2)_8$]$Br_4\cdot 6H_2O$ was characterized fully by X-ray crystallography. The structure of the tetra-cation comprises of a central, eight-membered Pt_4S_4 ring fused onto two outer, six-membered Pt_3S_3 rings. The mechanism of product formation was not studied, but clearly it is very complicated.

The cyclic thiolato complex [Pt{$SCH_2C(O)CH_2$}(PPh_3)$_2$] readily reacts with electrophiles such as alkyl halides to afford the platinum(II)–thioether complexes [Pt{$RSCH_2C(O)CH_2$}X(PPh_3)$_2$] (R = Me, X = I; R = Et, X = Br; R = $PhCH_2$, X = Cl) (**141**) and [$RPPh_3$]X rather than the products of oxidative addition to the platinum(II) center.[348] The reaction appears to proceed via the unstable cationic intermediate [Pt{$RSCH_2C(O)CH_2$}(PPh_3)$_2$]$^+$X$^-$ (**142**), as determined by ^{31}P NMR spectroscopy.

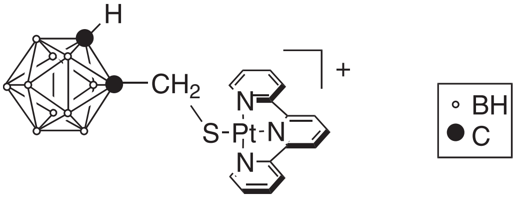
The first examples of DNA metallointercalators containing a 1,2- or 1,7-carborane thiolato ligand have been reported.[349] For example, treatment of [Pt(OTf)(terpy)]$^+$ (terpy = 2,2′:6′,2”-terpyridine) with 1-$HSCH_2$-1,2-$C_2B_{10}H_{11}$ leads to the formation of [Pt(1-SCH_2-1,2-$C_2B_{10}H_{11}$)(terpy)]$^+$ (**143**). The DNA-binding properties of several complexes have also been described.



(141)



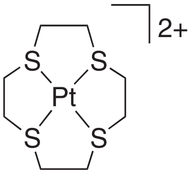
(142)



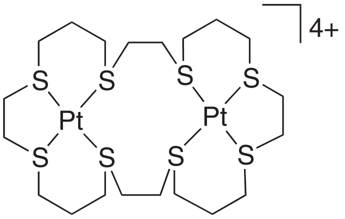
(143)

6.5.4.5.3 *Macrocyclic S-donor ligands*

The synthesis, X-ray structure, NMR, and UV–visible spectroscopy, and electrochemistry of a macrocyclic platinum(II) complex containing the tetradentate 1,4,7,10-tetrathiacyclodecane ligand, [12]aneS_4 (**144**) have been reported.[350] Related complexes including [Pt([13]aneS_4)]$^{2+}$ and [Pt([16]aneS_4)]$^{2+}$ have also been prepared, and molecular mechanics calculations complemented



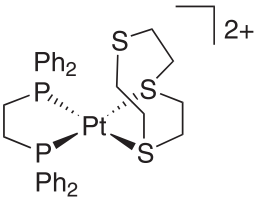
(144)



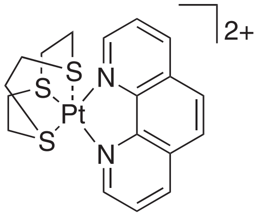
(145)

the study. The related complexes $[Pt([14]aneS_4)]^{2+}$ and $[Pt([15]aneS_4)]^{2+}$ have been reported elsewhere.[252] Schröder and co-workers have independently reported the synthesis and electrochemistry of a series of $[Pt([n]aneS_4)]^{2+}$ ($n = 12$, 14, 16) complexes.[351] The dinuclear species $[Pt_2([28]aneS_8)]^{4+}$ (**145**) was also prepared and characterized.

The macrocyclic thioethers 1,4,7-trithiacyclononane and 1,4,7-trithiacyclodecane form complexes of the type $[Pt([n]aneS_3)L_2]^{2+}$ ($n = 9$ or 10; $L = PPh_3$; $L_2 =$ dppm, dppe, dppp, 1,4-bis(diphenylphosphino)butane, 1,5-bis(diphenylphosphino)pentane, 1,2-bis(diphenylphosphino)benzene, *cis*-1,2-bis(diphenylphosphino)ethene), e.g., $[Pt([9]aneS_3)(dppe)]^{2+}$ (**146**).[352,353] All complexes were shown to possess a *cis* arrangement of the S_2 and P_2 donor atoms, with only two of the three S-atoms in the macrocycle coordinated to the platinum(II) center. In contrast, when diimine ligands are used in place of the chelating tertiary phosphines, five-coordinate platinum(II) complexes are formed. For example, the synthesis, NMR, and X-ray study of $[Pt([9]aneS_3)(phen)]^{2+}$ (phen = 1,10-phenanthroline; (**147**)) has been described.[354] The X-ray structure confirms the distorted square-pyramidal geometry of the complex, with the phen ligand and two of the three S atoms of the $[9]aneS_3$ ligand occupying the square plane; the remaining S atom is located at the apical position of the square-pyramid. Variable-temperature NMR spectroscopy demonstrates that the complex is fluxional, with the macrocylic ligand undergoing rapid, intramolecular 1,4-metallatropic shifts.



(146)



(147)

Treatment of $[PtCl_4]^{2-}$ with the macrocyclic oxathiaethers 1-oxa-4,7-dithiacyclononane ($[9]aneS_2O$) and 1,10-dioxa-4,7,13,16-tetrathiacyclooctadecane ($[18]aneS_4O_2$) results in the formation of $[Pt([9]aneS_2O)_2]^{2+}$ and $[Pt([18]aneS_4O_2)_2]^{2+}$, respectively.[355] The X-ray structures of the hexafluorophosphate salts were also reported, confirming the square-planar geometry of the PtS_4 unit.

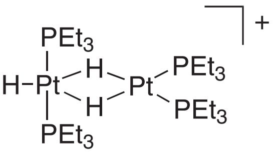
6.5.4.6 Platinum(II) Complexes with Hydrido and Dihydrogen Ligands

6.5.4.6.1 Hydrido ligands

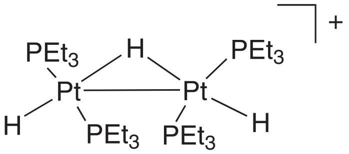
The stable dihydridoplatinum(II) complexes *cis*- and *trans*-$[PtH_2(PR_3)_2]$ (R = Me, Et) have been isolated and characterized.[356] Their preparation involves the formal oxidative addition of dihydrogen gas to the platinum(0) precursor $[Pt(C_2H_4)(PR_3)_2]$ at room temperature to afford an equilibrium mixture of the two isomeric products, the position of which is dependent upon a number of factors. For example, the ratio of *cis*:*trans* isomers depends upon the nature of the solvent and the phosphine ligand. When the trimethylphosphine ligand is used, the conversion of the *trans* to the *cis* isomer in toluene and acetone solution occurs with $K_{eq} = 0.3$ and $2.2\,mol^{-1}\,dm^3$ at 298 K, respectively, reflecting the greater degree of solvation of the *cis* isomer in acetone solution owing to its greater dipole moment. Furthermore, the value of K_{eq} is approximately one order of magnitude smaller when the bulkier triethylphosphine ligand is present in the complex. Under certain conditions, analytically pure *trans*-$[PtH_2(PEt_3)_2]$ can be isolated as unstable, off-white crystals. However, the complex is indefinitely stable both as a solid and in solution under an atmosphere of dihydrogen at ambient temperatures. A detailed study of the kinetics of *cis*–*trans* isomerization and reductive elimination of H_2 in $[PtH_2(PMe_3)_2]$ has also been reported.[357]

When a toluene solution of $[PtH_2(PEt_3)_2]$ is exposed to a CO_2 atmosphere (1 atm), an equilibrium mixture ($K_{eq} = 2\,atm^{-1}$ at 298 K) containing both the corresponding formato species *trans*-$[PtH(O_2CH)(PEt_3)_2]$ and the precursor complex is formed.[358] In polar solvents such as acetonitrile or acetone, the cationic diplatinum(II) species $[Pt_2(\mu\text{-}H)_2(H)(PEt_3)_4]^+$ (**148**) and free formate ion are formed rapidly and quantitatively. The reaction appears to be completely reversible as bubbling H_2 gas through a solution of the dinuclear complex regenerates the $[PtH_2(PEt_3)_2]$ with loss of CO_2. In a related study, UV-irradiation of the oxalato complex $[Pt(ox)(PEt_3)_2]$

(ox = oxalate) in MeCN solution under 1 atm of H_2 affords $[Pt_2(\mu\text{-}H)_2H(PEt_3)_4]^+$ with the liberation of CO_2.[359] Another transient species formed when $[PtH_2(PEt_3)_2]$ was treated with formic acid or CO_2 in acetone solution, and it was identified to be the isomeric dinuclear species $[Pt_2(\mu\text{-}H)H_2(PEt_3)_4]^+$ (**149**). The same complex can be prepared exclusively by UV-irradiation of $[Pt(ox)(PEt_3)_2]$ in MeOH solution at 298 K to afford *trans*-$[PtH(OMe)(PEt_3)_2]$,[8] which converts to $[Pt_2(\mu\text{-}H)H_2(PEt_3)_4]^+$; slow isomerization to the thermodynamically favored $[Pt_2(\mu\text{-}H)_2H(PEt_3)_4]^+$ occurs upon heating. Alternatively, the addition of small amounts of pyridine or iodide ion to $[Pt_2(\mu\text{-}H)H_2(PEt_3)_4]^+$ catalyzes the isomerization reaction.[359]



(**148**)



(**149**)

The highly reactive mono- and dihydrido platinum(II) complexes *trans*-$[PtClH(PMe_3)_2]$ and *cis*/*trans*-$[PtH_2(PMe_3)_2]$ can be prepared by the reaction of *cis*-$[PtCl_2(PMe_3)_2]$ with one and two equivalents, respectively, of sodium naphthalide in THF solution under a H_2 atmosphere.[360] The source of hydride in these reactions is H_2, as confirmed by deuterium-labeling studies, with sodium naphthalide acting only as an electron-transfer reagent. The X-ray structures of *trans*-$[PtClH(PMe_3)_2]$ and *trans*-$[PtH_2(PMe_3)_2]$ (as its naphthalene adduct) were also reported. The latter complex is extremely unstable, losing H_2 under a N_2 atmosphere, but crystals of the complex are indefinitely stable under a H_2 atmosphere at room temperature. In solution, $[PtH_2(PMe_3)_2]$ exists as an equilibrium mixture of *trans* and *cis* isomers with the latter favored in polar solvents owing to its higher dipole moment. The energetics of the *cis*–*trans* isomerization process were also reported.

A series of *cis*-dihydridoplatinum complexes of the type $[PtH_2\{Cy_2P(CH_2)_nPCy_2\}]$ ($n = 2$–4) have been prepared by the exposure of the platinum(0) species $[PtCy_2P(CH_2)_nPCy_2]$ or $[Pt(C_2H_4)\{Cy_2P(CH_2)_nPCy_2\}]$ to a pressurized H_2 atmosphere.[26] NMR studies in C_6D_6 solution provide strong evidence of a dynamic process involving *cis*-dihydride to η^2-dihydrogen exchange, i.e., involving platinum(II) and platinum(0), respectively.

Five-coordinate hydrido complexes of platinum(II) containing the tetradentate tertiary phosphine ligand 1,1,4,7,10,10-hexaphenyl-1,4,7,10-tetraphosphadecane have been reported (**150**).[361] Both chiral and *meso* derivatives of the flexible phosphine ligand were used, and a number of coordination geometries were observed that appeared to depend upon the nature of the counterion. Five-coordinate hydridoplatinum(II) complexes containing the bidentate tertiary phosphine ligands dmpe and 1,2-bis(diethylphosphino)ethane (depe) have also been reported.[362] Treatment of $[Pt(dmpe)_2]^{2+}$ or $[Pt(depe)_2]^{2+}$ with $NaBH_4$ on alumina affords $[PtH(dmpe)_2]^+$ or $[PtH(depe)_2]^+$, respectively, in good yields. The depe complex can also be generated electrochemically. Other five-coordinate hydridoplatinum(II) complexes have also been reported, including $[PtH(PP_3)]^+$ (PP_3 = tris(2-(diphenylphosphino)ethyl)phosphine)[363] and $[PtHL(PP_2)]^+$ (PP_2 = bis(2-(diphenylphosphino)ethyl)phenylphosphine; L = PPh_3, PBu_3, PPh_2H, PCy_2H, dppm).[364]

The synthesis, characterization, and the relative thermodynamic hydricities of hydridoplatinum(II) species-containing bidentate phosphine ligands $[PtHL_2]^+$ (L_2 = dppe, depe, dmpe, 1,3-bis(dimethylphosphino)propane [dmpp]) have been determined, with the best hydride donor found to be $[PtH(dmpe)_2]^+$.[365]

Dinuclear hydridoplatinum(II) species containing secondary phosphine ligands, *cis*-$[Pt_2H_2(PHBu^t{}_2)_2(\mu\text{-}H)(\mu\text{-}PBu^t{}_2)]$ (**151**) and *trans*-$[\{PtH(PHBu^t{}_2)(\mu\text{–}PBu^t{}_2)\}_2]$ (**152**), have been prepared by the reaction of *trans*-$[PtCl_2(PHBu^t{}_2)_2]$ with $NaBH_4$ in THF solution under reflux conditions.[366] If the reaction is conducted in the presence of free $PHBu^t{}_2$, then *cis*-$[Pt_2H_2(PHBu^t{}_2)_2(\mu\text{-}H)(\mu\text{-}PBu^t{}_2)]$ is selectively formed in high yield.

The protonation of the *cis*-dihydridomethylplatinum(IV) derivative of hydridotris(3,5-dimethylpyrazolyl)borate, $[Pt(H)_2Me(Tp')]$ (Tp′ = hydridotris(3,5-dimethylpyrazolyl)borate), with $[H(OEt_2)_2][BAr^f{}_4]$ ($BAr^f{}_4$ = tetrakis(3,5-trifluoromethylphenyl)borate) occurs in the presence of MeCN at −78 °C to afford the platinum(II) species $[PtH(MeCN)(Tp'{+}H)]^+$ (**153**) containing a bidentate Tp′ ligand that is protonated at the nitrogen atom of the free pyrazolyl ring.[367] When suitable donor ligands are absent from solution, the red–purple, dinuclear species $[Pt_2\,(\mu\text{-}H)_2(Tp'{+}H)_2]^{2+}$ (**154**) is formed instead, again with the protonated Tp′ acting as a bidentate ligand. The latter is a rare example of a dinuclear μ-hydridoplatinum species that is stabilized by N-donor ligands.

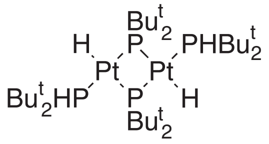
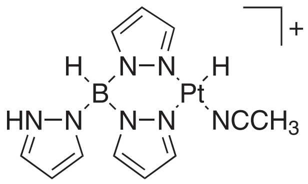
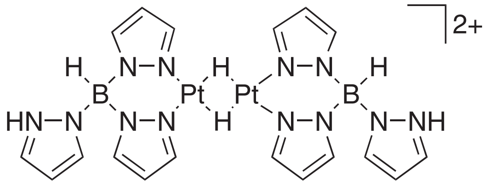
(151)



(152)



(153)

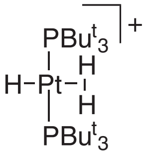


(154)

Protonation of $[Pt(SO_2)(PPr^i_3)_2]$ with $[H(OEt_2)_2]BAr^f_4$ in diethyl ether solution affords the labile hydrido species *trans*-$[PtH(OEt_2)(PPr^i_3)_2]^+$ in high yield.[368] The addition of alkyl and aryl halocarbon (RX_n) compounds to the complex leads to the formation of isolable, air-stable complexes of the type *trans*-$[PtH(\eta^1\text{-}XRX_{n-1})(PPr^i_3)_2]^+$ ($R = CH_2$, $X = Cl$, $n = 2$; $R = Ph$, $X = Br$ or I, $n = 1$), in which the halogen acts as a donor atom to the platinum(II) center. The halocarbon ligands are readily displaced by donor solvents such as THF to afford *trans*-$[PtH(THF)(PPr^i_3)_2]^+$.

6.5.4.6.2 *Dihydrogen ligands*

The first example of a platinum(II)–dihydrogen complex, $[PtH(\eta^2\text{-}H_2)(PBu^t_3)_2]^+$ (**157**), has been prepared by the protonation of *trans*-$[Pt(H)_2(PBu^t_3)_2]$ with CF_3SO_3H or, alternatively, by the reaction of $[PtH(PBu^t_3)_2]^+$ with H_2.[369] Deuteration experiments and NMR spectroscopy confirm the formulation of the product as a dihydrogen complex. Hydrogen-2 NMR studies reveal both Pt–D and Pt(DH) resonances for the deuterated complex, including the first report of a metal–H_2 spin–spin interaction. Other NMR experiments confirm that no intramolecular scrambling of the H/H_2 ligands occurs on the NMR time-scale. *Ab initio* calculations complemented this work. The preparation of the related complex *trans*-$[PtH(\eta^2\text{-}H_2)(PPr^i_3)_2]^+$ has also been described.[368]



(155)

Protonation of complexes of the type *trans*-$[Pt(H)X(PCy_3)_2]$ ($X = SiH_3$, H, Me, Ph, Cl, Br, I, CN, CF_3SO_3) and *trans*-$[Pt(H)L(PCy_3)_2](BAr^f_4)$ (L = CO, 4-picoline) using strong acids such as $[H(OEt_2)_2]$ $[BAr^f_4]$ at low temperatures results in the three reaction outcomes depending on the site of proton attack, i.e., the hydrido ligand, the ligand located *trans* to the hydrido ligand, or the metal center.[370] All of the complexes that form the unstable dihydrogen adduct, *trans*-$[Pt(H_2)X(PCy_3)_2]$, have a strong σ-donor ligand located *trans* to the hydrido ligand, i.e., X = H, Me, and Ph. The enhanced basicity of the *trans* hydrido ligand appears to make it more amenable to protonation.

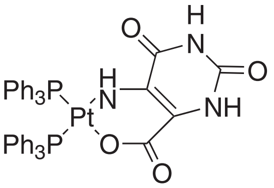
6.5.4.7 Platinum(II) Complexes with Mixed Donor-atom Ligands

6.5.4.7.1 *Bidentate NO and OS ligands*

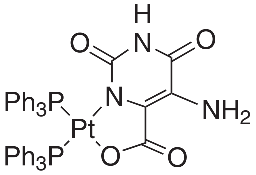
Platinum-195 NMR spectroscopy has been used to probe the reversible and intramolecular HH to HT isomerization of the α-pyridonato-bridged diplatinum(II) complex $[Pt_2(en)_2L_2]^{2+}$

(L = α-pyridonate, $C_5H_4NO^-$).[371] At 312 K and pH 6.5, the kinetic parameters for the isomerization process were determined to be $k_f = 7.4(2) \times 10^{-5}$ s^{-1}, $k_r = 13.9(2) \times 10^{-5}$ s^{-1}, and $K_{eq} = 0.53$. The values of $\Delta H^\ddagger$ (114(5) kJ mol^{-1}) and $\Delta S^\ddagger$ (40(10) J mol^{-1} K^{-1}) were determined by means of an Eyring plot. The mechanistic data are consistent with cleavage of the α-pyridonato Pt—N bond during the isomerization process.

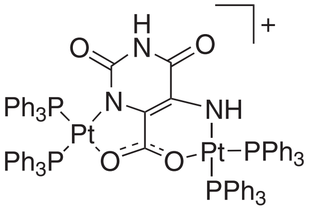
5-Aminoorotic acid can exhibit up to three coordination modes with platinum(II).[372] Treatment of [$PtCl_2$(COD)] with two equivalents of PPh_3 and an excess of 5-aminoorotic acid in the presence of Ag^+ affords two isomers of [Pt(aoaH_2)(PPh_3)$_2$] ((**156**) and (**157**)), where 5-aminoorotic acid acts as a dianionic bidentate ligand. Only one isomer is formed when dppe was used instead of PPh_3. Further reaction of complex (**157**) with $NaBF_4$ results in the formation of the dinuclear species [Pt_2(aoaH)(PPh_3)$_4$]$^+$ (aoaH_4 = 5-aminoorotic acid; (**158**)), in which the 5-aminoorotic acid acts as a trianionic ligand. The presence of several H-bonding groups on the periphery of the complexes leads to various supramolecular structures being formed in the solid state, with dimers and cyclic tetramers elucidated by X-ray crystallography.



(**156**)

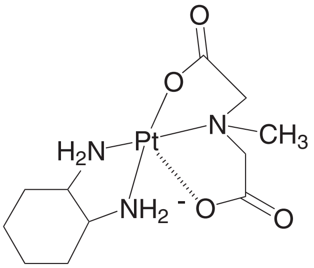


(**157**)



(**158**)

The preparation and characterization of diastereomeric *N*-iminodiacetatoplatinum(II) complexes of (*R*,*S*)- and (*R*,*R*)-1,2-chxn have been reported,[373] where the substituted iminodicarboxylato ligand is bonded to the metal center in a tridentate manner (**159**). One arm of the ligand forms a stable five-membered *N*,*O*-chelate, and the remaining carboxylate group interacts with the positively charged metal center to form a zwitterionic species. Unequal proportions of the diastereomers are formed in solution.



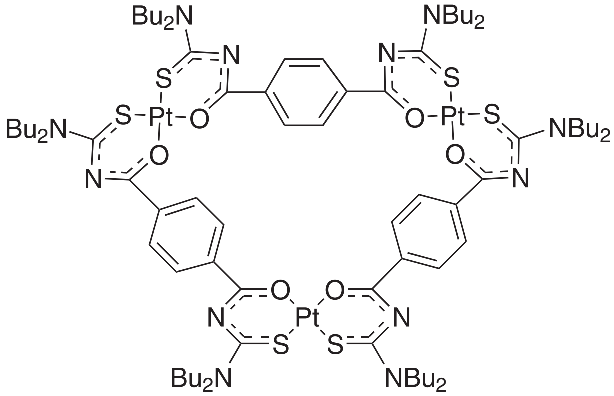
(**159**)

Treatment of the bischelating ligands 3,3,3′,3′-tetra(Bu^t)-1,1′-terephthaloylbis(thiourea) ({H_2L^1}$_2$) or 3,3,3′,3′-tetraethyl-1,1′-isophthaloylbis(thiourea) ({H_2L^2}$_2$) with [$PtCl_4$]$^{2-}$ results in the formation of the tri- or dinuclear metallacyclic species, *cis*-[Pt(L^1-*S*,*O*)]$_3$ (**160**) or *cis*-[Pt(L^2-*S*,*O*)]$_2$ (**161**), respectively.[374] The stoichiometry of the reaction appears to depend upon the relative positions of the chelating S,O moieties around the arene ring.

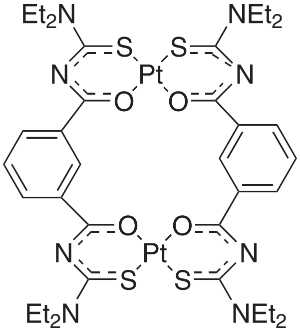
A series of mixed-ligand thiosalicylato complexes of the type [PtL(PPh_3)Y_2] (Y_2 = thiosalicylate; L = pyridine, 4-methylpyridine, picolinic acid hydrazide, imidazole) have been prepared by the reaction of [$PtCl_2$(COD)] with PPh_3, thiosalicylic acid, and *N*-donor ligand in MeOH solution.[375] The X-ray structure of the pyridine derivative (**162**) was determined, the first example of where a platinum atom is coordinated to a N, O, P, and S donor atom set.

6.5.4.7.2 Bidentate PO, PS, and PN ligands

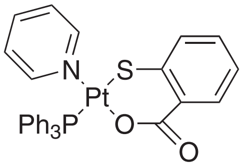
Treatment of [PtX_2(COD)] (X = Cl, I) with the unsymmetrical ligands $Ph_2P(CH_2)_nR$ (n = 2, R = OMe, NMe_2, SMe; n = 3, R = NMe_2) leads to the formation of the chelate complexes



(160)



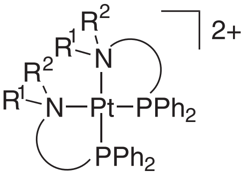
(161)



(162)

$[PtX\{Ph_2P(CH_2)_nR\}_2]^+$ and $[Pt\{Ph_2P(CH_2)_nR\}_2]^{2+}$, a process that is dependent upon the nature of the nonphosphorus donor atom and on the size of the chelate ring that is formed.[376] Halide abstraction by the use of one or two equivalents of Ag^+ is required for the formation of the chelated species in the case of $R = OMe$ and NMe_2 ($n = 3$), otherwise the nonchelated complex *cis*-$[PtX_2\{Ph_2P(CH_2)_nR\}_2]$ is formed exclusively. In contrast, when $Ph_2P(CH_2)_2NMe_2$ is added to $[PtCl_2(COD)]$, the chelate complex $[PtCl\{Ph_2P(CH_2)_2NMe_2\}_2]^+$ is formed in the absence of Ag^+, indicating the stability of the final complex is determined by the "bite" of the chelating ligand with the sufficiently nucleophilic NMe_2 group. When one equivalent of $Ph_2P(CH_2)_2SMe$ is used, the chelate complex $[PtX_2\{Ph_2P(CH_2)_2SMe\}]$ is formed, but the addition of a second equivalent of ligand gives a mixture of products, and the involvement of ion-paired species has been inferred.

Sadler and co-workers have prepared a series of bischelated aminophosphine complexes of the type $[Pt(R^1R^2N(CH_2)_nPPh_2)_2]^{2+}$ ($n = 2$, 3; R^1 and $R^2 = H$, Me, Bz, Cy) (**163**).[377] The N-donor atoms of the chelate can become dissociated from the metal center and thus generate up to two vacant coordination sites that can allow rapid reaction of the complex with potential biological ligands such as nucleobases. This process is influenced by a number of factors, including the nature of the R^1 and R^2 groups, pH, chloride ion concentration, and even the value of n. The ring-opening process was observed both in the solid state[377] and in solution.[378]



(163)

6.5.5 PLATINUM(III)

Platinum(III) complexes are remarkably rare and most examples date from less than 30 years ago. The great majority are dimeric species with only a few authenticated stable monomers reported. Most of the dimers are bridged by bidentate ligands and are almost exclusively doubly or quadruply bridged, the latter giving rise to the classic "lantern" structure.

6.5.5.1 Monomeric Platinum(III)

The first example of an isolated monomeric platinum(III) complex was reported by Uson *et al.* in 1984.[379] $[NBu_4][Pt(C_6Cl_5)_4]$ was obtained by oxidation of $[NBu_4]_2[Pt(C_6Cl_5)_4]$ with halogens or $TlCl_3$ and was characterized by X-ray crystallographic, spectroscopic, and magnetic methods. The Pt—C bond lengths are indistinguishable in the platinum(III) 2.086(14) Å and platinum(II) 2.094(8) Å oxidation states.

Bond *et al.* showed that electrochemical oxidation of $[Pt(\eta^1\text{-}S_2CNEt_2)(\eta^3\text{-}P_2P')]^+$ ($P_2P = Ph_2P(CH_2)_2P(Ph)(CH_2)_2Ph_2$) gives the moderately stable platinum(III) complex $[Pt(\eta^1\text{-}S_2CNEt_2)(\eta^3\text{-}P_2P')]^{2+}$.[380] ESR spectroscopy was used to confirm the presence of paramagnetic platinum(III) and it was suggested that bulky ligands are needed to stabilize monomeric platinum(III).[380]

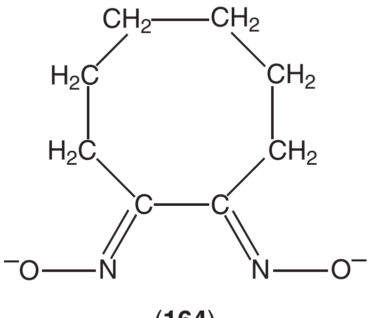
Caseric and co-workers have reported that $[Pt(NH_2Octyl)_4][Pt(mnt)_2]$ can be oxidized with iodine to give $[Pt(NH_2Octyl)_4][Pt(mnt)_2]_2$ in which the anion $[Pt(mnt)_2]_2^-$ has platinum in the formal oxidation state III.[381] There has been some debate about whether mnt should be described as a dinegative dithiolate or a neutral dithioketone, but its structure is more consistent with the former. Thus, the description of the metal as platinum(III) is sound, though the additional positive charge is probably distributed throughout the complex.

Monomeric platinum(III) complexes have been observed frequently as transient species in electrochemical or pulse radiolysis studies and they are proposed as an intermediates in reductive elimination and oxidative addition reactions of platinum(IV) and platinum(II) respectively.[382–388]

6.5.5.2 Unbridged Dimers

The first unbridged platinum(III) dimer, $[PtCl_3\{(Z)\text{-}HN{=}C(OH)Bu^t\}_2]_2$, was reported by Natile and co-workers in 1991[389] and arose from the oxidation of *cis*-$[PtCl_2\{(Z)\text{-}HN{=}C(OH)Bu^t\}_2]$ with chlorine. The Pt—Cl bonds *trans* to the Pt—Pt bond are 2.458(2) Å long, significantly longer than those in the equatorial planes (2.306(3), 2.328(3) Å), consistent with the metal–metal bond exerting a strong trans influence. Prolonged exposure of the platinum(III) complex to chlorine yields the platinum(IV) complex *cis*-$[PtCl_4\{(Z)\text{-}HN{=}C(OH)Bu^t\}_2]$.

Soon after, Heath and co-workers reported an unsupported dimer with α-dioximato ligands ($[PtCl_2(C_8doH)_2]$ (C_8doH is shown in (**164**)) obtained by controlled oxidation of $[Pt(C_8doH)_2]$ with either $PhICl_2$ or *p*-$ClC_6H_4ICl_2$.[390] Addition of further oxidant produced the platinum(IV) complex $[PtCl_2(C_8doH)_2]$. The Pt—Pt bond length (2.696,4(5) Å)[390] is similar to that observed in the first reported example, 2.694(1) Å[389] indicating that this is a normal value for an unsupported Pt^{III}—Pt^{III} bond. The Pt—Cl bond length (2.386(2) Å) is shorter than the axial Pt—Cl bond length in $[PtCl_3\{(Z)\text{-}HN{=}C(OH)Bu^t\}_2]_2$, suggesting that steric strain contributes to the latter, but consistent with a strong *trans* influence from the Pt—Pt bond. The same group obtained an unsupported dimer, $[Pt_2Cl_2(acac)_4]$ (acac = acetylacetonate), by oxidation of $[Pt(acac)_2]$ with chlorine.[391]



(**164**)

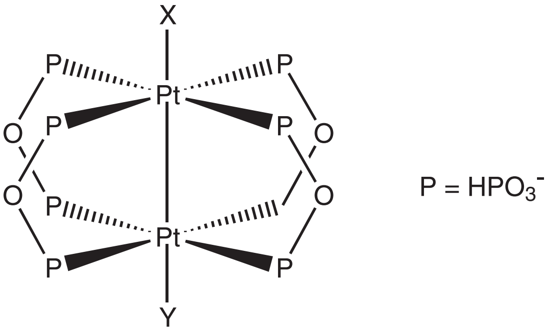
6.5.5.3 O,O-Bridged Dimers

6.5.5.3.1 Sulfate and hydrogenphosphate-bridged dimers

The sulfate bridged dimer $K_2[Pt_2(SO_4)_4(H_2O)_2]$ was among the first platinum(III) compounds prepared and the analogous hydrogenphosphate bridged complexes $[Pt_2(HPO_4)_4(L)_2]^{2+}$ are equally well known.[392] The structures of a number of these complexes have been determined as a variety of salts and with a variety of ligands (L) in the axial sites.[393–396] As with other dimeric systems, the Pt—Pt bond exerts a significant *trans* influence on the axial ligand and vice versa. Appleton and co-workers have examined the ^{195}Pt, ^{15}N, and ^{13}C NMR spectra of sulfate- and phosphate-bridged dimers, showing that the *J*(Pt—Pt) coupling constants decrease with increasing *trans* influence of the axial ligands.[397] They concluded from these and other observations that both Pt atoms undergo rehybridization when the axial ligand on one of the metals is replaced.[397] They also used ^{195}Pt NMR spectroscopy to follow the reactions of sulfate- and hydrogen phosphate-bridged complexes with halides.[398] Stranger *et al.* have assigned the electronic spectroscopy of such complexes, assigning the intense UV band at about 45,000 cm^{-1} to predominantly SO_4 or $HPO_4 \rightarrow \sigma^*(PtO_b)$ LMCT transitions.[399]

6.5.5.3.2 *Pyrophosphito-bridged dimers*

The pyrophosphito-bridged dimers, $[Pt_2(pop)_4XY]^{n-}$ (pop = $P_2O_5H_2^{\ 2-}$; (**165**)), form one of the largest and most widely studied groups of platinum(III) dimers. Crystal structures have been determined for a wide variety of complexes including X = Y = Cl, Br, I, NO_2, MeCN, SCN, imidazole, and SEt_2, and X = Me, Y = I.[400–406] The *trans* influence of these axial ligands follows the usual trend with the Pt—Pt bond lengths ranging from 2.676 Å to 2.782 Å, the shortest being for X = Y = MeCN and the longest being for the complex with X = Me, Y = I. The UV–Vis, IR, and Raman spectra also reflect the trans influences of the axial ligands.[404,407,408] The rates of aquation and substitution at the axial ligand sites have been studied and been found to be suggestive of an interchange mechanism.[409,410]



(**165**)

6.5.5.3.3 *Acetato-bridged dimers*

Bisacetato-bridged platinum(III) dimers have been known of for many years, but surprisingly, the first "lantern-shaped" tetrakis-acetatodiplatinum(III) complex was only reported in 1992. $[Pt_2(\mu\text{-}CH_2CO_2\text{-}O,O')_4(H_2O)_2]^{2+}$ was obtained from a solution of $K_2[Pt(NO_2)_4]$ in a mixture of glacial acetic acid and perchloric acid.[411,412] The Pt—Pt bond in this complex is remarkably short at 2.390(2) Å.[411,413] In aqueous solution one of the acetate ligands is rapidly lost.[411,413] The electronic structure of $[Pt_2(\mu\text{-}CH_2CO_2\text{-}O,O')_4(H_2O)_2]^{2+}$ has been analyzed using Xα-SW MO calculations and indicates a Pt—Pt single bond.[414]

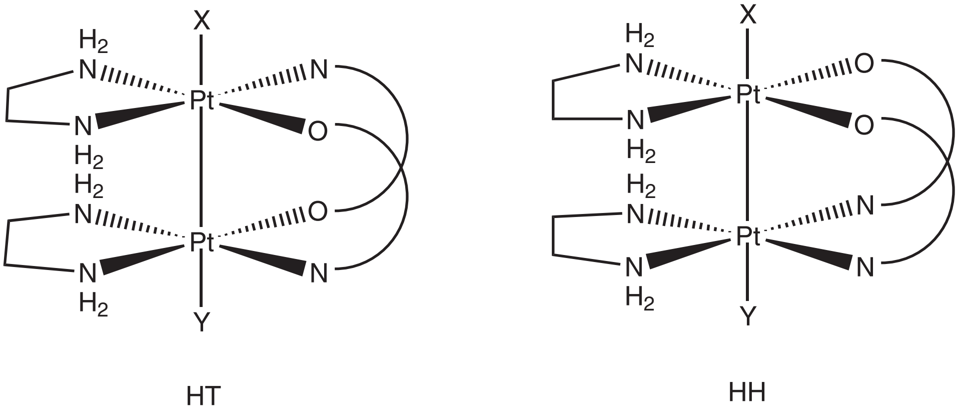
6.5.5.4 N,S and S,S-bridged Dimers

Goodgame and co-workers have described a series of dinuclear platinum(III) complexes with four bridging pyrimidine-2-thione or 2-thiouracil ligands $[Pt_2(pyrmS)_4XY]$ (pyrmS = pyrimidine-2-thione).[415–417] Somewhat unusually, these were first prepared by direct reaction between the ligand and $[PtI_4]^{2-}$,[415,416] but were also prepared by reduction of the platinum(IV) precursor $[PtCl_6]^{2-}$.[417] Structures were determined for pyrmS, X = Y = Cl, I; X = Cl, Br, Y = pyrimidine-2-thione, and pyrmS = 2-thiouracil, X = Y = I.[415–417] The Pt—Pt bond lengths range from 2.518(1) Å in the dichloro complex to 2.554(1) Å in the complex with mixed bromo and pyrimidine-2-thione ligands in the axial positions. Similar complexes with bridging pyridine-2-thiol and 4-methylpyridine-2-thiol ligands were obtained by Ooi and co-workers by reacting these ligands with *cis*-$[PtCl_2(NH_3)_2]$ and *cis*-$[PtCl_2(MeCN)_2]$, respectively, and then stirring the bridged platinum(II) products in chloroform.[418] The complexes were obtained with axial chloro ligands and these were readily substituted with other halides or thiocyanate. The structure of the dichloro complex $[Pt_2Cl_2(pyt)_4]$ (pyt = pyridine-2-thiol) revealed a Pt—Pt bond length of 2.532(1) Å.[418] In all structures in these series, the coordination geometry about the platinum(III) centers is *cis*-N_2S_2.[415–418]

There are very few example of S,S-bridged dimers, though tetrakisdithiocarboxylatoplatinum(III) dimers were reported before their carboxylato analogues. $[Pt_2I_2(R_2CS_2)_4]$, R = Me, $PhCH_2$ or Me_2CH, were obtained by iodine oxidation of dimeric platinum(II) complexes.[419,420] The Pt—Pt bond lengths in the latter two compounds are 2.598(1) Å and 2.578(1) Å respectively,[420] substantially longer than that in the acetate analogue.

6.5.5.5 N,O-bridged Dimers

Modern platinum blue chemistry arose serendipitously from the study of the interaction between cisplatin and pyrimidines. The anticancer activity of these platinum blues, coupled with their often intractable nature led Lippard and co-workers to study the analogous α-pyridone (α-pyr) complexes and in the process they found a convenient route to dinuclear platinum(II) complexes.[421–424] Nitric acid and nitrous acid oxidation of the platinum(II) dimer $[Pt_2(\alpha\text{-pyr})_2(NH_3)_4]^{2+}$ gave the nitrate and nitrite capped complexes $[Pt_2XY(\alpha\text{-pyr})_2(NH_3)_4]^{2+}$, X = Y = NO_3^- or NO_2^-, respectively.[421] In the presence of halide anions, these axial ligands are replaced.[423] Oxidation of the *cis*-diamminepyridone blue with nitric acid gave a HH dimer with X = NO_3^-, Y = H_2O (**166**).[422] Nitric acid oxidation of the platinum(II) dimer in which the ammine ligands had been replaced by en also gave a HH dimer with X = NO_3^-, Y = NO_2^-.[424] Matsumoto *et al.* report similar syntheses of the ammine analogues of these complexes.[425,426] The HH dimers were found to be more reactive than the HT.[424]



(**166**)

Lippert and co-workers have reported a similar series of *N*,*O*-bridged platinum(III) dimers in which the bridging ligands are the pyrimidines, 1-methyluracil, 1-methylthymine, or 1-ethylthymine. Chemical oxidation of dimeric platinum(II) complexes gave $[Pt_2XY(L)_2(NH_3)_4]^{2+}$, X,Y = NO_3^-, NO_2^-, H_2O, Cl^-, or Br^-, L = 1-MeU, 1-MeT, 1-EtT.[427–430] They too found that the HT dimers are more stable than the HH.[430]

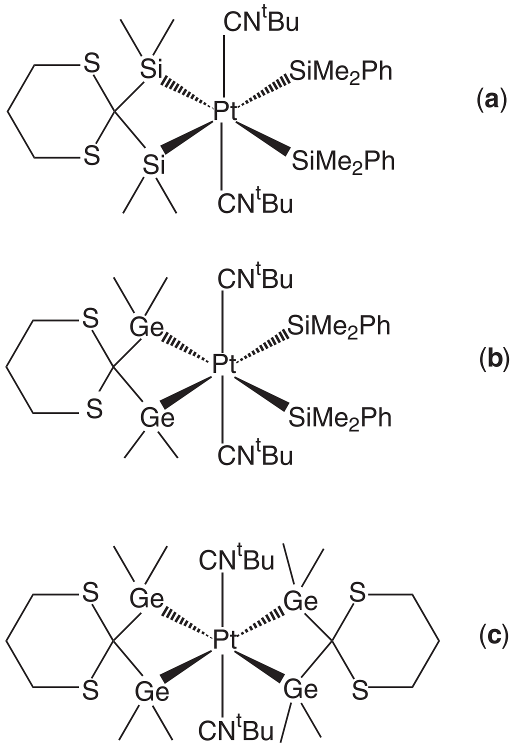
6.5.6 PLATINUM(IV)

6.5.6.1 Five-coordinate Platinum(IV) Complexes

Five-coordinate or 16-electron platinum(IV) complexes have been avidly sought for many years because of their relevance as intermediates in catalytic processes. However, the first two structurally characterized five-coordinate platinum(IV) complexes have only recently been described.[431] One of these, $[PtMe_3\{(NArCMe)_2CH\}]$ ($Ar = 2,6\text{-}Pr^i{}_2C_6H_3$),[432] is an organometallic complex and hence beyond the scope of this review. The other, $[PtH_2(SiEt_3)(Tp'+H)]^+$, was prepared both by protonation of one of the arms of the Tp′ ligand in the six-coordinate platinum(IV) complex $[PtH_2(SiEt_3)(Tp')]$ or by treatment of the platinum(II) intermediate $[PtH(solvent)(Tp'+H)]^+$ with $SiEt_3H$.[431] The structure of this complex was not unequivocally established because the hydride ligands could not be located. However, the combination of the structure with the NMR data is sufficient to provide strong evidence for a five-coordinate platinum(IV) complex, stabilized by the strong *trans*-influence of the silyl ligand and the bulkiness of the Tp′ ligand.

6.5.6.2 Group IV Complexes

Si—Si and Si—Ge bonds oxidatively add to platinum(0) to give platinum(II) silyl complexes as described in Section 6.5.2.1.7(iii), and 2,2-bis(disilanyl)dithiane double-oxidatively adds to $[Pt_3(CNBu^t)_6]$ to give the platinum(IV) complex shown in (**167a**).[53] The related 2,2-bis(silylgermyl)dithiane produces a mixture of germyl- and silylgermyl-platinum(IV) complexes shown in (**167b**) and (**167c**).[53]



(**167**)

6.5.6.3 Group V Complexes

There are numerous platinum(IV) complexes with nitrogen donors, most of which have been prepared as potential anticancer drugs or in the study of the reactions of such drugs. These compounds are described below in Section 6.5.6.5.

Platinum(IV) complexes of phosphine and arsine ligands formed by oxidation with chlorine or bromine are well known. Chloro complexes such as *cis*-$[PtCl_2(PEt_3)_4]^{2+}$ can be generated by electrolysis of the platinum(II) complex *cis*-$[PtCl_2(PEt_3)_2]$.[433] Similar platinum(IV) complexes have been studied by ^{195}Pt NMR spectroscopy.[434] In contrast, analogous iodo complexes are less well known and reaction with iodine frequently yields platinum(II) polyiodides, platinum(IV) polyiodides or mixed valence complexes. However, oxidation of $[Pt(L–L)_2]I_2$, (L–L = dmpe or o-$C_6H_4(AsMe_2)_2$) with concentrated nitric acid gives the platinum(IV) complex $[Pt(L–L)_2I_2](NO_3)_2$.[435]

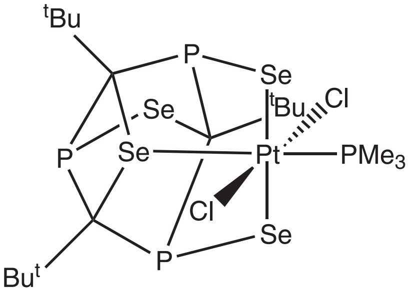
Platinum(II) and platinum(IV) complexes have been prepared using the constrained diphosphine ligands, 1,2-bis(diphenylphosphino)ethyne, and *cis*- and *trans*-1,2-bis(diphenylphosphino)-ethene.[412,436,437] The ethyne and *trans*-ethene ligands are unable to form chelate rings and act as bridging ligands in dinuclear platinum complexes.[437,438] However, the *cis*-ethene ligand can form a chelate and produces mononuclear complexes of the type $[PtCl_2(P{=}P)_2]^{2+}$.[436]

6.5.6.4 Group VI Complexes

Platinum(IV) complexes with six oxygen donors are rare but $K_6Na_2[Pt(OH)_2(HTeO_6)_2]{\cdot}12H_2O$ with chelating tellurato ligands and axial hydroxo ligands was obtained by reaction of $K_2[PtCl_6]$ with telluric acid in KOH.[439] The axial and equatorial Pt—O bond lengths are indistinguishable.[439]

Oxidative addition of the disulfide like salt $[\{SC(NMe_2)_2\}_2]Cl_2{\cdot}2H_2O$ to am(m)inechloroplatinum(II) complexes gives rise to platinum(IV) complexes with thiourea and chloro ligands added in trans positions.[440] For example, oxidation of $[PtCl_3(NH_3)]^-$ gives *cis*-$[PtCl_4(NH_3)(tmtu)]$. Oxidation of *trans*-$[PtCl_2(NH_3)_2]$ and $[PtCl(dien)]^+$ gives similar complexes, but they undergo light dependent isomerizations to *fac* and *trans*, *mer* configurations.[440] *cis*-$[PtCl_2(dmimt)_2]$ (dmimt = 1,3-dimethylimidazoline-2-thione) undergoes a similar trans addition of dmimt and chloro ligands, evidently as a result of spontaneous aerial oxidation.[441] Tetrasulfurtetranitride (S_4N_4) reacts with $[PtCl_2(PMe_2Ph)]_2$ to give a platinum(IV) complex with the S_4N_4 coordinated as a tridentate via two sulfur donors and one nitrogen donor.[442] Refluxing in chloroform results in isomerization such that the coordination is via one sulfur donor and two nitrogen donors.[443] Similarly, S_2N_2H forms a bidentate complex with platinum(II) $[Pt(S_2N_2H)(PR_3)_2]^+$ which is oxidized by bromine to the platinum(IV) complex *trans*-$[PtBr_2(S_2N_2H)(PR_3)_2]^+$.[183] This latter complex undergoes isomerization at room temperature to give the cis complex.[183] Ammonium polysulfide reacts directly with $[PtCl_6]^{2-}$ to give the optically active $(NH_4)_2[Pt(S_5)_3]{\cdot}2H_2O$ which reacts with concentrated hydrochloric acid to give a complex that was formulated as $(NH_4)_2[PtS_{17}]{\cdot}2H_2O$.[444]

Chlorine or bromine oxidation of $[Pt([16]aneSe_4)]^{2+}$ gives the platinum(IV) complexes, *trans*-$[Pt([16]aneSe_4)X_2]^{2+}$ (X = Cl or Br) with Pt—Se bond lengths of 2.496 Å to 2.502 Å.[442] Similarly, halogen oxidation of $[PtX_2(L–L)]$ (X = Cl or Br, L–L = o-$C_6H_4(SeMe)_2$) gives the platinum(IV) complexes $[PtX_4(L–L)]$ with Pt—Se bond lengths of 2.432 Å to 2.441 Å.[445] The novel cage compound $P_3Se_4C_3Bu^t{}_3$ undergoes a surprising reaction with $[PtCl_2(PMe_3)]_2$, oxidatively adding to the metal via cleavage of the Se—Se bond to give a facially coordinated tridentate ligand with three selenium donors in the platinum(IV) complex $[PtCl_2(PMe_3)(P_3Se_4C_3Bu^t{}_3)]$ (**168**).[446]



(**168**)

6.5.6.5 Am(m)ine Complexes

Platinum(IV) complexes have been known to be anticancer active since the original studies in this area by Rosenberg.[447] Consequently numerous platinum(IV) complexes have been prepared for biological testing. Until recently, the great bulk of these were *trans*-dihydroxo complexes prepared by peroxide oxidation of platinum(II) or *trans*-dihalo complexes prepared by halogen oxidation or by haloacid treatment of the dihydroxo complexes. However, workers at Johnson Matthey extended the range of complexes available greatly by developing new reactions of the *trans*-dihydroxo complexes.[448,449] In particular, they showed that the hydroxo ligands react with anhydrides to give *trans*-dicarboxylato complexes.[448,449] Many of these new complexes have demonstrated excellent antitumor activity[437] and one, *cis*,*trans*, *cis*-[$PtCl_2(COOMe)_2$(cyclohexylamine)(NH_3)] (JM216), underwent extensive clinical trials as an orally administered anticancer agent.[450] Other groups have produced related compounds and characterized them crystallographically, establishing that the Pt—O bond lengths to the axial carboxylates are similar to those to hydroxide ligands.[451–454] Beck and co-workers showed that acyl chlorides also react with the hydroxo ligands to produce similar compounds.[455] Sohn and co-workers have prepared a large set of complexes with axial and equatorial hydroxo ligands and reacted these with anhydrides to produce di-, tri- and tetracarboxylatoplatinum(IV) complexes.[456–460] The same group has shown that the axial hydroxo ligands react with trimethylsilylchloride to give $SiOMe_3^-$ bound in these positions.[461] Oxidation of platinum(II) in methanol has been shown to lead to mixed *trans*-methoxo, hydroxoplatinum(IV) complexes and subsequent boiling in methanol leads to the *trans*-dimethoxo complexes.[462] Peroxide oxidation of dihydroxo bridged platinum(II) complexes yields the equivalent hydroxo bridged platinum(IV) dimers with axial hydroxo ligands.[463]

6.5.6.6 Amino Acid and Peptide Complexes

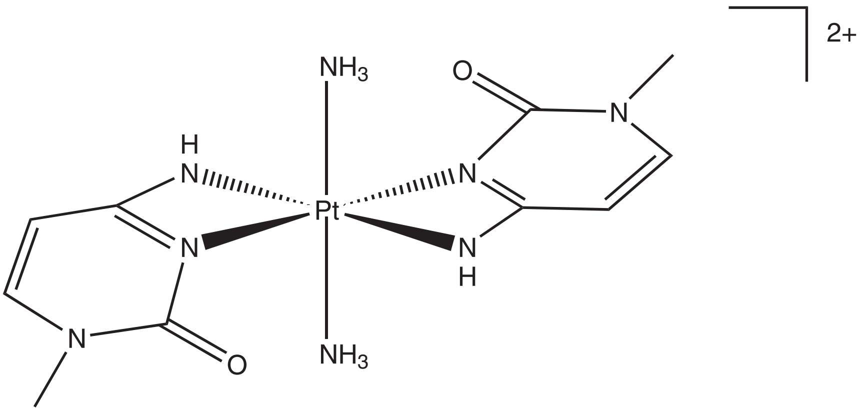
There are remarkably few platinum(IV) complexes of amino acids and peptides but a number have emerged in recent years. Early attempts to produce glycylglycine complexes of platinum(IV) by hydrogen peroxide oxidation of the platinum(II) complex *trans*-[$PtCl_2$(glycylglycine)$_2$] resulted in hydrolysis of the peptide and formation of the amino acid complex *trans*,*trans*-[$PtCl_2(gly)_2$] with the glycine ligands coordinated via the amine and carboxylate groups.[464] Direct reaction of the platinum(IV) precursor $Na_2[PtCl_6]$ with glycine yielded *cis*-[$PtCl_2(gly)_2$] whereas reaction of glycine or D-alanine with the crown ether salt [Na(18-crown-6)]$_2$[$PtCl_6$]·3H_2O gives the anionic complexes $[PtCl_4(gly)]^-$ and $[PtCl_4(\text{D-ala})]^-$.[465] When the latter reactions mixtures are exposed to light from a halogen lamp the neutral complexes [$PtCl_4(glyH)_2$] and [$PtCl_4$(D-alaH)] are obtained instead.[465,466] Addition of dipeptides to solutions of KI and $H_2[PtCl_6]$ yielded anionic complexes with tridentate and bidentate dipeptide ligands: K[Pt(dipep)Cl_3] and K[Pt(dipepH)Cl_4] (dipep = glycylglycine, glycyl-L-alanine, L-alanylglycine and L-alanyl-L-alanine).[467] The same group prepared complexes of the type $[PtCl(dipep)(OH)_2]^-$ and $[PtCl_2(Hdipep)(OH)_2]^-$ (dipep as above) by hydrogen peroxide oxidation of the platinum(II) complexes.[468] Halogen oxidation of [PtX_2L_2] (X = Cl, Br; L = glyOEt, glygly-OEt) generated the platinum(IV) complexes [PtX_4L_2].[469]

6.5.6.7 Nucleobase Complexes

A range of platinum(IV) nucleobases complexes have been prepared by the oxidation of platinum(II) complexes with nucleobases already bound. For example, Lippert and co-workers have reported a uracil complex obtained by chlorine oxidation,[470] guanine and adenine complexes by hydrogen peroxide oxidation,[471,472] and a 1-methylthymine complex by gold(III) oxidation.[473] Hydrogen peroxide oxidation of a platinum(II) complex of 1-methylcytosine gave the expected *trans*-dihydroxoplatinum(IV) complex which was stable under strongly acidic conditions.[474] However, at higher pH values ring closure occurred with displacement of the hydroxo ligands to give N_3,N_4-bound 1-methylcytosine ligands which formed four-membered chelate rings (**169**).[474] Other workers reported a similar complex of 1-methylcytosine and suggested on the basis of spectroscopic evidence that following ring closure, the Pt–N_3 bond was displaced by a water ligand.[475]

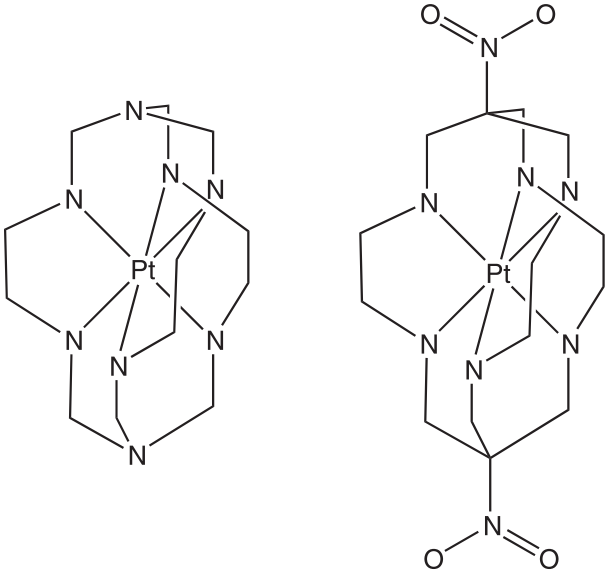
6.5.6.8 Macrocyclic and Macrobicyclic Complexes

Halogen oxidation of platinum(II) complexes of macrocyclic ligands generally gives rise to *trans*-dihaloplatinum(IV) complexes. In a case reported by Lawrance and co-workers, this occurred but pendant amine groups of the ligand were also completely chlorinated to give dichloroamino groups.[476]



(**169**)

Sargeson and co-workers have reported the use of $[Pt(en)_3]^{4+}$ in template reactions to produce the platinum(IV) complexes of the macrobicyclic ligands sep and $(NO_2)_2$sar (**170**).[477] These reactions are analogous to those that occur around cobalt(III). However, in contrast to the $[Co((NO_2)_2sar)]^{3+}$ system, reduction of the pendant dinitro groups did not yield amines, but hydroxyamine groups.[478]



(**170**)

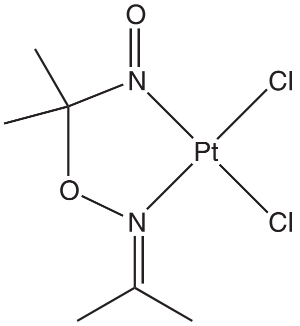
6.5.6.9 Porphyrin Complexes

The first reported porphyrin complexes of platinum(IV) date from 1980 and were obtained by hydrogen peroxide oxidation of platinum(II) porphyrin complexes in an acidic medium (HCl).[479] Since then oxidation of platinum(II) complexes of other porphyrins has been achieved by the same method,[480] and by chlorine,[481] or bromine[482] oxidation. Reaction with iodine did not lead to oxidation and treatment of platinum(IV) porphyrin complexes with iodide resulted in reduction to platinum(II).

The Soret, α and β bands in the visible spectra of platinum(IV) porphyrin complexes occur at longer wavelengths than their platinum(II) analogues,[482] ^{1}H NMR resonances are all shifted downfield,[482] the ^{13}C resonances of the α carbons are shifted upfield, and the ^{1}H–^{195}Pt and ^{13}C–^{195}Pt coupling constants are reduced.[480] Whereas excitation of platinum(II) porphyrin complexes by 35 ps flashes at 355 nm and 532 nm persists for more than 10 ns, that of the platinum(IV) complexes decays with a time constant of about 45 ps, an effect that has been attributed to a low-lying ring-to-metal charge transfer state.[483]

6.5.6.10 Reactions of Coordinated Ligands

Ligands coordinated to platinum(IV) undergo a variety of reactions. For example, Freeman has reported the nitrosation of ethane-1,2-diamine to *N*,*N*′-dinitroso-ethane-1,2-diamine by reaction of $[PtCl_2(bipy)(en)]^{2+}$ with KNO_2.[484] Oxidation of *cis- and trans*-$[PtCl_2(Me_2C{=}NOH)_2]$ with chlorine results in the expected *trans*-dichloroplatinum(IV) complexes.[485] The *trans* isomer is stable but the *cis* undergoes a novel coupling of the oxime ligands to give the complex shown in (**171**).[485] Sargeson and co-workers have shown that template formation of macrobicyclic ligands, developed firstly on cobalt(III), can also be achieved on platinum(IV).[141] The most extensively studied reactions are those of coordinated organonitriles. Kukushkin and Pombeiro have reported an extensive series of studies of the reactions of complexes of the type *trans*-$[PtCl_4(RCN)_2]$ ($R = Me$, Et, CH_2Ph, Ph). Reaction with ketoximes, aldoximes, dialkylhydroxyamines, *vic*-dioximes, or chloro- and amidooximes results in iminoacylation,[486–489] reaction with alcohols produces imino ester ligands,[490] and reaction with water generates nitriles.[491]



(**171**)

An important class of reactions are those involving the axial hydroxo ligands of platinum(IV) complexes, typically obtained by hydrogen peroxide oxidation. For example, reaction of $[Pt(NH_3)_5(OH)]^{3+}$ with SO_2 or HSO_3^- results in the formation of the sulfito complex $[Pt(NH_3)_5(OSO_2)]^{2+}$.[492] This reaction is believed to occur by direct attack on the coordinated hydroxide rather than displacement of this ligand. Reactions with carboxylate anhydrides and acyl halides to produce bound carboxylates described above in Section 6.5.6.5 similarly take place by attack on the coordinated hydroxide.[447,448,455] Multidentate ligands with unbound carboxylate and alcohol arms undergo reactions with axial hydroxides resulting in ring closure,[493–496] although it is not known in this case whether the reaction occurs via displacement of, or attack on, the hydroxide.

6.5.6.11 Ligand Exchange Reactions

Platinum(IV) complexes are highly inert and therefore undergo unassisted ligand-exchange reactions only very slowly. The presence of even trace amounts of platinum(II) can dramatically increase the rate of such reactions as a result of ligand-bridging mechanisms as proposed by Pearson and co-workers.[497] Ligand exchange can also be accelerated by reductive–elimination–oxidative–addition (REOA) processes and ligand-assisted mechanisms, the former occurring via a platinum(II) intermediate and the latter via a X–X–Pt bridge labilizing the *trans* ligand.[498]

The interest in platinum(IV) complexes as anticancer agents has increased the interest in the reactions of platinum(IV), particularly those with reducing agents (Section 6.5.6.12) and those with nucleobases. A number of groups have demonstrated that platinum(IV) complexes can undergo slow ligand exchange reactions with nucleobases such as 9-methylxanthine, 9-methylhypoxanthine, and guanosine-5′-monophosphate.[499–504] These reactions have half-lives of the order of a few days, but the presence of 10% of the corresponding platinum(II) complex increases the rate of reaction with 9-methylxanthine by 30-fold.[500] It has been argued that as a result of such reactions it is possible that platinum(IV) complexes are themselves anticancer active and do not require reduction to platinum(II). However, the slowness of the unassisted reactions and the low likelihood of platinum(II) catalysis in high dilution biological environments suggests that significant biological effects are unlikely. Choi and co-workers have shown that the readily reduced platinum(IV) complex [$PtCl_4$(1,2-chxn)] oxidizes guanine to 8-oxoguanine.[505,506] The 8-oxoguanine ligand can be displaced from the platinum center by an excess of guanine.[505,506]

Dunham and Abbott have studied ligand exchange in *cis*- and *trans*-[$Pt(ox)_2(H_2O)_2$] and shown that it occurs too slowly to be involved in the formation of metal–metal bonded polymers.[507] They also observed a trans to cis isomerization that occurred without ligand exchange and proposed a Bailar or Ray-Dutt twist process.[507]

The reaction of platinum(IV) complexes with ascorbate results in very slow reduction and for [$PtCl_2(OH)_2$(*N*,*N*-dmen)], in the formation of the oxalate complex [$Pt(C_2O_4)Cl(OH)$(*N*,*N*-dmen)].[508]

6.5.6.12 Kinetics and Mechanism of Platinum(IV) Reduction

The anticancer activity of platinum(IV) complexes, and the belief that reduction is needed to initiate this activity, had generated substantial interest in the rates and mechanism of reduction by biologically relevant reductants such as thiols, ascorbic acid, and methionine. Reduction of platinum(IV) to platinum(II) usually proceeds as a single two-electron step and is usually first-order with respect to both platinum(IV) and reductant concentrations.

Studies of the reduction of the tetracyanoplatinum(IV) complexes *trans*-[$Pt(CN)_4X_2]^{2-}$ ($X = Cl$ or Br) by SCN^-, $S_2O_3{}^{2-}$, CN^-, and $SO_3{}^{2-}$ led to the conclusion that the mechanism involved X^+ transfer to the reducing agents.[509,510] Elding and co-workers have undertaken extensive studies of the same complexes as models for anticancer active complexes.[511–513] Reduction by thiols occurs with a [RSH]:[Pt^{IV}] stoichiometry of 2:1, is first order with respect to each reactant and yields RSSR and $[Pt(CN)_4]^{2-}$.[511] A halide-bridged electron transfer was postulated with both RSH and RS^- contributing, though the latter being far more reactive.[511] Oxidation by methionine, though occurring with a 1:1 stoichiometry, was via a similar mechanism.[512] It was suggested that reduction by methionine may be competitive with reduction by thiols, particularly in acidic conditions.[512] Reduction by the platinum(II) complexes $[Pt(NH_3)_4]^{2+}$ and $[Pt(en)_2]^{2+}$ also occurred via halide bridged mechanisms.[513] The same group have studied the reduction of *trans*,*trans*,*trans*-[$PtCl_2(OH)_2$(*c*-$C_6H_{11}NH_2)(NH_3)$] by thiols, finding similar reaction mechanisms to those suggested for the tetracyano complexes.[514] Others have similarly proposed outer-sphere activated complexes in the reduction of hexachloro and ammine/chloro complexes by ascorbic acid and hydroxyamine and a variety of α-hydroxy acids,[515,516] but in the case of reduction by Sn^{II} and Fe^{II} have suggested an inner sphere mechanism.[515] Sadler and co-workers have shown that iodoplatinum(IV) complexes react with thiols more rapidly than expected, and substantially more rapidly than chloro analogues.[517] For example, *cis*,*trans*-[$PtI_2(OH)_2$(en)] reacts with the cysteine of albumin giving a sulfenic acid derivative.[517]

The platinum(II) catalyzed reduction of *cis*,*cis*,*trans*-diaminedihalodihydroxoplatinum(IV) complexes by ascorbate has been reported to proceed via a long-lived platinum(IV)–ascorbate radical.[518] Ascorbate reduction of complexes with halides in the axial sites has been reported to proceed via reductive attack on one of these halides.[519] This group also showed that reduction by Asc^{2-} occurred seven orders of magnitude more rapidly than reduction by $HAsc^-$ and that H_2Asc is unreactive.[519] Reduction by thiols and methionine is strongly dependent on pH because of a similar variation in reactivity of the protonated and unprotonated forms of the reductants.[505,514]

The reduction potentials of platinum(IV) complexes have been shown to depend most on the nature of the axial ligands; those with axial chloro ligands are most readily reduced, those with axial carboxylato ligands are intermediate and those with axial hydroxo ligands are the most difficult to reduce.[452,520,521] Choi *et al.* have shown that the rates of reduction follow the same trends.[522] The rates of reduction of diaminetetrachloro- or tetraaminedichloro-platinum(IV) complexes has been shown to depend on the steric bulk of the amine ligands, with bulkier substituents promoting reduction.[523,524]

6.5.6.13 Novel Mechanisms of Platinum(II) Oxidation to Platinum(IV)

Platinum(II) oxidation to platinum(IV) usually occurs via oxidative addition of oxidants such as the halogens and hydrogen peroxide. Aerial oxidation is rare, but has recently been reported for platinum(II) complexes with one or two tridentate ligands that position additional coordinating groups above and below the coordination plane. For example, complexes of the tridentate [9]aneN_3 are oxidized by molecular oxygen to platinum(IV).[525,526] In one case, a novel peroxo intermediate was obtained and crystallographically characterized.[526] The deprotonated amide ligand *N*,*N*,*N*′,*N*′-tetra(*N*-methylacetamide)ethane-1,2-diamine similarly facilitates aerial oxidation of platinum(II) to platinum(IV).[527]

6.5.6.14 Hydride Complexes

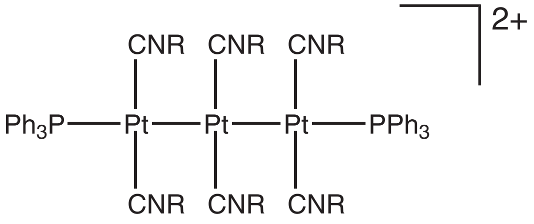
Platinum(IV) hydrides are relatively rare, with monohydride, dihydrides, and only recently trihydrides being reported as reviewed by Puddephatt.[528] The tripodal ligands triphos and Tp′ allow the formation of a stable trihydrides.[529,530] $[PtCl_2(triphos\text{-}P,P')]$ reacts with sodium borohydride to give the trihydride $[PtH_3(triphos)]$.[529] $[Pt(H)(Me)_2(Tp')]$ reacts with Et_3SiH to give the dihydride $[Pt(H)_2(SiEt_3)(Tp')]$ which in turn reacts with methanol to give the trihydride $[Pt(H)_3(Tp')]$.[530] A salt like hexahydride complex complex $K_2[PtH_6]$ has been prepared by the reaction of potassium hydride and platinum sponge under high-pressure conditions and has been characterized by X-ray powder diffractometry.[531]

6.5.7 MIXED OXIDATION AND MIXED METAL COMPLEXES

Platinum is unusual in the extraordinary variety of mixed-valence compounds that it forms. Many of these have novel spectroscopic, electronic, and structural properties.

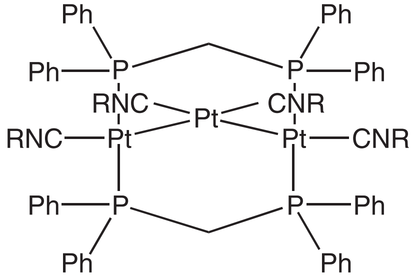
6.5.7.1 Platinum(0)/Platinum(I)

Reaction of the platinum(0) complex, $[Pt(C_2H_4)(PPh_3)_2]$, with either of the platinum(II) complexes, $[PtCl_2(PPh_3)_2]$ or $[Pt(CN\text{-}xylyl)_4]^{2+}$, yields the linear trinuclear cluster $[Pt_3(PPh_3)_2(CN\text{-}xylyl)_6]^{2+}$ (**172**) with an average oxidation state of 2/3.[532] The same complex was obtained by controlled potential electrolysis of $[Pt(CN\text{-}xylyl)_4]^{2+}$, giving $[Pt_3(CN\text{-}xylyl)_8]^{2+}$, followed by reaction with PPh_3.[86] Reaction of $[Pt_3(CN\text{-}xylyl)_8]^{2+}$ with dppm gave the A-frame complex $[Pt_3(dppm)_2(CN\text{-}xylyl)_4]^{2+}$ (**173**), a complex that could also be obtained by reaction of $[Pt_2(dppm)_2(CN\text{-}xylyl)_2]^{2+}$ with $Hg[Pt_3(CN\text{-}xylyl)_6]_2$.[86]



$$\left[Ph_3P{-}\overset{CNR}{\underset{CNR}{Pt}}{-}\overset{CNR}{\underset{CNR}{Pt}}{-}\overset{CNR}{\underset{CNR}{Pt}}{-}PPh_3\right]^{2+}$$

(**172**)

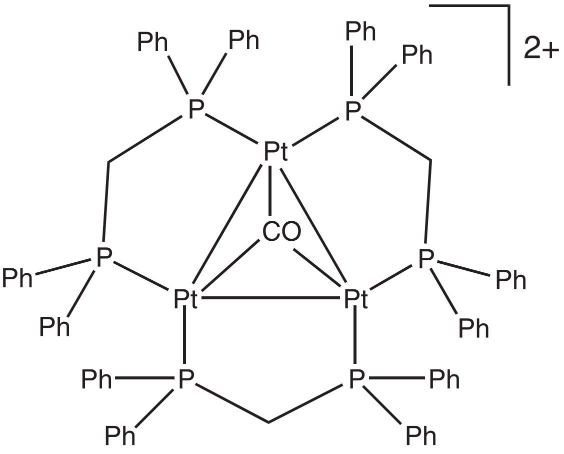


R = xylyl

(**173**)

Clusters of platinum atoms are of interest as models for the adsorption of species onto the surface of metallic platinum. Models for terminal and two-fold (μ_2) binding are plentiful, but are rare for three-fold (μ_3) binding. However, the preparation of $[Pt_3(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^{2+}$ (**174**) by reaction of $[Pt(O_2CCF_3)_2(dppm)_3]$ with CO, provides a carbonyl bridging three Pt atoms as model for this type of binding.[533] The Pt—Pt bond lengths range from 2.613 Å to 2.650 Å,[533] similar to those in the linear (2.639 Å) and A-frame (2.593 Å) complexes described above.[86,532] This complex undergoes a variety of reactions and these have been reviewed extensively by Puddephatt *et al.*[534]

For example, it adds one or two carbonyls to give $[Pt_3(\mu_3\text{-}CO)(CO)(\mu\text{-}dppm)_3]^{2+}$ and $[Pt_3(\mu\text{-}CO)(CO)_2(\mu\text{-}dppm)_3]^{2+}$, respectively.[535] In contrast, the halide bridged complex does not add carbonyl even though the halide is only weakly bound.[535] It also adds one isocyanide ligand to give the intermediate $[Pt_3(\mu\text{-}CO)(CNMe)(\mu\text{-}dppm)_3]^{2+}$ and a second resulting in displacement of the carbonyl to give $[Pt_3(CNMe)_2(\mu\text{-}dppm)_3]^{2+}$.[536] Other reactions include those with hydride, halides, SnX_3^-, and phosphines.[534]



(**174**)

All of these trinuclear clusters are 42e and this is the most common electron count. However, a 46e cluster, $[Pt_3(\mu\text{-}CO)(\mu\text{-}dppm)_4]^{2+}$ has been obtained by reacting $[Pt_3(\mu\text{-}dppm)_3(PPh_3)]$ with CO.[537] The Pt—Pt bond lengths (2.620–2.648 Å) are remarkably similar to those in the 42e clusters.[537]

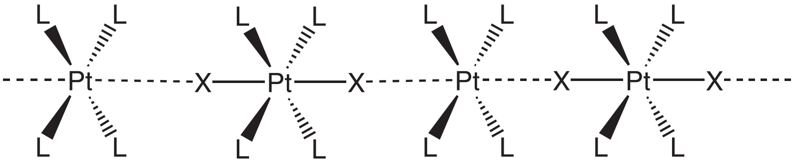
Mixed palladium/platinum analogues of these trinuclear clusters have also been reported. The first of these, $[PtPd_2Cl(PPh_2)_2(PPh_3)_3]^+$, was prepared by the reaction of $[PdCl(PPh_3)_3]^+$ with $[PtCl(PPh_3)_3]^+$.[538]

6.5.7.2 Platinum Blues

The compounds known as the "platinum blues" are in fact a series of compounds with colors ranging from violet through blue and green to tan or dark red and have average oxidation states ranging from 2.18 to 2.5.[539] Their structures and activities have been reviewed thoroughly by Matsumoto and Sakai[539] and here we limit our comments to the general principles. Although the discovery of the platinum blues dates from nearly 100 years ago, the recent interest arose from their incidental discovery in the study of the reactions of cisplatin with pyrimidines and the subsequent discovery of the anticancer activity of these new platinum blues.[539] The difficulty in characterizing these compounds led the study of α-pyridonates by Lippard and co-workers and the first structural characterizations of the platinum blues as tetrameric systems.[539,539a] Since then a variety of systems have been structurally characterized including octameric complexes, the first of which was $[Pt_8(NH_3)_{16}(C_2H_4NO)_8]^{10+}$ with an average oxidation state of 2.25.[540] The relationship between geometric parameters and the average platinum oxidation state has been examined in detail in a recent study by Sakai *et al.*[541]

6.5.7.3 Linear Chain Complexes

The localized-valence halogen-bridged platinum(II)/platinum(IV) complexes (**175**) are of interest because of their highly anisotropic electrical and optical properties. The complexes are characterized by broad and intense intervalence bands in their electronic spectra.[542] Partial oxidation of [PtCl(dien)]Cl with iodine yields the mixed valence species $[PtI(dien)][PtI_3(dien)]I_2$,[543] but when 4Me-dien is used, the mixed valence compound is only obtained if it is trapped quickly, before isomerization of the meridional platinum(IV) complex to a facial form.[544] Although these species nominally have localized valences, the extent of delocalization increases as the bridging halide goes from chloride to bromide to iodide.[545] This trend has been attributed to the decrease in electronegativity and a consequent decrease in the effective atomic charge on the platinum(IV) center. When mixtures of chloride and bromide are used, the anions are essentially distributed randomly along the chains.[546]



(175)

Partial oxidation of $[Pt_2(pop)_4]^{4-}$ with halogen (X_2, X = Cl, Br, I) leads to the formation of $K_4[Pt_2X(pop)_4]\cdot nH_2O$.[547] The structure of the bromide revealed linear PtPtBrPtPtBr chains with equal Pt—Br distances, consistent with a fully delocalized platinum(2.5) system (spin density wave state, SDW).[547] Clark and co-workers, on the basis of spectroscopic data on these and related complexes, suggested that the Pt—X bond lengths are not equal and that the chains consist of platinum(II) and platinum(III) complexes.[548,549] The crystal structure of the chloride revealed different Pt—Cl distances, consistent with the spectroscopic evidence.[550] The difference between the bromide and chloride systems was subsequently confirmed by low temperature crystal structures though both can be described as having charge density wave (CDW) states.[551] These complexes exhibit the electronic spectra of the oxidized and reduced forms and have an intervalence charge-transfer band.[552] The effects of pressure on the spectra of these complexes were attributed to increased orbital overlap on increased ligand field interactions.[552] Yamashita *et al.* have recently shown that the iodide analogue exists in either the SDW or CDW state depending on the counter-ion present and on the temperature.[553] The related complex $[Pt_2I(dta)_4]$ (dta = $MeCS_2^-$) exhibits semiconducting behavior below 300 K, attributed to a $IPt^{2+}–Pt^{3+}–I–Pt^{2+}–Pt^{3+}–I–$ state, and a metallic phase above this temperature attributed to a $–I–Pt^{2.5+}–Pt^{2.5+}–I–Pt^{2.5+}–Pt^{2.5+}–I–$ state.[554,555]

6.5.7.4 Mixed Metal Systems

Halide bridged nickel(II)/platinum(IV) and palladium(II)/platinum(IV) complexes with one-dimensional linear-chain structures have been studied extensively.[556–559] These are analogous to the linear-chain platinum(II)/platinum(IV) systems described in Section 6.5.7.3 and have similar broad and intense intervalence bands.[556–559] However, they have weaker metal–metal interactions resulting in more localized valences than the all platinum analogues.[556–559]

The first copper(II)/platinum(IV) analogue, $[Cu(en)_2][PtX_2(en)_2](ClO_4)_4$ (X = Cl, Br) was reported by Oshio *et al.* and they reported that these compounds too had an intense intervalence band.[560] Clark *et al.* questioned this and showed that the intense colors were due to the presence of a proportion of the platinum(II)/platinum(IV) compound and that they were more accurately formulated as $[Cu_xPt_{1-x}(en)_2][PtX_2(en)_2](ClO_4)_4$.[561] When $x = 1$, the compounds are pale in color, are not dichroic and there is no resonance enhancement of the ClPtCl stretching mode.[561] Subsequently, a method was reported for preparing stoichiometric $[Cu(1,2\text{-chxn})_2][PtX_2(1,2\text{-chxn})_2]X_4$ (X = Cl, Br) in high purity allowing more complete studies of the properties of these mixed metal species.[562]

Trimeric cyanide bridged iron(II)/platinum(IV) complexes of the type $[(CN)_5Fe\text{-}(\mu\text{-}CN)\text{-}PtL_4\text{-}(\mu\text{-}NC)\text{-}Fe(CN)_5]^{4-}$ ($L_4 = (en)_2$ or $(NH_3)_4$) have been described by Bocarsly and co-workers.[563,564] These complexes have intervalence charge transfer bands in the visible region and are novel because they undergo two-electron charge transfer following irradiation into these bands resulting in the formation of $[PtL_4]^{2+}$ and two equivalents of $[Fe(CN)_6]^{3-}$.[563,565,566] A dimeric analogue $[(NH_3)_5PtL_4\text{-}(\mu\text{-}NC)\text{-}Fe(CN)_5]\cdot 6H_2O$, has been prepared and exhibits similar spectroscopy and electrochemistry to the trimeric complexes.[567] Polymeric and oligomeric analogues have been prepared from $[(CN)_5Fe\text{-}(\mu\text{-}CN)\text{-}Pt(NH_3)_4]$ units, the growth of which is controlled by the oxidation state of the iron center.[568] Related molybdenum species, $[(CN)_7Mo\text{-}(\mu\text{-}CN)\text{-}PtL_4\text{-}$

(μ-NC)-Mo(CN)$_7$]$^{4-}$ ($L_4 = (en)_2$ or $(NH_3)_4$), have been reported recently,[569] as has a thallium complex, [(CN)$_5$PtTl(CN)]$^-$.[570] All of these complexes are of interest for the storage and conversion of solar energy and for the construction of molecular wires.

6.5.7.5 Mixed Oxidation State Clusters

Platinum forms a wide variety of clusters and these are of interest as models for metallic platinum surfaces and catalysis on such surfaces. Many of these clusters are based on stacked triangles[23,571] or bicapped pentagonal prisms.[571] Many smaller clusters are also derived from triplatinum building blocks.[16]

Only large clusters usually adopt the face-centered cubic structure of metallic platinum. A novel cuboctahedral cluster [Pt$_{15}$H$_x$(CO)$_8$(PBu^t$_3$)$_6$] has been reported by Spencer *et al.*[572] and the first octahedral cluster [Pt$_6$(CO)$_6$(μ-dppm)$_3$]$^{2+}$ was only reported recently.[573]

Large platinum carbonyl clusters have been investigated as models for the adsorption of carbon monoxide on platinum surfaces and on platinum electrodes. An issue is how large the clusters must be before they adopt the properties of the bulk metal. Teo *et al.* have investigated the magnetic properties of the clusters [Pt$_6$(CO)$_{12}$]$^{2+}$, [Pt$_9$(CO)$_{18}$]$^{2+}$, [Pt$_{19}$(CO)$_{22}$]$^{2+}$, and [Pt$_{38}$(CO)$_{44}$H$_x$]$^{2+}$ and found that they have properties very similar to those of small crystallites.[574] Dahl and co-workers have investigated the vibrational spectroscopy of seven redox forms of the cluster [Pt$_{24}$(CO)$_{30}$]^n ($n = 0$ to -6) as models for CO adsorption on platinum electrodes and observed that the frequency of the CO vibration decreased almost linearly with n.[575] The same group has investigated the similar cluster [Pt$_{26}$(CO)$_{32}$]$^{2-}$ using ^{252}Cf-plasma desorption mass spectrometry.[576]

6.5.7.6 Mixed Metal Clusters

There is an enormous variety of mixed metal clusters, the great majority of which are organometallic and, therefore, beyond the scope of this review. Werner-type examples generally have combinations of phosphine, carbonyl, and hydride ligands and have the platinum in low or zero oxidation states. For example, complexes of the type [M(CO)$_4$(μ-PPh$_2$)(μ-H)Pt(PR$_3$)$_2$] have been reported for M = Cr, Mo, and W and for R = Et.[577] [Pt(C$_2$H$_4$)(PPh$_3$)$_2$] adds one PtPPh$_3$ unit to [Re$_2$(μ-H)$_2$(CO)$_8$] to give three isomeric forms of [Re$_2$Pt(μ-H)$_2$(CO)$_8$(PPh$_3$)$_2$][578] and adds up to three PtPPh$_3$ units to [Re$_2$(CO)$_{10}$] to give [Re$_2$Pt$_n$(μ-CO)$_{2n}$(CO)$_{10-2n}$(PPh$_3$)$_2$] ($n = 2$, 3).[579] [Re$_2$(μ-H)(CO)$_8$] reacts with [Pt(COD)$_2$] to give the bow tie geometry [Re$_4$Pt(μ-H)$_6$(CO)$_{16}$] which can be deprotonated in base,[580] and the same group has reported rhenium/platinum clusters with phosphine and carbonyl ligands.

Many mixed metal clusters are derived from triplatinum units and these have been reviewed extensively by Imhof and Venanzi.[16] As an example, gold forms a variety of cluster compounds with platinum including [Pt$_3$Au(μ-CO)$_3${P(Cy)$_3$}$_4$]$^+$ which reacts with sulfur dioxide to give SO$_2$-bridged species.[581] Higher nuclearity clusters involving gold and copper have been reported more recently including complexes of the type [Pt(AuPPh$_3$)$_8$(CuCl)]$^{2+}$, [Pt(CO)(AuPPh$_3$)$_8$(CuCl)]$^{2+}$, [Pt(CO)(AuPPh$_3$)$_7$(CuCl)$_2$]$^+$, [Pt(CO)(Ag)$_2$(AuPPh$_3$)$_7$]$^{3+}$,[582] [PtAg(AuPPh$_3$)$_8$]$^{3+}$, [Pt(CO)Ag(AuPPh$_3$)$_8$]$^{3+}$,[583] [Pt(PPh$_3$)(AuPPh$_3$)$_6$(Cu$_4$Cl$_3$PPh$_3$)]$^+$, and [Pt(PPh$_3$)(AuPPh$_3$)$_6$(Cu$_4$I$_3$)]$^+$.[584]

Very high nuclearity clusters have been widely sought. For example, the series of complexes [Ni$_{38}$Pt$_6$(CO)$_{48}$H$_{6-n}$]$^{n-}$ ($n = 4$, 5) have been investigated as molecular models for bimetallic "cherry" crystallites.[585] There has been a recent report of the binding of platinum to the E$_9$$^{3-/4-}$ Zintl ions (E = Ge, Sn, or Pb).[586] [Pt(PPh$_3$)$_4$] reacts with K$_4$Sn$_9$ to yield [Sn$_9$Pt$_2$(PPh$_3$)]$^{2-}$.[586]

6.6.1 INTRODUCTION: PURPOSE AND SCOPE

The chapter on copper in the first edition of *Comprehensive Coordination Chemistry* (*CCC*), published in 1987,[1] presented a contemporary overview of the field. Since then there has been an explosion of growth in the coordination chemistry of copper in both the nonbiological and biological areas. As part of an ongoing series, this article attempts to provide an overview of the major developments in the field since 1982, allowing a certain degree of overlap in order to preserve continuity.

The properties of metal-coordinated compounds, whether in classical inorganic coordination complexes, in organometallic compounds, or in bioinorganic model compounds, are determined in large measure by the nature of ligands bound to the metal ion. Focus is therefore placed on the design of chelating ligands whose metal-binding sites differ in the nature of the donor atom. The purpose of this article is to update the progress made (i) in the design of chelating ligands, and (ii) in the development of systematic coordination chemistry of copper thereof. A large amount of structural data for coordination complexes of copper with various ligand types has been accumulated, giving rise to an opportunity to look into their structural varieties in a systematic manner. This chapter addresses at the appropriate point the importance and relevance of coordination chemistry in the context of bioinorganic chemistry. It is worth mentioning here that the coordination chemistry of metal ions, including copper, in the biosphere and geosphere is covered in Volume 8.

The material included in this chapter has been organized by oxidation state, with further subdivision into ligand donor type, and was obtained from reports published in primary research journals. The article will cover coordination complexes of copper in three oxidation states: Cu^{III}, Cu^{II}, and Cu^{I}. The sections dealing with specific ligand donor types cut across several structural types. In view of the all-inclusive nature of the previous review of *CCC*(1987), no effort will be made here to present a comprehensive account. Instead, specific cases will be chosen for discussion because they exemplify important concepts concerning the relationship of ligand structure to metal complex properties.

This chapter deals mainly with structural aspects of compounds; magnetic behavior of ligand-bridged dinuclear/polynuclear copper(II) centers has also been emphasized. Only those structures that exist as discrete molecules, as opposed to a polymeric network extending throughout the crystal lattice, will be considered. Specifically excluded are kinetic and mechanistic work and work related to stability constants, as is purely magnetic work, except where some direct relationship to coordination chemistry is involved. The present review also does not cover categorically multinuclear copper cluster compounds, neither does it attempt to explore organometallic compounds involving copper, extensive supramolecular networks, and work of an essentially catalytic nature.

Understandably, every reference cannot be cited and selection has had to be severely limited. Priority is given mainly to work since about the mid-1980s, but frequent references to reviews are provided in the text, both to those which are mainly comprehensive listings of papers and to those which deal critically with a particular topic leading back into earlier work. Whenever possible, references have been chosen with the latter feature in mind, particularly where several reports on one topic have appeared at about the same time. It is suggested that readers take note of two review articles from the late 1990s on copper.[2,3] Owing to limitations of space the references given here are to the more frequently cited journals and review journals, and preference has been given to those published in English before October 2001. In order to illustrate more clearly how each ligand molecule is coordinated to the copper center(s), a diagrammatic representation of the structures has been made.

6.6.2 COORDINATION COMPOUNDS OF COPPER(III)

6.6.2.1 Amine Ligands

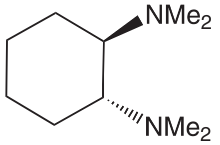
The activation of molecular oxygen by copper plays a central role in synthetically useful stoichiometric and catalytic oxidative conversions of organic molecules and in biological systems.[4–26]

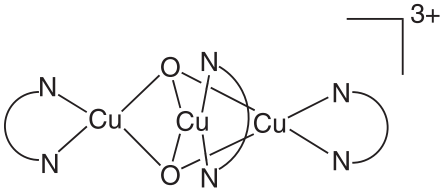
In 1996 Stack and co-workers reported an unusual 3:1 (copper:O_2 stoichiometry) reaction between a mononuclear copper(I) complex of a *N*-permethylated (1R,2R)-cyclohexanediamine ligand with dioxygen. The end product of this reaction, stable at only low temperatures (X-ray structure at −40 °C) is a discrete, mixed-valence trinuclear copper cluster (**1**), with two Cu^{II} and a Cu^{III} center (Cu–Cu: 2.641 and 2.704 Å).[27] Its spectroscopic and magnetic behavior were also investigated in detail. The relevance of this synthetic complex to the reduction of O_2 at the trinuclear active sites of multicopper oxidases[4–8] was discussed. Once formed, it exhibits moderate thermal stability, decomposed by a non-first-order process in about 3 h at −10 °C. In the presence of trace water, the major isolated product was the bis(μ-hydroxo)dicopper(II) dimer (**2**).

Continuing their efforts with similar ligands, they prepared a thermally sensitive crystal of a bis(μ-oxo)dicopper(III) compound (**3**).[28] Average Cu–O bond distance and Cu–Cu distance are 1.806 Å and 2.743 Å, respectively. Spectroscopic and kinetic parameters for this compound were also investigated. They also studied the reactivity properties of the copper–dioxygen complexes.[25]

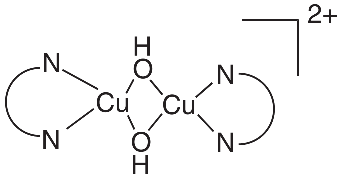
6.6.2.2 Pyridine-based Ligand

In a major breakthrough, Suzuki and co-workers[29] demonstrated that a tetradentate ligand produced the bis(μ-oxo)dicopper(III) complex (**4**) (each copper ion has a square planar structure,

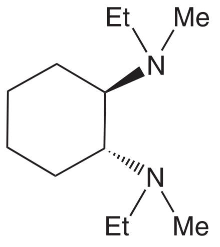


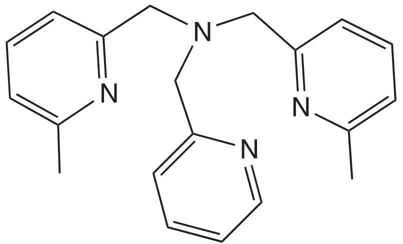


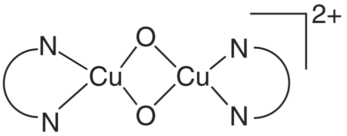
$[(L)_3Cu_3O_2][CF_3SO_3]_3{\cdot}4CH_2Cl_2$ (**1**)



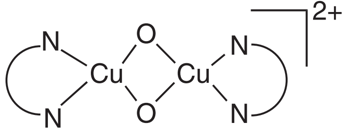
$[(L)_2Cu_2(OH)_2][CF_3SO_3]_2$ (**2**)







$[(L)_2Cu_2(O)_2][CF_3SO_3]_2{\cdot}4CH_2Cl_2$ (**3**)



$[(L)_2Cu_2(O)_2][PF_6]_2{\cdot}2Me_2CO$ (**4**)

composed of a N_2O_2 donor set with two 6-methyl-2-pyridylmethyl sidearms which interact weakly with each copper ion in the axial positions; Cu–Cu: 2.758 Å), that can be reversibly converted to the copper(I) species (Section 6.6.4.2.2 (iv)) at −80 °C in CH_2Cl_2 by the bubbling through of N_2. Absorption spectral and resonance Raman studies were also done. They structurally characterized the corresponding bis(μ-hydroxo)dicopper(II) complex $[(L)Cu(OH)]_2[ClO_4]_2$ (Cu–Cu: 2.9368 Å) as well.

6.6.2.3 Deprotonated Amide Ligands

Amide groups are well known to offer two potential binding sites for metal-ion complexation (O vs. N-coordination).[30] For neutral amides complexation occurs generally at the oxygen atom, which is the most basic site. Amide deprotonation makes the nitrogen more basic than the oxygen atom, and complexation at nitrogen can be observed. The crystal structure of the complexes presented in this section and those presented in Section 6.6.3.4 are in agreement with these results.

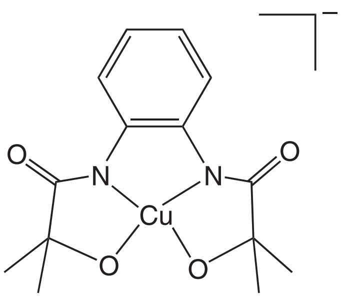
Interest in copper compounds of the rare III oxidation state has mounted substantially since about 1980. Quite a few copper(III)-compatible ligand environments have been discovered. Collins *et al.*[31] designed a series of polyanionic chelating (PAC) ligands containing *N*-amido and oxido donors to demonstrate that this family of ligands is a source for stabilizing the copper(III) state. The structure of complex (**5**) revealed a square-planar environment for the metal center. The $Cu{-}N_{amido}$ bond distances are 1.813(4) Å and 1.804(4) Å, very similar to those found for the copper(III) tripeptide complex of tri-α-aminoisobutyric acid (1.801(4) Å and 1.804(5) Å).[31,32] As a further matter of general interest, the Cu^{III}/Cu^{II} couple provides an excellent analytical tool for assessing the relative donor capacities of ligand complements. The property that Cu^{III}/Cu^{II} couples have of being highly sensitive to ligand environments has been exploited to assess the relative donor properties of a series of ligands containing *N*-amido, phenolato, and alkoxido donors. The possible noninnocence of these ligands that contain aromatic groups was considered, and an approach for determining the best formal oxidation-state assignments for the metal centers in potentially ambiguous cases was introduced.

Using a deprotonated hydroxyiminoamide ligand, Krüger and co-workers[33] structurally characterized a discrete copper(III) compound (**6**). The square-planar structure is retained even in solution. Absorption and redox properties of this complex were also investigated.

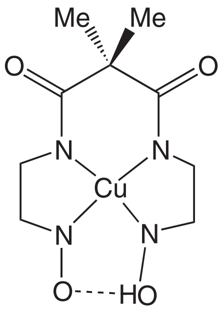
In 2000 Hofmann and co-workers[34] demonstrated that their copper(I) ethylene complex (Section 6.6.4.1) could be oxidized by O_2 irreversibly, yielding a bis(μ-oxo)dicopper(III) complex (**7**). The anionic iminophosphanamide ligand $[Bu^t{}_2P(NSiMe_3)_2]^-$ is highly basic and, because the small N–Cu–N bite angle of the neutral copper(I) complex leads to increased Lewis acidity of the copper center, provides better back-bonding capability, therefore stabilizing the copper(III) oxidation state.

6.6.2.4 Thiol Ligand

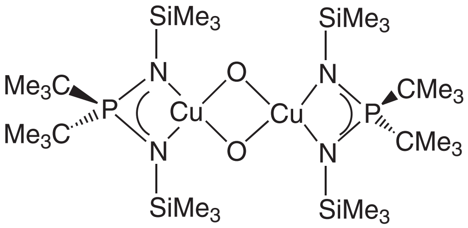
Krüger and co-workers[35] were successful in stabilizing remarkably a discrete copper(III) complex (**8**) containing aliphatic thiolate as the supporting ligand. They established the point that thiolate ligands can lower Cu^{III}/Cu^{II} redox potential. A very interesting paramagnetic copper(III) complex containing an octahedral CuS_6 coordination polyhedron was synthesized by Wieghardt and co-workers.[36] They first synthesized and structurally characterized a copper(II) complex, $[(L)Co^{III}Cu^{II}Co^{III}(L)][PF_6]_2$ (Section 6.6.3.5) (L is the hexadentate macrocyclic trianion 1,4,7-tris(4-*tert*-butyl-2-sulfidobenzyl)-1,4,7-triazacyclononane). One-electron oxidation of this compound yielded $[(L)Co^{III}Cu^{III}Co^{III}(L)]\ [ClO_4]_3\cdot 2Me_2CO$. EXAFS (extended X-ray absorption spectroscopy) clearly established the copper(III) state in this complex. Temperature-dependent magnetism and EPR spectral parameters established the $S = 1$ ground state of the copper(III) center. It is worth mentioning here the inherent problem associated with thiol oxidation[37] by copper(II) (Section 6.6.3.3.1).



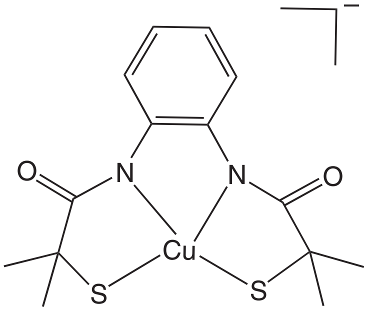
$[PPh_4][Cu(L)]\cdot 2H_2O$ (**5**)



$[Cu(HL)]$ (**6**)



$[(L)_2Cu_2(O)_2]$ (**7**)



$[Ph_4P][Cu(L)]$ (**8**)

6.6.2.5 Macrocyclic Ligands

Tolman and co-workers discovered a novel phenomenon: that when the copper(I) complex of 1,4,7-triisopropyl-triazacyclononane[38] is oxygenated at −78 °C there exists an equilibrium between the two oxygenated species $[Cu^{II}_2(\mu\text{-}\eta^2{:}\eta^2\text{-}O_2)]^{2+}$(side-on peroxodicopper(II)) and $[Cu^{III}_2(\mu\text{-}O)_2]^{2+}$[bis($\mu$-oxo)dicopper(III)], depending on the solvent chosen, with CH_2Cl_2 favoring the former species and THF favoring the latter.[39] They structurally characterized the bis-(μ-oxo)dicopper(III) compound (**9**), supported by tribenzyl-substituted ligand. They investigated absorption and resonance Raman features of such species and also carried out kinetic studies. The core geometry is contracted, compared to those of the bis(μ-hydroxo)dicopper(II) compounds that result from decomposition of the bis(μ-oxo) complexes upon warming.[40] Structural analyses of the decomposition products (complexes (**10**)–(**12**)) showed that they arise from N-dealkylation of the original capping macrocycles. Using a sterically hindered dinucleating bis(triazacyclononane) ligand they characterized one more bis(μ-oxo)dicopper(III) compound[41] (**13**), and investigated how supporting ligand topology influences the structure and reactivity of copper–dioxygen complexes.[21,22,24]

6.6.3 COORDINATION COMPOUNDS OF COPPER(II)

6.6.3.1 Nitrogen Donor Ligands

6.6.3.1.1 Polydentate aliphatic amine ligands

In the case of cytochrome c oxidases[42–44] (which catalyze the reduction of dioxygen to water, the final step in aerobic metabolism), a binuclear iron–copper assembly is the site of dioxygen binding and subsequent reduction. As a part of providing synthetic examples for heme Fe^{III}-bridging ligand–Cu^{II} systems for this enzyme, Holm and co-workers[45–49] structurally characterized an extensive series of monomeric copper(II) (as well as copper(I); Section 6.6.4.2.1) complexes of tetradentate ligands (Figure 1 and Table 1). These ligands coordinate in a tripodal manner, enforcing trigonal bipyramidal geometry at the metal; each arm of the ligand forms a puckered, five-membered chelate ring, with the ring conformations synchronized to impart an axial C_3 twist to the bound ligand. By use of these ligands, (distorted) trigonal bipyramidal (TBP) and tetragonal pyramidal (TP) arrangements, respectively, were stabilized with attendant axial and equatorial coordination. In many places throughout this chapter the geometry of a five-coordinate species has been defined in terms of a structural index parameter τ ($\tau = 0$ for square-pyramidal/tetragonal-pyramidal, and $\tau = 1$ for trigonal-bipyramidal geometries).[50]

As a part of their ongoing investigations into the reaction of dioxygen with copper(I) complexes to identify copper–superoxo/peroxo intermediate species, Schindler and co-workers[51–53] have also provided examples of a number of mononuclear copper(II) complexes (Table 1) (as well as copper(I); Section 6.6.4.2.1).

Comba and co-workers described a simple and efficient method for the determination of solution structures of weakly coupled binuclear copper(II) complexes.[54] The technique involves the combination of molecular mechanics[55,56] and EPR spectroscopy. From this standpoint they reported the structure of the complex (**29**). Using an acyclic tertiary tetraamine ligand, Bernhardt reported[57] crystal structure of the complex (**30**), along with its redox properties.

6.6.3.1.2 Heterocyclic nitrogen donor ligands

In the blue, Type I copper proteins plastocyanin and azurin, the active-site structure comprises the trigonal array [CuN_2S] of two histidine ligands and one cysteine ligand about the copper,

together with a weak axial methionine interaction.[4,5,8,19,58–60] This coordination geometry is largely retained in the oxidized and reduced forms of these proteins. Furthermore, in both forms the active-site geometry is considerably removed from the normally preferred geometries of Cu^{II}(tetragonal/square planar) and Cu^{I}(tetrahedral). Investigations of the coordination chemistry of copper(II) with chelating ligands incorporating pyridine, pyrazole, imidazole, and benzimidazole continue to be stimulated by interest in developing models for copper proteins, and in understanding the factors which give rise to the relationship between the coordination geometry and the nature of the donor atoms and redox potentials.[37,61,62]

(i) Imidazole-containing ligands

Imidazole is a ubiquitous ligand for copper in proteins, as the coordinating side-chain of the amino-acid histidine. The presence of imidazole ligation has been confirmed crystallographically in several proteins and enzymes having mono-, bi-, and trinuclear copper centers.[58] The ubiquity of copper–imidazole bonding in copper-containing biomolecules has stimulated the synthesis and characterization of many imidazole-based ligands, where imidazole is present solely as, or as a part of, multidentate ligands and their copper complexes, in order to relate the spectroscopic properties of low-molecular-weight complexes to the natural systems. The complexes considered in this section are compiled in Table 2.

Nearly tetrahedral Cu^{I}/Cu^{II} model complexes that are well defined, approximately isostructural, and that contain biologically relevant ligation can be used to probe important questions about the active sites of copper metalloproteins that embody this structural feature. Schugar and co-workers characterized complexes (**31**)–(**34**) and studied their absoption and EPR spectral properties.[63–66] Using a sterically demanding bidentate ligand, both Cu^{I} (Section 6.6.4.2.2(i)) and Cu^{II} complexes were prepared. X-ray structural analyses of compound (**34**)

revealed a pseudotetrahedral CuN(imH)$_4$ chromophore, with approximate D_{2d} point symmetry. The ligand exerts an unprecedented degree of geometric control of the coordination spheres for complexes of this type. The CuN$_2$/CuN$'_2$ dihedral angle is close to the ideal tetrahedral angle of 90°. Geometric constraints within the nine-membered chelate rings cause intraligand N–Cu–N angles to exceed the tetrahedral value, flattening (D_{2d}) the otherwise tetrahedral CuN$_4$ units; additional ligand-field effects result in a larger angle. Electrochemical measurements for the $[CuL_2]^{2+}/[CuL_2]^+$ couple in MeCN revealed a reversible redox reaction at a fairly positive potential. Using Cu^{I} and Cu^{II} complexes, as their BF_4^- salts of the *N*-methyl derivative of the ligand present in complex (**34**), the electron self-exchange rate in MeCN was determined by ^{1}H NMR techniques.[66] Garner and co-workers synthesized a series of sterically hindered imidazole proligands and investigated their copper coordination chemistry. Complex (**35**) is an example.[67] Electrochemical and EPR spectroscopic studies have also been done. The new diimidazole ligand was also synthesized by them and was shown to form a four-coordinate bis(diimidazole) Cu^{II} complex (**36**), as well as a Cu^{I} complex (Section 6.6.4.2.2(i)). The structural analysis revealed that the N–Cu–N angles are constrained by (i) the bite angle of the ligand to 94 ± 2°; and (ii) the interligand steric interactions, which lead to the dihedral angle of the interligand planes of 68.2°. The steric bulk of the ligand, through interligand interactions between the phenyl groups substituted at the 4-positions of the imidazole rings, prevents the adoption of square-planar geometry. The dihedral angles observed for both structures reveal that in each case the CuN$_4$ geometry is intermediate between tetrahedral and square planar. The X-band EPR spectrum for the powdered complex is typical of an approximately D_2 CuN$_4$ center

[Cu(L)$_2$][BF$_4$]$_2$·CH$_2$Cl$_2$ (**36**) possessing a d_{xy} ground state. Charge-transfer bands dominate the UV–vis spectra, and the complex is intensely colored. The EPR and electronic spectra indicate that the complex has a very similar structure in the solid state and in solution. The redox properties were also examined. In MeCN, electron self-exchange rate was also determined.[68] Using a variety of tridentate and tetradentate ligands with mixed donor sets (amine–imidazole, imidazole–pyridine), a number of mononuclear complexes (**37**)–(**42**) have been studied.[69–71] EPR spectroscopic and cyclic voltammetric studies of these complexes were also made. Hydrogen bonding between bromide and the imidazole-NH atoms in compound (**37**) tie the individual molecules into an infinite two-dimensional network.[69] The structure of complex (**38**) reveals that the two nitrite anions are oriented differently, with one NO_2^- ion acting as a monodentate ligand and the other as (pseudo)didentate (one O atom behaving as semi-coordinate).[69] The potential of complexes (**37**) and (**38**) as active-site analogues of copper nitrite reductases (reduction of nitrite, to produce nitric oxide)[72] has also been studied. Interestingly, the alcoholic O atom of the Schiff base ligand is not coordinated in complex (**43**)/(**44**).[73,74]

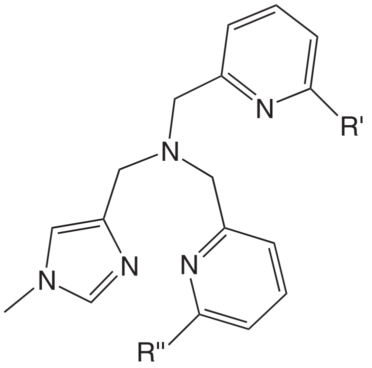
Copper–zinc superoxide dismutase (SOD) contains an imidazolate-bridged Cu^{II}–Zn^{II} heterodinuclear metal center in its active site.[4,8,19,75,76] The copper ion is coordinated to four imidazole N atoms of histidine residues and a solvent (water) in distorted square-pyramidal geometry, while the zinc ion, located at a distance of 6.2 Å from the copper ion, is coordinated to a carboxylato O atom of an aspartic acid residue and three imidazole N atoms of histidine residues in a distorted tetrahedral structure. New dinucleating ligands having two metal-binding sites bridged by an imidazole binding have been designed and synthesized as model ligands for copper–zinc SOD by Fukuzumi and co-workers.[77,78] The corresponding mononucleating ligand has also been synthesized for comparison (complexes (**45**)–(**47**)).[77] The copper ions in the imidazolate-bridged Cu^{II}–Cu^{II} homodinuclear complexes ((**48**) and (**50**)) and Cu^{II}–Zn^{II} heterodinuclear complex (**49**) have pentacoordinate geometries.[78] The coordination site occupied by a solvent can be susceptible to ligand substitution, providing a binding site for substrate superoxide. Magnetic measurements of complexes (**48**) and (**50**) have shown an antiferromagnetic (AF) exchange interaction with a coupling constant of $2J$ (singlet–triplet energy gap) $= -73.4\,cm^{-1}$ and $-145.9\,cm^{-1}$, respectively. The Cu^{II}–Zn^{II} distance of 6.197(2) Å agrees well with that of native enzyme. The EPR spectrum of complex (**49**) showed a signal which is characteristic of mononuclear trigonal-bypyramidal Cu^{II} complexes. The cyclic voltammetric behavior of these complexes was investigated in detail. The complexes catalyzed the dismutation of superoxide at biological pH; the SOD activity increased in the order (**50**) < (**48**) < (**49**). These monomeric, homodinuclear, and heterodinuclear complexes react with H_2O_2 in the presence of a base at $-80\,°C$ yielding hydroperoxo Cu^{II} species (absorption and resonance Raman studies). The EPR spectral behavior of such species was also investigated.

From the standpoint of modeling Type I copper proteins,[4,5,59,60] a variety of imidazole-based ligands containing thioether sulfurs and imidazole groups have been synthesized.[61,62] The structures and spectroscopic properties of their copper(II) complexes (**51**)–(**53**) and (**55**)–(**60**) were investigated.[65,79–82] To characterize apical copper(II)–thioether bonding, the complex (**51**) was



R' = R'' = H; [(L)Cu(MeCN)][ClO_4]$_2$·MeCN (**45**)

investigated, to reveal discrete Cu^{II} monomers having tetragonal N_4S_2 ligand donor sets with equatorial CuN_4 and axial CuS_2 coordination.[65] Electronic and EPR spectral studies were also done. The compound (**54**) has a Cu_2Cl_2 core with bis(μ-chloro) bridges. The Cu–Cu separation is 3.552 Å.[79] All these compounds were characterized further by EPR and absorption spectroscopy.

Using a new tripodal ligand, Sorrell and co-workers synthesized compound (**61**).[83] The dioxygen reactivity of the pseudotetrahedral complex of this ligand of composition $[(L)Cu(MeCN)][BF_4]$ (not structurally characterized) was examined. In MeOH at −78 °C, the thermal decomposition of the side-on peroxodicopper(II) adduct in the presence of water yields a bis(hydroxide)-bridged dicopper(II) dimer (not structurally characterized), $[(L)Cu(OH)]_2[BF_4]_2$, which further reacts with atmospheric CO_2 to produce a carbonato-bridged compound (**62**).

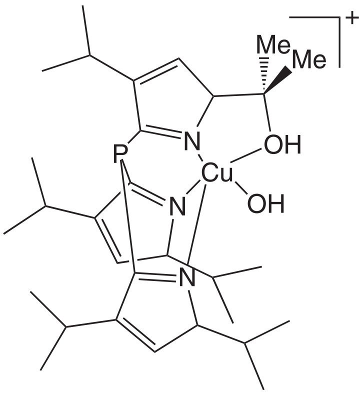
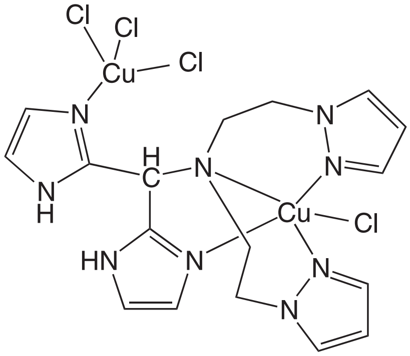
Dopamine β-hydroxylase (DβH) is a copper-containing glycoprotein that hydroxylates dopamine at the benzylic position to norepinephrine.[84] During the attempted crystallization of the bis(hydroxide)-bridged dicopper(II) dimer, a side product was subsequently isolated (complex (**63**)), revealing intramolecular hydroxylation at a formally benzylic position of the tris(imidazolyl)phosphine ligand.[85] The copper(II) center has an axially compressed TBP structure.

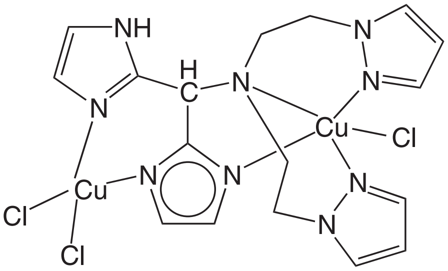


[(L)Cu(OH)][BF$_4$]·1.625CH$_2$Cl$_2$ (**63**)

A dinucleating ligand containing imidazoles and pyrazoles was designed and synthesized.[86] The synthesis and characterization of the copper(II) complexes were described, with the study aimed at modeling the active site of copper–zinc superoxide dismutase (SOD).[4,8,19,75,76] Both non-imidazolato-bridged complex (**64**) (Cu–Cu distance: 6.104(1) Å) and imidazolato-bridged complex (**65**) (Cu–Cu distance: 5.566(1) Å) were obtained. Both structures show two copper centers in two different coordination environments: a distorted square pyramid ($\tau = 0.13$ for the imidazole-bridged complex, and $\tau = 0.12$ for the non-imidazole-bridged complex) and a distorted tetrahedron. Temperature-dependent magnetic susceptibility study of complex (**65**) shows AF behavior with $2J = -96\,\mathrm{cm}^{-1}$. From pH-dependent EPR and electronic spectra, this complex has been demonstrated to be stable over quite a wide pH range, including the physiological pH values. A low concentration of complex (**65**) catalyzes the dismutation of superoxide at physiological pH.



[(L)Cu$_2$Cl$_4$] (**64**)



[(L)Cu$_2$Cl$_3$] (**65**)

(ii) Benzimidazole-containing ligands

The incorporation of benzimidazole, in addition to mimicking the imidazole donor function, would result in distortions in coordination geometries, owing to its steric bulk. From this standpoint a number of complexes have been reported (Table 3).[87–89]

From the standpoint of modeling copper nitrite reductases[72] using benzimidazole-containing chelating ligands, Casella and co-workers[90] synthesized a number of mononuclear copper complexes; quite a few of them had nitrite bound ligands. The copper(I) complexes exhibited such activity and reacted rapidly with NO$_2$$^-$ in the presence of stoichiometric amounts of acid to give NO and the corresponding copper(II) complexes. Under the same conditions, the reactions between the copper(I) complexes and NO$^+$ yielded the same amount of NO, indicating that protonation and dehydration of bound nitrite are faster than its reduction.

Table 3 Stereochemistries of copper(II) complexes of benzimidazole-based chelating ligands.

[Cu(L)$_2$][ClO$_4$]$_2$·2H$_2$O (**70**)

Hemocyanin and tyrosinase are dinuclear copper-containing proteins that bind or activate dioxygen.[4,5,7–26] Hemocyanin functions as a dioxygen carrier, and tyrosinase, as a monooxygenase, which hydroxylates monophenols (tyrosine) and further oxidizes the *o*-diphenol to an *o*-quinone. The ubiquitous plant enzyme catechol oxidases,[91] in contrast to tyrosinases, catalyze exclusively the oxidation of catechols to the corresponding *o*-quinone by molecular oxygen, without acting on monophenols. The resulting highly reactive quinones autopolymerize to form brown polyphenolic catechol melanins, a process thought to protect the damaged plant from pathogens or insects. In the course of their investigations on functional modeling of tyrosinase

During the last two decades a large number of chelate ligands comprising heterocyclic N-donor, thiolate, and/or thioether S-donor centers have been studied,[37,61,62] in connection with attempts to mimic the structure, spectroscopy, and redox behavior of "Type I" copper centers in "blue" copper proteins.[4,5,8,19,59–61] Using a mixed benzimidazole/thioether bidentate ligand, Kaim and co-workers[95] synthesized a copper(I) (Section 6.6.4.2.2(ii)) and a copper(II) complex (**81**). Using bridged bis(benzimidazole)–thioether-containing ligands capable of providing N_2S donor sets, two distinct environments have been found in the crystal structures of (**82**) and (**83**).[96] As a part of their sustained efforts to model "Type I" copper centers, using two tridentate ligands, Addison and co-workers[97] recently investigated two compounds (**84**) and (**85**). Using a linear quadridentate N_2S_2 donor ligand, Addison *et al.* reported the structure of complex (**86**).[50] Along the same lines, Reedijk and co-workers[98] investigated the coordination chemistry of complexes (**87**) and (**88**), and Palaniandavar and co-workers[99,100] prepared a number of copper(I) (Section 6.6.4.2.2(ii)) and copper(II) complexes (**89**)–(**92**) with bis(benzimidazole)–thioether-containing ligands.

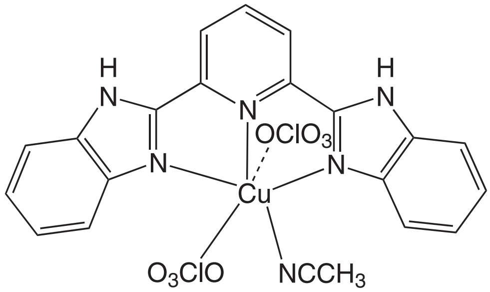
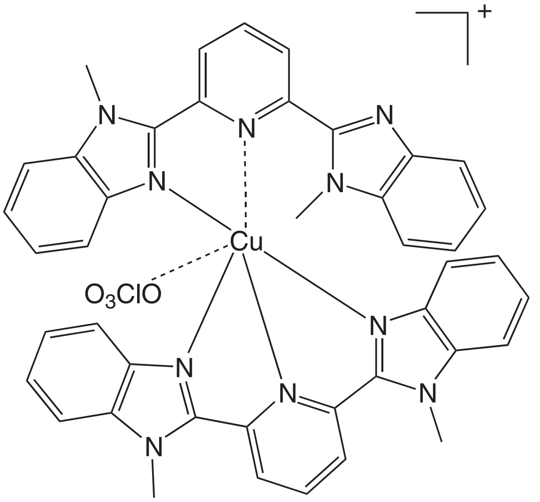
$[(L)Cu(H_2O)(OClO_3)_2]$ (**86**)

The synthesis and coordination chemistry of an asymmetric multidentate ligand designed for modeling coordination-number asymmetry at metal sites in binuclear metalloproteins were reported.[101] A dinuclear copper complex of this ligand demonstrates proof-of-concept for inducing coordinative unsaturation at one metal of the binuclear pair, and subsequent reaction with N_3^- illustrates site-directed reactivity. The copper ion in mononuclear complex (**93**) is present in distorted square-pyramidal geometry ($\tau = 0.43$). The hydroxo oxygen of the ligand does not participate in metal coordination. On the other hand, a structural analysis of the



$[(L)Cu(MeCN)(OClO_3)_2]$ (**87**)



$[(L)_2Cu(OClO_3)][ClO_4]$ (**88**)

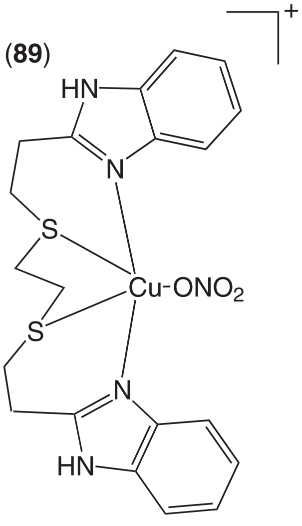
$[(L)Cu][ClO_4]_2 \cdot 2MeCN$ (**91**)



$[(L)Cu(ONO_2)][NO_3]$ (**90**)

binuclear complex (**94**) reveals that as a result of the inherent asymmetry of the ligand, one copper ion has distorted trigonal-bipyramidal ($\tau = 0.83$) geometry, while the other copper ion has distorted square-planar geometry. The potential for site-directed reactivity at a square-planar site was demonstrated by adding 0.5 equivalent of N_3^- ion to the binuclear copper complex in MeCN. The structure of the resulting azido-bridged complex (**95**) shows that the two copper ions within the binuclear unit are still coordinated by the ligand nitrogens, the acetate, and the ligand alkoxy oxygen.

$[(L)Cu_2(O_2CMe)][ClO_4]_2\cdot 2H_2O$ (**94**)

Müller *et al.*[102] designed a new dinucleating ligand which allows for the "tuning" of the metal–metal distance, to provide a tentative coordination chemical modeling of hemocyanin and tyrosinase. The complex (**96**) of the unrestricted ligand presents an open conformation with discrete (4 + 2) copper coordination environments. The two halves of the ligand are rotated out of the *cis*-coplanar conformation by 116.6°, resulting in a relatively long Cu–Cu distance of 6.16 Å. Two oxygenation products of the dicopper(I) complex of a restricted ligand, which best approaches the geometry of a "Type III" site, were isolated. One is a tetranuclear copper(II) cluster (**97**), best described as a symmetric Cu_4O_4 eight-membered ring (Cu–Cu distances of 3.05 Å, 3.50 Å, and 6.30 Å). The other one is a dicopper(I) complex (Section 6.6.4.2.2(ii)).

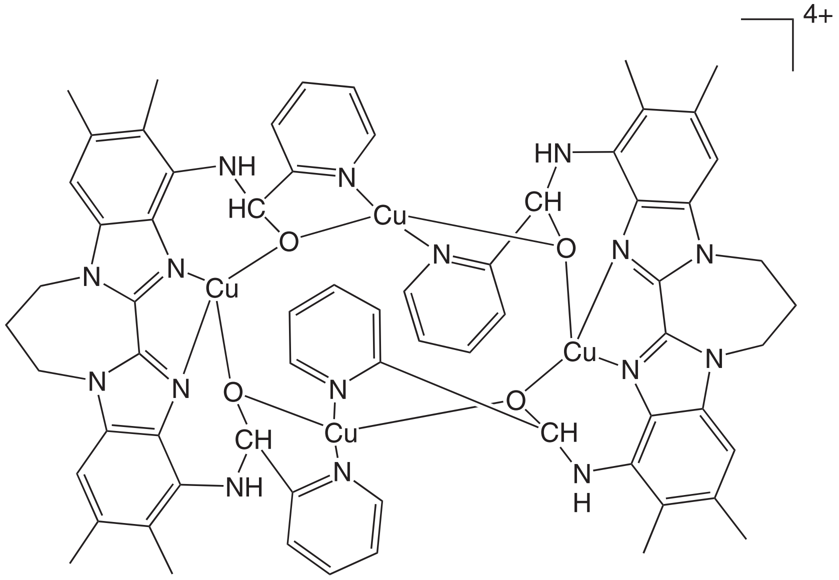
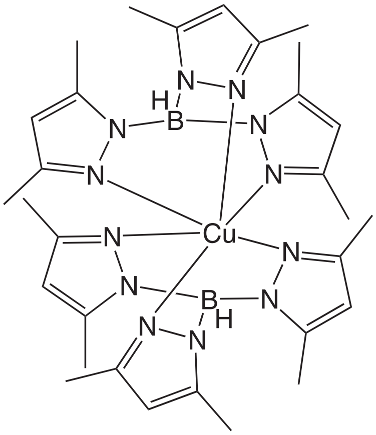
(iii) Pyrazole-containing ligands

A wide range of pyrazole-containing chelating ligands[103–107] have been designed, and their copper compounds have been studied as models for copper proteins.[18–20,62,105,106] Among them, tris(pyrazol-1-yl)borate or "scorpionate" ligands by Trofimenko and co-workers[103,104] have become increasingly important in the development of biomimetic coordination chemistry, with three histidine-like donors that can hold three *cis* sites fixed while leaving other coordination sites open. Notable successes include the work of Kitajima *et al*. with the hindered ligand hydrotris(3,5-diisopropyl-pyrazol-1-yl)borate in the syntheses of biomimetic copper(I) (Section 6.6.4.2.2(iii)), and copper(II) complexes. Kitajima *et al*. reported[108] the structure of complex (**98**), revealing an elongated rhombic octahedron with a CuN_6 chromophore. Very interestingly, Trofimenko *et al*. reported the structure of complex (**99**) (distorted tetrahedral). This is the first instance of a scorpionate free acid, acting as ligand.[109] Although this complex decomposed when

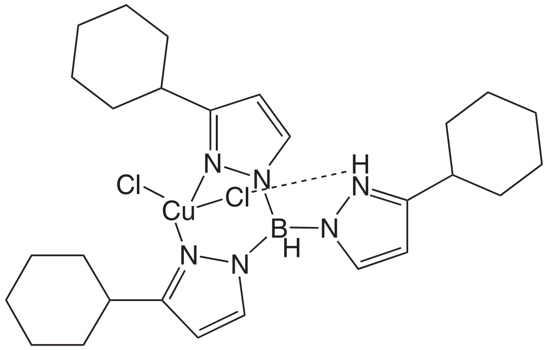


$[\{H_2(L)O_2\}_2Cu_4][ClO_4]_4$ (**97**)

chromatographed, it reacted cleanly with aqueous $NaHCO_3$ solution to yield the carbonato-bridged dicopper(II) complex $[\{Cu(L)\}_2(OCO_2)]$ (**100**) (the core is similar to complex (**62**); Cu–Cu distance 4.058 Å). In 2001, structures of two new complexes ((**101**) ($\tau = 0.34$) and (**102**) ($\tau = 0.30$)) were reported.[110]



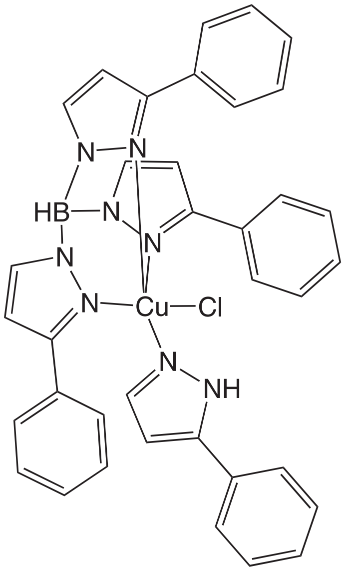
$[Cu(L)_2]$ (**98**)



$[(L)CuCl_2]$ (**99**)

From the standpoint of modeling copper–dioxygen chemistry of relevance to Hc/Tyr, Murray *et al.* reported in 2001[111] the results of their investigation of the reactivity towards dioxygen for two copper(I) complexes of the ligand tris(pyrazolyl)methane. One copper(I) complex was slowly oxidized in CH_2Cl_2 to form a bis-ligand complex (**103**). For the other complex, reversible oxygenation occurred in CH_2Cl_2 solution at ~7 °C to yield a side-on peroxo complex (structural type (**108**): see below). Thermal decomposition of this species generated a strongly antiferromagnetically coupled di-μ-hydroxo bridged complex (**104**) (structural type: (**10**) to (**12**)).

In their pursuit of modeling "Type I" copper proteins, Kitajima *et al.* reported[112] a rare, tetrahedrally coordinated complex (**105**), which displayed an EPR spectrum consistent with the presence of the unpaired electron in the d_{z}^{2} orbital.[1] They also isolated a square-pyramidal DMF adduct (complex (**106**)). They were successful in providing structural proof of a copper(II) complex (trigonal pyramidal) with $C_6F_5S^-$-coordinated complex (**107**), with CuN_3S chromophore.[113] The X-ray analysis (poor data set) of a closely similar complex with Ph_3CS^- as the



[(L)CuCl(L')Cl] (**101**)

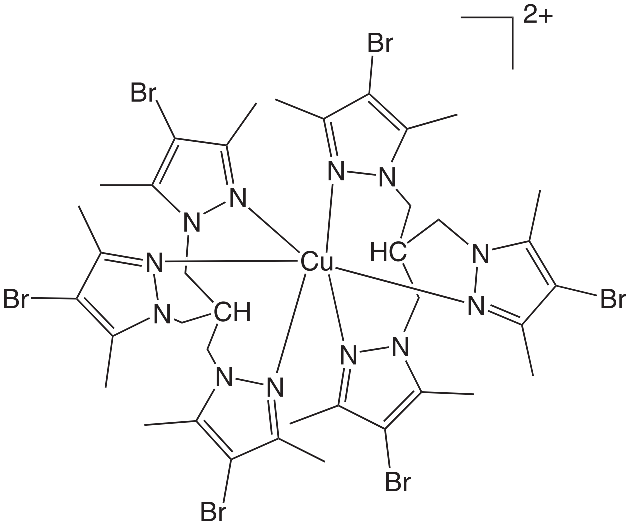
L' = 5-phenylpyrazole



$[Cu(L)_2][PF_6]_2 \cdot 2CH_2Cl_2$ (**103**)

thiolate ligand was also achieved. Tolman and co-workers characterized the first three-coordinate complexes of Cu^{II} ((**107a**) and (**107b**)), including a close structural analogue of the trigonal 'Type I' copper protein active sites.[114]

During the course of modeling copper–dioxygen chemistry, Kitajima *et al.* reported the synthesis of a μ-peroxo dinuclear complex with a 3,5-dimethyl-substituted tris(pyrazolyl)borate ligand, which showed remarkable physicochemical similarities to oxy-Hc and oxy-Tyr. Using a 3,5-di-isopropyl-substituted terminal ligand, they provided the first structural proof of the existence of μ-η^2:η^2 peroxo dicopper(II) core (**108**) (copper geometry: distorted square pyramidal; Cu–Cu: 3.560 Å),[115,116] and reported detailed characterization properties, which eventually led to the structural characterization of oxy-Hc.[117] They were successful in preparing a similar core with a 3,5-di-phenyl-substituted ligand.[116] They also synthesized and thoroughly characterized

di-μ-hydroxo bridged complexes (**109**) (Cu–Cu: 2.937 Å)[115,118] and (**110**) (Cu–Cu: 3.059 Å).[119] The importance of μ-η^2:η^2 peroxide was highlighted.[120] In this endeavor they characterized a number of very interesting complexes: (**111**)[118], two carbonato-bridged complexes [(**112**), Cu–Cu: 4.044 Å,[121,122] and (**113**), Cu–Cu: 4.140 Å[119]], an alkylperoxo complex (**114**),[123] and a μ-hydroxo-/μ-azido-bridged complex (**115**) (Cu–Cu: 3.713 Å).[124] Kitajima and co-workers were also successful in providing the first example of a side-on superoxocopper(II) complex (**116**).[125]

Using a fluorinated tris(pyrazolyl)borate ligand, Gorun and co-workers[126] synthesized a complex (**117**) ($\tau = 0.06$). This group very successfully isolated and structurally characterized a dinuclear oxygenated complex, revealing that the crystal contains about 80% μ-η^2:η^2 peroxo complex (**118**) (structural type: (**108**)) and 20% bis(μ-hydroxo) complex, (**119**) (structural type: (**109**)/(**110**)).[127]

From the viewpoint of modeling nitrite reductases,[72] Tolman and co-workers provided a number of structurally characterized complexes: (**120**) ($\tau = 0.73$),[128] (**121**) (tetrahedral),[128] and (**122**) (approximately tetrahedral).[128,129] Detailed structure and bonding aspects of coordinated NO were investigated, and its relevance to biology and heterogeneous catalysis was discussed.[130] In an elegant manner, they modeled N_2O generation by copper proteins and heterogeneous catalysts, through reductive disproportionation of Cu–NO species. To prove the reaction sequence, they isolated a nitrite-bound square-pyramidal complex (**123**).[131]

As a part of designing new, pyrazole-based ligands and exploring their copper coordination chemistry, Reedijk and co-workers synthesized two new complexes (**124**) (distorted octahedral) and (**125**) (tetrahedral), with two didentate bispyrazole ligands having an aliphatic spacer.[132] Along the same lines, Pons *et al.* synthesized phenyl/pyridyl/pyrazole-based ligands and investigated their copper coordination chemistry: (**126**) (distorted square planar).[133] A large number of pyrazole-containing, nonplanar chelating ligands with additional donor sites (aliphatic amine, pyridyl groups, etc.) have been synthesized[107] to have a variable copper stereochemistry. A few representative examples with tridentate ligands include: (**127**) ($\tau = 0.40$),[134] (**128**) ($\tau = 0.12$),[135] (**129**) ($\tau = 0.10$),[136] (**130**) (distorted tetrahedral) and (**131**) (distorted tetrahedral),[137] (**132**) ($\tau = 0.54$),[138] (**133**) ($\tau = 0.35$), and (**134**) ($\tau = 0.18$).[139] Using two tridentate ligands, Feiters and co-workers have structurally characterized six copper(II) complexes ((**135**)–(**140**))[140] with variable molecular structure and, as a consequence, varying electronic environment. The purpose of this

In 2000 Meyer and co-workers reported a novel example of unusual μ_4-peroxo coordination (complex (**146**)), as well as of a structurally analogous complex in which the O–O linkage is formally cleaved and replaced by two OH units (**147**), while at the same time the overall tetranuclear framework is fully conserved.[145]

Using a tripodal ligand, Driessen and co-workers characterized a complex with CuN$_4$O coordination (**148**), ($\tau = 0.465$).[146] Using a sterically hindered analogue of this tripod, Sorrell *et al.* prepared a complex with a CuN$_4$O chromophore (complex (**149**)).[147] The higher Cu^{II}/Cu^{I} redox potential value for the methyl derivative relative to unsubstituted ligand was explained as due to "environment" effects. Colbran and co-workers designed a bulkier ligand and characterized three copper(II) complexes [(**150**) ($\tau = 0.06$), (**151**) ($\tau = 0.16$), and (**152**) ($\tau = 0.17$)].[148] A *o*-xylyl-based ligand gave two complexes: a monomeric (**153**) (strongly distorted tetrahedral) and a dimeric (**154**) ($\tau = 0.11$; Cu–Cu: 3.480 Å).[149] When 1,3,5-tris(pyrazol-1-ylmethyl)benzene was used as ligand, complex (**155**) was obtained.[150] Using the bidentate ligand 2-(3,5-dimethylpyrazol-1-ylmethyl)pyridine, Mukherjee and co-workers characterized a nitrite-bound complex (**156**) ($\tau = 0.13$).[151] Using a chiral tridentate ligand of similar class, complex (**157**) ($\tau = 0.13$) was reported.[152] Using the combination of a tridentate and a bidentate ligand, Mukherjee and

(iv) Pyridine-containing ligands

Karlin and co-workers were the first to demonstrate the binding and activation of molecular oxygen with dinuclear copper complexes of *m*-xylyl-bridged bis-2-(2-pyridyl)ethylamine ligands.[4,9–17] This result attracted a large number of inorganic chemists to model tyrosinase activity. Reaction of O_2 with a dinuclear copper(I) compound resulted in hydroxylation of the ligand (C—H → C—OH) to produce the dinuclear copper(II) complex (**166**) (Cu–Cu: 3.121 Å)[158] and (**167**) (Cu–Cu: 3.082 Å).[159] Using the endogenous bridge (phenolate), they varied the exogenous bridge and characterized complexes (**168**) (Cu–Cu: 3.128 Å), (**169**) (Cu–Cu: 3.265 Å), and (**170**) (Cu–Cu: 3.348 Å).[160] This gave them a unique opportunity to study their magnetostructural properties. During this endeavor they reported a mononuclear azido complex (**171**),[161] as well as a dinuclear complex (**172**) (Cu–Cu: 3.185 Å).[161,162] As part of ongoing investigations of copper(I) dioxygen reactivity, they modified their original ligand system and demonstrated the feasibility of such aromatic-ring-hydroxylation reactions in a quite general manner: (**173**) (Cu–Cu: 3.108 Å)[163] and (**174**) (Cu–Cu: 3.091 Å).[164] They proposed a mechanism of aromatic hydroxylation by demonstrating novel 1,2-methyl migrations and the NIH shift in copper chemistry.[165] During the course of their systematic investigations to pinpoint the ligand's conformational aspects necessary to bring about such reactions, they provided many more examples: (**175**) (Cu–Cu: 3.060 Å),[166] (**176**) (Cu–Cu: 3.037 Å),[167] (**177**) (Cu–Cu: 3.6517 Å), and (**178**) (Cu–Cu: 3.7413 Å).[168] The hydrolysis reaction of complex (**178**) with DMF, to generate complex (**177**), provides an example of the stoichiometric hydrolysis of an unactivated secondary amide under mild conditions.

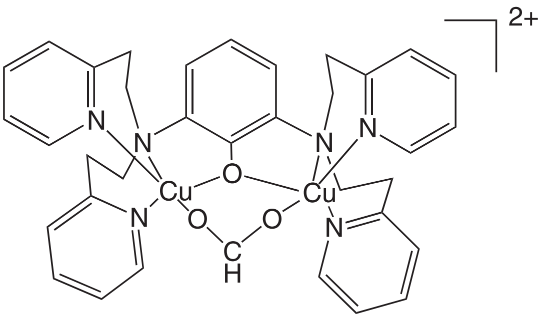
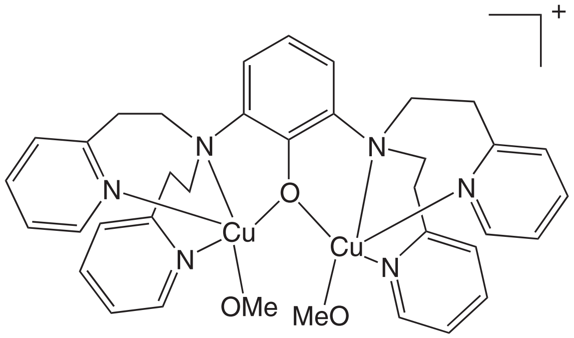
$[(L)Cu_2(OH)][PF_6]_2$ (**176**)

Inspired by the results of aromatic-ring hydroxylation from the laboratory of Karlin and co-workers, a few groups provided further examples of such reactivity, including some structurally characterized complexes of modified *m*-xylyl-based pyridine-donor ligands (Schiff base and non-Schiff base acyclic ligands), as well as aliphatic amine donor ligands: (**179**) (Cu–Cu: 2.990 Å),[169] (**180**) (Cu–Cu: 3.015 Å),[170] and (**181**) (Cu–Cu: 2.999 Å).[171,172] A *m*-xylyl-based ligand system that was used by Mukherjee and co-workers in the formation of complex (**181**) also resulted in the isolation of a bis(μ-hydroxo)dicopper(II) complex (**182**) (Cu–Cu: 3.004 Å).[171,172] Casella and co-workers demonstrated that when their dicopper(I) complex



[(L)Cu$_2$(O$_2$CH)][PF$_6$]$_2$·MeCN (**177**)



[(L)Cu$_2$(OMe)$_2$][ClO$_4$] (**178**)

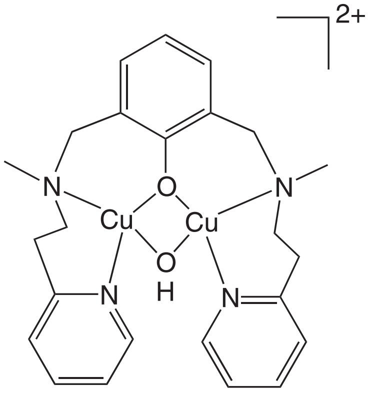
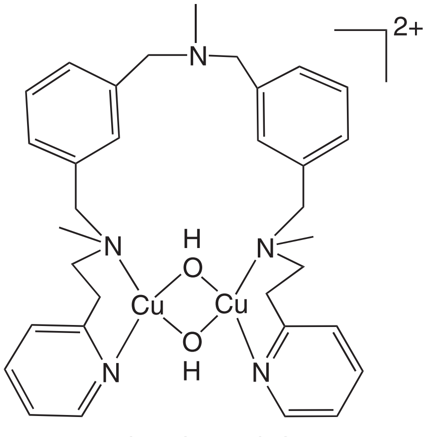
[(L)Cu$_2$(OH)(OH$_2$)][ClO$_4$]$_2$ (**180**)

reacted with dioxygen, a partial aromatic hydroxylation of the ligand occurred. Definitive evidence of the monooxygenase activity resulted from the structure of the hydroxylated dicarbaldehyde product (compound (**183**)).[173] Fenton, Schindler, and their co-workers also provided examples of intramolecular ligand hydroxylation and conducted mechanistic studies on their Schiff base systems: (**184**) (Cu–Cu: 3.0294 Å) and (**185**) (Cu–Cu: 3.0309 Å).[174] In all these aromatic-ring hydroxylation studies copper(I) complexes of designed ligands react with molecular oxygen, which becomes activated and transfers one O atom to the ring (electrophilic attack of the peroxo-copper(II) intermediate); the other O atom ends up as hydroxide ion and is coordinated to the resulting dicopper(II) center.[175–177]

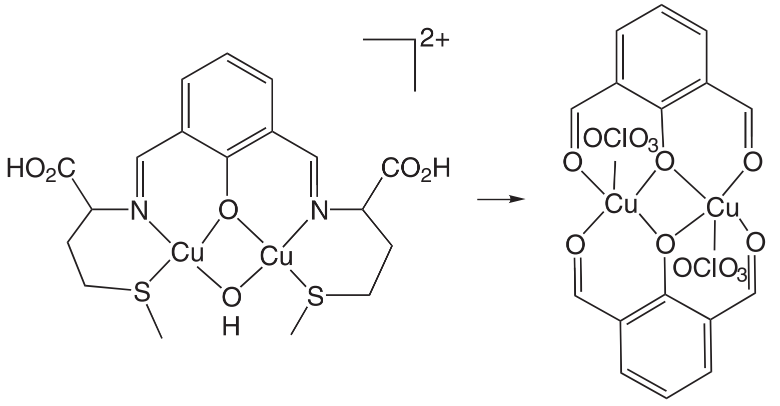
During the course of this investigation Solomon *et al.* have thoroughly investigated spectroscopic properties, electronic structural properties, and kinetic aspects of these systems.[7,12,14,16] Karlin and co-workers provided examples of the (acylperoxo)dicopper complex (**186**) (Cu–Cu: 3.197 Å)[178] and the catecholato-bound complex (**187**) (Cu–Cu: 3.248 Å).[179] Reaction of a phenoxo-bridged dicopper(I) complex (Section 6.6.4.2.2(iv)) with NOPF$_6$ resulted in the addition of a nitrosyl ligand to the dinuclear center to give complex (**188**) (Cu–Cu: 3.08 Å).[180] This compound has relevance to nitrite reductase model studies.[72] Using various xylyl-based ligands, many compounds have been characterized with different nuclearities: (**189**) (Cu–Cu: 5.873 Å),[181] (**190**) (Cu–Cu: 7.520 Å),[181] (**191**) (Cu–Cu: 11.71 Å),[182] (**192**) (it has, however, a mesityl-based ligand) (Cu–Cu distances: 3.106 Å, 3.119 Å, 7.458 Å, and 7.777 Å),[183] and (**193**) (it has, however, a tripodal ligand) (Cu–Cu distances: 5.834 Å, 6.239 Å, and 8.774 Å).[184] Using a mesityl-based new ligand, Kim and co-workers characterized a trinuclear mixed-valent compound (**194**), due to oxidation of a copper(I) compound (Section 6.6.4.2.2(iv)).[185]



[(L)Cu_2(OH)][ClO_4]$_2$ (**181**)



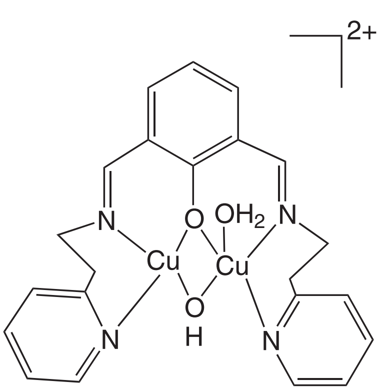
[(L)$Cu_2(OH)_2$][ClO_4]$_2$ (**182**)



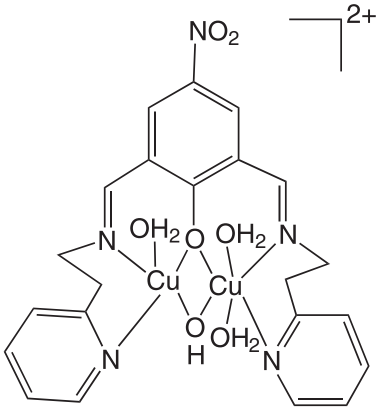
[(L)$_2Cu_2(OClO_3)_2$] (**183**)

Using a designed ligand, Itoh, Fukuzumi, and their co-workers provided a well-characterized functional model of DβH:[84] a mononuclear precursor complex (**195**) and a ligand hydroxylated complex (**196**).[186,187] This report inspired many groups to investigate aliphatic hydroxylation reactions. Réglier and co-workers have contributed substantially to providing suitable functional models of this enzyme. During the course of their investigation they characterized the complexes: (**197**) and (**198**),[188] (**199**),[189] and (**200**).[190] Using a copper(I) complex (Section 6.6.4.2.2(iv)) of a designed ligand, Tolman and co-workers demonstrated that the bis(μ-oxo)dicopper(III) species is capable of hydroxylating aromatic rings.[191] This work invited a re-examination of the mechanism of aromatic-ring hydroxylation reactions of relevance to tyrosinase activity.[192]

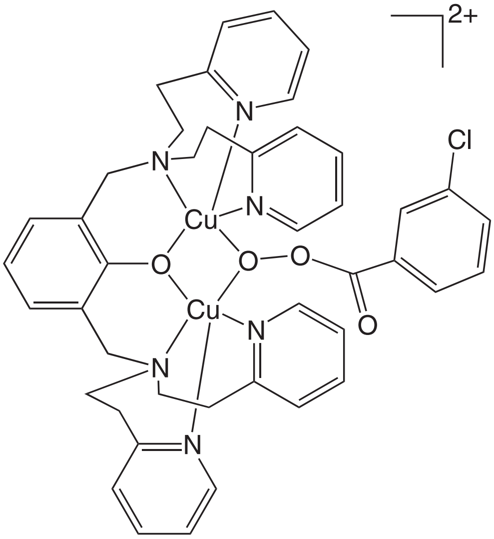
To investigate copper coordination chemistry with the bidentate, non-planar di-pyridylmethane ligand, complexes (**201**) (monomeric) and (**202**) (dimeric; structural type: (**154**))[193] and—using a sterically hindered variety of this ligand—complex (**203**)[194] were characterized. To study the basic chemistry of relevance to the active site of phenylalanine hydroxylase,[13] which effects the hydroxylation of phenylalanine to give tyrosine, Karlin and co-workers structurally characterized complexes (**204**)[195] and (**205**).[196] Using a tridentate ligand, Karlin and co-workers characterized a solid of composition [{[Cu(L)}$_2$O$_2$][BArF]$_2$ (**206**). In contrast to the crystal structure, which shows an "intermediate" Cu_2O_2 core (Cu–Cu: 3.45 Å), spectroscopic studies (EXAFS and resonance Raman) revealed that it is a mixture of primarily side-on peroxo (core structure: (**108**)) and 5–20% of bis(μ-oxo) (core structure: (**4**)).[197] The dioxygen adduct is most stable as a cold solution in CH_2Cl_2, but decomposes on warming to generate a bis(μ-hydroxo)dicopper(II) complex (**207**) (Cu–Cu: 3.012 Å).[198] Using a closely similar tridentate ligand, they reported a chloro-bridged complex (**208**).[199] To address a fundamental question of structural ambiguity (hydroxide or fluoride bridges?), Holm and co-workers reported the structure of (**209**) (Cu–Cu: 3.137 Å)[200] of



[(L)Cu_2(OH)(H_2O)][BF_4]$_2$ (**184**)



[(L)Cu_2(OH)(OH_2)$_3$][BF_4]$_2$ (**185**)

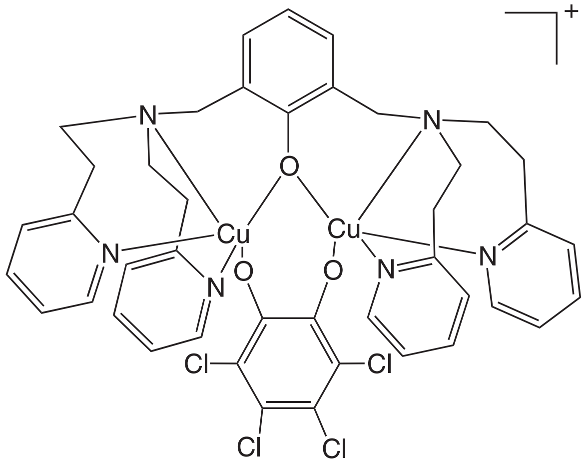


[(L)Cu_2(*m*-$ClC_6H_4C(O)O_2$)][ClO_4]$_2$·MeCN (**186**)

a previously reported complex of Karlin *et al.*[201] During the course of their investigation they observed a novel ligand oxygenation reaction (complex (**210**); Cu–Cu: 3.011 Å), which had a resemblance to that catalyzed by DβH.[84]

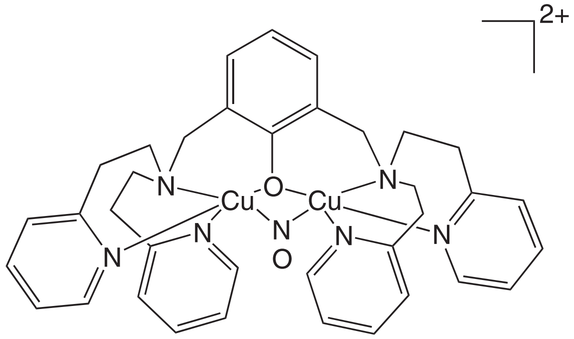
Using a well-known tridentate ligand, dipicolylamine, Addison and co-workers reported their novel observation: two different coordination geometries ((**211**) and (**212**): $\tau = 0.38$) in the same unit cell of [Cu(L)$_2$][BF_4]$_2$.[202] Palaniandavar *et al.* reported the structural pathways of complex (**213**) ($\tau = 0.33$): an example of the uncommon "see-saw" stereochemistry.[203] Using a bridged ligand system with aliphatic spacer, Karlin *et al.* reported the structure of the product (**214**) (Cu–Cu: 3.070 Å) from oxidation of a dicopper(I) complex.[204] Using a designed ligand, Karlin and co-workers demonstrated catalytic oxygenation and oxo-transfer to a ketone, by characterizing a μ-1,3-bridged gem-diolate unsymmetrical dicopper(II) complex (**215**) (Cu–Cu: 5.583 Å).[205]

Using a strapped tridentate ligand, Kodera *et al.* reported the structure of complex (**216**) (Cu–Cu: 2.989 Å) and studied the oxidation of various phenols with H_2O_2 catalyzed by the triflate salt of this compound.[206] In a major breakthrough, this group reported reversible O_2 binding of a room-temperature-stable μ-η^2:η^2 peroxo dicopper(II) complex (**217**) (structural core:(**108**);stereochemistry at the copper center: square pyramidal; Cu–Cu: 3.477 Å).[207] Interestingly, the Cu–Cu distance is slightly longer than that of complex (**108**); however, the O–O bond length, 1.485 Å, of this complex is slightly longer than the 1.412 Å of (**108**). They reasoned that the observed result is attained owing to the large distortion of the Cu_2O_2 core.



$[(L)Cu_2(L')][[PF_6]$ (**187**)

$L' = Cl_4C_6O_2(2-)$



$[(L)Cu_2(NO)][PF_6]\cdot 2CH_2Cl_2$ (**188**)

To better understand copper–dioxygen coordination chemistry with varying ligand type, Karlin and co-workers synthesized and investigated spectroscopic and redox properties of many complexes: (**218**) ($\tau = 1.005$) and (**219**) ($\tau = 0.19$),[208] (**220**) ($\tau = 0.50$),[209] (**221**) ($\tau = 0.19$) and (**222**) ($\tau = 0.06$),[210] (**223**) ($\tau = 0.91$) and (**224**) (Cu–Cu: 3.444 Å).[211] In a major breakthrough, this group provided the first structurally characterized (−90 °C) example of a trans-(μ-1,2-peroxo)dicopper(II) complex (**225**) (Cu–Cu: 4.359 Å),[212,213] supported by two tripodal ligands. The system exhibited reversible binding of dioxygen.

To provide a model for nitrite reductases[72] Karlin and co-workers characterized a nitrite-bound complex (**226**) ($\tau = 0.05$).[214] In an endeavor to model nitrite reductase activity, Tanaka and co-workers prepared a few mononuclear complexes: (**227**) ($\tau = 0.74$)[215] (**228**) ($\tau = 0.82$),[216] (**229**) ($\tau = 0.97$),[217] (**230**) ($\tau = 0.16$),[217] (**231**) ($\tau = 0.07$),[217] and (**232**) ($\tau = 0.43$ and $\tau = 0.53$)[217] and studied the electrochemical reduction of NO_2^-. As a part of their activity on modeling heme–copper terminal oxidases, Holm and co-workers prepared complex (**233**) ($\tau = 0.96$).[218] Using a sterically hindered tris(pyridylmethyl)amine, Canary *et al.* prepared a complex (**234**) ($\tau = 1.00$), studied its redox behavior, and discussed various factors that may contribute to the difference (higher potential for the new complex) in the redox potential of a Cu^{II}/Cu^{I} couple between substituted and unsubstituted ligands.[219]

As a part of their work on copper(I)-dioxygen chemistry, Schindler and co-workers[220] synthesized copper(I) (Section 6.6.4.2.2(iv)) and copper(II) complexes ((**235**): $\tau = 0.12$, and (**236**): $\tau = 0.08$) of a few tetradentate ligands, varying in their flexibility due to the presence of different chelate ring-forming arms, and studied their redox properties. Karlin and co-workers observed a

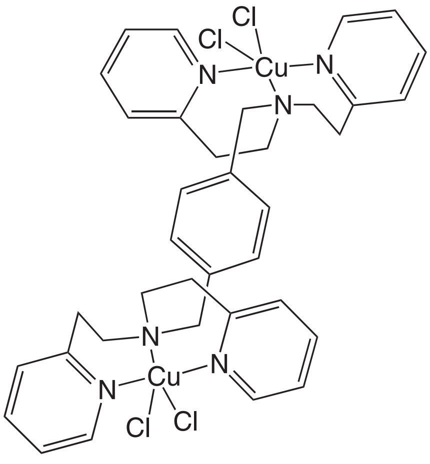
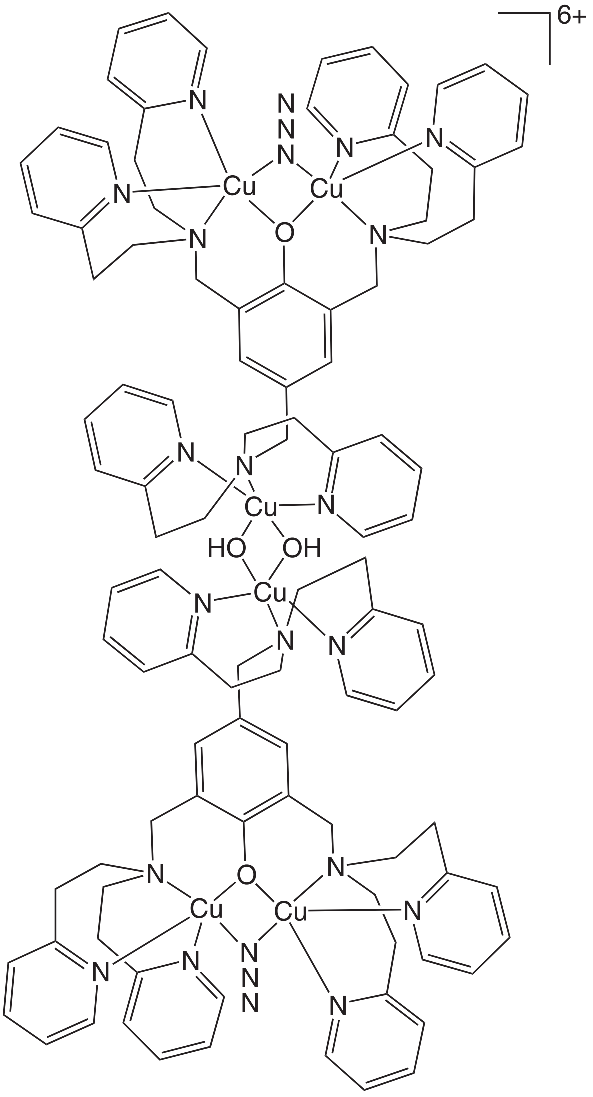
$[Cu_2(L)_2(H_2O)_2][ClO_4]_4\cdot 2H_2O$ (**190**)



$[(L)Cu_2Cl_4]\cdot 2H_2O$ (**191**)

reaction between a dicopper(I) complex with dioxygen/CO$_2$ which resulted in the formation of a carbonato-bridged complex (**237**) (Cu–Cu: 5.375 Å).[221]

Complexes with ligands bearing alkylpyridine pendant arms attached to an ethylenediamine framework were prepared, and their spectral and redox properties were studied: (**238**), (**239**), and (**240**) ($\tau = 0.10$).[222]



[{(L)Cu_3(OH)(N_3)}]$_2$[PF_6]$_6$·4MeCN (**192**)

In an elegant approach, Comba and co-workers initiated molecular-mechanics-based models that allow the rational design of ligand systems which are able to stabilize copper–dioxygen compounds. As a part of this investigation, complexes (**241**) ($\tau = 0.12$),[223] (**242**) ($\tau = 0.31$),[224] and (**243**) ($\tau = 0.85$)[224] were synthesized and the reactivity of copper(I) complexes (Section 6.6.4.2.2(iv)) with dioxygen was investigated.

Using two pentadentate ligands derived from tris(2-pyridylethyl)amine, Spiccia and co-workers reported complexes (**244**) ($\tau = 0.17$) and (**245**) ($\tau = 0.45$).[225] Scheidt and co-workers reported structures of two five-coordinate complexes, copper(I) (Section 6.6.4.2.2(iv)) and copper(II) (**246**) of the same ligand, and studied their electron-transfer kinetics.[226] To confirm the synthesis of a novel unsymmetrical geometrical isomer, the complex (**247**) ($\tau = 0.51$) was structurally characterized.[227] Using a potentially hexadentate ligand, complex (**248**) ($\tau = 0.10$) was reported.[228] Using a 2,2′-dipyridylamine-based ligand, complex (**249**) was reported.[229] Mixed amine/pyridine tridentates exhibiting facial coordination are rare, so using a tridentate di-2-pyridylmethanamine ligand, complex (**250**) with CuN_6 coordination was characterized and its redox property investigated.[230] Along a similar line of thought, complex (**251**) was characterized.[231,232] Stack and co-workers[233] developed an efficient modular protocol for synthesizing a series of facial-capping

tris-pyridyl ligands. This group of ligands allowed systematic variations of the steric demands at the periphery of the ligand. This ligand series generated bis-chelate complexes ((**252**)–(**255**)), with the copper(II) ligated in a tetragonally distorted octahedral coordination environment. For the ligand present in (**255**), the complex—due to its moisture sensitivity—gave a monoligated tris-aqua complex (**256**). Using a new ligand, tris(2-pyridyl)methylamine, Durrant and co-workers

characterized[234] a six-coordinate CuN$_6$ complex (**257**); one pyridyl arm from each ligand remained non-coordinated. Two sterically hindered tris-pyridylmethane ligands were designed by Kodera *et al.* Using an unsubstituted ligand, they prepared complex (**258**) ($\tau = 0.15$). Under aerobic conditions, the ligands reacted with CuX$_2$ (X = Cl or Br), became oxygenated at the methane position, and characterized a mononuclear complex (**259**) ($\tau = 0.05$) and four triangular copper(II) complexes ((**260**) is a prototypical example; $\tau = 0.57$, Cu–Cu: 3.302 Å; weakly antiferromagnetically coupled).[235]

(v) *Bipyridine-containing ligands*

To impose a coordination environment around copper, Müller *et al.* reported structures of a copper(I) (Section 6.6.4.2.2(v)) as well as a copper(II) complex (**261**) ($\tau = 0.73$) with their designed ligand, and studied their spectral and redox properties.[236] Using nonplanar tetradentate ligands, complexes (**262**) (square planar),[237] (**263**) ($\tau = 0.66$),[238] and (**264**) (square pyramidal)[239] were characterized. Using various 2,2′-bipyridine-based ligands, dinuclear (noninteracting) complexes (**265**) (Cu–Cu: 7.718 Å),[240] (**266**) (Cu–Cu: 5.81 Å),[241] and (**267**) (Cu–Cu: 8.020 Å)[241] were characterized. In complex (**265**) each copper atom is bound to three N atoms of the ligand and to one O atom of the sulfato group, giving square-planar coordination. However, the structure is disordered, with some of the copper atoms being hydrated. Using a μ-hydroxo-/μ-aqua-/ μ-acetato-bridged dicopper(II) complex (Section 6.6.3.6.2), Chakravarty and co-workers demonstrated[242] ascorbate oxidation, leading to the formation of a catalytically active oxalate-bridged dicopper(II) complex (**268**). This chemistry has relevance to DβH.[84]

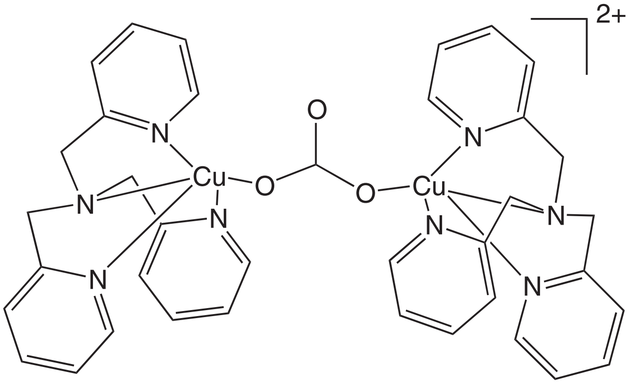
In a continuation of their earlier work,[1] Hathaway and co-workers investigated crystal structures, electronic properties, and structural pathways for a series of five-coordinate complexes with two 1,10-phenanthroline (phen) ligands and axial ligands: $[(phen)_2CuCl]Y$ [$Y = BF_4^-{\cdot}0.5H_2O$ (**269**), PF_6^-(**270**), $CF_3SO_3^-{\cdot}H_2O$ (**271**) or BPh_4^- (**272**)],[243] $[(phen)_2Cu(H_2O)][Y]_2$ [$Y = CF_3SO_3^-$(**273**) or ClO_4^-(**274**)],[244] and $[(phen)_2CuBr]Y$ [$Y = Br^-{\cdot}H_2O$ (**275**), ClO_4^-(**276**), $NO_3^-{\cdot}H_2O$ (**277**), PF_6^-(**278**), and BPh_4^-(**279**)].[245]

A series of copper(II) complexes with ring-substituted phen-ligands have been synthesized and their molecular structural and electronic structural properties have been investigated.[246] Each structure ((**280**): $\tau = 0.72$, (**281**): $\tau = 0.81$, (**282**): $\tau = 0.88$, (**283**): $\tau = 0.83$, and (**284**): $\tau = 0.68$) is characterized by a distorted trigonal-bipyramidal arrangement of ligands around copper.

In an effort to investigate the kinetics of nitrite reductase activity,[72] Ford and co-workers[247] investigated NO reduction with complex (**285**). Using a phen-/pyrazole-based ligand, Hodgson and co-workers[248] characterized the complex (**286**) ($\tau = 0.30$) and studied its redox property. Interestingly, the first alumina-supported syntheses of chiral bipyridines and of a chiral C_2-symmetric terpyridine were conducted under microwave irradiation. The structure of complex (**287**) ($\tau = 0.58$) proved the claim.[249]

(vi) Other heterocycle-containing ligands

Using a triazole-/pyrimidine-containing hybrid ligand, terminally coordinated in a thiocyanate-bridged copper(II) dimer, Haasnoot *et al.* reported[250] the structure of the β isomer of complex (**288**), revealing that the Cu–SCN distance is relatively short compared to other Cu–SCN



[{(L)Cu}$_2$(CO$_3$)][ClO$_4$]$_2$·2EtCN (**237**)

distances. This originates from the fact that in this compound the Cu—SCN bond is in an equatorial position, which is uncommon for copper(II)–thiocyanate complexes.[251]

Oshio *et al.* reported[252] the structures of two dicopper(II) complexes (**289**) ($\tau = 0.72$) and (**290**) ($\tau = 0.44$) supported by a pyrazine-bridged ligand and differing only in solvent of crystallization.

They also investigated the redox properties in detail. With a ligand varying in chelate ring size, they reported the complex (**291**) ($\tau = 0.07$) and demonstrated that increased chelate ring size is the dominant factor in determining the stability of copper(I) rela-tive to copper(II). A more flexible (six-membered chelate ring formation) ligand is capable of modifying the coordination structure

as the copper is reduced, and therefore is reduced more easily than a five-membered chelate ring-forming ligand.[253]

The study of exchange interactions between transition-metal ions and copper(II) in particular has been an active field of research (Section 6.6.3.6).[254–256] In this context, Verdaguer and co-workers investigated complexes (**292**) and (**293**), supported by flexible 2,2′-bipyrimidine.[257]

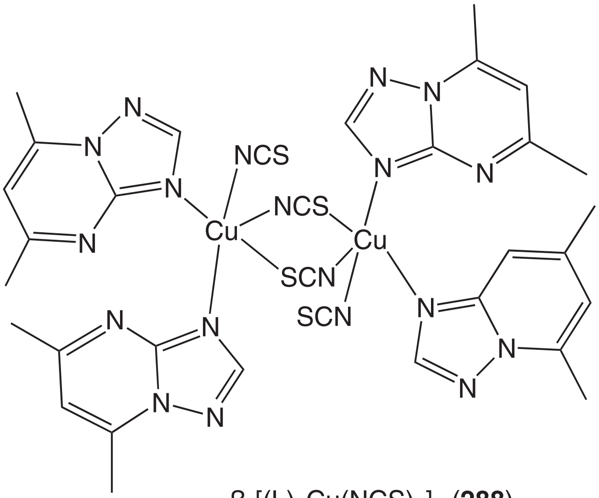
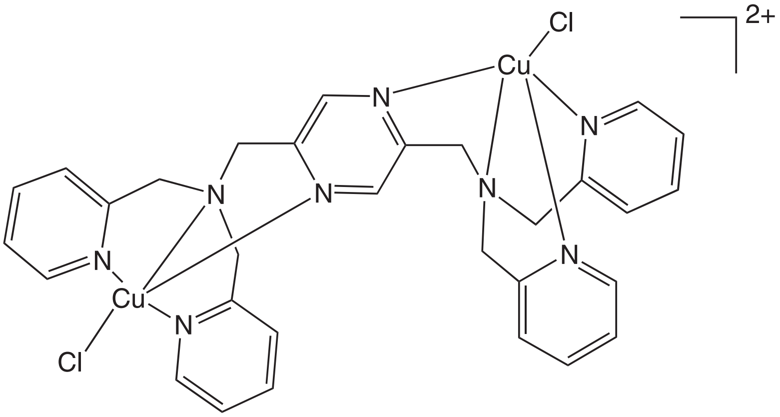
6.6.3.2 Oxygen Donor Ligands

6.6.3.2.1 Phenol-based ligands

Copper(II) complexes with phenoxo ligands have attracted great interest, in order to develop basic coordination chemistry for their possible use as models for tyrosinase activity (dimeric complexes) and fungal enzyme galactose oxidase (GO) (monomeric complexes). The latter enzyme catalyzes the two-electron oxidation of primary alcohols with dioxygen to yield aldehyde and



ß-$[(L)_2Cu(NCS)_2]_2$ (**288**)



$[(L)Cu_2Cl_2][ClO_4]_2$·2MeOH (**289**)
$[(L)Cu_2Cl_2][ClO_4]_2$ (**290**)

hydrogen peroxide.[260–262] In the tyrosinase–cresolase activity, a monophenol binds to the axial position of one of the two copper centers of the oxy-site prior to catalytic activation. In the galactose oxidase in resting form, the copper(II) ion is square pyramidal, weakly bonded to a tyrosinate in the axial position and to another tyrosinate, two histidine residues, and a water (pH 7) or an acetate (from buffer, pH 4.5) ligand in the equatorial sites. Evidence has been provided for the same type of active site in glyoxal oxidase, which catalyzes the oxidation of aldehydes to carboxylic acids.[262] Quite a few excellent reviews are available on phenoxo-bridged dicopper(II) systems.[175–177,263,264]

Sorrell *et al*. provided a number of structurally characterized examples of dimeric complexes of pyrazole-phenol-based ligands: (**296**) (one Cu square pyramidal and the other distorted TBP; Cu–Cu: 3.054 Å; $2J = -420\,\mathrm{cm}^{-1}$),[265] (**297**) (one Cu square pyramidal and the other distorted TBP; Cu–Cu: 3.562 Å; $2J = \sim 0$)[266] and (**298**) (both Cu tetragonal; Cu–Cu: 3.765 Å; $2J = -1{,}800\,\mathrm{cm}^{-1}$).[266] Using a tridentate, mixed-functionality ligand, Carrano and co-workers[267] characterized three complexes (**299**) (mononuclear: no phenol coordination), (**300**) (mononuclear: one phenol coordinates, the other does not; Cu–Cu: 3.000 Å), and (**301**) (dinuclear, with one four-coordinate and the other five-coordinate; one phenol coordinate in a bridging mode, the other does not coordinate). Nag and co-workers reported[268] the structure of a dinuclear system (**302**), comprising of acetylacetonate and a pyrazole-phenol-based ligand (both Cu square planar; Cu–Cu: 3.03 Å; $2J = -110\,\mathrm{cm}^{-1}$). Structure and reactivity of novel tetrahedral phenoxo copper(II) complexes

were reported[269] by Fujisawa *et al.* as models for the reaction intermediates of the tyrosinase-catalyzed oxidation of phenols. A representative complex $[\{HB(3,5\text{-}^iPr_2pz)_3\}\text{-}Cu(OC_6H_4\text{-}4\text{-}F)]$ (**303**) was structurally characterized. Halcrow *et al.*[270] were able to stabilize, in solution, an antiferromagnetically coupled copper(II)–phenoxy radical species of relevance to

GO.[260–262] During this investigation they characterized three complexes: (**304**) ($\tau = 0.08$), (**305**) ($\tau = 0.38$), and (**306**) ($\tau = 0.30$) (they structurally characterized a closely related copper(II) system ($\tau = 0.07$)),[271] that when oxidized by one-electron showed absorption spectral features similar to that of the active form of GO). Using a dinucleating phenolate-based ligand with terminal pyrazole groups, Mukherjee and co-workers reported complex (**307**) ($\tau = 0.06$; Cu–Cu: 3.0983 Å; $2J = -1204\,\mathrm{cm}^{-1}$).[272] Palaniandavar reported an axially coordinated phenolate ligand in the complex (**308**) ($\tau = 0.16$), which has structural relevance to GO.[273,274] They also reported complexes

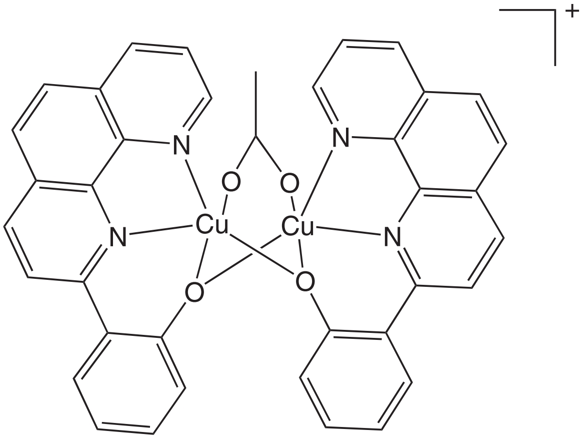
$[(L)_2Cu(O_2CMe)][PF_6]\cdot 1.5CH_2Cl_2$ (**319**)

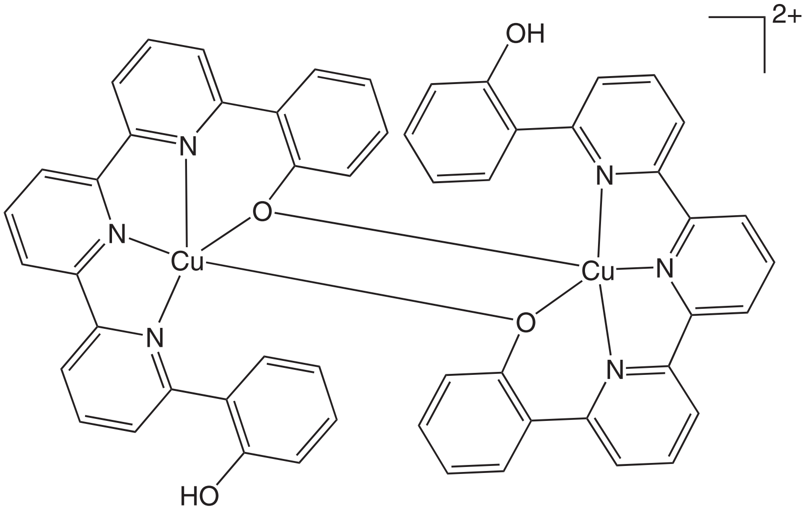
Cu–Cu: 3.153 Å).[279] They also structurally characterized a complex similar to complex (**310**) ($\tau = 0.17$), with a water molecule as solvent of crystallization and without the NO_2 substituent in the ligand.[279] Neves *et al.*[280] reported an interesting structure (complex (**318**)) in which the two phenol oxygen atoms remain protonated and coordinate to copper in an axial fashion.

To explore the coordination abilities of mixed phenol-bpy/phen/terpy polydentate chelating ligands, Ward *et al.* investigated complexes (**319**) (Cu–Cu: 3.050 Å; moderate AF coupling),[281,282] (**320**) (moderate AF coupling),[283] and (**321**) (Cu–Cu: 3.324 Å; weak AF coupling).[284]

In a major breakthrough, Stack and co-workers reported[285,286] biomimetic functional models of GO that catalytically oxidize benzylic and allylic alcohols to aldehydes with O_2 under mild conditions. They demonstrated that modest structural mimicry is sufficient to transfer an unusual, ligand-based radical mechanism to a simple chemical system (complex (**322**)). Krüger very nicely highlighted this work.[287] Chaudhuri, Wieghardt, and their co-workers were successful in bringing structural models of GO to homogeneous catalysis and reported structures of a few very interesting complexes: (**323**),[288] (**324**),[289] and (**325**).[290] They thoroughly investigated their electronic structural properties.[262] Garner and co-workers[291] also reported their success story in preparing phenoxyl radical complexes of copper(II): (**326**) and (**327**). Structural and spectroscopic models for GO have also been provided from the groups of Whittaker (complex (**328**); $\tau = 0.47/0.42$, Cu–Cu: 3.05 Å);[292] Itoh (complexes (**329**): $\tau = 0.35/0.06$, Cu–Cu: 3.16 Å, and (**330**): $\tau = 0.33/0.20$, Cu–Cu: 3.14 Å);[293] and Hahn (complex (**331a**) $\tau = 0.20/0.10$, Cu–Cu: 3.2729 Å).[294] Pierpont and Ruf provided a simple model for the GO and reported[295] structures of two copper(II) complexes: a linear arrangement of three Cu^{II} ions (complex (**331b**); at the center of the molecule, a planar



$[(L)_2Cu_2(O_2CMe)][PF_6]$ (**320**)



$[\{(L)Cu\}_2][PF_6]_2\cdot 5MeCN$ (**321**)

$[Cu(OMe)_4]^{2-}$ anion is bridged to outer square-pyramidal $\{Cu(L)\}^+$ cations) and a mononuclear square-pyramidal complex (**331c**).

As a part of their activity on magnetic and electrochemical studies on dinuclear copper(II) complexes, Fenton and co-workers reported complex (**332**) (Cu–Cu: 2.957 Å; $2J = -493\,cm^{-1}$).[296] It should be mentioned here that the magnetic properties of copper pairs are satisfactorily accounted for by considering the symmetry of the magnetic orbitals of the two interacting metallic fragments. Direct electronic communication is necessary for antiferromagnetic interaction, and so the overlap between metal magnetic orbitals (Cu–O–Cu bridge angle, Cu–Cu distance, displacement of Cu atoms from the coordination plane, etc.) and the highest occupied orbital(s) of the intervening atom(s) is the major determining factor for antiferromagnetic (AF) coupling (singlet–triplet gap ($2J$) is expressed in cm^{-1}; the value is negative for AF coupled systems and positive for ferromagnetic (F) coupled systems).[254–256,297–299]

In dinuclear transition-metal bio-sites the metal ions are often found in chemically or geometrically distinct environments.[101,264] For example, the unsymmetrical nature of the dicopper site in Hc is demonstrated in the X-ray crystal structure of deoxyHc,[58] and sequence homology studies on tyrosinases have shown that whilst one of the copper sites has been highly conserved throughout evolution, the structure of the second copper site has been quite variable. Inspired by this fact, the design of unsymmetric dinucleating ligands came into being. From this background many interesting dicopper(II) systems were reported: (**333**) (one Cu is square pyramidal and the other one distorted TBP; Cu–Cu: 3.24 Å; $2J = -42\,cm^{-1}$),[300,301] (**334**) (it is however,

Kahn and co-workers and Murray and co-workers carried out pioneering magnetostructural correlations work in phenolato-bridged dicopper(II) systems: (**342**) (Cu–Cu: 2.993 Å; $2J = -161\ \mathrm{cm}^{-1}$),[309] (**343**) (Cu–Cu: 2.977 Å; $2J = 43\ \mathrm{cm}^{-1}$),[309] (**344**) (square-pyramidal; Cu–Cu: 2.872 Å; weak ferromagnetic coupling),[310] (**345**) (distorted SP; Cu–Cu: 3.263 Å; $2J = -72\ \mathrm{cm}^{-1}$),[310] (**346**) (Cu–Cu: 3.603 Å; $2J = -244\ \mathrm{cm}^{-1}$),[310] and (**347**) (Cu–Cu: 3.655 Å; $2J = -280\ \mathrm{cm}^{-1}$).[310] Many workers investigated similar systems and studied their chemistry as well: (**348**) (distorted SP; Cu–Cu: 3.265 Å; $2J = -93\ \mathrm{cm}^{-1}$),[311] (**349**) (distorted SP; Cu–Cu: 3.030 Å; $2J = -299\ \mathrm{cm}^{-1}$),[312] (**350**) (distorted square planar and SP; Cu–Cu: 2.9708 Å; $2J = -113\ \mathrm{cm}^{-1}$; ^{1}H NMR studies were also done),[313] (**351a**) (SP and distorted TBP; Cu–Cu: 3.011 Å; ^{1}H NMR studies were also done),[314] (**351b**) (sixfold coordination and distorted tetragonal pyramid with the water molecule as its apex; Cu–Cu: 3.014 Å; dimeric units linked by perchlorate groups to one-dimensional infinite chains along the *c*-axis),[315] (**352**) (distorted SP; Cu–Cu: 4.090 Å),[316] (**353**) (distorted TBP; Cu–Cu: 3.026 Å; $2J = -94\ \mathrm{cm}^{-1}$),[316] (**354**) (distorted SP; Cu–Cu: 3.785 Å; $2J = 4.2\ \mathrm{cm}^{-1}$),[317,318] (**355**) (distorted five-coordinate geometry; Cu–Cu: 3.348 Å; uncoupled; EPR active (rhombic spectrum) both at room temperature and at 77 K),[319] (**356**) (SP; Cu–Cu: 3.549 Å; $2J = -80\ \mathrm{cm}^{-1}$),[320] (**357**) (SP; Cu–Cu: 4.128 Å; uncoupled),[320] (**358**) (SP; Cu–Cu: 3.020 Å; $2J = -675\ \mathrm{cm}^{-1}$),[320] (**359**) (Cu–Cu: 2.924 Å),[321] (**360**) (TBP; Cu–Cu: 2.989 Å),[322] (using the ligand present in complex (**360**), Torelli *et al.* reported pH-controlled change of the copper(II) coordination; they structurally characterized three complexes: μ-phenoxo-/μ-hydroxo-bridged: Cu–Cu 2.96 Å; diaqua-μ-phenoxo-bridged: Cu–Cu 4.32 Å; and an unusual unbridged

dimeric complex; and they carried out temperature-dependent magnetic and redox studies. The μ-phenoxo-/μ-hydroxo-bridged complex exhibited catecholase activity),[323] (**361**) (distorted SP and distorted TBP; Cu–Cu: 3.255 Å; $2J = -443\,cm^{-1}$),[324] (**362**) (distorted SP; Cu–Cu: 2.994 Å; $2J = -809\,cm^{-1}$),[324] (**363**) (distorted TBP; Cu–Cu: 3.131 Å; $2J = -388\,cm^{-1}$),[324] and (**364**) (distorted SP; Cu–Cu: 3.726 Å; uncoupled).[325]

Krebs and co-workers synthesized a series of dinuclear copper(II) complexes as models for catechol oxidase:[91] (**365**) (distorted SP; Cu–Cu: 2.902 Å), (**366**) (distorted five-coordinate geometry; Cu–Cu: 3.002 Å), (**367**) (distorted SP; Cu–Cu: 2.995 Å), (**368**) (distorted five-coordinate geometry; Cu–Cu: 2.938 Å), and (**369**) (distorted SP; Cu–Cu: 2.874 Å). These complexes were characterized by spectroscopic and electrochemical methods. From kinetic analysis, a catalytic order for catecholase activity (aerial oxidation of 3,5-di-*tert*-butylcatechol) was obtained.[326]

In a major development, this group[327] reported a thermally stable peroxocopper(II) complex (**370**) (Cu–Cu: 2.994 and 3.030 Å; $2J = -510\,cm^{-1}$). An interesting tetranuclear oxo-bridged complex (**371**) (Cu–Cu: 2.749 Å and 2.862 Å; $2J = -720\,cm^{-1}$)[328] was also reported. For both these systems, detailed spectroscopic investigation was carried out. Investigations in MeOH solution provided evidence that the latter complex (oxo-bridged) can be converted into the former, peroxo-bridged complex. They also provided examples of oxo-bridged copper tetrameric complexes: (**372**) (all coppers have TBP geometry; by copper pairing, two of the Cu–Cu distances (average 3.000 Å) are significantly shorter than the other four (average 3.193 Å)), and (**373**) (with the corresponding distances: 2.992 Å and 3.216 Å, respectively).[329] They also analyzed, in detail, their magnetic behavior.

Partial hydrolysis of a potentially heptadentate Schiff-base tripodal ligand derived from tris-(2-aminoethyl)amine and 2-hydroxyacetophenone, induced by copper(II) salts, was reported and the final copper(II) complex (**377**) was characterized.[333] Using salicylaldehyde as a co-ligand, with a copper(II) complex (**378**), catalytic epoxidation was demonstrated.[334]

6.6.3.2.2 Alcohol-based ligands

As a part of their efforts to model dinuclear copper active sites, Reed and co-workers reported, using alkoxo-based dinucleating ligands, a few very interesting systems from the viewpoint of magnetostructural correlations: (**379**) (TBP; Cu–Cu: 3.325 Å; $2J = -278\,\mathrm{cm}^{-1}$), (**380**) (TBP; Cu–Cu: 3.459 Å; $2J = 24\,\mathrm{cm}^{-1}$) and (**381**) (SP; Cu–Cu: 3.615 Å; diamagnetic).[335–337] They used the concept of 'ligand orbital complementarity' to explain the magnetic properties of these

complexes, despite their very close structural similarity. By independently applying the same concept, Kida *et al.*[338] also contributed to magnetostructural correlation studies: complexes (**382**) (distorted SP; Cu–Cu: 3.0463 Å; $2J = -745\,\text{cm}^{-1}$) and (**383**) (distorted SP; Cu–Cu: 2.998 Å). Mazurek *et al.*[339,340] conducted similar studies: complexes (**384**) (SP; Cu–Cu: 2.928 Å; $2J = -284\,\text{cm}^{-1}$) and (**385**) (planar coordination; Cu–Cu: 3.359 Å; $2J = -240\,\text{cm}^{-1}$). Buchanan, Hendrickson and their co-workers reported complex (**386**) (planar coordination; Cu–Cu: 3.349 Å; $2J = -545.6\,\text{cm}^{-1}$).[341] Nishida *et al.* also contributed to magnetostructural correlation work by reporting a large number of systematically varied complexes: (**387**) (planar coordination; Cu–Cu: 3.502 Å; $2J = -165\,\text{cm}^{-1}$), (**388**) (planar coordination; Cu–Cu: 3.495 Å; $2J = -170\,\text{cm}^{-1}$), (**389**) (planar coordination;

Cu–Cu: 3.482 Å; $2J = -160\,\text{cm}^{-1}$), (**390**) (planar coordination; Cu–Cu: 3.129 Å; uncoupled), and (**391**) (planar coordination; Cu–Cu: 3.644 Å; $2J = -635\,\text{cm}^{-1}$);[342–344] (**392**) (planar coordination; Cu–Cu: 3.502 Å; $2J = -95\,\text{cm}^{-1}$), (**393**) (planar coordination; Cu–Cu: 3.502 Å; $2J = -165\,\text{cm}^{-1}$), (**394**) (planar coordination; Cu–Cu: 3.495 Å; $2J = -170\,\text{cm}^{-1}$), (**395**) (planar coordination; Cu–Cu: 3.482 Å; $2J = -160\,\text{cm}^{-1}$) and (**396**) (planar coordination; Cu–Cu: 3.644 Å; $2J = -635\,\text{cm}^{-1}$);[345] (**397**) (planar coordination; Cu–Cu: 3.401 Å; $2J = -595\,\text{cm}^{-1}$; a complex almost identical to (**385**) but without water of crystallization was reported: planar coordination; Cu–Cu: 3.349 Å; $2J = -310\,\text{cm}^{-1}$).[346] From this standpoint, two more complexes (**398**) (distorted SP; Cu–Cu: 3.320 Å; $2J = -260\,\text{cm}^{-1}$) and (**399**) (distorted TBP; Cu–Cu: 3.359 Å; $2J = 32.8\,\text{cm}^{-1}$) were reported.[347] Differences in the magnetic behavior of the two copper centers were rationalized using the "ligand orbital complementary" concept.

Kodera and co-workers demonstrated[348] that complex (**400**) (distorted TBP; Cu–Cu: 2.926 Å; $2J = -148\,\text{cm}^{-1}$; they also characterized a closely similar ethoxy-bridged complex with two molecules of MeCN) catalyzes the quantitative oxidation of 2,4-di-*tert*-butylphenol to 3,3′,5,5′-tetra-*tert*-butyl-2,2′-dihydroxybiphenyl with H$_2$O$_2$. Krebs and co-workers provided models for the

catechol oxidases:[91] complexes (**401**) (distorted square planar; Cu–Cu: 3.033 Å; $2J = -1020\,cm^{-1}$) and (**402**) (one of the two copper atoms is coordinated by the O atom of the disordered MeOH: one Cu has a distorted square planar and the other a distorted SP geometry; Cu–Cu: 3.017 Å; $2J = -630\,cm^{-1}$).[349] The latter complex was able to oxidize 3,5-di-*tert*-butylcatechol (3,5-DTBC) to the corresponding quinone. Reedijk and co-workers reported[350] complex (**403**) (distorted square planar coordination; Cu–Cu: 2.9896 Å; $2J = -773\,cm^{-1}$), and demonstrated that the compound is catalytically active in the oxidative coupling of 2,6-dimethylphenol and leads to a high selectivity in poly(1,4-ethylene ether) over the unwanted side product. Using a potential dinucleating ligand, Malachowski *et al.* reported[351] a mononuclear complex (**404**), which showed catalytic properties towards the aerial oxidation of 3,5-DTBC.

As a part of their continued activity in the modeling of Hc and/or Tyr, Karlin *et al.* reported complex (**405**) (Cu–Cu: 2.995 Å).[352] The same group demonstrated the hydrolysis of unactivated esters and MeCN hydration by a hydroxo-dicopper(II) complex (**406**) (Cu–Cu: 3.685 and 5.192 Å).[353] Mukherjee and co-workers reported an endogenous alkoxide and an exogenous pyrazolate bridged dicopper(II) complex (**407**) ($\tau = 0.07/0.24$; Cu–Cu: 3.377 Å; $2J = -550\,\text{cm}^{-1}$).[354] Neves *et al.* reported[355] a very interesting complex (**408**), in which each copper(II) center has a phenol group coordinated axially without deprotonation. It is worth mentioning here that a mononuclear copper(II)–phenol complex was reported by Masuda *et al.*[356] This might have implications for substrate binding at the active site of tyrosinase. Krebs reported[357] complex (**409**) (distorted SP; Cu–Cu: 3.382 Å). This complex exhibits catecholase activity; however, the activity is low. Hahn and co-workers reported complex (**410**) ($\tau = 0.18$; Cu–Cu: 3.001 Å).[294] Magnetostructural correlations and catecholase-like activities were reported with complexes (**411**) (distorted square planar; Cu–Cu: 2.8067 Å; $2J = 81\,\text{cm}^{-1}$), (**412**) (distorted square planar; Cu–Cu: 2.8690 Å; $2J = 25\,\text{cm}^{-1}$), (**413**) (distorted square planar; Cu–Cu: 2.9279 Å; $2J = -42\,\text{cm}^{-1}$) and (**414**) (distorted square planar; Cu–Cu: 2.975 Å; $2J = -86\,\text{cm}^{-1}$).[358]

6.6.3.3 Sulfur Donor Ligands

6.6.3.3.1 Thiol and thioether-containing ligands

Reaction of a Cu^{II} salt with a thiol is known to lead to a redox decomposition (Cu^{II} + RSH → Cu^{I} + RSSR).[37] Therefore, the number of structurally characterized copper(II)–thiolate complexes will definitely be less. The structure of the first stable Cu^{II} complex (**415**) (CuN$_2$S$_2$ coordination), that incorporates deprotonated thiol ligation, was reported by Schugar and co-workers in 1986.[359] They conducted spectroscopic studies as well. Kitajima and co-workers reported[113] a CuN$_3$S system (complex (**107**); Section 6.6.3.1.2(iii)). Using a nonmacrocylic ligands, Krüger and co-workers reported[35] complex [Et$_4$N]$_2$[Cu(L)]·H$_2$O (**416**) (structural type: (**8**)), again with CuN$_2$S$_2$ coordination.

A few thioether-ligated copper(II) complexes have been reported, however (cf. Section 6.6.3.1.2): (**417**) (essentially square planar),[360] (**418**) (two crystalline forms: one TBP and other SP),[361] (**419**) (SP),[362] (**420**) (SP),[362] (**421**) (TBP),[362] (**422**) (SP),[363] (**423**) (SP),[363] (**424**) (two independent complexes: SP and octahedral),[364] (**425**) (TBP).[364] In the complexes (**420**) and (**421**), EPR spectra revealed that the interaction between the unpaired electron and the nuclear spin of the halogen atom is dependent on the character of the ligand present. For (**424**) and (**425**), spectral and redox properties were also investigated. Rorabacher *et al.*[365] nicely demonstrated the influence of coordination geometry upon Cu^{II}/Cu^{I} redox potentials, and reported structures of complexes (**426**) and (**427**). Both the Cu^{I} (Section 6.6.4.5.1) and Cu^{II} complexes have virtual C_{3v} symmetry.

$[(L)_2Cu_4(OH)_2][ClO_4]_4\cdot 9MeCN\cdot Et_2O$ (**406**)

As part of their activity to provide models for the Cu_B center of DβH,[84] Réglier and co-workers[366] reported the structure of complex (**428**) (SP). An oxidation of the sulfide ligand was observed when this complex reacted with H_2O_2. Kodera *et al.* spectroscopically demonstrated[367] stabilization of the hydroperoxo-copper(II) species, which is a key intermediate in O_2 activation by DβH,[84] when complex (**429**) ($\tau = 0.39$; also structurally characterized a di-hydroxo-bridged complex $[(L)Cu(OH)]_2[ClO_4]_2\cdot 2MeCN\cdot H_2O$) was reacted with H_2O_2 at −40 °C. Chakravarty and co-workers[368] provided a structural model for this enzyme: complex (**430**). Interestingly, the complex is catalytically active in the oxidation of ascorbic acid by dioxygen mediated by a copper(I) species.

6.6.3.4 Amide Ligands

In their pursuit of determining solution structures of dinuclear copper complexes as carried out for complex (**29**) (Section 6.6.3.1.1), Comba reported complex (**431**) ($\tau = 0.02$; Cu–Cu: 6.9 Å, comparable with the values of 7.2 Å predicted by molecular mechanics calculations and 6.7 Å obtained from the simulated EPR spectrum).[54] They reported[369] complexes (**432**) (square planar) and (**433**) (Cu–Cu: 3.35 Å) as well. As part of studying magnetic properties of mono-, di-, and

trinuclear copper(II) complexes, Costes *et al.*[370] reported complex (**434**) (tetrahedrally distorted square planar). Interestingly, the sodium atoms and the water molecules play an important part in stabilizing the structure, since they are simultaneously bonded to atoms belonging to different unit cells. In their pursuit of stabilizing copper(III) Julve, Journaux, and their co-workers[371,372] reported primarily square-planar complexes (**435**)–(**437a**). To demonstrate oxidations of C—H and O—H bonds by isolated copper(III) complexes, Mayer and co-workers reported the structure of copper(II)

complex (**437b**).[373] The redox properties were also investigated. Krüger and co-workers reported[33] square-planar copper(II) complexes $[Et_4N][Cu(L)]$ (**438**) (cf. complex (**6**)) and (**439**). The spectroscopic and redox properties were studied in detail.

As part of a synthetic analogue approach to metallobleomycins (a family of glycopeptide antibiotics, which in the presence of metal ions like Fe^{2+} and Cu^{2+} and molecular oxygen become activated and subsequently cleave double-stranded DNA),[374–376] a large number of copper(II) complexes of deprotonated peptide ligands resembling fragments of the metal-chelating sections of bleomycins have been synthesized by Mascharak and co-workers.[377–383] In these studies they not only characterized mononuclear and dinuclear complexes with variable stereochemistry ((**440**) to (**457**); complex (**440**) (Cu–Cu: 3.542 Å);[377] complex (**448**) (Cu–Cu: 3.2235 Å);[381] complex (**449**) (Cu–Cu: 3.0943 Å);[381] complex (**451**) (Cu–Cu: 5.3433 Å);[382] complexes $[(L)Cu(py)(H_2O)]$ (**453**), $[(L)Cu(bpy)]$ (bpy = 2,2′-bipyridine) (**454**), $[(L)Cu(Me_2bpy)].NaClO_4.MeCN$ (Me_2bpy = 6,6′-dimethyl-2,2′-dipyridyl) (**455**), and $[(L)Cu(Me_2phen)]\cdot NaClO_4\cdot 1.2MeCN\cdot 0.4C_6H_5Me$ (Me_2phen = 2,9-dimethyl-1,10-phenanthroline); (**457**) has a similar structure to that of (**456**)), but also

investigated in a systematic manner their spectral and redox properties. In some cases they did DNA nicking experiments to examine the potential of the complexes as a functional model of the bleomycins. Along similar lines, Kimura and co-workers reported[384,385] complexes (**458**)–(**460**). From the same perspective, Shepherd *et al.*[386] characterized complex (**461**) and also studied DNA nicking experiments. Réglier and co-workers achieved[387,388] hydroxylation of aliphatic C—H bonds by copper(I) complexes and dioxygen (modeling of DβH[84]) and characterized a number of copper(I) complexes ((**462**)–(**466**)) with amide O coordination. Using a bidentate, deprotonated pyridinecarboxamide ligand, Mukherjee and co-workers reported a tetrahedrally distorted CuN_4 complex (**467**).[389] It was neatly demonstrated from cyclic voltammetric experiments that for the Cu^{II}/Cu^{I} couple, an anodic shift of 0.6–0.7 V could be observed by merely changing the copper stereochemistry from square planar to distorted tetrahedral. Using a substituted variety of this ligand, this group reported a copper(II) complex (**468**) with a TBP geometry ($\tau = 0.69$).[390] Spectroscopic and redox properties were studied in detail. Using a tridentate pyridinecarboxamido ligand, Mukherjee

and co-workers reported two singly hydroxo-bridged dicopper(II) complexes (**469**) (distorted square planar; Cu–Cu: 3.437 Å; Cu–OH–Cu angle: 131.6 °; $2J = -334\,cm^{-1}$) and (**470**) (distorted square planar; Cu–Cu: 3.370 Å; Cu–OH–Cu angle: 126.6 °; $2J = -296\,cm^{-1}$).[391] In each molecule in their crystal lattices, sodium or potassium ions are tetrahedrally coordinated by four amido oxygen atoms from four different dimeric units. Using a similar tridentate ligand with additional coordination groups, Borovik and co-workers, in their target of assembling supramolecular structures in crystal lattices, reported complex (**471**).[392] Kajikawa *et al.* reported an interesting complex (**472**) (the structure of a closely similar complex of composition $[\{(L)CuCl\}_2]SO_4 \cdot 8H_2O$ was also reported).[393,394]

In order to construct new types of binding and activating models of dioxygen molecules, Jitsukawa, Masuda and their co-workers have synthesized a novel group of tripodal tetradentate ligands and successfully utilized them in the formation of mononuclear copper(II) complexes with novel structural features (complexes (**473**)–(**488**)).[395–403] This group of ligands has four

characteristic functional groups, i.e., four coordination sites for metal ions, two/three NH groups for hydrogen bonds to fix a small molecule such as dioxygen, two/three hydrophobic *tert*-butyl groups to protect the small bound molecule and to prevent dimerization of coordinated metal centers, and electron-withdrawing pivaloylamino groups to stabilize the copper(I) state. These complexes (TBP geometry) have also been characterized by electronic absorption, EPR and NMR spectral, and cyclic voltammetry. The structure of complex (**473**) was originally wrongly reported,[395] which was pinpointed by Tolman and co-workers[396] and eventually realized by this

amide oxygen is no longer coordinated; and the azide ion is coordinated), (**481**) (however, now uncoordinated pyridine is coordinated; amide oxygen is no longer coordinated; hydroxide ion is coordinated) and (**487**) (however, the amide oxygen is no longer coordinated and each Cu atom has two chloride ions), respectively.

Using the pyrazinecarboxamide ligand, complexes (**489**) and (**490**) were reported.[404] Using a tridentate ligand, complex (**491**) was reported.[405] In this complex the crystal packing is achieved by intermolecular hydrogen bonding. Mathur and co-workers reported[406] the structure of a complex (**492**) ($\tau = 0.59$) and demonstrated its catechol oxidase activity.[91] The two complexes (**493**) ($\tau = 0.33$) and (**494**) ($\tau = 0.55$) were reported[407] and their spectroscopic and redox properties investigated.

The concept of "ligand complex" was nicely demonstrated in the structures of complexes (**495**) (Cu–Cu: 3.1172 Å; $2J = -164\ \mathrm{cm}^{-1}$)[408] and (**496**) (Cu–Cu: 3.097 Å, 4.984 Å, and 5.108 Å).[409] For both the complexes, spectroscopic and redox properties were also studied.

In their pursuit of modeling substrate adduct to the reduced active site of nitrite reductases, Tolman *et al.* thoroughly characterized[410–412] complexes (**497**) (nitrite-bridged, mixed-valent complex), [(i-Pr_3TACN)Cu(O_2CMe)$_2$] (**498**), [(i-Pr_3TACN)Cu(OSO_2CF_3)(H_2O)][CF_3SO_3] (**499**) and demonstrated associated chemistry. Synthesis and characterization of a copper complex of

$[Et_2N(N_2O_2)]^-$(**500**), stabilized with respect to NO release in aqueous solution, was also documented. During this endeavor, complex [(i-Pr_3TACN)Cu(O_2CMe)] (bidentate acetate coordination) (**501**) and a carbonato-bridged complex (**502**) were characterized.[413]

From their continued activity from the standpoint of dioxygen activation by copper(I) complexes of relevance to Hc/Tyr modeling, Tolman's group demonstrated an unusual ligand oxidation by a (μ-η^2:η^2-peroxo)dicopper(II) species and structurally characterized a complex (**503**) (Cu–Cu: 3.0392 Å),[414] via the intermediacy of a novel bis(μ-alkylperoxo)dicopper intermediate. To investigate the reactivity of peroxo- and bis(μ-oxo)dicopper complexes with catechols, this group characterized a catechol-bound complex (**504**), as well as a semiquinone-bound complex (**505**).[415] With the goal of understanding how the nature of the tridentate macrocyclic supporting ligand influences the relative stability of isomeric (μ-η^2:η^2-peroxo- and bis(μ-oxo)dicopper complexes, a comparative study of the O_2 reactivity of Cu^I compounds supported by the 10- and 12-membered macrocycles was made by Tolman, Alvarez, and their co-workers.[416] In addition to structurally characterizing Cu^I complexes (cf. Section 6.6.4.6), they characterized a dihydroxo-bridged dicopper(II) complex (**506**) (structural type: (**10**)), a carbonato-bridged complex (**507**) (structural type: (**112**)), and a new peroxo-dicopper(II) complex (**508**) (structural type: (**108**)).[416] As a part of their activity on modeling GO,[260–262] they characterized complexes (**509**) to (**514**).[417,418] In an attempt to answer why the active form of GO possesses a diamagnetic ground state, Wieghardt and co-workers characterized complex (**515**).[419] In 2001, Halfen *et al.* demonstrated enhanced reactivity of copper catalysts for olefin aziridination and characterized the

Chaudhuri *et al.* reported two novel isomeric tautomeric bridging complexes (**518**) (Cu–Cu: 2.97 Å; Cu–OH–Cu angle: 100.1°; $2J = -90\,\mathrm{cm}^{-1}$) and (**519**) (Cu–Cu: 3.03 Å; Cu–O–Cu angle: 88.6°; $2J = 74\,\mathrm{cm}^{-1}$).[421] Using complex (**520**), static and dynamic Jahn–Teller distortions in the CuN_6 polyhedron were nicely demonstrated.[422] Using a functionalized TACN ligand, Wieghardt and co-workers characterized complex (**521**) (distorted SP).[423] Using a 3-*tert*-butyl-substituted variety of phenol-appended ligand, they structurally characterized complex $[Cu(H_2L)][ClO_4]$ (**522**) (distorted SP; out of three phenol groups one remained uncoordinated, one coordinated as phenolate, and one as phenol).[423] Chaudhuri *et al.* characterized a spin-frustrated, imidazolate-bridged trinuclear copper(II) complex (**523**).[424] Wieghardt and co-workers also characterized complexes (**524**)[425] and (**525**) (cf. Section 6.6.2.4).[36] As part of their activity (see below), Spiccia and co-workers reported complex (**526**).[426]

Selective derivatization of parent TACN[427] and particularly syntheses of a large number of linked-TACN[428,429] resulted in the isolation of interesting complexes: (**527**) (the solid-state structure of this complex also contains an aggregate of $[Na(BF_4)_2]^-$ units which form a polymeric

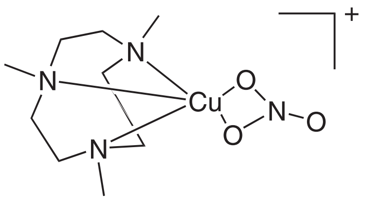
chain structure);[427] (**528**);[427] (**529**) (pseudo-square pyramidal; Cu–Cu: 2.947 Å; Cu–OH–Cu angle: 99.6 °; $2J = -318\,cm^{-1}$);[430] (**530**) ($\tau = 0.05/0.07$; Cu–Cu: 2.940 Å; $2J = -54\,cm^{-1}$);[431] (**531**) ($\tau = 0.0/0.06$; Cu–Cu: 2.962 Å; $2J = -538\,cm^{-1}$);[431] and (**532**) ($\tau = 0.07$; Cu–Cu: 3.006 Å; $2J = 188\,cm^{-1}$).[431] Using 1,3,5-tris(1,4,7-triazacyclonon-1-ylmethyl)benzene, Spiccia *et al.* structurally characterized[432] complex $\{(L)Cu_3(\mu\text{-}OH)(\mu_3\text{-}HPO_4)(H_2O)][PF_6]_3{\cdot}3H_2O\}_n$ (**533**), the polymeric lattice of which contains trinuclear copper(II) sites with structural similarities to laccase and ascorbate oxidase.[4–7,433] These trinuclear sites consist of two 'Type III' copper(II) centers, at a separation of 3.557 Å, linked by a hydroxo bridge and two phosphate oxygens; while another phosphate oxygen links these two centers to the further removed 'Type II' copper(II) center, establishing separations of 4.561 Å and 5.474 Å. The molecule has an $S = 1/2$ molecular ground state arising from antiferromagnetic coupling. The biological existence of trinuclear metal centers has been highlighted by Fenton and Ōkawa.[433]

From structural studies (complex (**534**) and Section 6.6.4.6) on both the oxidation states, Addison and co-workers nicely provided evidence of the role of ligand framework conformability in Cu^{II}/Cu^{I} redox potentials.[434] Using a very rigid bis-bispidine tetraazamacrocycle which is highly preorganized for coordination to copper(II) (complex (**535**)), Comba and co-workers provided evidence[435] that this ligand induces extremely high ligand fields for the copper(II) center. Using pyrazole-based macrocyclic ligands, Driessen and co-workers characterized complexes (**536**)



$[(L)Cu(O_2NO)][ClO_4]$ (**526**)

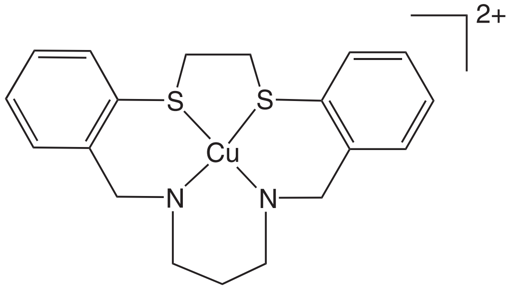
(SP; Cu–Cu: 7.14 Å),[436] (**537**) ($\tau = 0.20$; Cu–Cu: 8.668 Å),[437] and (**538**) ($\tau = 0.25$; Cu–Cu: 6.814 Å).[437] The complex (**539**) ($\tau = 0.17$; Cu–Cu: 7.24 Å) catalyzes the oxidative polymerization of 2,6-dimethylphenol.[438] Using an imidazolato-bridged dicopper(II) complex (**540**) (square planar N_4 environment for each copper with axial positions occupied by a water molecule on one Cu and two weakly bound triflates on the other Cu; Cu–Cu: 5.92 Å) of a macrocyclic Schiff base ligand, Burrows and co-workers provided a model for a hydrolytic enzyme (hydrolysis of *p*-nitrophenyl acetate). EPR and magnetic measurements in the solid state showed antiferromagnetic coupling between the metal ions. Interestingly, electrochemical studies indicated a single, quasi-reversible, two-electron reduction of Cu^{II} at $E_{1/2} = -0.435$ V vs. SCE (saturated calomel electrode).[439] Two imidazolate-bridged complexes $Cu^{II}Cu^{II}$((**541**): $2J = -88\ cm^{-1}$; Cu–Cu: 5.95 Å) and $Cu^{II}Zn^{II}$((**542**); Cu–Zn: 5.93 Å) of a macrobicyclic ligand (cryptand) were also synthesized and their redox properties investigated. All the results indicated that these complexes act as good models for SOD.[440]



$[Cu(L)][ClO_4]_2$ (**534**)

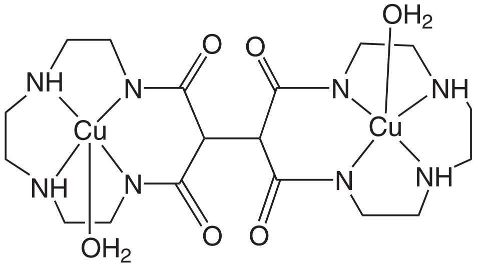
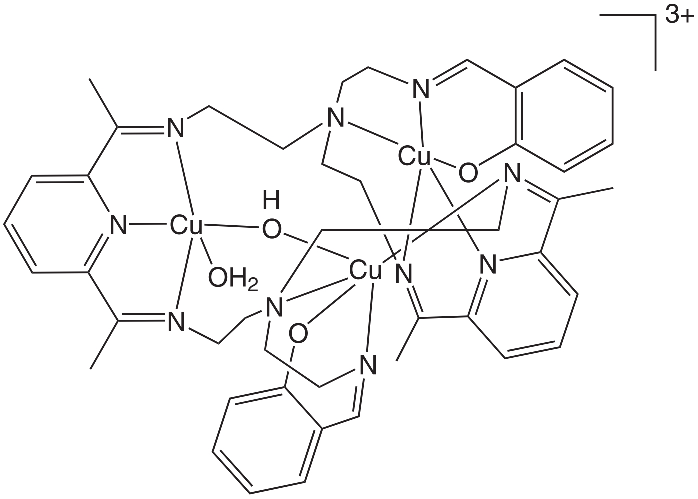
Fenton and co-workers reported[444] the first-generation model for the trinuclear copper site in ascorbate oxidase[4–7,433] by reporting the complex (**546**) (a single Cu^{II} atom 4.9 and 5.9 Å distant from a pair of Cu^{II} atoms that are 3.6 Å apart and hydroxy-bridged). A study of the magnetic properties shows that the trinuclear copper(II) can be regarded as a mononuclear site, non-interacting with a moderately coupled copper pair ($2J = -202\,cm^{-1}$). As a part of their activity in the coordination chemistry with cryptand ligands, Fenton and co-workers reported[445] the structure of the complex (**547**) (distorted TBP; Cu–Cu: 4.6 Å).



$[(L)Cu_2(H_2O)_2]\cdot 12H_2O$ (**545**)



$[(L)Cu_3(OH)][ClO_4]_3\cdot 2H_2O$ (**546**)

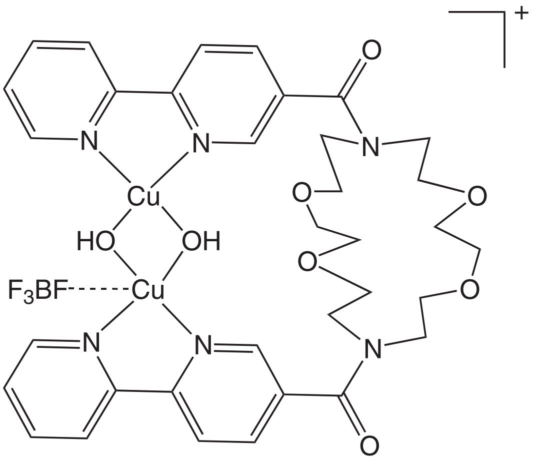
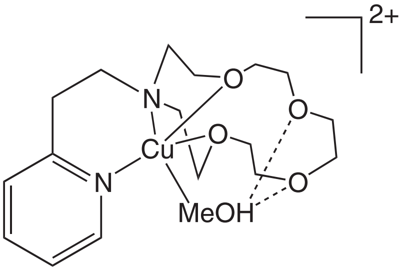
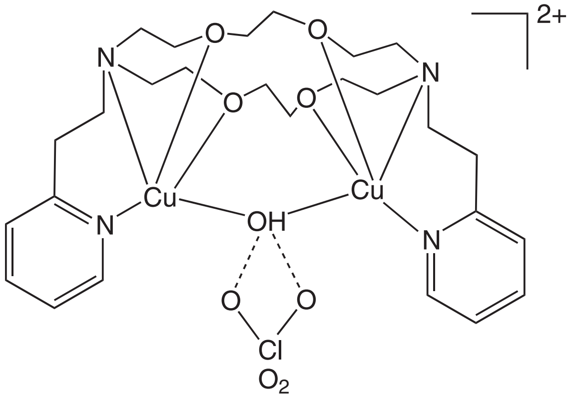
From the standpoint of magnetostructural correlations in bis(μ_2-phenoxide)-bridged macrocyclic dinuclear copper(II) complexes,[450] Thompson *et al.* reported complexes (**553**) (SP; Cu–Cu: 3.1184 Å; Cu–O–Cu 103.65 °; $2J = -784\,\mathrm{cm}^{-1}$), (**554**) ($\tau = 0.34/0.41$, Cu–Cu: 3.115 Å; distorted SP, Cu–Cu: 3.102 Å; Cu–O–Cu 102.4 °, 107.5 °, 102.9 °, 106.1 °; $2J = -801\,\mathrm{cm}^{-1}$) and (**555**) (SP; Cu–Cu: 2.997 Å; Cu–O–Cu 98.8 °; $2J = -689\,\mathrm{cm}^{-1}$).[451] Nolte and co-workers reported[452,453] a dihydroxo-bridged complex (**556**) (one of the coppers is pentacoordinated and the other is hexacoordinated; Cu–Cu: 3.542/3.778 Å).[452] Two molecules are linked by hydroxo ligands, forming a tetranuclear



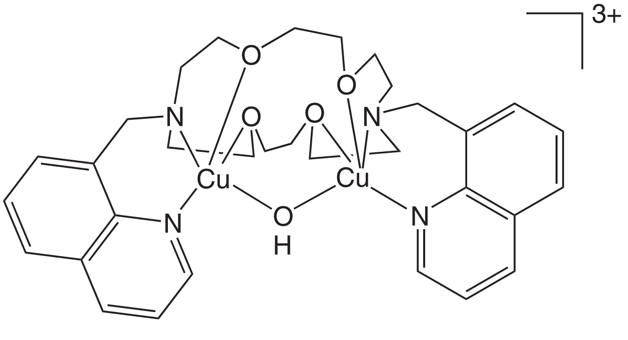
$[(L)Cu_2(OH)_2(F_2BF_2)][BF_4]\cdot 2H_2O$ (**556**)



$[(L)Cu(MeOH)][ClO_4]_2$ (**557**)



$[(L)Cu_2(OH)(O_2ClO_2)][ClO_4]_2$ (**558**)



$[(L)Cu_2(OH)][ClO_4]_3\cdot Me_2CO$ (**559**)

complex. Magnetic susceptibility and EPR measurements suggested that it has a triplet ground state ($2J = 16\,cm^{-1}$). This group also reported a mononuclear complex (**557**) ($\tau = 0.51$) and a dinuclear complex (**558**) ($\tau = 0.62$; Cu–Cu: 3.4592 Å).[453] Wang *et al.* reported the first bridged dicopper(II) complex (**559**) (distorted SP; Cu–Cu: 3.526 Å) of a bibracchial lariat ether.[454] As a part of their activity on heteroditopic cryptand chemistry,[455] Bharadwaj and co-workers provided an example of the imposition of distorted geometry (complex (**560**)).[456] In this complex the O atom of the water molecule is strongly bonded to the Cu^{II} ion, while its H atoms are H-bonded to the nearest benzene rings. Using a group of diazamesocyclic ligands, Bu *et al*. reported three complexes: (**561**) ($\tau = 0.02$), (**562**) ($\tau = 0.30$; Cu–Cu: 3.494 Å; $2J = 1.16\,\mathrm{cm}^{-1}$), (**563a**) ($\tau = 0.30$; Cu–Cu: 3.0324 Å; $2J = -574\,\mathrm{cm}^{-1}$),[457] (**563b**) ($\tau = 0.38$), (**563c**) ($\tau = 0.29$), and (**563d**) ($\tau = 0.34$; Cu–Cu: 3.396 Å; $2J = 2.24\,\mathrm{cm}^{-1}$).[458]

6.6.3.6 Ligand-bridged Systems

Dinuclear and multinuclear transition-metal complexes comprising two or more metal centers bridged by multidentate ligands have been the subject of an enormous amount of work, particularly in the latter years of the twentieth century. Such complexes can exhibit metal–metal interactions, such as energy or electron transfer, magnetic coupling, and intervalence transfer. These interactions are mediated by the bridging ligand. Such compounds are used to model important bioinorganic systems. It is to be mentioned here that the coordination chemistry of such systems is covered in Volume 7. Therefore only selected systems having some relevance to the bioinorganic chemistry of copper will be discussed. Readers are suggested to consult review articles.[2,3,459–461]

6.6.3.6.1 Carbonate ligands

Studies on di- and trinuclear metal complexes bridged by carbonate or hydrogencarbonate are mainly noted from three areas: (i) fixation and activation of CO_2 from the viewpoint of environmental protection;[462–464] (ii) functional models for zinc-containing carbonic anhydrase (Volume 8); and (iii) the relationship between the bridging modes of carbonate and magnetic properties.

From this background, many carbonato-bridged polynuclear compounds of varying nuclearity, with many different terminal ligands (Figure 2), have been reported: $[(Et_4dien)_2Cu_2(H_2O)(OCO_2)][ClO_4]_2\cdot H_2O$ (**564**)[465] (TBP; Cu–Cu: 5.233 Å; $2J = -17.8\ cm^{-1}$); $[Cu(EtMe_4dien)_2Cu_2(H_2O)_2(OCO_2)][ClO_4]_2\cdot 2H_2O$ (**565**)[465] [SP; hydrogen bonds form a tetranuclear copper(II) unit; Cu–Cu: 5.937 Å; $2J = -125.5\ cm^{-1}$]; $[(Cu(petdien))_2(OCO_2)][ClO_4]_2$ (**566**)[466] (TBP; Cu–Cu: 4.601 (structure at 294 K) and 4.494 (structure at 92 K) Å; $2J = -215\ cm^{-1}$); $[(bapma)_3Cu_3(OClO_3)_3(OCO_2)][ClO_4]$ (**567**)[467] (SP; Cu–Cu: 4.87 Å; $3J = 12.6\ cm^{-1}$); $[(bapa)_4Cu_4Br_2(OCO_2)]Br_4$ (**568**)[468] (μ_4-carbonate ligand disordered; $2J = -275\ cm^{-1}$, $-8\ cm^{-1}$, $-57\ cm^{-1}$, and $-31\ cm^{-1}$); $[(bapma)_4Cu_4Cl_2(OCO_2)]Cl_4\cdot 12H_2O$ (**569**)[468] (μ_4-carbonate ligand disordered; $2J = -390\ cm^{-1}$, $22\ cm^{-1}$, $-10\ cm^{-1}$,

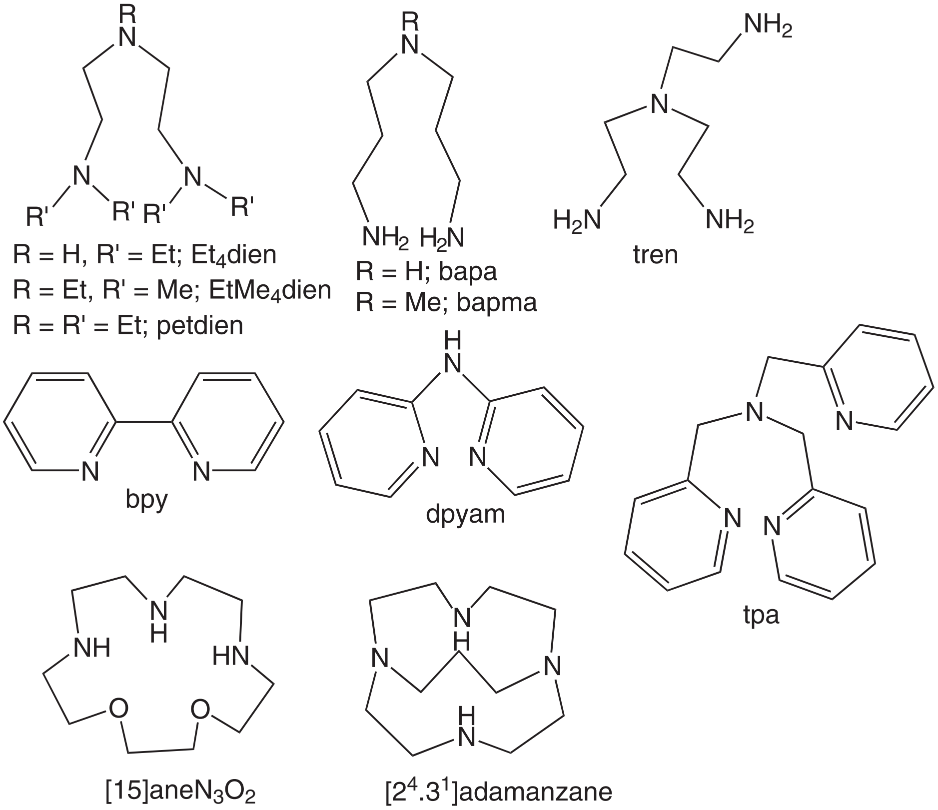

Figure 2 Carbonato-bridged polynuclear compounds of varying nuclearity with different terminal ligands.

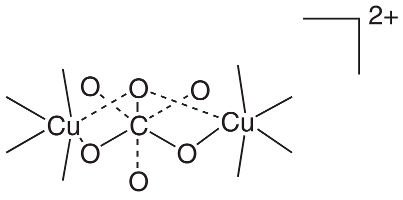
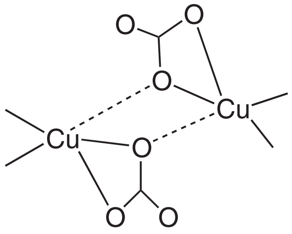
$[(phen)_2Cu(O_2COH)][ClO_4]$ (**575**)

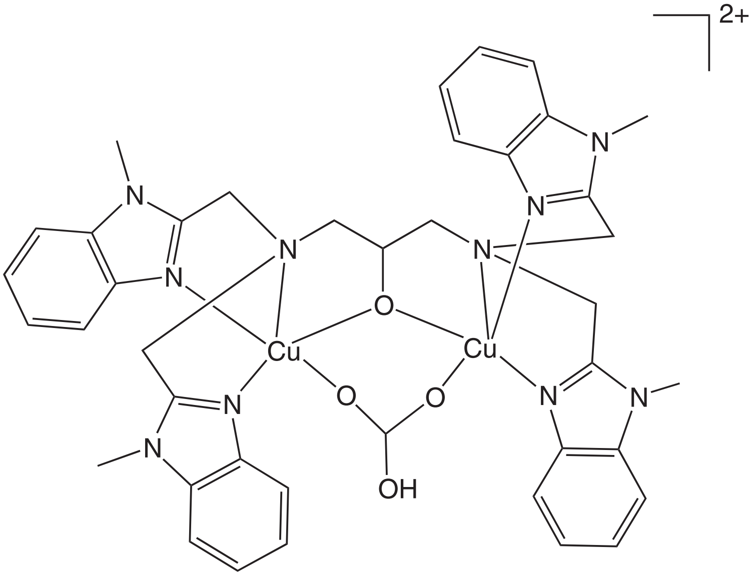


$[(dpyam)_4Cu_2(OCO_2)][ClO_4]_2\cdot 4H_2O$ (**576**)

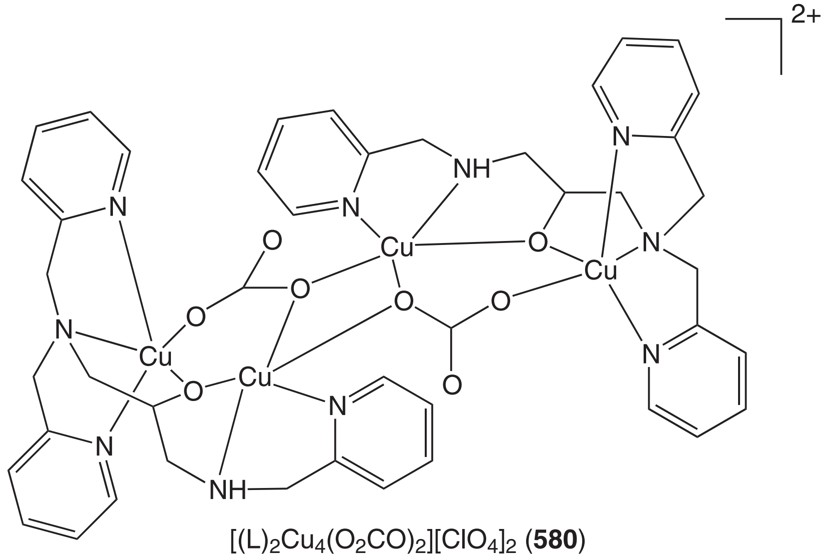


$[(dpyam)_2Cu_2(OCO_2)_2]\cdot H_2O$ (**577**)

very interesting mononuclear, bicarbonate-bound (both monodentate and bidentate) complexes ((**574**) and (**575**)). Youngme *et al.* reported two carbonato-bridged complexes [(**576**) ($\tau = 0.13$, 0.30; Cu–Cu: 5.555 Å; $2J = -90.4\,\mathrm{cm}^{-1}$) and (**577**) ($\tau = 0.20$, 0.22; Cu–Cu: 3.247 Å; $2J = -9.9\,\mathrm{cm}^{-1}$)].[473] Many such complexes have been reported: $[(Cu(tpa))_3(OCO_2)][ClO_4]_4$ ((**578**), structural type: (**570**); TBP;



$[(L)Cu_2(O_2COH)][BF_4]_2 \cdot 5H_2O$ (**579**)

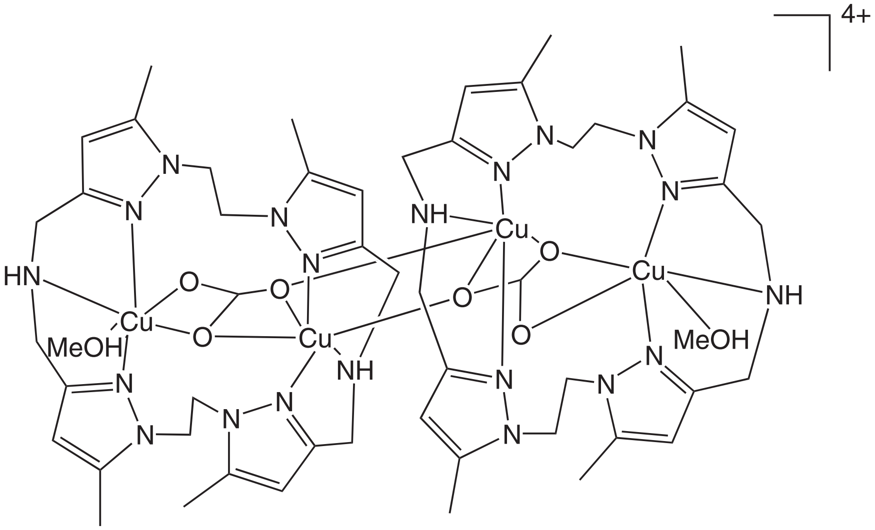


$[(L)_2Cu_4(O_2CO)_2][ClO_4]_2$ (**580**)

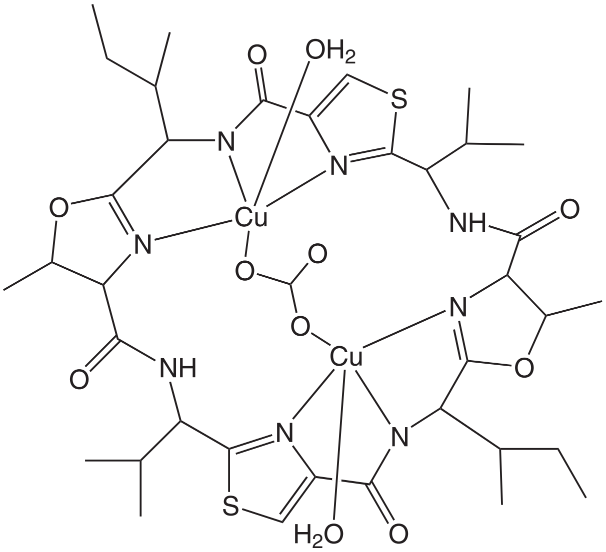
Cu–Cu: 4.91, 4.96, and 5.06 Å; $3J = -1.19\ \mathrm{cm}^{-1}$),[474] (**579**) (distorted SP; Cu–Cu: 3.440 Å; $2J = 36.3\ \mathrm{cm}^{-1}$),[475] (**580**) (distorted SP; Cu–Cu: 3.446 Å; $2J = -90.4\ \mathrm{cm}^{-1}$; exhibits reversible CO_2 fixation).[476] Using macrocyclic terminal ligands (Figure 2), complexes $[\{Cu(L)\}_3(OCO_2)]$-$[ClO_4]_4$ (L = [15]aneN_3O_2) (**581**) ($\tau = 0.19$; $3J = 8.2\ \mathrm{cm}^{-1}$),[477,478] $[\{Cu(L)\}_3(OCO_2)][ClO_4]_4$ (L = $[2^4.3^1]$adamanzane) (**582**) ($\tau = 0.57$; Cu–Cu: 4.64, 4.72, and 5.00 Å; $3J = 17.2\ \mathrm{cm}^{-1}$),[479] and (**583**) (elongated octahedral; Cu–Cu: 3.240 and 4.601 Å)[480] ((**581**)–(**583**); structural type: (**570**)) were reported. Using a natural cyclic peptide, complex (**584**) (distorted SP; Cu–Cu: 4.43Å; $2J = 1.6\ \mathrm{cm}^{-1}$) was thoroughly characterized.[481]

6.6.3.6.2 *Other bridged systems*

Lippard and co-workers synthesized[482] a hexaimidazole ligand to encapsulate two copper ions in a biomimetic environment, and reported a very interesting dicopper(II) complex (**585**) (D_{2d}



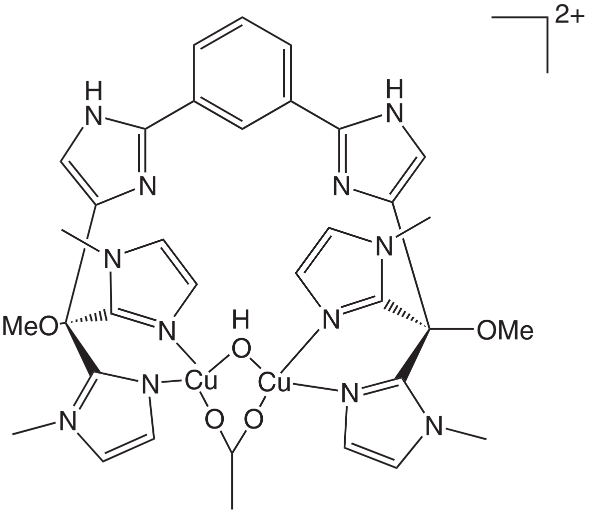
$[(L)_2Cu_4(OCO_2)_2(MeOH)_2][ClO_4]_4 \cdot 4MeOH$ (**583**)



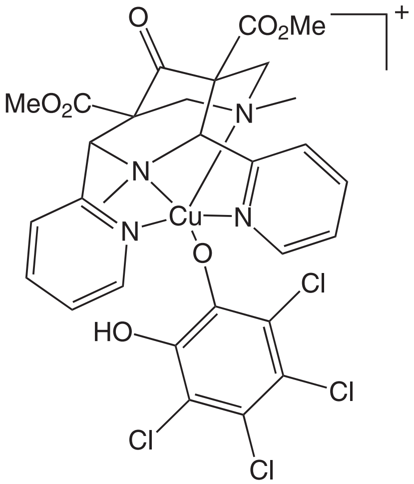
$[(L)Cu_2(OCO_2)(H_2O)_2]$ (**584**)

distorted square planar; dihedral angle between the best least-squares planes through the two copper coordination spheres is 62.5°). The most interesting feature of this structure is that a methanol solvent molecule, used to grow crystals, is inserted into the cavity defined by the bis(imidazolyl)benzene linker. Solid-state, temperature-dependent (6–300 K) measurements revealed the presence of a weak ferromagnetic coupling ($2J = +2.6(2)\,cm^{-1}$) in this compound. EPR spectral properties were also studied. Comba and co-workers reported[483] structural models of substrate-bound catechol oxidase[91] (complexes (**586**)–(**589**)). The compound with a bridging catecholate was shown to be catalytically the most active.

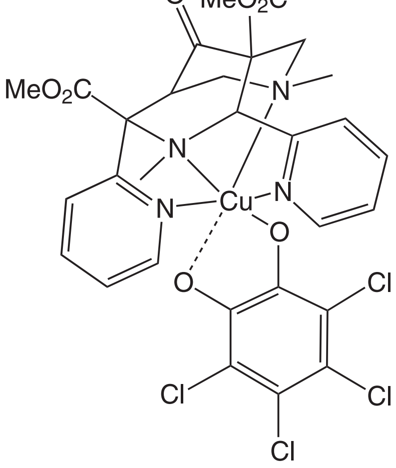
From the viewpoint of molecular magnetism,[484,485] Julve *et al.* reported[486] complex (**590**) (elonagated tetragonal octahedral; Cu–Cu: 3.435 Å; $2J = -374\,cm^{-1}$). Escuer *et al.* demonstrated the versatility of the cyanato ligand by doing magnetostructural studies on dimeric complexes: $[(Et_5dien)Cu(NCO)][ClO_4]$ (**591**) (square planar), (**592**) (axially elongated SP; Cu–Cu: 5.397 Å; $2J = 0.5\,cm^{-1}$), and (**593**) ($\tau = 0.27$; Cu–Cu: 3.216 Å; $2J = -4.6\,cm^{-1}$).[487] Continuing with their activity, this group also investigated complexes (**594**) (axially elongated SP; Cu–Cu: 6.89 Å; $2J = -7.5\,cm^{-1}$), (**595**) (distorted SP; Cu–Cu: 7.569 Å; $2J = -28\,cm^{-1}$) and (**596**) (axially elongated



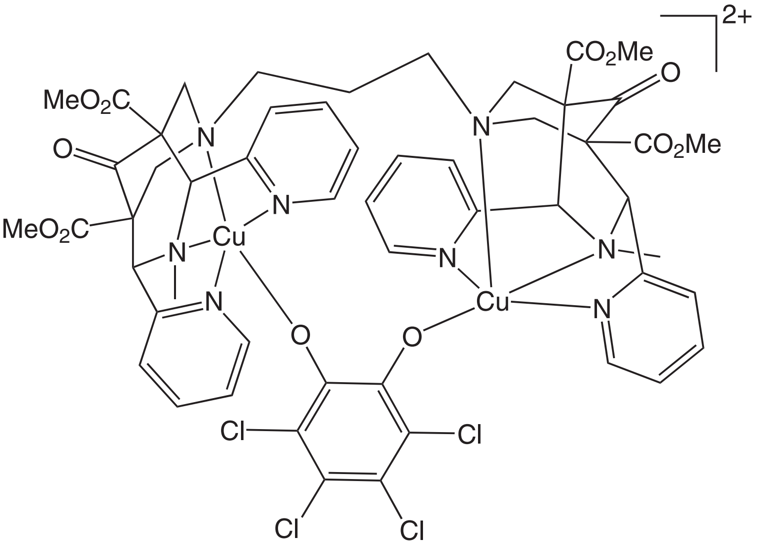
$[(L)Cu_2(OH)(O_2CMe)][ClO_4]_2\cdot 1.5THF\cdot MeOH$ (**585**)



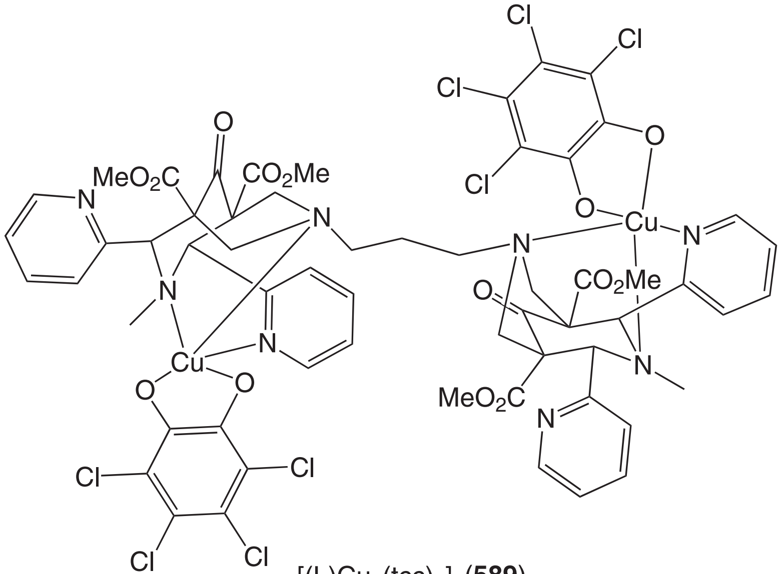
$[(L)Cu(tccH)][ClO_4]$ (**586)**
(H_2tcc = tetrachlorocatechol)



$[(L)Cu(tcc)]$ (**587**)
(H_2tcc = tetrachlorocatechol)



$[(L)Cu_2(tcc)][ClO_4]_2$ (**588**)



$[(L)Cu_2(tcc)_2]$ (**589**)

SP; Cu–Cu: 5.289 Å; $2J = -3.6\,cm^{-1}$).[488] Spiccia and co-workers studied a mononuclear complex $[(tpa)Cu(CN)][ClO_4]\cdot 0.5H_2O$ (Figure 2) ((**597**); TBP), as well as two cyanide-bridged complexes [(**598**) (TBP; Cu–Cu: 5.084 Å; $2J = -106.4\,cm^{-1}$) and (**599**) (TBP; Cu–Cu: 4.982 Å; $2J = -174.2\,cm^{-1}$)].[489] McCleverty, Ward, and co-workers reported structural, magnetic, and EPR spectroscopic properties of tetranuclear grid-like copper(II) complexes with pyrazolate bridges:[490] (**600**) (SP; Cu–Cu: 3.963 and 4.080 Å), (**601**) (MeOH is coordinated like DMF in complex (**600**): SP, Cu–Cu: 3.939 and 3.984 Å) and (**602**) (SP; Cu–Cu: 3.216 Å).[491] Tokii and co-workers investivated magnetostructural studies on bis-(μ-pyrazolato)-bridged dicopper(II) complexes: (**603**)–(**606**) (distorted TBP); (**607**) (distorted square bipyramidal). They structurally characterized a complex $[(bpy)_2Cu_2(4\text{-}Mepz)_2(H_2O)_2][NO_3]_2$ as well, having a structure closely similar to that of (**607**). Magnetic susceptibility data conform to $2J$ values in the range -143 to $-268\,cm^{-1}$.[492] Chou *et al.* reported three pyrazolato-bridged complexes (**608**)–(**610**). In these complexes with additional bridges, redox and magnetic studies were also performed.[493] Pons *et al.* provided example (complex (**611**))[494] of an unexpected chlorination of a pyrazole ligand during crystallization of a mononuclear precursor. McKenzie and co-workers reported[495]

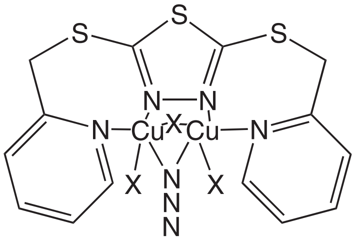
Thompson and co-workers systematically studied[499,500] magnetostructural correlations with many interesting azido-bridged complexes, with endogenous equatorial diazine bridge exhibiting both ferromagnetic and antiferromagnetic coupling between the Cu^{II} centers. A few representative examples are complexes (**616**)–(**624**). Axial sites at both coppers involve a disordered array of partial waters and partial chloride ions (complex (**624a**)). From these studies they demonstrated that the μ_2-1,1-azido bridge can propagate antiferromagnetic coupling if the bridge angle is large enough, and that the critical angle for accidental orthogonality (ferromagnetic coupling) for the azido bridge is ≈108.5°.

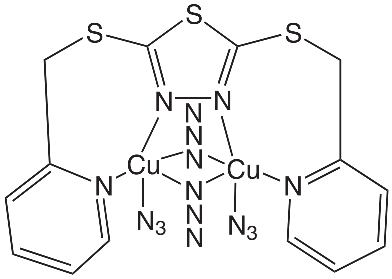
From the viewpoint of molecular-based magnetic materials,[484,485] Ray Chaudhuri and co-workers reported the end-to-end azide-bridged complex (**625**).[501] Manoharan and co-workers systematically investigated molecular and electronic structural aspects of azido-bridged complexes (**626**) (distorted SP; Cu–Cu: 5.632 Å), (**627**) (contrary to (**626**), in this complex each copper has a weak perchlorate O coordination; Cu–Cu: 5.410 Å) and ($[(dpt)Cu(\mu{-}N_3)]_2[ClO_4]_2$ (**628**) (structural type: (**593**)); dpt = dipropylenetriamine (Figure 2); Cu–Cu: 3.416 Å).[502] Akagi *et al.* reported a linear trinuclear copper(II) complex (**629**), bridged by oximato and azido groups (elongated octahedral; Cu(central)–Cu(terminal): 3.4008 Å; $2J = -532\,cm^{-1}$).[503]

Christou, Hendrickson, and co-workers reported triply bridged, ferromagnetically coupled dicopper(II) complexes (**630**) and (**631**).[504–506] Perlepes *et al.* reported alkoxo-/carboxylato-bridged complexes (**632**) and (**633**).[506] Using hydroxo-/carboxylato-bridged dicopper(II) complexes, Chakravarty and co-workers investigated magnetostructural correlations; complexes (**634**) and (**635**)

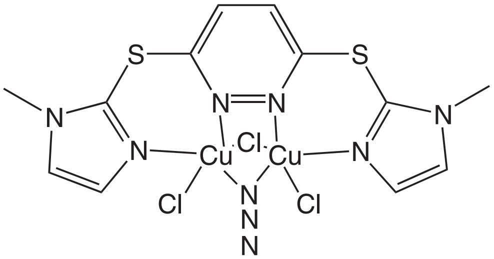


X = Cl: $[(L)Cu_2(N_3)Cl_3]\cdot MeCN$ (**616**)

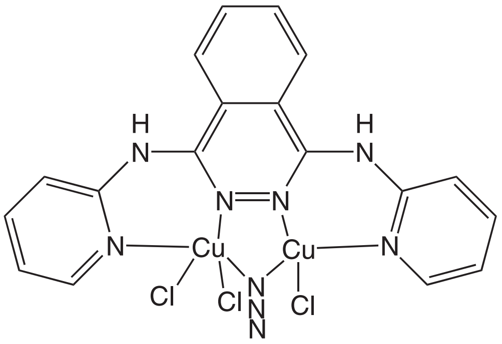
X = Br: $[(L)Cu_2(N_3)Br_3]\cdot MeCN$ (**617**)



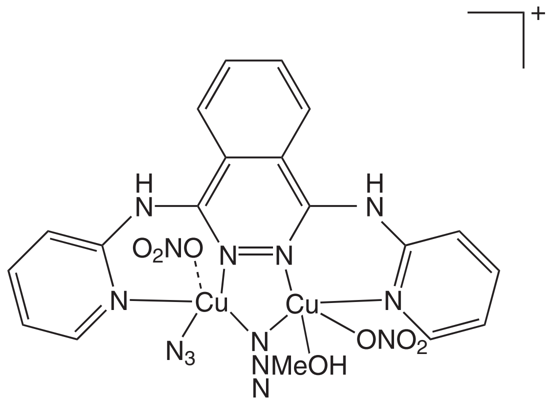
$[(L)Cu_2(N_3)_4]$ (**618**)



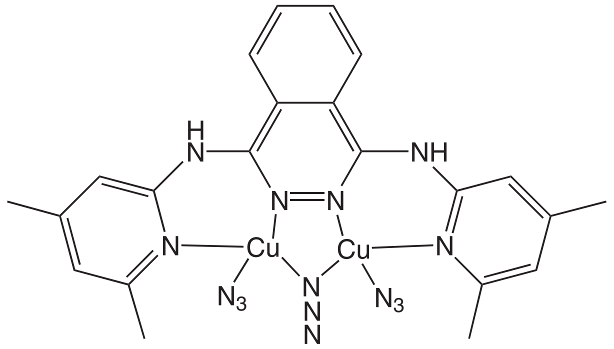
$[(L)Cu_2(N_3)Cl_3]\cdot 0.5MeOH$ (**619**)



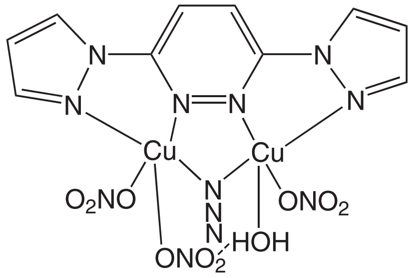
$[(L)Cu_2(N_3)Cl_3]\cdot CH_2Cl_2$ (**620**)



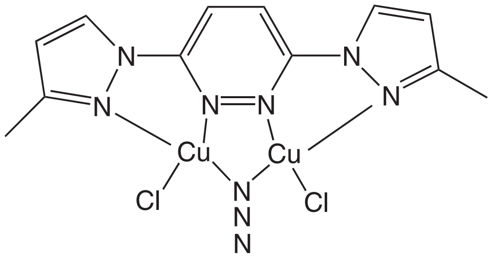
$[(L)Cu_2(N_3)_2(ONO_2)(MeOH)][NO_3]\cdot MeOH$ (**621**)



$[(L)Cu_2(N_3)_3]\cdot 0.33H_2O$ (**622**)



$[(L)Cu_2(N_3)(ONO_2)_3(H_2O)_{1\cdot 6}]$ (**623**)



$[(L)Cu_2(N_3)Cl_3(H_2O)_{1\cdot 5}]$ (**624a**)

represent prototypical examples.[507] Tokii *et al.* studied closely similar complexes, (**636**) and (**637**).[508] Using a single-pot reaction, Walton and co-workers reported a complex (**638**) (SP; Cu–Cu: 3.491 Å; $2J = -152.1\ cm^{-1}$) of a *m*-xylyl-based Schiff base ligand.[509]

To address the role of the apical donor in the decomposition of copper(II) benzoate under the DOW-phenol process, Comba and co-workers reported complex (**639**).[510] Ruiz, Journaux, and co-workers demonstrated[511] ferromagnetic coupling through spin polarization in a dinuclear copper(II) metallacyclophane complex (**640**). Actually, the structure affords an intricate two-dimensional network. Sletten and co-workers reported weak, antiferromagnetically coupled dicopper(II) complexes (**641**) and (**642**), with thiocyanato bridges.[512] Rodríguez *et al.* reported a chloro-bridged dimer (**643**) with an unusual structure (distorted SP; the two pyramids share a base-to-apex edge, with the basal planes being perpendicular) and ferromagnetic coupling.[513]

Using a macrocyclic ligand, an interesting μ-chloro- and μ-hydroxo-bridged complex (**644**) (TBP; Cu–Cu: 3.223 Å) was reported.[514] Wieghardt, Chaudhuri, and co-workers reported a very weakly antiferromagnetically coupled complex (**645**), with two chloro bridges and a carboxylato bridge. Applying magnetostructural concepts, they rationalized their result.[515] They investigated

$[(L)Cu(H_2O)(NCS)_2]\cdot2H_2O$ (**642**)

co-workers reported[519] two thermally stable neutral β-diketiminato copper(I) olefin complexes (**654**) and (**655**), and with the same ligand a bis-hydroxo-copper(II) dimer $[(L)Cu(OH)]_2$ (complex (**656**); structural type: (**2**)). The dimer results from the reaction of the Cu^I ethylene complex with O_2 via the proposed intermediacy of a $Cu^{III}{}_2O_2$ species (structure (**4**)). With the ligand that is present in complex (**7**), Hofmann and co-workers reported[520] a remarkably stable copper(I) ethylene complex (**657**), which catalyzes cyclopropanation of styrene with α-carbonyl diazoalkanes at room temperature. They also structurally characterized an analogous norbornene complex. Arnold *et al.* demonstrated[521] the incorporation of an alkoxide functional group into an N-heterocyclic carbene ligand. Using this anionic chelating ligand, they reported the first non-macrocyclic, square-planar Cu^I centers (complex (**658**)). It should be mentioned here that these strong σ-donor ligands can significantly increase the reactivity of many homogeneous catalysts.

6.6.4.2 Nitrogen Donor Ligands

Copper proteins present interesting problems of structure for the copper(I) oxidation state. They are difficult to probe in detail, and what we do know of them suggests they are rarely regular or predictable.[58] In plastocyanin the copper(I) coordination sphere is made up of three strongly

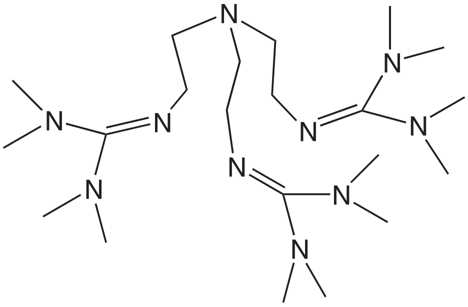
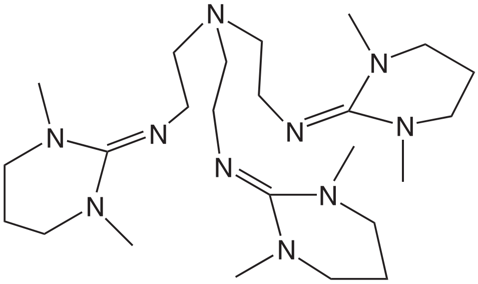
binding ligands (two histidines and one cysteine) and a weak interaction at 2.9 Å with methionine. The stereochemistry is sufficiently far from ideality that describing it in terms of a distorted tetrahedron that is tending toward an elongated trigonal pyramid has a rather limited utility.

6.6.4.2.1 Polydentate aliphatic amine ligands

A list of structurally characterized copper(I) complexes of tripodal aliphatic amines is provided in Table 4 (cf. Section 6.6.3.1.1 for corresponding mononuclear or dinuclear copper(II) complexes). Copper(II) complexes [(L)CuCl]Cl (**664**) and [(L)Cu(MeCN)][ClO_4]$_2$ (**665**) with the ligand that is present in complex (**662**) were also structurally characterized.[522]



[Cu(L)]Cl (**662**)



[Cu(L)][ClO_4] (**663**)

6.6.4.2.2 Heterocyclic nitrogen donor ligands

(i) Imidazole-containing ligands

Sorrell *et al.* reported the complex (**668**) (distorted trigonal; Cu–Cu, 3.139 Å).[523] Schugar and co-workers reported complex (**669**) (pseudotetrahedral; corresponding copper(II) complex, structural type: (**34**)).[66] Garner and co-workers reported complex (**670**), intermediate between tetrahedral and square planar; (corresponding copper(II) complex, structural type: (**36**)).[68] Sorrell *et al.* reported complex (**671**) (T-shape) and investigated its oxygenation behavior.[524] Along similar lines, Kurtz *et al.* reported complex (**672**). Moreover, they were successful in isolating and characterizing a side-on copper(II)-peroxo complex.[525] Riordan and co-workers designed two cavitand-based imidazolyl ligands and reported their copper(I) complexes: (**673**) (trigonal planar) and (**674**) (trigonal planar).[526]

(ii) Benzimidazole-containing ligands

Using benzimidazole ligands, Reed and co-workers provided examples of variable coordination number and distorted geometries: (**675**) (distorted trigonal pyramid; Cu–Cu: 5.35 Å), (**676**) (distorted trigonal pyramid), (**677**) (trigonal pyramid; Cu–Cu: 7.99 Å) and (**678**) (trigonal planar; Cu–Cu: 12.46 Å).[527] With a bidentate imidazole/thioether ligand, Kaim and co-workers reported a copper(I) complex $[(L)Cu(PPh_3)_2][BF_4]$ (**679**) (corresponding copper(II) complex, structural type: (**81**)).[95] Palaniandavar *et al*. also provided examples of trigonal planar copper(I) complexes (corresponding copper(II) complex: structural type (**92**)): $[Cu(L)][NO_3]$ (**680**) and $[Cu(L)Cl]$ (**681**).[100] Using a potentially tridentate benzimidazolylpyridine ligand, Williams *et al*. reported an unusual double-helical copper(I) complex (**682**) (linearly coordinated by benzimidazoles, with a slight distortion toward a tetrahedral structure resulting from the weak interaction with the pyridines).[528] Müller *et al*. reported a dinuclear copper(I) complex (**683**) (distorted tetrahedral; Cu–Cu: 4.59 Å), resulting from the oxygenation of a dicopper(I) complex (cf. (**96**) and (**97**)).[102]

(iii) Pyrazole-containing ligands

From the standpoint of mimicking Hc/Tyr activity using substituted hydrotris(pyrazolyl)borates as capping ligands, Kitajima *et al.* reported distorted tetrahedral complexes (**684**)[118] and (**685**).[115] In order to provide a structural/functional model of nitrite reductases[72] Tolman *et al.* thoroughly characterized quite a few substrate-bound copper(I) complexes: (**686**) (linear; Cu–Cu: 3.284 Å),[129] (**687**) (distorted trigonal planar; Cu–Cu: 2.544 Å)[529] and (**688**) (highly distorted geometry).[529] Gorun and co-workers demonstrated[530] reversible binding of dioxygen (copper(II)–peroxo species) at ambient conditions with the complex (**689**).

With pyrazole-based chelating ligands, Sorrell and co-workers structurally characterized monomeric as well as dimeric copper(I) complexes: monomeric (**690**) (distorted trigonal pyramid)[147] and (**691**) (T-shaped structure);[531] and dimeric (**692**) (linear; Cu–Cu: 6.350 Å)[532] and (**693**) (T-shaped; Cu–Cu: 5.100 Å).[533] This group also investigated the redox properties of these complexes. Using a similar kind of ligand, Driessen and co-workers reported structures of copper(I) complexes (**694**) (distorted trigonal pyramid),[534] (**695**) (distorted tetrahedral; Cu–Cu: 2.9511 Å) and (**696**) (distorted tetrahedral).[535] Using a sterically hindered tris(pyrazolylmethyl)amine ligand, Colbran and co-workers reported complex (**697**) (ligand as that in complexes ((**150**)–(**152**)) (trigonal pyramid).[148] Using a tridentate pyrazolylmethylpyridine ligand, Manoharan and co-workers characterized the complexes (**698**) (distorted tetrahedron) and (**699**).[536] Using the ligand present in the complex (**129**), a dicopper(I) complex (**700**) (Cu–Cu: 3.028 Å) with Cu_2I_2 unit was reported.[136]

(iv) Pyridine-containing ligands

The structure of a copper(I) complex [Cu(L)][BPh$_4$] (trigonal pyramidal: three pyridyl groups in the trigonal plane and tertiary amine at the apex; ligand as that in complex (**4**)) was also determined.[29] The structure of complex [Cu$_2$(L)(MeCN)$_2$][BF$_4$]$_2$ (ligand as that in complex (**179**))[169] and complex [Cu(L)][BPh]$_4$ (ligand as that in complex (**220**))[209] were also reported.

Using the ligand present in copper(II) complex (**246**), the corresponding copper(I) complex [Cu(L)][BF$_4$] (**701**) (TBP geometry) was also structurally characterized.[226] Using a systematically varied set of tris(2-pyridyl)methoxymethane ligands used in the syntheses of copper(II) complexes ((**252**)–(**256**)), corresponding copper(I) complexes [(L)Cu(MeCN)][CF$_3$SO$_3$] [(**702**) (L as in (**252**)); (**703**) (L as in (**255**)/(**256**))]; [(L)Cu(PPh$_3$)][CF$_3$SO$_3$] [(**704**) (L as in (**253**))]; [(L)Cu(PPh$_3$)][CF$_3$SO$_3$]·0.5Me$_2$CO [(**705**) (L as in (**255**)/(**256**))]; [Cu(L)$_2$][CF$_3$SO$_3$].Me$_2$CO [(**706**) (L as in (**252**))]; [Cu(L)$_2$][CF$_3$SO$_3$] [(**707**) (L as in (**253**))]; and [Cu(L)$_2$][CF$_3$SO$_3$]·0.5Me$_2$CO [(**708**) (L as in (**254**))] were also thoroughly characterized. Two distinct coordination modes were observed for the Cu^{I} complexes, both in solution and the solid state. One is a pseudotetrahedral coordination comprised of the facial-capping, tris-pyridyl ligand and a monodentate ligand. The other structural type is also a pseudotetrahedral Cu^{I} monomer formed by two tris-pyridyl ligands coordinated in a bidentate manner, with preferable binding by the non-methoxy pyridyl subunits. With the exception of the most sterically hindered ligand, which displays only monoligation to Cu^{I}, all ligands form both types of Cu^{I} complexes, and the formation is controlled by stoichiometry.[233]

Karlin and co-workers synthesized a large number of mononuclear and dinuclear copper(I) complexes in their pursuit to understand the oxygenation behavior of copper(I) complexes (cf. Section 6.6.3.1.2(iv)). A listing of such complexes is provided in Table 5 . Tolman and co-workers provided the answer to the question of bis(μ-oxo)dicopper(III) core being capable of hydroxylating

[a] When only complex number is indicated, structures along with chemical formula are presented in this article. [b] The bonding parameters are closer to those observed for purely tricoordinate structures, with closely similar ligands. [c] $[(L)Cu(MeCN)][ClO_4]$ (L = tris(2-pyridylmethyl)amine) assumes distorted tetrahedral geometry.[218] [d] L = tris(2-pyridylmethyl)amine; dangling uncoordinated pyridyl arm from the ligand. [e] One pyridyl group carries a $-CO_2Me$ substituent. [f] Dangling uncoordinated quinolyl group from the ligand.

an arene ring. To prove it, they synthesized a copper(I) complex (**734**) (T-shaped geometry) and investigated its oxygenation behavior spectroscopically.[191] Yamauchi and co-workers studied[555] the effects of a side-chain aromatic ring on the dioxygen reactivity of copper(I) complexes. They reported two complexes (**735**) (distorted tetrahedral) and (**736**) (tetrahedral). They were able to stabilize the $Cu^{III}_2(\mu\text{-}O)_2$ species. Recently, using a tailor-made 1,8-naphthyridine-based ligand, Lippard and co-workers reported[556] an interesting dicopper(I) complex (**737**) with Cu–Cu interaction

trigonal planar; Cu–Cu: 4.156 Å) and (**739**) (distorted trigonal planar; Cu–Cu: 8.157 Å). This group thoroughly characterized these complexes, along with their redox properties.[181] Using a tridentate ligand with pyrazine spacer, Oshio reported[253] the complex $[Cu_2(L)][ClO_4]_2$ (**740**) (L as that in (**291**); trigonal pyramidal; Cu–Cu: 6.743 Å) and also studied its redox properties.

Using a mesityl-based ligand (cf. complex (**194**)), Kim and co-workers structurally characterized complexes (**741**) (distorted trigonal; Cu–Cu: 7.162 Å, 7.823 Å, and 7.949 Å), (**742**) (distorted trigonal planar; Cu–Cu: 7.2371 Å, 7.3418 Å, and 7.8659 Å), and (**743**) (trigonal; Cu–Cu: 7.986 Å).[185]

The copper(I) analogue $[Cu(L)][ClO_4]$ (**744**) (distorted tetrahedral) of copper(II) complex (**201**) was also synthesized and its redox property investigated.[193] Structures of complex (**745**) (distorted tetrahedral)[557] and complex (**746**) (pseudotetrahedral; Cu–Cu: 4.764 Å)[558] were also reported.

Copper(I) analogues $[(L)Cu(MeCN)][CF_3SO_3]$ (**747**) [yellow, four-coordinate (two amine donors, one of the two pyridinyl groups and an MeCN] and $[(L)Cu(MeCN)][BF_4]$ (**748**) [red, five-coordinate (two tertiary amine, two pyridinyl and an MeCN] [L as that in copper(II) complex (**241**)] were structurally characterized and redox properties of these complexes were also investigated.[224]

(v) Bipyridine/phenanthroline-containing ligands

The structures of $[Cu(bpy)_2][ClO_4]$ (bpy = 2,2′-bipyridyl) (**749**) (pseudotetrahedral),[559] $[(L)Cu(MeCN)][ClO_4]$ (L = 2,9-dimethyl-1,10-phenanthroline) (**750**) (Y-shaped planar)[560] were

(vi) Other heterocycle-containing ligands

The copper(I) analogue $[Cu(L)][ClO_4]$ (**758**) (distorted pseudotetrahedral) of complex (**294**) was prepared and its properties investigated.[258] Using a bis(diazine) heterocyclic ligand structure of the complex (**759**) was determined.[564]

6.6.4.3 Phosphorus Donor Ligands

The first copper(I) complex of tris(hydroxymethyl)phosphine ((**760**); tetrahedral) has been reported by Samuelson and co-workers.[565] This group addressed the question of anion-controlled nuclearity and metal–metal distances in copper(I)-bis(diphenylphosphino)methane complexes, and in this endeavor they reported the structures of complexes (**761**) (Cu–Cu separation: 3.005–3.128 Å), (**762**) (Cu–Cu separation: 3.165 Å) and (**763**) (tetrahedral; Cu–Cu: 3.293 Å).[566] They synthesized and provided structural evidence of oxyanion- encapsulated copper(I) complexes of this ligand. The complexes (**764**) (distorted tetrahedral; Cu–Cu: 3.143 Å), (**765**) (distorted tetrahedral; Cu–Cu: 3.424 Å), (**766**) (distorted trigonal; Cu–Cu: 3.170 Å), and (**767**) (Cu–Cu: 3.032–3.077 Å) were reported. They studied solid-state emission spectra of these complexes.[567] During this pursuit they

synthesized and characterized complex (**768**).[568] The structure of a copper(I) complex (**769**) (distorted tetrahedral) of polydentate phosphinoamines has been reported.[569]

6.6.4.4 Oxygen Donor Ligands

As part of their activity in investigating the oxygenation behavior of dicopper(I) complexes with *m*-xylyl-based ligands, using a dinucleating ligand with amine and pyrazole as terminal donor sites, Sorrell *et al.*[570] reported the first copper(I) dimer ((**770**): distorted tetrahedral; Cu–Cu: 3.825 Å) having only a single phenolate bridge. This group also reported the structure of a monomeric copper(I) phenolate complex ((**771**): distorted trigonal pyramidal).[571]

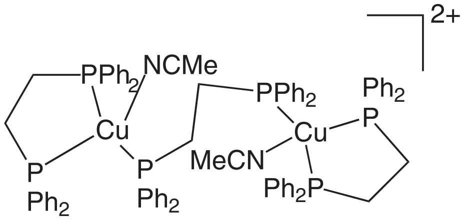
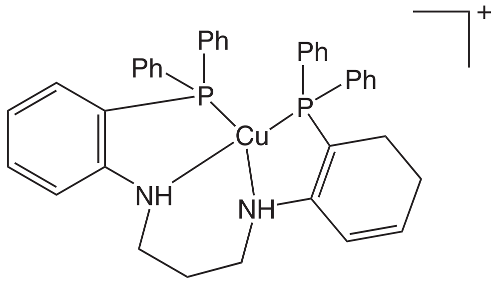
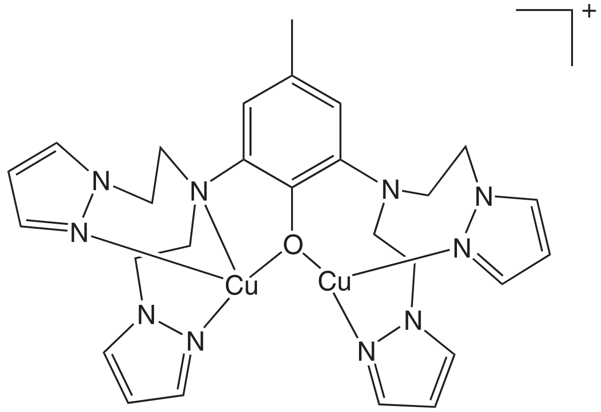
[(L)$_3$Cu$_3$(Cl)(OWO$_3$)] (**767**)



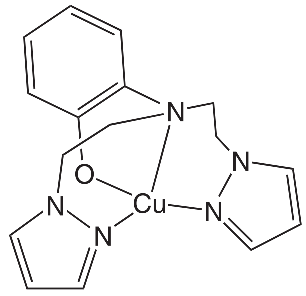
[{(L)Cu(MeCN)}$_2$][ClO$_4$]$_2$ (**768**)



[Cu(L)][BF$_4$]·MeCN (**769**)



[Cu$_2$(L)][BF$_4$] (**770**)

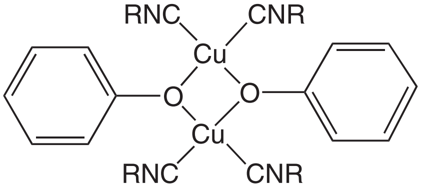


[Cu(L)] (**771**)

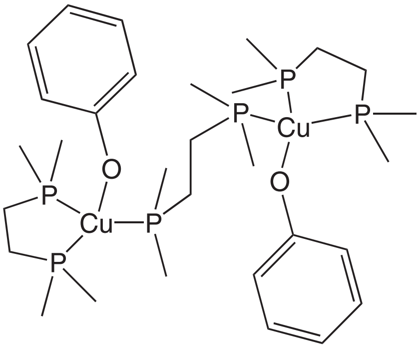
The copper-alkoxo unit, which is usually synthesized *in situ*, plays a significant role in metal-promoted transformations of organic substrates by copper(I). To determine the reaction form of the Cu–OPh unit, Floriani and co-workers structurally characterized four complexes: (**772**) (pseudotetrahedral; Cu–Cu: 3.223 Å), (**773**) (pseudotetrahedral), (**774**) (anion: linear coordination) and (**775**) (planar trigonal).[572] Using 3,3,6,6-tetramethyl-1-thia-4-cycloheptyne as terminal ligand the structural characterization of a copper(I)–alkyne complex (**776**) (Cu–Cu: 2.940 Å) was reported.[573]

Reactions of copper(I) aryloxides with PhNCS were investigated by Samuelson and co-workers,[574] who characterized three complexes: (**777**) (tetrahedral), (**778**) (trigonal; 2.829 Å), and (**779**) (trigonal; average Cu–Cu: 2.6895 Å). Mono- ((**780**): tetrahedral) and dinuclear ((**781**): pseudotetrahedral; Cu–Cu: 3.242 Å) alkoxide–copper complexes with PPh$_3$ ligands were reported.[575] In 2001 Cotton and co-workers reported structures of two copper(I) complexes ((**782**): trigonal; Cu–Cu: 2.707 Å, and (**783**): trigonal; Cu–Cu: 2.833 Å) bridged by dicarboxylates.[576]

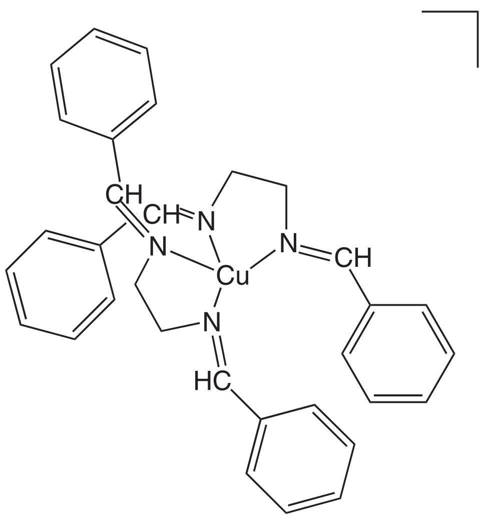
Using a low-spin, tris-chelate iron(II) complex (coordinated by three bidentate azo-oxime ligands providing Fe^{II}N$_6$ coordination) as a facially capping tridentate ligand (the oxime oxygens function as donor sites), Chakravorty and co-workers characterized copper(I) complex (**784**) (distorted tetrahedral) [also copper(II) complex (**785a**): elongated octahedral] and investigated



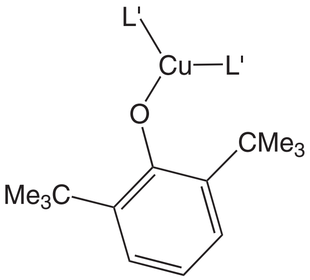
$[(PhO)Cu(L')_2]_2$ (**772**)
L' = *p*-Me-C_6H_4-NC



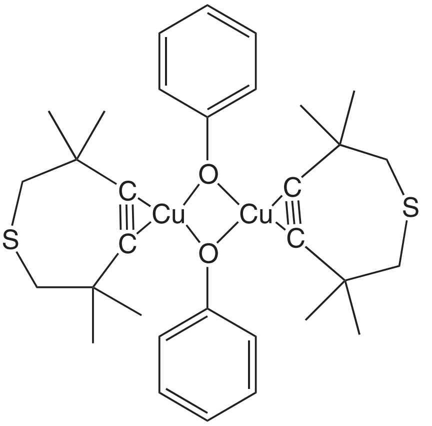
$[(PhO)_2Cu_2L_3]$.THF (**773**)



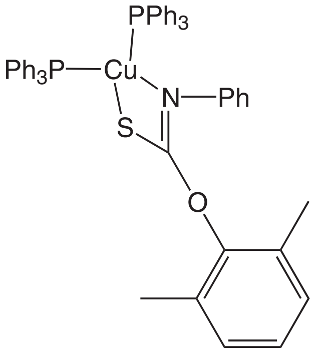
$[Cu(L)_2]^+[Cu(2,6\text{-}Me_2C_6H_3O)_2]^-$ (**774**)



$[(L)Cu(L')_2]$ (**775**)
L' = *p*-Me-C_6H_4-NC

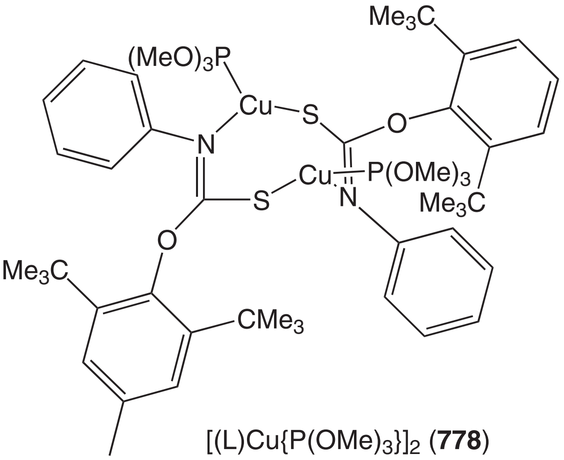


$[(L)Cu(OPh)]_2$ (**776**)

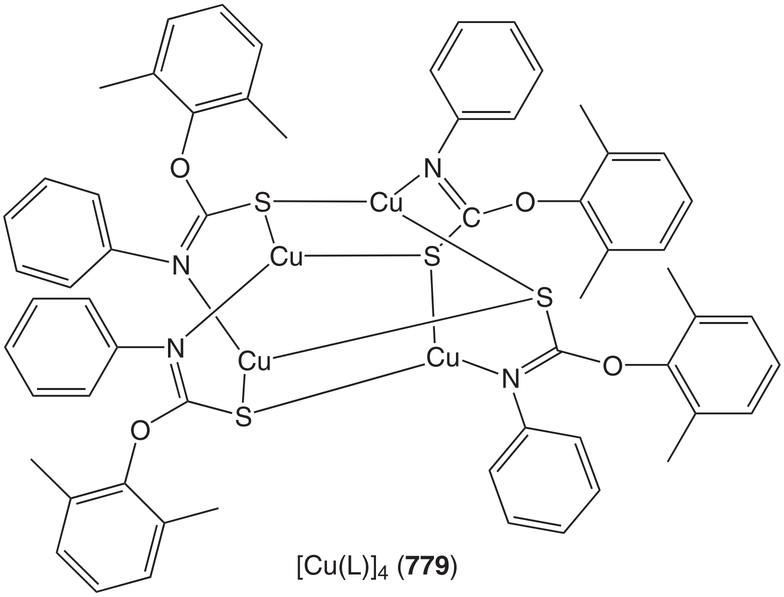


$[(L)Cu(PPh_3)_2]$ (**777**)

their properties.[577] Similarly, Chaudhuri and co-workers characterized a trinuclear complex (**785b**) (tris(nioximato)-bridged $Mn^{IV}Cu^{II}Mn^{IV}$ tetracation; niox = cyclohexane-1,2-dione dioximate dianions; each Mn^{IV} ion is terminally coordinated by 1,4,7-trimethyl-1,4,7-triazacyclononane).[578]



[(L)Cu{P(OMe)$_3$}]$_2$ (**778**)



[Cu(L)]$_4$ (**779**)

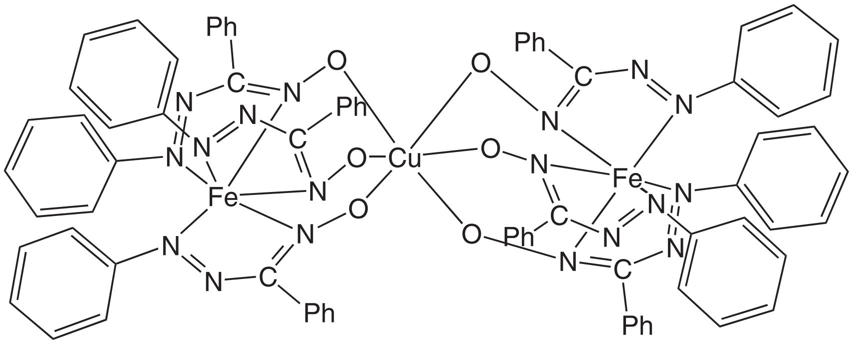
[{Fe(L)$_3$}Cu(PPh$_3$)] (**784**)

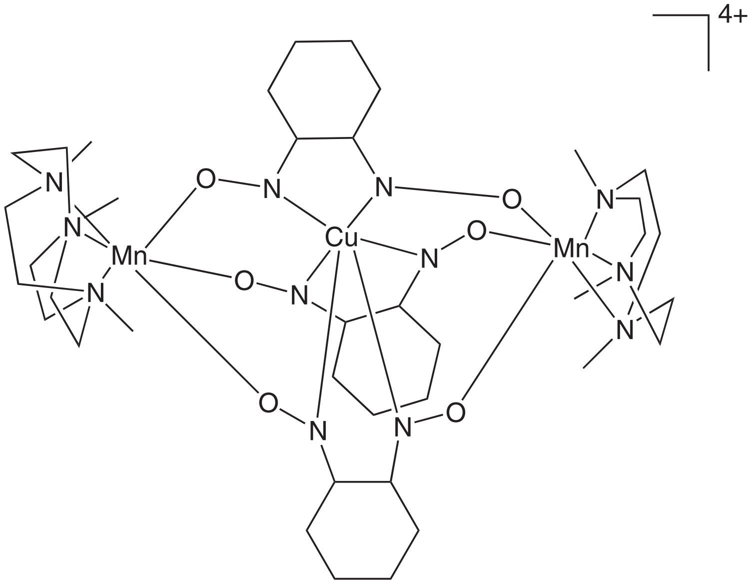


[{Fe(L)$_3$}$_2$Cu]·2CH$_2$Cl$_2$ (**785a**)

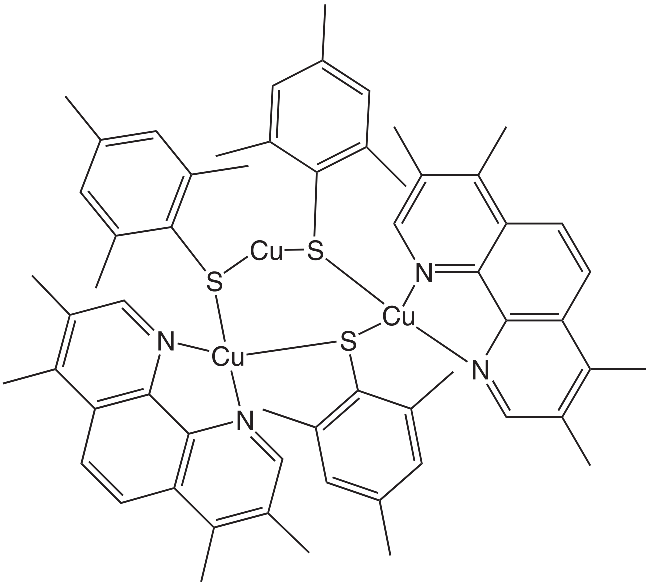
6.6.4.5 Sulfur Donor Ligands

6.6.4.5.1 Thiol- and thioether-containing ligands

The copper(I) complexes [Cu(L)] (**786**) [L as in Cu^{II} complex (**426**)], and (**787**) (L as in Cu^{II} complex (**427**)], were also structurally characterized.[365] From the standpoint of aggregation behavior of copper(I) thiolates[579] through substituent size and ancillary chelate ligands, Kaim



[LMn{(L')$_3$Cu}MnL][ClO$_4$]$_4$ (**785b**)

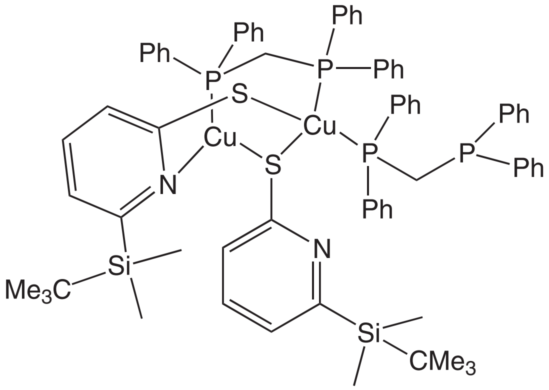


[(L)$_3$Cu$_3$(L')$_2$]·0.5EtOH (**788**)
L' = 3,4,7,8-tetramethyl-1,10-phenanthroline

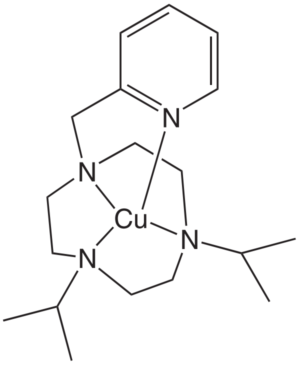
and co-workers reported crystal structure of complex (**788**) (distorted trigonal pyramidal and linear; Cu–Cu: 2.715 Å, 3.014 Å, and 3.733 Å).[580] Using a silylpyridine-2-thionate as ligand, Sousa and co-workers reported the structure and physicochemical properties of a dimeric copper(I) complex (**789**) (distorted trigonal planar; Cu–Cu: 3.733 Å).[581]

6.6.4.6 Macrocyclic Ligands/Cryptands

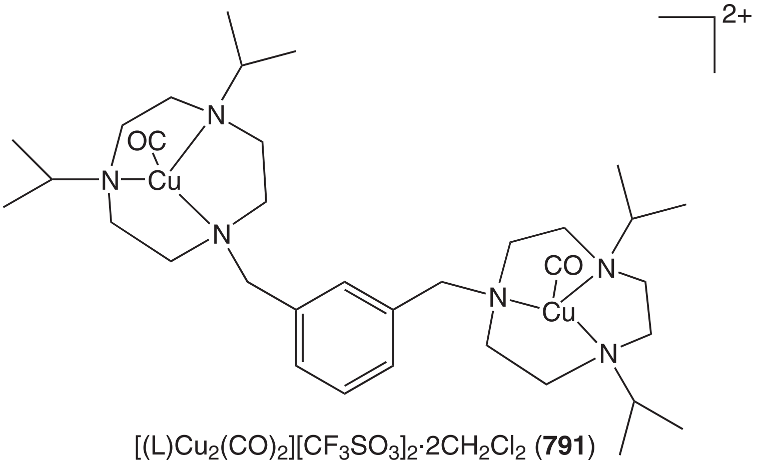
Tolman and co-workers investigated the oxygenation behavior of a copper(I) complex (**790**) (trigonal pyramidal) and demonstrated the formation of end-on peroxo-dicopper(II) species.[582]



[(L)$_2$Cu$_2$(L')$_2$] (**789**)
L' = bis(diphenylphosphino)methane



[Cu(L)][CF$_3$SO$_3$] (**790**)

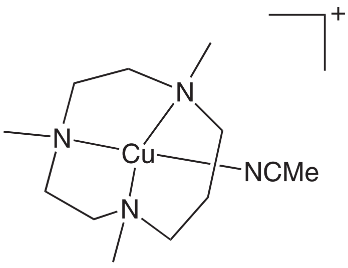


[(L)Cu$_2$(CO)$_2$][CF$_3$SO$_3$]$_2$·2CH$_2$Cl$_2$ (**791**)

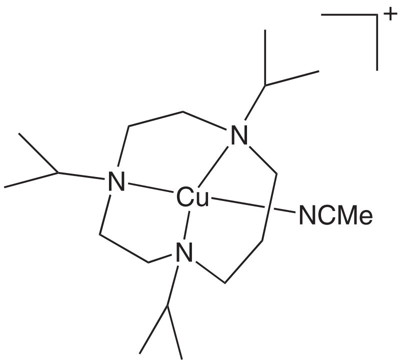
From this perspective they reported the structure (complex (**791**); Cu–Cu: 10.061 Å) of a *m*-xylyl-based TACN ligand.[583] Structures of four mononuclear copper(I) complexes ((**792**)–(**795**)), supported by tridentate macrocycle, were also reported by this group. They investigated their oxygenation behavior and in each case clean formation of side-on peroxo-dicopper(II) species was demonstrated.[416]

In their effort to model nitrite reductases,[72] Tolman and co-workers reported[410–412] structures of substrate-bound copper(I) complexes (**796**) (distorted tetrahedral) and (**797**) (distorted tetrahedral). Using hybrid triazacyclononane (TACN)-pyridyl ligands, this group reported[584] structural and properties of complexes (**798**) and its 6-phenyl-substituted pyridyl derivative [Cu(L)][SbF$_6$]. The copper(I) geometry in both complexes is distorted trigonal pyramidal. They structurally characterized a copper(II) complex [(L)Cu(ONO)][CF$_3$SO$_3$]·CH$_2$Cl$_2$ (L as that in (**798**); however, without the phenyl substituent in the pyridyl ring) (**799**) as well. Low-temperature oxygenation experiments demonstrated the formation of trans-1,2-peroxo species.

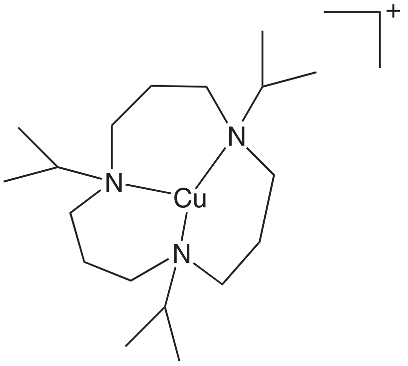
Using 1,4,8,11-tetraazacyclotetradecane, the structure of complex (**800**) (distorted trigonal planar; Cu–Cu: 6.739 Å) was determined. Reactivity with O$_2$ was investigated to demonstrate the formation of trans-1,2-peroxo species.[585] As part of their work with copper(I) complexes with O$_2$, the structure of a dicopper(I) complex ((**801**): distorted tetrahedral; 7.04 Å), supported by macrocyclic ligand environment, was reported by Comba and co-workers.[586] Tolman and co-workers structurally characterized a three-coordinate copper(I)–phenoxide complex (**802**) (planar T-shaped) that models the reduced form of GO.[587] The copper(I) analogue [Cu(L)][CF$_3$SO$_3$]·0.43MeOH (**803**) of a copper(II) complex (**534**) was also reported to demonstrate the role of ligand framework conformability in Cu^{II}/Cu^{I} redox potentials.[434] Wilson and co-workers



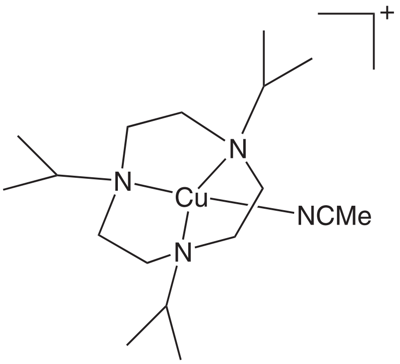
$[(L)Cu(MeCN)][ClO_4]$ (**792**)



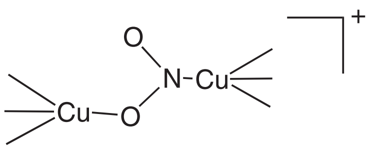
$[(L)Cu(MeCN)][SbF_6]$ (**793**)



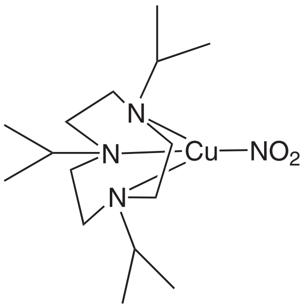
$[Cu(L)][ClO_4]$ (**794**)



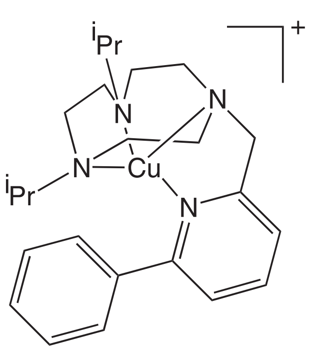
$[(L)Cu(MeCN)][BPh_4]$ (**795**)



$[(i\text{-}Pr_3TACN)_2Cu_2(ONO)][PF_6]$ (**796**)



$[(L)Cu(NO_2)]$ (**797**)



$[Cu(L)][SbF_6]$ (**798**)

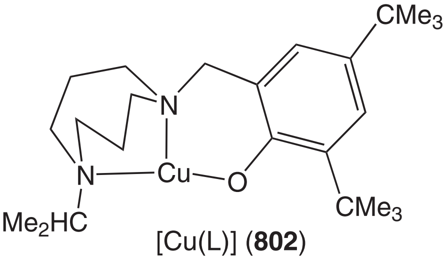
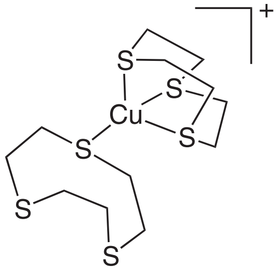
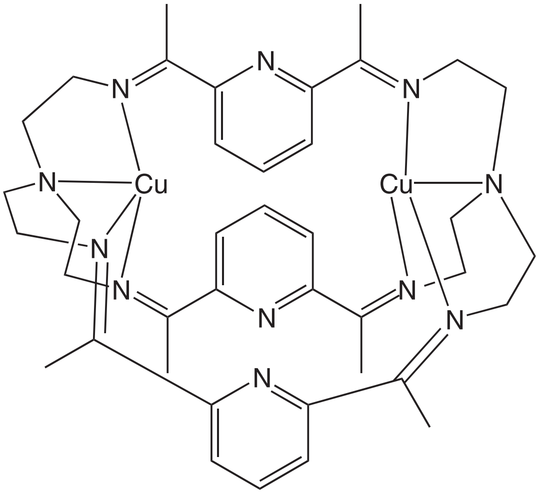
$[(L)Cu(MeCN)]_2$ (**801**)



[Cu(L)] (**802**)



$[Cu(L)_2][PF_6]$ (**804**)



$[Cu_2(L)][BF_4]_2$ (**806**)

reported the structure of a copper(I) complex (**804**) having CuS_4 coordination.[588] Rorabacher and co-workers reported the structure of a complex $[Cu(L)][ClO_4]\cdot 0.25H_2O$ (**805**) (flattened tetrahedral; L as that in complexes (**551**)/(**552**)).[449] Using a Schiff-base cryptand, Fenton and co-workers structurally characterized a dicopper(I) complex (**806**) (trigonal pyramidal; Cu–Cu: 6.25 Å).[445]

ACKNOWLEDGMENTS

The greater part of this manuscript was prepared during the author's stay in the laboratory of Prof. (Dr.) Siegfried Schindler, Institut für Anorganische Chemie, Universität Erlangen-Nürnberg, Erlangen, Germany, as part of a joint collaborative project funded by the Volkswagen Foundation. I wish to express my warmest thanks to Prof. Schindler and Prof. (Dr.) Rudi van Eldik of the same Institute for their cooperation.

Silver and Gold

M. C. GIMENO and A. LAGUNA
University of Zaragoza-C.S.I.C., Spain

6.7.1 INTRODUCTION

In spite of the similarity of electronic structures and ionization potentials, the chemistries of Ag and Au differ more than might be expected. Main differences between silver and gold are consequence of the relativistic effects, which are especially important for gold. There is a contraction of the 6*s*-orbitals and this stabilization diminishes the energy gap between these and the 5*d*-orbitals, which also undergo an expansion. Both of these effects are much less pronounced in silver, with the result that the energetic separation of the valence *d* and *s* shells of gold is significantly smaller than that in silver.

(i) The first consequence of these effects is the color of gold. Gold has an absorption beginning at 2.4 eV, attributed to a transition from the filled 5*d* band to the Fermi level (essentially the 6*s* band). It therefore reflects red and yellow light and strongly absorbs blue and violet. The analogous absorption for silver, however, lies in the ultraviolet, at around 3.7 eV.

(ii) A marked reduction in the lengths of covalent bonds involving gold atoms is often found and the covalent radius of gold is smaller than that of silver. Schmidbaur has recently confirmed this in the isomorphous di-coordinated complexes $[M(PMes_3)_2]BF_4$ (M = Ag, Au; Mes = mesityl).[1] The estimated covalent radius for silver and gold is 1.33 Å and 1.25 Å, respectively, so di-coordinated gold is smaller than silver in about 0.09(1) Å.

(iii) In gold, more than in silver, both states are now available for bonding. The closed shell $5d^{10}$ is no longer chemically inert and can interact with other elements, i.e., with other gold atoms in molecules or clusters. It also becomes possible to rationalize bonding between two gold(I) centers with equal charge and a closed shell $5d^{10}$ configuration, which is a very difficult fact to explain in terms of classical bonding. The metal atoms approach each other to an equilibrium distance of between 2.7 Å and 3.3 Å. This range includes the distance between gold atoms in gold metal and approaches, or even overlaps with, the range of distances established for the few authentic Au—Au single bonds. This effect has been called by Schmidbaur as *aurophillic attraction* or *aurophilicity*.[2]

(iv) The small difference of energy among the *s*, *p*, or *d*-orbitals leads to the efficient formation of linear two-coordinate complexes in gold(I). However, silver(I) prefers the formation of three- and four-coordinate derivatives.

(v) The destabilization of the 5*d*-orbitals permits explanation of the ease of formation of the oxidation state III in gold, which is almost absent in silver; and the stabilization of the 6*s*-orbitals, the formation of a gold(I) oxidation state which is unknown in silver.

Theoretical calculations play a key role in understanding the origin of these differences and also in the development of gold and silver chemistry. Bonding between closed-shell atoms was successfully traced in several early theoretical investigations by extended Hückel quantum chemical calculations.[3–6] Based on the hybridization concept, the nature of the bonding interaction could be qualitatively rationalized in the language of chemists. The introduction of relativistic effects in more advance calculations has shown that bonding between closed-shell metal atoms or ions may be strongly enhanced by these effects.[7–16] Since relativistic effects have been known to reach a local maximum for gold in particular, aurophilicity was accepted as a logical consequence of these contributions. Actually aurophilic bonding is considered as an effect based largely on electron correlation of the closed-shell components, somewhat similar to van der Waals interactions but unusually strong.[14] All of these studies have consistently shown that calculations will reproduce the attractive forces between the gold atoms really well only if relativistic affects are included.

Studies carried out with silver proved that compounds can be found which show convincing evidence for such closed-shell interactions.[15–19] In many of the examples the metal–metal contacts are enforced by the ligands to give what is called "ligand-supported interactions." The number of unsupported contacts is extremely limited[17] and estimations of the energies involved gives values of only a few kilocalories, close to those of standard van der Waals interactions. Nevertheless it is clear that there are small contributions from metallophilic bonding which should not be ignored.

Since the early 1980s the chemistry of gold and silver has been in a continuous expansion, not only well-established areas of research have developed but also new innovative approaches have allowed a great diversification of the research interests.

The chemistry of silver in high oxidation states is not much abundant and is limited to complexes with very electronegative ligands such as $[Ag^{III}F_6]^{3-}$, $[Ag^{III}(OH)_4]^-$, etc. or with special ligands, such as porphyrins and *N*-donor macrocycles.[20] Recently, the trivalent fluoride AgF_3 or the oxides Ag_2O_3 or Ag_3O_4 (Ag^{II}/Ag^{III}) have been reported.[21–23] Oxidation of silver(I) salts in the presence of nitrogen ligands gives the corresponding silver(II) complexes, they are paramagnetic and their electronic spectra are in agreement with square coordination.[20]

Silver(I) coordination chemistry produces a stream of unusual structures, and a great number of complexes with all type of donor ligands have been prepared. An important feature of the chemistry of silver(I) is the great tendency to form supramolecular compounds: polynuclear species, oligomers, polymers, clusters, etc.

The silver(I) carbonyl complexes $[Ag(CO)]^+$, $[Ag(CO)_2]^+$, and the stable $[Ag\{HB[3,5\text{-}(CF_3)_2pz]_3\}(CO)]$ (where pz = pyrazolyl) have been characterized spectroscopically and crystallographically, they indicate little or no Ag to CO π-back bonding.[24–26]

Silver(I) forms several complexes with very weakly coordinating ligands such as CH_2Cl_2 or other halogenated derivatives.[27–29] It has a relatively low affinity for oxygen atoms, although quite a few complexes with β-diketonates, carboxilate, crown ethers, etc. are known. However, it forms numerous complexes with the donor atoms S, Se, P, and As. Important sulfur ligands are thiolates, dithiocarbamates, thioureas (tu), and thioethers. With thiolates, many oligomers have been described[30,31] of the type $[Ag(SR)]_n$ and with other ligands cluster-type complexes are easily obtained, including five- and six-coordinate complexes with sulfur macrocycles. With phosphines and arsines, many stable compounds are known and their structures depend on the steric requirements of the ligands. A combination of diphosphine and chalcogenide silver(I) derivatives, $[Ag_4(\mu_4\text{-}E)(\mu\text{-dppm})_4]^{2+}$ (E = S, Se, Te; dppm = bis(diphenyl phosphino)methane) has been found to be luminescent.[32,33] High nuclear silver chalcogenide clusters stabilized with phosphine ligands have been prepared; they possess interesting structural frameworks and range from small to very large clusters, e.g., $[Ag_{172}Se_{40}(SeBu^n)_{92}(dppp)_4]$[34] (where dppp = 1,3-bis(diphenylphosphino)propane). Complexes with nitrogen donor ligands are very stable and numerous, they also form unusual structures that goes from normal molecular species to supramolecular 2D and 3D networks. Flexible ligands are typical building elements, rigid rod-like organic units are used to connect metal centers and long flexible-chain bidentate ligands have shown the ability to produce unique interwoven extended structural motifs.[35]

Although the Ag···Ag interactions are not very strong, there are many examples of complexes, which contain Ag···M contacts. Silver forms very stable heteropolynuclear complexes with different structural motifs, among them it is worth mentioning the species where silver interacts with platinum, gold, iron, mercury, etc.

The chemistry of gold has experimented a great advance in all oxidation states. Gold(V) is limited to the presence of very electronegative groups, $[AuF_6]^-$.[36] Gold(IV) complexes are available by electrochemical oxidation of gold(III) derivatives with ligands able to delocalize electron density such as dithiolates.

Gold(III) gives stable complexes with N, S, P, and C-donor ligands and also with oxygen-based ligands. Orthometallated species have been synthesized. The geometry is generally square-planar but with bidentate ligands pseudo-pentacoordination can be achieved.

The chemistry of mononuclear gold(II) species is not very extensive because most of them are prepared by reduction of the gold(III) species with ligands able to delocalize electron density. A rich chemistry on dinuclear diamagnetic gold(II) derivatives have been carried out on bis(ylide) gold(II) species, $[Au_2X_2\{\mu\text{-}(CH_2)_2PPh_2\}_2]$,[37] they have a great stability that allows a great variety of substitution reactions. The first metal–xenon compound, $[AuXe_4](Sb_2F_{11})_2$ obtained by reduction of AuX_3 with elemental xenon, deserves special mention.[38] The geometry is square-planar and the bonding between gold and xenon is of the σ-donor type, with a charge of approximately 0.4 per xenon atom. Other Au^{II}–Xe and the first Au^{III}–Xe compounds have been reported.[39]

Gold(I) is by far the most studied oxidation state of this metal. The most striking phenomenon was the tendency of the linear gold(I) compounds to associate in dimers, oligomers, or even polymers via short gold(I)–gold(I) interactions. These attractions are weaker than most covalent or ionic bonds, but stronger than other van der Waals and comparable in strength to typical hydrogen bonds, ca. $33\,kJ\,mol^{-1}$. The most convincing example of aurophilicity is found in polyaurated molecules. Double auration at halide anions to give V-shaped cations with small angles are known for chloride and bromide. Oxide anions have shown to accept up to four gold atoms to give trigonal pyramidal or tetrahedral complexes. Sulfide, selenide, and telluride anions can reach coordination numbers from two to six, and the resulting complexes have structures clearly determined by Au–Au interactions. Nitrogen became pentacoordinate, phosphorus hexacoordinate, and arsenic tetracoordinate in homoleptic phosphine species. Carbon was one of the first examples of polyauration and pentacoordinate and hexacoordinate compounds have been described.[2] This work has also been extended to several ligands containing these atoms, such as alcoxides, thiolates, selenolates, amine, etc.[2]

Although the [AuCl(CO)] complex has been known since 1925, the linear dicarbonyl cation $[Au(CO)_2]^+$ has been obtained as thermally stable UF_6^{2-} or $Sb_2F_{11}^{2-}$ salts only recently; in these compounds back-bonding to CO is almost entirely absent.[40,41]

Many gold(I) complexes are susceptible of having optical properties and consequently in the last few years several reports have dealt with luminescence in gold complexes.[34,42,43] It has been shown that the luminescence has its origin in the nature of the ligands, in the geometry around the metal center, and in the presence of metal–metal interactions. In this area important development has been made in gold-heterometal complexes (Cu, Ag, Tl, Ir, etc.).[43] Many Au···Au bonded species show intense photoluminescence in the UV–visible region if investigated in the solid state, although this effect may vanish in solution. It has also demonstrated that luminescence of gold complexes can be triggered by solvatation of the donor-free solid substrate either from the vapor phase or by dissolving the material in a solvent. Bachman *et al.* have reported the construction of striking "rotator phases" of gold complexes based solely on their metal–metal interactions. The behavior of gold complexes in these rotator phases could potentially be modified to produce interesting and useful structures, such as metal-based liquid crystals or photoluminescent materials.[44]

Gold clusters, where the gold has an oxidation state intermediate between 0 and +1, have been synthesized with several nuclearities, from the smallest Au_4^{2+} units to the largest structurally characterized gold cluster, $[Au_{39}Cl_6(PPh_3)_{14}]^{2+}$,[45] although spectroscopic evidence exist for the cluster $[Au_{55}Cl_6(PPh_3)_{12}]$.[46] Important work has been done in the area of high-nuclearity mixed-metal clusters, mainly of gold and silver, whose metal framework is based on vertex-sharing polyicosahedra.[47]

Monomeric zerovalent gold complexes are rare; they are thermodynamically too unstable to be used in chemical transformations. Recently the reduction of gold(I) complexes with the macrocyclic silacalix[n]phosphinine ligands has allowed the synthesis of gold(0) derivatives.[48] These ligands possess an adequate electronic balance between σ-donating and π-accepting properties in such a way that they might act as equivalent to carbonyl groups. Gold is unique among the transition metals in its ability to form isolable nonmetallic compounds that contain a monoatomic anion. The compounds NMe_4Au and $CsAu{\cdot}NH_3$ are recent examples.[49,50]

These metals and their complexes also have special characteristics that made them adequate for several uses. Gold possesses special characteristic features, which make it unique, such as high chemical and thermal stability, mechanical softness, high electrical conductivity, and beautiful appearance. All these attributes will rise to many relevant applications. For example, gold is an indispensable element for nanoscale electronic devices because it is resistant to oxidation and mechanically robust. The well-known elegant red color in Venetian crystal glass arises from surface plasmon absorption of blue light by gold nanoparticles a few tens of nm in size. Gold compounds have already been used successfully for the treatment of rheumatoid arthritis. Also gold is an outstanding element for use as heterogeneous catalysts operating at ambient temperature because it is catalytically active at low temperature (200–350 K compared with Pd and Pt at 400–800 K); in the last few years several uses in homogeneous catalysis have been found.[51–58] Silver(I) exhibits a rich biological chemistry, serving as a widely used antibacterial agent[59,60] and a transcriptional initiator in plants[61] and mammals.[61–63] β-Diketonate compounds found use as precursors for chemical vapor deposition (CVD) of silver films.[64] Silver stilbazole compounds have liquid crystal behavior.[65] Silver clusters in zeolite host may have found an application for new information storage or optical materials.

The presentation of the material in this review largely follows an order of decreasing oxidation states and, in each oxidation state, a categorization by donor atom will be presented. It covers the major developments in coordination chemistry since the early 1980s. Previous literature can be found in *CCC (1987)* or *Comprehensive Organometallic Chemistry*.[66–69] Reviews, which have been published since the early 1980s, include for silver surveys of structural chemistry,[70] organosilver chemistry,[71] high oxidation states,[21] liquid crystal,[59–65] and coordination chemistry.[72,76] The reader is referred to gold surveys on general organogold chemistry[71,78,79] and more specialized accounts on topics such as structural chemistry (X-ray and Mössbauer data),[80–86] coordination chemistry,[87–91] aurophilicity,[92–96] high-coordinated compounds,[97] aryl gold chemistry,[98,99] luminescence properties,[34,42,43,100] bioinorganic chemistry,[101–105] liquid crystals,[106] dendrimers,[107] cluster chemistry,[108–112] and theoretical calculations.[14,16,113,114] Also of interest is the book "*Gold, Progress in Chemistry, Biochemistry and Technology*."[115]

6.7.2 SILVER

6.7.2.1 Silver(III)

Silver(III), with a d^8 electronic configuration, forms only a limited number of stable compounds because of the inaccessibility of a suitable ligand framework to coordinatively bind the unusual, higher valent central metal while, at the same time, resisting intramolecular electron transfer. They are thermodynamically and kinetically unstable.

The long known silver oxide AgO is really a mixed-valence oxide that contains Ag^{III}. Due to its important use in batteries,[116] a new economical and high yield process for its preparation has been reported.[117] It consists of the oxidation of an aqueous, alkaline silver nitrate solution with mixtures of sulfur dioxide and oxygen in air, or with mixtures of sulfite solutions and oxygen in air. Another example of well-characterized silver(III) compounds is the stoichiometric Ag_2O_3, which is prepared by anodic oxidation of neutral aqueous solutions of $AgClO_4$ or $AgBF_4$.[22] The structure shows that silver is coordinated by an almost square-planar array of oxygen atoms; the AgO_4 groups are linked via common O-atoms to give a 3D network structure. Oxidation to lower potentials leads to the silver(II, III) oxide Ag_3O_4.[23] The silver atoms are exclusively in a square-planar environment.

Diamagnetic salts of the $[AgF_4]^-$ ion were first described by Hoppe in 1957 and they are isomorphous with their $[AuF_4]^-$ relatives.[118] More recently the use of krypton fluoride in anhydrous hydrogen fluoride has allowed the synthesis of $[AgF_4]^-$ at room temperature,[119] but this powerful oxidative fluorinator failed in getting any oxidation state beyond Ag^{III}, despite the relative ease of oxidation by that reagent of $[AuF_4]^-$ to $[AuF_6]^-$.[120] Another high yield, room temperature synthesis of $K[AgF_4]$ is obtained by reaction of AgF_2 in liquid anhydrous hydrogen fluoride with KF and sunlight or UV-irradiated F_2.[121] In addition, a facile route to $[AgF_4]^-$ using O_2F, generated *in situ*, has been described.[122] The ^{109}Ag NMR spectrum of $[AgF_4]^-$ has a chemical shift far from any other silver compound, thus reflecting the extreme chemical properties of this anion.[123] The UV–visible spectra for Ag^{III} fluorides have also been reported.[124] The unstable $NO[AgF_4]$ has also been described.[125] The synthesis of AgF_3 has been a matter of controversy. It was first claimed by Bougon, Lance, and Seances in 1983.[126] They described a red–brown, highly reactive solid, made by fluorination of the metal or its mono- or difluoride in anhydrous HF, by KrF_2 at room temperature. The X-ray powder diffraction data[125,126] showed that the red–brown solid was not structurally related to AuF_3. Furthermore, the solid proved to be weakly paramagnetic,[125] thus raising the possibility of some Ag^{III} being in the triplet state. AgF_3 was also claimed by Kiselev *et al.* to be formed in the interaction of AgF_2 with O_2F_2 in ClF_5.[127] The X-ray powder data showed that the compound was no isomorphous with AuF_3. Recently, red, diamagnetic AgF_3 has been obtained by Bartlett and co-workers as a precipitate by adding to $[AgF_4]^-$, in anhydrous HF solutions, fluoro acids such as BF_3, PF_5, or AsF_5.[24,128] It is isostructural with AuF_3 and the structure consists of a silver atom in a elongated octahedron; the AgF_4 square units are joined by symmetrical fluoro bridges in *cis*, forming a helical chain. It is thermodynamically unstable and loses F_2 in contact with anhydrous HF at ~20 °C, giving Ag_3F_8, a mixed-valence compound $Ag^{II}Ag^{III}{}_2F_8$ that is identified as the previously claimed AgF_3. Also another mixed-valence fluoride, $Ag^{II}Ag^{III}F_5$, is prepared by reaction of AgF^+ with $[AgF_4]^-$ in anhydrous HF.[24]

The tetrahydroxoargentate(III) ion, $[Ag(OH)_4]^-$, is a strongly oxidizing square-planar system that can be prepared by the electrochemical oxidation of a silver anode in 1.2 M NaOH. It is the simplest source of tervalent silver in solution. Rush and Kirschenbaum have carried out kinetic studies upon the substitution reactions of $[Ag(OH)_4]^-$ with a variety of substrates including phosphate, borate, carbonate, and arsenate,[129] and its reduction by H_2O_2,[130] $[Mo(CN)_8]^{4-}$ and $[W(CN)_8]^{4-}$,[131,132] N_3^-,[133] $S_2O_3^{2-}$,[134] AsO_2^-,[135] $H_2PO_2^-$,[136] 4-Bu^{t}PhO$^-$,[137] SO_3^{2-},[138] SCN^-,[139] CN^-,[140] and $EDTA^{4-}$[141] The results indicate that silver(III) is reduced through a variety of mechanisms. In the oxidation of azide and thiosulfate, transient Ag^{III}-substrate complexes could be detected, $[Ag(OH)_3N_3]^-$ or $[Ag(OH)_3(S_2O_3)]^{2-}$. In other cases, the redox occurs within the five-coordinate intermediate. In the oxidation of oxoanions such as arsenite, sulfite, or hypophosphite, five-coordinate intermediates are also possible, and a two-electron redox step (inner sphere) and oxygen atom transfer is involved.

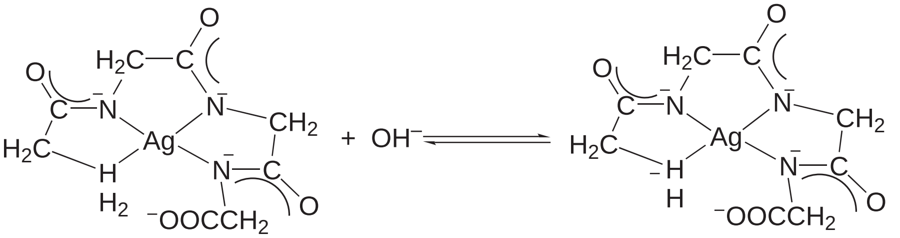
Silver(III) forms stable complexes with biguanide ligands. The kinetics of the oxidation of formic acid,[142] hydrogen peroxide,[143] hydrazine,[144] H_3PO_2,[145] NO_2^-,[146] oxalic acid, and dioxalate[147] by the ethylenebis(biguanide)silver(III) cation have been investigated. The electron transfer from organic or metal complex reductants to the silver(III) complex has been studied by stopped-flow techniques in aqueous media.[148] The kinetics of the oxidation of ascorbic acid by a silver(III) compound with a related tetraaza macrocyclic ligand have been investigated and the mechanism has been shown to be inner sphere.[149] Silver(III) compounds with periodate or tellurate were reported many years ago, and they were believed to be octahedrally coordinated. The X-ray structure of $K_5[Ag(HIO_6)_2]\cdot 2H_2O$ reveals planar four-coordinate silver[150] and the spectroscopic studies of $Na_5[Ag\{TeO_4(OH)_2\}_2]$ and $Na_5[Ag\{IO_5(OH)\}_2]$ indicates the same coordination for silver. [151] This type of complexes are strong oxidants, and representative examples of this aspect of their chemistry are the reactions with aldehydes,[152] alcohols,[153] amines,[154] $CH_2{=}CHX$

($X=CN$, $CONH_2$, CO_2^-),[155] and pyrimidine nucleobases.[156] A kinetic study of the oxidation of azide by $[Ag^{III}(H_2TeO_6)_2]^{5-}$ shows that the reaction proceeds through the fast formation of a $[Ag^{III}(TeO_4)_2(OH)_3N_3]^{5-}$ intermediate, followed by a slow reaction with H_2O to give $[AgI(TeO_4)_2(OH)_4]^{7-}$ and N_3^+, a one-step, two-electron process.[157]

A relatively long-lived $Ag^{III}_{(solv)}$ species, generated in anhydrous HF solutions of AgF_3 in the presence of strong F^- acceptors acids (AsF_5, SbF_5, BiF_3), has been put forward as the most powerful oxidant known, capable of oxidizing O_2 to O_2^+.[158]

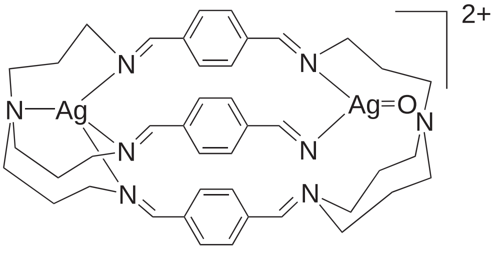
The electrochemistry of silver porphyrin complexes has been reinvestigated in compounds [Ag{TPP(*p*-X)}]. Up to four reversible electron reactions were observed for each complex which corresponds to the formation of $[Ag^{III}\{TPP(p\text{-}X)\}]^+$, $[Ag^{III}\{TPP(p\text{-}X)\}]^{2+}$ anion radical, the Ag^I complex, and Ag^I anion radical.[159] Also evidence for residual paramagnetism in silver(III) metalloporphyrin complexes has been reported, this is attributed to the presence of Ag^{II} in small amounts and may have found a use in generating molecular conductors or semiconductors.[160] The Ag^{II} complex with the 14-membered tetraaza macrocycle ligand undergoes a reversible one-electron oxidation process to give an authentic Ag^{III} species. The Ag^{III}/Ag^{II} redox couple potential (0.835 V vs. Ag/AgCl) is affected by variation in the acidity of the solution, indicating that the complex behaves as a fairly strong acid (pK = 2.6).[161]

Silver(III) complexes with polypeptides[162] such as triglycine (G_3) and tetraglycine (G_4) or with *vic*-dioximate[163] ligands such as dimethylglioximate, diphenylglioximate, and cyclohexane-1,2-dione dioximate have been obtained by direct reaction of $[Ag(OH)_4]^-$ and the ligands in alkaline solutions. For the polypeptide complexes the kinetics of the formation reactions are complex. In Equation (1) the proposed structures for the protonated $[Ag(H_{-3}G_4)]^-$ and $[Ag(H_{-4}G_4)]^{2-}$ are shown. The *vic*-dioximate complexes are intensively colored with two ligand-to-metal charge transfer bands; they undergo an internal redox within several minutes.

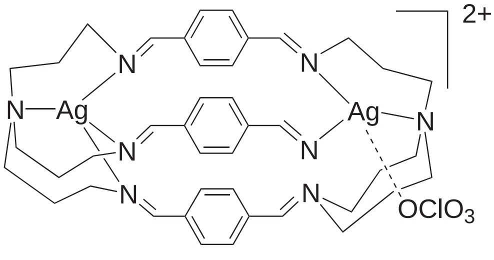


(1)

A mixed valence silver(I)–silver(III) crypate complex (**1**) has been obtained by condensation of tris(3-aminopropyl)amine and terephthaldehyde in the presence of $AgNO_3$. The silver(III) center is coordinated to two imino nitrogens and to one oxygen atom, in a trigonal planar geometry.[164] The nature of (**1**) has been questioned by a subsequent reinvestigation of its crystal structure. According to this second interpretation the complex has two silver(I) atoms, one four-coordinate and the other disordered between a tetrahedral AgN_4 (22%) and trigonal planar AgN_3 (78%, (**2**)) with a long interaction to the oxygen atom of the perchlorate anion.[165] Consequently, the theoretical studies in the Ag=O bond length gave a higher value to that found experimentally, 1.59 Å.[166]



(1)

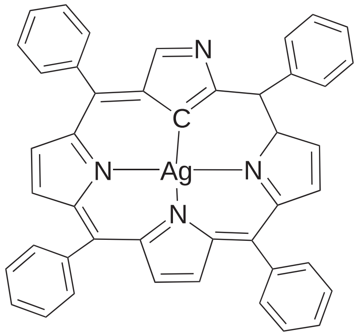


(2)

Oxidation of the complexes $[Ag(Py)_4][MoF_6]$ and $[Ag(Py)_2][UF_6]$ in acetonitrile by MoF_6 and UF_6, respectively, leads to the silver(III) compounds $[Ag(Py)_4(NCMe)][MoF_6]_3$ and $[Ag(Py)_2(NCMe)_3][UF_6]_3$, which are strong oxidizing agents.[167] Other pyridine silver(III) complexes have been obtained by oxidation of silver nitrate and ammonia with ammonium peroxydisulfate in aqueous ammonia solution. At high pH *trans*-$[Ag(Py)_2(N_2)_2](OH)_3$ was obtained, which was converted to $[Ag(Py)_2(N_2)_2](ClO_4)_3$, and at lower pH *trans*-$[Ag(Py)_4](ClO_4)_2(NO_3)$ was isolated.[168]

(Trifluoromethyl)argentates(III) complexes of the type $[Ag(CF_3)_n(CN)_{4-n}]^-$ have been prepared by oxidation of $[Ag(CF_3)CN]^-$ with bromine. The stability decreases with an increasing number of CN groups. Substitution reactions in these complexes give $[Ag(CF_3)_nX_{4-n}]^-$ (X = Cl, Br) or $[Ag(CF_3)_3R]^-$ (R = Me, C_2Cy).[169] $[Ag(CF_3)_3(MeCN)]$ is formed in numerous reactions of $M[Ag(CF_3)_4]$ with acidic compounds. This complex reacts with halides to give $[Ag(CF_3)_3X]^-$ (X = Cl, Br) or with $Cd(C_2F_5)_2$ to yield $[Ag(CF_3)_3(C_2F_5)]^-$. Oxidation of trifluoromethylsilver(I) compounds with tetraethyl thiuram disulfide leads to the neutral silver(III) complex $[Ag(CF_3)_2(S_2CNEt_2)]$.[170] Another related organometallic compound of silver(III), $[N(PPh_3)_2][Ag(CF_2H)_4]$, has been obtained by oxidation of the corresponding silver(I) compound.[171] Also the reaction of diethyldithiocarbamate with silver(I) in the presence of hydrogen peroxide gives $[Ag_2(S_2CNEt_2)_2(OH)_2](ClO_4)_2$.[172]

The first example of an air-stable silver(III) complex of an *N*-confused tetraphenylporphyrin (5,10,15,20-tetraphenyl-2-aza-21-carboporphyrin argentate(III) (**3**)) has been described.[173] The complex is diamagnetic and the electrochemistry shows that ring reduction or oxidation is possible.



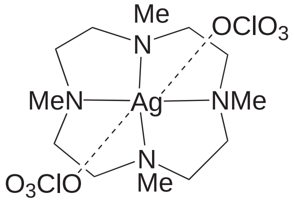
(**3**)

6.7.2.2 Silver(II)

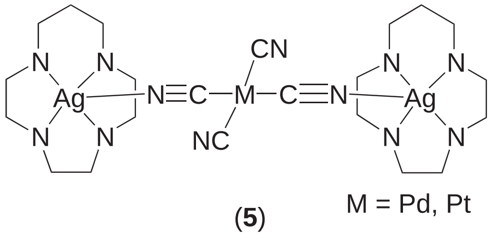
As d^9 species, silver(II) compounds are expected to be paramagnetic and in practice with the notable exception of AgF_2, the compounds are mostly magnetically dilute with μ_{eff} consistent with one unpaired electron. Many examples of planar four-coordinate compounds are known, and a smaller number of six-coordinate complexes (with Jahn-Teller distortion). The only simple silver(II) compound appears to be the fluoride, AgF_2, and a wide range of related fluorides has been characterized. Heterocyclic nitrogen ligands stabilize silver(II) and many examples have been known for a long time.

The Ag^{II} oxidation state is peculiar for fluoro ligand systems. Although, in its ligand-field effects, oxygen is close to fluorine, Ag^{II} does not occur in oxides where AgO is $Ag^IAg^{III}O_2$. However, the attempts to disproportionate AgF_2 did not succeed. The mixed-valence fluoride $Ag^IAg^{III}F_4$ has been obtained as a red–brown diamagnetic solid by interaction of Ag^+ salts, in anhydrous liquid hydrogen fluoride (aHF), with AgF_4^-. This compound transforms exothermically to brown, paramagnetic AgF_2 below 0 °C.[174] Disproportionation of Ag^{II} in Ag^I and Ag^{III} has been achieved with $Ag^{II}FAsF_6$,[175] which disproportionates in aHF to colorless Ag^IAsF_6 and a black pseudotrifluoride $(Ag^{II}F^+)_2Ag^{III}F_4^-AsF_6^-$.[174] This type of compound, $(AgF)_2AgF_4MF_6$, is also generated by oxidation of AgF_2 or AgF^+ salts in aHF with F_2 or in solutions of $O_2^+MF_6^-$ salts (M = As, Sb, Pt, Au, Ru).[174] The reaction of AgF_2 with excess of SbF_5 in aHF gives the adduct $AgF_2 \cdot 2SbF_5$, the silver atom is square-planar with two different Ag—F bond lengths and other two long Ag—F distances.[176] Mixed fluoride complexes where the silver atom has a trigonal bipyramidal geometry are $AgM^{II}{}_3M^{IV}{}_3F_{20}$ (M^{II} = Cd, Ca, Hg; M^{IV} = Zr, Hf).[177] Other silver(II) fluorides of the type $Ag[MF_6]_2$ (M = Nb, Ta) or $Ag[AuF_4]_2$ have been described.[178,179] Blue solutions of AgF_2 in aHF with BF_3 or AsF_5 oxidize Xe to Xe^{II} at ~20 °C.[180] A potent oxidant $Ag^{II}{}_{(solv)}$ has been generated by treatment of $AgFAsF_6$ with AsF_5 or $AgAsF_6$ with O_2AsF_6 in aHF; it is capable of oxidizing O_2 to O_2^+.[158] The reaction of $AgMF_6$ (M = Ir, Ru, Bi, Sb) with F_2 in aHF gave $(AgF^+)_n(MF_6^-)_n$.[158,181] The reaction of UF_6 and AgF in aHF has been re-investigated and the new results support the formation of an intermediate red solid, proposed to be Ag_2UF_8, which subsequently decomposes to AgF_2 and $AgUF_6$.[182]

Silver(I) in the presence of tetraaza macrocyclic ligands disproportionates to Ag^0 and the Ag^{II} derivatives. Recent studies have shown that disproportionation depends upon the ring size of the macrocycle, thus while 14-, 15-, and 16-ring tetraaza macrocycles cause disproportionation, larger rings do not.[183,184] The smaller ring sizes lead to strong Ag–N interaction, which raises the antibonding 4*d*-orbitals sufficiently so that removal of an electron is facilitated. The electrochemical behavior of this type of complexes has been studied. The behavior is complex and both solvent and ligand dependent.[185,186] Also the rate constants for the electron transfer reactions of these complexes have been determined by pulse radiolysis. The self-exchange rate constants reveal slow exchanges for $d^{9/10}$ couples and fast exchanges for $d^{8/9}$ couples.[187] The crystal structures for two silver(II) complexes with macrocycles have been reported, complex (**4**) and other with the ligand 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane.[188,189] The environment about the Ag^{II} is approximately square-planar. Two bimetallic Ag^{II} coordination polymers, $[Ag(cyclam)M(CN)_2(\mu\text{-}CN)_2]_n$ (M = Pd, Pt; cyclam = 1,4,8,11-tetraazacyclotetradecane) (**5**), were synthesized by reaction of $[Ag(cyclam)](ClO_4)_2$ with $K_2[M(CN)_4]\cdot3H_2O$.[190]



(**4**)



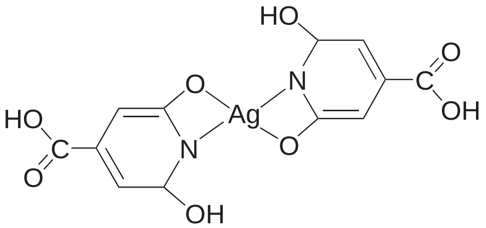
(**5**)

A mixed-valence complex $[Ag^{II}(tmc)(BF_4)][Ag^I_6(C_2)(CF_3CO_2)_5(H_2O)]\cdot H_2O$ (tmc = 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane) has been prepared, in which a $[Ag^{II}(tmc)(BF_4)]^+$ cationic column induces the assembly of a anionic zig-zag chain constructed from edge-sharing silver(I) triangulated dodecaedra, each enclosing a C_2^{2-} species. The Ag···Ag distances lie in the range 2.818–3.366(1) Å, which is suggestive of significant argentophilic interaction.[191]

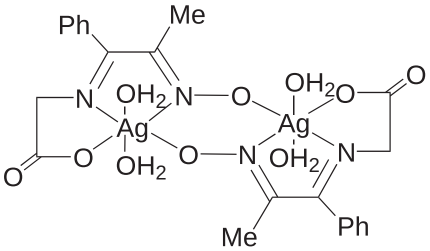
Another class of nitrogen donor ligands, which favor Ag^{II} over Ag^I, is porphyrins, which like macrocycles provide strong in-plane ligand fields, which facilitate oxidation of the metal. The electrochemical reduction of silver(II) porphyrins results in generation of an unstable $[Ag^I$(porphyrin)] which rapidly demetallates to form Ag^+ ions and the free porphyrin base;[192] also the oxidation and reduction processes has been investigated.[159] The electronic structures of $[Ag^{II}$(porphyrin)] have been investigated by $X\alpha$-calculations.[193] Water-soluble silver(II) complexes have been prepared mainly using modified tetraphenylporphyrin, with $p\text{-}Me^+NC_5H_4{}^+$, $p\text{-}Me_3{}^+NC_6H_4{}^-$, or $p\text{-}O_3SC_6H_4$ groups replacing phenyl.[194–197] Silver(II) complexes with tetraphenylporphyrin, octaethylporphyrin, etioporphyrin, and the one-electron oxidation compounds has been examined by NMR spectroscopy. A metal-centered oxidation occurs for the silver(II) compounds in contrast with the behavior of copper(II) where the oxidation is porphyrin-centered.[198] The oxidation of the labile silver(I) complex $[Ag_2(tmptp)]$ (tmptp = 5,10,15,20-tetra(3′-*N*-methylpyridinio)porphyrin with peroxodisulfate to give the silver(II) compound was found to be first order each in silver(I) and peroxodisulfate ions and zero order in porphyrin.[199] Single-crystal EPR spectra have been obtained for two spin-labeled silver porphyrins doped into zinc tetraphenylporphyrin. For each of the complexes four conformations were obtained.[200] The crystal structures of silver(II) derivatives of *meso*-tetraphenylporphyrin have been carried out. The Ag—N distances are found to be statistically nonequivalent, and this probably arises from asymmetric lattice packing.[201] Fast-atom bombardment mass spectrometry has been used to study porphyrins and their metal complexes; rates of demetallation and inter- and intramolecular electron transfer processes have been investigated. The one-electron reduction of AgP occurs via an excited state intermediate and the rate of electron transfer from the porphyrin ring to Ag^{II} is $2\times10^{11}\,s^{-1}$.[202] Two Ag^{II} complexes of tetra-(3′-nitrophenyl)porphyrin and tetra-(3′-aminophenyl)porphyrin have been prepared and their ESR spectra reported.[203] A phenanthroline capped porphyrin which combines in a rigid fashion a 2,9-diphenyl-phen (phen = 1,10-phenanthroline) unit and a meso-diphenyl porphyrin reacts with $AgNO_3$ with a initial complexation to the phen unit but further addition of silver produces the oxidation to Ag^{II} and coordination to the porphyrin unit.[204] When 5,10,10,15,20-tetrakis(4-carboxyphenyl)porphyrin, H_2L, is added to a silver colloid, prepared by reduction of $AgNO_3$ by $NaBH_4$, in 0.02 M phosphate buffer, a complex [AgL] is formed. SERS (Surface-Enhanced Raman Spectra) spectral data have been collected for the surface complex and have been compared with the resonance Raman spectrum of [Ag(TTP)].[205] The dimer formation constants for silver porphyrins have been obtained through EPR measurements.[206]

The preparation and characterization of the silver(II) complex [AgL] (where H_2L = tetraneopentoxyphthalocyanine) has been reported. Electrochemical studies show that oxidation to stable $[Ag^{III}L]^+$ occurs followed by further oxidation to the radical cation $[AgL]^{2+}$. Reduction to $[Ag^{I}L]^-$ leads to demetallation on the electrochemical time scale.[207]

Silver(II) forms stable complexes with other nitrogen donor ligands such as pyridine, substituted bipyridine, phenanthroline, or citrazinic acid. They are usually obtained by reaction of a silver(I) salt with peroxodisulfate in the presence of the ligand. The complex $[Ag(Py)_4](S_2O_8)$ has been used as oxidation reagent in the oxidation of organic compounds.[208] The 6,6′-dimethyl-1,2′-bipyride and 2,9-dimethyl-phen ligands form complexes of the type $[Ag(NO_3L)]PF_6{\cdot}NH_4PF_6$ which ESR spectra indicate extensive delocalization involving the nitrato ion.[209] The silver(II) complex $[Ag(H_2L)_2]$ (**6**) with citrazinic acid (H_3L) has the ligand acting as mixed bidentate through the nitrogen and one oxygen atom. It reacts with other nitrogen donor ligands such as pyridine and picoline to give the complexes $[Ag(H_2L^1)_2L^2{}_2]$.[210] The Ag^{II} complex (**7**) of a Schiff base has been proposed to have a dimeric structure based on its low magnetic moment of 1.63 BM and the presence of Ag–O and Ag–N stretches in the far-IR.[211]



(**6**)



(**7**)

The nature of Ag^{II} in solution and the kinetics and mechanisms of Ag^{II} oxidations of a variety of inorganic and organic substrates have been studied, complexes $[Ag(Py)_4]^{2+}$ and $[Ag(bipy)_2]^{2+}$ are typical examples.[212–215]

Silver(II) complexes in the gas phase have been prepared with several nitrogen- and oxygen-donor ligands including pyridine, tetrahydrofurane, benzene, CO_2, etc. The complexes are of the type $[AgL_n]^{2+}$, and the compound $[Ag(CO_2)_4]^{2+}$ is particularly stable.[216]

6.7.2.3 Silver(I)

6.7.2.3.1 Complexes with carbon donor ligands

Isolable silver(I) carbonyl complexes have been reported only recently. Previously $[Ag(CO)_n]^+$ species had been detected in zeolite host or in strongly acidic media at low temperatures and high CO pressures.[217,218] The use of very large weakly coordinating anions such as $B(OTeF_5)_4{}^-$, $Zn(OTeF_5)_4{}^{2-}$, $Ti(OTeF_5)_6{}^{2-}$, and $Nb(OTeF_5)_6{}^-$, has allowed the isolation and structural characterization of the Ag^I carbonyl complexes $[Ag(CO)]^+$ and $[Ag(CO)_2]^+$.[25,26] They are prepared under CO pressure at low temperature (Equation (2)):

$$Ag(OTeF_5) + B(OTeF_5)_3 \xrightarrow[298\text{ K, }36\text{ h}]{\text{excess CO}} [Ag(CO)_2][B(OTeF_5)_4] \tag{2}$$

This complex rapidly looses one molecule of CO, leaving $[Ag(CO)][B(OTeF_5)_4]$ and reversibly takes up another equivalent of CO at high pressure. The latter has a short C—O bond length (1.077(16) Å), long Ag—C distance (2.10(1) Å), and very high value of υ(CO) (2,204 cm^{-1}) suggested little or no π-backbonding, a situation that is virtually unprecedented in metal carbonyl

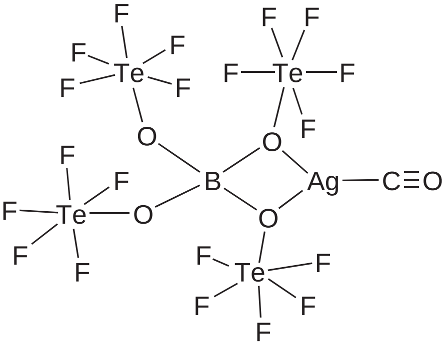


Figure 1 Structure of $[Ag(CO)][B(OTeF_5)_4]$.

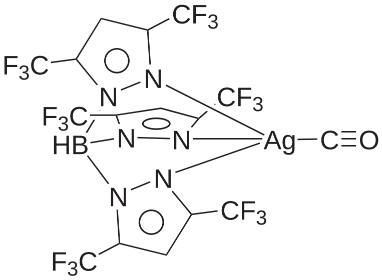
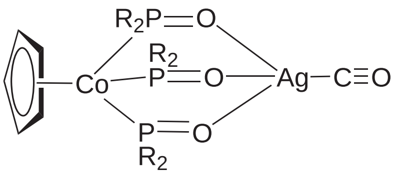
chemistry. The structure shows a trigonal planar geometry for silver bound to the carbonyl and two oxygen atoms of the anion (Figure 1).

The structure of $[Ag(CO)_2]^+$ is linear and it weakly bonds to two or more $B(OTeF_5)_4{}^-$ anions. These complexes decompose at room temperature giving $[Ag(CO)(OTeF_5)]$, CO, and $B(OTeF_5)_3$. The $Zn(OTeF_5)_4{}^{2-}$ and $Ti(OTeF_5)_6{}^{2-}$ adducts are more stable when subjected to subambient pressures of CO.

A silver tricarbonyl complex $[Ag(CO)_3][Nb(OTeF_5)_6]$ has been prepared from $Ag[Nb(OTeF_5)_6]$ under 13 atm of CO for 4 h at 298 K. It is stable at 196 K and 5–10 torr, but readily looses CO in toluene solution at 298 K.[219] An IR spectroscopic study of $Ag[Nb(OTeF_5)_6]$ in solution as well as in the solid state under variable CO pressure reveals the stepwise formation of $[Ag(CO)]^+$, $[Ag(CO)_2]^+$, and $[Ag(CO)_3]^+$, with increasing pressure favoring the higher carbonyl. The υ(CO) IR band for the tricarbonyl species is assigned at 2,192 cm^{-1}.[220] An analysis of the Ag—CO bonding in silver carbonyls has been carried out on the basis of Fenske-Hall calculations. The nonclassical behavior of the C—O stretching frequency trends has been attributed to uncompensated CO-to-metal σ-donations due to the very weak metal-to-ligand π-back donation.[221] The Ag—CO bond dissociation energies for $[Ag(CO)_n]^+$ complexes, $n = 1$–4, has been found by collision-induced dissociation mass spectrometry to be 0.92 eV, 1.13 eV, 0.57 eV, and 0.47 eV, respectively,[222] verifying earlier predictions by *ab initio* calculations. Quantum chemical investigations at the MP2 and CCSD(T) level with relativistic effective core potentials for the metals have been reported for homoleptic carbonyl complexes of the group 11 d^{10} metal cations with up to six carbonyl ligands. The complexes $[Ag(CO)_n]^+$ are predicted to be bound species for $n = 1$–6.[223] Addition of CO or CNBu to $[Ag\{HB[3,5\text{-}(CF_3)_2pz]_3\}]$ gives the corresponding $[Ag\{HB[3,5\text{-}(CF_3)_2\ pz]_3\}(CO)]$ (**8**) or $[Ag[HB\{3,5\text{-}(CF_3)_2pz]_3\}(CNBu)]$ complexes.[27] These complexes show much higher υ(CO) and υ(CN) values compared with the free ligand and seem to have predominantly σ-type Ag–ligand interaction. Similar silver(I) carbonyl or isocyanide complexes with a tripodal ligand $[Co(C_5H_5)\{P(O)R_2\}_3]^-$ (L_R) (R = OMe, OEt, OPr^i) have been obtained and are of the form $[AgL_R(CO)]$ (**9**) or $[AgL_R(CNBu^t)]$. The υ(CO) appears at 2,147 cm^{-1} which is the closer value to that found in free CO (2,143 cm^{-1}).[224] All the silver(I) carbonyl species are considered to be nonclassical because of the relatively little π-backbonding present, similar fact is found in copper carbonyl species.[225]



(**8**)



(**9**)

Silver(I) isocyanide complexes have been known for a long time and they were usually prepared by alkylation of silver cyanide.[226] More recent reports include the study of steric effects of ligands in silver(I) isocyanide complexes. The reaction of $AgPF_6$ with CNR in a 1:2 molar ratio gives $[Ag(CNR)_2]PF_6$ ($R = 2,4,6\text{-}Bu^t{}_3C_6H_2$, $2,4\text{-}Bu^t{}_2\text{-}6\text{-}MeC_6H_2$, $2,6\text{-}Me_2C_6H_3$) and further reaction with CNR yields $[Ag(CNR)_3]PF_6$ with the exception of the bulky $CN(2,4,6\text{-}Bu^t{}_3C_6H_2)$. The structure of $[Ag\{CN(2,4,6\text{-}Bu^t{}_3C_6H_2)\}_2]$ shows a distorted tetrahedral geometry with the PF_6 acting as bidentate ligand.[227] Other isocyanide silver(I) complexes of stoichiometry $[Ag(CNR)_4]ClO_4$ ($R = Me$, Cy, Bu^t) and $[Ag(CNCy)_2]ClO_4$ have been reported together with substitution reactions. Phosphine or arsine ligands produce complete isocyanide displacement whereas nitrogen donor ligands, polydentate phosphines, or phosphites give complexes of the type $[Ag(CNR)(bipy)]ClO_4$ ($R = Cy$, Bu^t), $[Ag(CNCy)(Py)]ClO_4$, or $[Ag(CNCy)L_3]ClO_4$ ($L_3 = (Ph_2PCH_2)_3CMe$, $P(OMe)_3$).[228]

Complexes with bridging cyanide groups have been synthesized. The $[Ag(CN)_2]^-$ anion is used to form additional coordination bonds through the nitrogen atoms of the cyano groups. It can act as an isolated counterion in structures with ionic character such as $[Ni(bipy)_3]_2[Ag(CN)_2]_3{\cdot}Cl{\cdot}9H_2O$;[229] as a ligand when bonded via one bridging cyano group in complexes such as $[(PPh_3)_2N][ClPh_3Sn(\mu\text{-}NC)Ag(CN)]$,[230] $[L_nMCNAgCN]$ ($L_nM = [FeCp(dppe)]^+$ (dppe = 2-bis(diphenylphosphino)ethane), $[RuCp(PPh_3)_2]^+$),[231] or $[Cr(en)_2\{Ag(CN)_2\}]ClO_4$ (en = 1,2-ethylenediamine);[232] or as bridging spacer between central atoms giving rise to polymeric structures as in complexes such as $[Cu(bipy)_2\{Ag(CN)_2\}_2][Ag(CN)_2]{\cdot}2H_2O$,[233] $[Zn(en)_2\{Ag(CN)_2\}_2][Ag(CN)_2]$[234], or $[Cu(en)_2Ag(CN)_2][Ag(CN)_2]$.[235] The dicyanodargentate(I) anion is also useful to build up multidimensional coordination polymers. Cd^{2+}, $[Ag(CN)_2]^-$, and the monodentate 4-methylpyridine are self-assembled from an aqueous solution to build up the 1D polymer chain complex $[Cd(4\text{-}Mepy)_4\{Ag_2(CN)_3\}][Ag(CN)_2]$ and an interwoven 2D network host clathrate $[Cd(4\text{-}Mepy)_2\{Ag(CN)_2\}_2]{\cdot}4\text{-}MePy$.[236] When L is an ambidentate bridging ligand such as 4,4′-bipyridine and pyrazine, 3D complexes $[Cd(4,4'\text{-bipyridine})_2\{Ag(CN)_2\}_2]$ with doubly interpenetrating and $[Cd(pyrazine)\{Ag_2(CN)_3\}\{Ag(CN)_2\}]$ with triply interpenetrating lattice structures are obtained.[237] The less bulky monodentate NH_3 in $[Cd(NH_3)_2\{Ag(CN)_2\}_2]$ gives a 3D warp-and-woof interwoven structure of two sets of 2D networks.[238] Other $Cd^{2+}\text{-}[Ag(CN)_2]^-\text{-}L$ systems have been studied (where L = 4-aminopyridine, aminoethanol, imidazole, *N*-methyl, or 2-methylimidazole) and several modes of coordination have been achieved.[239,240] The $[Ag(CN)_2]^-$ anion has also been used in the construction of host–guest[241,242] and low-dimensional magnetic systems.[243] Reaction of $AgClO_4$ with 2,5-dimethyl-2,5-diisocyanohexane (TMB) gives the complex $[Ag_2(TMB)_3](ClO_4)_2$. The structure consists of pairs of···AgCN∼NCAgCN∼HCAg···infinite chains with another TMB ligand is bonded to silver.[244] The treatment of $(Ph_4P)[WCpS_3]$ with AgCN gives an helical polymer $[\{W(C_5Me_5)S_3\}_2Ag_3(CN)]_n$ (Figure 2).[245] The complex η-$(BEDT\text{-}TTF)_2[Ag(CN)_2]$ (BEDT-TTF = bis(ethylenedithio)tetrathiafulvalene) exhibit semiconducting properties although the band structure calculation predicts metallic behavior.[246]

Recently the vibrational spectroscopy and determination of the crystal structure of AgCN was carried out by using powder neutron diffractometer data.[247] The structure is composed of a packing of parallel, linear $[AgCN]_n$ chains with Ag···Ag separations that exceed 3.88 Å. AgCN dissolves in aqueous solutions of a soluble silver salt giving double salts of the type $3AgCN{\cdot}2AgF{\cdot}3H_2O$,[248] $AgCN{\cdot}2AgNO_3$,[249] $AgCN{\cdot}2AgClO_4{\cdot}2H_2O$,[249] or $AgCN{\cdot}AgF{\cdot}4CF_3$

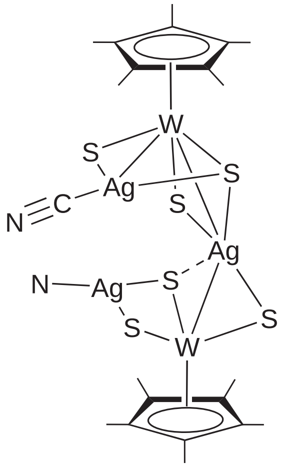


Figure 2 Structure of the repeating unit of $[\{W(C_5Me_5)S_3\}_2Ag_3(CN)]_n$.

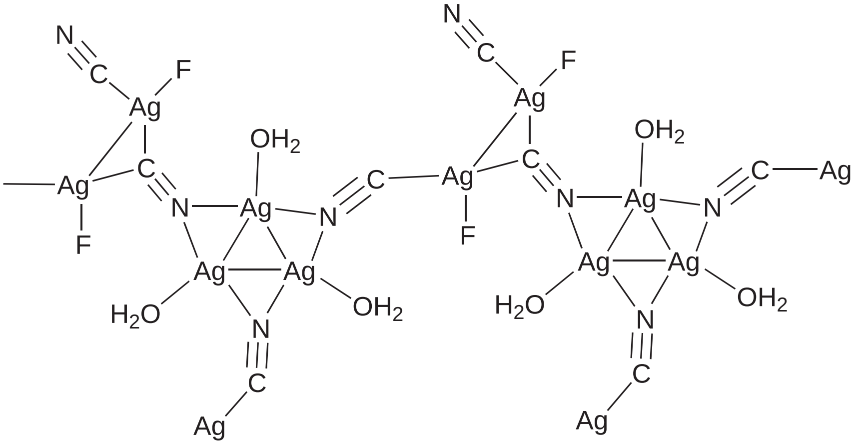

Figure 3 Layer structure of $3AgCN{\cdot}2AgF{\cdot}3H_2O$.

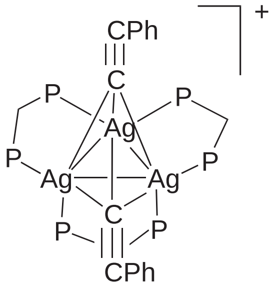
$CO_2{\cdot}2L$ (L = MeCN, H_2O).[250] In the nitrate salt the AgCN component essentially retains the linear $[AgCN]_n$ characteristics of neat silver cyanide, whereas in the perchlorate salt the $[AgCN]_n$ chain is significantly perturbed to assume a zig-zag conformation, and breaks up completely into fragments in $3AgCN{\cdot}2AgF{\cdot}3H_2O$. In the latter the structure consists of a layer-type architecture of a zig-zag $[AgCN]_n$ chain as a building unit, and an interaction of the ordered cyanide group with two other neighboring Ag^I ions leads to an unprecedented μ_4-$\eta^1\kappa C$:$\eta^1\kappa N$ coordination mode (Figure 3). The trifluoroacetate salt has a similar structure. The driving force for dissolving AgCN in aqueous solutions of a soluble silver salt is attributed to both argentophilicity and the tendency of the cyanide ligand to achieve its highest ligation number.

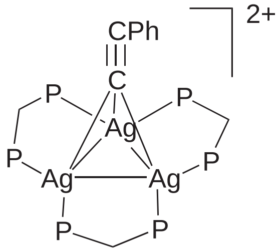
Argentophilic attraction has been found in $Tl[Ag(CN)_2]$; this compound displays photoluminescence that has been explained in terms of excited-state Ag—Ag interactions leading to exciplex formation, $*[Ag(CN)_2{}^-]_3$.[251] Several photochemical studies have been carried out with this type of compound.[252–255]

The insoluble alkynylsilver or acetylidesilver complexes are regarded as coordination polymers $[RC{\equiv}CAg]_n$ with cross-linking between the metal atoms and the ethynyls of adjacent $RC{\equiv}CAg$ units. The addition of a ligand can partly break down the polymeric structure. The 1:1 complexes of alkynyl silver compounds with tertiary phosphines build oligomeric or polymeric structures in which alternating $[Ag(C{\equiv}CR)_2]$ units π-donate to adjacent $[Ag(PMe_3)]^+$ units rather than monomeric $[Ag(C{\equiv}CR)(PR_3)]$ molecules.[256,257] The 1,3-bis(*o*-propargyl)-*t*-butylcalyx[4]arene derivative reacts with $AgNO_3$ to give the alkynyl species that further react with PPh_3 to yield the $[Ag(C{\equiv}CR)(PPh_3)]$ complex.[258] Several alkynyl silver(I) compounds with diphosphines have been synthesized and they exhibit luminescence in both the solid state and in solution.[259,260] The reaction of $[PhC{\equiv}CAg]_n$ with dppm yields $[Ag_3(\mu_3\text{-}\eta^2\text{-}C{\equiv}CPh)_2(dppm)_3]^+$ (**10**).[261] Other trinuclear silver(I) acetylides have been prepared by reaction of the silver diphosphine complexes $[Ag_2(\mu\text{-}PP)_2(MeCN)_2]^{2+}$ with $RC{\equiv}CLi$, they are of the stoichiometries $[Ag_3(\mu\text{-}PP)_3(\mu_3\text{-}\eta^1\text{-}C{\equiv}CR)](BF_4)_2$ (PP = dppm, R = Ph (**11**), $4\text{-}NO_2C_6H_4$, $4\text{-}MeOC_6H_4$; PP = $Pr^nN(PPh_2)_2$, R = Ph) or $[Ag_3(\mu\text{-}PP)_3(\mu_3\text{-}\eta^1\text{-}C{\equiv}CR)_2]PF_6$.[262] By reaction of $[Ag_2(\mu\text{-}dppm)_2(MeCN)_2](BF_4)_2$ with 1,4-diethynylbenzene in the presence of $LiBu^n$ the complex $[Ag_3(\mu\text{-}dppm)_3(\mu_3\text{-}\eta^1\text{-}C{\equiv}CC_6H_4C{\equiv}C)Ag_3(\mu\text{-}dppm)_3](BF_4)_4$ (**12**) is obtained.[263]

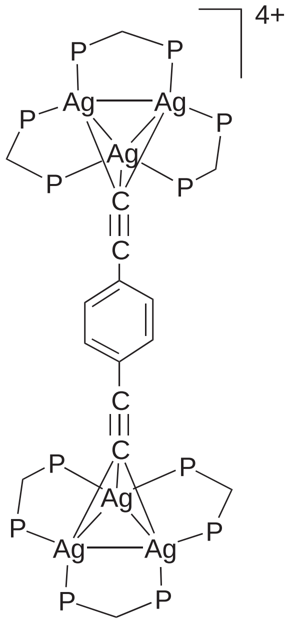
The organometallic substituted acetylides $L_nMC{\equiv}CR$ or organometallic bridged 1,4-diynes $RC{\equiv}CML_nC{\equiv}CR$ (R = singly bonded organic ligand; ML_n = organometallic building block) can further coordinate other metal centers as silver.[264] There are many complexes that lie in the organometallic chemistry of silver and which will not be discussed here. The reaction of $[PtCl_2(THT)_2]$ (THT = tetrahydrothiophene) with $[AgC{\equiv}CR]_n$ gives the cluster compounds $[Pt_2Ag_4(C{\equiv}CR)_8]$ (R = Ph, Bu^t) (**13**).[265]. This complex reacts with anionic or neutral ligands (molar ratio 1:4) to give trinuclear compounds such as $(Bu_4N)_2[\{Pt(C{\equiv}CR)_4\}(AgX)_2]$ (X = Cl, Br) or $[\{Pt(C{\equiv}CR)_4\}(AgL)_2]$ (L = $CNBu^t$, Py). The reaction in a 1:1 molar ratio gives the hexanuclear species $(Bu_4N)_2[Pt_2Ag_4(C{\equiv}CR)_8X_2]$ or $[Pt_2Ag_4(C{\equiv}CR)_8(Py)_2]$.[266] Also it serves as a precursor for polymeric materials, thus in the reaction with bipy this ligand bridges the equatorial silver atoms giving a polymeric complex.[267] Also in the reaction with $AgClO_4$ (molar



(10)

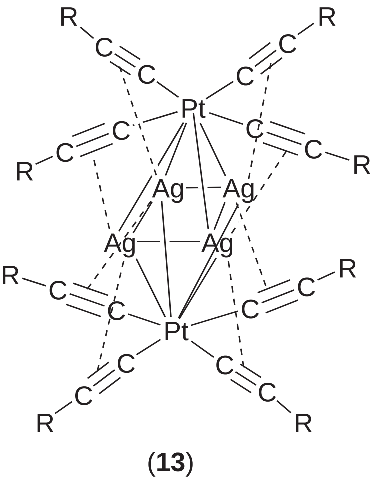


(11)

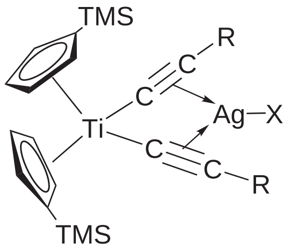


(12)

ratio 1:4) the complex acts as an octadentate chelating agent through the external alkynyl coordination sites, the perchlorate ligands can react further with bipy in different molar ratios to give polynuclear derivatives.[267,268] Other types of complexes are formed by reaction of $[Ti(\eta^5\text{-}C_5H_4TMS)_2(C{\equiv}CR)_2]$ with silver salts and are of the form $[Ti(\eta^5\text{-}C_5H_4TMS)_2(C{\equiv}CR)_2(AgX)]$ (**14**) (X = Cl, Br, I, CN, SCN, NO_2, NO_3, ClO_4, OTf, S_2CNEt_2, $SC_6H_2NMe_2$-2).[269,270] The complex $[Ti(\eta^5\text{-}C_5H_4TMS)_2(C{\equiv}CR)_2(AgOTf)]$ reacts with several ligands such as THT, NCMe, NCPh, $P(OMe)_3$, PPh_3, and $P(C{\equiv}CPh)_2(CH_2Ph)$ to give $[Ti(\eta^5\text{-}C_5H_4TMS)_2(C{\equiv}CR)_2Ag(OTf)L]$ (OTf = trifluoromethanesulfonate).[271]



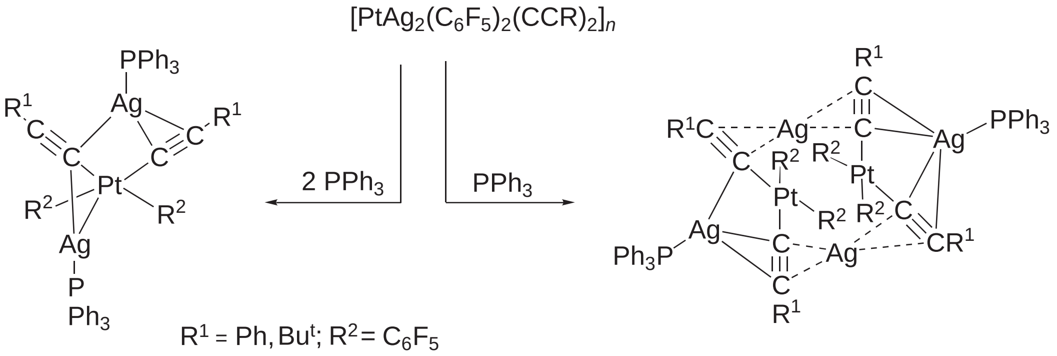
(13)



(14)

Similar complexes are prepared with platinum and are of the type $Bu_4N[Pt(C_6F_5)_2(C{\equiv}CR^1)_2(AgPR^2_3)]$ (R^1 = Ph, Bu^t; R^2 = Ph, Et) which are obtained by reaction of the tetranuclear platinum–silver complex $(Bu_4N)_2[Pt_2Ag_2(C_6F_5)_4(C{\equiv}CR)_4]$ with phosphine.[272] The polynuclear complexes $[PtAg_2(C_6F_5)_2(C{\equiv}CR)_2]_n$ (R = Ph, Bu^t) must have a polymeric structure with the silver atoms η^2-bonded to the acetylide groups; the *t*-butylacetylide derivative reacts with acetone to give $[Pt_2Ag_4(C_6F_5)_4(C{\equiv}CBu^t)_4(Me_2CO)_4]$.[273] Both react with neutral ligands to give $[PtAg_2(C_6F_5)_2(C{\equiv}CR)_2L_2]$ or $[Pt_2Ag_4(C_6F_5)_4(C{\equiv}CR)_4L_2]$ (L = PPh_3, $CNBu^t$, Py).[274] The crystal structure of $[PtAg_2(C_6F_5)_2(C{\equiv}CPh)_2(PPh_3)_2]$ reveals two different types of unsymmetrical μ_3-σ

and μ-η^2,σ-edge-bridging alkynyl ligand (Scheme 1). The reaction of *trans*-$[Pt(C{\equiv}CBu^t)_2(PMe_2Ph)_2]$ with $AgClO_4$ gives *trans*-$[PtAg_2(MeCN)_x(\mu\text{-}C{\equiv}CBu^t)_2(PMe_2Ph)_2](ClO_4)_2$ that reacts further with Py to give the neutral derivative *trans*-$[PtAg_2(ClO_4)_2(Py)_2(\mu\text{-}C{\equiv}CBu^t)_2(PMe_2Ph)_2](ClO_4)_2$.[276] Silver(I) also binds in a η^2 fashion to alkynyl manganese complexes such as $[Mn(C{\equiv}CBu^t)(CO)_3(dppe)]$ to give $[Mn\{AgP(2\text{-}MeC_6H_4)_3\}(\mu\text{-}C{\equiv}CBu^t)(CO)_3(dppe)]^+$.[277]



Scheme 1

Various homo- or heteronuclear cluster species which contain both σ- and π-bonded alkynyl groups have been synthesized and characterized, e.g., $[Ag_5(C{\equiv}CPh)_6]^-$,[278] $[Au_2Ag_2(C{\equiv}CPh)_4(PPh_3)_2]^-$,[279,280] $[Ag_6Cu_7(C{\equiv}CPh)_{14}]^-$,[281] $[Ag_3(C{\equiv}CBu^t)_2X]_n$ (X = *p*-toluenesulfonate, NO_3),[282] and $[Ag_{14}(C{\equiv}CBu^t)_{12}X]BF_4$ (X = Cl, Br, I).[282]

Several studies have been carried out with the alkynediide silver compound Ag_2C_2. This salt dissolves in aqueous solutions of another soluble silver compound giving double salts of the type $Ag_2C_2{\cdot}8AgF$,[283] $Ag_2C_2{\cdot}2AgClO_4{\cdot}2H_2O$,[284] $Ag_2C_2{\cdot}mAgNO_3$ ($m = 1, 5, 5.5, 6$),[285] $2Ag_2C_2{\cdot}12AgCF_3CO_2{\cdot}3MeCN$,[286] $Ag_2C_2{\cdot}6AgCF_3CO_2{\cdot}3MeCN$,[286] and $4Ag_2C_2{\cdot}23AgCF_3CO_2{\cdot}7C_2H_5CN{\cdot}2.5H_2O$;[286] triple salts $Ag_2C_2{\cdot}AgF{\cdot}4AgCF_3SO_3{\cdot}2L$ (L = CH_2CN, C_2H_5CN);[287] or quadruple salts $2Ag_2C_2{\cdot}3AgCN{\cdot}15AgCF_3CO_2{\cdot}2AgBF_4{\cdot}9H_2O$.[288] In all of these silver(I) multiple salts, the C_2^{2-} species is always encapsulated inside a Ag_n ($n = 6$–9) polyhedral cage or $(C_2)_2@Ag_{13}$ double cage and stabilized trough mixed σ–π interactions with its vertexes.

The compound *trans*-perfluoro-1-methyl-1-propenylsilver has been shown to be tetrameric, $[CF_3CF{=}C(CF_3)Ag]_4$, and it is a suitable precursor to prepare pure silver films by plasma-enhanced CVD, or to deposit silver films under MOCVD conditions.

Arylsilver compounds are air, moisture, and light sensitive, but are sufficiently thermally stable to allow isolation and characterization. They are prepared by reaction of a silver salt with the aryllithium or magnesium compounds. Mesityl silver $[Ag(2,4,6\text{-}Me_3C_6H_2)]_4$ (**15**) has a tetrameric structure.[289–292] The related complex with the bulkier phenyl-substituted ligand $2,4,6\text{-}Ph_3C_6H_2$ was originally formulated as monomeric[293] but has recently been disproved.[294] Di- and trinuclear gold(I)–silver(I) complexes containing Mes groups acting as bridges between two metal centers have also been described. The reaction of $[Au(Mes)(PPh_3)]$ with $[Ag(OTf)L]$ leads to complexes $[(PPh_3)Au(\mu\text{-}Mes)AgL]OTf$ (L = THT, PPh_3).[295] The structure of the complex where L = THT is a dimer with the THT acting as a bridging ligand. Similarly, the treatment of $[Au(Mes)(PPh_3)]$ with AgOTf in a 2:1 ratio gives the trinuclear Au_2Ag derivative $[\{(PPh_3)Au(\mu\text{-}Mes)\}_2Ag]OTf$ (**16**).[296]

The reaction of *N*-benzyl-*C*-imidazolyllithium with $[Ag(NO_3)(SMe_2)]$ affords the corresponding *C*-imidazolylsilver (Equation (3)), which has been proposed by molecular weight determination to be trimeric.[297] *N*-Functionalized *C*-imidazolylsilver compounds or carbene-type silver complexes are obtained by reaction of the imidazolium salt with Ag_2O or Ag_2CO_3; some of these are shown in Figure 4:[298,299]

(3)

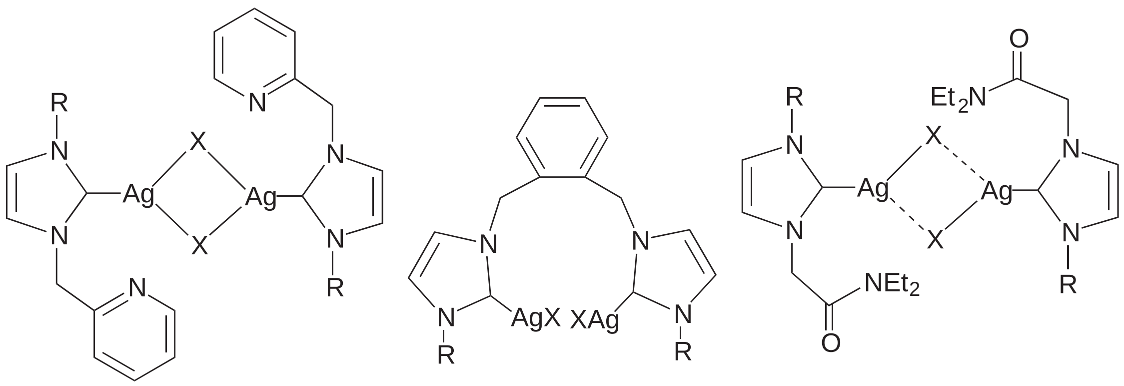


Figure 4 *C*-imidazolylsilver compounds.

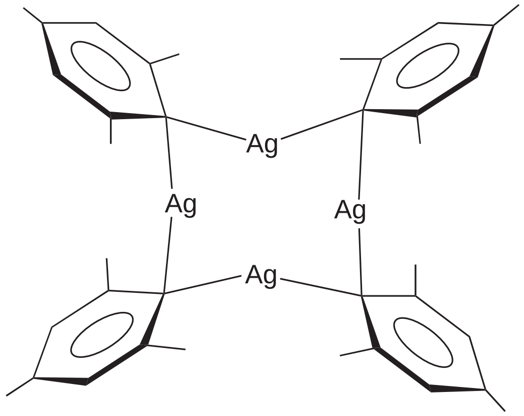
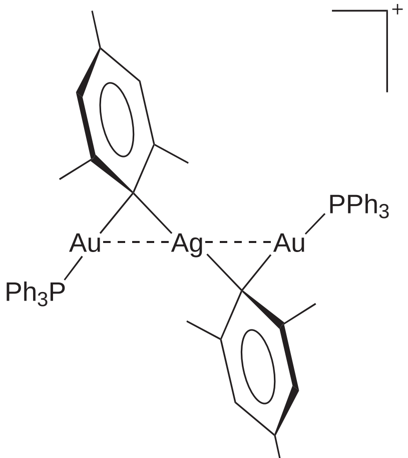


(15)



(16)

Pentafluorophenyl derivatives of the type [AgR] where prepared many years ago. A new method consists of the reaction of $Bu_4N[AuR_2]$ with $AgClO_4$ (Equation (4)):[300,301]

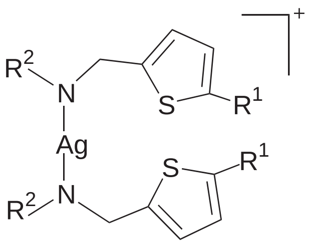
$$Bu_4N[AgR_2] + AgClO_4 \longrightarrow (NBu_4)ClO_4 + 2\,[AgR] \qquad (4)$$

The reaction of AgR (R = 2,4,6-$C_6F_3H_2$, C_6F_5, C_6Cl_5) with neutral ligands L gives the complexes $[Ag_2R_2L]_2$ (L = Py, 3-FPy, THT, bipy) for which a tetranuclear structure is proposed.[302] Reaction of AgCl with the double ylide hexaphenylcarbodiphosphoran $C(PPh_3)_2$ gives the complex $[AgCl\{C(PPh_3)_2\}]$.[303]

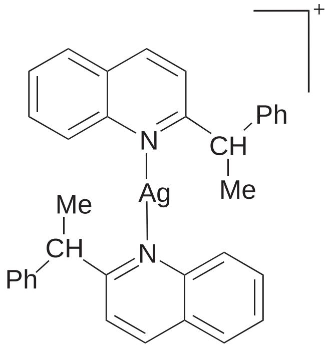
6.7.2.3.2 Complexes with nitrogen donor ligands

(i) Complexes with monodentate ligands

Mononuclear silver(I) complexes with nitrogen ligands can have several coordination numbers, the simplest is dicoordinated and compounds of the type $[AgL_2]^+$ occur for a variety of ligands such as NH_3,[304–308] 1,2-4,triazol-5-one,[309] melamine,[310] 2,6-Me_2Py,[311,312] $NCCl$,[313] NCH,[314] 9-methylhypoxantine,[315,316] 5-methyl-2-(2,3-diaza-4-(5-methyl-2-thyenyl)buta-1,3-dienyl)thiophene,[317] succinimide,[318,319] pyridine-4-carbonitrile,[320] 4-benzoylpyridine,[320] thiophene-2-carbaldehyde imine (**17**),[321] Py,[322] benzotriazole,[323] 9-ethylguanine,[324] substituted sulfonylureas,[325] 2-arylazopyridines,[326] (–)-1-phenylethyl-2-quinolyl (**18**),[327] pyrazole,[328] nitroimidazole,[329] and methylimidazole.[330] The silver(I) compound with the ligand 1-(*p*-$MeOC_6H_4$)-4-(CHNOH)-imidazole is highly active *in vitro* against the growth of epimastigotic forms of *Trypanosoma cruzi.*[331]

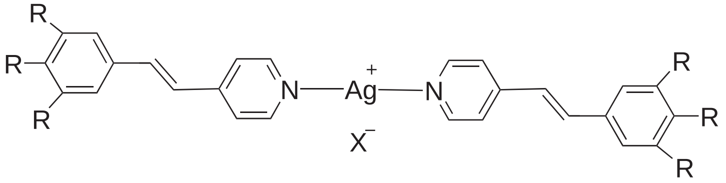


(17)



(18)

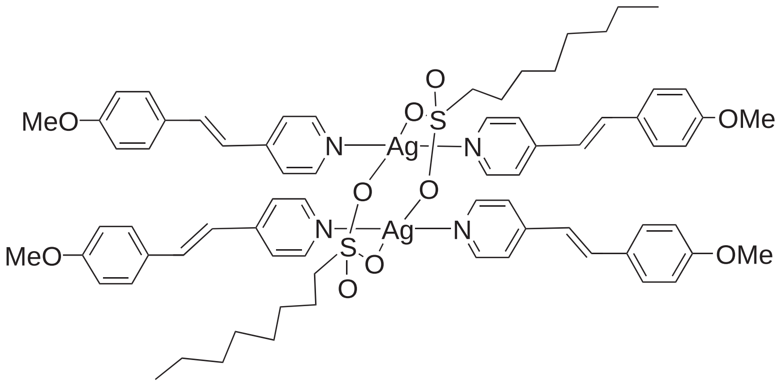
Alkoxystilbazoles can react with a variety of silver salts, AgX, to yield the two-coordinate linear complexes (**19**). They show liquid crystalline behavior that strongly depends on the anion, the alkoxy chain length, and other substituents which may be present on the stilbazole.[59–65]



R = H, $OC_nH_{2n\text{-}1}$

(19)

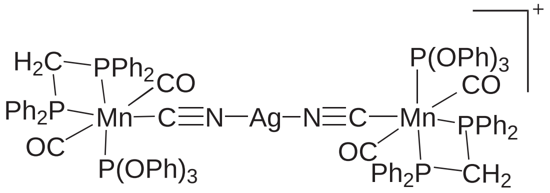
They have been prepared with several anions,[332–335] the tetrafluoroborate salt exhibits S_A and S_C phases[332,333] but the triflate shows a nematic phase.[334] One of the problems in studying these complexes was the very high temperatures at which the phases existed and the fact that decomposition was often observed in the upper reaches of the S_A phases. Reduction of these temperatures was achieved by changing the small anions for dodecyl sulfate that also make that more materials exhibit nematic S_A and S_C phases, and another more viscous phase appeared, named cubic phase S_D. With the anion octyl sulfate[336] the crystal structure of one of the complex with 4-metoxystilbazole could be achieved (**20**), with this anion the cubic phase was not present.



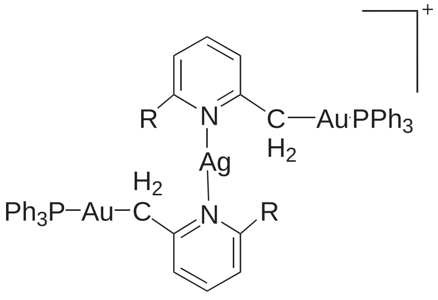
(20)

Another approach to get new liquid crystals is the lateral fluorination of the stilbazole ligands,[337] which is a common and highly effective tool to exert control over mesomorphism, crystal phase stability, and physical properties. Other modifications include the use of more alkoxy substituents and other alkyl sulfate anions.[338–344] Ionic silver amino complexes also display liquid crystalline behavior at rather low temperatures; they are of the form $[Ag(NH_2n\text{-}C_nH_{2n+1})_2]X$ ($X = NO_3$, $n = 6, 8, 10, 12, 14$; $X = BF_4$, $n = 8, 10, 12, 14$).[345]

Silver(I) is also bonded to two nitrogen atoms in heteropolynuclear complexes such as [Ag{(μ-NC)MnL$_x$}$_2$]PF$_6$ (**21**) or [Ag{(μ-NC)MnL$_x$}$_2$](PF$_6$)$_3$ (L$_x$ = *trans*-(CO)$_2$[P(OEt)$_3$](dppm) or *trans*-(CO)(dppm)$_2$),[346] or in the mixed silver–gold derivative [Ag{Au(2-CH$_2$-6-RC$_5$H$_3$N)(PPh$_3$)}$_2$]ClO$_4$ (**22**) (R = H, Me).[347] Complexes in which silver is bonded to a nitrogen ligand as 3-ferrocenylpyridine or 1,1′-bis(2-pyridylthio)ferrocene and triphenylphosphine are [Ag(FcPy)(PPh$_3$)][348] and [Ag$_2$(PPh$_3$)$_2${Fc(SPy)$_2$}](OTf)$_2$ (Fc = ferrocenyl).[349] Other complexes include [Ag(NO$_3$)(2-NCPy)], only characterized by IR and elemental analysis,[350] silver(I) disulfonylamides [Ag{N(SO$_2$)$_2$C$_6$H$_3$-4-X}(NCMe)][351] and the bridging pyrazolate ligand in complex [PtCl(PPh$_3$)$_2$(μ-3,5-Ph$_2$pz)AgCl].[352]

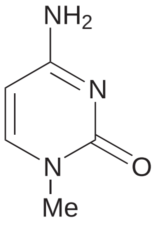


(**21**)

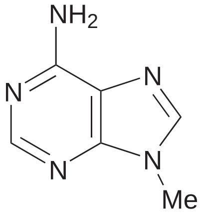


(**22**)

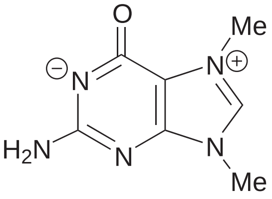
Three-coordinate silver(I) complexes with nitrogen donor ligands are of the form [AgXL$_2$] (L = 3-ferrocenylpyridine, X = OTf; L = 3- or 4-NCPy, 2-, 3-, or 4-NCC$_6$H$_4$NH$_2$, X = NO$_3$).[348,350] The model nucleobases (**23**)–(**25**) have been synthesized and their interaction with silver(I) studied; the complexes formed are of the type [Ag(**23**)(**25**)(NO$_3$)]$_2$·[(**23**)(**24**)(PF$_6$)]·10H$_2$O or [Ag(**23**)(**24**)(H$_2$O)]NO$_3$. An XRD study of the latter complex reveals that ligand (**23**) bonds through atom N^3 whilst ligand (**24**) is coordinated through atom N^7.[353]



(**23**)



(**24**)



(**25**)

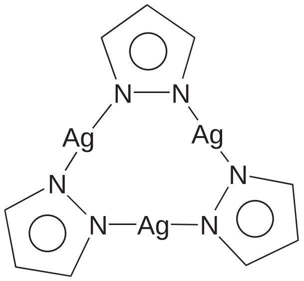
Other tri-coordinate silver(I) complexes are the bridging pyrazolate complexes such as [Ir(η^5-C$_5$Me$_5$)(pz)$_3$Ag(PPh$_3$)], [Ir(η^5-C$_5$Me$_5$)(pz)$_3${Ag(PPh$_3$)}$_2$]BF$_4$, and [Ir(η^5-C$_5$Me$_5$)(PPh$_3$)-(pz)$_3$Ag (PPh$_3$)]BF$_4$.[354–357] Silver complexes with azooximato ligands [Ag{PhN=NC(R)=N(O)}{PhN=NC(Me)=N(OH)}$_2$]$_2$ are dimers through hydrogen bonds.[358] The structure of complexes with aminopyridines has been reported for [Ag(4-NH$_2$Py)$_2$]NO$_3$ and [Ag{2,6-(NH$_2$)$_2$Py}$_3$]NO$_3$.[359] The reaction of Ag(OTf) with *N,N*′-diphenylformamidine gives the [Ag(OTf)L$_2$] complex where the silver(I) center is three coordinate.[360]

Homoleptic mononuclear tetra-coordinate silver(I) complexes have also been reported and are of the type [Ag(Py)$_4$]$^+$,[361] [Ag(NCMe)$_4$]$^+$,[362,363] or [Ag(S$_4$N$_4$O$_2$)$_2$]$^+$.[364] The reaction of polymeric silver(I) imidazolate [Ag(im)]$_n$, which shows a wide spectrum of excellent antimicrobial activities against bacteria yeast and mold, with PPh$_3$ gives [Ag(im)(PPh$_3$)$_3$].[365] Another tetra-coordinate derivative is the bis(acridine)silver(I), [Ag(NO$_3$)(C$_{13}$H$_9$N)$_2$], with the nitrate acting as bidentate ligand.[366] The heteronuclear complex [{Co(NH$_3$)$_5$(μ-pyrazine)}$_2$Ag(H$_2$O)$_2$] has been characterized structurally.[367]

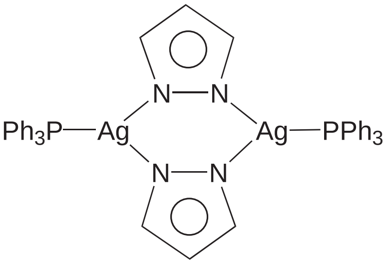
Thermodynamics of complex formation of silver with several ligands such amines,[368] hindered pyridine bases,[369] nitrogen donor solvents,[370] and azoles[371] have been carried out. Other studies include the secondary-ion mass spectra of nonvolatile silver complexes,[372] the relationship between Lewis acid–base behavior in the gas phase and the aqueous solution,[373] or the rates of hydride abstraction from amines via reactions with ground-state Ag$^+$.[374]

(ii) Complexes with polydentate ligands

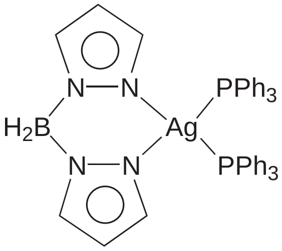
Pyrazoles and imidazoles ligands have a very rich coordination chemistry with many metals. Silver(I) complexes are known long time ago but this area has been growing. As early as 1889 Büchner[375] reported the synthesis of the insoluble silver salt $[Ag(pz)]_n$ that always has been claimed to be polymeric. The *ab initio* crystal structure determination from powder diffraction data confirms its polymeric nature and, by changing the synthetic method, a trimeric $[Ag(pz)]_3$ (**26**) structure has also been isolated.[376] The structure for the diphenyl pyrazolate trimer $[Ag(3,5\text{-}Ph_2pz)]_3$ has also been reported.[377] The reaction of Ag_2O with $[3,5\text{-}(CF_3)_2pzH]$ gives $[Ag\{3,5\text{-}(CF_3)_2pz\}]_3$, the complex exists both as trimers and pairs of trimers with a Ag···Ag interaction of 3.307,3(13) Å.[378] Treatment of $[Ag(pz)]_n$ with PPh_3 gives complexes with bridging pyrazolate ligands $[Ag_2(\mu\text{-}pz)(PPh_3)_2]$ (**27**) and $[Ag_2(\mu\text{-}pz)(PPh_3)_3]$.[379] The reaction of these complexes with heterocumulenes such as CS_2, COS, CO_2, or RNCO produces the insertion of the heterocumulene in the N—Ag silver bond.[379] The coordination of the 3,5-bis(2-pyridyl)pyrazole (HbPypz) ligand with silver(I) has been studied. In the dinuclear $[Ag_2(HbPypz)_4](ClO_4)_2$ there are two four-coordinate $[Ag(HbPypz)_2]^+$ units linked by intramolecular hydrogen bonds; while the compound $[Ag(HbPypz)]_n(ClO_4)_n$ is polymeric where the silver atom is three coordinate, chelated by two nitrogen atoms of the ligand and the other is bridging with other silver center.[380] Heteropolynuclear complexes with bridging pyrazolate complexes have been prepared such as $[Pd_2Ag_4(3,5\text{-}Me_2pz)_8]$[381] and $[\{(\eta^5\text{-}C_5H_5)Ir(\mu\text{-}pz)(\mu\text{-}N{=}C(R)pz)Ag\}_2](BF_4)_2$ (R = Me, Ph, Bz).[382]



(**26**)



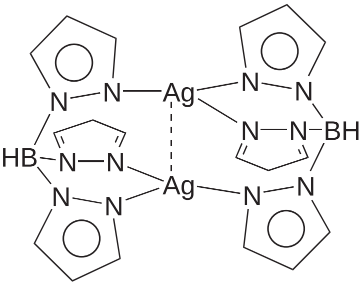
(**27**)



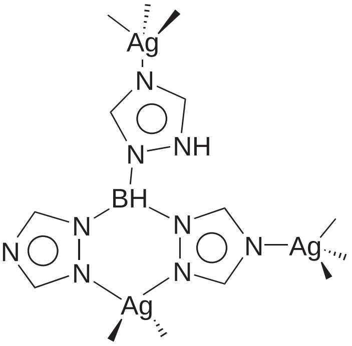
(**28**)

Bis(pyrazolyl)borate compounds have also been reported and are of the type $[Ag\{(pz)_2BH_2\}\{P(4\text{-}MeC_6H_4)_3\}]$, $[Ag\{(pz)_2BH_2\}(PPh_3)_2]$ (**28**), $[Ag\{(pz)_2BPh_2\}L]$ (L = $P(4\text{-}MeC_6H_4$, $CNBu^t$, $P(OPh)_3$, 0.5 $Ph_2PCH_2PPh_2$), or $[Ag\{(3,5\text{-}Me_2pz)_2BH_2\}L]$ (L = $PEtPh_2$, PCy_3).[383,384]

Silver(I) complexes are known with the tris(pyrazolyl)borate $[HB(pz)_3]^-$ and the methyl, phenyl, bromo, or trifluoromethyl-substituted derivatives. The structure of the silver tri(pyrazolyl)borato species has been a puzzle since it was first reported.[385,386] It was suggested that the structure could be oligomeric, but recently the crystal structure of the compound $[Ag\{HB(3,5\text{-}Me_2pz)_3\}]_2$ shows that it has a dimeric structure[387] where the silver(I) centers are tricoordinated by a bidentate arm of one ligand and a monodentate arm of the other ligand (**29**). The related complexes $[Ag\{HB(4\text{-}Brpz)_3\}]_2$, $[Ag\{HB(4\text{-}Mepz)_3\}]_2$, $[Ag\{HB(3,5\text{-}Me_2pz)_3\}]_2$, $[Ag\{HB(3\text{-}Mepz)_3\}]_n$, $[Ag\{B(pz)_4\}]_n$, and $[Ag\{B(im)_4\}]_n$ have also been reported.[388,389] The structure of the [hydrotris(1,2,4-triazolyl)borato]-silver(I) consist of a 2D coordination polymer (**30**).[390]

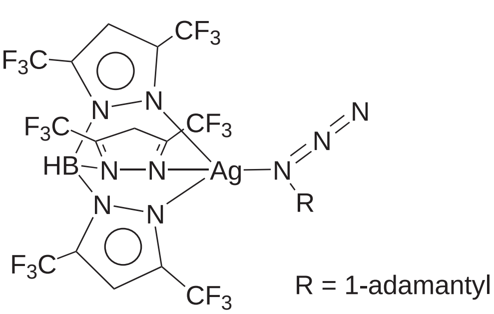


(**29**)

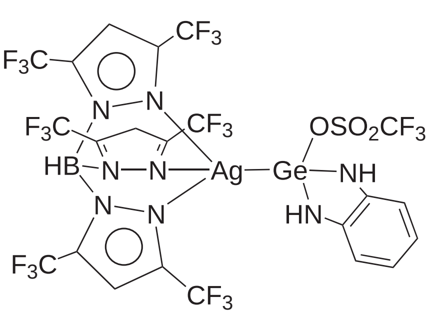


(**30**)

Complexes of the type $[Ag\{HB(pz)_3\}(PR_3)]$ are known for a variety of phosphine ligands and it has been observed that the ligand properties of $[HB(pz)_3]^-$ are dependent on the cone angle and basicity of the phosphine. Also the solution and solid-state behavior differs greatly.[391] The complexes with the related ligands $[HB(3,5\text{-}Me_2pz)_3]^-$, $[HB(3,5\text{-}Ph_2pz)_3]^-$, and $[HB(4\text{-}Brpz)_3]^-$ have also been described.[389,391,392] The reaction of $[Ag\{HB(3,5\text{-}Me_2pz)_3\}(PPh_3)]$ with 1-methylimidazolyl-2-thione (Hmimt) gives the compound $[Ag\{HB(3,5\text{-}Me_2pz)_3\}(Hmimt)(PR_3)]$ in which the $[HB(3,5\text{-}Me_2pz)_3]^-$ probably acts as a bidentate donor.[391] Considerable work has been carried out with polyfluorinated tris(pyrazolyl)borate ligands, which play an important role in stabilizing silver(I) complexes with small unsaturated molecules. Examples are the carbonyl complex mentioned in Section 6.7.2.3.1 or other adducts with nitriles, ethylenes, alkynes, isocyanides, azides (**31**), ethylene oxide, or propylene sulfide ligands.[393–395] The complexes with THF or toluene ligands obtained by reaction of $Na[HB\{3,5\text{-}(CF_3)_2pz\}_3]$ with AgOTf in THF or toluene are useful starting materials.[393,396] Adducts containing phosphine ligands[397] or unsupported silver—germanium[398] bonds (**32**) have also been prepared.

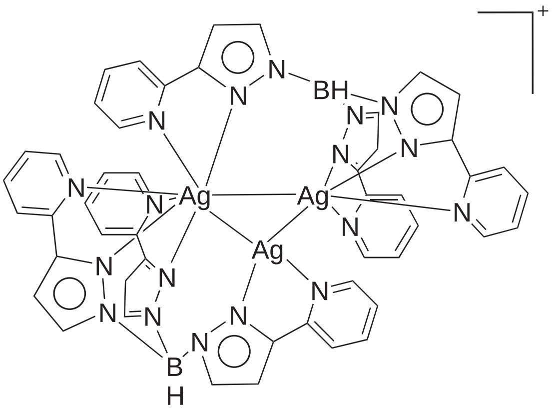


(31)

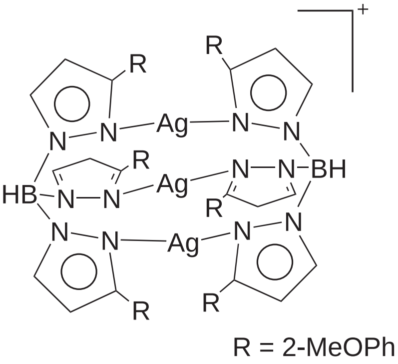


(32)

Silver(I) poly(pyrazolyl)borate complexes containing isocyanide ligands have also been prepared for the ligands $[HB(3,5\text{-}Me_2pz)_3]^-$, $[HB(3,5\text{-}Ph_2pz)_3]^-$, $[HB(3\text{-}Mepz)_3]^-$, and $[B(pz)_4]^-$, the latter behaves as a tridentate ligand.[399] A series of silver(I)-bidentate phosphine adducts with poly(pyrazolyl)borate ligands have been described. In the solid state they are three- or four-coordinate with the bidentate donors $[H_nB(pz)_{4-n}]^-$ but in solution different species can exist depending on the chain which links the two phosphorous atoms and also on the stoichiometry ratio. The structures for the complexes $[Ag\{(pz)_2BX_2\}(dppf)]$ (X = H, pz; dppf = 1,1′-bis(diphenylphosphino)ferrocene) have been reported.[400] The tetrakis(pyrazolyl)borate ligands coordinate in a bi- or tridentate mode in silver(I) complexes with tertiary phosphine ligands, as in $[Ag\{(pz)_2B(pz)_2\}(PPh_3)]$.[401] An interesting derivative $[Ag_3L_2]ClO_4$ (**33**) is obtained with the tris[3-(2-pyridyl)-pyrazol-1-yl]borate. It contains a triangular Ag_3^{3+} cluster core encapsulated by two ligands, each Ag^I being coordinated by a bidentate arm from each of the two ligands.[402] An unprecedented trinucleating bridging mode for a tris(pyrazolyl)borate ligand occurs in the 2-methoxyphenyl-substituted derivative. In the complex $[Ag_3\{(3\text{-}MeOPhpz)_3BH\}_2]ClO_4$ (**34**), the silver centers are bonded to one pyrazolyl nitrogen atom of each ligand.[403]

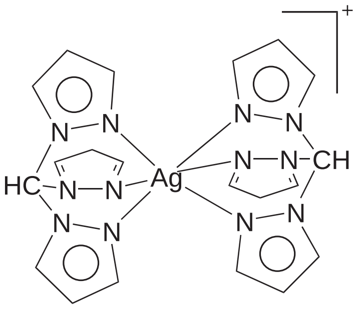


(33)

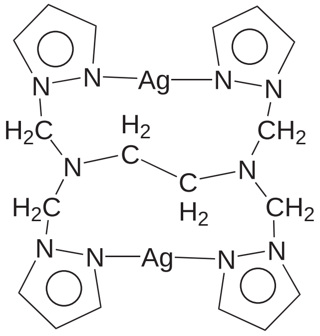


(34)

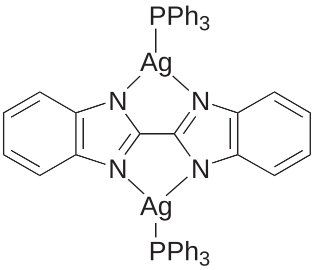
The analogue tris(pyrazolyl)methane ligand has also been used to synthesized silver(I) complexes of the type $[Ag(OTf)\{(pz)_3CH\}]$, $[Ag\{(pz)_3CH\}(CNBu^t)]OTf$, and the six-coordinate $[Ag\{(pz)_3CH\}_2]OTf$ (**35**).[404] Bis(pyrazolyl)methane ligands of the type $Me_2C(pz)_2$, $H_2C(3,5\text{-}Me_2pz)_2$, or $H_2C(4\text{-}NO_2pz)_2$ have been used to form complexes of the type [AgXL] ($X = NO_3$, OTf) or $[AgL_2]X$ ($X = BF_4$, ClO_4).[405] Siver(I) nitrate forms the dinuclear complex (**36**) with a potentially hexadentate tetrapyrazolyl ligand; the silver atoms are two coordinate.[406] The tetrakis(pyrazol-1-ylmethyl)methane react with $AgNO_3$ to yield a dinuclear $[Ag_2L_2]$ complex with the silver centers three-coordinated to two pyrazolyl units of one ligand and one of the other ligand.[407]



(35)



(36)

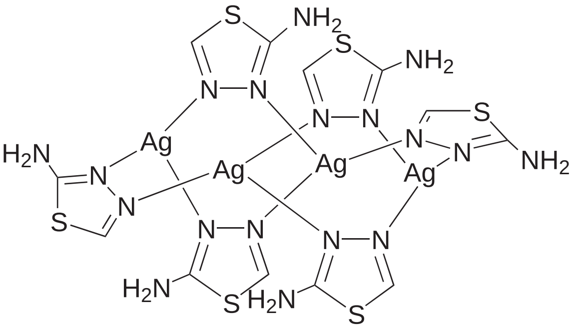


(37)

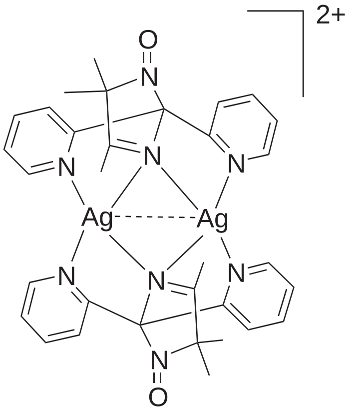
Related ligands are imidazoles. The reaction of $AgNO_3$ or $AgBF_4$ in neutral or weakly acidic solutions with the nitroimidazole gives the polymeric silver nitroimidazolate $[Ag(NO_2im)]_n$, whereas in strongly acidic solutions yields the complex $[Ag(NO_2imH)_2]^+$.[329] *Ab initio* techniques have been employed for the structure determination of polymeric silver imidazolate, $[Ag(im)]_n$, from X-ray powder diffraction data. It consist of parallel chains with alternating *cis*, *trans* arrangement of the imidazolate rings with respect to the polymer backbone.[408] Silver(I) complexes with phosphine ligands and imidazole and the substituted methyl or phenyl derivatives have been reported. They have several stoichiometries as $[Ag(PR_3)_{4-n}(im)_n]^+$, $[AgX(PR_3)_{3-n}(im)_n]$, or the dinuclear complexes $[Ag_2(\mu\text{-}X)_2(PR_3)_2(im)_2]^+$.[409] The tris[2-(1-methylimidazolyl)]methoxymethane (timm) forms the species $[Ag(timm)]^+$, which has luminescence behavior.[410] The reaction of silver acetate with 2,2-bibenzimidazole ($bbimH_2$) and PPh_3 yields the complexes $[Ag(bbminH_2)(PPh_3)_2](COOMe)$ and $[Ag_2(\mu\text{-}bbmin)(PPh_3)_2]$ (**37**).[411]

The 1,3,5-tris(benzimidazol-2-ylmethyl)benzene (tbid) reacts with $AgNO_3$ to afford the compound $[Ag(tbib)(PPh_3)]NO_3$.[412] The reaction of 2-amino-1,3,4-thiadiazole (atdz) reacts with $AgClO_4$ to yield the complex $[Ag_4(atdz)_6](ClO_4)_4$ (**38**) in which two metal centers are bridged by two atdz ligands to form a six-membered $N_2M_2N_2$ framework, two of these units are connected by a further bridging ligand.[413] *N*(1)-Alkyl-2(arylazo)imidazoles $p\text{-}R^1C_6H_4N{=}NC_3H_2NN(1)R^2$ ($R^1 = H$, Me, OMe, Cl, NO_2; $R^2 = Me$, Et) yield cationic bis-chelated complexes with silver(I).[414,415] Coordination studies of bis(benzimidazole) ligands with silver(I) have been carried out and the structure of the complex with the 1,7-bis(benzimidazol-2-yl)-2,6-dithiaheptane ligand shows the linear coordination mode to the silver center.[416] The reaction of 2,5-dihydro-4,5,5-trimethyl-2,2-di-2-pyridyl-imidazole-1-oxyl with $AgSbF_6$ gives the complex $[Ag_2L_2](SbF_6)_2$ (**39**), the compound forms a four-membered ring with a short Ag···Ag distance of 2.839(2) Å.[417] Silver(I) complexes with isothiazole-based ligands bearing substituents with additional donor sites in the five position of the heterocycle, $3\text{-}Me\text{-}5\text{-}RC_3HNS$ ($R = CH{=}N(CH_2)_2Py$, $CH{=}NCH_2Py$, $CH_2N(CH_2CH_2NEt_2)_2$, $(CH_2)_2SMe$) have been synthesized. All the compounds are dinuclear and the silver centers are coordinated to two nitrogen atoms of the ligands or one nitrogen and one sulfur and to the oxygen atoms of the triflate anion.[418] A dinuclear silver complex with the ligand 1,2,4-triazole, $[Ag_2(NO_3)_2(\mu\text{-}C_2N_3H_3)_2]$, has been described.[328]

Other polydentate ligands are polyamines and related ligands. Stability constants of silver(I) complexes with polyamines in dimethyl sulfoxide,[419] *N*-methyl-substituted 4-methyldiethylenetriamines,[420] or ethylene- or *N*- or *C*-methylated ethylenediamine in aqueous solution have been reported.[421] The structure of the silver 1,3-diaminopropane complex, $[Ag\{NH_2(CH_2)_3NH_2\}]ClO_4$,[422] and complex formation with 1,4-diaminobutane and 1,5-diaminopentane have been reported.[423] A dinuclear silver(I) compound with ethylenediamine $[(enH)Ag(en)Ag(enH)_2]^{4+}$ has

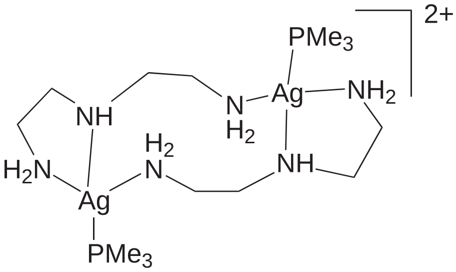


(38)

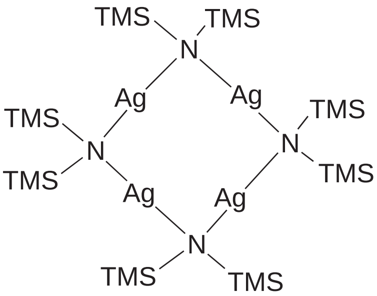


(39)

been prepared and consist of linear Ag-atoms with bridging en and terminal enH.[424] The square-planar metal site $M(en)_2$ (M = Ag, Cu) in the structure of ethylenediamino CuM-bis(tetraborate) hydrate has been determined crystallographically to be occupied by 40% Cu^{2+} and 60% Ag^+.[425] Silver(I) forms polymeric chain compounds with polydentate nitrogen acyclic ligands such as diethylenetriamine (dien), 2,2′,2″-triaminotriethylamine (tren), and *N*,*N*′-bis(aminoethyl)propane-1,3-diamine (tetraen). The addition of monodentate ligands such as phosphines or isocyanides to these compounds leads to the formation of simpler binuclear species as $[Ag_2(dien)_2(PMe_3)_2](PF_6)_2$ (**40**).[426] Thermally stable silver(I) amides $[\{Ag(\mu\text{-}NR_2)\}_4]$ (R = TMS (**41**), $NCMe_2(CH_2)_3CMe_2$) have been prepared from AgNCO and $Sn(NR_2)_2$, there are tetranuclear compounds comprising a square of Ag-atoms.[427] The formation of a $[Ag\{N(SO_2CF_3)_2\}]$ complex from Ag_2CO_3 and $HN(SO_2CF_3)_2$ and its use as an effective $[N(SO_2CF_3)_2]^-$ transfer agent have been reported.[428]

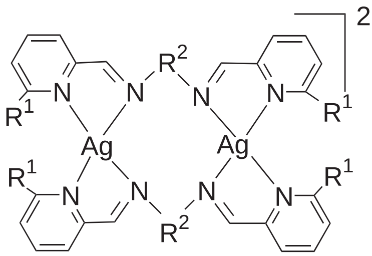


(40)

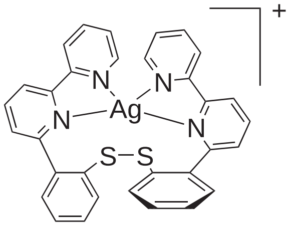


(41)

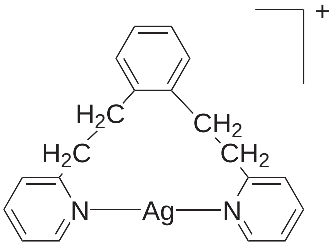
Silver(I) complexes with bipyridine, dimethylpyridine, or phenanthroline have been synthesized and have shown strong cytotoxicities *in vitro* to both normal and carcinoma cells.[429] This bis(chelate) complexes with the tetramethyl substituted bipyridine[430] and the 2,4′-bypiridine[431] ligands have been reported. The ligand 1,1′-bis(2-pyridylthio)ferrocene, $Fc(SPy)_2$, forms complexes with silver(I) of the type $[Ag(OTf)\{Fc(SPy)_2\}]$, $[Ag(PPh_3)\{Fc(SPy)_2\}]OTf$, $[Ag_2\{Fc(SPy)_2\}_3]OTf$, or $[Ag(L\text{-}L)\{Fc(SPy)_2\}]OTf$ (L-L = phen, $(SPPh_2)_2CH_2$).[349] Similar complexes are obtained with the 1,2-bis(2-pyridylthio)-1,2-dicarba-*closo*-dodecaborane ligand.[432] The reaction of 1,1′-bis(2-pyridyl)ferrocene with $RhCl_3{\cdot}3H_2O$ in the presence of $AgNO_3$ gives the silver complex $[Ag(ClO_4)L]$, which is a dimer with perchlorate bridges.[433] The reaction of the pyridine-imine 6—R^1—Py—2—CH=NR^2 ligands with Ag(OTf) or $AgClO_4$ results in the formation of the bis(chelate) complexes.[434,435] The related ligands (*R*,*S*)-1,2-(6-R^1Py-2-CH=N)$_2R^2$ (R^1 = H, Me; R^2 = Cy, Et) react with Ag(OTf) to yield the dinuclear complexes (**42**).[436,437] Similarly, the coordination behavior with the related thienyl ketimine ligands with silver(I) have been studied and complexes with stoichiometry 2:2 and 2:1 respectively, have been obtained. The silver atoms are bonded mainly to the imine N-atoms with large contacts to the sulfur thiophene atoms.[438–441]



(42)



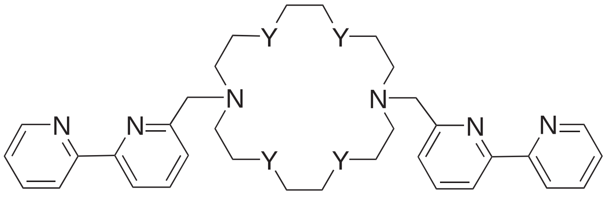
(43)



(44)

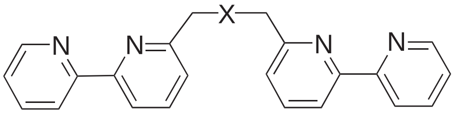
Other bis(chelate) silver(I) derivatives are obtained with ligands derived of two bipyridine moieties linked by a bridging unit such as 1,4-bis(5′-methyl-2,2′-bipyridine-5-ethyl)-benzene,[442] bis(6′-2,2′-bipyridyl)phthalate or terephthalate,[443] or 2,2′-bis[6-(2,2′-bipyridyl)]diphenyldisulfide (**43**).[444] The compound $[Ru(tpy)(\eta^2\text{-tpt})(OH_2)](ClO_4)_2$ (tpy = 2,2′:6′,2″-terpyridine, tpt = 2,4,6-tripyridyltriazine) reacts with $AgClO_4$ (2:1 ratio) to afford the bis-chelate complex $[\{Ru(tpy)(\eta^3\text{-tpt})\}_2Ag](ClO_4)_3$.[445] The 1,2-bis(2-pyridylethynyl)benzene ligand coordinates to silver(I) in a *trans*-chelating fashion (**44**).[446]

The ligands 2-(2-pyridylsulfanyl)quinoline, 2-(2-pyridylsulfanyl)benzothiazole, and dibenzothiazolesulfide react with $AgNO_3$ with formation of dinuclear complexes where the ligands bridge the two silver centers through the nitrogen atoms.[447] Similar complexes are obtained with the 1,4-bis(2-pyridyloxy)benzene ligand.[448] The crystal structure of $[Ag(NO_3)L]$ in which L is 6,6′-dimethyl-2,3′-bypiridine has been determined. In the solid state, dimers are present due to interactions between symmetry related cations.[449] Silver(I) complexes with the new bipyridine derived ligands (**45**) and (**46**) have been prepared and are of the type $[Ag_2(\mathbf{45})]^{2+}$ and $[Ag(\mathbf{46})]^+$. In the dinuclear complexes, it is proposed that each silver atom is bound in an *N*,*N*′-mode to the bipyridine moieties, in addition to interactions with O or S-atoms.[450]



X = O or S

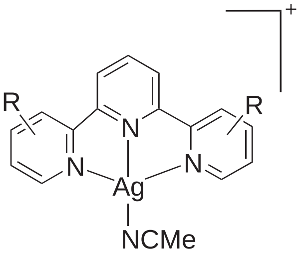
(45)



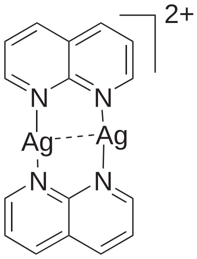
X = N(tosyl), $N(tosyl)(CH_2)_2N(tosyl)(CH_2)_2N(tosyl)$

(46)

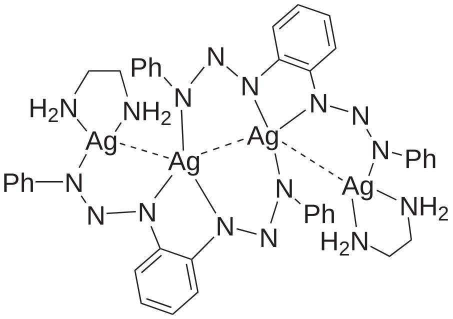
Heteroleptic bis(phenanthroline) silver(I) complexes using 2,9-diarylphenanthrolines as well as unsubstituted or 4,7-disubstituted phenanthrolines have been prepared.[451] The bis(chelate) complexes have also been obtained for the C_{60}-phenanthroline,[452] the 2,9-dimethyl-phen,[453] and the 6,6′dibromo-2,2′-bipyridine derivatives.[454] The structure of $[AgBr\ (phen)(PPh_3)]$ has been reported.[455] The coordination of silver(I) with 2,2′:6′,2″-terpyridine (terpy) and 6,6″-diphenyl-2,2′:6′,2″-terpyridine has been investigated. In weakly coordinating solvents there is evidence of formation of dinuclear double-helical species, but in solvents such as acetonitrile the square-planar complexes $[AgL(MeCN)]BF_4$ (**47**) have been isolated. For terpyridine two cations are associated through a Ag–Ag interaction of 3.1698(12) Å.[456] Treatment of $AgClO_4$ with terpy in acetonitrile gives species of stoichiometry $4AgClO_4\cdot 5terpy\cdot MeCN$, which is shown by X-ray analysis to contain two independent cations, the four-coordinate $[Ag(terpy)(NCMe)]^+$ and the five-coordinate $[Ag_3(\mu\text{-terpy})_2(terpy)_2]^{3+}$.[457] Another five-coordinate silver complex $[Ag(terpy)(PPh_3)_2]ClO_4$ has been reported. Two phosphorus and a central pyridine occupy the equatorial sites, while the two distal pyridines occupy the axial sites forming a distorted trigonal bipyramidal geometry.[458] The ligand 2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine forms a mononuclear pentacoordinate complex $[AgL]PF_6$, in contrast to the double-helical binuclear complexes formed with the first row transition metal ions.[459] The 1,8-naphthyridine (napy) ligand has also been used to prepare dinuclear silver(I) derivatives of the type $[Ag_2(napy)_2](ClO_4)_2$ (**48**), which has a Ag—Ag distance of 2.748(2) Å, shorter than that found in metallic silver.[460,461] The NO_3^- salt has also been reported.[462] A dinuclear complex with the phthalazine ligand has been described, $[Ag_2(C_8H_6N_2)_4](NO_3)_2$, which has two bridging and two monodentate ligands.[460] Bridging bis (triazenido) groups support a rhombus of silver(I) atoms in the complex $[Ag_4L_4]$ that results from the reaction of $AgNO_3$ with $Na[PhN_3C_6H_4N_3(H)Ph]$ (NaL).[463] The reaction of $[Ag(NH_3)_2]^+$ with 1,2-bis(phenyltriazenido)benzene and ethylenediamine gives the tetranuclear complex $[Ag_4\{(PhN_3)_2C_6H_4\}(en)_2]$ (**49**).[464]



(**47**)

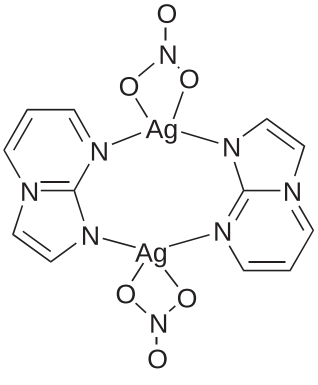


(**48**)

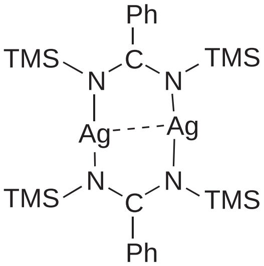


(**49**)

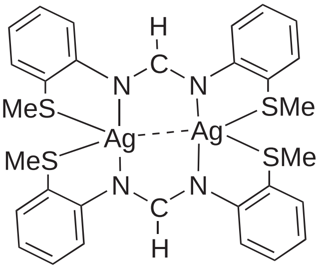
Other dinuclear silver(I) complexes with bridging nitrogen ligands are those with 7-azaindolate,[465] 8-amino-quinoline,[328] 1,1′-diazaferrocene,[466] and 1,2,4-triazolo-1,5-pyrimidine (**50**). In the latter, the nature of the anion appears to play an important role in the stereochemistry of the silver center.[467] Other dinuclear[468,469] silver(I) complexes with substituted triazolopyrimidine ligands and also polymeric species have been obtained.[470] With a related ligand, the anionic form of 4,7-dihydroxo-7-oxo-1,2,4-triazolo-1,5-pyrimidine ($7tpO^-$) and bypyrimidine (bpm) a tetranuclear Ag^I–Pt^{II} complex, $[Pt_2Ag_2(7tpO)_4(bpm)_2\ (H_2O)_2](NO_3)_2$ has been described.[471] Silver(I) complexes with amidinate ligands have been prepared from the reaction of $PhC(NTMS)[N(TMS)_2]$ with AgO_2CMe[472] (**51**) or from more complex amidinate ligands bearing substituents than can coordinate the silver center with silver acetate, e.g. with (**52**).[473] The bis(μ-N,N'-η^2-N',O'-di(*o*-methoxyphenyl)-formidinato)disilver(I) complex is the first example of a room temperature fluorescent d^{10}–d^{10} compound.[474] Theoretical studies of the N,N'-di-*p*-tolylformidinato complex have been carried out, concluding that there is little or no direct metal–metal bonding in these molecules.[475]



(**50**)



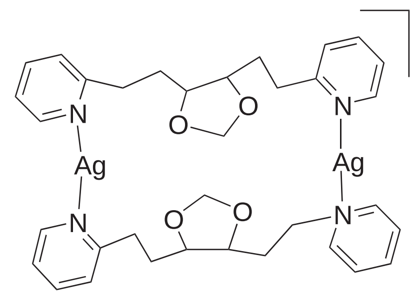
(**51**)



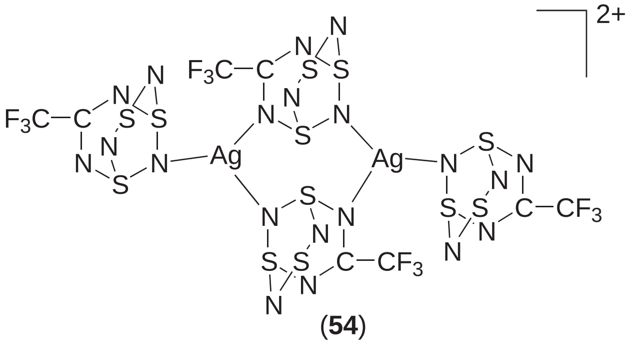
(**52**)

The reaction of silver azide, for which an explosive luminescence has been observed,[476] with $AgNO_3$ in aqueous solution gives the salt $AgN_3{\cdot}2AgNO_3$, in which the azide unit exhibits an unprecedented bridging hexadentate coordination mode as an encapsulated species inside a trigonal prism.[477] Different products have been obtained from the reaction of silver triflate with a racemic mixture or with enantiomerically pure (*R*,*R*) or (*S*,*S*) forms of the ligand 4,5-bis[2-(2-pyridyl)ethyl]-1,3-dioxolane. With the former, the dimeric *meso*-complex (**53**) has been isolated, while with the latter, the *R*,*R* or *S*,*S* forms, respectively, of the polymeric $[AgL]_n^+$ have been characterized.[478] The [2-(6-methyl)pyridyl]trimethylsilylamide (Hmpsa) ligand reacts with $AgNO_3$ and LiBu to give the tetrameric amido complex $[Ag_4(mpsa)_4]$. The ligand bridges the silver(I) centers in a "head-to-head" and "tail-to-tail" fashion to give a cyclic structure.[479] The

1,1,2,3,3-pentacyanopropenide ligand coordinates as bidentate ligand in the complex $[Ag\{NCC[C(CN)_2]_2\}(PPh_3)_2]$.[480] A similar complex with two phosphine ligands and two nitrogen atoms is obtained with the ligand 4-(4-methylphenyl-3,5-bis(2-pyridyl)-4H-1,2-4-triazole).[481] Heterocyclic ligands have been prepared by dimerization of 2-thiouracils and the formation of complexes with silver have been studied.[482] The bicyclic ligand $CF_3CN_5S_3$ reacts with $Ag(AsF_6)$ to form complexes of the type $[Ag(CF_3CN_5S_3)]AsF_6$ or $[Ag(CF_3CN_5\text{-}S_3)_2]AsF_6$ (**54**), the coordination takes place through the nitrogen atoms.[483]



(**53**)



(**54**)

The silver cluster with bridging amido ligands $[Ag_6Cl_2(NHPh)_4(PPr^n{}_3)_6]$ have been obtained from the reaction of silver chloride, tertiary phosphine and litiated aniline.[484] The metallacryptand $[Ag_{12}(NPEt_3)_8](SiF_6)_{1.5}$ has been obtained by reaction of AgF with the silylated phosphinoimine $TMSNPEt_3$.[485] In the cation, the silver atoms are located on the edges of a nearly undistorted cube and the N-atoms of the ligand occupy the vertices, a fluoride atom is in the center of the cube and has contacts with all the silver atoms.

Silver(I) complexes with macrocyclic nitrogen ligands are also very numerous. Mono- or homodi-nuclear silver-containing molecular clefts can be synthesized from the cyclocondensation of functionalized alkanediamines or triamines with 2,6-diacetylpyridine, pyridine-2,6-dicarbaldehyde, thiophene-2,5-dicarbaldehyde, furan-2,5-dicarbaldehyde, or pyrrole-2,5-dicarbaldehyde in the presence of silver(I).[486–497] The clefts are derived from bibracchial tetraimine Schiff base macrocycles and have been used, via transmetallation reactions, to complex other metal centers. The incorporation of a range of functionalized triamines has provided the conformational flexibility to vary the homodinuclear intermetallic separation from ca. 3 Å to an excess of 6 Å, and also to incorporate anions as intermetallic spacers. Some examples of the silver(I) complexes obtained are shown in Figure 5.

Similarly, by Schiff-base condensation reactions have been used to generate free cryptands from triamines and dicarbonyls in [2+3] condensation mode. These ligands react with silver(I) compounds to give dinuclear or trinuclear macrocyclic compounds where Ag···Ag interactions may be present. Thus, with a small azacryptand a dinuclear complex with a short Ag···Ag distance (**55**) is found.[498] With bigger azacryptand ligands also dinuclear complexes as (**56**) are achieved but without silver–silver interaction.[165,499–501] A heterobinuclear Ag^I—Cu^I cryptate has also been

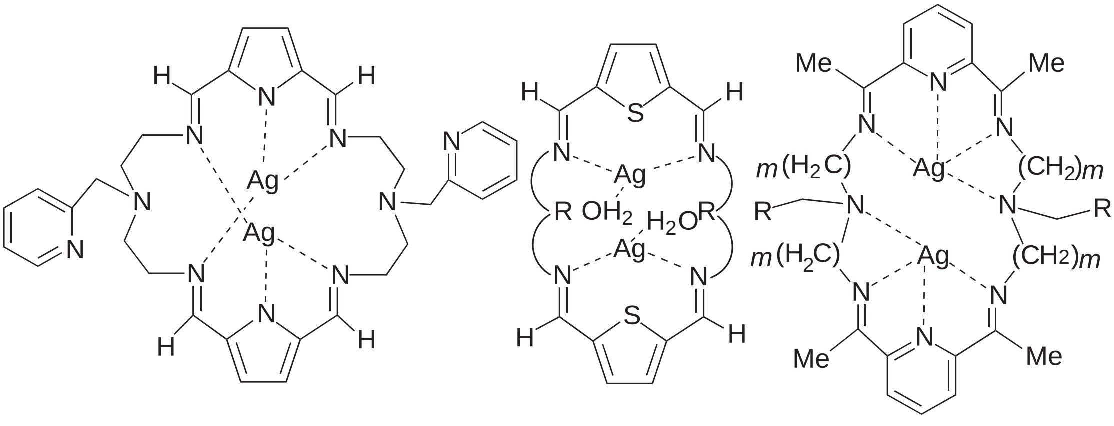


Figure 5 Some examples of silver complexes with Schiff base macrocycles.

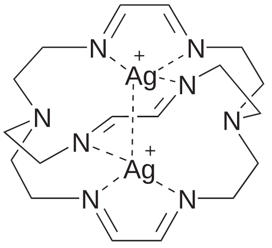
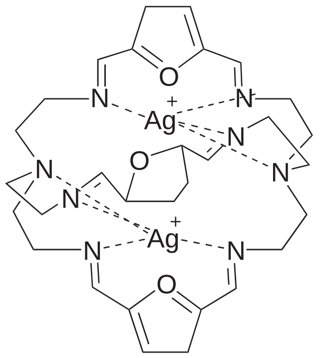
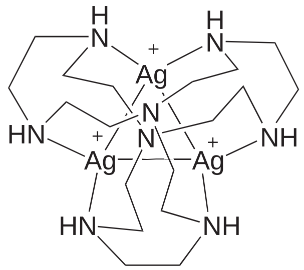
synthesized.[502] Aminocryptand ligands have been less studied but a disilver and a trisilver derivative (**57**) have been obtained.[503]



(55)

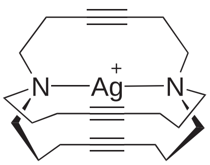


(56)

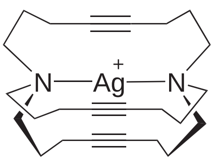


(57)

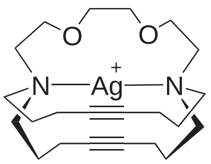
Silver(I) cryptates with a series of (1,k+2)diazabicyclo[k,l,m]alkanes in which the bridges contain either alkyne or benzene such as (**58**), (**59**), or (**60**) have been prepared. The incorporation of a silver ion into the cages results in drastic changes of the conformations of the ligands. The driving force for this change is a close interaction between the nitrogen centers and the metal. As a side effect of these conformational changes close contacts between the silver ion and the triple bonds in the solid state and solution have been observed.[504,505]



(58)

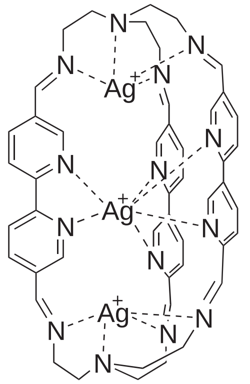


(59)

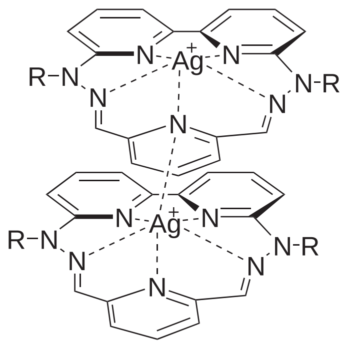


(60)

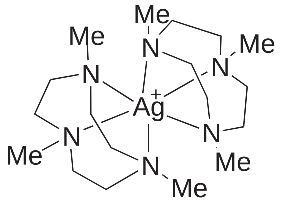
The macrocyclic tris-bipyridine ligand forms a trinuclear silver derivative (**61**).[506] Other macrocyclic ligands containing bipyridine or phenanthroline moieties react with $AgBF_4$ to give $[Ag_2L_2](BF_4)_2$; the crystal structure reveals a dimeric structure with two distinct silver environments (**62**).[507] The complex formation between silver(I) ions and the macrocyclic ligand 1,4,7-triazaciclononane (L^1) and its tri-*N*-methylated derivative (L^2) has been investigated. Complexes of the type $[AgXL^1]$ (X = Cl, Br, I) or $[AgXL^2]$ (X = CN, SCN) and $[AgL^1{}_2]^+$ or $[AgL^2{}_2]^+$ (**63**) have been obtained.[508]



(61)

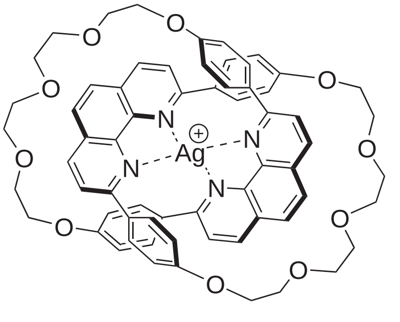


(62)

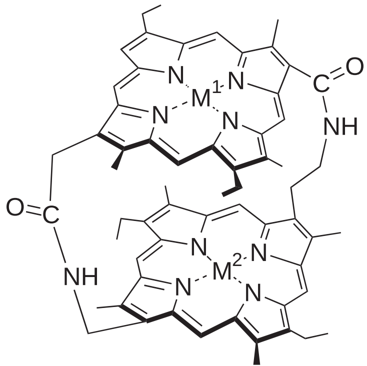


(63)

Several silver(I) complexes of the macrocyclic Schiff base derived from the [2+2] condensation of terephthalaldehyde and 3-azapentane-1,5-diamine or *N*,*N*′-bis(3-aminopropyl)methylamine have been described.[509,510] The reaction of 2,11-diaza-difluoro-*m*-[3,3]-cyclophane with 2,6-bis (bromomethyl)pyridine lead to the 3 + 3 addition product, which gives a complex with two silver atoms.[511] Complexation studies of the silver(I) cation by catenands have been carried out. Complex (**64**) represents a probable structure for one of these complexes.[512–514] The synthesis of heterobimetallic "face to face" dimeric porphyrins (**65**) is achieved using silver as the protecting group in one of the coordination centers.[515] The structure of hexamethylenetetramine-silver(I) chloride has been carried out showing three Ag^I cations with different coordination numbers, octahedral, tetrahedral, and tetragonal pyramidal.[516] A series of differently functionalized *all*-homocalixpyridines and their open-chain analogues have been synthesized. These macrocycles show a pronounced selectivity towards soft metal ions such as Ag^I, one example is the trinuclear complex (**66**).[517] Also bis-calix[4]arene with imine units show high selectivity towards Ag^+.[518]

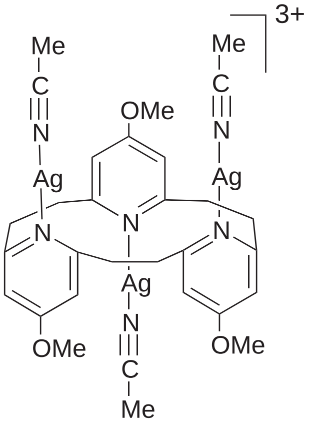


(**64**)



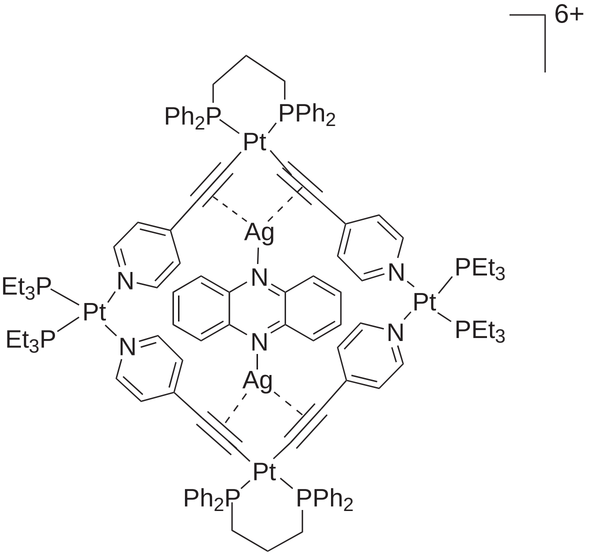
(**65**)

$M^1 = M^2 = Ag$
$M^1 = Co; M^2 = Ag$



(**66**)

Host–guest complexes such as (**67**) have been prepared from molecular squares involving Lewis base receptor sites, such as $\{\text{cyclobis}[(\textit{cis}\text{-(dppp)Pt(4-ethynylpyridyl)}_2)(\textit{cis}\text{-LM})]\text{Ag}_2\}^{6+}(\text{OTf})_6$, where $M = Pd^{II}$ or Pt^{II} and $L = dppp$ or $2PEt_3$, by reaction with pyridine, pyrazine, phenazine, or 4,4′-dipyridyl ketone.[519]



(**67**)

(iii) Supramolecular compounds

Recent years have witnessed considerable interest in the development of rational synthetic routes to supramolecular architecture from self-assembly of component metal complexes. These solid materials with well-defined, discrete network topologies are attractive to chemists not only for aesthetic reasons but also for their potential applications in many areas. Silver(I) complexes with *N*-donor ligands give rise to an interesting array of stoichiometries and geometric configurations, with the coordination numbers of two to six all occurring. They adopt novel structures such as multidimensional helical, honeycomb channel, interwoven diamondoid, graphite framework, etc.

The majority of silver compounds with helical structures have concentrated on the use of oligopyridines and oligophenanthrolines. They can be single-, double-, or triple-stranded helicates.[520–559] The ligands involved in this type of structure are listed in Figure 6. The silver complexes with triazolate, tetrazolate $[\mathrm{Ag(tetz)(PPh_3)_2}]_n$, and *L*-histidine $[\mathrm{Ag(Hhis)}]_n$ have effective antibacterial and antifungal activities.[536,537,539]

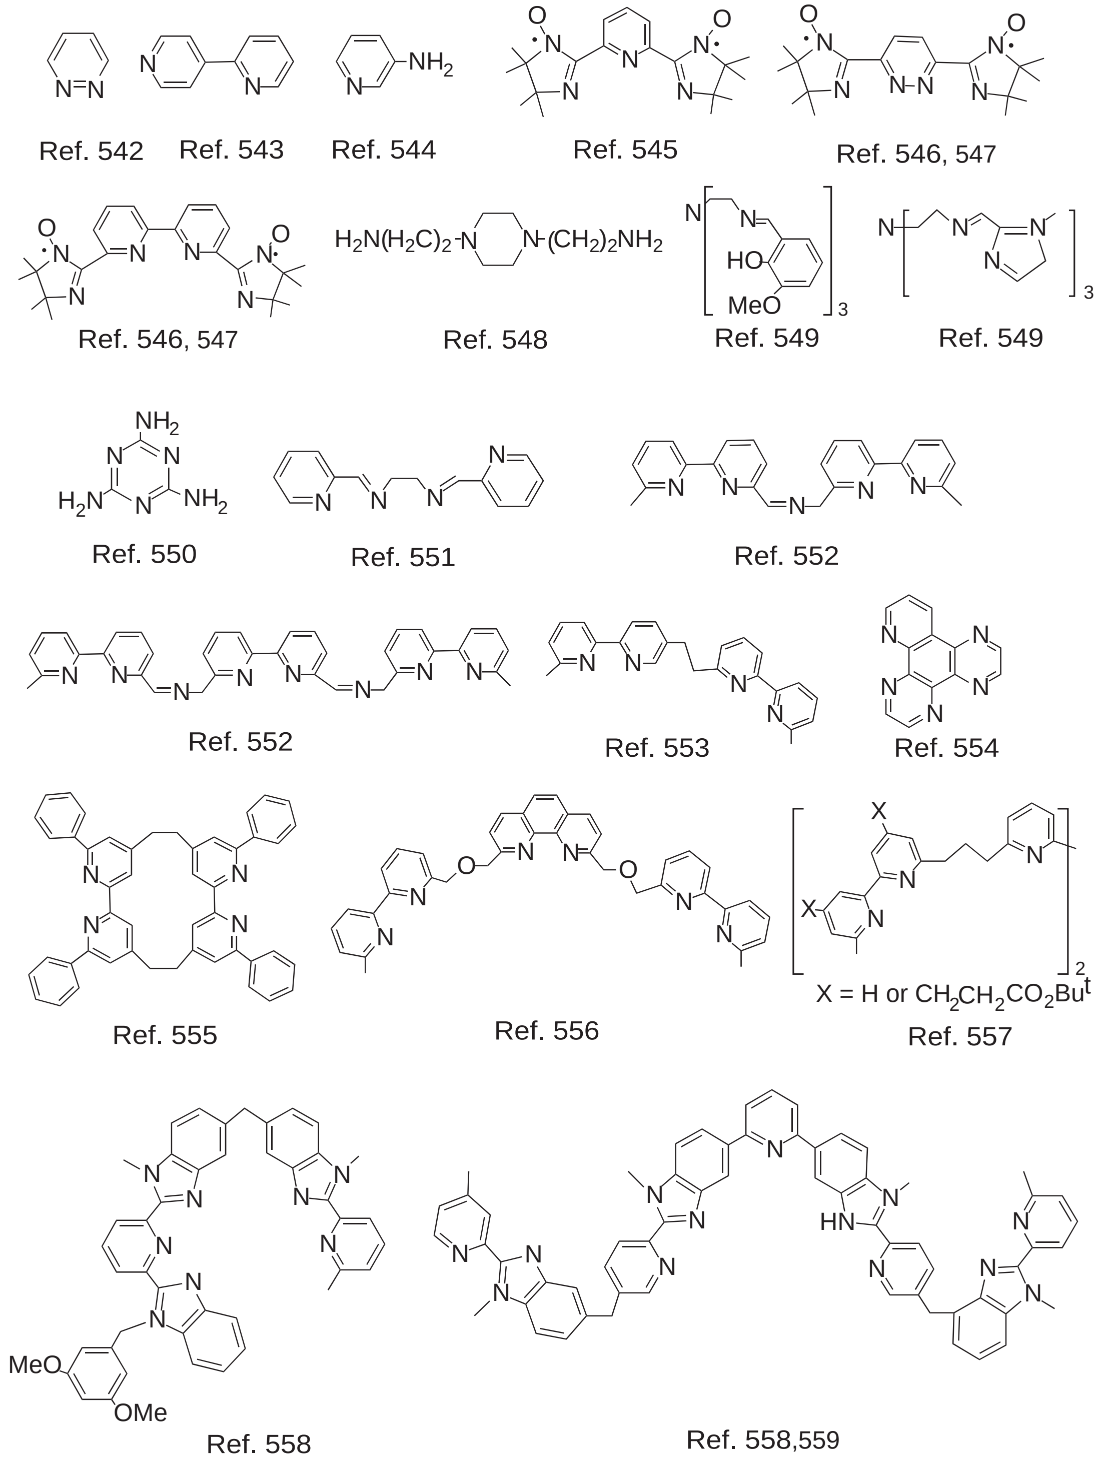

Figure 6 Ligands which form silver(I) complexes with helical structures.

1D-, 2D-, or 3D polymeric structures have been constructed using rigid nitrile ligands such as those shown in Figure 7. If the cyano groups have opposite directions they can act as road-like bridging ligands in the construction of diamondoid frameworks.

Polymeric silver(I) complexes have also been achieved with cyanosulfanes, they react with silver(I) according to Equation (5).

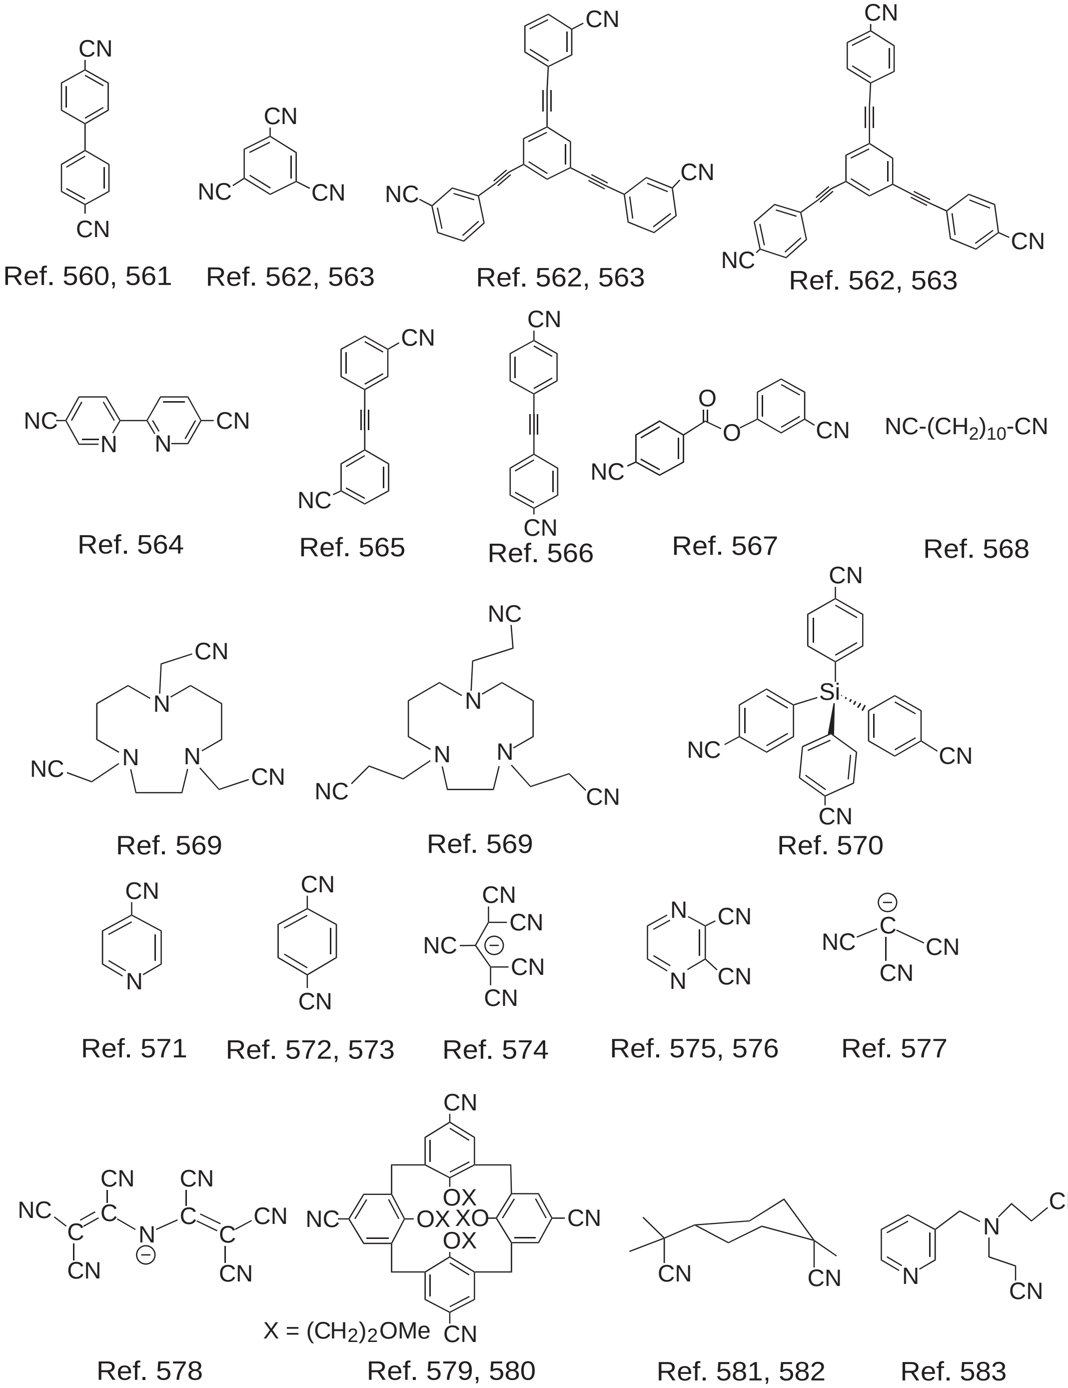

Figure 7 Rigid nitrile ligands which form polymeric silver(I) complexes.

$$2\ \mathrm{S}_n(\mathrm{CN})_2 + \mathrm{Ag(AsF_6)} \xrightarrow{\mathrm{SO_2}} [\mathrm{Ag\{S}_n(\mathrm{CN})_2\}_2]\mathrm{AsF_6} \qquad (5)$$

$$n = 3, 4$$

The dicyanosulfanes serve in these complexes as bridging ligands and undergo coordination through their terminal nitrogen atom, giving a chain polymer ($n = 3$) or a layer polymer ($n = 4$).[584] The tricyanofluoroborate anion, $\mathrm{FB(CN)_3^-}$, forms a network polymer $[\mathrm{Ag\{BF(CN)_3\}(NCMe)}]_n$ with silver(I), which exhibits 1D channels along the *b*-axis.[585]

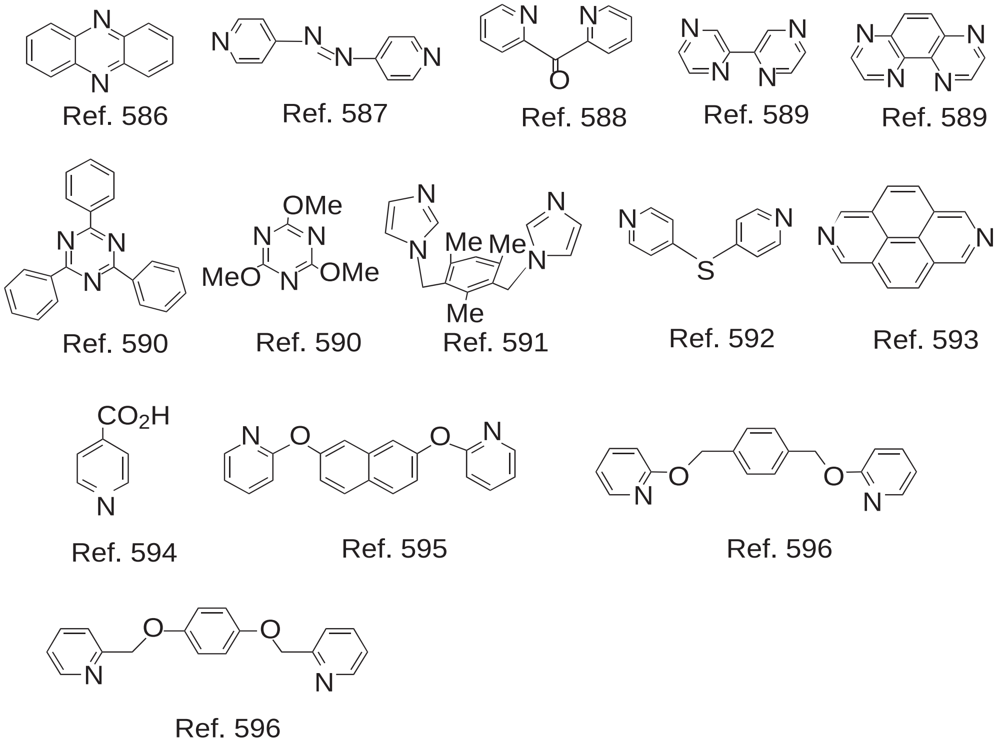

Figure 8 Ligands which form silver(I) complexes with supramolecular structures through π-π interactions.

Planar coordination compounds with aromatic ligands, especially those having extended π-systems, show π–π interactions in the solid state. The ligands shown in Figure 8 form complexes with silver(I) which have a supramolecular structure through π–π interactions.[586–596]

Hydrogen bonding also plays an important role in the construction of metal aggregates. Amide moieties have a well-established propensity to engage in complementary hydrogen bonds resulting in either in infinite ribbons (through head-to-head interactions), or in infinite chains via equivalent N—H···O interactions. Figure 9 shows the ligands involved in this type or silver(I) aggregates.[470,597–604]

In some of these type of polymeric materials there are two forces that organize the polymer strands into a supramolecular structure, and are usually hydrogen bonds and π–π interactions, this happens with the complex $[1,2,4,5\text{-}C_6H_2\{CH_2OCH_2C(pz)_3\}_4Ag_2(BF_4)_2]_n$.[605]

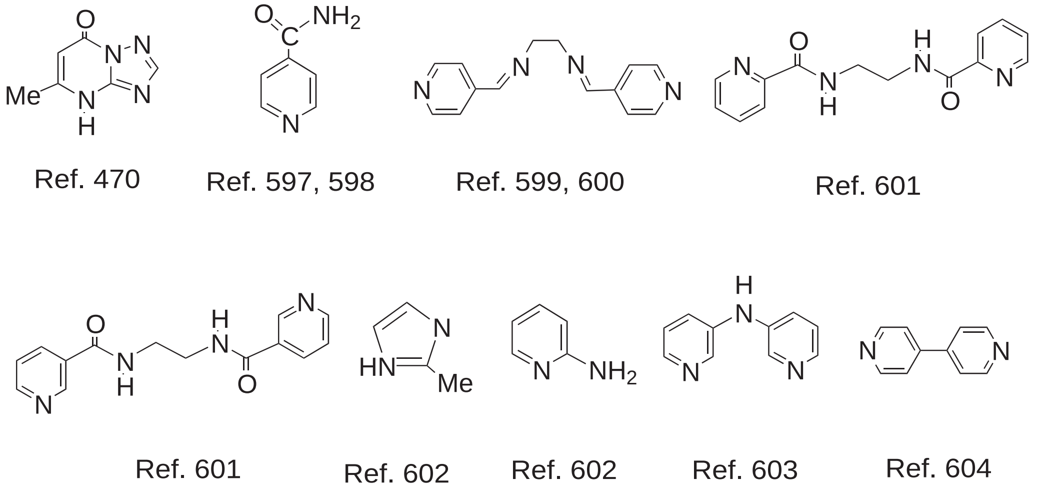

Figure 9 Ligands which form silver(I) complexes with supramolecular structures through hydrogen bond.

Pyrazines and substituted pyrazines have long been known to act as exo-bidentate ligands to linearly bridge metal ions, and then have also been employed for the self-assembly of polymeric materials. With pyrazine (prz) varying the reaction conditions and stoichiometry, 1D, 2D, and 3D structures containing silver(I) atoms with several coordination modes have been prepared.[606–609] A 3D racemate is present in $[Ag_2(2,3\text{-}Me_2prz)_3](SbF_6)_2$.[610] A sawhorse connection has been achieved in the compound $[Ag(NO_2)(pyz)]_n$.[611] With 2,2′-bipyrazine an infinite loop has been obtained.[612]

Silver(I) complexes with polyamines also form molecular aggregates, thus hexamethylenetetramine yields 2D and 3D coordination networks,[613] polymeric chains are obtained with diethylenetriamine, tris(2-aminoethyl)amine, or *N*,*N*′-bis(aminoethyl)propane-1,3-diamine,[426] and 2D networks are formed with thiocyanate and bridging polyamines.[614]

Pyridine and related ligands gives silver(I) aggregates with different structural motifs. The complexes $[AgBr(3\text{-}MePy)]_n$ and $[AgBr(4\text{-}MePy)]_n$ give a tube and a stair polymer structural type, respectively.[615] The silver adducts with thiocyanate instead of bromo give 2D polymers.[616] The adduct of silver(I) chlorine with quinoline gives a polymer comprising Ag_5X_4 face-centered motifs linked in a linear polymeric array through the silver atoms of the opposite corners of the face.[617] Polymeric structures have also been described with the ligands *trans*-1,2-bis(2-pyridyl) ethane,[618] bipyridine, and thiocyanate,[619] 2-pyridinolate,[620] 2-pyridylketone,[621] 4,4-bipyridine,[622] 1,3-bis(pyridyl)propane,[623] *N*,*N*′-bis(2-pyridylmethyl)piperazine,[624] 1,6-bis(4′-pyridyl)-2,5-diazahexane,[625] and 2-(2-pyridyl)quinoxaline.[626] A cylindrical-shaped coordination polymer is formed by self-assembly of 2,2,4,4,6,6-hexakis(4-pyridylmethoxy)-2λ^5,4λ^5,6λ^5-cyclotris(phosphazene) with $AgNO_3$.[627] Two more silver(I)-phosphazene polymers have been reported from the reaction of $[\text{—N=PPh}_2\text{–}]_n$ and $[\text{—N=P(NHCy)}_2\text{–}]_n$ with AgOTf and $AgNO_3$, respectively.[628,629] 1,2-Bis (4-pyridyl)ethyne, 1,4-bis(2-pyridyl)butadyine, and 1,4-(4-pyridyl)butadyine give 1D or 2D frameworks depending on the anion of the silver salt.[630–632] Polypyridyl ligands such as 2,3-di-2-pyridylquinoxaline, 2,3-di-2-pyridyl-5,8-dimethoxyquinoxaline, and 2,3,7,8-tetrakis(2-pyridyl)pyrazino[2,3-*g*] gives box-like dinuclear or chain polymeric silver(I) complexes.[633] The mode of coordination of the multidentate ligand 2,2′-dimethyl-4,4′-bipyrimidine depends on the metal ion, anion, metal-to-ligand ratio, and crystallization conditions, with silver(I) 2D and 3D networks being obtained.[634] A novel synthetic procedure has been reported for the preparation of soluble, well-defined silver(I) coordination polymers from 4,4″-bis((9-aryl)-2-*o*-phenanthrolinyl)-2′,5′-dihexyl-*p*-terphenyl, which consist of the exclusion of all molecules that might act as competitive ligands for the metal ions of the polymer.[635]

Self-assembly of azolate ligands and silver cations also leads to supramolecular networks. The species $[Ag(tetrazolate)]_n$ or $[Ag(tetrazolate)\cdot AgNO_3]_n$ have a 3D structure with a $\mu^4\text{-}\eta^1{:}\eta^1{:}\eta^1{:}\eta^1$ bonding mode.[636] The ligands 2,6-bis(pyrazolyl)pyrazine[637] and 2-(3-pyridyl)benzimidazole[638] form silver(I) complexes with tubular coordination networks or low-dimensional structures, respectively. The chemical reaction of imidazole with metallic silver has been studied by surface-enhanced Raman scattering and X-ray photoelectron spectroscopy and show that the product formed is silver(I) imidazolate, which covers the surface of the metal as a monolayer.[639] The 1:1 complex formed by silver(I) and 2,1,3-benzothiadiazole consists of two-coordinate silver atoms and bridging ligands.[640]

An spontaneous assembly of 15 components is reported in the synthesis of $[Ag_9L_6](OTf)_9$ where L is the hexadentate, tris-chelating 6,6-bis[2-(6-methylpyridine)]-3,3′-bipyrazine. The structure consists of a 3 × 3 grid of Ag-atoms (average Ag···Ag = 3.72(3) Å), sandwiched between two almost perpendicular sets of three parallel L ligands (Figure 10).[641]

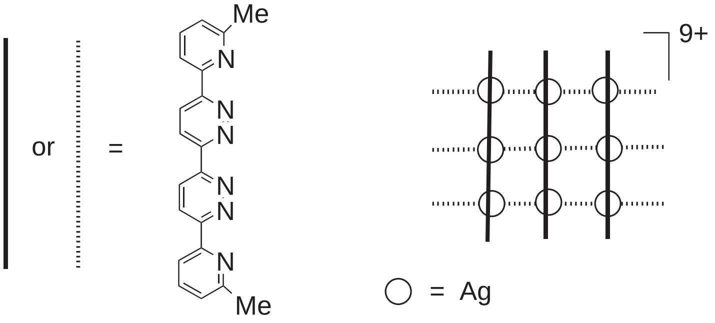

Figure 10 Assembly of components in $[Ag_9L_6](OTf)_9$.

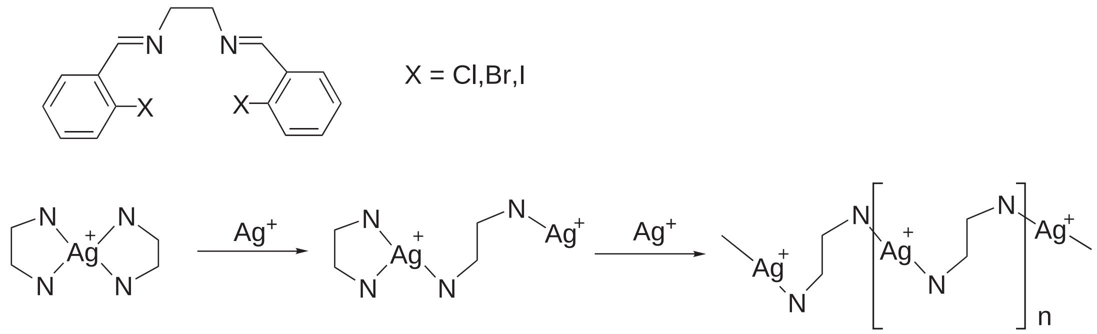
The reaction of AgOTf with a flexible diimine ligand in 1:2 and 1:1 ratio leads to the mono- or dinuclear complex, respectively. They further react with AgOTf to give coordination polymers. These complexes are models for the chain-growth process required in the formation of coordination polymers (see Scheme 2).[642,643] Similar complexes are obtained with the 1,4-di-*t*-butyldiazabut-1,3-diene derivative.[644]



Scheme 2

A trinuclear complex with a bridging tridentate cyanide ion and 1.5 molecules of the tetrapodal ligand 1,2,4,5-tetrakis(pyrazol-1-ylmethyl)benzene has been described. These units assemble further into large macrocyclic rings, and these rings then interlock to produce a 2D metallopolymeric network.[645] Another silver(I) polymeric complex has been prepared with the ligand amidoselenato, $Ag_2SeO_3N{\cdot}3NH_3{\cdot}2H_2O$.[307]

Heterometallic polymers are formed by reaction of $[PtI_2(PP)]$ (PP = 1,2-[bis(2-pyridyl)phosphino] ethane (d(Py)pe) or cyclopentane (d(Py)pcp) with excess of $AgNO_3$, which gives the complexes $[Pt_2\{d(Py)pe\}_2Ag_4(NO_3)_8(H_2O)_2]_n$ or $[Pt_2\{d(Py)pcp\}_2Ag_6(NO_3)_{10}]_n$. These compounds contain the $[Pt_2(PP)_2]^{4+}$ units, with each diphosphine ligand *P*,*N* bonded to platinum, connected via bridging $AgNO_3$ cluster, the Ag being bound to the pyridyl nitrogen or nitrate oxygen atoms.[646]

Bovine copper–zinc superoxide dismutase (Cu_2Zn_2SOD) is one of the most thoroughly characterized nonheme metalloproteins. This protein serves as unique ligand in reactions where the native metal ions are replaced by another as silver to form derivatives such as Ag_2Cu_2SOD, Ag_2Co_2SOD, Ag_2Ni_2SOD, and Ag_2Zn_2SOD, in which it is believe that the imidazole bridges are not maintained.[647,648]

6.7.2.3.3 Complexes with phosphorus, arsenic, antimony, or bismuth donor ligands

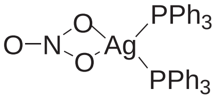
(i) Complexes with monodentate ligands

Numerous phosphine complexes (and some arsine and stibine analogues) are known. With monophosphines these are mainly of the type $[AgX(PR_3)_n]$ with $n = 1$–4. The 1:1 compounds are tetrameric, with either cubane or chair structures depending on the steric requirements of both X and PR_3. Several studies in solution or in the solid state of the coordination of one to four phosphine ligands to a silver center have been performed. They reveal that steric effects as well as electronic effects are important on the coordination behavior of the complexes. For example with phosphine ligands such as $P(NMe_2)_3$, $P(NMeCH_2)_3CMe$, or $P(\text{–}NCH_2CH_2\text{–})_3$, only with the smaller ligand $P(\text{–}NCH_2CH_2\text{–})_3$ coordination number four could be achieved. However, the ligand $P\text{–}(OCH_2)_2CHO\text{–}$ is shown to form only a monoligated Ag^I complex in solution despite its very small steric requirements, whereas $P(OCH_2)_3CEt$ and even larger phosphites such $P(OPr^i)_3$ form isolable four-coordinate complexes. Other two- and three-coordinate silver(I) compounds with phosphite ligands have been described, such as $[Ag\{P(OPr^i)_3\}_n]^+$ ($n = 3$, 4), $[Ag\{P(OPh_3)\}]^+$, $[Ag\{P(OBu^t)_3\}_2]^+$, and $[AgX\{P(OBu^t)_3\}]$ (X = Cl, Br, BF_4).[649,650]

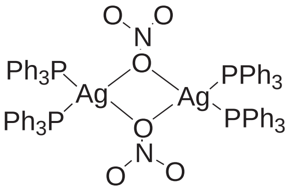
By using $PR^1{}_2R^2$ or $As(C_5H_9)_3$ ligands of intermediate size between PCy_3, which form two-coordinate species, and PPh_3, which form four-coordinate species, several three-coordinate ($R^1 = Ph$; $R^2 = Ph$, Cy, C_5H_9) or two-coordinate ($R^1 = C_5H_9$, Cy; $R^2 = Ph$) complexes have been obtained.[651,652] With the bulky ligand $P(Mes)_3$ only dicoordination, $[Ag\{P(Mes)_3\}_2]PF_6$, is achieved.[1,653] With the related sterically hindered and very basic phosphine ligand $P[2,4,6\text{-}(MeO)_3C_6H_2]_3$ the complexes $[AgX\{P[2,4,6\text{-}(MeO)_3C_6H_2]_3\}]$ (X = Cl or Br) have been obtained. Both are mononuclear and exhibit an almost linear silver(I) center. Phosphorus-31 NMR studies show that in solution the reaction with another equivalent of phosphine takes place to generate the species $[Ag\{P[2,4,6\text{-}(MeO)_3C_6H_2]_3\}_2]X$.[654] Two-coordinate species have also been achieved with PPh_3; the reaction of $AgBF_4$ with two equivalents of PPh_3 in acetonitrile gives $[Ag(NCMe)(PPh_3)_2]BF_4$. The acetonitrile ligand is loosely bound and recrystallization in CH_2Cl_2/hexane results in the isolation of the low-coordinate phosphine complex $[Ag(PPh_3)_2]BF_4$.[655] The crystal structure of $[Ag(PPh_2Me)_2]ClO_4$ has been reported and shows a linear geometry for the silver(I) center.[656]

Silver chloride reacts with triphenylphosphine to give either $[AgCl(PPh_3)_2]$ or $[AgCl(PPh_3)_3]$, depending on the solvent, whereas silver bromide and iodide afford the tris(triphenylphosphine)-silver(I) halides. These complexes react with $SnCl_2$ to yield the trichlorostanniosilver derivatives.[657] The crystal structures for $[AgX(PPh_3)_3]$ (X = Cl, Br, I) have been reported.[657–660] The structures of the silver(I) derivatives $[AgBr(PPh_3)_2]$ and $[Ag_2X_2(PPh_3)_4]$ (X = Cl or Br) show discrete monomeric units for the former and dimeric four-coordinate silver(I) units with bridging halides for the latter.[661] The solid state structures of $[AgX(PPh_2Bu)]$ (X = Cl, Br, I) have been determined crystallographically and shown to consist of Ag_4X_4-cubanes.[662] A ^{31}P NMR study for $[AgI(PMe_3)]$ shows two resonances that are assigned to the tetranuclear and mononuclear forms of the complex.[663]

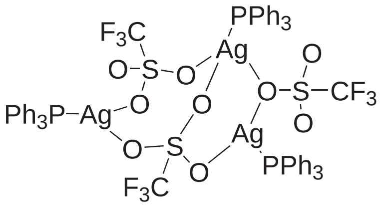
Several studies have been carried out with triphenylphosphine–silver complexes with various anions. They show different structural motifs and most of them have been characterized by XRD studies and solid-state cross-polarization magic-angle spinning (CPMAS) NMR spectroscopy. The complexes $[Ag(NO_3)(PPh_3)_n]$ ($n = 1$–4) have been prepared and characterized structurally by solid-state ^{31}P NMR or XRD studies. The value of J(AgP) decreases with increasing coordination number. For $n = 1, 2,$ or 3 the NO_3^- groups are weakly coordinated and it is ionic in $[Ag(PPh_3)_4]NO_3$.[664] Also the nitrato complexes $[Ag(NO_3)(PPh_3)_2]$, $[Ag(NO_3)\{P(3\text{-}MeC_6H_4)_3\}_2]$, and $[Ag\{P(CH_2CH_2CN)_3\}_2]NO_3$ (with a linear geometry) have been studied by solid-state magic-angle spinning (MAS) ^{31}P NMR spectra and XRD.[665,666] The complex $[Ag(NO_3)(PPh_3)_2]$ has been characterized as a mononuclear complex with a bidentate nitrato ligand[664,667] (**68**) or as a dinuclear complex with a bridging nitrato group (**69**).[668] Trifluoromethanesulfonate(phosphine) silver(I) complexes of the type $[Ag(OTf)(PR_3)_n]$ ($PR_3 = PPh_3$, PPh_2Me; $n = 1$–4) have also been characterized structurally. The solid-state structures display a wide variety of nuclearities, silver coordination numbers, and trifluoromethane coordination modes, depending on the phosphine. Thus, for $[Ag(OTf)(PPh_3)]$ (**70**) the structure is a trimer with bridging triflates, and for $[Ag(OTf)(PPh_2Me)]$ it is a tetramer with a chair geometry, further linked into chains by Ag–phenyl interactions. The complexes $[Ag(OTf)(PR_3)_2]$ present a dimer (PPh_3) with bridging triflates or monomer (PPh_2Me).[669–671]



(68)



(69)



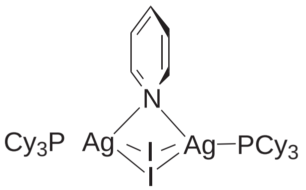
(70)

The structure of $[Ag(O_2CMe)(PPh_3)_2]$ has been reported and consists of a dimer with bridging acetate groups through only one oxygen atom.[672] Other complexes have been reported with several anions such as formiate, sulfate, selenate, or phosphate. The species $[Ag(O_2CH)(PPh_3)_2]$ and $[Ag(O_2CH)(PPh_3)_3]$ have been prepared showing a trigonal planar or tetrahedral geometry, respectively.[673,674] The silver complexes with the oxyanions show different stoichiometries. The compounds $[Ag_2(EO_4)(PPh_3)_4]\cdot 2H_2O$ (E = S, Se) contain the anion bridging the two silver atoms via two oxygen atoms. The $[Ag(HEO_4)(PPh_3)_2]$ (E = S, Se) derivatives contain two independent molecules in which the protonated oxyanion is terminally bound to the silver atoms by a single oxygen atom. In one of them the silver atom makes an extra bond to the oxygen of the water. In the complex $[Ag(H_2PO_4)(PPh_3)_2]$ the silver atom is also three-coordinate.[675]

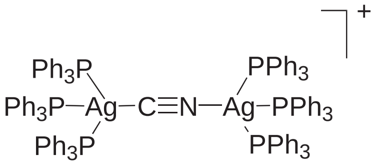
Similar studies have been carried out with $AsPh_3$ and $SbPh_3$. The complexes $[Ag(NO_3)(AsPh_3)_n]$ ($n = 1$–3),[676] $[Ag(NO_3)(SbPh_3)]$, and $[Ag(NO_3)(SbPh_3)_3]$ have been prepared and are isomorphous with the triphenylphosphine analogues.[677,678] The 1:1 adducts are polymers with bridging nitrato groups. The other complexes have the expected four-coordinate geometry with the silver atom bonded to the nitrato group and to the P/As/Sb ligands.

The four-coordinate homoleptic complexes $[Ag(EPh_3)_4]^+$ (E = P, As, Sb) have been characterized structurally with several anions; for PPh_3, with NO_3^-,[664] $[SnPh_2(NO_3)_2(Cl,NO_3)]^-$ (disordered distribution between Cl^- and NO_3^-),[679] ClO_4^-,[680] PF_6^-,[681,682] and BPh_4^-;[683] for $AsPh_3$, with $[SnPh_2(NO_3)_3]^-$,[676] $[Sn_2Ph_4(NO_3)_4(OH)_2]^{2-}$,[684] ClO_4^-,[685] and BF_4^-.[686] The latter allows comparison with the isostructural gold complex reflecting that the covalent radii of gold is found to be 6% smaller than silver. For $SbPh_3$, with ClO_4^- [685] and BF_4^- have been characterized.[687] Also the complexes $[Ag(SbR_3)_4]BF_4$ ($R_3 = Me_3$, Et_3, Ph_2Me, $PhMe_2$, $Me_2(2\text{-}BrC_6H_4)$) have been prepared.[687]

Spectroscopic and structural studies have been carried out on 1:1 and 1:2 adducts of silver(I) salts with tricyclohexylphosphine, $[AgX(PCy_3)]$ (X = Cl, Br, I) and $[AgX(PCy_3)_2]$ (X = CN, I, Br, Cl, SCN, NCO, NO_3, ClO_4). The 1:1 chlorine and bromine adducts have a dimeric structure with bridging halide ligands. The iodine derivative is a cubane but recrystallization from pyridine gives a novel dimer $[Ag_2I_2(Py)(PCy_3)_2]$ (**71**). The 1:2 adducts have the expected three-coordinate planar geometry.[688,689] The complexes $[Ag(NO_3)(PCy_3)_2]$ and $[Ag(ClO_4)(PCy_3)_2]$ have also been described as tetrahedral or trigonal planar, respectively.[690] The analogous $[AgX(AsCy_3)_2]$ (X = Cl, Br, I, NO_3, NCO, CN) structures have been synthesized and characterized structurally, the chlorine and nitrate are dimers, the bromine and iodine are cubane tetramers, and the cyanide is a linear polymer.[691] The adducts AgCN:EPh_3 (E = P, As, Sb) (1:2) and AgCN:PPh_3 (1:1) have been characterized and show for the 1:2 adducts of PPh_3 and $AsPh_3$ complexes of the form $[(Ph_3E)_3Ag(CN)Ag(EPh_3)_3][Au(CN)_2]$ (**72**) and for $SbPh_3$ adduct and the 1:1 of PPh_3 the structures are single-stranded polymers of the form $\cdots Ag(EPh_3)_2(CN)Ag(EPh_3)_2\,(CN)\cdots$ (E = P, Sb).[692] The structure of $[Ag(NCS)(PPh_3)_3]$ have been reported.[693]



(71)



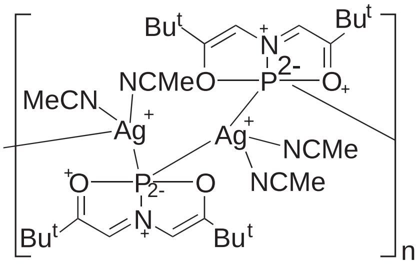
(72)

With $AsPh_3$ the adducts $[AgX(AsPh_3)_n]$ ($n = 1$–3; X = Cl, Br, I, SCN) have been studied and the 1:1 complexes are tetramers,[694] the 1:2 dimers,[695] and the 1:3 mononuclear complexes.[696] The species $[AgX(SbPh_3)_n]$ ($n = 2$, X = Cl, Br, I; $n = 3$, X = Cl, Br, I, SCN, NCS, CN) present similar structures.[678,698] Another crystal structure determination for $[AuCl(AsPh_3)_3]\cdot 0.5Me_2CO$ has been determined.[697]

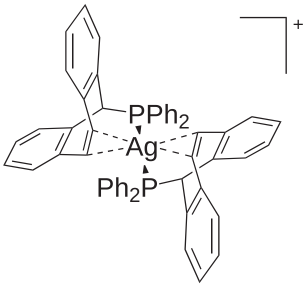
The reaction of Ph_3SiLi with PMe_3 and AgCl gives $[Ag(SiPh_3)(PMe_3)_3]$, the first Ag–Si complex reported.[699] The stability of compounds in the series $[Ag(SiR^1{}_3)(PR^2{}_3)_n]$ ($n = 1$–3; R^1 and R^2 aryl or alkyl), $[Ag_2(SiR_3)_2(\mu\text{-ddpm})]$ and $[Ag_2(SiR_3)_2(\mu\text{-dppe})]$ increases in going from monodentate to bidentate phosphine ligands and for the monodentate examples, complex stability increases with n.[700] Di-*t*-butyl(trichlorogermyl)phosphine reacts with silver bromide to give $[Ag_4Br_4(Bu^t{}_2PCl)(Bu^t{}_2PGeCl_3)_2]$; the structure has a cubane-like $(AgBr)_4$ core with two silver atoms coordinated by a chlorophosphine and the other two by trichlorogermylphosphine.[701]

Phenyl/2-pyridyl phosphines $P(2\text{-}Py)_nPh_{3-n}$ ($n = 1$–3) form 1:1 complexes with AgCl. The insoluble $[AgCl(PPy_3)]$ is probably a coordination polymer, but $[AgCl(PPh_2Py)]$ is a tetrameric complex where the silver and the chlorine atoms form a distorted cube. The coordination of the PPh_2Py ligand to silver is only through the phosphorus atom.[702] Similarly with the phosphine ligand $PPh_2(2\text{-}NH_2C_6H_4)$ which gives the silver(I) complexes $[Ag(EtOH)_2\{PPh_2(2\text{-}NH_2C_6H_4)\}_2]NO_3$ and $[Ag\{PPh_2(2\text{-}NH_2C_6H_4)\}_3]NO_3$, the coordination of the ligand is only through the phosphorus atom.[703] The tetrahedral species $[Ag\{PPh_2(2\text{-}NH_2C_6H_4)\}_4]PF_6$ has been also prepared and is a potential anticancer agent. Preliminary biological studies have shown it to be active against three mouse tumor cell lines *in vitro* with cytotoxicities being comparable to those of cisplatin.[704]

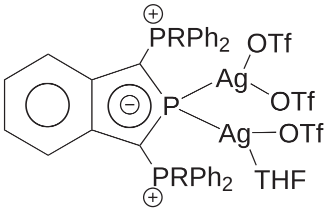
The stepwise formation of $[AgL_n]PF_6$ ($n = 1$–4) for L = PPh_3 and 5-phenyldibenzophosphole has been observed *in situ* by stopped-exchange solution ^{31}P NMR spectroscopy.[705] A series of phosphole complexes of the type $[AgXL]_4$ or $[AgXL_2]_2$ (X = Cl, Br, I; L = 1-phenyl-3,4-dimethylphosphole) or $[AgXL_2]_2$ or $[AgXL_3]_4$ (X = Cl, Br, I; L = 1-phenyldibenzophosphole) have been prepared.[706] A four-coordinate silver(I) complex is formed with the phosphorus ligand 5-aza-2,8-dioxa-1-pnictabycyclo[3.3.0]octa-2,4,6-triene. The silver atom is in an unusual square-planar geometry.[707] The reaction of $[Ag(NCMe)_4]SbF_6$ with this ligand in a 1:1 ratio gives the polymeric complex (**73**).[708] Silver(I) complexes with ferrocenylphosphine ligands have been synthesized. $FcCH_2PPh_2$ or Fc_2PhP ($Fc = (\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)$) react with AgOTf or $[Ag(OTf)(PPh_3)]$ to yield complexes of the type $[Ag(OTf)(PFc_2Ph)_2]$, $[Ag(PPh_2CH_2Fc)_3]OTf$, or $[Ag(OTf)(PPh_3)L]$.[709,710] The triflate ligand in $[Ag(OTf)(PFc_2Ph)_2]$ can be substituted by bidentate ligands such as $S_2CNEt_2^-$ or $(SPPh_2)_2CH_2$.[710] Dibenzotropylidene phosphines (tropp) reacts with silver(I) trifluoromethanesulfonate to give the complexes $[Ag(\mu\text{-}OTf)(tropp)]$ or $[Ag(tropp)_2]OTf$ (**74**), the structures show a weak interaction between the metal center and the alkene moiety.[711] The treatment of bis(phosphonio)isophosphindolide salts with silver salts gives mono- or dinuclear complexes depending upon the anion; the triflate form both mono- or dinuclear (**75**).[712] The cyclotetraphosphazene ligands $[P_4N_4Ph_4(\mu\text{-}C_6H_4)_2]$ and $[P_3(PS)N_4Ph_4(\mu\text{-}C_6H_4)_2]$ form mononuclear AgL^+ complexes identified by mass spectroscopy.[713] The thermodynamics of complex formation between silver(I) and PPh_3, dppm, dppe, or dppp has been investigated in propylene carbonate. Triphenylphosphine forms successive mononuclear complexes, dppm only polynuclear species, whereas mono- and polynuclear are formed by dppe and dppp.[714] Electrospray mass spectrometry has been used to investigate the relative ligand properties of the triphenylpnictogen ligand EPh_3 (E = P, As, Sb, Bi)[715] or other phosphines[716] towards silver(I). The formed species increases in coordination number from two for PPh_3 to four for $SbPh_3$, with donor ability decreasing and M—E bond length increasing; the $BiPh_3$ species are unstable.[715]



(**73**)

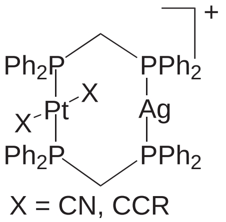


(**74**)

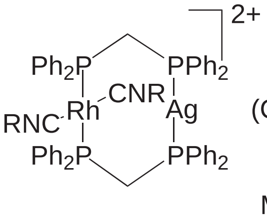


(**75**)

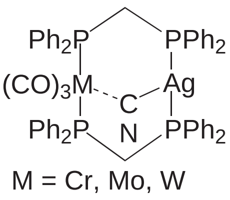
Heteronuclear complexes have been reported in which silver(I) is bound to a phosphine ligand. Heterobimetallic complexes of platinum, rhodium, or group 6 metals and silver with bridged dppm have been obtained, e.g., (**76**)–(**79**).[717–722] The complex $[Pt(C{\equiv}CPh)_2(\mu\text{-}PPh_2CHMePPh_2)_2AgCl]$ has also been described.[723] The compound $[Pt(CN)_2(\mu\text{-}dppm)_2Ag(OTf)]$ has an absorption at 317 nm (77 K), attributed to $a^1(d\sigma^* \rightarrow p\sigma)$ excitation with significant $Pt(CN)_2P_2$MLCT (MLCT = metal to ligand charge transfer) contribution, which generates an emission at 435 nm.[724]



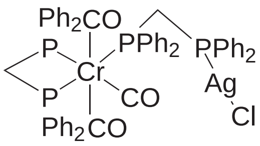
(**76**)



(**77**)

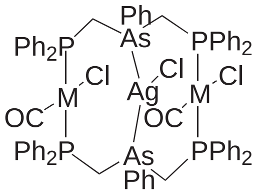


(**78**)



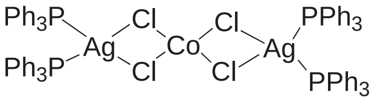
(**79**)

Rhodium or iridium complexes with the tridentate ligand bis[(diphenylphosphino)methyl] phenylarsine (dpma) react with silver ions to give the trimetallic complexes $[M_2AgCl_3(CO)_2(\mu\text{-}dpma)_2]$ (**80**).[725,726] The reactivity of $[CoCl_2(PR_3)_2]$ ($PR_3 = PPh_3$, PPh_2CH_2COPh) with $AgBF_4$ has been tested and gives $[Ag(PR_3)_2]Cl$, but the triphenylphosphine derivative in the presence of more PPh_3 gives $[Ag_2CoCl_4(PPh_3)_4]$ (**81**).[727] Reaction of the lithium salts of the anionic complexes $[M(\eta^5\text{-}C_5H_4PPh_2)(CO)_3]^-$ (M = Cr, Mo, W) with $AgBF_4$ affords the compounds $[MAg(\mu,\eta^5\text{-}C_5H_4PPh_2)]_2$ (**82**). The mixed silver–gold compound can be obtained by mixing solutions of the silver and the gold complex.[728,729] The reaction of $[Au(Mes)(dppm)]$ with $AgClO_4$ in a 1:2 molar ratio gives $[\{Au(Mes)\}_2(\mu\text{-}dppm)_2Ag]ClO_4$.[730]

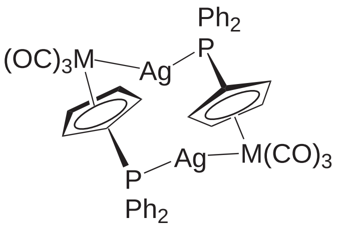


M = Rh, Ir

(**80**)



(**81**)

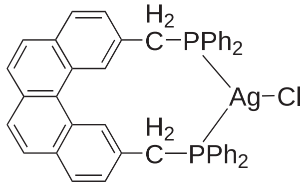


M = Cr, Mo, W

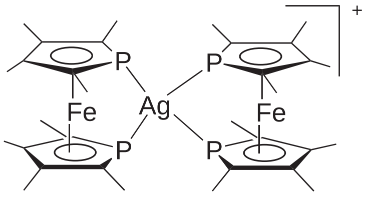
(**82**)

(ii) Complexes with polydentate ligands

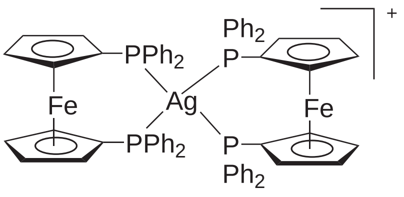
Silver(I) complexes with bidentate diphosphines tend to be dimers or tetramers; however, with unusual diphosphines, mononuclear complexes have been obtained. With the rigid 2,11-bis[(diphenylphosphino)methyl)benzo[c]phenanthrene complexes of the type [AgX(PP)] (**83**) (X = $SnCl_3$, NO_3, ClO_4) have been reported in which the diphosphine is acting as a chelate.[731] A dinuclear complex with bridging fluoro ligands is obtained with the same ligand.[732] Stable bis-chelate complexes with diphosphines such as dppe, $Et_2PCH_2CH_2PPh_2$, $Et_2PCH_2CH_2PEt_2$, $Ph_2PCH{=}CHPPh_2$, and $Ph_2P(CH)_3PPh_2$ have been detected, and some of them isolated, by ^{109}Ag{^{31}P} INEPT (insensitive nuclei enhancement via polarization transfer) pulse sequences.[733,734] The bis(dppe) silver(I) nitrate, $[Ag(dppe)_2]NO_3$, and the *cis*-1,2-bis(diphenylphosphino)ethylene derivative, $[Ag(PPh_2CH{=}CHPPh_2)_2][SnPh_3(NO_3)_2]$ have been prepared and characterized structurally showing a tetrahedral nature.[735,736] These bis-chelate complexes have been shown to exhibit antitumor activity against P388 leukemia in mice, as well as antifungal and modest antibacterial properties.[737–739] Although the mechanism for the cytotoxicity is not known, tumor cell mitochondria are likely targets for these large lipophilic cations,[740,741] and indeed the complex $[Ag\{Ph_2P(CH_2)_2PEt_2\}_2]NO_3$ exhibits selective primary antimitochondrial activity in yeast.[742] Similar complexes have been synthesized with bidentate pyridyl phosphines which have more hydrophilic characteristics. The degree of hydrophilicity depends critically on the position of the N atom in the pyridyl ring. The 1:2 adducts with 1,2-bis(di-*n*-pyridylphosphino)ethane (dnpype) for $n = 2$–4 have been prepared and are monomeric for d^3pype and d^4pype and more water soluble than the 2-pyridyl complex which crystallizes as dimeric $[\{Ag(d^2pype)\}_2]^{2+}$. The latter exists in solution as equilibrium mixtures of monomeric, dimeric, and trimeric species. These complexes show potent and selective antitumor activity against a panel of human cultured ovarian carcinoma cell lines.[743,744]



(**83**)



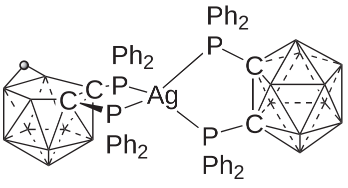
(**84**)



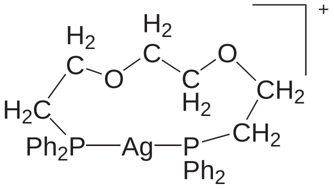
(**85**)

Electrocrystallization of 7,7,8,8-tetracyanoquinodimethane (TCNQ) with diphosphaferrocene $(\eta^5\text{-}Me_4C_4P)_2Fe$ with a silver anode affords the complex $[Ag\{(\eta^5\text{-}Me_4C_4P)_2Fe\}_2]^+[TCNQ]^-$ (**84**).[745] Dppf also gives the bis-chelate compound $[Ag(dppf)_2]ClO_4$ (**85**).[746] The 1:1 adducts have different structures, with the ClO_4^- anion a dimeric structure with bridging perchlorate has been proposed, but with nitrate a dimeric with bridging dppf and chelated NO_3^- ligands is obtained.[746,747] Mononuclear silver(I) complexes with dppf acting as chelating ligand can be achieved by reaction of $[Ag(OClO_3)(dppf)]_2$ with monodentate or bidentate ligands to give three coordinate complexes of the type $[Ag(dppf)L]ClO_4$ (L = PPh_3, $SPPh_3$) or four coordinate of the type $[Ag(dppf)(LL)]ClO_4$ (LL = dppf, phen, bipy, $(SPPh_2)_2CH_2$) or $[Ag(S_2CNEt_2)(dppf)]$.[746] The ligand bis(neopentylidenephosphonito)ferrocene also forms the bis-chelate silver(I) complex.[748] A derivative of the dppf ligand, $[Fe\{\eta^5\text{-}C_5H_3(PPh_2)(CHMeNMeCH_2CH_2NMe_2)(\eta^5\text{-}C_5H_4PPh_2)\}]$, reacts with AgOTf and excess of MeO_2CCH_2NC in CD_2Cl_2 to yield a tetracoordinated silver(I) complex. In solution, it has been observed that the NMe_2 group lies close to the active hydrogen atoms of the coordinated isocyanate. There is interest in this reaction in connection with the catalysis of the aldol reaction.[749]

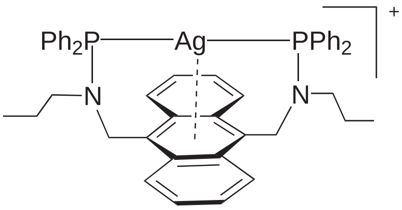
The ligand 1,2-bis(diphenylphosphino)-*o*-carborane possesses a rigid *o*-carborane moiety that causes the chelating mode of the diphosphine ligand to be preferred to the bridging mode. Complexes of the type $[Ag\{(PPh_2)_2C_2B_{10}H_{10}\}_2]ClO_4$, $[Ag\{(PPh_2)_2C_2B_{10}H_{10}\}L]ClO_4$ (PR_3, $AsPh_3$, $SPPh_3$, $PyCO_2H$), and $[Ag\{(PPh_2)_2C_2B_{10}H_{10}\}(LL)]ClO_4$ (LL = phen, bipy, $(SPPh_2)_2CH_2$) can be easily formed by substitution reactions on $[Ag(OClO_3)\{(PPh_2)_2C_2B_{10}H_{10}\}]$, which is obtained by reaction of $AgClO_4$ with the diphosphine.[750] Similar complexes have been obtained with the *nido* diphosphine $[7,8\text{-}(PPh_2)_2\text{-}7,8\text{-}C_2B_{19}H_{10}]^-$ in which the carborane cage has been partially degraded by removal of one boron atom. The complex $[Ag\{(PPh_2)_2C_2B_9H_{10}\}\{(PPh_2)_2C_2B_{10}H_{10}\}]$ (**86**) with a *closo* and a *nido* diphosphine has been synthesized.[751] Silver(I) complexes with diphosphines acting as *trans*-chelating ligands have been obtained with $Ph_2P(CH_2)_2O(CH_2)_2O(CH_2)_2PPh_2$ (**87**)[752] or with an anthraceno-diphosphine (**88**)[753] or with 2,11-bis(dialkylphosphinomethyl)benzo[c]phenanthrene.[754,755] The anthraceno-diphosphine has an η^6-antracenyl group bonded to silver; the addition of PPh_3 breaks this bond and the new complex shows strong photoluminescence. However, attempts to isolate these species have been unsuccessful and (**88**) is recovered.



(**86**)



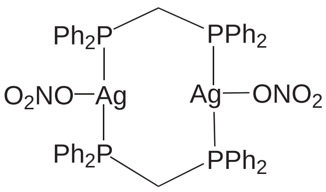
(**87**)



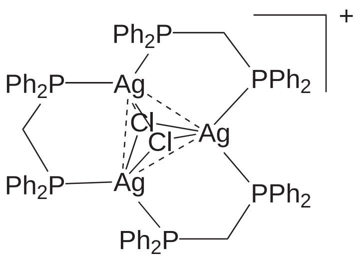
(**88**)

The stability in solution of tetrahedral silver(I) complexes of the type $[Ag(LL)_2]PF_6$ with (R^*,R^*)-(±)- or (R^*,S^*)-1,2-phenylenebis(methylphenylphosphine) and their arsenic isosteres have been studied. They rearrange in solution by intermolecular ligand distribution and by inversion of the tetrahedral metal stereocenter.[756] Crystallization of 1:2 silver(I) halide/pseudohalide:dppp mixtures from acetonitrile results in the isolation of the compounds [AgX(dppp-P,P′)(dppp-P)] (X = Cl, Br, I, CN). However, with SCN^- the bis-chelate derivative is obtained, $[Ag(dppp)_2]SCN$.[757] The azine-diphosphine *Z*,*Z*-$Ph_2PCH_2CBu^t{=}NN{=}CBu^tCH_2PPh_2$ affords the three-coordinate compound [AgCl(PP)] with the diphosphine acting as a chelating ligand.[758]

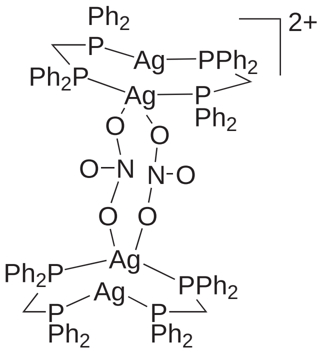
Dppm has been used widely in coordination chemistry. Silver(I)–dppm complexes have been reported in several ratios and they present different structural frameworks. Due to the bite angle of dppm this ligand usually acts as bridging ligand. The $[Ag_2(dppm)_2]^{2+}$ core structure is present in $[Ag_2X_2(dppm)_2]$ (X = NO_3 (**89**), O_2CCH_2Ph, O_2CMe)[759–762] or $[Ag_2X\,(Py)_2(dppm)_2]$.[763] The tri- and tetranuclear 1:1 species have been reported in $[Ag_3Br_2(dppm)_3]Br$,[764,765] $[Ag_3Cl_2(dppm)_3]X$ (X = ClO_4^-, $[SnPh_2(NO_3)_2Cl]^-$) (**90**),[766,767] or $[Ag_4(NO_3)_2(dppm)_4](PF_6)_2$ (**91**).[759]



(**89**)

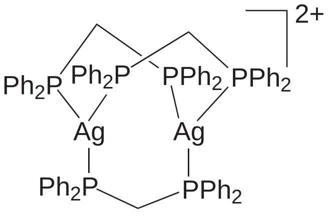


(**90**)

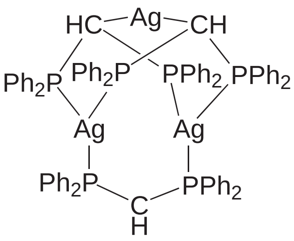


(**91**)

The dinuclear 2:3 species have been characterized in $[Ag_2(\mu\text{-dppm})_3](OTf)_2$ and $[Ag_2(\mu\text{-dppm})_3](NO_3)_2$ (**92**), with the silver centers three coordinate by three phosphorus atoms of different dppm ligands.[761,768] A tetranuclear species $[Ag_2(\mu\text{-}O_2CMe\text{-}O,O')(\mu\text{-}O_2CMe\text{-}O)(\mu\text{-dppm})]_2$ has been obtained by reaction of dppm with two equivalents of AgOAc. [762] The reaction of $[Ag(Mes)]_4$ with dppm gives a trinuclear compound $[Ag_3(dppm\text{-}H)_3]$ (**93**) in which the dppm ligand has been deprotonated with the formation of mesithylene. In the structure, two of the silver centers are three coordinate to three different phosphorus atoms and the other silver atoms is bonded to two carbon atoms.[291,292]



(92)

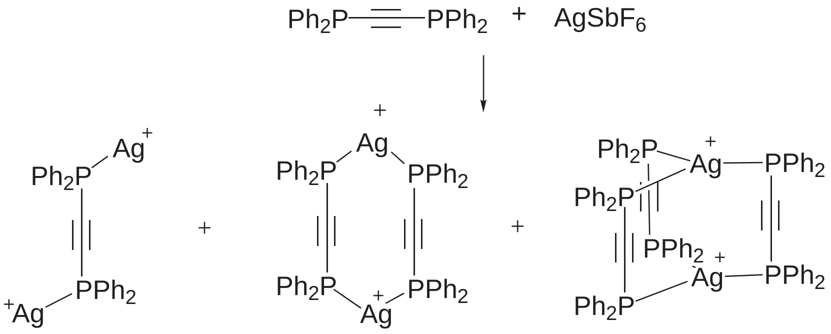


(93)

Spectroscopic and structural investigation of dinuclear silver(I) complexes with bis(dicyclohexylphosphino)methane (dcpm) such as $[Ag_2(\mu\text{-dcpm})_2]X_2$ ($X = OTf, PF_6$) and $[Ag_2(\mu\text{-}O_2CCF_3)_2(\mu\text{-dcpm})]$ have been carried out. All the complexes have short Ag—Ag distances and the UV–visible absorption band at 261 nm is assigned to a $4d\sigma^* \rightarrow 5p\sigma$ transition originating from Ag^I–Ag^I interactions. These compounds exhibit photoluminescence in the solid state at room temperature.[769] The reaction of $Ph_2PNHPPh_2$ with AgCl yields $[Ag_2Cl_2\{\mu\text{-}(PPh_2)_2NH\}]$ for which in the solid state the cluster structure $[Ag_4Cl_4\{\mu\text{-}(PPh_2)_2NH\}_2]$ is assumed.[770] The treatment of $Ph_2PNHPPh_2$ with the ylide complex $[Ag(CH_2PPh_3)_2]ClO_4$ gives the dinuclear compound $[Ag_2\{\mu\text{-}(PPh_2)_2N\}_2]$; this complex can react further with $[Au(C_6F_5)THT]$ or $[Ag(OClO_3)(PPh_3)]$ with coordination of the gold or silver atoms to the nitrogen atoms to give $[Ag_2\{\mu\text{-}(PPh_2)_2N\}_2\{Au(C_6F_5)\}_2]$ or $[Ag_2\{\mu\text{-}(PPh_2)_2N\}_2\{Ag(OClO_3)(PPh_3)\}_2]$.[771] The reaction of $LiN(PPh_2)_2$ with $[Ag_2Cl_2\{\mu\text{-}(PPh_2)_2NH\}]$ leads to a mixture of the dinuclear complexes $[Ag_2\{\mu\text{-}(PPh_2)_2N\}_2]$ and $[Ag_2\{\mu\text{-}(PPh_2)_2N\}\{\mu\text{-}(PPh_2)_2NH\}]$.[770]

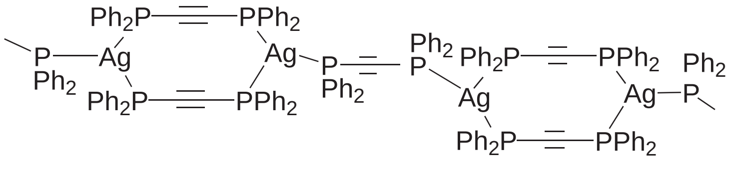
Bis(dialkylphosphino)ethane ligands form very stable bis-chelate complexes; however, two complexes with a $[Ag_2L_4]^{2+}$ core ($L = $ dppe, $Me_2P(CH_2)_2PMe_2$), with two diphosphines bridging and the silver atoms are also bound to water molecules.[772,773] The compound $[Ag_2\{PBu^t{}_2(CH_2)_2PBu^t{}_2\}(H_2O)_2](BF_4)_2$ has a dinuclear structure with a bridging diphosphine ligand and the silver atoms are also bound to water molecules.[774] Bis(dialkylphosphino)propane forms dinuclear complexes with the $[Ag_2L_2]^{2+}$ core, which have been characterized for dppp with the NO_3^- anion and for $Bu^t{}_2P(CH_2)_3PBu^t{}_2$ with the BF_4^- anion.[774–776] The complex $[Ag_2(dppb)_2]NO_3$ (dppb = 1,4-bis(diphenylphosphino)butane) has the same structural framework.[776] The thermodynamic parameters of the complexation of silver(I) with dppm, dppe, dppp, and triphosphines in DMSO and ^{31}P NMR studies confirm that very stable complexes of the type $[Ag_2L_2]^{2+}$ are formed.[777]

In the diphosphines bis(diphenylphosphino)alkyne and *trans*-1,2-bis(diphenylphosphino)ethylene, due to the rigid backbone, the orientations of the lone pairs are restricted, so that these ligands cannot point inwards and set up the metals for anion bridging. The reaction of $Ph_2PC{\equiv}CPPh_2$ with $AgSbF_6$ in a 1:1 molar ratio gives a mixture of the 1:2, 2:2, and 3:2 complexes (Equation (6)):

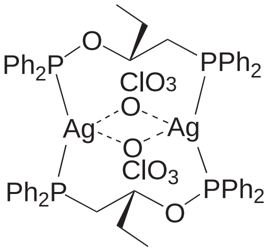


(6)

The species $[Ag_2(PPh_2C{\equiv}CPPh_2)_3]^{2+}$ have been prepared with several anions such as OTf^-, BF_4^-, NO_3^-, and SbF_6^-. When crystals of $[Ag_2(PPh_2C{\equiv}CPPh_2)_3](OTf)_2$ are stored in its supernatant for 16 weeks, conversion occurs to the isostoichiometric $[Ag_2L_3(OTf)_2]_n$ coordination polymer (**94**). For *trans*-$Ph_2PCH{=}CHPPh_2$ evidence for the discrete $[Ag_2L_3]^{2+}$ cages has been found in solution, although crystallization only gives the ring-opened polymeric structure $[Ag_2L_3X_2]_n$.[778,779]



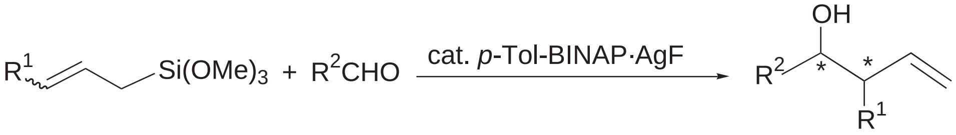
(94)



(95)

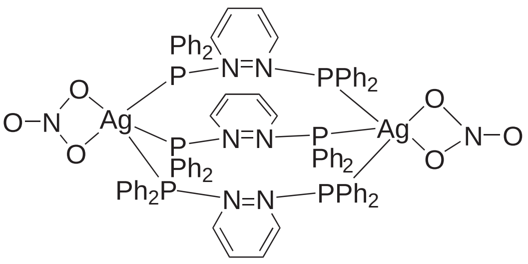
The reaction of silver nitrate with *R*,*R*-DIOP (4R,5R-*trans*-4,5-bis[(diphenylphosphino)-methyl]-2,2-dimethyl-1,3-dioxalane), gives a helical infinite chain complex [Ag(NO$_3$)(*R*,*R*-DIOP)].[780] By treatment of this compound with NaX, or by direct reaction of AgX with *R*,*R*-DIOP, the dinuclear derivatives [AgX(*R*,*R*-DIOP)]$_2$ (X = Cl, Br, I, SCN) are obtained. The structure consists of two silver centers bridged by diphosphine and two halide ligands.[781] Similar complexes are obtained with the chiral ditertiary ligand $Ph_2PCH_2CHEtOPPh_2$ (*R*,*S*) which yields the silver dinuclear compounds [AgX(PP)]$_2$ (X = Cl, Br, ClO$_4$ (**95**)).[782]

The complex *p*-Tol-BINAP·AgF (*p*-Tol-BINAP = 2,2′-bis(di-*p*-tolylphosphanyl)-1,1′-binapthyl) catalyzes the asymmetric addition of allylic trimethoxysilanes to aldehydes (Equation (7)).[783] The process can provide various optically active homoallylic alcohols with high enantioselectivity (up to 96% ee) and a remarkable γ and *anti*- selectivities are observed for the reaction with crotylsilanes, irrespective of the configuration of the double bond:

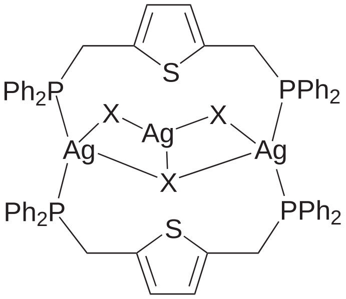


(7)

Linear polymeric silver(I) complexes of the type $[Ag(\mu\text{-}L)(MeCN)_2]_n(ClO_4)_n$ (L = 2,6-bis(diphenylphosphino)pyridine) have been synthesized by the self-assembly reaction of the ligand with $[Ag(MeCN)_4]ClO_4$.[784] A dinuclear complex has been obtained with this ligand, $[Ag_2(\mu\text{-}L)_3](ClO_4)_2$, in which the silver atoms are triply bridged by the phosphine ligand.[785] A related complex $[Ag_2(\eta^2\text{-}NO_3)(\mu\text{-}L)_3]$ (**96**) has been obtained for L = 3,6-bis(diphenylphosphino)pyrazine.[785] 2,5-Bis(diphenylphosphinomethyl)thiophene (dpmt) produces various polynuclear silver(I) complexes of the type $[Ag_2(\mu\text{-dpmt})_3](BPh_4)_2$, $[Ag_2Cl_2(\mu\text{-dpmt})]$, and $[Ag_3X_3(\mu\text{-dpmt})_2]$ (X = Br, I) (**97**).[786]



(96)

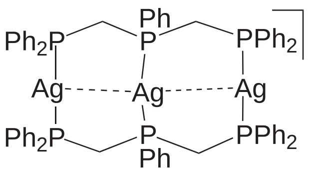


(97)

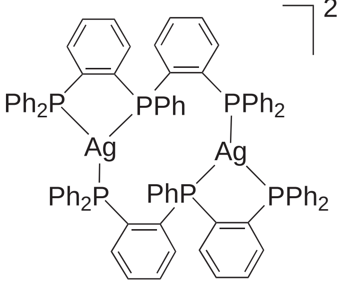
A heterobimetallic compound containing a Cp_2Ti^{IV} unit linked via diphenylphosphinoacetate to a silver(I) center has been isolated, $[TiCp_2\{\mu\text{-}OCOCH_2PPh_2)_2AgCl]$.[787] In the complex

$[Mo(CO)_4\{(Pr^i_2N)_4P_4O_4\}]$ the Mo-atom binds two of the four phosphorus atoms of the P_4O_4 heterocycle, leaving the other two available for further coordination to silver giving $[Mo(CO)_4\{(Pr^i_2N)_4P_4O_4\}Ag(NO_3)]$.[788] The dinuclear rhenium–silver complexes $[ReH_3(PCy_3)_2(\mu\text{-}L)(\mu\text{-}H_2)_2AgI]$ ($L = Ph_2PC({=}CH_2)PPh_2$, dppm) have been prepared from AgI and $[ReH_5L(PCy_3)_2]$.[789]

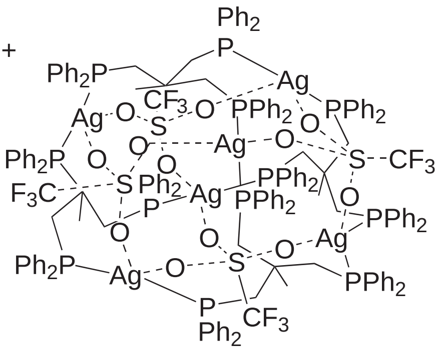
Several silver(I) complexes have been prepared with triphosphine ligands. Bis(diphenylphosphinophenylphosphine) reacts with AgOTf in a 3:2 molar ratio to give the luminescent complex $[Ag_3L_2](OTf)_3$ (**98**), the ClO_4^- salt was obtained by metathesis.[790] The bis[2-(diphenylphosphino)phenyl]phenylphosphine ligand reacts with AgCl to give the mononuclear tetrahedral compound [AgClL]. A dinuclear complex $[Ag_2L_2](BF_4)_2$ (**99**) is obtained by reaction of $AgBF_4$ with the triphosphine; it has a very short Ag···Ag distance of 2.8569(8) Å.[791] A mononuclear complex, [AgI(triphos)], has been prepared with the 1,1,1-tris(diphenylphosphinomethyl)ethane ligand.[792] In the presence of templating anions such as OTf^-, ClO_4^-, or NO_3^-, 2:3 molar mixtures of triphos and silver(I) cations give novel hexanuclear cages, which result from an unusual "endo-methyl" geometry of the ligand (**100**).[793]



(98)

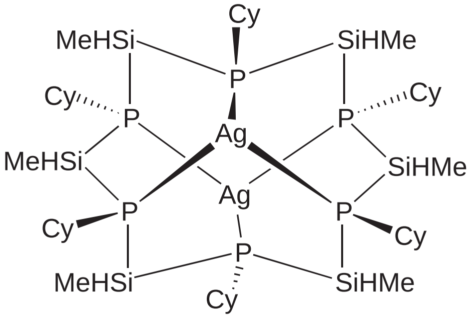


(99)

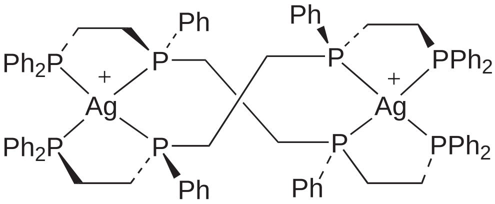


(100)

The reaction of the cyclic P_3-ligand 1,3,5-triphospha-2,4,6-trisilacyclohexane with AgOTf results in the synthesis of complex (**101**) with a cyclic P_6 ligand.[794] Optically pure (*S*,*S*)-(+)-$(PPh_2CH_2CH_2)_2(PPhCH_2CH_2PPh)$ spontaneously self-assembles into left-handed double-stranded D_2-double helix (**102**) and C_2-side-by-side helix conformers of the disilver(I) cation.[795]



(101)

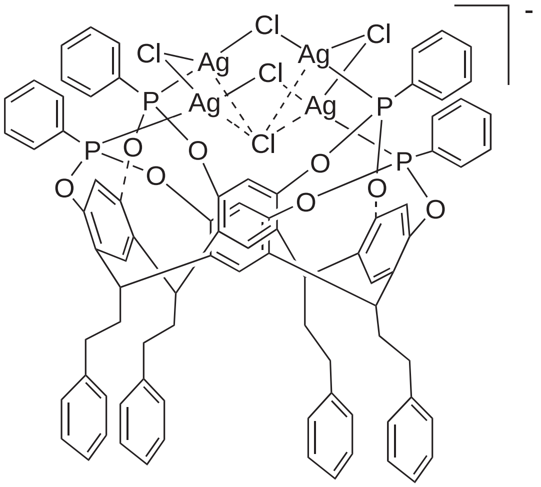


(102)

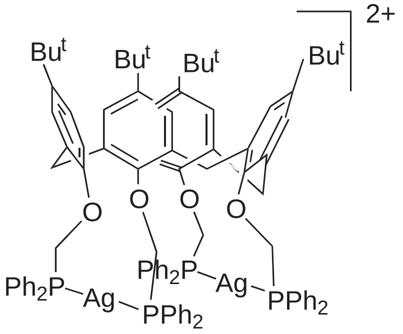
A tetraphosphonitocalixresorcinarene ligand $(PhCH_2CH_2CHC_6H_2O_2PPh)_4$ (bowl) forms a tetrasilver(I) complex $[Ag_4(\mu\text{-}Cl)_4(bowl)]$ and the chlorine inclusion compound $[Ag_4(\mu\text{-}Cl)_4(\mu_4\text{-}Cl)(bowl)]^-$ (**103**). The chlorine ligands are easily replaced by bromine or iodine.[796,797] The anionic complex acts as host for the selective binding of metal cations.[798] A related ligand 5,11,17,23-tetra-*t*-butyl-25,26,27,28-tetrakis(diphenylphosphinomethoxy)calix[4]arene reacts with two equivalents of $AgBF_4$ to form complex (**104**).[799]

(iii) Phosphide- or arsenide-bridged polynuclear complexes

Silver(I) phosphide or arsenide complexes have been synthesized. The reaction of AgCl with Ph_2PTMS in the presence of a tertiary phosphine gives polynuclear complexes such as

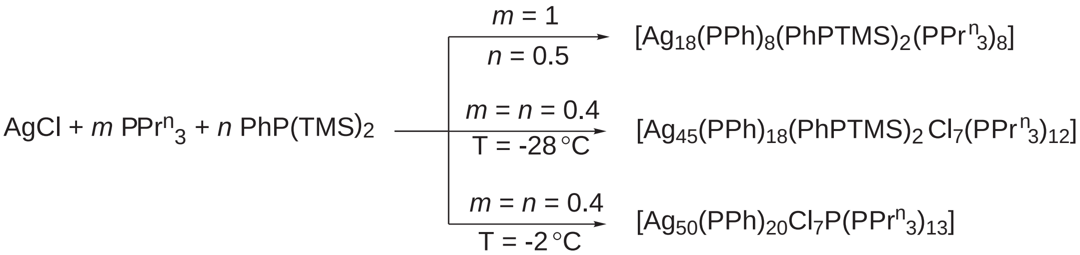


(**103**)



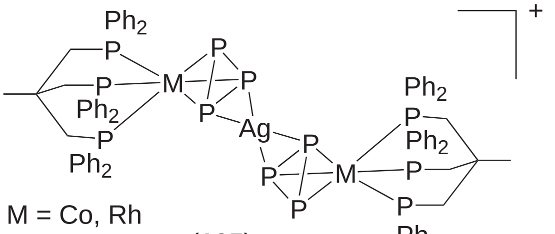
(**104**)

$[Ag_3(PPh_2)_3(PR_3)_3]$ ($PR_3 = PBu^n{}_2Bu^t$, $PPr^i{}_3$), $[Ag_4(PPh_2)_4(PR_3)_4]$ ($PR_3 = PMePr^n{}_2$, $PPr^n{}_3$), $[Ag_4(PPh_2)_4(PEt_3)_4]_n$, and $[Ag_6(PPh_2)_6(PBu^t{}_3)_2]$.[800,801] The reaction of AgCl with $PhP(TMS)_2$ and a tertiary phosphine provides access to phosphinidine-bridged silver clusters (Scheme 3).[802] Similarly the treatment of AgCl with the arsenic derivative $PhAs(TMS)_2$ afford the arsinidine-bridged silver clusters $[Ag_{14}(AsPh)_6Cl_2(PR_3)_8]$ ($PR_3 = PMePr^n{}_2$, $PPr^n{}_3$, PEt_3) or $[Ag_4(As_4Ph_4)_2(PR_3)_4]$ ($PR_3 = PEt_3$, $PPr^n{}_3$).[803]

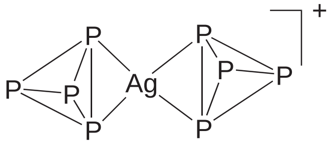


Scheme 3

The treatment of the $[MP_3(triphos)]$ compounds (M = Rh, Co) with silver(I) derivatives yields the complexes $[\{(triphos)MP_3\}_2Ag]$ (M = Co; X = ClO_4, PF_6; M = Rh; X = OTf, PF_6) (**105**).[804] The silver aluminates $AgAl[OC(CF_3)_2(R)]_4$ (R = H, Me, CF_3) react with solutions of white phosphorus P_4 to give complexes that bind one or two almost undistorted tetrahedral P_4 molecules in an η^2 fashion such as $[Ag(P_4)_2]^+[Al\{OC(CF_3)_3\}_4]^-$ (**106**), $[Ag(P_4)\{Al\{OC(CF_3)_2\}_4\}]$, and $[Ag(P_4)\{Al\{OC(CF_3)_2\}_4\}]_2$. The $Ag(P_4)_2{}^+$ ion has an almost planar coordination environment around the Ag^+ ion due to $d_{x^2-y^2}(Ag) \rightarrow \sigma^*(PP)$ backbonding.[805]



(**105**)



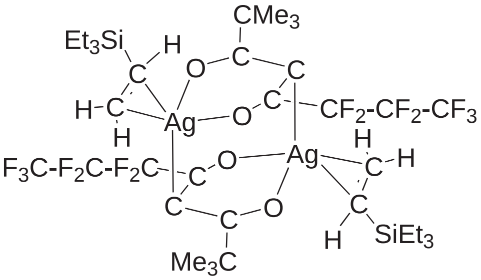
(**106**)

6.7.2.3.4 Complexes with oxygen donor ligands

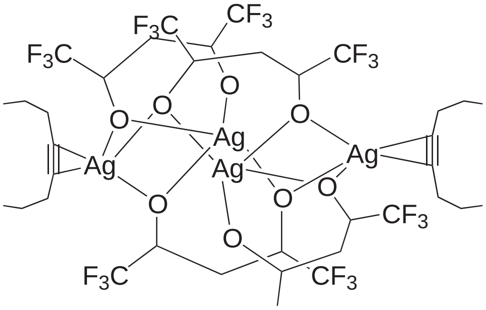
Silver(I) complexes with oxygen donor ligands have been prepared with three different types of ligands: β-diketonates, carboxylates, and crown ethers.

Silver(I) β-diketonate derivatives have received significant attention due to the ease with which they can be converted to the elemental metal by thermal decomposition techniques such as metal organic chemical vapor deposition (MOCVD).[59] The larger cationic radius of silver(I) with respect to copper(I) has caused problems in achieving both good volatility and adequate stability of silver(I) complexes for the use in CVD apparatus. These problems have been overcome with the new techniques such as super critical fluid transport CVD (SFTCVD), aerosol-assisted CVD (AACVD), and spray pyrolysis, where the requirements for volatile precursors are less stringent.

These type of complexes are generally obtained by reaction of Ag_2O with the β-diketone in the presence of other ligands. Some β-diketone silver(I) compounds have been prepared by treatment of $AgNO_3$ with the diketone in dry methanol and acetonitrile but only characterized by elemental analysis and IR spectroscopy.[806] Several compounds have been prepared with alkene ligands of the type [Ag(hfac)(alkene)] (hfac = 1,1,1,5,5,5-hexafluoro-2,4-pentanedionato; alkene = C_6H_{10}, C_7H_{12}, C_8H_{14}, C_8H_{12}, C_8H_8, $CH_2{=}CHTMS$).[807–809] Several of these complexes have been patented as precursors for thermal CVD of silver. However, sublimation of these complexes is generally accompanied by much decomposition, probably because of the formation of involatile $[Ag(hfac)]_n$.[807] Many such compounds are actually more complex than indicated by the formula [Ag(hfac)(alkene)], e.g., the complex with 1,5-cyclooctadiene is properly formulated as $[Ag_2(\mu\text{-hfac})_2(COD)_2]$ and with norbornadiene (NBD) it is $[Ag_4(\mu\text{-hfac})_4(NBD)_2]$.[810,811] Other compounds with alkene ligands are of the type [Ag(β-diketonate)(VTES)] (VTES = vinyltriethylsilane; β-diketonate = hfac, 1,1,1-trifluoro-2,4-pentanedionato (tfac), 2,2-dimethyl-6,6,7,7,8,8,8-hepta-fluoro-3,5-octanedionato (fod) (**107**)). Hot-wall chemical vapor experiments revealed that complex [Ag(hfac)(VTES)] is suitable as a precursor to deposit pure silver films in the temperature range 160–280 °C.[812] The reaction of hfac with Ag_2O in the presence of dimethyl-1,5-cyclooctadiene (mixture of isomers) gives, after recrystallization, the isomerically pure compound $[Ag(hfac)(1,5\text{-}Me_2COD)]$; the structure is a dimer with a short Ag—Ag distance of 3.0134(3) Å. Decomposition of this complex in a biphasic HCl/CH_2Cl_2 mixture liberates $1,5\text{-}Me_2COD$ that subsequently is used to synthesize $[Cu(hfac)(1,5\text{-}Me_2COD)]$, which is a useful liquid precursor for Cu CVD.[813] Alkyne ligands also form complexes of stoichiometry $[\{Ag(hfac)\}_nL]$ ($n = 1$, L = PhC≡CPh, TMSC≡CTMS; $n = 2$, L = 2-butyne, 2-hexyne, 3-hexyne, 4-octyne (**108**)) that have potential use as CVD precursors.[814]



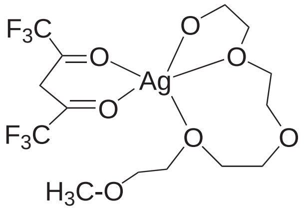
(**107**)



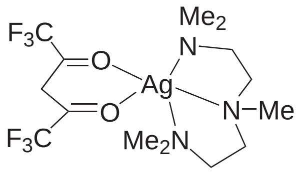
(**108**)

Polyether adducts of hexafluoropentanedionatosilver(I) have also been synthesized and are of the type $[Ag(hfac)(LL)]_n$ (LL = diglyme, tryglyme, tetraglyme) or $[Ag(hfac)(tetraglyme)_{0.5}]_n$. The products show good solubilities in a range of hydrocarbon solvents and fluids such as supercritical carbon dioxide ($scCO_2$).[815] The adduct [Ag(hfac)(tetraglyme)] (**109**) has been successfully applied to the fabrication of silver-based films through a single-step route involving its thermal reduction to metallic silver.[816] This type of complex can also be stabilized by multidentate amines such as $Me_2N(CH_2)_2NHMe$, $Me_2N(CH_2)_2NMe(CH_2)_2NMe_2$ (**110**), or $Me_2N(CH_2)_2NMe(CH_2)_2NMe(CH_2)_2NMe_2$, these complexes also present a good solubility in $scCO_2$.[817] The methyl-isocyanide complex [Ag(hfac)(C≡NMe)], which has a trigonal planar geometry, produces thermal CVD of silver at 320 °C to give silver films with carbon and oxygen impurities; pure silver films can be obtained at 250 °C in the presence of hydrogen.[818] The reaction of Ag_2O with Hhfac yields the asymmetric dimer (**111**), with the chelating hfac ligand in both the endo- and exodentate modes. The water molecule is readily displaced by a variety of ligands to give mononuclear

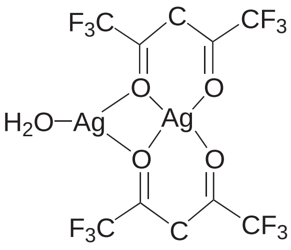
[AgL(hfac)] (L = SMe_2, SEt_2, SPr_2, SBu_2, 1,4-oxathiane).[811] The use of aerosol vaporization methods has allowed efficient CVD from complexes [Ag(hfac)(SR_2)].[819]



(109)



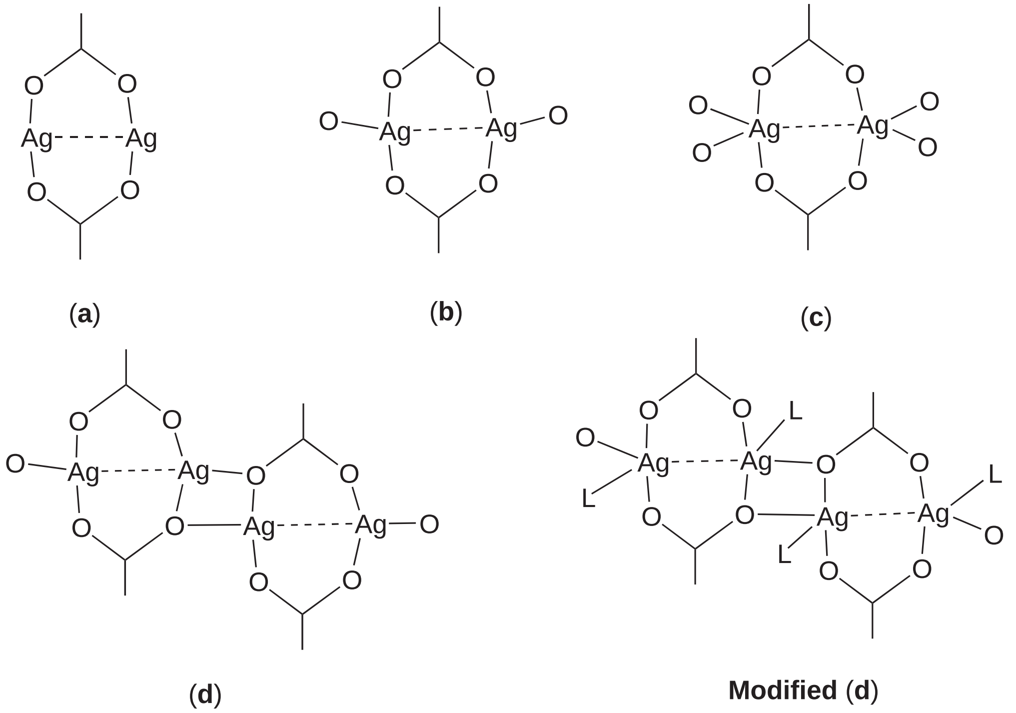
(110)



(111)

Complexes with phosphine ligands are more stable and although with PPh_3 are involatile with more volatile phosphines, the species [Ag(β-diketonate)(PR_3)] (β-diketonate = hfac, fod; PR_3 = PMe_3, PEt_3) are excellent precursors for the thermal CVD of silver films at temperatures of 250–350 °C.[820–822] The valence electronic structures of [Ag(hfac)(PMe_3)] and [Ag(fod)(PEt_3)] have been studied by recording their photoelectron spectra and by performing Xα-SW calculations on the model compounds [Ag{(HC(O)CHC(O)H}{PH_3}] and have been compared with the copper ones. The binding energies in analogous compounds follow the sequence Ag 4*d* > Cu 3*d* with an energy difference of almost 2 eV. Hence, decomposition of the silver(I) complexes by disproportionation is expected to be much less favorable than for the Cu^I analogs.[823]

Silver(I) carboxylate compounds are light sensitive which, together with their poor solubility, makes structural characterization difficult. The structural analogues betaine derivatives ($R_3N^+CH_2CO_2^-$) can form stable silver(I) complexes which are soluble in water and ethanol. Their structures are composed of either discrete dimers or polymeric chain/networks constructed by the linkage of dimeric subunits, and the structures have been classified into four principal types (Scheme 4):[824,825] type a consists of discrete [Ag_2(carboxylate-O,O′)$_2$] dimers without any axial ligand (*o*-$HOC_6H_4CO_2$, *p*-$HOC_6H_4CO_2$, $PhCO_2$, 2,6-$(OH)_2C_6H_3CO_2$, glutarate);[826–830] b and c have additional oxygens in the terminal positions of the dimer (*o*-$NH_2COC_6H_4OCH_2CO_2$, $NCCH_2CO_2$, $HOCH_2CO_2$, *N*-acetylanthranilate, *p*-nitrosalicylate, 3,5-$(NO_2)_2C_6H_3CO_2$,



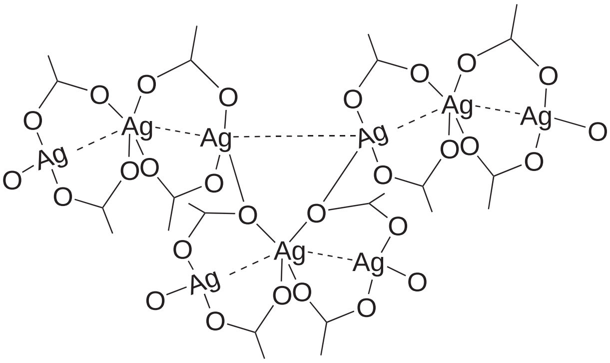
(a) (b) (c)

(d) Modified (d)

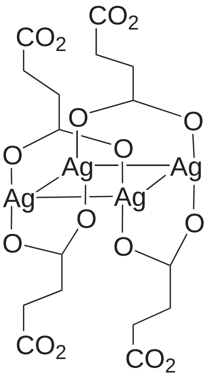
Scheme 4

1,2-(O_2C)-4,5-$(HO_2C)C_6H_2)$;[824,826,831–836] while in type d dimers, terminal oxygens extend the structure into a polymer through adjacent carboxyl groups ($NH_3(CH_2)_2CO_2$, *o*-$O_2NC_6H_4CO_2$, $Ph_3P(CH_2)_2CO_2$, citrate).[837–840] There is also a modified type D that has an additional axial ligand attached to each metal atom ($PhCO_2$, $Me_3NCH_2CO_2$, $PyCH_2CO_2$, $Py(CH_2)_2CO_2$, $Me_3(CH_2)_2CO_2$, $Me_2NPyCH_2CO_2$, $O_2C(CH_2)_2N(CH_2CH_2)_3CH_2CO_2$, 4-$FC_6H_4CH_2CO_2$, $Et_3NCH_2CO_2$, $O_2CCH(R)(CH_2)_2CH(R)CO_2$ ($R = Py$, NMe_3), maleate, *N*-phthaloglycinate, oxalate (ox), *cis*-butenedioate).[841–852] In some cases the ligand can be another carboxylate group that acts as triply bridging ligands.[853] In these compounds there exist short Ag···Ag distances indicating some degree of metal–metal interaction.

Exceptions to these structures are extremely rare but some have been reported that are not based on dimeric subunits[826,854–856] as the polymeric species $[Ag_3\{MeN(CH_2CO_2)CH_2CO_2\}_2]_n(ClO_4)_n$ (**112**),[857] or $[Ag(O_2CPyCH_2CO_2)]_n \cdot nH_2O$,[858] the tetrameric $[Ag_2\{O_2C(CH_2)_2CO_2\}_2]_2$ (**113**),[859] the pentameric $[Ag_5L_4]NO_3$ (LH = *N*-oxide-2-pyridinecarboxylic acid) with a six-membered ring of the carboxylate ligand[860] or in $[Ag_{10}(Me_2NpyCH_2CO_2)_{12}(OTf)_2(H_2O)_4](OTf)_8 \cdot 4H_2O$.[861]



(112)

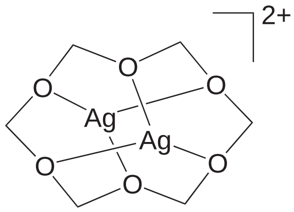


(113)

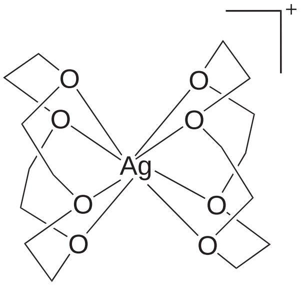
Water-soluble silver(I) complexes have been prepared with the (*R*)-(+)- and (*S*)-(–)-2-pyrrolidone-5-carboxylic acid and (*R*)-(–)- and (*S*)-(+)-5-oxo -2-tetrahydrofurancarboxylic acid. They show effective antibacterial and antifungal activities. The structures consist of left- and right-handed chiral helical polymers and corresponds to types b or d.[862,863] When a neutral donor ligand is incorporated in the silver carboxylate coordination sphere other structures can be found as, for example, with phosphine[864–874] or ammonia[875] ligands which lead to mono- or dimeric complexes or with phthalazine the compound is a 1D polymer with planar $[Ag(\mu\text{-phthalazine})]_2^{2+}$ dimers which are side-on bridged by the phthalate carboxylates.[876] With ammonia, a zig-zag polymeric chain in $[Ag_2(p\text{-}NO_2C_6H_4CO_2)_2(NH_3)]_n$[877] or a dinuclear compound in $[Ag_2\{o\text{-}C_6H_4(CO_2)_2\}(NH_3)_2]$[878] has also been described. The synthesis of several silver(I) complexes with substituted nicotinic acid derivatives has been carried out, showing the different structural chemistry types depending of the degree of protonation of the nicotic acid.[879] Siver(I) complexes with the monocarboxylic acid antibiotics monensin, lasalocid, and D-lactobionate have been reported.[880–883] Mixed silver–antimony carboxylates have also been obtained with tartrate and citric acid such as $[AgSb(C_4H_2O_6)(H_2O)]$ or $[Ag_2Sb_2(HL)_4]$ (H_3L = citric acid),[884,885] or silver–gadolinium $[AgGdL_2(OH_2)_3] \cdot 3H_2O$ (H_2L = 2,6-$(HO_2C)Py$),[886] or silver–arsenic $[Ag_5As_4(\text{tartrate})_4(H_2O)_5X]_n$ ($X = ClO_4$, NO_3),[887] or silver–iridium $[AgIr(COD)(\mu\text{-}O_2CCF_3)_2]_n$.[888] New aspects of the reaction of Ag^+ cations with the EDTA ion have been reported.[889] The compound $[Ag\{Cu(EDTA)(H_2O)\}] \cdot H_2O$ has been prepared.[890] A tetrathiacalix[4]arene derivative in 1,3-alternating conformation and bearing four carboxylic acid groups reacts with $AgNO_3$ to give the complex $[Ag_4(L\text{-}4H)]$ which form a 2D coordination network.[891]

With the related ox ligand, the 3D complex $[Fe^{II}(bipy)_3]_n[Ag^ICr^{III}(ox)_3]_n$ or the tetranuclear $[AgCr(bipy)(\mu\text{-}ox)_2(H_2O)_2]_2$ have been obtained.[892,893]

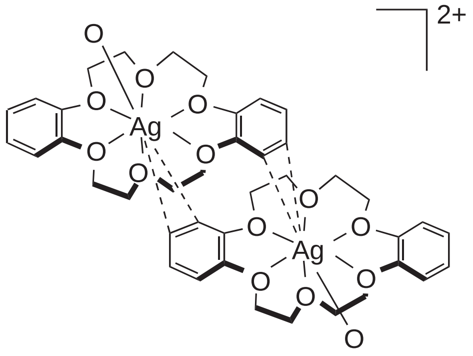
Several silver(I) complexes with crown-ethers have been synthesized. The reaction of $(CH_2O)_3$ with $AgAsF_6$ in liquid SO_2 gives the 12-membered ring $[Ag_2(OCH_2)_6](AsF_6)_2$ (**114**).[894] Similarly, the treatment of $AgAsF_6$ with ethylene oxide in liquid SO_2 leads to the formation of the crown-ether complex $[Ag(OCH_2CH_2)_8]AsF_6$ (**115**).[895] The complex formation of noncyclic polyethers, crown ethers, and large crown ethers in propylene carbonate have been reported; the data indicate that in the large crown ethers more than six donor atoms take part in the interaction with the cation.[896,897] The most frequently used crown ether is the dibenzo-18-crown-6-ether for which several crystal structures have been reported.[898–901] The complexes have been synthesized in different solvents and it is shown that silver(I) prefers an octahedral coordination and forms close dinuclear complexes based on cation-π interaction in a η^2-fashion (**116**).[901]



(114)



(115)



(116)

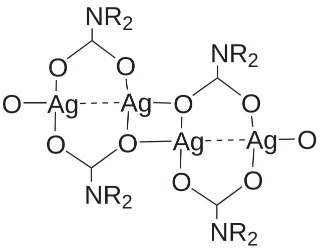
Measurements of the standard Gibbs transfer energies, $\Delta G_t°$, of the [Ag(18-crown-6)]ClO_4 complex at 303 K show the transfer from MeOH to MeOH/MeCN solutions to be thermodynamically unfavorable.[902] A study of the extraction of the complex K[$Ag(CN)_2$] by dicyclohexane-18-crown-6 in various media has been reported.[903] In silver(I) complexes with 15-crown-5 and benzo-15-crown ethers of the type [AgL_2]SbF_6 there exists weak intermolecular interactions through C—H···O hydrogen bonds.[904] Others such as dibenzo-16-crown-4 shows high silver(I) ion selectivity over alkaline metals.[905] Complexation studies of silver ions with unsubstituted and dicyclohexane-substituted 3M-crown-M ethers in dipolar aprotic solvents and alcohols have been studied.[906] Also complex formation between the dibenzo-30-crown-10 with silver(I) has been investigated by a conductimeter method in the solvents 1,2-$C_2Cl_2H_4$, $MeNO_2$, MeCN, and Me_2CO at 298 K.[907] A silver(I) derivative of a calix[4]arene bis(crown-6) [$Ag_2L(NO_3)(H_2O)_{1+x}(DMF)_{0.5}$] has been prepared; the two silver atoms are coordinated to the crown ethers.[908] Bisphenol-A copolyether and copolyesters carrying calix[4]arene units in the main chain have been obtained and the binding properties towards silver(I) cations studied.[909]

Silver(I) complexes with other *O*-based ligands have been reported. *N*,*N*-Dialkylcarbamato complexes of the type [$Ag(O_2CNR_2)$] have been only recently prepared according to Equation (8):

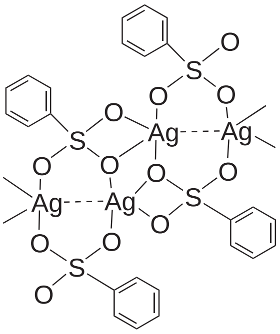
$$Ag_2O + 2\,CO_2 + 2\,R_2NH \longrightarrow 2\,[Ag(O_2CNR_2)] + H_2O \qquad (8)$$

$$R = Me, Et$$

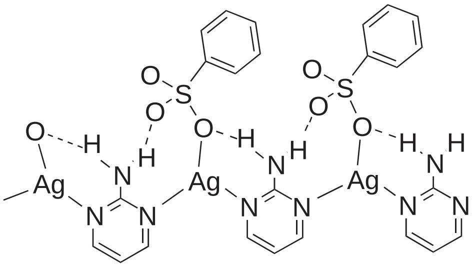
The structure of the methyl derivative (**117**) consists of dinuclear eight-membered rings with slightly distorted linearly two-coordinated Ag-atoms and an intramolecular Ag—Ag distance of 2.837(2) Å; the dinuclear units are joined further by Ag—O bonds to form an infinite array. The reaction with PPh_3 gives the mononuclear [$Ag(O_2CNEt_2)(PPh_3)_2$].[910,911] Silver(I) *p*-toluenesulfonate (pts) adducts with nitrogen bases such as pyridine, 2-aminopyrimidine, 4,6-dimethyl-2-aminopyrimidine, and 3- or 4-aminobenzoic acid of the type [Ag(pts)L] have been reported. The structures are dimeric or polymeric, as for example [Ag(pts)(2-aminopyrimidine)] (**118**), with stabilization enhanced by hydrogen bonding.[912,913] The urea adduct [$\{Ag(pts)\}_2(urea)_2]_n$ has also been synthesized and is a ribbon polymer based on a urea-*N*,*O*-bridged cyclic dimer in which the silver centers have trigonal bipyramidal $AgNO_4$ stereochemistry.[914] The crystal structures of silver(I) methanesulfonate,[915] bromomethanesulfonate,[916] 2-pyridinesulfonate,[917] 3-pyridinesulfonate,[918] aminesulfonate,[919] 1,4-disulfonatebutane,[920] and *p*-toluenesulfonate[913] (**119**) have been described. Supramolecular polymers with lamellar structure have been prepared by self-assembling of 4,4′-bipyridine and alkyl sulfonates.[921]



(117)



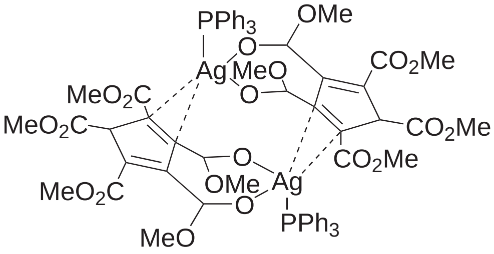
(118)



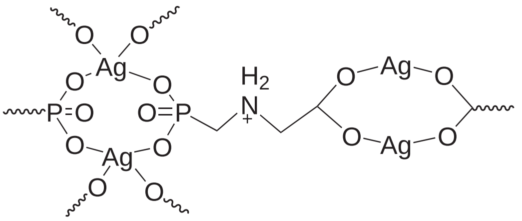
(119)

The crystal structures of silver(I) arenesulfonyl amides such as $[Ag\{N(SO_2C_6H_4\text{-}4\text{-}X)\}_2]\cdot H_2O$ (X = Cl, Br) and $[Ag\{N(SO_2Ph)(SO_2Me)\}]$ have been reported. The structures consist of infinite ribbons that are associated by means of hydrogen bonds into lamellar layers.[922] Potassium thiosulfatoargentate(I) is used as an antimicrobial material and its structure has been refined in the monoclinic system as $K_{10}[Ag_6(S_2O_3)_8]$.[923] Silver(I) hydrogen sulfates, $[Ag(H_3O)(HSO_4)_2]$, $[Ag_2(HSO_4)_2]\cdot H_2SO_4$, and $[Ag(HSO_4)]$, have been synthesized from Ag_2SO_4 and sulfuric acid. The silver atoms are coordinated to more than six oxygen atoms forming a 3D hydrogen network.[924] The crystal structure of disilver(I) sulfoacetate $[Ag_2(O_3SCH_2CO_2)]$ has been determined and has two types of silver(I) atoms, one is octahedral and the other tetrahedral.[925]

A series of silver(I) derivatives of pentakis(methoxycarbonyl)cyclopentadiene have been prepared from the diene and silver acetate, including $[Ag\{C_5(CO_2Me)_5\}(OH_2)]_n\cdot(1.5H_2O)_n$, $[Ag\{C_5(CO_2Me)_5\}(PPh_3)]_2$ (**120**), $[Ag\{C_5(CO_2Me)_5\}(PPh_3)_2]$, $[Ag\{C_5(CO_2Me)_5\}(dppe)]$, and $[Ag\{C_5(CO_2Me)_5\}(triphos)]$.[926,927] A silver complex with the herbicide glyphosate [*N*-(phosphonomethyl)glycine = H_3L], $[Ag_2(H_2L)]_n$ (**121**) has been synthesized.[928]



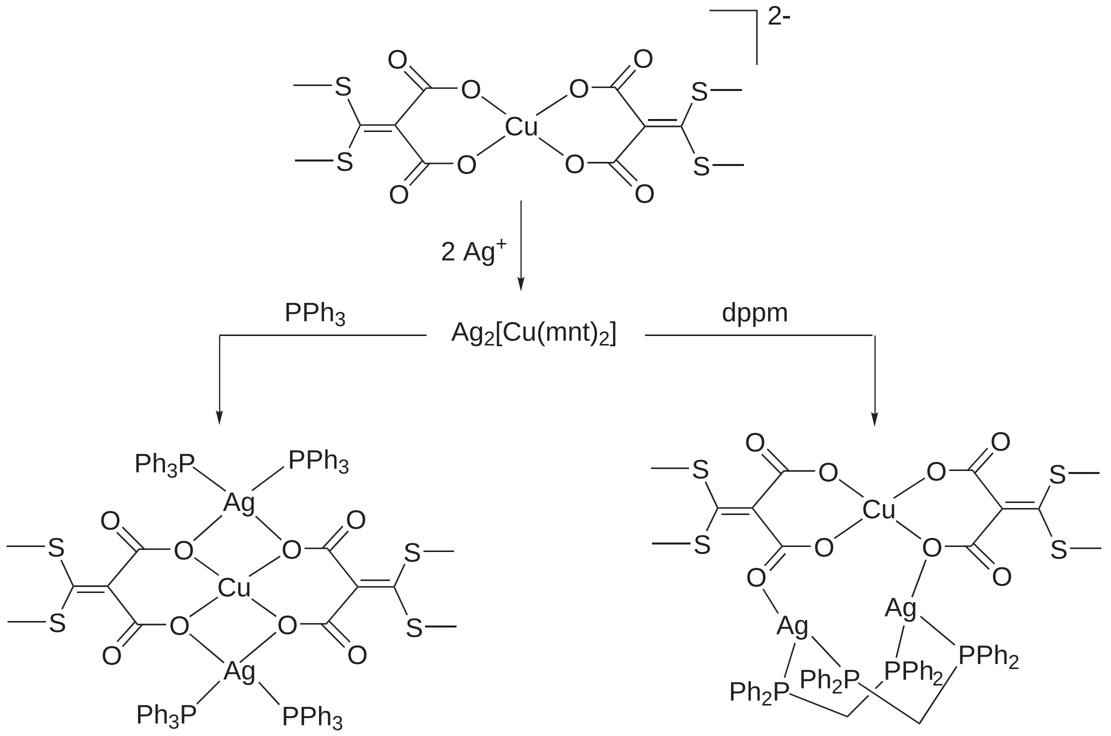
(120)



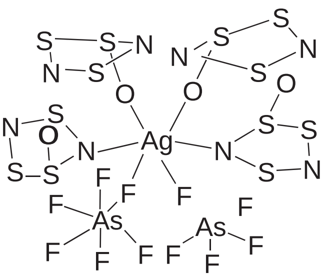
(121)

Cyclic or acyclic ligands of the type S_3N_2O[929] or $S(NSO_2)_2$,[930] form silver(I) complexes in which coordination takes place via nitrogen or oxygen. The complexes $[Ag(S_3\text{-}N_2O)_2]AsF_6$ (**122**) and $[Ag_4\{S(NSO)_2\}_9](AsF_6)_4$, with two different silver atoms, one octahedral with the ligand coordinated through the oxygen atoms (**123**) and one unsymmetrically coordinated by the six nitrogen atoms, have been isolated. Silver triflate reacts with the very stable high polymer MEEP (polydi{2-(2-methoxyethoxy)ethoxy}-phosphazene prepared from the sodium salt of 2-(2-methoxyethoxy)ethanol and poly(dichlorophosphazene) in the presence of NBu_4Br) to give the complexes $[(AgOTf)_x\cdot MEEP]$.[931] Pentafluoroorthotellurate ($OTeF_5^-$) or teflate is a bulky and electronegative pseudohalide that induces coordinative insaturation by means of nonbonded interactions with other ligands in a metal complex; the crystal structure of $Ag(OTeF_5)$ as toluene solvate (**124**) has been determined.[932] This ligand has allowed the synthesis of silver complexes with very weakly coordinating ligands (see Section 6.7.2.3.6).

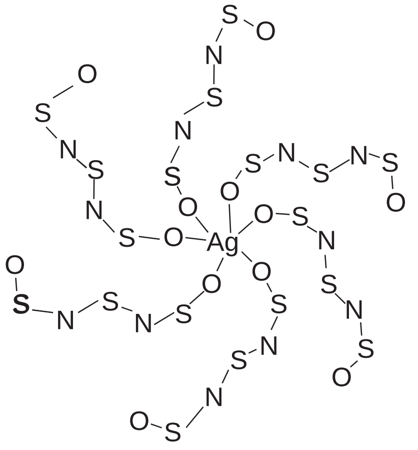
Trinuclear disilver(I)–copper(II) complexes, $[Ag(PPh_3)_2]_2[Cu(mtm)_2]$ and $[Ag_2(dppm)_2][Cu(mtm)_2]$ (mtm = [bis(methylthio)methylene]malonate), have been prepared (Scheme 5).[933]



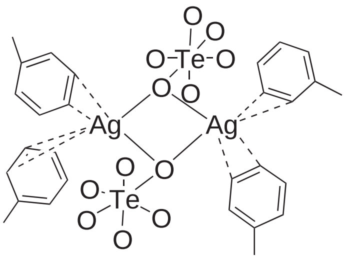
Scheme 5



(122)

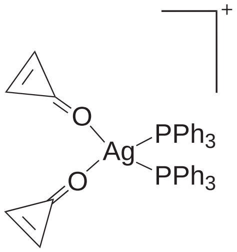


(123)

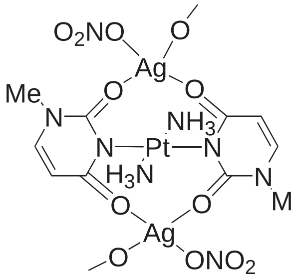


(124)

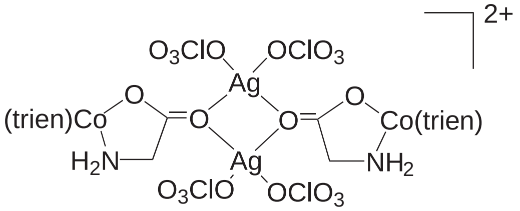
Several silver(I) complexes in which the metallic center is coordinated to ketone oxygen atoms of various ligands have been reported. The crystal structure of the 2:1 adduct of the cyclic peptide *N*,*N*-dimethylpyperazine-1,5-dione (cyclosarcosylsarcosine) with silver(I) nitrate shows that the Ag^I ion interacts with the carbonyl oxygen atoms of the peptide moiety.[934] Complexes of the type $[Ag(ketone)(PPh_3)_2]$ (ketone = phenalenone, diphenylcyclopropenone, tropone, bis(phenalenone), bis(diphenylcyclopropenone) (**125**), bis(tropone)) have been obtained by reaction of $[Ag(BF_4)(PPh_3)_2]$ with the ketone.[935,936] The ligand 1-methyluracilato bridges a platinum and two silver atoms in the complex $[PtAg_2(C_5H_5N_2O_2)_2(NO_3)_2(H_2O)]{\cdot}H_2O$ (**126**).[937] The redox and cation binding properties of a series of four quinone-functionalized calix[4]arenes have been studied in acetonitrile. All four compounds when reduced to the monoanion state demonstrate an interaction with Ag^+ to varying degrees.[938] A comparative analysis of the oxidizing and complexing properties of the DMSO-HX (X = Cl, Br, I) and DMSO-HX-ketone (X = Br, I; ketone = acetone, acetylacetone, acetophenone) systems towards silver has been performed.[939] The structure of the tetranuclear Ag—Co complex (**127**) has been reported.[940] A silver(I) nitrate–urea complex, $[Ag_2(NO_3)_2\{OC(NH_2)_2\}_2]_n$, has been described, it contains two independent silver atoms, one three-coordinated to two nitrate ions and one oxygen of the urea, the other is four-coordinated to two nitrate ions an urea molecule in a *N*,*O*-mode.[941]



(**125**)

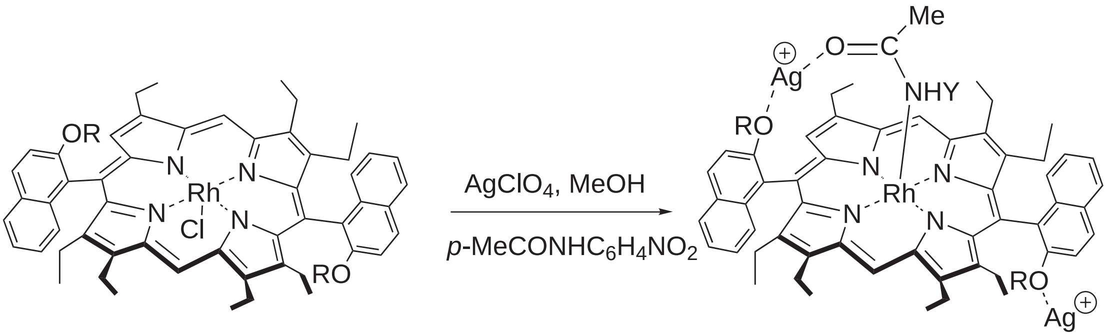


(**126**)



(**127**)

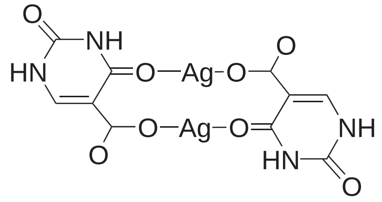
Calixspherands bearing OR substituents form kinetically stable silver(I) complexes.[942] Silver(I) complexes with isoorotate and 2-thioisoorotate ligands as (**128**) have been synthesized and their antimicrobial activity tested.[943] The synthesis of $[AgL(PPh_3)_2]$ where HL is 2,4,6-trichlorophenol and related complexes have been reported, the silver atom is three-coordinated. [944] The reaction of *N*,*N′*-bis(salicylidene)-1,4-diaminobutane (H_2L) with $AgNO_3$ or $AgClO_4$ gives the species $[Ag_2(H_2L)_3]_n(NO_3)_{2n}$ or $[Ag_2(H_2L)_3]_n(ClO_4)_{2n}$. The structures are 3D, noninterpenetrating networks in which the silver(I) centers are coordinated to three phenol groups; there are unsupported Ag···Ag contacts of 2.934(2) Å. Both complexes display intense blue photoluminescence in acetonitrile which may imply that the polymers disaggregate into oligomers.[945] A Ag—Rh system results from the interaction of $AgClO_4$ with a rhodium(III) porphyrin; it activates amides and esters towards alcoholysis reactions under mild and neutral conditions of the two metal ions (Equation (9)):[946]



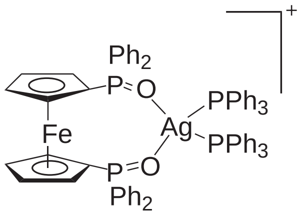
R = H, Me

Y = *p*-$C_6H_4NO_2$

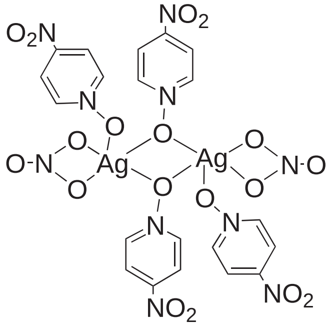
(9)



(**128**)



(**129**)



(**130**)

The crystal structure of $[Ag(NO_3)(OPPh_3)]$ has been reported, consisting of a distorted square-based pyramid with the silver atom bonded to two $OPPh_3$, two oxygens of the nitrate group and to an oxygen of the symmetry-related nitrate group.[947] The reaction of 1,1′-bis(diphenyloxophosphoryl)ferrocene (dpopf) with silver(I) salts gives complexes of the type $[Ag(OClO_3)(dpopf)]$, $[Ag(dpopf)_2]ClO_4$, and $[Ag(dpopf)(PPh_3)]ClO_4$ or the dinuclear $[Ag_2(PPh_3)_2(\mu\text{-dpopf})](ClO_4)_2$. Substitution reactions of the perchlorate ligand in $[Ag(OClO_3)(dpopf)]$ lead to the species $[Ag(LL)(dpopf)]$ ($LL = (PPh_3)_2$ (**129**), bipy, $(SPPh_2)_2CH_2$).[948]

The crystal structures of $[Ag(1,4\text{-dioxane})]AsF_6$[949] and $[Ag_2(1,4\text{-oxathiane})](NO_3)_2$[950] have been reported. Two adducts of the 4-nitropyridine *N*-oxide with silver nitrate have been characterized, one is a mononuclear tetracoordinated compound $[Ag(NO_3)(ONC_5H_4NO_2)_2]$ and the other is a dinuclear pentacoordinated species $[Ag_2(NO_3)_2(\mu\text{-}ONC_5H_4NO_2)_2(ONC_5H_4NO_2)_2]$ (**130**).[951,952] In the mixed compound *trans*-$[RhCl_2(py)_4]NO_3\cdot AgNO_3$ exists the dinitroargentate(I) ion in a distorted tetrahedral environment.[953]

The solid-state structure of $[Ag_2(H_2P_2O_7)]$ has revealed the presence of infinite $[H_2P_2O_7{}^{2-}]_n$ units which run parallel to the crystallographic *b*-axis; hydrogen bonding is an important structural feature.[954] In the compound $Ag_4K_6P_{10}O_{30}\cdot 10H_2O$ the structural moiety $[P_{10}O_{30}]^{10-}$ is present; four-coordinate silver atoms are incorporated into the Ag_4O_{10} cluster.[955] The compound $Ag_{20}O_{33}H_{22}(ClO_4)_4$ is formed by electrochemical oxidation of aqueous $AgClO_4$; the solid-state structure consists of $[H_{22}O_{17}]^{12-}$ clusters linked together via Ag—O bonds, resulting in a 3D network.[956]

6.7.2.3.5 Complexes with sulfur, selenium, and tellurium donor ligands

(i) Thiolates, selenolates, and tellurolate silver(I) complexes

Homoleptic silver(I) thiolates AgSR have been known and used for a long time,[957,958] but until recently with little definitive information about their structures. They are insoluble or slightly soluble, yielding unreliable high molecular weights in solution, indicative of nonmolecular crystal structures. These compounds dissolve due to the presence of thiolate ions.

The ring size was found to be dependent on the steric properties of the thiol; thus primary alkanethiolates give only polymeric $[AgSR]_n$, while some secondary alkanethiolates give $[AgSR]_{12}$ and tertiary alkanethiolates give $[AgSR]_8$. The $AgSCMeEt_2$ derivative has a 1D nonmolecular structure which consist of planar zig-zag —S—Ag—S—Ag— chains (Figure 11a).[959] However, in benzene solutions there is an interconversion in the molecular $[AgSCMeEt_2]_8$ (Figure 11b).[959]

The X-ray structure of $[Ag(SCy)]_n$ reveals cyclic molecules, $n = 12$, with weak linkages across the ring between sulfur and silver atoms; the silver atoms have a linear coordination.[960] The structures for the AgSR complexes with $R = (CH_2)_2Me$, $(CH_2)_3Me$, $(CH_2)_5Me$, $(CH_2)_7Me$, Ph, $4\text{-}FC_6H_4$, $4\text{-}BrC_6H_4$, $4\text{-}MeC_6H_4$, and $4\text{-}MeOC_6H_4$ have been obtained by using X-ray powder diffraction studies. The solid-state structure of each complex exhibits ${}^2_\infty[AgSR]$ layers in which the substituents are oriented at right angles to the layer of silver and sulfur atoms.[961] The increase of the steric bulk of the thiol substituents has been one approach to overcome the problem of structural characterization, since they should exhibit a reduced tendency to bridge metal centers, thereby yielding discrete molecular species. The use of sterically hindered (triorganosilyl)methanethiolates has lead to the characterization of trimeric $[AgSC(SiMe_2Ph)_3]_3$ (**131**) and tetrameric species $[AgSC(TMS)_3]_4$ (**132**). With the less hindered ligands $-SCH(TMS)_2$ an octameric compound or with $-SCH_2(TMS)$ a polymeric derivative are obtained.[962] With the ligand $-SC_6H_4$-2-TMS, a Ag_4S_4 eight-membered cycle of alternating silver and sulfur atoms is formed, but further

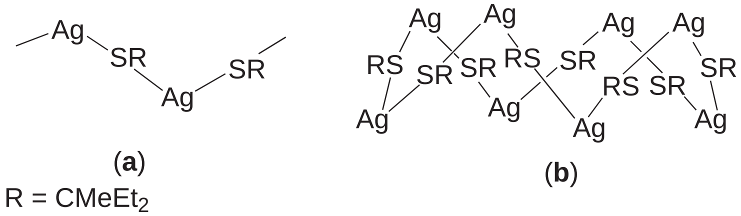


Figure 11 The two structures of $[Ag(SCMeEt_2)]$.

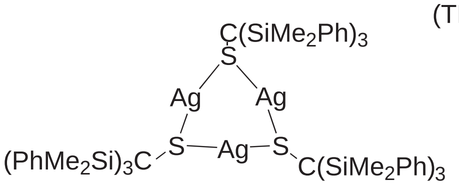
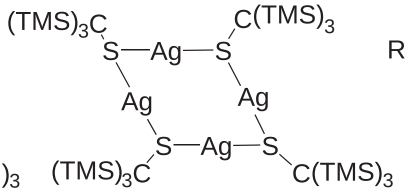
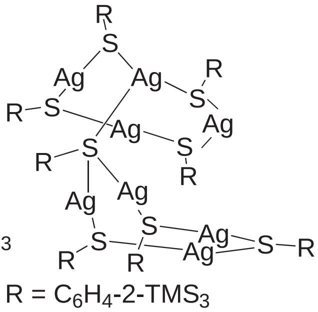
Ag$\cdots$S interactions produce a bis-cyclic structure [{Ag(SC_6H_4-2-TMS)}$_4$]$_2$ (**133**).[963] Also the tetrameric [Ag{SSi(OBu^t)$_3$}]$_4$ has been described.[964]



(**131**)

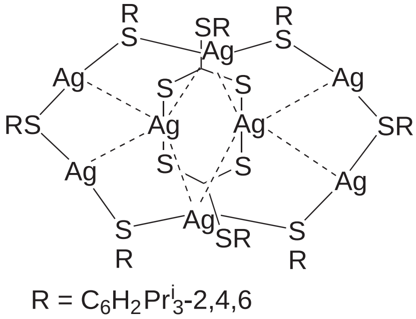


(**132**)

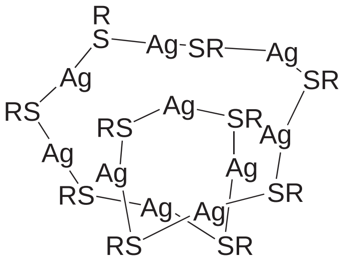


(**133**)

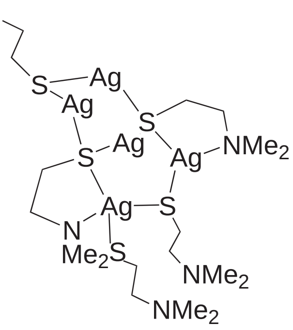
The silver thiolate complex [{Ag($SC_6H_2Pr^i$-2,4,6)}$_4$]$_n\cdot$($CHCl_3$)$_n$ consists of a 1D double (Ag–SR)$_n$ strand belt polymer.[965] This compound reacts with CS_2 to give the insertion derivative [{Ag($S_2CSC_6H_2Pr^i$-2,4,6)}$_2${Ag($SC_6H_2Pr^i$-2,4,6)}$_6$]$\cdot$8$CHCl_3$ (**134**).[965] This complex reacts with more CS_2 and after recrystallization the decanuclear silver thiolate [Ag($SC_6H_2Pr^i_3$-2,4,6)]$_{10}$ (**135**) is isolated.[966] The structure of the 2-dimethylaminoethylthiolatosilver(I) compound [{$AgSCH_2CH_2NMe_2$}$_5\cdot$0.5H_2O]$_n$ shows a ribbon polymer where the repeating unit (**136**) is a plane of five silver atoms linked by thiolates sulfurs into two fused six-membered rings.[967] The reaction of $AgNO_3$ with HSR (HSR = 2-(SH)-6-($SiMe_2Ph$)Py) produces the complex [AgSR]$_6$ in addition to [Ag_8(SR)$_6$][Ag(NO_3)$_2$]$_2\cdot$2MeOH$\cdot CH_2Cl_2$.[968]



(**134**)



(**135**)

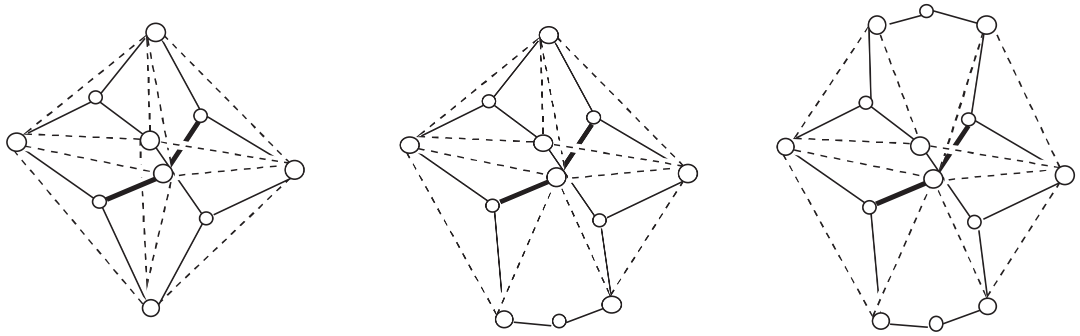


(**136**)

The family of primary silver thiolate compounds $AgSC_nH_{2n+1}$ (n = 4, 6, 8, 10, 12, 16, or 18), which in the solid state consists of $^2{}_\infty$[AgSR] layers, behaves as thermotropic liquid crystals. On heating, they display successively lamellar (smectic A), cubic, and micellar mesophases.[969]

The structures of some anionic silver thiolate complexes of the type [Ag_5(SPh)$_7$]$^{2-}$,[970,971] [Ag_5(SBu^t)$_6$]$^-$,[970] [Ag_6(SPh)$_6$]$^{2-}$,[972] and [Ag_{12}(SPh)$_{16}$]$^{4-}$[972] have been determined or are assumed to be similar to copper structures; [Ag_4(SPh)$_6$]$^{2-}$ has not been crystallized but may exist in solution.[972] Dance proposed a sequence of expanding *closo* polyhedra with bridging benzenethiolate ligands only (Figure 12). The structure of Et_4N[Ag(SAd)$_2$] (Ad = adamantyl) has been reported and the M—S (M = Cu, Ag, Au) bond length compared, with the silver distance 0.05 Å shorter than the Au—S one.[973] The homoleptic thiolate silver(I) derivatives (Et_4N)$_2$[Ag(SC_6H_4X-4)$_3$] (X = Cl, Br) and (Et_4N)$_2$[Ag_4(SC_6H_4X-4)$_6$] have been characterized structurally, confirming in the former the three-coordination.[974]

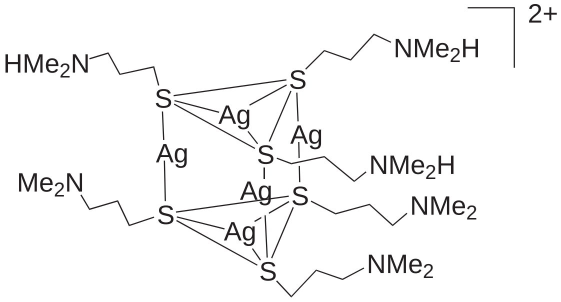
The introduction of an amine function as a solubilizing group in the thiol group is an alternative method for obtaining crystalline silver(I) thiolate derivatives. Therefore, complexes with 3-aminepropane-1-thiol and related ligands[975] of the type [Ag_5{μ_2-S(CH_2)$_3$ $NHMe_2$}$_3${μ_2-S(CH_2)$_3NMe_2$}$_3$]$^{2+}$,[975–977] (**137**) {[Ag_{13}(SC_5H_9NHMe)$_{16}$]$^{13+}$}$_n$,[978] and [{Ag_8(μ_4-$SC_2H_4NH_3$)$_6$-Cl_6}Cl_2]$_n$[979] have been isolated. Silver–cysteamine complexes with potential biological interest have been studied.[980] Water-soluble thiolate silver(I) complexes which are susceptible to having antimicrobial activity have been prepared with thiomalic and thiosalicylic acids; the structure



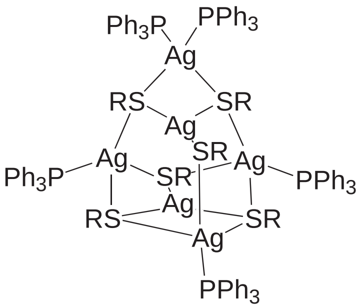
Ag_4S_6 Ag_5S_7 Ag_6S_8

Figure 12 Idealized cage polyhedra.

is proposed to be polymeric and bonded through the S-atoms.[981–983] The complex $\{Na[Ag(SC_6H_4\text{-}COO)]\cdot 2H_2O\}_n$ has been commercialized as an antimicrobial agent.[984] The crystal structure of $K_{12}[Ag_8(SC_6H_4COO)_{10}]\cdot 12H_2O$ has been reported.[985,986] The ligand 2-dimethylamino-3,4-dioxo-cyclobut-1-en-thiolate, $Me_2NC_4O_2S^-$ (dimethylaminothiosquarate) forms the complex $[Ag_2L_3]^-$.[986]



(137)

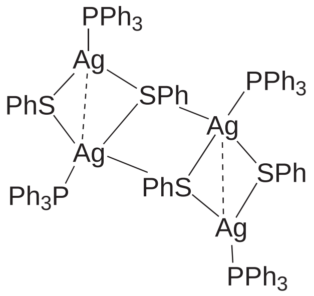


(138)

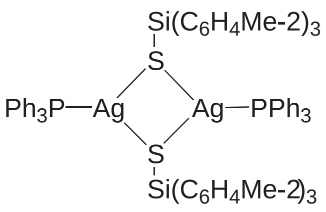
Other approaches consist of the reaction of silver thiolates with small amounts of bulky and structure-terminating heteroligands, such as tertiary phosphines. In this manner, complexes of the type $[Ag_5(SC_6H_4Cl)_6(PPh_3)_5]$ (**138**), $[(AgSCMeEt_2)_8(PPh_3)_2]$, and $[(AgSBu^t)_{14}(PPh_3)_4]$ have been obtained by reaction of the corresponding silver thiolate compound with triphenylphosphine.[987,988]

Treatment of $[Ag(PPh_3)_4]NO_3$ with benzenethiol in the presence of triethylamine gave the tetrameric compound $[Ag(SPh)(PPh_3)]_4$ (**139**).[19] A series of silver(I) trialkoxysilanethiolates $[Ag(S\text{-}SiR^1{}_3)(PPh_3)_2]$ ($R^1 = OBu^t$, OBu^s, OPr^i) and triarylsilanethiolates $[Ag(SSiR^2{}_3)(PPh_3)]$ ($2R{=}C_6H_4Me\text{-}2MeC_6H_4$, Ph) have been synthesized by reaction of $[Ag(ACAC)(PPh_3)]$ with the corresponding thiol (ACAC = acetylacetonate). The structure of $[Ag\{SSi(C_6H_4Me\text{-}2)_3\}(PPh_3)]_2$ (**140**) is a dimer.[989] The reaction of 1-(SH)-1,2-$C_2B_{10}H_{11}$ with $[Ag(OTf)(PPh_3)]$ and Na_2CO_3 gives $[Ag_2(SC_2B_{10}H_{11})(OTf)(PPh_3)_2]$ (**141**), which is also a dimer in the solid state.[990] Complexes of the type $[Ag\{S(CH_2CHOHCH_2OR)\}(PPh_3)_2]_2$ (R = H, Me, Et) have been also reported.[991] The structure of $[Ag(SCN_4Ph)(PPh_3)_2]$ with the 1-phenyl-1H-1,2,3,4-tetrazole-5-thiolate ligand has been described.[992] The silver(I) complexes with 2-thionicotinic acid (H_2mna) and 2-thiobenzoic acid (H_2mba), $[Ag(Hmna)(PPh_3)_n]$ ($n = 2, 3$) or $[Ag(Hmba)(PPh_3)_3]$ have been obtained and their antimicrobial activities tested.[993,994] A similar $[Ag(SR)(PPh_3)_3]$ compound with SR = 4-(methylthio)-2-thioxo-1,3-dithiole-5-thiolate has been reported.[995]

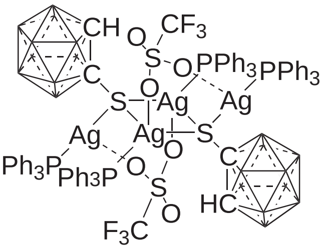
Silver(I) trifluoromethanethiolate ($AgSCF_3$) has been used to prepare trifluoromethyl aryl sulfides by reaction with iodide.[996] A mixed silver–zinc thiolate complex $[Ag_4Zn_2(SC_6H_2\text{-}Pr^i\text{-}2,4,6)_6(OTf)_2]$ has been prepared by reaction of AgOTf with $Zn[N(TMS)_2]_2$ in the presence of the thiol.[997] Solid-state ^{109}Ag NMR can be a sensitive environment probe for silver thiolates,[998] overall for biological thiolates ligands as cysteine,[999] or proteins such as metallothionein.[1000,1001]



(139)

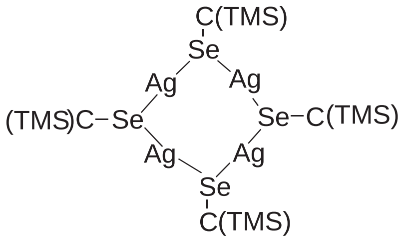


(140)

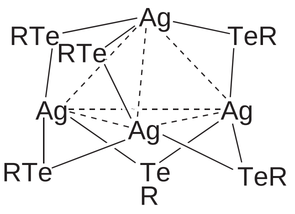


(141)

Far less abundant are selenolate or tellurolate silver(I) complexes. The reaction of $AgNO_3$ with (DME)LiSeC(TMS) yields the compound $[Ag\{SeC(TMS)_3\}]_4$ (**142**).[1003] The tellurolate complex $(Ph_4P)_2[Ag_4(TeC_4H_3S)_6]$ (**143**)[1004] and the analogous $(Me_4N)_2[Ag_4(SePh)_6]$[1005] have been reported.



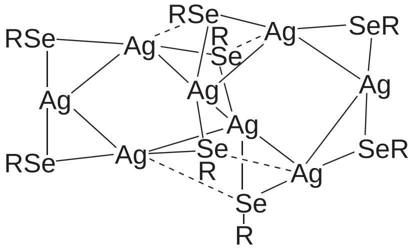
(142)



R = C_4H_3S

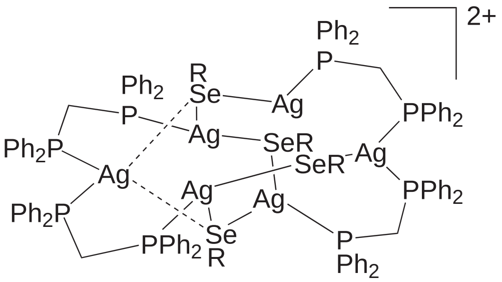
(143)

The homoleptic aryl selenolate complex $[Ag(SeC_6H_2Pr^i_3\text{-}2,4,6)]_8$ (**144**) has been synthesized by reaction of $AgNO_3$ with the selenol in acetonitrile and in the presence of NEt_3. The cluster exhibits a strong optical limiting effect with threshold of $0.2\,J\,cm^{-2}$, which is about 2.5 times lower than that of C_{60} in toluene under identical experimental conditions.[1006] Silver thiolate and selenolate derivatives of the type $[Ag_6(\mu\text{-dppm})_4(\mu_3\text{-EAr})_4](PF_6)_2$ (**145**) (EAr = SPh, SC_6H_4Me-4, SePh, SeC_6H_4Cl-4) have been prepared and the luminescence properties studied.[1007] The selenolates $[Ag_4(SePr^i)_4(dppm)_2]$ and $[Ag_8(SeEt)_8(dppp)]_n$ have been prepared from AgSCN or AgO_2CPh in the presence of the diphosphine and RSeTMS at low temperature.[1008] By the same procedure, silver thiolates and tellurolates of the type $[Ag_2(SPh)_2\ (triphos)]_n$, $[Ag_7(SPh)_7(dppm)_3]$, $[Ag_{22}Cl(SPh)_{10}(PhCO_2)_{11}(DMF)_3]_n$, or $[Ag_7(TePh)_7(dppp)]$ have been synthesized.[1009]



R = $C_6H_2Pr^i_3$-2,4,6

(144)



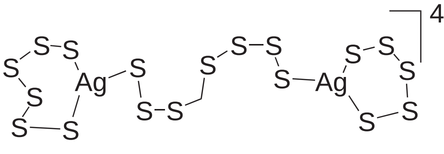
R = C_6H_4Cl-4

(145)

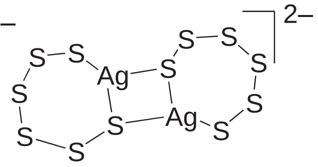
The complexes $[M(\mu\text{-}C_7H_4NS_2)(COD)]_2$ (M = Rh, Ir) and $[Rh(\mu\text{-}C_7H_4NS_2)(CO)(PPh_3)]_2$ react with silver compounds to give the heterometallic derivatives with the silver(I) atoms bonded to the thiolate sulfur atoms. The structure of $[Rh_2Ag_2(\mu_3\text{-}C_7H_4NS_2)_2(ClO_4)]$ shows a short Rh—Ag distance.[1010]

(ii) Sulfide, selenide, telluride, and polychalcogenide silver(I) complexes

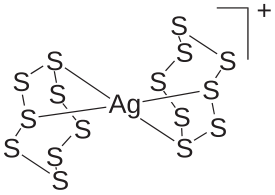
Polysulfide silver(I) complexes have been obtained and are of the form $(Ph_4P)_4[Ag_2S_{20}]\cdot S_8$ (**145**),[1011] $(Ph_4P)_2[Ag_2(S_6)_2]$ (**146**),[1012] and $Ph_4P[AgS_9]$.[1012] Cyclooctasulfur can act as a ligand in complexes such as $[Ag(S_8)_2]AsF_6$ (**147**).[1013]



(**146**)

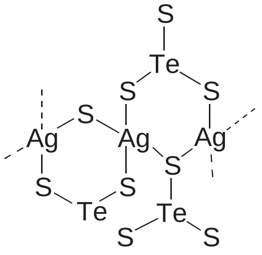


(**147**)

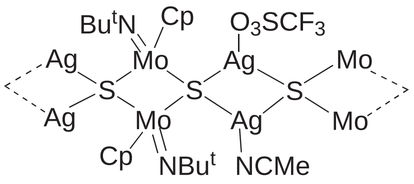


(**148**)

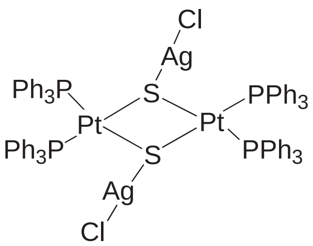
By cleavage of the S—C bond in the presence of phosphine silver(I) complexes polynuclear complexes with bridging sulfido ligands are obtained, such as $[Ag_{11}(\mu_5\text{-}S)(\mu_4\text{-}S_2CNEt_2)_3(\mu_3\text{-}S_2CNEt_2)_6]$.[1014] Other materials can serve also as a S^{2-} source, as is the case of MoS_4^{2-} which also gives the species $[Ag_{11}(\mu_5\text{-}S)(\mu_4\text{-}S_2CNR_2)_3(\mu_3\text{-}S_2CNR_2)_6]$[1015] or $S_2P(OEt_2)_2^-$ which gives the cluster $[Ag_8(\mu_6\text{-}S)\{S_2P(OEt_2)_2\}_6]$.[1016] Other silver sulfide cluster as $[Ag_{14}(\mu_6\text{-}S)(SPh)_{12}(PPh_3)_8]$ has been synthesized just leaving solutions of $[Ag(S_2CSPh)(PPh_3)_2]$ in CH_2Cl_2.[1017] By the same procedure, decomposition of an CS_2 insertion product, the cluster $(HNEt_3)_4[Ag_{50}S_7(SC_6H_4Bu^t\text{-}4)_{40}]$ has been isolated.[1018] A quasi-1D barium silver(I) sulfide, $Ba_2Ag_8S_7$, containing mixed S^{2-}/S_2^{2-} ligands has been prepared by electrochemical synthesis.[1019] Hydrothermal conditions in alkaline solutions were employed for the preparation of the 3D materials $NH_4[Ag_2(AsS_2)_3]$ and $(NH_4)_5[Ag_{16}(AsS_3)_7]$.[1020] 2D polychalcogenide materials, $AAgTeS_3$ (A = K, Rb, Cs), have been prepared and their structures consist of $[AgTeS_3]_n^{n-}$ networks (**149**).[1021] Other sulfides are $AgLa_3GeS_7$,[1022] $BaSC_3AgS_6$,[1023] or $AgPbBi_3S_6$.[1024]



(**149**)



(**150**)

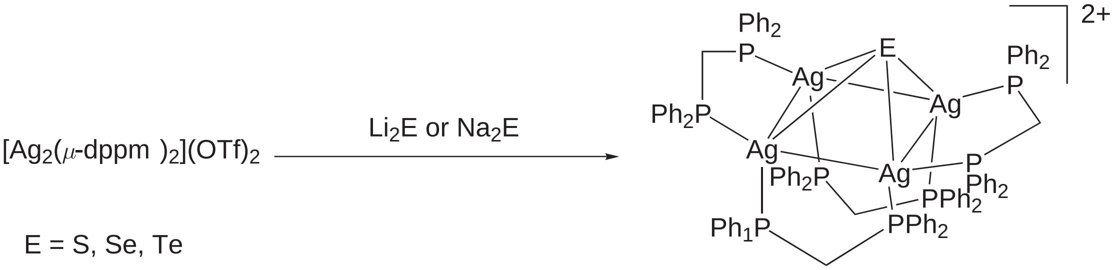


(**151**)

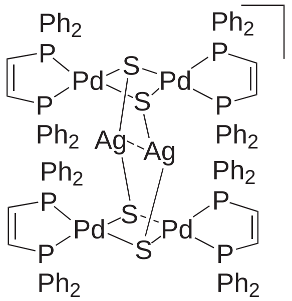
The reaction of $[Ag_2(\mu\text{-}dppm)_2](OTf)_2$ with Na_2E or Li_2E (E = S, Se, Te) gives the tetranuclear complexes $[Ag_4(\mu_4\text{-}E)(dppm)_4](OTf)_2$ with a quadruply bridging chalcogenide ligand (Equation (10)).[1025] Excitation of the complexes in the solid state and in fluid solutions with l > 350 nm results in intense and long-lived green to orange luminescence. The transitions associated with the emissions of the silver(I) clusters originate essentially from a ligand-to-metal charge-transfer ($E^2 \rightarrow Ag_4$) excited state, with mixing of a metal-centered (*d-s*/*d-p*) silver(I) state.[259,260,1026]

Mixed silver–metal sulfide complexes have been reported and are of the type $[MoCp(NBu^t)S]_5[Ag(MeCN)OTf]_3[AgOTf]_2$ (**150**),[1027] $[Ag_2Pt_4(\mu\text{-}S)_4(PPh_3)_8](BF_4)_2$,[1028] $[Ag_2Pt_2Cl_2(\mu_3\text{-}S)_2(PPh_3)_4]$ (**151**),[1029] $[Ag_2\{Pt_2Cl_2(\mu_3\text{-}S)_2(PPh_3)_4\}_2]^{2+}$,[1029] $[AgPt_2(\mu_3\text{-}S)_2(PPh_3)_5]^+$,[1029] $[Ag_2Pd_2Cl_2(\mu_3\text{-}S)_2$

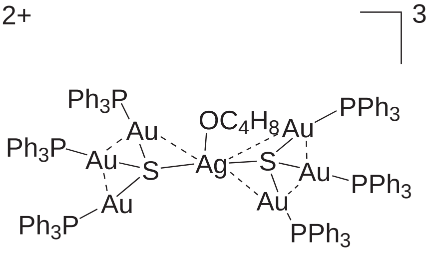
(dppf)$_2$],[1030] [$Ag_2Pd_4(\mu_3\text{-}S)_4\{cis\text{-}(PPh_2)_2(CH{=}CH)\}$] (**152**),[1031] [$\{S(AuPPh_3)_3\}_2Ag](BF_4)_3$ (**153**),[1032] or $Bu_4N[S\{Au(C_6F_5)_3\}_2(AgPPh_3)]$ (**154**).[1034]



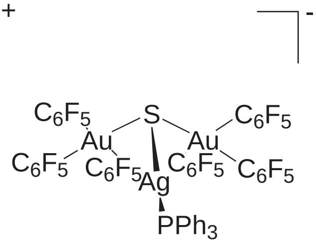
(10)



(**152**)



(**153**)

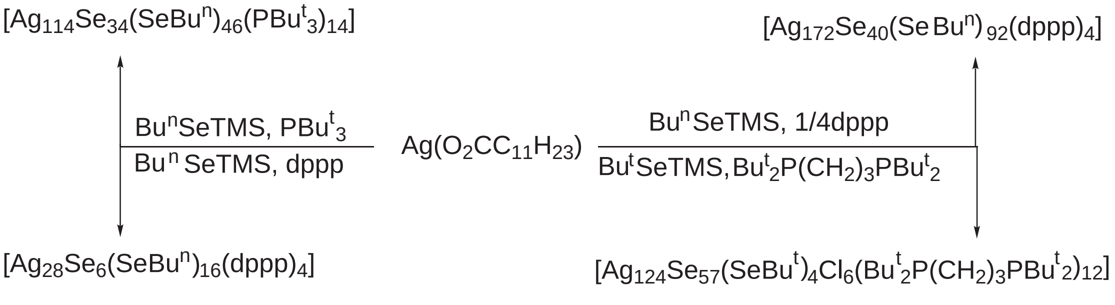


(**154**)

Silver(I) complexes with bridging selenide ligands are not as numerous. The reaction of AgS_2CNEt_2 with $(Et_4N)_2MoSe_4$ or Na_2Se yields the polynuclear silver cluster [$Ag_{11}(\mu_5\text{-}Se)(\mu_4\text{-}S_2CNEt_2)_3(\mu_3\text{-}S_2CNEt_2)_6$] (**155**).[1034] Fenske and co-workers have synthesized several high nuclearity silver(I)–selenide clusters using as a selenium source RSeTMS and by reaction with silver salts and in the presence of phosphines in order to stabilize the compounds (Schemes 6 and 7).[34,1008] The silver–platinum cluster [$Ag_2Pt_2(\mu_4\text{-}Se)_2Cl_2(PPh_3)_4$] (**156**) have been obtained mixing [$PtCl_2(PPh_3)_2$], [$Ag(O_2CR)$], and $Se(TMS)_2$.[1035]

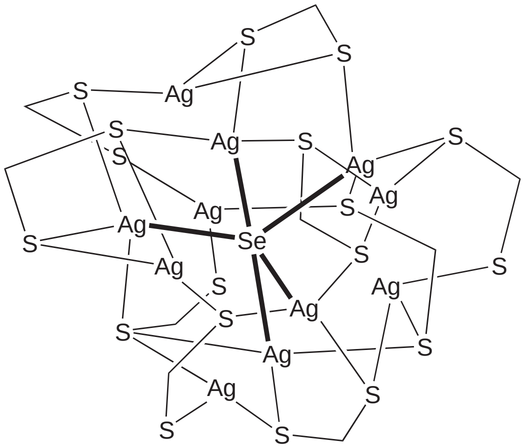
$$[Ag_{30}Se_8(SeBu^t)_{14}(PPr^n{}_3)_8] \xleftarrow[PEt_3]{Bu^tSeTMS} Ag(O_2CPh) \xrightarrow[PPr^n{}_3]{Bu^tTMS} [Ag_{90}Se_{38}(SeBu^t)_{14}(PEt_3)_{32}]$$

Scheme 6

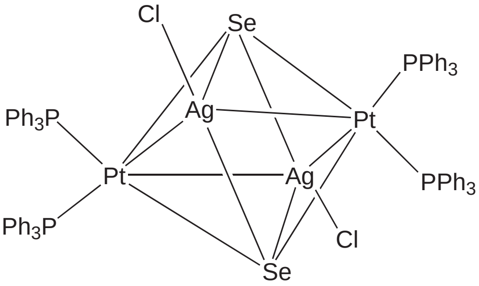


Scheme 7

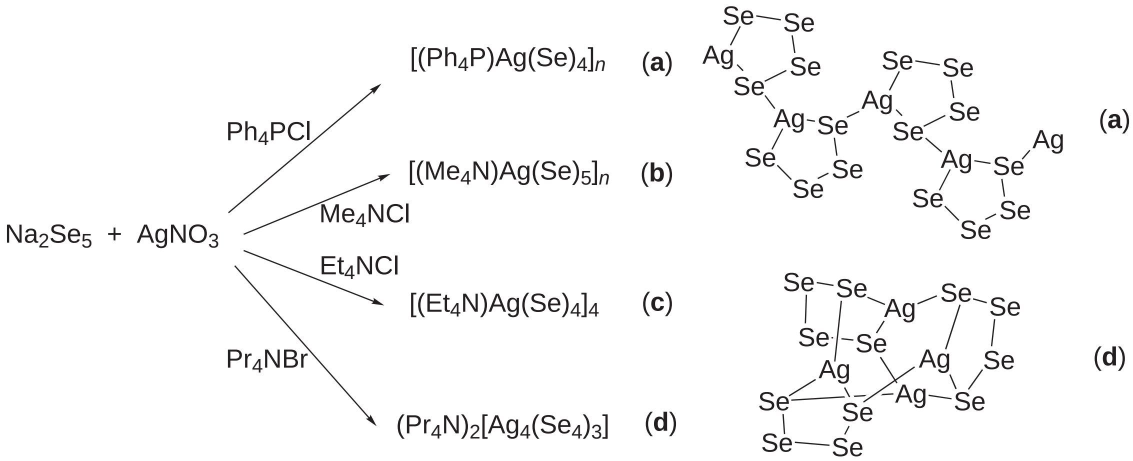
Kanatzidis and co-workers have obtained polyselenides of varied stoichiometry depending upon reaction conditions. The reaction of $AgNO_3$ with Na_2Se_5 gives different complexes in function of the cation (Scheme 8).[1036,1037] A similar compound $(Ph_4P)_2[Ag_4(Se_4)_2(Se_5)]$ has been obtained from Na_2Se_4 generated "*in situ*."[1038]



(**155**)



(**156**)

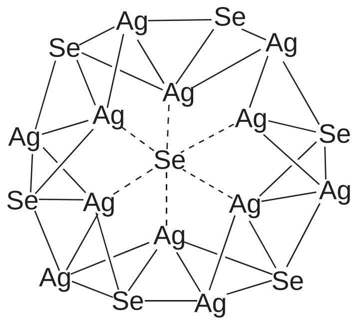


Scheme 8

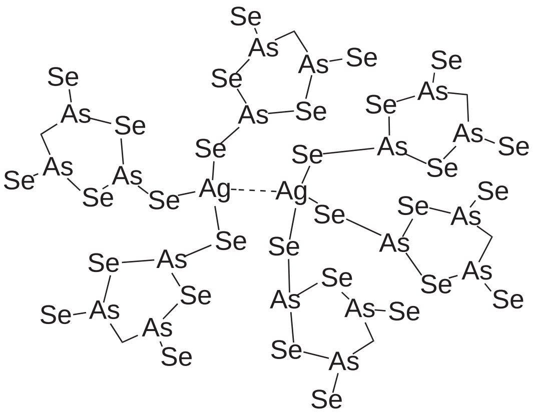
The compound $K_2Ag_{12}Se_7$ (**157**) has been prepared from potassium polyselenide and silver powder in supercritical ethylene diamine.[1039] $RbAg_2As_3Se_6$ possesses a unique 3D silver–selenoarsenate framework ${}^{3}{}_{\alpha}[Ag_2As_3Se_6]^-$ which is assembled from $[As_3Se_6]^{3-}$ rings and $Ag_2{}^{2+}$ dumbbell units (**158**).[1040] Discrete complexes incorporating heteropolychalcogenide ligands, $[Ag_2Te(TeS_3)_2]^{2-}$ and $[Ag_2Te(TeSe_3)_2]^{2-}$ (**159**), have also been obtained.[1041]

The interaction between Ag^+ and selenium in the bloodstream has been studied *in vitro* by means of the HPLC-inductively coupled argon plasma-mass spectrometry (ICPMS) method. The metal ions and selenide form the unit complex $(AgSe)_n$ and then this unit binds to selenoprotein to form the ternary complex $[(AgSe)_n]$·selenoprotein in the bloodstream.[1042]

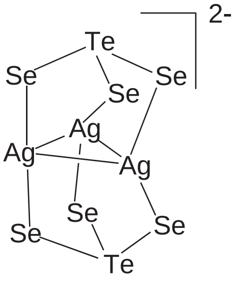
Mixed silver telluride–tellurolate complexes have been prepared in a similar manner to those of selenium. The reactions of a silver salt with RTeTMS in the presence of phosphines as stabilizing agents are reported in Scheme 9.[1043–1046]



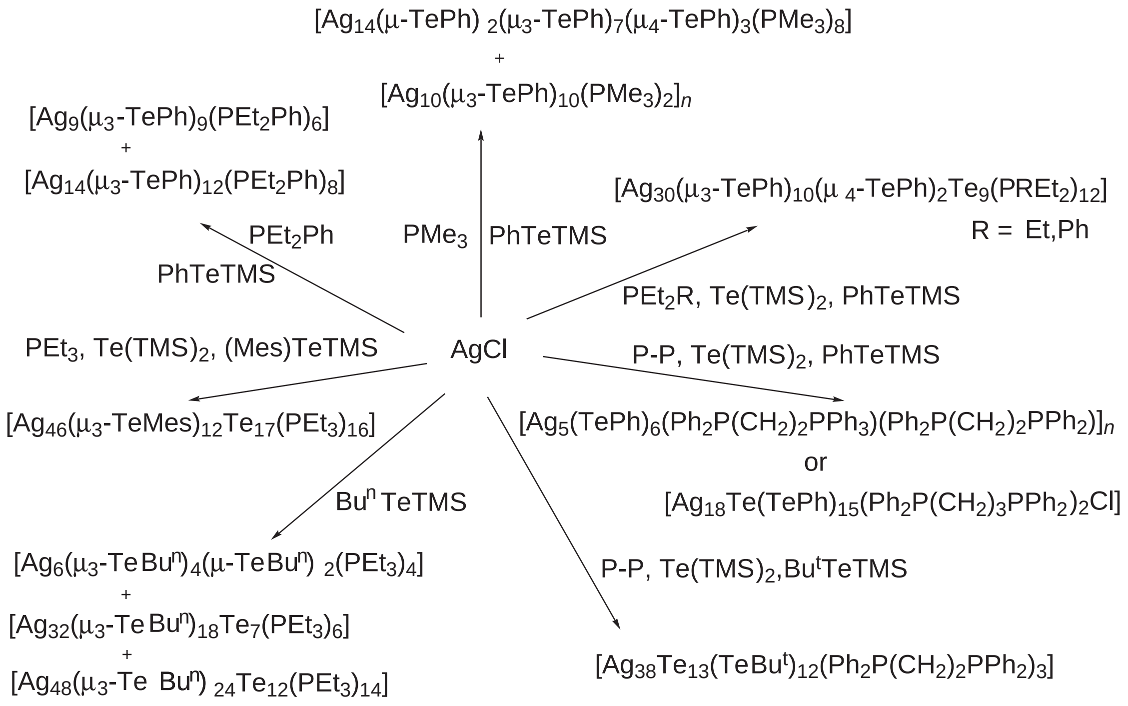
(**157**)



(**158**)

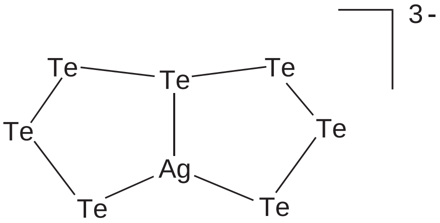


(**159**)

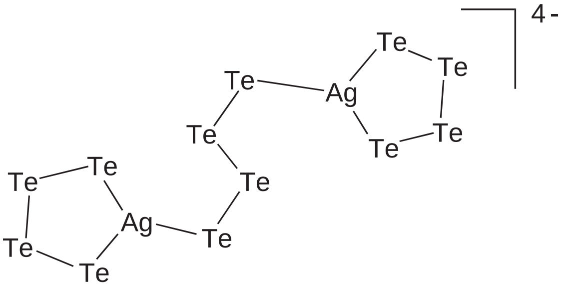


Scheme 9

The homoleptic telluride compound $(PPh_4)_2(NEt_4)[AgTe_7]$ (**160**) has been prepared by mixing $Li_2Te/Te/Na/[AgI(PMe_3)]/PEt_3$ following by addition of the cations.[1047] If metallic sodium is not used, the compound $(NEt_4)_4[(Te_4)Ag(\mu\text{-}Te_4)Ag(Te_4)]$ (**161**) is obtained.[1048] This complex is also obtained by treatment of Na_2Te_3 with $AgNO_3$ in DMF and in the presence of $(PPh_4)Br$.[1049] The reaction of $AgBF_4$ and K_2Te in DMF in the presence of $(NEt_4)Cl$ leads to the formation of $Me_4N[AgTe_4]$.[1050]



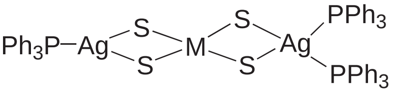
(**160**)



(**161**)

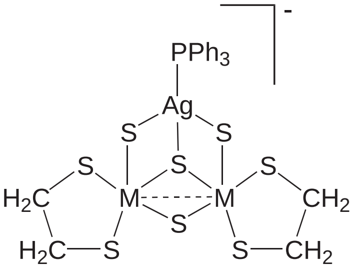
Ternary and quaternary metal telluride materials have been prepared from the metallic elements in telluride fluxes, as the compounds $CsAg_5Te_3$,[1051] $K_{0.33}Ba_{0.67}AgTe_2$,[1052] $CsFe_{0.72}Ag_{1.28}Te_2$,[1053] and $Cs_2Ag_2ZrTe_4$. The latter has a structure that comprises 2D slabs of Ag- and Zr-centered tetrahedral separated by Cs^+ cations.[1054] Gas-phase silver chalcogenide ions of the type $[Ag_{2n-1}E_n]^-$ ($E = S$, Se, Te) with $n \leq 14$ have been investigated by laser-ablation Fourier transform ion cyclotron resonance mass spectrometry.[1055]

Mixed metal sulfide clusters are those synthesized from MS_4^{2-} ($M = Mo$, W) and VS_4^{3-} anions and silver cations in the presence of various ligands. Many of these silver compounds, together with copper compounds, have been extensively studied because of their relevance to biological systems and industrial significance.[1056] For the W(Mo)/S/Ag system many discrete complexes have been obtained, such as $[(PPh_3)_2AgS_2MS_2Ag(PPh_3)\cdot 0.8CH_2Cl_2]$ (**162**),[1057] $Et_4N[(PPh_3)_2AgS_3MECu(CN)]$ ($E = S$, O),[1058,1059] $[\{Ag(PPh_3)\}_3MS_4\{S_2P(OEt_2)_2\}]$,[1060–1062] $[(EPh_3)_4Ag_4W_2S_8]$ ($E = P$, As),[1063,1064] $(Bu_4N)_2[M_2Ag_3(\mu_3\text{-}S)_2(\mu\text{-}S)_4(S_2CNEt_2)]$,[1065] $[Ag_6S_6M_2(SCMe_3)_2O_2(PPh_3)_4]$,[1066,1067] $[WS_4Ag_3I(AsPh_3)_3](SAsPh_3)$,[1068] $[WAg_3OS_3(PPh_3)_3\{S_2P(PPr^i)_2\}]$,[1069] $Et_4N[AgM_2S_4(S_2C_2H_4)_2(PPh_3)]$ (**163**),[1070] $Et_4N[AgCuWS_4(CN)(PPh_3)_2]$,[1071] $[\{Ag_3MoS_3Cl\}(E)(PPh_3)_3]$ ($E = O$, S) (**164**),[1072,1073] $[(PPh_3)_2AgSe_2WSe_2Ag(PPh_3)]$,[1074,1075] or $[MS_4X\{Ag(PR_3)_3\}]$ ($X = Cl$, Br, $IR_3 = Ph_3, Ph_2Me$)[1076–1080] ($M = Mo$, W). Some of these complexes display very strong nonlinear optical properties.[1062,1064,1069,1074]

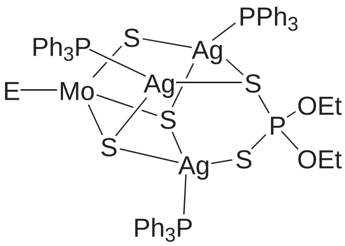


M = Mo, W; E = S, O

(**162**)

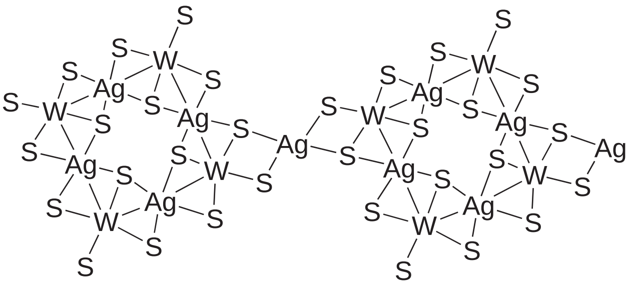


(**163**)



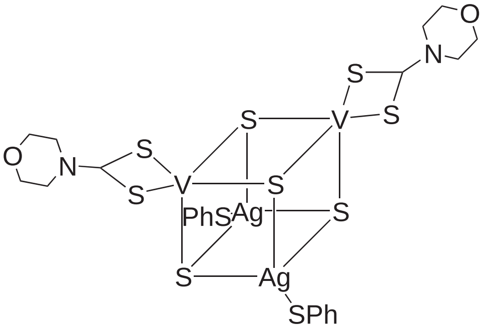
(**164**)

Polymeric species have also been described, such as $[(PPh_4)\cdot AgMoS_4]_n$,[1081,1082] $[AgMS_4\cdot 4MePyH]_n$,[1083] $[(TMEDAH_2\cdot W_2Ag_2S_8\cdot TMEDA\cdot H_2O]_n$,[1084] $[WS_4Ag\cdot NH_3C(CH_2OH)_3\cdot H_2O]_n$,[1085] $[WS_4Ag\cdot NH_3C(CH_2OH)_3\cdot 2DMF]_n$,[1086] $[W_4S_{16}Ag_5\cdot Ln(DMF)_8]_n$ (**165**) ($Ln = Nd$, Pr, La)[1087,1088] $[WS_4Ag\cdot HNEt_3\cdot DMF]_n$,[1089] $[W_4S_{16}Ag_4\cdot 2Ca(DMSO)_6]_n$,[1090] $[N(C_6H_5CH_2)(C_2H_5)_3\cdot MoAgS_4]_n$,[1091] $[Mo_2Ag_2S_8\cdot Ca(DMSO)_6]$,[1091] or $[Mo_3Ag_3S_{12}\cdot Nd(DMNd(DMSO)_8]_n$.[1091]

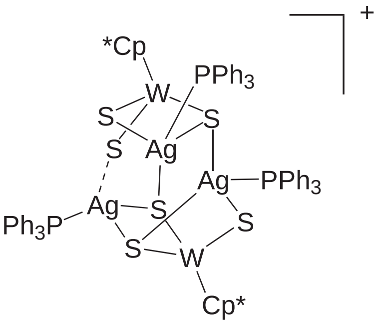


(**165**)

With other transition metal sulfides the mixed vanadium–silver cubane-like cluster, $(Et_4N)_2[Ag_2V_2S_4\{S_2CN(OC_4H_8)_2\}_2(SPh)_2]$ (**166**)[1092] and $[\{\eta^5\text{-}C_5Me_5)WS_3\}_2Ag_3\ (PPh_3)_3]NO_3$ (**167**), have been reported.[1093]



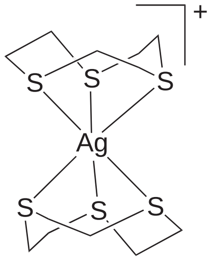
(**166**)



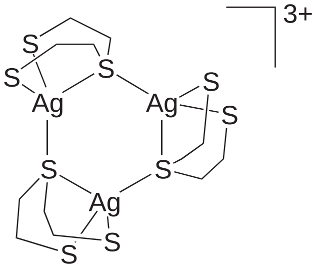
(**167**)

(iii) Thioether silver(I) complexes

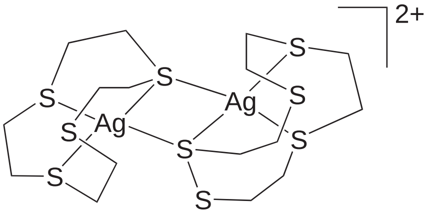
The chemistry of silver(I) with crown thioethers has developed in the last years,[1094,1095] but now numerous examples with a great variety of ligands have been reported. The first homoleptic silver compounds have been described with 1,4,7-trithiacyclononane ([9]aneS_3), [Ag([9]aneS_3)$_2$]OTf (**168**), which is octahedral and shows a reversible oxidation assigned to the Ag^I/Ag^{II} couple,[1096,1097] and the trimeric species [Ag_3([9]aneS_3)$_3$]$^{3+}$ (**169**).[1097] The complexes [AgX([9]aneS_3)] ($X = Cl$, Br) have also been described.[1098] Larger thioethers macrocycles also binds silver(I) and thus complexes of the type [Ag([12]aneS_3)$_n$]OTf ($n = 1, 2$),[1098] [Ag_2([15]aneS_5)$_2$]$^{2+}$ (**170**),[1099] [Ag([16]aneS_6)]ClO_4 (tetrahedral),[1100] or [Ag([18]aneS_6)]$^+$,[1101] (**171**) have been isolated. The latter can be oxidized to the Ag^{II} compound that is stabilized under acidic conditions.



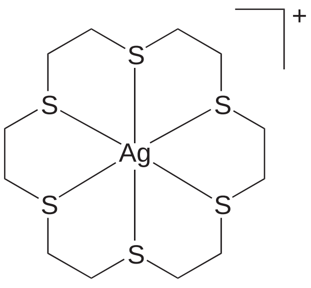
(**168**)



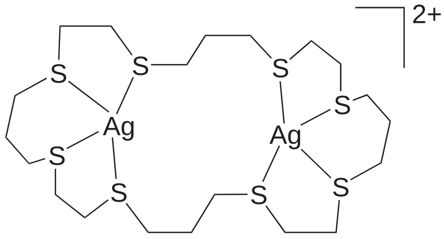
(**169**)



(**170**)



(171)



(172)

With larger ring size the complexes tend to be polymeric as $[Ag([16]aneS_4)(BF_4)]_n$,[1102] $[Ag_2([14]aneS_8)(OTf)_2(MeCN)]_n$,[1102] $[AgBr([18]aneS_6)]$,[1098] or $[Ag_2([24]aneS_8)(OTf)_2(MeCN)_2]_n$.[1103] In the compound $[Ag_2([28]aneS_8)](NO_3)_2$ (**172**), the macrocycle has a sufficiently large cavity to encapsulate two silver(I) atoms.[1103] With $[15]aneS_5$ monomeric $[Ag([15]aneS_5)]B(C_6F_5)_4$, dimeric $[Ag_2([15]aneS_5)_2](BPh_4)_2$, or polymeric species $[Ag_n([15]aneS_5)_n](BF_4)_n$ are obtained depending upon the cation.[1104] The substituted thiocrown ethers $[19]aneS_6$-OH and $[20]aneS_6$-OH have been synthesized and the silver complexes $[Ag([19]aneS_6\text{-}OH)]OTf$ and $[Ag([20]aneS_6\text{-}OH)]BF_4$ obtained; the silver centers are bonded to four sulfur atoms in a distorted tetrahedral geometry.[1105] The $[16]aneS_4\text{-}(OH)_2$ macrocycle coordinates to silver in an exodentate fashion, with four macrocycles coordinating to each distorted tetrahedral Ag and four Ag-atoms bound to each macrocycle forming a polymeric structure.[1106]

These silver(I) crown thioether complexes have been used as templates for the synthesis of extended polyiodide networks, such as $[Ag_2([15]aneS_5)_2]I_{12}$, $[Ag([18]aneS_6)]I_7$, $[Ag([18]aneS_6)]I_3$, and $[Ag([9]aneS_3)_2]I_5$,[1107,1108] or as building blocks for the formation of coordination polymers constructed form Ag(hfac) and $[14]aneS_4$ or $[9]aneS_3$.[1109] The solvent extraction of Ag^I by $[14]aneS_4$, $[18]aneS_6$, and related ligands has been described.[1110–1118]

Silver(I) derivatives with macrocyclic thioether ligands with different substituents in the alkyl chain have also been obtained. Several compounds have been reported with macrocyclic ligands such as thiacyclophane derivatives (Figure 13).[1120–1127] With the ligand 2,5,8-triathia[9]-*o*-cyclophane (L_1) the complex $[Ag(L_1)_2]OTf$ has been obtained, the silver center has a tetrahedral coordination to both the free ligand *exo*- and the fully organized *endo*-conformation of the ligand.[1119] The ligand L_1 forms an octagonal complex with a $[Ag_4S_4]^{4+}$ cavity (**173**).[1128]

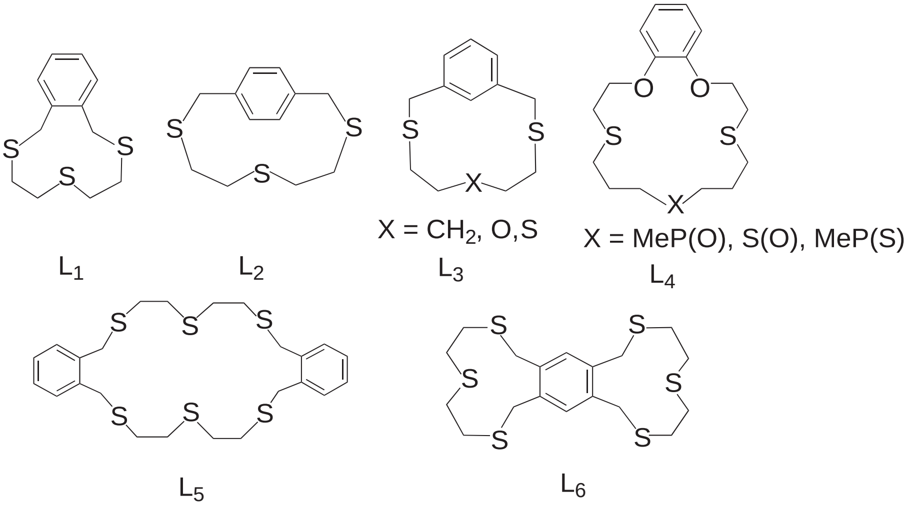


Figure 13 Some thiocyclophane derivatives which form silver(I) complexes.

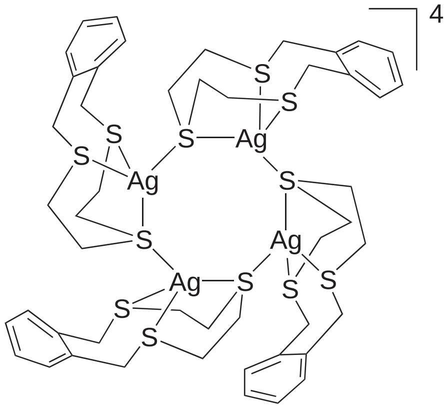
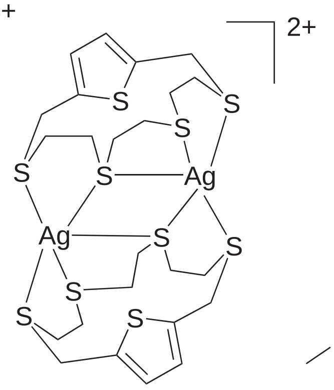
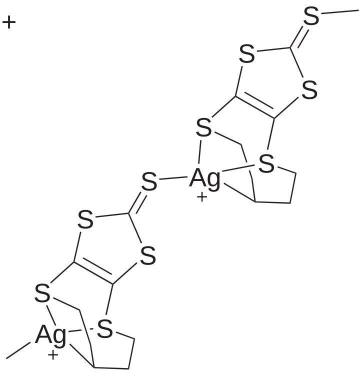


(173)



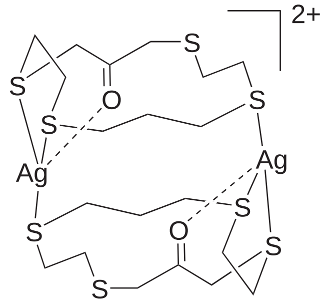
(174)



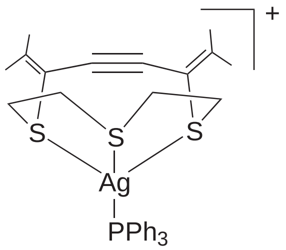
(175)

The thiophenophane $C_{12}H_{18}S_4$ ligand forms a $[Ag_2L_2]^{2+}$ complex (**174**) where the silver atoms are in a distorted trigonal bipyramidal geometry.[1129] Crown thioethers complexes containing rigid 1,2-dithioethene units have been described, they are polymers when there is a thione group (**175**) or monomers in the case of a carbonyl group.[1130,1131]

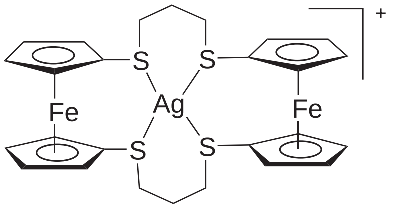
Thia-crown ethers incorporating propan-2-one units and dimeric silver(I) compounds as (**176**) and other polymeric species have been prepared.[1132,1133] Other substituents can be diisopropylidene groups which form complexes of the type $[AgL(PPh_3)]OTf$ (**177**),[1134] pyridazine,[1135] or phthalazine[1136] ligands or even organometallic compounds as ferrocene in (**178**).[1137]



(176)

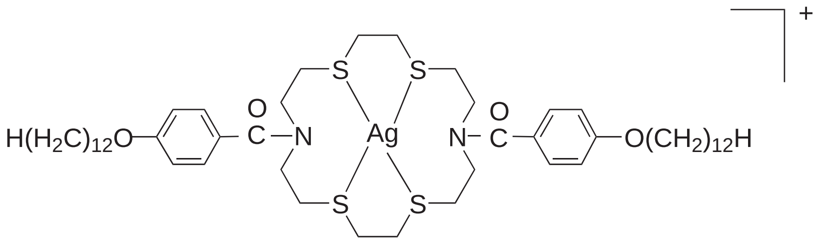


(177)



(178)

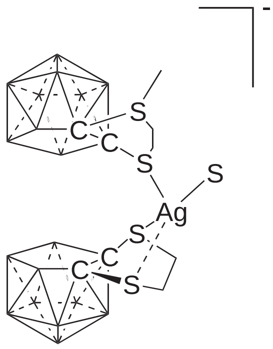
A zinc phthalocyanine complex with four fused [13]aneS_4 functional groups forms the monomeric pentanuclear $ZnAg_4$ complex, where each Ag atom is presumably coordinated by a [13]aneS_4 ring.[1138] Nonmesogenic ligands containing an N_2S_4 macrocycle coordinate to silver(I) to form mesomorphic structures. It has been proposed that the mesomorphic behavior of the silver complex (**179**) is caused by its segregation of its polar and apolar regions, resulting in an amphiphilic material.[1139,1140]



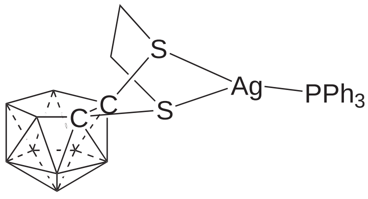
(179)

Macrocyclic thioethers which contain a carborane backbone have also been prepared and the silver(I) complexes obtained. The reaction of $AgNO_3$ with the sulfur-containing macrocyclic ligand

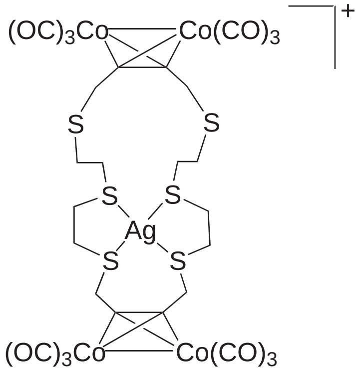
$[7,8\text{-}\mu\text{-}(SCH_2CH_2S)\text{-}7,8\text{-}C_2B_9H_{10}]^-$ leads to the complex $[Ag\{7,8\text{-}\mu\text{-}(SCH_2CH_2S)\text{-}7,8\text{-}C_2B_9H_{10}\}]^-$ which is a chain polymer (**180**). By addition of PPh_3 the chain is broken and discrete species $[Ag(PPh_3)_4][Ag\{7,8\text{-}\mu\text{-}(SCH_2CH_2S)\text{-}7,8\text{-}C_2B_9H_{10}\}(PPh_3)]$ are obtained.[1141] With the cyclic ligands $[7,8\text{-}\mu\text{-}\{S(CH_2)_nS\}\text{-}7,8\text{-}C_2B_9H_{10}]^-$, several silver(I) complexes have been prepared with PPh_3 or bipy as auxiliary ligands, such as (**181**).[1142,1143] Reaction of $[Co_2\{\mu\text{-}C_2(CH_2SCH_2CH_2)_2S\}(CO)_6]$ with $AgBF_4$ and PPh_3 gives $[Co_2\{\mu\text{-}C_2(CH_2S\text{-}CH_2CH_2)_2S\}(CO)_6\{Ag(PPh_3)\}]BF_4$. The dimeric cobalt compound produces a 1:1 adduct (**182**) when treated with $AgBF_4$.[1144]



(180)

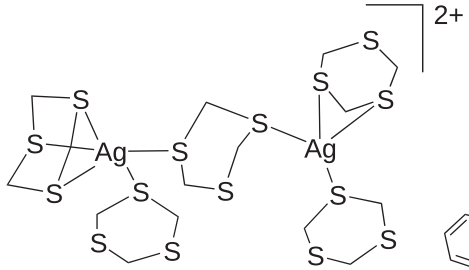


(181)

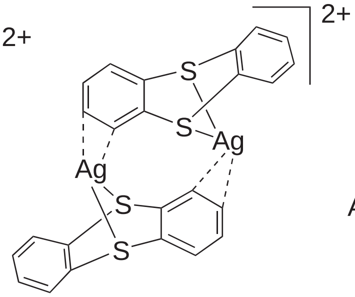


(182)

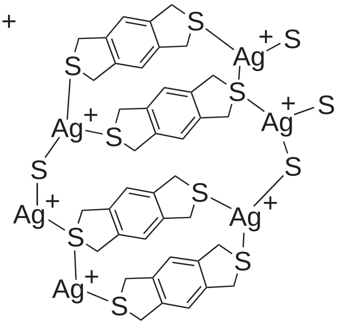
Other silver(I) complexes have been reported with cyclic thioethers, such as $[Ag_2\{(CH_2S)_3\}_5]^{2+}$ (**183**) with the trimeric thioformaldehyde as ligand,[1145] or the thianthrene (**184**),[1146] or the 2,11-dithia[3.3]paracyclophane which forms an infinite network,[1147] or with a dithia ligand which form the polymeric compound (**185**).[1148] The arsathiane ligand *cyclo*-$(EtAsS)_n$ reacts with silver triflate to form $[Ag\{$*cyclo*-$(EtAsS)_2]OTf$, in which the silver atom is sandwiched between two crown-shaped ligands having their S-atoms directed towards the metal.[1149] 1,4-Thioxane gives two types of polymeric complexes with silver triflate.[1150] The structure of $[Ag_2(htcod)(pic)](picH)$ (htcod = 1,4,7,10,13,16-hexathiacycloctane; pic = picrate) has been reported.[1151]



(183)



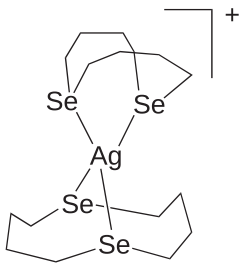
(184)



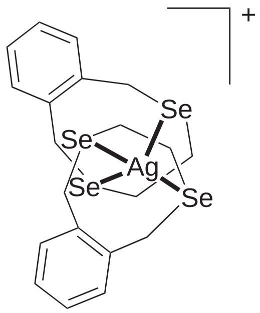
(185)

Silver(I) complexes with macrocyclic selenoethers (**186**) and (**187**) are not well represented and have been prepared with the ligands $[8]aneSe_2$ and 3*H*-1,4,5,7-tetrahydro-2,6-dibenzodiselenonine, respectively.[1152] Another example is the reaction of 1,3-dihydrobenzo[c]tellurophene with $AgBF_4$ which yields the complex $[AgL_4]BF_4$, where the ligand coordinates through the tellurium atom.[1153] The thermodynamic parameters and relative cations selectivity for complexation of some cations with 1,5,14,18-tetraselena-8,11,21,24-tetraoxacyclohexacosane have been studied, showing high Ag^+ selectivity.[1154] The reaction of $AgAsF_6$ with $(CH_2Se)_3$ in liquid SO_2 at $-196\,^\circ C$ gives the compound $[Ag\{(SeCH_2)_3\}_2]AsF_6$ (**188**).[1155]

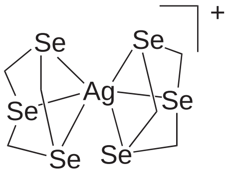
Coordination studies of acyclic thioether ligands to silver(I) centers has also been studied. Poly(alkylthio)aromatic systems have been used to form supramolecular silver(I) compounds. With the ligand 2,3,5,6-tetrakis(isopropylthio)benzoquinone the compound has a linear chain structure in which silver(I) has a tetrahedral coordination.[1156] A similar structure has the compound with the hexakis(methylthio)benzene,[1157] but with the hexakis(tolylthio)benzene the silver



(186)

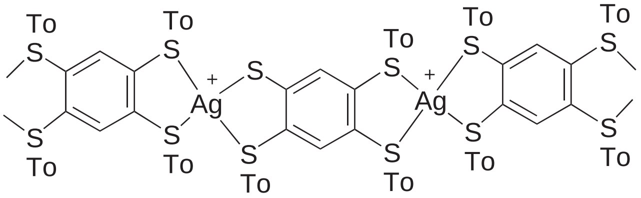


(187)

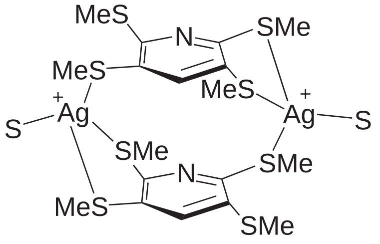


(188)

prefers a square planar coordination geometry and a zig-zag polymer structure (**189**).[1158] With the ligand 2,3,4,5-tetrakis(methylthiol)pyridine the compounds $[Ag_3L_4]$ $(ClO_4)_3$ (**190**) and $[Ag_2L_2](C_2F_5CO_2)_2$ have been prepared and they show 2D structures. In (**190**) the ligands are positioned face to face by the two Ag atoms and form a box structure; the π–π stacking between pyridine rings gives the 2D framework.[1159]



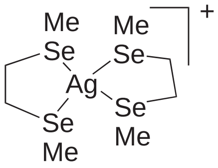
(189)



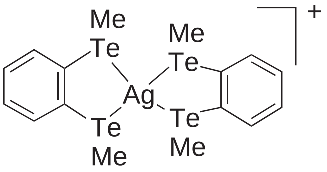
(190)

The silver(I) complexes with the tetrakis(methylthio)tetrathiafulvalene ligand have been reported, the nitrate salt presents a 3D structure with an unprecedented 4.16-net porous inorganic layer of silver nitrate,[1160] the triflate salt presents a two interwoven polymeric chain structure.[1161] The latter behaves as a semiconductor when doped with iodine. With a similar ligand, 2,5-bis-(5′,5′-bis(methylthio)-1′,3′-dithiol-2′-ylidene)-1,3,4,6-tetrathiapentalene, a 3D supramolecular network is constructed via coordination bonds and S···S contacts. The iodine-doped compound is highly conductive.[1162] (Methylthio)methyl-substituted calix[4]arenes have been used as silver-selective chemically modified field effect transistors and as potential extractants for Ag^I.[1163,1164]

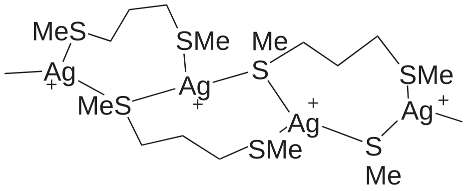
The coordination chemistry of a series of bidentate ligands, $RE(CH_2)_nER$ and o-$C_6H_4(ER)_2$ (E = S, Se; $n = 1$–3; E = Te; $n = 1$ or 3) with silver(I) has been studied and has shown that subtle ligand variations can have a dramatic influence upon the structures of the compounds produced, generating simple mononuclear bis(chelate) species, as $[Ag\{MeSe(CH_2)_2SeMe\}_2]^+$ (**191**) or $[Ag\{o\text{-}C_6H_4(TeMe)_2\}_2]^+$ (**192**), linear chain polymers, as $[Ag_n\{MeS(CH_2)_3SMe\}_n]^{n+}$ (**193**) or 3D networks, as $[Ag_n\{PhSe(CH_2)_3SePh\}_n]^{n+}$.[1165–1167] These complexes have been examined by ^{77}Se, ^{125}Te, and ^{109}Ag NMR spectroscopies and showed no ^{77}Se–^{109}Ag or ^{125}Te–^{109}Ag coupling, indicating labile behavior of those ligands in solution.[1168] Related work of the coordination of $MeTe(CH_2)_3TeMe$ has been reported and the compound is polymeric with each Ag atom coordinated by four different ligands which bridge the silver centers in a 2D network.[1169] With the tripod ligand $MeC(CH_2SeMe)_3$ by treatment with AgOTf the compound $[Ag\{MeC(CH_2SeMe)_3\}]OTf$ has been isolated; the structure is a polymeric chain with the silver atoms three-coordinated.[1170]



(191)



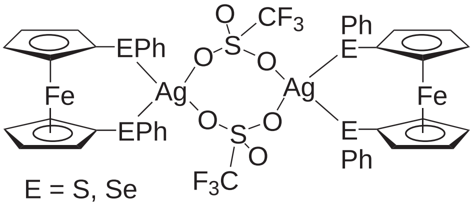
(192)



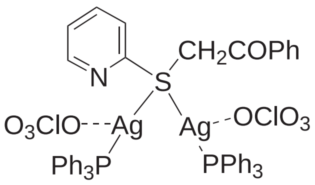
(193)

The reactions of 1,4-bis(phenylthio)butane with silver salts in varied conditions leads to the formation of four 2D coordination polymers with different network structures: $[Ag_2L_3(ClO_4)_2]_n$, $[Ag_2L_3(ClO_4)_2{\cdot}MeOH]_n$, $[AgL_2]_n(ClO_4)_n$, and $[AgL(NO_3)]_n$.[1171] With 1,3-bis(propylthio)butane the structure of the adduct $3AgNO_3{\cdot}2L$ has been described.[1172] 1,3-(Bis(phenylthio)methyl)benzene forms the complex $[AgL(NO_3)]_n$ which structure has linear polymeric chains of alternating trigonal silver(I) cations and bridging ligands bonded trough the sulfur atoms.[1173] The silver complex of the piperazin-2-one derivative with –SMe substituents was prepared and studied as a model of a nonheme metalloprotein, spectroscopic date indicate coordination to silver through the S-atoms.[1174] Ni-phthalocyanines with four and eight alkylthio functional groups form $[NiL][Ag(NO_3)]_4$ and $[NiL][Ag(NO_3)]_2$ complexes, respectively, which have been proposed to be polymeric.[1175,1176] Silver complexation to small molecule cyclotriphosphazenes and high polymeric poly(organophosphazenes) with methylthio groups such as $[NP(OCH_2CH_2SMe)_2]_n$, $[NP(OCH_2CH_2CH_2CH_2SMe)_2]_n$, $[NP(OCH_2CH_2CH\ (SMe)CH_2CH_2SMe)_2]_n$, or $[NP(OCH_2C_6H_4SMe)_2]_n$, have been studied.[1177] Stability constants have been measured for Ag^+ with diethylsulfide, ethy(2-chloroethyl)sulfide, and bis(2-chloroethyl)sulfide in acetone, DMSO, DMF, and methanol.[1178] The complexes $[Ag(NO_3)(SMe_2)]$ and $[Ag(SMe_2)_2]PF_6$ have been obtained.[1179] The relative effectiveness of Bu_2E (E = S, Se, Te) in the extraction of gold and silver has been studied by using atomic absorption spectrometry; for the extraction of silver(I) ions the selenium and tellurium derivatives prove to be better than the sulfur analogue.[1180] The crystal structures of the THT derivatives $[AgI(THT)]_4$,[1181] and $[Ag(THT)_2]BF_4$,[1182] have been reported.

Silver(I) complexes with 1,1′-bis(alkyl(aryl)thio)ferrocene or 1,1-bis(phenylseleno)ferrocene have been reported. They are mononuclear as $[Ag\{Fc(XR)_2\}_2]^+$ (X = S, R = Me, Pr^i, Ph; X = Se, R = Ph)[1183,1184] or dinuclear as $[Ag(OTf)\{Fc(XPh)_2\}]_2$ (**194**) (X = S, Se)[1183] complexes in contrast to those found with dithio- or diselenoether ligands. The compounds $[Ag_2(OClO_3)_2\{\mu\text{-}S(CH_2COPh)Py\}(PPh_3)_2]$ and $[Ag(OClO_3)\{S(CH_2COPh)Py\}(PPh_3)]$ (**195**) have been described.[1185]



(194)

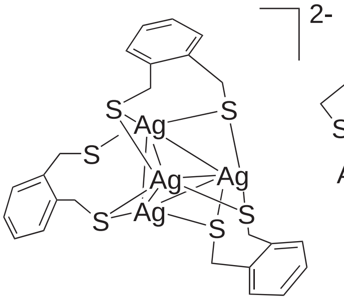


(195)

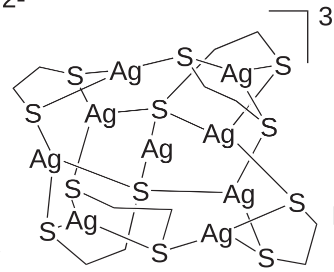
(iv) Silver(I) complexes with polydentate sulfur ligands

Homoleptic dithiolate silver(I) complexes are usually polynuclear species and several have been prepared, such as $[Ag_4(SCH_2C_6H_4CH_2S)_3]^{2-}$ (**196**),[1186] $[Ag_9(SCH_2CH_2S)_6]^{3-}$ (**197**),[1187] $[Ag_6(i\text{-}mnt)_6]^{6-}$ (**198**),[1188,1189] $[Ag_8(i\text{-}mnt)_6]^{4-}$,[1189] $[Ag_4(i\text{-}mnt)_4]^{4-}$,[1190] $[Ag_2(mnt)]$,[1191,1192] and $[Na([2.2.2]\text{-}cryptand]_4$ $[Ag_4(mnt)_4]$[1193] (i-mnt = $S_2C{=}C(CN)_2$; mnt = $S_2C_2(CN)_2$). The mixed silver–gold dithiolate compound $[Ag_4Au_2(SCH_2CH_2S)_4]^{2-}$ has also been reported.[1187] The electrochemical oxidation of silver in acetonitrile solutions of $R(SH)_2$ (R = 1,2-C_2H_4, 1,2-C_3H_6,1,3-C_3H_6, 1,4-C_4H_8, 2,3-C_4H_8, 1,5-C_5H_{10}, 1,6-C_6H_{12}) gives the insoluble homopolymeric Ag_2S_2R compounds in high yield.[1194] A silver–dmit polymer with a 3D supramolecular network, $[(Et_4N)_2\{Ag_4(dmit)_3\}{\cdot}DMF]_n$ (dmit = 1,3-dithiole-2-thione-4,5-dithiolate) has been described.[1195] A variety of spectroscopic methods have been used to deduce the solid-state structure of $[Ag_2\{S(CH_2)_5S\}]$; the data is consistent with a layered geometry similar to that adopted for neutral Ag thiolates with primary, unbranched alkane chains.[1196] Stability constants and enthalpies of formation for the $[AgL]^{2-}$ and $[AgL_2]^{5-}$ complexes, where $H_3L = HSCH_2CH(SH)CH_2SO_3H$, have been derived from potentiometric and calorimetric measurements.[1197]

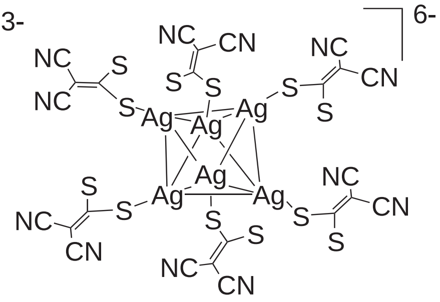
Dithiolate silver(I) compounds with phosphine as auxiliary ligands such as $[Ag(PPh_3)_2][Ag(mnt)(PPh_3)_2]$,[1198,1199] $[Ag_8(mnt)_6(PPh_3)_4]^{4-}$,[1200] $[Ag_9(mnt)_6(PPh_3)_6]^{3-}$,[1200] $[Ag_4(\mu_4\text{-}i\text{-}mnt)_2(\mu\text{-}dppm)]$ (**199**),[1201] $[Ag_5\{S_2CC(CN)P(O)(OEt)_2\}_2(dppm)_4]PF_6$, and $[Ag_4\{S_2CC(CN)P(O)(OEt)_2\}_2\text{-}(dppm)_4]$[1202] have been synthesized.



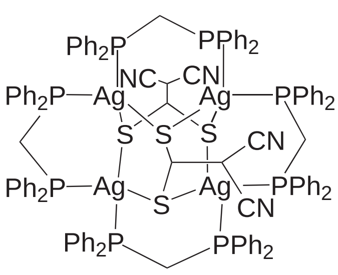
(196)



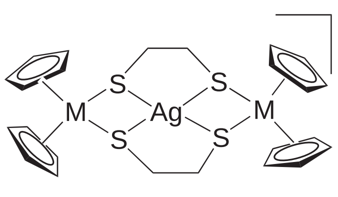
(197)



(198)

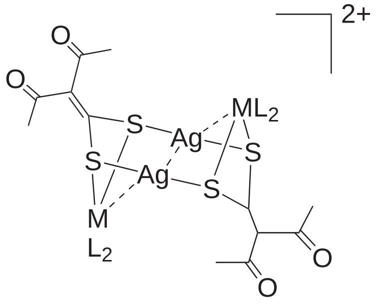


(199)



M = Ti, Zr

(200)

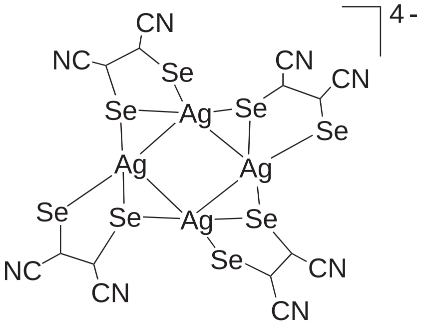


M = Pd, Pt; L_2 = COD, $2PPh_3$

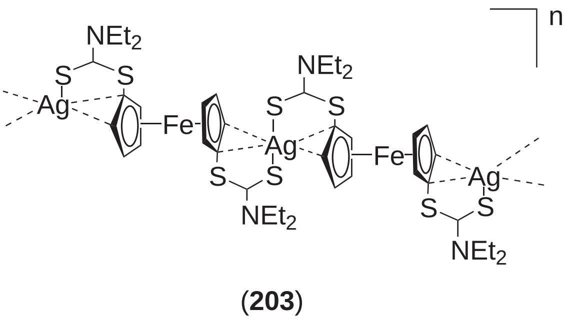
(201)

The zirconium or titanium dithiolate complexes $[Cp_2M\{\mu\text{-}S(CH_2)_nS\}_2MCp_2]$ (M = Zr, Ti) act as macrocyclic ligands and form 1:1 complexes with silver(I) ions as (**200**).[1203–1205] Maleonitriledithiolate complexes of Ni, Pd, and Pt of the type $[M(mnt)_2]^{2-}$react further with silver salts in the presence of phosphine or diphosphine ligands to give heterometallic complexes such as $[M(mnt)_2\{Ag(PR_3)\}_2]$ (M = Ni; $PR_3 = PMe_3$, PEt_3, PCy_3; M = Ni, Pd, Pt; $PR_3 = PPh_3$, $PBu^n{}_3$) or $[Ni(mnt)_2\{Ag(PP)\}]$ (PP = dppf, dppm).[1206,1207] The treatment of $[Pd(mnt)\{O_2S_2C_2(CN)_2\}_2]^{2-}$ with $AgClO_4$ results in the formation of $[AgPd(mnt)\{O_2S_2C_2(CN)_2\}]_2{}^{2-}$. The structure consists of a double decker with the silver atom bridging the Pd moieties trough the sulfur atoms.[1208] Similar reactions have been carried out with the complexes $[M\{S_2C{=}C\{C(O)Me\}_2\}L_2]$ (M = Pd, Pt; L_2 = COD, $(PPh_3)_2$), which react with $AgClO_4$ to yield $[MAg_2\{S_2C{=}C[C(O)Me]_2\}L_2](ClO_4)_2$ (**201**) or with $AgClO_4$ in the presence of PPh_3 to give $[MAg\{S_2C{=}C[C(O)Me]_2\}(PPh_3)_4]ClO_4$.[1209]

Maleonitrilediselonate (MNS) silver(I) complexes have been reported and are of the type $[Na([2.2.2]\text{-cryptand})_4[Ag_4(MNS)_4]$ (**202**),[1193] $[M([2.2.2]\text{-cryptand}]_3[Ag(MNS)_2]$[1193] (M = Na, K), or $[K([2.2.2]\text{-cryptand}]_3[Ag(MNS)(Se_6)]$.[1210,1211]



(202)

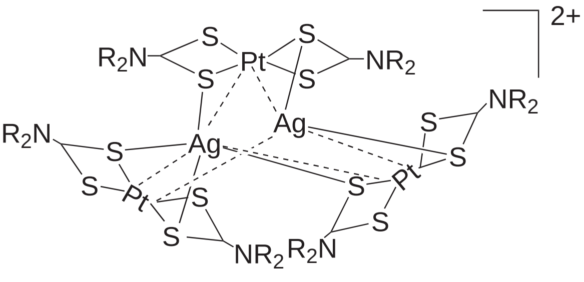


(203)

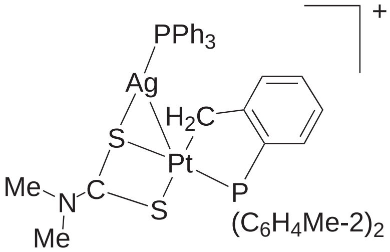
Dithiocarbamates have been used as ligands for a long time. Recently the structure of $[Ag(S_2CNEt_2)]_6$ has been reported and the compound is hexanuclear.[1212] Complexes of the type

$[Ag(S_2CNR_2)(PPh_3)_2]$ and $[Ag(S_2CNR_2)(dppe)]$ (R = Et, EtOH) have been synthesized.[1213] The ligand 1,1′-bis(diethyldithiocarbamate)ferrocene forms a polymeric silver(I) species $[Ag\{Fc(S_2CNEt_2)_2\}]_n(ClO_4)_n$, (**203**) in which the silver atom is bonded to two sulfur atoms of different ferrocene moieties and also to the cyclopentadyenil ring in a η^2 fashion.[1214]

Mixed metal–silver dithiocarbamate complexes have been reported. The platinum–silver derivatives $[Pt_3Ag_2(S_2CNR_2)_6]^{2+}$ (R = Et, Pr^i, Bu^n) have been obtained by reaction of $[Pt(S_2CNR_2)_2]$ with AgX (X = ClO_4, BF_4).[1215,1216] Crystallographic studies of the Pr^i and Bu^n species show that there are discrete cations that are held together by metal–metal bonding and long Ag—S interactions (**204**); the Et species are polymeric with unsupported Ag—Pt bonds. These cations have been observed by electrospray mass spectrometry.[1217] Other Pt—Ag dithiocarbamate derivatives have been prepared from $[M\{CH_2C_6H_4P(C_6H_4Me\text{-}2)_2\}(S_2CNMe_2)]$ by reaction with silver salts and are of the type $[M\{CH_2C_6H_4P(C_6H_4Me\text{-}2)_2\}(S_2CNMe_2)Ag\text{-}(PPh_3)]ClO_4$ (**205**) or $[M_2\{CH_2C_6H_4P(C_6H_4Me\text{-}2)_2\}_2(S_2CNMe_2)_2Ag\{Ag(OClO_3)\}]ClO_4$ (M = Pd, Pt).[1218] A mixed silver–gold dithiocarbamate complex $[Au_2Ag(S_2CNEt_2)_2\{\mu\text{-}(PPh_2)_2C{=}CH_2\}]ClO_4$ has been obtained.[1219]



(**204**)



(**205**)

The oxidation product of the dialkyldithiocarbamate, the tetraalkylthiuramdisulfide has also been used as ligand in silver(I) chemistry. The complexes $[Ag\{CH_2(S_2CNR_2)_2\}]OTf$ (R = Me, Et, Bz) have been obtained and probably are oligo- or polymeric species.[1220] Desulfonation–fluorination of thiuramdisulfides with AgF produces a simple route to diorgano(trifluoromethyl) amines, R_2NCF_3, thiocarbamoyl fluorides, $R_2NC(S)F$, and $Ag(S_2CNR_2)$.[1221] Tetramethylthiuram monosulfide(L) forms silver(I) complexes of the type AgX·L (X = Cl, Br, I);[1222] the crystal structure of $[Ag(ClO_4)L]$ has been determined.[1223]

Several dithiocarboxylate silver(I) complexes have been synthesized and characterized structurally such as $[Ag_2(S_2CPh)_2]$,[1224] $[Ag_4\{S_2CC_6H_3Me_3\text{-}2,4,6)\}_6]^{2-}$,[1224] $[Ag_4(S_2C\text{-}o\text{-}Tol)_4\ Py_4]$,[1225] $[Ag_4(S_3C\text{-}o\text{-}Tol)_4]$,[1226] $[Ag_4(S_2C\text{-}p\text{-}Tol)_4]_n$ (**206**),[1227] $[Ag(S_2COEt)(PPh_3)_2]$,[1228] and $[Ag(S_2C\text{-}p\text{-}Tol)(PPh_3)]_2$ (**207**).[1229] The reaction of $[AgCl(PPh_3)]_4$ with C_5Me_5Li and an excess of CS_2 gives the compound $[Ag(S_2CC_5Me_5)(PPh_3)_2]$.[1230] Insertion of CS_2 in a Ag—S(thiolate) bond also gives the dithiocarboxylate compound $[Ag(S_2CSBu^t)(PPh_3)_2]$.[1231] Related ligands are phosphoniodithiocarboxylates such as S_2CPEt_3 which forms the silver(I) complex $[\{Ag(S_2CPEt_3)_2\}_2](ClO_4)_2$ (**208**),[1232] or with the dithiooxalate ligand the compound $[Ag(S_2C_2O_2Me)(PPh_3)_2]$ is described.[1233]

Monothiocarboxylate silver(I) derivatives have been also described and the homoleptic are of the type $Ph_4P[Ag\{SC(O)Me\}_2]$ and $Et_3NH[Ag\{SC(O)Ph\}_2]$; the latter has a dimeric structure in the solid state (**209**).[1234] Adducts with phosphine or diphosphine ligands have been prepared such as $[Ag_4(PPh_3)_4\{SC(O)Me\}_4]$ (**210**) or $[Ag_3\{\mu\text{-}SC(O)R\}_2(\mu\text{-}dppm)_3]X$ (X = ClO_4, NO_3; R = Me, Ph), respectively.[1235,1236]

Dialkyldithiophosphinates $Ag(S_2PR_2)$ were reported to be polymeric in 1968.[1237] Complex formation between silver(I) and $R_2PS_2^-$ (R = Et, Pr^n, Ph) has been studied by potentiometric methods and the stabilities of the complexes determined.[1238] However, the crystal structure of the diisopropyldithiophosphinate silver compound $[Ag\{S_2P(OPr^i)_2\}]_6$ (**211**) shows it as a hexanuclear derivative.[1239] With these type of ligands compounds of the type $[Ag\{S_2P(OEt)_2\}(PPh_3)]_2$ (**212**) and $(Me_4N)_2[Ag\{S_2P(OEt)_2\}_2]_2$ have been described.[1240,1241] A similar hexanuclear compound has been obtained with diselenophosphinate ligands, $[Ag\{Se_2P(OPr^i)_2\}]_6$ whereas with $(OEt)_2PSe_2^-$ the polymeric species $[Ag\{Se_2P(OEt)_2\}]_n$ is obtained. The clusters $[Ag_{10}(\mu_{10}\text{-}Se)\{Se_2P(OR)_2\}_8]$ (R = Et, Pr^i) have also been obtained; the structure consists of a decasilver cluster with an encapsulated selenium atom in a distorted *cis*-bicapped trapezoidal-prismatic geometry, surrounded by eight ligands having three different coordination modes.[1242]

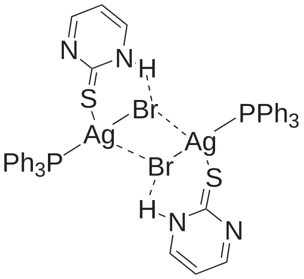
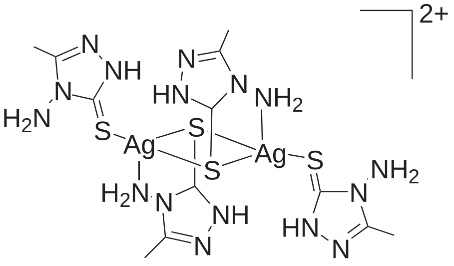
(v) Silver(I) complexes with other sulfur donor ligands

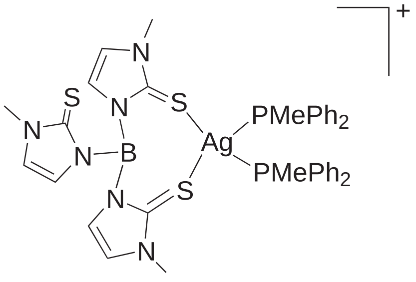
Silver(I) complexes with heterocyclic thiones are well represented. Many of them possess phosphines as auxiliary ligands and are of the type $[AgX(PPh_3)_2L]$ (X = Cl, Br), $[Ag(PPh_3)_2L]NO_3$, or $[AgBr(PPh_3)L]_2$ (**213**) (L = pyridine-2-thione, pyrimidine-2-thione, benz-1,3-imidazoline-2-thione, 1-methyl-1,3-imidazoline-2-thione, 5-methoxyl-benz-1,3-imidazoline-2-thione).[1243–1246] Homoleptic compounds of the type $[Ag(HL)_2]NO_3$ (HL = 4-amino-1,2-4-Δ^2-triazoline-5-thione, 4-amino-3-ethyl-1,2,4-Δ^2-triazoline-5-thione) have been reported; the structure consists of dimeric (**214**) and polymeric species due to the versatile coordination ability of the ligand.[1247] Similar polymeric complexes are formed with pyridine-2-thione (HPyS), $[\{Ag(HPyS)_2\}_2X_2]_n$ (X = BF_4, ClO_4), or $[\{Ag_4(HPyS)_6\}(NO_3)_4]$.[1248] 1-Azacycloheptane-2-thione reacts with $AgNO_3$ to give the complex $[Ag_4(C_6H_{11}NS)_8](NO_3)_4$.[1249] The ligand 4-amino-6-methyl-1,2,4-triazine-thione-5-one gives the silver complexes $[AgL_2]NO_3$ and $[AgL(PPh_3)]NO_3$.[1250] The reaction of Hmimt with $AgNO_3$ has been studied and the species $[Ag(Hmimt)]NO_3$, $[Ag(Hmimt)_2]NO_3$, and $[Ag(Hmimt)_3]NO_3$ have been synthesized.[1251] The borate derivative $HB(mimt)_3$ reacts with $AgNO_3$ in the presence of mono- or bidentate phosphine ligands to give complexes such as $[Ag\{HB(mimt)_3\}(PR_3)_n]$ ($n = 1$, P(m-tolyl)$_3$; $n = 2$, $PMePh_2$ (**215**)) or $[Ag\{HB(mimt)_3\}(PP)]$ (PP = dppf, dppe, $Ph_2P(CH_2)_3PPh_2$, $Ph_2P(CH_2)_4PPh_2$).[1252] The reactions of $AgNO_3$ with imidazoline-2-thione, 1,3-diazinane-2-thione, and their derivatives lead to the complexes of general formula $[Ag(NO_3)L]$.[1253]



(**213**)



(**214**)



(**215**)

Supramolecular compounds are formed by treatment of silver salts and the ligand 4,5-ethylenedithio-1,3-dithiole-2-thione ($C_5H_4S_5$), such as the polymeric chain $[\{Ag(C_5H_4S_5)_3\}\cdot ClO_4\cdot MeCN]_2$ or the 2D $[Ag(C_5H_4S_5)OTf]_n$. All are assembled by S···S contacts.[1254]

The crystal structures of the complexes $[Ag(C_{12}H_{17}N_2S)_2]NO_3$,[1255] $[Ag(C_5H_6S_5)_3]PF_6$ ($C_5H_6S_5$ = 4,5-di(methylthio)-1,3-dithia-2-thione-4-cyclopentene),[1256] $[Ag(C_6H_7NS)_4]BF_4$ (C_6H_7NS = 1-methyl-2(1H)-pyridinethione),[1257] $[Ag(C_7N_2S_2)_2]Br$,[1258] and [AgBr(mbi)] (mbi = methyl-2-thiobenzimidazole) have been reported.[1259]

Phosphines or diphosphines can be oxidized with elemental sulfur or selenium and the resulting ligands have been used to coordinate silver(I) centers. The tris(diphenylthiophosphoryl)methanide ligand $(SPPh_2)_3C^-$ gives the silver compounds $[Ag\{(SPPh_2)_3C\}(PR_3)]$ (**216**) ($PR_3 = PBu^n{}_3$, PPh_3).[1260,1261] 1,1′-Bis(diphenylthiophosphoryl)ferrocene (dptpf) and 1,1′-bis(diphenylselenophosphoryl)ferrocene (dpspf) form the mononuclear complexes $[Ag(dptpf)]^+$ or $[Ag(dpspf)]^+$ with *trans*-chelating ligands (**217**).[1262–1265] For the sulfur derivative other linear, three- or four-coordinate silver compounds of the type $[Ag_2(\mu\text{-dptpf})(PPh_3)_2](ClO_4)_2$, $[Ag(dptpf)(PPh_3)]ClO_4$, and $[Ag(dptpf)_2]ClO_4$, or the polymeric chain $[Ag_2(\mu\text{-dptpf})\{(SPPh_2)_2CH_2\}_2]_n$ have been obtained.[1264]

With the selenium derivative complexes of the type [Ag(dpspf)(LL)]OTf (LL = $(SPPh_2)CH_2$, $(SePPh_2)_2CH_2$, bipy, phen) have been reported.[1265] Other silver complexes with chalcogenide derivatives are those formed with the mixed ligands $EPPh_2(CH_2)_2SRS(CH_2)_2PPh_2E$ (E = S, Se; R = $(CH_2)_2$, $(CH_2)_3$, C_6H_4) that are of the type $[AgL]^+$, as, for example, (**218**).[1266] The reaction of $AgAsF_6$ with $(SPMe_2)O$ gives $[Ag\{(SPMe_2)O\}_2]PF_6$, which has a tetrahedral geometry.[1267] The silver(I) derivative with the dithioimidodifosfinato ligand $[Ag\{(SPPh_2)_2N\}(PPh_3)]$ has been described.[1268] A silver complex with the bis(diphenylselenofosforyl)amine, $[Ag\{(SePPh_2)_2NH\}_2]Br$, has been described.[1269] The ligand $\{SP(2,4,6\text{-}Bu^t{}_3C_6H_2)\}_2(\mu\text{-}CH_2)(\mu\text{-}S)$ forms 1:1 complexes with Ag^+, extracting it from aqueous solutions selectively over Pd^{2+}, Cu^{2+}, Ni^{2+}, Fe^{3+}, and $UO_2{}^{2+}$; it is proposed that bind silver using the P=S atoms.[1270] The treatment of $(SPPh_2)_2C{=}CH_2$ with $AgClO_4$ yields the mono- and dinuclear complexes $[Ag_2\{\mu\text{-}(SPPh_2)_2C{=}CH_2\}_2](ClO_4)_2$ and $[Ag\{(SPPh_2)_2C{=}CH_2\}_2]ClO_4$, respectively.[1271]

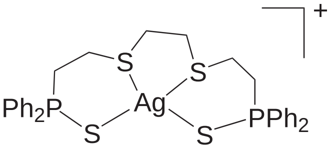
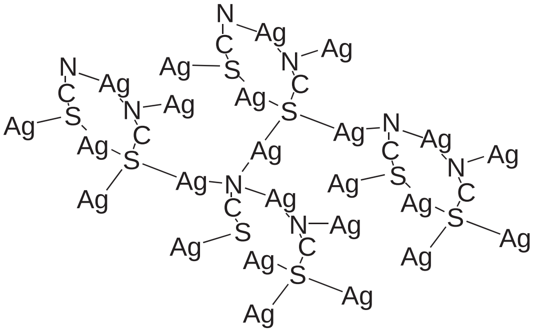
(217)

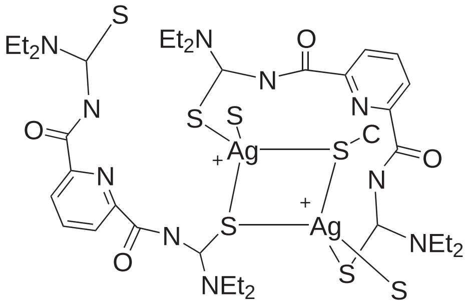


(218)

The coordination modes of the ambident thiocyanate ligand in their metal complexes exhibit a considerable diversity. The double salts $AgSCN{\cdot}2AgNO_3$ (**219**) and $AgSCN{\cdot}AgClO_4$ feature an unprecedented μ_5-1,2,3κS:4,5κN coordination mode of the thiocyanate ligand, which generates a 2D or 3D network.[1272] Similar results are obtained with the AgSeCN.[1273]



(219)

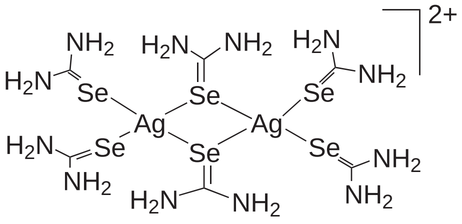


(220)

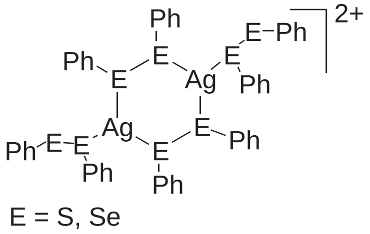
Several crystal structures with thiocyanate as ligands have been reported, such as $[Ag(SCN)(Ettu)]_2$ (Ettu = ethylthiourea),[1274] $[Ag(SCN)(2,6\text{-}Me_2Py)]$,[616] β-AgSCN,[1275] $[\{Ag_2(SCN)_4\}C_{18}H_{36}N_4]$ ($C_{18}H_{36}N_4$ = 5,7,7,12,14,14-hexamethyl-1,4,8,11-tetrazatricyclo[9.3.1.1]hexadecane),[1276] $Cs_3M[Ag_2(SCN)_7]$ (M = Ba, Sr),[1277] $Cs_2[AgZn(SCN)_5]$,[1278] $CaCs_2[Ag_2(SCN)_6]$,[1279] $[Cd(en)_{1.5}Ag(SCN)_3]$,[1280] and $Q_4[Ag_2Fe_2(SCN)_{12}]$ (Q = NBu_4, NEt_4).[1281] The coordination of silver(I) by thiocyanate, cyanide, and iodide in molten KSCN, KSCN-KCN, and KSCN-KI mixtures have been described.[1282]

Silver(I) complexes with tu, selenourea, or some of their derivatives have been reported. The formation of Ag^+ complexes with tus and *N*-substituted tus has been studied in EtOH, and the determined thermodynamic parameters for AgL^+, AgL^{2+}, and AgL^{3+} were compared to those of methanol.[1283] An *N,N'*-disubstituted tu has been proposed as a spectrophotometric reagent for Ag^+ determination.[1284] Complexes of the type $[AgXL(PPh_3)_2]$ (X = Cl, Br; L = tus, aminothiourea, dithiooxamide) have been synthesized.[1285] The synthesis and crystal structures of a family of silver cyanide complexes of thioureas (tus) and substituted tus are reported, they are of the type (AgCN)(tu), $(AgCN)(tu)_2$, $(AgCN)_2(Ettu)_2$, etc. All the structures involve either 1D or 2D polymeric arrays held together by bridging S and CN groups.[1286] An helical polymeric chain, $[Ag_2(tepytu)_3{\cdot}(ClO_4)_2]_n$ (**220**) (tepytu = *N,N',N'',N'''*-tetraethyl-*N,N'*-pyridine-2,6-dicarbonyl-bis (tus)), has been obtained.[1287]

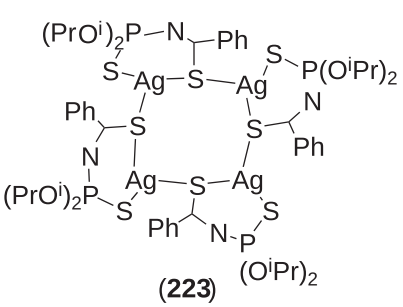
Selenourea silver(I) derivatives such as $[Ag_2\{\mu\text{-}SeC(NH_2)_2\}_2\{SeC(NH_2)_2\}_4]Cl_2$ (**221**),[1288] $[Ag(NO_3)\{SeC(NH_2)_2\}]$, and $[Ag(NO_3)\{SeC(NH_2)_2\}_2]$ have been prepared.[1289] The crystal structures of $[AgI(Et_2tu)]$,[1290] $[Ag(Me_2tu)_n]ClO_4$ ($n = 2, 3$),[1291] $[Ag(Et_2btu)]_4$ (Et_2btu = 1,1-diethyl,3-benzoyl-tu),[1292] $[Ag(SH)(Et_2btu)]$,[1293] have been determined.



(**221**)



(**222**)



(**223**)

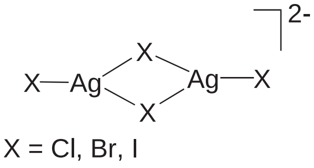
Diphenyldisulfide or diphenyldiselenide react with $AgAsF_6$ in liquid SO_2 to give $[Ag_2(Ph_2E_2)_4](AsF_6)_2$ (E = S, Se) (**222**).[1294] A dimeric compound has been prepared with the ditelluride, $[Ag_2\{Te_2(p\text{-}F\text{-}C_6H_4)\}_2]$.[1169]

Some complexes with thiosemicarbazide $SC(NH_2)NHNH_2$ (tsc) have been prepared, such as $[AgI(tsc)_2]_2$,[1295] $[Ag_2Br_2(tsc)_3]$,[1295] $\beta\text{-}Ag(Et_2tsc)$,[1296] $[AgL_2]^+$ (L = 2-methylindole-3-carboxyaldehide thiosemicarbazone).[1297]

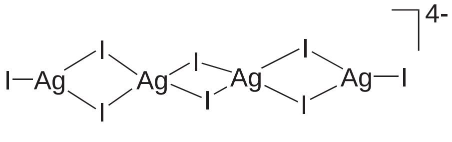
Other silver compounds with sulfur donor ligands such as fosforiltioamides, $[Ag_4\{SC(Ph)NP(OPr^i)_2S\}_4]$ (**223**),[1298] *N*-(thio)phosphorylated bis(thio)ureas,[1299,1300] (*N*,*N*-diethylthiocarbamoylmethyl)diphenylphosphine sulfide $[Ag\{Ph_2P(S)CH_2C(S)NEt_2\}_2]NO_3$,[1301] or *N*,*N*′-dimethylthioformamide $[Ag(SCHNMe_2)_3]_2^{2+}$,[1302] have been reported. Stability constants for member of series of silver(I) complexes incorporating DMSO, tus, and thiocyanate ligands have been measured.[1303]

6.7.2.3.6 *Complexes with halide and hydride donor ligands*

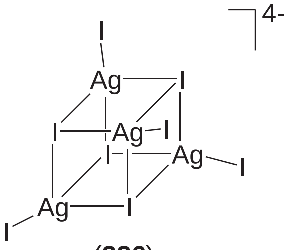
Homoleptic silver(I) halide complexes have been known for a long time, they have various stoichiometries and coordination numbers. $[AgX_2]^-$ compounds have been reported in complexes such as $[K(crypt\text{-}2,2,2)][AgCl_2]$,[1304] $Me_4N[AgI_2]$,[1305] and $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)][AgCl_2]$,[1306] which depending upon the cation are polymeric species or discrete molecules. $[AgX_3]^{2-}$ have been described in $(PPh_3Me)_2[AgI_3]$[1307,1308] and $(NH_4)_2[AgI_3]$,[1309] which have a trigonal-planar geometry. $[Ag_2X_3]^-$ (X = Br, I) are polymeric species.[1309] $[Ag_2X_4]^{2-}$ (**224**) (X = Cl, Br, I) are dinuclear with a distorted trigonal planar geometry for silver.[1304,1310–1313] The mixed halide species $(AsPh_3Me)[Ag_3I_3X]$ (X = Cl, Br, I) have been synthesized and the silver is four-coordinate.[1314] Other silver polyhalide anions are $[Ag_2Cl_5]^{3-}$,[1311] $[Ag_4Br_8]^{4-}$,[1304] and $[Ag_4I_8]^{4-}$,[1311,1315] which has two different structures (**225**) or (**226**), $[Ag_4I_5]^-$,[1316] $[Ag_3I_5]^{2-}$,[1317] and $[Ag_7I_{11}]^{4-}$ which has a 1D, twisted double chain,[1318] or the polymeric species $[Ag_5I_6]^-$,[1319,1320] $[Ag_5I_7]^{2-}$,[1321] and $[Ag_5Br_8]^{3-}$.[1322] The structure of Rb_2AgCl_3 consists of polymeric $[AgCl_3]^{2-}$ anions composed of corner-sharing slightly distorted $AgCl_4$ tetrahedra, with Rb^+ ions situated between the chains.[1323] An applied theoretical study has been performed on the conformations of polymetal iodide complexes $[Ag_mI]_{m-1}$; they have an overall tendency to prefer bent conformations with short metal–metal separations.[1324] Electrochemical studies of silver chloro complex formation in low-temperature chloroaluminate melts have been carried out.[1325] The electronic structure of silver chloride has been probed by use of *ab initio* Hartree–Fock methods. The results support the fact that the bonding in AgCl is strongly (but not exclusively) ionic in nature, and also confirm the importance of correlation effects.[1326] Photoluminescence has been found in mixed AgCl—AgBr crystals of stoichiometry $AgCl_{0.45}Br_{0.55}$.[1327]



(224)

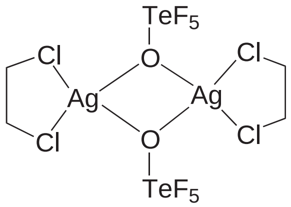


(225)

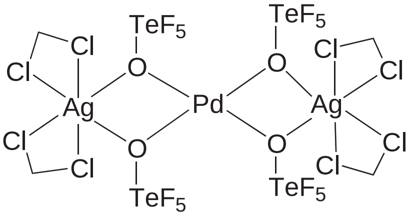


(226)

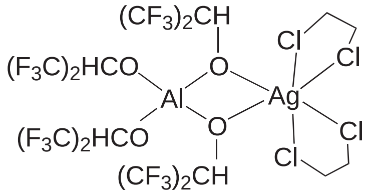
Halocarbons are poor Brönsted bases. Their donor powers as Lewis bases to metal ions are usually regarded as weak. Recently several silver(I) and other metal complexes with halocarbons, even with those as CH_2Cl_2 which is considered as noncoordinating ligand in Gutmann's classic study of solvent donor numbers, have been described.[1328,1329] The compound $AgOTeF_5$ is extraordinarily soluble in dichloromethane and 1,2-dichloroethane, the $OTeF_5^-$ oxyanion renders metal ions in MX_m compounds very electron poor and open to coordination by extremely weak donors.[932] Thus from saturated chlorocarbon solutions of $AgOTeF_5$ or in the presence of $PdCl_2$ the complexes $[Ag(OTeF_5)(CH_2Cl_2)]_2$ $[Ag(OTeF_5)(1,2\text{-}C_2H_4Cl_2)]_2$ (**227**), $[Ag_2(CH_2Cl_2)_4Pd(OTeF_5)_4]$ (**228**), and $[Ag_2(1,2\text{-}C_2H_4Cl_2)_4Pd(OTeF_5)_4]$, have been isolated.[27,28,1330] With larger and more weakly coordinating anions as $Ti(OTeF_5)_6^{2-}$, $Nb(OTeF_5)_6^-$, or $Sb(OTeF_5)_6^-$ other complexes have been obtained, such as $[Ag(CH_2Cl_2)_3]_2[Ti(OTeF_5)_6]$, $[Ag(CH_2Br_2)_3][Nb(OTeF_5)_6]$, and $[Ag(1,2\text{-}C_2H_4Br_2)_3][Sb(OTeF_6)_6]$.[1331,1332] The silver salts with the weakly coordinating anions polyfluoroalkoxyaluminates $AgAl(OR_F)_4$ also form complexes with the weakly basic solvents CH_2Cl_2 or $1,2\text{-}C_2H_4Cl_2$, of the type $[Ag(C_2H_4Cl_2)_2Al\{OCH(CF_3)_2\}_4]$ (**229**), $[Ag(CH_2Cl_2)Al\{OC(Me)(CF_3)_2\}_4]$, $[Ag(CH_2Cl_2)Al\{OC(CF_3)_3\}_4]$, and $[Ag(C_2H_4Cl_2)Al\{OC(CF_3)_3\}]$.[1333]



(227)

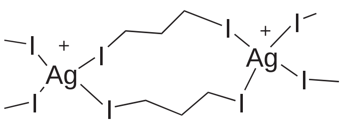


(228)

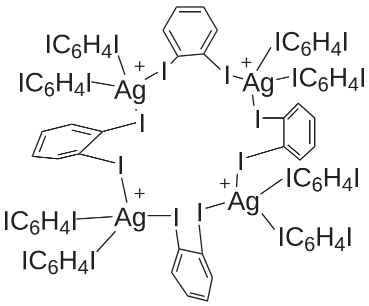


(229)

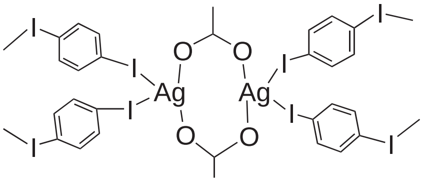
Compounds containing iodocarbon–silver(I) bonds have long been suspected as intermediates in the reactions of the alkyl iodides with the silver salts, but only recently complexes have been isolated. The reaction of $AgPF_6$ or $AgNO_3$ with diiodomethane, 1,3-diiodopropane, and aryliodides has been studied and four-coordinate complexes such as $[Ag\{I(CH_2)_3I]\}_2]PF_6$ (**230**), $[Ag(ICH_2I)_2]PF_6$, $[Ag(1,2\text{-}I_2C_6H_4)_3]PF_6$ (**231**), and $[Ag(1,2\text{-}BrIC_6H_4)_4]PF_6$ prepared.[1334,1335] These reactions have been carried out in organic media using ethylene to help solubilize silver salts but they have also been carried out in aqueous solutions, where adducts of the type $AgNO_3 \cdot C_nH_xI_y$ are obtained; if the silver concentration is high, the inverse compounds $[Ag_3I]NO_3$ are also synthesized.[1336] Silver(I) iodide complexes with carboxylate ligands have been reported, such as $[Ag_2(O_2CCF_3)_2(RI_2)_2]_n$ ($R = CH_2$, C_6H_4 (**232**)), $[Ag_2(O_2CCF_3)(IC_6H_5)]_n$, $[Ag_4(O_2CCF_3)_4(H_2O)_2(p\text{-}IC_6H_4Me)_2]_n$, $[Ag_2(O_2CCCl_3)_2(HO_2CCl_3)_2(1,2\text{-}I_2C_6H_4)]_n$, $[Ag_2(O_2CCl_3)_2(HO_2CCl_3)(IC_6H_5)]_n$, or $[Ag_4(hfac)_4(p\text{-}IC_6H_4Me)_2]$.[1337,1338] Most of them are polymeric species with dinuclear silver carboxylate units bridged iodocarbon ligands.



(230)



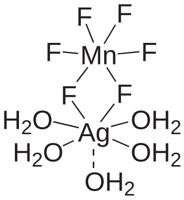
(231)



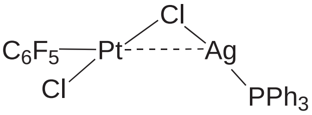
(232)

The reaction of $AgClO_4$ with tetraidoethylene in benzene or toluene yields the complexes $[Ag(ClO_4)(C_2I_4)(C_6H_6)_2]$ or $[Ag(ClO_4)(C_2I_4)]$, the latter has a 2D framework and in both, the iodocarbon coordinates via σ-donation of a halogen lone pair.[1339] Silver polymers with iodine–silver interactions are also obtained in the reaction of silver acetate with triiodobenzoic acid, tris(4-iodophenyl)amine, and 5,7-diiodo-8-hydroxyquinoline.[1340]

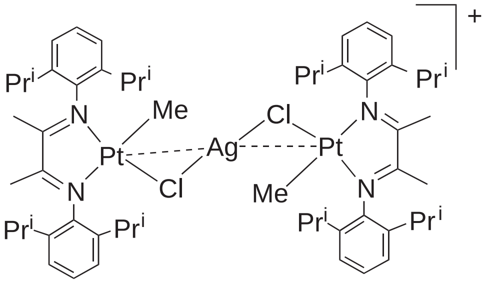
Other silver–halogen complexes are the heterometallic species. An unusual seven-coordination has been observed in the structure of $AgMnF_4 \cdot 4H_2O$ (**233**).[1341] The reaction of *trans*-$[PtX_2(C_6F_5)L]^-$ and Ag^+ affords polymeric $[PtAgX_2(C_6F_5)L]_n$ ($X = Cl$, $L = PPh_3$, THT, *p*-$MeC_6H_4NH_2$, Py; $X = Br$, $L = PPh_3$). The structure consists of a polymeric chain with the silver atoms bridging between chlorine ligands and with a short distance Ag—Pt of 2.855(2) Å. Addition of PPh_3 breaks the Ag—Cl bonds of the chain and forms the dinuclear $[PtAg(C_6F_5)Cl(\mu\text{-}Cl)(PPh_3)_2]$, containing a longer Pt—Ag distance of 2.945(1) Å (**234**).[1342] The reaction of $[Ag(ClO_4)(PPh_3)]$ with *trans*-$[PtBr_2(C_6Cl_5)(PPh_3)]^-$ yields the dimeric complex $[(Ph_3P)(C_6Cl_5)BrPt(\mu\text{-}Br)Ag(PPh_3)]_2$, in which the Pt···Ag interaction is supported by a bromine bridging ligand.[1343] Halogen-bridging silver–palladium derivatives, such as [(tmda)(*p*-tolyl)Pd(μ-I)AgL] (tmda = *N*,*N*,*N*′,*N*′-tetramethylenediamine; $L = [CpCo\{P(OR)_2O\}_3]^-$; R = Me, Pr^i) have been described.[1344] Halide abstraction by silver salts is a widely used reaction but sometimes the intermediate species have been isolated, as in the reaction of [PtClMe(N—N)] with $AgBF_4$ which gives the compound $[Me(N—N)Pt(\mu\text{-}Cl)Ag(\mu\text{-}Cl)Pt(N—N)Me]BF_4$ (**235**),[1345] or in the reaction of *trans*-$[RuCl_2(PP)_2]$ with silver salts which gives mixtures of Ru—Cl—Ag complexes.[1346]



(233)

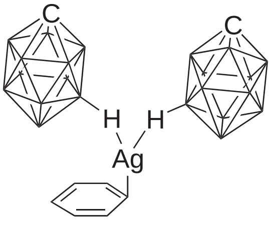


(234)

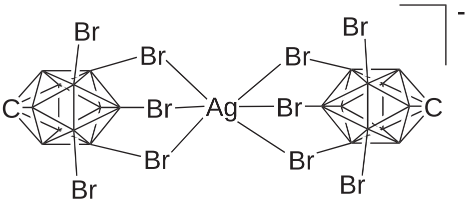


(235)

Monoanionic carborane anions based around $[closo\text{-}1\text{-}CB_{11}H_{12}]^-$ are among the most inert and least coordinating anions currently known. The high chemical stability and low nucleophilicity allows the stabilization of cationic species not isolable with other anions. The silver salt of this compound was crystallized as $Ag(CB_{11}H_{12}) \cdot 2C_6H_6$ (**236**), in which the silver is bonded to two carborane groups via terminal B—H bonds and to one molecule of benzene in a η^1 fashion.[1347] Other silver salts of some of these derivatives such as Ag(7,8,9,10,11,12-$Br_6CB_{11}H_5$) or Ag(7,8,9,10,11,12-$Br_6CB_{11}H_5)_2^-$ (**237**),[1348–1350] Ag(6,7,8,9,10-$Br_5CB_9H_5$) (η^2-C_7H_8),[1350] Ag[Co(1,2-$C_2B_9H_{11})_2$], or Ag[Co(8,9,12-Br_3-1,2-$C_2B_{10}H_{11}$)],[1350] Ag(12-$BrB_{11}H_{11}$),[1351] Ag(12-$FCB_{11}H_{11}$)$(C_6H_6)_2$,[1352] Ag(6,8-$F_2CB_9H_8$) $(C_6H_6)_2$,[1353] Ag($CB_{11}H_6X_6$) ($X = Cl$, Br, I),[1354] Ag (1-Me-$CB_{11}H_5X_6$) ($X = H$, Cl, Br, I),[1355] Ag(1-H-$CB_{11}Y_5X_6$) ($X,Y = Cl$, Br, I),[1356] have been described.

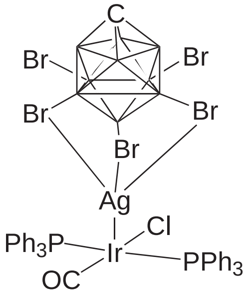


(**236**)

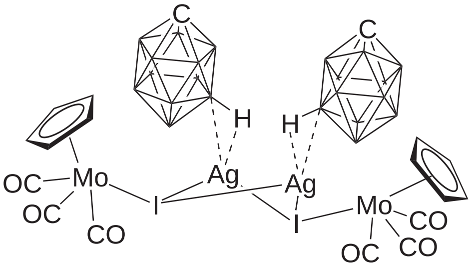


(**237**)

Halide abstraction reactions with these carborane derivatives gives sometimes intermediate products rather than metathesis, as in the reaction of Ag(6,7,8,9,10-$Br_5CB_9H_5$)(η^2-C_7H_8) with [IrCl(CO)(PPh_3)] that yields an Ir—Ag adduct (**238**),[1350] or the reaction of [MoCpI(CO)$_3$] with Ag($CB_{11}H_{12}$) which gives (**239**).[1357,1358]

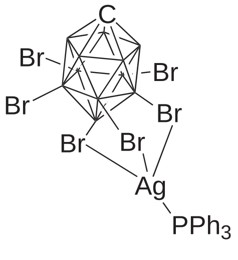


(**238**)

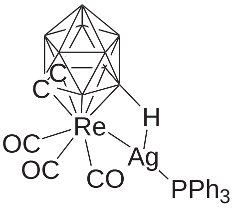


(**239**)

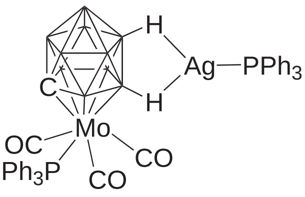
Silver phosphine or stibine complexes with carborane anions have also been isolated and are of the type [Ag($C_2B_8H_{11}$)(PPh_3)]$_2$,[1359] [Ag($CB_{11}H_{12}$)(PPh_3)] (**240**),[1360] [Ag($CB_{11}H_{12}$)$(PPh_3)_2$]$_2$,[1360] [Ag($CB_{11}H_6Br_6$)$(PPh_3)_n$] ($n = 1, 2$),[1360] or [9,9′-{Ag$(SbPh_3)_2$}$_2$-4,9,4′,9′-(μ-H)$_4$-7,8,7′,8′-*nido*-$(C_2B_9H_{10})_2$].[1361] The reaction of Cs[Re(CO)$_3$(η^5-7,8-$C_2B_9H_{11}$)] with $AgBF_4$ in the presence of ligands such as PPh_3, dppe, tris(pyrazol-1-yl)methanes, amines, di-, and terpyridyls, affords the silver complexes of the type [ReAg (μ-10-H-η^5-7,8-$C_2B_9H_{10}$)(CO)$_3$(PPh_3)] (**241**) or [{ReAg(μ-10-H-η^5-7,8-$C_2B_9H_{10}$)(CO)$_3$}$_2$(μ-L-L)] which have B—H—Ag bonds.[1362,1363] In a similar manner the compound [2,2,2-(CO)$_3$-2-PPh_3-7,12-{Ag(PPh_3)}-*closo*-2,1-$MoCB_{10}H_9$] (**242**) has been obtained.[1364]



(**240**)

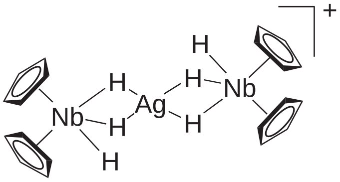


(**241**)

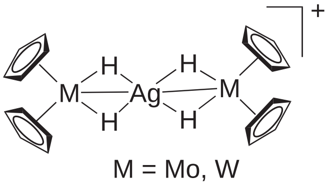


(**242**)

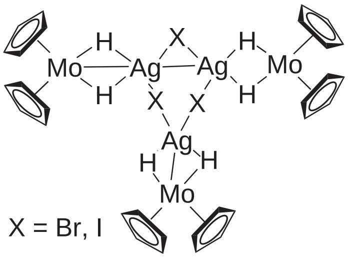
Polynuclear complexes associated with transition metal polyhydrides and silver cations have been described; those which present silver—metal bonds are more numerous and they will be discussed in Section 6.7.2.3.6(i). The reaction of $[Nb(C_5H_3R^1R^2)_2H_3]$ with $AgBF_4$ gives the adducts $[\{Nb(C_5H_3R^1R^2)_2H_3\}_2Ag]^+$ (**243**) ($R^1 = H$, TMS; $R^2 = TMS$) in which the silver binds to two hydrides of each niobium center.[1365] Treatment of $[MoCpH(CO)_2(PMe_3)]$ with $AgBF_4$ in THF or acetonitrile leads adducts with bridging hydride bonds such as $[\{MoCp(\mu\text{-}H)(CO)_2(PMe_3)\}_2Ag]BF_4$ $[MoAgCp(\mu\text{-}H)(CO)_2(PMe_3)(MeCN)_n]$.[1366] The complexes $[Ag(MCp_2H_2)_2]X$ (**244**) (M = W, X = BF_4; M = Mo, X = PF_6) and $[MoCp_2(\mu_2\text{-}H)Ag(\mu_2\text{-}H)WCp_2]$ have been prepared by reaction of $[MCp_2H_2]$ with the silver salts.[1367–1369] Also the reactivity with silver(I) halides have been carried out and the compounds $[Ag(MoCp_2H_2)_2Cl]$, $[Ag_3(MoCp_2H_2)_3X_3]$ (**245**) (X = Br, I), and $[Ag_3(MoCp_2H_2)_4Br_2]PF_6$[1368] have been prepared.



(**243**)



(**244**)



(**245**)

6.7.2.3.7 Complexes with mixed donor ligands

Mixed donor ligands have attracted a great dealt of interest mainly because of the possibility of combining soft and hard Lewis bases. This is the case of the *P*,*N*-donor ligands, mainly pyridyl phosphine ligands. Silver complexes with diphenyl(2-pyridyl)phosphine acting as mixed donor ligand have been prepared and are of the type $[Ag_2Cl_2(PPh_2Py)_3]$ (**246**),[1370] $[Ag_2(NO_3)_2(PPh_2Py)_2]$,[1371] or $[Ag_2(PPh_2Py)_n]^{2+}$ ($n = 2$, 3).[1372,1373] The latter complexes are dinuclear with two *P*,*N* bridging ligands and for $n = 3$ the third ligand is coordinate to one silver atom through the phosphorus. The thermodynamic parameters for the Ag^I complexation with PPh_2Py in DMSO and propylene carbonate have been determined, showing that the mononuclear species are *P*-coordinated and in the dinuclear the ligand is bridging the silver atoms.[1374] Similar studies have been carried out with other *P*,*N*-ligands.[1375] The dinuclear compound $[Ag_2(PPh_2CH_2CH_2Py)_2](PF_6)_2$,[1376] and the mononuclear four-coordinate $[Ag(PPh_2CH_2CH_2Py)_2]^+$ have been prepared. The latter reacts with more phosphine to give $[AgL_3]^+$ and $[AgL_4]^+$ species.[1377] Dinuclear silver complexes with the ligand $(Bzim)Ph_2P$ (Bzim = 1-benzyl-2-imidazolyldiphenylphosphine), $[Ag_2\{PPh_2(Bzim)\}_2]^{2+}$ (**247**), have been obtained.[1378,1379] With the methyl-substituted derivative a polymeric compound $[Ag_2(NO_3)\{PPh_2(Meim)\}_2]_n(NO_3)_n$ has been achieved.[1380] A dinuclear compound has been described with the 2-[bis(diisopropylphosphino)methyl]-1-methyl imidazole, $MeimCH(PPr^i{}_2)_2$, in which the ligand is *P*,*P*,*N* bonded.[1381] The ligand 3,6-bis(diphenylphosphino)pyridazine self-assembles with Ag^+ cations to form the polymeric chain $[Ag_2(\mu\text{-}PPh_2C_4H_2N_2PPh_2)(MeCN)_2]_n(ClO_4)_{2n}$ (**248**).[784]

The polydentate ligands 2-(diphenylphosphino)-6-[3-(2′-pyridyl)pyrazol-1-yl)pyridine and 2-(diphenylphosphino)-6-(pyrazol-1-yl)pyridine react with $[Ag(NCMe)_4]ClO_4$ to give the dinuclear complexes where the ligands are *P*,*N*,*N* bonded as in (**249**).[1382] The reaction of two equivalents of $AgBF_4$ with 6,6-bis(diphenylphosphine)-2,2′-bipyridyl (P_2-bipy) gives the complex $[Ag_4(P_2\text{-bipy})_2](BF_4)_4$. Addition of Br^- or I^- leads to complexes $[Ag_4X_2(P_2\text{-bipy})_2](BF_4)_2$ which are in equilibrium between two species with a μ_2-X or a μ_3-X (**250**) ligand; these complexes add further solvent molecules. All of them have photoluminescent properties that can be attributed to structural rearrangements associated with ligand coordination.[1383] A trinuclear compound $[Ag_3(\mu\text{-}P_2\text{-bipy})_3](PF_6)_3$ has also been synthesized.[1384] The ligands $Ph_2PCH_2N(R)Py$ (R = H, Cy) give silver complexes with different coordination modes such as $[Ag(\mu\text{-}PPh_2\ CH_2NHPy)\ (NCMe)]_n(ClO_4)_n$, $[Ag(PPh_2CH_2NHPy)_2(2\text{-}PyNH_2)]ClO_4$, $[Ag\{PPh_2CH_2N(Cy)Py\}_2]ClO_4$, or $[Ag_2\{\mu\text{-}PPh_2CH_2N(Cy)Py\}_2](ClO_4)_2$ (**251**).[1385] A similar ligand 1-[(diphenylphosphino)methyl]-4-(2-pyridyl)piperazine gives also a dinuclear *P*,*N* silver(I) complex.[1386]

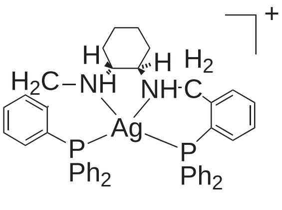
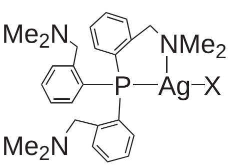
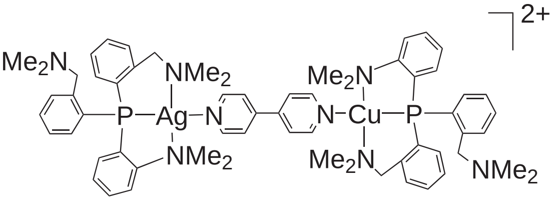
A series of bidentate PN and tetradentate P_2N_2 aminophosphine ligands form stable silver(I) complexes characterized by NMR spectroscopy and (**252**) by XRD.[1387,1388] $P(C_6H_4NMe_2\text{-}2)_3$ yields on treatment with AgX ($X = Cl$, Br, O_2CCF_3) the monomeric T-shaped planar silver(I) complexes (**253**).[1389,1390] The reaction of $[Ag(OTf)\{P(C_6H_4NMe_2\text{-}2)_3\}]$ with 4,4-bipyridine leads to the displacement of the triflate ligand; further reaction with $[Cu\{P(C_6H_4NMe_2\text{-}2)_3\}]PF_6$ gives the bimetallic compound $[AgCu(4,4\text{-bipy})\{P(C_6H_4NMe_2\text{-}2)_3\}_2](OTf)(PF_6)$ (**254**).[1391]



(**252**)



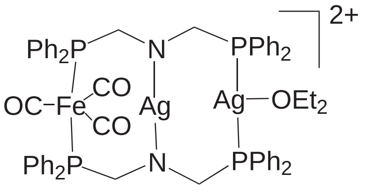
(**253**)



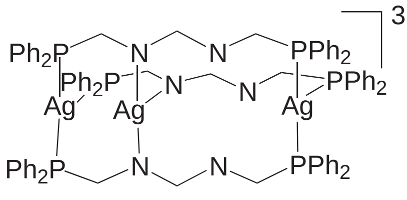
(**254**)

Treatment of AgOTf, $N(CH_2CH_2NH_2)_3$, and $2\text{-}Ph_2PC_6H_4(CHO)$ lead to the template synthesis of a trinuclear complex with a heptadentate ligand $[Ag_3\{[(2\text{-}Ph_2PC_6H_4)CH{=}NCH_2CH_2]_3N\}_2](OTf)_3$; the silver centers are penta *P*,*P*,*N*,*N*,*N* or tetra *P*,*P*,*N*,*N* coordinated.[1392] The platinum or iron derivatives with the 2,6-bis(diphenylphosphino)pyridine ligand act as a host and encapsulate silver atoms to form the complexes $[PtAg_2Me_2(\mu\text{-}PPh_2PyPPh_2)_2(CNMe)_2](BF_4)_2$ or $[FeAg_2(CO)_3(\mu\text{-}PPh_2PyPPh_2)_2(OEt_2)](ClO_4)_2$ (**255**), both containing metal–metal dative Pt → Ag or Fe → Ag bonds which are stabilized by argentophilic interaction.[1393] The trinuclear complex with 2,7-bis(diphenylphosphino)-1,8-naphthyridine ligand

(**256**) shows a intraligand emission with lifetime of 5 μs on excitation at 330–370 nm in acetonitrile at room temperature.[1394]

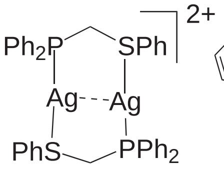


(**255**)

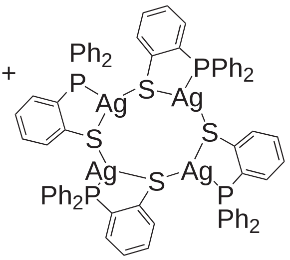


(**256**)

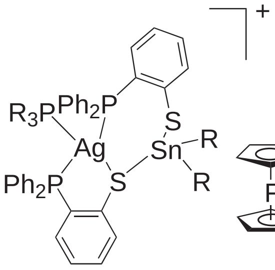
Silver complexes with *P,S* mixed donor ligands have been obtained, such as $[Ag\{PPh_2(CH_2)_2\text{-}SEt\}_2]ClO_4$[1395] or $[Ag_2\{PPh_2CH_2SPh\}_2](ClO_4)_2$ (**257**).[1396] The $[AgL_n]^+$ complex formation for $L = Ph_2PCH_2SPh$, $Ph_2P(CH_2)_2SR$ (R = Me, Et, Ph) has been studied in propylene carbonate, and shows that Ph_2PCH_2SPh behaves as a monodentate *P*-donor but $Ph_2P(CH_2)_2SR$ acts as bidentate *P,S* chelates. The structure of $[Ag_2\{\mu\text{-}PPh_2(CH_2)_2SEt\}_2](ClO_4)_2$ consists of co-crystallized open-chain and dimeric forms of the complex.[1397] The $[AgL]BF_4$ complex where $L = PhP(CH_2)_2S(CH_2)_2S(CH_2)_2PPh_2$ has been studied by MS, IR, and NMR spectroscopies. The ^{31}P NMR spectra suggest a static behavior of the phosphines, but fast exchange of the thioether atoms.[1398] Silver complexes of the anionic forms of 2-(diphenylphosphino)benzenethiol $[2\text{-}(Ph_2P)C_6H_4SH]$ and 2-(diphenylphosphino)-6-(trimethylsilyl)benzenethiol $[2\text{-}(Ph_2P)\text{-}6\text{-}(TMS)C_6H_3SH]$ have been prepared and are tetrameric (**258**).[1399] $[SnR_2(SC_6H_4PPh_2)_2]$ (R = Me, Et) reacts with $[Ag(OTf)(PR_3)]$ ($PR_3 = PPh_3$, PPh_2Me) to afford the mixed-complexes $[AgSn(\mu\text{-}SC_6H_4PPh_2)R_2(PR_3)]OTf$ (**259**).[1400] Other complexes as (**260**),[1183] the hexanuclear $[Ag(2\text{-}PPh_2C_6H_4CO_2)]_6$ with P,O-,[1401] $[Ag_2\{PPh_2(CH_2)_nPPh_2S\}_2](NO_3)_2$ with P,S-[1402] and $[Ag(PPh_2CH_2PPh_2Se)_2]Cl$ with P,Se-mixed donor[1403] ligands, have also been reported.



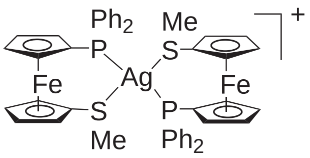
(**257**)



(**258**)



(**259**)



(**260**)

The most thoroughly studied mixed *S,N*-ligand is pyridine-2-thiolate because of its versatile coordination modes. The compound $[Ag(SPy)]_n$ has a graphite-like array of silver(I) ions and has a semiconductor behavior. The PyS^- ligand acts as a μ_3-*N,S,S* bridge. $[Ag_5(SPy)(HSPy)BF_4]_n$ has a layered structure with the coordination modes of PyS^- showed in Figure 14.[1404]

Depending upon temperature reaction and solvent used other polymeric species such as $[Ag_6(\mu_3\text{-}SPy)_4(\mu_4\text{-}SPy)_2]_n$ and $[Ag(\mu_2\text{-}(HSPy)Cl]_n$ have been obtained.[1405] A related polymeric compound $[Ag_6(\mu_3\text{-}SC_4N_2H_3)_4(\mu_2\text{-}SC_4N_2H_3)_2]_n$ has been prepared from the assembly reaction of AgSCN and sodium pyrimidine-2-thiolate.[1406] The $[Ag(ER)]_6$ (E = SiSe) complexes have been obtained with the sterically hindered RMe_2SiPyS^-, $(RMe_2Si)_2PyS^-$, or $6\text{-}TMSPySe^-$ ligands. Electrochemical oxidation of anodic silver in acetonitrile solution of the RSH or RSeH

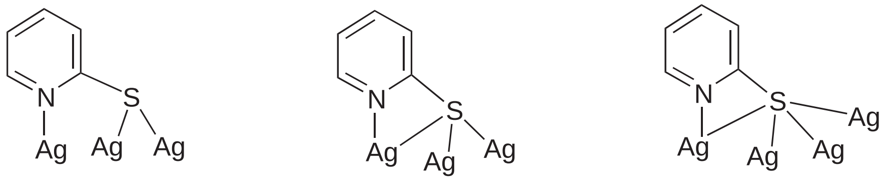


Figure 14 Coordination modes of pyridine-2-thiolate in $[Ag_5(Spy)(HSpy)BF_4]_n$.

compounds is another method to obtain these complexes.[1407–1411] The reaction of PySH with Ag_2O has been reported to give $[Ag_2(SPy)_2]$. The ligands PySMe or $PySCH_2COPh$ yields the dinuclear $[Ag_2(PySMe)_2](ClO_4)_2$ or the trinuclear $[Ag_3(ClO_4)_3(\mu_3\text{-}PySCH_2COPh)(PPh_3)_3]$.[1185,1412] The tetranuclear butterfly clusters of Ag^I and the mixed Ag^I—Cu^I of the type $[Ag_2M_2(mt)_4(PPh_3)_2]$ (M = Ag, Cu) have been obtained by reaction of the metal acetates with 2-mercaptothiazoline (Hmt) in the presence triphenylphosphine.[1413]

Several ligands containing pyridine or related groups and sulfur atoms have been synthesized and the silver complexes studied; the ligands used are shown in Figure 15. Many of the complexes have a supramolecular structure.

Silver(I) complexes with mixed donor *S*,*O*-ligands have been described with 1-hydroxypyridine-2-thione (**261**),[1437,1438] *cyclo*-*L*-methionylglycine,[1439] acyclic polyethers (**262**),[1440–1442] dithio- and trithio-oxalate,[1443] or chlorosulfate.[1444]

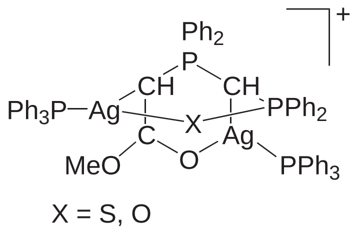
(**264**)



(**265**)

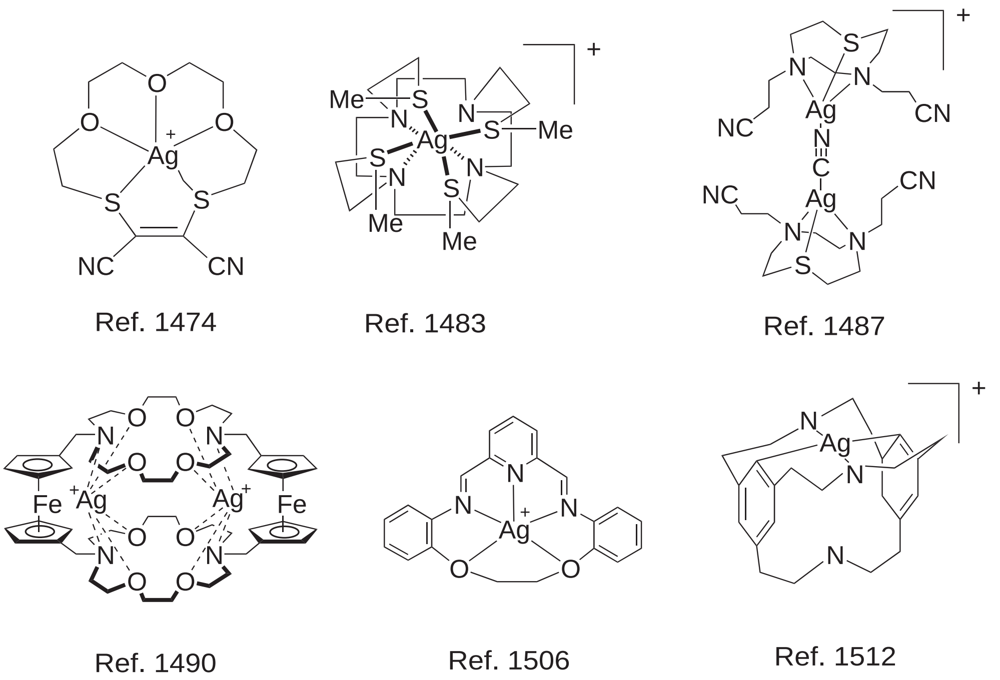


Figure 16 Some examples of silver(I) complexes with mixed donor macrocyclic ligands.

Naphthalenedicarboxylates coordinate to silver(I) atoms through the oxygen atoms and an η^2-coordination mode involving the aromatic rings.[1468] The reaction of $AgNO_3$ with $Li[CH_2PPh_2S]$ yields $[Ag(CH_2PPh_2S)]_2$ (**264**) in which the ylide C,S bridges the two silver atoms; in the solid state a ID chain structure is present with short intramolecular Ag···Ag separations of 2.990(2) Å.[1469] The mixed silver(I)–gold(I) compound $[AgAu(CH_2PPh_2S)_2]$ has also been obtained; it presents a short Ag—Au interaction of 2.9124(13) Å.[1470] The compounds $[Ag_2\{C(TMS)_2Py\}_2]$ and $[Ag(OTf)(Bu^t\text{-DAB})]$ (Bu^t-DAB = 1,4-di-*t*-butyldiazabuta-1,3-diene with a N,C mixed ligand have been reported.[644,1471] The silver complexes with mixed S,C or O,C mixed-donor ligands have been obtained with methanide ligands in $[Ag_2(SPPh_2CHPPh_2Me)_2](ClO_4)_2$, $[Ag(XPPh_2CHPPh_2Me)_2](ClO_4)_2$ or $[Ag_2(XPPh_2CHPPh_2CHCO_2Me)(PPh_3)_2]ClO_4$ (**265**) (X = O, S).[1471–1473]

Silver(I) complexes with macrocyclic ligands that possess *O*/*N*/*S* as donor atoms have been studied extensively;[1474–1533] in Figure 16 a selection of some silver complexes with this type of ligands can be seen.

(i) Complexes with silver–metal bonds

Many carbonyl and carbonyl metallate complexes of the second and third row, in low oxidation states, are basic in nature and, for this reason, adequate intermediates for the formation of metal—metal bonds of a donor–acceptor nature. Furthermore, the structural similarity and isolobal relationship between the proton and group 11 cations has lead to the synthesis of a high number of cluster complexes with silver—metal bonds.[1534,1535] Thus, silver(I) binds to ruthenium,[1536–1556] osmium,[1557–1560] rhodium,[1561,1562] iron,[1563–1572] cobalt,[1573] chromium, molybdenum, or tungsten,[1574–1576] rhenium,[1577,1578] niobium or tantalum,[1579] or nickel.[1580] Some examples are shown in Figure 17.

Complexes with silver(I)—rhodium(I) bonds have been prepared by addition of AgX to Rh—Rh bonds, as $[Rh(\mu\text{-AgX})(\eta^5\text{-}C_5Me_5)(\mu\text{-CO})]_2$,[1581,1582] $[Rh_2(\eta^5\text{-}C_5H_5)(\mu\text{-CO})(\mu\text{-dppm})(\mu\text{-AgX})]$,[1583–1585] or $[Rh_2\{\mu\text{-Ag}(PPh_3)\}\{\mu\text{-1,8-}(NH)_2C_{10}H_6\}(CO)_2(PPh_3)_2]ClO_4$.[1586] The reaction of $[Rh(\eta^5\text{-}C_5H_5)(CO)(PPh_3)]$ with $AgPF_6$ gives the adduct $[Ag\{Rh(\eta^5\text{-}C_5H_5)(CO)(PPh_3)\}_2]PF_6$.[1587] The complex $[Rh_3Ag_3H_9\{(PPh_2CH_2)_3CMe\}_3]^+$ (**266**) has been obtained by treatment of $[RhCl\{(PPh_2CH_2)_3CMe\}_3]$ with AgOTf in methanol (hydrides not located).[1588] The reaction of *cis*-$[Rh(C_6F_5)_2L_2]^-$ with $[Ag(OClO_3)(PPh_3)]$ gives complexes with Ag—Rh unsupported bonds, as show the structure of *cis*-$[RhAg(C_6F_5)_2(PPh_3)\{P(OPh)_3\}_2]$ (**267**).[1589] The luminescent 1D heterometallic chain, $\{[Rh_2(dfpma)_2(NCMe)_4]_2[Ag(NCMe)_4][PF_6]\}$ (dfpma = bis(difluorophosphine)

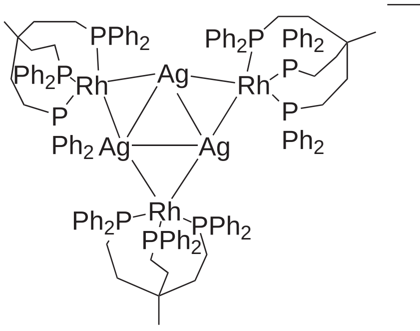
Ref. 1575

Ref. 1577

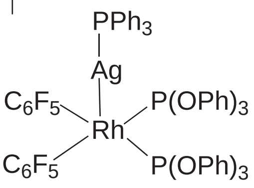
Ref. 1579

Figure 17 Some examples of metal carbonyl complexes with M-Ag bonds.

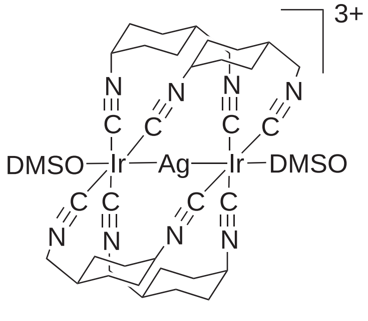
methylamine) has been obtained.[1590] Complexes with Ag—Ir bonds such as $[AgIr_2(dimen)_4(DMSO)_2](PF_6)_3$ (**268**) or $[AgIr_2(dimen)_4(PPh_3)_2](PF_6)_3$ (dimen = 1,8-diisocyanomenthane) have been reported.[1591–1593] The complexes $[Ag\{ReH_7(PPhPr^i{}_3)_2\}_n]^+$ ($n = 1, 2$) present a silver rhenium bond (hydrides not located by XRD).[1594] Silver(I)—mercury bonds have been described in $[AgHg_2(\mu\text{-dppm})_3]^{3+}$[1595] and $[Ag_2Hg(Mes)_2X_2]_2$ (X = OTf, ClO_4).[1596]



(**266**)



(**267**)



(**268**)

Compounds with Ag—Pt bonds are well represented. A method to prepare this type of complexes developed by Forniés and co-workers is the reaction of electron-rich platinum complexes such as anionic pentachloro- or pentafluorophenyl species with silver salts.[1597–1599] The treatment of mononuclear $(Bu_4N)_2[Pt(C_6F_5)_{4-x}(C_6Cl_5)_x]$ or $(Bu_4N)[Pt(C_6F_5)_{3-x}(C_6Cl_5)_xL]$ with [AgXL] or AgX compounds leads to the synthesis of Pt → Ag complexes such as (**269**) and (**270**).[1600–1603] The use of $(Bu_4N)_2[PtCl_2(C_6F_5)_2]$ with silver salts also leads to compounds with silver—platinum bonds assisted by other covalent interactions, as in compound (**271**).[1231,1604–1606]

Starting from anionic dimeric complexes such as $(Bu_4N)_2[Pt_2(\mu\text{-}X)_2(C_6X_5)_4]$ or $(Bu_4N)_2[Pt_2(\mu\text{-}C_6F_5)_2(C_6F_5)_4]$ polynuclear complexes as (**272**) are obtained.[1607–1610] Other precursors for the synthesis of Ag—Pt compounds are the anionic dinuclear complexes with bridging dppm and halide or hydroxo ligands, $[Pt_2(C_6F_5)_2(\mu\text{-}X)(\mu\text{-dppm})]^-$,[1611,1612] or the acetylacetonate complex $[Pt(C_6F_5)_2(ACAC)]^-$.[1613,1614]

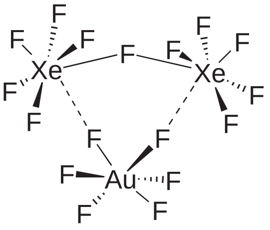
Other examples of complexes with silver—platinum bonds are (**273**)–(**275**),[1615–1617] a W—Pt—Ag cluster,[1618] the coordination polymers $Ag_2[Pt(ox)_2]\cdot 2H_2O$ and $[Ag(H_2O)]_2[Ag_2(OTf)_4][Pt\,(ACAC)_2]_2$,[1619] and the helical complex $[\{Pt(phpy)_2\}_2\{Ag(acetone)_2\}]_n(ClO_4)_{2n}$ (Hphpy = 2-phenylpyridine).[1620]

6.7.3 GOLD

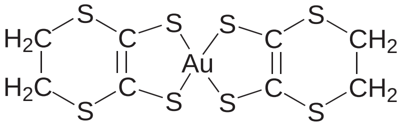
6.7.3.1 High Oxidation States

High oxidation states are known with very electronegative ligands such as fluorine. The yellow crystalline AuF_7 is prepared by disproportionation of AuF_6 and can be isolated at −196 °C, it decomposes in AuF_5 and F_2 at 100 °C.[1621] AuF_6 is obtained by oxidation of AuF_5 with fluorine.[1621] The pentafluoride AuF_5 is formed by vacuum pyrolysis of either $[KrF][AuF_6]$ (at 60–65 °C)[1622,1623] or $[O_2][AuF_6]$ (at 160–200 °C).[1624] An electron diffraction study of AuF_5 has indicated that the vapor phase consists of di- and trimeric molecules with the gold octahedrally coordinated.[1625]

The $[AuF_6]^-$ complex anion is known with a variety of simple (Na^+, K^+, Ca^{2+})[1623,1626,1627] or more complex ($[KrF]^+$, $[XeF_5]^+$, $[Xe_2F_{11}]^+$)[120,1622,1623,1626] counteranions. They are bright yellow to green solids, which are extremely sensitive to oxygen and moisture. The compound $[Xe_2F_{11}][AuF_6]$ was first prepared by fluorination of AuF_3 with XeF_2 in the presence of XeF_6.[120,1628] In the solid state the gold is octahedrally surrounded by the fluorine atoms and bonded to the dimeric xenon cation by two of the fluorine atoms (**276**).[1629,1630] The complex $Ag[AuF_6]$ was also synthesized and the structure was found to be of $LiSbF_6$ type by Synchrotrom X-ray powder diffraction.[1631,1632] The stability of the high oxidation states in group 11 fluorides has been studied by relativistic Möller-Pleset (MP) and coupled cluster methods. Relativistic effects stabilize higher metal oxidation states. As a result, the hexafluoro complex of group 11 elements with nuclear charge 111 and oxidation state +5 is the most stable compared to the other congeners.[1633]



(**276**)



(**277**)

The evidence for the existence of oxidation state +IV is not yet convincing. Some complexes with dithiolene or dithiolate systems have been reported such as [Au(dddt)$_2$] (**277**) (dddt = 5,6-dihydro-1,4-dithiin-2,3-dithiolate),[1634] [Au(1,2-$S_2C_6H_4$)$_2$],[1635] [Au{$S_2C_2(CN)_2$}$_2$]·$C_{20}H_{10}$,[1636] and [Au(dtpdt)$_2$] (dtpdt = 2,3-dihydro-5,6-thiophenedithiolate) or [Au(α-tpdt)$_2$] (α-tpdt = 2,3-dithiophenedithiolate).[1637] They have been prepared by chemical or electrochemical oxidation of the corresponding gold(III) derivatives. The molecular orbital calculations suggest that the metal ions of the molecules are best described as d^8 ions as expected for a square planar gold(III) compound, and therefore the unpaired electron in each molecule resides largely on the ligands.

6.7.3.2 Gold(III) Complexes

6.7.3.2.1 Complexes with carbon donor ligands

The majority of gold(III) complexes with carbon donor ligands are with alkyl or aryl donor ligands. Monoalkylgold(III) compounds are not well represented, and only a few trifluoromethyl compounds of the type [Au(CF_3)X_2(PR_3)] (X = Br, I; R = Me, Et, Ph)[1638] have been reported. These are formed by oxidative addition of halogen to the corresponding trifluoromethyl(phosphine)gold(I) derivative. However, monoarylgold(III) species are more abundant and various methods exist for their synthesis:

(i) oxidative addition of halogen to the respective gold(I) complex,
(ii) transmetallation reaction with HgR_2,
(iii) electrophilic substitution by gold(III) of one aromatic ring (metalation), or
(iv) substitution reactions on monoarylgold(III) derivatives.

The first method has been used with haloaryl,[1639–1643] *ortho*-nitrophenyl,[1644] mesityl,[255] or ylidegold(I)[1645–1648] complexes, which are sufficiently stable to undergo the oxidative addition without cleavage of the gold–carbon bond, an example can be seen in Equation (11):

$$[\mathrm{Au(C_6F_5)(THT)}] + \mathrm{Cl_2} \longrightarrow [\mathrm{Au(C_6F_5)Cl_2(THT)}] \qquad (11)$$

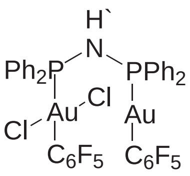
The reaction between [Hg(C_6F_5)$_2$] and Me_4N[AuCl_4] gives Me_4N[Au(C_6F_5)Cl_3] in high yield (Equation (12)):[1643]

$$\mathrm{Hg(C_6F_5)_2} + \mathrm{Me_4N[AuCl_4]} \longrightarrow \mathrm{Me_4N[Au(C_6F_5)Cl_3]} + \mathrm{Hg(C_6F_5)Cl} \qquad (12)$$

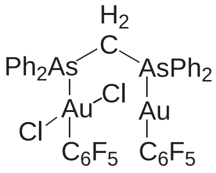
Recently the synthesis of arylgold(III) species by C—H bond activation has been re-investigated. The reaction of anhydrous gold(III) chloride [AuCl_3]$_2$ with aromatic hydrocarbons (ArH), such as benzene, toluene, xylenes, mesitylene, cumene, methoxybenzene, and chlorobenzene, and the following treatment with 2,6-lutidine (lut), gave the complexes [AuArCl_2(lut)].[1649] The ^{1}H NMR spectra revealed that auration towards aromatic compounds take place regiospecifically at the position with higher electron density and with less steric hindrances.

The THT ligand in [AuRX_2(THT)] and in other complexes can be displaced easily for other neutral or anionic ligands (e.g., phosphine, amines, halide, etc.), and a wide variety of derivatives have been obtained. Au Mössbauer spectra of $[Au(C_6F_5)Cl_2(phen)]$ support the existence of a weak interaction of gold(III) with the second donor atom of the phen, approaching pentacoordination.[1526] This type of complex can further react with $AgClO_4$ to give the four-coordinate cationic complexes $[Au(C_6F_5)X(phen)]ClO_4$.[1640]

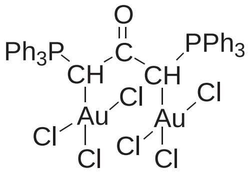
Oxidation of the dinuclear gold(I) complexes, $[\{Au(C_6F_5)\}_2\{\mu\text{-}(PPh_2)_2NH\}]$[1650] or $[\{Au(C_6F_5)\}_2\{\mu\text{-}(AsPh_2)_2CH_2\}]$,[1651] with halogens gives the corresponding gold(II) derivatives, these are unstable in solution and isomerization to the mixed gold(III)–gold(I) complexes (**278**, **279**) is observed. Similarly, oxidation addition of chlorine to the dinuclear ylidegold(I) complex $[Au_2Cl_2\{\mu\text{-}\{CH(PPh_3)\}_2CO\}]$ gave the gold(III) derivative (**280**).[1652]



(**278**)



(**279**)



(**280**)

Usually, the monoarylgold(III) complexes obtained by an arylation or cyclometalation processes contain aryl moieties, which act as bidentate *C*,*N* or *C*,*S* or tridentate *C*,*N*,*N* donor ligands. Then it will be treated in Section 6.7.3.2.7.

Gold(III) complexes with two gold—carbon bonds are well known and abundant. They are prepared for one of the main established methods for organometallic gold(III) derivatives: Oxidation of gold(0) or gold(I) compounds with halogens or thallium reagents, using arylating or alkylating compounds such as tin, mercury, Gridnard, or lithium compounds, and finally by substitution reactions. In many cases the unit $Au^{III}R_2{}^+$ is used as "syntom" in order to coordinate mono- or bidentate ligands to the gold(III) center and the reactivity is not focused on the organic ligand. These particular cases will be seen in the appropriate sections.

The simplest compounds are of the type $[Au_2(\mu\text{-}X)_2R_4]$ and they have been known for a long time, the organic ligand being unsubstituted alkyl groups in the majority of the cases.[67] An improved synthesis has been published recently for $[Au_2(\mu\text{-}Cl)_2Me_4]$,[1653] which was previously obtained in low yield with Grignard agents or MeLi, and uses $SnMe_4$ as alkylating agent (Equation (13)):

$$2\ HAuCl_4 + 4\ SnMe_4 \longrightarrow [Au_2(\mu\text{-}Cl)_2Me_4] + 4\ SnMe_3Cl + 2\ HCl \tag{13}$$

Other alkylgold(III) compounds are $[Au_2(\mu\text{-}X)_2(CF_3)_4]$ (X = Br, I) synthesized by co-condensation of gold with CF_3Br and CF_3I, respectively, and may be sublimed at room temperature.[1654] Trifluoromethylated compounds are potentially useful precursors for CVD studies as they are expected to show enhanced volatility.[1655] *cis*-$[Au(CF_3)_2I(PMe_3)]$ is formed in quantitative yield by oxidative addition of trifluoromethyl iodide to $[Au(CF_3)(PMe_3)]$, the reaction is proposed to proceed via radical intermediates.[1524,1656]

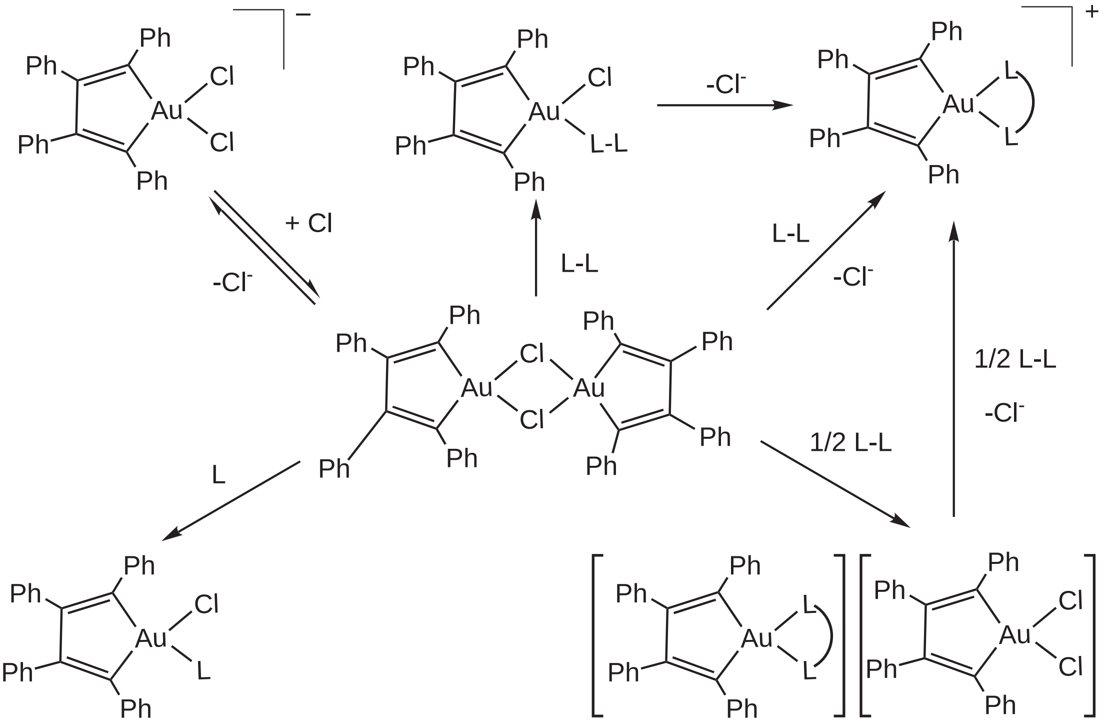
Diarylaurate(III) complexes of the type $[AuR_2X_2]^-$ (R = C_6F_5, C_6Cl_5; X = Cl, Br) are known for a variety of polyhalophenyl ligands. They were first prepared by oxidative addition of halogen to the corresponding organogold(I) compound $[AuR_2]^-$ or by oxidative addition of the corresponding gold(I) complex with $[TlR_2X]_2$.[98,99,1641] Reaction of *trans*-$[Au(C_6F_5)_2X_2]$ with a silver salt results in the abstraction of halide to give the dimeric diarylgold(III) halides *cis*-$[Au_2(\mu\text{-}X)_2(C_6F_5)_4]$ (X = Cl, Br) (Equation (14)):[1657]

$$2Bu_4N[Au(C_6F_5)_2X_2] + 2AgClO_4 \longrightarrow Au_2(\mu\text{-}X)_2(C_6F_5)_4] + 2AgCl + 2Bu_4NClO_4 \tag{14}$$

Reactivity of these dimeric complexes have been studied for $[Au_2(\mu\text{-}Cl)_2(C_6F_5)_4]$; it reacts with salts of anionic ligands such as sodium azide, potassium thiocyanate, $AgCF_3COO$, or Tl(ACAC) to give the corresponding dinuclear pseudo-halide derivatives or the monomeric $[Au(C_6F_5)_2(ACAC)]$. The cleavage of the chloro bridges by mono- or bidentate neutral ligands yields $>$complexes of the type $[Au(C_6F_5)_2Cl(L)]$ (L = Py, PPh_3) or $[Au(C_6F_5)_2(L\text{-}L)][Au(C_6F_5)_2Cl_2]$ (L-L = bipy, phen, 1,2-$(AsMe_2)C_6H_4$).[1657] Similar complexes have been obtained with pentachlorophenyl as aryl ligand.[1641] The reaction of $[Au_2(\mu\text{-}Cl)_2(C_6F_5)_4]$ with two equivalents of $AgClO_4$ in solvents (S), such as acetone or diethyl ether, gives stable solutions of $[Au(C_6F_5)_2(S)_2]ClO_4$, that can be used "*in situ*", after removal of AgCl, to further react with neutral or anionic ligands affording complexes of the type $[Au(C_6F_5)_2(L)_2]ClO_4$ (L = THT, PPh_2Me, $Ph_2PCH_2PPh_2$, bipy) or $[Au(C_6F_5)_2(ACAC)]$, $Bu_4N[Au(C_6F_5)_2(CN)_2]$, or $[\{Au(C_6F_5)_2\}_2(BiBzIm)]$ (BiBzIm = 2,2′-bibenzimidazolate).[1658] The oxidation of the biaryl complex $[Au_2(\mu\text{-}C_6H_4\text{-}C_6H_4)(PPh_3)_2]$ with tetraethylthiuram disulfide produces the mononuclear gold(III) derivative $[Au(C_6H_4\text{-}C_6H_4)(\mu\text{-}S_2CNEt_2)]$.[1659,1660]

An alternative synthesis of diarylgold(III) halides uses organomercurials as arylating reagents, and compounds of the type *cis*-$NMe_4[AuR_2Cl_2]$ can be obtained where R = 2-$NO_2C_6H_4$ or 2-Me-6-$NO_2C_6H_3$,[1659,1660] or *cis*-$[N(PPh_3)_2][Au(mes)_2Cl_2]$.[1661] The compounds may be derivatized by substitution of one or both halide ligands with various reagents, thus complexes of the type *cis*-$NMe_4[Au(2\text{-}NO_2C_6H_4)_2(CN)_2]$, *cis*-$[AuR_2Cl(PPh_3)]$, or *cis*-$[AuR_2\{(PPh_2)_2CH_2\}]^+$ can be obtained.[1659–1661]

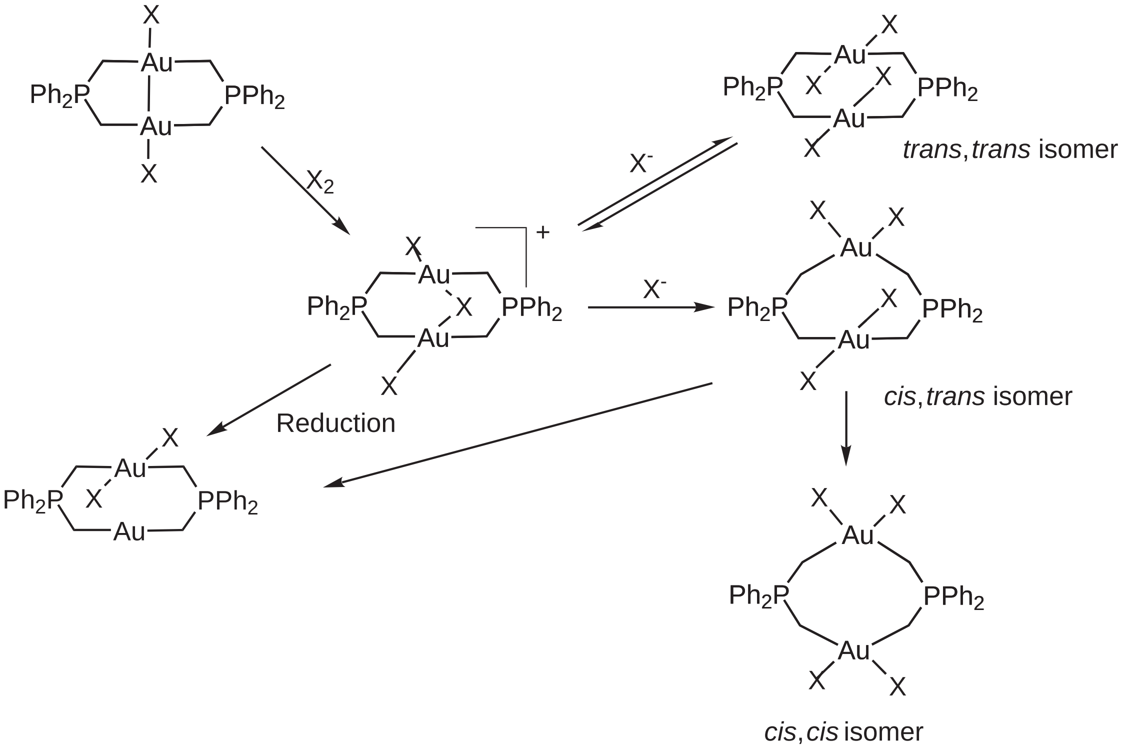
Heterocyclic gold(III) derivatives $[Au_2(\mu\text{-}Cl)_2(C_4Ph_4)_2]$ and $[AuCl(C_4Ph_4)(THT)]$ (C_4Ph_4 = 1,2,3,4-tetraphenylbuta-1,3-diene-1,4-dyil) have been obtained by reaction of $SnMe_2(C_4Ph_4)$ with $[AuCl_3(THT)]$. The treatment of $[Au_2(\mu\text{-}Cl)_2(C_4Ph_4)_2]$ with various anionic and neutral ligands leads to cleavage of the chloride bridges, some of the resulting products are illustrated in Scheme 10. The crystal structure indicates a distorted square-planar geometry for the metal.[1662] The reaction of $[AuCl_2(L\text{-}L)]^+$ with two equivalents of $Mg(2,4,6\text{-}Me_3C_6H_2)X$ leads to the diaryl species $[Au(2,4,6\text{-}Me_3C_6H_2)_2(L\text{-}L)]^+$ (L-L = bipy, phen, dpphen).[1663] The treatment of the biaryl complex $[Au_2(C_6H_4C_6H_4)(PPh_3)_2]$ with tetraethylthiuram disulfide gives the gold(III) diaryl complex $[Au(C_6H_4C_6H_4)(S_2CNEt_2)]$.[1663,1664]



Scheme 10 Reaction of $[Au_2(\mu\text{-}Cl)_2(C_4Ph_4)_2]$ with mono and bidentate ligands.

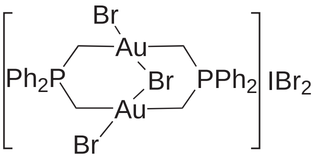
Mononuclear gold(III) ylide complexes may be prepared by oxidative addition of halogens of suitable gold(I) precursors. This approach is exemplified by complexes of general types *trans*-$[Au(C_6F_5)Cl_2(ylide)]$ (ylide = CH_2PPh_3, CH_2PPh_2Me, CH_2PPhMe_2)[1645] and *trans*-$[AuX_2\{CH(PPh_3)COR\}_2]^+$ (R = Me, OMe, OEt; X = Cl, Br).[1646,1648] *Trans*-$[Au(C_6F_5)Cl_2(CH_2PPh_2Me)]$ reacts with potassium thiocyanate to give *trans*-$[Au(C_6F_5)(SCN)_2(CH_2PPh_2Me)]$.[1645]

The dinuclear gold(I) ylide complexes, $[Au_2\{(CH_2)_2PR_2\}_2]$ (R = Me, Ph), react with two equivalents of halogens or thionyl chloride to give the gold(III) derivatives $[Au_2X_4\{(CH_2)_2PR_2\}_2]$ (X = Cl, Br) (Scheme 11).[1665–1669] The treatment of $[Au_2\{(CH_2)_2PPh_2\}_2]$ with CCl_4 in tetrahydrofurane affords the gold(III) compound with halogens and halomethane as ligands, $[Au_2Cl_3(CCl_3)\{(CH_2)_2PPh_2\}_2]$.[1670] The oxidation of the alkylhalidegold(II) species $[Au_2X(CHX_2)\{(CH_2)_2PPh_2\}_2]$ or $[Au_2X(CH_2X)\{(CH_2)_2PPh_2\}_2]$ with halogens leads to the *cis,cis* and *trans,trans* gold(III) compounds $[Au_2X_3(CH_2X)\{(CH_2)_2PPh_2\}_2]$ (see Scheme 11).[1671]

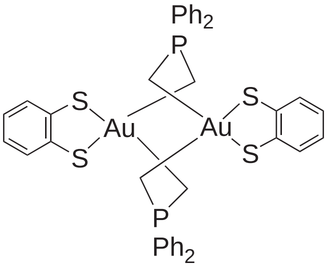


Scheme 11 Gold(III) and mixed Gold(I)/Gold(III) ylide complexes.

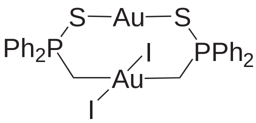
An interesting gold(III) ylide derivative was obtained as by-product in one of these reactions and has a bromine bridging ligand, $[Au_2Br_2(\mu\text{-}Br)\{\mu\text{-}(CH_2)_2PPh_2\}_2](IBr_2)$ (**281**). The latter has been postulated as an intermediate in these types of reactions.[1669]



(**281**)



(**282**)



(**283**)

The dinuclear carbonyl-stabilized ylide gold(I) complexes $[Au_2\{\mu\text{-}\{CH(PPh_3)\}_2CO\}_2](ClO_4)_2$ or $[Au_2\{\mu\text{-}[CH(CO_2Me)]_2PPh_2\}_2]$ also react with an excess of halogen to give the gold(III) compounds $[Au_2Cl_4\{\mu\text{-}[CH(PPh_3)]_2CO\}_2](ClO_4)_2$ or $[Au_2X_4\{\mu\text{-}[CH(CO_2Me)]_2PPh_2\}_2]$ (X = Cl, I), respectively.[1668,1672] The reaction of 1,2-benzenethiol with the ylide gold(II) complex, $[Au_2(O_2CPh)_2\{(CH_2)_2PPh_2\}_2]$ does not lead to the substitution of the benzoate ligand, but a disproportionation reaction occurs and the gold(III) complex $[Au_2(S_2C_6H_4)_2\{\mu\text{-}(CH_2)_2PPh_2\}_2]$

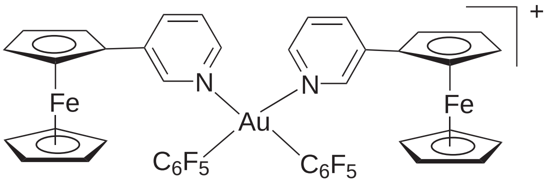
(**282**) can be isolated.[1673] Mixed valent ylide gold(I)–gold(III) compounds have also been reported. $[Au_2Br_2\{\mu\text{-}(CH_2)_2PPh_2\}_2]$ can be synthesized both by reduction of the gold(III) species $[Au_2Br_4\{\mu\text{-}(CH_2)_2PPh_2\}_2]$ with AgCN or by oxidation of $[Au_2(CN)_2\{\mu\text{-}(CH_2)_2PPh_2\}_2]$ with Br_2, followed by spontaneous reduction.[1674] The dinuclear gold(I) complex with the methylenethiophosphinate ligands, $[Au_2(\mu\text{-}CH_2PPh_2S)_2]$, can be oxidized with iodine to the asymmetrical $[Au_2I_2(\mu\text{-}CH_2PPh_2S)_2]$ (**283**),[1675] this compound is also available from the isomerization of the corresponding gold(II) derivative in nitromethane and other weakly protonic solvents, such as acetone.[1676]

Mixed perhalophenyl-isocyanide gold(III) derivatives of the type $[AuRI_2(C{\equiv}NC_6H_4C_6H_4OC_nH_{2n+1}\text{-}p)]$ ($R = C_6F_5$; $n = 8$; $R = C_6F_4Br\text{-}o$, $n = 10$) and $[(\mu\text{-}4,4'\text{-}C_6F_4C_6F_4)\{AuX_2C{\equiv}N(C_6H_4)_mOC_nH_{2n+1}\text{-}p)\}_2]$ ($m = 1, 2$; $n = 4$, 6, 8, 10, 12) have been prepared and the liquid crystal behavior has been studied. In spite of the bulkiness of some of these groups, large ranges of N or S_A phases are obtained.[1677] The structure of $Ph_4As[Au(CN)_4]$ has been reported and consist of two kind of layers, one composed for cations and the other of anions.[1678]

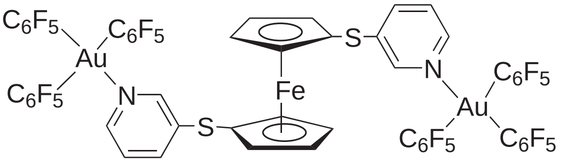
6.7.3.2.2 *Complexes with nitrogen donor ligands*

The gold(III) halides exhibit Lewis acidic behavior and readily react with nitrogen donor ligands. Complexes of the type $[AuX_3L]$ with L = pyridine,[1679] substituted pyridines,[1680] *t*-butylamine,[1681] 1,4-benzodiazepin-2-ones,[1682,1683] 2-phenylthiazole,[657] 3,3′-dimethyl-2,2′-biquinoline,[1684,1685] acetimine,[1686] 1-[(2-chlorophenyl)diphenylmethyl]-1H-imidazole,[1687] nucleosides,[1688] or nucleobases[1689] have been obtained from Au_2Cl_6 or tetrahaloaurate and the corresponding nitrogen base. $[AuCl_3Py]$ can also be prepared by a thermal decomposition of $[Hpy][AuCl_4]$ above 195 °C. In some cases the reaction of tetrachloroaurate with amines results in the reduction of gold(III) to yield mixed valence complexes $[AuL_2][AuCl_4]$ (L = aminoalcohol)[1679] or the gold(I) derivatives, e.g., with *n*-butylamine[1679] or with the alga *Chlorella vulgaris*.[1690] The Au^{III} binding in the nucleobase compounds have been found to be via the N(7) of the purine ring. The complex with the 1-[(2-chlorophenyl)diphenylmethyl]-1H-imidazole ligand is active against *in vitro* cultures of *Trypanosoma cruzi*, the causative agent of Chagas disease. The reaction of $[AuCl_3(THT)]$ with the pyrazolate iridium complex $[Ir(pz)(CO)(PPh_3)_2]$ leads to the heterobimetallic compound $[Ir(\mu\text{-}pz)AuCl_3(CO)(PPh_3)_2]$, which easily decomposes to $(Aupz)_n$.[1691] Substitution reactions on $[AuBr_4]^-$ by several pyridine and substituted pyridine ligands have been done and the kinetics of the forward and reverse reaction has been studied showing a dependence of the second-order rate constants upon the amine basicity.[1680]

Gold(III) complexes with monodentate nitrogen ligand have also been prepared starting from (pentafluorophenyl)gold(III) compounds. Thus, the reaction of $[Au(C_6F_5)_3(OEt_2)]$ or $[Au(C_6F_5)_2(OEt_2)_2]ClO_4$ with 3-ferrocenylpyridine (FcPy)[348] or 1,1′-bis(2-pyridylthio)ferrocene $(Fc(SPy)_2)$[349] gives the gold(III) complexes $[Au(C_6F_5)_3(FcPy)]$, $[Au(C_6F_5)_2(FcPy)_2]ClO_4$ (**284**) or $[\{Au(C_6F_5)_3\}_2\{Fc(SPy)_2\}]$ (**285**).



(284)

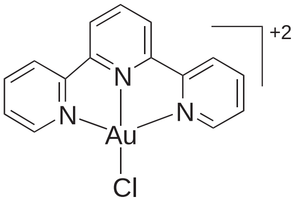


(285)

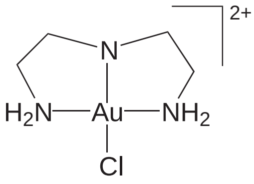
The complex *trans*-$[AuBr_2(ptm)(PEt_3)]$ (ptm = phthalimide) was prepared by oxidative addition to the corresponding gold(I) derivative, this complex rapidly isomerizes to the *cis* isomer.[1692] Similarly, the complexes with the acetimine ligands $[AuCl_3(NH{=}CMe_2)]$ and $[AuCl_2(NH{=}CMe_2)_2]ClO_4$ have been obtained by oxidation with $PhICl_2$ from the corresponding gold(I) precursor.[1686]

An excess of the nitrogen base affords complexes $[AuCl_2L_2]Cl$, as was shown with L = pyridine[1679] or adenosine.[1693] With the bidentate and tridentate ligands bipy-bipyridine, terpyridine, or substituted terpyridines, bis(2-aminoethyl)amine and bis(2-aminoethyl)amide cationic complexes $[AuCl_2(bipy)]^+$,[1694] $[AuX(terpy)]^{2+}$ (X = Cl (**286**), OH),[1695,1696] [AuCl(4′-MeS-terpy)],[1697] $[AuCl\{NH(CH_2CH_2NH_2)\}_2]^{2+}$, and $[AuCl\{N(CH_2CH_2NH_2)\}_2]^+$ (**287**),[1698] are obtained. The compounds $[AuR_2(bipy)]$ (R = Mes, CH_2TMS) present a luminescent behavior.[1698]

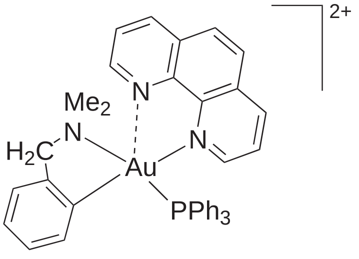
The treatment of gold(III) complexes with the rigid bidentate ligand phen allows the synthesis of pseudo-pentacoordinate gold(III) derivatives. This is the case of $[Au(dmp)(phen)PPh_3](BF_4)_2$ (**288**) (dmp = 2-(dimethylaminomethyl)phenyl)[1699] or $[AuCl(C_4Ph_4)(phen)]$.[1662] The donor atoms of the phenanthroline ligand occupy one equatorial and the axial position of a square pyramid with distances 2.154(8) Å and 2.627(10) Å in (**288**).



(**286**)

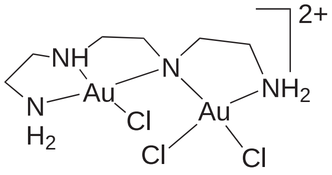


(**287**)

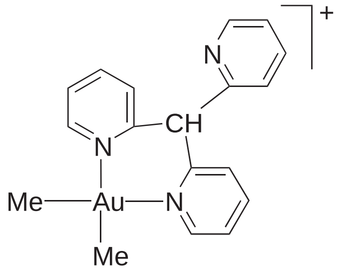


(**288**)

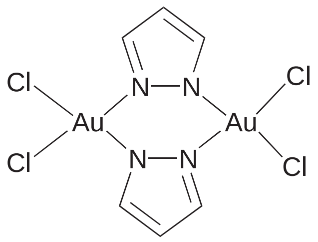
The same behavior is observed in the square-pyramidal complexes $[Au(CN)_2X(L\text{-}L)]$ (L-L = phen, 5-Mephen, 2,9-Me_2phen; X = Cl or Br) formed by reaction of *trans*-$[Au(CN)_2X_2]^-$ and the bidentate ligands. They undergo in solution a very rapid intramolecular exchange of the apical and basal nitrogen atoms, together with the loss of the halogen giving the square-planar derivatives $[Au(CN)_2(L\text{-}L)]^+$.[1700] Pentacoordination is also achieved with the ligand di-2-pyridyl ketone oximato (dpk-o) in the complex $[AuCl(dpk\text{-}o)_2]$, which has a Au—Cl distance of 2.911(2) Å.[1701] The structure of trichloro(diethylenetriamine)gold(III), $[AuCl_3(dien)]$, has been determined by EXAFS spectroscopy, that suggest that the gold(III) center has a pseudooctahedral coordination with the three nitrogen atoms from the dien ligand an one chlorine in the equatorial plane and two Au—Cl axial bonds. An XRD study confirms the overall structure but yields long axial Au—Cl lengths of 3.121 Å and 3.183 Å.[1702] The reaction of tetrachloroauric acid with triethylenediamine gives the dinuclear complex $[Au_2Cl_3(trien)]^{2+}$ (**289**).[1703]



(**289**)



(**290**)



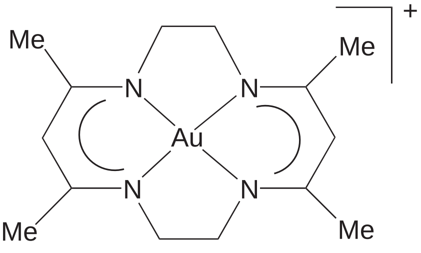
(**291**)

With more flexible ligands, such as the tridentate tris(2-pyridil)methane (tpm), tris(2-pyridil)-methanol (tpmo), or tris(1-pyrazolyl)methane (tpzm), the corresponding dimethylgold(III) complexes $[Au(Me)_2AuL]^+$ (L = tpm (**290**), tpmo, or tpzm) exhibit a *cis* square-planar coordination, with the ligands L functioning as bidentate ligands.[1704]

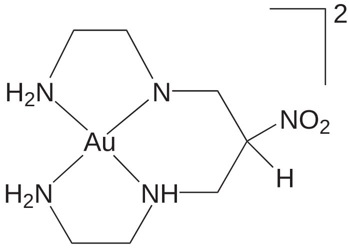
Dinuclear gold(III) complexes with bridging pyrazolato ligands of the type $[Au_2(\mu\text{-}N\text{-}N)_2Cl_4]$ (N-N = pz (**291**), 3-Me,5-Ph-pz, 3,5-Ph_2,4-Cl-pz) are obtained from the corresponding trimeric gold(I) complexes $[Au(N\text{-}N)]_3$ by oxidation with aqua regia.[1705] $[Au_2(\mu\text{–}pz)_2Cl_4]$ is also obtained by addition of potassium hydroxide in methanol to the gold(III) pyrazole compound $[AuCl_3(Hpz)]$.[1705] Oxidation of the trimeric pyrazolate compound $[Au_3(3,5\text{-}Ph_2pz)_4]$ with one equivalent of chlorine gives the mixed gold(I)–gold(III) complex $[Au_3Cl_2(3,5\text{-}Ph_2pz)_3]$.[1706] Gold(III) complexes with tris- and tetrakis(pyrazol-1-yl)borate ligands have been described and are of the type $[AuCl_2\{N,N'\text{-}(pz)_3BH\}]$, $[Au\{N,N'\text{-}(pz)_3BH_4\}_2]ClO_4$, $[AuRCl\{N,N'\text{-}(pz)_4BH\}]$ (R = $C_6H_3(N{=}NC_6H_4Me\text{-}4')\text{-}2\text{-}Me\text{-}5$), or $[AuR\{N,N'\text{-}(pz)_4B\}]ClO_4$ (R = $C_6H_4CH_2NMe_2$).[1707]

The cytotoxic activity of some of these complexes with polydentate nitrogen ligands have been tested. The complex $[AuCl_2(phen)]Cl$ has shown to be highly cytotoxic towards the A2780 tumor cell line either sensitive or resistant to cisplatin; the solution chemistry studies point out that the fragment $[Au^{III}phen]^{3+}$ is stable in solution for several hours, even under physiological conditions. The predominant species existing in solution under physiological conditions is likely to be $[Au(OH_2)_2(phen)]^+$.[1708,1709] Other complexes with polyamines such as $[Au(en)_2]Cl_3$ and $[AuCl(dien)]Cl_2$ were found to have cytotoxic properties against a human tumor cell line.[1710]

Bis(ethylenediamine)gold(III) chloride reacts with β-diketonates in aqueous base via Schiff base condensation to form complexes of gold(III) with a 14-membered macrocyclic tetraaza ligand such as (**292**).[1711–1713] The X-ray structure showed the cation to be nearly planar. Delocalization of π-electrons within the six-membered β-diketonate rings was indicated by the observed pattern of C—C and C—N distances. Open-chain tetraaza ligand complexes in which condensation of only one β-diketonate has occurred, can be isolated as intermediates in this reaction. They may be used for further condensation with a different β-diketonate. Oxidation of this complex with trityl tetrafluoroborate introduces a double bond in position C2–C3.[1712,1714]



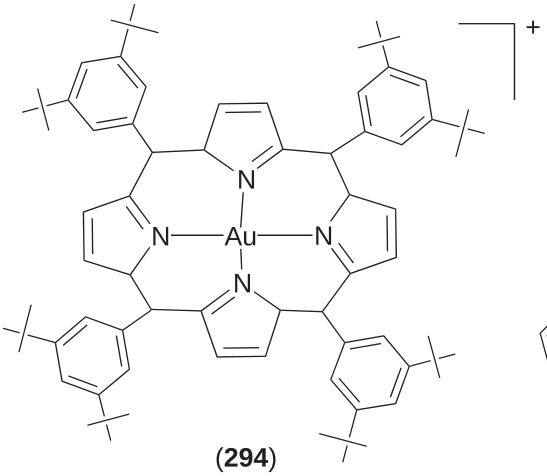
(**292**)



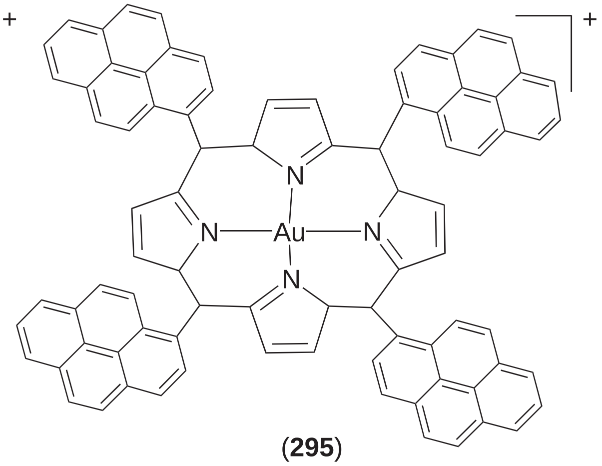
(**293**)

Other complexes with tetraaza macrocycles have been prepared by reaction of $[Au(en)_2]Cl_3$, ethylenediamine, or nitroethane and formaldehyde, although with nitroethane an acyclic ligand was also obtained (**293**).[1715,1716] A gold(III) complex with a hexaaza macrocycle (1,8-dimethyl-1,3,6,8,10,13-hexaazacyclotetradecane) has been obtained by a transmetallation reaction from the nickel compound $[NiL]^{2+}$ by reaction with $[AuCl_4]^-$.[1717] The chemistry of tetraazamacrocycles in aqueous solution has been reported.[1718]

Gold(III) porphyrins have been used as acceptors in porphyrin diads[1719,1720] and triads[1721] due to their ability to be easily reduced, either chemically or photochemically. A new method for the incorporation of gold(III) into porphyrins (**294**) has been described and consist of the disproportionation of $[Au(THT)_2]BF_4$ in mild conditions.[1722] The complex tetrakis(1-pyrenyl)porphyrinatogold(III) acetate was prepared by metalation of the atropisomeric mixture of the free-base porphyrin ligand with $[AuCl_4]^-$ in glacial acetic acid (**295**).[1723] Optical studies have been carried out and have shown that this system has the potential to serve as a novel type of catalytic photonuclease for the long-wavelength sensitized cleavage of DNA and other guanine-containing nucleic acids.[1724]



(**294**)



(**295**)

Addition of ammonia to tetrachloroauric(III) acid of gold(III) oxide hydrate yields a highly explosive yellow solid. Although this fulminating gold, as it is called, is probably the oldest known gold nitrogen compound, known since the Middle Ages, its constitution remained unknown until recently. Primary studies concluded that these reactions afford products of compositions $[NH\{AuCl(NH_2)\}_2]$ or $Au_2O_3{\cdot}3NH_3$. The latest studies show that fulminating gold is part of a reversible equilibrium with $[Au(NH_3)_4]^{3+}$ and $NH_4[AuCl_4]$. Both products are stable and not explosive. $[Au(NH_3)_4]^{3+}$ is a weak acid that in the pH range 2–5 slowly hydrolyzes to give $[Au(NH_3)_3OH]^{2+}$, but at higher pH the tetraamine ion transforms in its conjugate base $[Au(NH_2)(NH_3)_3]^{2+}$ that finally forms fulminating gold.[1725] It can be assumed that fulminating gold is a product of further deprotonation and partial hydrolysis of $[Au(NH_2)(NH_3)_3]^{2+}$.

Substitution reactions of $[Au(NH_3)_4]^{2+}$ in acidic solution by halogens were studied by Skibsted. The ammine ligands are substituted by Cl^- or Br^- to finally yield the tetrahalo anions $[AuX_4]^-$, while with I^- reduction to $[AuI_2]^-$ occurs.[1726–1728] Since the rate of substitution of ammonia by chloride or bromine is lowered by five orders of magnitude after substitution of two of the first ammine ligands, it was possible to isolate the complex *trans*-$[AuBr_2(NH_3)_2]Br$.[1729] Other complexes described with ammine as ligands are $[AuBr_3(NH_3)]$[1730] obtained by substitution in the chloro derivative[1731] or $[Au(C_6F_5)_3(NH_3)]$ or $[Au(C_6Cl_5)_2Cl(NH_3)]$, prepared by substitution of the labile ligand tetrahydrothiophene[1732] or cleavage of chlorine bridges.[1641] Dimethylamido complexes of the type $[AuMe_2(NR_2)]_n$ have been synthesized by reaction of $[AuMe_2(NH_3)_2]^+$ with KNH_2, LiNHMe, or $LiNMe_2$.[1733] The structure of $[AuMe_2(NMe_2)]_2$ was established and is a dimer[1734] whereas a tetranuclear structure similar to that in $[AuMe_2(OH)]_4$ is proposed in the others.

The structures of the tetraazido complexes $AsPh_4[Au(N_3)_4]$[1735,1736] and $Na[Au(N_3)_4]{\cdot}2H_2O$ have been determined.[1737] In the first one the tetraazidogold(III) anion adopts a whirl-wind configuration with the symmetry C_4, while a lower symmetry was found in the sodium salt. Bridging azido, thiocyanate, or cyano ligands are also presented in organometallic complexes of gold(I) and gold(III), as in $[Au(C_6F_5)_3(\mu\text{-}X)Au(PPh_3)]$, $[Au(C_6F_5)_2(PPh_3)(\mu\text{-}X)Au(C_6F_5)]$, $[Au(C_6F_5)_3(\mu\text{-}X)Au(C_6F_5)_2(PPh_3)]$, and $[Au(C_6F_5)_3(\mu\text{-}X)Au(C_6F_5)_3]$ ($X = N_3^-$, SCN^-, CN^-)[505,1738,1739] or $[Au_2(\mu\text{-}X)_2(C_6F_5)_4]$ ($X = N_3^-$, SCN^-).[1657] Some nitrile complexes have been obtained by substitution of the diethyl ether ligand in $[Au(C_6F_5)_3(OEt_2)]$ by NCR (NCR = NCMe, NCPh, NCPr, $NCCH{=}CH_2$, *o*-$(NC)_2C_6H_4$).[1740]

6.7.3.2.3 Complexes with phosphorus, arsenic, antimony, or bismuth donor ligands

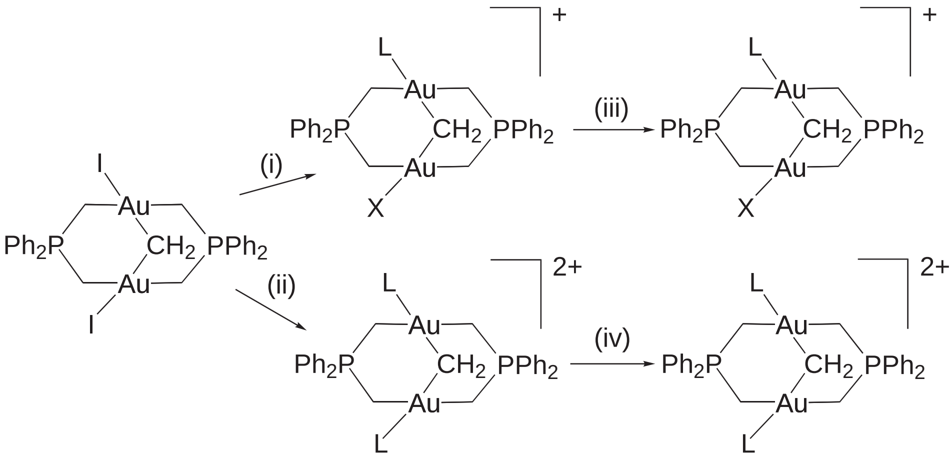
Most of the (phosphine)gold(III) complexes known in the literature have a square-planar stereochemistry. They are generally stable and can be prepared by two methods: oxidation of the corresponding gold(I) complexes, or substitution processes of weakly coordinated ligands.

(i) Monodentate ligands

Complexes $[AuX_3(PR_3)]$ (X = Cl, Br; $PR_3 = PMe_3$, PEt_3, PPh_3, 1-phenyl-3,4-dimethylphosphole, or 1-phenyldibenzophosphole) are prepared by oxidation of the gold(I) derivative $[AuX(PR_3)]$ with the corresponding halogen.[1741–1743] Mixed halogen derivatives $[AuX^1X^2{}_2(PR_3)]$ can also be prepared in an analogous way, probably as pure solid compounds, but in solution the NMR spectra have shown that all possible combinations and isomers of formula $[AuX_nX'_{3-n}(PR_3)]$ are present.[1743] The structures of $[AuX_3(PR_3)]$ molecules show that the Au—X bond *trans* to the phosphorus atoms is longer than the others. $[AuBr_2Cl(PR_3)]$ molecules are substitutionally disordered in the crystal, probably with two-thirds bromine and one-third chlorine on each site.[1743] The gold(III) complex *trans*-$[AuBr_2(ptm)(PEt_3)]$, which isomerizes readily to give the *cis*-isomer, has been prepared by oxidative addition of bromine to *trans*-$[Au(ptm)(PEt_3)]$.[1692]

Displacement of tetrahydrothiophene or diethyl ether from $[Au(C_6F_5)_3(THT)]$, $[Au(C_6F_5)_3(OEt_2)]$, or cleavage of the chloro bridges in $[Au_2(\mu\text{-}Cl)_2(C_6F_5)_4]$ by phosphine, arsine, or stibine ligands gives complexes of the type $[Au(C_6F_5)_3L]$ ($L = PMePh_2$, $P(OPh)_3$, $FcCH_2PPh_2$, $FcPh_2P$, $AsPh_3$, $SbPh_3$, 2-$PPh_2C_6H_4SH$), or $[Au(C_6F_5)_2Cl(PPh_2Fc)]$.[709,1732,1744–1746] Addition of PPh_3 to solutions of the cyclometallated derivatives [Au(C-N)RCl] (C-N = 2-$C_6H_4N{=}NPh$; $R = C_6F_5$, CH_2COMe) leads to displacement of the nitrogen atom of the chelate ligand and the formation of $[Au(C\text{-}N)RCl(PPh_3)]$.[1747,1748] The complex with $R = C_6F_5$ slowly decomposes in solution to give a mixture of $[Au(C_6F_5)PPh_3]$, 2-C_6F_5-$C_6H_4N{=}NPh$, and $[Au(C\text{-}N)Cl_2(PPh_3)]$.[1748] With the cyclometallated complexes $[Au(C\text{-}N)Cl_2]$ (C-N = 2-$C_6H_4CR_2C_5H_5N$, R = H, Me), the reaction with PPh_3 leads to the formation of cationic compounds $[Au(C\text{-}N)Cl(PPh_3)]^+$.[1749]

The methylene-bridged dinuclear gold(III) complex $[Au_2(\mu\text{-}CH_2)\{\mu\text{-}(CH_2)_2PPh_2\}_2I_2]$ reacts with $[Ag(OClO_3)L]$ (L = PPh_3, PPh_2Me, THT) to give the cationic derivatives $[Au_2(\mu\text{-}CH_2)\{\mu\text{-}(CH_2)_2PPh_2\}_2IL]ClO_4$ or $[Au_2(\mu\text{-}CH_2)\{\mu\text{-}(CH_2)_2PPh_2\}_2L_2](ClO_4)_2$ when a 1:1 or 1:2 molar ratio is used, respectively. When L is THT this can be displaced easily by other ligands such as $AsPh_3$ (Scheme 12).[1750]



Scheme 12 (i) $[Ag(OClO_3)L]$, (ii) 2 $[Ag(OClO_3)L]$, (iii) $AsPh_3$(L = THT), (iv) 2 $AsPh_3$ (L = THT); L = PPh_3, PPh_2Me, THT.

The gold(III) complex $[Au(C_6F_5)_3(PPh_2C{\equiv}CH)]$ has been synthesized and contains a phosphinoalkyne. Reactions with sodium alkoxides lead to the single or double addition to the alkyne-phosphine fragment giving $[Au(C_6F_5)_3(PPh_2CH{=}CHOR)]$ or $[Au(C_6F_5)_3\{PPh_2CH_2{=}C(OR)_2\}]$ (R = Me, Et).[1751]

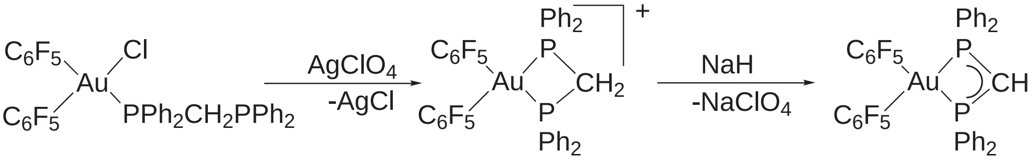
(ii) Polydentate ligands

The reaction with potentially bidentate ligands (L-L) takes two different courses:

(i) phenylene-1,2-bis(dimethylarsine), $Ph_2PCH_2PPh_2$, $Ph_2PNHPPh_2$, or $Ph_2PC({=}CH_2)PPh_2$ act as monodentate ligands in $[Au(C_6F_5)_3(L\text{-}L)]$[1271,1650,1732] and
(ii) $Ph_2P(CH_2)_2PPh_2$ (dppe) functions as a bridging ligand in a binuclear derivative $[\{Au(C_6F_5)_3\}_2(\mu\text{-dppe})]$.[1732]

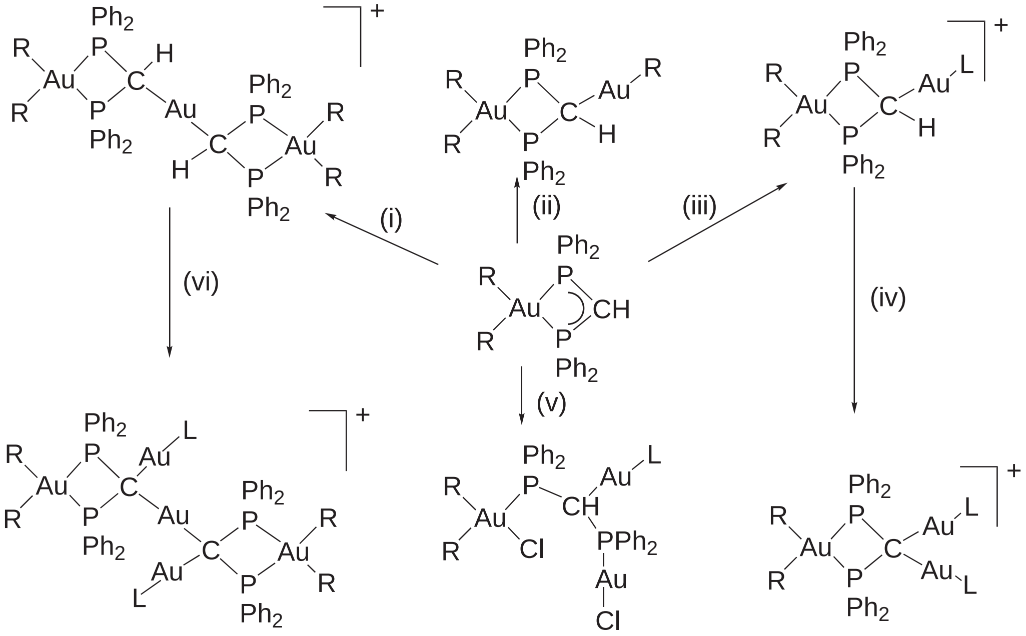
The complex $[Au(C_6F_5)_3\{Ph_2PC({=}CH_2)PPh_2\}]$ reacts with gold(I) compounds with coordination of the gold(I) center to the uncoordinated phosphorus atom to give complexes of the type $[Au(C_6F_5)_3(Ph_2PC({=}CH_2)PPh_2)AuX]$ (X = Cl, C_6F_5, ACAC) or $[\{Au(C_6F_5)_3(Ph_2PC({=}CH_2)PPh_2)\}_2Au]ClO_4$.[1271]

The cleavage of binuclear $[\{Au(Cl)(C_6F_5)_2\}_2]$ with the diphosphine $Ph_2PCH_2PPh_2$ gives *cis*-$[Au(\mu\text{-}Cl)(C_6F_5)_2(PPh_2CH_2PPh_2)]$, which has a ^{31}P NMR spectrum analogous of that of $[Au(C_6F_5)_3(PPh_2CH_2PPh_2)]$, showing the presence of one uncoordinated phosphorus atom. Both derivatives react with $[Au(OClO_3)(PPh_3)]$ or $[AuX(THT)]$ (X = Cl or C_6F_5), to form cationic binuclear complexes of the types *cis*-$[Au(Cl)(C_6F_5)_2(PPh_2CH_2PPh_2)Au(PPh_3)]ClO_4$ and $[Au(C_6F_5)_3(PPh_2CH_2PPh_2)Au(PPh_3)]ClO_4$, or of neutral *cis*-$[Au(Cl)(C_6F_5)_2(PPh_2CH_2PPh_2)AuX]$ and $[Au(C_6F_5)_3(PPh_2CH_2PPh_2)AuX]$, respectively.[1732] The abstraction of chlorine from *cis*-$[Au(Cl)(C_6F_5)_2(PPh_2CH_2PPh_2)]$ by $AgClO_4$ gives *cis*-$[Au(C_6F_5)_2(\mu\text{-}PPh_2CH_2PPh_2)]ClO_4$. The reaction of the latter with NaH causes both deprotonation of the methylene group and elimination of the perchlorate anion to give the neutral (phosphino)methanide complex $[Au(C_6F_5)_2(\mu\text{-}PPh_2CHPPh_2)]$ (Scheme 13).[1744,1752] Similar reactions are obtained with the diarsine ligand $Ph_2AsCH_2AsPh_2$.[1651]



Scheme 13

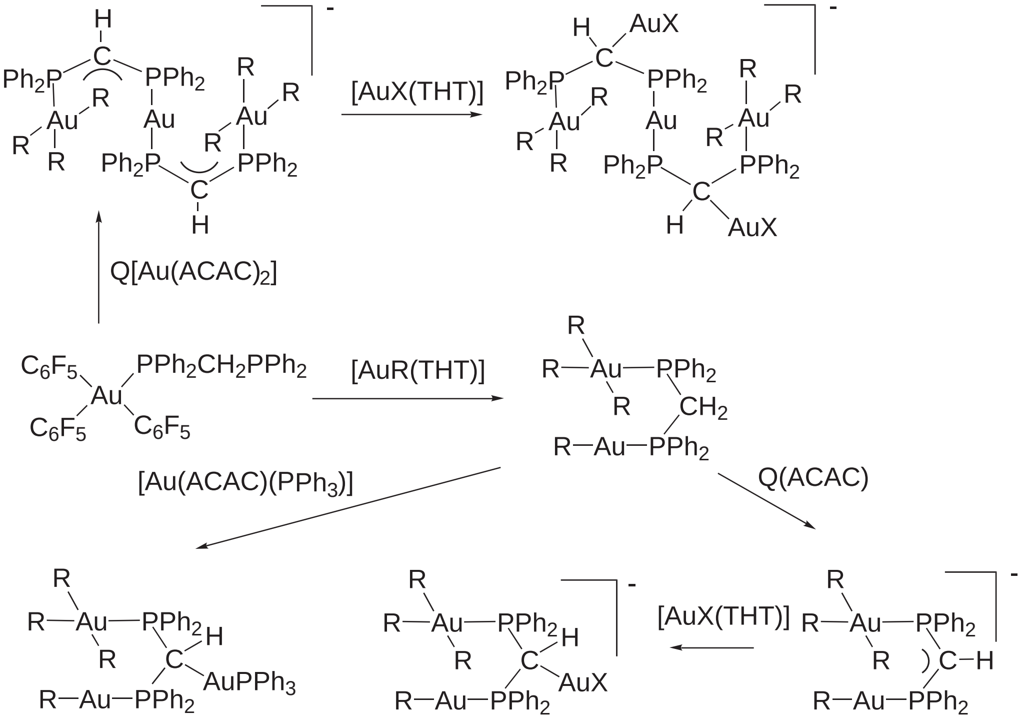
The complex $[Au(C_6F_5)_2(\mu\text{-}PPh_2CHPPh_2)]$ can act as C-donor nucleophile in reactions with $[Au(OClO_3)(PPh_3)]$, $[AuX(THT)]$, $[Au(THT)_2]ClO_4$, or $[Au(ACAC)(PPh_3)]$ to form the dinuclear or trinuclear complexes. The use of acetylacetonate (ACAC) complexes allows the double deprotonation of the methylene group and the coordination of two gold(I) centers to the methanediide C-atom (Scheme 14).[1752–1754]



Scheme 14 R = C_6F_5, L = PPh_3; (i) $[Au(THT)_2]ClO_4$, (ii) AuR(THT)], (iii) $[Au(OClO_3)L]$, (iv) $[Au(ACAC)L]$, (v) $2[AuClL]$, (vi) $2[Au(ACAC)L]$.

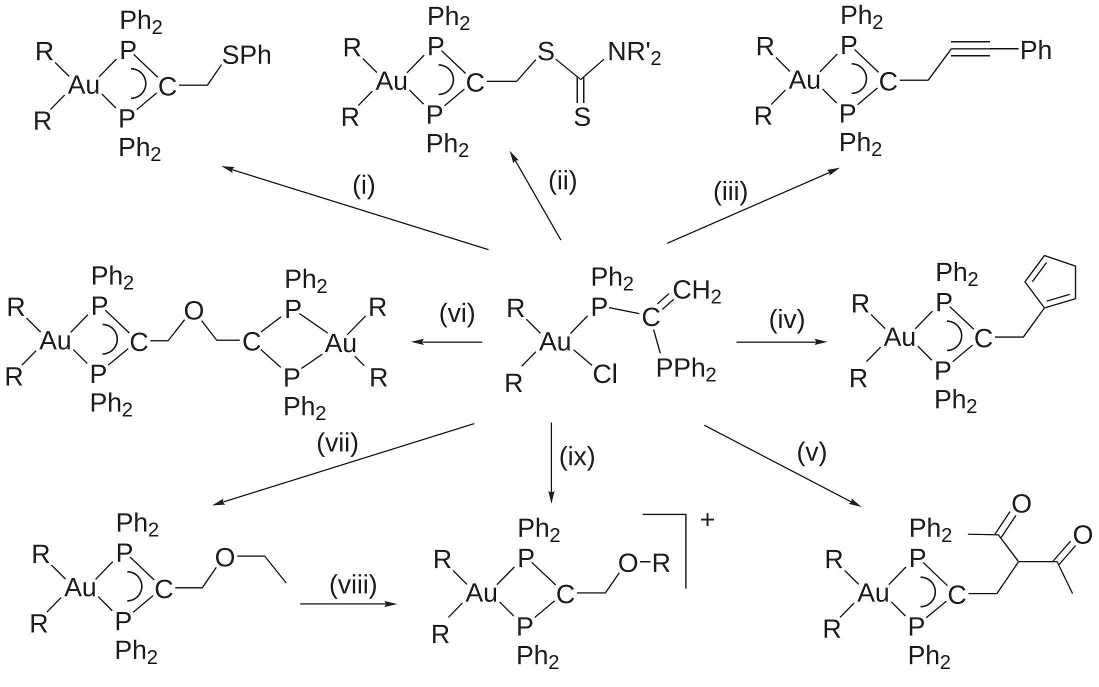
Other phosphinomethanide gold(III) complexes have been obtained starting from $[Au(C_6F_5)_3(PPh_2CH_2PPh_2)]$ by reaction with acetylacetonate salts. Thus the treatment with $Bu_4N[Au(ACAC)_2]$ affords the anionic trinuclear compound $Bu_4N[\{Au(C_6F_5)_3(PPh_2CHPPh_2)\}_2Au]$, that can further react with the gold(I) complexes $[AuX(THT)]$ with coordination of the AuX fragment to the methanide carbon (Scheme 15).[1755] Also the uncoordinated phosphorus atom in $[Au(C_6F_5)_3(PPh_2CH_2PPh_2)]$ can displace tetrahydrothiophene from $[Au(C_6F_5)(THT)]$ giving $[Au(C_6F_5)_3(PPh_2CH_2PPh_2)Au(C_6F_5)]$, and the latter can react further with acetylacetonate complexes to yield new mixed gold(I)–gold(III) methanide derivatives (Scheme 15).[1756]

The bidentate ligands 3,4-bis(diphenylphosphinoamino)toluene and 1,2-bis(diphenylphosphinoamino)benzene reacts with the gold(III) compounds $[Au(C_6F_5)_3(OEt_2)]$ or $[Au(C_6F_5)_2(OEt)_2]ClO_4$ to give complexes $[Au(C_6F_5)_3\{(PPh_2NH)_2C_6H_4R\}]$, $[\{Au(C_6F_5)_3\}_2\{\mu\text{-}(PPh_2NH)_2C_6H_3R\}]$, or $[Au(C_6F_5)_2\{(PPh_2NH)_2C_6H_3R\}]ClO_4$ (R=H,Me). The amino group can be deprotonated with $NBu_4(ACAC)$ and further coordinate a $AuPPh_3^+$ fragment yielding (**296**). Mixed gold(I)–gold (III) species of the type $[\{Au(C_6F_5)_3\}(AuX)\{\mu\text{-}(PPh_2NH)_2C_6H_4R\}]$ are obtained from $[Au(C_6F_5)_3\{(PPh_2NH)_2C_6H_4R\}]$ by reaction with $[AuX(THT)]$ ($X = Cl$, C_6F_5).[1757] The complexes $[AuCl_2\{\mu\text{-}(PR_2)_2C_2B_9H_{10}\}]$ ($R = Pr^i$, Ph (**297**)), which possess a bidentate chelate *nido*-carborane diphosphine ligand, have been obtained by heating solutions of $[AuCl_3(THT)]$ with the *closo*-diphosphines $(PR_2)_2C_2B_{10}H_{10}$.[1759,1760] The vinylidenebis(diphenylphosphine) reacts with



Scheme 15 R = C_6F_5; X = Cl, C_6F_5; Q = NBu_4, $N(PPh_2)_2$.

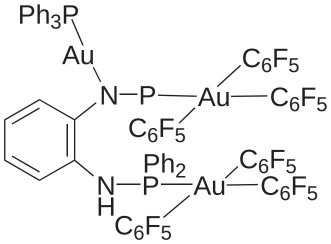
$[Au_2(\mu\text{-}Cl)_2(C_6F_5)_4]$ to yield $[Au(C_6F_5)_2Cl\{PPh_2C(=CH_2)PPh_2\}]$. The coordination of this diphosphine to the gold(III) center strongly activates the carbon–carbon double bond, and this complex, therefore, undergoes Michael-type additions with several carbon-, sulfur-, or oxygen-based nucleophiles. The addition takes place at the terminal carbon of the double bond, giving methanide-type complexes (Scheme 16).[1761]



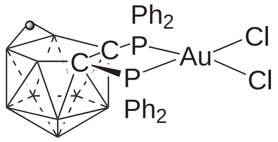
Scheme 16 R=C_6F_5 (i) NaSPh, (ii) $NaS_2CNR'_2$, (iii) AgCCPh, (iv) TlCp, (v) Tl(ACAC), (vi) 1/2 Ag_2O, (vii) NaOEt, (viii) $HClO_4$, (ix) $AgClO_4$ + OR.

The reaction of the dinuclear complexes *trans*-$[MX_2(AsPh_2CH_2AsPh_2AuX)_2]$ (M = Pd or Pt; X = Cl or Br) with the appropriate dihalogen leads to the gold(III) compounds *trans*-$[MX_2(AsPh_2CH_2AsPh_2AuX_3)_2]$ or *trans*-$[MX_4(AsPh_2CH_2AsPh_2AuX_3)_2]$.[1762] The palladium complex $[Pd(C_6F_5)_2(PPh_2CH_2PPh_2)_2]$ reacts with two equivalents of $[Au(C_6F_5)_3(THT)]$ to give the heteronuclear derivative $[Pd(C_6F_5)_2(PPh_2CH_2PPh_2)_2\{Au(C_6F_5)_3\}_2]$.[1763]

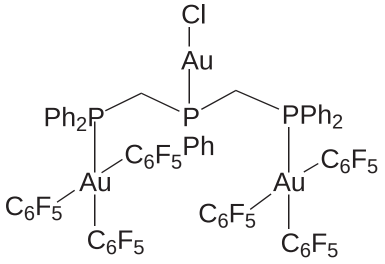
The triphosphine ligand bis(diphenylphosphinomethyl)phenylphosphine (dpmp) forms mono- or dinuclear gold(III) derivatives of the types $[\{Au(C_6F_5)_3\}_2(dpmp)]$, in which the gold(III) fragments are coordinated to the ended phosphorus or $[Au(C_6F_5)_3(dpmp)]$, for which the crystal structure shows the gold coordinated to the central phosphorus atom, although two isomers are observed in solution. $[\{Au(C_6F_5)_3\}_2(dpmp)]$ reacts with gold(I) compounds to give the mixed-valence trinuclear complexes $[\{Au(C_6F_5)_3\}_2(AuX)(dpmp)]$ (X = Cl (**298**), C_6F_5).[1764] With the related ligand bis(diphenylphosphinoethyl)phenylphosphine (dpep) the gold(III) derivatives $[\{Au(C_6F_5)_3\}_2(dpep)]$ or $[\{Au(C_6F_5)_3\}_3(dpep)]$ have been synthesized. The latter shows a luminescent behavior, which is not common for gold(III) complexes.[1765]



(**296**)



(**297**)

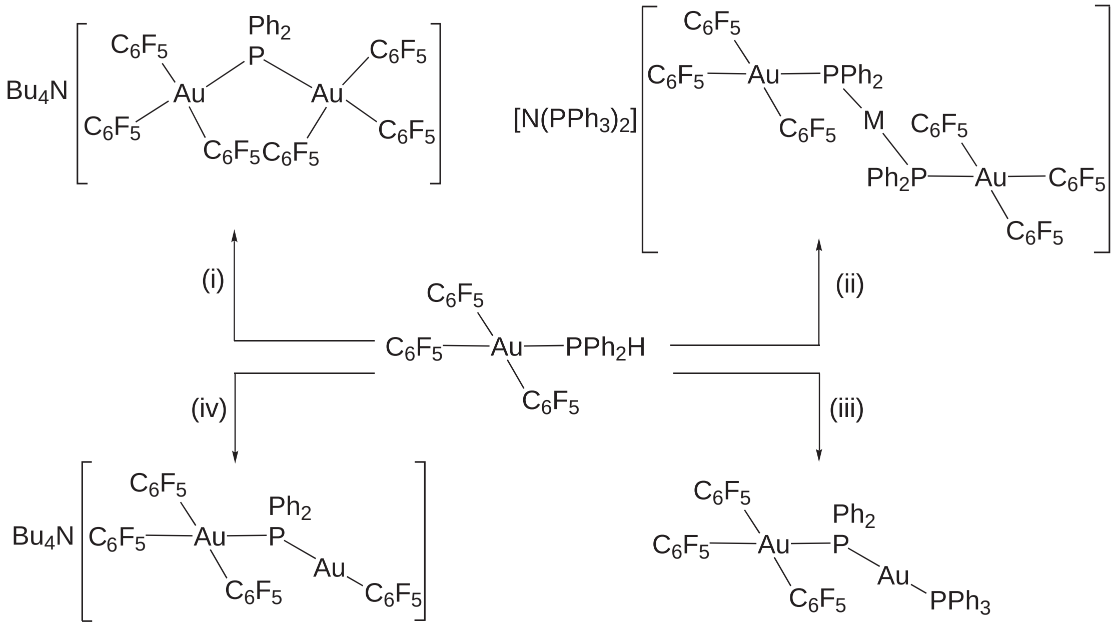


(**298**)

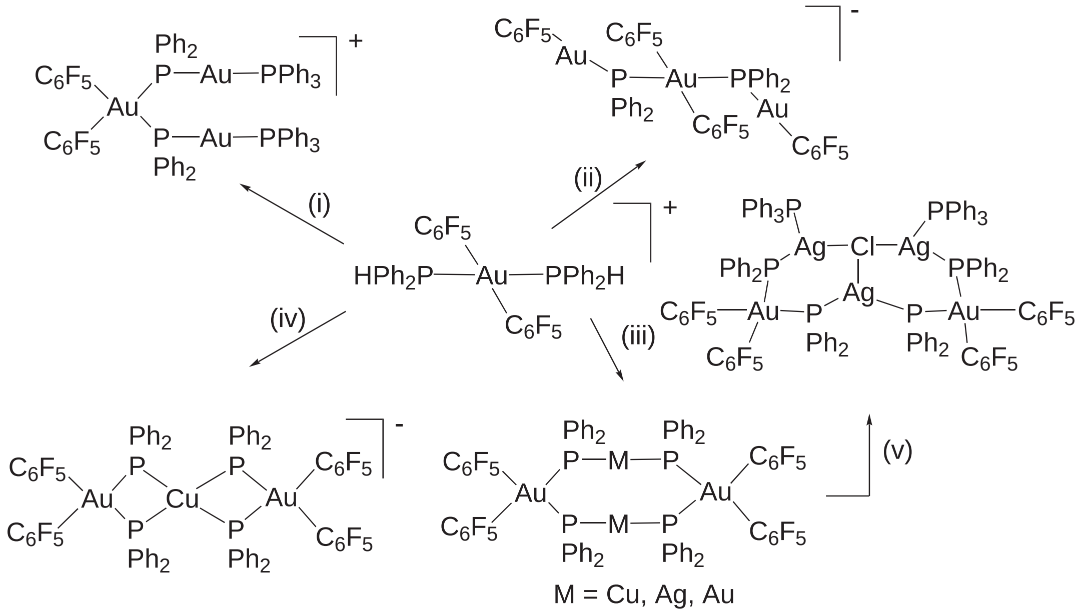
Other gold(III) complexes with triphosphines as ligands are those obtained with the 1,1,1-tris(diphenylphosphinomethyl)ethane (triphos) which form compounds of the type $[Au(C_6F_5)_3(\eta^1\text{-triphos})]$ or $[Au(C_6F_5)_2(\eta^2\text{-triphos})]Cl$. The uncoordinated phosphorus atoms in $[Au(C_6F_5)_3(\eta^1\text{-triphos})]$ are used for further coordination to other gold(I) centers to give $[Au(C_6F_5)_3(\mu\text{-triphos})(AuX)_2]$ (X = Cl, C_6F_5), $[Au(C_6F_5)_3(\eta^1,\eta^2\text{-triphos})(AuPPh_3)]$, or $[\{Au(C_6F_5)_3(\mu\text{-triphos})\}_2Au]$. Compound $[Au(C_6F_5)_2(\eta^2\text{-triphos})]Cl$ reacts with $[Au(C_6F_5)_3(THT)]$ to yield $[Au(C_6F_5)_2(\mu\text{-triphos})Au(C_6F_5)_3]Cl$.[1766] Heterodinuclear complexes of the type $[M(CO)_4(\eta^2,\eta^1\text{-triphos})Au(C_6F_5)_2X]$ (M = Mo, W; X = Cl, C_6F_5) with this triphosphine ligand are achieved by reaction of $[M(CO)4(\eta^2\text{-triphos})]$ with $[Au(C_6F_5)_3(THT)]$ or $[Au_2(\mu\text{-Cl})_2(C_6F_5)_4]$.[1767] The reaction of $[Au(C_6F_5)_2(ACAC)]$ with the tris(diphenylphosphino)-methane ligand affords the gold(III) methanide complex $[Au(C_6F_5)_2\{(PPh_2)_2CPPh_2)\}]$. Further reaction of this complex with the gold(I) compounds $[AuX(THT)]$ or $[Au(THT)_2]ClO_4$ or the silver(I) salt $AgClO_4$ gives the dinuclear $[Au(C_6F_5)_2\{(PPh_2)_2CPPh_2\}AuX]$ (X = Cl, C_6F_5) or trinuclear $[\{Au(C_6F_5)_2\{(PPh_2)_2CPPh_2\}\}_2M]ClO_4$ (M = Au, Ag). With gold(III) the following derivatives are obtained $[Au(C_6F_5)_2\{(PPh_2)_2CPPh_2\}Au(C_6F_5)_2X]$ (X = Cl, C_6F_5) or $[\{Au(C_6F_5)_2\{(PPh_2)_2CPPh_2\}\}_2\{Au(C_6F_5)_2\}]ClO_4$.[1768]

(iii) Bridging phosphido ligands

Although the chemistry of phosphido-bridged transition metal complexes is well represented, the corresponding gold chemistry has only recently developed. The synthesis of gold(III) derivatives with diphenylphosphine PPh_2H and further treatment with acetylacetonate compounds gives stable phosphido-bridged gold(III) derivatives. Thus the reaction of $[Au(C_6F_5)_3(THT)]$ or $[Au(C_6F_5)_2(OEt_2)_2]ClO_4$ with diphenylphosphine leads to the complexes $[Au(C_6F_5)_3(PPh_2H)]$ or $[Au(C_6F_5)_2(PPh_2H)_2]ClO_4$, that are useful starting materials to prepare polynuclear derivatives by reaction with acetylacetonate compounds (see Schemes 17 and 18).[1769,1770] The reaction of PPh_2H with $[Au_2(\mu\text{-Cl})_2(C_6F_5)_4]$ gives directly the phosphido-bridged species $[Au_2(\mu\text{-PPh}_2)_2(C_6F_5)_4]$.[1771] The treatment of the mixed gold(III)–silver(I) diphenylphosphide complex $[Au(C_6F_5)_3(\mu\text{-PPh}_2)Ag]_2$ with $[AgCl(PPh_3)_2]$ leads to the insertion of the latter to give $[\{Au(C_6F_5)_2(\mu\text{-PPh}_2)_2AgPPh_3\}_2(\mu\text{-Ag})(\mu_3\text{-Cl})]$ (Scheme 18).[1772]



Scheme 17 (i) $[N(PPh_3)_2][Au(C_6F_5)_3(ACAC)]$, (ii) $1/2[N(PPh_3)_2][Au(ACAC)]$, $AgClO_4+$ $[N(PPh_3)_2]ACAC$, (iii) $[Au(ACAC)(PPh_3)]$, (iv) $[Au(C_6F_5)(THT)]$, $NBu_4(ACAC)$.



Scheme 18 (i) $2[Au(ACAC)(PPh_3)]$, (ii) $2[Au(C_6F_5)(THT)]$, $2NBu_4(ACAC)$, (iii) $[N(PPh_3)_2]$ $[Au(ACAC)_2]$, $AgClO_4$ or $[Cu(NCMe)_4]OTf + [N(PPh_2)_2]ACAC$, (iv) $[Cu(NCMe)_4]OTf+$ $[N(PPh_2)_3]ACAC$, (v) $[AgCl(PPh_3)_2]$.

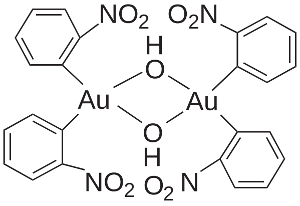
6.7.3.2.4 Complexes with oxygen donor ligands

Gold shows low affinity for binding to oxygen ligands. Generally these complexes are thermally unstable as the Au—O bond is very weak, and for this reason gold compounds with oxygen ligands are expected to be highly reactive and they may display an interesting reaction chemistry.

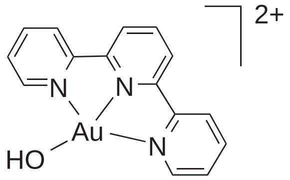
For example gold(III) complexes with β-diketonates or alkylsiloxydes, are likewise employed as precursors for CVD.[1773,1774] Another promising result in the field of homogeneous catalysis is the discovery that gold(III) alkoxo complexes promoted the condensation of benzaldehyde with compounds containing an active methylene group.[1775]

(i) Hydroxo, oxo, and alkoxo complexes

Gold(III) hydroxo complexes are generally obtained by reaction of the corresponding precursor with NaOH or KOH in aqueous solution. The hydroxo-bridged complex $[Au(C_6H_4NO_2\text{-}2)_2(\mu\text{-}OH)]_2$ (**299**) has been obtained either by reaction of $Na[Au(C_6H_4NO_2\text{-}2)_2(OPh)_2]$ with traces of water in CH_2Cl_2/*n*-hexane solution or by treatment of the dichloroaurated complex with NaOH.[1776] Monomeric gold(III) hydroxo complexes have been described very recently and all of them feature a polypyridine as coligand. The terpy derivative $[Au(OH)(terpy)](ClO_4)_2$ (**300**)[1696] was isolated in the course of equilibrium and kinetic studies of gold(III) complexes with terpy carried out in aqueous solution. The intermediate species $[Au(OH_2)(terpy)]^{3+}$ behave as a strong acid that dissociates completely into the corresponding hydroxo complex, isolated as the perchlorate salt.



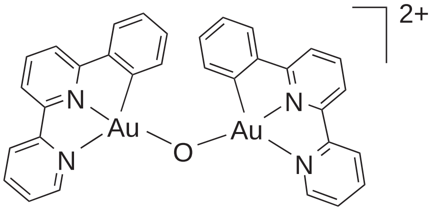
(**299**)



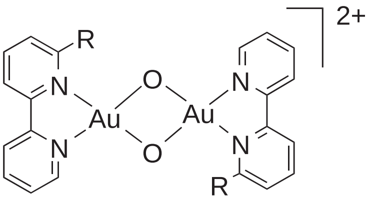
(**300**)

Treatment of the cyclometallated complex $[Au(C,N,N)Cl]PF_6$ (HC,N,*N* = 6-(1,1-dimethylbenzyl)-2,2′-bipyridine) with KOH in aqueous media gave the hydroxo complex $[Au(C,N,N)(OH)]PF_6$.[1777,1778] This complex has been evaluated as a potential antitumor agent, and the preliminary studies show relevant cytotoxic effects towards a variety of tumor cell lines.[1778,1779] Other monomeric hydroxo complexes are the two bipy derivatives, $[AuCl(OH)(bipy)]PF_6$ and $[Au(OH)_2(bipy)]PF_6$, which have been obtained by the hydrolysis of $[AuCl_2(bipy)]PF_6$ in aqueous solution.[1780] These compounds undergo proton exchange in ROH solution to give the corresponding alkoxides. The electrochemical behavior of the oxo species shows an irreversible one-electron reduction process.[1781]

Oxo complexes are, in most cases, obtained by deprotonation or by condensation of hydroxo species. The cyclometallated derivatives $[Au_2(C,N,N)_2(\mu\text{-}O)]X_2$ (C,N,*N* = $N_2C_{10}H_7(CMe_2C_6H_4)$-6, $N_2C_{10}H_7(CHMeC_6H_4)$-6; X = PF_6, BF_4)[1782] (**301**) and the 2,2′-bipyridine derivative $[Au(\mu\text{-}O)(6\text{-}R\text{-}2,2'\text{-}bipy)]_2(PF_6)_2$ (R = H, CH_2Me, $CHMe_2$, CMe_3, CH_2CMe_3) (**302**)[1783] are rare examples of metal oxo complexes with an unsupported M-O-M bridge (M = late transition metal).



(**301**)



(**302**)

Gold(III) alkoxo complexes are stabilized by a variety of ancillary ligands. Some of them, as with $[Au_2(\mu\text{-}OTMS)_2Me_4]$ which was synthesized some time ago[1784] have found recent applications as precursor for CVD.[1785] Thermally stable aryloxo and fluoroalkoxo complexes of the type

$[AuMe_2(OR)(PPh_3)]$ ($R = Ph$, *p*-Tol, CH_2CF_3, $CH(CF_3)_2$) have been prepared by metathesis of *cis*-dimethyliodo(triphenylphosphine)gold(III) with potassium alkoxides (Equation (15)):[1786]

$$cis\text{-}[AuMe_2I(PPh_3)] + KOR \longrightarrow cis\text{-}[AuMe_2(OR)(PPh_3)] + IK \qquad (15)$$

The reaction of these complexes with metal hydrides of the type $[CoH(CO)_4]$, $[MnH(CO)_3]$, $[MoHCp(CO)_3]$, $[WHCp(CO)_3]$, or $[WHCp(CO)_2(PMe_3)]$ progresses with the liberation of alcohol, ethane, and the corresponding gold(I) derivatives.[1787]

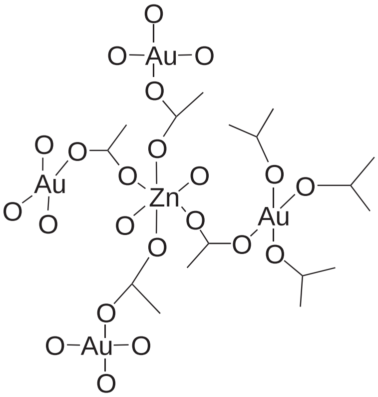
The reaction with active methylene compounds results in the hydrogen abstraction to give the alcohol and the organogold derivatives.[1786]

These alkoxo complexes are also capable of cleavage of the C—Si bond of $TMSCF_3$. The gold(III) fluoroalkoxides *cis*-$[AuMe_2(OR)(PPh_3)]$ ($R = CH_2CF_3$, $CH(CF_3)_2$) can act as catalysts for the Knöevenagel condensation reaction.[1775]

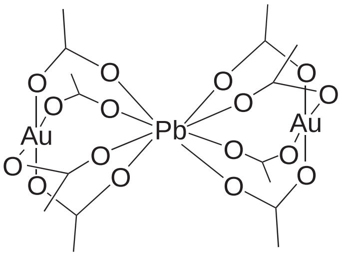
Some alkoxo complexes of the type *cis*-$[AuMe_2(OR)(PPh_3)]$ ($R = Me$, Et, Pr^i) have been prepared *in situ* from *cis*-$[AuMe_2I(PPh_3)]$ and sodium alkoxide in alcohol or by alcoholysis of *cis*-$[AuMe_2(CH_2CH{=}CHMe)(PPh_3)]$ in methanol; the highly reactive alkoxide species readily insert carbon monoxide to give the alkoxocarbonyl complexes *cis*-$[AuMe_2(COOR)(PPh_3)]$.[1788,1789] Other gold(III) alkoxo complexes are $[AuMe_2\{OCH(Ph)CH_2CH{=}CH_2\}(PPh_3)]$,[1790] $Na[Au(C_6H_4NO_2\text{-}2)_2(OPh)_2]$,[1776] $[Au(N,N,C)(OR)]PF_6$ ($N,N,C = N_2C_{10}H_7(CMe_2C_6H_4)\text{-}6$, $N_2C_{10}H_7(CHMeC_6H_4)\text{-}6$, 2,2′-bipy; $R = Me$, Et, Pr^i, $CH_2C_6H_4NO_2\text{-}3$, Ph, *p*-Tol),[1791] $[AuCl(OR)(bipy)]PF_6$ or $[Au(OR)_2(bipy)]PF_6$ ($R = Me$, Et, Pr^i).[1780]

(ii) Complexes with other oxygen donor ligands

Mixed-metal salts with carboxilate, sulfate, or acetate have been synthesized. The gold(III) sulfates $MAu(SO_4)_2$ ($M = Na$, K, Rb) are obtained by evaporation of $Au(OH)_3$ and Na_2SO_4 in concentrated sulfuric acid. The gold atoms are coordinated by four oxygen atoms of different SO_4^{2-} groups, forming an infinite chain;[1792] in the cesium salt there are 2D layers.[1793] The salts $M(AuX_4)_2$ ($X = O_2CMe$, O_2CEt; $M = Pb$, Zn, Ca, Sr) are prepared by reaction of $M(OH)_2$ with $HAuCl_4$, followed by treatment with acetic or propionic acid, or by reaction of aurates $M[Au(OH)_4]_2$ with the carboxylic acids.[1794,1795] The structure of $Zn(Auac_4)_2{\cdot}2H_2O$ (**303**) is a layer polymer and the one of $Pb(Auac_4)_2$ (**304**) is a molecular unit as the $Sr(Auac_4)_2$. The structure of $(Pb_3Cl_2ac_3)(AuCl_4)$ has also been described.[1796] Another acetate complex is $[Au(2\text{-}C_6H_4CH_2NMe_2)(ac)_2]$.[1797]



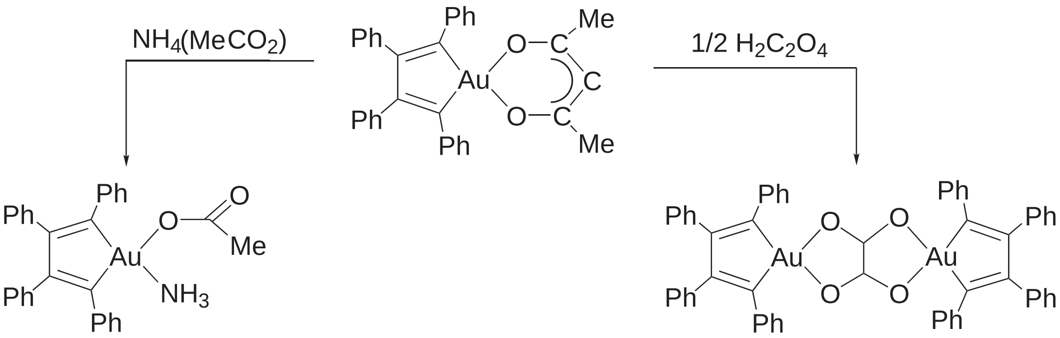
(303)



(304)

The complex dimethyl(acetylacetonato)gold(III), $[AuMe_2(ACAC)]$,[1798] is of great interest as a precursor for the CVD of gold. A gas-phase electron diffraction study indicates a square-planar structure in which the acetylacetonate ligand is bonded to gold(III) via both oxygen atoms. The mechanism of thermal and photochemical decomposition of this complex and its dimethyl-*d*6 congener have been studied by UV–visible and ^1H NMR spectroscopy. It proceeds with reductive elimination of ethane and protonation of the acetylacetonate ligand.[1799] The complex $[Au(C_4Ph_4)(ACAC)]$ can be prepared from the aura cyclopentadiene species $[AuCl(C_4Ph_4)(THT)]$

or $[Au_2(\mu\text{-}Cl)_2(C_4Ph_4)_2]$, by reaction with Tl(ACAC), and has been used as a starting material in the synthesis of several other complexes with oxygen donor ligands (Scheme 19).[1799]



Scheme 19

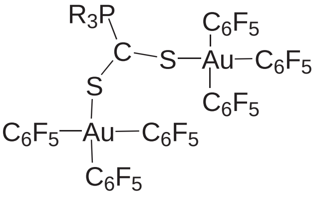
Tris(pentafluorophenyl)gold(III) complexes with weakly bonded oxygen ligands have been synthesized, as $[Au(C_6F_5)_3L]$ (L = OEt_2, $OCMe_2$, dioxane, EtOH) or with phosphine oxides as $[Au(C_6F_5)_3L]$ (L = $OPPh_3$, $OAsPh_3$). The compound $[Au(C_6F_5)_3(OEt_2)]$ is a useful starting material to introduce "$Au(C_6F_5)_3$" fragments.[1740]

6.7.3.2.5 *Complexes with sulfur, selenium, or tellurium donor ligands*

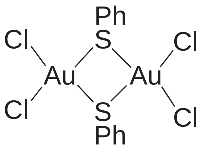
Gold(III) forms very stable bonds with sulfur and many complexes are known; however, fewer examples for selenium and tellurium have been reported.

(i) Complexes with monodentate ligands

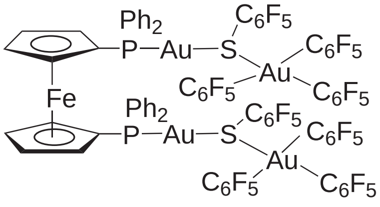
Complexes of the type $[Au(C_6F_5)_3(SPR_3)]$ ($PR_3 = PPh_3$, PPh_2Me) or $[Au(C_6F_5)_3(SPPh_2CH_2PPh_2R)]ClO_4$ (R = Me, $CH_2C_6F_5$, CH_2CO_2Me, CH_2Ph) have been obtained by displacement of the weakly coordinated ligand diethyl ether in $[Au(C_6F_5)_3(OEt_2)]$.[1740] Similarly the complexes $[Au(C_6F_5)_3(HL)]$ (HL = heterocyclic thiones, $C_3H_5NS_2$, $C_4H_4N_2S$, C_5H_5NS, $C_7H_5NS_2$, $C_7H_6N_2S$).[1801] The cationic complex $[Au(C_6F_5)_3(SPPh_2CH_2PPh_2Me)]ClO_4$ reacts with NaH to yield the neutral methanide species $[Au(C_6F_5)_3(SPPh_2CHPPh_2Me)]$ that gives the mixed-valence complexes $[Au(C_6F_5)_3(SPPh_2CH(AuX)PPh_2Me)]$ (X = Cl, C_6F_5) by reaction with [AuCl(THT)] or $[Au(C_6F_5)(THT)]$.[1471] Sulfocyanato or selenocyanato complexes of gold(-III) are also known, such as $[N(PPh_3)_2][Au(C_6Cl_5)_3(SCN)]$, $[Au(SCN)_3(CH_2PR_3)]$ ($PR_3 = PPh_3$, PPh_2Me, $PPhMe_2$),[1645] or $Ph_4As[Au(SeCN)_4]$.[1802] Diphenylselenide can also act as a ligand in the gold(III) derivative $[AuCl_3(SePh_2)]$.[1803] The structures for complexes $[AuCl_3L]$ (L = $S(CH_2Ph)_2$, SPh_2, THT),[1804–1807] $[AuBr_3L]$ (L = $S(CH_2Ph)_2$, SMe_2),[1808,1809] and the mixed-valence $[AuX_2S(CH_2Ph)_2]$ (X = Cl, Br)[1804,1810] have been reported. Tris(pentafluorophenyl)gold (III) complexes with phosphonium dithiocarboxylates of the type $[Au(C_6F_5)_3(S_2CPR_3)]$ or $[\{Au(C_6F_5)_3\}_2(S_2CPR_3)]$ (**305**) ($R_3 = Cy_3$, Et_3, Bu_3, $PhMe_2$, $PhEt_2$)[1811] or with methyldithiocarbamates $[Au(C_6F_5)_3\{S(MeS)CNHR\}]$ (R = $4\text{-}MeC_6H_4$, $2\text{-}MeC_6H_4$, $4\text{-}MeOC_6H_4$, $3,5\text{-}Me_2C_6H_3$) have been prepared.[1812]



(305)



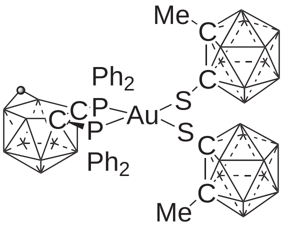
(306)



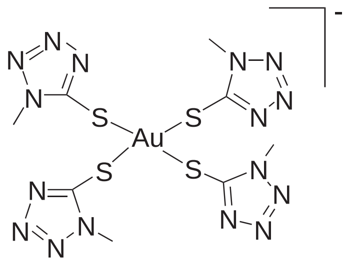
(307)

The reaction of $PhCH_2SSCH_2Ph$ with $[AuCl(CO)]$ yields the dinuclear thiolategold(III) complex $[Au_2Cl_4(\mu\text{-}SPh)_2]$ (**306**),[1813] which has a similar structure to $[Au_2Me_4(\mu\text{-}SEt)_2]$,[1814] but in the former the intramolecular gold–gold separation is much shorter 3.357(1) Å and the intermolecular separation is 3.416(1) Å. The reaction of the dithiolategold(I) complex $[Au_2(SC_6F_5)_2(\mu\text{-}dppf)]$ with two equivalents of $[Au(C_6F_5)_3(OEt_2)]$ or with half of $[Au(C_6F_5)_2(OEt_2)_2]ClO_4$ affords the mixed-valence compounds $[Au_4(\mu_2\text{-}SC_6F_5)_2(C_6F_5)_6(\mu\text{-}dppf)]$ (**307**) or $[Au_5(C_6F_5)_2(\mu_2\text{-}SC_6F_5)_2(\mu\text{-}dppf)]_2(ClO_4)_3$.[1815]

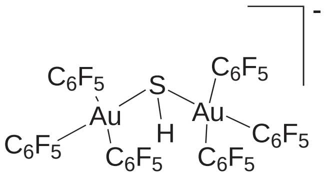
The ligand 1-methyl-2-thiolate-1,2-dicarba-*closo*-dodecaborane forms gold(III) complexes of the type $Bu_4N[Au(C_6F_5)_3(SCB_{10}H_{10}CMe)]$ or $[Au\{(PPh_2)_2C_2B_9H_{19}\}(SCB_{10}H_{10}CMe)_2]$ (**308**); they are readily obtained from the corresponding gold(III) precursors and Na_2CO_3.[1816] Tetrakisthiolate gold(III) derivatives have been synthesized, as $[Au(SR)_4]^-$ (**309**) or $[Au(C_6H_4CH_2NMe_2H)(SR)_3]$ (SR = 1-methyl-1,2,3,4-tetrazole-5-thiolate).[1817–1819] The treatment of Bu_4N $[AuBr(C_6F_5)_3]$ with NaSH leads to the first (hydrosulfido)gold(III) compound $Bu_4N[Au(C_6F_5)_3(SH)]$, that readily reacts with $[Au(C_6F_5)_3(OEt_2)]$ to give $Bu_4N[\{Au(C_6F_5)_3\}_2(SH)]$ (**310**); the isolobal analogy existing between the hydrogen atom and the fragments $AuPR_3^+$ or $AgPR_3^+$ can be envisaged in the synthesis of the substituted derivatives $Bu_4N[Au(C_6F_5)_3(SMPPh_3)]$ (M = Au, Ag).[1033]



(308)

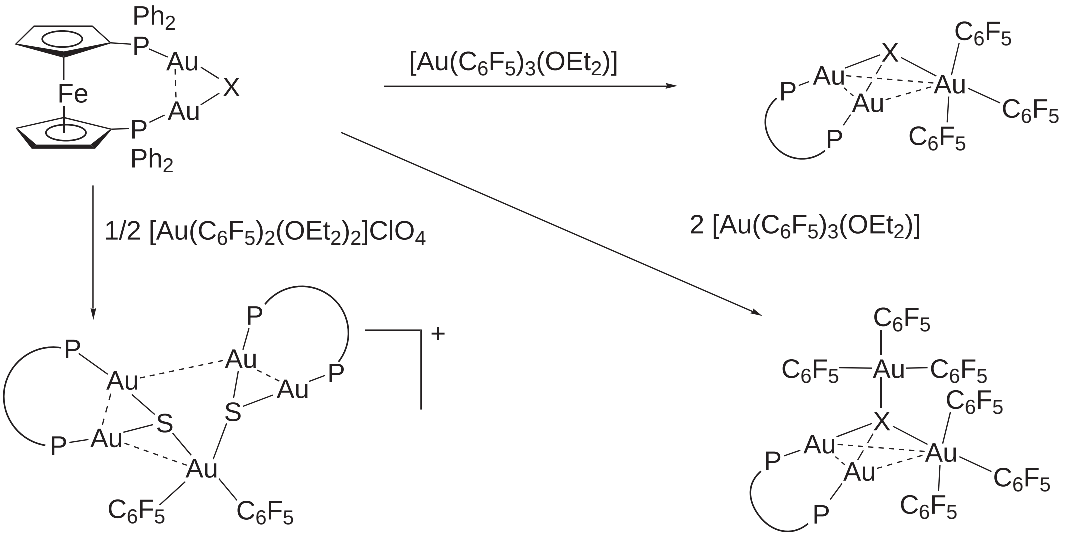


(309)



(310)

Mixed gold(I)–gold(III) sulfur and selenium centered complexes have been described by reaction of $[X(AuPPh_3)_2]$ or $[X\{Au_2(\mu\text{-}dppf)\}]$ (X = S, Se) with gold(III) complexes, such as $[Au\text{-}(C_6F_5)_3(OEt_2)]$ or $[Au(C_6F_5)_2(OEt_2)_2]ClO_4$ (Scheme 20). The complexes thus obtained have the sulfur or selenium atoms as triply or quadruply bridging ligands. Weak gold(I)–gold(III) interactions have been observed in the triply bridging complexes and theoretical studies show that although weaker than gold(I)–gold(I) there exist gold(I)–gold(III) interactions. The quadruply bridging species have a tetrahedral geometry at the central heteroatom and then no short gold(I)–gold(III) contacts are observed.[1820–1822] Another mixed gold(I)–gold(III) sulfido complex is $[\{AuCl_2\}_2(\mu\text{-}SAuCl)_2]^-$.[1823] The tetramethylthiourea complex $[AuBr_2\{SC(NMe_2)_2\}_2][AuBr_2]$ has been reported.[1824]

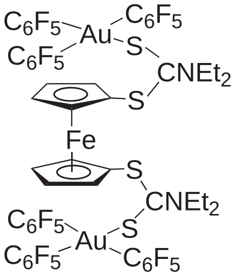


Scheme 20 X = S, Se; P – P = $Fe(C_5H_4PPh_2)_2$.

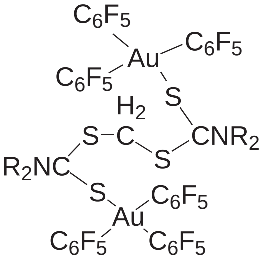
(ii) Complexes with bidentate ligands

The gold(III) complexes bound to bidentate sulfur ligands such as dithiocarbamate, dithiolate, etc. are more numerous. They form very stable square-planar gold(III) compounds that have in many cases interesting redox properties because they can be oxidized to gold(IV) complexes or reduced to gold(II) species. Because of the ability of this type of ligand to delocalize electron density it is clear that in most cases they are not truly real valence complexes. Furthermore, some of these types of square-planar gold complexes have produced organic superconducting properties while others display nonlinear optical properties.

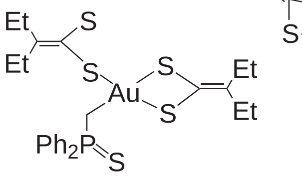
Homoleptic dithiocarbamategold(III) derivatives of the type $[Au(S_2CNR_2)_3]$ or $[Au(S_2CNR_2)_2]^+$ have been known for a long time. New studies have lead to the synthesis of gold(III) complexes with amino acid-substituted dithiocarbamates of the type $[Au\{S_2CNHCH(R)CO_2H\}_3]$ (R = Me, Pr^i, Bu^t).[1825] The reaction of *N*,*N*,*N*′,*N*′-tetramethylthiuran disulfide with gold(III) compounds of the type $[AuX_3L]$ leads to complex $[Au(S_2CNMe_2)_2]Br$ with two bidentate chelate dithiocarbamate ligands.[1826] The reaction of $[AuCl(CO)]$ with $[TcN(S_2CNEt)_2]$ affords the gold(III) compound $[Au(S_2CNEt_2)_2][TcNCl_4]$ that shows in the lattice the expected square-planar coordination for gold and long-range contacts between the technetium atoms and the sulfur atoms of the $[Au(S_2CNEt_2)_2]^-$ units.[1827] Complexes of stoichiometry $[AuX_2(S_2CNR_2)]$ have been reported as $[AuCl_2\{S_2CN(CH_2\text{-}CH_2OH)_2\}]$[1828] or $[Au(C_6F_5)_2(S_2CNR_2)]$ (R = Me, Et, CH_2Ph);[1829] the latter is obtained by reaction of $[Au_2(\mu\text{-}Cl)_2(C_6F_5)_4]$ with $Na(S_2CNR_2)$ and also by oxidative addition of $[Tl(C_6F_5)_2Cl]$ to the dinuclear gold(I) derivatives $[Au_2(\mu\text{-}S_2CNR_2)_2]$. Complexes where the dithiocarbamate ligands are bonded to two different metals, or in which they are coordinated as monodentate ligands, have also been described as $Bu_4N[Au(C_6F_5)_3(S_2CNR_2)]$ or $Bu_4N[\{Au(C_6F_5)_3\}_2(S_2CNR_2)]$.[1829] With the 1,1′-bis-(diethyldithiocarbamate)ferrocene ligand, $Fc(S_2CNEt_2)_2$, the complexes $[\{Au(C_6F_5)_3\}_2\{Fc(S_2CNEt_2)_2\}]$ (**311**) or $[\{Au(C_6F_5)_2Cl\}_2\{Fc(S_2CNEt_2)_2\}]$ have been reported.[1830] Similar complexes are obtained with the methylenebis(dialkyldithiocarbamate) ligands, $[\{Au(C_6F_5)_3\}_2\{CH_2(S_2CNEt_2)_2\}]$ (**312**).[1220] Other derivatives with mono- and bidentate dithiocarbamate ligands are $[Au(CH_2PPh_2S)(S_2CNEt_2)_2]$ (**313**) and $[Au(C_6H_4CH_2NMe_2)(S_2CNEt_2)]^+$.[1831,1832] The reaction of $[AuBr_2(S_2CNEt_2)]$ with an excess of $Et_4N(B_9H_{14})$ leads to the complexes $[4\text{-}(S_2CNEt_2)\text{-}$*aracno*$\text{-}4\text{-}AuB_8H_{12}]$ and $[6,9\text{-}(S_2CNEt_2)_2\text{-}$*aracno*$\text{-}6,9\text{-}Au_2B_8H_{10}]$ (**314**).[1833] The mixed gold(I)–gold(III) complex $[AuI(S_2CNBu_2)(3\text{-}Me\text{-}C_6H_3PPh_2AuI)]$ has been prepared by oxidation of the dinuclear gold(I) complex.[1834]



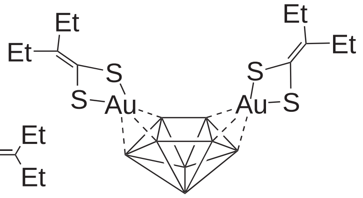
(311)



(312)

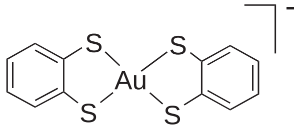


(313)

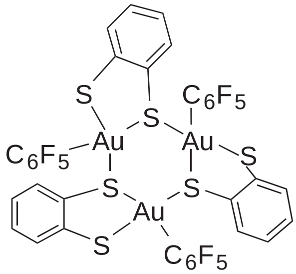


(314)

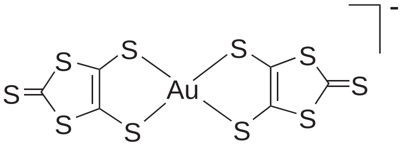
Dithiolate ligands have two negative charges and form very stable homoleptic anionic gold(III) complexes. The mnt ligand is one of the most used and the complex $[Au(mnt)_2]^-$ is easily obtained by reaction of $Na_2(mnt)$ with $HAuCl_4$; the complex has been obtained with several cations such as NBu_4^+,[1835,1836] organic cations,[1837–1841] $[Au(PPh_3)_2]^+$,[1842] and it is worth mentioning the cation $[Pt(CNMe)_4]^{2+}$ because the structure consists of linear chains of the cations and the two anions.[1843] With the related i-mnt ligand the structure of $Bu_4N[Au(i\text{-}mnt)_2]$ has been described.[1844] Other types of complexes with mnt have been obtained using tin complexes; the reaction of $[SnMe_3(mnt)]$ with gold(III) derivatives such as $[AuCl_3(THT)]$, $[AuCl(PPh_3)]$, or $Bu_4N[AuBr_4]$ yields the compounds $[AuCl(mnt)(THT)]$, $[AuCl(mnt)(PPh_3)]$, or $Bu_4N[AuBr_2(mnt)]$, respectively. Substitution reactions of the tetrahydrothiophene lead to complexes of the type $Me_4N[AuCl_2(mnt)]$, $[AuCl(mnt)(Py)]$, or $[Au(mnt)(L\text{-}L)][AuCl_2(mnt)]$ (L-L = bipy or phen).[1845] Benzene- or toluene-dithiolate ligands have also being used widely in gold chemistry. The homoleptic species $[Au(S_2C_6H_4)_2]^-$ (**315**) or $[Au(3,4\text{-}S_2C_6H_3Me_2]^-$ are readily obtained by treatment of $[AuCl_4]^-$ with the dithiol or by oxidation of gold in the presence of the dithiol.[1846–1852] Pentafluorophenyl dithiolate complexes have been described recently from [Au(C$_6$F$_5$)Cl$_2$L] (L = THT, PR$_3$, AsR$_3$) using tin or zinc derivatives as dithiolate transfer agents, and compounds of the type [Au(C$_6$F$_5$)(S-S)L] (S-S = S$_2$C$_6$H$_4$, 3,4-S$_2$C$_6$H$_3$Me) are obtained. When the ligand is THT, this is also displaced and a trinuclear complex, [Au(C$_6$F$_5$)(S-S)]$_3$ [S-S = 1,2-S$_2$C$_6$H$_4$ (**316**), 3,4-S$_2$C$_6$H$_3$Me], is isolated. Further reaction of the trinuclear complexes with neutral or anionic ligands breaks the Au$_3$S$_3$ ring, and mononuclear compounds are obtained.[1853,1854]



(**315**)

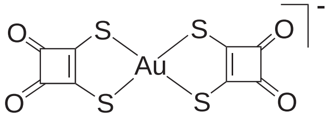


(**316**)

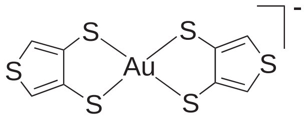


(**317**)

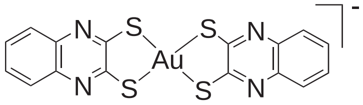
Homoleptic gold(III) complexes with other related dithiolate ligands, as dmit (**317**),[1855–1864] dddt,[1865,1866] 1,3,5-trithiepin-6,7-dithiolate,[1867] dithiosquarate (**318**),[1868,1869] 6,7-dihydro-6-methylene-5H-1,4-dithiepine-2,3-dithiolate,[1870] 3,4-thiophenedithiolate (**319**),[1637] quinoxaline-3,3-dithiolate (**320**),[1871] 2,2-diacetylethylene-1,1-dithiolate,[1872] or *o*-carborane-1,2-dithiolate have been reported.[1873]



(**318**)

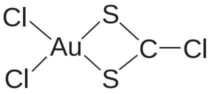


(**319**)

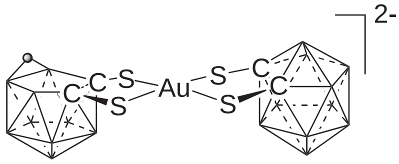


(**320**)

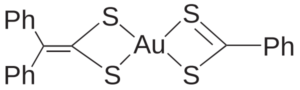
Complexes of the type [AuX$_2$(S-S)]$^-$ have been prepared for dmit (X = C$_6$F$_5$),[1874] 1,3,5-trithiepin-6,7-dithiolate (X = Cl),[1875] *o*-carborane-1,2-dithiolate (X = Cl, C$_6$F$_5$, C$_6$F$_3$H$_2$),[1876] 2,2-diacetylethylene-1,1-dithiolate (X = Cl),[1877] 1,2-bis(methylthio) vinylene-1,2-dithiolate (X = Cl),[1878] or chlorodithioformato (X = Cl) (**321**).[1879] Other stoichiometries are present, for example, in (Bu$_4$N)$_2$[Au(S$_2$C$_2$B$_9$H$_{10}$)(S$_2$C$_2$B$_{10}$H$_{10}$)] (**322**) with a *closo* and a *nido* dithiolate ligands,[1873] in the mixed [Au(S$_2$C$_2$Ph$_2$)(S$_2$CPh)] (**323**),[1880] or in [Au(3,4-S$_2$C$_6$H$_3$Me)(dbbipy)]PF$_6$ (dbbipy = 4,4′-di-Bu^t-2,2′-bipyridine).[1881]



(**321**)

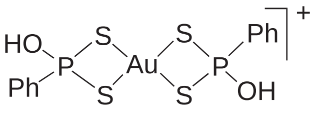


(**322**)

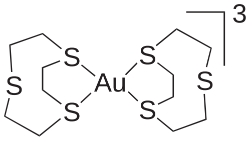


(**323**)

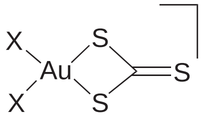
Thio- or selenophosphoryl ligands have been used to coordinate gold(III) and complexes such as [Au(C$_6$F$_5$)$_2${(SPPh$_2$)$_2$CH$_2$}],[1882] [Au(C$_6$F$_5$)$_2${(SPPh$_2$)$_2$C(AuAsPh$_3$)$_2$}],[1883] [AuX$_2${(SPPh$_2$)$_2$N}] (X = Cl, Br, I),[1884] or [AuX$_3${Fe(C$_5$H$_4$PPh$_2$E)$_2$}] (X$_3$ = (C$_6$F$_5$)$_3$, (C$_6$F$_5$)$_2$Cl; E = S, Se) have been described.[1265,1885] The compound [Au(C$_6$F$_5$)$_2${(SPPh$_2$)$_2$C=CH$_2$}]ClO$_4$ undergoes Michael addition reactions to the double bond with several nucleophiles.[1886] Other gold(III) complexes with sulfur-based donor ligands are [Au{S$_2$PPh(OH)}$_2$]Cl (**324**) with a dithiophosphonato ligand,[1831] the dithione derivative [AuI$_2$(C$_7$H$_{12}$N$_2$S$_2$)]I$_3$, obtained by oxidation of metallic gold with the bis-iodine adduct of *N*,*N*′-dimethylperhydrodiazepine-2,3-dithione,[1887] [Au{[9]aneS$_3$}$_2$](ClO$_4$)$_3$ (**325**),[1888] or the trithiocarbonate derivatives [AuX$_2$(CS$_3$)]$^-$ (**326**), [Au(CS$_3$)$_2$]$^-$, and [Au(CS$_3$)(L-L)]OTf (L-L = bipy, phen).[1889] The compound (Et$_4$N)$_4$KAuAs$_4$Te$_8$ contains two As$_2$Te$_4^{4-}$ anions coordinating to a Au^{3+} cation forming a square-planar AuTe$_4$ unit (**327**).[1890]



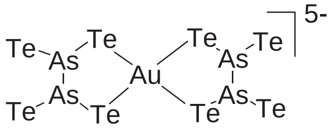
(324)



(325)



(326)



(327)

6.7.3.2.6 Complexes with halides as donor ligands

Mixed-valence gold(I)/gold(III) halides of the type $M_3Au_3X_8$ ($M = NH_4$, Rb; X = Br, I) and $Rb_3Au_3Cl_8$ have been characterized structurally and consist of linear $[AuX_2]^-$ and square planar $[AuX_4]^-$ anionic units.[1731] The structures of the related $Rb_2AgAu_3I_8$ and $Cs_2AgAuBr_6$ have also been reported.[1891,1892] The physical properties of $Cs_2Au_2X_6$ (X = Cl, Br, I) have been studied.[1893,1894] AuF_3 is reduced in superacidic HF/SbF_5 solutions giving three products, $Au_3F_8{\cdot}2SbF_5$ with a layered structure, $Au_3F_7{\cdot}3SbF_5$ with a ribbon structure and $[Au(HF)_2](SbF_5)_2$ with a square-planar structure.[1895]

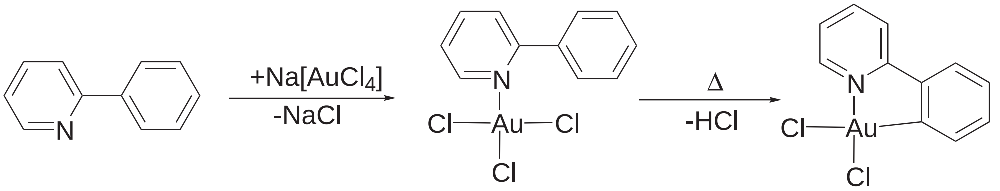
The tetrahalide complexes have been characterized with several cations or more complicated systems, as in $[AuF_4]^-$,[120,179,1896,1897] $[AuCl_4]^-$,[1898–1906] $[AuBr_4]^-$,[1907,1908] or $[AuI_4]^-$.[1909] The dialkylimidazolium tetrachloroaurate salts behaves as ionic liquids.[1906] The complex $(NH_4)_2[(AuI_4)\{AuI_2(\mu_2\text{-}I_4)\}]$ has been prepared and has $I_4{}^{2-}$ anions as ligands.[1910] The compounds $AuBiX_6$ (X = Cl, Br) have been synthesized by mixing AuX_3 and BiX_3 in sealed glass ampoules.[1911] Kinetic studies of the X^- exchange on $[AuX_4]^-$ square-planar complexes (where $X = Cl^-$, CN^-) have been performed at acidic pH in the case of the chloride system and as a function of pH for the cyanide system.[1912]

Gold(III) halides as catalysts have been employed, e.g., $H[AuCl_4]$ catalyzes the hydroxylation of alkenes,[1913] oxidation of alkanes,[1914] or the two-phase (gas–liquid) autoclave reaction between alkyne and tributylamine hydrochloride (as a source of HCl) to give $CH_2{=}CH_2Cl$.[1915] $H[AuCl_4]$-impregnated active carbon at 100–120 °C has also been used as catalyst in the addition of HCl to alkyne.[1916,1917] $AuCl_3$ has been used to catalyze C—C and C—O coupling reactions,[1918–1921] or cyclization of alpha-hydroxyallenes to 2-5-dihydrofurans.[1922]

6.7.3.2.7 Complexes with mixed donor ligands

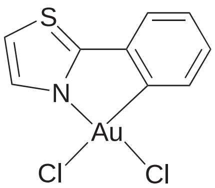
Cyclometallation by gold(III) is believed to proceed through direct C—H bond activation of the heterosubstituted molecule. The first cycloauration was established in 1989 with phpy by Constable and Leese.[1923] The cyclometallated complexes obtained by cycloauration can be classified into two categories: (i) Complexes bearing a bidentate *N*,*C*-chelate ligand, and (ii) Complexes having a terdentate *N*,*N*,*C*-chelate ligand.

Most of the substrates that give both types of cycloaurated complexes are limited to pyridine derivatives, although recently a few exceptions have been reported with thiazoles and imidazoles. The reaction of substituted pyridine ligands such as phpy,[1749,1924] 2-benzoylpyridine,[1924] 2-anilinopyridine,[1925,1926] 1-(2-pyridylamino and 2-pyrimidinylamino)naphthalene,[1927] 2-phenoxypyridine,[1811] 2-(phenylsulfanyl)pyridine,[1925] 2-(2-thienyl)pyridine,[1928] 2-(3-thienyl)pyridine,[1928] 2-(alkylsulfanyl)pyridine,[1929] or papavorine[1930] at room temperature yields the nonmetallated compounds which, upon heating, are transformed into the metallated complexes $[Au(N,C)Cl_2]$. The process with phpy is illustrated in Scheme 21.

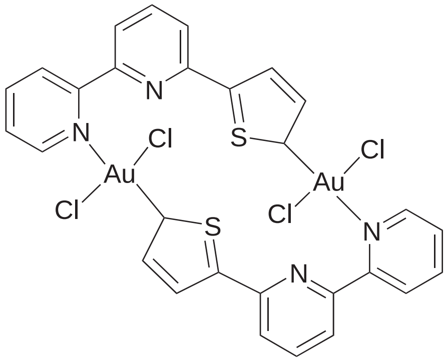


Scheme 21

Recently the cycloauration of 1-ethyl-2-phenylimidazole or 2-phenylthiazole (**328**) has been reported by refluxing solutions of $Na[AuCl_4]\cdot 2H_2O$ and the ligand in the presence of a silver salt.[1931,1932] The ligand 6-(2-thienyl)-2,2′-bipyridine although has the possibility of acting as terdentate N,N,C ligand gives analogous reactions with $[AuCl_4]^-$ to the bidentate N,C ligands (**329**).[1933–1935]

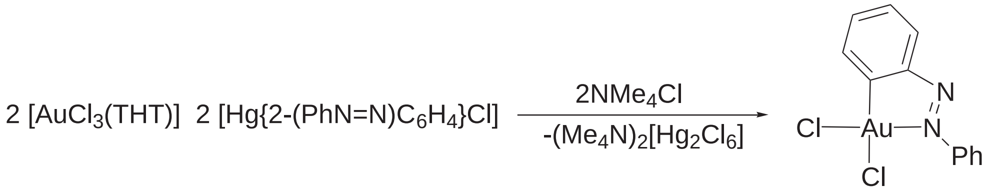


(**328**)

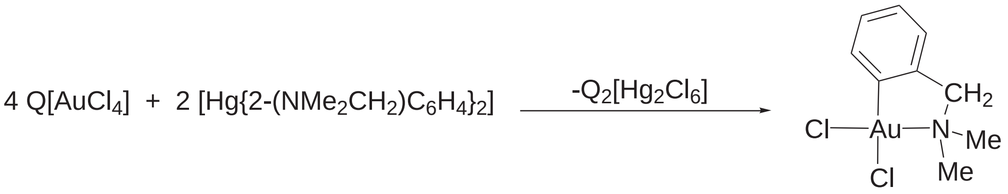


(**329**)

However, cycloauration is, sometimes, difficult to achieve with direct activation of a C—H bond and transmetallation reaction of organomercury or organotin compounds with the appropriate gold compounds is, hence, frequently used. This procedure has been used with azobenzene,[1936] *N*,*N*′-dimethylbenzilamine,[1937,1938] 4,4′-dimethyl-2-phenyl-1,3-oxaazoline,[1938] 1-(dimethyl- or methylaminomethyl)naphthalene,[1938] 1,3-bis(dimethylaminomethyl)benzene,[1938] substituted phpys,[1939] 2-phenyl-4-(methylcarboxylato)quinoline,[1939] and 4-butyl-*N*-(3,4,5-trimethoxybenzilidene)aniline.[1940] Two examples are illustrated in Equations (16) and (17):



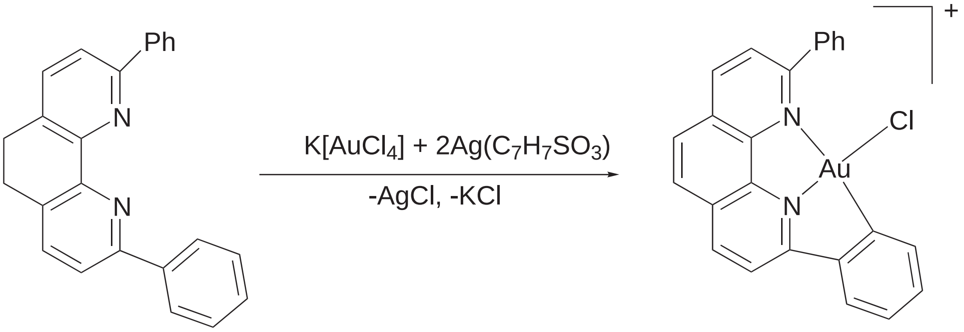
(16)



(17)

Sequential arylations allows the synthesis of complexes with two different ligands. If the second aryl group does not carry a potential donor group, complexes of the type [Au(N,C)ArCl] are obtained.[1643,1748,1941,1942] Upon treatment with phosphine or chloride, some of the *N*,*C*-chelated diarylgold(III) chloride complexes undergo reductive elimination of the aryl ligands to give biaryls. The high-yield reaction proceeds at room temperature and can be used for the synthesis of both symmetrical and asymmetrical products.[1943]

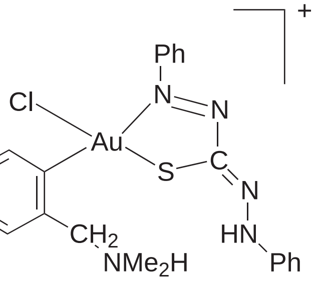
Complexes having a tridentate *N*,*N*,*C* chelate derived from 2,9-diphenyl-phen,[1944] 4-(4-methoxyphenyl)-6-phenyl-2,2′-bipyridine,[1945] 6-benzyl-2,2′-bipyridine,[1946] or 6-Bu^t-2,2′-bipyridine[1946] have been prepared from heating solutions of the ligand and $[AuCl_4]^-$ with the assistance of a silver salt. Equation (18) shows one example.



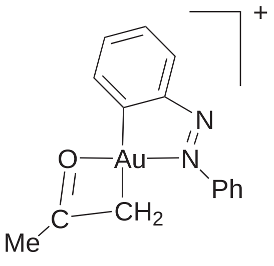
(18)

A cyclometallated derivative that also possesses a tridentate N,C,N ligand is [Au{2,6-$(NMe_2CH_2)_2C_6H_3$}Cl][Hg_2Cl_6] but in this case it was obtained from the gold(III) precursor and the organomercury reagent.[1938] The compounds [Au(N,N,C)Cl]X (N,N,C = anion of 2,9-diphenyl-phen; X = $C_7H_7SO_3$, ClO_4) present a luminescent behavior and there are powerful photooxidants.[1944] The electrochemical behavior of cyclometallated gold(III) complexes has been studied; they show an irreversible one-electron reduction.[1947]

The chloro ligands in the N,C chelate complexes can be easily displaced by other neutral or anionic ligands affording a great variety of complexes, but in some cases cleavage of the Au—N bond occurs. Examples of substitution reactions in the cyclometallated complexes are those with thiosalicylic acid in the presence of a base, which give the complexes [Au(N,C)($SC_6H_4CO_2$)],[1948] and also a range of four-membered ring systems including auracyclobutane,[1949] auraureylene,[1950] auracyclobutan-3-one,[1951] as well as other related metallacyclic complexes.[1820,1952] The antitumor and antimicrobial activity of *N*,*C*-chelate ligands[1952,1953] and also of thiosalicylic ligands has been reported previously. Consequently the activity of these compounds against P388 leukemia has been tested, although only the compound [Au(2-Py-4-MeC_6H_3)($SC_6H_4CO_2$)] shows good activity.[1953,1954] The reaction of [Au(2-$NMe_2CH_2C_6H_4$)Cl_2] with other bidentate donor ligands such as diphenyl thiocarbazone, PhNHNHC(S)NNPh, progresses with cleavage of the Au—N bond and protonation of the dimethylamino group (**330**).[1955,1956] The reaction of [Au{2-(PhN=N)C_6H_4}Cl_2] with $AgClO_4$ in acetone yields to the synthesis of [Au(C,N)(μ-CH_2COMe)]ClO_4 (**331**) with a bridging acetonyl ligand, although the complex is very instable and rapidly decomposes in solution[1747] It has been observed that these metallated derivatives [Au(C,N)Cl_2][1957–1963] and [Au(C,N,N)Cl][1782] produce the carbon–hydrogen activation of ketones leading to ketonyl species.



(**330**)



(**331**)

The reaction of the dinuclear gold(I) complex [Au_2{μ-2,6-$(NMe_2CH_2)C_6H_3$}$_2$] with an excess of CH_2I_2 affords the gold(III) ammonium species (Equation (19)).[1964]

Other gold(III) complexes with bidentate mixed-donor ligands include salicylaldiminate(esal) complexes. The complex [$AuCl_2$(esal)] (**332**) exhibits favorable cytotoxic properties towards a number of human tumor cell lines either sensitive or resistant to cisplatin. The ability of this complex to bind DNA may represent the mechanism for its cytotoxic action as proposed for other gold(III) complexes.[1965,1966] Square-planar gold(III) derivatives have been obtained with *N*,*N*,*Z*-tridentate hydrazones (Z = S, O).[1967] Gold(III) forms complexes with tetradentate Schiff base ligands such as *N*,*N*′-propylenebis(salicylideneimine) (sal_2pn) or *N*,*N*′-ethylenebis(salicylideneimine) (sal_2en) of the type [Au(sal_2pn)]Cl or [Au(sal_2en)]Cl (**333**). An improved method of synthesis has been reported from the reaction of Bu_4N[$AuCl_4$] with the ligands. Radiochemical studies with ^{198}Au show that these complexes are also formed at the tracer level from $Bu_4N[^{198}AuCl_4]$.[1968]

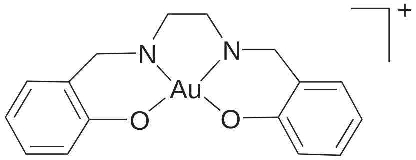
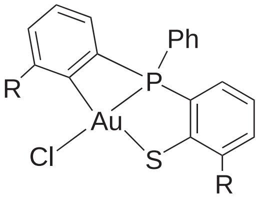
(332)

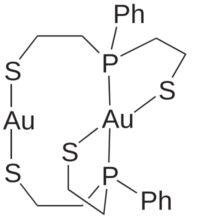


(333)

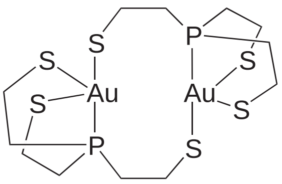
The potentially tri- and tetradentate phosphinothiolates $PhP(2,3\text{-}C_6H_3RSH)_2$ (R = H, TMS) and $P(C_6H_4SH)_3$ have proved to be powerful chelating ligands that are able to stabilize gold(III) despite the reducing capacity of both aromatic thiols and phosphines. This may be explained by the rapid chelation of *P* and thiolate *S*-donor atoms, which stabilizes a square planar d^8 complex.[1969] The reaction of $[Au(2\text{-}NMe_2CH_2C_6H_4)Cl_2]$ with $PhP(C_6H_4SH)_2$ gives the complex (**334**) and small amounts of the dinuclear mixed-valence complex (**335**). Treatment of $[AuCl(PPh_3)]$ with $P(C_6H_4SH)_3$ gives an intermediate gold(I) complex, which oxidizes in air to the gold(III) derivative (**336**).



(334)



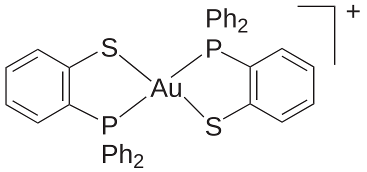
(335)



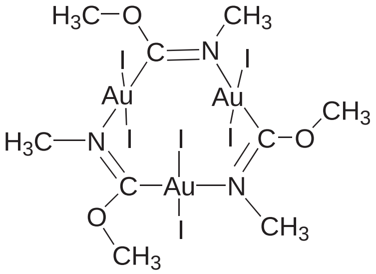
(336)

The reaction of tetrachloroaurate(III) with two equivalents of 2-(diphenylphosphino)benzenethiol gives a cation that can be precipitated from solution as the tetraphenylborate salt, $[Au(2\text{-}PPh_2C_6H_4S)_2]BPh_4$ (**337**). Very surprisingly, the electrochemical behavior corresponds to a reversible single-electron transfer process and indicates that this gold(III) can be reduced to gold(II) and that the gold(II) state has reasonable stability on the electrochemical time scale.[1970]

The compounds $[Au_3I_n(MeN{=}COMe)_3]$ ($n = 2, 4, 6$) obtained by stepwise addition of iodine to the cyclic tetranuclear gold(I) complexes $[Au_3(MeN{=}COMe)_3]$ have been revisited. The structure of $[Au_3I_6(MeN{=}COMe)_3]$ (**338**) consists of columns of the molecular units united by weak iodine···iodine interactions which range in length from 3.636(2) Å to 3.716(2) Å. The solid-state molecular packing of the di-iodo and tetra-iodo complexes reveal no unusual features.[1971]

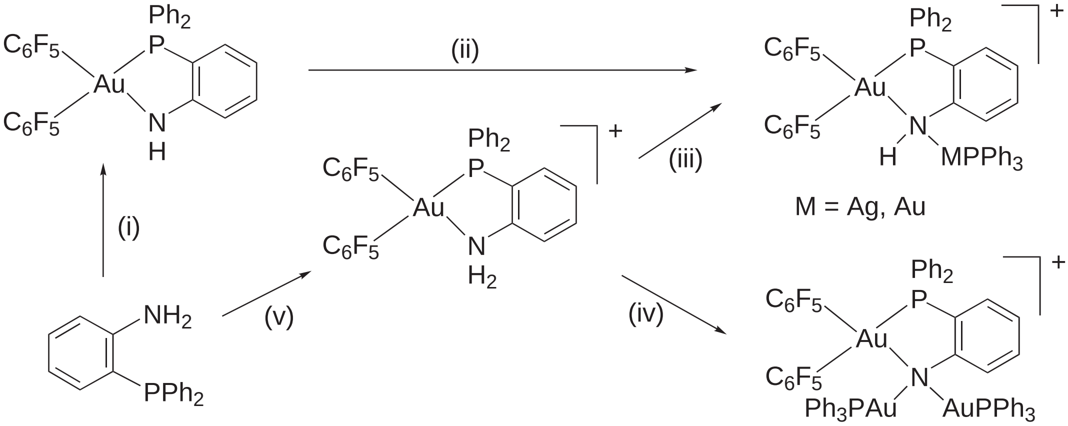


(337)



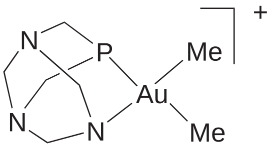
(338)

The 2-(diphenylphosphino)aniline (PNH_2) ligand reacts with the gold compounds $[Au(C_6F_5)_2(OEt)_2]ClO_4$ or $[Au(C_6F_5)_2(ACAC)]$ to yield the P,N chelate complexes $[Au(C_6F_5)_2(PNH_2)]ClO_4$ or $[Au(C_6F_5)_2(PNH)]$. The amino group in the latter can coordinate a $AgPPh_3^+$ fragment and in the cationic complex one or two protons of the NH_2 group can be substituted by its isolobal fragment $AuPPh_3^+$ by using $[Au(ACAC)PPh_3]$ (Scheme 22).[1972]

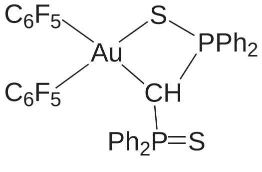


Scheme 22 (i) $[Au(C_6F_5)_2(ACAC)]$, (ii) $[Ag(OClO_3)(PPh_3)]$, (iv) 2 $[Au(ACAC)(PPh_3)]$, (v) $[Au(C_6F_5)_2(OEt_2)]ClO_4$.

The reaction of $[Au_2(\mu\text{-}Cl_2)Me_4]$ with 3,7-dimethyl-1,5,7-triaza-3-phosphabicyclo[3.3.1]nonane (L) gives $[AuMe_2L][AuMe_2Cl_2]$ (**339**) with a chelate P,N ligand.[1973]



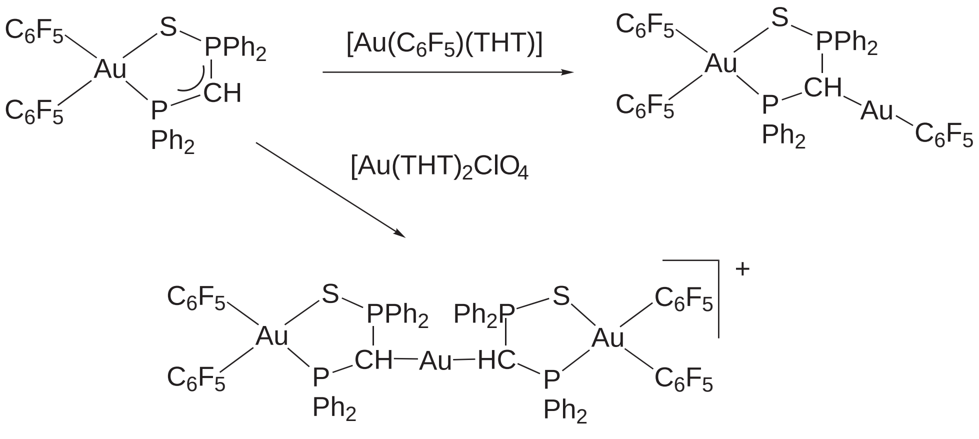
(339)



(340)

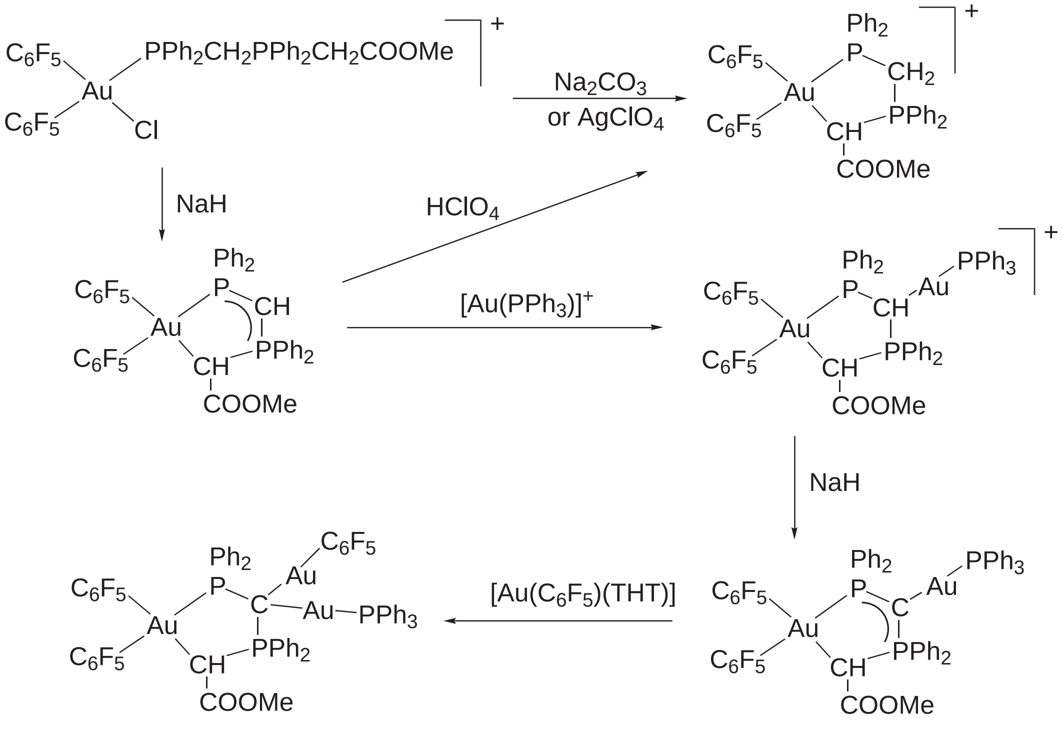
Another type of complex with mixed donor ligands is that derived from phosphino-methanide ligands. The reaction of $[Au(C_6F_5)_2\{(SPPh_2)_2CH_2\}]ClO_4$ with NaH provokes the deprotonation of the methylene group and the new ligand bond gold(III) as a S,C chelate ligand (**340**).[1882] Complex (**340**) reacts with $[Au(C_6F_5)(THT)]$ or $[Au(THT)_2]ClO_4$ (molar ratio 2:1) with displacement of the tetrahydrothiophene ligand and coordination to the sulfur atom to give dinuclear $[Au(C_6F_5)_2\{(SPPh_2)_2CH\}AuC_6F_5]$ or trinuclear derivatives $[\{Au(C_6F_5)_2\{(SPPh_2)_2CH_2\}_2Au]ClO_4$.

A way of increasing the acidity of methylene protons in the diphosphine $PPh_2CH_2PPh_2$ involves oxidation of one or two phosphorus centers. The reaction of *cis*-$[Au(C_6F_5)_2Cl(PPh_2CH_2PPh_2)]$ with elemental S gives *cis*-$[Au(C_6F_5)_2Cl(PPh_2CH_2PPh_2S)]$, which reacts further with $AgClO_4$ to give a five-membered auracycle, *cis*-$[Au(C_6F_5)_2(PPh_2CH_2PPh_2\text{-}S)]ClO_4$. The CH_2 can be easily deprotonated with NaH to open up further reaction pathways (Scheme 23).[1974]



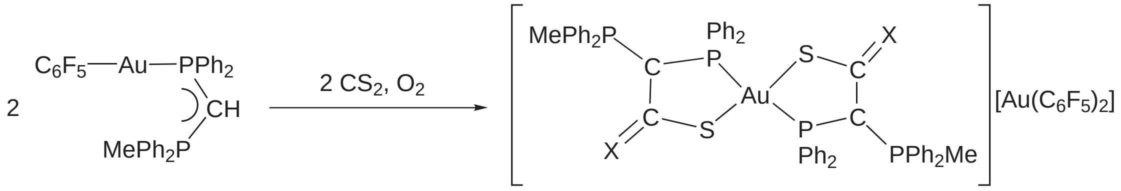
Scheme 23

The reaction of the complex *cis*-$[Au(C_6F_5)_2Cl(PPh_2CH_2PPh_2CH_2COOMe)]ClO_4$ with NaH gives a five-membered auracyclic methanide derivative (Scheme 24).[1975] Double deprotonation takes place, but affects both methylene groups. With weaker deprotonating agents, such as Na_2CO_3, or after chlorine abstraction with $AgClO_4$, deprotonation occurs selectively at the CH_2COOMe group. $[Au(C_6F_5)_2(PPh_2CHPPh_2CHCOOMe)]ClO_4$ reacts with $[Au(PPh_3)(THT)]ClO_4$ to yield $[Au(C_6F_5)_2\{[PPh_2CH(AuPPh_3)PPh_2CHCOOMe]\}]ClO_4$, which can further be deprotonated with NaH to give $[Au(C_6F_5)_2\{(PPh_2C(AuPPh_3)PPh_2CHCOOMe)\}]$.[1976] This new methanediide derivative can incorporate other gold(I) fragments such as $AuPPh_3^+$ or $Au(C_6F_5)$. In a similar manner, the complexes *cis*-$[Au(C_6F_5)_2Cl(SPPh_2CH_2\ PPh_2CH_2R)]ClO_4$ ($R = H$, Ph) react with Na_2CO_3 or NaH to give four-membered methanide auracycles $[Au(C_6F_5)_2(SPPh_2CHPPh_2CH_2R)]ClO_4$ or $[Au(C_6F_5)_2(SPPh_2CPPh_2CH_2R)]$, respectively. The methanediide carbon atom can act as C-nucleophile and coordinate other gold(I) compounds.[1977]



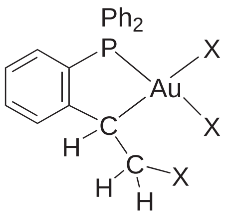
Scheme 24

The methanide carbon of $[Au(C_6F_5)(PPh_2CHPPh_2Me)]$ reacts with carbon disulfide or isothiocyanates affording the gold(III) derivatives $[Au\{PPh_2C(PPh_2Me)C(X)S\}_2][Au(C_6F_5)_2]$ (X = S, 4-ClC_6H_4N, C_6H_5N) through a carbon–carbon coupling reaction (Equation (20)).[1978] The reaction of $[Au\{PPh_2C(PPh_2Me)C(S)S\}_2]ClO_4$ with two equivalents of $[Au(C_6F_5)(THT)]$ gives $[Au\{PPh_2C(PPh_2Me)C(SAuC_6F_5)S\}_2]ClO_4$, which is a vapochromic material and can be used for the detection of some volatile organic compounds (VOCs). This material changes color from black to orange in the presence of organic vapors.[1979]

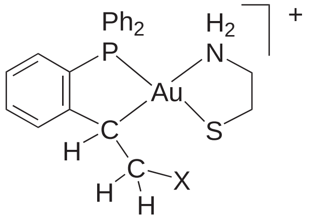


(20)

Other complexes with P,C-donor ligands are those derived of the diphenyl-2-styriylphosphine (sp), which have been reinvestigated. The gold(I) compound [AuCl(sp)] can be oxidized to gold (III) with chlorine, bromine, but not iodine. The initial product $[AuX_3(sp)]$ undergoes a reversible rearrangement in which a Au—X bond adds across the stiryl double bond to give $[AuX_2(sp\text{-}X)]$ (**341**) (sp-X = 2-$CH(CH_2X)C_6H_4PPh_2$). The carbon bond halide can be replaced by methoxy by reaction with methanol. The halogen atoms bonded to the gold(III) center can be substituted for a variety of ligands such as OAc, CN, SCN, or the chelate ligands $SCH_2CH_2NH_2$ (**342**) or S_2CNEt_2.[1980]



(341)



(342)

The reaction of *cis*-$[Au(C_6F_5)_2(OEt_2)_2]ClO_4$ with 2-thiol-pyridine yields the gold(III) compound *cis*-$[Au(C_6F_5)_2(PyS)]$ with the pyridinethiolate ligand (PyS) acting as N,S chelate.[1801] The oxidation of $[(Ph_3P)_2N][Au(CH_2PPh_2S)_2]$ with Br_2 gives $[AuBr(CH_2PPh_2S)_2]$, which contains a monodentate and a bidentate chelating $CH_2PPh_2S^-$ ligand.[1831]

6.7.3.3 Gold(II) Complexes

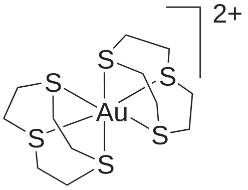
The number of complexes with gold in a formal oxidation state of two have increased considerably and nowadays this oxidation state can be considered as a common oxidation state in gold chemistry. However, the number of gold(II) complexes is very scarce if compared with the more common gold(I) or gold(III) derivatives. The energy required to reach Au^{2+} from atomic gold is not very far from that required to form either Cu^{2+} or Ag^{2+} and to attain M^{3+}, less energy is required for Au than for Cu and Ag. Therefore, this argument is not enough to justify the lack of stability for this oxidation state 2+ in gold. There is a strong tendency for disproportionation to give Au^+ and Au^{3+} because the odd electron in d^9 metal complexes is in $d_{x^2-y^2}$ orbital (octahedral tetragonally distorted or square planar arrangement) which has a much higher energy compared with copper and can be easily ionized. The formation of a gold–gold bond gives more stable compounds and the Au_2^{4+} core species are the most stable and abundant types of gold(II) complexes. Then mononuclear gold(II) derivatives are not very abundant and further study confirmed that they were mixed gold(I)–gold(III) complexes such as the halides $CsAuX_3$ ($= Cs_2Au^IAu^{III}X_6$, X = Cl, Br, I).[1893] Because of the special characteristics of the gold(II) chemistry categorization by donor atom will not be performed.

6.7.3.3.1 Mononuclear gold(II) complexes

Mononuclear gold(II) complexes, consistent with a d^9 configuration, must be paramagnetic ($\mu_{\text{eff}} = 1.79$ MB) and show a hyperfine four-line EPR signal, in accordance with the nuclear spin of ^{197}Au (I = 3/2). These two properties are evidence of a real gold(II) complex in addition to their stoichiometry.

In 1992, Herring *et al.* produced a clear ESR and magnetic evidence for Au^{2+}, as a species present in partially reduced $Au(SO_3F)_3$ and as a solvated ion in the strong protonic acid HSO_3F.[1981] Recently, Bartlet and co-workers prepared and structurally characterized Au^{II} fluoro complexes.[1982] Gold dissolves around 20 °C with F_2 in anhydrous HF acidified with SbF_5 to give a red solution from which orange crystals of $Au(SbF_6)_2$ crystallize. Exhaustive fluorination results in total conversion of the gold to an insoluble crystalline red solid which is $Au^{II}(SbF_6)_2Au^{II}(Au^{III}F_4)_2$. Solvolysis of $Au(SbF_6)_2$ in anhydrous HF results in disproportionation to gold and the mixed-valence fluoride $Au^{II}Au^{III}{}_2F_8$. In $Au(SbF_6)_2$, the gold(II) atom is at the center of an elongated octahedron of F ligands, the fluor atoms of the approximately square AuF_4 unit are at 2.09(2) Å and 2.15(2) Å × 2, each F provided by a different SbF_6 species. The two long Au—F interatomic distances are at 2.64(2) Å.

Most of the compounds already described were prepared with unsaturated *S*-donor ligands such as dithiocarbamates, dithiolates, etc. The addition of DMF to the previously reported gold(II) complexes with *o*-aminobenzenedithiolate (abt) gives the deep blue complex $[Au(abt)_2(DMF)_2]$. This shows a magnetic moment of 1.76 MB and a four-lined EPR spectrum in agreement with a monomeric formulation.[1983] The reaction of these abt gold complexes with SCN^-, $SeCN^-$, NCO^-, and CN^- affords new paramagnetic species which are postulated to remain as gold(II) compounds. Bis(1,2-dicyanoethylene-1,2-dithiolato)aurate(II), $[Au(mnt)_2]^{2-}$, is stable, however, all the attempts to crystallize failed and it has been characterized by single crystal EPR, ENDOR, or multi-frequency powder-EPR spectra.[1984,1985] The reduction of $Bu_4N[Au(dmit)_2]$ electrochemically and with $BH_4{}^-$ leads to unstable monomeric gold(II) species $[Au(dmit)_2]^{2-}$, which has been characterized by X-band EPR spectra.[1986] More precisely described is the mononuclear gold complex $[Au([9]aneS_3)_2](BF_4)_2$ (**343**) obtained by reduction of $HAuCl_4 \cdot 3H_2O$ with two equivalents of $[9]aneS_3$ in refluxing HBF_4 (40%)/MeOH and further extraction with $MeNO_2$.[1888,1987] It has been studied by XRD and shows an octahedral disposition of six sulfur atoms around the gold center, with a Jahn-Teller distortion. The apical Au—S distance 2.839(5) is longer than those in the plane, 2.462(5) Å and 2.452(5) Å. The EPR spectrum shows hyperfine four line EPR signals at g = 2.010; the delocalization trough the ligand is limited. The oxidation and reduction reactions of $[Au([9]aneS_3)_2]^{2+}$ by an outer-sphere oxidizing reagent $[Ni([9]aneS_3)_2]^{3+}$ have been studied.[1988] Another gold(II) derivative with a thiacrown ether $[12]aneS_4$ has been obtained, $[Au\{[12]aneS_4\}]^{2+}$, which possesses only one ligand coordinated to the gold(II) center.[1988]



(**343**)

The gold(III) complex with the ligand 2-(diphenylphosphino)benzenethiolate, $[Au(2\text{-}PPh_2C_6H_4S)_2]$ shows in the cyclic voltammetry experiments that the gold(II) species has a reasonable stability on the electrochemical time scale.[1970] The gold(III) porphyrin $[AuL]PF_6$ (L = 5,10,15,20-tetrakis(3,5-di-*t*-butylphenyl)porphyrin undergoes reduction at the central ion to give initially the gold(II) porphyrin, overturning the long held assumption that reduction of such complexes only occurs at the macrocycle, followed by a formation of a porphyrin π-anion radical and dianion at more negative potentials.[1990] Stable gold(II) complexes with nitrogen- and oxygen-containing ligands such as CO_2, Me_2CO, THF, pyridine, etc. have been prepared in the gas phase. The successful ligands are characterized by being good σ-donor–π-acceptor molecules and the most stable are those with large dipole moment and a high ionization energy.[1991,1992]

Recently the first metal–xenon compound has been obtained by reduction of AuF_3 with elemental xenon.[38] Attempts to synthesize the elusive AuF the reduction of gold(III) was carried out with xenon, which is a very mild reducing and very weakly coordinating agent. Surprisingly the reaction stopped at the Au^{2+} state and resulted in a completely unexpected complex, the cation $AuXe_4{}^{2+}$, which crystals can be grown at −78 °C. Removal of gaseous xenon under vacuum results in the crystallization of $Au(SbF_6)_2$.[1982] The crystal structure of $(Sb_2F_{11})_2[AuXe_4]$ shows a regular square with Au—Xe bond lengths ranging from 2.728(1) Å to 2.750(1) Å. Three weak contacts between the cation and the anion complete the coordination sphere around the gold atom with Au—F distances of 2.671 Å and 3.153 Å (Figure 18).

In the complex xenon functions as a σ-donor toward Au^{2+}. This is reflected in the calculated charge distribution within the cation, where the main part of the positive charge resides on the xenon atoms. Relativity plays a large role in stabilizing this and other predicted Au—Xe compounds; about half of the Au—Xe bonding energy comes from relativistic effects.[1993]

A further study of this reaction[39] has shown that if the concentration of SbF_5 is fairly high, complex $[AuXe_4]$ $[Sb_2F_{11}]_2$ forms as the sole product in two crystallographically different modifications, the triclinic already considered and another monoclinic, which has been seldom observed. Both modifications differ only in the cation–anion interactions, with a long Au···F contact of 2.928(7) Å in the monoclinic form. By a variation of the xenon pressure and the acid strength of the HF/SbF_5 other species have been isolated such as *cis*-$[AuXe_2][Sb_2F_{11}]_2$, *trans*-$[AuXe_2][SbF_6]_2$, $[Au_2Xe_2F][SbF_6]_3$, and the first Au^{III}–Xe complex $[AuXe_2F][SbF_6][Sb_2F_{11}]$. Their structures are collected in Figure 18.

6.7.3.3.2 Dinuclear gold(II) complexes

As earlier mentioned, one of the reasons of the poor stability of gold(II) complexes is the unfavorable energy of the odd electron. The formation of a metal—metal bond in dinuclear gold(II) complexes giving diamagnetic species provides an extra stability. Thus, the number of

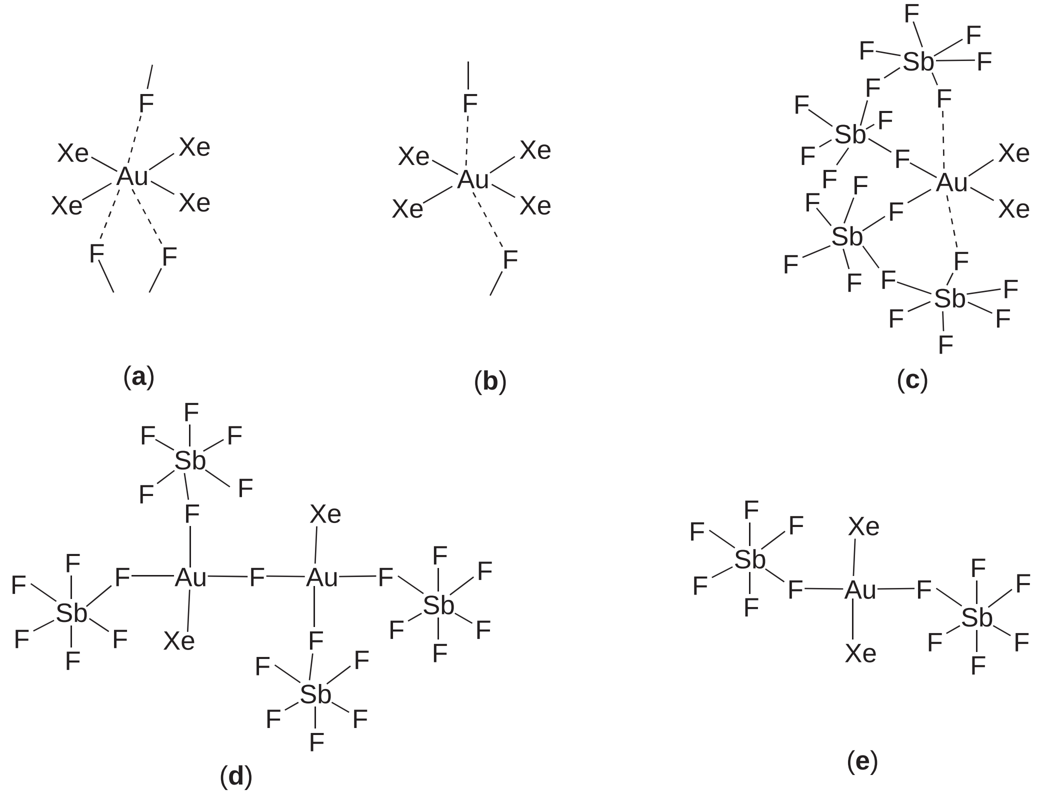


Figure 18 (a) triclinic $[AuXe_4]^{2+}$; (b) monoclinic $[AuXe_4]^{2+}$; (c) $[AuXe_2]^{2+}[Sb_2F_{11}]^{2-}$; (d) $[Au_2Xe_2F]^{+}[SbF_6]^{-}$; (e) *trans*-$[AuXe_2]^{+}[SbF_6]^{-}$.

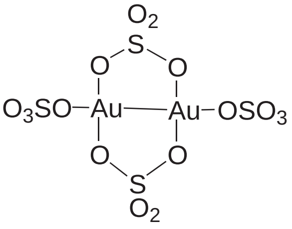
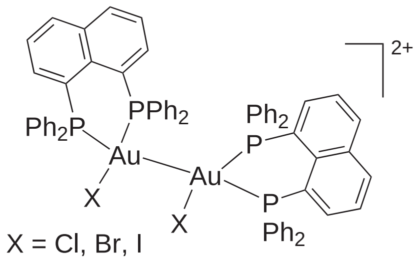
gold(II) complexes containing the Au_2^{4+} core has been increasing in the last decades and different stoichiometries are known. Most of the dinuclear gold(II) compounds are synthesized from the corresponding gold(I) precursors by oxidative addition of halogen. This method works properly with a great variety of dinuclear gold(I) complexes. These include symmetric and asymmetric doubly bridged compounds, monobridged dinuclear derivatives, or without any bridging ligand. The bridging ligands vary from diphosphines, dithiocarbamates and related species, ylide ligands, and mixed-donor ligands of the types C,S or C,P. Experimentally it has been confirmed that the oxidation of a dinuclear gold(I) complex to a gold(II) derivative gives more stable complexes when the gold is bonded to carbon donor ligands. This is really true in the case of bis-ylide ligands. Although the most commonly used oxidants are halogens, others have been used such as haloalkyl RX, $[Hg(CN)_2]$, nitroalkanes, N_2O_4, $[Tl(C_6F_5)_2Cl]$, tetraethylthiuram disulfide, $[Ag(OClO_3)(PPh_3)]$, or $[Ag(NCMe)_4]PF_6$.

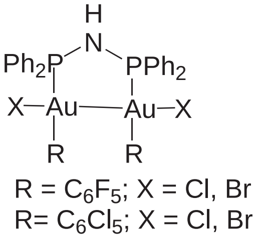
The sulfate salt $AuSO_4$ has been long referred to as a mixed-valent compound in many chemistry textbooks, in spite of the lack of information about its crystal structure. Recently the crystal structure has been established and shows that $AuSO_4$ is the first simple inorganic compound known to contain the cation Au_2^{4+}. This cation is coordinated by two chelating sulfate groups and two monodentate SO_4^{2-} ions (**344**). The gold–gold distance is 2.49 Å, the shortest known for the dinuclear gold(II) complexes.[1994] The monodentate sulfate anions act as chelating ligand to another Au_2^{4+} ion leading to infinite sheets. The compounds $[Au_2X_2(dppn)]$ (dppn = 1,8-bis(diphenylphosphino)naphthalene; X = Cl, Br, I) react with $[Ag(NCMe)_4]PF_6$ and dppn in acetonitrile with oxidation of the gold center to give $[Au_2X_2(dppn)](PF_6)_2$ (**345**), which has two monomeric units connected by a single unsupported Au^{II}—Au^{II} bond.[1995,1996]



(344)



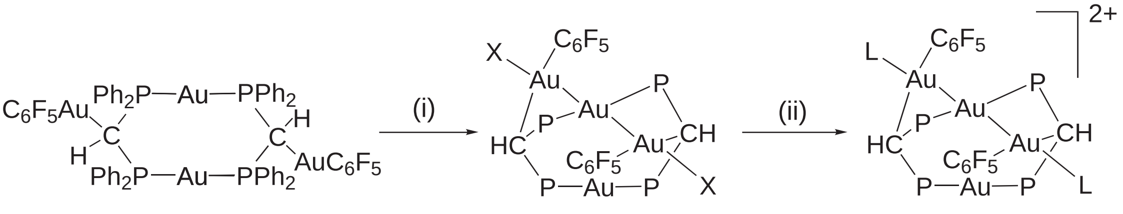
(345)



(346)

Not many gold(II) compounds with *P*-donor ligands have been synthesized and these are not very stable. Dinuclear gold(I) complexes with only one bridging ligand such as $[Au_2X_2\{\mu\text{-}(PPh_2)_2NH\}]$ undergo an oxidative addition of halogen to yield the gold(II) compounds (**346**).[1650]

The reaction of the tetranuclear complex $[Au_2\{\mu\text{-}(PPh_2)_2CHAu(C_6F_5)\}_2]$ with chlorine or bromine does not oxidize the two gold centers of the diauracycle to give the usual gold(II) derivatives with an X—Au—Au—X backbone. Instead, a new type of reaction occurs, probably because of the presence of other gold(I) centers in close proximity.[1997] Displacement reactions using silver salts, such as $[Ag(OClO_3)(THT)]$ or $[Ag(OClO_3)(PR_3)]$ afford cationic complexes (Scheme 25). The structure of the blue PPh_3 derivative shows a linear chain of three gold atoms in a P—Au—Au—P backbone. The assignment of the oxidation states in the linear chain is not straightforward, only two possibilities with integral oxidation states are possible, Au^{II}–Au^{I}–Au^{II} or Au^{I}–Au^{III}–Au^{I}. The former seems more plausible because is close to heteropolynuclear Au^{II}–Pt^{II}–Au^{II} described by Fackler (see below).[2009]



Scheme 25 (i) Cl_2 or Br_2 and (ii) 2 $[Ag(OClO_3)PR_3]$ (L = THT, PPh_3, PPh_2Me, $P(Tol)_3$).

Dinuclear gold(II) complexes with *S*-donor ligands are known for dithiocarbamate[1998] or dithiolate[1844,1999] ligands. They are obtained by oxidative addition with halogens or $(SCN)_2$ or $(SeCN)_2$ to the corresponding gold(I) complexes (Equations (21) and (22)). Although dithiolate complexes are more stable than the dithiocarbamate ones, both decompose in solution to the mixed $[Au^{III}(S\text{-}S)_2][Au^{I}X_2]$. The structure of $(Bu_4N)_2[Au_2X_2\{\mu\text{-}S_2C{=}C(CN)_2\}]$ shows one of the shortest distance found for a gold—gold bond, 2.550(1) Å.

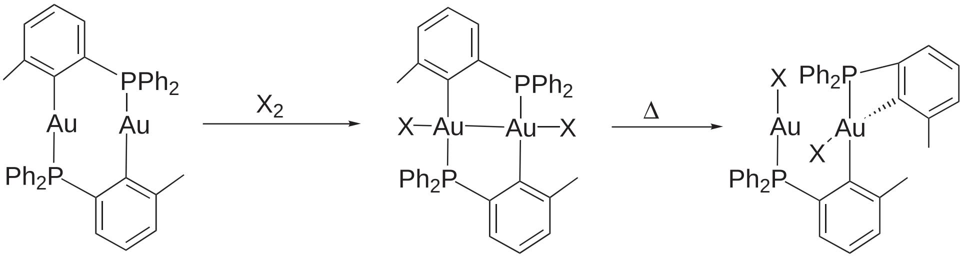
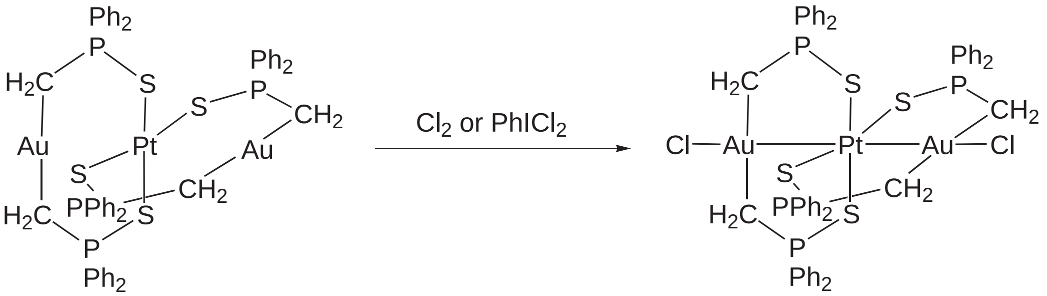
(349)

The digold(II) dihalide complexes containing the cyclometallated phosphine isomerize by coupling of the carbanions at the dimetal center to give digold(I) complexes of the corresponding 2,2′-biphenyl-substituted ligands.[2004] Substitution of the benzoato ligands in this type of complex for C_6F_5 or SCN affords new gold(II) derivatives, $[Au_2X_2(\mu\text{-}2\text{-}PR_2C_6H_4)_2]$ (R = Ph, Et; X = C_6F_5, SCN).[2005] The oxidative addition of the dinuclear $[Au_2(\mu\text{-}C_6H_3\text{-}2\text{-}PPh_2\text{-}6\text{-}Me)_2]$ with halogens gives gold(II)–gold(II) derivatives, which in solution isomerize to colorless heterovalent complexes (Scheme 26). These complexes have been characterized by ^{197}Au Mössbauer and X-ray photoelectron spectroscopy.[2006–2008]



Scheme 26

A heteropolynuclear gold(II) complex with the ligand $SPPh_2CH_2^-$ has been reported by Fackler and co-workers by oxidation with Cl_2 or $PhICl_2$ of the trinuclear species $[Au_2Pt(\mu\text{-}CH_2PPh_2S)_2]$ (Equation (23)).[2009] The gold–platinum distances are 2.668(1) Å and 2.662(1) Å, clearly in the range of metal—metal bonds. Although a Au^{II}–Pt^{II}–Au^{II} assignment of the oxidation states can be made, a more correct description, based on Fenske-Hall calculations, is that a $[Au\text{–}Pt\text{–}Au]^{6+}$ moiety is formed.



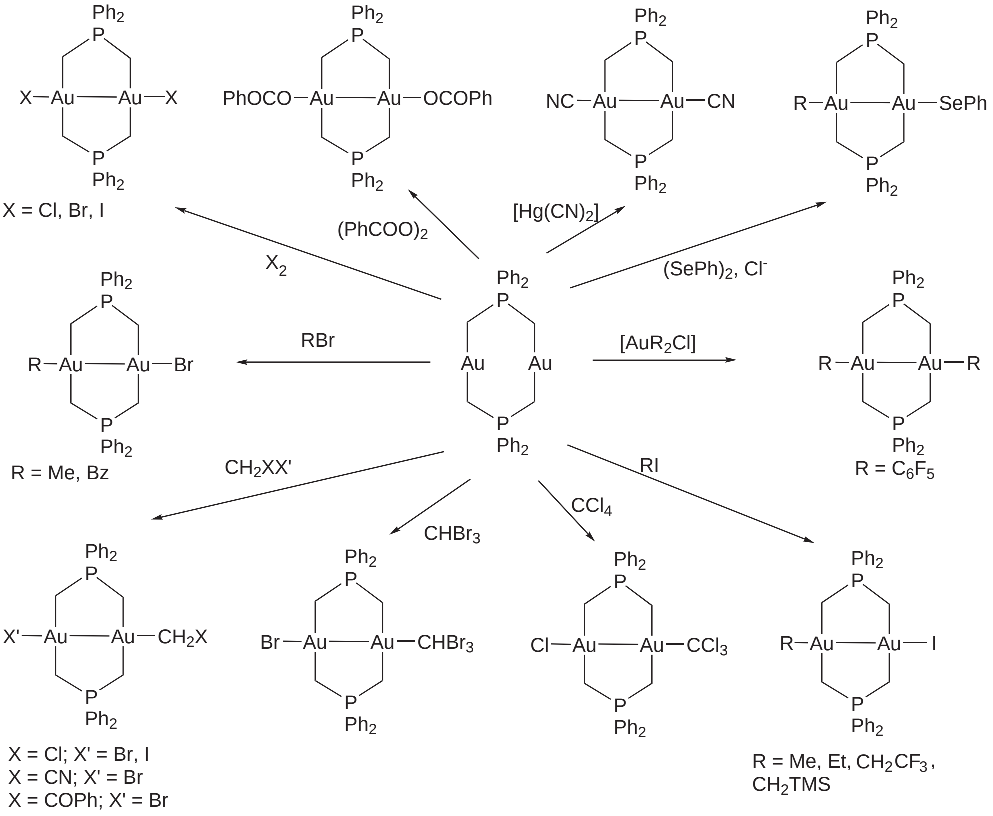
(23)

As we have commented earlier the majority of gold(II) derivatives, and the most stable, have been prepared with bis-ylide ligands. Complexes of the type $[Au_2\{\mu\text{-}(CH_2)_2PR_2\}_2]$ are useful starting materials for the development of gold(II) chemistry. Other ylide dinuclear gold(I) complexes such as $[Au_2\{\mu\text{-}[CH(CO_2R)]_2PPh_2\}_2]$ ($R = Me$, Et) react with Cl_2 or I_2 to give the gold(II) complexes, although these are not so stable.[1672]

The reaction of $[Au_2\{\mu\text{-}(CH_2)_2PR_2\}_2]$ with halogens,[2009–2013] XCH_2CH_2X,[1665] or RS-SR[2014–2017] reagents (where $R = COPh$, $(RCOO)_2$, (S_2CNR_2), (SePh)) yields the corresponding gold(II) derivatives. Addition of haloalkanes to dinuclear gold(I) bis-ylide complexes also affords gold(II) species. Considerable effort has been expended to elucidate the course of this type of oxidative addition reaction,[2018] experimental evidence support the notion that the order of reactivity of such substrates is inversely proportional to the carbon–halogen bond dissociation energies.[2019] As shown in Scheme 27, $[Au_2\{\mu\text{-}(CH_2)_2Ph_2\}_2]$ reacts with alkyl halides RX ($X = Br$, I) to give asymmetrically substituted bicyclic digold(II) complexes.[1665,2011,2020,2021] The reaction is reversible if R bears no electron-withdrawing substituents.[2020] NMR spectroscopic data indicate that in solution the Au^{II} alkyl halide complexes are in equilibrium with the Au^{I} complex and the halocarbon.[2011] In the solid state, the gold(II) methyl bromide and methyl iodide complexes undergo a thermally induced reductive elimination to give $[Au_2\{\mu\text{-}(CH_2)_2PR_2\}_2]$ and MeBr or MeI, respectively.[2011] Furthermore, $[Au_2\{\mu\text{-}(CH_2)_2\ PR_2\}_2]$ catalyzes S_N2 halogen exchange MeBr and CD_3I in a process which is though to involve a S_N2 reaction between the free alkyl halide and the postulated intermediate $[Au_2(Me)\{\mu\text{-}(CH_2)_2\ PR_2\}_2]X$ or $[Au_2(CD_3)\{\mu\text{-}(CH_2)_2PR_2\}_2]X$.[2011,2021] There is no indication that the alkyl halides RX add to $[Au_2\{\mu\text{-}(CH_2)_2PR_2\}_2]$ by two-electron oxidation of a single gold center.

Other oxidizing agents used to generate the bis(ylide) species are $Hg(CN)_2$,[2022] N_2O_4,[2023] and $[Tl(C_6F_5)_2Cl]$[2024] which give the complexes $[Au_2X_2\{\mu\text{-}(CH_2)_2\ PR_2\}_2]$ ($X = CN$, NO_2, C_6F_5, respectively).

Another general procedure to prepare gold(II) complexes consists of substitution reactions on gold(II) derivatives. Halide ligands can be substituted by neutral donor ligands[2025–2032] such as tetrahydrothiophene, Py, ylide, phosphine, etc., to give the corresponding cationic complexes, or with other anionic ligands[2023–2030,2033,2034] such as pseudohalides, carboxylates, dithiocarbamates, tu derivatives, etc. Scheme 28 summarizes the gold(II) derivatives obtained by substitution reactions.

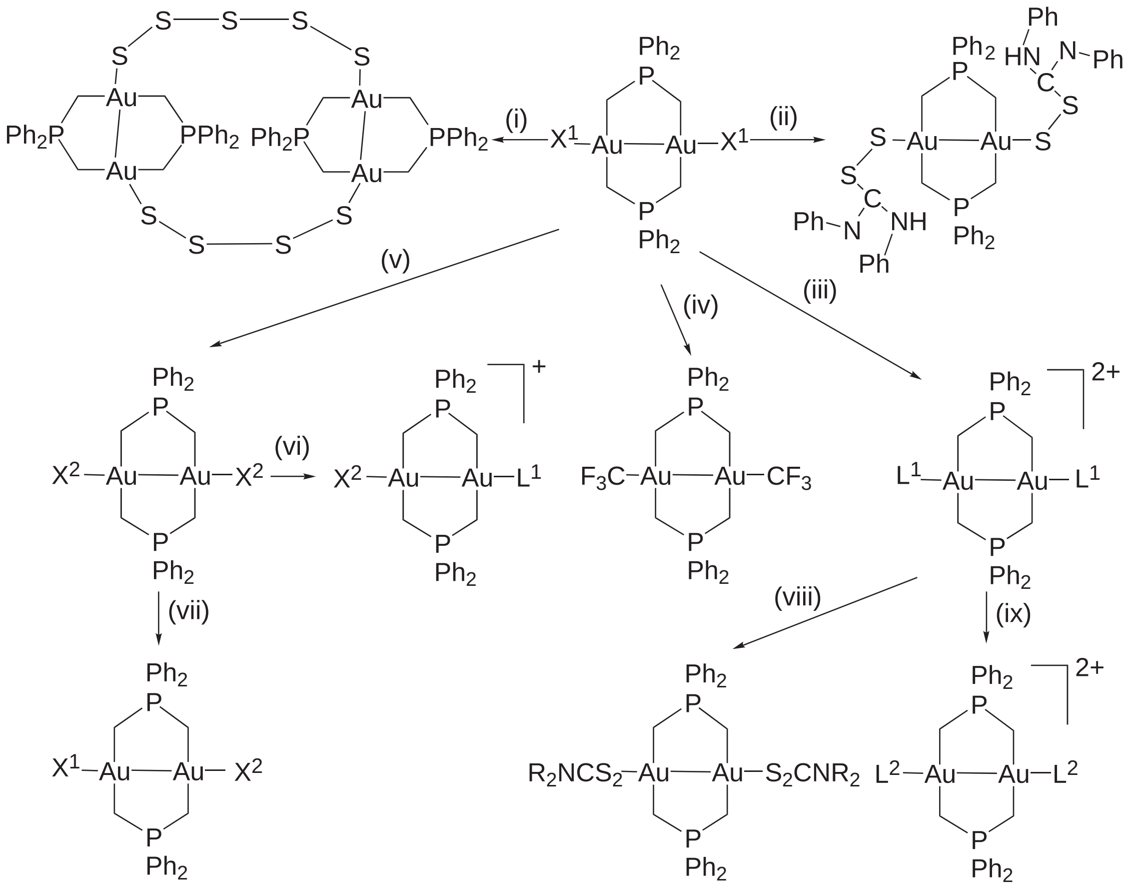


Scheme 27

The tetrahydrothiophene ligand is very labile and then it can be easily replaced by any other neutral or anionic ligand. The reaction with the silver salts of formula $[Ag(OClO_3)L]$ is very useful because it allows the synthesis of cationic symmetric or asymmetric-substituted gold(II) compounds.[2026–2029,2035] Substitution of chlorine or THT in $[Au_2Cl\{\mu\text{-}(CH_2)_2PR_2\}_2(PR_3)]ClO_4$ or $[Au_2\{\mu\text{-}(CH_2)_2PR_2\}_2(PR_3)(THT)](ClO_4)_2$ is also possible in the dinuclear asymmetrically bridged complexes. The preparation of asymmetrical gold(II) complexes can also be achieved by mixing equimolar quantities of the symmetrical derivatives.

Dinuclear gold(II) derivatives with two different bridging ligands have also been synthesized, all of them have the ylide $(CH_2)_2PPh_2^-$ ligand and other bridging ligand that can be diphosphines such as $Ph_2PCH_2PPh_2$ or $Ph_2PNHPPh_2$,[2036] dithiocarbamates,[2036] xanthates,[2037] 2-pyridinethiolate,[2038] phosphoniodithioformate,[2039] or dithiophosphinate (Figure 19).[2040] The gold(II) complexes with ylide and phosphoniodithioformate ligands undergo substitution reactions with silver salts to afford tricationic gold(II) complexes, $[Au_2\{\mu\text{-}(CH_2)_2PPh_2\}(\mu\text{-}S_2CPCy_3)(PR_3)_2](ClO_4)_3$ ($PR_3 = PPh_3$, $P(4\text{-}MeOC_6H_4)_3$).[2039]

An interesting class of substitution reactions in these gold(II) derivatives is those where the new ligands are metal complexes. The reaction of gold(II) $[Au_2(C_6F_5)_2\{\mu\text{-}(CH_2)_2PR_2\}_2]$ with gold(III) $[Au(C_6F_5)_3(OEt)_2]$ gives the pentanuclear complex $[\{Au_2R[\mu\text{-}(CH_2)_2PR_2]_2\}_2(AuR_2)][AuR_4]$ ($R = C_6F_5$) (Equation (24)).[2025] Its backbone is a linear chain of five gold atoms, all of which have square-planar geometry. The Au—Au distances of 2.755(1) Å and 2.640(1) Å are characteristic of metal–metal bonds, the former corresponding to the unsupported gold–gold bond. Extended Hückel calculations indicate that the system is better described as Au^{III}–Au^{I}–Au^{I}–Au^{I}–Au^{III}.



Scheme 28 (i) H_2S, $X^1 = O_2CPh$, (ii) $SC(NHPh)_2$, O_2, OH^-, (iii) $2[Ag(OClO_3)L^1]$ ($L^1 = THT, PPh_3$), (iv) $Cd(CF_3)_2$, (v) AgX^2 ($X^2 = Br, SCN, NO_3, MeCO_2, C_6F_3H_2, C_6F_5, S_2CN^-(CH_2Ph)_2$), (vi) $[Au(PPh_3)L^1]ClO_4$ ($X^2 = C_6F_5$, $L^1 = PPh_3$, THT, $P(Tol)_3$, $AsPh_3$, py; $X^2 = C_6F_3H_2$, $L^1 = PPh_3$, THT, (vii) $[AuX^1(PPh_3)]$ ($X^2 = C_6F_5$, $X^1 = NO_3, MeCO_2, ClO_4$; $X^2 = C_6F_3H_2$, $X^1 = ClO_4$), (viii) $2NaS_2CNR_2$ ($R = Me, Et, C_4H_8$), (ix) $2L^2$ ($L^1 = THT$, $L^2 = py, AsPh_3, SbPh_3, CH_2PPh_3, S(MeS)CHNR$ ($R = 4\text{-}MeC_6H_4, 2\text{-}MeC_6H_4, 4\text{-}MeOC_6H_4, 3,5\text{-}Me_2C_6H_3$).

The unit $[Au_2R[\mu\text{-}(CH_2)_2PR_2]_2]^+$ is readily accessible from many complexes such as $[Au_2R(THT)\{\mu\text{-}(CH_2)_2PR_2\}_2]^+$ or $[Au_2R(OClO_3)\{\mu\text{-}(CH_2)_2PR_2\}_2]$ ($R = C_6F_5$, 2,4,6-$C_6F_3H_2$). The reaction of these gold(II) complexes with either organoaurate $Bu_4N[AuR_2]$ or the gold(I) bis-ylide $[Au_2\{\mu\text{-}(CH_2)_2PR_2\}_2]$, both compounds with a high nucleophilic character, allows the synthesis of gold chain complexes (Scheme 29).[2028]

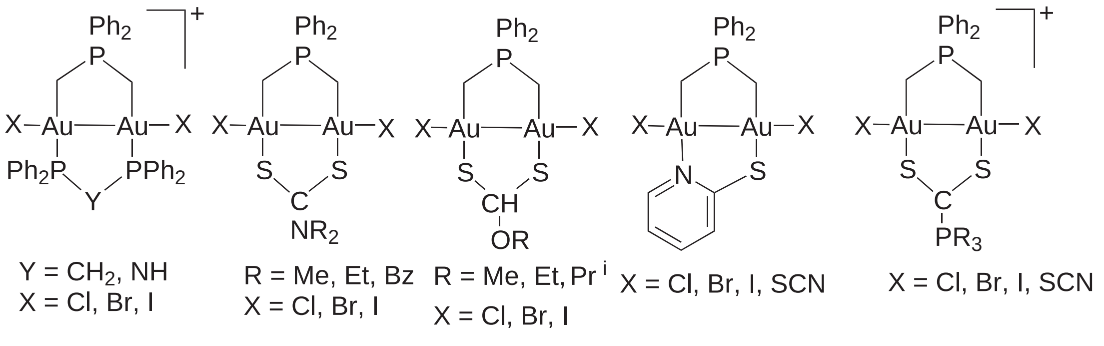


Figure 19 Some examples of asymmetric bridged gold (II) complexes.

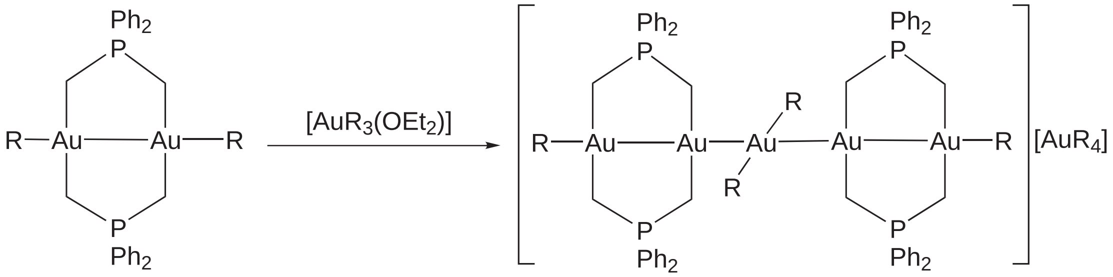
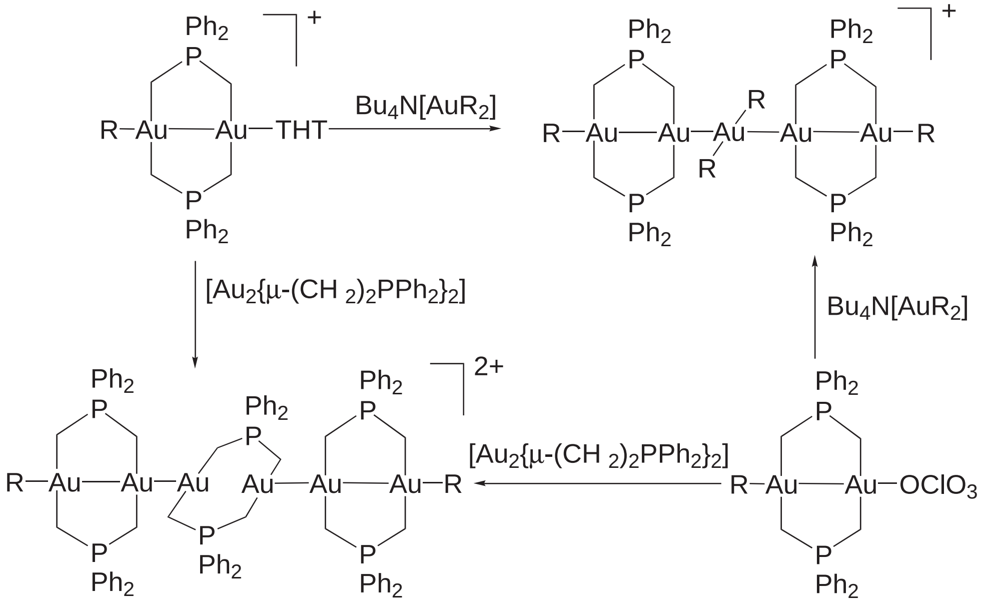
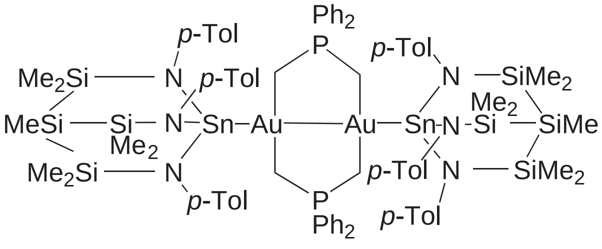


(24)



Scheme 29 R = C_6F_5, 2,4,6-$C_6F_3H_2$, Me.

Other heteropolynuclear gold(II) complex that can be obtained by replacement of halide groups in bis(ylide)gold(II) species by other anionic nucleophilic metal complex is the tin derivative $[Au_2\{Sn[N(p\text{-Tol})SiMe_2]_3SiMe\}_2\{\mu\text{-}(CH_2)_2PPh_2\}_2]$ (**350**).[2041]



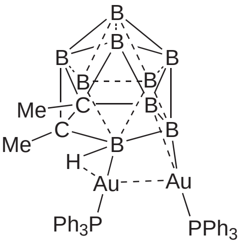
(**350**)

Other less useful general synthetic procedures that have been used to prepare gold(II) compounds area comproportionation reaction between the gold(III) $[Au_2Br_4\{\mu\text{-}(CH_2)_2PPh_2\}_2]$ and gold(I) $[Au_2\{\mu\text{-}(CH_2)_2PPh_2\}_2]$ to give $[Au_2Br_2\{\mu\text{-}(CH_2)_2PPh_2\}_2]$,[2021] or the simple oxidation in air with 2-thiol-pyridine or 2-sulfanylbenzothiazole of the gold(I) bis-ylide.[2042]

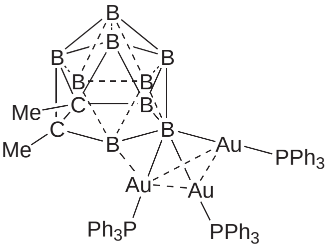
6.7.3.4 Gold(I) Complexes

6.7.3.4.1 Complexes with boron donor ligands

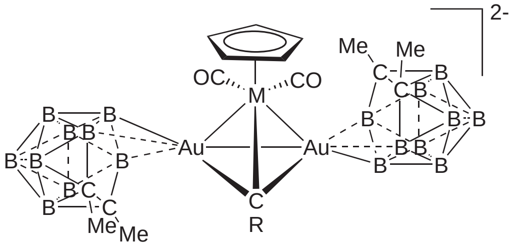
Only a limited number of complexes containing gold–boron bonds have been reported in the last two decades. Much of the work done in gold borane chemistry was often guided by the isolobal principle that suggests close analogies for species with protons and AuL^+ cations as functional groups.[2043] The reaction of the methylated *nido*-carborane, $Na_2(C_2B_9H_9Me_2)$, with $[AuCl(PPh_3)]$ gives the anionic species $[Au(C_2B_9H_9Me_2)(PPh_3)]^-$, which was isolated as the tetraethylammonium salt.[2044] This reaction clearly resembles protonation of the carborane. Further auration of this complex with $[AuCl(PPh_3)]$ leads to the dinuclear compound $[Au_2(C_2B_9H_9Me_2)(PPh_3)_2]$. The structure shows that each gold atom is predominantly bonded to one boron atom of the open carborane face, but there are also gold contacts between both gold atoms, to one of the neighboring boron atoms and to one of the hydrogen atoms (**351**).[2045] Deprotonation of this complex using NaH followed by treatment with $[AuCl(PPh_3)]$ yields the trinuclear complex (**352**), with the three gold atoms predominantly bonded to a single boron atom, with short gold–gold interactions.[2045] The gold carborane derivative $Me_4N[Au(C_2B_9H_9Me_2)(PPh_3)]$ has been used to prepare several mixed metal complexes in which gold atoms are bonded to rhodium,[2043,2046] iridium,[2043,2047] and platinum.[2048] The *nido*-carborane $C_2B_9H_{12}^-$ reacts with $[AuCl(PPh_3)]$ to afford the compound $[Au(C_2B_9H_{12})(PPh_3)]$,[2049] or $[Au(9\text{-}SMe_2\text{-}7,8\text{-}C_2B_9H_{10})(PPh_3)]$.[2050] Treatment of $Tl[$*closo*$\text{-}1,2\text{-}Me_2\text{-}3,1,2\text{-}TlC_2B_9H_9]$ with $[AuCl(THT)]$ followed by addition of the alkylidene complexes $[M(\equiv CR)(CO)_2(C_5H_5)]$ ($M = Mo$, $R = C_6H_4Me\text{-}4$, $C_6H_3Me_2\text{-}2,6$; $M = W$, $R = C_6H_4Me\text{-}4$) and $(NEt_4)Cl$ yields the salts $(Et_4N)_2[10,10'\text{-}$*endo*$\text{-}\{Au_2M(\mu_3\text{-}CR)(CO)_2(C_5H_5)\}\text{-}7,7',8,8'\text{-}Me_4\text{-}$*nido*$\text{-}7,7',8,8'\text{-}(C_2B_9H_9)_2]$ (**353**) and $Et_4N[10\text{-}$*endo*$\text{-}\{AuM(\mu\text{-}CR)(CO)_2(C_5H_5)\}\text{-}7,8\text{-}Me_2\text{-}$*nido*$\text{-}7,8\text{-}C_2B_9H_9]$.[2051]



(351)



(352)

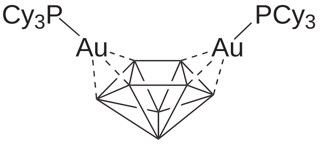


(353)

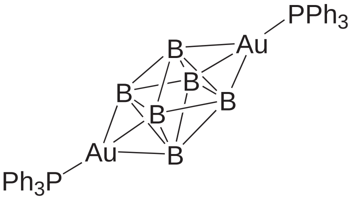
The reaction of $[AuMe(PCy_3)]$ with $B_{10}H_{14}$ gives methane and the aurated complex $[Au(B_{10}H_{13})(PCy_3)]$ with a η^2 boron cage,[2052–2054] whereas the reaction with $B_{10}H_{12}(PPh_3)_2$ causes partial degradation of the B_{10} cluster and leads to $[Au_2(B_8H_{10})(PCy_3)_2]$ (**354**) with a double η^3 boron cluster.[2055] The gold complex with the 7,8-dicarba-9-nickela-undecaborane, $[Au(9\text{-}C_5H_5\text{-}7,8,9\text{-}C_2NiB_8H_{10})(PPh_3)]$,[2056] and a ruthenadecaborane gold derivative,[2057] have been reported. The dinuclear gold complex containing a hexaborate as bridging ligand, $[Au_2(\mu\text{-bis-}\eta^3\text{-}B_6H_6)(PPh_3)_2]$ (**355**), have been obtained from $[AuCl(PPh_3)]$ and $[B_6H_6]^{2-}$. Two different polymorphs have been characterized structurally in which the gold atoms display strongly distorted tetrahedral coordination to three boron atoms and one phosphorus atom.[2058,2059] The crystal structure of the pentaborane cluster $[Au(B_5H_8)(PPh_3)]$ has been reported.[2060]

Polyauration of a single boron atom was accomplished using a phosphineborane $(Cy_3P)(TMS)BH_2$ which, upon treatment with the oxonium salt $[O(AuPPh_3)_3]BF_4$, gives the tetra-aurated compound $[(Cy_3P)B(AuPPh_3)_4]BF_4$ (**356**).[2061] Surprisingly, stoichiometric substitution could only be carried out with an oxonium salt bearing bulky tertiary phosphines such as $P(o\text{-}Tol)_3$, giving $[(Cy_3P)B\{Au(o\text{-}Tol)_3\}_3]$.[115,2062]

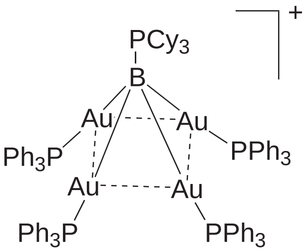
Au–B bonds are also present in metal clusters with interstitial or peripheral boron atoms. An example is the cluster $[Fe_4(CO)_{12}BH(AuPPh_3)_2]$, which was prepared by reaction of $[AuCl(PPh_3)]$ with the carbonyl iron dihydride. With the oxonium salt the reaction proceeds to the trinuclear gold derivative $[Fe_4(CO)_{12}B(AuPPh_3)_3]$ (**357**).[2063–2070] The ruthenium analogues and complexes with other ligands have been also synthesized as, for example, (**358**).[2071–2079]



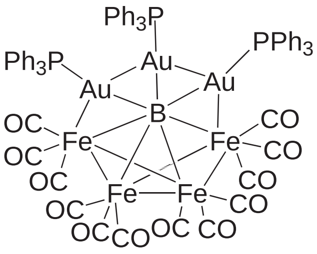
(354)



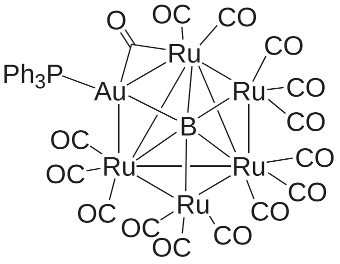
(355)



(356)



(357)



(358)

6.7.3.4.2 *Complexes with carbon donor ligands*

The first carbonyl complex of gold, [AuCl(CO)], was prepared in 1925[2080,2081] and since then only a few more derivatives have been obtained. The [AuBr(CO)] derivative was prepared later and is unstable in the solid state.[2082,2083] The reductive carbonylation of $Au(SO_3F)_3$ in fluorosulfonic acid leads via $[Au(CO)_2]^+$ (solvent) to solid $[Au(SO_3F)(CO)]$ (Scheme 30).[2084] $[Au(CO)_2]^+$ salts are produced in strongly ionizing protic acids or in Lewis acids such as SbF_5.

$$Au(SO_3F)_3 + 3\ CO \xrightarrow[HSO_3F]{25\ ^\circ C} [Au(CO)_2]^+ + CO_2 + S_2O_5F_2 + SO_3F^- \xrightarrow[HSO_3F]{\Delta} [Au(SO_3F)(CO)] + CO$$

Scheme 30

The oxidation of metallic gold by UF_6 in liquid HF in the presence of CO gives $[Au(CO)_2][UF_6]$ (Equation (25)):[40]

$$Au + 2\ CO + UF_6 \xrightarrow{\text{HF liq.}} [Au(CO)_2][UF_6] \qquad (25)$$

Carbonylation of $[Au(SO_3F)(CO)]$ in pure SbF_5 gives $[Au(CO)_2][Sb_2F_{11}]$.[41] The reaction of $[Au(SbF_6)_2{\cdot}Au(AuF_4)_2]$ with AsF_3 in HF/SbF_5 and in the presence of CO yields $[Au(CO)_2]_2(SbF_6)(Sb_2F_{11})$.[2085] The mixed valence $[Au_2Cl_4(CO)]$ has also been prepared.[2082,2083] The tris(pyrazolyl)borate analogous to silver (complex **8**) $[Au\{HB\{3,5\text{-}(CF_3)_2pz\}_3\}(CO)]$ has been reported.[2086] All the compounds exhibit υ(CO) IR frequencies at higher wave numbers than free CO, indicating insignificant π-back donation from gold to CO. This deduction is supported further by Mössbauer spectroscopy,[2087] the crystal structure determination of [AuCl(CO)],[2088] and *ab initio* calculations.[2089,2090] A new gold catalyst, $[Au(CO)_n]^+$ ($n = 1$, 2), has been synthesized by reaction of Au_2O_3 in concentrated sulfuric acid, and exhibits high catalytic activity for carbonylation of alkenes.[2091]

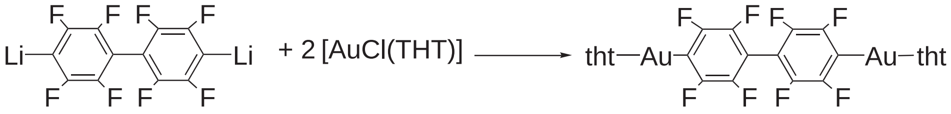
Complexes of the type [AuRL] may contain a great variety of organic ligands such as alkyl, aryl, vinyl, or alkynyl, whereas the neutral donor ligand L is most commonly a tertiary phosphine. Also many polynuclear complexes are known which have the C–Au–L moiety with bridging polyfunctional ligands. Alkyl- or aryl-gold(I) complexes are usually synthesized by reaction of an alkyllithium or a Grignard reagent with a gold(I) halide compound. The oxonium salt, $[O(AuPPh_3)_3]BF_4$, can be used instead of $[AuCl(PPh_3)]$ and shorter reaction times and higher yields are obtained.[2092,2093] Methylgold(I) derivatives have been obtained with several ligands as $[AuMe(AsPh_3)]$,[2094] [AuMe(TPA)] (TPA = 1,3,5-triaza-7-phosphaadamantane),[2095] $[Au_2Me_2\{\mu\text{-}(PPh_2)_2C(CH_2)_2\}]$,[2096] or $[Au_3Me_3(\mu\text{-dmmp})]$ (dmmp = bis(dimethylbis(dimethylphosphinomethyl)methylphosphine)[2097,2098] which show interesting photophysical properties. The nature of bonding in $[AuMe(PMe_3)]$ has been studied theoretically and indicates a small 5*d* contribution to the overall bonding.[2099] If relativistic effects are included the results suggest that the contribution of the Au 5*d* electrons to the overall bonding is appreciable.[2100] A structural study of this complex by gas-phase electron diffraction has also appeared.[2101]

Haloalkylgold(I) complexes can be prepared by photochemical insertion of fluoroalkenes into the gold–carbon bond of methylgold(I) complexes.[2102] Other routes include direct auration of halocarbons, such as $CHCl_3$, MeCN, HCl_2CN, with $[O(AuPPh_3)_3]BF_4$ (Equation (26)),[2103,2104] or the reaction of $Cd(CF_3)_2$ with the gold(I) halide precursors.[1638,1656] The structure of $[Au(CF_3)(PPh_3)]$ has been reported:[2105]

$$CHCl_3 + [O(AuPPh_3)_3]BF_4 \xrightarrow{NaH} [Au(CCl_3)(PPh_3)] \qquad (26)$$

The chloromethyl derivative $[Au(CH_2Cl)(PPh_3)]$ has been prepared by reaction of $[AuCl(PPh_3)]$ with $Mg(CH_2Cl)Cl$. Substitution reactions on this complex with LiI, NaOMe, or PPh_3 lead to $[Au(CH_2X)(PPh_3)]$ (X = I, OMe) or $[Au(CH_2PPh_3)(PPh_3)]Cl$.[2106] $[Au(CH_2Cl)(PPh_3)]$ reacts with $[PtMe_2(bipy)]$ with oxidative addition of the metal complex to give $[PtClMe_2\,(CH_2AuPPh_3)(bipy)]$.[2107] The complex $[Au(CH_2SPh)(PMe_3)]$ has also been obtained by treatment of $LiCH_2SPh$ and $[AuCl(PMe_3)]$.[2106] Trimethylsilylmethyl gold(I) complexes, $[Au(CH_2TMS)L]$, have been synthesized by reaction of $Mg(CH_2TMS)Cl$ with [AuClL] (L = $AsPh_3$, PPh_3); the derivative with $AsPh_3$ undergoes substitution reactions with several phosphine and diphosphine ligands.[2108]

Arylgold(I) compounds can be similarly prepared to alkyl derivatives via the organolithium or the Gridnard route. These methods have been used to prepare pentachlorophenyl,[1641] 4,4′-octafluorobiphenyl (Equation (27)),[2109] 2,4,6-tris(trifluoromethyl)phenyl,[1642,2110] triphenylarsine,[2002,2003] bipyridine,[1661] terphenyl,[2111,2112] and Mes[289,290,295,2112] derivatives. The structure of the Mes complex $[Au(Mes)]_5$ is a pentamer with a five-pointed star shape:[2111,2112]



(27)

Other methods consist of the use of organosilver or organomercury aryl species, which have been used with 2,4,6-trinitrophenyl (Equation (28)),[2113,2114] polyhalophenyl,[2115] or Mes derivatives (Equation (29)):[2116]

$$(Ph_3PBz)[AuCl_2] + [Hg\{2,4,6\text{-}(NO_2)_3C_6H_2\}_2] \xrightarrow{\hspace{2em}} (Ph_3PBz)[Au\{2,4,6\text{-}(NO_2)_3C_6H_2\}Cl] \qquad (28)$$
$$- [Hg\{2,4,6\text{-}(NO_2)_3C_6H_2\}Cl]$$

$$Et_4N[AuCl_2] + [Ag(mes)]_4 \xrightarrow{\hspace{4em}} Et_4N[Au(Mes)Cl] + AgCl \qquad (29)$$

Treatment of (phosphine)gold(I) halides or tris(phosphinegold(I))oxonium salts with $Na(BPh_4)$ affords arylgold(I) phosphine species through an unusual phenyltransfer reaction (Equation (30)).[2117,2118] A complex with a bridging tetrachlorophenyl group, $[PtCl(PPh_3)_2(\mu\text{-}C_6Cl_4)Au(PPh_3)]$, has been obtained by reaction of $[Au(C_6Cl_4H)(PPh_3)]$ with $Pt(PPh_3)_3$:[2119]

$$[O(AuPBu^t_3)_3]BF_4 + Na(BPh_4) \xrightarrow{\hspace{3em}} 3\,[AuPh(PBu^t_3)] + NaBF_4 + PhBO \qquad (30)$$

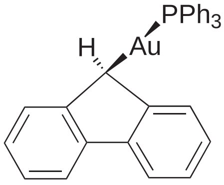
Gold(I) complexes containing cyclopentadienyl or related ligands have been prepared either by the organolithium method as $[AuR(PR_3)]$ ($R = C_5H_5$, C_5Me_5; $PR_3 = PMe_3$, PPr^i_3, PPh_3)[2120] or by direct auration with $[O(AuPPh_3)_3]BF_4$ (Equation (31)).[2121,2122] The structure of $[Au(C_5Ph_2H_3)(PPh_3)]$ has been reported:[2123]

$$[O(AuPPh_3)_3]BF_4 + 3\,C_5Ph_4H_2 \longrightarrow 3\,[Au(C_5Ph_4H)(PPh_3)] + (H_3O)BF_4 \qquad (31)$$

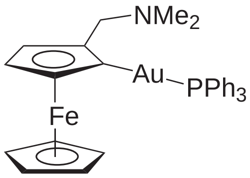
The pentakis(methoxycarbonyl)cyclopentadiene is a strong acid that displaces weaker organic acids upon interaction with their metal salts (Equation (32)):[2124]

$$[Au(CO_2Me)(PPh_3)] + C_5(CO_2Me)_5H \longrightarrow [Au\{C_5(CO_2Me)_5\}(PPh_3)] + MeCO_2H \qquad (32)$$

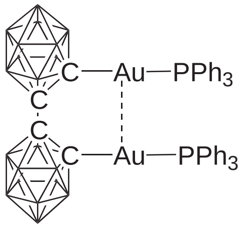
These complexes present a fluxional behavior in solution with rapid migration of the $Au(PR_3)$ group around the η^1-C_5 ring even at low temperatures; however, the tetraphenylcyclopentadienyl complex has been found to be stereochemically rigid.[2121] Other related ligands are 9-fluorenyl (**359**),[2125] Fc,[2126] dimethylaminoferrocenyl (**360**),[2127] and metallocene complexes of cobalt,[2128] rhodium,[2128] or chromium.[2129] Other compounds with Au—C bonds have been obtained with other organic moieties, including those derived of carboranyl anions (**361**),[2094,2130,2131] iminoalkyl,[2132] silylcyclopropil ethers,[2133] pyrazolone derivatives,[2134] alkyl with carbonyl or sulfonyl groups,[2135–2138] and ylide ligands.[1646,1648,2139–2147]



(359)

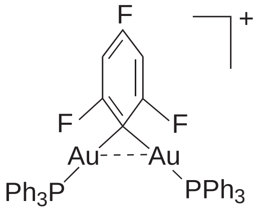


(360)

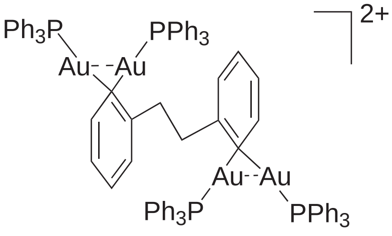


(361)

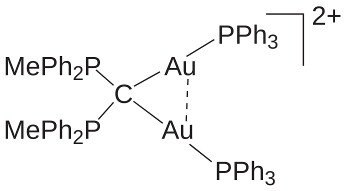
Other types of compounds with carbon donor ligands are those derived from the multiauration of the carbon giving species from two up to six gold atoms coordinated around a carbon donor ligand. The first examples were obtained in 1974 with the tolyl and Fc derivatives by protonation of the aryl moieties, which liberates $AuPPh_3^+$ that attacks a second molecule of the aryl gold complex.[2148] Another method to prepare this type of complex is treatment with the oxonium salt, $[O(AuPPh_3)_3]BF_4$. Similar complexes have been obtained with other organic units, such as $[MeC_6H_4\{Au_2(dppm)\}]BF_4$,[2149] $[2,4,6\text{-}C_6F_3H_2(AuPPh_3)_2]ClO_4$ (**362**), $[2,4,6\text{-}Me_3C_6H_2(AuPPh_3)_2]ClO_4$, $[Ph_4C_5(AuPPh_3)_3]BF_4$,[2150] $[(CN)_2C(AuPPh_3)_3]BF_4$,[2151] *N*-alkylated barbituric acid,[2152,2153] or $[(Ph_3PAu)_2C_6H_4(CH_2)_2\text{-}C_6H_4(AuPPh_3)_2](BF_4)_2$ (**363**).[2154] Ylide or methanide complexes have been obtained where the two protons of a methylene unit have been substituted by two gold phosphine units; the main method used is reaction with acetylacetonate gold complexes.[2155] Thus, ylide complexes of the type $[Ph_3PCH(AuPPh_3)_2]^+$,[2156] $[(Ph_2MeP)_2C(AuPPh_3)_2]^{2+}$ (**364**),[2157] $[(PPh_3)(CONMe_2)C(AuPPh_3)_2]$,[1647] $[(TMS)_2C\{B(NPr^i_2)_2\}_2C(AuPPh_3)_2]$,[2158] $[OC\{(PPh_3)C(AuPPh_2Me)_2\}_2]$,[1652] $[(EtCO_2)CH(AuPPh_3)PPh_2(CO_2EtC)(AuPPh_3)_2]^+$ (**365**),[1672] or $[(R_3P)(Py)C(AuPPh_3)_2]^+$,[2159,2160] have been reported.



(362)

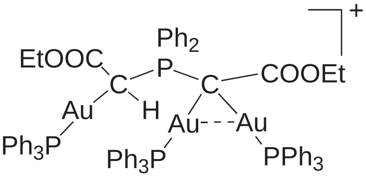


(363)

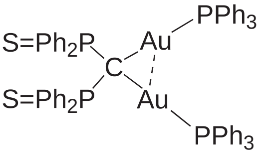


(364)

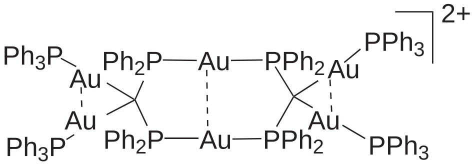
Also in methanide complexes, mainly derived of $Ph_2PCH_2PPh_2$ and its derivatives, substitution of two protons for gold(I) phosphine units has been achieved in gold(III) complexes (see Section 6.7.3.2.3(ii)), $[(SPPh_2)_2C(AuPPh_3)_2]$ (**366**),[2161] $[(SPPh_2)(RPPh_2)C(AuPPh_3)_2]ClO_4$,[230] $[\{(Ph_3PAu)_2\}_2\{C(PPh_2)_2Au\}_2](ClO_4)_2$ (**367**),[2162,2163] or in heteropolynuclear complexes.[2164–2166]



(365)

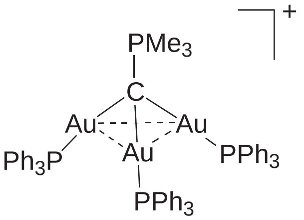


(366)

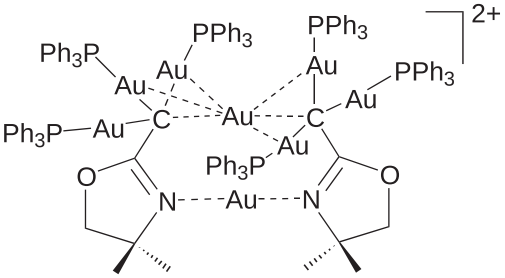


(367)

Further auration of a single carbon atom has been reported and thus complexes with three, four, five, or even six gold atoms have been obtained. The silylated ylide $Me_3P{=}CH(TMS)$ reacts with $[AuCl(PPh_3)]$ in the presence of CsF to give $[(Me_3P)C(AuPPh_3)_3]Cl$ (**368**).[2157] Another method of obtaining this type of complex is the use of $[O(AuPPh_3)_3]BF_4$ or $[Au(ACAC)(PPh_3)]$, and thus the reaction with $[(R_3Si)_2CH(AuPPh_3)]$ ($R = Me_3$, Me_2Ph) gives a mixture of the di- and triaurated species $[(R_3Si)_2C(AuPPh_3)_2]$ and $[(R_3Si)_2C(AuPPh_3)_3]BF_4$.[2167,2168] Similarly the reaction of Me_3SO^+ with three equivalents of $[Au(ACAC)(PPh_3)]$ leads to the trinuclear compound $[Me_2OSC(AuPPh_3)_3]^+$.[2169] Tetraaurated species have been synthesized, generally by reaction of $C[B(OMe)_2]_4$, $CH_2[B(OMe)_2]_2$, or $MeC[B(OMe)_3]_3$ with mixtures of $[AuCl(PR_3)]$ and CsF; the same method is used to get higher polyaurated species. Then complexes such as the oxazolinyl derivative (**369**),[2170] $[RC(AuPPh_3)_4]BF_4$ where R can be H,[2156] Me,[2171] PMe_3,[2157] $SOMe_2$,[2169] or with other phosphines or diphosphines such as PCy_3,[2171,2172] or $(PPh_2CH_2CH_2)_2C_6H_4$,[2171] have been reported. These complexes have a square-pyramidal structure with short gold–gold interactions.



(368)



(369)

The homoleptic $[C(AuPCy_3)_4]$ (**370**) is only obtained with very bulky phosphines and has the expected tetrahedral geometry.[2173] In the presence of less steric demanding phosphines, such as PPh_3 or $P(C_6H_4\text{-}Me)_3$, the pentacoordinated species $[C(AuPR_3)_5]^+$ (**371**) is produced in high yield,[2174] which possesses a trigonal pyramidal geometry with short gold–gold contacts among the equatorial gold atoms. These pentacoordinate species can accommodate another AuL^+ fragment and, under suitable conditions, the hexacoordinate compounds $[C(AuPR_3)_6]^{2+}$ (**372**) are obtained for a great variety of phosphines or diphosphines.[2,2175–2178] They have an octahedral geometry with short gold–gold interactions, equivalent phosphorus atoms in ^{31}P NMR, and a septet for the central carbon atom in the ^{13}C NMR. Conventional as well as ^{252}Cf-plasma desorption mass spectrometric studies have also been reported.[2179] A better reaction pathway for the hexaaurated species has been developed which consists of the reaction of $TMSCHN_2$ with $[O(AuPR_3)_3]^+$ in the presence of NEt_3 in dichloromethane.[2180]

Development of acetylidegold(I) complexes has expanded in recent years. The preference of gold(I) for a linear coordination, together with the linearity of the $C{\equiv}C$ bond of the acetylide unit and its π-unsaturated nature, have made the metal acetylides attractive building blocks for molecular wires and organometallic oligomeric and polymeric materials, which may possess unique properties such as optical nonlinearity,[2181] liquid crystallinity,[2182,2183] or luminescence.[2184] Polymeric gold acetylides $[Au(C{\equiv}CR)]_n$ have been known for a long time. The oligomeric

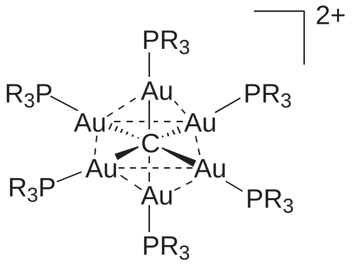
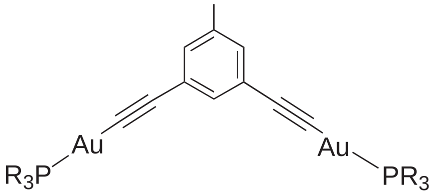
(371)

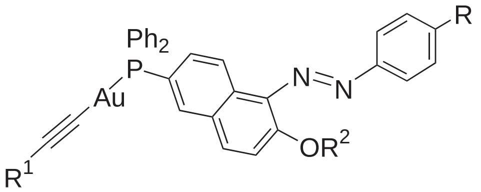


(372)

$[Au(C{\equiv}CBu^t)]_n$ has been prepared by reaction of $[Au(NH_3)_2]^+$ with $HC{\equiv}CBu^t$; its structure is a catenate with η^1 and η^2 coordination around the gold atoms.[2185,2186] Complexes of the type $[Au(C{\equiv}CR)L]$ are obtained by a variety of synthetic routes, including the reaction of $[Au(C{\equiv}CR)]_n$ with a donor ligand, reaction of [AuClL] with $HC{\equiv}CR$ in the presence of Et_2NH, CuX, NaOR, etc. The neutral complexes $[Au(C{\equiv}CR)L]$ or $[Au(C{\equiv}CRC{\equiv}CR)L]$ are known mainly with tertiary phosphines and for a great variety of substituents R (see compounds (**373**) and (**374**), as some examples),[258,2187–2207] and other ligands, such as amine,[2185,2208] or phen.[2189] Anionic complexes of the type $[Au(C{\equiv}CR)X]^-$ (X = Cl, Br, I; R = H, Ph) have also been reported.[2192,2209,2210]



(373)



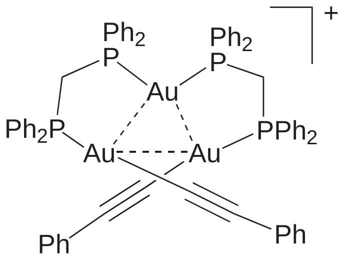
(374)

Unsubstituted alkyne gives dinuclear gold(I) acetylides $[Au_2\ (C{\equiv}C)(PR_3)_2]$,[2098,2189,2190,2211,2212] and polyines also yield similar type of compounds.[2212–2217] Polynuclear gold(I) acetylides with diphosphines have grown in the last years because of the luminescence properties of many of these complexes. The first report on the luminescence of gold(I) acetylides appeared in 1993 in which the emissive behavior of the complex $[Au_2(C{\equiv}CPh)_2(\mu\text{-dppe})]$ was described.[2218] The reaction of $[Au(C{\equiv}CPh)]_n$ with diphosphines, as dppm, affords the compound $[Au_3(C{\equiv}CPh)_2(\mu\text{-dppm})_2][Au(C{\equiv}CPh)_2]$ (**375**),[2219] but with other diphosphines, such as 2,6-bis(diphenylphosphino)pyridine (dppy) yields a polynuclear complex $[\{Au_2(\mu\text{-dppy})(C{\equiv}CPh)_2\}_n]$.[2220] Also, complexes with monodentate diphosphines such as $[Au(C{\equiv}CBu^t)(PR_2CH_2PR_2)]$ have been prepared.[2196] Other complexes with acetylide ligands and diphosphines, triphosphines, or tetraphosphines, as, for example, (**376**) or (**377**), have been obtained and the luminescent properties tested for some of them.[2206,2207,2221–2227]

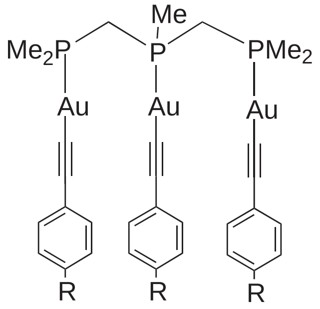
Thermolysis of the dinuclear $[Au_2(C{\equiv}CBu^t)_2(\mu\text{-}PPh_2CH_2PPh_2)]$ in refluxing toluene leads to the intermolecular elimination of $HC{\equiv}CBu^t$ and formation of complex (**378**).[2228]

Polymer complexes have been prepared from diphosphines and acetylides, both of which are bridging ligands, as, for example, (**379**).[2229] Gold(I) di- and triacetylide complexes have been used to obtain rigid-rod polymers.[2217,2225,2230,2231] Bifunctional alkyne ligands such as $R_2PC{\equiv}CH$ (R = Ph, Pr^i) form complexes $[AuCl(PPh_2C{\equiv}CH)]$ that upon treatment with a base eliminate HCl and give the polymers $[\{Au(PPh_2C{\equiv}C)\}_n]$.[2232]

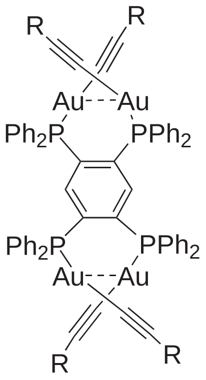
The same reactions have lead to the discovery of organometallic catenanes by self-assembly of an oligomeric digold(I) diacetylide $[\{(AuC{\equiv}CCH_2OC_6H_4)_2X\}_n]$ and a diphosphine ligand $Ph_2P(CH_2)_nPPh_2$.[2233] Systematic investigations of this unusual reaction have shown that the number of methylene spacer groups n in the diphosphine ligand and the nature of the hinge group X are key factors in determining if the self-assembly will give a simple ring by 1 + 1 assembly, a [2]catenane by 2 + 2 assembly,[2233–2235] or a double braided [2]catenane by 4 + 4 assembly (Scheme 31).[2236,2237]



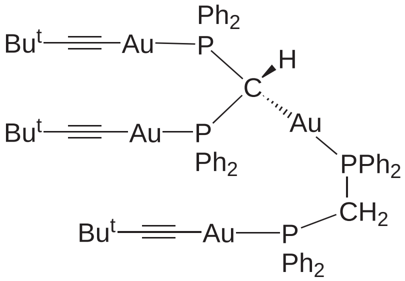
(375)



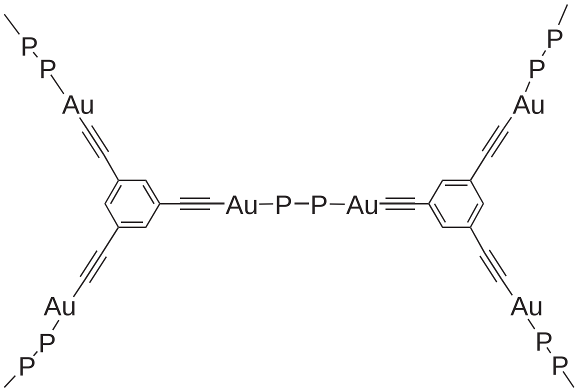
(376)



(377)



(378)

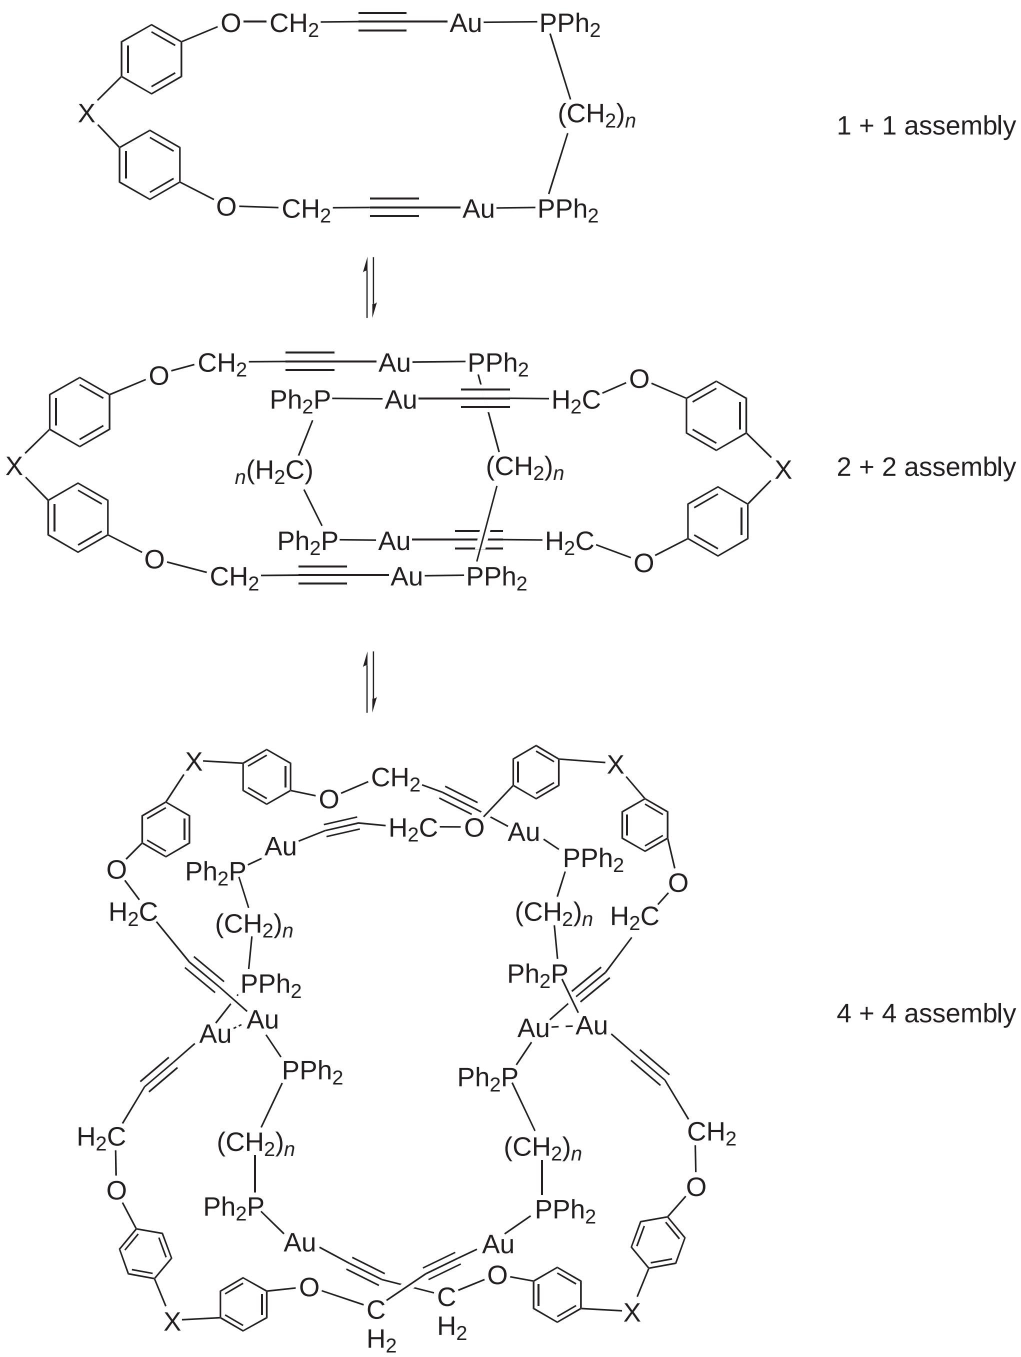


(379)

Mixed gold(I)–gold(III) complexes have been obtained by reaction of $[Au(C_6F_5)_3(PPh_2C{\equiv}CH)]$ with acetylacetonate compounds such as $[Au(ACAC)(PPh_3)]$ or $[(Ph_3P)_2N][Au(ACAC)_2]$ to yield $[Au(C_6F_5)_3\{PPh_2C{\equiv}CAu(PPh_3)\}]$ or $[(Ph_3P)_2N]$ $[\{Au(C_6F_5)_3(PPh_2C{\equiv}C)\}_2Au]$.[1751] Some heteropolynuclear gold-containing acetylides of iron,[2238] ruthenium,[2238] molybdenum,[2239] tungsten,[2239,2240] or platinum have also been described.[2241]

(Isonitrile)gold(I) complexes have attracted increasing attention because of their potential use in new domains of applications such as MOCVD precursors for the deposition on thin gold films[2187,2242,2243] or liquid crystals.[2182,2244–2251] Most of the complexes described are of the type $[AuX(CNR)]$ ($X = Cl$, Br, I, SCN; $R = Me$, Ph, Bu^t;[2252,2253] NO_3; $R = Et$, Bu^t, 2,6-$Me_2C_6H_3$,[2254] $X = Cl$, Br, I, CN; $R = o$-xylyl[2255]). All species show Au···Au interactions in the solid state, but with different modes of aggregation. The complexes $[AuCl(CNR)]$ ($R = C_nH_{2n+1}$; $n = 2$–12) assemble by aurophilic interactions into structures similar to those seen for the (1-n)-alcohols (bilayers with hydrogen bonding) and also show temperature-dependent polymorphism consistent with the formation of rotator phases.[44] The reaction of $[AuCl(CNMes)]$ with $[GeCl_2(diox)]$ gives a compound $[AuGeCl_3(CNMes)]$, which crystal structure shows a string of alternating $[Au(CNMes)_2]^+$ cations and $[Au(GeCl_3)_2]^-$ anions with short gold–gold distances.[2255] Upper-rim functionalized calix[4]arenes with chloro(isonitrile)gold(I) groups have also been prepared.[2256]

The majority of gold(I) carbene complexes are pure organometallic compounds and the are out of the scope of this work. Some halide or triphenylphosphine carbene complexes are known and they will be considered here. Nucleophilic addition of alcohols or amines to gold-coordinated isocyanides is one of the best-established methods to obtain gold carbene derivatives. The reaction of $H[Au(CN)_2]$ with propene oxide and estirene oxide yields (cyano)carbene complexes (**380**) avoiding the intermediate step.[2257] A cyclic carbene compound is obtained by reaction of a dinuclear isocyanide with amine (Scheme 32).[2258]



Scheme 31

Carbene complexes have also been prepared by transmetallation reactions. Lithiated azoles react with gold chloride compounds and after protonation or alkylation the corresponding dihydro-azol-ylidene compounds, e.g., (**381**) or (**382**), are obtained.[2259–2264] Silver salts of benzimidazol have also been used to obtain carbene derivatives.[2265] Mononuclear gold(I) carbene complexes also form when trimeric gold(I) imidazolyl reacts with ethyl chlorocarbonate or ethyl idodate.[2266,2267] The treatment of gold halide complexes with 2-lithiated pyridine followed by protonation or alkylation also yields carbene complexes such as (**383**).[2268] Some of these carbene complexes show luminescent properties.[2269–2271]

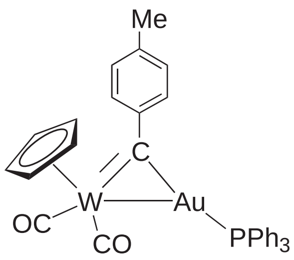
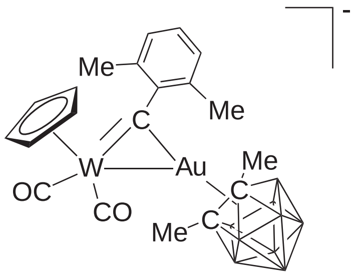
Alkylidene complexes of group 6 metals of mixed group 6 with platinum or cobalt derivatives react with $[AuCl(PPh_3)]$, [AuCl(THT)], or $[Au(C_2B_9H_9Me_2)(THT)]^-$ to give di- or trimetallic species with bridging alkylidene ligands such as (**384**) or (**385**).[2051,2272–2279]



(**384**)



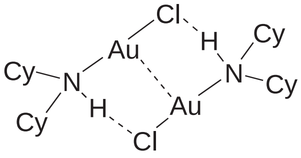
(**385**)

[AuCl(alkene)] (alkene = *cis*-cyclooctene, norbornene, *endo*-dicyclopentadiene) complexes have been obtained by reaction of [AuCl(CO)] with the alkene.[2280,2281] The structure of [AuCl($C_{10}H_{12}$)] shows the ligand η^2-bonded to gold via the C=C bond in the norbornene ring and the molecules are associated into dimers through Au···Au interactions.[2281]

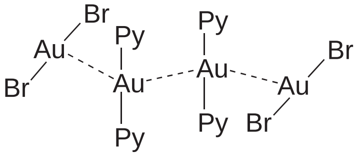
The dicyanoaurate anion $[Au(CN)_2]^-$ is one of the most simple molecules that show aurophilic interactions,[2282–2284] and thus has been used as building blocks to obtain supramolecular structures as in the complexes of Cu^{II} with $[Au(CN)_2]^-$ and different amines.[2285–2287] It has been found that solutions of K[Au(CN)$_2$] in water and methanol exhibit a strong photoluminescence.[2288] Also the optical charge transfer in the ion paraquat^{2+}$[Au(CN)_2]^-$ (paraquat^{2+} = *N*,*N*′-dimethyl-4,4′-bipyridinium^{2+}) has been reported and shows that Au^I is a very weak CT donor.[2289] Gold(I) cyanide complexes with neutral [Au(CN)(PR$_3$)][2290–2293] or anionic ligands $[Au(CN)SR]^-$,[2290,2294] undergo homoleptic rearrangement to form two different complexes. The structure of [Au(CN)(PPh$_3$)] has been described.[2295] The isocyanate [Au(CNO)(PPh$_3$)] and fulminate [Au(N-CO)(PPh$_3$)] compounds have been prepared by reaction of [Au(NO$_3$)(PPh$_3$)] with CO.[2296]

6.7.3.4.3 Complexes with nitrogen donor ligands

Gold(I) complexes with amine ligands have not been extensively studied until recently, perhaps because of their limited stability. This can be rationalized in terms of incompatibility of the soft metal center with the hard nitrogen donor. Additional stabilization of these compounds may be provided by aurophilic interactions or by the formation on N—H···X hydrogen bonds. The first complex reported with stoichiometry [AuClL] was the unstable [AuCl(pip)] (pip = piperidine).[2297] This is a tetramer with Au···Au contacts of 3.301(5) Å, hydrogen bonding was not noticed but later was been showed to be present. By reaction of [AuCl(THT)] with several aliphatic amine ligands molecular structures [AuClL] have been found for dicyclohexylamine, 2,2,6,6-tetramethylpiperidine, methylpyridine, and ferrocenylpyridine. For the complexes with crystal structures available they are loose dimers with aurophilic interactions and hydrogen bonding (**386**).[348,2298–2300] However, with pyridine or 3-bromopyridine as ligands the complexes [AuX(Py)] (X = Cl, Br, I) exist in the solid state as salts $[Au(Py)_2]^+[AuX_2]^-$; these form Au$_4$ linear or zig-zag chains (**387**).[2301–2303]



(**386**)

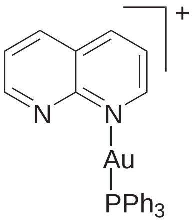


(**387**)

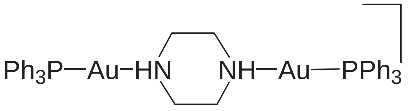
The complexes [AuClL$_2$] are all ionic in nature, no structure is known with this empirical formula. Then complexes of the type [AuL$_2$]X have been described for L = 4-hydroxymethyl-1,5-dimethylimidazole,[2304] NH$_3$,[2305] pip,[2300] pyrrolidine,[2300] morpholine,[2300] cyclohexylamine,[2300] and benzylamine.[2300] In these ionic complexes hydrogen bonding appears to be more important than in the neutral derivatives. The use of disulfonylamines, which are good hydrogen bond acceptors, as counterions increases the stability of gold(I)–amine complexes.[2306] Some crystal structures have shown more than one structural type in the crystal. With L = pyrrolidine, a by-product of stoichiometry [Au$_3$Cl$_3$L$_4$] was obtained in which two molecules of [AuClL] crystallized together with [AuL$_2$]Cl.[2307] For L = 2-aminopyridine one molecule of [AuClL] crystallized with one molecule of [AuL$_2$]Cl and in the crystal arrange in the form + neutral –.[2308] The complexes [AuCl(NH$_2$R)] (where R = long chain alkyl group) self-organize in the solid state into a fibrous material; decomposition of the complexes inside the supramolecular framework yields a monolayer of ordered gold nanoparticles.[2309]

Amine complexes stabilized with phosphine ligands of the type $[AuL(PR_3)]^+$ have been obtained for L = bipy,[2310] phen,[2310,2311] quinoline,[2311] acridine,[2311] benzo[h]quinoline,[2311] naphthyridine (**388**),[2311] 2,2′-biquinoline,[2311] di-2-pyridyl-ketone,[2311] di-2-pyridylamine,[2311] 2-(2-pyridyl)-benzimidazole, [2311] ferrocenylpyridine,[348] 2-nitroaniline,[2312] 4-methoxyaniline,[2312] NHPh$_2$,[2312] NHEt$_2$,[2312] NMe$_3$,[2312] quinuclidine,[2313] NEt$_3$,[2314] 2-aminothiazoline,[2315] histidine,[2316]

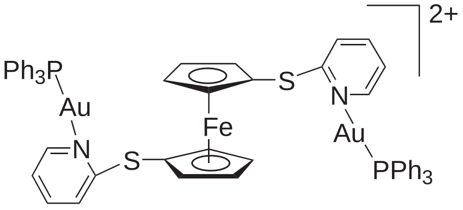
NH_2R (R = H, alkyl),[2317] and NH_2Bu^t.[2318] Dinuclear gold(I) complexes have been obtained by treatment of $[Au(BF_4)(PPh_3)]$ with diamines such as $Pr^i_2NH(CH_2)_2NHPr^i$ or 1,4-piperazine (**389**) or with 1,1′-bis(2-pyridylthio)ferrocene (**390**).[1184] Weak hydrogen bonding with the BF_4^- anions is found.[2319]



(**388**)

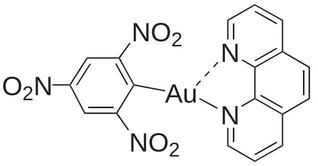


(**389**)

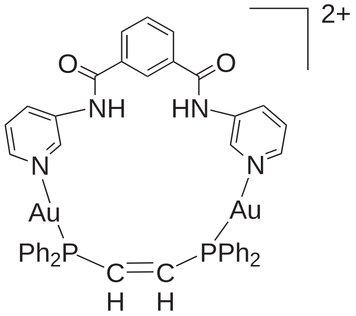


(**390**)

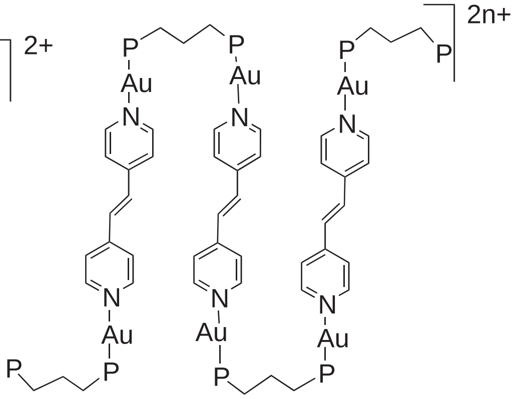
Organometallic derivatives with bidentate nitrogen ligands have also been described such as $[Au(C_6F_5)L]$ where $L = NH_2(CH_2)_nNH_2$,[2320] $[Au_2(C_6F_5)X\{\mu\text{-}NH_2(CH_2)_nNH_2\}]$ ($X = C_6F_5$, Cl),[2320] $[Au(C_6F_5)_2(\mu\text{-bipy})]$,[2320] $[Au_2(\mu\text{-}C_6F_4\text{-}C_6F_4)(phen)_2]$,[2109] $[Au(C_6F_4\text{-}C_6F_4H)(phen)]$,[2109] $[Au(C_6Cl_5)(phen)]$,[1641] or $[Au(2,4,6\text{-}(NO_2)_3C_6H_2)(dmphen)]$ (**391**) (dmphen = 2,9-dimethyl-phen) where a pseudotricoordination is observed.[2114]



(**391**)



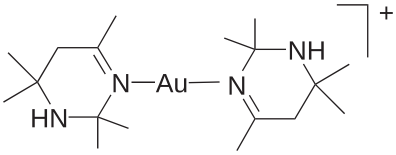
(**392**)



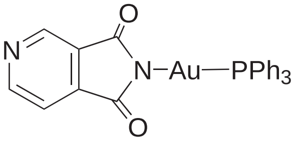
(**393**)

The reaction of the ligand *N,N′* bis(pyridin-3-yl)-1,3-benzenedicarboxamide with $[Au_2(O_2CCF_3)(\mu\text{-PP})]$ yields the macrocyclic compound (**392**) when the diphosphine is *trans*-$Ph_2PCH{=}CHPPh_2$, but a helical polymer for PP = dppe.[2321] With the bidentate ligand *trans*-1,2-bis(4-pyridyl)ethylene the reaction with $[Au_2(O_2CCF_3)_2\{\mu\text{-}(PPh_2)_2(CH_2)_n\}]$ gives for $n = 2$ the cyclic compound and for $n = 3$ or 4 1D linear or U-shaped polymers (**393**).[2322] In the same reaction with 4,4′-bipyridine in solution the complexes exist as an equilibrium mixture of linear oligomers and cyclic compounds; when $n = 1$, 3, or 5 they exist as 26-, 30-, and 34-membered macrocyclic rings, respectively, and only when $n = 1$ there are significant intramolecular Au···Au contacts. Some of these compounds are strongly emissive at room temperature and in the solid state.[2323]

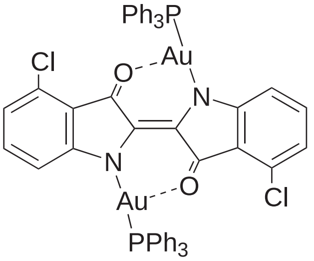
Imine gold(I) compounds have been synthesized and are of the type $[AuCl(NH{=}CR_2)]$ or $[Au(NH{=}CR_2)_2][AuCl_2]$ (obtained as mixtures solution), or $[Au(NH{=}CR)(PR_3)]BF_4$ (R = Ph, NMe_2; $PR_3 = PPh_3$, Pr^{i3}).[2324,2325] The complex $[Au(NH{=}CMe_2)_2]OTf$ has been obtained by reaction of $[Au(NH_3)_2]OTf$ with acetone.[2326] The reaction of $[Au(ACAC)(PR_3)]$ with the ammonium salts $(NH_3R)Cl$ dissolved in the appropriate ketone $MeCOR^2$ gives the neutral $[Au(NR{=}CMeR)(PR_3)]$.[1686] The species $[AuCl(NH{=}CPh_2)]$ and $[Au(NH{=}CMe_2)_2]OTf$ crystallize as polymeric chains with aurophilic interactions and hydrogen bonding. Treatment of $[AuCl(THT)]$ with NH_3 in acetone leads to the acetonine complex (**394**), one of the ligands can be displaced for PPh_3 or Cl^-.[1686,2327]



(394)



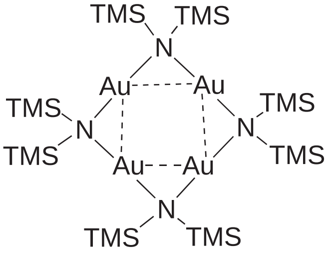
(395)



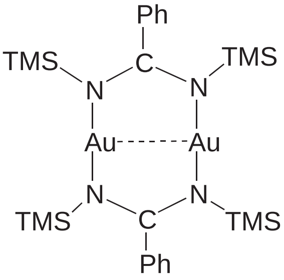
(396)

A great variety of gold(I) complexes with anionic *N*-donor ligands has been synthesized. Examples of the type [AuL(PR$_3$)] have been obtained for several nitrogen ligands such as the anions of ptm,[1692,2328,2329] hydantoin,[2330] the imide of 3,4-pyridine dicarboxylic acid (**395**),[2330] 4,4′-dichloroindigo,[2331] isatin,[2331] 5-bromoisatin,[2331] 2-indolone,[2331] oxopurine,[2332,2333] or 4-nitroaniline,[2334] succinimide,[2335] 2,3-dioxoindolinyl,[2336] 1-amino-anthracene-9,10-dione,[2337] benzodiazepiones,[2338] pyrimidinedionato,[2339] adeninate,[2340] or 7-aza-indolyl.[2341] Dinuclear complexes, [Au$_2$(μ-L)(PR$_3$)$_2$], have also been prepared for the dianions of 4,4′-dichloroindigo (**396**),[2330] or oxopurine,[2331] 4-nitroaniline,[2334] pyrrole derivative,[2342] or nucleobases or nucleosides.[2343,2344]

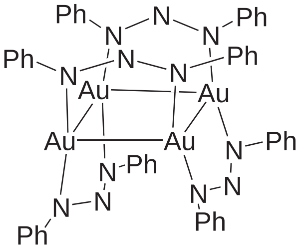
Gold(I) derivatives with bis(trimethylsylyl)amides have been reported and are of the type [Au{N(TMS)$_2$}(PPh$_3$)][2345] or the homoleptic [Au$_4${N(TMS)$_2$}$_4$] (**397**),[2346] which has been obtained from the reaction of AuCl with LiN(TMS)$_3$. The related [Au{N(CN)$_2$}(PPh$_3$)] has also been reported.[2347] Disulfonylamides give gold(I) complexes of the type [Au{N (SO$_2$R)$_2$}(PPh$_3$)] (R = Me, 4-ClC$_6$H$_4$, 4-NO$_2$C$_6$H$_4$, F) or [Au{N(SO$_2$R)$_2$}(THT)] (R = Me, 4-ClC$_6$H$_4$, 4-IC$_6$H$_4$).[2348,2349] Amidinato gold(I) complexes have been described and are dinuclear, as [Au$_2${C(Ph)(NTMS)$_2$}$_2$][475] (**398**) or tetranuclear as [Au$_4${CH(NPh)$_2$}$_4$].[2350] The triazenido ions RN$_3$R$^-$ react with AuI in liquid ammonia to form the tetranuclear complex (**399**), which has an analogous structure to that of the tetranuclear formamidinato compound.[2351] The structure of the azido complex [Au(N$_3$)(PPh$_3$)] has been reported.[1736]



(397)



(398)

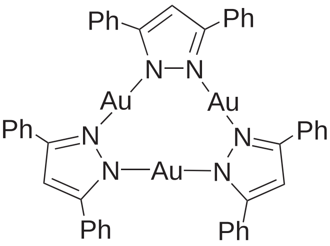


(399)

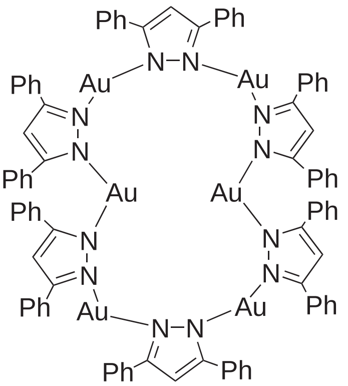
Gold(I) complexes with azole ligands although not as numerous as those of silver are well represented. The reaction of [AuCl(PPh$_3$)] with Na(3,5-Ph$_2$pz) gives the trinuclear [Au(3,5-Ph$_2$pz)]$_3$ (**400**),[377] which is isostructural with the silver and copper analogues.[2352] If in the reaction AgOCOPh is added, the hexamer derivative [Au(3,5-Ph$_2$pz)]$_6$ (**401**) is obtained.[2353] The trinuclear complexes have been prepared with different substituents,[2354–2357] or with phenyl groups substituted with two or three aliphatic (decyloxy) chains,[2358,2359] or with octyl groups,[2360] which gives mesogenic pyrazolato gold complexes. Oxidation of the trinuclear pyrazolates with Cl$_2$ or I$_2$ is possible and yields the mixed Au^{I}–Au^{III} derivatives [Au$_3$X$_2$(3,5-R$_2$pz)$_3$] (R = Ph, Bz).[1706,2361,2362]

Gold(I) complexes with neutral azoles have been prepared and are of the type [Au(PPh$_3$)(3,5-Me$_2$pzH)]BF$_4$,[2363] [AuXL]$_2$, (X = Cl, Br; L = *N*-methylimidazole, *N*-ethylimidazole, *N*-propylimidazole, 2-methylbenzoxazole, 2,5-dimethylbenzoxazole),[2364] [Au(Him)(PPh$_3$)]Z (HZ = picrid acid),[2365] [AuCl(pyrazole)],[2366] or [Au$_2$(Hpz)(μ-PP)]$^{2+}$ (**402**) (PP = dppm, dppe, dppp).[2367,2368]

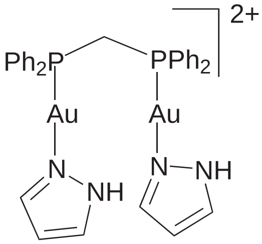
Neutral complexes with azolate ligands of the type [AuL(PPh$_3$)], with L representing differently substituted pyrazolates,[2251,2366] imidazolates,[365,2369,2370] benzidimidazolates,[2371,2372] triazolate,[2373] tetraazolate (**403**),[536] or 2,2′-bibenzimidazolates (**404**),[2374,2375] have been prepared. The structure of the [Au(1,2,4-triaz)(PPh$_3$)] is a dimer with Au···Au interactions (**405**).[2373] The antimicrobial



(400)

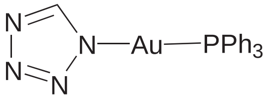


(401)

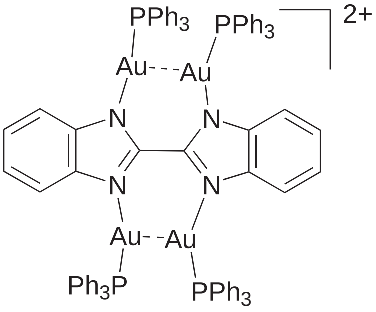


(402)

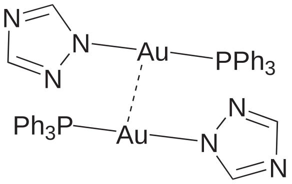
activity of complexes $[AuL(PPh_3)]$ (L = pyrazolate or imidazolate) has been tested and show selective and effective activity against two Gram-positive bacterias and modest activity against yeast.[2376] The structure of the anionic complex $[AuL_2]^-$ with L = 4-hydroxymethyl-1,5-dimethylimidazole has been reported.[2304] Heterometallic complexes with bridging pyrazolate ligands have been described with iridium,[354,1691] rhenium,[2377] and platinum.[352]



(403)

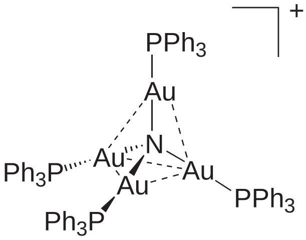


(404)

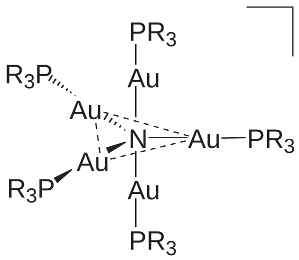


(405)

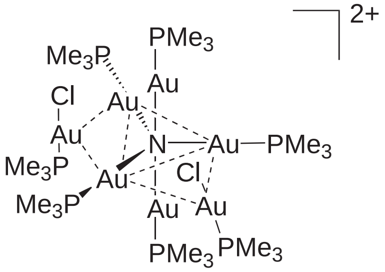
In recent years the coordination of gold(phosphine) fragments to the nitrogen atoms of several amine derivatives has been achieved. Tetracoordination of nitrogen by gold atoms in ammonium cations $[N(AuPR_3)_4]^+$ (**406**) is well established; the first derivative was reported in 1980 and was obtained by the reaction of $[O(AuPPh_3)_3]BF_4$ with ammonia at $-60\,^\circ C$ in THF.[2378] Other methods of preparation include the use of $[AuX(PPh_3)]$ ($X = BF_4$, PF_6) and Au^- in liquid ammonia,[2379] the reaction of tris(trimethylsilyl)amine or hexamethyldisilazane with $[AuCl(PPh_3)]$ and CsF,[2380] or by reaction of $(NH_4)ClO_4$ with $[Au(ACAC)(PPh_3)]$.[2381] Derivatives with other phosphine ligands such as PMe_3,[2318] or PBu^t are also known.[2382] Several structure determinations of different tetragold ammonium salts revealed a strongly distorted tetrahedral structure of the central Au_4N core, probably caused by aurophilic effects.[2318,2379,2380,2382–2384] The attempts to accomplish hypercoordination of nitrogen by gold atoms were successful and the reaction of $[N(AuPPh_3)_4]^+$ with $AuPPh_3^+$ led to the isolation of the dication $[N(AuPPh_3)_5]^{2+}$ (**407**).[2385] This represents a unique case of nitrogen pentacoordination in molecular chemistry and has attracted considerable interest regarding the bonding. Quantum-chemical studies on various levels of sophistication have been carried out and confirm a diamagnetic configuration for the trigonal bipyramidal structure.[8–10,2386,2387] The use of PMe_3 leads to an adduct of the dicationic species with two molecules of $[AuCl(PMe_3)]$, $[N(AuPMe_3)_5][AuCl(PMe_3)]_2(BF_4)_2$ (**408**).[2388] In a later study of hypercoordinated nitrogen complexes, it was shown that in a new solvate the lattice contains three independent dications and that highly distorted structures should be expected as the rule rather than an exception.[2389] On the basis of a incomplete crystal structure determination, the formation of $[N(AuPPh_3)_6]^{3+}$ was assumed as an additional product of the reaction of $AuPPh_3^+$ cations and Au^- in liquid ammonia.[2379,2390] Further investigations have shown that only the compound $[N(AuPPh_3)_4]^+$ is formed, besides small amounts of $[N(AuPPh_3)_5]^{2+}$.[2391]



(406)

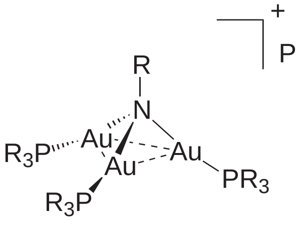


(407)

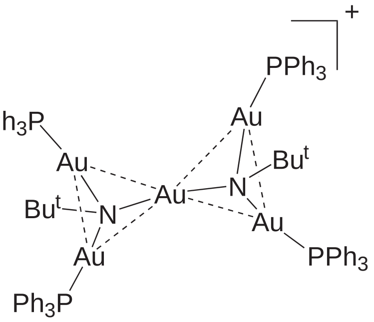


(408)

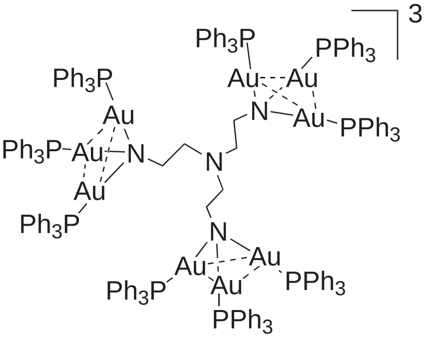
The first two members of the series of these ammonium-centered complexes, i.e., $[Au(NH_3)(PPh_3)]^+$ or $[H_2N(AuPPh_3)_2]^+$ have been obtained by reaction of $(NH_4)ClO_4$ with $[Au(ACAC)(PPh_3)]$ but not the third one $[HN(AuPPh_3)_3]^+$.[2381] However, a great number of complexes with monosubstituted amines $[RN(AuPR_3)_3]^+$ (**409**) are known. The reaction of the oxonium cation $[O(AuPR_3)_3]^+$ with RNH_2 or RCNO leads to the μ-imido clusters $[RN(AuPR_3)_3]^+$ where R can be an aryl, alkyl, or sylyl group.[1502,2313,2318,2382,2392–2396] The treatment of $[AuCl(PPh_3)]$ with Bu^tNHLi gives the complex $[\{Bu^tN(AuPPh_3)_2\}_2Au]Cl$ (**410**) which has a structure with two Au_3N pyramids sharing one gold.[2397] Diamines such as $NH_2CH_2CH_2NH_2$, $NH_2C_6H_4NH_2$, $RN(CH_2CH_2NH_2)_2$, or $N(CH_2CH_2NH_2)_3$ can also be aurated with the oxonium salt as, for example, (**411**),[2398,2399] as well as aminopyridines such as 8-aminoquinoline to give (**412**).[2400] The same reactions have been carried out with phosphine imines,[2401,2402] hydrazines (**413**),[2403–2407] hydroxyamines,[2408] carbodiimide,[2409] sulfoximine,[2410] or azirine,[2411] for which partially or fully aurated species have been isolated.



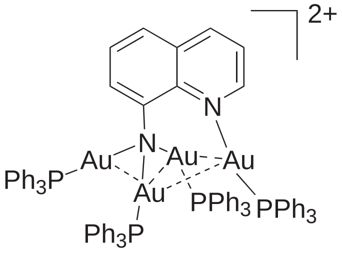
(409)



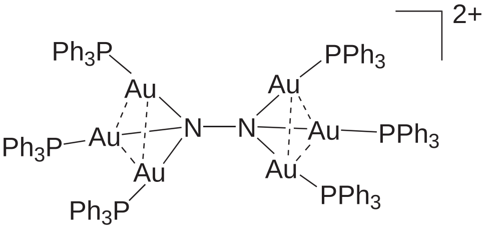
(410)



(411)



(412)



(413)

Some gold(I) derivatives have been obtained with other type of *N*-donor ligands as acetonitrile; the compound $[Au(NCMe)_2]^+$ can be obtained by halide-catalyzed electrolysis of gold metal in MeCN.[2412] This cation is very moisture sensitive and thermally labile, but the more stable cation $[Au(NCPh)_2]^+$ has been obtained by oxidation of gold with the nitrosyl cation in benzonitrile.[2413] From EXAFS spectroscopic studies it has been suggested that the solvated gold(I) cations are tetra-coordinate in pyridine or acetonitrile solutions.[2414] Other gold(I) complexes have been reported with the benzophenoneazine ligand, $[Au(C_6F_5)(Ph_2C{=}N{-}N{=}CPh_2)]$,[2415] the 1,5-di-*p*-tolylpenta-aza-1,4-dien-3-yl $[Au\{N(N{=}N\text{-}p\text{-}Tol)_2\}(PPh_3)]$,[2416] the nitrido osmium complex $[OsO_3N(AuPPh_3)]$ (**414**),[2417] or with the macrocyclic ligand 1,4,8,11-tetra-azacyclotetradecane (**415**).[2418]

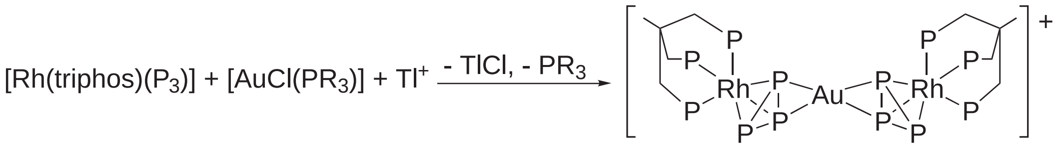
6.7.3.4.4 Complexes with phosphorus, arsenic, antimony, or bismuth donor ligands

(i) Phosphide- or arsenide-bridged polynuclear complexes

This section is dedicated to complexes which formally contain the units: (i) P_3^{3-}, (ii) E^{3-}, (iii) $(RE)^{2-}$, or (iv) $(R_2E)^-$ (E = P or As) as ligands. These moieties commonly act as bridging ligands for equivalent or different gold centers. Important examples include standard homoleptic species such as $[E(AuPPh_3)_4]^+$ (E = P, As) or hypercoordinated cations $[P(AuPPh_3)_5]^{2+}$ and $[P(AuPPh_3)_6]^{3+}$. Other systems have the phosphide groups bridging gold and other transition metal atoms.

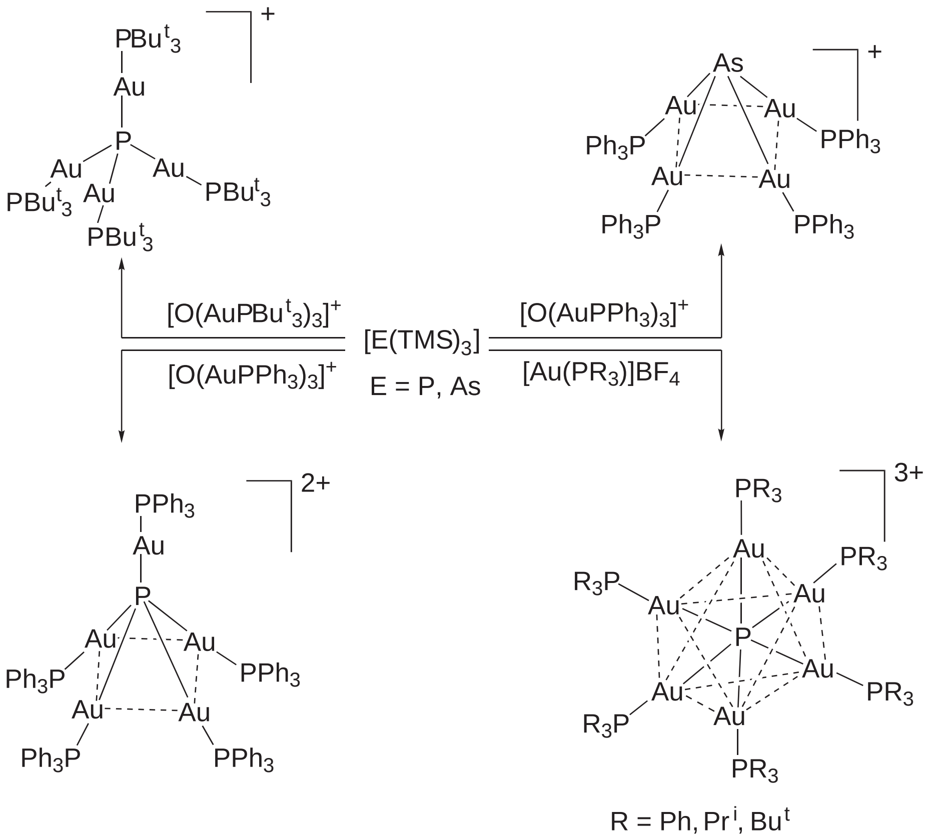
(a) P_3^{3-}. The trinuclear compounds $[Au\{M(triphos)(P_3)\}_2]PF_6$ [M = Co, Rh, or Ir; can be obtained by treatment of a dichloromethane solution of $[M(triphos)(P_3)]$ with $[AuCl(PR_3)]$ (R = Me or Ph) or $[Au_2Cl_2\{PPh_2(CH_2)_nPPh_2\}]$ (n = 1 or 2) in the presence of $TlPF_6$.[2419] The structure shows that the gold atom is bound to two pairs of phosphorus atoms of the P_3 units with a coordination geometry intermediate between tetrahedral and square planar (Equation (33)):



(33)

(b) E^{3-}. A series of unusual gold(I) complexes in which a central atom of phosphorus or arsenic (formally P^{3-} or As^{3-} ions) acts as a bridging ligand for several $[AuPR_3]^+$ units has emerged from recent systematic studies with silylpricogenides as the starting materials. These include the cationic derivatives: $[As(AuPPh_3)_4]^+$,[2380] $[P(AuPBu^t_3)_4]^+$,[2420] $[P(AuPPh_3)_4\{Au(PPh_3)_2\}]^{2+}$,[2421] $[P(AuPPh_3)_5]^{2+}$,[2422,2423] and $[P(AuPPh_3)_6]^{3+}$.[2424] The preparation of these complexes is summarized in Scheme 33.

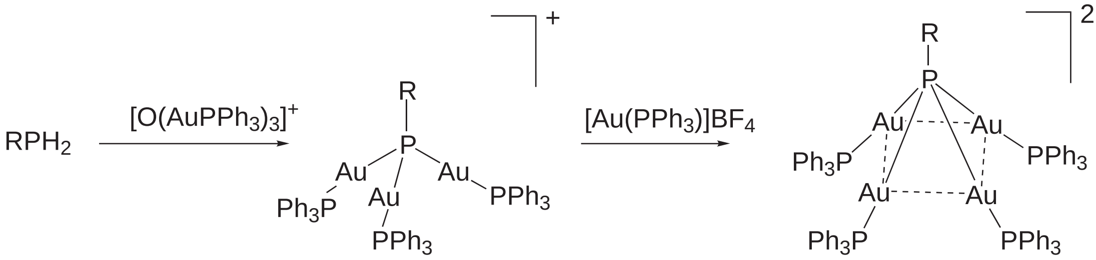
The tetra(auro)arsonium cation $[As(AuPPh_3)_4]^+$ has a square-pyramidal structure, instead of the classical tetrahedral geometry found in $[N(AuPPh_3)_4]^+$,[2] probably because the radius of the arsenic is too large to allow for metal–metal bonding in a tetrahedral structure. If a lone pair of electrons is allocated to the As apex, then the $AsAu_4$ core has to be described as electron deficient.[8,9] It is very likely, however, that the Au···Au contacts at the base of the As-capped pyramid (less than 3 Å) strongly contribute to the stability of the compound. Likely enough the structure of the cation $[P(AuPBu^t_3)_4]^+$ shows a distorted tetrahedral of PAu_4 skeleton, because closer contacts than those found in the structure (3.40 Å) are clearly ruled out by the bulkiness of the PBu^t_3 ligands.[2420] The severe distortion of the skeleton provides evidence that the system is still gaining in stabilization from the formation of the Au···Au contacts. The reaction of $[O(AuPPh_3)_3]BF_4$ with PH_3 leads to a mixture of products such as $[P(AuPPh_3)_4\{Au(PPh_3)_2\}](BF_4)_2$, $[P(AuPPh_3)_5](BF_4)_2$, and $[Au\{P(AuPPh_3)_4\}_2](BF_4)_3$.[2421] The structure of the first dication contains pentacoordinate phosphorus atoms in an irregular coordination geometry



Scheme 33

with one of the five gold atoms attached to two PPh$_3$ ligands. The cation [Au{P(AuPPh$_3$)$_4$}$_2$]$^{3+}$ can be considered as the result of the interaction of two [P(AuPPh$_3$)$_4$]$^+$ units, which must be strong nucleophiles, with a further gold(I) center. The structure of the dication [P(AuPPh$_3$)$_5$]$^{2+}$ reveals a square-pyramidal arrangement of the gold atoms in contrast to the trigonal-bipyramidal structure expected by classical bonding arguments.[2423] For the trication species [P(AuPPh$_3$)$_6$]$^{3+}$ an octahedral structure has been proposed.[2424] Distortions of the regular geometry again arise owing to the influence of the gold–gold interactions, which govern the geometry and are responsible for the stability of this type of compound.[8,9] The hapticity of the central P-atom is easily monitored by ^{31}P NMR spectroscopy in these cases.[2421]

(c) (RE)$^{2-}$. The (RE)$^{2-}$ (E = P or As) units can act as bridging ligand for two, three, or even four gold atoms. Thus, primary phophines[2425–2427] or arsines,[2425] REH$_2$ [E = P, As; R = Ph, 2-MeC$_6$H$_4$, 2,4,6-(Bu^t)$_3$C$_6$H$_2$] can be triply aurated on treatment with a stoichiometric amount of the oxoniun reagent [O(AuPPh$_3$)$_3$]BF$_4$ to give species of the type [RE(AuPPh$_3$)$_3$]$^+$ (Scheme 34) which have a tetrahedral coordination at the P or As atom with long intermetallic distances. In

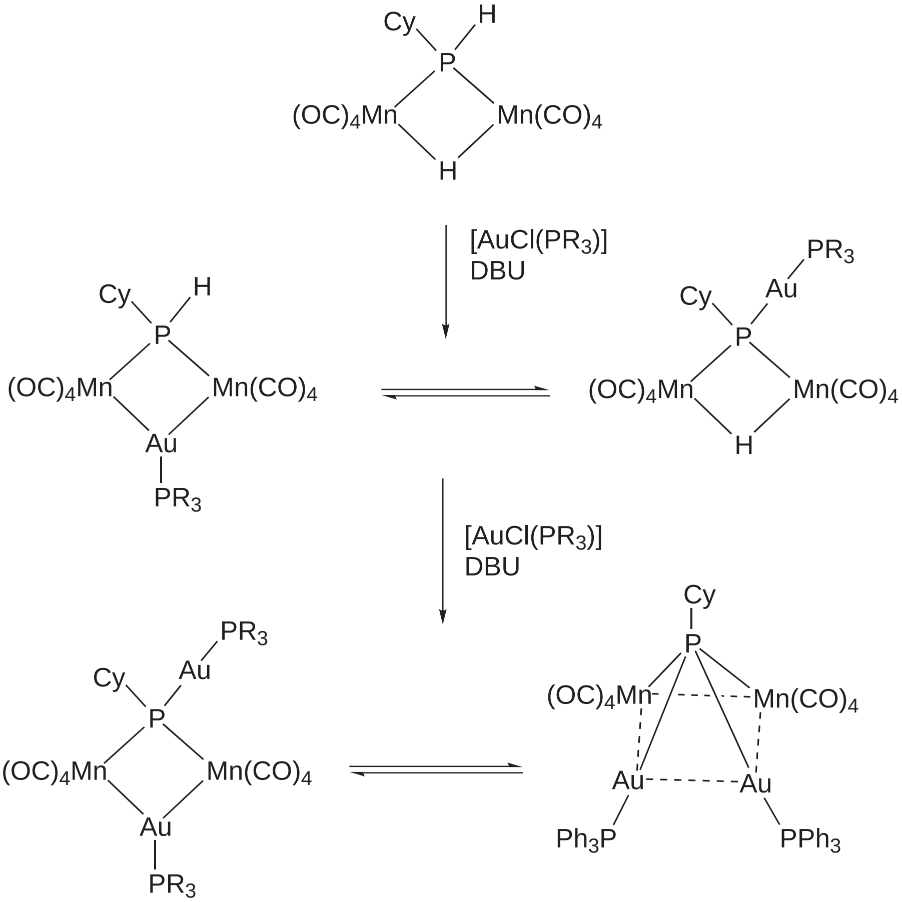


Scheme 34

$[RP(AuPPh_3)_3]^+$ $[R = 2,4,6\text{-}(Bu^t)_3C_6H_2]$,[2427] with its extremely bulky group R, the phosphorus atom is attached to a single gold atom on one side of the RP plane and to a pair of gold atoms on the other (Au⋯Au 3.15 Å). In solution rapid site exchange renders the $AuPPh_3$ units NMR equivalent. In the case of the phosphorus compounds, the electrophilic addition of a further $[(AuPPh_3)_3]^+$ unit produces novel hypercoordinate dications $[RP(AuPPh_3)_4]^{2+}$ with a square-pyramidal PAu_4 core and short Au⋯Au distances.

When a bulky phosphine is used ($L = PBu^t_3$), the addition of $[AuL]^+$ does not lead to a trinuclear cation $[\{2,4,6\text{-}(Bu^t)_3C_6H_2\}P(AuL)_3]^+$, but the neutral dinuclear derivative $[\{2,4,6\text{-}(Bu^t)_3C_6H_2\}P(AuL)_2]$ can be obtained from the reaction of $[2,4,6\text{-}(Bu^t)_3C_6H_2]PH_2$ upon treatment with the oxonium reagent.[2427] Analogous reactions to those shown in Scheme 32, but starting from the diprimary aromatic phosphine $1,4\text{-}C_6H_4(PH_2)_2$, lead to the hexanuclear $[1,4\text{-}(LAu)_3PC_6H_4P(AuL)_3]^{2+}$ ($L = PPh_3$ or PBu^t_3) or octanuclear complexes $[1,4\text{-}(Ph_3PAu)_4PC_6H_4P(AuPPh_3)_4]^{4+}$, with two polynuclear units in the *trans* position.[2426] With the diphosphines $1,2\text{-}C_6H_4(PH_2)_2$ the triaurated species, $[1,2\text{-}(LAu)_3PC_6H_4P(AuL)_3]^{2+}$, can be obtained but in the NMR spectra rapid intramolecular scrambling of the $AuPR_3^+$ units to give probably species of the type $[1,2\text{-}(LAu)_4PC_6H_4P(AuL)_2]^{2+}$ have been observed.[2428]

There are some examples with a $(CyP)^{2-}$ group bridging three or even four heterometallic centers. The dimanganese complex $[Mn_2(\mu\text{-}H)(\mu\text{-}PCyH)(CO)_8]$ reacts with equimolar amounts of $[AuCl(PR_3)]$ (R = Cy, Ph, *p*-C_6H_4OMe, *p*-C_6H_4F) in the presence of a nonnucleophilic base (DBU) to afford mono- or diaurated pairs of isomers: $[Mn_2(\mu\text{-}AuPR_3)(\mu\text{-}PCyH)(CO)_8]$ and $[Mn_2(\mu\text{-}H)\{\mu\text{-}PCy(AuPR_3)\}(CO)_8]$, $[Mn_2(\mu\text{-}AuPR_3)\{\mu\text{-}PCy(AuPR_3)\}(CO)_8]$ and $[Mn_2(AuPR_3)_2(\mu_4\text{-}PCy)(CO)_8]$ (Scheme 35), by replacement of the H-atoms by the isolobal $[AuPR_3]^+$ units.[2429] In solution, there are dynamic equilibria whose displacement depends on the nature of the R groups and on the solvent used.

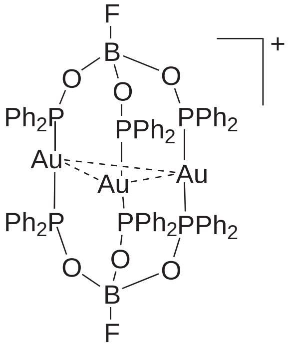


Scheme 35

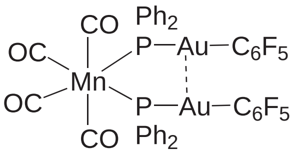
(d) $(R_2E)^-$. Polymers of the formula $[AuPR_2]_n$ (R = Et, C_8H_{17}, Ph, 4-MeC_6H_4, 4-$Bu^tC_6H_4$) have been prepared by reaction of secondary phosphines with a variety of gold(I) compounds, such as [AuClL] (L = tetrahydrothiophene, thiodiglycol), in the presence of bases,[2430–2432] or with $[AuMe(PPhMe_2)]$ or $[(PPh_3)_2N][Au(ACAC)_2]$, but their true structure is still uncertain. $[AuPPh_2]_n$ reacts with $[(PPh_3)_2N][AuX_2]$ (X = Cl, Br, I) to give $[(PPh_3)_2N][(AuX)_2(\mu\text{-}PPh_2)]$ (Equation (34)). The structure of the anion with X = Br shows the presence of a bridging phosphido group and a linear coordination on the gold(I) atoms. The Au—Au distance of 3.256(1) Å is indicative of a weak interaction.[2430,2431]

(34)

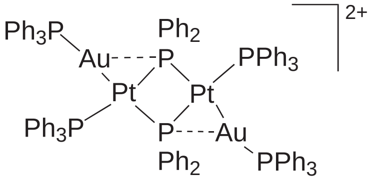
Oxidation of phosphido groups can give phosphinito derivatives. The reaction of $[(PPh_3)_2N][Au(ACAC)_2]$ with PPh_2H (molar ratio 1:2), after air oxidation, leads to a phosphinito gold(I) complex $[(PPh_3)_2N][Au\{P(O)Ph_2\}_2]$.[2432] Other phosphinito or phosphito gold complexes have been prepared by reaction of $PR_2(OH)$ with $[AuMe(PR_3)]$ and are neutral as $[Au(POPh_2)(PR_3)]$,[2433,2434] $[Au\{PO(OR)_2\}(PR_3)]$,[2433,2434] or $[Au(POPh_2)\{P(OH)Ph_2\}]_2$;[2435] the latter appear as dimers with synergistic hydrogen bonding and aurophilic bonding. The reaction of $[Au(POPh_2)\{P(OH)Ph_2\}]_2$ or $[AuCl(PPh_2OH)]$ with BF_3 gives a reassembly of the metal and ligand components to give large cage-type molecules as $[FB(OPPh_2AuPPh_2O)_3BF]BF_4$ (**416**) or $[FB(PPPh_2Au)_3Cl_3(AuPPh_2O)_3BF]BF_4$, respectively.[2436,2437]



(416)



(417)



(418)

There are some examples with phosphido groups acting as bridging ligands between gold(I) and other metallic centers. The deprotonation of the PPh_2H ligand in manganese or iridium complexes (namely, $[Mn(CO)_5(PPh_2H)]$,[2438] $[Mn(CO)_4(PPh_2H)_2]$,[2438] $[Ir_4(CO)_{11}(PPh_2H)]$[2439,2440]) in the presence of gold(I) complexes $[AuCl(PR_3)]$, [AuX(THT)] (X = C_6F_5, Cl), and $[Au(PPh_3)]BF_4$ yield heteronuclear derivatives with $(PPh_2)^-$ groups bridging a gold and manganese or iridium centers, as in the following example (**417**).[2441] The reaction of $[Pt_2(\mu\text{-}PPh_2)_2(PPh_3)_2]$ with $[AuCl(PPh_3)]$ in the presence of $TlPF_6$ leads to the electrophilic addition of two $[AuPPh_3]^+$ groups to platinum to give $[Au_2Pt_2(\mu\text{-}PPh_2)_2(PPh_3)_4]^{2+}$ (**418**), which contains an incipient triply bridging diphenylphosphido ligand, with Au—P distances of 2.682(7) Å and 2.629(7) Å.[2441] The reaction of $[Cr_2Cp_2(\mu\text{-}PH_2)(\mu\text{-}H)(CO)_4]$ with $[AuCl(PPh_3)]$ leads to the formation of the high nuclearity cluster $[\{CrCp(CO)_2\}_6(\mu_4\text{-}P)_3(\mu_4\text{-}Au)_3]$.[2442] Mixed gold(III)–gold(I) diphenylphosphido complexes have been recently prepared and those have been considered in Section 6.7.3.2.3.

(ii) Complexes with monodentate phosphines, arsines, or stibines

The number of gold(I) complexes containing tertiary phosphines, arsines, or stibines as ligands is large because of the wide use of the fragment AuL^+, mainly with L = PPh_3, in the synthesis of gold(I) complexes. However, in many cases the reactivity is focused on the other ligands and the $AuPPh_3^+$ unit is just a suitable precursor. These complexes will be treated in the corresponding section.

These complexes are generally of the formula $[AuX(ER_3)]$ (E = P, As, Sb; R = alkyl or aryl). The most usual methods of synthesis are as follows:

(a) Reduction of tetrachloroauric acid with the tertiary phosphine, arsine, or stibine, which can act both as the reducing agent and as the ligand, is a straightforward high-yield reaction (Equation (35)), which can be carried out with cheap reagents and with a great variety of solvents, without any special preconditions. One equivalent of the ligand is lost in the process, however, and this aspect needs to be considered whenever more costly components are necessary.

(b) Displacement of a weakly coordinating ligand from [AuClL] by a phosphine, arsine, or stibine ligand. Complexes with L = alkyl sulfide (obtained by reduction of $[AuCl_4]^-$ with SR_2)[2443] or CO (obtained by the reaction of anhydrous Au_2Cl_6 with CO at atmospheric pressure)[2444] are used commonly as starting materials. The chlorine atom can be substituted by other anionic or neutral ligands to form derivatives of the type $[AuX(ER_3)]$ or cationic $[Au(ER_3)_2]Cl$, respectively.

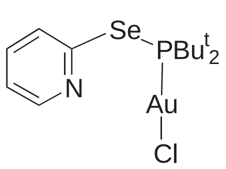
(c) Introduction of $[AuPR_3]^+$ groups at a reaction site by the use of derivatives $[AuX(PR_3)]$ where $X = ClO_4$, BF_4, CF_3SO_3, or any other anionic weekly coordinating ligand, or reagents able to removed protons and coordinate one or more $[AuPR_3]^+$ groups as [Au(ACAC) (PPh_3)] or $[O(AuPR_3)_3]^+$, respectively.

$$[AuCl_4]^- + 2ER_3 \longrightarrow [AuCl(ER_3)] + ER_3Cl_2 + Cl^- \qquad (35)$$

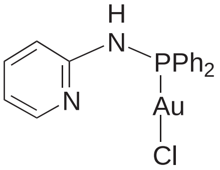
Numerous complexes of the type $[AuX(PR_3)]$ have been prepared with a great variety of phosphine ligands. Although this type of complexes has been know for many years there has been a resurgence of interest because recent studies have shown that short intermolecular gold–gold contacts can group the monomeric units into pairs, rings, or chains. The important prerequisite for this type of aggregation is the presence of structurally nondemanding ligands PR_3 or X. These interactions are associated with rather small bond energies estimated to be in the order of 25–37 kJ mol^{-1} for each Au···Au bond, and any overcrowding of the substituents can prevent aggregation.[92,93] Dimers are observed, for example, with primary phosphines, as in $[AuCl\{PH_2(2,4,6\text{-}Bu^t{}_3C_6H_2)\}]$,[2445] or with secondary phosphines, as in $[AuCl\{PH(o\text{-}Tol)_2\}]$,[2446] but not with the bulky $PHBu^t{}_2$ or $PHPh(2,4,6\text{-}Bu^t{}_3C_6H_2)$ which form independent monomers.[2446,2447] In $[AuBr(PHPh_2)]$ there are two independent molecules with an Au—Au distance of 3.256(1) Å.[2431] The monomers with small phosphines $[AuCl(PMe_3)]$,[2448] $[AuCl(PCl_3)]$,[2449] or $[AuBr\{PH_2(o\text{-}Tol)\}]$[2450] are aggregated in the solid state through Au···Au contacts of 3.081–3.386 Å to give chains of gold atoms. A theoretical study by Pyykkö *et al.* suggests that the Au···Au interaction in $[AuX(PH_3)]_2$-type complexes increases as the softness of the ligand X increases.[2451] If medium or large phosphine or arsine ligands are present there are generally no intermolecular Au···Au interactions in the lattice.

Many complexes of stoichiometry $[AuCl(PR_3)]$ have been reported with $PR_3 = P(NMe_2)_3$,[2402] $PF_2(NMe_2)$,[2452] $PF_2(2,5\text{-}Me_2C_6H_3)$,[2452] PPh_3,[2453] $PPr^i{}_3$,[2448] $PBu^t{}_3$,[2177] PEt_3,[2454] PCy_3,[2455,2456] $P((CH_2)_2CN)_3$,[2457,2458] PCy_2Ph,[2459] PMe_2Ph,[2460] $PPh_2(CH_2CONHMe)$,[2461] $PTol_3$,[2462–2464] $PMes_3$,[2465] $P\{2,4,6\text{-}(MeO)_3C_6H_2\}$,[2466,2467] $PPh_2(2\text{-}Py)$,[2468] $P(2\text{-}Py)_3$,[2469] $PPhFc_2$,[2470] PPh_2CH_2Fc,[709] $PPh_2C{\equiv}CH$,[2471] $PPr^i{}_2C{\equiv}CH$,[2232] PPh_2CH_2TMS,[2032] $PPh_2CH_2CO_2H$,[2472] $PPh_2(OH)$,[2473] $P(4\text{-}MeOC_6H_4)_3$,[2474] $PPh_2NHCH(Me)CO_2$,[2475] PCl_2Ph,[2476] $PHPh(2,4,6\text{-}Bu^t{}_3C_6H_2)$,[2477] $PPh_2(C_6H_4NMe_2)$,[2178] $PPh(C_6H_4NMe_2)_2$,[2178] $P(C_6H_4NMe_2)_3$,[2178] $[AuX(ER_3)]$ (X = Br, I; $ER_3 = PCy_3$ PMe_3),[2478,2479] or $[AuX(PMes_3)]$ (X = Cl, Br, I),[2480] and have been characterized by XRD, showing the expected linear coordination for gold(I). A structural study has been carried out on complexes $[AuX(PMe_2Ph)]$ (X = Cl, Br, I) and shows association into trimers or dimers in the solid state through aurophilic interactions.[2481] These complexes show emission from two excited states,[2482] as has been observed also for compounds $[AuX\ (EPh_3)]$ (X = Cl, Br; E = P, As).[2483] The effects of substituents on aurophilic and π–π interactions in complexes $[AuX\{P(C_6H_4R)_3\}]$ and $[AuX\{P[C_6H_3(CF_3)_2]_3\}]$ (X = Cl, SPh, SPy; R = Me, CF_3) has been studied.[2484]

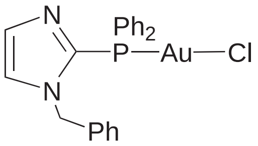
Other *P*-donor ligands have also been used in the synthesis of linear mononuclear gold derivatives. Potentially bidentate ligands, as $L = PPh_2(CH_2)_2SMe$,[2485] $PPh_2CH_2PPh_2Se$,[2486] $PPh_2(2\text{-}OHC_6H_4)$,[2487] $PPh_2(2\text{-}OTMSC_6H_4)$,[2473] $PPh_2(2\text{-}NH_2C_6H_4)$,[2487] $Ph_2PNHP(O)Ph_2$,[2488] $Bu^t{}_2PSepy$ (**419**),[2489] $PPh_2NH(2\text{-}Py)$ (**420**),[2490] $PPh_2Bzim(CH_2Ph)$ (**421**),[1378] and $PPh_2(CH_2)_2CONHMe$[2491] lead to mononuclear complexes [AuClL] with the gold bound to the chlorine and the phosphorus atoms.



(419)

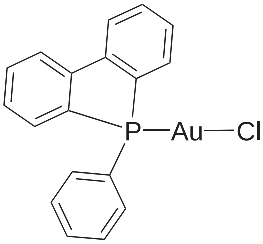


(420)

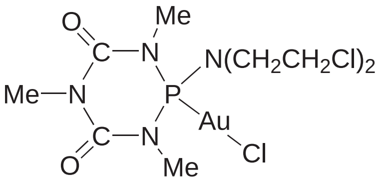


(421)

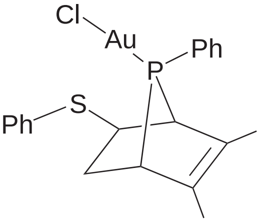
Phosphole ligands such as 1-phenyldibenzophosphole or 1-phenyl-3,4-dimethylphosphole or $PC_5H_3(TMS)_2$-2,5 form complexes of the type [AuClL];[2492,2493] the structure of (**422**) shows gold–gold interactions between two independent molecules. P-mono- and bis-(2-chloroethyl)-amino-substituted heterocyclic compounds react with [AuCl(THT)] with displacement of tetrahydrothiophene to give the corresponding chloro complexes, as for instance complex (**423**). These derivatives have potential antitumor activity.[2494] Another chloro(phosphine) gold(I) complex with highly potent activity against human cancer cell is (**424**).[2495]



(422)

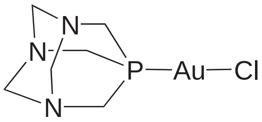


(423)

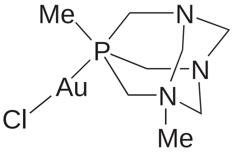


(424)

The reaction of the cage-type ligand TPA with [AuCl(THT)] gives [AuCl(TPA)] (**425**), and a similar reaction was observed with the protonated TPA ligand to give [AuCl(TPA·HCl)].[2496] The small cone angle of the phosphine ligand allows a short intermolecular aurophilic interaction. Reductive cleavage of the methyl phosphonium salt ($TPAMe^+I^-$) by sodium in liquid ammonia affords the new bicyclic ligand $(PMe)(CH_2)_5N_2(NMe)$, which reacts with $[AuCl(SMe_2)]$ to give complex (**426**), which is a monomer.[2497]



(425)

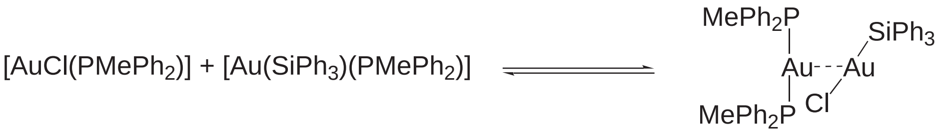


(426)

An interesting physical property exhibited by gold(I) compounds with short Au···Au contacts is the visible luminescence observed under UV excitation in the solid state, especially at liquid nitrogen temperature. In mononuclear gold(I) complexes the luminescence has been associated with a trigonal, noncentrosymmetric structure obtained either through intermetallic interactions, or three-coordination associated with a metal centered (MC) pz → ds phosphorescence.[2496,2498] Other possible absorption modes, such as ligand centered (LC) or ligand-to-metal charge transfer (LMCT) are also observed depending upon the types of ligands present. The luminescence spectra of [AuCl(TPA)] and [AuCl(TPA·HCl)] are substantially different and are correlated with the change in the Au···Au interaction. At 78 K [AuCl(TPA)] luminesces intensely red (674 nm), while the protonated [AuCl(TPA·HCl)] luminesces yellow (596 nm). The emission bands in both complexes blue-shift as the temperature is increased. The interpretation of the phenomena is supported by extended Hückel MO calculations.[2496] [AuCl(TPA)] is readily converted into the corresponding bromide or iodide, by reacting with HBr (aqueous) or KI in acetone, respectively.[2498] They have two emission bands with relative intensities which depend upon the excitation wavelength used.

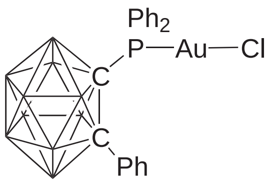
The chiral phosphine ligand (2-hydroxybutyl)diphenylphosphine (racemic mixture) forms the racemic chiral complex [AuClL]. Metathesis reactions with KBr or KI lead to the corresponding bromide or iodide complexes, respectively. In the crystal, pairs of enantiomers are aggregated by two long hydrogen bonds between the hydroxy group and the halogen substituent.[2499] With chiral secondary phosphines the complexes [AuX(PHMePh)] (X = Cl, Br, I) have been obtained, the structures for Cl and Br show chain-like supramolecular aggregates through aurophilic Au—Au contacts. The chain contains both enantiomers following the sequence ...RSRSRS...[2500] Gold(I) complexes with polyaromatic phosphines PAr_nPh_{3-n} (Ar = naphthyl, naphthyl, anthracenyl, Fc, biphenyl, or phenanthrenyl) of the type $[AuX(PR_3)]$ (X = Cl, NO_3) have been synthesized. The relative complexing abilities of the phosphines follows quite closely the order of the calculated cone angles, indicating that steric factors are the dominant influence in determining the reactivities of these polyaromatic phosphines.[2501] Gold(I) complexes with phosphinoketimines $P(N{=}CPh_2)_nPh_{3-n}$ ($n = 1$–3) of the type [AuClL] have been reported showing that the gold(I) center always prefers coordination to the phosphorus atom than to the nitrogen one.[2502]

A new example with an intermolecular Au···Au interaction (2.9807(4) Å) is obtained in the reaction of $[AuCl(PMePh_2)]$ with $[Au(SiPh_3)(PMePh_2)]$ (Equation (36)). In solution, the compound is in equilibrium with the mixture of the monomers.[2503] Similarly, the complex $[Au(SiR^1{}_3)(PR^2{}_3)]$ undergoes ligand redistribution in solution to give the homoleptic species; $[Au(SiPh_3)(PMe_3)]$ crystallizes as the heteroleptic complex.[2504] The reaction of [AuClL)] with $[GeCl_2(dioxane)]$ affords $[Au(GeCl_3)L]$ (L = $AsPh_3$, $PPhMe_2$), the complexes are dimers in the crystal with short Au—Au or Au–Cl contacts.[2313,2505]

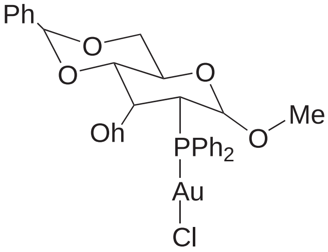


(36)

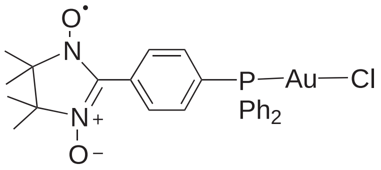
Other [AuClL] complexes with monophosphines are those derived of *o*-carborane (**427**),[2506] pyranoside group (**428**),[2507] α-dimethylamino(3)ferrocenophan-2-yl,[2508] calix[4]arene derived phosphites,[2509] or aminoxyl radical-substituted phosphines (**429**),[2510] for which ferromagnetic interactions have been observed.



(427)

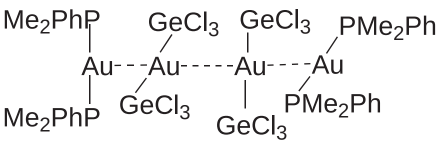


(428)

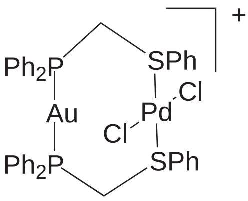


(429)

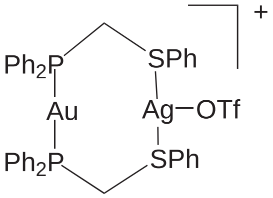
Homoleptic complexes of the type $[AuL_2]^+$ with L = PPh_2CH_2TMS,[2032] PCy_3,[2455,2456] $P(CH_2CH_2CN)_3$,[2457] PPh_3,[2511] $PBu^n{}_3$,[2512] $P(2,4,6\text{-}Me_3C_6H_2)$,[1,2513] $PPhFc_2$,[1745,2501] $PPhMe_2$,[2505] PPh_2CH_2Fc,[709] PPh_2CH_2SPh,[2514] $Ph_2PNHP(O)Ph_2$,[2488] $P(CH_2OH)_2CH_2Fc$,[2515] or with mixed ligands $[AuL^1L^2]^+$ ($L^1 = PPh_2CH_2TMS$,[2032] $PPhFc_2$,[1745] $P(CH_2SPh)_3$;[2516] $L^2 = PPh_3$) have also been synthesized with several phosphine or arsine as ligands. In some cases the mixed phosphine derivatives are in equilibria with the homoleptic species.[2032] The crystal structures of isostructural silver and gold complexes with the trimesitylphosphine ligand[1] lead to the experimental evidence that gold is smaller than silver as was theoretically predicted in calculations using relativistic and correlation effects.[2517–2519] The complex $[Au(PPhMe_2)_2]^+[Au(GeCl_3)_2]^-$ (**430**) forms a chain of gold atoms where unexpectedly the sequence is $+--+$, which is clearly at variance with the simple rules of Coulomb forces.[2505] Heterometallic complexes with the phosphine ligand PPh_2CH_2SPh have been synthesized from $[AuCl(PPh_2CH_2SPh)]$ or $[Au(PPh_2CH_2SPh)_2]OTf$; they react with $[PdCl_2(NCPh)_2]$ or AgOTf to give $[\{AuCl(PPh_2CH_2SPh)\}_2PdCl_2]$, $[AuPdCl_2(PPh_2CH_2SPh)_2]OTf$ (**431**), or $[AuAg(PPh_2CH_2SPh)_2]OTf$ (**432**), respectively.[2514,2520]



(430)



(431)



(432)

High coordinated gold(I) complexes with monodentate phosphines, arsines, or stibines have been reported. It was first demonstrated, by ^{31}P NMR studies, that bis-, tris-, and even tetrakis (phosphine)gold(I) complexes exist in solution. Owing to rapid ligand exchange on the NMR time scale the individual complexes can only be observed at low temperatures. The linear complexes [AuX(PR$_3$)] interact with an excess of phosphine to give a series of species including primarily [AuX(PR$_3$)$_2$], [Au(PR$_3$)$_3$]X, or [Au(PR$_3$)$_4$]X as components of equilibria, as shown in Equation (37). The maximum coordination number attainable depends on the particular ligand used. For bulky phosphines, as PR$_3$ = PCy$_3$, only the two-coordinated cation [Au(PCy$_3$)$_2$]$^+$ is accessible, but with PR$_3$ = PBu$_3$, P(4-Tol)$_3$, or PPh$_2${CH$_2$CH$_2$(2-Py)} both [Au(PR$_3$)$_2$]$^+$ and [Au(PR$_3$)$_3$]$^+$ are detected; for PR$_3$ = PEt$_3$, PMe$_2$Ph, P(OEt)$_3$, or P(OCH$_2$)$_3$CEt finally the two-, three-, and four-coordinated species are observed.[2521–2524]

$$[\mathrm{AuX(PR_3)}] \xrightleftharpoons{\mathrm{PR_3}} [\mathrm{AuX(PR_3)_2}] \rightleftharpoons [\mathrm{Au(PR_3)_2}]\mathrm{X} \xrightleftharpoons{\mathrm{PR_3}} [\mathrm{Au(PR_3)_3}]\mathrm{X} \xrightleftharpoons{\mathrm{PR_3}} [\mathrm{Au(PR_3)_4}]\mathrm{X} \tag{37}$$

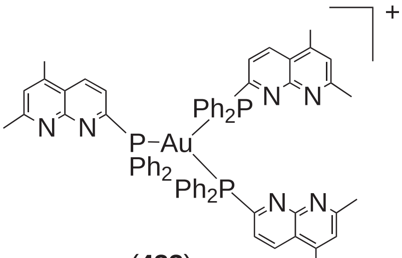
Electrospray mass spectrometry is a technique that allows pre-existing ions to be transferred from solution to the gas phase with minimal fragmentation, followed by conventional mass analysis. Recently electrospray mass spectra have been studied for a number of cationic phosphinegold(I) complexes in dichloromethane/methanol solution.[2525] For derivatives of the types [Au(PR$_3$)$_2$]$^+$ and [Au(PR$_3$)$_3$]$^+$, the intact cations were observed, but ions of the type [Au(PR$_3$)$_4$]$^+$ where not detected in the gas phase. Even the three-coordinated [Au(PR$_3$)$_3$]$^+$ are relatively unstable in the gas phase, and the ions [Au(PR$_3$)$_2$]$^+$ are readily produced.

Three-coordinate complexes with two phosphines are commonly of the type [AuX(PR$_3$)$_2$]. They show Au—P distances rather longer than those in two-coordinate complexes and P—Au—P angles somewhat wider than 120°; the extend of the distortion depends on the ligands X and PR$_3$. Some recent results of structure determinations are as follows: PR$_3$ = PPh$_3$, X = Cl [135.7(1)°], Br [132.45(8)°], I [132.13(7)°],[2526] SCN [127.8(1)°],[2527] C(CN)$_3$ [161.23(9)°],[2528] S$_2$COEt [130.1(1)°];[2529] PR$_3$ = PCy$_2$Ph, X = Cl [158.24(5)°],[2530] PR$_3$ = P(CH$_2$CH$_2$CN)$_3$, X = S$_2$COEt [145.3(1)°].[2529] In solution the complex [AuCl(PPh$_2$CH$_2$Fc)$_2$] is in equilibrium with linear, three-, and four-coordinated species.[709] Some of these three-coordinate bis(phosphine) gold(I) complexes luminesce in the solid state, as well as in solution.[2529,2531] The emission is attributed to metal centered $pz \rightarrow (d_{x^2-y^2}, d_{xy})$ transition. An example of three-coordinate derivative with triphenylstibine is [Au(2-C$_6$H$_4$NO$_2$)(SbPh$_3$)$_2$].[1644]

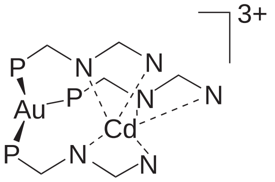
The most regular three-coordination is observed in compounds where all the three ligands are identical, as in [Au(PPh$_3$)$_3$]$^+$ salts. Despite the cations being formally identical, small differences are observed in the structures with different anions, such as B$_9$H$_{12}$S$^-$,[2532] BF$_4^-$,[2533] NO$_3^-$,[2534] [Mo(SC$_6$F$_5$)$_4$(η^5-C$_5$H$_5$)]$^-$,[2535] SiF$_5^-$,[2536] or Cl$^-$.[2537] The cation of [Au(PCy$_2$Ph)$_3$]ClO$_4$, obtained by reaction of [AuCl(PCy$_2$Ph)] with an excess of PCy$_2$Ph in the presence of (NH$_4$)ClO$_4$, also has an almost ideal trigonal planar geometry [P—Au—P angles of 119.3(3)°].[2538] The three-coordinate gold(I) compound with the ferrocenyl phosphine PPh$_2$CH$_2$Fc has also been described, [Au(PPh$_2$CH$_2$Fc)$_3$]ClO$_4$.[709] The complexes [Au(TPA)$_3$]Cl and [Au(TPPTS)$_3$]$^{8-}$ (TPPTS = tris[(3,3′,3″-phosphinidyne-tris(benzenesulfonate)) show luminescence in aqueous solution.[2539]

Four-coordinate complexes with monodentate ligands have also been reported. The X-ray crystal structures of three modifications of the compound [Au(PPh$_3$)$_4$]BPh$_4$ have been determined, none of which shows the expected simple tetrahedral geometry.[2540] Thus, the chloroform solvate contains a trigonal planar $Au(PPh_3)_3$ unit bound to other phosphine with a very long Au···P contact (3.95 Å). However, the cation of $[Au(PMePh_2)_4]PF_6$, obtained by reaction of $K[AuBr_4]$ with an excess of $PMePh_2$, shows a nearly regular tetrahedral geometry.[2541] The structure of $[Au(AsPh_3)_4]BF_4$ has been carried out and also shows a very regular tetrahedral geometry.[686] The cations of the triphenylstibine complexes $[Au(SbPh_3)_4]X$ ($X = ClO_4$, $[Au(C_6F_5)_2]^-$, or $[Au\{2,4,6\text{-}(NO_2)_3C_6H_2\}_2]^-$)[2114,2542–2544] show also a tetrahedral coordination at the gold atom, with Sb—Au—Sb angles of 107.8–111.0°. The compounds are readily obtained by addition of $SbPh_3$ to solutions of $[AuR(THT)]$ [$R = C_6F_5$, $2,4,6\text{-}(NO_2)_3C_6H_2$].[2114,2544] An equilibrium between the neutral three-coordinate $[AuR(SbPh_3)_2]$ and the ionic four-coordinate complex $[Au(SbPh_3)_4][AuR_2]$ has been proposed in solution.[2114]

The compounds $[AuX(PR_3)_3]$ ($PR_3 = PPh_3$, X = Cl, SCN, $GeCl_3$;[2545–2549] PR_3 = 1-phenyldibenzophosphole, X = Cl)[2492] show the presence of a four-coordinate gold atom in a distorted tetrahedral geometry, with rather long Au—P and Au—X distances. The water soluble and luminescent gold(I) complex $[AuI(MeTPA)_3]I_3$ ((MeTPA)I = 1-methyl-1-azonia-3,5-diaza-7-phosphaadamantane iodide), has been obtained by reaction of $[AuCl(SMe_2)]$ with three equivalents of (MeTPA)I.[2117] The coordination environment of the gold center is approximately trigonal planar and the iodine is weakly coordinated to the gold atom perpendicular to the AuP_3 plane [Au—I distance 2.936(1) Å]. The solid shows a yellow emission (598 nm) at 77 K and an orange emission (686 nm) at 140 K. $[AuI(MeTPA)_3]I_3$ undergoes an unusual phenyl-transfer reaction in aqueous solution with $NaBPh_4$ to form $[AuPh(MeTPA)_3]BPh_4$. An analogous phenyl-transfer reaction has been observed between $[Au(TPA)_3]Cl$ and $NaBPh_4$, which leads to $[AuPh(TPA)]$.[2117] Reaction of 7-diphenylphosphino-2,4-dimethyl-1,8-naphthyridine (dpnapy) with $[AuCl(THT)]$ affords the tricoordinate compound $[Au(dpnapy)_3]^+$ (**433**); the latter shows strong affinity towards Cu^I and Cd^{II} (**434**) ions.[2550]



(433)



(434)

Although in most of the above reports structural information is based on X-ray data, Au Mössbauer spectroscopy has also been successfully employed for the investigation of two-, three-, and four-coordination in gold(I) complexes.[2551] An increase in coordination numbers leads to a decrease in the isomer shift (IS) by 1–2 mm s^{-1} (three-coordination) or 2–4 mm s^{-1} (four-coordination) relative to two-coordination. For the same ligands, the quadrupole splitting (QS) for three-coordinated complexes is expected to be very similar to that for the two-coordinate derivatives, while that for complexes with T_d symmetry should be zero.

Gold(I) complexes of the type $[AuCl(PPh_3)_n]$ ($n = 1$, 2) or $[Au(NO_3)(PPh_3)]$ show an excellent performance towards oxidative addition carbonylation or aromatic amines to form corresponding carbamates, and also towards the carbonilation of aliphatic amines to produce either alkylureas or formamides.[2552,2553] Cationic gold(I) compounds of the type $[AuL]^+$ where L = phosphine, phosphite, or arsine are excellent catalysts for the addition of alcohols to alkynes.[2554]

(iii) Complexes with polydentate ligands

Bi-, tri-, and tetradentate phosphines or arsines have been used quite frequently as bridging ligands between gold(I) centers. Dinuclear (chloro)gold(I) complexes of ditertiary phosphines with the phosphorus atoms bridged by one to eight carbon atoms, of the type $[Au_2Cl_2\{\mu\text{-}(PPh_2)_2(CH_2)_n\}]$ ($n = 1$–8) have been prepared from $[AuCl(CO)]$ or $[AuCl(SR_2)]$ with the corresponding bidentate phosphine. They can adopt different structural patterns, as the result of the formation of Au···Au bonds (see Figure 20). The crystal lattice of the 1,4-bis(diphenylphosphino)butane ($n = 4$) or hexane ($n = 6$) derivatives contain independent molecules (type a),[2555,2556] which show no intra- or intermolecular Au···Au interactions in contrast with the

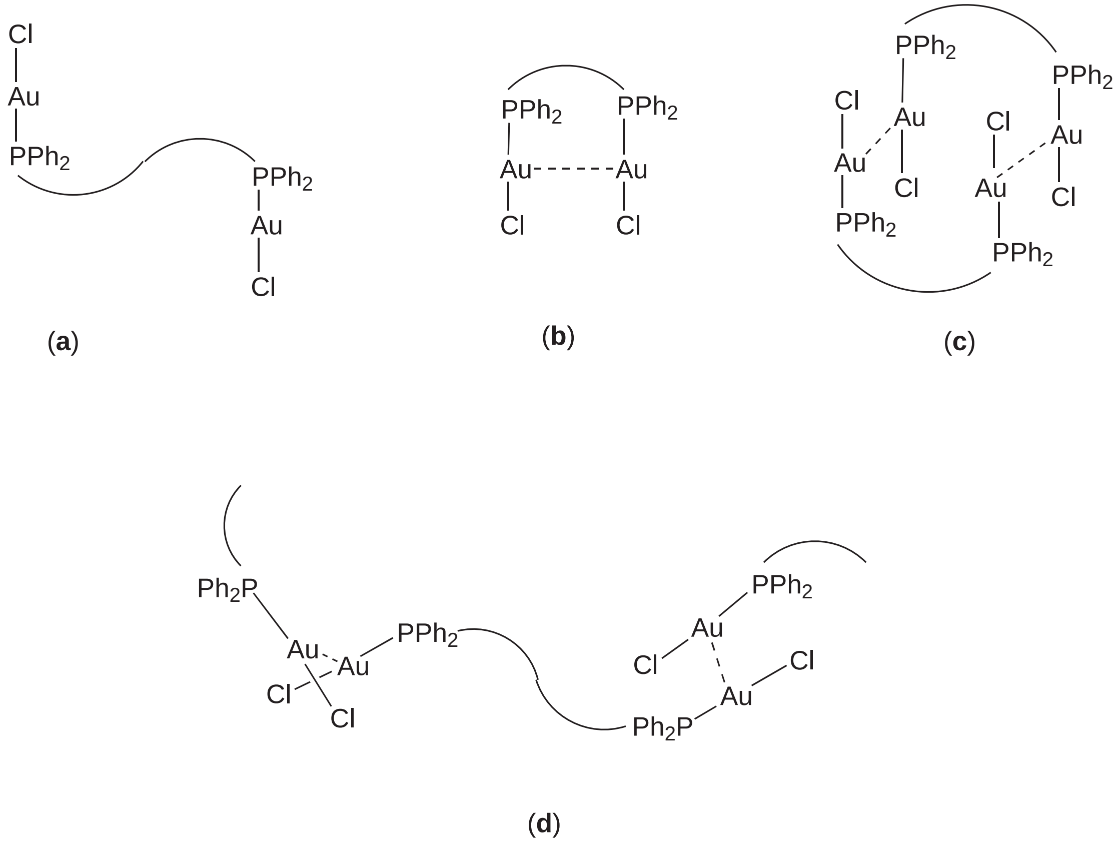


Figure 20 Different structural patterns of [$Au_2Cl_2\{\mu\text{-}PPh_2(CH_2)_n\}$].

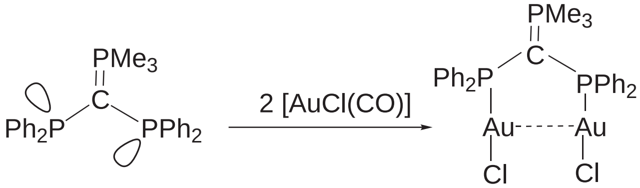
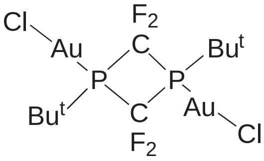
structures of the related gold complexes with shorter or longer chain diphosphines, where intra- ($n = 1$, type b)[2557] and intermolecular metal–metal interactions with formation of discrete dimers (type c),[2558,2559] or polymeric chains (type d) are found.[2555,2556,2560,2561] The completely different packing of the monomeric molecules of [$Au_2Cl_2\{\mu\text{-}(PPh_2)_2(CH_2)_4\}$] and the two polymorphic forms of [$Au_2Cl_2\{\mu\text{-}(PPh_2)_2(CH_2)_2\}$], where the short Au···Au contacts give rise to dimers or to a polymeric chain structure, are particularly remarkable, since the conformation of the free phosphines show a close relationship. It has been suggested that packing effects with or without solvent molecules determine the conformation of these molecules; in fact for [$Au_2Cl_2\{\mu\text{-}(PPh_2)_2(CH_2)_2\}$] the presence of dichloromethane in the crystal leads to a transformation of the dimeric units present in the solvent-free crystal modification to a polymeric chain. For $n = 3$ and larger chains the complexes show monomeric dinuclear molecules connected through intermolecular Au···Au contacts of ca. 3.30 Å to give polymeric chains.

Analogous structures occur in other diphosphine complexes of the type [$AuCl_2\{\mu\text{-}(PPh_2)_2X\}$][2562–2569] and thus monomeric molecules without Au···Au interactions are found when $X = C{=}PPh_3$; monomeric molecules with intramolecular metal–metal contacts are formed for $C{=}PMe_3$, $CH_2{=}CC{=}CH_2$, bicyclopropyl, *cis*-CH=CH, and polymeric compounds with intermolecular Au···Au interactions are obtained for *trans*-CH=CH, $CH_2C({=}CH_2)CH_2$, or $C({=}CH_2)$. Chains are also obtained for the arsino-phosphino ligand $PPh_2CH_2CH_2AsPh_2$,[2570] or for the bis(diisopropylphosphino)ethane ligand.[2571] In the complexes with the diphosphine $PPh_2C({=}PMe_3)PPh_2$, the ligands change their ground state syn/anti orientation to a symmetrical syn/syn conformation upon coordination to gold(I) (Equation (38)). From temperature-dependant NMR studies the energy of the Au···Au interaction has been estimated to be in the order of 29–33 kJ mol^{-1}.[2562,2563] Another example of the conformation-determining attractive interaction between gold(I) centers is the change in the conformation of the butadiene skeleton when 2,3-bis(diphenylphosphino)-1,3-butadiene is coordinated to two gold atoms in [$Au_2Cl_2\{\mu\text{-}PPh_2C({=}CH_2)C({=}CH_2)PPh_2\}$].[2565]

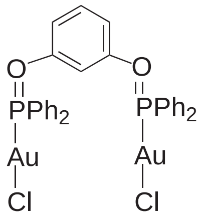


(38)

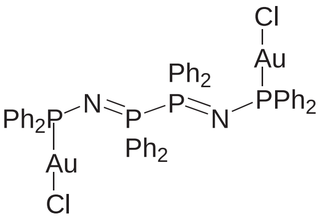
Other bidentate ligands used in the synthesis of dinuclear gold(I) derivatives are $PBu^t_2OPBu^t_2$,[2572] $Ph_2PNHPPh_2$,[2573–2575] 1,1-bis(diphenylphosphino)ferrocene,[2576–2579] 1,2-bis(diphenylphosphino)-1,2-dicarba-*closo*-dodecaborane,[2580] $Ph_2PCF_2PPh_2$,[2581] $Ph_2PN(o\text{-}C_6H_4OMe)PPh_2$,[2582] dihydrobenzoxazaphosphorinone derivatives,[2494,2583] 1,4-$Ph_2PC_6H_4PPh_2$, and 4,4 $Pr^i_2PC_6H_4C_6H_4PPr^i_2$,[2225] $Ph_2PCH_2C_6H_4CH_2PPh_2$,[2584] $Ph_2P(CH_2)_2O(CH_2)_2PPh_2$,[752] $Ph_2P(CH_2)_2PEt_2$,[2585] $n\text{-}Py_2P(CH_2)_2PnPy_2$ ($n = 2, 3, 4$),[2586] $Bu^tP(\mu\text{-}CF_2)_2PBu^t$ (**435**),[2587] $Ph_2P(CH_2)_2CONH(CH_2)_2$ $NHCO(CH_2)_2PPh_2$,[2491] 2,5-bis(diphenylphosphinomethyl)thiophene,[786] 2,9-bis(diphenylphosphino)-1,8-naphthyridine,[1384] 3,4-bis(diphenylphosphinoamino)toluene,[1757,1758] 1,2-bis(diphenylphosphinoamino)benzene,[1757] 1,3,5,7-tetramethyl-9,10-(*o*-phenylene)-4,9-dioxa-8, 10-diphospha-adamantane,[2588] 1,3-bis(diphenylphosphinito)benzene (**436**),[2589] *N*,*N*′-diethyl-*N*,*N*′-bis(diphenylphosphino)urea,[2590] 1,1,3,3,4,4,6,6-octaphenyl-1,3,4,6-tetraphosphazene (**437**),[2591] $Ph_2P(CH_2)_2NR(CH_2)_2PPh_2$ (R = H, NO),[2592] or 1,1′-diphenyl-2,2′,5,5′-tetrahydro-3,3′,4,4′-tetramethyl-1H,1′H-2,2′-biphosphole (**438**).[2593] Complexes of the type $[Au_2X_2(\mu\text{-}PP)]$ where X can be an anionic ligand other than chlorine, pseudohalogen, aryl, silyl group, etc. or even a neutral ligand, as tetrahydrothiophene, ylide, and phosphine that gives cationic complexes of the type $[(AuL_2)_2(\mu\text{-}PP)]_2^+$ have also been synthesized.[505,1650,1651,1757,2109,2110,2147,2577,2580,2594–2596]



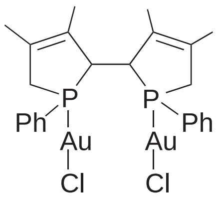
(435)



(436)

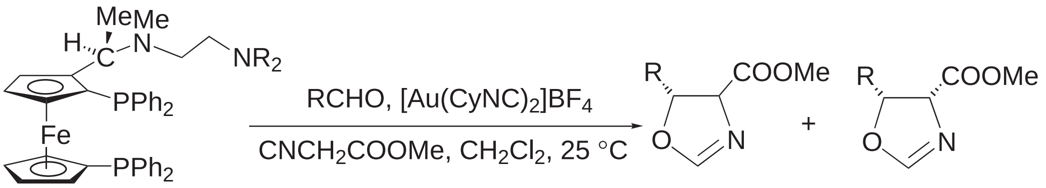


(437)



(438)

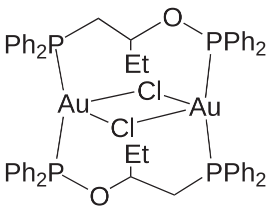
Hayashi and co-workers have reported a very efficient synthesis of optically active dihydrooxazoles involving a gold(I)-catalyzed coupling of isocyanoacetate esters with aldehydes in the presence of the chiral diphosphine $[(\eta^5\text{-}C_5H_4PPh_2)\{\eta^5\text{-}C_5H_3(PPh_2)CHMeNMeCH_2CH_2NR_2\}Fe]$ (R = Me, Et) (PP) (Equation (39)).[2597] The dinuclear $[Au_2Cl_2(\mu\text{-}PP)]$ and trinuclear $[Au_3Cl_3(\mu\text{-}PP)]$ complexes have been isolated.[2598]



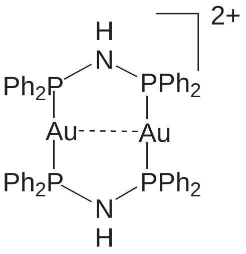
(39)

With higher diphosphine/gold ratios other structural patterns can be obtained. The dinuclear derivatives $[Au_2(\mu\text{-}PP)_2]^{2+}$ are known with a great variety of diphosphines R_2PXPR_2 where X can be CH_2,[2196,2557,2599–2607] $(CH_2)_2$,[2604,2608,2609] $(CH_2)_3$,[2608,2610] $C{=}CH_2$,[2569] $C(CH_2CH_2)$,[2096] $CHCH_2OMe$,[2096] CH_2CHEtO (**439**),[782] $C{=}C{=}CMe_2$,[2611] NH (**440**),[1650] or NEt.[2612] Analogous complexes have been described with $Ph_2AsCH_2AsPh_2$.[1651,2313] Most of these derivatives are three-coordinate by bonding to the anionic ligand that can be Cl, Br, I, S_2CNEt_2, or BH_3CN and also by formation of Au···Au interactions with molecules such as $[AuCl(GeCl_3)]^-$. The complexes $[Au_2\{(PR_2)_2CH_2\}]^{2+}$ (R = Me, Ph, Cy) are luminescent in the solid state and in solution, and several studies have been carried out related to aurophilic attraction and luminescence.[2601,2613–2618]

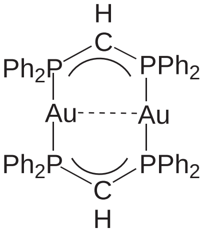
The high luminescent complex $[Au_2\{(PPh_2)_2\text{-}CH_2\}](OTf)_2$ with a triplet excited state can be used in light-emitting diodes.[2619]



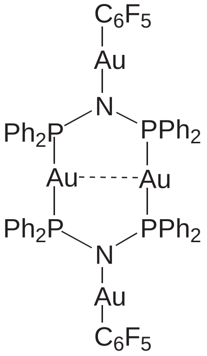
(439)



(440)



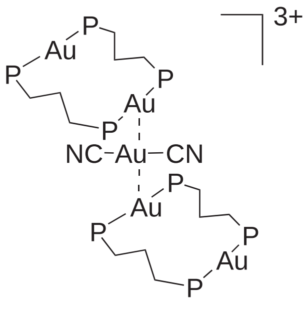
(441)



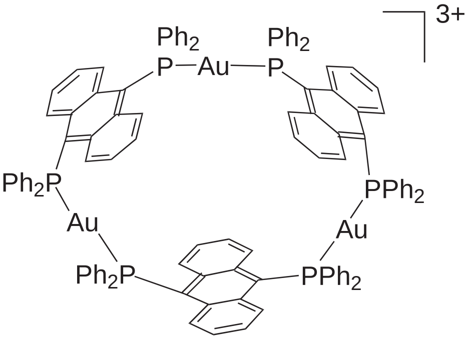
(442)

The dinuclear derivatives $[Au_2\{(PR_2)_2X\}]^{2+}$ (X = CH$_2$, NH) can be easily deprotonated to give the neutral complexes $[Au_2\{(PR_2)_2Y\}]$ (Y = CH (**441**), N).[771,2620–2622] Further coordination of the C or N atoms to other metal complexes gives tetra- or hexanuclear derivatives as, for example, (**442**).[771,2162,2163,2622]

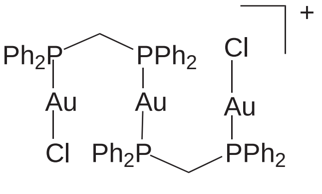
Studies of gold(I) cations with empirical formula $[Au\{PPh_2(CH_2)_nPPh_2\}]^+$ show that the complexes crystallizes as rings for $n = 3$ or 5 but as a polymer when $n = 4$. The ring complexes can be connected through aurophilic bonding by addition of $[Au(CN)_2]^-$ as, for example, in (**443**).[2623] With the diphosphine 9,10-bis(diphenylphosphino)anthracene the reaction 1:1 with $[AuCl(SMe_2)]$ gives the trinuclear complex $[Au_3(\mu\text{-PP})_3]^{3+}$ (**444**).[2624] This luminescent gold ring is shown to be an inorganic analogue of cyclohexane in terms of structure and solution dynamics. Other stoichiometries with diphosphine ligands are of the type $[Au_3Cl_2(\mu\text{-PP})_2]^+$ which are known for dppm (**445**),[1744,2625] or $Ph_2PNEtPPh_2$,[2612] the mixed gold(I)–gold(III) $[Au\{\mu\text{-}(AsPh_2)_2CH_2\}_2\{Au(C_6F_5)_3\}_2]ClO_4$,[1651] or the methanide complexes $Bu_4N[Au\{\mu\text{-}(PPh_2)_2CH\}_2\{Au(C_6F_5)_3\}_2]$, $Bu_4N[Au\{\mu\text{-}(PPh_2)_2CH(AuX)\}_2\{Au(C_6F_5)_3\}_2]$ (X = Cl, C$_6$F$_5$), $[Au\{\mu\text{-}(PPh_2)_2C(AuPPh_3)_2\}_2\{Au(C_6F_5)_3\}_2]ClO_4$,[1755] and $[AuCl(\mu\text{-}PPh_2CH_2PPh_2)AuCH(PPh_2AuCl)_2]$.[2626] Another type is the dinuclear derivative $[Au_2(C_6F_5)\{(PPh_2)_2C_2B_9H_{11}\}(PPh_3)]$ with an anionic bridging diphosphine ligand and two different terminating ligands.[2627]



(443)



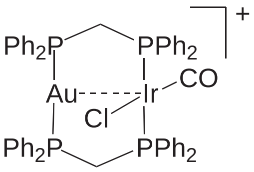
(444)



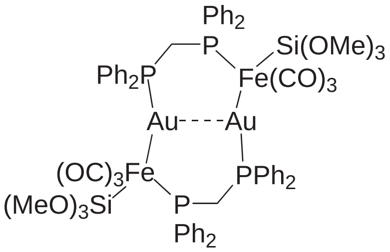
(445)

Dppm has also been used to synthesize heterodinuclear complexes with the diphosphine bridging gold and other metal atoms. Thus, a number of heterometallic derivatives with gold and iridium as (**446**),[2628–2631] nickel,[2632] palladium or platinum,[1763,2633,2634] iron as (**447**),[2635–2637] molybdenum, or tungsten,[721,2638] are known. Other bimetallic systems with rhodium or platinum and gold have been obtained with the 2-[bis(diphenylphosphino)methyl]pyridine as (**448**).[2639,2640] Reaction of *trans*-$[MCl_2(AsPh_2CH_2AsPh_2)_2]$ (M = Pd, Pt) with [AuCl(THT)] leads to the trinuclear complexes *trans*-$[MCl_2(AsPh_2CH_2AsPh_2AuCl)_2]$. With the bis(diphenylstibino)methane the result is different and the dinuclear derivative $[AuCl_2\{\mu\text{-}(SbPh_2)_2CH_2\}]$ is obtained.[1762]

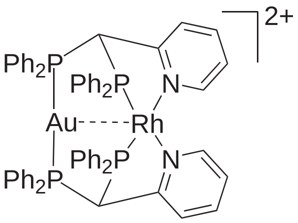
Other heteronuclear complexes are those of the bis(diphenylphosphino)methanide and the group 6 metals, $[M(CO_4)\{(PPh_2)_2CHAu(PPh_3)\}]$ (M = Cr, Mo, W).[2641]



(**446**)

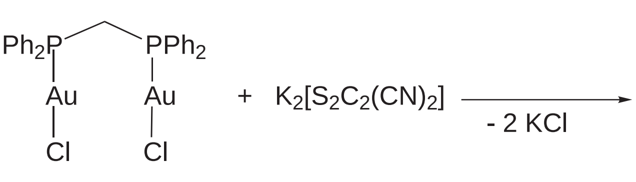


(**447**)

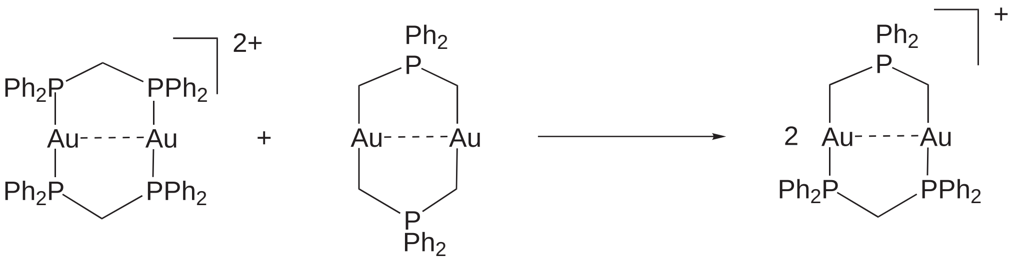


(**448**)

Most of the dinuclear gold(I) complexes are homobridged diauracycles with the same bridging ligand on each side, but some examples of heterobridged derivatives have been reported. These contain a diphosphine in addition to other bidentate ligand such as bis(diphenylphosphino)-methanide,[2096,2621] bis(ylide),[2626,2642] dithiolate,[2643,2644] dithiocarbamate,[2642,2645] xantate,[2037] phosphoniodithioformate,[2039] dithiophosphinate,[2040] or pyridine-2-thiolate.[2038] They can be obtained by reaction of the $[Au_2X_2(\mu\text{-PP})]$ complexes with the bidentate ligand as shown in Equation (40), or by ligand exchange reactions between two different homobridged dinuclear compounds, as shown in Equation (41). Other examples with dithiolate ligands can be seen in Section 6.7.3.4.5.

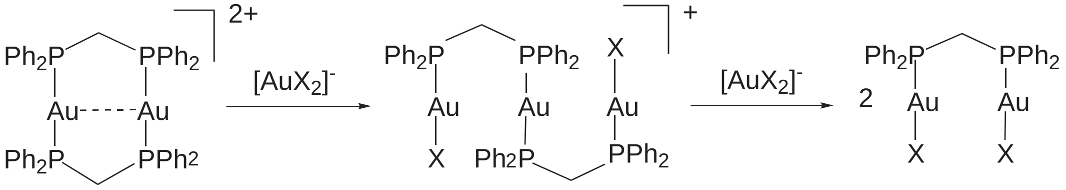


(40)



(41)

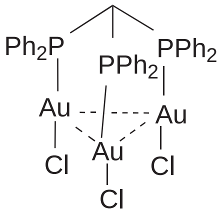
Bidentate ligand transfer also occurs between di- and mononuclear complexes via donor–acceptor intermediates. Reactions of the cationic complex $[Au_2(\mu\text{-dppm})_2]^{2+}$ with $[AuX_2]^-$ (X = Cl, Br) salts lead to tri- or dinuclear derivatives depending on the molar ratio (1:1 or 1:2) (Scheme 36).[2645]



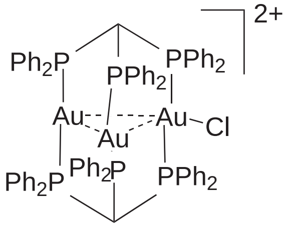
Scheme 36

Tri-tertiary phosphines react with gold(I) complexes of the type $[AuX(SR_2)]$ and function as templates for the synthesis of trinuclear derivatives of the type $[Au_3X_3(\mu\text{-}L)]$. The gold atoms can be aggregated in equilateral triangles or in other forms, depending of the nature of the phosphine. Ligands imposing structure-bases constraints, as $HC(PPh_2)_3$, lead to complexes $[Au_3X_3\{(PPh_2)_2CH\}]$ (X = Cl (**449**), Br, I, C_6F_5)[2646,2647] with a triangular all-*cis* arrangement of the three gold atoms and rather short Au···Au contacts, whereas the conformation of the free ligand is all-*trans*.[2646] Other stoichiometries, as with the dinuclear $[Au_2\{\mu\text{-}(PPh_2)_2CHPPh_2\}_2](ClO_4)_2$,[2647] trinuclear $[Au_3Cl\{\mu_3\text{-}(PPh_2)_3CH\}_2](ClO_4)_2$ (**450**), $[Au_3\{\mu_3\text{-}(PPh_2)_3CH\}_2](ClO_4)_3$,[2647,2648] and tetranuclear as $[Au_2\{\mu\text{-}(PPh_2)_2CHPPh_2Au(C_6F_5)\}_2]$ $(ClO_4)_2$ (**451**).[2647] The trinuclear derivative $[Au_3Cl\{\mu_3\text{-}(PPh_2)_3CH\}_2](ClO_4)_2$ shows a photoluminescent behavior.[2648] The CH group of these complexes can be deprotonated to give tris(phosphine)methanide derivatives such as $[Au_2\{\mu\text{-}(PPh_2)_2CPPh_2\}_2]$ or $[Au_2\{\mu\text{-}(PPh_2)_2CPPh_2AuX\}_2]$.[2647] Heteronuclear complexes with this ligand have been obtained with gold and rhodium,[2649] such as $[Rh(COD)\{(PPh_2)_2CHPPh_2Au(PPh_3)\}](BF_4)_2$ or with gold and group 6 metals, such as $[M(CO_4)\{(PPh_2)_2CHPPh_2AuX\}]$ (M = Cr, Mo, W; X = Cl, C_6F_5).[2650]

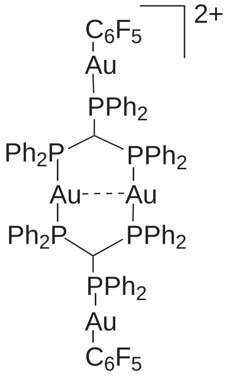
Bis[2-(diphenylphosphino)phenyl]phenylphosphine (TP) is a very inflexible ligand with a rigid backbone and gives the trinuclear complex $[Au_3Cl_3(TP)]$ (**452**), that has a compact unsymmetrical structure in the solid state which is retained in solution owing to the fixation of the gold atoms through intermetallic contacts.[2651]



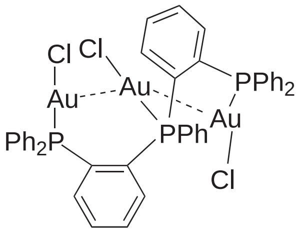
(449)



(450)



(451)



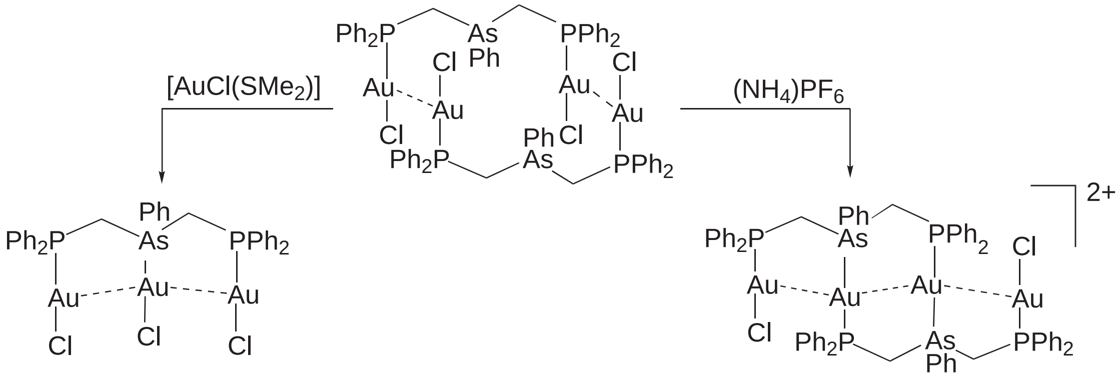
(452)

The more flexible ligands $MeC(CH_2PR_2)_3$ (R = Me, Ph) form complexes of the type $[Au_3X_3\{(PR_2CH_2)_3CMe\}]$ (R = Me, Ph),[1766,2652,2653] or $[Au_2(C_6F_5)_2\{(PPh_2CH_2)_2C(Me)PPh_2O\}]$.[1766] The compound $[Au_3Cl_3\{(PMe_2CH_2)_3CMe\}]$ has a layer structure with two of the gold atoms associated via intramolecular Au···Au contacts and the pair of gold atoms are further aligned in chains through intermolecular Au···Au contacts.[2653] Heteropolynuclear complexes with gold and group 6 metals have been described with the triphosphine $(PPh_2CH_2)_3CMe$.[1767] The related $N(CH_2PPh_3)_3$ yields the trinuclear derivatives $[Au_3X_3\{(PPh_2CH_2)_3N]$ (X = Cl, Br, I); for Cl or Br an aggregation into layers through Au—X contacts is observed, but for I the molecules are linked into strings through short intermolecular Au···Au contacts.[2654]

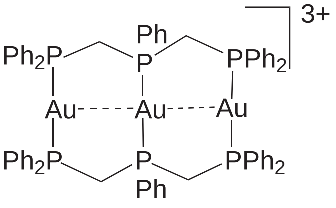
Interesting tri- and tetranuclear complexes have been obtained with flexible tridentate ligands of the type $RE(CH_2PR_2)_2$ (R = Me, Ph; E = P, As). The reaction of $PhAs(CH_2PPh_2)_2$ with two equivalents of $[AuCl(SMe_2)]$ yields the dinuclear $[Au_2Cl_2\{(PPh_2CH_2)_2AsPh\}]$, which crystallized as a dimer with intermolecular gold–gold interactions.[2655] Further treatment with $[AuCl(SMe_2)]$ produces the trinuclear $[Au_3Cl_3\{(PPh_2CH_2)_2AsPh\}]$ (Scheme 37), which has a bent Au_3 chain. Precipitation of half of the halogen from the binuclear complex gives $[Au_4Cl_2\{(PPh_2CH_2)_2AsPh\}]$, which has a bent Au_4 chain.

With the triphosphines $RP[(CH_2)_nPR_2]_2$ (R = Me, Ph; n=1, 2) other tri- and tetranuclear species can be obtained as, for example, (**453**)–(**455**).[1764,1765,2656–2660] These compounds show photoluminescence at room temperature.

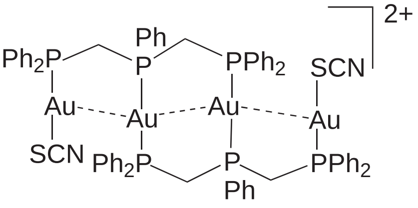
The dinuclear complex $[Au_2Cl_2\{(PPh_2CH_2)_2AsPh\}]$ is a convenient building block for the synthesis of polynuclear aggregates because it contains an uncoordinated arsenic atom, which should make it capable of coordinating another metal, such as palladium, rhodium, or iridium as, for example, (**456**).[2661,2662] The triphosphine $PhP(CH_2PPh_2)_2$ allows the formation of similar heteronuclear complexes with iridium, such as $[Au_3IrCl_3(CO)\{PhP(CH_2PPh_2)_2\}_2]PF_6$ (**457**) or



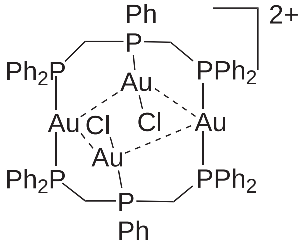
Scheme 37



(**453**)

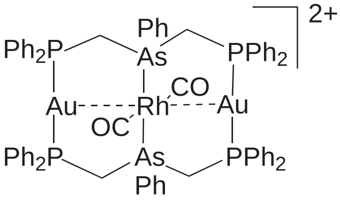


(**454**)

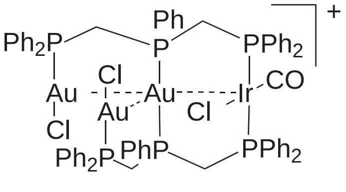


(**455**)

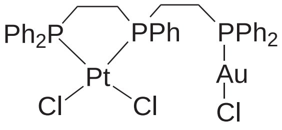
$[Au_2Ir(CN)_2\{PhP(CH_2PPh_2)_2\}_2]PF_6$.[2663] The metallomacrocycle $[IrCl_2\ (CO)_2\{PhP(CH_2PPh_2)_2\}_2]$ is a useful starting material for the preparation of trinuclear derivatives and then it reacts with $[AuCl_4]^-$ to give $[Ir_2AuCl_4(CO)_2\{PhP(CH_2PPh_2)_2\}_2]$;[2664] a similar compound is obtained by treatment with [AuCl(CO)] followed by Cl_2.[2665] Other adducts are obtained by reaction of $[Ir_2AuCl_2(CO)_2\{PhP(CH_2PPh_2)_2\}_2]$ with sulfur dioxide.[2666] Mixed palladium or platinum and gold derivatives as (**458**) have been synthesized starting form $[MCl\{PhP(CH_2CH_2PPh_2)_2\}]Cl$ by reaction with Au^I solutions.[2667] A dimeric gold(I) triphospholyl complex has been obtained by reaction of 1-trimethylstannyl-3,5-di(Bu^t)-1,2,4-triphosphol with $[AuCl(PPh_3)]$.[2668]



(**456**)



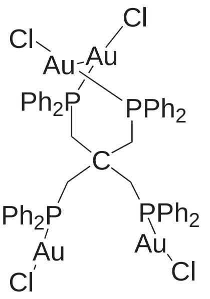
(**457**)



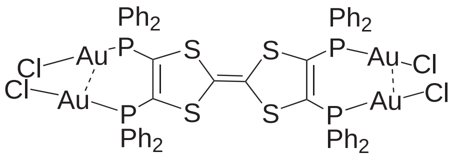
(**458**)

Tetrakis(diphenylphosphinomethyl)methane $C(CH_2PPh_2)_4$ reacts with four equivalents of $[AuCl(SMe_2)]$ to give the tetranuclear complex $[Au_4Cl_4\{(PPh_2CH_2)_4C\}]$ (**459**). The changes in structure and conformation as compared to that of the free ligand are due to intermolecular Au···Au interactions for one pair of gold atom centers.[2652] Another tetradentate ligand, L, derived from a calix[4]resorcinarene by incorporation of four phosphonite donors, leads to the bowl shape complex $[Au_4Cl_4L]$. The latter forms inclusion complexes with amines and alkali metal cations but not with other potential substrates.[2669,2670] Other tetranuclear gold(I) complexes with calixarene–phosphine ligands are those derived of *p*-Bu^t-calix[4]-$(OCH_2PPh_2)_4$ (L),[799] or related ligands.[2671] The stepwise formation of this complex by reaction of this ligand with [AuCl(THT)] under conditions that allow the mechanism to be resolved, has led to the isolation of a calixarene polymer $[Au_2Cl_2L]_n$.[2672] The ligands tetrakis(diphenylphosphine)tetrathiafulvalene,

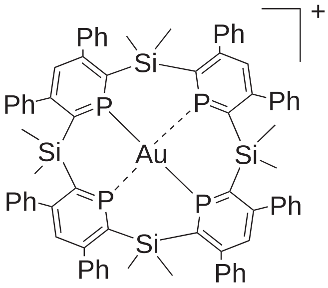
$(PPh_2)_2TTF$, and 1,4,8,11-tetrakis(diphenylphosphinomethyl)-1,4,8,11-tetraazacyclotetradecane (L) also form tetranuclear derivatives such as $[Au_4Cl_4\{(PPh_2)_4TTF\}]$ (**460**)[2673] or $[Au_4X_4L_4]$ (X = Cl, Br, I).[2674] The complexes with the tetraaza moiety are 2D polymers and show interesting multistate photoluminescence in the solid state. Other gold(I) complexes with potentially tetradentate ligands are those derived of a phosphinine macrocycle (**461**),[48] or those obtained by reaction of $(Bu^tP)_4$ with $AuBr_3$ which gives $[AuBr(PBu^t)_4]$ or $[Au_2Br_2(PBu^t)_4]$.[2675] Gold(I) complexes with dentritic polymers containing phosphorus donor ligands have been described,[2676,2677] those are of generation 2,[2678] with 16 and 32 ω-phosphine chain-ends of generations 2 and 3,[2461,2491] or the generation 10 characterized by high-resolution electron microscopy.[2679]



(**459**)

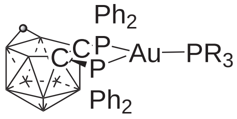


(**460**)

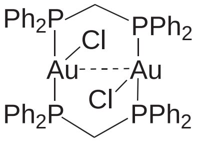


(**461**)

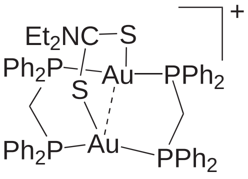
Three-coordinate neutral or cationic complexes of the type [AuX(P-P)] (X = Cl, C_6F_5) or $[AuL(P-P)]^+$ (L = THT, PR_3, $AsPh_3$, ylide, $SPPh_3$) with a bidentate chelate phosphine ligand have been obtained for $Fe(C_5H_4PPh_2)_2$,[2577,2680,2681] $Fe(C_5Me_4PPh_2)_2$,[2682] $C_2B_{10}H_{10}(PPh_2)_2$,[2580] and *Z*,*Z*-$PPh_2CH_2C(Bu^t){=}NN{=}C(Bu^t)CH_2PPh_2$.[758] Three-coordinate neutral complexes of the type $[Au(P\text{-}P)PR_3]$ (**462**) have been obtained with the anionic *nido*-diphosphine ligand $[7,8\text{-}(PPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}]^-$.[2683] In the dinuclear complexes considered above, $[Au_2X_2(\mu\text{-P-P})]$, the metal atoms can be three coordinate by bonding of the anion X. The coordination of the ligand X is nearly perpendicular to the P—Au—P-axis, which is approximately linear (P—Au—P angles, 156–170°) and leads to a T-shape coordination array at the gold atoms, which have short Au···Au contacts. Some examples are $[Au_2Cl_2(\mu\text{-dppm})]$ (**463**)[2602] and $[Au_2(S_2CNEt_2)(\mu\text{-dppm})](BH_3CN)$ (**464**).[2603] The dinuclear platinum complex $[Pt_2(\mu\text{-S})(\mu\text{-dppm})(\eta^1\text{-dppm})_2]$ can act as a tridentate ligand. It reacts with $[AuCl(SMe_2)]$ to give a trinuclear complex with a three-coordinate gold atom (**465**).[2684]



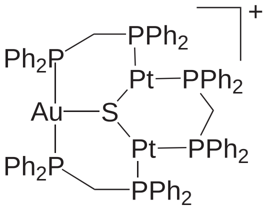
(**462**)



(**463**)

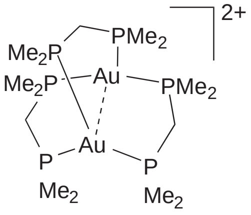


(**464**)

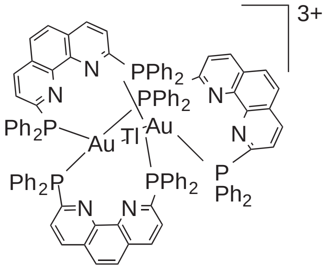


(**465**)

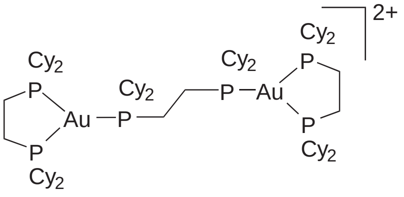
With diphosphine ligands only several three-coordinate gold(I) complexes have been achieved. The reaction of $[AuCl(PPr^i_3)]$ with $Me_2PCH_2PMe_2$ leads to the dinuclear derivative $[Au_2\{\mu\text{-}(PMe_2)_2CH_2\}_3]Cl_2$ (**466**), which is readily converted in the tetrafluoroborate salt; the compound has a short gold–gold interaction.[2685,2686] The resonance Raman and electronic luminescence spectra of $[Au_2\{\mu\text{-}(PMe_2)_2CH_2\}_3](ClO_4)_2$ have been studied, which present an intense band at 256 nm and a weaker at 300 nm. The first is assigned to a $^1(d\sigma^*{\to}p\sigma)$ transition, with metal–metal character.[2687] The structure of $[Au_2(2,6\text{-}PPh_2PyPPh_2)_3](ClO_4)_2$ is similar but the intramolecular Au···Au distance is very large.[2688] The complex displays photoluminescence at 520 nm in fluid solutions at room temperature. The ligands 2,9-bis(diphenylphosphino)-1,8-naphthyridine or 2,9-bis(diphenylphosphino)-1,10-phananthroline form three-coordinate gold(I) metallocryptates which encapsulate Na^+, K^+, or Tl^+ ions as, for example, (**467**).[1384,1394,2689] Compounds of the type $[Au_2(\mu\text{-PP})(PP)_2]$ have been described for $Cy_2P(CH_2)_2PCy_2$ (**468**),[2690,2691] dppf,[2577] or for mixed diphosphines as in $[Au_2(\mu\text{-PP})\{(PPh_2)_2C_2B_9H_{10}\}_2]$ (dppe, dppp).[2683] When the diphosphine is *trans*-$Ph_2PCH{=}CHPPh_2$ the reaction of $[Au_2Cl_2(\mu\text{-PP})]$ with $AgCF_3CO_2$ in the presence of the diphosphine gives a 1D “chain-link fence” polymer of stoichiometry $[Au_2(PP)_3]^{2+}$.[2692] In a similar reaction but with the ligand $Ph_2P(CH_2)_4PPh_2$ crystallizes, as the dicyanoaurate(I) salt, the compound that contains fused $[Au_6(\mu\text{-}PP)_6]$ rings (**469**).[2692]



(466)



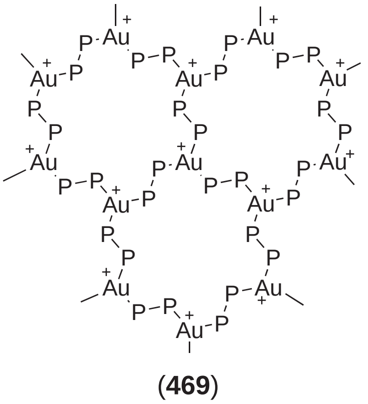
(467)



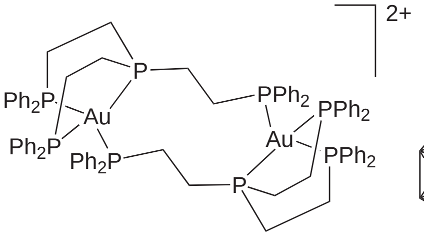
(468)

Reactions of the tripod ligand tris(diphenylphosphinoethyl)amine (NP_3) with [AuXL] also produces three-coordinate complexes as the dinuclear $[Au_2(NP_3)_2](BPh_4)_2$ or the mononuclear $[Au(NP_3)]PF_6$. These complexes exhibit a brilliant greenish yellow luminescence under hand-held UV lamp.[2693] Luminescence from a three-coordinate gold(I) center is a general phenomenon where the origin of the emission has been assigned to a metal-centered transition $p_z \rightarrow (d_{x^2-y^2}, d_{xy})$.[2539]

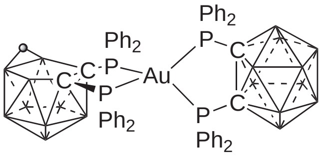
Four-coordinate homoleptic species of the type $[Au(L\text{-}L)_2]^+$ where L-L can be a diphosphine or diarsine have been obtained for L-L = $Ph_2P(CH_2)_2PPh_2$,[739,2585,2694–2697] $Et_2P(CH_2)_2PEt_2$,[2585] $Et_2P(CH_2)_2PPh_2$,[2585] *cis*-$Ph_2PCH{=}CHPPh_2$ (dppey),[2585] $Ph_2P(CH_2)_3PPh_2$,[2585] $MePhEC_6H_4PPhMe$ (E = P, As),[2698] $Me_2AsC_6H_4AsMe_2$,[2544] dppf,[2577] $(PPh_2)_2C_2B_{10}H_{10}$,[2580] dppn,[2699] bis((diphenylphosphino)methyl)phenylarsine,[2700] tris(2-(diphenylphosphino)ethyl)phosphine (**470**),[2701] or 1,2-bis(di-*n*-pyridylphosphino)ethane (dpnpy, *n* = 2, 3, 4).[2586] Salts of $[Au(dppe)_2]^+$, $[Au(dppey)_2]^+$ or $[Au(dpnpy)_2]^+$ have been reported to have a good cytotoxic and a broad spectrum of antitumor activity.[2586,2696,2697] In the trinuclear compound $[Au_3Cl_2\{(PPh_2CH_2)_3CMe\}]Cl$ the central gold atom is four coordinate.[2702] Mixed four coordinate gold(I) complexes with diphosphines have been prepared with the 1,2-bis(diphenylphosphino)-*o*-carborane ligand and are of the type $[Au\{(PPh_2)_2C_2B_{10}H_{10}\}(P\text{-}P)]ClO_4$ (P-P = dppe, $1,2\text{-}Ph_2PC_6H_4PPh_2$, dppey),[2703] or with one *nido*- and one *closo*-carborane diphosphine as $[Au\{[(PPh_2)_2C_2B_9H_{10}]\{(PPh_2)_2C_2B_{10}H_{10}\}]$ (**471**).[2704]



(469)

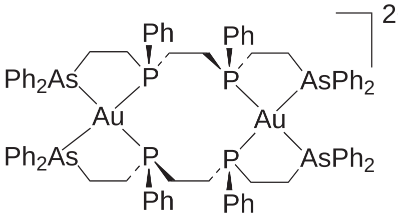


(470)

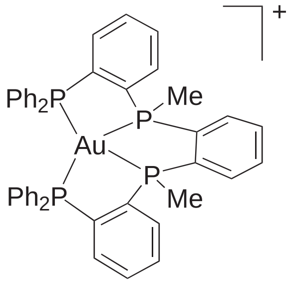


(471)

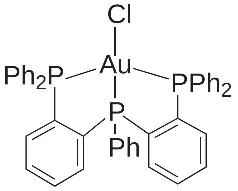
Stereoselective self-assembly of double-stranded dinuclear helicates of the type $[Au_2L_2](PF_6)_2$ can be achieved with the highly flexible tetradentate ligands (*S*,*S*)-$Ph_2E(CH_2)_2P(Ph)(CH_2)_2P(Ph)(CH_2)_2EPh_2$ (E = P, As). In these complexes, two molecules of the (*S*,*S*)-ligand bind stereospecifically to two metal ions (which are four coordinate) to give dinuclear metal helicates of M helicity, in which each metal center has the S-configuration (**472**).[2705,2706] With the chiral tetra (tertiary phosphine) (Rp*,Rp*)-1,2-bis[(2-dimethylphosphinophenyl)methylphosphino]benzene a mononuclear tetrahedral compound (**473**) has been isolated.[2707] Treatment of the rigid tridentate ligand bis[2-(diphenylphosphino)phenyl]phenylphosphine with $[AuCl(SMe_2)]$ yields the four-coordinate complex [AuClL] (**474**).[791]



(472)



(473)



(474)

6.7.3.4.5 *Complexes with oxygen donor ligands*

Although Au—O bonds are intrinsically weak, gold complexes with oxygen-based ligands are thought to be involved in the catalytic activity of gold dispersed on transition metal oxides in some relevant heterogeneous catalytic processes,[53,56,2708] as well as in the catalytic addition of alcohols to alkynes carried out by cationic gold(I) complexes in homogeneous phase.[2554]

Gold(I) complexes with oxygen donor ligands are usually of the general formula [AuXL], where L is commonly a tertiary phosphine and X is an anionic oxygen ligand. This type of complex is relevant not only as catalytically active species[2554] or catalytic precursors,[2254,2709–2711] but even in most auration reactions where the gold(I) oxo complexes $[O(AuPR_3)_3]^+$ are the most effective aurating reagents, and also for gold deposition processes both from solution and from vapor.[1774,2712]

Hydrolysis of gold(I) in aqueous acetonitrile solutions gives $Au(OH)_3$ and the gold(I) hydroxo complex [Au(OH)(MeCN)], which has not been isolated in the solid state.[2713] The complex $[Au_2(\mu\text{-}OH)(PMes_3)_2]BF_4$ has been isolated from the reaction of $[AuCl(PMes_3)]$ with $AgBF_4$ and NaOH.[2714]

The oxonium cation $[O(AuPPh_3)_3]^+$ was first synthesized by Nesmeyanov *et al.* by reaction of $[AuX(PPh_3)]$ with Ag_2O and a suitable salt in acetone solution or by reaction of $AuPPh_3{}^+$ (generated *in situ* from $[AuX(PPh_3)]$ and Ag^+) with water in basic media.[2715] Since then it has been widely used as an aurating agent in the synthesis of organometallic complexes or highly aurated species. A great amount of complexes $[O(AuPR_3)_3]^+$ with a variety of phosphine or arsine ligands L have been prepared in a similar manner[2151,2394,2402,2403,2715–2722] (e.g., $PR_3 = PPh_3$, $PMePh_2$, PMe_2Ph, PCy_3, $PMes_3$, $PEtPh_2$, PPr^iPh_2, $P(p\text{-}ClPh)_3$, $P(o\text{-}Tol)_3$, $P(C_6H_4OMe\text{-}4)_3$, $P(OEt)Ph_2$, $P(OMe)_3$, PEt_3, $PBu^t{}_3$, PMe_3, $PPr^i{}_3$, $P(NMe_2)_3$, $AsPh_3$). Trigold oxonium salts are also obtained by hydrolysis of some gold(I) complexes with nitrogen ligands.[2313,2381]

The solid-state structure of these complexes depends on the size of the phosphine ligand used. Thus, for more sterically demanding phosphines such as $P(o\text{-}Tol)_3$,[402] the structure consists of trigonal OAu_3 pyramid with the oxygen atom in the apical position (Figure 21a). For phosphine ligands such as PPh_3 or medium size, the structure is also based on trigonal-pyramidal $[O(AuPR_3)_3]^+$ cations, which undergo intermolecular aggregation to for centrosymmetric dimers (Figure 21b). The intermolecular interactions between the cations cause the gold atoms to form a rectangular Au_4 subunit, with the six gold atoms of the dimer forming a six-membered ring with a chair conformation. For the smallest tertiary phosphine PMe_3 the monomeric unit, which is also an OAu_3 pyramid, are aggregated through shared edges to give a tetrahedron Au_4 subunit (Figure 21c). The dimerization of the trigold oxonium cations have been studied theoretically showing that for the $OAu_3{}^+$ unit the tetrahedral dimerization was calculated to be slightly favorable while the addition of phosphine ligands leads to a preference for a rectangular dimer structure.[2723] The reaction of these trigold oxonium cations with [AuClL] compounds have been studied in solution and show rapid exchange processes leading to equilibrium mixtures.[2716]

The hyperaurated oxygen-centered complexes $[O(AuPR_3)_4]^{2+}$ (**475**) have been synthesized in high yield by reaction of the trigold oxonium salt with $[Au(BF_4)(PR_3)]$ ($R = Ph$, *o*-Tol). The complex with $R = o$-Tol has been characterized structurally and the central oxygen atom has an imposed, by crystal symmetry, tetrahedral geometry coordinated by four gold atoms. The gold—gold distances are 3.359,0(4) Å, that although longer than those found in related complexes indicate significant bonding interaction contributing to the overall stability of the complex.[2724]

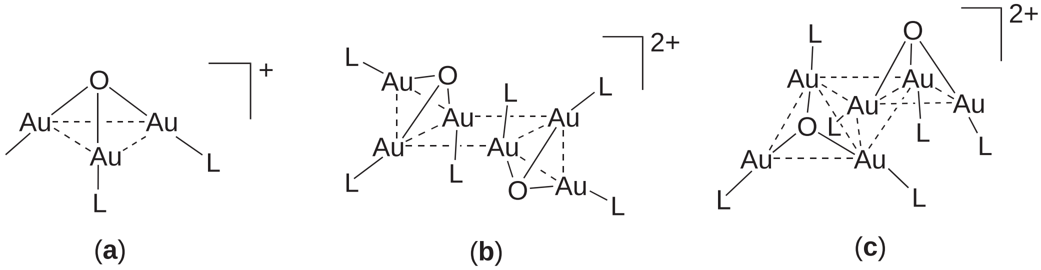


Figure 21 Different structures of $[O(AuL)_3]^+$ cations.

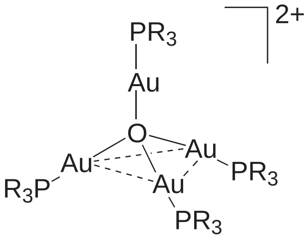
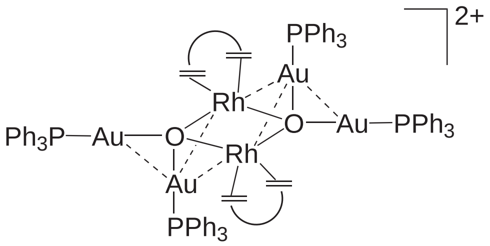
Heteronuclear μ-oxo complexes have been prepared by oxo/halide exchange reactions, then the reaction of metal halide complexes with the gold oxonium species gives complexes of the type $[Rh_2(dien)_2\{O(AuPPh_3)_2\}(BF_4)_2$ (**476**) (dien = COD, NBD) or $[Pt(COD)_2\{OAu(PR_3)\}_2]$.[2725,2726]



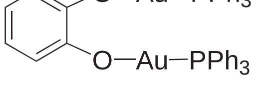
(475)



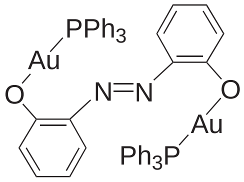
(476)

The decomposition, either thermal or under N_2, of $[O(AuPR_3)_3]OTf$ (R = Ph, Me) in organic solvents has been studied; the phosphine acts as an efficient oxygen trap and gold nanoparticles are produced.[2727]

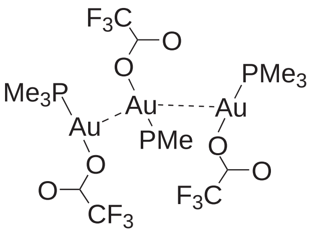
Mono- or dinuclear gold(I) aryloxy complexes have been obtained by reaction of $[O(AuPR_3)_3]^+$ with the aryl group or with the potassium salt. Several derivatives with substituted phenols, 8-hydroxiquinoline, pyrochatecol, or 2,2′-dihydroxyazobencene, such as (**477**) or (**478**) have been reported.[2728–2735] Alkoxy gold(I) derivatives such as $[Au(OR)(PR_3)]$ (R = Bu^t, $CH(CF_3)_2$, CH_2CF_3) have been prepared by metathesis of the chloride species.[1787,2736] These alkoxydes can abstract protons from various organic compounds or metal-hydrides to give the corresponding organogold compounds or species having M—Au bonds and free alcohol.[2138, 2736] Other interesting reactions carried out with the alkoxo or ariyloxo species are the selective ring opening of thiiranes to give 2-(alkoxy- or aryloxy)ethylsulfanylgold(I) complexes or the C—Si bond cleavage of trihalomethyltrimethylsilane to give $[Au(CF_3)(PR_3)]$ complexes.[2737,2738] Siloxane gold(I) compounds of the type $[Au(OTMS)(PR_3)]$ ($PR_3 = PPh_2Me$, PMe_3) have been reported and the structure consists of dimers with short Au···Au contacts for PMe_3 and monomers for PPh_2Me.[2739,2740]



(477)

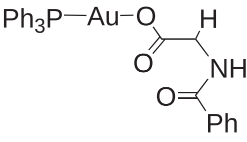


(478)

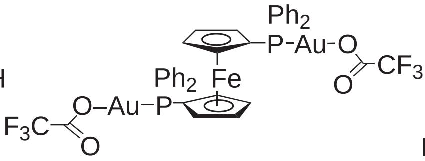


(479)

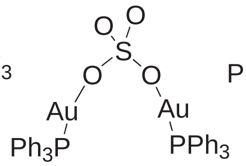
Carboxylate gold(I) complexes are also not very numerous in spite of some of them showing significant antitumor activity.[2741,2742] The majority of compounds reported have the stoichiometry $[Au(O_2CR)(PR_3)]$ and are know for acetate,[2743,2744] benzoate,[2745] lactate,[2746] isobutyrate,[2746] pivalate,[2747] dichloroacetate,[2748] *o*-carboxybenzoyl-ferrocene,[2749] or for the fluorocarboxylates trifluoroacetate,[2750–2752] pentafluoropropionate,[2747] $O_2CC_6F_{13}$, $O_2CC_7F_{15}$, $O_2CC_8F_{17}$, $O_2CC_9F_{19}$, $O_2CC_6F_5$, or $O_2CC_3F_6$.[2753] The structure of $[Au(O_2CCF_3)(PMe_3)]$ (**479**) features trimers with two short aurophilic interactions. Decarboxylation of some of these complexes at temperatures under 100 °C produces carbon dioxide, metallic gold, phosphine, and organic products.[2746] Gold(I) complexes with the amino acid derivatives *N*-acetylglycinato,[2754] *N*-benzoylglycinato (**480**),[2754] or *N*-benzoyl-L-alaninato,[2755] have been described. Dinuclear carboxylate compounds have been obtained and are of the type $[Au_2(O_2CR)_2(\mu\text{-P-P})]$ (R = Me, CF_3, Et, Ph; P-P = dppf, dppm); the structure of $[Au_2(O_2CCF_3)_2(\mu\text{-dppf})]$ (**481**) shows the carboxylate to act as monodentate.[2756]



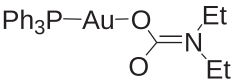
(480)



(481)



(482)



(483)

Gold(I) complexes with oxoanions such as sulfate (**482**),[2757] nitrate,[2254,2709,2744,2758–2760] trifluoromethanesulfonate,[2751] or organosulfonates,[2761] have been obtained. Other gold(I) complexes with oxygen donor ligands are those derived of carbamate, $[Au(O_2CNEt_2)(PPh_3)]$ (**483**),[911] acyl species, $[Re_2(\mu\text{-}PPh_2)_2\ (CO)_7Au\{(OCR)(PPh_3)\}]$ (R = Me, Bu^n, Bu^t, Ph),[2762] or nitrosodicyanomethanido.[2347] The chemistry of oxoaurates(I) has been recently reviewed.[2763]

6.7.3.4.6 Complexes with sulfur, selenium, and tellurium donor ligands

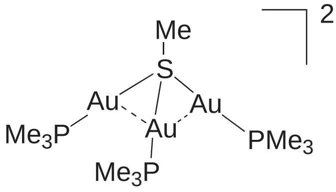
(i) Thiolates, selenolates, and tellurolate gold(I) complexes

Gold thiolates are an extremely important class of gold compounds that have found several applications. In medicine, they are well know for their antiarthritic, antitumoral, and antimicrobial activities.[101–105,2764] The commercial myocrisin, allochrysine, solganol, or auranofin are among the most important antiarthritic compounds. In addition, solganol has *in vitro* inhibitory effects on human immunodeficiency virus (HIV) I,[2765] and auranofin has been found to be highly cytotoxic to tumor cells and active against i.p. P388 leukemia.[2766,2767] Gold(I) thiolates are contained in most "liquid golds" for the glass and ceramic industry,[2768–2770] and also are important in the fields of nanoparticles, nanostructured films, modem electronics, and optoelectronics.[2712,2771–2778]

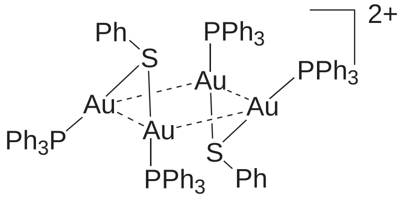
Gold(I) thiolate complexes have different stoichiometries, the neutral $[Au(SR)(PR_3)]$ complexes are very numerous and have been synthesized for a great variety of thiolate and tertiary phosphine ligands. The phosphine is usually PPh_3 (otherwise state) and the substituent R in the thiolate moiety can be Me (PMe_3),[2779] Ph ($PR^1_3 = PPh_3$, TPA),[2780–2784] 2,4,6-$C_6H_2R^2_3$ (R^2 = Me, Et, Pr^i),[2653] $C_6H_4NMe_2$-4,[2785] $C_6H_4NMe_3{}^+$,[2785] C_6H_4OMe-2 ($PR^1_3 = PPh_3$, TPA),[2784,2786] $C_6H_4NO_2$-4,[2787] C_6H_4Cl-2,[2657] C_6Cl_5,[2788] C_6H_4Cl-3,[2784] 3,5-$C_6H_3Cl_2$ (TPA),[2784] 2,3,4,6- tetra-*O*-acetyl-β-D-glucopyranoside ($PR^1_3 = PEt_3$, tris(1-ethyl-2-isopropylimidazol-5-yl)phosphine),[2789,2790] $C_6H_4CO_2H$-2 ($PR^1_3 = PPh_3$, PCy_3)[993,2791–2793] $C_6H_4CO_2H$-3 ($PR^1_3 = PPh_3$, PCy_3),[2794] $C_6H_4CO_2H$-4 ($PR^1_3 = PPh_3$, PEt_3, PPh_2Py),[2795] 2-Py-3-CO_2H,[994] 1-methylimidazole (PCy_3),[2365] purine-6-thiolate ($PR_3 = PPh_3$, P(*o*-Tol)$_3$),[2796,2797] Py (PPh_3, PPh_2Py, methyl-4,6-*O*-benzylidene-3-deoxy-3-diphenylphosphino-α-D-altropyranoside),[2507,2798,2799] pyrimidine-2-thiolate (methyl-4,6-*O*-benzylidene-3-deoxy-3-diphenylphosphino-α-D-altropyranoside),[2799,2800] $Si(OR^2)_3$ (R^2 = Pr^i, Bu^s, Bu^t),[2674] 6-R^2-thiouracilato (R^2 = Pr^n, Me; $PR_3 = PCy_3$, PEt_3),[2797,2802,2803] C_6F_5,[2804] 2-benzoxazolethiolate,[2805] quinoline-8-thiolate,[2787,2806] 2-thiouracilo,[739,2807] 8-thiotheophyllinato,[2808] 1-R^2-1,2,3,4-tetrazole-5-thiolate (R^2 = Me, Ph),[1819] $C_6H_4SnBu^t{}_2Cl$-2,[2809] $CR^2{}_2CO_2R^2$ (R^2 = H, Me),[2810] $SiPh_3$,[2740] 2-thiothiazoline,[2811] 2,5-dihydro-2,2,5,5-tetrakis(trifluoromethyl)-4-thiazolylthio,[2812] 3-(ethoxycarbonylsulfanyl)-5,6-dihydro-1,4-dithiine-2-thiolate,[2813] 4-(methylthio)-2-thioxo-1,3-dithiole-5-thiolate,[995] 5-amino-1,3,5-thiadiazole-2-thiolate ($PR^1_3 = PPh_3$, PMe_3),[2814] $C(OR^2){=}NPh$ (R^2 = Me, Et; $PR_3 = PPh_3$, PCy_3),[2815] $FcCH{=}N(CH_2)_2$,[2816] 4-oxo-2-thiopyrimidines (PPh_3, PPh_2Me, $AsPh_3$),[2817] 1-thiolate-1,2-dicarba-*closo*-dodecaborane (PPh_3, PPh_2Me, $AsPh_3$),[2818] pyridine-1-oxide-2-thiolate,[2818] 4-amino-2-pyrimidine-thiolate,[2820] or $C_5Cl_4Mn(CO)_3$.[2821] Thiolate complexes with isocyanide ligands of the type $[Au(SC_6H_4CO_2H)(CNR^1)]$, $[Au(SPy)(CNR^1)]$, $[Au(SQuin)(CNR^1)]$

(Quin = quinoline; $R^1 = Bu^t$, Mes), or $[Au(SPh)\{CN(CH_2)_nEt\}]$ ($n = 3$, 4) have also been synthesized.[2822–2824] Many of these complexes are known to aggregate via intermolecular aurophilic contacts or intermolecular gold–sulfur coordination (Au···S) depending on the electronic or steric nature of the substituents; with other substituents such as $C_6H_4CO_2H$ hydrogen bonding is also possible. These interactions lead to interesting supramolecular structures often associated with intriguing photophysical properties. In Figure 22 are collected several thiolate gold(I) complexes with different secondary interactions.

Further aggregation of gold atoms around the thiolate group is possible and then many complexes of stoichiometry $[RS(AuPR_3)_2]^+$ or the four-coordinated $[MeS(AuPMe_3)_3]^{2+}$ (**484**) have been obtained. The structure of the dinuclear complex also depends on the substituent of the thiolate group and could be monomers or dimers through Au···Au interaction. They have been prepared for thiolate groups such as SMe,[2779] SPh (**485**),[2782,2825,2826] SPh (PPh_2OH),[2589] S(*p*-Tol),[2827] $SC_6H_4CO_2H$-4,[2795] $SC_6H_4CO_2H$-2,[2828] SCH_2Ph,[1813,2828] 4-amino-2-pyrimidinethiolate,[2820] quinoline-8-thiolato,[2806] $SC_6H_4NH_2$-2,[2829] $S(CH_2)_2OH$,[2830] $SC_2B_{10}H_{10}Me$,[2818] or SBu^t.[2831] In the complex $[HOCH_2CH(OH)CH_2S\{Au_2(PPh_3)_3\}]BF_4$ there are a linear gold(I) atom and a three-coordinated one.[2832]



(484)



(485)

Gold(I) diphosphine ligands of the type $[Au_2X_2(\mu\text{-P-P})]$ react with thiols to give dinuclear complexes such as $[Au_2(Sp\text{-Tol})_2(\mu\text{-P-P})]$ (P-P = dppe, dppp, dppb, $Ph_2P(CH_2)_5PPh_2$, dppf),[2596,2833,2834] $[Au_2(SMe_2)\{\mu\text{-}(PPh_2CH_2)_2C_6H_4\}]$,[2584] $[Au_2(SPh)(\mu\text{-P-P})]$ (P-P = $(PPh_2O)_2C_6H_4$ dppf, $Ph_2PCH{=}CHPPh_2$),[2589,2834,2835] $[Au_2(SC_2B_{10}H_{10}Me)_2(\mu\text{-dppe})]$,[2818] $[Au_2(SC_6F_5)_2(\mu\text{-dppf})]$,[1815] $[Au_2(2\text{-Spym-4-NH}_2)_2(\mu\text{-P-P})]$ (P-P = dppf, dppm (**486**)),[2820] $[Au_2(SR)_2(\mu\text{-P-P})]$ (SR = 2-amino-5-thiolate-1,3,4-thiadiazolate; P-P = dppm, dppe, $Ph_2PCH{=}CHPPh_2$),[2814] $[Au_2(S\text{-benzo[15]crown-5})_2\{\mu\text{-}(PR_2)_2CH_2\}]$ (R = Ph (**487**), Cy),[2836] $[Au_2(SQuin)_2(\mu\text{-P-P})]$ (P-P = dppp, dppb),[2837] $[Au_2(SC_6H_4CO_2H\text{-4})_2(\mu\text{-P-P})]$ (P-P = dppb, dppf),[2795] $[Au_2(SC_6H_4\text{-}CO_2H\text{-2})_2(\mu\text{-dppe})]$,[2838] or $[Au_2(SC_6H_4F\text{-4})_2\{\mu\text{-}(PPh_2)_2NPh\}]$.[2839] A tetranuclear derivative $[Au_4(\mu\text{-S-}p\text{-Tol})_2(\mu\text{-dppe})_2]$ has also been obtained.[2827] The complex $[Au_2(SC_6F_5)_2(\mu\text{-ddpf})]$ can react further with $[Au(OTf)(PPh_3)]$ to give the four-coordinate sulfur species $[Au_4(SC_6F_5)_2(\mu\text{-ddpf})(PPh_3)_2](OTf)_2$ (**488**).[1815] In the complexes $[Au_2(S\text{-benzo[15]crown-5})_2\{\mu\text{-}(PR_2)_2CH_2\}]$ the gold–gold separation is large, but the addition of K^+ ions produces a sandwich complex with the crownether, and then force the formation of a Au···Au interaction. This formation is clearly detected by the electronic spectra where a change in the luminescence properties is observed.

Other types of complexes are those in which the thiolate ligand bridges the gold atoms as in $[Au_2(\mu\text{-SMe})\{\mu\text{-}(PPh_2CH_2)_2C_6H_4\}]^+$ (**489**),[2584] or $[Au_2(\mu\text{-SC}_6F_5)(\mu\text{-dppf})]$, the latter crystallizes as dimers through aurophilic interactions.[1815] Tri- and tetraphosphine gold(I) complexes also react

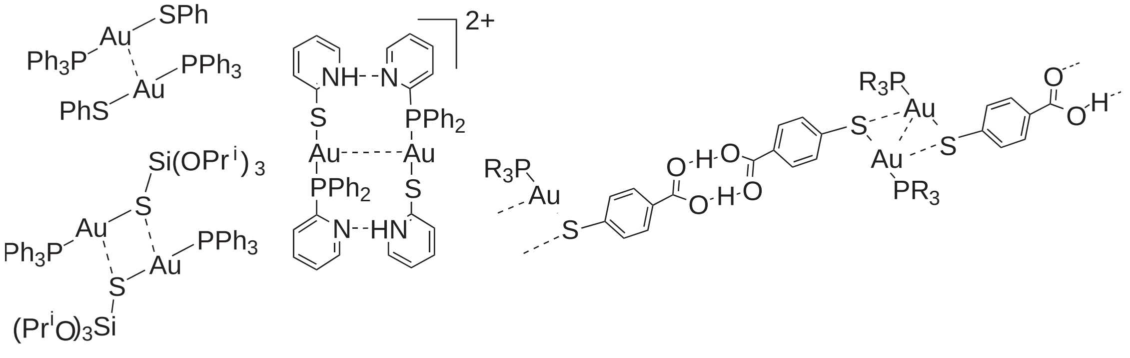


Figure 22 Some thiolate gold(I) complexes with several secondary interactions.

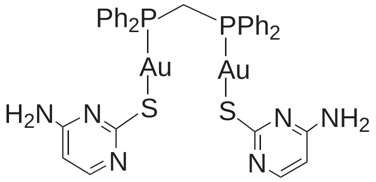
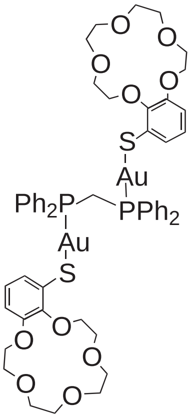
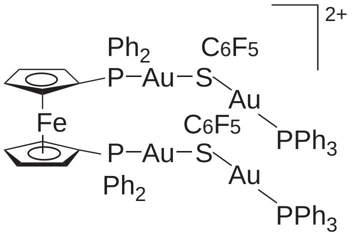
with thiols to give trinuclear $[Au_3(SR)_3P_3]$ (SR = STol, SQuin) or $[Au_3(\mu\text{-SMe})_2P_3]^+$ (**490**) (P_3 = 1,3,5-tris[(diphenylphosphanyl)methyl]trimethylbenzene, $Ph_2P(CH_2)_2PPh(CH_2)_2PPh_2$),[1765,2840] or tetranuclear $[Au_4(SQuin)_4P_4]$ (**491**) (P_4 = tris(2-diphenylphosphinoethyl)phosphine).[2837]



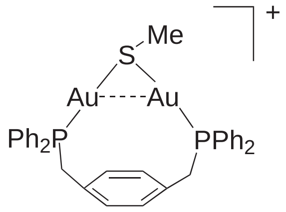
(**486**)



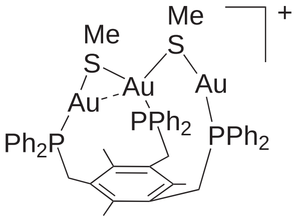
(**487**)



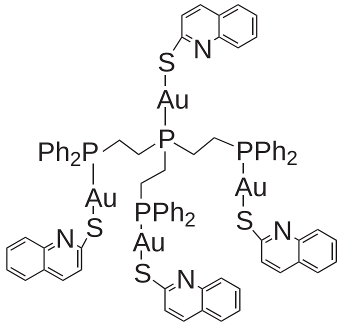
(**488**)



(**489**)

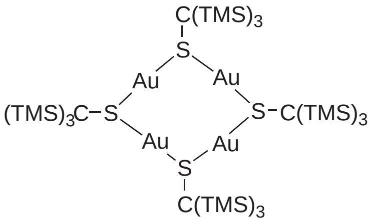


(**490**)

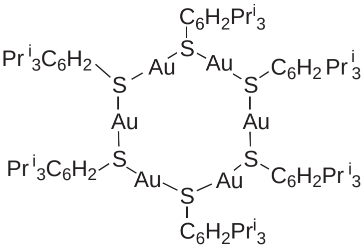


(**491**)

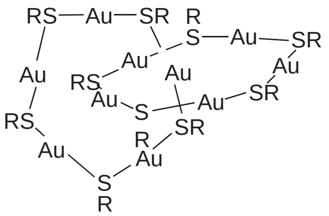
Polymeric thiolate compounds $[Au(SR)_n]$ are usually insoluble and only a limited number have been characterized as the cyclic rings $[Au_4\{SC(TMS)_3\}_4]$ (**492**),[2841] $[Au_4\{SSi(OBu^t)_3\}_4]$,[2842] $[Au_6\{S(2,4,6\text{-}C_6H_2Pr^i_3)\}_6]$ (**493**),[2843,2844] or the catenane $[Au_{10}(SC_6H_4\text{-}p\text{-}CMe_3)_{10}]$ (**494**).[2845]



(**492**)

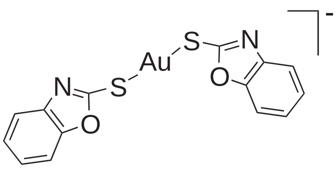


(**493**)

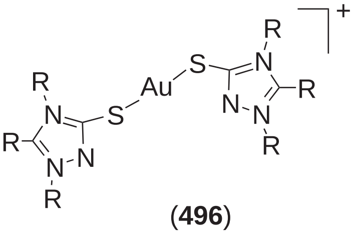


(**494**)

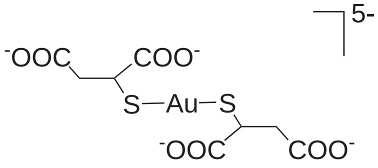
Anionic homoleptic thiolate compounds of the type $[Au(SR)_2]^-$ have been obtained with SR = benzoxazole-2-thiolate (**495**),[2846] pyrimidine-2-thiolate,[2846] 2,3,4,6-tetra-*O*-acetyl-1-thiolate-β-D-glucopyranosate,[2846] 2-thiouracilate,[2846] 2,3-dihydro-benzimidole-2-thiolate,[2846] $SCH(CO_2H)CH_2CO_2H$,[2846] SCH_2CH_2OH,[2846] $SCMe_2CH(CO_2^-)NH_3^+$,[2846,2847] SC_6H_4R (R = H, *o*-Me, *o*-OMe, *o*-Cl, *m*-Me, *m*-OMe, *m*-Cl, *p*-Me, *p*-OMe, *p*-Cl),[2848] $SC_6H_4CO_2H$-2,[2849] $SC_6H_4CO_2H$-4,[2795] 2-dimethylaminothiosquarato,[985,986] $SC_2B_{10}H_{10}Me$,[2818] triazolium-thiolates (**496**),[2850] $SC_6H_4(SnClBu^t_3\text{-}2)$,[2809] SPh,[2851] SCN_4Ph,[1819] $S(2,4,6\text{-}C_6H_2Pr^i_3)$,[2842] or S(adamantyl).[973] The compound $[Au(SPyCO_2H\text{-}6)(SPyHCO_2H\text{-}6)]$ shows antimicrobial activity against bacteria, moulds, and yeasts.[1424] The ammonium salts of the 2:1 thiomalate–gold (**497**) complexes have been described and the structure of both racemic and optically pure samples have been described.[2852] The structure of the antiarthritic drug gold thiomalate (myochrysine) has been solved and crystallized as a mixed sodium/cesium salt $Na_2Cs[Au_2L(LH)]$. It is a polymer in the solid state that consists of two interpenetrating spirals, with approximate four-fold symmetry.[2853] The only gold(I) compounds which contains the SH^- ligand are the complex $[(PPh_3)_2N][Au(SH)_2]$ which has been obtained by reaction of $[(PPh_3)_2N][Au(ACAC)_2]$ with a CH_2Cl_2 solution saturated with H_2S,[2854] and the species $[AuR(SH)]^-$ ($R = C_6F_5$, $C_6H_4NO_2$-2, 2,4,6-$C_6H_2(NO_2)_3$).[2855] Other anionic thiolate gold(I) complexes of the form $[AuX(SR)]^-$,[2818,2848,2850] or $[Bu^tS(AuCl)_3]^-$,[1823] have also been reported. The complexes $Bu_4N[Au(SC_6H_4R)_2]$ show luminescence in the solid state, the emission maxima ranges from 438 nm (blue emission) to 529 nm (green emission).[2848]



(495)

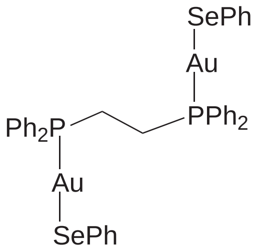


(496)

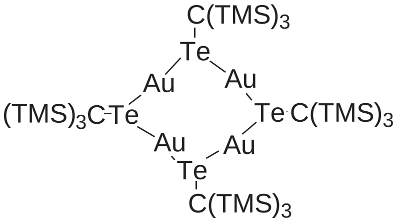


(497)

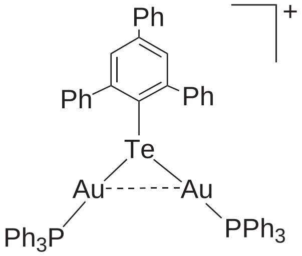
Gold(I) complexes with selenolates and tellurolates are far less numerous, with selenium compounds of the type $[Au(SeR)(PPh_3)]$ (R = Ph, naphthyl),[2856,2857] $[RSe(AuPR_3)_2]^+$ (R = Ph, C_6F_4Cl, CH_2Ph, naphthyl, $C_6H_4NH_2$-4, C_6H_4Cl-4; $PR_3 = PPh_3$, PPh_2Me, $PPhMe_2$),[2856–2859] or $[Au_2(SePh)_2(\mu\text{-P-P})]$ (P-P = dppm, dppe (**498**)),[2857] or the heterodinuclear $[WCp(CO)_3Se(CH_2TMS)AuPPh_3]SbF_6$,[2860] have been reported. For tellurium only the compounds $[Au_4\{TeC(TMS)\}_4]$ (**499**), $[Au\{TeC(TMS)_3\}(PPh_3)]$, and $[(2,4,6\text{-}Ph_3C_6H_2Te)(AuPPh_3)_2]^+$ (**500**) have been synthesized and characterized structurally.[2841,2861] All the compounds have similar structures to those found with the thiolate ligands.



(498)



(499)



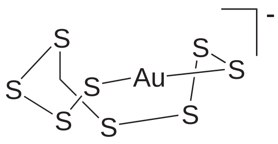
(500)

Several bioinorganic studies on thiolate gold(I) complexes have been carried out, as, for example, the study of reactions of gold(0) with amino acids,[2862] interaction of antiarthritic thiolates with albumin,[2863,2864] determination of gold levels in rats after topical application,[2865] competition of thiols and cyanide for gold(I),[2295] reactions of auranofin in aqueous hydrochloric acid, exchange reactions with $SeCN^-$ or tu,[2866–2868] or Mössbauer spectra of antiarthritic gold drugs.[2869]

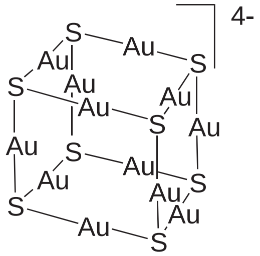
(ii) Sulfide, selenide, telluride, and polychalcogenide gold(I) complexes

In aqueous solutions of polysulfides, gold salts form thio- or polysulfidoaurates(I); the thioaurates $[AuS]^-$, $[AuS_2]^{3-}$, and the trisulfidoaurate(I) $[AuS_3]^-$ were reported many years ago.[2870] The cyclic polysulfide $Ph_4As[AuS_9]$ (**501**) has been prepared by reaction of $K[Au(CN)_2]$ and tetraphenylarsonium polysulfide.[2871] Depending on the sulfur content of the polysulfide solution, salts of the cyclic anion $[Au_2S_8]^{2-}$ are also obtained.[2872] The cubane-like thioaurate $(Ph_4As)_4[Au_{12}S_8]$ (**502**) can be prepared by treatment of the gold sulfides Au_2S, Au_2S_3, and $[AuCl_4]^-$ in aqueous solutions of Na_2S, followed of addition of Ph_4AsCl.[2873] The mixed $(Me_4N)_2[Au_2(S_2Te{=}S)_2]$ has also been described.[1041] The reaction of AuCN with Na_2Se_5 gives the compound $[Au_2Se_2(Se_4)_2]^{2-}$, where oxidation to gold(III) has been produced,[2874] but with other polyselenides as Na_2Se_3 or K_2Se_4 the gold(I) compounds $[Au_2(Se)_2(Se)_3]^{2-}$ or

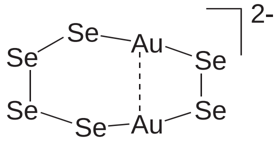
$[Au_2(Se)_2(Se)_4]^{2-}$ (**503**) are obtained.[2875] The reaction of AuCN with Na_2Se gives a cubane similar to that of sulfur $Na(Et_4N)_3[Au_{12}Se_8]$ but with the sodium atom in the center of the cube.[2876]



(501)

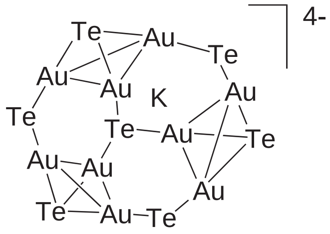


(502)

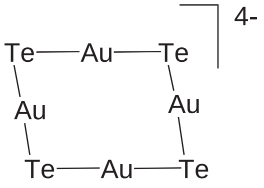


(503)

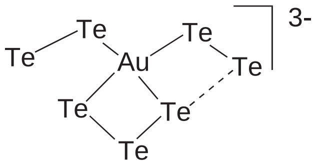
Gold–tellurium polyanions have been prepared from the extraction of ternary K—Au—Te alloys. By heating a 5% excess of K with $AuTe_2$ a material of the composition K_3AuTe_2 is obtained. The treatment with Ph_4PBr in methanol y dimethylformamide gives the compounds $(Ph_4P)_4[KAu_9Te_7]$ (**504**) or $(Ph_4P)_2[K_2Au_4Te_4(DMF)_2(MeOH)_2]$. Dissolving the alloy KAuTe in ethylenediamine the compound $(Ph_4P)_2[K_2Au_4Te_4(en)_4]$ (**505**) is obtained.[2877] By several extractions with ethylenediamine of ternary and quaternary alloys the compound $[(Ph_3P)_2N][Au_2Te_4]$ has been isolated.[2778] Another approach to gold(I) polytellurides is the reaction of AuCN with Te_n^{2-} which gives $[AuTe_7]^{3-}$ (**506**) anions.[2879,2880] The compound $[Au_3Te_4]^{3-}$ has been obtained by electrochemical synthesis.[2881]



(504)



(505)

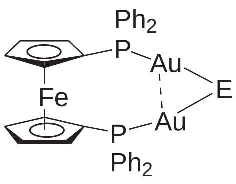


(506)

Polychalcogenides of the type $K_2Au_2SnS_4$,[2882] $K_2Au_2Sn_2S_6$,[2882] $(Et_4N)_2[Au(Ag_{1-x}Au_x)_2Sn_2Te_9]$,[2883] $(Bu_4N)_3[AuSn_2Te_6]$,[2884] $K_2Au_2Ge_2S_6$,[2885] $K_2Au_2Sn_2Se_6$,[2885] $Cs_2Au_2SnS_4$,[2885] $A_3AuP_2Se_8$ (A = K, Rb, Cs),[2886] $A_2Au_2P_2Se_6$ (A = K, Rb),[2886] A_2AuPSe_4 (A = K, Rb, Cs),[2886] $AAuP_2Se_7$ (A = K, Rb),[2886] A_2AuES_4 (A = K, Tl; E = P, As),[2887] KAu_5P_2-S_8,[2887] $A_2Au_2Cd_2S_4$ (A = Rb, Cs), or $K_2Au_4CdS_4$[2888] have also been obtained.

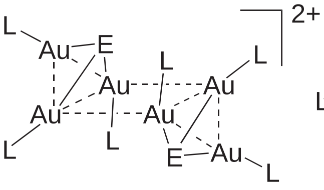
Complexes with bridging sulfido ligands, such as $[S(AuPEt_3)_2]$ or $[S(AuPPh_3)_3]Cl$ were synthesized a long time ago by reaction of $[AuBr(PEt_3)]$ with Na_2S or by treatment of $[AuCl(PPh_3)]$ with H_2S in ethanolic pyridine, respectively. $[S(AuPPh_3)_2]$ was claimed to be unstable or an intermediate in the synthesis of $[S(AuPPh_3)_3]Cl$.[2889,2890] A high yield synthesis for $[S(AuPPh_3)_2]$ has been developed recently and involves the reaction of $[AuCl(PPh_3)]$ with Li_2S in ethanol.[2891] The corresponding selenide derivative $[Se(AuPPh_3)_2]$ is obtained in a two-step reaction from $[AuCl(PPh_3)]$ and selenourea followed by treatment with aqueous Na_2CO_3.[2892] These complexes are excellent starting materials for the synthesis of highly aurated homoleptic sulfur- or selenium-centered derivatives. Similar μ_2-bridging sulfido or selenido gold species have been obtained with diphosphines such as dppf (**507**),[2893,2894] 1,4-bis[(diphenylphosphino)methyl]benzene (S),[2584] or 2,5-bis[(diphenylphosphino)methyl]thiophene (S).[786] In the structure of these complexes the main features are short Au···Au distances and an acute Au—S—Au angle.[2892–2896]

Complexes with μ_3 chalcogenide ligands are known for sulfur, selenium, and tellurium. There are several methods for their synthesis, as, for example, the reaction of $[AuX(PR_3)]$ with $E(SiR_3)_2$ (E = S, Se, Te), addition of $[AuX(PR_3)]$ to $E(AuPR_3)_2$, or addition of a sulfur source to $[O(AuPPh_3)_3]^+$. Several complexes with different phosphine ligands, such as PPh_3,[2717,2891,2897,2898] PPh_2Me,[2891] PMe_3,[2899] PPr^i_3,[2899] $PPhMe_2$,[2899] or methyl 4,6-*O*-benzylidene-3-deoxy-3-(diphenylphosphino)-α-D-altropyranoside (mbpa),[2900] have been prepared. Another homoleptic compound with a triply bridging sulfido ligand is $(Et_4N)_2[S\{Au(C_6F_5)\}_3]$, obtained by bubbling H_2S through a solution of $Et_4N[Au(C_6F_5)Cl]$.[2855] Only the complexes with



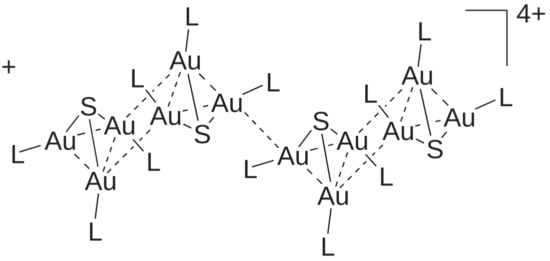
E = S, Se

(507)



L = PPh3

(508)

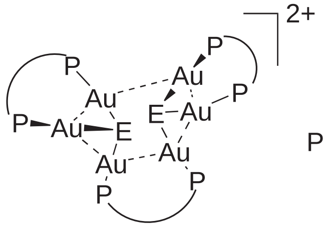


L = PMe3

(509)

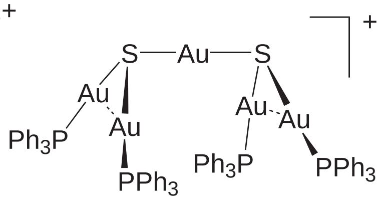
PPh_3 have been obtained for the selenido and tellurido complexes.[2895,2901] The structure of these complexes resembles those of the trigold oxonium cation. Furthermore, it becomes increasingly obvious that steric and electronic effects play a decisive role in the strength of the Au···Au interaction and the supramolecular aggregation of the chalcogen-centered cations. The basic structural framework consists of a trigonal pyramidal EAu_3 with the chalcogen atom in the apical position and short gold–gold contacts in the base of the pyramid. However, the size of the phosphine influences the further aggregation of the molecules. For the bulky PPr^i_3 or mbpa the structure is monomeric, for PPh_3 (**508**), PPh_2Me, or $PPhMe_2$ are dimers, and with PMe_3 the compound crystallizes as two monomeric units (A and B) which form dimers A_2 and B_2, then this dimers aggregate forming a chain through a single Au···Au interaction (**509**).[2899] Pseudopotential *ab initio* calculations on EAu_3^+ and $S(AuPH_3)^{3+}$ (E = S, Se) have been carried out and they reproduce closely the experimental values, if both correlation and relativistic effects are included.[11,2894]

The complexes $[E\{Au_2(\mu\text{-dppf})\}]$ (E = S, Se) also serves as building blocks for preparing polynuclear triply bridging chalcogenide complexes such as (**510**).[2893,2894] The crystal structure of $[\{S(Au_2PPh_3)_2\}_2Au][SnMe_3Cl]$ (**511**) has been reported.[2902]

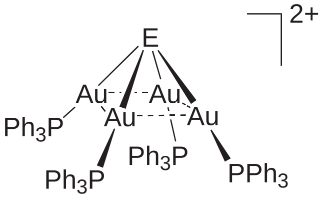


E = S, Se; P–P = dppf

(510)



(511)

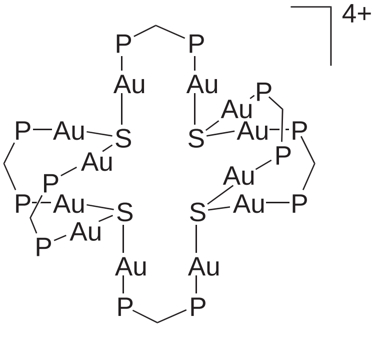


(512)

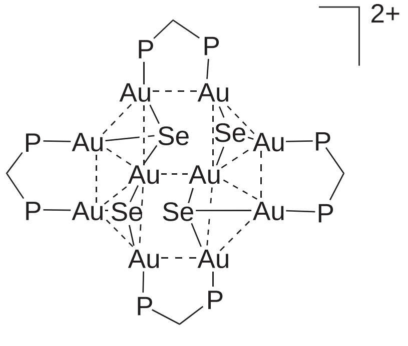
Further addition of $AuPPh_3^+$ fragments to $[E(AuPPh_3)_2]$ affords the complexes with a μ_4-chalcogenide ligand, $[E(AuPPh_3)_4](OTf)_2$ (**512**) (E = S, Se). The structure corresponds to a square pyramid with the chalcogen atom at the apex and aurophilic bonding among the gold atoms at the base, that clearly contributes to the stability of the complexes.[2903,2904]

Other quadruply bridging species have been obtained by reaction of $[E\{Au_2(\mu\text{-dppf})\}]$ with two equivalents of $[Au(OTf)(PR_3)]$ or by addition of $[Au_2(OTf)_2(\mu\text{-ddpf})]$ to give $[E\{Au_2(\mu\text{-dppf})\}(AuPR_3)_2]^{2+}$ or $[E\{Au_2(\mu\text{-dppf})\}_2]^{2+}$, respectively.[2893,2894] Complexes with a μ_5 and μ_6 bridging chalcogenide ligands, $[E(AuPPh_3)_5](OTf)_3$ and $[E(AuPPh_3)_6](OTf)_4$ (E = S, Se), have been prepared by adding more $AuPPh_3^+$ fragments to the $[E(AuPPh_3)_2]$ complexes.[2891,2894] Unfortunately these complexes could not be characterized by X-ray crystallography.

High-nuclearity gold(I) sulfide complexes with bridging diphosphine ligands have been synthesized by bubbling H_2S through ethanol/pyridine solutions of $[Au_2Cl_2(\mu\text{-P-P})]$.[2905–2907] They have the general formula $[Au_{10}(\mu_3\text{-S})_4\{\mu\text{-}(PPh_2)_2NR\}_4]X_2$ (R = alkyl or aryl; X = PF_6 or ClO_4), $[Au_{12}(\mu_3\text{-S})_4(\mu\text{-dppm})_6]X_4$ (**513**), or $[Au_6(\mu_3\text{-S})_2\ \{\mu\text{-}(PPh_2)_2NR\}_3]X_2$ (R=alkyl or aryl; X = PF_6 or ClO_4). These compounds display rich luminescence properties; intense green and orange emissions were observed upon excitation at L > 350 nm both in the solid state and in solution.[2905–2909] The selenium derivatives $[Au_{10}Se_4(\mu\text{-dppm})_4]^{2+}$ (**514**) and $[Au_{18}Se_8(\mu\text{-dppe})_6]^{2+}$ have been obtained by reaction of $[Au_2X_2(\mu\text{-P-P})]$ with $Se(TMS)_2$.[2910]



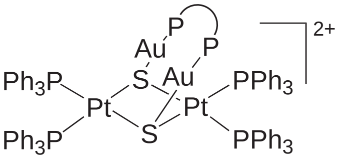
(513)



P–P = dppm

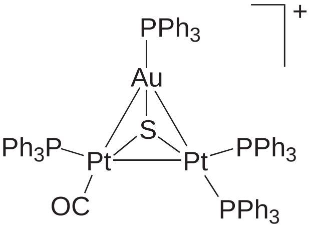
(514)

Heteropolynuclear complexes with bridging chalcogenide ligands have also been synthesized, as those obtained by reaction of $[Pt_2(\mu\text{-}S)_2(PPh_3)_4]$ with gold(I) complexes, to give species such as $[Pt_2(\mu\text{-}S)_2(AuPPh_3)(PPh_3)_4]^+$,[2911–2913] $[Pt_2(\mu\text{-}SAuCl)_2(PPh_3)_4]$,[2912] or $[Pt_2(\mu\text{-}S)_2\{Au_2(P\text{-}P)\}(PPh_3)_4]^{2+}$ (**515**) (P-P = dppm, dppf).[2913] Other complexes are $[Pt_2(PPh_3)_3(CO)(\mu_3\text{-}S)(AuPPh_3)]^+$ (**516**),[2914] the silver(I) derivative $[\{S(AuPPh_3)_3\}_2Ag(THF)]^{3+}$,[1032] or the manganese compound $[Mn_2(\mu\text{-}SAuPPh_3)(CO)_6(\mu\text{-}dppm)]$.[2915] The selenium complex $[Pd_2Au_2Se_2\ (SeH)_2(PPh_3)_4]$ (**517**)[1035] has also been obtained.

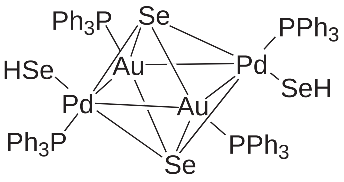


P–P = dppm, dppf

(515)



(516)

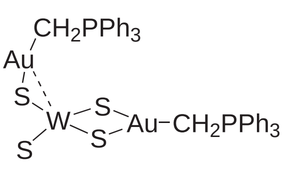


(517)

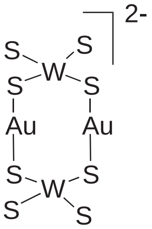
Other mixed metal sulfide or selenide compounds are those synthesized from MS_4^{2-} (M = Mo, W) and VS_4^{3-} anions and gold cations in the presence of various ligands. The reaction of MS_4^{2-} with $[AuX(PR_3)]$ gives the complexes $[MS_4(AuPR_3)_2]$ (M = Mo, W) in which the gold(I) atoms are three coordinate and have been characterized for $PR_3 = PEt_3$,[2906] PPh_3,[2917,2918] PPh_2Me,[2919] $AsPh_3$,[2920,2921] and PCy_3.[2922] Asymmetric compounds are obtained with the ylide ligands $[WS_4(AuCH_2PPh_3)_2]$ (**518**),[2920] or in the oxo-sulfide $[MoOS_3(AuPPh_3)\{Au(PPh_3)_2\}]$.[2917] Heteropolynuclear complexes such as $[MS_4(AuPPh_3)_3]OTf$ and $[MS_4(AuPPh_3)_4](OTf)_2$ have been described.[2923] The inorganic ring system $(Ph_4P)_2[Au_2(WS_4)_2]$ (**519**) has been prepared from $(NH_4)_2[WS_4]$ and $Na_3[Au(S_2O_3)_2]$ in the presence of $(PPh_4)Br$,[2924] the analogous with WOS_3^{2-} has also been obtained.[2925] Another tungsten–gold derivative is $[WCpS_3(AuPPh_3)]$.[1093] The treatment of $(NH_4)_3VS_4$ with $[AuCl(PPh_3)]$ or $[Au(PPh_3)_2]ClO_4$ gives the heteropolynuclear species $[VS_4(AuPPh_3)_3]$ or $[VS_4(AuPPh_3)_2\{Au(PPh_3)_2\}]$ (**520**), respectively.[2926] The selenium analogues $[MSe_4(AuPR_3)_2]$ (M = Mo, W; $PR_3 = PPh_3$, PPh_2Me),[1074,2927,2928] $[WSe_4(AuPPh_3)\{Au(PPh_3)_2\}]$,[2929] $Ph_4P[MSe_4(AuPPh_3)]$,[2930] $(Ph_4P)_2[MSe_4(AuCN)_2]$ (**521**), or $(Ph_4P)[MSe_4(AuCN)]$ (M = Mo, W) have also been obtained.[2930] With $NbSe_4^{3-}$ the complexes $[NbSe_4(AuPPh_3)_2\{Au(PPh_3)_2\}]$ and $[Nb_2Au_2Se_4Cl_2\ (PMe_3)_6]$ have been reported.[2931] Some of these complexes with ME_4^{2-} (E = S, Se) have luminescent and nonlinear optical properties.[1074,2922]

(iii) Gold(I) complexes with polydentate sulfur ligands

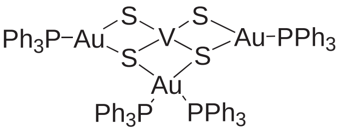
The most important and well-represented gold(I) complexes with polydentate sulfur ligands are dithiolate ligands. Gold(I) complexes with mnt have been synthesized by metathesis reactions and are of the type $[Au_2(\mu\text{-}mnt)(PR_3)_2]$ ($PR_3 = PPh_3$ (**522**), PEt_3, $P(OPh)_3$, PCy_3), $(Bu_4N)[Au(\mu\text{-}mnt)(PR_3)]$,



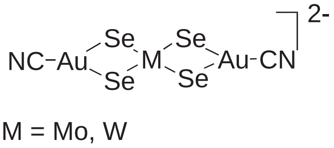
(518)



(519)

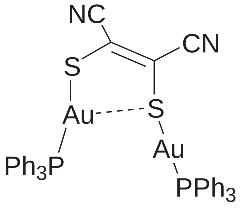


(520)

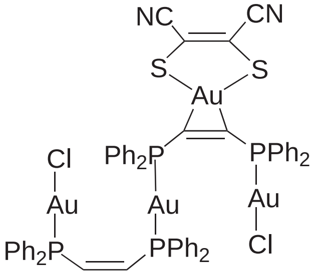


(521)

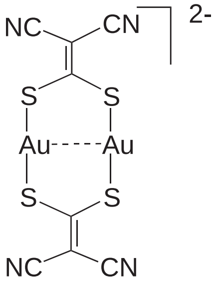
or [Au$_2$(μ-mnt)(μ-dppm)].[1845,2643,2932,2933] The structure consists of mononuclear three-coordinate species or dinuclear complexes with a bridging dithiolate ligand and Au$\cdots$S or aurophilic interactions, except when bulky phosphines as PCy$_3$ are used. The complex [Au$_4$Cl$_2$(μ-mnt){(PPh$_2$)$_2$(CH$=$CH)}] (**523**) has a gold(I) center coordinated to the dithiolate and the ethylene moiety.[2934] With the ligand *i*-mnt, the dinuclear derivatives [Au$_2$(μ-*i*-mnt)$_2$]$^{2-}$ (**524**) present a luminescent behavior.[1844,1999,2935]



(522)

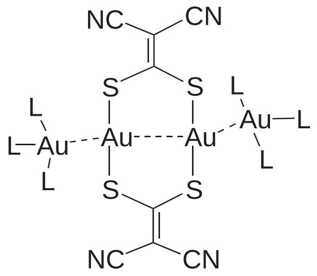


(523)

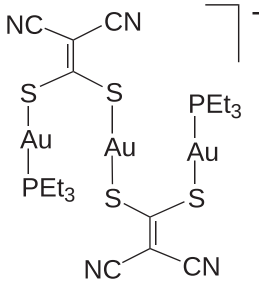


(524)

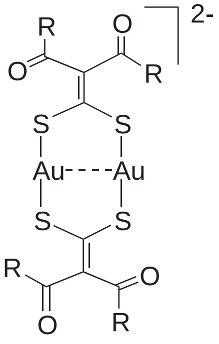
The reaction of [AuL$_3$]Cl (L = phophatriazaadamantane) with K$_2$(*i*-mnt) gives a high luminescent tetranuclear compound (**525**) with an unsupported Au$\cdots$Au interaction.[2936] Other complexes are [Au$_2$(μ-*i*-mnt)(PPh$_3$)$_2$][2937,2938] or [Au$_2$(μ-*i*-mnt)(P-P)] (P-P = PR$_2$(CH$_2$)$_n$PR$_2$; R = Ph, n = 1, 2, 3, 4; R = Me, n = 1, 2; Ph$_2$AsCH$_2$AsPh$_2$, Ph$_2$PCH$=$CHPPh$_2$),[2644,2939,2940] which has a similar structure to those with mnt, but with formation of a chain through aurophilic interactions, and [Au(PEt$_3$)$_2$][Au$_3$(μ-*i*-mnt)$_2$(PEt$_3$)$_2$] (**526**).[2941] Similar complexes are obtained with the related 1,1-ethylenedithiolate ligands, 2,2-diacetyl- or 2,2-dibenzoyl-ethylene-1,1-dithiolate as, for example, (**527**), which have been synthesized by insertion of CS$_2$ on β-diketonate complexes.[1872,1877] Heteropolynuclear complexes with the *i*-mnt ligand as the platinum–gold derivative [Pt(μ-*i*-mnt)$_2$(AuPPh$_3$)$_2$] have been described.[2933]



(525)



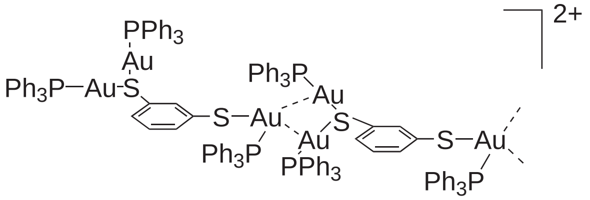
(526)



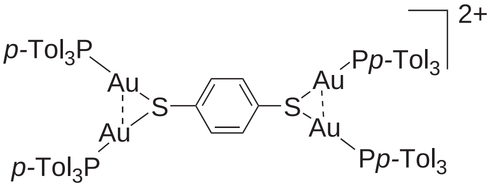
(527)

The ligands phenylene-1,2-dithiolate, or its 4-methyl derivative, have been thoroughly studied in their gold(I) complexes and di-, tri-, and tetranuclear derivatives have been prepared of the type a–c (Figure 23).[1849–1851,2643,2831,2932,2942–2945] Types a and b have been synthesized by reaction of the alkaline or ammonium salt with aurating agents such as [AuXL] or $[O(AuPR_3)_3]^+$. Type c is obtained in the case of PEt_3 where a partial loss of ligand leads to a vacancy in the coordination sphere of gold and formation of a cluster compound.

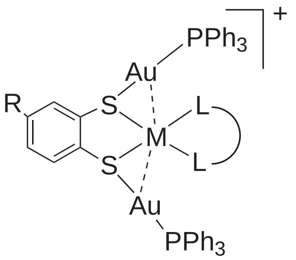
With the phenylene-1,3-dithiolate di- and trinuclear complexes have also been obtained.[1850,2946] The trinuclear complex aggregates into 1D array through head-to-tail aurophilic contacts (**528**); a similar compound is obtained with the biphenylene-4,4-dithiolate. The phenylene-1,4-dithiolate affords tetranuclear derivatives of the form $[(p\text{-}Tol_3PAu)_2SC_6H_4S(AuPp\text{-}Tol_3)_2](BF_4)_2$ (**529**). Complexes of osmium, rhodium, or iridium with this ligands can further coordinate gold atoms to give heteropolynuclear species as (**530**).[2947,2948]



(**528**)

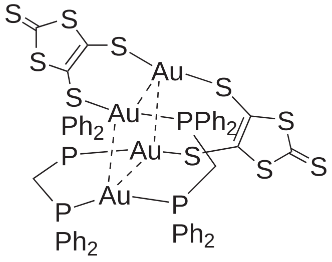


(**529**)

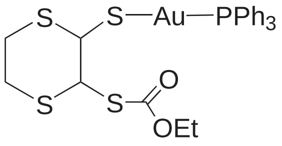


R = H, Me; M = Rh, Ir

(**530**)



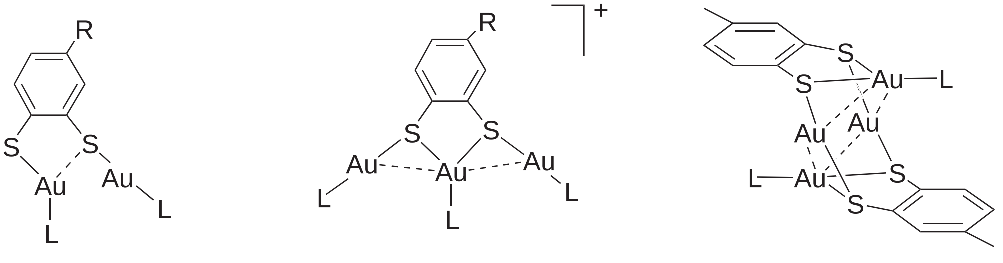
(**531**)



(**532**)

The ligands dmit yields compounds of the type $[Au_2(C_6F_5)_2(\mu\text{-dmit})]^{2-}$, $[Au(dmit)(PPh_3)]^-$, $[Au_2(dmit)(PR_3)_2]$, $[Au_2(\mu\text{-dmit})(dppe)]$, $[Au_2(\mu\text{-dmit})(L\text{-}L)]^-$ (L-L = $(CH_2)_2PPh_2$, S_2CNR_2), or $[Au_4(dmit)_2(dppm)_2]$ (**531**).[1874,2949–2951] Similar complexes have been prepared with the 2-selenoxo-1,3-dithiole-4,5-dithiolate or 2-thione-1,3-dithiole-4,5-diselenolate derivatives.[2952,2953] The reaction of 2,5,7,9-tetrathiabicyclo[4.3.0]non-1(6)-en-8-one (TTBEO) with NaOR in the presence of [AuClL] gives thiolene as (**532**) instead of the dithiolene species, the latter are obtained by transmetallation reactions through the zinc complex(I).[2954]

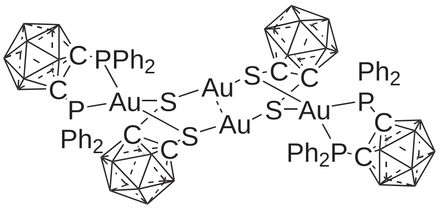
The 1,2-dithiolate-*o*-carborane ligand also yields di- and trinuclear derivatives, such as $[Au_2(\mu\text{-}S_2C_2B_{10}H_{10})(PPh_3)_2]$, $[Au_2(\mu\text{-}S_2C_2B_{10}H_{10})(P\text{-}P)_2]$ (P-P = dppm, dppe, dppp, $Ph_2PCH{=}CHPPh_2$), $(Bu_4N)_2[Au_2(\mu\text{-}S_2C_2B_{10}H_{10})_2]$, $(Ph_3PMe)_2[Au_2(\mu\text{-}S_2C_2B_{10}H_{10})(C_6F_5)_2]$, or $[Au_3(\mu_3\text{-}S_2C_2B_{10}H_{10})(PPh_3)_3]OTf$ and the novel tetranuclear species $[Au_4(S_2C_2B_{10}H_{10})\{(PPh_2)_2C_2B_{10}H_{10}\}_2]$ (**533**).[2955,2956] Long-chain thiolates have been used as building blocks for the synthesis of coordination



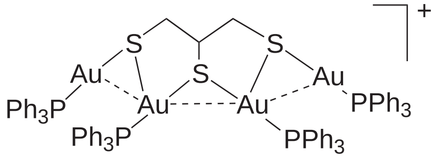
(**a**) (**b**) (**c**)

Figure 23 Some gold(I) complexes formed with $4\text{-}RC_6H_3S_2^-$ ligands; R = H, Me; L = PR_3, CNR.

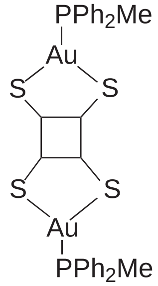
polymers; these are of the type $[Au_3\{S(CH_2)_2S\}(PPh_3)_3]^+$, $[Au_3\{S(CH_2)_3S\}(PPh_3)_3]^+$, $[Au_4\{S(CH_2)_nS\}(PPh_3)_4]^{2+}$ ($n = 4$, 5, 6), $[Au_2\{S(CH_2)_nS\}(PPh_3)_2]$, $[Au_4\{(SCH_2)_2(CHS)\}(PPh_3)_4]^+$ (**534**), $[Au_4\{(SCH_2CH_2)_2(X)\}(PPh_3)_4]^{2+}$ (X = O, S), or $[(AuPPh_3)_2\text{-}\{SCH_2CH(CH_2OH)S\}(AuPPh_3)_2]^{2+}$.[2829,2831,2943,2957] Mixed Au—Ag or Au—Cu complexes, $[M_4Au_2(SCH_2CH_2S)_4]^{2-}$ (M = Cu, Ag), have been obtained with the ethane dithiolate ligand.[1187] 1,3,4-Thiadiazole-2,5-dithiolate gives open-chain $[Au_2(S\text{-}S)(PR_3)_2]$ or cyclic $[Au_2(S\text{-}S)(P\text{-}P)]$, that depending of the steric size of the phosphine, aggregate in strings with long Au···S bonds or a 2D network through aurophilic interactions.[2958] The tetrathiosquarate ligand gives the three-coordinate compound $[Au_2(S_4C_4)(PPh_2Me)_2]$ (**535**)[2959] and the related dithiosquarate affords the dinuclear $[Au_2(S_2O_2C_4)_2]^{2-}$.[1868]



(533)

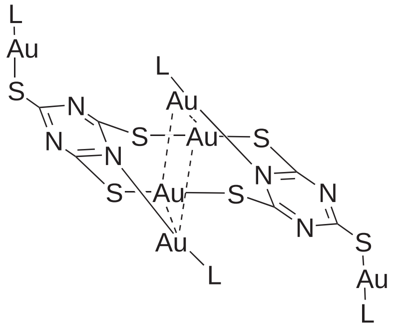


(534)

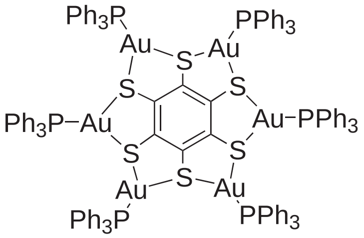


(535)

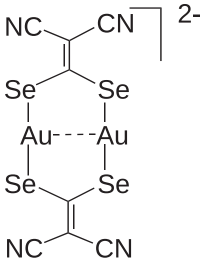
Trithiocyanuric acid gives the trinuclear derivatives $[Au_3(S_3C_3N_3)L_3]$ (L = PPh_3, Bu^tNC, $P(OMe)_3$, $P(OPh)_3$, PCy_3), that by loss of one ligand L yields the hexanuclear species $[Au_6(S_3C_3N_3)L_4]$ (**536**) (L = $PPhMe_2$, Bu^tNC).[2960,2961] The mononuclear compound $[Au(S_3H_2C_3N_3)(PPh_3)_3]$ has also been prepared.[2962] Benzenehexathiol reacts with $[AuCl(PPh_3)]$, in the presence of triethylamine, to yield the hexanuclear golden wheel $[Au_6(S_6C_6)(PPh_3)_6]$ (**537**).[2963] The analogue compound with $PPh(CH{=}CH_2)$ further reacts with $PPhH_2$, in the presence of α-azoisobutylnitrile, to give a macrocycle 36-membered ring.[2964]



(536)



(537)



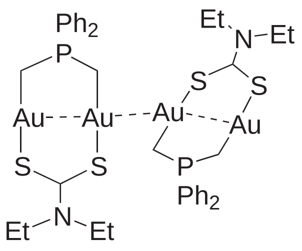
(538)

Other dithiolate complexes are of the type $[Au_2(\mu\text{-}S\text{-}S)(\mu\text{-}P\text{-}P)]$ (P-P = dppf, dppm; S-S = $S(CH_2)_3S$),[2643,2834] $[Au_2(\mu\text{-}S\text{-}S)(PPh_3)_2]$ (S-S = 1,4-diethyl-3,6-dithiopiperazine-2,5-dithiolate),[2965] or those derived of the partially methylated dithiolates $[Au(dmitMe)(PPh_3)]$ or $[Au(mntMe)(PPh_3)_2]$.[995] Diselenolate gold(I) derivatives are not numerous and only the analogues to dmit and *i*-mnt with selenium have been synthesized as $(Bu_4N)_2[Au_2\{\mu\text{-}Se_2C{=}C(CN)_2\}_2]$ (**538**).[2966]

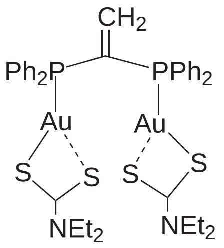
Heteropolynuclear complexes are obtained in the reaction of the S-bridged $Co^{III}Ni^{II}Co^{III}$ trinuclear complex, $C_2C_2\text{-}[Ni\{Co(aet)_2(en)\}_2]^{4+}$ (aet = 2-aminoethanethiolate), with Au^I that yields $C_2C_2\text{-}[Au_2\{Co(aet)_2(en)\}_2]^{4+}$.[2967] A similar compound is obtained with rhodium, $[Au_3\{Rh(aet)_3\}_2]^{3+}$.[2968] A mixed Pd—Co—Au derivative, $[Au_2\{Pd\{Co(aet)_2(en)\}_2\}_2]^{6+}$ has also been reported.[2969] The penicillaminato complexes of Ni or Co react with gold(I) to give the bridged sulfur derivatives $[Au_2Ni_2\{SCMe_2CH(NH_2)COO\}_4]^{2-}$ or $[Au_3\{Co\{SCMe_2CH(NH_2)\text{-}COO\}\}_3]$, respectively.[2970,2971]

Dimeric gold(I) complexes with dithiocarbamate ligands possess a strong propensity to aggregate and form chains with short intermolecular Au···Au contacts, they have been known for a long time but new structural characterizations have come into light. Thus compounds of the type

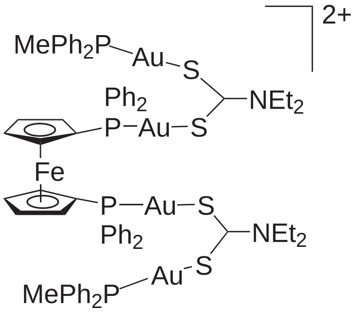
$[Au_2(S_2CNR_2)_2]$ where R can be Et,[2972,2973] CN,[2974] C_2H_4OMe,[2810] or C_5H_{11},[2975] have been characterized. The compound $[Au_2\{S_2CN(C_5H_{11})_2\}_2]$ interacts in a reversible way with VOC vapors with a dramatic change in the color and a positive "switching on" of luminescence.[2975] Dinuclear derivatives but with different bridging ligands, as $[Au_2(\mu\text{-L-L})(\mu\text{-}S_2CNR_2)]$ (L-L = $(CH_2)_2PPh_2$, dppm, dppe, $Me_2PCH_2PMe_2$; R = Me, Et, Bz),[2642,2645,2939] have been obtained by ligand exchange reactions between the homoleptic compounds. The structure of $[Au_2\{\mu\text{-}(CH_2)_2PPh_2\}(\mu\text{-}S_2CNEt_2)]$ (**539**) reveals the presence of dimeric units with inter- and intramolecular Au···Au interactions.[2642] Mixed dithiocarbamate-phosphine complexes with different stoichiometries, such as $[Au_2(\mu\text{-}S_2CNEt)(\mu\text{-P-P})_2]^+$ (P-P = dppm, $(PPh_2)_2C{=}CH_2$),[1219,2603] $[Au_2(\mu\text{-}S_2CNEt)(\mu\text{-P-P})]^+$, $[Au_2(S_2CNEt)_2(\mu\text{-P-P})]$ (P-P = dppf, dppe, $(PPh_2)_2C{=}CH_2$ (**540**)),[1219,2578,2976] $[Au_2M(S_2CNEt)_2(\mu\text{-P-P})]^+$ (M = Cu, Ag, Au),[1219] or $[Au_4(S_2CNEt)_2(\mu\text{-dppf})(PPh_2Me)_2]^{2+}$ (**541**) have been synthesized.[2578]



(539)

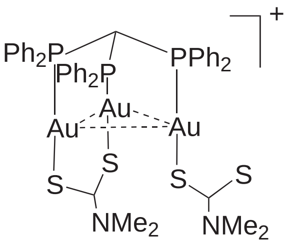


(540)

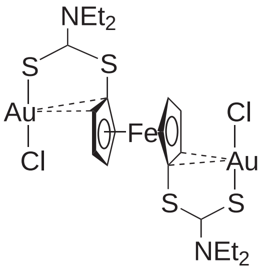


(541)

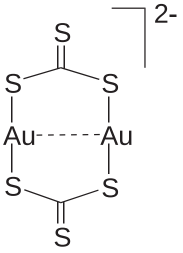
The reaction of triphosphine gold(I) complexes of the type $[Au_3Cl_3(\mu\text{-}P_3)]$ with several stoichiometric ratios of NaS_2CNR_2 gives the species with 1–3 dithiocarbamate ligands $[Au_3Cl_{3-x}(S_2CNR_2)_x(\mu\text{-}P_3)]$ ($x = 1, 2, 3$; $P_3 = (PPh_2)_3CH$, $(PPh_2CH_2)_2PPh$, $(PPh_2CH_2CH_2)_2PPh$), and also $[Au_3(S_2CNMe_2)_2\{(PPh_3)_3CH\}]^+$ (**542**) with one bridging and one terminal dithiocarbamate ligands.[1765,2977,2978] Some of these complexes present a luminescent behavior.



(542)



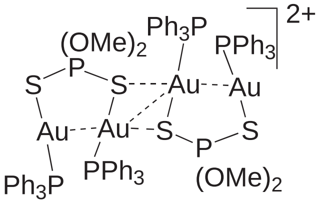
(543)



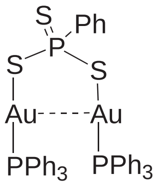
(544)

Mononuclear compounds of the type $[Au(S_2CNR)(PPh_3)_2]$ (R = pip, Pr^i)[2979,2980] and $[Au(S_2CNEt_2)(PR_3)]$ ($PR_3 = PCy_3$, $P(p\text{-}MeOC_6H_4)_3$)[2981,2982] have been structurally characterized. Monoalkylated dithiocarbamates have also been studied as ligands in gold(I) complexes such as $CH_2(S_2CNR_2)_2$, with complexes of the form $[Au_2(C_6F_5)_2\{CH_2(S_2CNR_2)_2\}]$, $[Au_2(PPh_3)_2\{CH_2(S_2CNR_2)_2\}]^{2+}$, or $[Au\{CH_2(S_2CNR_2)_2\}]^+$,[1220] S(MeS)NHR (R = Ph, $p\text{-}MeC_6H_4$, $o\text{-}MeC_6H_4$, $p\text{-}MeOC_6H_4$, $3,5\text{-}Me_2C_6H_3$) with compounds of the type $[Au\{S(MeS)NHR\}_2]^+$, or $[Au(C_6F_5)\{S(MeS)NHR\}]$,[1812,2983] or methylthiocarbamates as in $[Au\{SC(OEt)NHMe\}_2]Cl$,[2984] or $[Au\{SC(OEt)NPh\}(PPh_3)]$.[2985] The ligand $Fc(S_2CNEt_2)_2$ reacts with gold(I) complexes to afford species such as $[Au_2(PPh_3)_2\{Fc(S_2CNEt_2)_2\}](OTf)_2$ or $[Au_2Cl_2\{Fc(S_2CNEt_2)_2\}]$ (**543**); in the latter there exists an η^2 interaction between the gold atoms and the cyclopentadienyl ligand.[1830] The trithiocarbonate gold(I) complex $[Au_2(S_2C{=}S)_2]^{2-}$ (**544**) has been synthesized by reaction of $[Au(SH)_2]^-$ with CS_2.[2986] It has a very short Au···Au distance of 2.7998(4) Å and for this reason the electronic and resonance Raman spectra of the NBu_4^+ salt have been studied. An absorption band at 314 nm has been assigned as the metal–metal $^1(d\sigma^* \rightarrow p\sigma)$ transition.[2987]

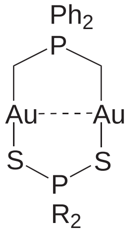
Organophosphor-1,1-dithiolato gold(I) compounds (which include dithiophosphinates ($S_2PR_2^-$), dithiophosphates ($S_2P(OR^1)_2^-$), or dithiophosphinates ($S_2PR^1(OR^2)^-$) have only been studied recently. The first examples were reported many years ago, and were also included in several of the early studies of the usage of gold compounds as lubrication additives.[2988–2990] The determination of the crystal structure of $[Au_2\{S_2P(OPr^i)_2\}_2]$ showed the presence of dimeric units forming a chain through aurophilic interactions. Recently other dinuclear complexes of the type $[Au_2(S_2PR_2)_2]$ have been characterized structurally, where R can be Ph, Me, Et, or ^{i}Bu.[2040,2991–2993] The reaction of $R_2P(S)SH$ with $[O(AuPR^2_3)_3]^+$ yields the dinuclear complexes $[Au_2(\mu\text{-}S_2PR^1_2)(PR^2_3)_2]^+$ (R^1 = Ph, OEt, OMe; R^2 = Me, Ph, *o*-Tol). These complexes can be discrete dinuclear compounds with intracationic Au···Au interactions or form supramolecular structures through intermolecular Au···Au or Au···S contacts as in (**545**), depending on the steric hindrance of the substituents.[2992,2994] With $Me_2P(S)SH$ only the monoaurated derivative was achieved.[2992] The reaction of the related $PhP(S)(STMS)_2$ with the oxonium salt gives $[PhP(SAuPPh_3)_3]BF_4$, which is unstable below −40 °C; with $PhP(S)(SNa)_2$ the treatment with $[AuCl(PR_3)]$ gives the dinuclear derivatives $[PhP(S)(SAuPR_3)_2]$ (**546**) (R = Me, Et, Pr^i, Ph, *o*-Tol).[2992,2995] Mixed dinuclear complexes such as $[Au\{\mu\text{-}(CH_2)_2PPh_2\}(S_2PR_2)]$ (**547**) or three-coordinated species as $[Au_2(S_2PR_2)_2(dppm)]$ (R = Me, Ph) have been obtained.[2040] Other phosphor-1,1-dithiolate ligands used have been of the type $S_2PR^1(OR^2)^-$ which gives the dinuclear derivatives $[Au_2\{S_2PR^1(OR^2)\}_2]$ (R^1 = Ph, *p*-C_6H_4OMe; $R^2 = CH_2CH{=}CH_2$, $SiPh_3$); some of then present luminescent properties.[2996,2997] The reaction of the Laweson reagent $(PR(S)S)_2$ with $[Au_2Cl_2(P\text{-}P)]$ gives the mixed compounds $[Au_2\{S_2P(S)R^1\}(P\text{-}P)]$ (R^1 = Fc; P-P = dppm, $Ph_2PNHPPh_2$); the related $[Au_2\{S_2P(O)R^1\}(P\text{-}P)]$ have also been obtained by treatment of $[Au_2\{S_2PR^1(OR^2)\}_2]$ with diphosphines.[2996] Theoretical studies have been carried out in the dimer $[Au_2(S_2PH_2)_2]$ and in the polymer $[Au_2(S_2PH_2)_2]_n$ showing that the staggered conformation is more stable that the eclipsed one.[2998] The reaction of $(S)P(SSiMe_3)_3$ with $[AuCl(PPh_3)]$ gives the compound $[Au_4(P_2S_6)(PPh_3)_4]$ (**548**).[2999]



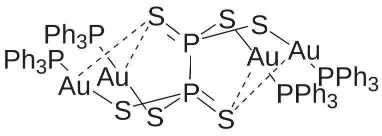
(**545**)



(**546**)



(**547**)



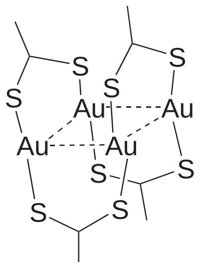
(**548**)

Homoleptic dithiocarboxylate complexes are tetrameric as $[Au_4(S_2CMe)_4]$ (**549**)[1880,3000] or hexameric as $[Au_6(S_2C_6H_4Me\text{-}2)_6]$ (**550**).[3001] Other derivatives with S_2CPh, or S_2C(*p*-Tol) have been prepared but their structure is unknown.[1880,3002] Other stoichiometries are $[Au(S_2CR)(PPh_3)]$ and $[Au(S_2CR)(PPh_3)_2]$, which have been obtained by the addition of PPh_3 to the $[Au(S_2CR)]_n$ species.[3002] Another method of synthesis is the insertion of CS_2 in a Au—C bond, as in $[Au(S_2CC_5Me_5)(PPr^i_3)]$.[1230] With related ligands such as triclorothioacetate or phosphonium dithiocarboxylates, the complexes $[Au\{SC(O)CCl_3\}(PPh_3)]$,[2751] $[Au_2X_2(\mu\text{-}S_2CPR_3)]$ (X = Cl, C_6F_5), $[Au_2(\mu\text{-}S_2CPR_3)_2]$ ($PR_3 = PEt_3$, $PPhMe_2$, PBu_3), or $[Au_2(S_2CPCy_3)\{(CH_2)_2PPh_2\}]$ have been synthesized.[1811,2039]

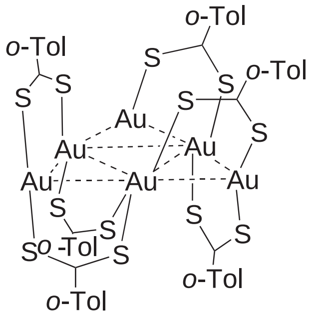
Dithiocarbonato or xantate ligands have also been used in gold(I) chemistry to prepare compounds of the type $[Au(S_2COR)]_n$ (which have been known for a long time and their structure is unknown[3003]) $[Au(S_2COR)(PR_3)]$, or $[Au(S_2COR)(PR_3)_2]$ (R = Me, Et, Pr^n, Pr^i, Bu, Cy; $PR_3 = PPh_3$, PEt_3, PCy_3, $P(o\text{-}Tol)_3$), in the complexes from which the structure is available the xantate ligand coordinates as monodentate to the gold(I) center, as in (**551**).[3004–3010] Complexes with ylide such as $[Au\{(CH_2)_2PPh_2\}(S_2COPr^i)]$,[2037] or triphosphines as $[Au_3Cl_{3-x}(S_2COEt)_x\{\mu\text{-}(PPh_2CH_2)_2PPh\}]$ (x = 1, 2, 3) are also known.[3011]

(iv) Gold(I) complexes with phosphine sulfide or selenide ligands

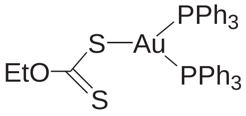
Phosphine sulfides or selenides are well-known ligands in gold(I) chemistry. With monophosphine complexes of the type $[AuX(SPR_3)]$ (X = Cl, Br, CN; $PR_3 = PPh_3$, PCy_3, PPh_2Py,



(549)



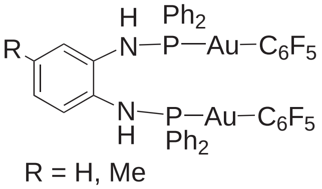
(550)



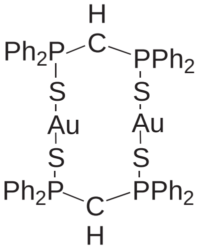
(551)

$PPh_2N{=}CPh_2)$,[1427,2449,2502,3012,3013] $[Au(SPPh_3)_2]PO_2F_2$,[3014] $[Au(PPh_3)(SPPh_2NCHN)]$,[3015] or the analogues with selenium $[AuX(SePR_3)]$ ($X = Cl$, Br, C_6F_5; $PR_3 = PPh_3$, PCy_3, $PTol_3$),[3016–3030] $[Au(SePPh_3)_2]SbF_6$,[3021] or $[Au(PPh_3)(SePR_3)]SbF_6$ ($PR_3 = PPh_3$, $PPhMe_2$)[3021] have been obtained.

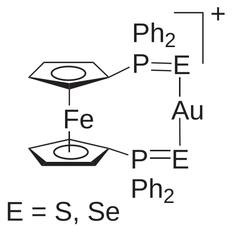
Gold(I) complexes with diphosphine disulfide ligands have been synthesized and are of the type $[Au_2X_2\{(SPPh_2)_2R\}]$ ($X = Cl$, Br, C_6F_5; $R = CH_2$, $(CH_2)_2$, $(CH_2)_3$, $Fe(C_5H_4)_2$, 4-R-1,2-$(NH)_2C_6H_3$ (**552**) (R = H, Me)),[1757,1882,1885,3022] $[Au_2(PPh_3)_2\{(SPPh_2)_2(CH_2)_n\}]^{2+}$ ($n = 1$, 2, 3),[3022] $[Au_2\{(SPPh_2)_2CH_2\}_2](ClO_4)_2$,[1882] and $[Au_2\{(SPPh_2)_2R\}_2]_2$ (R = CH (**553**), N).[1882,2161] The ligands $Fc(PPh_2E)_2$ (E = S, Se) act as *trans* chelate in their gold(I) compounds $[Au\{(EPPh_2)_2Fc\}]^+$ (**554**), for the selenium derivative the molecules are associated in trimers through aurophilic interactions.[1262,1265,1885] The ligand $(SPPh_2)_2CH_2$ can also act as chelate in gold(I) in the four-coordinate compound $[Au\{(SPPh_2)_2CH_2\}\{(PPh_2)_2C_2B_{10}H_{10}\}]ClO_4$.[2703]



(552)

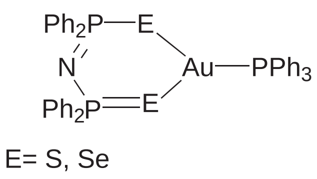


(553)

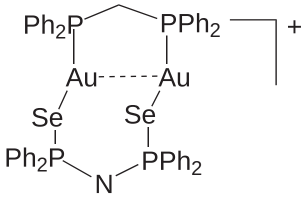


(554)

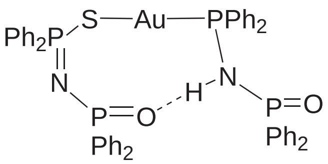
Dichalcogenoimidodiphosphinato $[R_2P(E)NP(E)PR_2]^-$ or mixed chalcogen donors $[R_2P(O)NP(E)PR_2]^-$ form homoleptic gold(I) complexes of stoichiometry $[Au_2\{(EPPh_2)_2N\}_2]$, the structure is unknown and could be dimers or polymeric species.[2161,3023] Three- and four-coordinate compounds such as $[Au\{(EPPh_2)_2N\}L_n]$ (E = S, Se; $L = PPh_3$ (**555**), PMe_3, $CNC_6H_3Me_2$-2,6, $n = 1$; E = Se; $L = PMe_3$, $n = 2$) have been obtained by reaction of $(SePPh_2)_2N^-K^+$ with $[AuClL]$.[1268,3023] Other types of complexes such as the linear $[Au_2\{(SePPh_2)_2N\}(PPh_3)_2]BF_4$ or the mixed dinuclear derivative $[Au_2\{\mu\text{-}(SePPh_2)_2N\}(\mu\text{-dppm})]^+$ (**556**) have been reported.[3023] With the mixed chalcogen donor ligands the complexes $[Au(SPPh_2NPPh_2O)(PPh_2C_6H_4NH_2\text{-}2)]$,[3024] $[Au\{(SePPh_2)_2N\}(PPh_2NHPPh_2OH)]$,[2488] or $[Au(SPPh_2NPPh_2O)(PPh_2NHPPh_2O)]$ (**557**),[3025] have been characterized structurally.



(555)

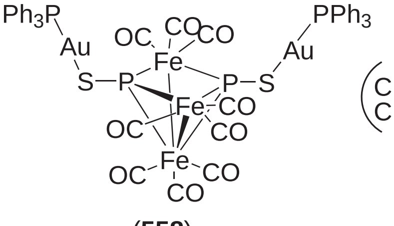


(556)

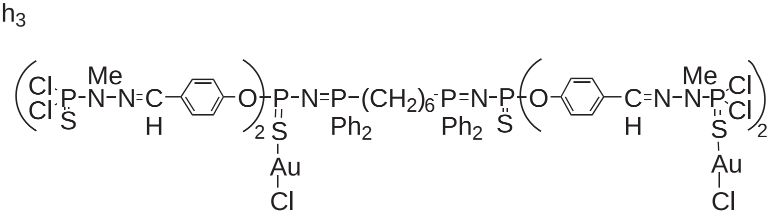


(557)

Other complexes with phosphine sulfides are the three coordinate $[Au\{(S\text{-}PPh_2)_2C(PPh_2S)\}(PPh_2Bu^n)]$,[3026] the μ_4-phospha-1-thiethane compound $[Fe_3(CO)_9(\mu_4\text{-}PS)(AuPPh_3)_2]$ (**558**),[3027] and the gold(I) dendrimers containing P=NP=NP=S or P=NP=S groups as (**559**).[3028]



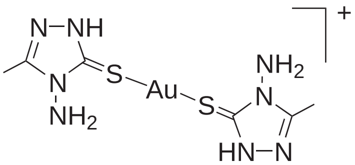
(558)



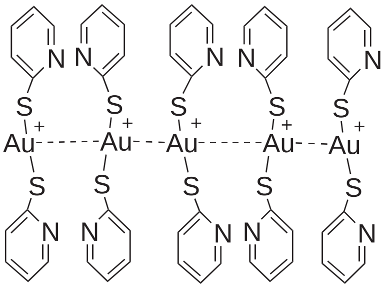
(559)

(v) Gold(I) complexes with other sulfur donor ligands

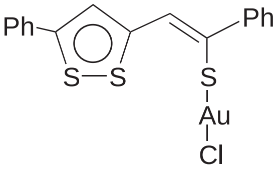
Gold(I) complexes with thiones are numerous and have several stoichiometries. The homoleptic $[AuL_2]^+$ have been obtained for L = imidazoline-2-thione,[3029] 4-amino-3-methyl-1,2,4-triazoline-5-thione (**560**),[3030] *N*-R-1,3-imidazoline-2-thione (R = Pr, Et),[3031,3032] 1,3-thiazoline-2-thione,[1801,3033] 1H-pyrimidine-2-thione,[1801] pyridine-2-thione,[1801] benzothiazoline-2-thione,[1801] or benzimidazole-2-thione.[1801] The structure of $[Au(C_5H_5NS)_2]ClO_4$ (**561**) shows that five of the six cations in the unit cell are linked by aurophilic interactions and the sixth is monomeric.[1801] Complexes of the type [AuXL] have also been reported for L = 1,3-thiazoline-2-thione,[1801] 1H-pyrimidine-2-thione,[1801] pyridine-2-thione,[1801,3034] benzothiazoline-2-thione,[1801] benzimidazole-2-thione,[1801] 1-methylpyridine-2-thione,[3035] *N*-R-1,3-imidazoline-2-thione (R = H, Pr, Et),[3031,3036,3037] ergothionine,[3038] substituted thiabenzenethionas,[2913] trithiapentalene derivative (**562**),[3039] and 1,3-dithiolane-2-thione.[3040]



(560)



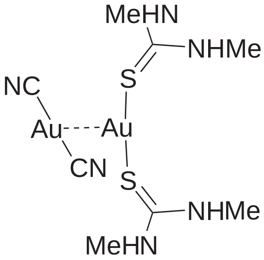
(561)



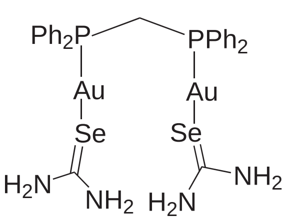
(562)

Gold(I) derivatives with tu or substituted tus have been synthesized and are of the form $[Au\{S{=}C(NHR)_2\}_2]^+$, where R can be H,[3041–3043] Me,[3036,3044] Et,[3044] or [AuXL] (L = $S{=}C(NMe_2)$, $S{=}C(NEt_2)(NHCOPh)$,[1824,3045] or $[Au(PPh_3)\{S{=}C(NHMe)_2\}]^+$.[1288] In the crystal structure of $[Au\{S{=}C(NHMe)_2\}_2][Au(CN)_2]$ the cation and anion are connected through Au···Au interactions (**563**).[3036] With selenourea the complexes $[Au(PPh_3)\{Se{=}C(NH_2)_2\}]^+$ and $[Au_2\{Se{=}C(NH_2)_2\}_2(\mu\text{-dppm})]Cl_2$ (**564**) have been obtained.[2892] Other gold(I) complexes which have ligands with an S=C moiety, are with *N*-phenylthiobenzamide,[3046] $Cy_2P(O)C(NHMe)(S)$,[3047] *N*,*N*′-dimethylthioformamide,[1302] or aminothiocarbamoyl-benzamidinato ligands (**565**).[3048]

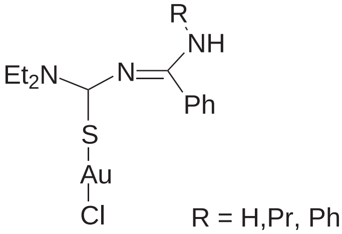
Thioether gold(I) derivatives of the type $[AuX(SR_2)]$ are widely used as starting materials and some crystal structure determinations have been reported for SMe_2,[1809,3049] $S(CH_2Ph)_2$,[3050] or THT.[3051,3052] In the structure of the chloro and bromo derivatives with tetrahydrothiophene the molecules form a chain through Au···Au interactions. In the iodo derivative they are cations and anions of the type $[AuL_2]^+[AuI_2]^-$ (L = tetrahydrothiophene or thetrahydroselenophene) that form a chain through aurophilic interactions (**566**).[3052] The salt with benzodisulfonylamide has also been reported.[3053] Other complexes with stoichiometry [AuClL] are those with L = 3-methyl-5-methylthiomethyl-isoxazole,[1425] or $SePh_2$.[1803] Cationic compounds of the type $[Au(SR_2)(PR_3)]^+$



(563)

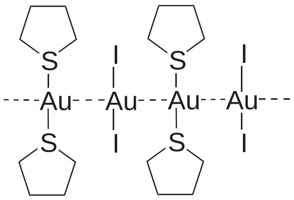


(564)

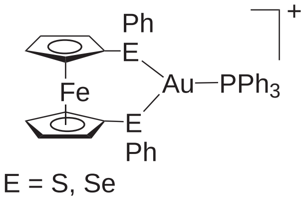


(565)

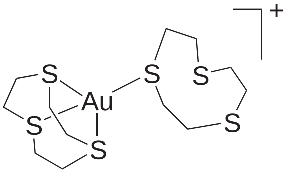
are known for $SR_2 = SMe_2$,[3054] SMepy,[1412] or the three-coordinate $[Au(PR_3)\{(EPh)_2Fc\}]^+$ (**567**) (E = S, Se).[1184] Gold(I) also forms complexes with cyclic thioethers such as [9]aneS$_3$, which form the tetrahedral $[Au\{[9]aneS_3\}_2]PF_6$ (**568**),[1888] or the linear $[AuCl\{[9]aneS_3\}]$,[3055] with [18]aneS$_6$ the tetrahedral $[Au\{[18]aneS_6\}]PF_6$,[3056] or with [15]aneS$_5$ and [28]aneS$_8$ forms the dinuclear $[Au_2\{[15]aneS_5\}_2][B(C_6F_5)_4]_2$,[3056] or $[Au_2\{[28]aneS_8\}](PF_6)_2$ (**569**),[1103] respectively.



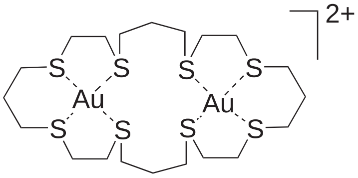
(566)



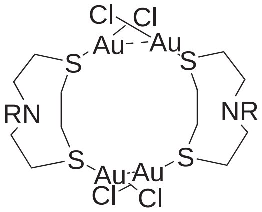
(567)



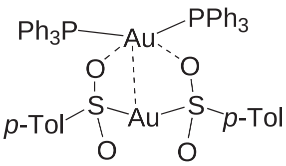
(568)



(569)



(570)



(571)

Other complexes with cyclic thioethers are those with 3,3,6,6-tetramethyl-1-thia-cycloheptine,[3057] 7-toluensulfonyl-7-aza-1,4-dithiacyclononane (**570**),[3058] or 1,10-dithia-4,7,13,16-tetraoxa-cyclooctadecane.[3059] With the cyclic selenoethers [8]aneSe$_2$ and 3H-1,4,5,7-tetrahydro-2,6-benzodiselenonine the dinuclear complexes $[Au_2Cl_2L]$ have been obtained, these are thought to involve linear Se—Au—Cl fragments.[1152]

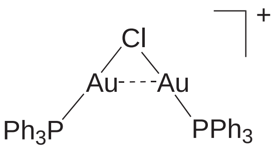
Thiocyanate gold(I) complexes have been investigating in the search of supramolecular structures. Complexes of the type [Au(SCN)L] with L = THT, PMe_3, 2,6-$Me_2C_6H_3NC$ have been characterized structurally showing that the THT complex form a polymer of alternating cations $[Au(THT)_2]^+$ and anions $[Au(SCN)_2]^-$, the PMe_3 shows dimers with aurophilic interactions and further aggregation through Au···S contacts, and with the isocyanide ligand are dimers with Au···Au and Au···S contacts.[3060] However, the complex $[Au(SCN)(PPh_3)]$ is a monomer in the crystal,[2758] and also $Ph_4As[Au(SCN)_2]$ shows no aurophilicity.[2518]

The organosulfinate complexes $[Au(SO_2R)L]$ (R = p-Tol, Me; L = PMe_3, PPh_3, 2,6$Me_2C_6H_3NC$, Bu^{t}NC) have been prepared by treatment of the silver sulfinate with [AuClL]. The crystal structure also consists of pairs of the homoleptic derivatives $[Au(PPh_3)_2]^+[Au(S_2O\text{-}p\text{-}Tol)_2]^-$ (**571**) bonded through aurophilic interactions.[2761]

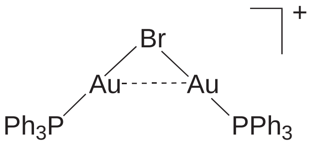
6.7.3.4.7 Complexes with halide donor ligands

Halide ligands are a very important type of ligands in gold(I) chemistry. Complexes such as [AuXL] or [$Au_2X_2(\mu$-L-L)] are amongst the most important coordination compounds, and are extensively used as convenient starting materials. Many of these derivatives have been treated in the corresponding section according to the donor atom of the L or L-L ligands, and then it will not be included here.

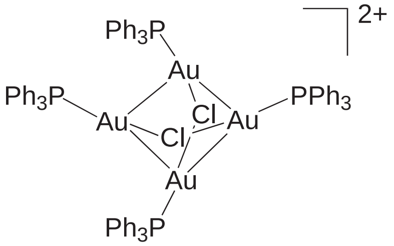
Halide anions can also act as single-atom bridges between two gold centers, these type of compounds can be achieved by reaction of [$AuX(PPh_3)$] with $AgBF_4$ (molar ratio 2:1) or by treatment of [$AuX(PPh_3)$] with $[Au(PPh_3)]^+A^-$ (A = ClO_4 or BF_4).[3061–3063] The structure of these compounds consists of the halide ligand bridging the two gold atoms that are located to a distance of 3.035 Å or 3.085 Å (two independent molecules) for the Cl (**572**) and 3.6477(1) Å for the Br species (**573**), the latter too large to be consider a bonding interaction.[3062,3063] In the SbF_6^- salt, the dinuclear chloronium cations undergo an intimate aggregation (**574**). This association is drastically affecting the structure of the monomeric units with a widening of the Au—Cl—Au angle and formation of more gold–gold interactions. The dimerization occurs against electrostatic repulsion, which appears to be offset by the gain in the number or aurophilic interactions (two vs. four).[3064]



(572)



(573)



(574)

Several crystal structure determinations of $[AuX_2]^-$ salts with different cations have been carried out for $[AuCl_2]^-$,[1823,1904,2854,3065–3068] $[AuBr_2]^-$,[3065,3069,3070] or $[AuI_2]^-$.[3065,3066,3071–3074] Many other structural determinations have been reported in which $[AuX_2]^-$ salts act as counterions of conducting or superconducting ion radical salts as bis-ethylenedithiotetrathiafulvalene (ET) and related organic donors.

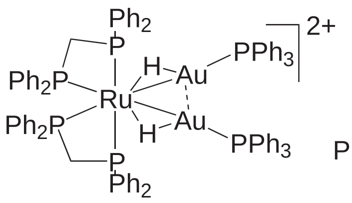
Historically, AuF has been one of the most elusive of all metal halides. At one time it was believed to be impossible to prepare, and theoretical papers speculating on how it might be observed or predicting spectroscopic and structural properties have been published until recently.[3075–3081] The existence of AuF has been confirmed by microwave spectroscopy, the sample has been prepared by laser ablation of Au metal in the presence of a F precursor.[3082] The gas-phase structure of AuI has also been determined by microwave spectroscopy.[3083]

6.7.3.4.8 Complexes with hydride donor ligands

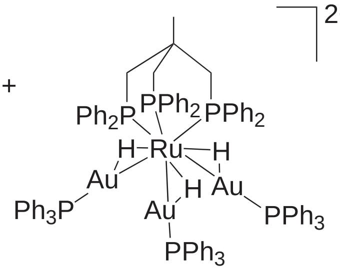
Gold hydrides have been desirable for a long time, a considerable number of theoretical studies have probed the structure of AuH by using density functional methods.[2518,3075,3077,3084–3086] It has been shown that the total charge on the Au-atom is reduced significantly from +0.48 to +0.27 by including relativistic effects. Recent ground-breaking solid-matrix investigations have provided the first experimental evidence for (H_2)AuH.[3087] The similar electronegativities of I and H has made a comparison between gold hydride and iodide compounds relevant.[3088]

Heteropolynuclear gold(I) complexes with bridging hydride ligands can be prepared by reacting the electrophilic fragment $AuPR_3^+$ and complexes with terminal M—H bonds or by reaction of metal hydrides with [$AuMe(PR_3)$]. Several examples of carbonyl–hydride ruthenium compounds react with gold–phosphine or gold–diphosphine fragments to give species with bridging hydride ligands such as [$Ru_4(CO)_{12}(\mu_3$-H)$(AuPPh_3)_3$],[3089,3090] [$Ru_4(CO)_{12}(\mu$-H)$(\mu_3$-H)$(AuPPh_3)_2$],[1540,1541] [$Ru_4(CO)_{12}(\mu$-H$)_2\{Au_2(\mu$-P-P)\}] (P-P = dppe, dppf),[3091,3092] and [$Ru_4(CO)_{12}H_3(AuPPh_3)$] has been found to be significantly more active and selective than [$Ru_4H_4(CO)_{12}$] for the catalytic isomerization of 1-pentene at 35 °C.[3093] Other complexes are derived of ruthenium phosphine species such as [$Ru(dppm)_2(\mu$-H$)_2(AuPPh_3)_2](NO_3)_2$ (**575**),[3094] [$Ru(dppm)_2(\mu$-H$)_2(AuPPh_3)]PF_6$,[3095]

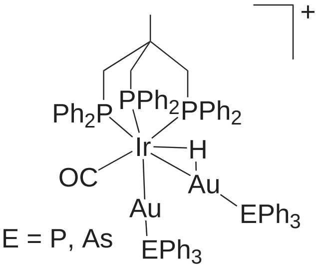
$[Ru(CO)(PPh_3)_3(\mu\text{-}H)_2(AuPPh_3)]PF_6$,[3096] $[Ru(PPh_3)_3(\mu\text{-}H)_3(AuPPh_3)_2]PF_6$,[3096] or $[Rutriphos(\mu\text{-}H)_3(AuPPh_3)_3](PF_6)_2$ (**576**).[3097] The complex $[Ru(CO)(PPh_3)_3(\mu\text{-}H)_2(AuPPh_3)]PF_6$ catalyzes the isomerization of 1-hexene to *cis*- and *trans*-2-hexene in CH_2Cl_2 at 25 °C and one atmosphere of N_2; the gold adduct increases the rate of the isomerization compared to the parent compound $[Ru(H)_2CO(PPh_3)_3]$ and is more selective towards producing *trans*-2-hexene.[3096] Gold–osmium compounds with bridging hydride ligands of the type $[Os(PPh_3)_3(\mu\text{-}H)_3(AuPPh_3)_2]$,[3096] $[Os_3(CO)_8(\mu\text{-dppm-P,P,C,C})H(AuPPh_3)]PF_6$,[3098] or $[Os_4H(CO)_{12}Au(PPh_2C{\equiv}CPPh_2)]_2$[3099] have also been obtained. The reaction of $[IrH(C_2H_4)(triphos)]$ or $[Ir(H)_2(C_2H_5)(triphos)]$ with two equivalents of $[AuCl(EPh_3)]$ in the presence of NH_4PF_6 affords the complexes $[IrCl(triphos)(\mu\text{-}H)(AuEPh_3)_2]PF_6$ ($E = P$, As) (**577**). The compound $[IrCl(triphos)(H)(AuEPh_3)]PF_6$ has a terminal hydride ligand in the solid state but bridging in solution.[3100] Similar rhodium derivatives $[Rh(triphos)(\mu\text{-}H)_2(AuPPh_3)_3](OTf)_2$[3101] or $[Rh(triphos)(\mu\text{-}H)(AuPPh_3)]BPh_4$[3102] have also been synthesized.



(**575**)

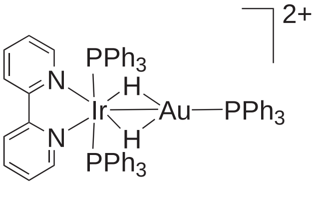


(**576**)

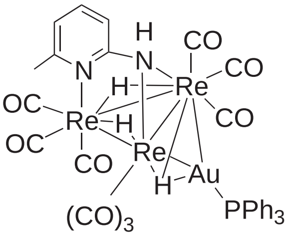


(**577**)

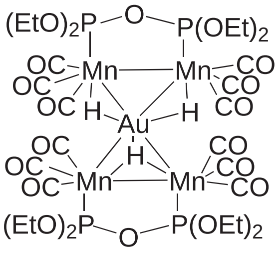
Replacement of hydride ligands for $AuPPh_3^+$ fragments has lead to the synthesis of the μ-H derivatives $[AuIr_3H_6(NO_3)(dppe)_3]BF_4$[3103] or $[Ir(PPh_3)_3(H)_2(\mu\text{-}H)(AuPPh_3)]$.[3104,3105] The reaction of $[Au(NO_3)(PPh_3)]$ with $[Ir(H)_2(PPh_3)_2(acetone)_2]BF_4$ at −78 °C gives the doubly hydrido-bridged adduct $[Ir(PPh_3)_2(acetone)_2(\mu\text{-}H)_2(AuPPh_3)]^{2+}$, but warming of the solution yields the mono-hydrido derivative $[Ir(PPh_3)_2(NO_3)(\mu\text{-}H)(AuPPh_3)_2]^+$.[3106] The doubled bridging hydrido complex $[Ir(bipy)(PPh_3)_2(\mu\text{-}H)_2(AuPPh_3)](BF_4)_2$ (**578**) has been synthesized by reaction of $[Ir(H)_2(bipy)(PPh_3)_2]$ with $[Au(NO_3)(PPh_3)]$.[3094] Mixed rhenium–gold derivatives with hydrido bridges have been prepared with phosphine as ligands in $[Re_2(H)_4(\mu\text{-}H)_2(PPh_3)_4(\mu\text{-}H)(AuPPh_3)]$,[3107] $[ReCl(CO)(PPhMe_2)(\mu\text{-}H)(AuPPh_3)]$,[1578] or with the trinuclear carbonyl clusters $[Re_3(CO)_9(\mu\text{-}H)_2(\mu\text{-MePyNH})(\mu_3\text{-}H)(AuPPh_3)]$ (**579**),[3108] or $[Re_3(CO)_8(PPh_3)(\mu\text{-}H)_3(\mu_3\text{-}H)(AuPPh_3)]$.[1577] The reaction of $[(PPh_3)_2N][MH(CO)_5]$ with $[AuCl(PPh_3)]$ in the presence of $TlPF_6$ gives the species $[M(CO)_5(\mu\text{-}H)(AuPPh_3)]$ ($M = Cr$, Mo, W); the structure of the chromium derivatives shows a bridging hydrido ligand with a Au—H distance of 1.72(11) Å.[1575,3109] Other metal carbonyl derivatives with bridging hydrido ligand are $[Mo_2(CO)_8(\mu\text{-dppm})(\mu_3\text{-}H)(\mu\text{-}AuPPh_3)]$,[3110] $[Mn_2(CO)_6(\mu\text{-dppm})(\mu_3\text{-}H)(\mu\text{-}AuPPh_3)_2]PF_6$,[3111] or $[\{Mn_2(CO)_6\{\mu\text{-}\{P(OEt_2)_2\}_2O\}(\mu\text{-}H)\}_2(\mu\text{-}H)_2(\mu_3\text{-}H)Au]$ (**580**).[3112]



(**578**)

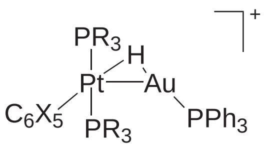


(**579**)



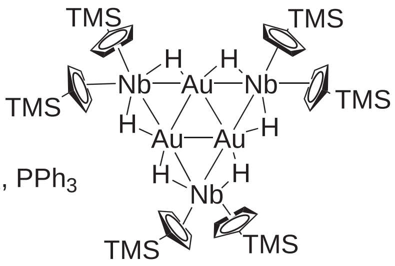
(**580**)

Platinum derivatives of the type $[PtH(C_6X_5)(PR_3)_2]$ react with gold phosphine species to yield $[Pt(C_6X_5)(PR_3)_2(\mu\text{-}H)(AuPPh_3)]^+$ (**581**) ($X = F$, Cl; $PR_3 = PEt_3$, PPh_3).[3113,3114] Gold–niobium clusters with bridging hydrido ligands have been obtained by reaction of $[NbH_3(C_5H_4TMS)_2]$ with $[Au\{N(TMS)_2\}(PPh_3)]$ which produces the triangular cluster $[Au_3Nb_3(\mu\text{-}H)_6\{C_5H_4(TMS)\}_3]$ (**582**),[3115,3116] or by treatment of $[NbH_3(C_5H_3R^1R^2)_2]$ with $[AuCl(THT)]$ in the presence of $TlPF_6$ which gives $[\{Nb(C_5H_3R^1R^2)_2H_3\}_2Au]PF_6$ (**583**) ($R^1 = H$, TMS; $R^2 = H$, TMS).[1365,3117]

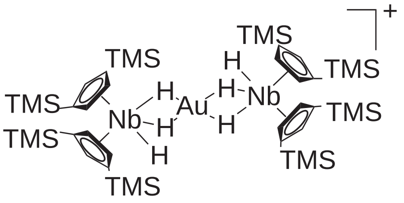


X = F, Cl; PR3 = PEt3, PPh3

(581)

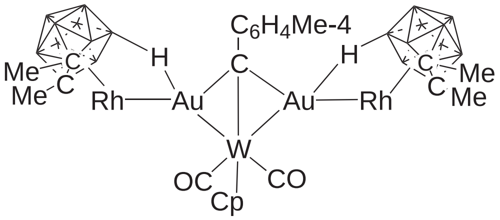


(582)

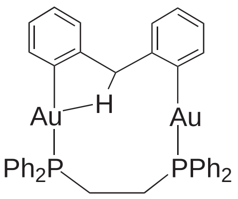


(583)

Nido-carborane metal complexes of ruthenium or rhodium also react with gold compounds to give bridging hydrido derivatives such as $[Ru(C_2B_9H_{11})(PPh_3)_2(\mu\text{-}H)(AuPPh_3)]$[3118] or $[Rh(C_2B_9H_9Me_2)(PPh_3)(\mu\text{-}H)(AuPPh_3)_2]$.[2043,2046] Other types of complexes with carborane ligands are those that have B—H—Au agostic interactions as $[Rh(C_2B_9H_9Me_2)\ (CO)_2(AuPPh_3)]$,[2277] $[WRh_2Au_2(\mu_3\text{-}CC_6H_4Me\text{-}4)(CO)_4Cp(C_2B_9H_9Me_2)_2]$ (**584**),[2277] $[WAu_2(\mu_3\text{-}CC_6H_4Me\text{-}4)(CO)_2\text{-}Cp(C_2B_9H_9Me_2)_2]$,[2051] or $[Au_2(C_2B_9H_9Me_2)_2(PPh_3)_2]$.[2045] This type of agostic interaction has also been postulated in some organometallic compounds such as $[Au_2\text{-}(\mu\text{-}C_6H_4CH_2C_6H_4)(PPh_3)_2]$[3119] or $[Au_2(\mu\text{-}C_6H_4CH_2C_6H_4)(\mu\text{-dppe})]$ (**585**).[3120,3121]



(584)



(585)

6.7.3.4.9 *Complexes with mixed donor ligands*

Triangular trigold(I) complexes of the type $[Au_3L_3]$, where L is a mixed donor ligand (Figure 24), have been known for over 20 years,[2355,2362,3122–3125] but it is only recently that some remarkable chemical reactivities and physical properties of these molecules have been recognized.

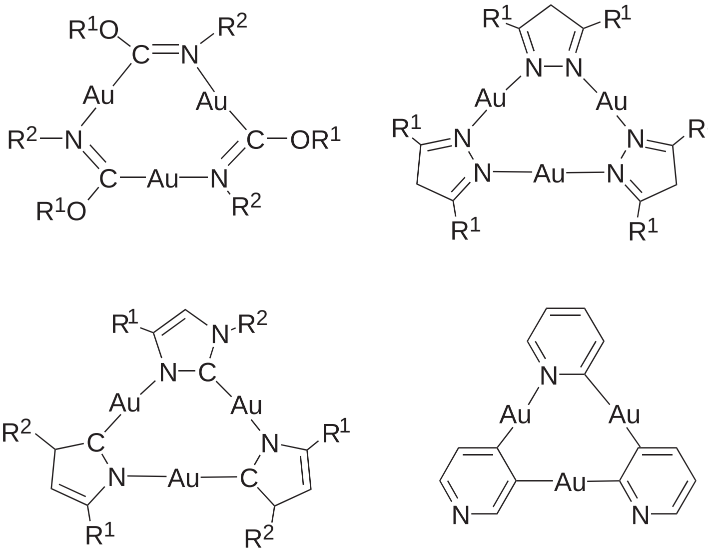


Figure 24 Triangular $[Au_3L_3]$ complexes.

The gold trimer $[Au_3(MeN{=}COMe)_3]$ displays the novel phenomenon termed solvoluminescence. After irradiation with near-UV light, crystals of this compound show a long-live photoluminescence that is readily detected by the human eye for tens of seconds after cessation of irradiation. Addition of dichloromethane of chloroform to these previously irradiated crystals produces a bright burst of light. For this phenomenon the solid-state structure is crucial and consists of individual molecules of Au_3L_3, which aggregate to form columnar stacks through Au···Au interactions. Then it is believed that energy storage involves charge separation within the solid, and this charge separation is facilitated by conduction of electrons along the columnar structure.[3126,3127] A similar complex $[Au_3(PhCH_2N{=}COMe)_3]$ does not associate into trigonal prismatic array but packs in a stair-step fashion with eight discrete molecules in the asymmetric unit. This compound does not display solvoluminiscence.[3128] Theoretical calculations of the complex $[Au_3(MeN{=}COR)_3]$ in gas phase and in chloroform solution have been carried out. The calculated structure and the vibrational frequency are in good agreement with the experimental results.[3129]

Charge-transfer adducts are formed with the gold(I) trimers $[Au_3(MeN{=}COR)_3]$ (R = Me, Et), which act as electron donors, and organic electron acceptors as nitro-9-fluorenes. The structures of these adducts involve mixed stacks in which the gold trimers and the planar nitro-fluorenes are interleaved.[3130] No luminescence has been observed from these solid charge-transfer adducts, which is not surprising since the luminescence of $[Au_3(MeN{=}COR)_3]$ is a property that is associated with the supramolecular organization in the solid.

The structure of the trimer $[Au_3(NC_5H_4)_3]$ has been studied and shows that individual molecules self-associate through aurophilic interactions into two distinct structural motifs that involve both extended chains of molecules connected by pairwise and individual Au···Au contacts, and discrete dimers linked by pairwise Au···Au interactions (Figure 25).[3131]

The reaction of [AuCl(THT)] with 2-(4′,5′-dihydro-4,4′-dimethyl-2′-oxazolinyl)-thien-*n*-yllthium ($n = 3, 5$) affords dimeric (**586**) or trimeric (**587**) gold(I) derivatives with mixed *N*,*C*-donor ligands.[2263] Other complexes with mixed N,C donor ligands which have been prepared in a similar manner are $[Au_2\{Fc(CH_2NMe_2\}_2]$,[2127] $[Au_2\{C_6H_4(CH_2NMe_2)\}_2]$,[3132] $[Au_2\{C_6H_3(CH_2NMe_2)_2\}_2]$,[1964] $[Au_2(\mu\text{-}2\text{-}C(TMS)_2\text{-}6\text{-}RPy)_2]$ (R = H, Me) (**588**),[644,1471,3133] or $[Au_2(\mu\text{-}2\text{-}CH_2\text{-}6\text{-}Py)_2]$.[347]

Complexes with mixed C,P or C,As donor ligands are derived of ortho-metalated phosphines or arsines or of methanide derivatives. The dinuclear complexes $[Au_2(C_6H_3\text{-}2\text{-}EPh_2\text{-}6\text{-}R)_2]$ (E = P (**589**), As; R = H, Me) are obtained by reaction of $2\text{-}EPh_2\text{-}6\text{-}R\text{-}C_6H_3Li$ with $[AuBr(PEt_3)]$ at −70 °C.[2002,2004,2006] The treatment of the dimer $[Au_2(C_6H_4PPh_2)_2]$ with methyltriflate yields, unexpectedly, $[Au_5(C_6H_4PPh_2)_4]^+$.[3134] The mixed dinuclear derivative $[Au_2(5\text{-}Me\text{-}C_6H_3\text{-}2\text{-}PPh_2)(S_2CNBu_2)]$ has also been obtained.[1834] The reaction of $[Au(C{\equiv}CBu^t)]$ with $(MeO)_2PCH_2\text{-}P(OMe)_2$ gives the complex $[Au_8Cl_2\{\mu_3\text{-}P(OMe)_2CHP(OMe)_2\}_2\{\mu_4\text{-}P(OMe)_2CP(OMe)_2\}_2]$, which has a μ_3- and a μ_4-PR_2CPR_2 ligand.[3135] The compound $[Au_4(\mu\text{-}CH_2SONMe_2)\{\mu_3\text{-}(PPh_2)_2CH\}\text{-}(\mu\text{-}dppm)]$ (**590**) has been obtained by treatment of $[Au_2Cl_2(\mu\text{-}dppm)]$ with $[Me_2S(O)NMe_2]BF_4$ under phase transfer catalysis conditions.[2626] The dinuclear $[Au_2\{(CH_2)_3PPh_2\}_2]$ (**591**) has been synthesized by reaction of [AuCl(CO)] with the zinc derivative $[Zn\{(CH_2)_3PPh_2\}_2]$.[2610]

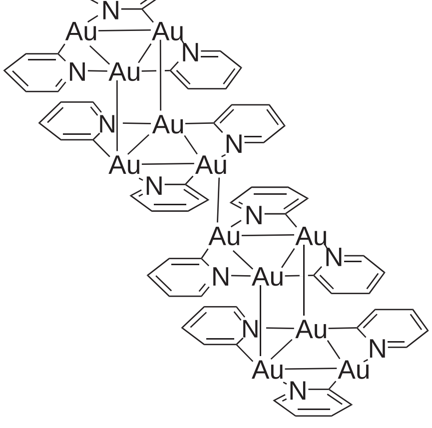

Figure 25 Structure of $[Au_3(NC_5H_4)_3]$.

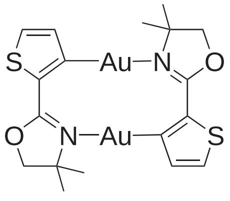
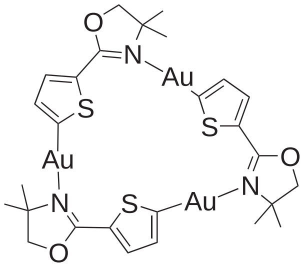
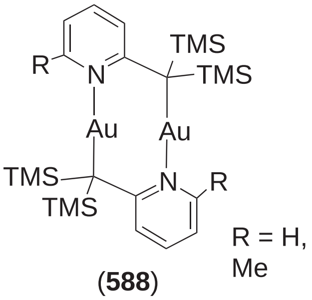


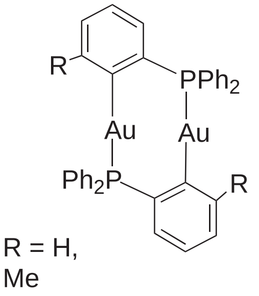
(586)



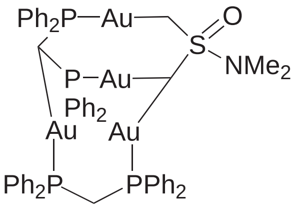
(587)



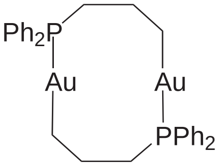
(588)



(589)

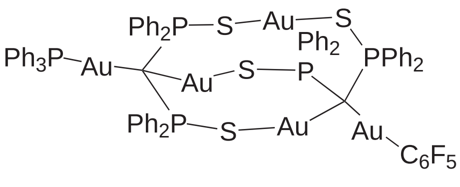


(590)

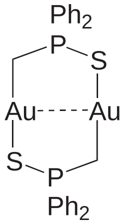


(591)

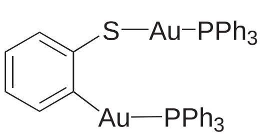
Complexes with C,S mixed donor ligands are also derived of methanide species and methalated thiolate ligands. The complexes $[Au_2(C_6F_5)_2(SPPh_2CHPPh_2Me)]$ or $[Au_2(SPPh_2CHPPh_2Me)_2](ClO_4)_2$ are obtained by reaction of the methanide ligand $SPPh_2CHPPh_2Me$ with the corresponding gold(I) precursor.[1471] Treatment of $[Au_2\{C(PPh_2S)_2\}(PPh_3)_2]$ with $[Au(C_6F_5)(THT)]$ gives the pentanuclear species $[Au_5(C_6F_5)\{(SPPh_2)_2C\}_2(PPh_3)]$ (**592**).[2161] Methylenethiophosphinate ligands have been used to synthesize dinuclear gold or gold/mercury compounds, which depending of the synthetic procedure species containing S—Au—C as in $[Au_2(CH_2PPh_2S)_2]$ (**593**) or S—Au—C/S—Hg—C or S—Au—S/C—Hg—C structural units are obtained.[1675,3136–3138] Also heterobimetallic Au/Tl, Au/Pb, and Au/Pt species have been obtained; these complexes are strongly luminescent which is associated to the presence of metal–metal interactions.[2009,3139] The treatment of 2-lithiobenzenethiolate with $[AuCl(PPh_3)]$ gives the complex $[Au_2(\mu\text{-}SC_6H_4)(PPh_3)_2]$ (**594**).[2809] Similarly the reaction of $[Mn\{C_5Cl_3(SLi)Li\}(CO)_3]$ with the $[AuCl(PPh_3)]$ yields $[Mn\{C_5Cl_3(SAuPPh_3)AuPPh_3\}(CO)_3]$.[2821]



(592)

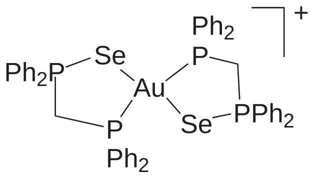


(593)

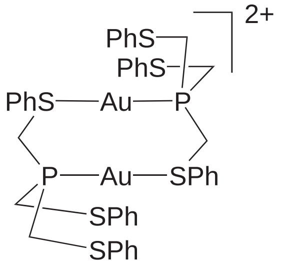


(594)

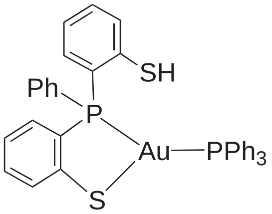
Gold(I) complexes with P,S (or Se) donor ligands are in many cases derived of phosphine sulfides or selenides as $[Au_2(PPh_2CH_2PPh_2Se)_2](ClO_4)_2$,[3140] and $[Au(PPh_2CH_2PPh_2Se)_2]^+$ (**595**),[1403,3141] $[Au_2(PPh_3)_2(\mu\text{-}SPPh_2Py)](BF_4)_2$,[1427] or phosphine thioethers such as $[Au_2(PPh_2CH_2SPh)_2]^{2+}$,[1396] and $[AuCl\{PPh_2(CH_2)_2SR\}]$ (R = β-cyclodextrin),[3142] $[Au_2\{(S\text{-}PhCH_2)_3P\}]^{2+}$ (**596**),[2516] or phosphine thiolates complexes as $[Au_2\{PEt_2(CH_2)_2S\}_2]$[3143] and $[Au(SC_6H_4PPhC_6H_4SH)(PPh_3)]$ (**597**).[1969] In the structure of $[Au(PPh_2CH_2PPh_2Se)_2]Cl$ the methylene protons of the phosphine act as hydrogen bond donor, with H···O distances as short as 2.20 Å, and also form C—H···Cl interactions.[1403] Other complexes with *P*,*S*-donor ligands are those with diorganophosphinothioformamido derivatives such as $[Au_2\{PR^1{}_2C(S)NR^2\}_2]$ (R^1 = Ph, Cy; R^2 = Ph, Me).[3144]



(**595**)

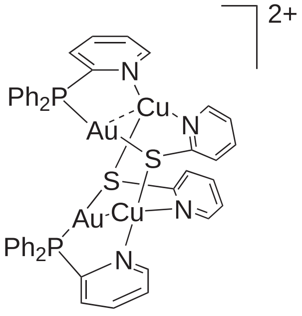


(**596**)

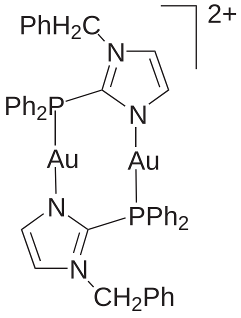


(**597**)

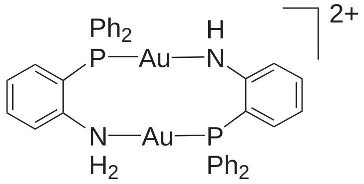
Difunctional ligands with *P*,*N*-donor centers as PPh_2Py, $PPh_2(Bzim)$ or $PPh_2C_6H_4NH_2$ have been used in gold(I) chemistry and compounds of the type $[Au_2(PPh_2Py)_2](BF_4)_2$,[1373] the polynuclear $[Au_2Cu_2(\mu\text{-}SPy)_2(\mu\text{-}PPh_2Py)_2](PF_6)_2$ (**598**), $[Au_2\{PPh_2(Bzim)\}_2]^{2+}$ (**599**),[1378,1379] the heterobridged $[Au_2\{PPh_2(Bzim)\}(P\text{-}P)]^{2+}$ (L-L = dppm, dppe, dppp),[3145] $[Au_2(PPh_2C_6H_4NH_2)_2](ClO_4)_2$ (**600**),[3146] or $[Au_6(PPh_2C_6H_4N)_2(PPh_3)_4](ClO_4)_2$[2487] have been synthesized. The reaction of $[Au_2(PPh_2C_6H_4NH_2)_2](ClO_4)_2$ with $AgClO_4$ in acetone leads to the compound $[Au_2(PPh_2C_6H_4N{=}CMe_2)_2](ClO_4)_2$.[3146] Also the mixed gold–silver derivative $[AuAg(PPh_2C_6H_4NH_2)_2](ClO_4)_2$ has been synthesized.[3146]



(**598**)

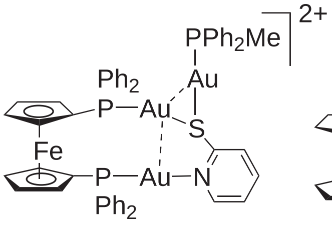


(**599**)

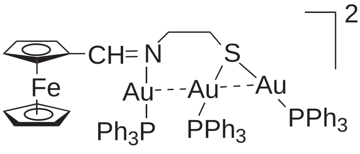


(**600**)

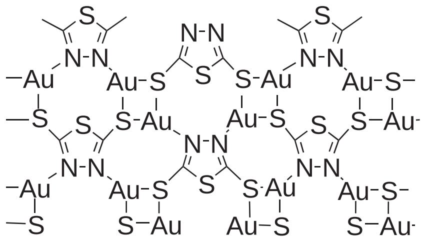
Gold(I) complexes with mixed *S*,*N*-donor ligands are mostly derived of thiolate ligands. The dinuclear luminescent complex with the ligand 4,6-dimethylpyrimidinethiolate, $[Au_2(4,6\text{-}Me_2pym\text{-}2\text{-}S)_2]$, crystallized as two independent dimers with short Au···Au distances, these planar dimers stack along the *a*-axis with pyridine moieties in adjacent molecules overlapping.[3147] Pyridinethiolate PyS^- can act as triply bridging ligand in $[Au_3(\mu_3\text{-}SPy)(\mu\text{-}dppf)(PPh_3)](OTf)_2$ (**601**).[2578] The ligand $FcCH{=}N(CH_2)_2S^-$ also acts as a triply or quadruply bridging ligand in $[Au_3\{S(CH_2)_2N{=}CHFc\}(PPh_3)_3](OTf)_2$ (**602**) or $[Au_4\{S(CH_2)_2N{=}CHFc\}(PPh_3)_4]\ (OTf)_3$.[2816] A similar ligand $NH_2(CH_2)_2SH$ can be polyaurated to yield the compound $[(Ph_2PAu)_3N(CH_2)_2\text{-}S(AuPPh_3)_2](BF_4)_2$.[2957] The complex $[Au_2(CNBu^t)_2(\mu\text{-}S_3C_2N_2)]$ looses the isocyanide ligands to give a polymeric material with a "knitted" network structure (**603**).[3148]



(**601**)

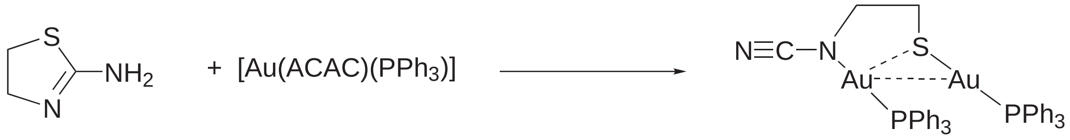


(**602**)



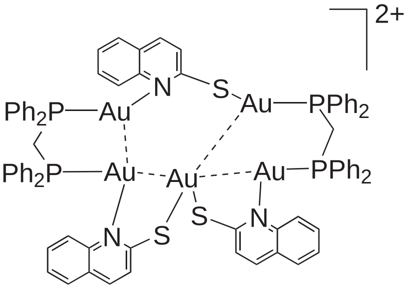
(**603**)

The treatment of 2-amino-4,5-dihydrothiazole with [Au(ACAC)(PPh_3)] evolves to an unprecedented ring-opening reaction to give the new ligand (2-cyanamide)ethylthiolate, stabilized as the dinuclear gold complex (Equation (42)).[2315]

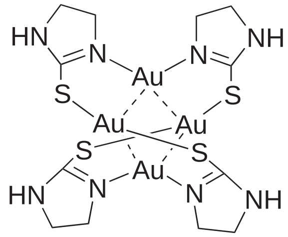


(42)

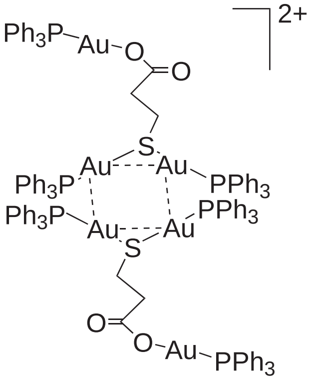
Other complexes with bridging N,S ligands are the 1,3-dimethyl-8-thioxantine derivative [$Au_2(\mu$-N,S){μ-$PMe_2(CH_2)_2PMe_2$}],[3149] or with quinoline thiolates [$Au_5(\mu$-SQuin$)_3(\mu$-dppm$)_2]^{2+}$ (**604**),[3150] deprotonated ethylenethiourea [Au_4(etu-H$)_4$] (**605**),[3151] or with 2-methoxyphenylimino(2-pyridyl)methylthio derivatives as [Au{SC(Py)=NR} (PPh_3)].[3152]



(604)



(605)



(606)

Gold(I) complexes with S,O mixed donor ligands such as [$(Ph_3PAu)_2S(CH_2)_nCOOAuPPh_3]BF_4$ ($n = 2$ (**606**), 3),[2828] or [$(Ph_3PAu)_2SCH(COOAuPPh_3)CH_2COOAuPPh_3]BF_4$ have been obtained.[2829] The compound [$Au_2(\mu$-$C_9H_6NO)(PPh_3)_2]BF_4$ with the quinolyl group interacting N,O with the gold atoms has been described.[2735] A dimeric gold(I) complex with a mixed Se,S thioselonolate ligand has been synthesized, [Au_2{SeSC=C(CN$)_2$}$_2]^{2-}$.[2966]

6.7.3.4.10 *Gold(I) complexes with Au^I—M bonds*

Heteronuclear compounds containing gold(I) and other metal atoms which present $Au^I\cdots M$ interactions are well represented in the area of metal carbonyl clusters. The addition of a $AuPR_3^+$ or $Au_2(\mu$-P-P$)^{2+}$ fragment to a metal cluster results in the formation of Au—M bonds often with retention of the cluster framework. Several reviews have been reported recently,[3153–3155] and so it will not be treated here. Some representative examples are found in Figure 26.

$Au^I\cdots Ag^I$ or $Au^I\cdots Tl^I$ interactions are present in polynuclear complexes with bridging ligands, many of these compounds have been seen in other sections and then will not be included here. The reaction of basic/donor gold(I) complexes with acid/acceptor complexes gives acid–basic or acceptor–donor derivatives. Thus, the treatment of the aurate(I) salts $[AuR_2]^-$ with Ag^+, in the presence of a ligand L, affords yellow or orange polymers of the type [$R_2Au(\mu$-AgL$)_2AuR_2]_n$ (**607**). They are available for a great variety of oxygen, nitrogen, sulfur, phosphorus, or carbon donor ligands and being $R = C_6F_5$, $C_6F_3H_2$, C_6Cl_5.[3163–3165] The structure consists of a rhomboidal arrangement of the four metallic centers, these units are further connected through aurophilic interactions. These complexes are only soluble in coordinating solvents. They lose the color in solution, which is related to cleavage of the gold–gold bonds. The optical properties of some of these derivatives have been studied and they are related to the $Au^I\cdots Au^I$ interactions. The absorption and emission spectra of [$(C_6F_5)_2Au(\mu$-$AgOCMe_2)_2Au(C_6F_5)_2]_n$ in acetone are consistent with molecular aggregation through gold–gold interactions when going from dilute to concentrated solutions.[3166] It is also luminescent in the solid state. The polymeric chain containing the dinuclear

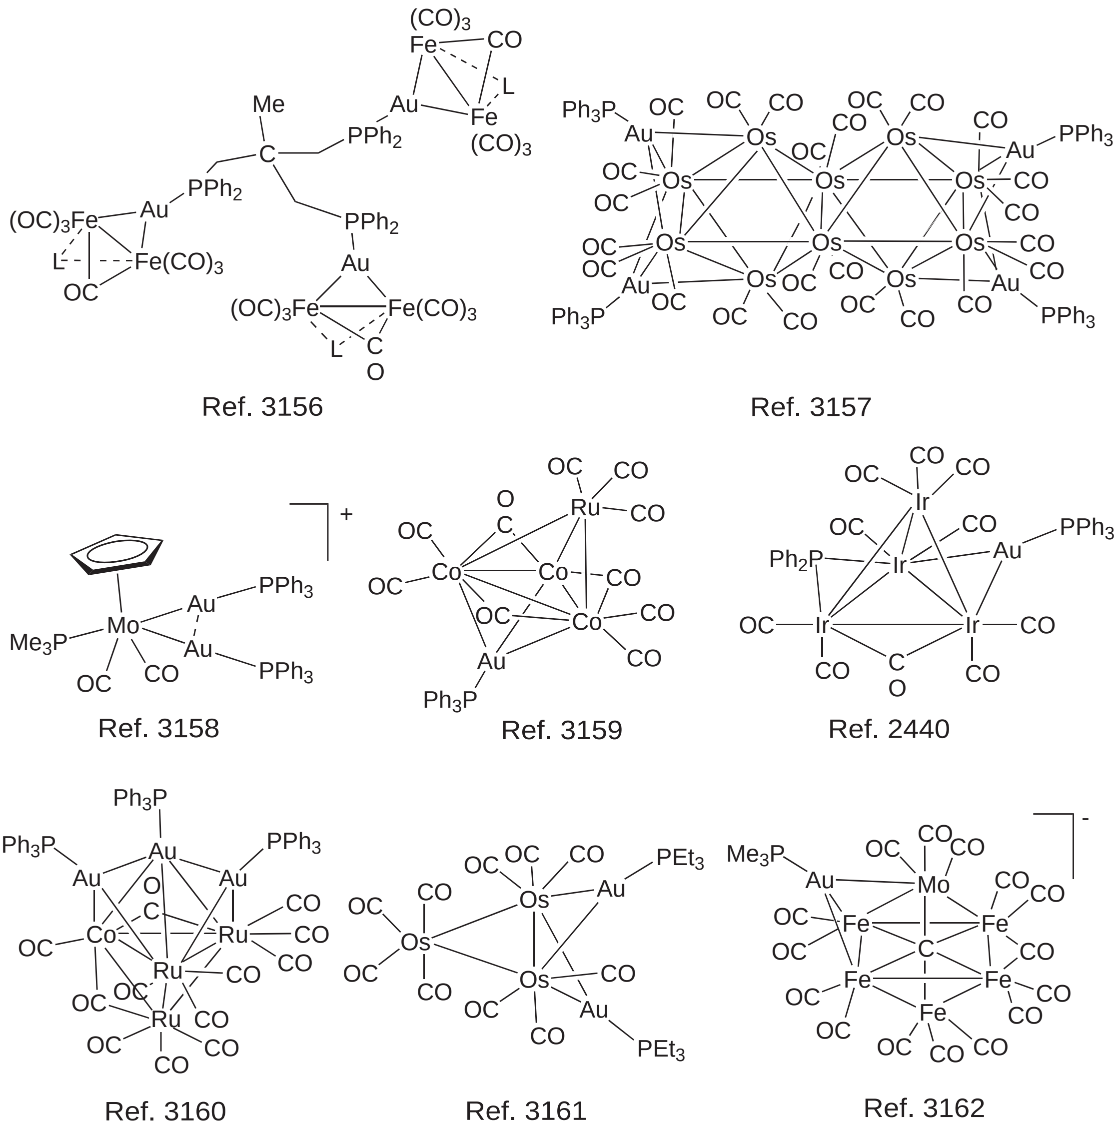


Figure 26 Some examples of carbonyl metal clusters with Au(I)-M bonds.

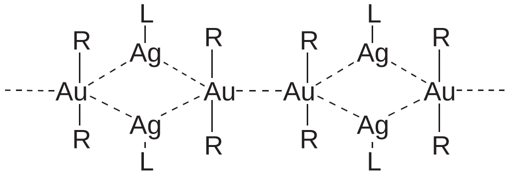
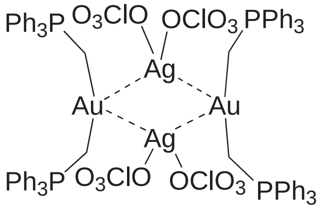
moiety $[Ag(Py)_3][Au(C_6F_5)_2]Py$, instead of the tetranuclear one, has been obtained by the same procedure.[3167] Formation of a chain can be avoided by using bulky ligands at the gold centers, which prevents further aggregation through aurophilic interactions. This has been possible with ylide ligands, and the compounds $[(R_3PCH_2)_2Au(\mu\text{-}AgL)_2Au(CH_2PR_3)_2]$ (**608**) ($PR_3 = PPh_3$, PPh_2Me, $PPhMe_2$; $L = OClO_3$, PPh_3) have been reported.[3168]

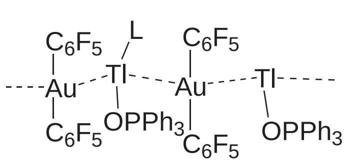


(**607**)

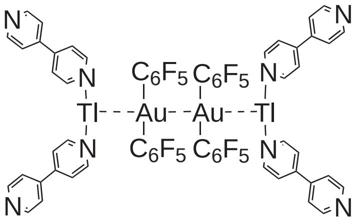


(**608**)

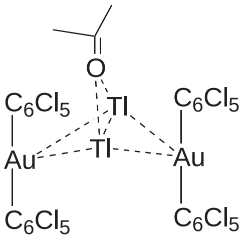
The electron rich aurate $[Au(C_6F_5)_2]^-$ also reacts with thallium salts in the presence of a ligand to give extended unsupported gold–thallium linear chain derivatives. The first example synthesized was [Tl(OPPh$_3$)$_2$][Au(C$_6$F$_5$)$_2$].[3169] Another derivative is [Tl(OPPh$_3$)][Tl(OPPh$_3$)-L][Au(C$_6$F$_5$)$_2$]$_2$ (**609**) (L = THF, acetone),[3170] in which the thallium centers show two different types of geometrical environments. These compounds also show a luminescent behavior. TD-DFT (density functional level using the time-dependent perturbation theory approach) calculations are in agreement with the experimental excitation spectra and confirm the qualitative explanation that the excitation has AuR$_2$ → Tl charge-transfer character, whereby the thallium centers act as fluorophores. Tetranuclear derivatives such as [Tl(bipy)]$_2$[Au(C$_6$F$_5$)$_2$]$_2$ (**610**) and [Tl(bipy)][Tl(bipy)$_{0.5}$(THF)][Au(C$_6$Cl$_5$)$_2$]$_2$ have been achieved using 4,4-bipyridine as auxiliary ligand.[3171] In the first case an Tl—Au—Au—Tl linear chain is formed and this unit is connected with others through bidentate bipyridine ligands forming a 2D array. Further Tl—F contacts form an infinite 3D network. The second example display a Tl—Au—Tl′—Au arrangement with bridging bipyridine ligands that form a 2D polymer. If in the reaction of [Au(C$_6$Cl$_5$)$_2$]$^-$ with Tl$^+$ no ligand is added, except the solvent, the compound [Au$_2$Tl$_2$(C$_6$Cl$_5$)$_4$](OCMe$_2$) is obtained. The structure consists of a butterfly tetranuclear unit with four unsupported gold–thallium interactions and a long Tl···Tl contact (**611**).[3172]



(609)



(610)



(611)

The trinuclear complexes [Au$_3$(p-MeC$_6$H$_4$N = OEt)$_3$] and [Au$_3$(Bzim)$_3$] (Bzim = 1-benzylimidazolate), which are colorless, can produce brightly colored materials by sandwiching naked Ag$^+$ or Tl$^+$ ions form linear-chain complexes (Figure 27) with luminescence properties as luminescence thermochromism.[3173,3174]

The reaction of these trimer derivatives with the π molecular acid trinuclear Hg^{II} complex [Hg$_3$(μ-C$_6$H$_4$)$_3$] produces a compound with acid–base stacking among the planar molecules (Figure 28).[3175]

Other gold(I) complexes with Au^I—C bonds, such as [Au$_2$(CH$_2$TMS)$_2$(μ-dppm)] or [Au$_5$(Mes)$_5$], react with naked Ag$^+$ to give complexes with unsupported gold(I)–silver(I) bonds, such as [{Au$_2$(CH$_2$TMS)$_2$(μ-dppm)}$_2$Ag]OTf (**612**)[3176] or [Au$_6$Ag(μ-Mes)$_6$]OTf (**613**).[3177] The compound [Au$_2${μ-C(PPh$_3$)Py}(PPh$_3$)$_2$]ClO$_4$ reacts with AgNO$_3$ to give [Au$_2$(μ-AgNO$_3$){μ-C(PPh$_3$)Py}(PPh$_3$)$_2$]ClO$_4$ (**614**) in which the silver(I) is bonded to the gold centers and the nitrogen of the pyridine group.[3178]

Au—Pt bonds have been described in several complexes, such as the isocyanide compounds [{Pt(CNC$_6$H$_3$Me$_2$-2,6)$_2$(PPh$_3$)}$_2$(μ-AuPPh$_3$)$_2$](PF$_6$)$_2$ (**615**),[3179,3180] or [{Pt(μ-CNC(Me$_2$)$_2$) C$_6$H$_4$C(Me$_2$)(PPh$_3$)}$_2$(μ-AuPPh$_3$)$_2$](PF$_6$)$_2$.[3181] Triangular platinum clusters easily add gold(I) phosphine fragments to give complexes such as [Pt$_3$Au(PR$_3$)$_4$(μ-CO)$_3$]$^+$ (PR$_3$ = PCy$_3$ (**616**), PPh$_3$),[3182,3183] [Pt$_3$Au(PCy$_3$)$_4$(μ-CO)$_2$(μ-SO$_2$)]PF$_6$,[3184] [Pt$_3$Au(PCy$_3$)$_3$(PC$_6$H$_4$F-4)(μ-Cl)(μ-SO$_2$)$_2$],[3184] [Pt$_3$Au$_2$

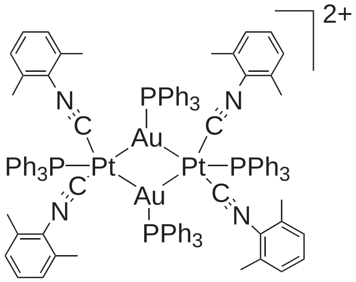
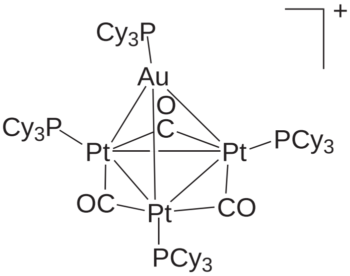
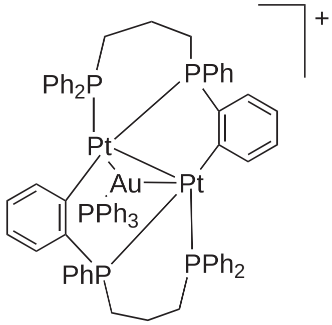
(PCy$_3$)$_3$(PC$_6$H$_4$F-4)$_2$(μ-Cl)(μ-SO$_2$)$_2$]PF$_6$,[3185] [{Pt$_3$(PPh$_3$)$_4$(μ-CO)$_3$}$_2$Au]PF$_6$,[3186] [Pt$_3$Au(PCy$_3$)$_4$-(μ-CO)(μ-CNR)$_2$]PF$_6$,[3187] [Pt$_6$Au$_2$(μ-CO)$_6$(μ-dppm)$_3$(PPr$^i_3$)$_2$](PF$_6$)$_2$,[3188] [{Pt$_3$(PCy$_3$)$_4$(μ-CO)$_3$}$_2${μ-Au$_2$ (PPh$_2$CH$_2$C$_6$H$_4$CH$_2$PPh$_2$)}]$^+$,[3189] [Pt$_3$(μ_3-S)(AuPPh$_3$)(μ-AgCl)(μ-dppm)$_3$]$^+$,[3190] [Pt$_3$(μ-dppm)$_3$ (AuPPh$_3$)]PF$_6$,[3191] [Pt$_3$(μ-dppm)$_3$(AuPMe$_3$)$_2$]PF$_6$,[3192] or [Pt$_2$Au(CNR)$_2$(μ-SO$_2$)(PCy$_3$)$_3$]PF$_6$.[3193] Dinuclear compounds with bridging diphosphines also give unsupported Au—Pt bonds, as in [Pt$_2$R$_2$(μ-dppm)$_2$(μ-AuX)] (R = C≡CBu^t, CN; X = I, Cl),[3194–3196] or [Pt$_2${PPh$_2$(CH$_2$)$_3$P(Ph) C$_6$H$_4$}$_2$(μ-AuPPh$_3$)]BF$_4$ (**617**).[3197] Platinum(0) phosphine complexes with Au—Pt bonds are [(Ph$_3$P)$_3$PtAu(PPh$_3$)]BF$_4$,[2726] [PtCl(PEt$_3$)$_2$(AuPPh$_3$)$_2$]OTf,[3198] or [Pt(NO$_3$)(PPh$_3$)$_2$(AuPPh$_3$)$_2$] PF$_6$.[3199] Mixed metal derivatives with bridging phosphide ligands form complexes with Au—Pt—M bonds as in [Pt(CO)(PCy$_2$H)(μ-PCy$_2$)(μ-AuPPh$_3$)WCp(CO)$_2$]PF$_6$[3200] or [WCp(CO)$_2$-(μ-PPh$_2$)(μ-CO)Pt (μ-PPh$_2$)(μ-AuPPh$_3$)WCp(CO)]PF$_6$.[3201] The reaction of the electron-rich [PtMe$_2$ (bipy)] with [AuX(PPh$_3$)] gives the complex [PtMe$_2$(bipy)(AuPPh$_3$)]X, with an unsupported Pt—Au bond.[3202] The compound [Pd$_3$Au(PPh$_3$)$_4$(μ-N$_3$)(μ-SO$_2$)$_2$] is one example of Au—Pd bond.[3203]



(**615**)



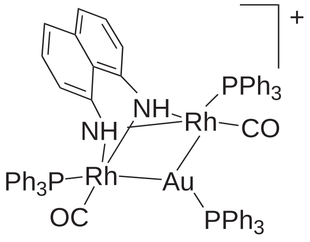
(**616**)



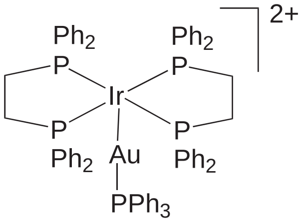
(**617**)

Carborane platinum or iridium compounds form M—Au bonds in their reaction with gold(I) phosphine complexes, as in $[Pt(CB_{10}H_{11})(PEt_3)_2(AuPPh_3)]$[3204] or $[Ir(C_2B_9H_9Me_2)(CO)(PPh_3)(AuPPh_3)]$.[2047]

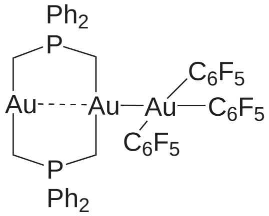
Complexes with Au—Rh or Au—Ir bonds have also been described such as $[Rh_2Cp_2(\mu\text{-dppm})(\mu\text{-CO})(AuPPh_3)]BF_4$,[3205] $[Rh_2(CNC_6H_3Me_2\text{-}2,6)_4(\mu\text{-Cl})_2(\mu\text{-AuPPh}_3)]PF_6$,[3206] $[Rh_2(CO)_2(PPh_3)_2\{\mu\text{-}1,8\text{-}(NH)_2C_{10}H_6\}(\mu\text{-AuPPh}_3)]^+$ (**618**),[1472] $[Ir(dppe)_2(AuPPh_3)](BF_4)_2$ (**619**),[3207] $[IrH(CO)(PPh_3)_3(AuPPh_3)]PF_6$,[3208] $[Ir_2(dimen)_4(PPh_3)(AuPPh_3)](PF_6)_3$[1592] or $[Ir_3(indenyl)_3(CO)_3(\mu\text{-AuPPh}_3)]\ PF_6$.[3209]



(**618**)



(**619**)



(**620**)

An example of a complex with a formal Au^I—Au^{III} bond is $[\{Au_2\{\mu\text{-}(CH_2)_2PPh_2\}_2Au(C_6F_5)_3]$ (**620**), which has been obtained by reaction of $[Au_2\{\mu\text{-}(CH_2)_2PPh_2\}_2]$ with $[Au(C_6F_5)_3(OEt_2)]$.[3210]

6.7.3.5 Gold Clusters

There is an important class of gold compounds in which the formal oxidation state is intermediate between 0 and +1. They can be homo- or heteronuclear compounds, for which excellent reviews have been published recently.[3153–3155,3211]

6.7.3.5.1 Homonuclear clusters

Several synthetic methods have been employed in the preparation of gold clusters compounds. Three main routes can be distinguished:

(i) Reaction of a suitable gold(I) precursor as $[AuX(PR_3)]$ ($X = $ halide, SCN, NO_3) with a reducing agent, such as $NaBH_4$, $Ti(\mu\text{-}C_6H_5Me)_2$, or CO, or even by photolysis of gold(I) azides. A representative example is given in Equation (43).[3212] Also a gold(III) precursor can be used, as in the reaction of $HAuCl_4$ with $NaBH_4$, that in the presence of PPh_3 gives the high nuclearity cluster $[Au_{39}Cl_6(PPh_3)_{14}]Cl_2$.[45]

(ii) Treatment of gold vapor in the presence of phosphine ligands as the example shown in Equation (44).[3213]

(iii) Reactions of gold clusters with other ligands or metal complexes. These types of reactions can progress with or without change in the metal skeleton. The first ones can be accompanied with an increase or decrease in the nuclearity, as exemplified in Equations (45) and (46):[3214,3215]

$$[Au(NO_3)(PPh_3)] + NaBH_4 \longrightarrow [Au_9(PPh_3)_8](NO_3)_3 \tag{43}$$

$$Au(g) + dppm \longrightarrow [Au_5(dppm\text{-}H)(dppm)_3](NO_3)_2 \tag{44}$$

$$[Au_9(PPh_3)_8]^{3+} + Bu_4NI \longrightarrow [Au_8I(PPh_3)_6]^+ \tag{45}$$

$$[Au_9(PPh_3)_8]^{3+} + 3\,[Au(C_6F_5)_2]^- \longrightarrow [Au_{10}(C_6F_5)_4(PPh_3)_5] \tag{46}$$

Other reactions where the cluster core remains intact are based on nucleophilic addition, elimination, and substitution reactions, as well as electrochemical interconversions. Some examples are given in Equations (47) and (48):[2714,3216]

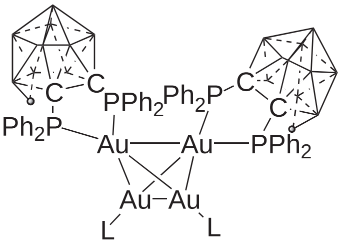
$$[Au_8(PPh_3)_6]^{2+} + 2\ PPh_3 \longrightarrow [Au_8(PPh_3)_8]^{2+} \quad (47)$$

$$[Au_4I_2(PPh_3)_4] + dppm \longrightarrow [Au_4I_2(dppm)_3] \quad (48)$$

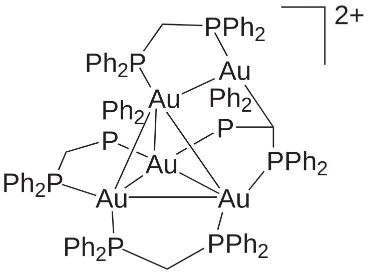
The nuclearity of structurally characterized homonuclear clusters goes from four to 39. The preparation of $[Au_{55}Cl_6(PPh_3)_{12}]$ from the reduction of $[AuCl(PPh_3)]$ with B_2H_6 has also been reported.[46,3217]

The bonding in gold cluster molecules has been interpreted using free electron models which are based on Stone's tensor surface harmonic theory.[3218–3220] High similarity has been found between alkali metals and gold in the spectra of molecular orbitals when they form clusters, and the primary bonding and antibonding interactions result from the overlap of the *s* valence orbitals.[3221,3222] For gold the 5*d*-orbitals are core-like and only hybridize slightly with the 6*s*, where the 6*p* valence orbitals are too high-lying to contribute significantly to the bonding. The geometries have been classified as (i) spherical polyhedral clusters characterized by a total of $12n+8$ valence electrons (n is the number of peripheral gold atoms), and (ii) toroidal or elliptical polyhedral clusters characterized by a total of $12n+6$ valence electrons.[109]

Tetranuclear clusters have been described and are of the type $[Au_4(PR_3)_4]^{2+}$ ($PR_3 = PMes_3$, $PBu^t{}_3$),[2714,3223] $[Au_4(\mu\text{-}X)_2(PPh_3)_4]$ ($X = I$, $SNCl_3$),[3224,3225] $[Au_4I(\mu_3\text{-}I)(dppm)_3]$,[3216] and $[Au_4\{(PPh_2)_2C_2B_9H_{10}\}_2L_2]$ (**621**) ($L = AsPh_3$, PPh_3, $P(4\text{-}MeC_6H_4)_3$, $P(4\text{-}OMeC_6H_4)_3$).[2704,3226] The structure corresponds to a tetrahedron of metal atoms. The compounds with the carborane diphosphine present a luminescent behavior. Theoretical calculations of the empty $[Au_4(PH_3)_4]^{2+}$ reproduce the experimental Au—Au distance in $[Au_4(PBu^t)_4]^{2+}$ and suggest that covalent and correlation bonding in this two electron, four center system are comparable.[3227]



(621)



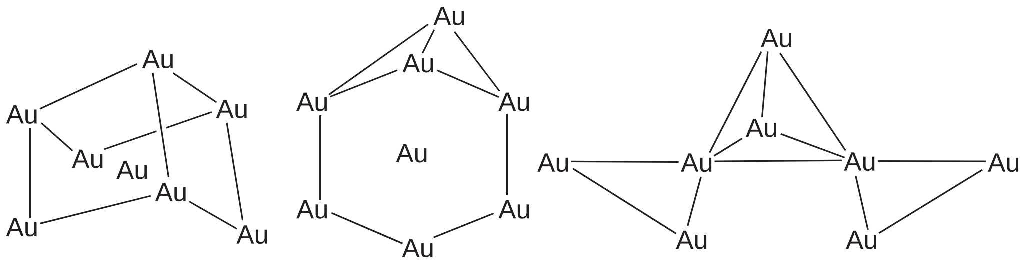
(622)

There is only one example of a pentanuclear cluster, namely $[Au_5(dppm)_3(dppm\text{-}H)](NO_3)_2$ (**622**), where the metal core adopts a spiked-tetrahedral geometry of gold atoms.[3213]

Several hexanuclear gold clusters have been prepared and are of the type $[Au_6(PR_3)_6]^{2+}$ (**623**) ($PR_3 = PPh_3$, $PPh(C_6H_4Me\text{-}2$, PPh_2Cy),[3228,3229] $[Au_6(dppp)_4]^{2+}$,[3230] or $[(H_{12}B_{10}Au)(\mu\text{-}AuPEt_3)_4(AuB_{10}H_{12})]$ (**624**).[2052] The geometry, although could be expected to be octahedral, consist of two edge-sharing tetrahedra. An octahedral cluster originally formulated as $[Au_6(PTol_3)_6]^{2+}$ was subsequently found to have an intersticial carbon atom.[2,3231] The compound $[(H_{12}B_{10}Au)(\mu\text{-}AuPEt_3)_4(AuB_{10}H_{12})]$ has an unusual structure. Only the heptanuclear gold cluster $[Au_7(PPh_3)_7]OH$ (**625**) has been prepared by evaporation of gold into a toluene solution containing PPh_3. The structure corresponds to a distorted pentagonal bipyramid, with the axial Au—Au bond being the shortest at 2.584(1) Å.[3214,3232]

Several octanuclear gold cluster have been characterized and are of the type $[Au_8(PPh_3)_8]^{2+}$,[3233,3234] $[Au_8(PPh_3)_7]^{2+}$,[3235] or $[Au_8(PMes_3)_6]^{2+}$.[2714] The structural skeletons for these compounds are different and are shown in Figure 29.

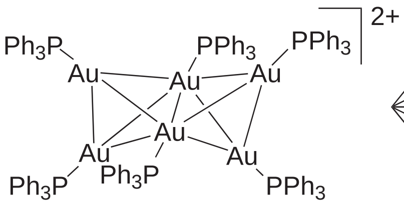
The majority of nonanuclear clusters have the stoichiometry $[Au_9(PR_3)_8]^{3+}$, they have been characterized structurally for the phosphine ligands $P(C_6H_4Me\text{-}4)_3$[3212] and $P(C_6H_4OMe\text{-}4)_3$[3236,3237] with different anions. It has been found that small changes result in large changes in the structure of the metal core, indicating small energy barriers between the different structural forms. Also pressure can induced skeletal isomerization of $[Au_9(PPh_3)_8](PF_6)_3$ in the solid state.[3238] The



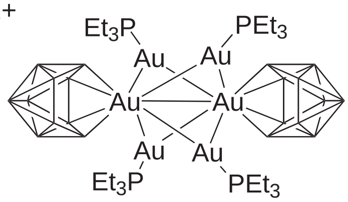
$[Au_8(PPh_3)_8]^{2+}$ $[Au_8(PPh_3)_7]^{2+}$ $[Au_8(PMes_3)_6]^{2+}$

Figure 29 Structures of Au_8 clusters.

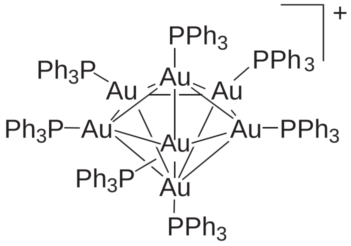
electrochemical behavior of these clusters has been studied and can be reduced in two consecutive one-electron step to give $[Au_9(PR_3)_8]^{2+}$ and $[Au_9(PR_3)_8]^{+}$.[3239,3240] The cluster $[Au_9(SCN)_3(PCy_3)_5]$ has also been obtained.[3241] The two different structural forms for nonanuclear clusters are shown in Figure 30.



(623)



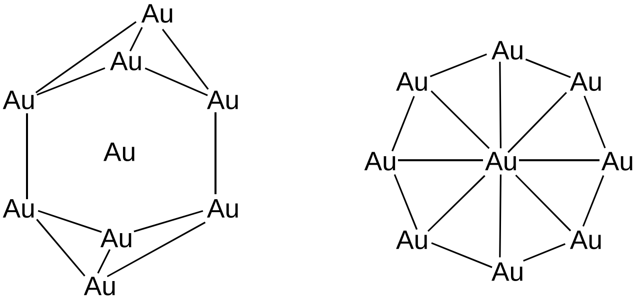
(624)



(625)

Decanuclear gold clusters have a structure derived of three trigonal bipyramidal Au_5 clusters sharing a common central atom and edge sharing (Figure 31a). They can be neutral as $[Au_{10}\{S_2C_2(\text{-}CN)_2\}_2(PPh_3)_7]$ or $[Au_{10}(C_6F_5)_4(PPh_3)_5]$,[3215] or cationic as $[Au_{10}Cl_3(PPhCy_2)_6]NO_3$.[3243] Other types of decanuclear gold clusters are those obtained by photolysis of a mixture of $[AuCl(PPh_3)]$ and $[AuN_3(PPh_3)]$ in the presence of $Na_2[VCp(CO_3)]$ or $Cr(CO)_6$. They have the stoichiometry $[Au(AuX)(AuPPh_3)_8]^{+}$ ($X = Cl$, NCO), and the structure consists of a centered square antiprism of nine Au atoms with one square face of the antiprism bridged by the AuX group (Figure 31b).[3244,3245]

Several undecagold clusters have been characterized by XRD, such as $[Au_{11}I_3(PR_3)_7]$ ($PR_3 = PPh_3$, C_6H_4F-4, C_6H_4Cl-4),[3233,3246,3247] $[Au_{11}(SCN)_3(dppm)_5]$,[3248] $[Au_{11}I(CNPr^i)_2(PPh_3)_7](PF_6)_2$,[3249] and $[Au_{11}(PPh_2Me)_{10}]^{3-}$.[3250] The structure of the mixed-ligands clusters corresponds to a C_{3v} metal skeletal framework and the homoleptic to a centered bicapped square antiprism (Figure 32). Other stoichiometries are known as, for example, $[Au_{11}Cl_2(PPh_3)_8]Cl$.[3251]



$[Au_9\{P(C_6H_4Me\text{-}4)_3\}_8]^{3+}$ $[Au_9\{P(C_6H_4OMe\text{-}4)_3\}_8]^{3+}$

$[Au_{11}I_3\{P(C_6H_4F\text{-}4)_3\}_7]$ $[Au_{11}(PPh_2Me)_{10}]^{3+}$

Figure 32 Structures of Au_{11} clusters.

Gold(I) compounds $[AuX(PPh_3)]$, where X is a weak coordinated ligand such as NO_3^-, ClO_4^-, BF_4^-, or OAc^-, react with CO to form clusters $[Au_9(PPh_3)_8]X_3$; if the solvent is dichloromethane fulminate, $[Au(CNO)(PPh_3)]$, and $[Au_{11}(CNO)_2(PPh_3)_8]^+$ are obtained.[3252]

The structure of the tredecanuclear cluster $[Au_{13}Cl_2(PPhMe_2)_{10}](PF_6)_3$ corresponds to a centered icosahedron of gold atoms (Figure 33).[3253] A similar structure, although with disorder, seems to have $[Au_{13}(dppm)_6](NO_3)_4$.[3254] Recently the cluster $[Au_{16}Cl_6(AsPh_3)_8]$ has been prepared by reduction of $[AuCl(AsPh_3)]$ with $NaBH_4$, and the structure is derived of a centered icosahedron of which one of the corners binds to three additional Au-atoms forming a tetrahedron pendent (Figure 34).[3255]

The largest structurally characterized gold cluster is $[Au_{39}Cl_6(PPh_3)_{14}]Cl_2$, which has a structure related to a hexagonal packed geometry with a 1:9:9:1:9:9:1 individual layers of gold atoms (Figure 35).[45] Attempts have been made to characterize the cluster $[Au_{55}Cl_6(PPh_3)_{12}]$ and the physical properties of these species have been widely studied.[3256]

6.7.3.5.2 Heteronuclear clusters

A novel series of Au—Ag supraclusters whose metal frameworks are based on vertex-sharing polyicosahedron have been reported. In the structure of these compounds the basic building block

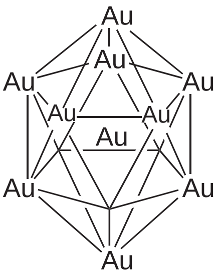

Figure 33 Core of $[Au_{13}Cl_2(PPhMe_2)_{10}]^{3+}$.

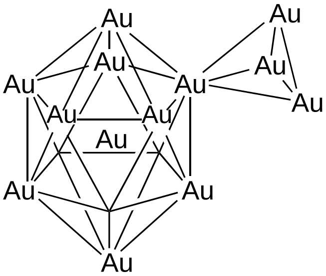

Figure 34 Core of $[Au_{16}Cl_6(AsPh_3)_8]$.

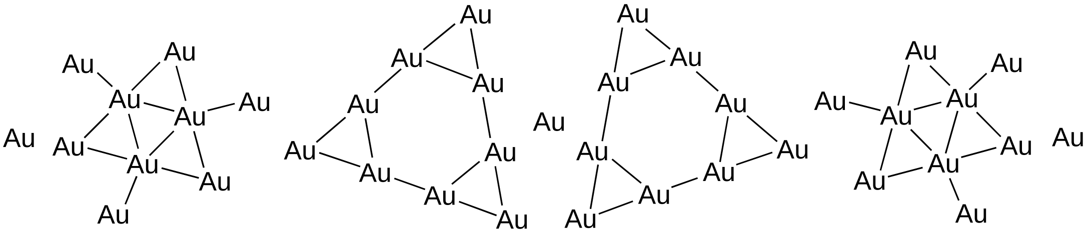

Figure 35 Layers of the cluster $[Au_{39}Cl_6(PPh_3)_{14}]Cl_2$.

is the 13-metal atom (Au_7Ag_6) icosahedra. These high nuclearity clusters have been termed "clusters of clusters" and they follow a well-defined growth sequence by successive additions of icosahedral units via vertex sharing.[47]

The first member of this vertex-sharing polyicosahedral cluster series is the 25-metal-atom clusters whose metal core can be considered as two icosahedra sharing a common vertex. They have been obtained by reducing a mixture of $[AuX(PR_3)]$ and $[AgX(PR_3)]$ with $NaBH_4$. Several of these types of clusters with different metal configurations have been reported, as, for example, $[(Ph_3P)_{19}Au_{13}Ag_{12}Br_8]^+$ (Figure 36).[3257–3263] Using the growth sequence by successive additions of icosahedral units via vertex sharing, the triicosahedral $[(p\text{-}Tol_3P)_{12}Au_{18}Ag_{20}Cl_{14}]$[3264–3266] and the tetraicosahedral $[(p\text{-}Tol_3P)_{12}Au_{22}Ag_{24}Cl_{10}]$[3267] clusters have been obtained. The 37-metal atom cluster $[(p\text{-}Tol_3P)_{12}Au_{18}Ag_{19}Br_{11}]^{2+}$ is related to the 38-metal atom cluster in that one of the two capping Ag moieties is replaced by a triply bridging halide.[3268] The structure of the triicosahedral clusters is three M_{13} atom (Au_7Ag_6) Au-centered icosahedra sharing three Au vertices in a cyclic manner (Figure 37), and the proposed structure for the tetraicosahedral cluster is four similar icosahedra arranged in a tetrahedral arrangement with six shared vertices.

The well-defined large bimetallic Au—Ag cluster as $[(Ph_3P)_{12}Au_{18}Ag_{20}Cl_{14}]$ can achieve nearly two orders of magnitude of attenuation of high-intensity laser power and, consequently opens the door to a new class of optical materials based on nanosized metal clusters.[3269]

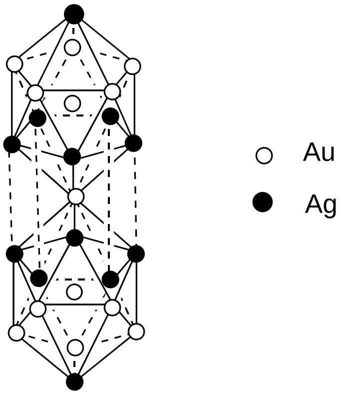

Figure 36 Core of $[(Ph_3P)_{19}Au_{13}Ag_{12}Br_8]^+$.

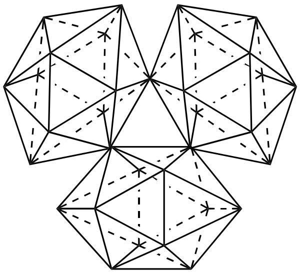

Figure 37 Core of Triiosahedral clusters.

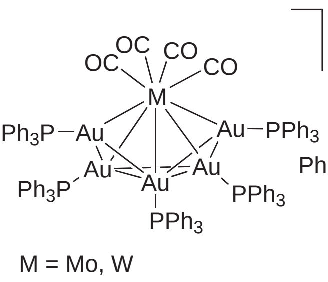
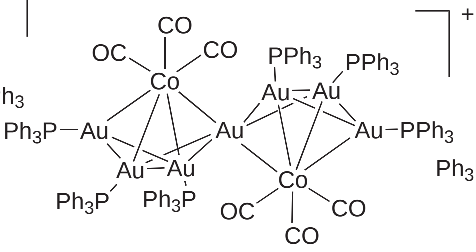
Trimetallic polyicosahedral superclusters such as $[(Ph_3P)_{10}Au_{12}Ag_{12}MCl_7]^+$ (M = Ni, Pt) or $[(Ph_3P)_{10}Au_{10}Ag_{13}Pt_2Cl_7]$ have been obtained by reduction of mixtures of $[M(AuPPh_3)_8](NO_3)_2$ (M = Pt, Ni) and $[AgCl(PPh_3)]_4$ with $NaBH_4$,[3270,3271] or by reaction of $[Pt(H)(PPh_3)(AuPPh_3)_7]^{2+}$ with $[Ag(NO_3)(PPh_3)]$,[3272] respectively. In a similar reaction of $[Pt(H)(PPh_3)(AuPPh_3)_7]^{2+}$ and $[AgI(PPh_3)]_4$, the trimetallic cluster $[(Ph_3P)_6Au_6Ag_6Pt(AgI_3)_2]$ was isolated. The structure is a icosahedron of the three metal atoms with two capping AgI_3 units.[3273]

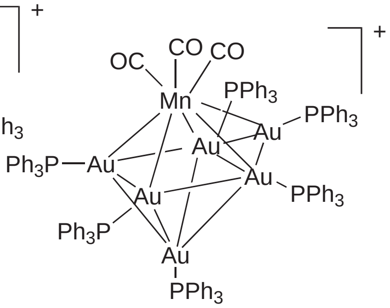
A large number of mixed metal–gold clusters are known where the metal can vary from an early transition metal, to the platinum group or coinage metals. With coinage metals, apart from the Au—Ag superclusters, centered icosahedral clusters of the type $[Au_9M_4Cl_4(PPh_2Me)_8](C_2B_9H_{12})$ (M = Au, Ag, Cu) have been obtained.[3274] With early transition metals,[3275] mixed gold clusters with vanadium as $[V(CO)_5(AuPPh_3)]$ or $[V(CO)_4(AuPPh_3)_6]^+$;[3276,3277] molybdenum and tungsten of the type $[M(CO)_4(AuPPh_3)_5]^+$ (**626**), $[M(CO)_3(AuPPh_3)_7]^+$ (M = Mo, W),[3278–3280] or $[MoCp(CO)_2\ (AuPPh_3)_4]^+$;[3281] cobalt as $[Co_2(CO)_6Au(AuPPh_3)_6]^+$ (**627**),[3279] $[Co(CO)_3(AuPPh_3)_4]^+$,[3278,3282] $[Co(CO)_2(AuPPh_3)_7]^{2+}$,[3283] or $[\{Co(CO)_4\}_2Au_6(PPh_3)_4]$;[3284] manganese as $[Mn(CO)_4(AuPPh_3)_4]^+$, $[Mn(CO)_4(AuPPh_3)_4]$, $[Mn(CO)_3(AuPPh_3)_6]^+$ (**628**), or $[(Ph_3PAu)_4\{AuMn(CO)_5\}_2]$;[3285–3289] or rhenium as $[Re(CO)_4Au(AuPPh_3)_3]$,[3289] have been described. In most of the cases photolysis of $[AuN_3(PPh_3)]$ in the presence of metal carbonyl complexes has been the synthetic method.



(**626**)



(**627**)

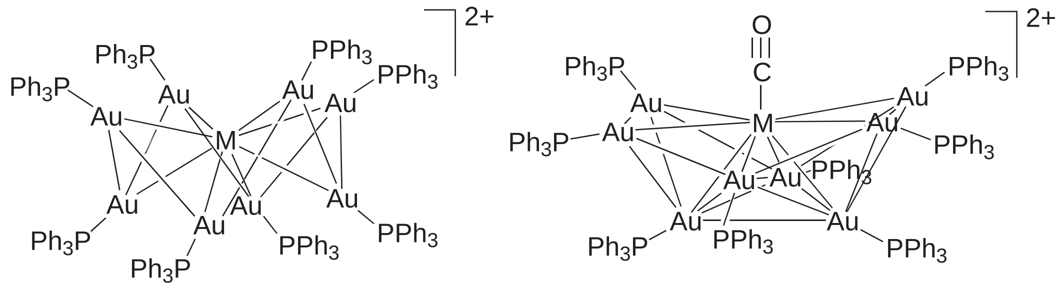


(**628**)

Mixed gold–platinum group metal complexes are numerous, amongst them the reactivity of the clusters $[M(AuPPh_3)_8]^{2+}$ (M = Pd, Pt), which possesses a central platinum atom, has been studied thoroughly. They are synthesized by reduction of mixtures of $[M(PPh_3)_4]$ and $[Au(NO_3)(PPh_3)]$.[3290–3292] These cluster compounds undergo several types of reactions as nucleophilic additions to go from 16-electron to 18-electron clusters,[3293–3295] an example is given in Equation (49). The change from a 16- to an 18-electron cluster provokes a change in the geometry from toroidal to spheroidal as can be seen in Figure 38:

$$[M(AuPPh_3)_8]^{2+} + CO \longrightarrow [M(CO)(AuPPh_3)_8]^{2+} \qquad (49)$$

M = Pd, Pt



$[M(AuPPh_3)_8]^{2+}$ M = Pd, Pt $[M(CO)(AuPPh_3)_8]^{2+}$

Figure 38 Structures of the 16- and 18-electron clusters.

Other types of reactions have been studied as, for example, a mixture of nucleophilic addition and substitution reactions.[3296–3298] An interesting reaction due to the potential catalytic applications is the reversible addition of H_2 to $[Pt(AuPPh_3)_8]^{2+}$ to give the 18-electron dihydrido cluster $[Pt(H)_2(AuPPh_3)_8]^{2+}$.[3299,3300] In nonbasic solvents the dihydrido cluster is stable and upon removal of the H_2 atmosphere, it rapidly loses H_2 to reform $[Pt(AuPPh_3)_8]^{2+}$. These reactions are completely reversible in pyridine solutions as shown in Equation (50):[3301]

$$[Pt(AuPPh_3)_8]^{2+} + H_2 \rightleftharpoons [Pt(H)_2(AuPPh_3)_8]^{2+} \xrightleftharpoons[HPy^+]{Py} [Pt(H)(AuPPh_3)_8]^{2+} \tag{50}$$

The reaction of these platinum or palladium clusters with transition metal compounds has also been studied and many cluster derivatives have been prepared for this method, which included reactions with gold,[3302–3306] silver,[3302,3303,3307–3310] copper,[3302,3303,3309–3311] or mercury complexes.[3307,3312–3314] Some examples are given in Equations (51) and (52):

$$[Pt(H)_2(AuPPh_3)_8]^{2+} + [Au(NO_3)(PPh_3)] \xrightarrow{Py} [Pt(H)(AuPy)(AuPPh_3)_8]^{2+} \tag{51}$$

$$[Pt(AuPPh_3)_8]^{2+} + MX \longrightarrow [Pt(MX)(AuPPh_3)_8]^{2+} \tag{52}$$

$$MX = AgNO_3,\ CuCl$$

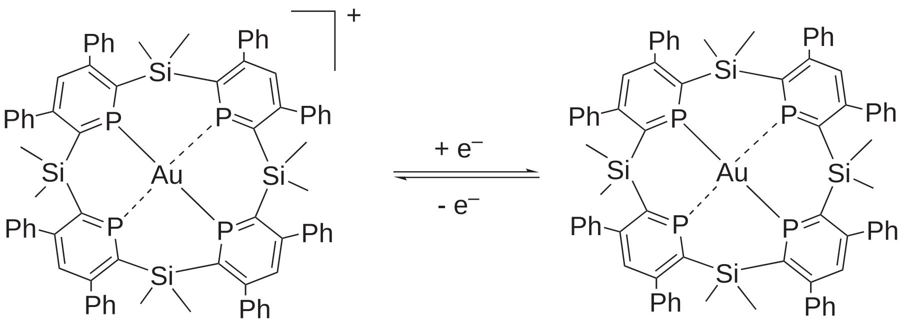
Other approach to mixed palladium–gold or platinum–gold clusters is by co-photolysis reactions of $[AuN_3(PPh_3)]$ and $[M(N_3)_2L_2]$ ($M = Pd, Pt$; $L_2 = dppe, (PPh_3)_2$). By this procedure several cluster compounds such as $[Pt(PPh_3)(AuPPh_3)_6(AuCl)_3]$,[3315] $[Pt(CO)(AuPPh_3)_6(AuCl)_3]$,[3315] $[Pd(AuPPh_3)_8(AuCl)_4]$,[3316] or $[Pd(AuPPh_3)_6(Au_2dppe)(AuCl)_4]$[3317] have been obtained. Also the reaction of $[Pt(PPh_3)_4]$ with $[Au(C{\equiv}CBu^t)]$ yields the mixed cluster $[Pt(C{\equiv}CBu^t)(PPh_3)(AuPPh_3)_6][Au(C{\equiv}CBu^t)_2]$.[3318]

Other mixed gold clusters have also been synthesized with iron as $[Fe(CO)_3(AuPPh_3)_5]^+$;[3319] iridium as $[IrAu_4(H)_4(PPh_3)_6]BF_4$;[3320] rhodium as $[Rh(POPr^i_3)_2(H)_2(AuPPh_3)_4]^+$,[3321] $[Rh(POPr^i_3)_2(H)(AuPPh_3)_5]^+$,[3321] or $[Rh(H)(CO)(PPh_3)_2(AuPPh_3)_2]^+$;[3322] rhenium as $[Re(H)_4(PPh_3)_2(AuPPh_3)_5]^{2+}$;[3322] or indium as $[Au_3In_3Cl_6(THF)_6(dppe)_3]$ or $[Au_3In_3Br_7(THF)_6(dppe)_2]^-$.[3323,3324]

6.7.3.6 Gold(0) Complexes

The complex $[Au_2(PPh_3)_2]$ has been prepared by reduction of $[AuI(PPh_3)]$ with sodium naphthalide. Its core unit is isoelectronic with mercurous halides Hg_2X_2; but, curiously enough, it has a dinuclear *trans* bent structure with d(Au—Au) = 2.76 Å and a Au—Au—P angle of 129°.[3325] There is no confirmation as yet of the original preliminary report.

The synthesis of silicalix[n]phosphinines, a new class of macrocycles incorporating sp^2-hybridized phosphorus atoms has allowed the preparation of gold(0) macrocycles. These ligands possess an adequate balance between σ-donating and π-accepting properties and then can act as macrocyclic equivalent of carbonyl groups. The reaction of these macrocycles with [AuCl(SMe$_2$)] in the presence of GaCl$_3$ yields the complexes [AuL][GaCl$_4$]. The electrochemical reduction of one of these derivatives allows the synthesis of the gold(0) compound (Equation (53)):[48]



(53)

6.7.3.7 Gold(–I) Compounds

Gold is unique among the transition metals in its ability to form isolable nonmetallic compounds that contain a monoatomic anion. The binary alkali metal aurides RbAu and CsAu have been known for about 50 years, but the ternary auride oxides M_3AuO (M = K, Rb, Cs) and the aurideaurates $Rb_5Au_3O_2$ and $M_7Au_5O_2$ (M = Rb, Cs) have been discovered only recently.[3326–3329] Using a macroreticular ion exchange resin with a high affinity toward caesium ions in liquid ammonia, it has been possible to exchange caesium for tetramethylammonium and the first compound of negatively charged gold with a nonmetal cation has been isolated, $NMe_4{}^+Au^-$.[49] An estimation of auride radius has been made of 1.9 Å, which is very similar to the bromine ion. CsAu dissolves in liquid ammonia forming a yellow solution that on removing ammonia, CsAu was not recovered directly, instead a new, intense blue solid crystallizes which has the composition $CsAu{\cdot}NH_3$.[50] The crystal structure exhibits features characteristic for low-dimensional systems. Slabs of overall composition CsAu are separated by single NH_3 layers. The gold atoms are shifted towards each other forming zig-zag chains with a Au···Au separation of 3.02 Å (4.36 Å in CsAu). This "auridophilic attraction" takes place between $d^{10}s^2$ anions but surprisingly yields a similar distance as the aurophilic attraction in d^{10} cations. The nature of this effect is not theoretically clear. Both the dispersion effects and the net bonding, resulting from partial oxidation from the top of 6*s* band, could play a role. The observed Mössbauer isomer shift at gold (CsAu 7.00 mm S^{-1}, RbAu 6.70 mm S^{-1}, $CsAu{\cdot}NH_3$ 5.96 mm S^{-1}, Au -1.23 mm S^{-1}) does not show a full -1 auride charge and keeps the latter possibility open.[3330]

6.8
Zinc

S. J. ARCHIBALD
University of Hull, UK

6.8.1 INTRODUCTION

Comparing the developments since the early 1980s with the zinc coordination chemistry reported in the first edition of *Comprehensive Coordination Chemistry* (*CCC*, 1987) reveals a number of areas where there have been particularly important advances. Ligand design coupled with the developing understanding of biological systems has allowed an expansion in the modeling of zinc enzyme active sites, resulting in the synthesis of systems which help to identify roles and structurally or functionally mimic zinc enzymes. There is also interest in the detection of zinc in biological systems, which has many functions, and detection can be considerably enhanced by the use of appropriately designed ligands.

Zinc has been called a "boring" element, but a dramatic increase in published research and potential applications stand against this.[1,2] Indeed, the very properties that lead to the tag of boring are those that make zinc an element of strong interest in biology, medicine, materials, and catalysis. A "galvanization of biology" has been observed, particularly with the discovery of zinc finger proteins and their key function in gene expression and also with the expanding understanding of its roles in the central nervous system and neurodegenerative disorders, and as a critical cofactor for many cellular functions.[3]

There is significant interest in zinc sulfide, selenide, and oxide materials and while extensive discussion is not appropriate here, a number of novel complexes that have been developed for their deposition characteristics of these important semiconductors will be highlighted in the context of the ligand types. Zinc has also been used in supramolecular building blocks as a structural element, much as in zinc finger proteins. In these cases the lack of redox chemistry is often the key factor in the choice of metal center. In porphyrin and phthalocyanine ligand systems the zinc center can impart important electronic effects altering the reactivity and redox potentials of the ligand. The catalytic applications of zinc in designed processes have increased, as might be expected for an element with a ubiquitous role in biological systems. Some of these processes will be discussed with reference to ligand design. In addition, compound types that previously had few or no examples have now been characterized, and an increased number of rare compounds such as fluorides and tellurium compounds are now known and further studied.

This review cannot claim to be a comprehensive account of all the coordination chemistry of zinc since the early 1980s. The approach has been to attempt selection of references by key workers or important results in areas where much work has been carried out. It is hoped that it will be possible by following the key references and articles to gain an overview of achievements and advances in the important areas. In many cases, examples where X-ray structural data is included have been selected preferentially for inclusion.

The particularly important properties of zinc that will be assumed throughout are the stable zinc(II) oxidation state and lack of redox chemistry, the flexibility in coordination number and geometry, and the Lewis acidity which is key to the catalytic roles. Some review articles specifically concerning the coordination chemistry of zinc have been published since 1982.[4–6] Review articles referring to specific areas of zinc chemistry will be referenced at the appropriate points. A number of important researchers have emerged over this period of zinc coordination chemistry and although a full representation of the body of work is not possible, key references should allow an appreciation of their contribution. References to particular enzyme active site models or the increased biological relevance of certain ligands are included in the text with the ligands utilized in these systems and a brief summary of some other important aspects of these areas provided at the end of the chapter. Throughout the chapter the use of zinc will indicate reference to zinc(II), the only oxidation state of any relevance, and if zinc metal, zinc(0), is discussed it will be specifically referred to.

6.8.1.1 Coordination Geometry Preferences

Coordination numbers of zinc are most commonly four to six, with three not quite so common, and two, seven and eight less often observed and more dependent on donor or ligand types. In the case of zinc, which can adopt a variety of distorted coordination geometries without significant energy penalty, it is highly useful to have a method to classify the closest classical geometry. In this work reference will occasionally be made to the method of Addison *et al.* for classifying geometry.[7] Distorted tetrahedral, five-coordinate geometries and octahedral are frequently observed geometries and the Cambridge Structural Database (CSD) contains a large number of square planar complexes due to the vast array of porphyrin and related ligand systems structurally characterized with zinc.

Two-coordinate zinc centers are known and around twenty have been structurally determined and deposited in the CSD.[8] A coordination number of two is mainly observed with amide, silyl, and alkyl donors, e.g., $Zn[Si(SiMe_3)_3]_2$, zinc bis(di-*t*-butylamide).[9–11] Extremely bulky thiophenolate and selenophenolate complexes of zinc also show structurally characterized two-coordinate zinc centers, with an S_2 or Se_2 donor set.[12,13] Trigonal planar geometry is more common for zinc especially with alkyl, amide, and bulky phenolate and thiophenolate ligands.[14–16] Dimeric or larger species can be formed and trigonal geometry is very much dependent on the steric bulk of the ligands. Three-coordinate complexes have also shown important properties as catalysts; for example, in the ring opening of cyclic monomers such as lactides.[17] Calculations show the distortion of trigonal planar geometries can be due to a mixed donor set around the zinc center.[18]

Trigonal–pyramidal geometry has been observed for zinc with an appropriately restricted ligand.[19] Square planar zinc is most often observed in porphyrin and phthalocyanine complexes where the ligand restricts the binding geometry. Examples of square planar geometry with oxygen are rare. The solid-state layer structure of $Ba_2Zn_3As_2O_2$ contains a planar ZnO_2^{2-} layer with the zinc having a square planar geometry. It is thought that the stability offered by the lattice structure overcomes the energetic penalty of the less favorable coordination geometry.[20] For similar reasons, a one-dimensional chain structure Sr_3ZnPtO_6 contains an unusual trigonal prismatic ZnO_6 motif; in this case the rigidity of the PtO_6 units are thought to enforce the unusual geometry.[21] Higher coordination numbers of seven and eight are unusual for zinc. For example, the coordination number of eight is observed in a tetraamide calixarene zinc structure.[22]

Studies into the coordination number preference of zinc have been carried out by comparing data in the CSD to *ab initio* molecular orbital calculations on hydrated structures.[23] They reveal a small energy difference between four- and six-coordinate structures. The data from the CSD suggests a preference for lower coordination numbers from sulfur. The flexibility of coordination geometry and number is important in solution as well as in the solid state and leads to equilibria of species with different coordination numbers. For example, zinc with the relatively simple ligand 1,2-ethylenediamine forms 1:1 and 1:2 metal to ligand ratio complexes in aqueous solution and equilibria exist between tetrahedral and octahedral species, with 50% and 90% existing as tetrahedral, respectively.[24] Of particular interest is the coordination environment of zinc in proteins and the preference for tetrahedral or octahedral geometry. Four-coordinate zinc plays a structural role in zinc finger proteins and enzymes. Calculations to determine the stability of this arrangement show the lowest energy ground state coordination number of zinc bound to one acidic or two or more neutral protein ligands to be four.[25] The decrease in coordination number on protein binding primarily reflects the requirements of the metal and ligands rather than constraints from protein binding site orientation. *Ab initio* calculations have been used to study four- and five-coordinate geometries with the ligands water, hydroxide ion, methanol, methoxide ion, and ammonia. The calculations, when compared with experimental data, gave closer results when solvent effects were included rather than the gas phase calculations.[26]

The symmetry of five-coordinate zinc complexes has been analyzed using continuous symmetry measures. This approach and the computational tool allow the degree of polyhedricity to be evaluated quantitatively. The methodology identifies the minimal distance of a given structure to a desired general shape with the same number of vertices.[27]

6.8.2 ANALYTICAL AND PHYSICAL TECHNIQUES FOR THE STUDY OF ZINC COORDINATION COMPLEXES

The use of different characterization and analytical techniques will be discussed when relevant with the examples of compounds studied; however, a few general techniques or examples are presented in this section.

IR and Raman spectroscopy have been commonly used and, for example, the effects of pressure on the Raman spectrum of a zinc compound with a N_2Cl_2 coordination sphere around the metal, have been investigated.[28] IR spectroscopy has been utilized in studies of the hydration of zinc in aqueous solution and in the hydrated perchlorate salt.[29] Gas phase chemistry of zinc complexes has been studied with some gas phase electron diffraction structures including amide and dithiocarbamate compounds.[30–32]

In the tradition of metal replacement to study the properties of zinc-containing proteins with cobalt analogs by UV–vis or EPR spectroscopy, a number of recent studies have been carried out using ^{113}Cd NMR on cadmium-containing analogs of zinc proteins and compounds. ^{113}Cd ($I=1/2$) has similar binding properties but there are a number of differences, not least the ionic radii of Zn^{2+} and Cd^{2+} (radii 0.69 and 0.92 Å respectively). Notwithstanding, this has been an extremely productive technique with a lot of information gained.[33] The abundant isotope of Zn with nuclear spin is the quadrupolar ^{67}Zn ($I=5/2$). Solution or liquid state NMR has been used but the large line width and poor receptivity inhibit the collection of useful data on biological samples.[34] Solid-state and single-crystal NMR of zinc compounds have now been investigated.[35] The use of single-crystal NMR can circumvent many of the difficulties involved in solid-state zinc NMR. A particular aim is to avoid using costly enriched zinc in the sample. Solid-state ^{67}Zn NMR experiments have been carried out using QE (quadrupolar echo) or QCPMG NMR.[36]

^{13}C NMR is a common tool to study zinc complexes.[37,38] ^{13}C NMR can be used in conjunction with other markers or variation allowing dynamic interpretation of the chemical shifts observed. For example: chemical shifts as a function of pH can give information about the protonation state of nitrogen-containing ligands, e.g., deprotonation occurs at the pyrrole-ring nitrogen rather than zinc-bound water.[39] ^{13}C relaxation measurements have been carried out in the presence of ^{67}Zn which shows induced relaxation, demonstrating that a cyano group can be directly bound to the metal center in carbonic anhydrase.[40] ^{13}C MAS and CPMAS experiments have been used to study a variety of zinc-containing solid-state systems but especially reactions occurring on the surface of catalysts such as those related to the highly important chemistry of methanol synthesis.[41] ^{1}H relaxation has been studied by NMR in bimetallic zinc complexes.[42] ^{31}P NMR studies of dithiophosphate zinc complexes have been carried out.[43,44] ^{15}N NMR studies have been used to provide evidence for the coordination of a deprotonated amide-containing ligand in the active site of a zinc enzyme.[45] NMR spectra of peptide complexes have also been reported.[46]

X-ray absorption spectroscopic measurements have been carried out on zinc proteins to determine structural properties. Investigation of coordination complexes and zinc binding peptides have assisted in the interpretation of the more complex systems.[47] Zinc and sulfur K-edge EXAFS have both been used to investigate the polyzinc species in metallothionein proteins and cadmium-substituted derivatives.[48] Zinc K-edge EXAFS has been used to determine the zinc coordination donor set in a variety of proteins.[49,50] The coordination structure of zinc ions on a Langmuir monolayer was observed using total reflection XAFS.[51] EXAFS has been used to determine the structures of solvated complexes and compare coordination numbers in solution and with variation in the solvent.[52] Zn and N K-edge XANES give structural information, and comparisons have been made with single-crystal X-ray data to demonstrate the utility of this technique.[53] There have not been many Zn K-edge XANES studies carried out, probably due to the absence of any pre-edge structure. The complexes studied are often tetrahedral zinc compounds in solid-state or doped materials.[54,55]

EPR spectroscopy and single-crystal EPR have been used to investigate systems where a ligand-based radical species can be generated and are useful for obtaining information regarding metal-bound radical species in the absence of any metal-based redox processes.[56] Mass spectrometry has been frequently used in the characterization of zinc complexes and the advent of electrospray mass spectrometry has had a particular impact on the investigation of polymetallic zinc compounds. The compounds of special interest here have included thiophenolate polyzinc compounds and metallothionein protein fragments.[57] A quadrupole ion trap mass spectrometer can be used to evaluate relative binding energies of complexes in solution.[58] Circular dichroism spectra have been recorded for a variety of zinc species, particularly those involved in supramolecular assemblies but also simpler monomeric complexes with chiral ligands.[59]

6.8.3 CARBON LIGANDS

6.8.3.1 Carbonyls

The CSD contains no known X-ray structures of zinc carbonyl compounds and much of the work reported is theoretical.[8] Semiempirical NDO calculations have been carried out to determine the dissociation and bonding energy of the species $Zn(CO)_6^{2+}$.[60] Phosgene chemical weapons are decomposed by zinc(II) and other ions in charcoal gas mask filters and, in studies to determine why saturation occurs, quantum chemical calculations were performed on the species $ZnCOCl_2$.[61] Calculations have been carried out on the interaction of carbonyls with zinc porphyrin and phthalocyanine compounds. Calculations on a Zn–CO derivative were carried out as part of a study of the effects on incorporating C_{60} as an electron acceptor in a zinc porphyrin CO system.[62] Density functional calculations were also completed on a six-coordinate zinc phthalocyanine complex with two axial carbonyl ligands.[63] Carbonyl bonding on a zinc oxide surface has been investigated by electronic structure calculations on $[ZnO_3CO]^{4-}$ and comparisons made with binding to copper(I) sites. The σ donation was found to be a third of that exhibited by copper(I) and π bonding not present in the zinc species.[64]

6.8.3.2 Cyanide and Isocyanide Ligands

A number of cyanide complexes of zinc have been structurally characterized, with bridging cyanide ligands frequently observed in both zinc and zinc-containing mixed metal species. Discrete mononuclear trispyrazolylborate zinc cyanide complexes have been synthesized and structurally characterized as part of a study of crystallographic disorder.[65] The zinc cyanide unit was partially replaced in the presence of halides as zinc chloride, zinc bromide, and zinc iodide. *t*-Butylisocyanide complexes of zinc were synthesized from chalcogenolate-bridged dimers resulting in four-coordinate monomeric zinc species with two selenium or sulfur donors and two isocyanide donors. The X-ray structure of the selenium derivative demonstrates a distorted tetrahedral coordination geometry.[66]

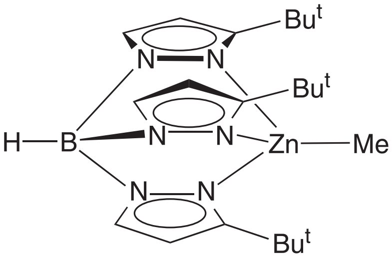
Zinc complexes of a fused pyrroloporphyrin, cyclopropanochlorin, that contain an appended isocyano group show dimer formation. The X-ray structure reveals five-coordinate zinc centers with bonding to four nitrogens from the chlorin macroycle and an intermolecular bond to the isocyano carbon.[67]

Both zinc and mixed-metal clathrate compounds are known containing cyanide bridged metal centers, e.g., $Zn(CN)_2$.[68] The mixed-metal clathrate compounds contain bridging cyanides between zinc and cadmium or copper. Both Cd–Zn and Cu–Zn compounds show tetrahedral zinc centers and carbon tetrachloride guest molecules. The cyanide ligands bridge the zinc and other metal centers to give a C_2N_2 coordination environment. The discrimination between the carbon and nitrogen atoms of the cyanide ligands was made on the basis of the X-ray data from a number of single-crystal structures.[69] A 3D network that also contains structural space for the inclusion of solvent molecules is formed from 2,4,6-tris(4-pyridyl)-1,3,5-triazine ligands and contains cyano groups bridging the zinc ions.[70] Alternate tetrahedral and octahedral zinc ions are observed in the polymeric crystal structure of $[Zn(pyridine)_2][Zn(CN)_4]$ with all cyano ligands μ_2-bridging. The pyridyl bound zinc is shown to be ZnN_6 and the other type of zinc center tetrahedral ZnC_4.[71] A coordination polymer with a chain structure is observed in the crystals of the complex $[K(benzo\text{-}18\text{-}crown\text{-}6)][Zn(CN)_3]$. A Zn–CN–Zn chain is formed with a terminal cyano group bridging to the potassium center.[72] A hydrogen bonded assembled chain structure is observed in the structure of dicyano(2,2′-dipyridylamine)zinc. The blue luminescent compound shows four-coordinate N_2C_2 coordination with the hydrogen bonds formed between the amine groups and cyano nitrogens.[73]

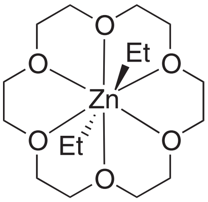
6.8.3.3 Alkyls and Aryls

There are over 140 zinc alkyl or aryl structures reported in the CSD in which more than half of the donors are noncarbon. Those selected for discussion show representative structures and coordination numbers, or particularly prevalent ligand systems.

Monomeric monoalkyl zinc complexes have been characterized with tris(pyrazolyl)borate ligands. The monomeric complexes include the structurally characterized methyl derivative (**1**).[74] A variety of tris(3-*t*-butylpyrazolyl)borate zinc alkyl and phenyl complexes have been synthesized, for example, by Chisholm and co-workers as catalyst precursors for ring opening polymerization reactions. These include ethyl, *t*-butyl, and phenyl derivatives.[75] A number of other tripodal ligand systems, including mixed donor tripods, have also been characterized with bound alkyl groups.[65,76–78] Monomeric species can also be synthesized, with diamine ligands such as TMEDA, of the formula [LZnClEt] or $[LZnEt_2]$.[79]



(**1**)



(**2**)

Dimeric structures with methyl or ethyl zinc units linked by bridging amides have been formed, e.g., $[MeZnNMe(CH_2)_2NMe_2]_2$, with the presence of moisture expanding the structure to incorporate six zinc atoms, a μ_4-oxo and the μ_2-amide ligand.[80] Trimeric hexametallocyclic structures are formed with a number of zinc alkyl species.[81,82] A dodecanuclear zinc phosphonate structure is known which incorporates ethyl ligands on the outer zinc atoms and contains a $Zn_4(\mu_4\text{-}O)$ core.[83] The complex bis(*N,N*-diethylmonothiocarbamato)zinc, $[Et_4Zn_4(OSCNEt_2)_2(NEt_2)_2]$, is a tetrameric cage complex with both the oxygen and the sulfur donor from the monothiocarbamato ligand binucleating, and terminal ethyl groups present. The variable temperature ^1H NMR reveals that the metal assembly remains intact in solution.[84]

The monocation tris(diethylether) ethylzinc is formed from diethyl zinc as a tetrakis(pentafluorophenyl)borate salt.[85] Longer-chain linear and cyclic ether complexes (**2**) of zinc alkyls have also been observed. The reaction between zinc dialkyls and primary amines gives a number of structurally diverse products dependent on the reaction conditions and the amine.[86] The iodomethyl 18-crown-6 complex of $Zn(CH_2I)_2$ shows a five-coordinate zinc center with three oxygen donor ligands. In the same unit cell the complex $ZnI(CH_2I)\cdot$18-crown-6 is also observed with a related O_3CI coordination donor set.[87] Halomethyl zinc reagents are very important in the Simmons–Smith reaction.[88]

A zinc-mediated carbon–carbon coupling reaction can be carried out on the metallated form of (*t*-butyldimethylsilyl)(2-pyridylmethyl)amine, formed in reaction with dimethylzinc. The isolated dimeric species can be reacted with further dimethyl zinc to give bis(methylzinc)-1,2-dipyridyl-1,2-bis(*t*-butyldimethylsilylamido)ethane, which contains two N_3C coordinated zinc centers.[89]

6.8.4 NITROGEN LIGANDS

6.8.4.1 Ammines and Amines

The chemistry of zinc ammine complexes is well known. There are X-ray structural examples of both the tetrahedral tetra-ammine and octahedral hexa-ammine.[90,91] Four- and five-coordinate mixed ligand complexes are common and participation in coordination networks as terminal ligands is observed.[92,93]

Open chain polyamine ligands have been widely studied. Often the coordination of zinc is compared with other first row transition metals and factors, such as behavior across a pH range, studied. The protonation patterns and stability constants are of particular interest. Octahedral zinc tris(ethylenediamine) structures have been characterized by X-ray diffraction with a number of different counter anions.[94] The X-ray structure of zinc tris(ethylenediamine) with fluoride counter ions reveals extensive hydrogen bonding.[95]

Synthesis and thermal decomposition of zinc thiocyanate complexes of cyclic bidentate amines piperazine, *N*-methyl piperazine, and 1,4-diazacycloheptane were studied. The thermal stability of the complexes showed piperazine the most stable and 1,4-diazacycloheptane the least stable.[96] The zinc complex of open chain polyamine 4,8,11,15-tetraazaoctadecane-1,18-diamine has been studied by potentiometry and ^{1}H and ^{13}C NMR. From these data sets, the coordination is shown to be by no more than four nitrogens from the hexaamine. Also, in contrast to the coordination of other characterized hexaamine ligands, it shows the ability to form binuclear species with zinc. Formation of predominant binuclear hydroxo species, dependent on pH, is observed.[97] ^{13}C NMR studies have been carried out on zinc complexes of 3,7-diazanonane-1,9-diamine and 1,2-diaminoethane.[98] The equilibria between branched hexaamine *N,N,N′,N′*-tetrakis(3-aminopropyl) ethylenediamine and zinc and other transition metal ions has been studied.[99] The zinc complexes of terminally methylated open-chain polyazaalkanes, $CH_3NHCH_2CH_2NH[CH_2CH_2NH]_n$-$CH_2CH_2NHCH_2CH_2NHCH_3$ ($n = 1$–5), have also been studied by potentiometry, direct microcalorimetry, and ^{1}H and ^{13}C NMR. The stability constants and the enthalpy of formation of the species $[ZnL]^{2+}$ are roughly constant along the series. Mononuclear complexes are formed and a coordination number of five is suggested for the complexes. The ligands where $n = 3$–5 also form binuclear complexes with stability increasing with the increasing number of nitrogen donors. Comparison with macrocyclic equivalents of these ligands show the macrocyclic effect is only observed for the shortest chain ($n = 1$) analog. For all the other ligands in this series and mono- or binuclear complexes the open chain ligand complexes have higher stability.[100]

A number of ^{13}C NMR studies on zinc amine complexes have been reported.[101–104]

6.8.4.2 Pyridyl Ligands

Pyridyl donors are common and feature in later sections as part of many multidentate ligands, such as macrocycles. Functionalized pyridyl donors will also be discussed and Section 6.8.4.7 provides examples of the bidentate bipyridyl and phenanthroline complexes.

Calorimetry investigations of zinc ions with functionalized pyridines have been carried out in both dimethylformamide and acetonitrile. The pyridines used were pyridine, 3-methylpyridine, and 4-methylpyridine. In DMF, for all three pyridines, four- and six-coordinate species formed and their formation constants, reaction enthalpies and entropies were determined. The stability increases linearly with increasing basicity of the pyridine derivative. The formation of the 3-methylpyridine complex is enthalpically less favorable and entropically more favorable than the others due to steric interactions with DMF in the first coordination sphere.[105] In acetonitrile complexes $[ZnL(MeCN)_5]^{2+}$ and $[ZnL_2(MeCN)_4]^{2+}$ exist and a structural change from octahedral to tetrahedral to give $[ZnL_3(MeCN)]^{2+}$ and $[ZnL_4]^{2+}$ is observed.[106] In DMF the formation of the zinc complexes is more favorable due to weaker solvation of the metal ion.

The zinc complexes with diphenyl-2-pyridylmethane, ZnL_2Cl_2 and ZnL_2Br_2, have been characterized by IR spectroscopy and conductivity measurements.[107] The $[(pyridyl)_2P(NSiMe_3)_2]^-$ ligand forms an aminoiminophosphoranate complex with zinc which structural characterization shows to be four-coordinate bound to two pyridyl and two amide nitrogen donors (**3**).[108]

The zinc complexes of bis(2-pyridylmethyl)amine have been studied by X-ray crystallography and ^{13}C NMR. The structures of $[ZnL_2](ClO_4)_2$ and $[ZnL_2]Cl_2{\cdot}6H_2O$ have been determined and ^{13}C NMR demonstrated to be applicable to distinguishing the isomers.[109]

The zinc chloride complex of 1-(2-pyridyl)-2-(2-thienyl)ethyne has been structurally characterized by single crystal X-ray diffraction showing the ligand is a monodentate nitrogen donor. The N_2Cl_2 tetrahedral coordination geometry reveals little apparent influence of the acetylene or thiophene groups.[110]

6.8.4.3 Imidazole Ligands

Imidazole is of particular relevance to biological mimic ligands due to the presence of histidine as a coordinating group for zinc in biological systems and has been a particular target for zinc complex formation.

6.8.4.3.1 Monoimidazole ligands

Simple imidazole complexes have been further studied with the monomeric complex $[Zn(imidazole)_2(CH_3CO_2)_2]$.[111] In the X-ray structure the metal is in a tetrahedral environment with a network of intermolecular hydrogen bonding between the non-coordinated imidazole nitrogen and the acetate oxygen.[112] A study of the stability of transition metal imidazole complexes by potentiometric titration in the presence of *N,N*-bis(2-hydroxyethyl)glycinate showed an interesting result for zinc in comparison with the other transition metals studied. A particularly high stability was observed on the formation of the ternary complex that could be attributed to a reduction in coordination number on binding of the imidazole, entropically favoring complex formation.[113] Equilibrium studies have also been carried out in the formation of binary and mixed ligand complexes with imidazole, histamine, and L-histidine.[114] The ligand 5-amino-4-carboethoxy-1-*para*-methoxyphenyl-imidazole forms a monomeric complex, ZnL_2Cl_2, which exhibits a distorted tetrahedral geometry and the zinc ion coordinates to the imidazole *N*-donor from each ligand.[115]

An imidazole/pyridyl ligand (**4**) coordinates to a copper(II) center and on deprotonation the imidazole reacts with bis(hexafluoroacetylacetonato)zinc to form a trimeric Cu_2Zn species bridged by imidazoles. The zinc ion is in an octahedral coordination environment with Zn–N distances of 2.029(2) Å.[116]

The ligand 4,5-bis(di(2-pyridylmethyl)aminomethyl)imidazole has been utilized in the formation of Cu–Zn dinuclear complex $[CuZnL(CH_3CN)_2](ClO_4)_3$. The resonance Raman spectra of hydroperoxo intermediates were studied.[117]

6.8.4.3.2 Bisimidazole ligands

Bouwman synthesized complexes of tridentate ligand *N,N*-bis(2-ethyl-5-methyl-imidazol-4-ylmethyl)aminopropane (**5**). $[ZnL_2]^{2+}$ complexes were synthesized with IR spectroscopic data indicating octahedral coordination.[118]

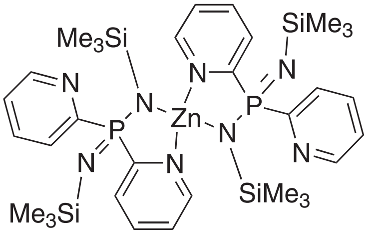
The biphenyl ligand functionalized with two imidazoles (**6**) was used to produce distorted tetrahedral complexes of zinc.[119] 2,2′-Biimidazole can act as a bidentate ligand coordinating to one zinc ion (**7**) or as a bridging ligand in the formation of dimeric species (**8**) with X-ray structures of both binding motifs.[120]

Bhalla *et al.* synthesized and studied the zinc complex of bis(1-methyl-4,5-diphenylimidaz-2-oyl) carbinol. The ligand coordinates as bidentate resulting in a slightly distorted tetrahedral geometry, $[ZnL_2]^{2+}$.[121]

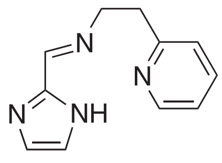
Breslow and co-workers were among the first to design polyimidazole ligands to mimic coordination in zinc enzymes.[122] Oxygen and sulfur-bridged bis-benzimidazole ligands 1-(*N*-methyl)benzimidazolyl-3-benzimidazolyl-2-oxapropane and 1-(5,6-dimethylbenzimidazolyl)-3-benzimidazolyl-2-thiapropane result, respectively, in coordination of an N_2O and an N_2 donor set on zinc complex formation.[123] Related benzimidazole ligands have been used as transfer agents for metal ions in a three-phase transport system.[124]

Monomeric complexes have been formed with the bis(benzimidazolylmethyl) sulfide ligands to give tetrahedral N_2S_2 coordinated zinc in combination with thiolates.[125] The benzimidazole ligand (**9**) shown has also been used to form polynuclear complexes with zinc and benzylthiolates.[126]

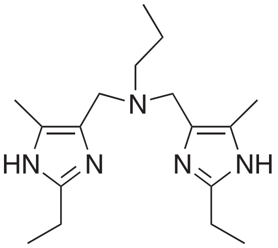
The mononuclear zinc complex of the ligand 1-(5,6 dimethylbenzimidazolyl)-3-benzimidazolyl-2-thiapropane has been structurally characterized.[123] The thioether bridge present in the ligand does not coordinate to the metal center. The thiapropane complex $ZnLCl_2$ shows a distorted tetrahedral geometry with an N_2Cl_2 coordination sphere. Identical to the coordination observed by Vahrenkamp in a symmetric bis-benzimidazole ligand with $ZnBr_2$.[127] Tridentate, bis(benzimidazole) pyridine, ligands with pyridyl and imidazole donors have been used in zinc complexation.[128]



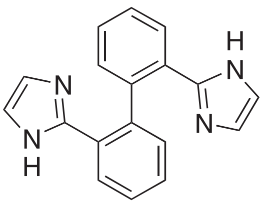
(**3**)



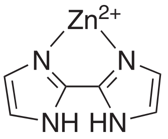
(**4**)



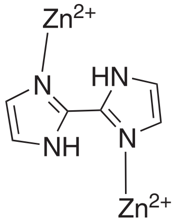
(**5**)



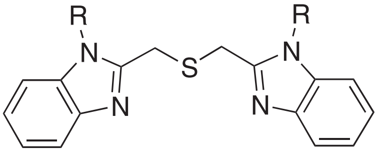
(**6**)



(**7**)



(**8**)

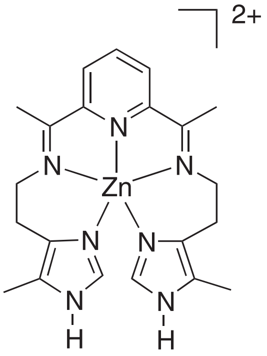


(**9**)

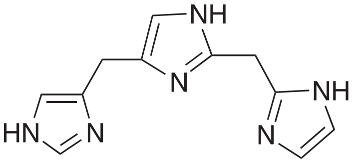
Pentadentate ligands with two imidazole nitrogen donors have been prepared and the zinc complex characterized (**10**). A distorted trigonal–bipyramidal geometry was observed around the metal center with all nitrogen donors from the ligand coordinated. Variable temperature NMR was used to calculate rate constants for the exchange processes involving the imidazole groups.[129]

6.8.4.3.3 Trisimidazole and greater

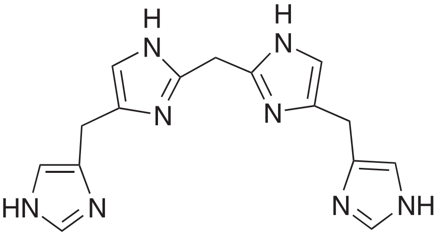
Gajda *et al.* have produced a number of zinc imidazole complexes with substituted imidazoles.[130–132] The ligands 4-(imidazol-4-ylmethyl)-2-(imidazol-2-ylmethyl)imidazole (**11**) and



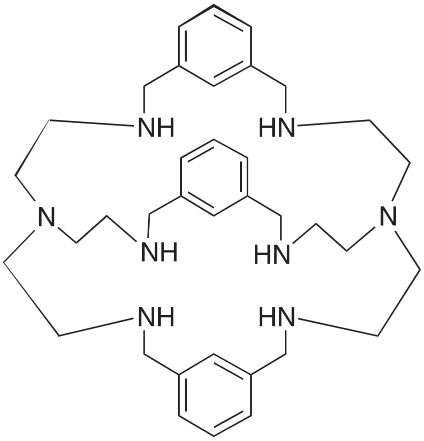
(**10**)



(**11**)



(**12**)



(**13**)

bis[4-(imidazol-4-ylmethyl) imidazol-2-ylmethane] (**12**) contain three and four imidazole groups respectively.[133] Potentiometric titrations were carried out to determine formation constants. It is anticipated that other ligands, such as solvent molecules, complete the coordination sphere and could be displaced. The binding of L-cysteine to the zinc complex was studied. Different ligand ratios gave different products and the introduction of cysteine resulted in formation of ternary complexes suggesting favored formation of N/S^- coordination around the zinc.

A cage-like complex results from the tris(imidazol-1-ylmethyl)benzene ligand in the presence of zinc acetate, $[Zn_3L_2(OAc)_6]$, and exhibits inclusion properties to neutral guest molecules in aqueous solution.[134]

Ligands with imidazoles groups attached to calixarenes show interesting complexation properties and the adjacent presence of a hydrophobic cavity mimics a further important element of many zinc enzyme active sites.[135–138] A *t*-butylcalix[6]arene is functionalized in alternating positions by three imidazole groups thus presenting three *N*-methyl imidazole donors next to a cavity. The ligand is shown to stabilize four coordinated zinc species with a variety of neutral molecules. Amino, nitrilo, ethanol, and formamide complexes were characterized by X-ray crystallography (Figure 1) showing the role of hydrogen bonding and CH/π interactions between the zinc-bound neutral molecule and the cavity.[135,136] The alcohol complex has a Zn—O distance of 1.993(3) Å compared with 2.0–2.1 Å in liver alcohol dehydrogenase.[135] The most remarkable aspect of this class of compound is the stability of the tetrahedral Zn funnel complexes.

6.8.4.3.4 *Bridging imidazolates*

Imidazoles are of interest as bridging ligands particularly with regard to mimics of the active site of Cu–Zn superoxide dismutase (SOD). Structures with imidazolate bridges have been

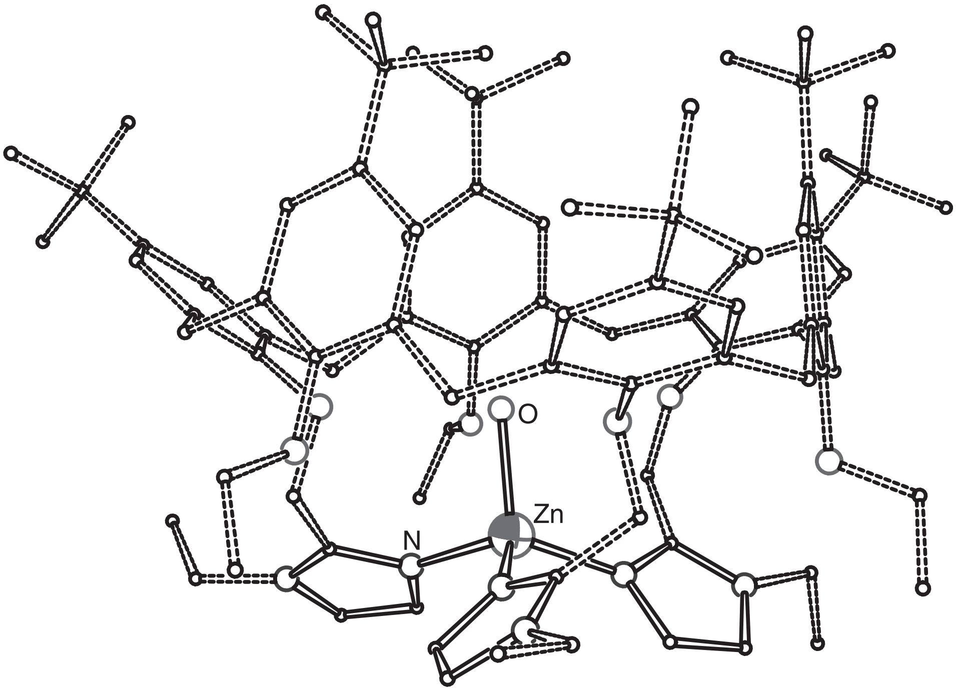


Figure 1 The molecular structure of the zinc complex of an imidazole-functionalized *t*-butylcalix[6]arene.[135]

characterized.[139–142] In particular, Ohtsu *et al.* have contributed a number of complexes of this type.[117,143,144] These compounds are often two independent mononuclear complexes bridged by the imidazolate and so may break apart. Imidazolate-bridged Cu–Zn hydroperoxo complexes have been generated and characterized as intermediates in Cu,Zn-SOD. The reaction between the heterodinuclear imidazolate bridged complex and hydrogen peroxide in the presence of triethylamine generates the hydroperoxo complex.[145] Spectroscopic characterization was carried out.

The imidazolate bridged Cu/Zn bimetallic complex of the cryptand (**13**) was structurally characterized and shown to have a Cu–Zn distance of 5.93 Å (native Cu, Zn-SOD 6.2 Å).[146] The complex shows some activity in the dismutation of superoxide at biological pH that is retained in the presence of bovine serum albumin.

Diethylenetriamineacetic acid has been used in the formation of homodinuclear zinc complexes with the bridging imidazole. The crystal structure of [LZn(imidazolate)ZnL]ClO_4 was obtained. The magnetics of the heterodinuclear Cu–Zn complex were studied and single crystal EPR of the Zn_2 dimer doped with the CuZn dimer.[139]

Bridging imidazolates have also been found in the copper(II)–zinc binuclear complexes with triethylenetetramine completing the coordination sphere of each metal center, [LCu(imidazolate)ZnL]$(ClO_4)_3$. The X-ray structure reveals a five-coordinate zinc center with a distorted tetragonal–pyramidal geometry and a Cu—Zn distance of 6.081(2) Å. As the pH is lowered to 9.6–10.3, the bridge is broken at the copper, which is in contrast to the equivalent diethylentriamineacetic acid or tris(2-aminoethyl)amine derivatives, where the bridge is broken at the zinc center.[141] The analogous structure is also known for an imidazolate bridged zinc dimer with the tris(2-pyridyl)-methylamine ligand.[147]

Dinucleating ligands have been used to incorporate the two metal centers with a bridging imidazole, 4,5-bis(di(2-pyridylmethyl)aminomethyl)imidazole and 4,5-bis(di(6-methyl-2-pyridylmethyl)amino-methyl)imidazole.[148] The X-ray crystal structure of the copper zinc complex [CuZnL$(CH_3CN)_2$](ClO4)$_3$ reveals a Cu^{II}—Zn distance of 6.197(2) Å. The zinc center is pentacoordinate bound to the imidazolate nitrogen, two pyridine nitrogens, the tertiary amine nitrogen and a CH_3CN. The solvent molecule can easily be exchanged and the complex was tested for SOD activity.[149]

6.8.4.4 Pyrazole, Triazole, and other Heterocycle Ligands

3-Amino-4-acetyl-5-methylpyrazole acts as a monodentate ligand binding to zinc via the tertiary ring nitrogen donor. The mononuclear 2:1 complex was structurally characterized with two monodentate nitrate anions completing the distorted tetrahedral coordination. Hydrogen bonding interactions linked neighboring molecules in the solid state.[150] 3-Methyl-5-phenylpyrazole is a monodentate ligand forming a monomeric compound ZnL_2Br_2, which similarly exhibits a distorted tetrahedral geometry.[151]

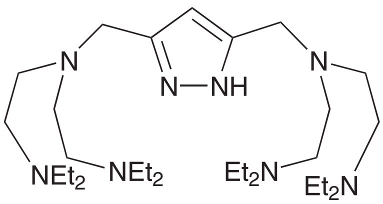
Spontaneous deprotonation of 1,2,4-1H-triazole in the presence of zinc chloride gives a solid state structure where each zinc has tetrahedral coordination with N_3Cl donors. The compound ZnLCl has 1,2,4-triazolato units each bridging three zinc atoms through the three nitrogen donors to form a corrugated layer structure. The shortest interlayer Zn...Zn separation is 5.701 Å.[152]

Reaction of 3-(2-pyridyl)pyrazole and 6-(3-pyrazolyl)-2,2′-bipyridine with zinc salts results in mononuclear pseudo-octahedral complexes $[ZnL_3](PF_6)_2$ and $[ZnL_2](PF_6)_2$ respectively. The ligands coordinate as neutral mononucleating chelates in a similar fashion to the bidentate 2,2′-bipyridine or tridentate 2,2′ :6′,2″-terpyridine respectively.[153]

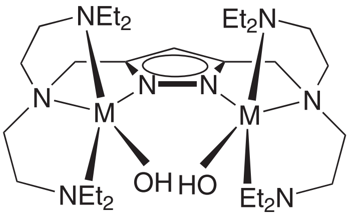
The bidentate ligand *N,N*-bis(pyrazol-1-ylmethyl)benzylamine forms a distorted tetrahedrally coordinated monomer, $ZnLBr_2$.[154] The ligand 1,6-bis(3,5-dimethyl-1-pyrazolyl)-2,5-dithiahexane forms a 1:1 complex with $ZnCl_2$ where the ligand binds in a bidentate fashion through the pyrazole nitrogen donors.[155] Reaction of 2,3,5,6-tetra(2-pyridyl)pyrazine with $ZnCl_2$ results in a mononuclear five-coordinate complex where the pyridylpyrazine ligand is tridentate.[156]

Compartmental pyrazole ligands (**14**) can be used to form bimetallic complexes (**15**).[157] This ligand enforces a separation distance between the metal ions. Stability constants were calculated showing a stability for both mononuclear and dinuclear compounds that was less than Cu^{II} but greater than Ni^{II}.

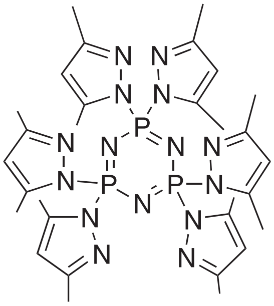
The pyrazole phosphazine ligand, hexakis(3,5-dimethylpyrazolyl)cyclotriphosphazene (**16**) forms a dizinc complex, that has been structurally characterized, and the analogous copper zinc complex.[158] Two $ZnCl_2$ units are coordinated, one distorted tetrahedral and one distorted trigonal–bipyramidal, separated by 7.51 Å. Cu^I and $ZnCl_2$ can also be coordinated giving a heteronuclear compound with a Zn–Cu separation of 6.798 Å.



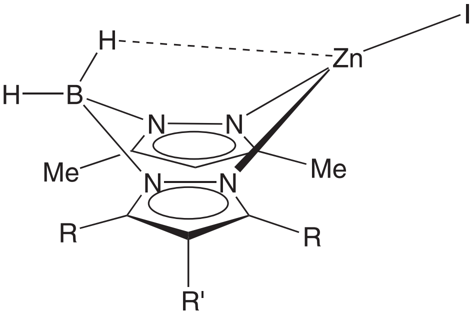
(**14**)



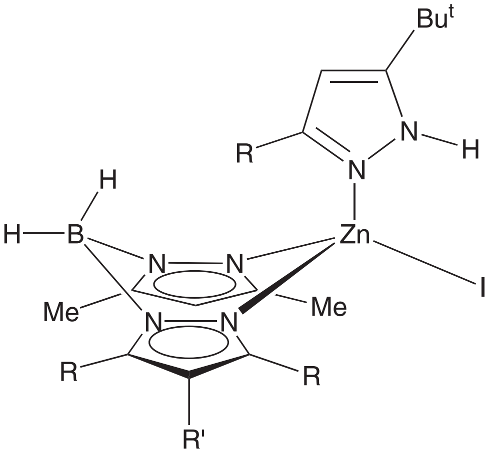
(**15**)



(**16**)



(**17**)



(**18**)

A series of unsymmetric bis(pyrazolylate) ligands have been synthesized and complexed with zinc via metathesis of a thallium derivative, (**17**) and (**18**). This allowed the synthesis and complexation of NNS and NNO pyrazolylborate derivatives.[159,160] Parkin and co-workers synthesized zinc complexes of a series of unsymmetric pyrazole-containing ligands.[161–163] The asymmetric bis(pyrazolyl)hydroborato zinc complex has been structurally characterized,[164] and will also be discussed in the context of its interaction with the B–H hydrogen in Section 6.8.9.2.

A highly fluorinated bis(pyrazolyl)borate ligand, dihydridobis(3,5-bis(trifluoromethyl)pyrazolyl)borate has been synthesized. The zinc triflate complex was prepared from the potassium salt of the ligand and exhibits distorted tetrahedral coordination which allows comparison of the amount of distortion, in relation to the electronic properties of substituents, with the methylated analog.[165]

The complex bis(1,2,6,7-tetracyano-3,5-dihydro-3,5-diiminopyrrolizimido)zinc (**19**) has been crystallographically characterized demonstrating a six-coordinate octahedral metal center with two longer apical bonds to the ether oxygen donor tetrahydrofuran ligands. The electronic absorption spectra, including the polarized single crystal reflection spectra, have been assigned on the basis of calculation and comparison to related systems.[166]

Zinc binding to triazole derivatives, 3,5-di(2-pyridyl)-1,2,4-triazole (**20**) and 3,5-di(2-pyridyl)-4-amino-1,2,4-triazole (**21**), was investigated due to the occurrence of the triazole group in a number of drugs that function via interaction with zinc-dependent enzymes. NMR and IR suggested varying coordination modes were possible with different anions (1:1 complex for $ZnCl_2$ and 2:1 complexes for $Zn(NO_3)_2$, $Zn(ClO_4)_2$ and $Zn(BF_4)$). The crystal structure from the zinc perchlorate showed a complex which was octahedrally coordinated to two 3,5-di(2-pyridyl)-4-amino-1,2,4-triazole and two water molecules. Each triazole ligand was bidentate with bonding to a pyridyl N and a triazole N.[167]

Two crystalline polymorphic forms are obtained in the formation of crystals of bis[hydrotris(1,2,4-triazolyl)borato]zinc. In the fast-crystallizing compound the zinc was shown to be coordinated to two tridentate chelate ligands by the endodentate nitrogens, forming a molecular monomeric complex; the slower-crystallizing compound was a coordination polymer with the borate centered ligand bridging three zinc centers via the exodentate nitrogen donor atoms.[168]

The ligand 2,5-bis(2-pyridyl)pyrazine was used in the synthesis of a range of zinc compounds to contrast with copper coordination polymers prepared with this ligand.[169] Three zinc compounds were structurally characterized, $[ZnCl_2L(DMF)]$, $[Zn_3(OAc)_6L_2]$, and $[Zn_3Cl_6L_3]$; respectively a distorted square planar monomer, a linear trimer, and a triangular arrangement of zinc centers.

The reaction of zinc bromide and pyrazine can give two different coordination polymers. $[ZnBr_2L]$ was structurally characterized demonstrating a 1D zigzag chain polymer which yields $[ZnBr_2L_2]$ on solid state reaction with pyrazine. The crystal structure of $[ZnBr_2L_2]$ shows a regular square-grid network with the axial bromides from one layer projecting into the grid cavity on an adjacent layer. This second structural type can be converted back into the first by heating.[170] The ligand 2,3,5,6-tetrakis(aminomethyl)pyrazine has two tridentate binding sites and forms a binuclear complex with zinc, $[Cl_2ZnLZnCl_2]$. The crystal structure reveals two five-coordinate zinc atoms, both in a trigonal–bipyramidal arrangement.[171]

6.8.4.5 Nucleobase and Nucleoside Ligands

Zinc binding directly to DNA and RNA bases has been studied, and in particular the interaction of zinc with the guanine N7.[172] Zinc binding directly to DNA can cause kinking or induce conformational changes.[173,174] NMR investigations of zinc oligonucleotide complexes have been carried out as part of a study to determine a sequence-selective metal binding pattern with binding predominantly to 5′-G in 5′-GG and 5′-GA steps.[175] This binding was preferred to GT and no evidence was found for binding in GC steps or to non-guanine residues. All binding was assumed to be to guanine N7. Spectroscopic studies have suggested that the zinc may also interact with the guanine O6.[176] Polymeric complexes of zinc have been structurally determined with the monomethyl phosphate-esters of cytidine and deoxycytidine 5′-monophosphate nucleotides.[177] A trinuclear complex with a Zn(OH)Zn(OH)Zn backbone is proposed to be a model for metal crosslinks in DNA, coordination to a endocyclic nitrogen of one base and an exocyclic oxygen of another base is observed (Figure 2).[178]

It has been suggested that zinc ions prevent formation of DNA quadruplexes containing guanine quartets by binding to the guanine N7 and O6. The quadruplexes are believed to be important to a number of areas of the genome including telomeres.[179]

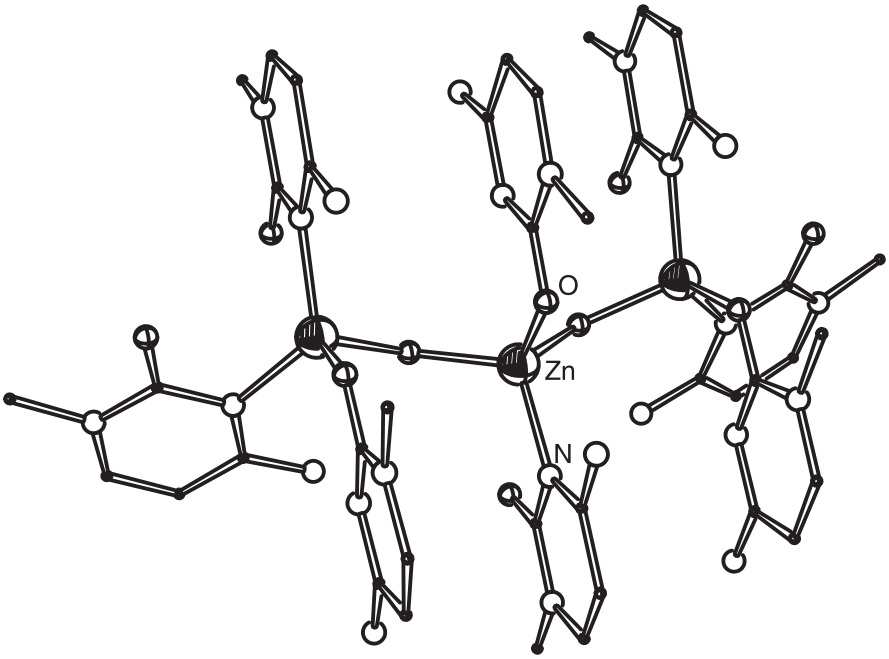


Figure 2 Molecular structure of the trinuclear zinc complex formed with 3-methylcytosine. All ligands are monodentate and bonding through either a nitrogen or exocyclic oxygen is observed.[178]

Zinc complexes of the purine analog ligand, 5,7-diphenyl-1,2,4-triazolo[1,5-alpha]pyrimidine, have been described and characterized spectroscopically and by X-ray crystallography.[180] The tris(pyrazolyl)borate derivatized ligand, tris(3-cumenyl-5-methylpyrazolyl)borate, stabilizes zinc complexes of nucleobases and related compounds. For example, uracil is coordinated via its deprotonated N1 and 6-methylthiouracil acts as a bidentate ligand bonding through N1 and S.[181]

Zinc cyclen ([12]aneN_4) complexes have been shown to bind to thymidine bases such as AZT. Interest came from the demonstrated action of the zinc cyclen complex against HIV-1.[182] The zinc binds to the deprotonated N(3) of the 3′-azido-3′-deoxythymidine and the X-ray structure shows a distorted square pyramidal N_5 coordination with Zn—N(3) = 2.053(8) Å. It is possible that hydrogen bonding contributes to the stability of the complex in solution although distances were long in the solid state. Potentiometric titrations of deoxyribonucleosides showed extremely selective binding of thymidine and its derivatives. This could be attributed to the formation of hydrogen bonds between the cyclen amino groups and the carbonyl oxygens of deoxythymidine. Strong binding to deoxythymidine and uridine bases over other nucleosides in aqueous solution shows the importance of the imide functionality.

Kimura and co-workers have also demonstrated that the acridine pendent cyclen ligand can expand on the recognition potential by providing "multipoint" binding.[183] The acridine may π-stack with the nucleobase or even insert into DNA or RNA to facilitate the zinc cyclen thymine base interaction. The X-ray structure shows a stacking interaction of the acridine with the pyrimidine ring of thymine when bound to the zinc. A distortion of the square pyramidal geometry around the zinc is observed to allow more favorable hydrogen bonding and π-stacking interactions. Fluorescence spectra indicated the relative strength of interaction of the coordinated thymine with the acridine. The complex of this deoxythymidine is stable and does not dissociate at physiological pH.

6.8.4.6 Amides, Amidinates, and Guanidinates

The zinc complex formed with *N,N*′-diphenylformamidinate is structurally analogous to the basic zinc acetate structure, as $[Zn_4(\mu_4\text{-}O)L_6]$, and the basic beryllium acetate structure. It is prepared by hydrolysis of zinc bis(diphenylformamidinate).[184] Mixed metal zinc lithium species were assembled from dimethyl zinc, *t*-butyl lithium, *N,N*′-diphenylbenzamidine and molecular oxygen. The amidinate compounds formed are dependent on the solvent and conditions. Zn_2Li_2 and

Zn_2Li_6 compounds are formed with bridging amidinate and oxo ligands.[185] The X-ray structure of the dinuclear complex of zinc with tetraphenyl oxalic amidinate shows two tetrahedral zinc centers each coordinated to two nitrogen donors from the ligand and two chloride ligands.[186] Multinuclear oxalamidinato complexes have been characterized with only zinc atoms or a combination of zinc and palladium or nickel atoms. The resulting heteronuclear complexes were structurally characterized and their catalytic reactions, such as ethene polymerization and Heck coupling, investigated with zinc playing an inactive structural role.[187,188] A trinuclear zinc complex was formed with deprotonation of tris(2-hydroxybenzylidene)triaminoguanidine. A propeller-like conformation was demonstrated by the X-ray structure with ammonia and water molecules completing the coordination sphere to give $[LZn_3(NH_3)_3(H_2O)_3]^+$. Triply bridging guanidinate cores are isoelectronic with characterized μ_3-carbonates.[189]

Amide and alkyl donors are often found in the same complexes and hence a number of amide compounds have already been mentioned in Section 6.8.3. Zinc alkylamides are of interest as precursors for the nitrogen doping of material in metal organic chemical vapor deposition (MOCVD). A number of bis[(alkyl)(trimethylsilyl)amide] zinc complexes have been prepared and characterized.[190] Linear N–Zn–N diamide units are known.[11,191] Inverse crown ethers were formed using Zn amide compounds $[Na_2Zn_2L_4(O)]$ and $[K_2Zn_2L_4(O_2)_x(O)_y]_n$, L = hexamethyldisilylamide.[192] The structures show trigonal planar zinc centers encapsulating oxygen or peroxide. Dimeric species exist with μ_2–amide groups in a compound with a CN_3 donor set around each zinc atom with the amide donors from *N,N,N′*-trimethylethylene-1,2-diamide or *N,N,N′*-trimethylpropylene-1,2-diamide.[80] Zinc complexes of dicyanamide, $Zn[N(CN)_2]_2$, have an extended lattice structure in the solid state. A 2D network is formed of tetrahedral zinc centers with each zinc bound to four μ_2 dicyanamide ligands forming a repeating square array.[193] The shortest zinc–zinc distance is 4.492 Å and is found between layers, contrasting with the structure of $Zn[C(CN)_3]_2$, which contains octahedral zinc centers forming an interpenetrating network.[194]

A series of compounds of zinc with a diazabutadiene ligand have been prepared to study the different oxidation states of the ligand when coordinated.[195,196] The studies were carried out using EPR spectroscopy and X-ray crystallography. Mono- and dicationic, neutral, and mono- and dianionic zinc diazabutadiene complexes were prepared and structurally characterized as $K_x[Zn({}^tBuNCHCHN{}^tBu)_2]$, $Zn({}^tBuNCHCHN{}^tBu)_2$, and $[Zn(({}^tBuNCHCHN{}^tBu)_2](OTf)_x$ ($x = 1, 2$). The formal charge on the ligand varies from + 2 to −2. The crystal structures of the monoanioanic and mono-and dicationic species show structural variations with the N—C bonds lengthening and the C—C bonds shortening with each reduction step with the distortion as expected from the occupation of the ligand π^* orbitals.

6.8.4.7 Bipyridine and Phenanthroline Ligands

Pyridyl-containing ligands have already been discussed but the large body of work involving bipyridyl type ligands is represented here. Bipyridine and polybipyridine ligands in particular have found application with zinc in the formation of supramolecular structures and examples will be mentioned in Section 6.8.4.9.

The tetracyanoquinodimethane salt of tris(1,10-phenanthroline)zinc has been synthesized, structurally characterized by X-ray diffraction, and the magnetic properties investigated.[197] No charge conduction was observed in the compound and the single-crystal and polycrystalline powder EPR spectra were recorded.[198] The kinetics and equilibrium of zinc complex formation with 2-chloro-1,10-phenanthroline in aqueous solution have been studied.[199] The formation of bis- and tris-phenanthroline complexes of zinc is known.[200,201] The preparation of heteroleptic bis-phenanthroline zinc complexes was attempted with sterically hindered 2,9-diarylphenanthroline and 4,7-disubstituted phenanthrolines. The products were sensitive to condition and methods of preparation and characterized by mass spectrometry and NMR.[202] The crystal structure of $[Zn(1,10\text{-phenanthroline})_2(CH_3CO_2)]BF_4$ has been reported with all three ligands binding as bidentate resulting in an octahedral N_4O_2 coordination sphere around the zinc ion.[203] Tris(1,10-phenanthroline)zinc shows enantioselective binding to DNA.[204]

Studies of the thermodynamics of formation of complexes of zinc with 2,2′-bipyridine in the presence of halide and thiocyanate ions in DMF has been carried out.[205] The zinc complexes of 2,2′-bipyridine with *N*-(benzenesulfonyl)glycine and *N*-(toluene-*p*-sulfonyl)glycine were synthesized and infrared data implied a structural analogy with the cadmium complexes. This suggests that the zinc promotes sulfonamide nitrogen deprotonation in the amino acid ligands in the solid state.[206]

A 2,7-disubstituted pyrene linker between two pyridyl groups (**22**) forms the $[Zn_2L_2]^{4+}$ complex with zinc trifluoromethansulfonate that is non-helical. The single-crystal X-ray structure of bis{2,7-bis[3-(6′-methyl-2,2′-bipyridin-6-yl)-2-oxapropyl]pyrene}dizinc reveals two six-coordinate octahedral zinc centers with an N_4O_2 donor set. The non-helical geometry shows the pyrene rings separated by 3.65 Å. The X-ray structure was in agreement with solution structure from NMR measurements. The NMR data from the equivalent compound with a 1,4-benzene linker in place of the pyrene linker demonstrated an equal mixture of helical and non-helical complexes in solution.[207]

Formation of the zinc complex of the derivatized bipyridyl ligand, *N*-methyl-2,2′-bipyridylium, has been investigated.[208] The planar tetraheterocyclic ligand 6,6′-bis(4-methylthiazol-2-yl)-2, 2′-bipyridine coordinates through the two bipyridine nitrogens, and more weakly through the thiazolyl nitrogen atoms. The crystal structure of the zinc complex shows a distorted octahedral environment with two water molecules completing the coordination sphere.[209] Zinc complexes of bipyridyl ligands with azo- and imino-linked chromophores, 4,4′-bis(dialkylaminophenylazo)-2, 2′-bipyridine and 4,4′-bis(dialkylaminophenylimino)-2,2′-bipyridine, have been synthesized for nonlinear optical studies by electric field-induced second harmonic generation.[210] 4-(*N*-*t*-Butylaminoxyl)-2,2′-bipyridine forms 1:1 complexes with bis(hexafluoroacetylacetonato) zinc. The crystallographic analysis shows mononuclear structures in which the bipyridine moieties are coordinated to the metal ions in a *cis* configuration and the aminoxyl groups do not participate in the coordination.[211]

The presence of zinc with bidentate nitrogen donor ligands in the formation of novel composite materials by hydrothermal reactions has been studied. A zinc-containing one-dimensional material, $[Zn(phenanthroline)MoO_4]$ was isolated from molybdate, and from vanadium oxide in the presence of zinc 2,2′-bipyridine $[Zn(2,2'\text{-bipyridine})_2V_4O_{12}]$ was obtained.[212,213]

N,N′-coordination was found in the zinc complex of 2,2′-dipyridyl diselenide, $[ZnLCl_2]$.[214] The tridentate ligand 6-(2-aminophenyl)-2,2′-bipyridine contains two pyridyl and one aniline donor ligand to form a complex of the form $[ZnL_2]^{2+}$. The X-ray structure shows a distorted octahedral metal center with each ligand twisting from planar to accommodate the meridional binding.[215]

6.8.4.8 Tripodal Nitrogen Ligands

Polydentate nitrogen donor tripod ligands are discussed in this section. Mixed donor ligands containing nitrogen donors are discussed in Section 6.8.11.

6.8.4.8.1 Tris(pyrazolyl)borate ligands

A large body of work with particular reference to the mimicry of mononuclear zinc enzymes has utilized tris(pyrazolyl)borate ligands. This ligand class offers a facial coordination mode of three pyrazole *N*-donors and can be functionalized in the three and five positions on the rings to increase steric bulk and vary the electronic properties of the ligand. The synthesis and complex formation with these ligands has been extensively reviewed.[2,216–219]

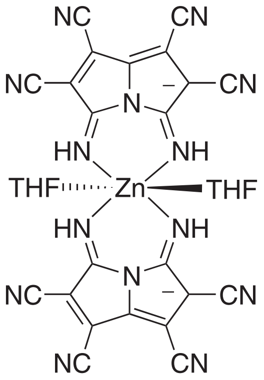
These versatile ligands have also shown applications in catalysis and more recently the formation of a variety of related ligands has led to varied donor sets and cavity properties from pyrazolylborate ligands. As this important area has been recently and extensively reviewed only a few representative examples will be discussed. Other examples appear elsewhere in relation to zinc coordination of other donors in the remaining coordination site or sites. A large volume of work has been produced recently in this area, particularly by the research groups of Parkin and Vahrenkamp.[181,220–228]

Catalysis of the formation of diethyl carbonate from ethanol and carbon dioxide has been observed with zinc hydroxide complexes of sterically restricted ligands, tris(3-cumenyl-5-methylpyrazolyl)borate and tris(3-*t*-butyl-5-methylpyrazolyl)borate. The zinc hydroxides could be converted to the alkyl carbonate complexes. For the cumenyl ligand reversible formation of the hydroxide and methyl carbonate in a methanol solution was observed by repeated bubbling with nitrogen or carbon dioxide.[229] Kitajima and co-workers studied the reactivity of zinc hydroxides complexed to less sterically bulky tris(pyrazolyl)borate ligands.[230]

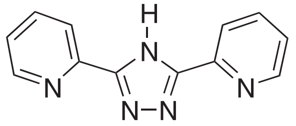
The reactions of carbon dioxide with zinc hydroxide complexes of the 3-*t*-butyl 5-methyl and 3,5-di-*iso*-propyl pyrazolyl derivatives were investigated. IR spectroscopy demonstrated formation of a bicarbonate derivative of the former complex and ^1H NMR showed a rapid reversible reaction. However, a slower transformation occurs from the bicarbonate complex to a bridged carbonate dimer. This contrasts with the behavior of the latter, and less sterically bulky hydroxide complex which shows more rapid formation of (μ-CO_3)Zn_2 complex where the carbonate is unsymmetrically bound.[231]

The X-ray structure of the unsubstituted tris(pyrazolyl)borato zinc nitrate has been solved showing a unidentate coordination mode for nitrate, in contrast with the *t*-butyl substituted ligand, which shows anisobidentate nitrate coordination due to the steric effects.[232] A partial explanation of the reduced activity of cadmium-substituted carbonic anhydrase is offered by Parkin on the basis of the comparison of nitrate coordination to cadmium and zinc trispyrazolylborate moieties. A contributing factor may be the bidentate coordination supported by the cadmium that does not allow the facile access to a unidentate bicarbonate intermediate, which could be highly important to carbonic anhydrase activity.[233]

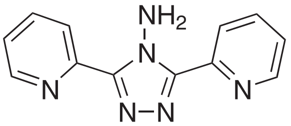
Pyridyl functionalized tris(pyrazolyl)borate ligands show some interesting properties including the formation of polynuclear zinc complexes.[234] Some of these contain extensive H bonding and have potential as models for multinuclear zinc enzymes such as phospholipase C or P1 nuclease.[235] A bis-ligand complex of the hydrotris(5-methyl-3-(3-pyridyl)pyrazolyl)borate ligand (**23**) shows octahedral coordination of all six pyrazole nitrogen donors despite the steric bulk.



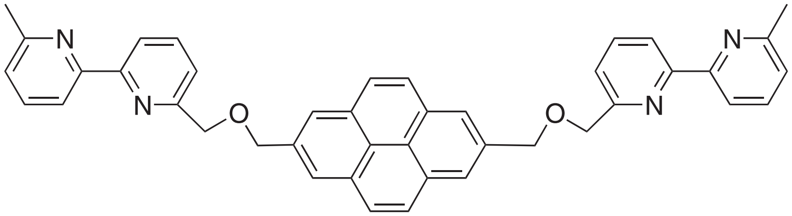
(**19**)



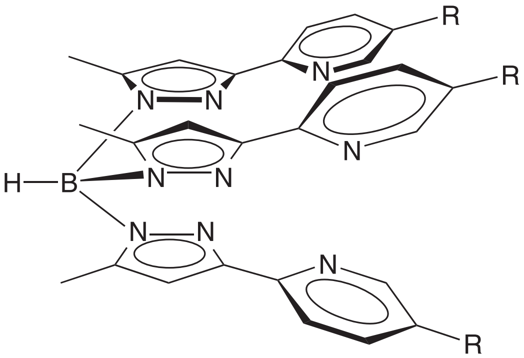
(**20**)



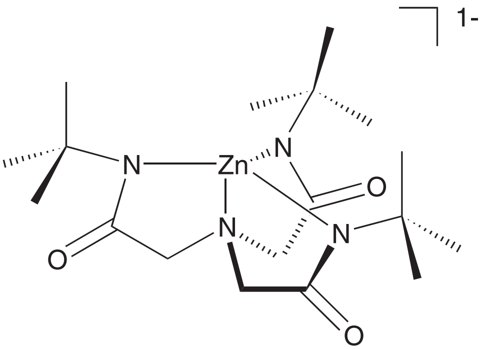
(**21**)



(**22**)



(**23**)



(**24**)

The zinc complex of hydrotris(3-*p*-cumenyl-5-methylpyrazolyl)borate with a bound 3,5-*t*-butyl-1,2-semiquinonate ligand has been prepared, the X-ray structure showing a five-coordinate metal center with three ligand nitrogens and two semiquinonate oxygens binding. The parent catecholate complex is unusually air stable but undergoes slow air oxidation to give the semiquinonate.[236] The hydroxide complex of this ligand has been prepared.[237] The hydroxide complex can be converted into a hydrosulfide complex and thermal condensations of the two derivatives result in molecular zinc oxide or sulfide dimeric species. The hydroxide also reacts to give alkylcarbonate, *O*-ethyldithiocarbonate, and thiocarbamate ligands under appropriate conditions.

The alcohol dehydrogenase enzyme has been modeled using the tris(3-cumenyl-5-methylpyrazolyl)borate ligand. The *iso*-propoxide complex can be oxidized by *N*-benzylnicotinamide chloride to acetone in a low yield. A stronger oxidant oxidizes phenolates with *o*-hydroxymethyl substituents to phenolates with *o*-formyl substituents. The presence of the zinc hydroxide complex showed increased reduction rates of benzaldehydes with electronegative substituents to corresponding benzyl alcohols by *N*-benzyldihydronicotinamide.[238]

The zinc acetate complex of tris(3-*t*-butyl-5-methylpyrazol-1-yl)borate was prepared as a structural model for carbonic anhydrase and comparison with the enzyme active site structures confirmed that the complexes are excellent structural models.[239] A mononuclear zinc hydroxide complex can also be formed with the tris(pyrazolyl) borate ligand system as a structural model for carbonic anhydrase.[240]

Zinc fluoride complexes of 3-*para*-tolyl and 3-*t*-butyl of hydrotris(3-R-5-methylpyrazol-1-yl) borato zinc complexes have been synthesized via complex formation in the presence of potassium fluoride. Facile substitution of the fluoride yields the zinc pyridyl, diethyl ether, or hydride derivatives.[241]

6.8.4.8.2 Other nitrogen donor tripodal ligands

Tris(2-aminoethyl)amine (tren) and hexamethyl tren form pentacoordinate complexes with a bound water. The enthalpies of ionization have been determined.[242] These results dispute the data from the systems that led to the view that solvent structure mediates the pK_a of zinc bound water in zinc hydrolytic enzymes. The effect was shown to be entirely enthalpic.

Borovik and co-workers developed a ligand, formed by deprotonation of tris((*N*-*t*-butylcarbamoyl)methyl)amine, to form trigonal–monopyramidal transition metal complexes.[19] The structure of the zinc complex (**24**) shows identical ligand coordination to the cobalt and nickel complexes and is crystallized as the tetraethylammonium salt. The unusual geometry is favored due to the presence of bulky *t*-butyl groups. The N amidate–zinc-N amidate angles in the trigonal plane are 119.5(5)° and the zinc sits 0.14 Å above this plane. The formation of chiral cavities was investigated with the related homochiral tripodal ligand tris(*N*-(*S*)-(−)-(α)-methylbenzylcarbomoylmethyl)amine (Figure 3).[243]

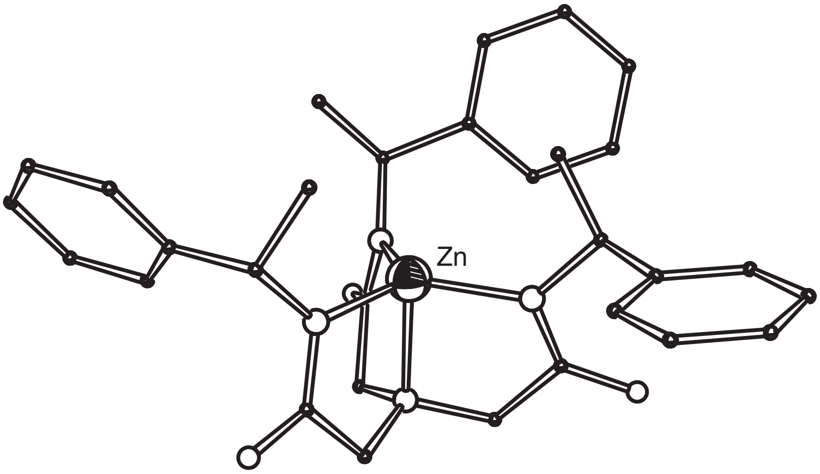


Figure 3 Molecular structure of the trigonal–monopyramidal zinc complex formed on deprotonation of tris(*N*-(*S*)-(−)-(α)-methylbenzylcarbamoylmethyl)amine.[243]

In reaction with zinc salts, the tridentate ligand tris(2-pyridyl)methylamine forms the crystallographically characterized $[ZnL(H_2O)_3]^{2+}$ cation with the three pyridine nitrogens face capping the octahedron and a hydrogen bonding network in the solid state.[244] This contrasts with the tetradentate ligand tris(2-pyridylmethyl)amine and its zinc halide complexes (chloride, bromide, and iodide), which were synthesized and studied. Electrospray mass spectrometry analysis of solutions, with added competing anions, was consistent with NMR data. The solid-state structures of $[ZnLCl]ClO_4$ and $[ZnLI]ClO_4$ contain trigonal–bipyramidal metal ions with the halide coordinated in an apical position.[245]

The zinc complex of the unsymmetrical pyrazoly/pyridyl tripod, bis(pyrazol-1-yl)(pyridin-2-yl) methane, has been structurally characterized and can be compared to trispyridyl donor ligands.[246] Similarly, instead of varying the nitrogen donor group of the tripod the bridgehead can be changed from a –CH to P or N. Structural studies allow comparisons of the phosphine and amine equivalents in the formation of 1:2 zinc tris(2-pyridyl)methylamine complexes, e.g., $[Zn(P(C_5H_4N)_3)_2]^{2+}$, with all structures showing trigonal distortion from octahedral geometry due to the restricted bite angle of the ligands.[247]

The ligand tris[2-(1-methylbenzimidazol-2-yl)ethyl] nitromethane (**25**) has been used in the formation of zinc complexes as models of the active site of carbonic anhydrase, and the formed complexes reveal affinity for the sulfonamide-containing enzyme inhibitor acetazolamide.[248]

Bis and tris(imidazolyl) phosphine ligand complexes of zinc have been of interest for a number of years as models of the active site of carbonic anhydrase and probed for reactivity with bicarbonate and carbon dioxide.[249] Recently, related phosphine ligand derivatives that are increasingly sterically demanding have been synthesized and studied. The comparison of X-ray structures of zinc nitrate tris(1-isopropyl-4-*t*-butylimidazolyl) phosphine ligand derivative (**26**), which has a charge of 1+, with the equivalent tris(3-*t*-butylpyrazolyl)hydroborato complex, which is neutral, demonstrates that the charged complex has a greater tendency to adopt bidentate coordination of the nitrate ligand.[250]

The coordination mode of nitrate to a number of transition metal ions bound to the ligand tris(1-isopropyl-4-*t*-butylimidazolyl)phosphine has been studied using X-ray crystallography.[250,251] The nitrate ligand coordination modes correlate with the activity of the metal-substituted carbonic anhydrases; those with a greater degree of asymmetry in the binding are the most active metals (Co, Zn). This may point to access to a monodentate rather than a bidentate coordination mode for the bicarbonate intermediate as a requirement for high CA activity. The zinc is five-coordinate with Zn—O distances 1.986 Å and 2.518 Å and the nitrate ligand anisobidentate.[251] This ligand has been used to characterize a highly important example of a zinc hydroxide complex with tris imidazole coordination, as is observed in the carbonic anhydrase active site.[252] The comparison between zinc and cadmium hydroxide complexes has also been made. These studies are of relevance to the active site of carbonic anhydrase and metal substituted forms.[253] The analogy of bicarbonate to nitrate is not always appropriate as bicarbonate has more than one option for bidentate binding; it could bond through the two oxygen atoms or an oxygen atom and a hydroxide.

The face capping ligand *cis,cis*-1,3,5-triaminocyclohexane provides the basis for a number of functionalized ligand and biomimetic complexes of zinc.[254,255] The zinc complexation chemistry of *cis,cis*-1,3,5-triaminocyclohexane and simple derivatives was thoroughly investigated by Vahrenkamp and co-workers. The nonfunctionalized ligand forms 1:1 ligand to metal ratio complexes with zinc acetate and zinc halides, and 2:1 complexes with zinc perchlorate and zinc triflate. The 2:1 compounds were not observed with the tris-*N*-methylated derivative. It was suggested that the 1:1 halide-containing complexes exhibit tetrahedral metal centers with one face capping N_3 ligand and an X-ray structure of the 2:1 complex of *cis,cis*-1,3,5-triaminocyclohexane with zinc triflate revealed an octahedral metal center coordinated by two N_3 face capping ligands. NMR solution studies show little or no ligand exchange in solution. Vahrenkamp also investigated Schiff base formation reactions with benzaldehyde forming a tris-iminophenyl derivative. This ligand was hydrolyzed on complexation with zinc.[256] Walton and co-workers have investigated the formation of cavity-type ligands from *cis,cis*-1,3,5-triaminocyclohexane, and Schiff base derivatives were formed from cinnamaldehydes (**27**).[257,258] These compounds are of relevance to the active site of the enzyme carbonic anhydrase. It was observed by Walton that the steric interactions were too unfavorable to allow coordination of the tris-iminophenyl derivative as a face capping ligand and partial hydrolysis occurred to give (**28**). Walton's compounds are of particular interest in modeling the enzyme carbonic anhydrase as they mimic not only the donor set of the active site but also aspects of the surrounding cavity. The related face capping triamine ligand 1,3,5-triamino-1,3,5-trideoxy-*cis*-inositol forms a 2:1 complex with zinc where each of the ligands is coordinated through the three nitrogen donors.[259] Brechbiel and co-workers have synthesized the hexadentate ligand, *N,N′,N″*-tris(2-pyridylmethyl)-*cis,cis*-triaminocyclohexane and structurally characterized the zinc complex.[260]

6.8.4.9 Supramolecular Compounds with Nitrogen Donor Ligands

Zinc is frequently used as a supramolecular building block due to its inert oxidation state and flexibility in coordination number and geometry.

A mononuclear zinc complex forms with 2,2′:6′,2″:6″,2‴-quaterpyridine.[261] Helical quinquepyridine derivatives can be formed with 6,6⁗-dimethyl-2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine. A dimeric monohelical (or single-stranded helicate) complex is formed with a hydroxy bridge between five-coordinate and four-coordinate zinc centers, $[Zn_2L(OOCCH_3)_2(\mu\text{-OH})][ClO_4]$.[262] The intermetallic distance is 3.277(4) Å and the Zn—O–Zn angle is 116.82(17)°. This structure contrasts with saturated helices as produced by Constable and co-workers with septipyridines where all donor atoms come from the same strand. The crystal structure of the zinc complex of 2,2′:6′,2″:6″,2‴:6‴,2⁗:6⁗,2⁗′-sexipyridine, $[Zn_2L_2](PF_6)_4{\cdot}2MeCN{\cdot}2H_2O$, confirmed the double-helical topology.[263] The solubilized septipyridine reacts with zinc acetate to give $[Zn_2L_2][PF_6]_4{\cdot}6MeCN$ which was structurally characterized to show a head-to-head directional double helicate.[264]

Spontaneous self assembly of a dinuclear triple helical complex is observed with linked bis-[4,5]-pineno-2,2′-bipyridines. Studies by electrospray mass spectrometry, CD and NMR determined that the major species in solution was a complex of Zn:L = 2:3 stoichiometry with a triple helical structure and an enantiomerically pure homochiral configuration at the metal centers. The preference for the formation of one of the possible stereoisomers over the other is of interest.[265] Another binuclear triple helical complex is formed from zinc addition to bis[5-(1-methyl-2-(6-methyl-2′-pyridyl)benzimidazolyl)]methane. Spectrophotometric titrations with a zinc solution shows successive formation of a triple helical complex $[Zn_2L_3]^{4+}$, a double helical complex $[Zn_2L_2]^{4+}$, and $[Zn_3L_2]^{6+}$.[266]

Metal complexes of pteridine have provided 3D H-bonded networks containing H bonding between pteridine ligands and water molecules, and π-stacking and H bonding between adjacent pteridine ligands. The complex $[ZnL(H_2O)_2].2H_2O$ has been prepared.[267]

Metal complexes of bilinones have helical chirality and the introduction of point chirality may give some insight into the structural features of chiral functional molecules including biomolecules. A chiral group was introduced at the helix terminal of 19-alkoxybilinone. A series of zinc derivatives (**29**) were examined to observe the helical chirality induction of the point chiral alkoxy group. Chiral induction was sensitive to the distance to the asymmetric carbon as well as to substituents on the asymmetric carbon. The compounds were studied by ^{1}H NMR and CD spectroscopy. In one case (R=(*R*)-2-methyl-1-phenylpropanoxy group) helical chirality induction was observed in >95% enantiomeric excess at 223 K in CD_2Cl_2.[268,269]

The template effect of a metal center in organizing two phenanthroline subunits has been exploited to form polypyrrole films from which the zinc center can be removed and rebound. The chelating ligand used is a 2,9-diphenyl-1,10-phenanthroline subunit functionalized with two pyrrole groups and on binding to zinc or another metal center the two ends are entwined leading to a highly entangled network on electropolymerization of the pyrrole rings. The ligand is related to those used by Sauvage in catenane formation. The zinc can be removed from the polymer with thiocyanate and no collapse of the 3D structure occurs. The facile rebinding of zinc suggests some organization is retained in the polymer. Electrochemical studies show the low-oxidation-state formal zinc(I) is remarkably stabilized by the entwined and entangled system.[270]

Chiral [2 + 2] metallomacrocycles, assembled from functionalized 2,2′-bipyridines and zinc, have been studied for the effect of guest molecules and linker length. Equimolar amounts of zinc triflate and the ligand (**30**) with $R{=}CH_2$ assemble exclusively into the chiral [2 + 2] metallomacrocycle $[Zn_2L_2]^{4+}$ at low concentrations ($<10\,\mathrm{mmol\,dm^{-3}}$) or in the presence of an aromatic guest molecule which binds in the cavity of the macrocycle. The X-ray structures of these compounds with either 1,2- or 1,4-dimethoxybenzene bound in the cavity were obtained. The structures demonstrate a variation in cavity size dependent on the substrate to maximize the possible interactions. The less rigid ligands, where $R = CH_2CH_2$ or OCH_2, show a mixture of oligomers when studied by NMR.[271]

Rebek and co-workers have generated a species containing a zinc ion coordinated in conjunction with a "deep" cavity in the metallocavitand species. The molecular cavity of 8 × 10 Å has a Zn-phenanthroline fragment at the top edge directed toward the cavity. The binding of the metallocavitand to quinclidine and DABCO was studied by UV-vis and ^{1}H NMR spectroscopy, demonstrating the binding and slow exchange kinetics. The cavity and the appended zinc ion are both involved in the binding, demonstrating the potential for these compounds in biomimetic hydrolysis or esterification reactions.[272]

The structure of coordination polymers formed with 3,6-bis(pyridin-3-yl)-1,2,4,5-tetrazine and zinc salts can be controlled by the choice of alcoholic solvents. Infinite lattice compounds of the form $\{[Zn_2L_2(NO_3)_4(MeOH)_2(\mu\text{-}L)]\}$ and $\{[Zn_2(\mu\text{-}L)_3(NO_3)_4](CH_2Cl_2)_2\}$ have been structurally characterized. The former structure shows an alternating single- and double-bridged species whereas the latter exists as a non-interpenetrated ladder complex.[273]

Two-dimensional planar interpenetrating networks have been formed using the spacer ligand 2,2′-bis-1,6-naphthyridine with a zinc salt.[274] Helicate structures have been synthesized which rely heavily on non-covalent interactions in the metal-assisted self-assembly process in solution.[275]

Incorporation of interactions such as π–π stacking can lead to further aggregation in the solid state. The use of biphenyl derivatives of terpyridine ligands [4′(4-biphenyl)-2,2′:6′,2″-terpyridine] (**31**) has given one such example.[276] The X-ray structure of the zinc complex reveals a pseudo-octahedral zinc ion forming a two-dimensional sheet with face-to-face π stacks with a centroid-to-centroid distance of 3.87 Å and also edge on face interactions. Luminescence studies were carried out showing strong blue emission with higher quantum yield (0.80) than the free ligand.

Blue luminescence of zinc complexes of pyridyl-containing complexes is an area of current interest.[277] Design of blue luminescent materials is of relevance to display applications, as blue-light-emitting diodes, and to this end Che examined solution luminescence of zinc pyridylamine complexes.[73,278] Che and co-workers studied the complex Zn_4O(7-azaindoyl)$_6$ which has a blue emission at 433 nm in the solid state.[279,280] In an attempt to improve on stability Wang *et al.* examined compounds with neutral 7-azaindole and an *N*-functionalized pyridyl derivative.[281] In contrast with other metal complexes of the neutral 7-azaindole (**32**), Zn(7-azaindole)$_2$(OAc)$_2$ is a blue luminescent compound and a *N*-(2-pyridyl) 2-azaindole (**33**) and its complexes were also studied. The 7-azaindole complex has extensive intramolecular H bonding around a four-coordinate Zn center with two pyridyl nitrogens and two monodentate acetates binding. The *N*-(2-pyridyl) 2-azaindole formed a 1:1 complex (**34**). The zinc complexes of the azaindole pyridyl derivatives formed complexes which did not have sufficient thermal stability for use in devices and showed rapid exchange in solution, but electroluminescent devices producing blue light were fabricated

with Zn(7-azaindole)$_2$(OAc)$_2$.[281] The shift of the emission to the visible part of the spectrum on zinc coordination has also been observed in tripyridyl compounds by Yang *et al.*[282]

Coordination networks can be crystallized from the zinc ion and 4,4′-bipyridyl.[283,284] Some of these networks, including that of Hoskins *et al.* show interpenetration of an independent grid such as square sheets.[285] These do not form spontaneously with bridging hydroxides as is observed with flexible bipyridyls.

Plater *et al.* structurally characterized a number of coordination network-type supramolecular structures with flexible bipyidyl ligands 1,3-bis(4-pyridyl)propane, 1,4-bis(4-pyridyl)butane, and 1,7-bis(4-pyridyl)heptane.[286] The characterization of the complex with the propane bridged ligand showed each zinc in a distorted tetrahedral environment with two pyridine nitrogen and two metal bridging hydroxide ligands. A $Zn_3(OH)_3$ six-membered ring forms the basis of the structure with Zn—O bond lengths in the range 1.908–1.934 Å. The other ligands give different solid state coordination network structures. All contain hydroxyl ion bridges and as chain lengths increase so does alkyl chain disorder. Coordination networks can also be formed with rigidly bridged pyridyl ligands such as 3,6-bis(pyridin-3-yl)-1,2,4,5-tetrazine (**35**). Three different zinc networks were formed and structurally characterized with the structural type controlled by the choice of alcoholic solvent.[273] Zinc nitrates were used in compound formation and hydrogen bonding observed to the metal-bound alcohols. Six-coordinate distorted octahedral zinc ions were observed.

Self-assembly methods have been used to form zinc bisquinoline assemblies with high refractive index and film uniformity.[287]

Other supramolecular structures such as catenanes and rotaxanes can be formed using zinc as a template ion; for example, a benzylic imine catenate formed by Leigh *et al.*[288] The reversible five-component assembly of a [2]catenane from a chiral metallomacrocycle and a dinaphtho-crown ether has been achieved. Zinc is used as the metal component and drives assembly via the coordination to a bipyridyl unit; π interactions between the aromatic components are also important.[289]

An ethidium bromide–peptide conjugate has been prepared that shows induction of chirality on binding to zinc.[290] Circular dichroism and spectroscopic studies show an increase in α-helicity of the 16 amino acid peptide and effects are thought to be synergistic between the ethidium group and the zinc. The changes in the secondary and tertiary structure on binding the zinc induce the chirality of the ethidium group and are very sensitive to changes in temperature and pH.

1,1′-(1,4-butanediyl)bis(imidazole) can be used a linker in the formation of coordination networks with zinc. X-ray structural studies show two different types of coordination polymers dependent on the anion present.[291] In each example zinc is five-coordinate trigonal bipyramidal, with three imidazole *N*-donors from three different bisimidazole ligands, a water *O*-donor and either a sulfate ion *O*-donor or a further water molecule completing the coordination sphere.

6.8.5 PHOSPHORUS AND ARSENIC LIGANDS

6.8.5.1 Phosphorus Ligands

The CSD reveals that the mean zinc phosphorus bond length is 2.404(5) Å based on all single-crystal X-ray structural data in the database and uncorrected for temperature.

A number of monomeric zinc complexes were synthesized from zinc powder in the presence of R_3PI_2 with aryl R groups resulting in triphenylphosphine, diphenylethylphosphine, or diphenylmethylphosphine ligands. The monomeric structure of $ZnI_2(PPh_2Me)_2$ is somewhat surprising as less bulky groups do not form the more sterically crowded monomeric species and formation of the species is attributed to favorable π stacking interactions.[292]

An air-sensitive homoleptic silyl phosphido zinc dimer (**36**) was structurally characterized with each zinc three-coordinate in a trigonal planar geometry.[293] Studies with ^{31}P NMR spectroscopy demonstrates that the phosphido complex remains dimeric in solution; however, the ligands undergo bridging to terminal site exchange with a barrier of 14.3(2) kcal mol^{-1}. The $P(SiMe_3)_2$ ligands have stronger bridging tendencies than the related amide, $N(SiMe_3)_2$, ligands.[294]

Dimeric zinc complexes of tertiary phosphines, $[Zn(PR_3)I_2]_2$, are also formed from zinc powder and R_3PI_2, (R = Me, Et, *n*-Pr, *n*-Bu). The crystal structure of the ethyl derivative demonstrates the dimeric nature of the complexes.[295] Metallation of diphenylphosphine with $ZnEt_2$ results in a trimeric species with a Zn_3P_3 core and bridging diphenyl phosphide ligands. Two protic ($HPPh_2$)

phosphine ligands act as donors to two of the zinc centers.[296] A related trimeric chair-shaped species is formed with dicyclohexylphosphine, giving two three-coordinate and one four-coordinate zinc center, $[Zn(Et)(\mu\text{-}P(cyclohexyl)_2)]_3$.THF. The tetrahydrofuran is an oxygen donor ligand bound to the four-coordinate zinc center.[297]

The X-ray structure of a tetrameric zinc species reveals a planar Zn_4P_4 ring with the phosphorus donor, a diorganophosphide, and hydroxide donors completing the coordination around the zinc, $[Zn_2(Bu^t{}_2P)_2(OH)(\mu\text{-}OH)]_2$.[298] The tetranuclear complex $[Zn_4Cl_4(PPh_2)_4(PPr_3)_2]$ is formed from zinc chloride and can be regarded as an intermediate on the route to polymeric $[Zn(PPh_2)_2]_n$.[299] Zinc chloride in the presence of tris(trimethylsilyl)phosphine forms tetranuclear complexes $[Zn_4Cl_4(P(SiMe_3)_2)_4(MeCN)_2]$ and addition of diethylphenyl phosphine to the reaction mixture results in the formation of $[Zn_{10}Cl_{12}(PSiMe_3)_4(PEt_2Ph)_4]$. Zinc iodide forms the binuclear complex $[ZnI_2P(SiMe_3)_2]_2$ in the presence of tris(trimethyl)silylphosphine and further reaction with tetra-*n*-butyl ammonium iodide results in the hexameric complex $[(NBu_4)]_2[Zn_6I_6(PSiMe_3)_4(C_4H_8O)_2]$.[300]

Zinc telluride and zinc selenide polymetallic species with phosphine ligands have been structurally characterized;[301] further details are discussed in Section 6.8.7. The use of mono- and bidentate phosphine ligands of varying steric bulk contributes to the variation of structural types in the formation of zinc tellurolate polyzinc species with Zn_{10}, Zn_{14}, and Zn_{16} species structurally characterized by Fenske *et al.*[302]

Phosphido-bridged multinuclear complexes have been formed from zinc chloride of the form $[Zn_4(PPh_2)_4Cl_4(PRR'_2)_2]$, where R and R′ are alkyl or phenyl groups. Related tetrameric structures can be formed with a bridging dialkyl phosphide or (trimethyl)silylphenyl phosphide.[303]

Three-coordinate zinc complexes have been characterized with a PS_2 or PSe_2 donor set with bulky thio- or selenophenolates and trimethyl- or dimethylphenylphosphine.[304] The reaction of zinc chloride with trimethylphosphine produces different products dependent on the reaction conditions. A monomeric and a dimeric species, $ZnCl_2(PMe_3)_2$ and $Zn_2Cl_4(PMe_3)_3$, have been structurally characterized by X-ray crystallography; the latter species has one bridging chloride ligand between a $Zn(PMe_3)_3$ unit and a $ZnCl_3$ unit.[305] A series of complexes with $SiPh_3$ or $SnCl_3$ coordinated and two phosphine ligands per zinc center have been characterized with trimethyl- and triphenylphosphine.[306] Zinc can be inserted in a cyclophosphazene unit resulting in a six-membered ring monomeric structure in the solid state.[307]

Dimeric phenoxide derivatives of zinc with coordinated tetrahydrofuran solvent show ligand exchange in the presence of tricyclohexylphosphine, $[Zn(O\text{-}2,6\text{-}F_2C_6H_3)_2{\cdot}PCy_3]_2$. The dimeric structure remains, with the phosphine ligands accommodated in the trans configuration. The ^{31}P NMR spectra, recorded in the presence of free tricyclohexylphosphine, indicate slow exchange of the phosphine ligands.[308] The zinc (2,6-di-*t*-butylphenoxide) dimeric complex that has the same structure has been formed with phosphine donors tricyclohexylphosphine and diphenylmethylphosphine. Again, slow phosphine exchange is observed but more rapid displacement of tricyclohexylphosphine with the smaller trimethylphosphine occurs.[309]

A triazacyclononane ligand with a diphenyl phosphine pendant connected via a propyl linker formed a dimeric complex of zinc $[Zn_2L_2Cl_3][ClO_4]$.[310]

Bis-phosphaallyl complexes of zinc have been prepared and characterized from cyclic aminophosphazanes and aminoiminophosphanes. The structure of the bis(1,3-diaza-2-phosphaallyl)zinc complex [Zn(RNPNR′)2] (R = R′ = C_6H_3Pr2i-2,6) was determined.[311]

Zinc bis(diethyldithiocarbamato) trialkylphosphine complexes were synthesized as single-source molecular precursors to zinc sulfide. The monomeric five-coordinate species were synthesized with alkyl = methyl or ethyl. The bidentate phosphine ligand, 1,2-bis(diethylphosphino)ethane, formed a dimeric zinc species with zinc bis(diethylthiocarbamate) $[(Et_2NCS_2)_2Zn]_2(\mu\text{-}L)$ and in the presence of a mixture of zinc and cadmium bis(diethylthiocarbamates) a heterobinuclear complex, $[(Et_2NCS_2)_2Zn](\mu\text{-}Et_2PCH_2CH_2PEt_2)[Cd(Et_2NCS_2)_2]$. The X-ray structures show five-coordinate zinc centers with a bridging phosphine ligand; ^{31}P NMR was used to study ligand exchange.[312]

Dialkyl zinc compounds form phosphine complexes of formula $RZnP(SiMe_3)_2$ on addition of one equivalent of bis(trimethylsilyl)phosphine. Solution and solid-state studies showed that the complexes are dimeric or trimeric in solution or the solid state. Bis(trimethylsilyl)phosphidomethylzinc crystallizes as a trimeric molecule with a Zn_3P_3 core in the twist-boat conformation. Bis(trimethylsilyl)phosphido-*n*-butylzinc, shows a similar central Zn_3P_3 fragment. The sterically more demanding trimethylsilylmethyl substituent forms a dimeric species of bis(trimethylsilyl) phosphido-trimethylsilylmethylzinc. Solution studies of bis(trimethylsilyl)phosphido-*iso*-propylzinc demonstrate a temperature-dependent equilibrium of the dimeric and trimeric species and the crystalline state contains a 1:1 mixture of these two oligomers. A monomeric bis(trimethylsilyl)phosphido-tris(trimethylsilyl)methylzinc has also been synthesized.[313]

The trinuclear complex [1,2-dipyridyl-1,2-*t*-bis(butyldimethylsilylamido)ethane] trizinc-bis (μ-triisopropylsilylphosphanediide) has one zinc coordinated in a bent geometry between two phosphorus donors.[314] The related compound bis[tris(trimethylsilyl)methylzinc] triisopropylsilylphosphandiide shows a similar coordination geometry around a zinc center with one of the shortest Zn—P bond distances (2.23 Å), attributed to the low coordination number.[315] A bidentate diphosphine ligand can act as a bridging ligand between two zinc centers resulting in a distorted trigonal–bipyramidal geometry with one phosphine bound to each zinc in μ-[1,2-bis (diethylphosphino)ethane]-*P*-*P*′-bis[bis(diethyl-dithiocarbamato-S,S′)zinc].[316]

A chloride-bridged Zn–V–Zn trimer contains terminal triphenylphosphine ligands bound to a tetrahedral zinc, each zinc with two bridging chloride and a terminal chloride.[317]

A number of zinc phosphine complexes have been synthesized due to interest in chemical vapor deposition; for example, $Zn(S\text{-}2,4,6\text{-}^tBuC_6H_2)_2(Ph_2PMe)$ and $[ZnI_2(PEt_3)]_2$.[295,304] The structure of bis[(diphenylphosphino)propyl] zinc shows a highly distorted tetrahedral environment with an alkyl and a phosphorus donor binding from each bidentate ligand.[318]

6.8.5.2 Arsenic Ligands

The limited number of characterized complexes of arsine and arsenide ligands contain some similar structural motifs to those exhibited for equivalent phosphorus ligands. Coordination numbers of two, three, or four are observed with monomeric up to decameric zinc complexes structurally determined by X-ray crystallography.

A monomeric zinc complex with arsine ligands can be formed from zinc powder and Me_3AsI_2 with the X-ray structure showing a significantly distorted tetrahedral $ZnI_2(AsMe_3)_2$ species. If the alkyl group is changed from methyl to ethyl a dimeric zinc species, $Zn_2I_4(AsEt_3)_2$, with two bridging iodide ligands was formed. This could be attributed to the increased steric bulk of the arsine ligand.[319]

A series of polyzinc compounds was synthesized in the reaction of zinc halides with tris(trimethysilyl)arsine.[320] The product obtained was dependent on the halide used, the solvent, and the presence of other phosphorus ligands. Polymetallic arsenide and arsine species with two, four, six, and ten zinc atoms were structurally characterized. A dimer with a bridging iodide and terminal arsine ligands was characterized in contrast to a dimer with bridging arsenide ligands in the presence of phosphine and chloride ligands.[300] A zinc complex of a dipivaloylarsenide ligand forms to give a tetrahedral zinc center with two chloride and two arsenide ligands. The structure also contains two lithium atoms bound to the pivaloyl oxygens and bridging with the zinc via the chlorides.[321]

Bis(trimethylsilyl)arsine reacts with diethyl- or dimethylzinc to form different arsenide complexes with the structure dependent on the steric demands of the alkyl group. In the presence of both methyl and ethyl groups alkylzinc bis(trimethylsilylarsenide) forms which has a trimeric solid state structure (**37**) with a six-membered Zn_3As_3 and Zn–As distances with an average of 2.48 Å.[322]

Two-coordinate zinc centers are observed in a dimeric complex (**38**) synthesized in the reaction of lithium tri-*iso*-propylsilylarsenide and tris(trimethylsilyl)methylzinc chloride. Again, the increased steric bulk of the alkyl groups on the zinc and arsenic centers is the major factor in determining the structural type.[323] Comparison of group 12 metals in the formation of metal–arsenic bonds confirmed that zinc formed the most stable compounds. A dimeric structure with bridging di(*tert*-butyl) arsenide groups was determined by X-ray crystallography and other species were characterized by molecular weight measurements in solution.[324]

6.8.6 OXYGEN LIGANDS

Zinc hydroxide and alkoxide species are particularly relevant to catalytic processes, often forming the active species. The cooperative effects of more than one zinc ion and bridged hydroxides are exploited in some enzymatic systems. Zinc alkyl phosphate and carboxylate materials have been important in the formation of framework compounds, often containing large amounts of free space for the inclusion of guest molecules. Aldehyde and ketone compounds are of low stability due to the poor donor capabilities of the ligands; however, a number of examples have recently been characterized.

Zinc oxide has various uses but the most important is as co-catalyst with CuO supported on Al_2O_3 for low-pressure synthesis of methanol from methane.[325]

Electron spectroscopic studies of methanol chemisorption on ZnO single-crystal surfaces were performed using XPS, NEXAFS, variable-energy photoelectron spectroscopy, and SCF-X alpha Scattered Wave molecular orbital calculations. The methoxide bonding and reactivity gave insight into the molecular mechanism of methanol synthesis.[326] Zinc coordination compounds are used as precursors in the formation of the zinc oxide materials; for example, a zinc copper maleate precursor has been structurally characterized and the dehydration and decomposition studied together with the final phases.[327] In relation to catalytic poisoning, photoelectron spectroscopic studies of H_2S binding to the surface zinc sites in ZnO have been carried out.[328] The properties of zinc oxide as a semiconductor are also of importance, for example, room-temperature ultraviolet nanowire nanolasers based on zinc oxide semiconductor nanowires have been synthesized. Such short-wavelength nanolasers could have many important applications including optical computing and information storage.[329]

A number of compounds with Zn_4O core, including carboxylate and carbamates, have been isolated and discussed as potential molecular models of bulk ZnO.[330,331]

6.8.6.1 Hydroxides and Hydrated Species

The trigonal–bipyramidal pentaaquo zinc species has been structurally characterized.[332] IR spectroscopy has been utilized in studies of the hydration of zinc in aqueous solution and in the hydrated perchlorate salt aqua ions $Zn(H_2O)_6^{2+}$.[29]

Zinc hydroxides with the metal ligated by nitrogen and sulfur are relatively rare. Most structures show dimeric zinc compounds with the hydroxide bridging the two metal centers. For example, in the presence of hydroxide, the potentially tetradentate ligand *N*-bis-2-(methylthio)ethyl-*N*-(6-neopentylamino-2-pyridylmethyl)amine acts as a tridentate ligand with an N_2S donor set and one of the thioether sulfur donors does not participate in the zinc coordination.[333] The X-ray crystal structure shows the remaining coordination sites are filled by two bridging hydroxide ligands forming a dimeric species (**39**). A hydrogen bonding interaction is present involving the proton on the secondary amine and the hydroxide oxygen and may contribute to the stability of the structure.

Borovik and co-workers have developed a tripod ligand $N[CH_2CH_2NHC(O)NHC(CH_3)_3]_3$, which offers a hydrogen bonding cavity around the metal ion on complexation.[334] The monomeric complex of zinc with a hydroxide ligand was structurally characterized. The source of the hydroxo ligand is water and the complex is synthesized under basic conditions. The complex has trigonal–bipyramidal coordination with the hydroxo group trans to the apical nitrogen. Intramolecular hydrogen bonds are formed from the ligand to the coordinated hydroxo and the Zn—O distance is 2.024(2) Å. This relatively long bond distance reflects the presence of hydrogen bonding and is markedly similar to that observed in carbonic anhydrase, where hydrogen bonding interactions are also present.

Comparison of zinc alkoxide and zinc hydroxide bond energies has been made. The relative heterolytic bond energies for hydroxide, methoxide, ethoxide, and *tert*-butoxide were determined from studies of a series of alkoxide exchange equilibria using a four-coordinate monomeric zinc tris(pyrazolyl)borate compound.[335]

H_3O_2 bridges have been characterized between zinc atoms and have been suggested as a resting form of active metal-bound hydroxides in dinuclear zinc complexes and as a possible structural or functional motif in multi-zinc enzymes such as phospholipase C or P1 nuclease. Tris(pyrazolyl) borate zinc dimers have been structurally characterized with this motif, $[L_3Zn_2O_2H_3]ClO_4$. The coordination around the zinc atoms was dependent on the tris(pyrazoyl)borate derivative but intriguingly in one example the Zn—OH group was involved in a hydrogen bonding interaction with a methanol included in the crystal lattice.[235] The reaction of carbon dioxide with a pyrazole compound containing the intramolecular bridge Zn—O_2H_3–Zn is enhanced relative to the Zn—OH–Zn equivalent.[336]

Zinc hydroxy double salts are layered materials similar to layered double hydroxides which show intercrystalline reactivity and incorporate organic compounds between layers.[337] Hydroxy double salts of high crystallinity can be obtained by reacting ZnO with organic metal salts in water. Zinc oxide crystals could then be prepared by thermal treatment of hydroxy zinc acetate.[338]

The hydrolysis of the zinc ion in varying anionic media has been investigated. In the pH range of 2.0 to 6.0 a dependence on the anion present is observed, with either sodium nitrate, sodium perchlorate, or sodium chloride at 0.5 M concentration. Only monomeric species were observed and $[Zn(OH)]^+_{(aq)}$ was found in all three solutions while $Zn(OH)_{2(aq)}$ was only found in the perchlorate solution, demonstrating the effect of the anionic medium on the formation and stability of the hydrolytic species.[339]

EXAFS has been used to determine the second hydration shell of zinc in aqueous solution. Aqueous solutions of zinc nitrate over a range of concentrations were examined and a Zn—O distance of 2.05 Å for the first shell of the six-coordinate zinc center found, which is unaffected by concentration. The second hydration shell shows a Zn—O distance which has no systematic trend but an average distance of 4.1 Å. The coordination number for the second shell is 11.6 ± 1.6 with unusual behavior for the most concentrated 2.7 M solution, which has a decrease in coordination number to 6.8 ± 1.5.[340]

6.8.6.2 Alkoxides and Aryloxides

Zinc alkoxide and aryloxide complexes have been of particular interest as enzyme models and catalysts. Tetrameric alkyl zinc alkoxides are a common structurally characterized motif.[81]

A series of zinc alkoxide complexes were characterized of the form $[RZnOR']_n$ where $n = 2$ or 4 (Figure 4). Complexes of the form $[Zn_3\{O(2,6\text{-}i\text{-}Pr_2C_6H_3)\}_4R_2]$ were produced by stoichiometry

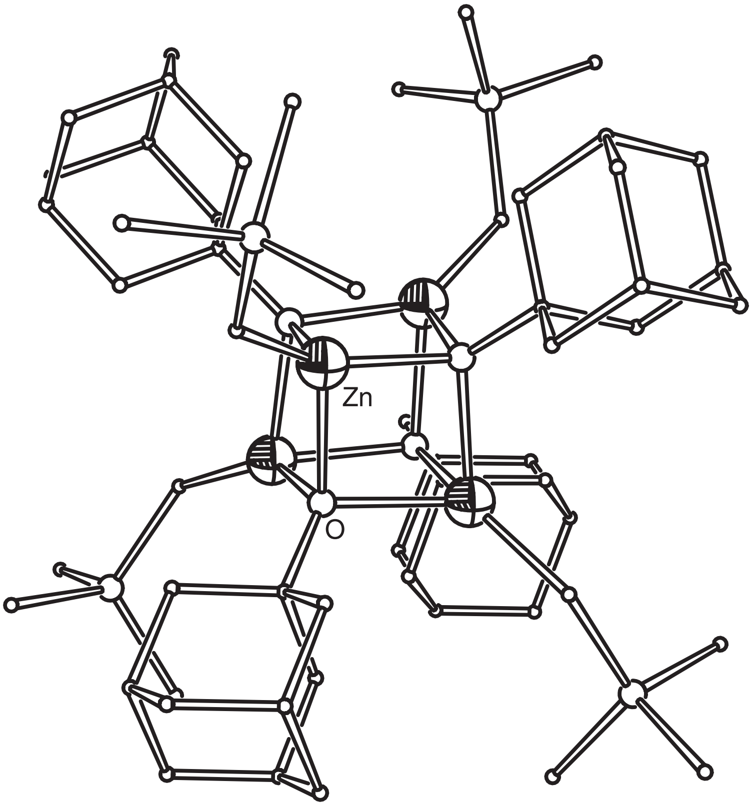

Figure 4 The molecular structure of a tetrameric zinc alkoxide formed from 1-adamantol with (trimethylsilyl)methyl groups also coordinated.[81]

change and reveal an almost linear Zn_3 array, in which the zinc centers are linked by bridging -OR′ groups.[81]

Some interest in soluble zinc bisaryloxides and alkoxides has been based on the production of zinc oxide materials.[341]

Zinc alkoxide complexes have been used as catalysts in the ring-opening polymerization of lactide. A number of zinc alkoxide complexes with tris(pyrazolyl)borate or tris(indazolyl)borate derivative ligands were synthesized. The tris(pyrazolyl)borate complex with 500 equivalents of L-lactide results in 90% conversion to polylactide within six days. This is considerably slower than the magnesium catalyst but the zinc complex has the advantage of decreased air and moisture sensitivity. The chiral tris(indazolyl)borate zinc catalyst shows only low enantioselectivity in the polymerization of racemic lactide but significant diastereoselectivity in the preferential polymerization of meso-lactide from a mixture of racemic and meso-lactide. Crystal structures of zinc alkyls and the zinc siloxide structure of the tris(pyrazolyl)borate derivative ligand were determined.[75] Soluble and volatile zinc dialkoxides have been prepared including an amido zinc alkoxide, $(Zn(\mu\text{-}OCEt_3)[N(SiMe_3)_2])_2$.[342]

The trigonal planar zinc phenoxide complex $[K(THF)_6][Zn(O\text{-}2,6\text{-}{}^tBu_2C_6H_3)_3]$ is formed by the reaction of a zinc amide complex, via a bis phenoxide, which is then further reacted with potassium phenoxide. The X-ray structure shows a nearly perfect planar arrangement of the three ligands with zinc only 0.04 Å out of the least squares plane defined by the three oxygen atoms.[15] Unlike the bisphenoxide complexes of zinc with coordinated THF molecules, these complexes are not catalytically active in the copolymerization of epoxides with CO_2. The bisphenoxide complex has also been structurally characterized and shown to be an effective polymerization catalyst.[343]

2,6-functionalized phenoxides can be used to form "double phenoxide" complexes where an alkali metal is also present in the phenoxide structure. The crystal structure of $Na[Zn(2,6\text{-diphenylphenoxide})_3(H_2O)]$ shows a four-coordinate zinc center with three phenoxide oxygen donors, bridging to the sodium, and a bound water molecule. In the presence of chloride a $Na[Zn_2(2,6\text{-diisopropylphenoxide})_4Cl]\cdot 3THF$ forms with the phenoxide ligand bridging the two tetrahedral zinc centers.[344]

The binding of phenoxyl radical species to zinc has been observed. The pendent arm macrocyclic ligand 1-ethyl-4,7-*t*-bis(3-butyl-5-methoxy-2-hydroxybenzyl)-1,4,7-triazacyclononane deprotonates on reaction with zinc to form a neutral complex, and the structure has been determined, $[ZnL]\cdot H_2O$. Via electrochemical methods a dichloromethane solution of the complex can be reversibly oxidized by two successive one-electron processes generating the stable phenoxyl mono- and diradicals. The oxidations are ligand centered generating phenoxyl radicals which have been studied by EPR and UV–vis spectroscopy. In the monoradical species the phenoxyl radical is localized on one phenyl ring. The diradical has a diamagnetic ground state.[345]

6.8.6.3 Aldehydes, Ketones, and Ethers

A number of chelating ketone ligands are reported in Section 6.8.11. Due to the weak binding, chelation helps to stabilize the complexes and there are few structural examples of monodentate ketone ligands.

Zinc halide complexes with acetophenone have been structurally characterized and form monomeric or polymeric structural motifs.[346] The bromide and iodide derivatives are monomeric and the chloride derivative is a coordination polymer with bridging chlorides.

The X-ray structures are known of a number of ketone ligands, including hexanedione and 4-methylcyclohexanone, that have bound as monodentate ligands in the fifth coordination site of zinc porphyrin complexes.[347,348] Oxaphlorin dimeric compounds are also known where the oxygen from a neighboring porphyrin ring coordinates in the fifth coordination site of a neighboring zinc porphyrin unit.[349]

Vahrenkamp and co-workers formed a number of chelate-stabilized ketone complexes with pyridylphenyl ketone. Octahedral complexes formed with a 2:1 ratio of ligand to zinc were formed with trifluoromethanesulfonate, chloride, and bromide anions. 1:1 reactions resulted in the formation of square pyramidal $[ZnL_2X]^+$ with $X = Br$, I, and a trigonal–bipyramidal dimer $[L_2Zn(NCS)_2]_2$ with thiocyanate bridges.[350]

Acetone has been structurally characterized as a ligand in a zinc crown ether (15-crown-5) complex, where the zinc is seven-coordinate bound to all five ring ether donors, a chloride, and the acetone molecule.[351]

The reported structural chemistry of zinc aldehyde complexes is dominated by Vahrenkamp and co-workers. A systematic investigation is reported over three papers published in 1999. All X-ray structures reported in these papers are aryl aldehydes and no aliphatic aldehyde structures with zinc were found in the CSD. Zinc is frequently exploited in preparative organic chemistry and enzyme-catalyzed transformations of organic carbonyl compounds.

The function of the zinc in these transformations is to bind to the carbonyl, resulting in activation by the Lewis acidic metal center. The aldehyde oxygen is only a weak donor and, as the important reactions with zinc are often catalytic, this has resulted in isolation of few compounds prior to the studies of Vahrenkamp. A systematic approach to the study of aldehyde coordination has been taken with variation in the other zinc donors or anions and the investigation of chelating aldehydes. Interesting results were also obtained with respect to competing donor ligands, further elucidating the donor qualities of the aldehydes. Water was shown to be a better ligand for the zinc ion and aliphatic aldehydes tended to undergo reaction, thus the synthesis of the complexes required restriction of the amount of water present and the use of aromatic aldehydes. Two to six aldehydes could be incorporated into octahedral complexes with the hexaaldehyde complex (**40**) only obtained in the presence of $SbCl_6^-$ as anion (Figure 5).[352]

The presence of halides in the coordination sphere with aldehydes is important as zinc halides are typically used in organic synthesis as organic carbonyl activators. Large excesses of aldehydes and anhydrous zinc halides were necessary. Both monomeric and polymeric structures with halide bridges were observed. Tetrahedral geometries were observed for mixed ligand, aldehyde, and halide complexes.[353]

For a liver alcohol dehydrogenase (LADH) model an NS_2O coordination sphere is required. The chelating aldehydes are ideal for the formation of this donor set when combined with bis(pentafluoro-thiophenolato)zinc. Structural data on the complexes with one equivalent of 6-methylpyridine-2-carbaldehyde, 6-methoxypyridine-2-carbaldehyde, 2-(dimethylamino)benzaldehyde) demonstrate that the coordination sphere for LADH has been reproduced to a close approximation and the corresponding alcohol complexes have also been characterized.[354] Other thiophenols have been used to form such complexes but have not been structurally characterized.[304]

Formation of aldehyde complexes from the zinc hydroxide complexes of tris(3-cumenyl-5-methylpyrazolyl)borate] was observed. The aldehyde ligands, such as pentafluorobenzaldehyde,

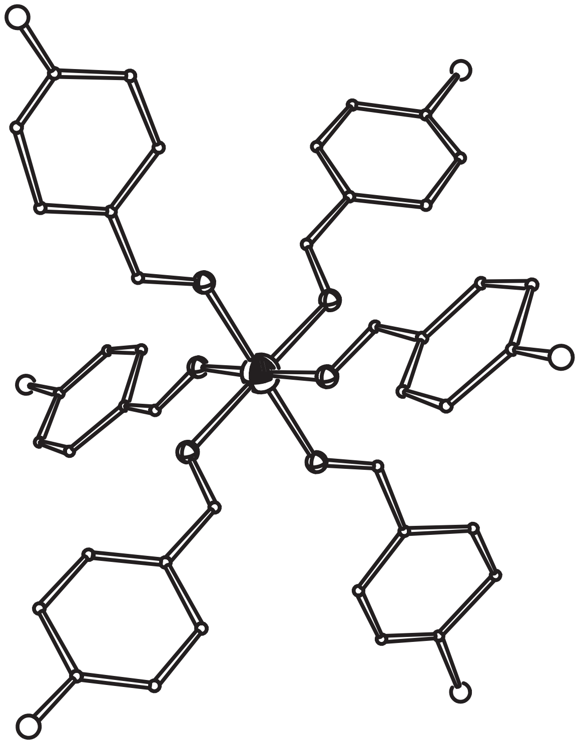

Figure 5 Molecular structure of a zinc hexaaldehyde complex (**40**).[352]

were bound as deprotonated aldehyde hydrates. Formyl phenols were deprotonated and coordinated as chelate ligands.[355]

Zinc porphyrin complexes with coordinated benzaldehyde in the fifth coordination site have also been structurally characterized.[347,356]

Again, weak coordination is expected for ether ligands to zinc, however, the larger number of structurally characterized examples is at least partially attributable to the frequent use of solvents such as diethyl ether or tetrahydrofuran which may provide additional ligands to the metal center.

There are a reasonable number of structurally characterized zinc compounds with bound THF molecules. For example, a six-coordinate zinc porphyrin complex with axial THF donors and a four-coordinate zinc center with two THF ligands and two phenolate ligands.[341,357] Although less common there are other structural examples of ether solvents, such as diethyl ether, coordinated.[358] The X-ray structure of zinc chloride with 1,4-dioxane ligands shows a monomeric four-coordinate zinc center with two 1,4-dioxane ligands.[359]

Markies *et al.* have studied the coordination of zinc to cyclic and acyclic polyether ligands. In some cases the zinc is not coordinated within the ligand cavity but only through two of the ether donors in the macrocyclic ring.[360] The bis(methoxyethyl)ether complex of zinc diphenyl (**41**) is five-coordinate with three ether oxygens coordinating from the acyclic ligand.[361]

6.8.6.4 Carboxylates

Monomeric, dimeric, and polymeric zinccarboxylates are known.

Dimeric zinc carboxylates do not have a large number of structurally characterized examples.[362,363] Quite a number of monomeric carboxylate and particularly salicylate complexes have been structurally characterized.[364–367]

Singh *et al.* have shown that, dependent on the solvent, zincacetate, pyridine mixtures can give a monomeric, dimeric, or polymeric product.[362] $[Zn(pyridine)_2(CH_3CO_2)_2]$ is four-coordinate with monodentate carboxylates. A dimeric tetraacetate structure is known with a metal–metal separation of 2.976 Å, $[Zn_2(MeCH{=}CHCO_2)_4(C_9H_7N)_2]$, with two quinoline units completing the ZnO_4N coordination at the zinc centers.[363] This compares with the zinc–zinc separation in the binuclear triacetate structure, $[Zn_2(MeCO_2)_3]^+$, of 3.264 Å.[368]

A polymeric chain structure is frequently observed for zinc carboxylates. Basic zinc carboxylates form a common tetrameric species, and altering conditions can result in an interconversion between the basic and regular carboxylates.[369] Mass spectrometry studies have been carried out on zinc acetate structures.[370]

6.8.6.4.1 Basic carboxylates

The basic zinc carboxylate structure with a Zn_4O core is now well characterized structurally with a number of examples.[371] It can also form part of higher nuclearity structures and coordination networks.[372,373]

The tetranuclear structure observed for basic zinc/acetate/$[Zn_4O(O_2CCH_3)_6]$ is also observed for basic zinc pivalate and benzoate. Solution studies showed an equilibrium between hydrated basic structures and the hydrated form of 3,1 bridging structures in the presence of a trace amount of water. Zinc crotonate shows a less common basic carboxylate polymeric structure, $[Zn_5(OH)_2\ (O_2CCHCHCH_3)_8]_n$.[369]

The influence of the alkyl chain on the reaction products of zinc hydroxide and aliphatic carboxylic acids was studied with structural types identified by IR spectroscopy. Straight chain acids produced zinc bis-carboxylates with the polymeric sheet structure with either reagent in excess. Branched chain carboxylic acids produced different structures dependent on the ratio of reagents and the bulk of the alkyl group. Mixtures of a zinc bis-carboxylate with an additional IR stretch and the tetrameric $Zn_4O(RCOO)_6$ in varying ratios resulted. Formation conditions appeared driven by how close the alkyl chains were packed in the varying structures with the possibility for steric interaction considerably reduced in the tetramer.[374]

The tetrazinc $[Zn_4(\mu_4\text{-}O)(\mu\text{-}CO_2CR)_6]$ can be prepared by a variety of methods with short straight chain carboxylic acids and this structural type identified by characteristic IR bands. The formation process and influence of water were monitored by IR spectroscopy and a mechanism of formation and decomposition proposed.[375] Further evidence for the validity of the mechanism, which relies on the presence of water shifting the equilibrium to the tetramer, was found in the formation of zinc complexes of straight chain fatty acids (C_6 to C_{18} chain lengths). IR spectroscopy studies detected the formation of the $[Zn_4(\mu_4\text{-}O)(\mu\text{-}CO_2CR)_6]$ species and the key factor in formation was shown to be the presence of water.[376]

6.8.6.4.2 Mixed-metal carboxylate compounds

Multinuclear mixed-metal complexes can be formed with carboxylate ligands.

Trinuclear zinc carboxylate structures of the form $MZn_2(MeCH{=}CHCO_2)_6(\text{quinoline})_2$ have been structurally characterized with M = Mn, Co, Ni, Zn, Cd, Mg, Ca, Sr. Structural variation is observed for the group 2 metals. The remaining complexes all show linear trimers with the central metal atom octahedrally coordinated and linked to each zinc by two bidentate and one monodentate carboxylate.[377] A basic benzoate octanuclear structure with four vanadium(III) and four zinc atoms has been characterized, $[VZnO(\text{benzoate})_3(THF)]_4\cdot 2THF$.[378]

A series of di-, tri-, and tetranuclear complexes containing lanthanide(III) and zinc ions have been characterized by single-crystal X-ray diffraction. Four different carboxylate-bridged structural types were characterized from the reaction of lanthanide and zinc nitrates in the presence of quinoline and carboxylic acids. Propionic and pivalic acid were used along with the following lanthanides: erbium, yttrium, dysprosium, and gadolinium. The first type is isostructural for Ln = Y or Er and contains a triply propionate bridged dimeric LnZn dimer, $[C_9H_7NH][LnZn(O_2CC_2H_5)_3(C_9H_7N)(NO_3)_3]\cdot H_2O$. Trinuclear $LnZn_2$ species are formed with Ln = Dy; in one structural type a symmetric structure shows both zinc ions triply bridged by pivalate ligands $[DyZn_2(O_2CCMe_3)_6(C_9H_7N)_2(NO_3)]$. The remaining trinuclear structure is unsymmetric with one zinc triply bridged to the dysprosium and the other zinc doubly bridged, $[DyZn_2(\mu\text{-}O_2CC_2H_5)_5(O_2CC_2H_5)\text{-}(C_9H_7N)_2(NO_3)(H_2O)]$. The tetranuclear Gd_2Zn_2 complex has two triply propionate-bridged dinuclear GdZn units linked by propionate groups bridging the two Gd ions, $[Gd_2Zn_2(O_2CC_2H_5)_8(C_9H_7N)_2(NO_3)_2(H_2O)_2]$.[379]

6.8.6.4.3 Polymeric or framework carboxylate compounds

Metal organic frameworks formed using benzene polycarboxylates have been extensively studied and have revealed some very interesting properties.

1,4-benzene dicarboxylate and 1,3,5-benzene tricarboxylate form different porous frameworks with zinc dependent on solvent and other conditions for formation. The frameworks can be considered as extended analogs of molecular polyzinc carboxylates. Gas sorption isotherm measurements revealed highly organized and accessible channels in a microporous structure for the 1,4-benzenedicarboxylate structures. The 1,3,5-benzene tricarboxylate structure did not show gas sorption due to zinc centers occupying the pores. Sorption of ethanol for this structure demonstrated that these zinc structures were unsaturated and could undergo coordination transitions. The materials produced have high thermal stability with air stability up to 300 °C and can have a free pore volume up to 55–60% of the crystal.[380] 1,3,5-benzenetricarboxylate has been used in the formation of molecular frameworks, which grow as homochiral single crystals. The interpenetrating nature of the networks is controlled by the auxiliary ligands bound. Ethylene glycol and 1,2-propanediol were used as auxiliary ligands with ethylene glycol acting as a unidentate ligand and giving a lower accessible solvent volume than the bidentate 1,2-propanediol. Crystallinity can be lost on removal of bound ligands and restored by exposure to alcohol vapor, allowing interconversion between the two network topologies. The crystals can be grown homochirally from enantiomerically pure diol templates. This is an interesting example of chiral molecules templating helix handedness in a chiral porous framework solid.[381] Selective guest binding by channels in a zinc–benzenetricarboxylate network was studied, $Zn_2L(NO_3)\cdot(H_2O)(C_2H_5OH)_5$, synthesized by diffusion of triethylamine into an ethanol solution containing 1,3,5-benzenetricarboxylic acid and zinc nitrate. The pore structure of this network has about 44% of volume comprising an extended channel system and similarly shows the facile removal and exchange of alcohols. The exchange is shown to be specific to alcohols and tetrahydrofuran, acetonitrile and acetone are not included in the channels. Solid state NMR, TGA, and X-ray powder and single-crystal techniques were used in the characterization. The specificity is due to the coordination to the zinc center as is demonstrated by the exclusion of molecules which are an appropriate size and shape but do not offer the possibility of this interaction.[382]

Polymeric compounds are formed from 1,3,5-benzene tricarboxylate and zinc with 2,2′-bipyridyl, phenanthroline, or a pyridyl-2-(1-methyl-1H-pyrazol-3-yl) derivative. A number of compounds were characterized with varying ligand protonation and some, such as [ZnL(pyridine-2-(1-methyl-4-nitro-1H-pyrazol-3-yl))(H_2O)], containing single-stranded coordinative chains.[383]

1,3,5-cyclohexanetricarboxylate can also be used along with zinc to construct open framework solids. The single-crystal X-ray structure of $Zn_3[L(C_5H_5N)]_2$ reveals one-dimensional channels with a diameter of about 6 Å.[384]

6.8.6.4.4 *Other carboxylate type ligands*

Zinc squarate ($C_4O_4^{2-}$) can form a solid state compound with a layered structure when DMSO is present, $[Zn(C_4O_4)(OH_2)_2(DMSO)_2]$. The DMSO occupies the axial positions at the six-coordinate zinc center and prevents formation of a 3D cage network. The compounds are insoluble at room temperature but are converted into the 3D cage network $[Zn(C_4O_4)(OH_2)_2]$ by heating in aqueous media.[385]

As a model of the active site of dihydroorotase, the crystal structure of diaquabis(L-dihydroorotato)zinc demonstrates that the ureido nitrogen adjacent to the coordinated carboxylate does not coordinate to the zinc ion.[386] Intramolecular hydrogen bonds are present between the non-coordinated carboxylate oxygen atoms and the coordinated water molecules, stabilizing this coordination geometry. Monodentate rather than bidentate binding of the ligand could be accounted for by the higher pK_a of the ureido group.

Zinc bis(methoxyacetate) has distorted octahedral coordination with bonds to a carboxylate and methoxy oxygen donor from each ligand and two water molecules completing the coordination sphere.[387] 2-Methyl 2-phenoxy propionate ligands form a one-dimensional polymer with a repeating pentamer unit, $[Zn_5L_{10}(H_2O)_2]$. A bidentate chelate mode with an acetate and the phenoxy oxygen donor is observed for some ligands[388] This contrasts with structures of other phenoxyalkanoic acids which are monomeric.

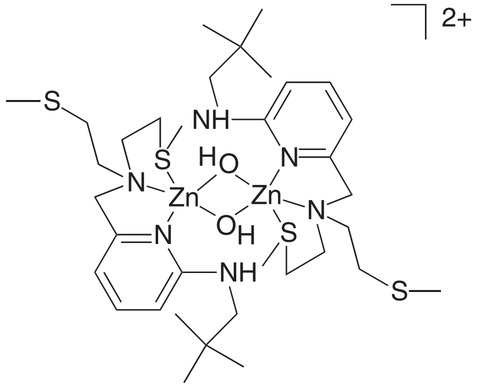
Zinc carboxylate interactions have been exploited as part of a fluorescent molecular sensor for uronic acids. The sensors feature two interactions; coordination of the carboxylate to the zinc and a boronic acid–diol interaction.[389] Photoluminescent coordination polymers from hydrothermal syntheses containing Zn_4O or $Zn_4(OH)_2$ cores with isophthalate or fumarate and 4,4′-bipyridine form two- and three-dimensional structures. Single X-ray diffraction of both dicarboxylates identified the network structure.[373]

Zinc oxydiacetate complexes have been formed in the presence of 2,2′-bipyridine, 1,10-phenanthroline, and imidazole. The X-ray structure of zinc oxydiacetate with no additional *N*-donor ligands is a polymeric sheet with ZnO_5 units bridged by carboxylates. The presence of 2,2′-bipyridine or 1,10-phenanthroline gives a mononuclear complex, [Zn(oxydiacetate)L(H_2O)], with distorted octahedral geometry and an N_2O_4 donor set. Thermal decomposition of these compounds gives ZnO.[390] However, in the presence of imidazole the X-ray structure shows polymeric chains in $[Zn(imidazole)_2(oxydiacetate)]_n$. Considerable H bonding is present in the chain structure formed by carboxylate bridged tetrahedral ZnN_2O_2 units.[391]

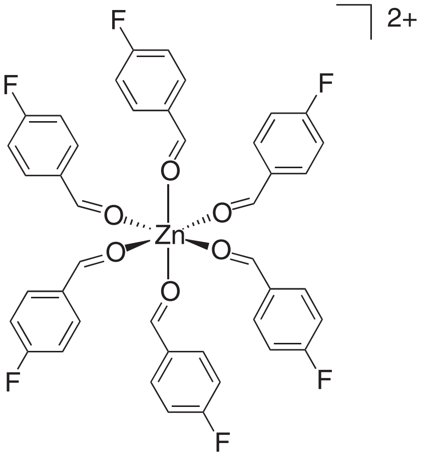
L-piperidine-2-carboxylic acid is a non-proteinogenic amino acid that is a metabolite of lysine. The zinc complexes of DL-piperidine-2-carboxylic acid, DL-piperidine-3-carboxylic acid, and piperidine-4-carboxylic acid have been studied. The X-ray crystal structures have been determined for the latter two. $[ZnCl_2(DL\text{-piperidine 3-carboxylate})_2]$ (**42**) is monomeric with a tetrahedral metal center and monodentate carboxylates. $[Zn_2Cl_4(\text{piperidine-4-carboxylate})_2]$ (**43**) contains two bridging carboxylates in a dimeric structure. IR studies suggest that the DL-piperidine-2-carboxylato zinc has monodentate carboxylate ligands coordinating.[392]

Bis(but-3-enoato)zinc, a two-dimensional coordination polymer, has been polymerized in the solid state by irradiation of a crystalline sample resulting in isotactic zinc poly(but-3-enoate).[393]

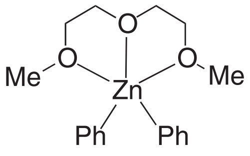
Carboxylate functionalized cobalt clusters have been used as "cluster ligands" in formation of zinc complexes. The carboxylate cluster $(CO)_9Co_3\{\mu_3\text{-}C[1,4\text{-}C_6H_4(CH_2)_2COOH]\}$ reacts with diethyl zinc to give $Zn[(CO)_9Co_3C[1,4\text{-}C_6H_4(CH_2)_2CO_2]_2$ which is analogous to the product formed under identical conditions with acetic acid as the carboxylic acid reagent. The Zn_4O core type structure, $Zn_4O[(CO)_9Co_3(CCO_2)]_6$, is formed in the reaction of equimolar amounts of diethyl zinc and $(CO)_9Co_3(\mu_3\text{-}CCOOH)$. The differing products formed are attributed to the



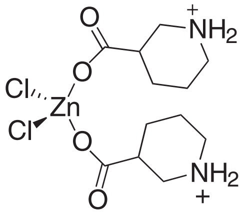
(39)



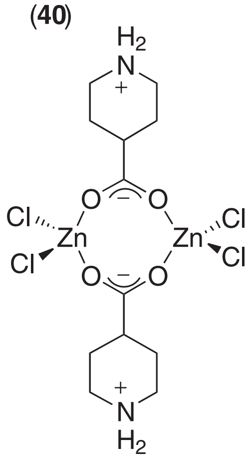
(40)



(41)



(42)



(43)

electronic interaction of the cobalt cluster with the carboxylate functionality. All complexes were studied by IR spectroscopy.[394] Dimeric carboxylates have been formed and structurally characterized with 2,2′-bipyridine ligands, $[Zn_2(bipyridine)_2(MeCO_2)_3]ClO_4$.[395]

Dimeric zinc complexes with bridging oxalate groups, $LZn(C_2O_4)ZnL$, are formed with tetradentate *N*-donor ligands *N,N′*-bis(2-pyridylmethyl)-1,2-ethanediamine, *N,N′*-bis(2-pyridylmethyl)1, 3-propanediamine, and *N,N′*-bis(2-pyridylmethyl)-*N,N′*-dimethyl-1,2-ethanediamine. Although not structurally characterized, by analogy and comparison of spectroscopic data it is suggested that the oxalate has two oxygen donors coordinating to each metal center.[396] In this compound further oxalate bridging is inhibited as the N_4O_2 zinc centers are coordinatively saturated; however, oxalates are frequently involved in solid state polymeric or layer structures via this mode of bridging.[397–399]

The water ligands in $[Zn(salicylate)_2(H_2O)_2]$ and the analogous 3,5-di-*t*-butyl salicylate derivative can easily be displaced by other ligands such as 2,2′-bipyridine or pyridine. For example, recrystallization from alcohols results in replacement of the water molecule with an alcohol solvent molecule. Crystals grown of the bipyridine analog in methanol result in the isolation of the structurally characterized octahedral complex, $[Zn(O_2CC_6H_4OH\text{-}2)_2(bipyridine)(MeOH)]$, which has one monodentate and one bidentate salicylate ligand with both coordinating through carboxylate oxygens. The coordination sphere is completed by a chelating bipyridyl and a methanol and there is extensive hydrogen bonding in the structure.[400]

The ligand 1-(*o*-carboxymethoxyphenoxy)-2-(*o*-hydroxyphenoxy)ethane acts as a monodentate carboxylate ligand in the formation of $[Zn(NH_4)_2L_4]$.[401] The four ligands participate extensively in hydrogen bonding resulting in two cavities where the hydrogen bonding is maximized for the ammonium cations.

The compound Zn_2(diacetoamidoglutarate)$_2$hexaaquo is dimeric with two slightly distorted trigonal–bipyramidal zinc centers. The *N*-protected amino acids bridge the two zinc centers, with each zinc coordinated to two carboxylate oxygens and the remaining three coordination sites occupied by water molecules.[402]

6.8.6.5 Phosphate and other Oxyanion Ligands

6.8.6.5.1 Phosphates and phosphonate ligands

Zinc phosphates and phosphonates can form highly interesting coordination networks, some in the presence of additional ligands. A number of compounds that have useful properties for the formation of zinc phosphate materials will also be discussed.

A zinc phosphonate tetramer can be used as a precursor to organic-containing networks or layered zinc phosphate materials.[403] The tetramer (**44**) has a Zn_4O core and six bridging phosphate ligands, $[O_2P(O^tBu)_2]^-$. A solution of this complex reacts with 1,6-hexanediamine to form a layered coordination network $\{Zn[O_2P(O^tBu)_2]_2[H_2N(CH_2)_6NH_2]\}n$. A one-dimensional polymer can be formed from the tetramer under acidic conditions$\{Zn\text{-}[O_2P(O^tBu)_2]_2\}n$.[404] Zinc phosphate materials are formed on clean loss of the "hydrocarbon shell" on heating.

A range of zinc phosphonates were prepared and structurally characterized by reaction of zinc nitrate with phosphonic acids in an autoclave in the presence of sodium hydroxide, including an enantiomerically pure zinc phosphonate—for example, $Zn(O_3PCH_2P(O)(C_6H_5)_2)$ and $Zn(O_3PCH_2P(O)(CH_3)(C_6H_5))$.[405,406]

$Zn(O_3PC_6H_5){\cdot}H_2O$ exhibits a reversible dehydration to yield isomorphous structures to the corresponding monohydrate derivative. It appears that the dehydration leaves a vacant coordination site on the zinc ion allowing intercalation of ammonia, but not carbon dioxide, oxygen, or ethylene. IR and TGA studies were supplemented by computer simulations which demonstrated the potential for intercalation of ammonia but the exclusion of larger primary amines such as propylamine.[407] The reaction of zinc acetate with diethyl hydroxymethylphosphonate forms $Zn(O_3PCH_2OH)$ where hydrolysis of the phosphonate to produce phosphonic acid has occurred *in situ*. The X-ray structure shows channels formed by phosphonate groups bridging the octahedral coordinated zinc atoms. The zinc atoms are coordinated by the three oxygens of the phosphonate group and the oxygen of the hydroxy group.[408]

The crystal structure of zinc phenylphosphonate was solved and demonstrated the anticipated layer structure with the phenyl rings occupying the interlamellar space.[409] The structure of zinc ethylphosphonate and (2-aminoethyl)phosphonate both show four-coordinate zinc centers in contrast to the coordination number of six in the phenylphosphonate compound.[410]

The presence of triethylenetetramine in the hydrothermal synthesis of open-framework zinc phosphates results in a number of frameworks with one- to three-dimensional structures. The structures include one-dimensional ladders, two-dimensional layer structures, and one structure where the tetramine is bound to the zinc center. The structural type was highly sensitive to the relative concentration of the amine and phosphoric acid.[411] Piperazine and 2-methylpiperazine can be used as templating molecules in solvothermal syntheses of zinc phosphates. The crystallization processes of the zinc compounds were investigated by real time *in situ* measurements of synchrotron X-ray powder diffraction patterns.[412]

Attempts have been made to incorporate functional groups into the phosphonates in zinc phosphonate structures. $Zn(O_3P(CH_2)_2CO_2H){\cdot}H_2O$ was reacted with aromatic amines but no amide formation was observed. However, $Zn(O_3P(CH_2)_2CONHC_6H_5)$ could be synthesized directly from zinc nitrate, (2-carboxyethyl)phosphonic acid, and aniline in a one-step procedure.[406]

Di-*t*-butyl phosphate complexes of zinc were synthesized as precursors for ceramic material formation. A tetrameric zinc complex was characterized from the treatment of zinc acetate with the phosphate resulting in a compound with a bridging oxo at the center, $[Zn_4(\mu_4\text{-}O)(\text{di-}t\text{-butyl phosphate})_6]$. In the presence of auxiliary donor ligands such as imidazole or ethylenediamine, monomeric complexes are formed, $[Zn(\text{di-}t\text{-butyl phosphate})_2(\text{imidazole})_4]$. It is also possible to convert the tetramer into the monomer by treating with a large excess of imidazole.[413]

An open-framework zinc phosphate synthesized under mild hydrothermal conditions possesses two interpenetrating helical channels.[414] Piperazine phosphate yields a variety of open framework structures in reaction with zinc, including linear chain, layer, and three-dimensional systems.[415]

A zinc phosphate material formed in the presence of *trans*-1,2-diaminocyclohexane forms with pores of 24-membered rings and a consequent large amount of free space in the structure, $Zn_3(PO_4)_2(PO_3OH)(\text{diaminocyclohexane}){\cdot}2H_2O$. The tubular channels formed show the *trans*-diaminocyclohexane templates and water near the walls and have an empty space diameter of about 8.6 Å.[416]

Zinc biphenylenebis(phosphonate) was obtained with a linear chain rather than a layer structure when the same preparative method was used as for the zinc phenylenebis(phosphonate) layer structure. The presence of base allows a solid phase transformation from the linear chain to the layer structure.[417]

A series of zinc diphosphonate complexes were synthesized in the presence of diamines of varying chain length.1-hydroxyethylidenediphosphonate bridges the metal ions with the protonated diamine (ethyl-, butyl-, pentyl-, or hexylenediamine) filling in channels or residing between chains. All four structures are different with one-, two-, and three-dimensional networks formed. The coordination number (4–6) and geometry also varies.[418]

Chloromethyl phosphonates can yield different network or layer structures dependent on preparation conditions or other coordinating groups present.[419] $Zn(O_3PCH_2Cl){\cdot}H_2O$ has a layered structure similar to $Zn(O_3PC_6H_5){\cdot}H_2O$. In the presence of urea another layer structure results with phosphonate oxygens bridging the zinc centers, the coordination changes with the urea participating to give tetrahedrally coordinated zinc centers with one urea and three phosphonate oxygens bound. $Zn_2Cl(O_3PCH_2Cl)(HO_3PCH_2Cl){\cdot}H_2O$ results when zinc chloride is used as starting material and contains both tetrahedrally and octahedrally coordinated zinc centers with the chloride bound to the tetrahedral zinc. The positioning of the chloromethyl group has an influence on the interlayer distances.

Anhydrous zinc phosphonate $Zn(O_3PCH_3)$ is unreactive with water but reacts with primary amines (chain length up to C_8) and ammonia to form intercalation compounds. The intercalation is shape selective as amines with branching at the α-carbon cannot coordinate to the zinc. Different structures are noted for even and odd carbon chain lengths with odd numbers of carbons in the alkyl chain forming a more efficiently packed interdigitated structure.[420]

Zinc phosphite compounds, $Zn(H_2PO_3)_2{\cdot}3H_2O$ and $Zn_3Na_2(HPO_3)_4$, have also been characterized in the solid state and revealed structures in contrast with those observed for the phosphates. The tendency to form structures with open cavities is greater due to the reduced bridging ability of the phosphite donor ligand.[421]

The zinc-pyridoxal 5′-phosphate-2-amino-3-phosphonopropionic acid system exhibits deprotonation of the coordinated phosphonate group to bind to the zinc center at increased pH but cannot be coordinated to the zinc ion below pH 8.5 when it is protonated and hydrogen bound to the phosphate group.[422]

The metal complex formation of a series of phosphonodipeptides containing glycyl, L-alanyl, L-leucyl, or L-phenylalanyl and a terminal aminomethylphosphonic acid residue was studied and stability constants determined. Zinc formed 1:1 metal-to-ligand molar ratio complexes with protonated, non-protonated, and deprotonated ligands. No formation of 1:2 metal-to-ligand ratio complexes was observed for zinc in contrast to the other transition metals studied.[423] Zinc complexes of phosphonic acid analogs of aspartic acid, glutamic acid, and asparagines have been studied.[424] Two aspartic acid analog ligands with the α-carboxylic acid replaced with a phosphonic acid group are proposed to yield a cyclic phosphonamidate in the presence of the zinc ion.[425] However, the aspartic acid analog with the β-carboxylic acid group replaced did not show this reaction. The reaction of a series of aminophosphonic acids was studied by NMR to provide further insight into this reaction, which appears to require neutral or slightly alkaline media.

The coordinating properties of a zinc 2,2′-bipyridyl unit with adenosine 5′-triphosphate and cytidine 5′-triphosphate were studied in aqueous solution. The binding of zinc to both phosphate and ATP nitrogen donor was observed with the potential for displacement of the ATP nitrogen donor by hydroxide.[426] The interaction of zinc with the phosphate groups in a platinum(II) bound 2′-deoxyguanosine 5′-monophosphate has been studied in aqueous solution, with little difference noted in the coordinating properties of the phosphate residue or backbone relative to the free nucleobase.[427]

6.8.6.5.2 Other oxyanion ligands

The zinc teflate $Zn(OTeF_5)_2$ has been synthesized and characterized by IR and ^{19}F NMR spectroscopy. The interaction with a number of weakly coordinating solvents was studied and the single-crystal X-ray structures determined for nitrobenzene derivatives $[Zn(OTeF_5)_2(PhNO_2)_2]_2$ and $Zn(OTeF_5)_2(PhNO_2)_3$.[428]

A barium zinc arsenate compound has been synthesized and structurally characterized, $BaZn_2(HAs_2O_7)AsO_4$, and is a rare example of a compound containing the hydrogen diarsenate group. Infinite sheets of $[Zn_2AsO_4]$ are held together by the HAs_2O_7 groups to form a three-dimensional network.[405,429]

Layered zinc arylsulfonates can be prepared from sodium arylsulfonate in the presence of zinc salts. Some compounds have been structurally characterized.[430]

Zinc benzenesulfonate, $Zn(C_6H_5SO_3)_2\cdot 6H_2O$, is prepared in aqueous solution and has a structure containing alternate layers of $[Zn(H_2O)_6]^{2+}$ and benzenesulfonate ions. They can be compared to layered metal phosphonates.[431]

Amine ligated transition metal complexes have been used as building blocks in the formation of composite metal oxide materials. These are attempts to apply coordination chemistry principles to provide control over the solid state materials formed i.e. incorporate organic ligands into the structure. Phases constructed from vanadium or molybdenum oxides are modified by the presence of a zinc complex. Examples include $[(2,2'\text{-bpy})_2Zn]_2[V_6O_{17}]$ and $[Zn(o\text{-phen})MnO_4]$.[212,432] The structure of the compound $[Zn(o\text{-phen})MnO_4]$ has the zinc ion in a square pyramidal coordination geometry bound to two phenanthroline nitrogens and three molybdate oxygens. Further structurally characterized hybrid organic–inorganic materials were obtained—$Zn(2,2'\text{-bipyridine})[V_2O_6]$ and $[V_6O_{17}\{Zn(\text{terpy})\}_2]$—by hydrothermal techniques from a mixture of zinc chloride, amine ligand, and V_2O_5.[213]

There has been particular recent interest in zinc nitrate complexes as coordination models for bicarbonate binding in carbonic anhydrase. The mono- or bidentate coordination modes have been studied with tris-pyrazolyl borate complexes and can be rationalized in the context of the enzyme activity.[433] Caution in this comparison is introduced by *ab initio* calculations on these model systems demonstrating both monodentate and bidentate coordination energy minima for nitrate binding to zinc.[434]

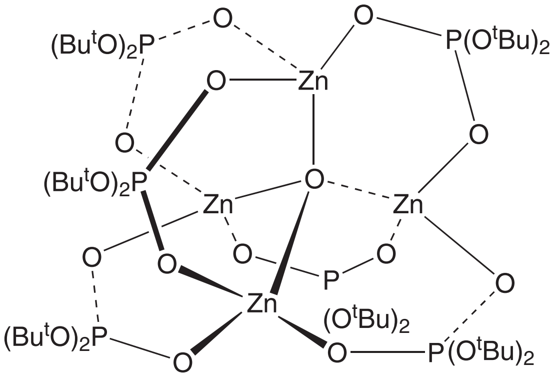
Zinc boryloxides with a tetrameric Zn_4O_4 core (**45**) have only recently been characterized. The single-crystal X-ray structure and multinuclear NMR spectroscopy studies were used as a basis for discussion of deformation of the central core.[435] Alkali metal zinc orthoborates $MZn_4(BO_3)_3$ ($M = K$, Rb, Cs) have been synthesized and single-crystal X-ray structures determined for $M = K$ and Rb.[436]

6.8.6.6 Ester and Phosphate Diester Binding and Hydrolysis

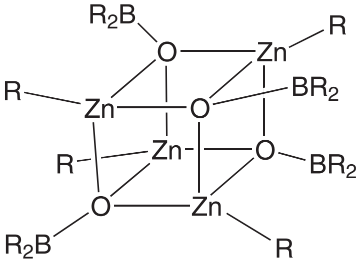
Hydrolysis reactions catalyzed by zinc centers and the formation of hydroxide bridged dimeric species have been the subject of much recent study, and reproduction of the activity of hydrolytic zinc enzymes has been the goal of many research groups.

The complexation of zinc by mixed oxa aza ligands (**46**), (**47**), and (**48**), and subsequent reactivity was investigated.[437] Two ligand ring sizes were studied. Structural characterization of the dizinc complex of (**46**) shows two identically coordinated zinc centers with distorted trigonal prismatic coordination of N_3O_2 and a bridging hydroxide completing the coordination sphere with a Zn—Zn distance of 3.543(2) Å. The ligand synthesized is ditopic for zinc and has also been functionalized with an ethanol pendent.[438] Potentiometric titrations show stable dizinc complexes are formed at neutral to alkaline aqueous solutions, with the alcohol pendent in (**47**) deprotonating with a pK_a of 6.9. A zinc coordinated water molecule undergoes hydrolysis with a pK_a of 8.46 that results in a system with a coordinated alkoxide and a Zn—OH nucleophile at slightly alkaline pH. This is analogous to the alkaline phosphatases that involve both a deprotonated serine and a Zn—OH in the hydrolysis of phosphate monoesters. The analogy is borne out by the increased hydrolysis rate of bis(*p*-nitrophenyl)phosphate by the dizinc complex of (**47**) over (**46**), with the higher activity due to the superior nucleophilicity of a zinc-bound alkoxide over a zinc-bound hydroxide. Crystallographic characterization of a stable analog of the dizinc macrocycle complex with diphenyl phosphate shows formation of a 1:2 complex with the two phosphates bridging the metal centers, and some evidence that the structure is retained in solution.[439]

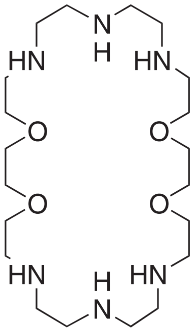
The hydrolysis of *p*-nitrophenyl acetate and bis(*p*-nitrophenyl phosphate) are frequently used to probe hydrolytic activity. A problem with some other dinuclear systems is that the Zn units are held together by bridging ligands which can be cleaved on reaction with the substrate.[440] This is not the case in a ditopic ligand such as those designed by Lippard and co-workers based on Kemp's triacid imide with a xylyl spacer.[441,442] Both zinc dimers and mixed metal dimers were formed and a structure characterized with a bridging phosphodiester (Figure 6).



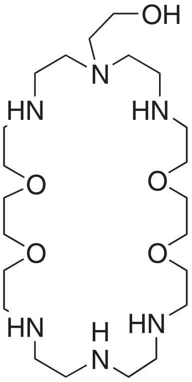
(**44**)



(**45**)



(**46**)



(**47**)

A structurally characterized example of a dinuclear zinc complex with a bridging phosphate monoester was provided by Kitajima and co-workers using the tris(pyrazolyl)borate ligand system. The P—O bond in a tris- or bis-phosphate ester is cleaved by a hydroxo zinc complex resulting in the monoester compound.[443]

Bimetallic zinc complexes formed with hexaazamacrocycles were studied in the hydrolysis of activated carboxyesters. Potentiometric titration demonstrated the dominant presence of a dinuclear hydroxo bridged species at $pH > 7$. *p*-Nitrophenyl acetate is hydrolyzed with no loss of catalytic activity for at least 2.7 catalytic cycles.[444]

Kimura and co-workers have made a major contribution to this area with dizinc azamacrocycle complexes characterized including phosphate ester X-ray structures.[445,446] They have also studied ligands with pendent alcohol groups.[447]

Two dinuclear complexes, with five-coordinate zinc centers, derived from tris((2-pyridyl)-methyl) amine were synthesized and bridging phosphate or phosphate ester groups. The X-ray structure of the phosphate monoester complex shows a syn–anti bridging mode in contrast to alkaline phosphatase in which it is syn–syn.[448] Fenton and co-workers have also studied other related dizinc species of compartmental ligands.[449]

Phosphate ester crystal structures have been determined of zinc 1,5,9-triazacyclononane including an interesting structure containing an oligophosphate bridged zinc unit.[450] The zinc complex of 1,5,9-triazacyclododecane was studied as a hydrolysis catalyst for substituted phenyl acetates.[451] Kinetic analysis suggested that hydrolysis occurs by a mechanism involving hydroxide attack of a metal-bound carbonyl.

Corrano and co-workers have characterized phosphate ester species with a mixed donor heteroscorpionate tripod zinc species.[452] Krebs and co-workers synthesized purple acid phosphatase mimics including a structurally characterized $Fe^{III}Zn^{II}$ phosphate bridged dimeric species.[453]

As already mentioned, Lippard and co-workers have also studied the μ-hydroxy dizinc unit found in metallohydrolases in a model system $[Zn_2L(\mu\text{-}OH)(\mu\text{-}O_2PPh_2)]^{2+}$, L = 2,7-bis [2-(2-pyridylethyl)-aminomethyl]-1,8-naphthyridine).[454] Hydrolysis of phosphodiesters and beta-lactams was studied and related to the P1 nuclease and beta-lactamase enzymes. The dinuclear complex

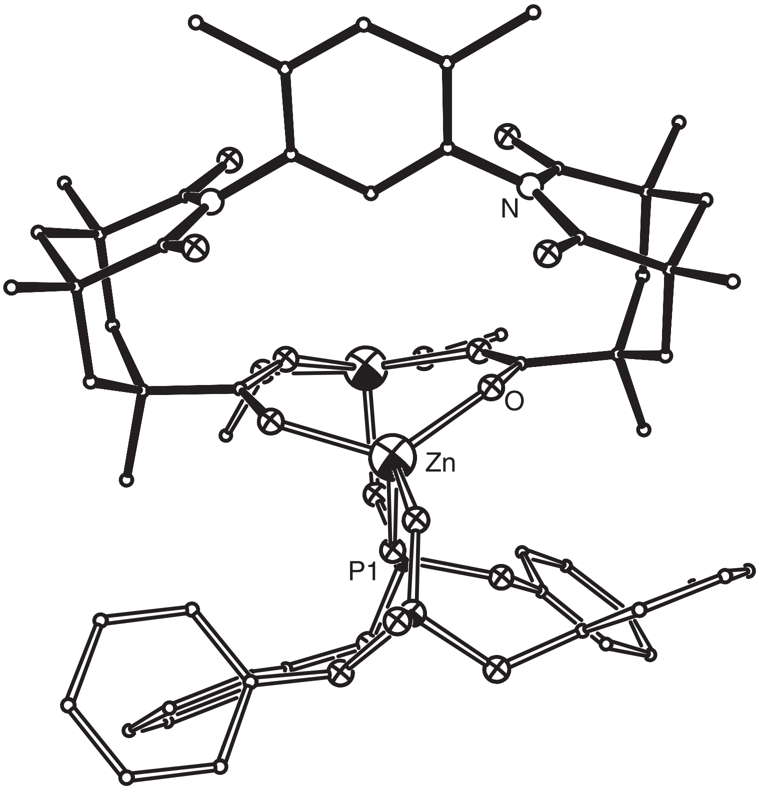


Figure 6 Molecular structure of a dimeric zinc compound with a bridging phosphodiester formed with ligands based on Kemp's triacid imide.[441]

was 1.8 times more reactive in hydrolysis of phosphodiesters than a mononuclear analog. However, some mononuclear complexes have equivalent reactivity to the dinuclear complex towards beta-lactam hydrolysis. The low reactivity of the bridging hydroxide could be attributed to the alignment of the substrate on binding being unfavorable and the diminished nucleophilicity of the hydroxide due to being simultaneously bound to the two zinc ions.

Dinuclear complexes with hydroxide bridged dizinc centers were synthesized with a ligand based on the phthalazine framework.[455] The dizinc complex of 1,4-bis(2,2′-dipyridylmethyl)phthalazine (**49**) is bridged by the phthalazine moiety, a water molecule, and a hydroxide ion. Both centers are pseudooctahedral with two pyridine donors and a water molecule occupying the remaining coordination sites.

6.8.6.7 Binding and Formation of Carbonate Species

Ito and co-workers observed the formation of zinc bound alkyl carbonates on reaction of carbon dioxide with tetraaza macrocycle zinc complexes in alcohol solvents.[456] This reversible reaction was studied by NMR and IR, and proceeds by initial attack of a metal-bound alkoxide species. The metal-bound alkyl carbonate species can be converted into dialkyl carbonate. Spectroscopic studies suggested that some complexes showed monodentate alkyl carbonates, and varying the macrocycle gave a bidentate or bridging carbonate. Darensbourg isolated arylcarbonate compounds from zinc alkoxides as a by-product from work on polycarbonate formation catalysis.[343]

X-ray structural data shows both the predicted structural types in the solid state with [14]aneN_4 (**50**) and [15]aneN_4 (**51**) showing chains of zinc macrocyles bridged by alkyl carbonate oxygens, and Me_4[14]aneN_4 (**52**) showing the monodentate methyl carbonate binding to a discrete Zn macrocycle unit (Figure 7).[457] The bridged complexes are tetrahedral and the discrete complex trigonal bypyramidal with the methyl groups providing steric hindrance.

Van Eldik attempted to achieve catalytic reactions with substituted nitrogen macrocycles and carbon dioxide but was unsuccessful in the synthesis of alkyl and aryl carbonates.[458] A bridging

μ_3-CO_3 species was formed and the X-ray structure solved. It is thought that the carbonate species forms on reaction with water, which was problematic in the selected strategy, as water was produced in the formation of the dialkyl carbonates. Other problems included compound solubility and the stability of the monoalkyl carbonate complex. Van Eldik and co-workers also carried out a detailed kinetic study of the hydration of carbon dioxide and the dehydration of bicarbonate both in the presence and absence of the zinc complex of 1,5,9-triazacyclododecane (12[ane]N_3). The zinc hydroxo form is shown to catalyze the hydration reaction and only the aquo complex catalyzes the dehydration of bicarbonate. Kinetic data including second order rate constants were discussed in reference to other model systems and the enzyme carbonic anhydrase.[459] The zinc complex of the tetraamine 1,4,7,10-tetraazacyclododecane (cyclen) was also studied as a catalyst for these reactions in aqueous solution and comparison of activity suggests formation of a bidentate bicarbonate intermediate inhibits the catalytic activity. Van Eldik concludes that a unidentate bicarbonate intermediate is most likely to the active species in the enzyme carbonic anhydrase.[460]

Paoletti *et al.* used a mixed aza oxo macrocycle (**53**) to form (μ_3-CO_3) carbonate species on absorption of atmospheric CO_2. The crystal structure showed a trimer with threefold symmetry and six-coordinate zinc centers.[461] This was described as CO_2 fixation; however, three equivalents of zinc complex are required for each CO_2 molecule and so it is not a catalytic process.

Synthesis of functional models of carbonic anhydrase has been attempted with the isolation of an initial mononuclear zinc hydroxide complex with the ligand hydrotris(3-*t*-butyl-5-methylpyrazolyl)borate. Vahrenkamp and co-workers demonstrate the functional as well as the structural analogy to the enzyme carbonic anhydrase. A reversible uptake of carbon dioxide was observed, although the unstable bicarbonate complex rapidly forms a dinuclear bridged complex. In addition, coordinated carbonate esters have been formed and hydrolyzed, and inhibition by small ions noted.[462] A number of related complexes are discussed in the earlier Section 6.8.4.

An unusual example of a solid-state complex of zinc containing both carbonate and hydrogen carbonate ligands has been structurally characterized, $NaA_2\{Zn_2[H(CO_3)_2](CO_3)_2(H_2O)_2\}$, A = K, Rb. The zinc is coordinated in a slightly distorted trigonal–bipyramidal geometry, and a layer structure, held together by hydrogen bonding, is formed with the potassium or rubidium atoms located between the layers. The hydrogen bond of the $[H(CO_3)_2]^{3-}$ anion is very short with O—O distance of 2.474(2) or 2.469(5) Å.[463]

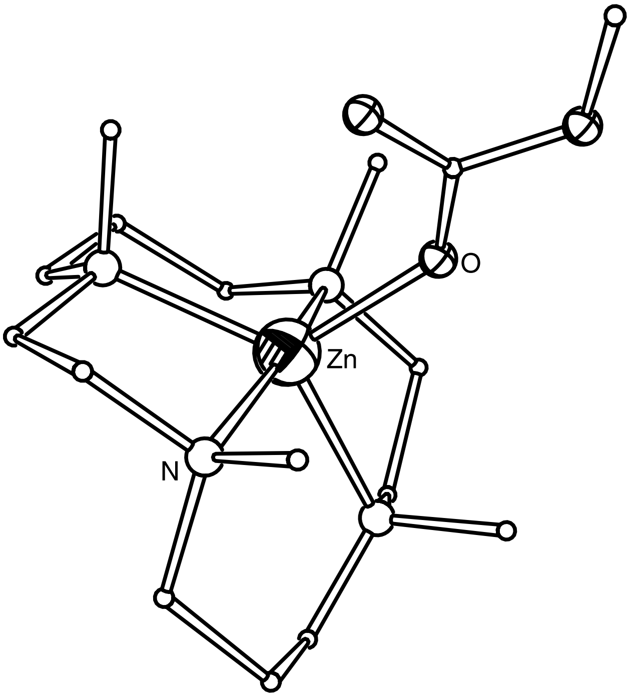

Figure 7 Molecular structure of zinc tetramethylcyclam (**52**) with a zinc-bound methylcarbonate. [457]

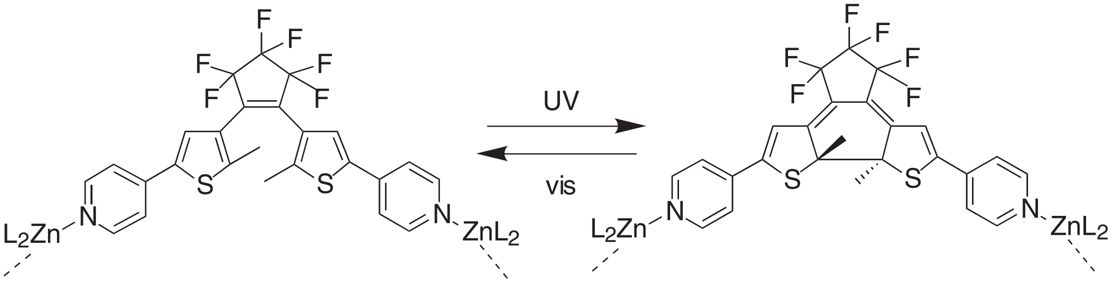
The ligand 1,3-bis[3-(2-pyridyl)pyrazol-1-yl]propane contains two bidentate chelating pyridyl/pyrazolyl fragments linked by a flexible trimethylene chain allowing variation in the binding geometry. In the structurally characterized zinc complex each ligand bonds in a tetradentate fashion to a five-coordinate zinc ion, the coordination sphere is completed by a carbonate oxygen from a μ_3 carbonate resulting in the species $[(ZnL)_3(CO_3)][ClO_4]_4$. The symmetrically bridging carbonate results from fixation of atmospheric CO_2.[464] Geometry around the metal centers is distorted trigonal bipyramidal ($\tau = 0.64$ using the Addison method).

Triply bridging carbonates between three zinc centers have been identified in nine different X-ray structures deposited in the CSD.[458,461,465–467] For example, a binuclear μ-OH zinc complex with a tetradentate *N*-donor ligand absorbs atmospheric carbon dioxide to a triply bridged carbonate.[468] Examples are also known where the metal atoms are in varying coordination environments. The complex cation $[Zn_3(\text{bipyridine})_6(\mu_3\text{-}CO_3)(H_2O)_2]^{4+}$ contains one penta- and two hexacoordinate zinc centers.[469] A tetrapodal compartmental ligand forms a tetrameric complex with zinc that contains the carbonate bridging between three of the four zinc centers.[470]

6.8.6.8 Acetylacetonate and Related Ligands

Zinc complex formation with 1,3-diketones in aqueous solution has been investigated with pentane-2,4-dione, 1,1,1-trifluoropentane-2,4-dione, and 4,4,4-trifluoro-1-(2-thienyl)butane-1,3-dione. The buffer dimethylarsinic acid was shown to have a catalytic effect on complex formation with pentane-2,4-dione and the proton transfer reactions were affected.[471,472] High-resolution solid state ^{13}C NMR studies of bis(2,4-pentanedionato) zinc complexes have been carried out.[473]

Photochromic compounds based on diarylethenes have been of interest due to their potential application in photonic switching devices. Materials involving these compounds and coordinated metal ions can show the desired changes on irradiation. Zn(1,1,1,5,5,5-hexafluoroacetylacetonate)$_2$ forms a linear chain polymer with1,2-bis[2-methyl-5-(4-pyridyl)-3-thienyl]perfluorocyclopentene which has been structurally characterized demonstrating an octahedral zinc center with axial pyridyl ligands from two different cyclopentene ligands. The single-crystal phase had photochromic activity, with irradiation at 366 nm the crystal turned blue on formation of the closed ring and on irradiation at 578 nm the blue color disappeared (Scheme 1).[474]



Scheme 1

Zinc dibenzoylmethanates have been synthesized and characterized by differential scanning calorimetry and solid state ^{13}C CPMAS NMR. Two forms have been studied by single crystal X-ray diffraction showing a monomer and a dimer. The monomer, ZnL_2 (**54**), has tetrahedral geometry with two bidentate ligands and the dimer Zn_2L_4 has two of the oxygens from the ligands bridging the octahedral zinc centers.[475] Other structurally characterized complexes include the Sn—Zn bond containing bis((dibenzoylmethanato)-(3-(dimethylamino)propyl))-tin-zinc[476] (**55**) and the zinc macrocycle complexes synthesized by Wieghardt and co-workers.[477] Additionally, either one or two pyridine ligands can be incorporated into the coordination sphere giving five- and six-coordinate complexes respectively.[478]

The zinc complex of 1,1,1,5,5,5-hexafluoroacetylacetonate forms coordination polymers in reaction with either 2,5-bis(4-ethynylpyridyl)furan or 1,2-bis(4-ethynylpyridyl)benzene. The X-ray crystal structures demonstrate an isotactic helical structure for the former and a syndiotactic structure for the latter in the solid state. Low-temperature ^{1}H and ^{19}F NMR studies gave information on the solution structures of oligomers. Chiral polymers were prepared from L_2Zn where L = 3-((trifluoromethyl)hydroxymethylene)-(+)-camphorate. Reaction with 2,5-bis(4-ethynylpyridyl)furan gave a linear zigzag structure and reaction with tris(4-pyridyl)methanol a homochiral helical polymer.[479]

Heterocyclic β-diketonate ligands have been studied in the formation of zinc complexes in the presence of other donor ligands. The chemistry of 4-acyl-5-pyrazolonate ligand donors with zinc has been relatively unexplored. 1-Phenyl-3-methyl-4-acyl-5-pyrazolone (**56**) formed bidentate 4-acylpyrazolonate complexes with zinc in the presence of donor ligands including amines, bipyridyls, and water. A six-coordinate monomer was structurally characterized and a range of complexes formed. Hydrogen bonding to the pyrazole nitrogen was thought to be an important factor in determining structural type.[480]

Ligands with pyrroldine-2,4-dione ring systems are of interest due to the presence of the potentially bidentate coordinating group in natural products, 3-acyl tetramic acids, that have a range of biological activities. The complexation of *N*-acetyl-3-butanoyltetramic acid (*N*-acetyl-3-butanoyl-4-hydroxypyrrolidin-2-one) to zinc depends on the ratio of ligand to metal, and gave different results to those observed for copper and cobalt, with deacetylation occurring in some cases.[481]

6.8.6.9 Other Oxygen Donor Ligands

Zinc carbamate complexes are well known, and the structural types and stabilities can be compared with thiocarbamates and dithiocarbamates which are discussed in Sections 6.8.11.1.3 and 6.8.7.1.4[482] Carbamates of zinc can be formed from the reaction of carbon dioxide with alkylzinc alkyl amides and further reaction with alkylzinc can give a distorted cubane structure.[483] The tetrameric diethylcarbamate species initially formed can also be used to produce monomeric or dimeric carbamate structures in reaction with amines; tetramethylethylenediamine forms a monomer $[(Me_2NCH_2)_2Zn(O_2CN(C_2H_5)_2)_2]$ with an octahedral zinc center and pyridine forms a dimer$[C_5H_5NZn_2Me(O_2CN(C2H5)2)3]$ with tetrahedral zinc centers.[484]

A tetranuclear complex is formed from $Rh(Hdmg)_2(PPh_3)Cl$ on reduction with zinc amalgam, $[Rh(Hdmg)(ClZndmg)(PPh_3)]_2$ (H_2dmg = dimethylglyoxime). The complex was characterized by

NMR, IR spectroscopy, and single-crystal X-ray diffraction. The structure is held together by a Rh—Rh bond and by the two zinc ions bridging oxygens from the dimethylglyoximate ligand.[485] Zinc has been used to mediate a ferromagnetic interaction between two paramagnetic metal ions.[486] However, the small value of the coupling probably limits the application of this strategy. The heterotrinuclear complex $[Cu_2Zn(Hdmg)_2(dmg)_2(H_2O)]$ has the zinc bridging to the copper centers via the oximate oxygens of the dimethylglyoximate ligands.

A tetrameric structure with the Zn_4O core can also be formed with the 7-azaindolate ligand, $[Zn_4O(C_7H_5N_2)_6]$, and has been structurally characterized. The tetramer displays intense photoluminescence at 448 nm in the solid state and 425 nm in acetonitrile with a lifetime and quantum yield of 0.1 μs and 0.17 μs respectively.[280]

A phthalocyanate complex with a peripheral catechol group can act as an oxygen donor ligand for zinc. A trispyrazolylborate complex of zinc hydroxide was treated with (2,3,9,10,16,17,23,24-octahydroxyphthalocyaninato)nickel(II) to displace the hydroxide ligand. This interaction was modeled in the complex formed by the addition of dihydroxyphthalimide to trispyrazolylborate zinc hydroxide, showing monodeprotonation of the catechol ligand.[487] Zinc catecholates have also been synthesized by direct electrochemical methods.[488]

To form stable complexes with semi-quinone-based redox active ligands a coligand is required to bind to the zinc; face capping tris(pyrazolyl)borate ligands have been used for this purpose.[236,489] Complexes have been constructed using the coligand hydrotris(3-cumenyl-5-methyl-pyrazolyl)-borate with 3,5-di-*t*-butyl-1,2-semiquinonate and the bis semi-quinonate from the catechol (**57**). The zinc 3,5-di-*t*-butyl-1,2-semiquinonate complex was structurally characterized and shows a distorted trigonal–bipyramidal geometry. The parent catecholate complex was unusually stable in air but in solution slowly oxidized to the semiquinonate.[236] The bis-catechol ligand has two zinc binding sites and both $S = 1/2$ and $S = 1$ species were generated by oxidation and characterized spectroscopically.[489]

6.8.7 SULFUR, SELENIUM, AND TELLURIUM LIGANDS

6.8.7.1 Sulfur Ligands

Zinc sulfur chemistry has been studied with particular reference to ZnS material formation and the characterization, and modeling of enzymes and proteins containing Zn—S bonding. In 1991 Christianson stated that typically the coordination patterns produced in nature for "structural zinc" have not been replicated; i.e., four cysteinate ligands bound or two histidine *N*-donors and two cysteine *S*-donors, with monodentate N's and aliphatic thiolates.[490] However, there have been many advances in recent years in the production of mixed donor set zinc complexes involving thiolates and thioether donors that will be presented. Some of these polydentate ligand systems will be discussed in Section 6.8.11. A large number of compounds have also been studied with the N_2S_2 coordination sphere and a preference noted for this donor set.[304,491,492] Zinc dithiocarbamates are well known and have important applications as antioxidants/antiabrasives in motor oils and as vulcanization accelerators in rubber.

In biology, the metallothioneins are a family of proteins that contain seven zinc ions chelated by twenty cysteine residues and their coordination chemistry has been reviewed.[493] Polyzinc species with thiolate ligands and bridged sulfur species have been of particular interest in the modeling of metallothioneins and also as molecular fragments to model the bulk properties of the zinc sulfide lattice. Zinc sulfide deposition has been extensively studied and characterized, and a number of molecular precursors will be discussed.[494,495] Some interesting advances in this area include the observation of the formation of sphalerite (ZnS) deposits in natural biofilms of sulfate-reducing bacteria, demonstrating how microbes control metal concentrations in groundwater- and wetland-based remediation systems. It also suggests biological routes for formation of low-temperature ZnS deposits.[496] Again bringing the areas of materials and biological sciences together, highly luminescent semiconductor quantum dots containing zinc sulfide can be covalently coupled to biomolecules for use in ultrasensitive biological detection. The quantum dots labeled with immunomolecules successfully recognize specific antibodies or antigens.[497]

6.8.7.1.1 Thiolates

In general, it is easier to form bridging sulfur ligands and polymetallic or polymeric compounds, rather than discrete complexes, with thiolate ligands.[498,499] Thiolates frequently form infinite lattice structures with tetrahedral zinc centers. The introduction of steric bulk and the potential for heteroleptic complex formation can result in the preferential isolation of discrete complexes. The tendency of zinc thiolates to form polymetallic species is well known, including the metallothioneins. Another area of interest has been as molecular fragments of sulfidic solids. Since the early 1980s there has been a major increase in the variety of structural types; mononuclear, oligomeric, and polymeric. Both monodentate and bidentate thiolate ligands with varying electronic and steric capabilities have been used in the formation of zinc compounds. Studies advancing the understanding of metallothioneins have been carried out on model systems and the proteins.[500]

The tendency to oligomerize can be countered by the use of sterically hindered thiolates.[358,501] Dependent on the degree of steric bulk, monomeric homoleptic complexes have been characterized with two- or three-coordinate geometries. The X-ray structures of a trigonal planar and a T-shaped zinc complex have been solved.[16,358,502] The rare two-coordinate monomeric zinc thiolate complex with 2,6-dimesitylphenylthiolate ligands (**58**) was also structurally characterized by X-ray crystallography and studied by IR and NMR.[12] A bent geometry is observed in contrast to the selenolate equivalent.

A number of *N*-donor multidentate ligands were used in conjunction with monodentate thiolate ligands (thiophenolate, benzylthiolate, benzene ethylthiolate) in the formation of a series of monomeric N_2S_2 complexes. The polydentate ligands all coordinated as bis *N*-donor ligands (bis(benzimidazolylmethyl)sulfides, 2,9-dimethylphenanthroline and bis(dimethylpyrazolyl-N-ethyl)amine) leaving uncoordinated donor atoms in some cases.[125] The polymeric zinc complex of benzothiazole-2-thiolate, $[Zn(C_7H_4NS_2)_2]$, forms mononuclear adducts in the presence of pyridine, 2,2′-bipyridine, and 1,10-phenanthroline. The complexes $[Zn(C_7H_4NS_2)_2(\text{pyridine})_2]$ and $[Zn(C_7H_4NS_2)_2\ (2,2'\text{-bipyridine})]$ were structurally characterized showing a distorted tetrahedral N_2S_2 geometry with coordination by two exocyclic S atoms of the benzothiazole-2-thiolates and two pyridyl nitrogen donors. Thermal degradation of all the complexes affords ZnS.[503] A series of monomeric complexes with 4-substituted thiophenolates and bidentate nitrogen donors, tetramethylethylenediamine, 2,2′-bipyridyl, and 1,10-phenanthroline have been synthesized, e.g., $[Zn(SC_6H_4(4\text{-}NH_2))_2(1,10\text{-phenanthroline})_2]$. The crystal structures showed O—H···S or N—H···S hydrogen bonding patterns in the solid, dependent on functional groups present.[504] Neutral zinc complexes with an N_2S_2 donor set from 2-(benzoylamino)thiophenolate and 1-methylimidazole have been synthesized. The monomeric distorted tetrahedral complex with two of each type of the monodentate ligands coordinated. The X-ray structure, IR analysis and ^{1}H NMR studies showed the presence of NH···S hydrogen bonding. The hydrogen bonding interactions have been considered as important in controlling the conformation and properties of complexes with S_2N_2 binding sites in proteins.[505] The luminescence spectra of bis(thiophenolato)(2,9-dimethyl-1,10-phenanthroline)zinc were correlated with the phase change of the solid at 77 K. Structure determinations for both phases suggested that the change in optical properties were due to rotation of the planes of the two thiol rings on a single zinc ion, from an approximately perpendicular to an almost face-to-face conformation, as the crystal was slowly warmed.[491]

An S_4 coordination sphere of the type seen in the Ada protein, where four cysteines coordinate, was achieved with the tridentate tris(2-mercapto-1-phenylimidazolyl)hydroborato ligand. The zinc thiophenolate derivative showed reactivity of the thiolate linkage (Figure 8).[506]

Dimeric zinc thiolate complexes of 2,4,6-*t*-butyl thiophenolate have been characterized by variable temperature and solid state NMR. The X-ray crystal structure shows that the dimeric structure has trigonal planar S_3 coordinated zinc centers with two bridging thiolates. In benzene solution a two-coordinate monomeric species is formed; however, the dimer exists at low temperatures in dichloromethane or toluene. EHMO calculations were carried out showing that the Zn—S bonds are essentially σ in character.[507] Luminescent dinuclear zinc complexes with the zinc ions in nonidentical coordination environments have been synthesized and studied, $[(\text{bipyridine})Zn_2(SC_6H_4\text{-Cl-}p)(\mu\text{-}SC_6H_4\text{-Cl-}p)(\mu\text{-OAc})_2]$. The X-ray crystal structure demonstrates that the dimer is held together by two bridging acetates and one bridging thiolate, with one zinc four-coordinate with a terminal thiolate and the other five-coordinate with a bipyridine ligand completing the coordination sphere. The luminescence, electrochemistry, and fluxional behavior in solution have been studied.[508]

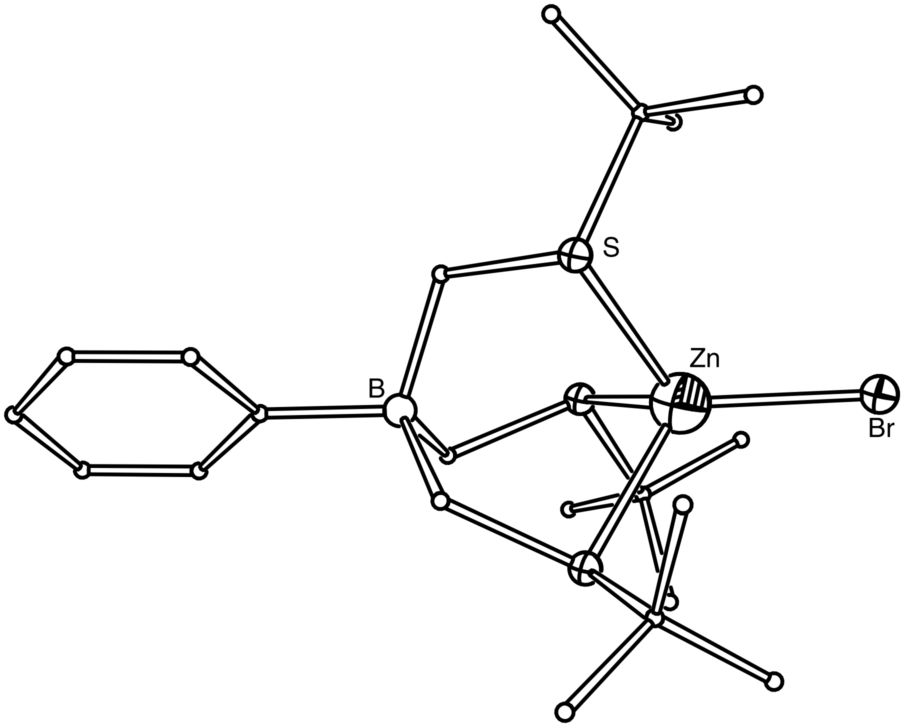

Figure 8 Molecular structure of the zinc complex of the tridentate tris(2-mercapto-1-phenylimidazolyl)-hydroborato ligand.[506]

1-(Methylthio)-*cis*-stilbene-2-thiol, Ph(SCH$_3$)C = C(SH)Ph, forms a dimeric zinc complex, Zn$_2$[(CH$_3$)S$_2$C$_2$Ph$_2$]$_4$, with bridging thiolates and equivalent five-coordinate zinc centers. In the presence of nitrogen donor ligands such as 4-(dimethylamino)pyridine and 2,2′-bipyridine, monomeric five-coordinate zinc complexes are formed with the –SMe groups binding weakly or not interacting. Ligand exchange in solution was monitored by ^{1}H NMR.[509]

A large number of polymetallic zinc species with terminal and bridging thiolate ligands have been characterized. Already discussed in Section 6.8.6 are the compounds with a μ_4-oxo giving a Zn$_4$O core. Equivalent compounds with a μ_4-sulfide are known but are much less common. A zinc compound with a Zn$_4$O core and bridging thiolate ligands to chromium(III) centers has been characterized. Chromium tris(2-aminoethanethiolate) in the presence of zinc ions formed the complex [{Cr(aminoethanethiolate)$_3$}$_4$Zn$_4$O]$^{6+}$. The X-ray structure shows the Zn$_4$O unit similarly arranged to previously discussed structures with the four chromium(III) atoms bridging via thiolate sulfur atoms.[510] Few examples of the Zn$_4$S core with μ_4-S related to the basic zinc carboxylate structure with a Zn$_4$O core have been structurally characterized. An example has been shown to be a discrete tetrameric structure with dialkyldithiophosphate ligands bridging the zinc centers (Figure 9).[511]

A further example, hexakis[μ-(dimethylarsinodithioate-S:S′)]-μ_4-thioxotetrazinc, [Zn$_4$(μ_4-S)-{μ-S$_2$As(CH$_3$)$_2$}$_6$], contains the Zn$_4$S core forming an irregular tetrahedron. The compound was studied by X-ray crystallography, electrospray mass spectrometry, UV spectroscopy, and DFT calculations.[512] Each of the zinc ions is tetrahedrally coordinated to four sulfur atoms in the discrete molecular complex. The emission and excitation spectra of the Zn$_4$(μ_4-S)$^{6+}$ core encapsulated in a borate cage have been studied and were identical to those of the dimethylarsinedithioate compound.[513]

The arrangement of zinc and sulfur atoms in the Zn$_4$S core is similar to the observed Zn$_4$O. Theoretical calculations demonstrated that the compound is a poor model of extended metal chalcogenide semiconductors (ZnS). Octanuclear zinc compounds have also been structurally characterized with this core. In the presence of an alkylammonium cation, a sulfide containing octanuclear zinc species was formed [BzEt$_3$N]$_2$[Zn$_8$(S)(SBz)$_{16}$].[126] The complexes with benzylthiolate

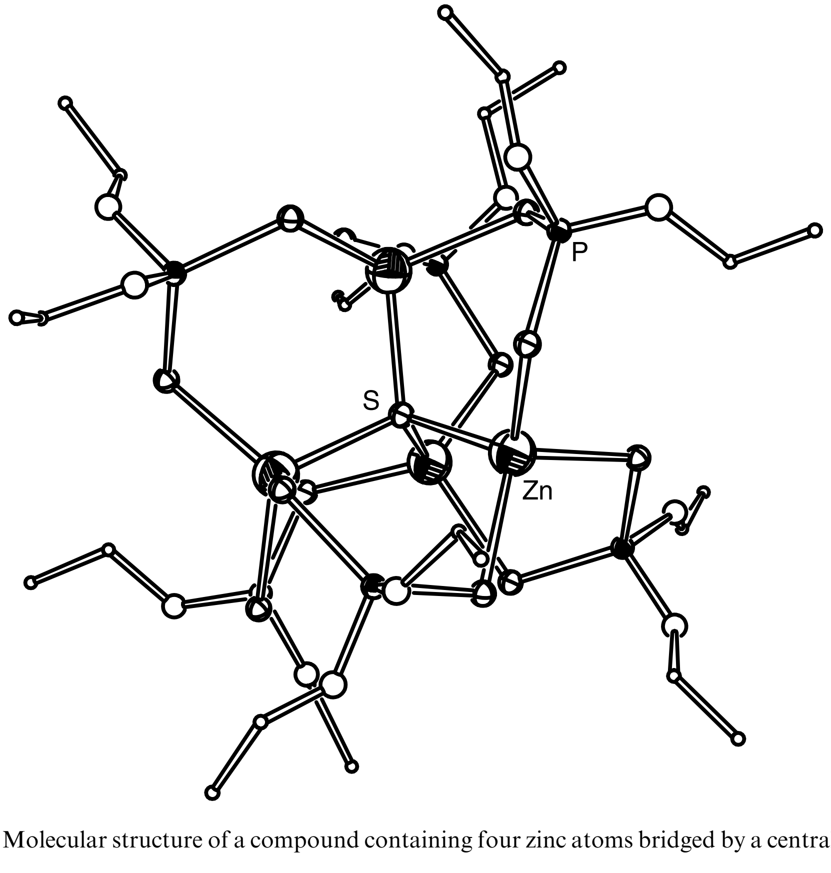

Figure 9 Molecular structure of a compound containing four zinc atoms bridged by a central sulfur.[511]

ligands form an arrangement based on a tetracapped octahedron and show interesting radical scavenging properties.[126,514] Varying the synthetic conditions allows controlled formation of tri- and octanuclear benzylthiolate complexes of zinc. A decanuclear compound is also known with the μ_4-S core, with a combination of sulfide, sulfate, and pyridine ligands completing the coordination about the zinc ions.[515]

There is of particular interest in zinc sulfur species that have properties between those of small molecules and extended lattices. The zinc thiophenolate complexes $Zn(SPh)_4{}^{2-}$ and $Zn_4(SPh)_{10}{}^{2-}$ were studied by electrochemical and spectroscopic methods as representations of tetrahedral fragments of the cubic zinc sulfide lattice. The mononuclear complex shows intraligand transitions and the tetranuclear complex a composite of both intraligand and ligand-to-metal charge-transfer transitions. Photodegradation and excitation of the charge-transfer absorption band were investigated.[516] Casarin and co-workers synthesized and investigated a series of zinc polymetallic species including those already mentioned ($[Zn(SPh)_4]^{2-}$, $[Zn_4\text{-}(\mu\text{-}SPh)_6(SPh)_4]^{2-}$, $Zn_{10}(\mu_3\text{-}S)_4(\mu\text{-}SPh)_{12}$, and $[Zn_{10}(\mu_3\text{-}S)_4(\mu\text{-}SPh)_{12}(SPh)_4]^{4-}$) by UV spectroscopy, X-ray photoelectron spectroscopy, and DFT calculations.[517] The lowest-energy absorption band is always an intraligand transition rather than a LMCT, and both the Zn and Cd compounds have similar spectra but none of the clusters was a particularly good model for bulk ZnS. The studies indicate a change in the nature of the frontier orbitals on moving from the smaller up to tetranuclear polyzincates to the decanuclear compounds. In the lower nuclearity compounds the frontier orbitals are delocalized and in the higher nuclearity compounds the HOMO and LUMO are highly localized, the former on the μ_3-S atoms and the latter on the peripheral zinc atoms. The species most relevant to bulk ZnS modeling was Zn_{10} $(\mu_3\text{-}S)_4(\mu_2\text{-}SPh)_{12}$ as a molecular model of ZnS nonpolar surfaces.[517] With all these systems care has to be taken in applying the properties of the polymetallic species as models of extended systems such as zinc sulfides.

Electrospray mass spectrometry was used to study polymetallic sulfide thiolate zinc anions, $[Me_4N]_4[S_4Zn_{10}(SPh)_{16}]$ and of the metal thiophenolate complexes $[Me_4N]_2[Zn(SPh)_4]$ and $[Me_4N]_2[Zn_4(SPh)_{10}]$.[57] The dissociation of the complexes at high cone voltages with the loss of fragments such as SPh^- and $[Zn(SPh)_3]^-$ gives relative stability data. Ligand exchange is of particular relevance to the formation of larger aggregates from structures with capping organics. A pyridyl containing zinc polymetallate $[Zn_{10}S_7(pyridine)_9(SO_4)_3]$ was synthesized from the thermolysis product of $[NMe_4]_4[Zn_{10}S_4(SPh)_{16}]$ which is thought to be $[Zn_{10}S_4(SPh)_{12}]$. The X-ray structure shows an unusual arrangement with a central Zn_4S connected to a Zn_6 hexagon via μ_3-sulfides. All zinc atoms are tetrahedral with sulfate ions bridging some, and the coordination sphere completed for nine of the zinc atoms by a pyridyl *N*-donor ligand.[515] The Zn—S connectivity in this cluster is different from that in the cubic or hexagonal lattices of ZnS, and from that commonly observed in other polymetallates formed by group 12 metals. Another approach is the use of counterions to give lower nuclearity species.[518,519] $[Me_4N]_4[S_4Zn_{10}(SPh)_{16}]$ in particular has been described as a molecular supertetrahedral fragment of the cubic zinc sulfide lattice.[520] Some other polyzinc species including $[NMe_4][Zn_8(Cl)(SPh)_{16}]_{16}$ have been characterized.[519,521] Sulfur L-edge XANES spectra were recorded for metallothionein species and model compounds. Some differences were observed from the expected well-defined tetrahedral geometries.[522]

Thiophenolate complexes have been discussed, however, a considerable amount of alkylthiolate zinc chemistry is also known. The zinc alkylthiolate complexes with methanethiolate, ethanethiolate, and *iso*-propylthiolate have been synthesized and characterized as precursors for ZnS formation. Thermolysis studies demonstrated the formation of ZnS and release of dimethylsulfide. Reactivity was similar with only the *iso*-propyl derivative showing much slower reaction.[523] The polyzincate $Zn_{10}S_4(SEt)_{12}L_4$ is a well-characterized neutral zinc sulfur compound.[524]

A trimeric species was formed with one equivalent of a bis(benzimidazole) ligand in the presence of benzylthiolates (**59**) (Figure 10). Zinc–zinc distances were in the range 3.069–3.958(2) Å.[126] Other zinc–thiolate trinuclear compounds include $Zn_3(CH_2SiMe_3)_3(SC_6H_2iPr_3)_3$ and $Zn_3(o\text{-}phen)_2(toluene\text{-}3,4\text{-}dithiolate)_3$ but have little structural similarity.[81,525]

Mixed metal zinc polymetallates are also known with bridging sulfur ligands. The luminescent heteronuclear rhenium(I)–zinc complex, $[\{(bpy)Re(CO)_3(\mu\text{-}SC_6H_4Me\text{-}p)\}_2Zn(bipyridine)](PF_6)_2$, was synthesized and structurally characterized.[526] The polymetallate $[(pyridine)_3Eu(\mu_2\text{-}SPh)_2(\mu_3\text{-}SPh)Hg(SPh)]_2$ reacts with zinc in tetrahydrofuran to give $[(THF)_3Eu(\mu_2\text{-}SPh)_2(\mu_3\text{-}SPh)Zn(SPh)]_2.THF$. The tetrameric metallospecies contains bridging and terminal thiolate ligands with Eu and Zn metal centers. Thermolysis gives a mixture of EuS and ZnS.[527] In the presence of zinc chloride, *N,N′*-bis(mercaptoethyl)-1,5-diazacyclooctane nickel(II) forms a heteropentanuclear structure, $([NiL]_3[ZnCl]_2)(BF_4)_2$ with bridging thiolate ligands and S_3Cl tetrahedrally coordinated zinc centers.[528]

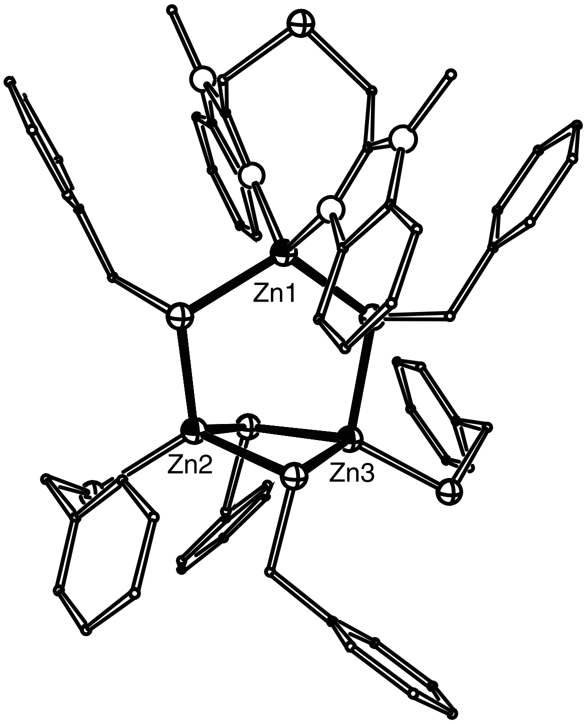

Figure 10 Molecular structure of a zinc trimer (**59**) with bridging benzyl thiolates and a bis(benzimidazole) ligand.[126]

Polymer formation is still observed with some sterically hindered thiolates, 2,4,6-*iso*-propyl thiophenolate, and 2,4,6-trimethyl thiophenolate complexes have been studied. They can be synthesized by the reaction of $Zn[N(SiMe_3)_2]_2$ with the appropriate arene chalcogenol. With the least steric bulk, the trimethyl derivative forms coordination polymers that can only be dissolved in strongly coordinating solvents. The *iso*-propyl derivative is more soluble forming oligomers in solution.[501]

The function and characterization of zinc polymetallic species in proteins has been an important area of research in recent years. The zinc thiol polymetallic species can have a protein structural role, regulate zinc homeostasis, participate in catalysis, and contribute to signal transduction.[3,529] They include metallothionein, CCHC zinc finger motifs in the HIV nucleocapsid protein, and the gene 32 protein from bacteriophage T4.[493,530,531] The latter two examples show zinc centers chelated entirely by protein residues with a mixture of cysteine thiols and histidine imidazoles coordinated. The degree of protonation of thiols in polyzinc compounds in proteins has been investigated by mass spectrometry. Electrospray mass spectrometry has demonstrated retention of thiol protons in some classes of protein coordinated zinc centers.[532] XAFS has been used to study the structural properties of zinc metallothioneins at 77 K and the structure showed close agreement with the similarly studied cadmium(II) analog.[533]

A range of complexes can be formed with dithiol ligands (1,2-benzenedithiol or 3,4-dimercaptotoluene), nitrogen donor ligands (1,10-phenanthroline and biquinoline), and zinc. X-ray crystal structure data showed a mononuclear complex, Zn(1,2-benzenedithiolate)(biquinoline); two binuclear species, $[Zn(1,2\text{-benzenedithiolate})(1,10\text{-phenanthroline})]_2$ and $[Zn(3,4\text{-dimercaptotoluene})(1,10\text{-phenanthroline})]_2$ and a trinuclear species, $Zn_3(3,4\text{-dimercaptotoluene})_3(1,10\text{-phenanthroline})_2$.[525] The redox chemistry and electronic spectra of the doubly deprotonated zinc complex of toluene-3,4-dithiol was studied. The formation of a one-electron ligand-based oxidation product was observed.[534] Alkanedithiols can be reacted electrochemically with zinc and the reaction of the product with carbon disulfide studied.[535] In bis(2-mercapto-1-methylimidazolyl) (pyrazolyl)hydroborato zinc, ZnL_2, analysis by X-ray diffraction demonstrates that the zinc exhibits a tetrahedral ZnS_4 structure with only sulfur donors coordinated. This is in contrast with other transition metal complexes of the same ligand showing the preference of zinc for this donor set and coordination sphere.[536]

Binding of bidentate sulfur ligands can also be of importance in the inhibition of zinc containing enzymes. An aminopeptidase which is essential for vancomycin antibiotic resistance in

Enterococcus faecium is inhibited by binding of dithiol ligands. The most potent inhibitors were dithiols with a two-carbon chain between the thiol groups. It is suggested that both thiols bind from the ligand forming a five-membered chelate ring with the zinc ion at the active site, preventing approach of the vancomycin substrate.[537]

Varying ratios of the ligands *N*-(2-thiophenyl)-2,5-dimethylpyrrole and *N*-methylimidazole were used to form tetrahedral zinc complexes with S_4, S_3N, and S_2N_2 coordination spheres. X-ray structural analyses and IR spectra were recorded for all compounds and the relevance to zinc finger proteins was discussed. The comparison to cobalt and cadmium structures showed only minor differences, supporting the theory that changes on substituting these metals into zinc proteins would be minor.[538]

6.8.7.1.2 Thioether ligands and methylation of cysteines

Thioether ligand complexes are not very common, however, studies since the mid 1990s have dramatically increased the number of structurally characterized examples. Almost all of these compounds are with chelate or macrocyclic ligands that will stabilize thioether coordination. Mixed donor multidentate ligands containing thioether donors will be discussed in Section 6.8.11.

A number of zinc-bound bidentate bis(thioether) donor ligands were characterized as distorted tetrahedral complexes of zinc dichloride. The complexes 2,3-bis(methylthio)hexane,1,2-bis (methylthio) cyclohexane, and *cis*-[5,6-bis(methylthio)-1,3-cycloheptadiene showed a variation in S—Zn—S angles.[539]

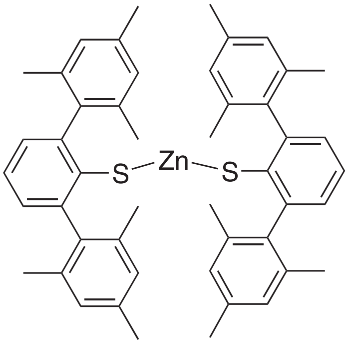
The X-ray structure of the bis(1,4,7-trithiacyclononane) zinc shows an unusual S_6 thioether-coordinated zinc center.[540] A rare monodentate thioether donor is observed in a phenyl-bridged zinc dimer that has been structurally characterized with a tetrahydrothiophene coordinated to each zinc center.[541]

There has been much recent interest in the role of zinc in activating cysteine residues to nucleophilic attack.[542–545] Alkyl group transfer to coordinated cysteine residues occurs in a number of zinc proteins, such as Ada (the *E. coli* DNA repair protein) and the cobalamin dependent and independent methionine synthases.

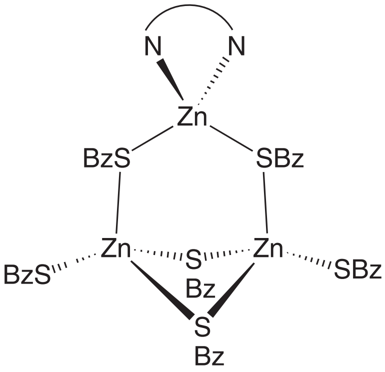
Lippard and co-workers have shown thiolate dissociation prior to alkylation in the reaction of $Zn(SPh)_4^{2-}$ with trimethyl phosphate as methyl donor. The kinetics of the reaction were studied and the presence of other amino acids modeled using compounds incorporating imidazole derivatives.[544,546] The dimeric dithiolate complex [1,5-bis(mercaptoethyl)-1,5-diazacyclooctanato (**60**)] zinc, $[LZn]_2$ has been investigated as a model for the active site of zinc-dependent methylation proteins by Darensbourg and co-workers.[543] The zinc complex has been characterized by X-ray crystallography, showing a dimeric structure with two five-coordinate zinc centers.[528] Alkylation of the thiolate and whether it remains bound in this state were the key issues in this study. It was postulated that the rigidity and chelate effect offered by the tetradentate ligand would encourage the sulfur to remain bound when alkylated. No evidence for thioether ligation after alkylation was observed for these compounds. The aim of encouraging thioether coordination was unsuccessful possibly due to geometric restraints, however, further alterations such as macrocycle formation show thioether coordination. It is suggested that the resultant thioether is still coordinated in the Ada protein. It is possible that either thiolate alkylation occurs while the thiolate is bound or that structural changes in the zinc binding site favor this coordination of the thioether.[543]

A non-dissociative mechanism was suggested by Vahrenkamp and co-workers in the alkylation of the tris(pyrazolyl)borate complex of ZnSR with methyl iodide, dimethylsulfate, or trimethylsulfonium iodide as the methylating agents.[542] Corrano and co-workers have also used a tripodal ligand system to investigate the methyl transfer reaction.[78] The heteroscorpionate ligands (**61**) have either an N_2S or N_2O donor set, and benzyl mercaptate or thiophenolate were coordinated to complete the coordination sphere. Methylation of the bound thiolate could be carried out with methyl iodide with the reaction rates and lack of solvent dependence consistent with a non-dissociative mechanism. There may be several mechanisms by which zinc complexes participate in the alkylation reaction of cysteine thiolates, with both inter- and intramolecular reactions occurring under different conditions.

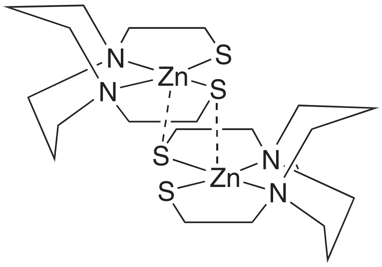
The binding of thioether ligands has been further studied by Berg and co-workers in an attempt to gain understanding of the role of the zinc in the reactivity regulation of the cysteine residues to alkylation. Variants of a consensus zinc finger peptide were modified to mimic the effects of cysteine alkylation and the metal binding and stability of the peptide structure studied. The zinc finger framework had a histidine residue replaced by methionine or S-methyl cysteine, which can be done with no loss of stability. ^{1}H NMR studies showed the structure of the peptide zinc complex was affected by methylation but only in the vicinity of the modification. Titration and alkylation experiments were carried out with the cobalt analog. As expected, the studies reveal that zinc has a lower affinity for thioether groups than cysteine or histidine.[545]



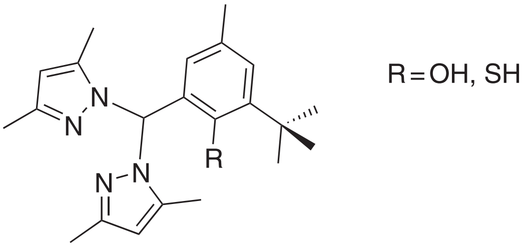
(**58**)



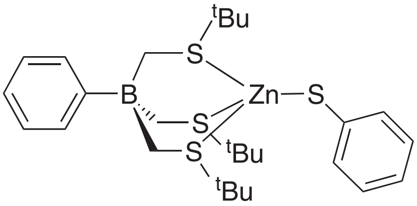
(**59**)



(**60**)



(**61**)



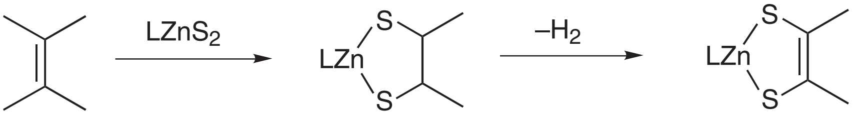
(**62**)

Models of the active site in *E. coli* methionine synthases were prepared by Riordan and coworkers using the S_3 donor ligand phenyltris((*t*-butylthio)methyl)borate (**62**) (Figure 8). In the zinc complex a thiophenolate ligand, LZn(SPh), mimics the homocysteine ligated form of the enzyme. Analogous complexes were formed with the NS_2 donor ligand phenyl(3-*t*-butylpyrazolyl)bis((*t*-butylthio)methyl)borate and the zinc complex with a thiophenolate ligand bound presented as mimicking the homocysteine ligated form of cobalamin independent methionine synthase. The average Zn—S bond length in the complex (2.37 Å) compares well with the EXAFS-derived distance observed for the enzyme (2.31 Å).[547] Other S_3 face-capping ligands are also known in zinc complexes.[548]

6.8.7.1.3 Dithiolates and polysulfides

Dithiolate ligands are of interest in biological and materials chemistry, and zinc polysulfido complexes can effect the dehydrogenative conversion of alkenes into dithiolates (Scheme 2).

If required, the dithiolate ligand can then be removed from the metal center. Zinc polysulfido complexes of diamines and triamines (ZnS_6(TMEDA), ZnS_4(PMDETA), and $ZnS_4(Me_3TACN)$) can react with electrophilic alkenes to give dithiolate complexes. TMEDA, Me_3TACN, and PMDETA complexes were investigated with the triazacyclononane ligand having the highest reactivity and the PMDETA complexes moderate reactivity. A number of alkenes with cyano, ester, and aldehyde functionalities were tested for reaction.[549]



Scheme 2

Some of the proposed dithiolate intermediates were synthesized for study. It was possible to remove the dithiolate ligand by reaction with other species. Crystal structure analysis of ZnS_4(PMDETA) and $ZnS_4(Me_3TACN)$ show five-coordinate species bound to two sulfur atoms from S_4 and the three ligand nitrogens.[549,550] Both have distorted geometries with one elongated Zn—N bond and the reactivity parallels the nucleophilicity of the compounds; the four-coordinate TMEDA species is considerably less nucleophilic.

Rauchfuss and co-workers have carried out extensive recent studies on dithiolate and polysulfide compounds.[551–553] Reactions of zinc powder with elemental sulfur can be controlled in donor solvents. The presence of the ligands tetramethylethylenediamine, *N*-methylimidazole, and 4-(*N,N*-dimethylamino)pyridine result in complexes of the type ZnS_6L_2 or ZnS_6L. The solid state structure of the tetramethylethylenediamine complex shows a tetrahedral geometry with a seven-membered ZnS_6 ring. The $[ZnS_{12}]^{2-}$ can be formed by ligand exchange of the amine ligand with a further S_6^{2-} ligand. The reactivity of the complexes and decomposition to ZnS was studied.[551] The ZnS_6L (L = tetramethylethylenediamine) complex can be used as a polysulfide transfer agent to prepare, for example, sulfur selenide species in isomeric purity.[552] Zinc dithiolates have also been used as a source for zinc sulfide materials.[554]

6.8.7.1.4 *Dithiocarbamates*

Zinc dithiocarbamates have been used for many years as antioxidants/antiabrasives in motor oils and as vulcanization accelerators in rubber. The crystal structure of bis[*N,N*-di-*n*-propyldithiocarbamato]zinc shows identical coordination of the two zinc atoms by five sulfur donors in a trigonal–bipyramidal environment with a zinc–zinc distance of 3.786 Å.[555] The electrochemistry of a range of dialkylthiocarbamate zinc complexes was studied at platinum and mercury electrodes. An exchange reaction was observed with mercury of the electrode.[556] Different structural types have been identified by variation of the nitrogen donor in the pyridine and *N,N,N′,N′*-tetramethylenediamine adducts of bis[*N,N*-di-*iso*-propyldithiocarbamato]zinc. The pyridine shows a 1:1 complex and the TMEDA gives an unusual bridging coordination mode.[557] The anionic complexes of zinc tris(*N,N*-dialkyldithiocarbamates) can be synthesized and have been spectroscopically characterized.[558]

Thermochemical studies of Zn(di-*n*-propyldithiocarbamate)$_2$ were carried out using solution-reaction calorimetry and differential scanning calorimetry.[559] Similarly, these values were determined for the di-*n*-butylthiocarbamate compound.[560] The mean metal–sulfur bond enthalpies were also calculated for each compound and the zinc–sulfur bond enthalpy has also been determined for bis(diethyldithiocarbamato) zinc.[561] Structural studies to determine the effects of solid state solvation of zinc bis(diethyldithiocarbamate) complexes with a morpholine ligand have been carried out, $[Zn(O(CH_2)_4NH)(S_2CN(C_2H_5)_2)_2]$. Solvation with morpholine or benzene leads to significant structural reorganization at molecular level with different Zn—N bond lengths, a reoriented heterocyclic ring of the coordinated morpholine molecule, and an enhanced contribution of trigonal–bipyramidal character to the geometry of the coordination polyhedra of the zinc center. The data was obtained from single-crystal X-ray studies and solid-state ^{13}C and ^{15}N CP/MAS NMR spectroscopy.[562]

Complexes of zinc dialkyldithiocarbamates with bidentate nitrogen ligands such as 1,10-phenanthroline have been structurally characterized.[563] The related complexes (4,4′-bipyridyl) bis(di(2-hydroxyethyl)dithiocarbamato)zinc and (4,4′-bipyridyl)bis(bis(*N*-methyl, *N*-ethanol-dithiocarbamato)zinc were synthesized and structurally characterized. Both complexes are dimeric with each zinc five-coordinate with an S_4N donor set. Comparisons are made to the parent dithiocarbamate ligands, with the thioureide C—N stretch at a lower value for these complexes and the cyclic voltammetry studies indicating a presence of excess electron density on the zinc ion relative to the dithiocarbamate ligands.[564]

6.8.7.1.5 Thioformamide, thiocyanate, thiophosphate, and other sulfur donor ligands

The formation of zinc complexes with *N,N*-dimethylthioformamide has been studied by crystallography and in solution by vibrational spectroscopy and large angle X-ray scattering.[565,566] Both solid state and solution studies show four-coordinate zinc complexes with Zn—S bond lengths of 2.34 (mean) and 2.362(5) Å. In large-angle X-ray scattering studies, the zinc ions in *N,N*-dimethylthioformamide solution are found to coordinate to four *N,N*-dimethylthioformamide molecules with Zn—S bond distances of 2.362(5) Å. Raman and far-IR spectra were assigned for both solution and solid state.[565] A series of single-crystal X-ray structures demonstrates the variation in geometry between the group 12 ions. The tetrahedral coordination geometry of $[Zn(SCHN(CH_3)_2)_4](CF_3SO_3)_2$ shows a mean Zn—S distance of 2.34 Å. Hydrogen bonding is observed between neighboring *N,N*-dimethylthioformamide ligands.[566]

The most stable structures and formation energies of zinc thiocyanate complexes have been calculated by *ab initio* density functional methods. The formation energies of the linkage isomers $[Zn(NCS)_4]^{2-}$, $[Zn(NCS)_2(SCN)_2]^{2-}$, and $[Zn(SCN)_4]^{2-}$ were determined. A comparison of the formation energies indicated that $[Zn(SCN)_4]^{2-}$ is the most stable isomer both in water and in dimethyl sulfoxide.[567]

A number of dialkyldithiophosphate zinc complexes were prepared and characterized in liquid and solid states, and as surface complexes on sphalerite. ^{31}P NMR was used to characterize the coordination modes, whether terminal chelating or bridging between two metal centers. Correlations were made between data for the structurally characterized *O,O*′-dicyclohexyldithiophosphate zinc and the NMR of the surface complexes demonstrating bridging coordination between two neighboring zinc atoms on the synthetic sphalerite.[568]

Harrison and co-workers reported the $([Zn_4(\mu_4\text{-S})\{\mu\text{-}S_2P(OC2H5)_2\}_6])$ as a by-product in the synthesis of $[Zn\{S_2P(OC_2H_5)_2\}_2]$ which contains the $Zn_4(\mu_4\text{-S})$ structural motif.[511] A series of zinc dialkyldithiophosphates have been investigated by this research group, including recording ^{31}P NMR spectra and studies of the reaction of these compounds with *N*-donor ligands. Monomeric complexes are formed in reaction with pyridine, 2,2′-bipyridine, and 2,2′-6′,2″-terpyridine with a combination of *N*-donor and thiophosphate ligands.[569,570]

As part of a study into the activation of metal catalysts in thiol or thiolate-rich environments, *S*-substituted coenzyme M and thioglycolate derivatives were investigated in a Ni-catalyzed cross-coupling reaction with a zinc co-factor; the role of zinc was shown to be in a transmetallation process.[571]

The interaction of carbon disulfide as a substrate in carbonic anhydrase model systems has been studied using density functional theory methods. A higher activation energy of CS_2 compared to CO_2 in the reaction with $[L_3ZnOH]^+$ was due to the reduced electrophilicity of CS_2. The reversibility of the reaction on the basis of these calculations is questionable with $[L_3ZnSC(O)SH]^+$ as intermediate.[572]

An example of thione coordination is demonstrated with the thiocarbonyl donor ligand 2,6-dimethyl-4H-pyran-4-thione, that gives a complex with zinc chloride of the form ZnL_2Cl_2. The crystal structure shows the zinc is tetrahedrally coordinated by two chloride and two sulfur donors and the compound was further studied by ^1H NMR and IR spectroscopy.[573] Both monomeric and dimeric heterocyclic thione complexes have been formed with zinc.[574,575]

The dithiolate ligand dithiosquarate forms mononuclear complexes with zinc in the presence of N_2 donor ligands 2,2′-biquinoline, 1,10-phenanthroline, and 1,4-diphenyl-2,9-dimethyl-1,10-phenanthroline. X-ray crystallography shows a tetrahedral complex with one equivalent of each ligand binding to the zinc center. The phenanthroline-based complexes are emissive in the solid state at room temperature and show multiple emissions at lower temperature, assigned as metal-assisted ligand-to-ligand charge transfer and intraligand π–π^* transitions.[576] Bipyridinium and phenanthrolinium acceptors of different reduction potentials form ion-pair charge-transfer complexes with zinc 1,2-dithiooxalates. Absorptions are observed in the range 390–490 nm, which can be attributed to ion-pair charge-transfer. The mean reorganization energy of the complexes exceeds the values found for the dithiolate systems. The X-ray structures of the compounds show the relative geometry of the two components.[577]

A dithiolate ligand forms a structurally characterized dizinc bisligand complex with both of the ligands bridging, bis{μ-[(dimercaptomethylene)propanedinitrilato-*S,S′*]}tetrakis(4-methylpyridine) dizinc.[578]

6.8.7.2 Selenium

6.8.7.2.1 Selenides

A number of zinc selenium complexes have now been characterized, with particular interest in the formation of zinc selenide semiconductors and quantum dots. In many cases analogous structures to those observed with thiol or thiolates are recorded. ^{77}Se NMR is frequently used in characterization, and comparison with the sulfur equivalent is relevant. Zinc selenium compounds are of particular interest as precursors for metal/selenide materials and their relevance as models for selenocysteine-containing metalloproteins.

The reaction of carbon diselenide with sodium and zinc chloride present results in the complexes $[Zn(C_3Se_5)_2]^{2-}$ (**63**) and $[Zn(CSe_4)_2]^{2-}$. X-ray structure showed the zinc ions were tetrahedral with four selenium atoms coordinated. The UV–vis spectra and ^{77}Se NMR spectra were recorded.[579] A tetrahedral selenolate complex can be formed from a ligand containing a 1,3-thiaselenole heterocycle. The zinc complex, bis(tetraphenylphosphonium)-bis(1,3-thiaselenole-2-selone-4,5-diselenolato) zinc, with the selenole ester-containing ligand was characterized in detail by NMR with extensive ^{77}Se and ^{13}C spectra recorded.[580]

The zinc bis(tetraseleno) anion, $[Zn(Se_4)_2]^{2-}$, has been crystallized with a number of cations, synthesized by a variety of methods, and its reactivity studied.[581–584] The compound (hexaseleno) (tetraseleno)zinc (**64**) was synthesized from zinc acetate in the presence of lithium polyselenide and structurally characterized, demonstrating seven-membered and five-membered $ZnSe_n$ rings.[585] Mixed donor neutral monomers have also been formed with imidazole *N*-donor ligands, $ZnSe_4$ (*N*-methylimidazole)$_2$.[553]

Polymeric network structures of zinc and selenium with *N,N′*-ethylenediamine have been formed and structurally characterized. The tetrahedral zinc centers are Se_3N coordinated with the diamine bridging to give two-dimensional slabs.[586]

6.8.7.2.2 Selenolates

A monomeric selenolato complex of zinc (**65**) was synthesized with a chelating oxazoline ligand.[587] The complex was characterized by X-ray crystal structure, ^{1}H, ^{13}C, and ^{77}Se NMR. These studies demonstrate that the compound is "helically" chiral and solution studies appear to show retention of chirality in solution. The zinc complex is tetrahedral with a Zn—Se average bond length of 2.378(1) Å.

A monomeric zinc selenophenolate, bis(phenylselenolato)zinc TMEDA, has been isolated and structurally characterized and used as a precursor in the size-controlled synthesis of ZnSe quantum dots. The growth temperature afforded the different-sized quantum dots that showed a variation in luminescence emission wavelength dependent on size.[588] A trigonal planar monomeric selenophenolate complex can be synthesized using the bulkier 2,4,6-(trifluoromethyl)selenophenolate. The complex has two of the selenophenolate ligands and a bisilylamide completing the trigonal coordination.[589] Bochmann *et al.* structurally characterized a number of zinc selenates including three-coordinate and four-coordinate monomeric species.[304,507,590]

Monomeric selenophenolate derivatives with pyridine have also been synthesized and characterized, $[Zn(SeC_6H_2Me_3\text{-}2,4,6)_2(pyridine)_2]$ with distorted N_2Se_2 tetrahedral coordination geometry.[591] Zinc areneselenolate complexes are usually infinite lattice solid state compounds with bridging selenolato ligands.[592] Zinc selenophenolate complexes have been characterized by single-crystal X-ray diffraction, showing tetrahedral metal centers, and far-infrared and Raman spectroscopy.[499] Increasing the steric hindrance from the (2,4,6-trimethylphenylselenato) group to the *t*-butyl equivalent results in different complexes dependent on the other ligands available. In the presence of one equivalent of *t*-butylisocyanide the compounds is thought to be dimeric with bridging selenolates and in the presence of excess of *t*-butylisocyanide the X-ray structure shows a monomeric species with an S_2C_2 donor set and distorted tetrahedral coordination geometry.[66] A dimeric species is formed in the presence of benzaldehydes or ketones. The X-ray structure of $[Zn(SeC_6H_2{}^tBu_3\text{-}2,4,6)(4\text{-methoxybenzaldehyde})]_2$ demonstrates two bridging selenolates between the tetrahedral zinc centers.[593] The complex $[Zn(CH_2SiMe_3)_2(SeC_6H_2{}^tBu_3\text{-}2,4,6)]_3$ contains a nonplanar six-membered Zn_3Se_3 ring and is characterized by X-ray diffraction, and ^1H NMR and IR spectroscopy.[82] The dimeric $[Zn(SeC_6H_2{}^tBu_3\text{-}2,4,6)_2]_2$ can be reacted with nitrogen, phosphorus, or sulfur donor ligands to give monomeric three-coordinate species. The ligands 2,6-lutidine, tetrahydrothiophene, trimethylphosphine, and methyldiphenyl phosphine all result in monomer formation and the solid-state structures show a wide variation in Se—Zn—Se angles from 129.0(2)° to 156.26(4)°. Theoretical interpretations of the hybridization of zinc were used to account for these variations. A four-coordinate monomeric complex, $[Zn(SeC_6H_2{}^tBu_3\text{-}2,4,6)_2L_2]$, could be formed in the presence of excess 1-methylimidazole but on recrystallization one ligand was lost to give the three-coordinate showing the balance between electronic and steric factors.[304]

The sterically demanding selenolate ligand, $HSeC_6H_3$-2,6-(mesityl)$_2$, reacts with zinc to form either two- or three-coordinate complexes in the solid state. If recrystallized from tetrahydrofuran the monomeric complex $Zn(HSeC_6H_3\text{-}2,6\text{-}(mesityl)_2)_2(THF)$ with two selenolate ligands and a coordinated THF is isolated; however, when recrystallized from hexane a two-coordinate monomeric complex with only the selenolate ligands is isolated. The two-coordinate complex appears to be the only example of this geometry with selenium. Intriguingly, the geometry of this complex is exactly linear in contrast to the analogous thiolate complex which has a bent conformation with Zn—S—Zn = 151.7°. Power and co-workers comment on a number of important factors to the setting of two-coordinate geometries but offer no simple explanation of this difference.[13]

The tetrameric zinc anion $[Zn_4(\mu\text{-SePh})_6(SePh)_4]^{2-}$ has been structurally characterized as the first example of a Zn_4Se_4 adamantane cage-type structure.[594] A further example was characterized by Bochmann and co-workers as part of a study of polymetallic zinc selenophenolates, in this case with chlorides replacing the terminal selenophenolates, $[Zn_4(\mu\text{-SePh})_6Cl_4]^{2-}$. Octameric zinc species were also characterized with either chloride or phosphine ligands resulting in anionic and neutral complexes respectively, $[Zn_8(\mu\text{-SePh})_{12}Cl_4]^{2-}$ and $Zn_8(\mu\text{-SePh})_{12}(SePh)_2\ (P^iPr_3)_2$.[301]

The heterotrinuclear linear selenolate complex, $[(OC)_3Fe(\mu\text{-SePh})_3Zn(\mu\text{-SePh})_3Fe(CO)_3]$, was synthesized and structurally characterized. The structure shows a zinc center in a $ZnSe_6$ octahedral environment.[595] A bimetallic complex containing europium and zinc has been characterized with three bridging selenophenolate ligands. Analysis of the structural data by Berardini *et al.* shows a clear polarization of the Se electron density away from the europium ion, making the Eu—Se bond longer and weaker.[596] A related structural motif with a triply bridged samarium zinc unit is observed; however, in this case the samarium is also singly bridged to a further zinc resulting in a coordination polymer in the solid state.[597] A tetracobalttetrazinc structure with Zn_4O core has been characterized with aminoethaneselenolato ligands bridging the cobalt(III) and zinc centers. Each zinc is bound to three bridging selenium atoms and the central oxo forms a cage-type structure.[598] The bis(1,2-diselenosquarato) zinc dianion is a tetrahedral monomer with coordination to the bidentate ligands via the selenium donors.[599]

A monomeric diselenocarbamate complex of zinc has been structurally characterized as a pyridine adduct, $[Zn(Se_2CNEt_2)_2(pyridine)]$, showing distorted trigonal–bipyramidal geometry. Mixed selenophenolate/diselenocarbamate complexes have been formed with a 1:1 ratio of each ligand to the zinc center.[591] The structural type is strongly influenced by functionalization on the selenophenolate ring. The (2,4,6-trimethylphenylselenato) zinc complex is a polymeric solid which dissolves in coordinating solvents.[501] The compound $Zn[Se_2CN(Me)\ CH_2CH_2CH_2NMe]_2$ is polymeric in the solid state with a Se_4N donor set. The *N*-donor is from a neighboring ZnL_2 unit, resulting in the polymeric arrangement. Attempts to grow ZnSe films were made and discussed.[600] The zinc complex with methyl(*n*-hexyl)diselenocarbamate was found to be a more effective precursor for ZnSe deposition by MOCVD than simpler derivatives and possible explanations were suggested.[601] Bis(μ_2-diethyldiselenocarbamato-*Se,Se,Se′*)-dimethyl dizinc gives a structure with four-coordinate zinc centers and two bridging selenium atoms.[602] Other related structures with variation in the alkyl groups are also known.[603]

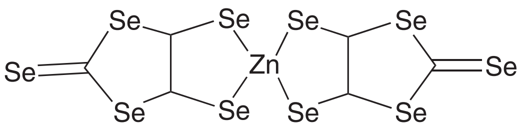
The preparation of ZnSe materials is an area of interest and study. The coordinating ability of the solvent used in the solvothermal synthesis of zinc selenide was demonstrated to play an important role in the nucleation and growth of nanocrystalline ZnSe.[604] Thermolysis of bis [methyl(*n*-hexyl)di-seleno]carbamato]zinc gave highly monodispersed particles characterized by electronic spectroscopy, photoluminescence, X-ray diffraction, and electron microscopy.[605]

6.8.7.3 Tellurium

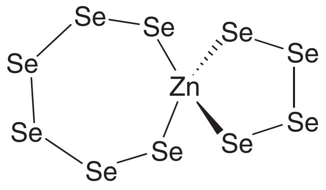
Although numbering even fewer than the structurally characterized selenium zinc complexes there are examples of zinc tellurides and tellurates with typical coordination numbers of three or four and species from monomeric up to polymeric.

Addition of K_2Te_3 to a solution of zinc acetate results in a compound containing the $[ZnTe_7]^{2-}$ complex ion. The heptatellurido zinc has a trigonal–planar coordination geometry, demonstrated by X-ray crystallography. The ligands are best described as a chelating $Te_4{}^{2-}$ ion and a terminal $Te_3{}^{2-}$ ion.[606] The bis(tetratellurido) zinc complex is an anion ($ZnTe_8{}^{2-}$) which shows the metal coordinated tetrahedrally by two $Te_4{}^{2-}$ chelates. The ^{125}Te NMR spectrum was recorded and compared with ^{77}Se NMR spectra from analogous compounds.[607] An ionic polymetallate results from zinc chloride in acetone in the presence $PhTeSiMe_3$ and tertiary phosphines, $[(HPPr_2R)\text{-}Pr\text{-}n]_2[Zn_8Cl_4Te(TePh)_{12}]$ ($R = n$-Pr, Ph). If the solvent is changed to tetrahydrofuran an uncharged Zn_{10} compound is isolated, $[Zn_{10}Te_4(TePh)_{12}(PR_3)2]$ ($R = Pr$-n, Ph). All compounds have been characterized by X-ray crystallography.[301]

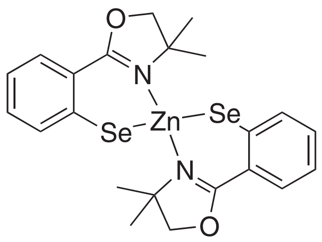
Zinc tellurolates have been synthesized with bulky silyl tellurolate ligands giving hydrocarbon solubility and enforcing low coordination numbers. The anion $[TeSi(SiMe_3)_3]$ gave the complex $Zn[TeSi(SiMe_3)_3]_2$ (**66**) which exists as a dimer, with two bridging and two terminal tellurolate ligands, in solution and in the solid state. In the presence of pyridine or 2,2′-bipyridine a monomer is formed, $Zn[TeSi(SiMe_3)_3]_2(pyridine)_2$ (**67**). The compounds were studied using ^{1}H and ^{125}Te NMR in solution and by single-crystal X-ray diffraction.[608]



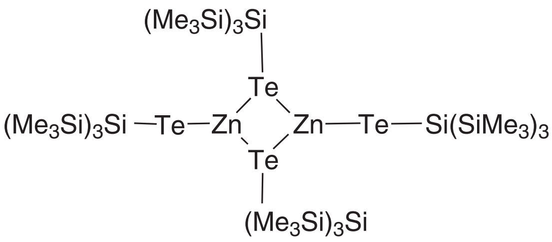
(63)



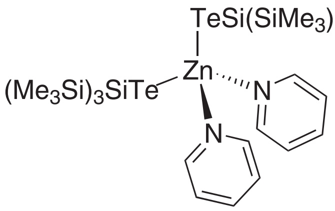
(64)



(65)



(66)



(67)

The monomeric compound bis(phenyltellurido)(TMEDA) zinc has been synthesized with, once again, a particular interest in the controlled deposition of a pure solid state compound, in this case ZnTe nanocrystals.[302,609]

TMEDA can also participate in the formation of multinuclear zinc telluride complexes with Zn_{10}, Zn_{14}, and Zn_{16} complexes structurally characterized. A comparison was carried out by Pfistner *et al.* replacing the diamine with a diphosphorus ligand, bis(diphenylphosphino)methane, and a new type of Zn_{12} structure was observed.[302] Li and co-workers produced polymeric network solids from diamines, *N,N'*-ethylenediamine and propylenediamine, with zinc and bridging telluride ligands.anchor > /anchor > These covalent inorganic–organic lattices show different topologies dependent on the conditions of synthesis or the diamine used. All structures show tetrahedral $ZnTe_3N$ units with μ_2-diamines and μ_3-tellurides.[610]

A number of zinc derivatives of a mesityl tellurolate, ($2,4,6\text{-}Me_3C_6H_2Te^-$), have been synthesized. A $[Zn(2,4,6\text{-}Me_3C_6H_2Te)_2]_n$ coordination polymer forms which can only be dissolved in strongly coordinating solvent. In the presence of one equivalent of trimethylphosphine a dimeric complex forms with two trigonal zinc centers whereas excess trimethylphosphine or other Lewis bases gave a four-coordinate monomeric adduct. The compound $[Zn(2,4,6\text{-}Me_3C_6H_2Te)_2(pyridyl)_2]$ was structurally characterized showing the expected tetrahedral zinc center; thermal deposition to form ZnTe was investigated.[611]

6.8.8 HALIDE LIGANDS

A number of zinc halide complexes, including bridging halides, have already been mentioned in the context of the other ligands systems discussed in this Chapter. Examples will be presented of catalytic systems and solution speciation, particularly in the presence of other coordinating ligands. There are now also a few zinc fluoride species that have been well characterized.

6.8.8.1 Chlorides, Bromides, and Iodides

The molecular structures from electron diffraction of zinc dichloride, zinc dibromide, and zinc diiodide have been reinvestigated.[612] The important effects halides have on geometry have also been investigated, in particular the changes from octahedral to tetrahedral geometry in the presence of chloride ions have been studied.[613]

There are a number of structurally characterized examples of the tetrahedral $[ZnCl_4]^{2-}$ anion.[614–616] Hydrogen bonding to the chlorine atoms involving NH groups and water molecules has been observed.[617] For example, the reaction of xanthine with zinc chloride in dilute hydrochloric acid results in a solid-state structure, $(Hxanthine)_2[ZnCl_4]$, in which the ions are linked by strong hydrogen bonding.[614] A polyimidazole ligand has been developed for the coordination of zinc tetrachloride (**68**), $[ZnCl_4]^{2-}$ via hydrogen bonding. The X-ray crystal structure shows that the inorganic ion is bound via protonation of imidazoles of the tripodal ligand resulting in NH…Cl hydrogen bonds.[618]

The stability of zinc monohalide complexes in alcohol and solvent mixtures containing methanol, dimethsulfoxide, acetonitrile, and water has been determined.[619] Formation of binary and ternary complexes of zinc ions with halides and 2,2'-bipyridine was studied by calorimetry in DMF at 25 °C.[205,620,621] The study of concentrated aqueous solutions and liquid hydrates of zinc chloride have been carried out using a number of spectroscopic techniques.[622] Four-coordinate compounds $[ZnX_2(DMF)_2]$ and $[ZnX_3(DMF)]^-$ were suggested to be present, amongst others, in the presence of bromide and iodide ions. The chloride ions gave a predominant species $[ZnCl_2(bpy)]$ which is present to a lesser extent for bromide and at very low level for iodide. This species is in equilibrium between four- and six-coordinate with two DMF molecules completing the coordination sphere. The concentration of the species $[ZnX(bpy)_2]^+$ is high for iodide, less for bromide, and this species is not found for chloride.

Heterocyclic nitrogen donors and their adducts with zinc chloride have been studied.[623,624] A large number of other ligand systems have also been characterized, for example, zinc halide adducts of 2,2-dimethylpropane-1,3-diamine and hexamethylphosphoramide have been studied.[625,626] The formation of mixed ligand complexes with chloride and substituted pyridines has been studied.[627] The zinc tris(pyridyl) chloride anion has also been structurally characterized.[628] Manganese(II) ions have been used to probe the stereochemistry in reactions of zinc halides with pyrazine.[629]

Although less common than zinc chlorides, there has been much synthetic and structural work carried out on zinc bromide and iodide complexes. For example, the 1:1 adduct of *N,N,N',N'*-tetramethyl-*o*-phenylenediamine with zinc bromide has been structurally characterized.[630] The ion exchange properties of zinc bromide and iodide have been studied in ethylene glycol.[631] The electrolytic behavior of zinc bromide in propylene carbonate has been studied and the conductance data shows the existence of dimers.[632]

6.8.8.2 Reactions and Catalysis

In the presence of zinc chloride, stereoselective aldol reactions can be carried out. The aldol reaction with the lithium enolate of *t*-butyl malonate and various α-alkoxy aldehydes gave anti-1,2-diols in high yields, and 2-trityloxypropanal yielded the syn-1,2-diol under the same conditions.[633] Stoichiometric amounts of zinc chloride contribute to the formation of aminonitropyridines by direct amination of nitropyridines with methoxyamine under basic conditions.[634] Zinc chloride can also be used as a radical initiator.[635]

Cycloaddition of 2-cyanoalk-2-enones with several conjugated dienes proceeded under zinc chloride catalysis.[636] Zinc halides have also shown reactivity with phenylacetylenes.[637] Zinc chloride is an effective Lewis acid catalyst in the Diels–Alder reactions of the keto esters and the effects on stereochemistry of catalysts used have been examined.[638]

Zinc chloride was used as a catalyst in the Friedel–Crafts benzylation of benzenes in the presence of polar solvents, such as primary alcohols, ketones, and water.[639] Friedel–Crafts catalysis has also been carried out using a supported zinc chloride reagent. Mesoporous silicas with zinc chloride incorporated have been synthesized with a high level of available catalyst. Variation in reaction conditions and relation of catalytic activity to pore size and volume were studied.[640] Other supported catalytic systems include a zinc bromide catalyst that is fast, efficient, selective, and reusable in the *para*-bromination of aromatic substrates.[641]

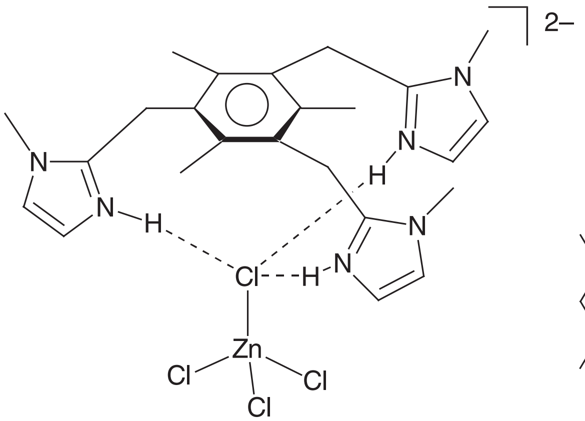
Zinc iodide catalysts are also known. Desulfonylative iodination of naphthalenesulfonyl chlorides has been carried out by treatment with zinc iodide in the presence of a palladium(II) catalyst.[642]

6.8.8.3 Fluorides

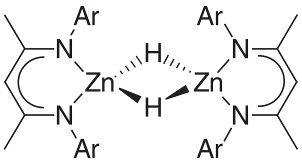
Fluoride ion selective spectrometry was used to determine the stability constants for zinc fluoride complexes in water at 25 °C, giving values $\beta_1[\mathrm{ZnF}_{(aq)}]^+ = 3.5 \pm 0.1$ and $\beta_2[\mathrm{ZnF}_{2(aq)}] = 3.8 \pm 0.5$.[643] These results demonstrate that the complexation of fluoride is very weak and in aqueous chemistry no species beyond ZnF^+ is of much importance. Organotitanium fluorides have been used as matrices for trapping “molecular” ZnF_2 and MeZnF.[644]

The structurally characterized fluoro[tris(3-*p*-tolyl-5-methylpyrazol-1-yl)hydroborato]zinc complex was synthesized by metathesis of the acetate complex with potassium fluoride or from the free ligand and zinc perchlorate in the presence of potassium fluoride, and used as a convenient precursor in the formation of hydride complexes.[241] Pyridyl-substituted tris (pyrazolyl)borate ligands give a dimeric structure with each zinc atom coordinated to four nitrogen donors and one fluoride with one of the pyridyl donors from the neighboring ligand coordinated.[234] Tris (1-*t*-butyl-2-thioimidazolyl)hydroborate coordinates as a face-capping S_3 ligand with a fluoride completing the tetrahedral coordination.[645]

The CSD revealed only one example of the fluoride-bridged dimeric $\mathrm{Zn}_2\mathrm{F}_2$, analogous to the commonly observed unit for the other halides. The compound characterized by Roesky and co-workers is the only structure known with fluoride-bridged zinc atoms.[646] Maggard *et al.* show a bridging fluoride between a molybdenum(V) and the zinc center in a coordination



(68)



(69)

polymer with pyrazine bridging the zinc centers.[647] An interaction with a fluorine from a hexfluorosilane, SiF_6 unit is observed in zinc coordination polymer.[648] A porous solid formed via a related route, with a pyridyl donor linker, shows a similar interaction in a coordination polymer with Zn—SiF_6–Zn bridges.[284]

6.8.9 HYDRIDE AND RELATED LIGANDS

6.8.9.1 Hydrides

There has been an increasing number of reports of the utilization of zinc hydride complexes as precursors in organic transformations and as reducing agents. Zinc hydrides have been less well investigated than the other group 13 hydrides due to the formation of polymeric and oligomeric species that are difficult to characterize.

Complexes of hydridozinc chloride and TMEDA can be formed by reaction of zinc hydride and zinc chloride in the presence of TMEDA. The reactions of the zinc hydride species with organic substrates have been investigated.[649] Roesky and co-workers have structurally characterized an example of a dizinc compound with a bridging hydride. No other examples of this type were found in the CSD. The complex $[\{HC(CMeNAr)_2\}Zn\ (\mu\text{-}H)]_2$ ($Ar = 2,6\text{-}Me_2C_6H_3$) (**69**) cannot be obtained directly by reaction of the ligand with zinc hydride but rather by initial formation of the analogous μ-F complex and subsequent reaction with triethylsilane.[646] The Zn—H bond lengths (1.766 Å) are longer than those observed in the terminal hydride structures. The bulky aryl substituents favor the formation of the electron-deficient three-center-two-electron Zn—H—Zn bonds.

There are a few structurally characterized zinc compounds with terminal hydrides. A zinc tetramer forms a cube with four phosphoraneiminate ligands, $[ZnH(NPMe_3)]_4$ has a terminal hydride ligand coordinated to each zinc center. The structure shows a virtually undistorted Zn_4N_4 cube with an average Zn—H bond distance of 1.50 Å and the compound is highly reactive.[650] A monomeric zinc hydride, tris(3-*tert*-butylpyrazolyl)hydroborato zinc hydride, has been synthesized, the structure determined and reactivity investigated.[651,652] Synthesis was carried out by transmetallation of a thallium compound with ZnH_2 but a related compound, tris(3-tolyl-5-methylpyrazolyl)hydroborato zinc hydride, was synthesized by reaction of the fluoride derivative with triethylsilane.[241]

Bridging hydrides can be present in heteromultimetallic species. A tantalum/zinc dimer is bridged by two hydride ligands and similarly a rhodium/zinc dimer is triply bridged by hydrides.[653,654] A structurally characterized trimeric Mn_2Zn complex has been synthesized from a manganese dimer with two bridging hydrides in reaction with zinc amalgam and TMEDA. The zinc–manganese edges in the product are bridged by the hydride ligands and the compound has been studied by NMR.[655]

6.8.9.2 Hydroborate Ligands

In recent years a number of zinc hydroborate complexes have been structurally characterized with one or more hydrogens interacting with the zinc center. The simplest is probably the tris(tetrahydroborato)zinc anion, $[Zn(BH_4)_3]^-$, which was crystallized as the tetraphenylphosphonium salt. The structure shows an octahedral zinc coordinated by three bidentate tetrahydroborate ligands.[656] Methylzinc tetrahydroborate is also known. The X-ray crystal structure shows a helical polymer with alternating methyl zinc and tetrahydroborate units. The BH_4^- acts as a bidentate ligand to two zinc centers giving a structure that resembles $Be(BH_4)_2$ with the MeZn unit replacing the beryllium. Reactions of the compound were investigated with disproportionation a common feature.[657] A chelating tetrahydroborate is also observed in a monomeric zinc complex with a TMEDA ligand and a chloride also coordinating.[658]

A tetrameric Zn_2V_2 compound contains both zinc-to-vanadium bridging hydride ligands and chelating tetrahydroborate groups.[659] The neutral borane ligand bis(trimethylphosphine)diborane acts as a bidentate donor in the formation of a monomeric complex with $ZnCl_2$. A hydrogen ligand is bound from each boron giving a five-membered chelate ring.[660] Parkin and co-workers have synthesized bispyrazolylborate complexes of zinc that have an N_2 donor set bound from the ligand, with an additional weak interaction with the B—H group. Monomeric complexes are formed with methyl or iodide ligands.[163,164] This research group has also investigated bis(mercaptoimidazolyl)borato zinc complexes, where similar interactions are observed. The 3-center-2-electron Zn···H—B interactions in the bis(mercaptoimidazolyl)borato zinc X-ray structures are at distances of between 1.77 and 2.06 Å.[661]

6.8.10 MACROCYCLIC LIGANDS

Macrocyclic complexes of zinc have inspired interest in varied areas such as supramolecular and biomimetic chemistry; including hydrolysis enzymes, such as phosphatases and esterases, and also for the fluorescent detection of zinc. The polyaza macrocycles and their *N*-functionalized derivatives are particularly well represented. An important aspect of macrocycle synthesis is the use of metal templates to form the ligand. Examples of zinc as a template ion will be discussed where relevant.

6.8.10.1 Azamacrocycles

Small-ring cyclic diamines have already been discussed in Chapter 1.20. The azamacrocycles offer the possibility for functionalization at the nitrogen donor groups and many examples will be presented from triazamacrocycles up to much larger polyaza macrocycles that will bind more than one zinc ion. Particular mention must be made of the large contribution of Kimura and co-workers to this area.

6.8.10.1.1 Ligands based on triaza crowns

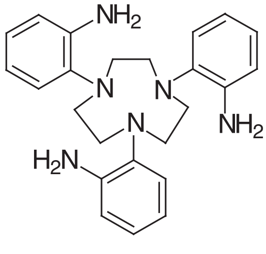
The crystal structure of trimethyltriazacyclononane zinc nitrate shows an unexpected octahedral environment.[662] The coordinated aquo ligands are hydrogen bonded to the nitrate counterion. It had typically been assumed that a tetrahedral or a square–pyramidal complex with bound water is formed for other aza-containing ligands. The pK_a was shown to be 10.9 followed by 12.3 for pK_{a2}. These results demonstrate that a decrease in coordination number increases the acidity as is borne out by the coordination numbers in zinc enzymes. Only a few zinc enzymes contain octahedral centers, such as glyoxalase 1; however, bound hydroxides are not implicated as intermediates in these enzymes. Weighardt and co-workers produced a binuclear complex with the same ligand by variation of the pH, counter ion and solvent. Using water as solvent and the perchlorate salt, the bis(hydroxo) bridged dimer was formed.[663]

^{1}H NMR studies of the zinc complex formed with the hexadentate aniline functionalized triazacyclononane ligand (**70**) showed C_3 symmetry in solution. It is suggested a six-coordinate complex is formed with all *N*-donors bound.[664] This compares with the benzyl amino derivative, 1,4,7-tris(*ortho*-aminobenzyl)-1,4,7-triazacyclononane.[665] The X-ray structure shows a six-coordinate octahedral coordination with average Zn—N distances of 2.23 Å. The solution NMR spectra were studied showing dynamic equilibria. Zinc forms six-coordinate complexes of amide functionalized triazacyclononane ligands (**71**) and (**72**).[666] The crystal structure of the zinc complex of 1,4,7-triazacyclononane monoacetate reveals a six-coordinate structure forming polymeric chains in the solid state bridged by the acetate pendent arm. The zinc is bound to the three ring nitrogens and an acetate oxygen from the ligand, a water molecule and a bridging acetate from an adjacent ligand. The solubility of the compound suggests the bridging acetate is not maintained in solution and ^{1}H and ^{13}C NMR were recorded.[667] The zinc complex of 1,4,7-triazacyclononane-*N,N′,N″*-tris(methylenephosphonate monoethylester) has been studied by potentiometry and NMR.[668] Triazacyclononane with one, two, or three pendent phosphine arms has been complexed to zinc. The complex with *N*-(diphenylphosphinopropyl)-1,4,7-triazacyclononane [$Zn_2L_2Cl_3$][ClO_4] has been structurally characterized by X-ray crystallography.[310] Secondary amine pendent arms in the ligands 1-(2-aminoethyl)- and 1-(3-aminopropyl)-1,5,9-triazacyclododecane form complexes with increased stability relative to tertiary amine pendents and allow an increase in coordination number. The structurally characterized complex of the 2-aminoethyl ligand [ZnL(ClO_4)]$^+$ reveals a trigonal–bipyramidal geometry.[669]

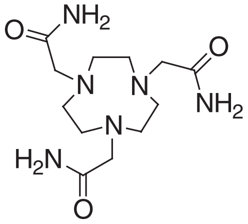
Bis(triazacyclononane) ligands (**73**) where the two macrocycles are linked with chains two to eight carbons in length have been complexed with zinc to form monomeric and dimeric complexes. A two- or three-carbon linker gives a monomeric complex with the X-ray structure showing an octahedral zinc bound to all six nitrogen donors. The five-carbon linker gives a complex $[Zn_2L(\mu\text{-}Cl)_3]_2(ClO_4)_2$ where each macrocycle in the ligand has one zinc bound to three nitrogen donors and three bridging chlorides link it to an adjacent molecule giving an octahedral coordination geometry. As with copper the most stable structure switches from monomeric to oligomeric complexes between a four- and five-carbon linker.[670]

Functionalization of the bis(triazacyclononane) compounds has been carried out to give ligands with 2-pyridyl-methyl pendent arms (**74**). The bridge has been varied including ethyl, propyl, *meta*-$CH_2C_6H_4CH_2$, and $CH_2CH(OH)CH_2$.[671] The crystal structure of the zinc complex of the ligand with the propanol linker showed deprotonation to form an alkoxide bridge between the two zinc centers giving a Zn—Zn separation of 3.904(2) Å. The coordination sphere for the two six-coordinate zinc ions is completed by the five nitrogen donors from each side of the ligand. This separation matches that found in alkaline phosphatase.[441] The ligand with the ethyl linker shows two six-coordinate zinc centers each with five nitrogen donors from the ligand and a bromide ion bound and a Zn—Zn distance of 6.545(9) Å. Solution structure was studied by NMR and compared with the solid state data.

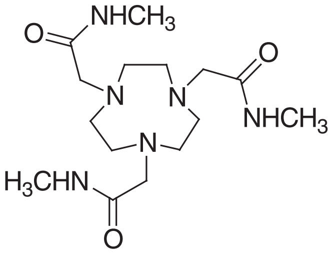
As already mentioned, larger ring size triazamacrocyclic ligand complexes have also been characterized. The zinc bromide complex of 1,5,9-triazacyclododecane has been characterized as a mononuclear complex with a tetrahedral zinc center.[672] Kimura and co-workers have extensively studied zinc complex formation with 1,5,9-triazacyclododecane-based ligands.[445,673–676] 1,6,11-triazacyclopentadecane forms a zinc complex of the composition $Zn_3L_2Cl_6$. NMR studies



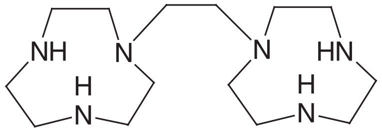
(**70**)



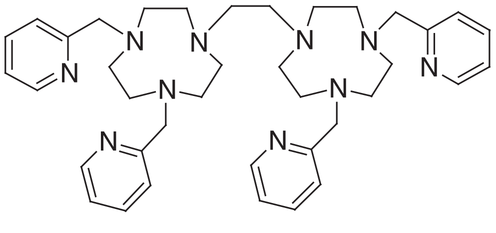
(**71**)



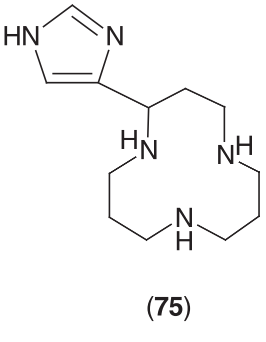
(**72**)



(**73**)



(**74**)



(**75**)

indicated that the zinc complex is stable in *N,N*-dimethylformamide and the formula was assigned as $[ZnLCl]_2[ZnCl_4]$, assuming a tetradral zinc center coordinated to the three macrocyclic nitrogens and a chloride ion.[677]

The crystal structure of the C-functionalized imidazole derivative of 1,5,9-triazcyclododecane (**75**) shows a five-coordinate zinc with four *N*-donors from ligand and chloride in a distorted trigonal–bipyramidal arrangement. The Zn—N imidazole bonds are the shortest at 2.025(3) Å.[678] Deprotonation of the imidazole group resulted in a bridging imidazolate to form dinuclear zinc complexes. The pK_a of 10.3 varies from the pK_a of bound water with similar ligands (as low as 7.3) and the complex is not catalytic for the hydrolysis of esters.

The zinc nitrate complexes of pyridyl functionalized 12[ane]N_3 ligands 1-(2-pyridylmethyl) -1,5,9-triazacyclododecane and 1-(2-pyridyl-2′-ethyl)-1,5,9-triazacyclododecane were formed. ^{13}C NMR studies were used to determine conformation in solution suggesting the former gave a trigonal–bipyramidal isomer in solution with a water bound and the latter gave a 2:1 mixture of tetrahedral and asymmetric trigonal–bipyramidal isomers. The crystal structure of the zinc complex of 1-(2-pyridyl-2′-ethyl)-1,5,9-triazacyclododecane reveals a tetrahedral geometry in the solid state.[679]

Tri- and tetraaza macrocycles *N*-functionalized with imidazole and pyrazole groups have been coordinated to zinc. The zinc complexes of functionalized 1,5,9-trizacyclododecane and 1,4,8, 11-tetraazacyclododecane have been synthesized, (**76**) and (**77**).[680–685] The formation constants with the mono-armed 1,5,9-triazacyclododecane were calculated and found to be higher than for the non-functionalized macrocycle and coordination was demonstrated to be through four nitrogen atoms.[684]

6.8.10.1.2 Ligands based on tetraaza crowns

The classification for this section is based on the number of nitrogens in the macrocyclic ring of the azacrown ligands. Many of the examples presented will also have nitrogen-containing pendent arms attached to the ring nitrogens, increasing the denticity of the ligand.

Complexation and determination of formation constants has been studied with the tetramethylcyclam (1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane) ligand.[686] A series of zinc N_4 donor macrocyclic complexes with different ring sizes were synthesized and characterized for comparison with cadmium derivatives.[687]

The zinc complex of the saturated macrocycle (1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19, 20,21,22-docosahydrodibenzo-[B,I][1,4,8,11] tetra-azacyclotetradecine), which is a 14[ane]N_4 (cyclam) ring incorporating two cyclohexyl rings into the macrocycle, has been prepared and characterized.[688] Two isomers of the ligand were separately complexed with zinc and characterized by NMR.

Macrocycles attached to redox responsive groups such as ferrocene (**78**) can give selective transition metal ion receptors. The X-ray structure reveals a five-coordinate zinc with distorted square–pyramidal geometry bound to the four macrocycle nitrogens and an iodide. In the solid state the two ferrocenyl groups are positioned on the same side of the ligand with distances to the metal center of 5.347(7) and 6.120(8) Å and these distances can be related to the redox behavior.[689]

The crystal structure of the zinc complex of 6,13-bis(2-pyridinyl)-1,4,8,11-tetraazacyclotetradecane (**79**) shows an octahedral zinc with minimal distortion which is in close agreement with that expected from force field calculations.[690]

Moore and co-workers have studied a number of tetraaza macrocycles with nitrogen-containing pendent arms. Pentadentate 14-membered aza macrocyclic ligands containing a pyridyl group, with a nitrogen-containing pendent arm, 2-pyridylmethyl and 1-pyrazolylmethyl, have been complexed with zinc and the structure determined of (3,11-dibenzyl-7-(2′-pyridylmethyl)-3,7,11,17-tetra-azabicyclo[11.3.1]-heptadeca-1(17),13,15-triene)zinc perchlorate.[691] A further crystal structure shows the zinc coordinated to all five nitrogen donors from the ligand in a distorted square–pyramidal geometry.[692] The zinc complex of a methyl functionalized version of this pyridine-containing macrocycle has been characterized.[693] The 3,11-dibenzyl and 3,7,11-tribenzyl derivatives of this ligand have also been complexed with zinc.[694]

Moore and co-workers have also studied the complexation of zinc with other tetraaza macrocycles and pendent arm derivatives. Zinc complexes of 11-(2′-dimethylaminoethyl)-1,4,7-trimethyl-1,4,7,11-tetra-azacyclotetradecane have been characterized.[695] A pyridine analog of this macrocycle and the related 11-methyl-1,4,7,11-tetra-azacyclotetradecane have also been complexed with zinc.[696]

The ligand 6,13-dimethyl-1,4,8,11-tetra-azacyclotetradecane-6,13-diamine coordinates as a hexadentate ligand to zinc in neutral aqueous solution. Potentiometric titrations were used to determine the stability constant for formation. The pK_a values were determined for five of the six possible protonation steps of the hexamine (2.9, 5.5, 6.3, 9.9 and 11.0).[697] Studies of the syn and anti isomers of 6,13-dimethyl-1,4,8,11-tetraazacyclotetradecane-6,13-diamine reveal that they offer different shapes for metal binding, which is reflected in the stability constants for 1:1 zinc:ligand ratio complexes. The selectivity of binding to the zinc ion compared to the cadmium(II) ion by both isomers is significant.[698]

The complexation of zinc with *N,N′,N″,N‴*-tetrakis(2-aminoethyl)-1,4,8,11-tetraazacyclotetradecane has been investigated by X-ray crystallography and potentiometry. The only complexes isolated in aqueous or methanol/water solvents contained the μ-hydroxo-bridged bimetallic cation $[Zn_2(OH)L]^{3+}$, although potentiometric titration data suggest the presence of small amounts of $[Zn(H_3L)]^{5+}$ at low pH. The crystal structure of $[Zn_2(OH)L]^{3+}$ showed two five-coordinate zinc ions bound to two tertiary amine donors, two primary amine donors and the bridging hydroxide. Substitution of the bridging hydroxo group by other bridging anions was unsuccessful. The pK_a for the aqua species, from which the μ-hydroxo species is formed, is <5.3. Zinc is shown to have a higher tendency for μ-hydroxo formation than the other group 12 metals.[699]

Zinc complexes have been characterized with hexadentate macrocycles formed from a tetraaza macrocycle functionalized with pyridylmethyl or pyrazolylemthyl groups.[700]

Larger tetraaza ring complexes are also known. The zinc complex of 1,5,9,13-tetraazacyclohexadecane ($[16]aneN_4$) has been characterized by X-ray crystallography showing a distorted tetrahedral geometry around the zinc ion in $Zn([16]aneN_4)][ClO_4]_2$. Molecular mechanics analysis was used to determine the possible conformations of the macrocycle over a range of Zn—N bond lengths. The calculation confirmed the expected stability increase for smaller tetrahedral metal ions such as zinc. The predicted conformer was the one observed in the structural characterization.[701]

Lippard characterized the structural effect of variation in the alkyl bridge length in tropocoronand complexes of zinc (**80**). Six complexes of ligands with bridge lengths from $n = m = 3$ to $n = m = 6$ were structurally characterized.[702] The complexes had distorted tetrahedral–square planar geometries, with the exception of the $m = n = 3$ adduct which was five-coordinate with an additional pyridine ligand.

The zinc iodide complex of a 15-membered diamine diimine macrocycle has been structurally characterized.[703]

A dinucleating ligand with two dimethylcyclam rings reacts with zinc perchlorate to give $[Zn_2L](ClO_4)_4$. This product spontaneously reacts with atmospheric carbon dioxide to give $[Zn_2(\mu\text{-}CO_3)L](ClO_4)_2\cdot 2H_2O$. X-ray analysis shows that two cyclam rings are arranged in a face-to-face manner with a bridging carbonate resulting in a Zn—Zn distance of 6.806(2) Å.[704]

Aza macrocycles have also been used as templating agents in the formation of zinc and other metal cation-containing aluminophosphates via hydrothermal synthesis.[705] The zeolite-like structures have been formed in the presence of cyclam- and hexaaza-based macrocycles.

Breslow demonstrated the catalytic effect of having not only a Lewis acid zinc center but also an auxiliary catalytic center held in close, but non-binding, proximity. An imidazole or thiophenol (**81**) demonstrated increase in effectiveness in cyclization of a phosphate derivative.[706,707] Pyridine pendents on this macrocycle gave a stability for zinc in line with the Irving Williams series for two pyridine and three pyridine pendents.[708] A contrast was noted with other metals (Ni, Cu, Cd, Pb, Fe, and In), all of which increase in stability with three pendent arms as does zinc; this was attributed to coordination preferences.

Electron transfer from a macrocycle (**82**), based on cyclen, complex to coordinated riboflavin proceeds via an inner sphere electron transfer pathway. The riboflavin coordinates through the imide and the relevance to the interception of biological electron transfer pathways is discussed.[709]

The catecholate and semiquinonate complexes of zinc with tetraaza macrocycles have been synthesized and CD spectra recorded.[710]

A bipyridine-containing macrocycle gives a color switching zinc complex. The color of the zinc complex solution varied with the solvent and the presence of acid or base (Scheme 3). The transformation between the solution colors is reversible. As shown in the scheme the conjugation of the ligand changes with the position of the facile hydrogen atom making the compounds very sensitive to the chemical environment (pH and solvent).[711]

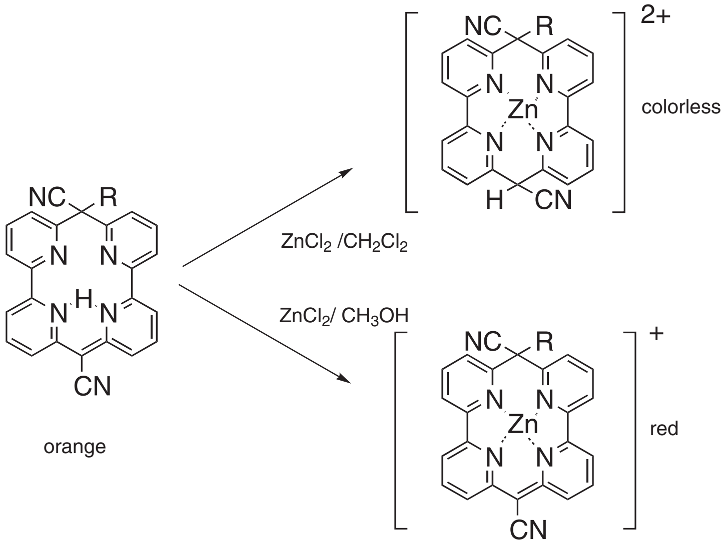
6.8.10.1.3 Ligands based on pentaaza crowns and larger

The X-ray structure of a mono-pyridyl containing pentaaza crown macrocycle (3,6,9,12-tetramethyl-3,6,9,12,18-penta-azabicyclo[12.3.1]octadeca-1(18),14,16-triene) with zinc perchlorate has been determined.[712]

An 18-membered hexaaza macrocycle containing four amine and two pyridine nitrogens (**83**) forms a helical complex of which the enantiomers have been resolved. The crystal structure of the complex as (3,6,14,17,23,24-hexaazatricyclo[17.3.1.1(8,12)]tetracosa-1 (23),8,10,12(24),19,21-hexaene)zinc trifluoromethanesulfonate, $[ZnL](CF_3SO_3)_2$ showing a six-coordinate zinc center. The rigidity afforded by the addition of the pyridyl group gives an exceptionally inert complex with zinc. Spin simulation analysis of the ^1H NMR spectra and the dihedral angles calculated were in agreement with those from the solid-state X-ray analysis; both gave *222* symmetry. The CD spectra were recorded of the resolved right- and left-handed helical isomers.[713] The binding constants for a series of metals including zinc were determined for hexaaza macrocycles with pyridyl and amine donors of varying ring sizes in the above ligand and



Scheme 3

(3,7,15,19,25,26-hexaazatricyclo[19.3.1.1(9,13)]hexacosa-1(25),9,11,13(26),21,23-hexaene).[714] As would be predicted by the Irving Williams series, the 1:1 zinc complexes were less stable than those for nickel(II) and copper(II) for both ligands. The zinc complexes were also more stable than those of cadmium(II) and lead(II) but the difference in the stability was smaller for the larger ring size.

The stability of zinc complexes of hexadentate polyamine macrocycles have been studied. A comparison of the ring size effects was made on moving from [18]aneN_6 (1,4,7,10,13,16-hexaazacyclooctadecane) to [24]aneN_6 (1,5,9,13,17,21-hexaazacyclotetracosane). Potentiometric titrations were carried out to determine the protonation and stability constants. A mononuclear complex was formed and the stability constant for $[Zn([24]aneN_6)]^{2+}$ was related to those of other transition metals, showing it to be less stable than copper(II), similar to nickel(II), and greater than cadmium(II).[715]

The structure of the dinuclear zinc [24]aneN_8 (or 1,4,7,10,13,16,19,22-octaazacyclotetracosane) complex was determined and complexes of the ligands [18]aneN_6, [21]aneN_7 and [36]aneN_{12}-synthesized. Trends were observed with variation in ring size;[716] [24]aneN_8 forms both mono- and dinuclear species, smaller macrocycles only mononuclear, and larger have more stable dinuclear; the larger the macrocycle the more stable the binuclear species. The structure of $[Zn_2([24]aneN_8)Cl_2]^{2+}$ shows two five-coordinate zinc ions with distorted square–pyramidal geometry bound to four macrocycle nitrogens and one chloride. The Zn—Zn distance is 5.44 Å.

The binuclear complex $[Zn_2([30]aneN_{10}(\mathbf{84}))NCS)](ClO_4)_3]$ was characterized crystallographically and the complexes of [27]aneN_9 and [33]aneN_{11} reported.[717] The dizinc macrocyclic complexes had stability constants around 20, the slight increase in stability on going to the larger macrocycles is attributed to the ease of accommodation of two zinc centers while minimizing any interactions between them. Hydroxo species are present above pH 8. The first zinc is coordinated by five macrocycle nitrogens and the second zinc is coordinated by four macrocycle nitrogens and one from the thiocyanate; both show distorted trigonal–bipyramidal geometry. The Zn—Zn distance is 6.40 Å.

6.8.10.2 Oxacrowns and Thiacrowns (see Chapter 1.18)

Some examples of oxa crown coordination have already been presented earlier in the context of other ligands coordinated, see Sections 6.8.3.3 and 6.8.6.3. A few further examples are included in this section.

Diffusion of solutions containing zinc chloride and crown ethers can give solid state structure where the zinc ion is coordinated to the crown ether oxygens.[718] A five-coordinate zinc is observed with distorted trigonal–bipyramidal geometry bound to a chloride, a water molecule, and three O donors from the crown ether. Alternately, recrystallization from organic solvents results in a structure where the zinc is no longer directly coordinated to the crown ether but interacts via a hydrogen bonding network. A tetrahedral $[ZnCl_3(H_2O)]^-$ and an octahedral hexaaquozinc are present for each crown ether in the structure. Such compounds are suggested to be snapshots of desolvation.

The zinc complexes with 15-crown-5 were revealed to be seven-coordinate with a number of examples crystallized with metal bound to the five crown ether donors and variation in the remaining two ligand positions.[351] Structural examples are known of zinc coordinated to 18-crown-6 by three ring oxygens and the remaining coordination positions occupied by iodide or alkyl iodide ligands.[87] The smaller 12-crown-4 ring results in a bis-ligand complex where the zinc is eight-coordinate with four ether donors from each macrocycle (Figure 11).[719]

The 1,4,7-trithiacyclononane ligand, $[9]aneS_3$, zinc complex was synthesized to compare with the electrochemistry of related complexes and showed an irreversible oxidation and an irreversible reduction at +1.30 V and −1.77 V vs. ferrocene/ferrocenium, and the X-ray crystal structure of the bis macrocycle zinc complex was reported.[540,720]

6.8.10.3 Mixed Donor Macrocycles (see Chapter 1.20)

A number of mixed crown ligands have been synthesized combining N, O, or S ligands. The larger, more flexible, ligand systems can show interesting coordination patterns as the zinc binds to its preferred donor set.

A series of mixed N/O and N/S donor macrocycles of varying ring sizes was synthesized to determine the effects on metal ion binding selectivity with a variation in macrocycle size giving ion recognition properties.[721,722] X-ray structural results of three zinc complexes showed either distorted trigonal–bipyramidal or distorted octahedral coordination geometry. Stability constants were calculated for the zinc complexes and trends analyzed. Non-coordination of ether and thioether donors was observed in a number of the compounds. The 17-membered ring with an N_5 donor set showed the highest stability constant for both cadmium and zinc complexes.

The properties of the complex formed with an N_2O_2 macrocycle containing pendent hydroxyethyl or carbamoylethyl has been investigated. The thermodynamic stability of 1:1 zinc to ligand ratio has been determined by potentiometry.[723] Similar studies have also been carried out on pyridylmethyl pendent arm derivatives of 14- to 17-membered N_2O_2 macrocycles at a 1:1 ratio, with the data indicating the involvement of the pyridyl nitrogen in coordination in solution.[724]

An 18-membered N_3O_3 macrocycle could not be synthesized with transition metal templates but the N_4O_2 analog (**85**) was successfully synthesized with a zinc template. This gave dinuclear μ-hydroxy bridged zinc complexes including a rare example of a single unsupported

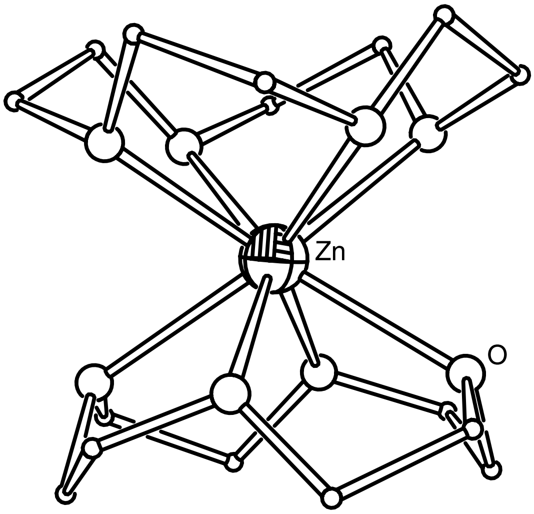


Figure 11 The molecular structure of zinc with two 14-crown-4 ether macrocycles giving an unusual coordination number of eight.[719]

μ-hydroxy zinc dimer. The metal ions are distorted square pyramidal bound to the four macrocyclic nitrogens and the oxygen from the bridging hydroxide. The reduced form of the macrocycle (**86**) was synthesized from the free ligand and complexed.[725] The zinc complex of the related N_3O_2 macrocycle (**87**) was also formed by condensation of 2,6-pyridinecarbaldehyde and 1,4-bis (2-aminophenoxy)butane as both a nitrate and perchlorate salt.[726] Similarly, the ether oxygen atoms in the macrocycle are not coordinated in the solid state. The reduced form (**88**) has also been synthesized and complexed.[727] The X-ray structure shows a distorted trigonal–bipyramidal geometry with the three macrocycle nitrogens, an acetonitrile, and a water molecule coordinated.

(88)

A seven-coordinate zinc complex (**89**) has been structurally characterized with a N_3O_2 15-membered macrocycle demonstrating a distorted trigonal–bipyramidal geometry with a monodentate nitrate and water completing the coordination sphere.[728] The complexation of the related macrocycle with a propyl bridge replacing the ethyl bridge between the two amine nitrogens was also studied. It was noted that the change from 15- to 16-membered ring made a large change in coordination properties for zinc but less so for cadmium. Two further zinc coordinated structures of the 15-membered ring ligand were determined. $ZnLI_2$ showed the zinc diiodide unit coordinated outside the macrocyclic cavity and $[ZnL(NO_3)]NO_3$ displayed a six-coordinate approximately trigonal–prismatic geometry bound to the N_3O_2 donors of the macrocycle and a nitrate oxygen.[729]

The complexation of other mixed oxa aza macrocycles has been studied, and protonation and stability constants of the zinc complexes of macrocycles 1,4,10,13-tetraoxa-7,16-diazacyclooctadecane-7,16-bis(malonate), the -7-malonate derivative and -7,16-bis(methylacetate) derivative have been determined by potentiometry at a 1:1 ligand-to-metal ratio.[730]

The pentadentate macrocyclic ligand 4,7-bis(2-hydroxybenzyl)-1-oxa-4,7-diazacyclononane forms a dimeric zinc species with bridging hydroxide ligands. The crystal structure of $[(LH)_2Zn_2(\mu\text{-}OH)](PF_6)$ shows two octahedrally coordinated zinc ions connected by a μ-hydroxo bridge. There are hydrogen bonding interactions from the coordinated phenolic and phenolate groups in both ligands. Ligand deprotonation allowed preparation of $[LZn(H_2O)ZnCl_2]$.[731]

A number of crown and related ligand systems have been synthesized with pendent arms that contain donors other than nitrogen. Potentiometric titration studies of dihydroxamate derivatives of dioxacyclam (**90**) were carried out. It is suggested that the ligand binds via the hydroxamate *O,O* and there is no evidence for bimetallic complex formation.[732]

^{13}C NMR studies suggest that 1,4,7,10-tetra-azacyclododecane-1,7-diacetic acid binds to zinc in a *cis* octahedral geometry—the two carboxylate oxygens are *cis* and the remaining four donors from the cyclen macrocycle. The formation constant was determined for the complex.[733]

The zinc complexes formed in aqueous solution with the 12-membered macrocycle 2,9-dioxo-1, 4,7,10-tetra-aza-4,7-cyclododecanediacetic acid and the 13-membered macrocycle 2,9-dioxo-1, 4,7,10-tetra-aza-4,7-cyclotridecanediacetic acid have been examined and stability constants determined. The structure of the zinc complex of the 12-membered macrocycle was determined by single-crystal X-ray analysis. The zinc has a distorted octahedral coordination sphere with two amine nitrogens, an amide nitrogen, and two acetate oxygen atoms from one ligand and an acetate oxygen from a neighboring complex. The acetate group links the zinc ions to form a one-dimensional array.[734]

Pendent arm 1,4,7-triazacyclononane macrocycles (**91**) and (**92**) have been used to stabilize the zinc-to-phenoxyl bond allowing characterization of these compounds.[477] The interest in the zinc complexes comes from the wide potential range in which it is redox stable allowing observation of the ligand-based redox processes, this allows study of the radical by EPR and the electronic spectra is unperturbed by *d–d* transitions. Macrocycles of the type 1,4,7-tris(2-hydroxybenzyl)-1,4,7-triazacylononane form a bound phenoxyl radical in a reversible one-electron oxidation of the ligand. The EPR, resonance Raman, electronic spectra, and crystal structure of the phenoxide complexes were reported. This compound can be compared to a zinc complex with a non-coordinated phenoxyl radical as a pendent from the ligand.[735]

Mixed N/O donor macrocycles (**93**) have been used to extract metals from solution via competitive metal transport.[736]

Kimura and co-workers have synthesized a series of alkoxide complexes with the alcohol functionality as a pendent arm.[447,674,737] A zinc complex of 1-(4-bromophenacyl)-1, 4,7,10-tetraazacyclododecane was also synthesized by the same workers to mimic the active site of class II aldolases. The X-ray structure shows a six-coordinate zinc center with five donors from the ligand and a water molecule bound. The ketone is bound with a Zn—O distance of 2.159(3) Å (Figure 12). Potentiometric titration indicated formation of a mixture of the hydroxide and the enolate. Enolate formation was also independently carried out by reaction with sodium methoxide, allowing full characterization.[738]

The zinc complex of a 14-membered *cis*-N_2S_2 dibenzo macrocycle with two pendent pyridylmethyl groups was studied (L = 8,11-bis(2-pyridylmethyl)5,6,7,8,9,10,16,17-octahydro-dibenzo[e,m][1,4]dithia[8,11]diazacyclotetradecine). In solution, $[ZnL]^{2+}$ takes up atmospheric carbon dioxide and transforms to the dinuclear complex $[(\mu\text{-}CO_3)(ZnL)_2](ClO_4)_2$. The structures of both complexes have been elucidated. The zinc atoms, which are situated outside the macrocyclic ring, are unsymmetrically bridged by the μ-carbonato group.[739]

6.8.10.4 Cryptands and Crossbridged Macrocycles

Cryptands and rigid crossbridged macrocyclic zinc complexes have been characterized with varying degrees of encapsulation.

Bharadwaj synthesized the zinc complex of a mixed donor cryptand (**94**). The X-ray structure shows that the zinc binds in the tetraamine cavity at the base of the ligand in a tetrahedral environment and not to the oxygen donors. This demonstrates the expansion potential of the cavity compared with the free ligand.[740]

Stability data via potentiometric titration has been determined for a number of octaminocryptands with different spacer groups and is shown to follow the Irving–Williams series trend resulting in selectivity for copper.[741] Zinc binding to a range of these ligands has been examined and compared with copper ions. Selectivity for copper is demonstrated with a pyridine spacer.[741]

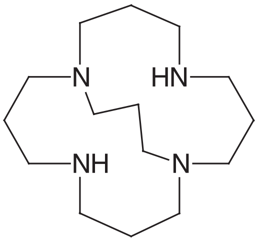
Sargeson and co-workers have structurally characterized encapsulated zinc in hexaaza cryptands.[742,743] Related cryptands (1-methyl-8-amino-3,13-dithia-6,10,16,19-tetraazabicyclo[6.6.6]-icosane and 1-methyl-8-amino-3-thia-6,10,13,16,19-pentaazabicyclo[6.6.6]icosane) incorporating thioether donors also formed complexes with zinc which were structurally characterized. In both cases the zinc ion was encapsulated in the macrobicyclic cavity and the octahedral coordination geometry distorted to the mixed nitrogen and thioether donor atoms.[744]

Strapped tetramines show conformationally rigid coordination environments that can lead to novel stability properties. The coordination properties of bowl-shaped cavities or adamanzanes such as the ligand 1,5,9,13-tetraazabicyclo-[7.7.3]nonadecane (**95**) were investigated.[745] The complex has slightly distorted tetrahedral coordination and a dissociation half life of 14 min at 40 °C in 5 M HCl. This contrasts with a smaller cavity in 1,8-crossbridged cyclam that forms six-coordinate complexes with the remaining two ligands chloride or aquo, and the former shown to be a chloro bridged dimer. The cavity is too small to encapsulate the zinc and imposes a higher coordination number.[746]

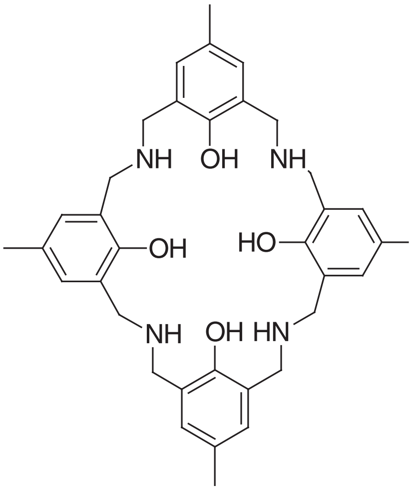
6.8.10.5 Compartmental Macrocycles (see Chapter 1.19)

Compartmental ligands contain binding sites for more than one metal center. The calixarene-related tetramino tetraphenolic polynucleating macrocyclic ligand (**96**) gives the structurally characterized [$LZn_4(OH)(CH_3CO_2)_3(CH_3OH)$]. The zinc ions are in an asymmetric kite arrangement with a hydroxo ligand bridging three of them with the fourth at a distance of 2.849(5) Å. Of the hydroxo bridged zinc centers, two are five-coordinate, and the other is six-coordinate. The fourth zinc ion has a distorted four-coordinate geometry.[747] The dizinc complex of a pyridyl functionalized compartmental ligand (**97**) was formed in reaction with the sodium salt of the ligand and characterized by NMR and mass spectrometry.[748]

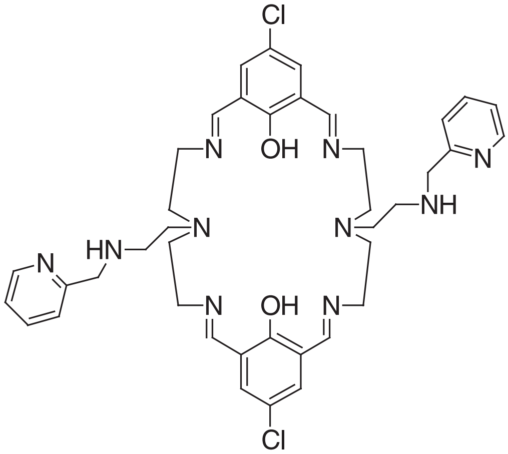
A mixed zinc barium dimeric complex (**98**) was formed with a ligand containing polyether and isothiosemicarbazide groups.[749] Ligand synthesis was carried out by templating around the barium ion but the monozinc complex could be isolated by removal of the barium ion from the Ba/Zn complex. The crystal structure of the barium zinc dimer complex [$ZnBaLI(CF_3SO_3)$



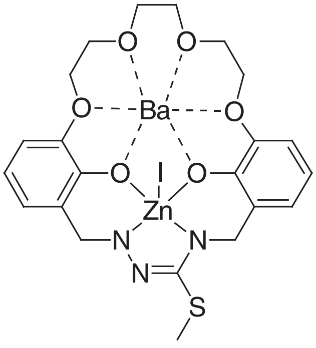
(95)



(96)



(97)



(98)

$(CH_3OH)]_2$ has a distorted square–pyramidal zinc center with the iodide in the apical position and a Zn—Ba distance of 3.736(1) Å. The iodide can be removed by treatment with a silver salt.

Okawa produced a series of heterobimetallic zinc–lead complexes using the unsymmetric compartmental ligand (**99**).[750,751] $ZnPbL(ClO_4)_2\cdot 2DMF\cdot MeOH$ and $[ZnPbL(OH)](ClO_4)$ have been structurally characterized. The activity towards hydrolysis of trisnitrophenylphosphate to bisnitrophenylphosphate was studied. The crystal structure of a bisnitrophenylphosphate analog $[ZnPbL(\text{bisnitrophenylphosphate})](ClO_4)$ reveals the phosphate ester group bridging the two metal ions binding through two oxygens.

A Robson-type compartmental macrocycle (**100**) gives dinuclear zinc complexes on complexation.[752] Both five-coordinate and six-coordinate zinc ions are observed, dependent on the anion present. The crystal structure for the compound $Zn_2L(ClO_4)_2\cdot 2H_2O$ reveals two independent dinuclear zinc complexes, one with two six-coordinate zinc centers with an intermetallic distance of 3.166 Å, and one with two five-coordinate zinc centers with a Zn···Zn distance of 3.177 Å. In the compound $[Zn_2L(N_3)_2]$ the two zinc atoms are five-coordinate, bound to the ligand and the azide anion and are separated by 3.333 Å. This type of macrocycle has also been used as a molecular building block in formation of ordered networks in the solid state. Two different molecular ladders were formed and structurally characterized with different ratios of 4,4′-bipyridine to the zinc complex building block, $[Zn_2L(H_2O)_2]^{2+}$.[753]

The zinc-templated condensation of 2,6-diformyl-4-methylphenol with 1,11-diamino-3,6,9-trioxaundecane gave a tetranuclear zinc complex $[Zn_4L(\mu\text{-}O_2CMe)_4][ClO_4]_2$, where H_2L is a [2 + 2] tetra-Schiff base macrocycle.[754] The X-ray structure shows a complex cation that is centrosymmetric and contains two pairs of zinc ions bridged by a phenolic oxygen and two acetate ligands. Another tetranuclear complex $[Zn_4L(\mu\text{-}OH)_2(\mu\text{-}O_2CMe)_2][ClO_4]_2$ can be isolated for structural analysis by changing the recrystallization solvent to methanol. In both complexes the four zinc ions are encapsulated in the macrocycle but in the second complex the two dimeric units formed by phenoxo and acetato bridges are also connected by two hydroxo bridges. Proton NMR spectroscopy was used to show that structural conversion is reversible. Reduction of the tetranuclear complex gave a dinuclear zinc complex of the imine reduced form of the ligand.

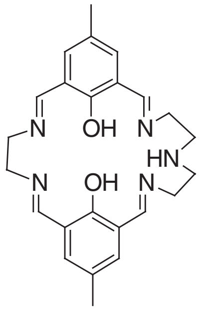
A heterotrinuclear complex, $[Cu_2Zn(\mathbf{101})][ClO4]_3\cdot 3H_2O$ was synthesized from the 38-membered macrocycle (**101**). The compound has been characterized by single-crystal X-ray diffraction showing the macrocycle complex twisted into a helical conformation. The zinc has a trigonal–bipyramidal N_3O_2 coordination sphere with all donor atoms from the macrocycle; the phenolic oxygen donors bridge to one of the copper ions.[755]

Dicompartmental ligands bearing picolyl pendent arms on the amine nitrogen donors were synthesized and the monozinc complex structurally characterized.[756]

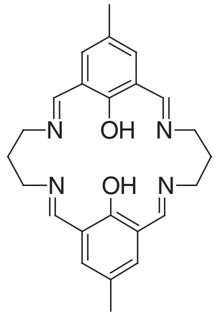
Thiolate-containing macrocycles have been of great interest due to the prevalence of thiolate ligands in a number of enzyme active sites and the interactions of zinc with thiolates in proteins.[757] Zinc complexes of thiolate-containing compartmental Schiff base macrocyles (**102**) and (**103**) formed with 2,6-diformyl-4-methylthiophenolate have been investigated. The structure of the zinc complex of the macrocycle with a secondary amine linker group (**102**) shows an unusual arrangement containing two zinc ions but no thiolate bridge.[758,759] It is postulated that this is due to the spatial arrangement of the donors. In the macrocycle formed with a shorter linker (**103**), a thio version of the Robson-type ligand, the zinc ions are coordinated in a square–pyramidal geometry. The structure of a tetranuclear zinc complex has been determined. The complex $[Zn_2(\mathbf{103})(\mu\text{-}OH)]_2[ClO_4]_2\cdot 2H_2O$ shows two unique dinuclear zinc units linked by two hydroxy bridges.[760]

6.8.10.6 Porphyrins and Phthalocyanines

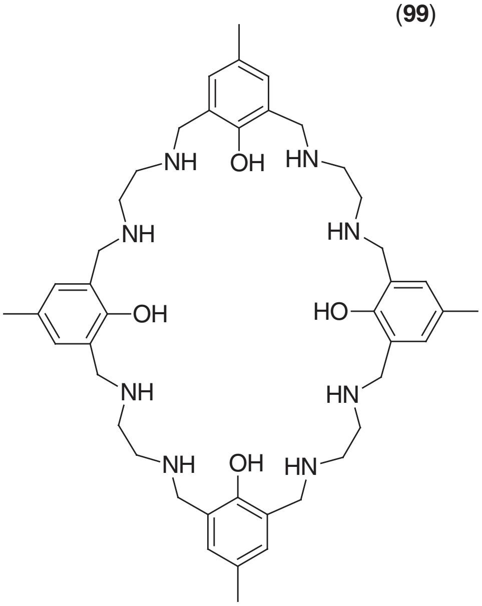
Square–planar zinc compounds predominate with these ligand types as would be predicted. This is in contrast to the prevalence of tetrahedral or distorted tetrahedral geometries for four-coordinate species that have been discussed thus far. Zinc porphyrin complexes are frequently used as building blocks in the formation of supramolecular structures. Zinc porphyrins can also act as electron donors and antenna in the formation of photoexcited states. Although the coordination of zinc to the porphyrin shows little variation, the properties of the zinc-coordinated compounds are extremely important and form the most extensively structurally characterized multidentate ligand class in the CSD. The examples presented here reflect only a fraction of these compounds but have been selected as recent and representative examples. Expanded ring porphyrins have also



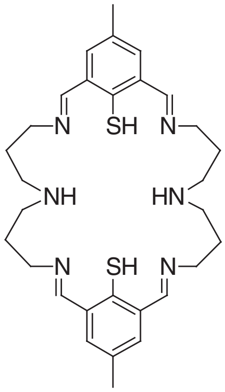
(99)



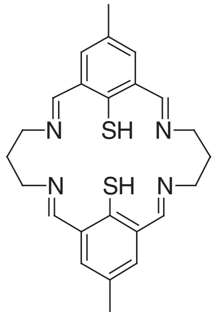
(100)



(101)



(102)



(103)

been characterized with zinc but show that the cavity is too large to accommodate binding to all ring nitrogens; for example, a porphocyanine incorporating a zinc dichloride unit binds through only two of the six ring nitrogens.[761]

6.8.10.6.1 *Porphyrin-based ligands (see Chapter 1.23)*

The functionalization of zinc porphyrin complexes has been studied with respect to the variation in properties. The structure and photophysics of octafluorotetraphenylporphyrin zinc complexes were studied.[762] Octabromoporphyrin zinc complexes have been synthesized and the effects on the ^{1}H NMR and redox potential of 2,3,7,8,12,13,17,18-octabromo-5,10,15,20-tetraarylporphyrin were observed.[763] The chiral nonplanar porphyrin zinc 3,7,8,12,13,17,18-heptabromo-2-(2-methoxyphenyl)-5,10,15,20-tetraphenylporphyrin was synthesized and characterized.[764] X-ray structures for cation radical zinc 5,10,15,20-tetra(2,6-dichlorophenyl)porphyrin and the iodinated product that results from reaction with iodine and silver(I) have been reported.[765] Molecular mechanics calculations, X-ray structures, and resonance Raman spectroscopy compared the distortion due to zinc and other metal incorporation into meso dialkyl-substituted porphyrins. Zinc disfavors ruffling over doming with the total amount of nonplanar distortion reduced relative to smaller metals.[766] Resonance Raman spectroscopy has also been used to study the lowest-energy triplet state of zinc tetraphenylporphyrin.[767]

Functionalization can be used to alter the redox properties of the zinc metalloporphyrin; the zinc heptanitroporphyrin shows facile reduction to the air-stable π-anion radical.[768] Modification of the zinc porphyrin at the β position with chlorine or bromine to induce saddling of the macrocycle, as demonstrated by spectral shifts, can be used as a strategy to lower the energy of the porphyrin HOMOs which can be important in catalysis applications.[769] The zinc complexes of the octaethyloxophlorin dianion and the oxidized stable free radical species were characterized by single-crystal X-ray diffraction. Both structures show a five-coordinate zinc center with an axial bound pyridine.[770] Substituent effects in axial ligation, by 1-methyl imidazole, of zinc tetraphenylporphyrin complexes have been studied. Relatively large entropy losses are associated with electron-donating substituents in the *para* position of the phenyl rings.[771] The reduction potentials of the zinc complexes of nonplanar tetrakis (pentafluorophenyl) porphyrins were analyzed electrochemically and were in agreement with the prediction that the resultant symmetry change from distortion of the macrocycle destabilizes the HOMOs.[772]

The kinetics of complexation to the zinc ion have been studied with a number of examples. The kinetics of zinc insertion into tetraphenyl porphyrin were compared to a capped porphyrin, a co-facial bis-porphyrin, and a spheroidal bis-porphyrin.[773] The insertion of the second zinc center into the bis-porphyrins was followed by HPLC. The insertion into the spheroidal bis-porphyrin was extremely slow and slower than the other porphyrins studied. The kinetics of incorporation of zinc into a large number of free base porphyrins of varying charges and structures has been investigated in *N,N*-dimethylformamide. Meso-phenyl rings substituted in the *para* position to donate electron density are more reactive to zinc complexation. Mercury(II) catalyzes the formation of the zinc complexes by rapid initial formation of the mercury(II) porphyrin, which is more reactive to zinc.[774] Mercury(II) has also been shown to enhance the incorporation of zinc into 5,10,15,20-tetrakis(4-sulfonatophenyl)porphyrin with formation of a heterodinuclear HgZn porphyrin intermediate suggested by the kinetic results and absorption spectra.[775] The zinc incorporation kinetics of porphyrins, chlorins, and isobacteriochlorins were compared. Tetraphenyl isobacteriochlorin had the highest reactivity with zinc in pyridine solvent with tetraphenyl chlorin showing higher reactivity than tetraphenyl porphyrin.[776] Rapid complexation of tetraphenyl porphyrin, in organic solution, with zinc at the solid–liquid interface was observed with zinc adsorbed on a silica surface.[777]

Ligands with more than one coordination site have been synthesized. A superstructured porphyrin ligand with an additional binding site for a second zinc ion was synthesized. The X-ray structure shows a bridging acetate ligand between the porphyrin cavity-bound zinc and the zinc bound to the appended tripodal chelator.[778]

Appended groups can also be used to change the coordination properties at the zinc porphyrin center. Picket fence and modified picket fence zinc porphyrin complexes have been formed and characterized. Modification products, such as one of the pivalamido groups being replaced by a methylamino or a hydroxybenzoylamino group, have been studied by ^{1}H NMR and electronic spectroscopy.[779] Other "picket fence" complexes include a tetrahydrothiophene picket zinc complex, zinc 5,10,15,20-tetrakis[*o*-(tetrahydro-2-thenoylamino)phenyl] porphyrin, which can bind two silver(I) ions to the thiophene pickets.[780] The bis-pocket porphyrin aquo(tetramesitylporphinato)zinc has been structurally characterized.[781] A variety of "basket handle" porphyrin zinc complexes have been synthesized with varying chain lengths.[782] UV–visible spectral measurements and electrochemical studies have shown a zinc complex of a tetraphenylporphyrin with an appended pyridyl group showing temperature-dependent formation of a five-coordinate compound with the pyridyl group bound intramolecularly.[783]

Aggregates or linked zinc porphyrins are common, including dimers and trimers. Co-facial zinc porphyrin dimeric units have been synthesized with xanthene bridges and X-ray structural and spectroscopic data collected (Figure 13).[784] Excitonic interactions in covalently linked zinc porphyrin dimers have been studied using the flash photolysis time-resolved microwave conductivity technique. Increasing the length of the linker group increases the electronic interaction between the two porphyrin units showing an inverse distance effect.[785] Diarylurea-linked porphyrin dimers and trimers have been formed.[786] [5-(Pyrazol-4-yl)-10,20-bis(*p*-tolyl)-15-(2-ethoxycarbonylphenyl)porphyrinato]-zinc forms a cyclic porphyrin trimer which is linked by both a coordinate bond to the pyrazole nitrogen and a hydrogen bond between the pyrazole and the 2-ethoxycarbonyl units. NMR, UV–vis, and IR spectra have been recorded in addition to electrochemical studies.[787] Bridged zinc tetraphenylporphyrin can be formed electrochemically in the presence of bis(diphenyl-phosphino)acetylene. Dimer formation occurs with bis(diphenylphosphonium)acetylene bridge.[788] Aromatic spacers bridging between two zinc porphyrins and a pyromellitimide gave a complex studied for the photo-induced charge separation. Solvent effects were also observed with solvent polarity having a marked effect on the lifetime of different states.[789] The zinc complexes of amino acid derivatized porphyrins have been synthesized and characterized, with the amino acid bridged dimeric species showing significant induced circular dichroism.[790]

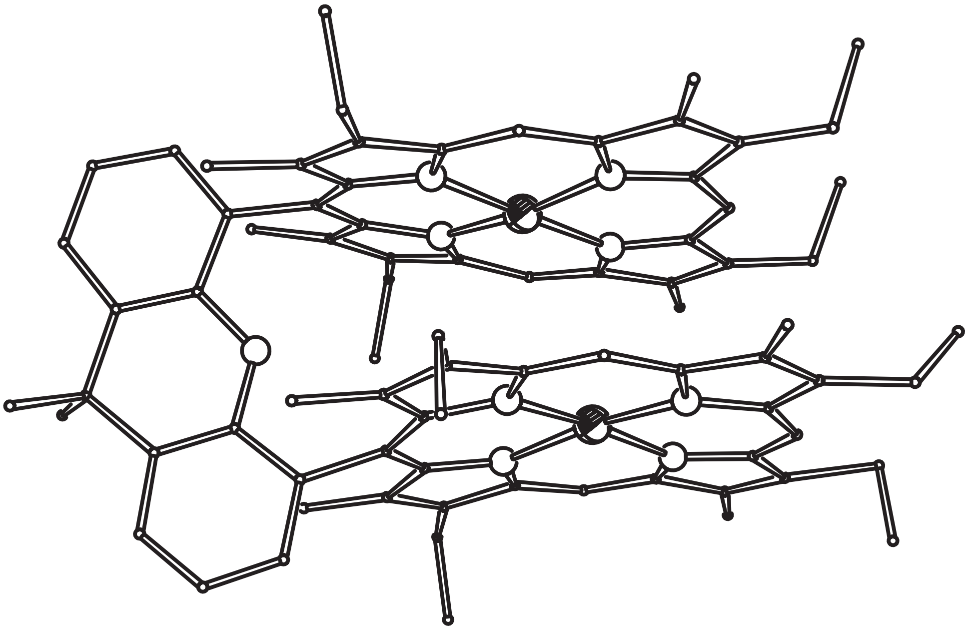


Figure 13 Molecular structure of a co-facial zinc porphyrin dimer with a xanthene spacer.[784]

Larger oligomeric and polymeric aggregates also form. Aggregates of free porphyrins can show quite different properties to the zinc porphyrinates due to the possibility for axial binding to the zinc ion. This is of specific interest in the fluorescent quenching properties.[791] Meso–meso linked porphyrin arrays have been synthesized as light-harvesting antennas and molecular photonic wire. Increase in the number of porphyrins resulted in the high-energy Soret bands remaining at almost the same wavelength (413–414 nm), while the low-energy exciton split Soret bands are gradually red-shifted, giving an increase in the exciton splitting energy.[792] A number of functionalized tetraphenylporphyrin zinc compounds have shown formation of meso–meso linked porphyrin arrays by one-pot electrochemical oxidation, with oligomers up to the octamer isolated from [5,15-bis(3,5-di-*t*-butylphenyl)porphyrinato]zinc as starting material.[793] Conjugated zinc porphyrin oligomers have been shown to form ladder-type structures by ^{1}H NMR, with linear bidentate ligands 1,4-diazabicyclo[2.2.2]octane and 4,4′-bipyridyl.[794] The oxidation of zinc-5, 15-diarylporphyrins by silver(I) gives a polymer, poly(zinc-5,15-porphyrinylene), in high yields.[795] Investigation has been carried out of photo-induced electron transfer at liquid–liquid (water/1,2-dichloroethane) interface with zinc tetra(3-carboxyphenyl) porphyrin. In particular, pH effects demonstrate the importance of hydrogen bonding to the self assembly at the interface.[796] Electropolymerization of zinc-10-bipyridinium-octaethyl-porphyrinate results in a polymer with a zigzag configuration and can give micrometer-long, wire-shaped linear polymers if 5,15-chloro substituted. The wires have two parallel strands based on the dimers formed in solution.[797] A template-directed formation of a hexameric wheel of covalently linked free base and zinc porphyrin units was demonstrated. The porphyrins were templated around a tripyridyl unit and linked at the meso position by diphenylethyne units, resulting in a face-to-face distance across the cavity of 35 Å.[798]

Non-covalently linked porphyrin arrays have been synthesized from nucleobase-substituted free base porphyrins and zinc porphyrin complexes. Hydrogen-bonded assemblies from rigid hydrogen-bonded guanosine to cytidine base pair porphyrins are formed from the functionalized units.[799] Conjugated fused tape-shaped arrays of covalently linked zinc porphyrins showed electronic absorption bands that reach into the infrared. It was shown that the oxidation potentials decreased upon increase in the number of porphyrins; both properties suggest potential use as molecular wires.[800] The photophysical properties of a series of ethynyl-bridged porphinato zinc oligomers have been investigated over the femtosecond and picosecond time scales. The linkage topology strongly influences the dynamics over these time scales.[801] (5-Pyridyl-10,15,20-triphenylporphyrinato)zinc forms a polymer with the pyridyl unit coordinating to the zinc center of a neighboring porphyrin complex. The X-ray structure reveals zigzag chains forming in the solid state. NMR studies demonstrated a similar structure in solution. Dimers and trimers could be formed from pyridyl- or dipyridyl-functionalized zinc porphyrins with zinc tetraphenylporphyrin.[802]

There are many sensor and receptor applications of zinc porphyrins. Dimeric zinc porphyrin tweezers have shown specific recognition properties for chiral monoalcohols and monoamines, inducing a preferred helicity in the dimeric compound.[803,804] Other bis(zinc porphyrin) tweezers show intercalation of a variety of Lewis base guests.[805] Water-soluble zinc porphyrin receptors incorporating a hydrophobic binding pocket and a carboxylate group to form electrostatic interactions was synthesized. The zinc is a Lewis acid site and the tetraphenyl porphyrins were substituted with long-chain alkyloxy groups to give the receptors. Selective binding to amines, α-amino acid esters, and oligopeptides in water was observed. Histamine was also bound and revealed imidazole coordination to the zinc center.[806] Selective anion receptors have been synthesized by functionalization of zinc porphyrins with ferrocene groups. Receptors based on 5,10,15,20-tetrakis(*o*-ferrocenyl-carbonylaminophenyl-substituted) zinc strongly bind to halide, nitrate, and hydrogen sulfate anions. The electrochemistry of the system shows perturbations of the porphyrin oxidation and ferrocene redox couples allowing electrochemical sensing.[807]

Zinc porphyrins have been used in the molecular recognition of carbohydrates. [5,15-bis (8-quinolyl)porphyrinato] zinc showed affinity for octyl glucoside and mannoside in chloroform solutions with ^{1}H NMR studies demonstrating that zinc coordination and hydrogen bonding to the quinolyl group were both important to the binding interaction.[808] Hydroquinone–quinone pairing has been used in molecular recognition with [5,10,15-triphenyl-20-(2,5-dihydroxyphenyl)-porphyrinato] zinc–quinone complexes.[809]

The photoactive properties and potential for use of some of these compounds as photoactive antennas have been explored. Electron transfer studies between C_{60} fullerene and zinc porphyrins linked by a short spacer unit have been studied. Varying lifetimes for the radical ion pairs have been observed.[810,811] Fullerenes have also been linked in a three-component system with a zinc tetraphenylporphyrin and a free base porphyrin.[812] The zinc porphyrin acts as an antenna molecule transferring the resultant singlet excited state energy to the lower energy free base porphyrin. A mixed metalloporphyrin trimer with one ruthenium and two zinc porphyrins templated by tripyridyltriazine has been synthesized and its properties investigated.[813] A zinc porphyrin and ruthenium(II) tris(2,2′-bipyridyl) have been linked by a platinum(II) unit and the compound shows excitation in the ruthenium fragment followed by rapid intermolecular transfer to the porphyrin triplet state.[814] A trimeric compound consisting of a zinc porphyrin, an iridium(III) bis-terpypyridine, and a gold(III) porphyrin was studied for multistep electron transfer producing a charge-separated state almost quantitatively and a lifetime of 450 ns^{-1}.[815] A zinc porphyrin–rhenium carbonyl complex has been characterized with the zinc tetraphenyl porphyrin linked with Re(CO)_3(4′-methyl-2,2′-bipyridyl) by an amide bond.[816] A covalently linked photosynthetic model *N,N,N′,N′*-tetraalkyl-*p*-phenylenediamine-zinc porphyrin-naphthoquinone has been investigated by experimental techniques, such as time resolved EPR, and *ab initio* calculations.[817]

The inclusion of additional fifth and sixth ligands in the coordination sphere of a zinc porphyrin compound has been of interest. The stability constants of five-coordinate complexes of zinc–octaethylporphyrin and zinc–tetraphenylporphyrin have been studied by absorption and steady-state fluorescent measurements in the presence of different donor molecules for axial ligation, over a temperature range of 20–60 °C.[818] The X-ray structure of the zinc 5,10,15,20-tetraphenylporphyrin complex as an 18-crown-6, dichloromethane solvate shows a five-coordinate zinc center with an axial water molecule. The displacement from the mean plane of 0.36 Å is compared with other five-coordinate zinc porphyrins with axial oxygen donors.[819] Six-coordinate zinc porphyrin complexes have been structurally characterized by X-ray diffraction; for example, zinc tetraphenylporphyrin with two axial tetrahydrofuran ligands.[357] The possibility of π–π interactions in the axial binding of amines to zinc porphyrins was investigated by comparing the binding of aromatic amines to zinc porphyrins with appended phenyl groups to the binding of butylamine. Enhanced binding of the aromatic amines was discussed in terms of ligand geometries and the superstructure.[820] Site selection was observed in imidazole binding to a single strapped zinc porphyrin.[821] Selective binding was observed within the cavity of a cyclic zinc porphyrin dimer.[822]

Other supramolecular structures such as dendrimers have also been synthesized with zinc-containing porphyrins. Sixteen free base and sixteen zinc porphyrin units were added at the fifth generation of dendritic poly(L-lysine) and intramolecular fluorescence energy transfer was observed.[823] Assembly of supramolecular arrays in the solid state has been achieved with the incorporation of an amide group for hydrogen bonding. Zinc meso-tetra(4-amidophenyl)porphyrin forms open two-dimensional arrays via hydrogen bonding of adjacent molecules.[824] Low-melting liquid crystal zinc porphyrins have been characterized with calimitic nematic mesophases. The control of the intermolecular π–π interaction by functionalization at the 5,15 positions on the zinc porphyrin reduces the melting and clearing points.[825] Supramolecular structures such as rotaxanes have been produced with zinc porphyrins acting as the stoppers on the thread. A copper(I) bis(1,10)phenanthroline forms the central part of the rotaxane and is involved in photoinduced electron transfer between the terminal porphyrin units.[826]

A trianionic zinc porphyrin anchored to a membrane by an imidazole link has been used to bind cytochrome c at the membrane surface. UV spectra confirmed the insertion of the zinc porphyrin into the phospholipid vesicle and was used to study surface association of cytochrome c.[827]

The 5-oxaporphyrin macrocycle is a modified porphyrin (with an oxygen atom instead of a meso-methine unit) and is produced during heme degradation. The diamagnetic zinc verdoheme analogs, with the monoanion of octaethyl-5-oxaporphyrin as ligand, undergo ring opening when treated with alkoxide ions, forming the zinc complex of the dianion of octaethylmethoxybiliverdin. The X-ray structure of the ring-opened product demonstrates a four-coordinate zinc complex where the geometry is controlled by the helical nature of the ligand and does not form a regular tetrahedral geometry (Figure 14).[828]

6.8.10.6.2 Phthalocyanine-based ligands (see Chapter 1.24)

Once again, a representative sample of zinc phthalocyanine complexes is presented highlighting particular areas of importance.

The X-ray structure of zinc naphthalocyanate has been determined with Zn—N bond lengths of 1.983(4) Å.[829] Pentanuclear complexes with a zinc phthalocyanine core and four ruthenium subunits linked via a terpyridyl ligand demonstrate interaction between the photoactive and the redox active components of the molecule. The absorbance and fluorescence spectra showed considerable variation with the ruthenium subunits in place.[830] Tetra-*t*-butylphthalocyaninato zinc coordinated by nitroxide radicals form excited-state phthalocyanine complexes and have been studied by time-resolved electron paramagnetic resonance.[831]

Tetrakis(2′,2′,3′,3′,4′,4′,5′,5′-octafluoropentoxy) phthalocyanine zinc was synthesized and characterized demonstrating the effects of the strongly electron-withdrawing groups on the electronic and spectroscopic properties of the complex.[832] Zinc phthalocyanate,

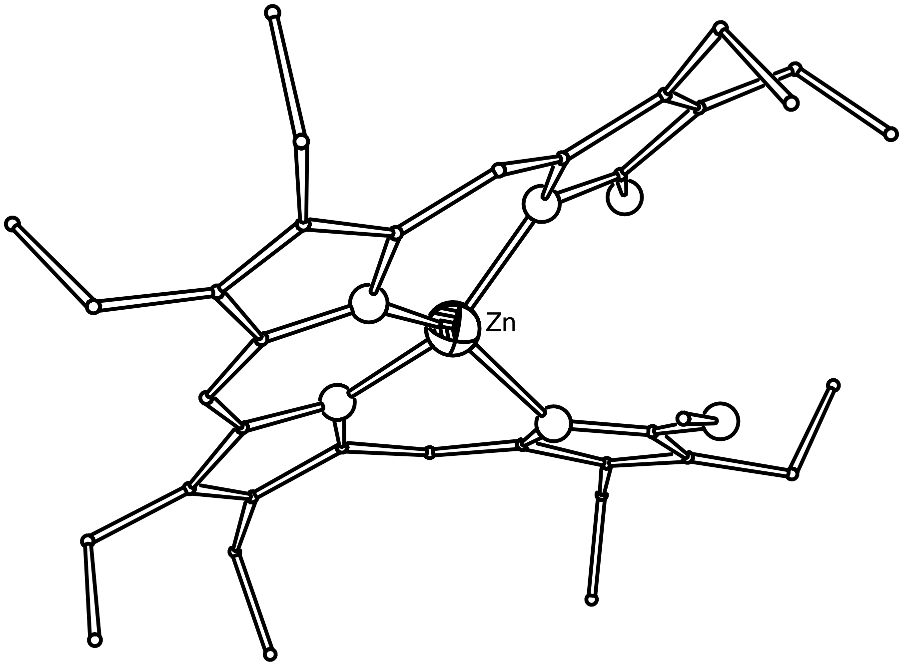

Figure 14 Molecular structure showing the helical nature of the zinc complex with a 19-methoxyoctaethylbilinone ligand formed on ring opening of the oxaporphyrin macrocycle.[828]

2,3,9,10,16,17,23,24-octabutylthiophthalocyaninato zinc with thio linkages to alkyl substituents have been characterized and spectral and electrochemical properties compared to the oxy-linked equivalent.[833]

The photochemical formation and the analysis of the absorption and magnetic circular dichroism spectra of the anion radical of zinc phthalocyanine were carried out. A complete assignment of the optical spectrum of the anion radical was proposed.[834] Similarly, spectroelectrochemical cells have been used to record absorption and magnetic circular dichroism spectra of zinc phthalocyanines and a band assignment scheme proposed.[835]

The redox potentials of zinc-substituted phthalocyanines are shown to be linearly dependent on the total Hammett substituent constant.[837] In 1987, Stillman and co-workers used the absorption and magnetic circular dichroism spectra of the zinc phthalocyanine and its π-cation-radical species to assign the observed bands on the basis of theoretical calculations. The neutral and oxidized zinc phthalocyanine complexes with cyanide, imidazole, and pyridine were used with the key factor in these studies the stability of the π-cation-radical species.[838] The structure of zinc chloro(phthalocyaninato) has been determined and conductivity investigated.[839]

Dinaphthotetraazaporphyrins are structural isomers of phthalocyanines. The zinc complex was formed and the properties compared to zinc phthalocyanines demonstrating a lower fluorescence quantum yield for the zinc-fused naphthalene porphyrin (D_{2h} symmetry) vs. the zinc phthalocyanine (D_{4h}).[836]

A porphyrin compound with a 2,9-dimethyl-1,10-phenanthroline functionality fused at the beta-pyrrole positions is a phthalocyanine analog, and formed a complex with zinc in the cavity and a further zinc binding to the phenanthroline group. The absorption and emission spectra of the compound with and without the external zinc demonstrated the strong effects of the second metal binding on the porphyrin π-system.[840]

Unsymmetrical zinc phthalocyanine analogs with three 15-crown-5 ether ligands appended at the 3,4-positions were synthesized and characterized. Introduction of alkali metal ions results in cofacial dimer formation with evidence for this dimerization from ^{1}H NMR.[841]

6.8.11 LIGANDS WITH MIXED DONORS

Mixed-donor ligands have been of particular interest in the modeling of enzyme active sites that may contain, for example, a mixture of cysteine and histidine ligands. The binding of some species is stabilized by a chelating ligand giving more examples of less well characterized donor groups, and in other cases the chelating ligands allow isolation of molecular species that would otherwise form bridged muiltimetallic compounds.

6.8.11.1 Bidentate Mixed Donor Ligands

6.8.11.1.1 N/O ligands

There are a number of important N/O bidentate ligands including the chelate stabilized ketone and aldehyde complexes, and amino acid complexes.

Zinc alkoxides are oligomeric or polymeric. The preparation of monomeric species is challenging and has resulted in the use of chelate ligands to try to stabilize them. The chelate ligand 2-pyridylmethanol, however, has been shown to give dinuclear and heptanuclear zinc structures $[(HL)_2Zn(\mu\text{-}Cl)_2Zn(HL)_2]ZnCl_4$ and $[Zn(ZnL_2)_6]Cl_2$. The Zn_7 compound contains bridging alkoxides and resembles a fragment of the brucite structure while the dimeric structure shows the relatively common Zn_2Cl_2 bridging motif.[842]

Chelating aldehydes such as 2-pyridine carbaldehyde and 2-dimethylamino benzaldehyde improve the stability of the aldehyde complexes via N,O chelation. NMR studies show that the complexes are present in solution without an excess of aldehyde and can be formed in the presence of donor ligands. The X-ray structures showed longer and weaker Zn—O bonds when more than one chelating ligand was present. IR demonstrates the variation in C=O bond strengths and how the environment of the zinc ion will influence potential catalytic activity via reaction rates or pathways. Tetrahedral chelate complexes, and octahedral bis- and tris-chelate complexes, were isolated.[843]

The complexes of zinc with pyridylphenylketone and pyridylphenylmethanol are stabilized by the chelate effect. The complexes formed were dependent on anions present and the ratio of the ligand. Pyridylphenylketone gave tetrahedral, square–pyramidal, trigonal–bipyramidal and octahedral complexes with either one or two ketone chelate ligands present and anions or solvent completing the coordination sphere. Only one analogous pyridylphenylmethanol complex was characterized, $ZnL_2(OSO_2CF_3)_2$. An octahedral complex was formed with three chelate alcohol ligands and polymeric zinc pyridylphenylmethoxide could be synthesized on deprotonation.[350]

Amino acid complexes, where the amino acid acts as a bidentate ligand donor towards zinc, have been isolated. The complexation behavior of racemic isovalinate and valinate towards zinc has been studied. The bidentate ligands form a number of complex types with zinc including a number of mononuclear complexes and a hexanuclear structure. The relevance of these compounds to conditions early in the history of the Earth and the possibility that amino acid complexes of zinc may have been some of the prebiotic compounds on Earth was discussed by Strasdeit *et al.* in the light of thermolysis reaction results.[844] The molecular structure of bis (L-leucinato) zinc shows it to be monomeric.[845] Amino acids containing a thiazolidine ring were studied via formation of zinc complexes with thiazolidinecarboxylic acid and the X-ray structure of trans-diaqua bis-(2-thiazolidinecarboxylato)zinc determined.[846]

Distorted octahedral geometry is observed with the 2-quinolinecarboxylate ligand in the complex [Zn(2-quinolinecarboxylato)$_2$(1-methylimidazole)$_2$] synthesized from zinc oxide.[847] 2-Pyridinecarboxylate esters act as bidentate NO ligands and a number of zinc complexes have been structurally characterized in the presence of halides. Zinc-to-ligand ratios of 1:1 and 1:2 have been used. Monomeric distorted octahedral complexes are demonstrated with the halides *cis* and the 2-pyridinecarboxylate esters coordinating via the pyridine nitrogen and the carbonyl oxygen atoms.[848]

The complexes formed from salicylhydroxamic acid and acetylsalicylhydroxamic acid (**104**) with zinc show loss of one ligand proton and loss of two ligand protons respectively. The zinc complex of the acetyl derivative appears to show coordination via the deprotonated amide and phenolate oxygen of the ligand. IR studies are presented.[849]

Chelating pyrazole ligands are also known. The pseudo-octahedrally coordinated zinc complex ZnL_2(pyridine)$_2$ was formed where L = 5-(4-methoxyphenyl)pyrazole-3-carboxylate.[850]

Polymeric or monomeric complexes are formed in the reaction between zinc halides and dimethyl(aminomethyl)phosphine oxide dependent on the ratio of reactants. The ligand can bind as bidentate to one metal center or bridge two metal centers through the amine N and phosphine oxide O atoms.[851]

6.8.11.1.2 N/S ligands

N/S mixed-donor ligands are of particular interest due to the biological relevance of the combination of these donors around zinc.

The ligand mercaptoethyl pyridine forms a monomeric ZnL_2 complex with the chelate ligand binding through the nitrogen and thioether sulfur.[125]

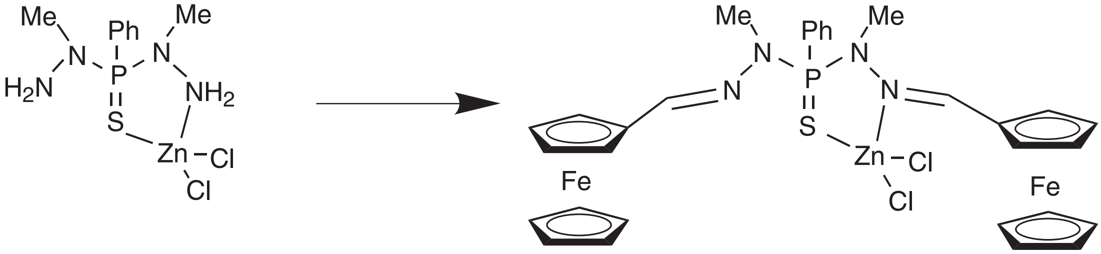
A tetranuclear complex is formed with (dimethylamino)ethanethiolate of type [$Zn_4L_4Cl_4$]. It can be obtained directly from the zinc chloride salt or from zinc acetate in the presence of HCl.[852]

The stability constants of zinc complexes of 4,6-dimethyl-2-thiopyrimidine have been determined by potentiometric measurements. The crystal structure shows infinite zigzag chains of ZnL_2 units with each zinc coordinated by an N_3S_2 donor set in a trigonal–bipyramidal geometry.[853]

The terephthalate anion was used to form hydrogen-bonded bridged zinc thiosemicarbazide complexes. The bidentate thiosemicarbazide ligands (**105**) are not displaced from coordination to the zinc center and the polymeric layer structure is based on hydrogen bonding interactions of ligands with the terephthalate anions. In contrast the addition of terephthalate to the zinc thiourea complex displaces two of the four unidentate thiourea ligands forming a zigzag chain network with zinc ions bridged by terephthalate groups. The thiourea ligands also bridge, linking the structure in a double strand motif.[854]

The synthesis of ferrocene-appended zinc complexes from a zinc phosphohydrazide, [PhP(S)(NMeNH$_2$)$_2$]ZnCl$_2$, with the ferrocene functionality added via a Schiff base condensation is presented in Scheme 4. A series of ferrocene-containing compounds including a macrocycle were synthesized by this method, showing a five-membered ring with the zinc bound to the S and *N*-donors of the phosphodihydrazone ligand.[855]

2-Mercaptomethylpyridine forms a zinc complex of the form ZnL_2, and the zinc has a tetrahedral N_2S_2 geometry.[125] Similarly, the monomeric tetrahedral zinc complex of 2-(dimethylamino)ethanethiolate, ZnL_2, was structurally characterized.[856]



Scheme 4

Zinc complexes of peptides with N-terminal cysteine are monomeric of the form ZnL_2 where the peptide is an anion with the SH deprotonated. Tetrahedral N_2S_2 coordination is observed with the chelating peptides and Zn(Cys-Gly-NH_2)$_2$ was structurally characterized.[857]

Bidentate ligand systems are also known with selenium and nitrogen donors. For example, Se/N bidentate phosphinochalcogenoic ligand and zinc amides react to form a distorted tetrahedral complex with two di-*t*-butylphosphinoselenoic isopropylamidate ligands.[590]

6.8.11.1.3 O/S and other ligands

O/S ligands, such as monothiocarbamates and thiocarboxylates, have been quite extensively characterized and some representative examples are discussed.

Sodium monothiocarbamate in the presence of zinc chloride gives zinc bis(diethylmonothiocarbamate).[84] A cage complex is formed from the reaction of $EtZnNEt_2$ with carbon disulfide, $[Et_4Zn_4(OSCNEt_2)_2(NEt_2)_2]$. The crystal structure shows the cage is comprised of two six-membered Zn_2CNOS metallocycles linked by pairs of Zn—S and Zn—O bonds. Both the oxygen and the sulfur atoms are binucleating in the observed binding mode for the monothiocarbamate ligand. The polymetallic cage structure was demonstrated to remain intact in solution by variable temperature ^{1}H NMR studies.[84] Zinc thiocarboxylate complexes $Zn(SOCR)_2$(3,5-dimethylpyridine)2 with $R = Me$ or ^{t}Bu were synthesized and their potential evaluated as precursors for zinc sulfide materials formation. It was anticipated that thiocarboxylic anhydride elimination would occur to give stoichiometric metal sulfides with clean removal of the ligands.

The complexes were shown to be monomeric in the solid state and have monodentate S-thiocarboxylate ligands. The thiocarboxylic anhydride elimination was studied by ^{1}H and ^{13}C NMR in solution, varying the R group and solvent.[858]

Some O–Se ligands are also known. *N,N*-diethyl-*N*′-benzoylselenoureato zinc has been characterized where the zinc is bidentately coordinated to the two ligands through the oxygen and selenium atoms, forming a distorted tetrahedral geometry.[859]

Se–S and P–S ligands are much less common with relatively few examples structurally characterized. The bidentate Se–S donor ligand $[N(SPPh_2)(SePPh_2)]^-$ forms a monomeric bis-chelate zinc complex which has been studied using X-ray diffraction and ^{31}P and ^{77}Se NMR.[860] Zinc complexes of bidentate S–P donor arenephosphinothiolate ligands have been synthesized by electrochemical oxidation of a zinc anode. The zinc thiolate complex formed in reaction with 2-(Ph_2P)-6-(Me_3Si)C_6H_3SH is of the form ZnL_2. Adducts can also be formed with bipyridine and phenanthroline ligands.[861] This compound is a rare example of a structurally characterized bidentate S/P ligand as part of a zinc complex.

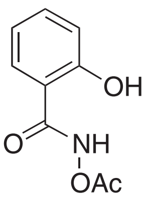
6.8.11.2 Tridentate Mixed Donor Ligands

There are a number of mixed-donor tripodal ligand systems which have been characterized with zinc coordinated, some of which will be discussed in this and the following sections.[125,466,862,863]

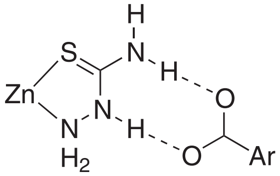
N,N-bis(2-hydroxy-di-3,5-*t*-butylphenyl)amine forms complexes of zinc which have ligand-based redox processes with four oxidation levels of the coordinated anion.[864] 2:1 and 1:1 complexes are formed in the presence of zinc with the 2:1 complex coordinated in an octahedral geometry and the 1:1 complex square planar with a triethylamine ligand completing the coordination sphere. The complexes, at the different redox levels, have been investigated by EPR, spectroelectrochemistry, ^{1}H NMR, and magnetochemistry, as appropriate.

Bis(pyrazolylethyl)ether derivatives (**106**) have been coordinated to zinc providing an N_2O donor set. The structural data shows that the ligand coordinates in a meridional rather than facial geometry limiting the application for the modeling of N_2O zinc enzyme sites. (derivatives R = i-Pr or Me).[161]

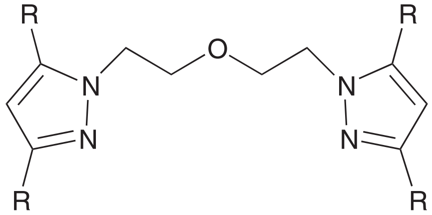
The 1-(*N*-methyl)benzimidazolyl-3-benzimidazolyl-2-oxapropane ligand (**107**) shows coordination through the N_2O donor set of the ligand, a water molecule and an acetonitrile to give a five-coordinate distorted trigonal–bipyramidal metal center.[123] This contrasts with the behavior of the related thiapropane ligand that forms bidentate complexes with zinc.



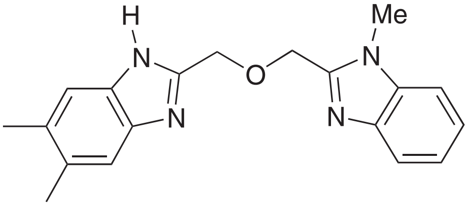
(**104**)



(**105**)



(**106**)



(**107**)

A tridentate NO_2 donor set complex was formed from 2-pyridinecarboxaldehyde N-oxide and 2-aminophenol and gave mononuclear and trinuclear compounds. The trinuclear zinc complex was structurally characterized and revealed bridging acetate groups, $[ZnLZn(OAc)_4ZnL]$.[865]

The zinc complex of 2-[[[2-(2-pyridinyl)ethyl]amino]methyl]phenol forms a dimeric species, $[ZnL(NO_3)]_2$, with the two phenolates bridging and each ligand offering an N_2O donor set.[866]

Zinc sites in enzymes are usually pseudo-tetrahedral with N, O, S donors from histidine, tyrosine, glutamic acid, aspartic acid, water or cysteine. A systematic evaluation of all the different possibilities was carried out with a heteroscorpionate ligand system (**61**). Seven heteroscorpionate complexes were structurally characterized in one study.[78] Five complexes revealed the expected tridentate coordination to the deprotonated ligand with the coordination sphere completed by acetate, thiophenolate, methylate, or chloride. All the compounds apart from the acetate structure showed pseudotetrahedral coordination. The acetate-containing structure is five-coordinate with an unsymmetrically bound acetate. Two of the structures showed different coordination modes. The diiodide zinc complex of the phenol ligand shows bidentate binding to the two nitrogen ligands and no bond to the phenol, giving a pseudotetrahedral geometry. Two equivalents of the thiophenol ligand gives a zinc bound to two bidentate ligands by one thiophenolate sulfur and one pyazolyl nitrogen.

A tridentate SNO ligand coordinates with a bipyridine to give ((2,2′-bipyridine)[2-(2-mercaptophenyl)iminophenoxy])zinc. The monomeric complex has a distorted trigonal–bipyramidal geometry with a phenolate and a thiolate coordinated. The synthesis was carried out electrochemically from anodic zinc in the presence of a disulfide-linked ligand precursor.[867]

Aliphatic thiosemicarbazones reveal varying coordination behavior dependent on the degree of deprotonation. The X-ray structure of the zinc complex of methyl pyruvate thiosemicarbazone shows different coordination of the two thiosemicarbazone ligands in the monomer, with one tridentate NOS and the other monodentate.[868]

Riordan and co-workers have examined zinc complexes of pyrazolyl-bis[(methylthio)methyl]-borate ligands as models for methionine synthase.[547,869] The ligand coordinates in a face-capping fashion with the desired NS_2 donor set.

The NSN donor ligand 5-(3,5-dimethylpyrazol-1-yl)-3-thia-1-pentaneamine forms 1:1 ligand-to-metal monomeric complexes with zinc chloride and nitrate salts.[870]

The potentially tridentate thiol ligand *N*-(2-mercaptoethyl)picolylamine shows zinc complex formation that varies with the anion and presence of other ligands. Trinuclear complexes are formed with non-coordinating anions $[Zn_3L_4]^{2+}$. In the presence of halides or acetate, 1:1 complexes are formed that are polymeric and dimeric respectively. The 2:1 complex can also be obtained with the ligands binding as bidentate, giving an N_2S_2 coordination sphere, and due to the free binding sites on the ligands this form can be converted to either the trinuclear compound or the polymer by reaction with zinc salts or HCl respectively.[871] The related N_2S ligand N-(2-mercapto-iso-butyl)picolylamine also forms the 2:1 zinc complex with two uncoordinated nitrogen donors and can be converted to the trinuclear compound.[872]

2-Methyl-1-[methyl-(2-pyridin-2-yl-ethyl)amino]propane-2-thiol (**108**) is a tridentate N_2S ligand with an aliphatic thiolate ligand. The single-crystal X-ray structures demonstrate that the zinc complexes are close structural analogs of the His_2Cys site found in peptide deformylase.[873]

Methyl pyruvate thiosemicarbazone in the presence of zinc chloride or acetate resulted in the formation of complexes with the ligand hydrolyzed or transesterified. The complexes with pyruvate thiosemicarbazone, ZnL_2, or ethyl pyruvate thiosemicarbazone, $ZnLCl_2$ were structurally characterized by single-crystal X-ray crystallography showing respectively a distorted octahedral and distorted square pyramidal geometry.[874]

The ligand *N,N*-bis(2-mercaptoethyl)benzylamine complexes zinc in the doubly deprotonated form resulting in a tetranuclear complex, Zn_4L_4, which has an unusual Zn_4S_4 metalacyclic structure.[875]

The compounds $Zn[E_2CN(Me)CH_2CH_2CH_2NMe_2]_2$ $E=Se$, S were synthesized and found to be polymeric in the solid state. Their potential as single-molecule precursors for material growth by low-pressure metal–organic chemical vapor deposition (LP-MOCVD) was evaluated by attempts to grow ZnS and ZnSe films.[600] The X-ray structures of the complexes show the two S or Se donors coordinating to one zinc center and the amine binding to a neighboring zinc atom resulting in the coordination polymer.

6.8.11.3 Tetradentate Mixed Donor Ligands

Mixed donor ligands based on tris(2-aminoethyl)amine, often referred to as tren, have been complexed with zinc. The replacement of one or two primary amines by hydroxy groups gives N_3O and N_2O_2 donor set ligands, 2-hydroxy-*N,N*-bis(2-amino ethyl)ethylamine and 2-amino-*N,N*-bis(2-hydroxyethyl)ethylamine respectively. The zinc complexes were formed and studied by potentiometric and NMR titrations. The zinc appears to show only weak interaction with the hydroxy group in acidic or neutral solution. The $[ZnL]^{2+}$ cation can be deprotonated at the hydroxyl group with one or two protons released dependent on the ligand. The stabilities of the compounds show a decrease with sequential replacement of $-NH_2$ with $-OH$. The crystal structure of 2-amino-*N,N*-bis(2-hydroxyethyl)ethylamine with zinc demonstrates a dimeric structure in the solid state, $[Zn(OH)(LH)ZnL]^{2+}$. Both zinc ions have a distorted trigonal–bipyramidal coordination geometry, one zinc is bound to the three nitrogens and one alkoxide from the monodeprotonated ligand and a hydroxide ion, the alkoxide group bridges to the second zinc ion which is additionally coordinated to the N_3O donor set of the remaining ligand.[876]

An unusual unsymmetric tripodal ligand, (2-picolyl)(*N*-pyrrolidinylethyl)(2-hydroxy-3,5-di-*t*-butylbenzyl)amine, with three different donor groups attached to the central amine was synthesized by Vahrenkamp and co-workers. The zinc complex of the N_3O ligand with an additional phenoxide coordinated was structurally characterized (Figure 15).[877]

The bis(*N,N'*-[dithiobis(ethylene)](4,6-dimethoxysalicylideneiminato)) zinc complex is characterized as a distorted tetrahedral complex with an N_2O_2 donor set from the tetradentate ligand.[878]

A tetradentate ligand 2-{bis[2-(2-pyridyl)ethyl]aminomethyl}phenolate complexes zinc with an N_3O donor set including pyridyl and phenolic groups. The X-ray structure reveals that a dimeric

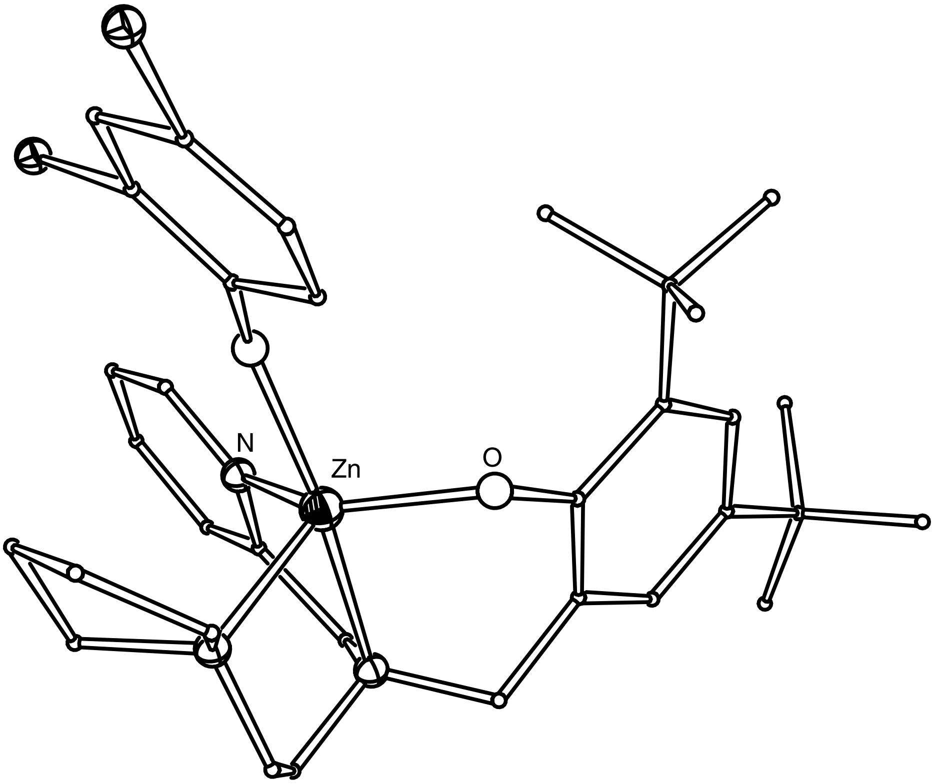


Figure 15 The molecular structure of the zinc complex formed with the unsymmetric tripod, (2-picolyl)(*N*-pyrrolidinylethyl)(2-hydroxy-3,5-di-*t*-butylbenzyl)amine and 2,4-dibromophenoxide.[877]

species has formed with the phenoxide oxygens bridging the two distorted square–pyramidal zinc centers with a zinc–zinc separation of 3.284 Å. The complexes were demonstrated to promote the hydrolysis of tris(*p*-nitrophenyl) phosphate.[879]

Zn and N K-edge XANES have been used to distinguish the coordination geometries in (1,2-ethanediylidene)-bis(*S*-methylhydrazonecarbodithionate) zinc complexes (**109**). The technique distinguished between tetrahedral species, square–pyramidal dimers, and square–pyramidal monomers, formed when pyridine was present. These studies were in conjunction with spectroscopic characterization and X-ray single-crystal data where possible.[53] The results demonstrated the value of this technique when single crystals could not be obtained.

The zinc complexes of tetradentate ligands derived from the condensation of (1R)-3-hydroxymethylenebornane-2-thione and symmetric diamines were synthesized. The binding to zinc occurs through the enethiolate imine form of the ligands. The complexes were studied by circular dichroism and NMR spectroscopy. In solution there are several species present due to the conformational flexibility offered by the chelate ligands. Increasing the length of the carbon chain in the diamine moiety from two to four carbon atoms favors tetrahedral geometry at the zinc center.[880]

A series of N_2S_2 donor set complexes of zinc with Schiff base ligands with thiopyrazolyl units, (**110**) and (**111**), were characterized by X-ray crystallography and NMR studies. For example, the structure of bis[4-(2,6-dimethylphenyliminomethyl)-1-methyl-3-phenylpyrazole-5-thiolato-N,S]zinc showed a similar geometry to horse liver alcohol dehydrogenase. The electronic spectra demonstrated the development of thiolate character on complexation of the mainly thione ligand.[881]

Solution studies of zinc binding to *N,N′*-dimethyl-*N,N′*-bis(2-mercaptoethyl)ethylenediamine and (2-mercaptoethyl)amine did not show formation of polynuclear complexes, as was observed for cadmium(II). The titrations carried out with a variation in excess of the ligands showed 1:1 complex formation with the tetradentate N_2S_2 ligand and 1:2 and 1:3 metal-to-ligand ratios for the bidentate (2-mercaptoethyl)amine ligand.[882] Tetradentate N_2S_2 Schiff base complexes of zinc incorporating pyrazole or oxazole heterocycles were synthesized and the configuration of the complexes determined by the chemical shift differences in the ^1H NMR spectra.[883]

Ferrocene-containing sulfur ligands have been used in complex formation with zinc. 3-Ferrocenyl-3-mercaptopropenale and 1,1′-bis(3-mercaptopropenale)ferrocene (**112**) form stable complexes as do their Schiff base derivatives with aniline or 1,2-ethylenediamine. The Fe^{II}/Fe^{III} redox couple shows only minor metal dependence, this is attributed to tetrahedral distortion.[884]

The ligand bis(2-picolyl)(2-hydroxy-3,5-di-*t*-butylbenzyl)amine is a tetradentate N_3O tripodal sligand which enforces a five-coordinate geometry in its complexes. Cleavage of tris(*p*-nitrophenyl) phosphate was investigated and LZnOH was shown to be the hydrolytically active species.[466] *N,N*-bis(2-picolyl)glycine was introduced as a ligand via a hydrolysis reaction of its ethyl ester with zinc. Monomeric complexes formed which were shown to be five- or six-coordinate dependent on the coligands.[885]

Zinc complexes of cyclohexane-1,2-dione bis(thiosemicarbazone) have been formed in the neutral and doubly deprotonated form. The X-ray structures show distorted square-based pyramidal geometries for both complexes $[ZnL(OH_2)]$ and $[Zn(H_2L)Cl]Cl$ with the water or chloride occupying the axial position.[886] The binuclear complex bis[1-phenylglyoxal bis(3-piperidylthiosemicarbazone)zinc] was synthesized by electrochemical methods and reveals a Zn_2L_2 with two tetradentate bis-thiosemicarbazone ligands bridging the metal centers.[887]

6.8.11.4 Pentadentate and Higher Denticity Mixed Donor Ligands

N_4O donor set ligands with pyridyl and phenolic arms form mononuclear complexes with approximately trigonal–bipyramidal coordination geometries.[888]

The pentadentate ligand 2,6-diacetylpyridinebis(thiosemicarbazone) produces complexes of zinc which vary structurally, dependent on the protonation state of the ligand and the solvent. The ligand in its neutral form results in a structurally characterized mononuclear complex with pentagonal–bipyramidal geometry. The planar ligand and two axial water molecules form the zinc-containing cation. The doubly deprotonated ligand forms dinuclear complexes with a 1:1 ligand-to-metal ratio. The coordination number of the zinc centers is dependent on solvent.[889]

Fenton and co-workers observed the hydrolysis of bis- and tris-nitrophenyl phosphate with the zinc complex of the pentadentate N_3O_2 ligand *N,N′*-{(salicylideneimino)-ethyl}-2-hydroxy-5-nitrobenzylamine.[890]

Pentadentate ligands with N_4S donors based on methyl 2-aminocyclopent-1-ene-1-dithiocarboxylate with pendent pyrazolyl groups (**113**) form complexes with zinc including a structurally characterized trigonal–bipyramidal zinc compound.[891]

The reaction of ligand *O,O′*-(*N,N′*-dipicolinylidene) diazadiphenyldisulfide with zinc chloride forms $[ZnClL]_2[Zn_2Cl_6]$, where the zinc center has octahedral coordination with the ligand pentadentate with an N_4S donor set.[892]

The zinc complex of a tripodal N_2S_2O pentadentate ligand undergoes amide alcoholysis of a coordinated amide group.[893] Examples of amide hydrolysis are known for other ligand systems.[894]

2,2′-[1,2-ethanediylbis(1,3-diazolidone-2-yl)]bis(1-oxo-pyridine) (**114**) is a pyridine *N*-oxide containing ligand used to complex zinc. The imidazolidone rings cleave on reaction with zinc perchlorate forming a hexadentate ligand (**115**) that coordinates zinc in a distorted octahedral environment as shown by structural characterization. In the presence of DMSO, however, the ligand is transformed back to the ring-formed four-coordinate ligand with two DMSO molecules filling the coordination sites. The mechanism relies on the strong Lewis acidity of the zinc.[895]

A hexadentate $N_2O_2S_2$ ligand (**116**) has been synthesized as a dithiaalkyl-substituted triazene-1-oxide and forms an unusual hexacoordinated zinc complex with thioether donors. Both the phenyl and the methyl derivatives form structurally characterized octahedral complexes.[896]

A number of ligands based on the encapsulating hexadentate edta ligand have been structurally characterized with zinc, including the 3,4-toluenediamine-*N,N′,N″,N‴*-tetraacetate.[897]

Hexadentate ligands 1,12-bis(2-pyridyl)-5,8-dioxa-2,11-diazadodecane and 1,12-bis(2-pyridyl)-5,8-dithia-2,11-diazadodecane have pyridine, amine, and ether or thioether donors offering an N_4O_2 or N_4S_2 donor set. The X-ray structures of the zinc complexes are distorted octahedral with the zinc center encapsulated by the ligand.[898]

An N_5O_2 donor open chain precursor for a macrocycle forms a seven-coordinate zinc complex.[899]

6.8.11.5 Liver Alcohol Dehydrogenase Models with Mixed Donor Ligands

There has been recent expansion of work in this area with major contributions from Vahrenkamp, Parkin, Corrano, and their co-workers. The main aim has been to reproduce the coordination sphere of the enzyme-bound zinc.[2,335,900–902]

LADH contains a tetrahedral zinc which is coordinated by one histidine nitrogen and two cysteine sulfurs. One aim is to make synthetic analogs of this coordination sphere that also feature the catalytically important water or hydroxide ligand in the fourth coordination site. Analogs containing bound substrates such as alcohols are also of interest.

The catalytic site of LADH has been modeled using the mixed donor NS_2 tripodal pyrazolylbis(thioimidazolyl)borate ligand (**117**) in complex formation with zinc iodide.[902] Vahrenkamp and co-workers synthesized the pyrazolylbis(thioimidazolyl)borate ligand from 1-(*o*-anisyl)-2-thioimidazole and formed the complex with zinc. This complex, which contains a neutral $ZnNS_2$ unit and binds to ethanol without forming the alkoxide, is an accurate structural model of the LADH active site showing good agreement with the enzyme structure.[903]

In any model system for an alcohol dehydrogenase enzyme the binding of aldehydes, ketones, and alcohols will be of particular interest. The compounds bis(pentafluorothiophenolato)zinc and bis(2,4,6-tri-*iso*-propylthiophenolato)zinc react with NO chelate ligands to form derivatives with bound aldehyde and alcohol donors as structural models for the LADH active site. Polymeric, tetrameric, and some structures with bridging thiolate or alkoxides were produced, however, the monomeric complexes $[(6\text{-methylpyridine-2-carbaldehyde})_2Zn(SC_6F_5)_2]$ and $[(6\text{-picolylmethanol})_2Zn(SC_6F_5)_2]$ demonstrated a bound alcohol and a bound aldehyde respectively, with the desired NS_2O coordination. The X-ray structures demonstrate almost superimposable geometry for these two complexes.[354]

Thiolate ligated zinc complexes have been characterized with a co-crystallized methanol molecule that is hydrogen bonded to a zinc-bound sulfur, and the possibility the alcohols may be activated without coordination to the metal center was discussed by Shoner *et al.*[904]

The substituted tris(2-thioimidazolyl)borate ligands with 1-R-2-thioimidazole groups where $R={}^tBu$ and $C_6H_4\text{-}p\text{-}CH(CH_3)_2$ yielded tetrahedral complexes on reaction with zinc salts. The labile S_3O bound zinc complexes formed with zinc perchlorate were used as starting materials for incorporation of substrates and complexes were formed with ethanol, *p*-nitrophenol, pyridine-2-carbaldehyde, and salicylic aldehyde. The ethanol formed a S_3O complex without deprotonation whereas nitrophenolate was the bound species in the case of nitrophenol. Some preliminary results showing promotion of both the dehydrogenation of 2-propanol and the hydrogenation of pentafluorobenzaldehyde were presented.[645]

Complexes of heteroscorpionate ligands, (3-*t*-butyl-2-hydroxy(or thio)-5-methylphenyl)bis(3,5-dimethylpyrazolyl)methane offering N_2O or N_2S donor sets have been characterized with zinc. The fourth ligand, resulting in a distorted tetrahedral geometry, was varied from halides to sulfur donors or alkyls. The ligand offers a useful comparison with the well-investigated tris(pyrazolyl)borate, N_3 donor ligand and initial studies of reactivity showed a variation in the reactivity properties for the zinc complexes of the three types of ligand.[78] Further comparisons with the ligand bis(3,5-dimethylpyrazolyl)(1-methyl-1-sulfanylethyl)methane and the octahedral and pseudotetrahedral complexes of zinc have been carried out. Of particular relevance to enzyme modeling is the variation in the binding mode of acetate from unidentate to anisobidentate as the ligand donor is changed from S to N to O.[452] The Zn–CH_3 complexes of the heteroscorpionate ligands (3-*tert*-butyl-2-hydroxy(or thio)-5-methylphenyl)bis(3,5-dimethyl-pyrazolyl)methane react with pentafluorothiophenol ($HSPhF_5$). The structures of four of the complexes revealed one or two coordinating thiophenolates dependent on the ratio of the reactants.[905]

Berreau and co-workers recently synthesized a tetradentate mixed nitrogen sulfur donor ligand *N,N*-bis-(2-methylthio)ethyl-*N*-(6-amino-2-pyridylmethyl) amine that was utilized in the formation of mononuclear zinc complexes with a methanol (**118**) or DMF molecule completing the coordination sphere. The X-ray structures demonstrated the presence of hydrogen bonding from the ligand to the bound solvent oxygen donor. This is again of relevance to the hydrogen bonding interactions found in liver alcohol dehydrogenase.[906]

6.8.12 COMPOUNDS CONTAINING ZINC–METAL BONDS

There are a number of structurally characterized compounds exhibiting zinc–metal interactions. Riera and co-workers show a zinc bipyridine unit bridging two manganese atoms in a trimeric unit.[907] A tetrameric cluster, of form Rh_2Zn_2, has the two zinc atoms bridging the Rh—Rh bond with a benzyl group completing the coordination.[908] A rhodium zinc trimer has been characterized that contains only one zinc, a zinc amide unit in this case, bridging the two rhodium centers. A terminal zinc amide has also been observed with an Rh—Zn bond.[909] A triply bridging $ZnPt_3$ cluster shows a zinc diiodide unit bound over the face of a triangular Pt_3 arrangement.[910] An aquo zinc species has also been observed to bind to platinum with the platinum acting as a weak

σ donor.[911] A hepta-rhenium carbonyl cluster has a face-capping μ_3-ZnCl unit.[912] Zn—Fe bonds have been observed in zinc–iron carbonyl compounds.[913] $[Zn_2Cl_2Fe(CO)_4(THF)_2]$ is a polymer in the solid state with each zinc tetrahedrally bound to two bridging chloride donors, a THF oxygen donor, and the iron center. In the presence of TMEDA a trimeric species was characterized, $[Zn_2Cl_2Fe(CO)_4L_2]$, with a ZnFeZn unit of metal–metal bonded atoms. This unit is analogous to that observed in the polymer without bridging chloride ligands between the zinc centers.

6.8.13 APPLICATIONS

6.8.13.1 Drug Applications (see Chapter 9.18)

Advances in drug applications include the use of zinc to reduce gastrotoxicity of some drugs and, in conjunction with designed ligands, for viral inhibition. Binding to zinc in enzyme active sites is a very important part of the action of a number of organic drugs. Other organic drugs may recruit zinc after administration.

Indomethacin (**119**) is a nonsteroidal anti-inflammatory drug that has side effects of inducing gastrointestinal ulceration and hemorrhages. The zinc, and copper, indomethacin complexes have been patented as veterinary pharmaceuticals. Five structures were solved with different coordinating solvents.[914] The dimeric structures, e.g., $[Zn_2L_4(\text{pyridine})_2]$, are five-coordinate dimers with the "paddlewheel" structure. In a number of solvents, including methanol, ethanol, and an aqueous/amine donor mixture, a six-coordinate monomer is formed, $[ZnL_2(MeOH)_2]$. Problems with toxicity to the stomach of the zinc compound may be related to the stability of the dimer. For similar reasons, complexes of 4-hydroxy-3-(5-methyl-3-isoxazolocarbamyl)-2-methyl-2*H*-1,2-benzothiazine-1,1-dioxide (Isoxicam), an anti-inflammatory drug, with zinc and other metals were studied spectroscopically and the zinc complex shown to be of formula $ZnL_2 \cdot 4H_2O$.[915]

The complex formation with zinc of drugs that have a relation to the status of zinc-containing species in the human body was also investigated. Captopril, Isoniazid, naldixic acid, and mercaptopurine formed structurally characterized complexes which tended to form polymeric species in the solid state.[92,916] The binding to the anti-tumor drug streptonegrin has also been studied.[917] Similarly, NMR and molecular dynamics studies of the binding of anti-cancer antibiotics tallysomycin and bleomycin show an interesting arrangement on zinc binding.[918] Studies of enzyme active sites in relation to the binding of ligands to zinc as directed inhibitors have been carried out.[919]

Kimura and co-workers have demonstrated the potent antiviral inhibitory action of zinc complexes of bi-cyclam ligands against HIV *in vitro*. A series of compounds, with variation in the bridge between the macrocycles, was synthesized and tested.[920]

The monomeric zinc complex of the xanthine oxidase inhibitor, alloxanthine, has been structurally characterized.[921] Potent and highly selective zinc-dependent inhibitors of several therapeutically important serine proteases have been designed and tested.[922] Removal of zinc from the retroviral zinc finger protein has shown antiviral action and may offer an anti-HIV strategy that restricts drug resistance development.[923–925] Cyclosporin A is an immunosuppressant drug used in organ transplantation and is thought to function via intracellular signaling events, and complexation of zinc and calcium suggests that it may act by regulating local concentrations of metal ions.[926] The equilibria for binding of zinc ions to ampicillin in the presence of different nucleobases were studied, as was the dimeric complex formation in the presence of chloride ions.[927,928] The crystal structure of the widely used topical burn drug zinc 2-sulfanilamidopyrimidine shows the structure is a one-dimensional polymer, which is relevant to the desired slow release of zinc ions when applied in therapy.[929]

6.8.13.2 Catalysts (see Chapter 9.1)

Zinc catalysts have shown a major increase in their possible applications. Some examples of catalysis using halide complexes, including immobilized catalytic systems, have been discussed in Section 6.8.8. Some areas such as asymmetric alkynylation of aldehydes have been recently reviewed.[930]

There are a number of examples of enantioselective catalysis with a zinc catalyst. The use of zinc as a catalyst in the Diels–Alder reaction of (*R,R*)-4,6-dibenzofurandiyl-2,2′-bis(4-phenyloxazoline) with cyclopentadiene shows high enantioselectivity. Chiral amplification is observed in the same reaction if the starting material is of low enantio purity, with 20% ee starting material converted to 96% ee for the cycloadduct product. Hydrogen bond formation in the zinc complex contributes to the mechanism of chiral amplification.[931] Chiral zinc catalysts have been used in the enantioselective reduction of ketones to secondary alcohols by polymethylhydrosiloxane. Enantiomeric excesses (ee) up to 88% were achieved in the presence of a zinc alkyl or zinc carboxylate with a chiral diamine. The process is of particular interest due to the economy and non-problematic scale up of the reaction.[932]

The zinc alkoxide of 2-methyl-1-(3-quinolyl)propan-1-ol was used in a catalytic amount to give ee up to 94% in the enantioselective alkylation of quinoline-3-carbaldehyde by diisopropylzinc.[933]

A few further general examples of zinc catalytic activity or reactivity include the following. Other zinc-containing systems include a zinc phenoxide/nickel(0) catalytic system that can be used to carry out the chemo- and regioselective cyclotrimerization of monoynes.[934] Zinc homoenolates have been used as novel nucleophiles in acylation and addition reactions and shown to have general utility.[935,936] Iron/zinc species have been used in the oxidation of hydrocarbons, and the selectivity and conditions examined.[362] There are implications for the mechanism of metal-catalyzed iodosylbenzene reactions with olefins from the observation that zinc triflate and a dizinc complex catalyze these reactions.[937]

Zinc polymerization catalysts have been extensively studied. Darensbourg investigated the coupling of carbon dioxide and epoxides with zinc phenoxide complexes including $Zn(2,6\text{-diphenylphenoxide})_2(THF)_2$.[343,938] Further research efforts were directed towards the minimization of the polyether formation side reaction. Other zinc catalysts have also found application in polycarbonate formation.[939] Different donor ligands for the zinc center were examined as the copolymerization appears to proceed via an anionic coordinative mechanism. Organophosphine ligands were examined, with variation in the substituents on the phosphorus, and changes in the reactivity observed. The X-ray structures of the phosphine/phenoxide complexes show both three- and four-coordinate monomeric complexes.[309,940] The complex $Zn(O\text{-}2,6\text{-}^tBuC_6H_3)_2(PPh_2Me)$ is trigonal–planar with P—Zn—O angles larger than O—Zn—O angles. The diphosphine compound $Zn(O\text{-}2,4,6\text{-}^tBuC_6H_2)_2(PMe_3)_2$ has a distorted tetrahedral geometry. Competitive binding studies of phosphines studied by ^{31}P NMR showed the greatest binding for smaller phosphines indicating that steric effects drive the binding. In the polymerization process with cyclohexene, oxide and carbon dioxide addition of phosphine did not significantly alter reactivity but did appear to reduce polyether linkage formation.

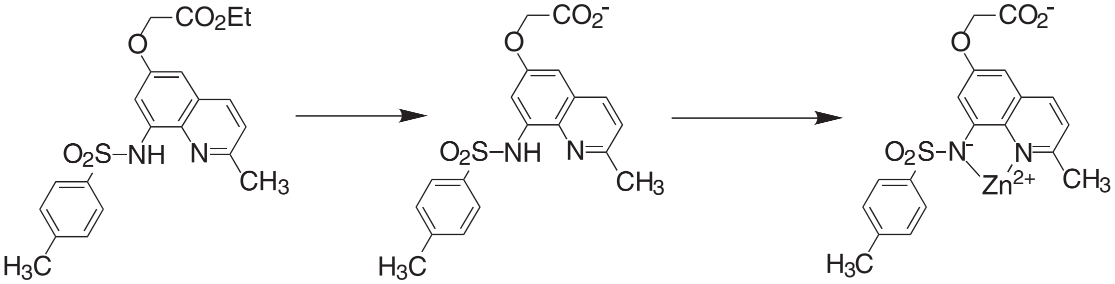
β-Diiminate zinc complexes are highly active catalysts in the copolymerization of epoxides and CO_2. Complexes that are catalytic are of the form ZnLX, where X is alkoxide, acetate, or bis(trimethylsilyl)amide. Changing the ligand geometries of the complexes allows variation in the catalytic behavior and activity.[941] The polymerization of lactide with diiminate zinc has also been studied.[942]

6.8.13.3 Fluorescent Detection of Zinc in Cellular Systems

A number of multidentate nitrogen donor ligands have been used in the detection of zinc in cellular systems. Zinc is the second most abundant transition metal in the brain. In the region of 90% of this zinc is bound to proteins but neurons have been shown to contain ionic zinc, with higher concentrations noted in the cerebral cortex and the limbic region.[943] There is a distinction between the detection of intracellular and extracellular zinc. A number of strategies have been described, from the simpler classical method of Timm's sulfide-silver stain[944] to protein- or peptide-based sensors. Kimura and Koike provide a review of progress in this area, with a particular focus on macrocyclic ligands.[945] The topic has also been more extensively reviewed by Burdette and Lippard.[946]

Detection of intracellular zinc ions is an important aim of biological studies in cell biology and neurology.[947–958] To clarify the role of zinc in neurotransmission, further study is required and ongoing in a number of research groups. Lippard and co-workers discuss the importance of zinc to the central nervous system and the form it is found in the brain, whether free ions or protein bound. In parts of the hippocampus pools of free zinc are found. As zinc can modulate ion channels it may play a role in a number of essential neurological processes and disorders. Levels of zinc in the body are regulated by zinc transport proteins and by metallothioneins, which are expressed mainly in the brain. Zinc can be released from synaptic vesicles and enter postsynaptic cells via voltage-dependent Ca^{II} channels.

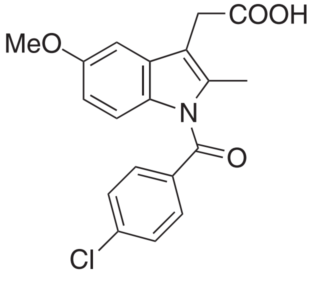
A number of strategies have been successfully pursued in the detection of zinc by fluorescence imaging with the use of proteins, peptides, and amine or macrocycle ligands with attached fluorophores.[948,956,957,959] As an example, a maltose binding protein has been converted into a zinc sensor via a process of rational design and the engineering of an increased affinity for zinc binding.[960] Quinoline-based probes have been used for the detection of intracellular zinc (Scheme 5). In particular, Zinquin, an arylsulfonamide derivative of 8-aminoquinoline, has shown, in a variety eukaryotic cells, 100 pM concentrations of intracellular zinc are revealed by a vesicle-like staining pattern.[961]



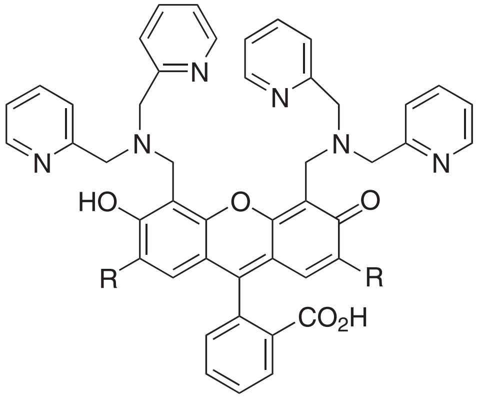
Scheme 5

Probes based on macrocyclic amines include dansylamidoethylcyclen, which can detect zinc at sub-nanomolar concentrations and probes containing xanthene as the chromophore with an ideal wavelength range for intracellular studies.[953,962] It is also important that the sensors can differentiate between the alkali metals, which are present at higher concentrations, and zinc. 2′,7′-dichlorofluorescein-based sensors have been used in biological systems and reveal concentrations up to ca. 0.3 mM in hippocampal nerve synaptic vesicles.[963]

Lippard and co-workers have developed zinc sensors for intracellular use based upon fluorescein, which has a number of attractive properties for sensor applications. The excitation and emission spectra of Lippard's zinpyr (**120**) compounds show ideal wavelengths for intracellular work and appropriate quantum yield and fluorescence enhancement.[946,947,958] The compound can bind two zinc ions but the 1:1 stoichiometry is responsible for the intensity increase with no change on binding the second zinc ion. The X-ray crystal structure of the zinc complexes was investigated. The structure of $[Zn_2L(H_2O)_2(ClO_4)_2]$ shows two zinc ions coordinated with each zinc trigonal–bipyramidal bound to the three nitrogen donors of one di-2-picolylamine arm, a phenolic oxygen, and a water molecule. The zinpyr compounds designed by Lippard and co-workers have shown improvements in the optical properties relative to other intracellular zinc sensors, attributed to the use of a fluorescein chromophore. They have demonstrated the potential for this system to monitor the intracellular zinc showing staining of the Golgi or



(**119**)



(**120**)

Golgi-associated vesicle. Further improvements in fluorescence enhancement on binding at physiological pH are a stated target for further research.

6.8.14 BIOLOGICAL CHEMISTRY OF ZINC

The increased knowledge of the role of zinc in biological systems has allowed study of the coordination chemistry of small-molecule mimics and the enzymes themselves.[964] A number of texts deal with biological aspects of zinc and zinc enzymes.[965–968]

Mimicry of some enzyme systems, such as alcohol dehydrogenase, carbonic anhydrase, Cu/Zn SOD, and phosphate diesterase, has already been discussed with the relevant ligands.

6.8.14.1 Zinc in Biological Systems (see Chapter 8.24)

The lack of zinc can also be a problem in biological systems and is responsible for disease states. For example, nitric oxide-dependent apoptosis can be induced in motor neurons by zinc-deficient SOD, and in some cases of amyotrophic lateral sclerosis, zinc-deficient SOD may participate in this type of oxidative mechanism involving nitric oxide.[969] One form of hereditary human hair loss or alopecia was mapped to a specific gene and a mutation found in affected individuals. The gene encodes a single zinc finger transcription factor protein with restricted expression in the brain and skin.[970] Zinc has been implicated in Alzheimer's via beta amyloid formation, and a role has been attributed for the cerebral zinc metabolism in the neuropathogenesis of Alzheimer's disease.[971]

The key roles for zinc in biological systems, particularly as structural components of a large number of proteins, are attributed to the ability to bind to a wide range of tetrahedral sites, lack of redox chemistry, and binding and exchange kinetics. The binding of zinc stabilizes the folded conformations of domains allowing interactions between the proteins and other biological molecules such as DNA.[3]

Zinc is present in presynaptic nerve terminals throughout the mammalian central nervous system and is thought to act as a modulator of synaptic transmission. Excessive exposure to extracellular zinc can damage central neurons. It has been demonstrated that zinc accumulates in degenerating neurons after ischemia, and that the accumulation occurs prior to neurodegeneration, offering therapeutic chelation possibilities. This toxic increase in zinc could be a key mechanism causing selective neuronal death after short ischemia.[972] Extracellular zinc concentration has also been shown to have a role in blocking aminobutyric acid-caused inhibition in a temporal mode epilepsy model. It is suggested that zinc is released from the terminals of certain granule cells during epileptic seizures.[973]

It has been demonstrated that extremely tight control is exhibited over the intracellular zinc concentrations by the metalloregulatory proteins controlling zinc homeostasis. It had previously been thought that intracellular zinc was available in a pool of free zinc ions in the micro- to picomolar concentration. An important study shows that these concentrations of free zinc are inconsistent with the concentrations required to trigger zinc uptake.[974]

The recruitment of zinc for a structural role, or to activate an enzyme, has been observed. The zinc ion induces the dimerization of human growth hormone (hGH), with two Zn ions associated per dimer of hGH. This is confirmed by replacement of possible zinc binding residues resulting in weakened binding of the zinc ion. Formation of a zinc–hGH dimeric complex may be important for storage of hGH in secretory granules.[975] In a toxic role, anthrax lethal factor is one of the three components of the secreted toxin and is a zinc-dependent protease that cleaves a protein kinase and causes lysis of macrophages.[976]

Many serine proteases are targets for therapeutic intervention because they often play key roles in disease. Potent and highly selective zinc-mediated serine protease inhibitors have been designed where the zinc binds to two residues from the enzyme active site and a chelating ligand from an administered drug, bis(5-amidino-2-benzimidazolyl)methane. This is an example where the drug or metal chelator is given and recruits a zinc atom physiologically.[922]

The importance of zinc may extend even further as the processes that control carbon uptake by marine phytoplankton are important in the carbon cycle, and the zinc enzyme carbonic anhydrase could be a limiting factor. The concentration of zinc available to some marine phytoplankton has been shown to affect bicarbonate uptake. It has been postulated that zinc levels may limit oceanic production and influence the global carbon cycle.[977]

6.8.14.2 Other Aspects of Zinc Enzyme and Protein Chemistry

Zinc is a constituent of over 300 enzymes with much research into the coordination of zinc to the protein backbone, and how its chemistry is modulated by the donor set and environment.[2] As well as the Lewis acid catalysis properties in enzymes, the structural role in zinc finger proteins has been a major area of research since the late 1990s. A number of reviews on zinc physiology, enzymology, and proteins in general have been published.[978–981] There is extensive analysis available to classify the mononuclear sites in zinc proteins and identification of structural relationships of the extended environment.[982,983]

The transport and storage of zinc has continued to be investigated with much work on metallothioneins. The oxidation of cysteine ligands in metallothioneins, and a possible role for selenium in the redox regulation of bound thiolates, are particular areas of interest.[984,985] The control of zinc transfer from metallothionein to zinc enzymes has been studied.[986] It is thought that thionein (apometallothionein) may participate in cellular regulatory processes. An effect of its enhanced synthesis *in vivo* could be reduction of the intracellular free zinc and modulation of zinc-dependent enzymes and proteins including zinc finger transcription proteins.[987] COM is a 62 amino acid protein that binds zinc via four cysteine residues. The specificity of binding and high relative affinity for zinc over cobalt were demonstrated.[988]

Theoretical calculations have been carried out on a number of zinc-containing enzymatic systems. For example, calculations on the mechanism of the Cu/Zn enzyme show the importance of the full protein environment to get an accurate description of the copper redox process, i.e., including the electronic effects of the zinc ion.[989] Transition structures at the active site of carbonic anhydrase have been the subject of *ab initio* calculations, in particular $[ZnOHCO_2]^+$, $[ZnHCO_3H_2O]^+$, and $[Zn(NH_3)_3HCO_3]^+$.[990]

Zinc is also used in biological studies to gain information about non-zinc containing systems. It can be a convenient redox inactive replacement for the study of complex systems with multiple redox centers. For example, the mechanism of quenching the triplet state of zinc cytochrome c by iron(II) and iron(III) cytochrome c has been studied. Zinc insertion has been used to get around the difficulty of studying two heme proteins with the same absorption spectra and provides rate constants for iron and iron-free cytochrome c quenching.[991]

Another stage in development is the engineering of zinc binding sites into proteins, for example, a zinc binding site of three histidines based on carbonic anhydrase has been engineered into a fluorescein-binding antibody and metal binding assessed by fluorescence quenching. Such compounds could potentially be useful for antibody catalysis with relatively few amino acid changes.[992]

Since their discovery in the 1980s, studies on how zinc fingers select and bind DNA and elucidate their role in switching on genes have been ongoing.[993,994] In particular, Berg and co-workers have carried out much research in this area.[995] Studies on metal binding specificity and kinetics of metal binding have been carried out with zinc finger peptides.[996,997] Pavletich *et al.* contributed an X-ray structure containing three zinc fingers bound to a DNA site.[998]

It has been suggested that two thiolates are required to maintain chelation of bound zinc to zinc finger proteins.[532,999] Electrospray ionization mass spectrometry investigations have shown that zinc bound to consensus peptide region of the three types of zinc finger arrays requires two deprotonated thiolates. Methylation studies showed that zinc could still be bound as long as two thiolate anions from cysteine side chains were present. The others could remain as thiols or be methylated without loss of chelating abilities.[999] A number of other mass spectrometry-based analyses of zinc finger proteins have been carried out.[1000,1001] The oxidation of zinc finger cysteines to thiolsulfinate has also been investigated.[1002]

Cadmium and Mercury

D. K. BREITINGER
University of Erlangen–Nürnberg, Erlangen, Germany

6.9.1 INTRODUCTION

6.9.1.1 Bibliography

This survey of the coordination chemistry of cadmium and mercury is based on, and continues, the reviews given in the first edition of this series.[1,2]

State-of-the-art overviews of the general chemistry of these elements are offered in recent editions of well-known textbooks.[3–5]

Periodical accounts of research in these fields are given in the Annual Reports on the Progress of Chemistry, Section A, Inorganic Chemistry.[6–17]

Accounts of the preparation, properties, characterization by physical methods and use of representative inorganic and organometallic compounds of cadmium and mercury have been published.[18,19]

References to reviews on special topics will be given where appropriate.

6.9.1.2 Scope of the Review

In a first part, experimental methods for studying formation, properties, structures and bonding in complex compounds of cadmium and mercury are briefly surveyed, usually with hints to reviews of the respective field and to examples of recent applications.

The growing importance of quantum-chemical calculations is dealt with in a short section, with emphasis on the consideration of relativistic effects, especially in systems containing mercury. These calculations aim at optimization of structures, determination of bond energies, simulation of spectra, and estimation of spectral parameters, independent of but complementary to experiments.

In the main part, dealing with complex compounds of cadmium and mercury, those with complicated organic ligands are not considered, neither are complexes with bio-relevance systematically described. However, it is unavoidable to address the formation of frameworks with the metals and certain organic ligands, and even seemingly simple compounds like $Cd(CN)_2$, especially in the presence of appropriate guest molecules, tend to form wide-pore host frameworks.

Organometallic compounds are considered only with strong restrictions, namely when organic ligands, e.g., methyl groups, are introduced to avoid formation of coordination polymers, as is the case with mononuclear metallo-onium complexes.

Typical solid-state systems like alloys, polynary halides, oxides, and higher chalcogenides (e.g., semi- and superconductors), and so on, are not included in this context.

Environmental aspects are not dealt with here; surveys on this topic are available in specialized compilations (see, e.g., refs. 20, 21).

6.9.2 METHODS FOR STUDYING FORMATION, PROPERTIES, STRUCTURES AND BONDING IN COMPLEX COMPOUNDS OF CADMIUM AND MERCURY

Experimental methods used for studies of Cd and Hg complexes in solution and in the solid state are reviewed briefly, with examples for the application of the method under discussion in recent work. In a separate section quantum-chemical studies, including consideration of relativistic effects, on existing and not-yet-existing species with Cd and/or Hg, are also surveyed.

6.9.2.1 Experimental Methods

6.9.2.1.1 UV/vis spectrometry, thermochemical and electrochemical techniques

Classical methods for the investigation of complex formation equilibria in solution (UV/Vis spectrometry, thermochemical and electrochemical techniques) are still in use (for an appraisal of these and other methods see, e.g., ref. 22). Examples for the determination of the ratio of metal to ligand in an Hg–protein complex by UV spectrometry are given in ref. 23, for the study of distributions of complex species of Cd in equilibria by combined UV spectrometry and potentiometry in ref. 24 and by potentiometry alone in ref. 25, and for the combination of calorimetry and potentiometry to obtain thermodynamic data in ref. 26.

6.9.2.1.2 NMR spectrometry

The growing importance of metal-nuclide NMR spectrometry, here of the nuclei ^{111}Cd, ^{113}Cd, and ^{199}Hg, is reflected in several reviews, from which only the more recent are mentioned;[27–32] the latter two references, with compilations of ^{199}Hg NMR data, are to be considered as complementary (solution and solid state).

Both of the nuclei ^{111}Cd and ^{113}Cd with spin $I = 1/2$, with similar abundances (12.75% and 12.26%, respectively) and receptivities (6.93 and 7.6 with reference to ^{13}C, respectively) are easily observed nowadays, but ^{113}Cd data are a bit more frequently reported in the literature. Chemical shifts $\delta(^{111,113}Cd)$ (usual references dimethylcadmium $Cd(CH_3)_2$ or 0.1 M aqueous solution of $Cd(ClO_4)_2$), coupling with other nuclei, e.g., ^1H, ^{13}C, ^{19}F, or ^{31}P, and temperature dependence of the NMR spectra provide insight into structure, bonding, and dynamics of Cd complexes in solution, whereas MAS-NMR spectra give informations on the complex species in the solid state.

With mercury only the nuclide ^{199}Hg ($I = 1/2$, abundance 16.84%, receptivity 5.42 re ^{13}C) is routinely measured, as ^{210}Hg ($I = 3/2$) with a large nuclear quadrupole moment can be painstakingly observed only under special conditions. Usually, dimethylmercury $Hg(CH_3)_2$, sometimes also aqueous $Hg(ClO_4)_2$ solution, are taken as references for the chemical shifts $\delta(^{199}Hg)$. Temperature-dependent NMR spectra of mercury compounds in solution reveal that exchange processes occur as in the corresponding cadmium species, sometimes more quickly, sometimes more slowly, depending on the ligands (appearance of heteronuclear couplings of the ^{199}Hg nuclei at lower temperatures, see e.g., ref. 33).

6.9.2.1.3 NQR spectrometry

In general, nuclear quadrupole resonance (NQR) spectrometry of solids with appropriate quadrupole nuclides yields information on electrical fields and field gradients, i.e., on charge distributions around these quadrupole nuclei, on molecular reorientations, and on fluxional behavior. Since the only quadrupole nuclide of interest here, namely ^{201}Hg (see above), has too low an abundance (13.22%), NQR spectrometry is not routinely applicable to this nucleus. However, mercury compounds containing, e.g., the halides Cl, Br, and I can readily be studied, since all naturally occurring nuclides of these elements ($^{35,37}Cl$, $^{79,81}Br$, ^{127}I) are “good” NQR nuclei. An instructive example for the study of fluxional behavior in solid pentachlorocyclopentadiene mercurials C_5Cl_5HgR by ^{35}Cl NQR, together with ^{13}C MAS NMR, is described.[34]

6.9.2.1.4 Diffraction methods on solids and solutions

Diffraction methods applied to crystalline coordination compounds in general—especially using X-rays, and to some extent also synchrotron radiation and neutrons—are now of paramount importance for the determination of structures. X-ray structure analysis on single crystals can now routinely be performed, even if special problems have to be solved again and again, e.g., treatment of twinning, determination of superstructures or of absolute configurations, analyses of disorder of different kinds. In the case of Cd, and even more with Hg compounds, special care has to be taken to reduce absorption by the proper choice of the wavelength and to perform the best possible absorption correction of the diffractometer data set. Even so, the location of light atoms besides mercury is not very accurate, due to the very different scattering power for X-rays. A remedy is provided by neutron diffraction, since the coherent scattering cross-sections for the light atoms and for mercury are similar and the absorption cross-section of Hg for neutrons is moderate (scattering cross-sections σ_{coh} for, e.g., N and Hg 11.01 and 20.24 barn (10^{-24} cm^2); absorption cross-sections σ_{abs} 1.90 and 372.3 barn, respectively).[35] A recommendable procedure nowadays is to determine the structure by X-ray diffraction (on single crystal or powder) and then to refine it on the basis of neutron powder diffraction data (Rietveld method). A generic survey and perspectives of the complementary use of X-ray and neutron diffraction is available[36], while one example for this combined structure determination is mercury cyanamide $HgCN_2$.[37]

Neutron diffraction on Cd compounds is not feasible, as one of the Cd nuclides (^{113}Cd) has an extremely high absorption cross-section for neutrons, yielding an average $\sigma_{abs}(Cd)$ of 2,520 barn (Cd metal is used for the shielding of neutron radiation).

X-ray diffraction also of solutions can provide insight into the structures of the dominating complexes present. A review outlines the experimental procedure and the processing of measured data in order to extract the structural information.[38]

6.9.2.1.5 X-ray absorption spectrometry

In order to gain information on the environments of certain atoms in dissolved species, in melts or in solids (crystalline or noncrystalline), which are not accessible to diffraction studies for one reason or another, X-ray absorption spectrometry (XAS) can be applied, with the analysis of the X-ray absorption near-edge structure (XANES) and/or the extended X-ray absorption fine structure (EXAFS). Surveys of these methods are available;[39,40] a representative study of the solvation of some mercury species, HgX_2, in water and dimethylsulfoxide (DMSO) by EXAFS and XANES, combined with quantum-chemical calculations, has been published.[41]

6.9.2.1.6 Photoelectron spectrometries

Charge distributions and bonding in compounds of Cd and Hg in the solid and gaseous states can be studied by the well-established X-ray photoelectron spectrometry (XPS) and ultraviolet photoelectron spectrometry (UPS), respectively. With XPS, inner-shell electrons are removed which are indirectly influenced by the bonding, i.e., distribution of the valence electrons. UPS sees this electron distribution directly, since it measures the residual kinetic energies of electrons removed from the valence shells of the atoms, or, better, from the outer occupied orbitals of the molecules. The most detailed information accessible by UPS is obtained on gases, and it is thus applied here to volatile compounds, i.e., to the halides mainly of Hg and to organometallic compounds.

6.9.2.1.7 Vibrational spectrometries

The equally well-established methods of optical vibrational spectrometry (IR and Raman), sometimes complemented by other methods, can answer quite different questions. Examples are studies of the solvation state of mercury halides HgX_2 in different solvents, and derivation of Lewis basicity or donor ability scales for these solvents based on the shift of the valence vibrations of dissolved HgX_2 molecules.[42,43] In another multimethod study (XANES, EXAFS, UV/Vis, IR, Raman) of the state of HgX_2 molecules occluded in several varieties of crystalline microporous silica (porosils), Raman spectra yielded information not only on the interactions between guest molecules and the host lattice, but also on the orientation of the HgX_2 guests;[44] in this case X-ray diffraction does not provide the information sought. In general, optical vibrational spectrometry, combined with inelastic neutron scattering where desirable and reasonable, gives hints as to the symmetry, structure, and bonding modes of complexes in dissolved and solid states, and yields the basis for force-field studies with empirical normal coordinate analyses. The valence force constants and their variations thus obtained are often a more sensitive measure for changing bond strengths than are differences in bond lengths.

6.9.2.1.8 Mass spectrometry

Mass spectrometry (MS) in its various forms, and with various procedures for vaporization and ionization, contributes to the identification and characterization of complex species by their isotopomer pattern of the intact ions (usually cation) and by their fragmentation pattern. Upon ionization by the rough electron impact (EI) the molecular peak often does not appear, in contrast to the more gentle field desorption (FD) or fast-atom bombardment (FAB) techniques. An even more gentle way is provided by the electrospray (ES) method, which allows all ionic species (optionally cationic or anionic) present in solution to be detected. Descriptions of ESMS and its application to selected problems are published;[45–47] also a representative application of this method in a study of phosphine–mercury complexes in solution is reported.[48]

6.9.2.2 Quantum-chemical Calculations

Progress in computer efficiency and in theory, especially with respect to relativistic effects in systems with heavy atoms, also led to an increasing number of quantum-chemical studies of cadmium- and mercury-containing species. These studies deal with apparently simple problems, like bonding in Hg_2,[49–51] and in increasing clusters Hg_n up to Hg_{40},[52] with calculation of NMR parameters in small organomercury species,[53] and with as-yet-hypothetical systems with Cd and Hg in the oxidation state +4.[54,55]

The primary effects of relativity are contraction and energetic stabilization of the 6*s* orbitals and expansion, destabilization, and spin-orbit splitting of the 5*d* orbitals, with consequences for the physical properties of the atoms and of the metals, and for bonding in their compounds; these effects are strongest with Au, slightly weaker with Pt and Hg.[56]

6.9.3 THE OCCURRENCE OF Cd AND Hg

Minerals dominated by cadmium are rare; the sulfide CdS (greenockite), especially, is very rarely found. However, cadmium is widespread in zinc ores in low concentrations (0.2–0.4%) and is separated during processing of these ores and production of zinc.

It is now established that cadmium, besides zinc, is accumulated in some native cysteine-rich proteins (e.g., metallothioneins) and the binding mode and sites in the protein are studied and largely understood.[57] Also, the detection and study of native Cd-enzymes and Cd-substituted Zn-enzymes is just beginning at the time of writing (for a short survey see ref. 58).

In contrast to cadmium, mercury occurs in various minerals—partly highly interesting in view of the mercury species present—and in enriched deposits. The most remarkable and important of these is the mine of Almadén, Spain, already known and exploited for cinnabar by the Romans, i.e., for more than two thousand years. Almadén still contributes about one-third of the world production of mercury. The geology and geochemistry of this region have been reviewed.[59] Recently, exploration in the Almadén district detected a new deposit, Nuevo Entredicho—even more remarkable in that the mercury content of this cinnabar/native mercury deposit locally rises up to 45% and that the deposit is actually monometallic, i.e., the HgS/Hg mixture contains other metals only at the trace level of some umpteen ppm, with lead reaching a maximum of more than 1,000 ppm in some parts. On the basis of the results of isotope analyses for sulfur and lead, conclusions on the geological and geochemical history of the deposit have been drawn.[60]

The common occurrence of a mercury(II) compound and metallic mercury in this and other deposits could lead to the secondary formation of minerals with mercury in lower oxidation states: for instance, in the intermediate oxidation state $+1\frac{1}{3}$ of the highly remarkable *triangulo*-Hg_3^{4+} entity in the minerals terlinguaite $(Hg_3)HgO_2Cl_2$[61–63] and kuznetsovite $(Hg_3)AsO_4Cl$;[64–66] or in the oxidation state +1 of the Hg_2^{2+} dumbbells in the long-known but only recently structurally studied mineral eglestonite $(Hg_2)_3Cl_3O_2H$,[67,68] in the newly found shakhovite $(Hg_2)_2Sb(OH)_3O_3$,[69,70] and in the deceptively simple-looking, but structurally complicated, poyarkovite Hg_3OCl (six independent Hg_2^{2+} groups!).[71]

Structural aspects of minerals and related synthetic materials with mercury in lower oxidation states and with oxocentered building blocks, OHg_n, have been reviewed.[72,73]

6.9.4 COORDINATION COMPOUNDS OF CADMIUM AND MERCURY

6.9.4.1 Higher Oxidation States of Cd and Hg; Quantum-chemical Studies

Some time ago experimental evidence for the electrochemical generation of a transient complexed Hg^{III} species was given,[74] but never since has an Hg^{III} compound been isolated and studied. Also, compounds with Hg^{IV}, corresponding to the well-known Au^{III}, have not yet been prepared.

With this situation in mind quantum-chemical calculations have been started, aiming at testing the possible existence of simple Hg^{IV} compounds, e.g., HgF_4,[54] and later on also of respective Zn and Cd species;[55] a complementary study was undertaken to confirm the questioned results of the former calculations.[75] As a result of these studies with comparative nonrelativistic and relativistic calculations, including electron correlation at different levels, HgF_4 (gas) can be considered to be thermodynamically stable (in contrast to ZnF_4 and CdF_4) with respect to decay into HgF_2 (gas) and F_2; a reaction energy (RE) of $+19\,kJ\,mol^{-1}$ (endothermic) has been recommended for $HgF_4 \rightarrow HgF_2 + F_2$.[75] A possible exothermic, gas-phase reaction yielding HgF_4 could be: $HgF_2 + KrF_2 \rightarrow HgF_4 + Kr$ ($RE = -94\,kJ\,mol^{-1}$).[54]

As expected, HgF_4 is square planar (cf. AuF_4^-), with a bond length r_e(Hg—F) = 188.4 pm[54,55] (189.1 pm[75]), optimized at the highest level. The bond lengths calculated at different levels, but always with consideration of relativistic effects, are shorter than those from nonrelativistic calculations (relativistic bond contraction). Reaction energies for the addition of F^- anions to HgF_4 and HgF_2, to yield HgF_5^-, HgF_6^{2-} and HgF_3^-, HgF_4^{2-}, respectively, have also been calculated, as well as the structures of these complex anions and of the dimers $(HgF_4)_2$ and $(HgF_2)_2$.[55,76] Calculated vibrational frequencies of the above neutral monomers and dimers should assist in the future identification of the products of the suggested fluorination reaction by vibrational spectrometry.[54,55] Totally symmetric harmonic frequencies of HgF_4 and HgF_2, calculated at various levels, are also reported[75].

Finally, calculations for $HgCl_2$ and $HgCl_4$ show unequivocally that the latter is rather unstable (strongly negative atomization energy).[75]

6.9.4.2 The +2 Oxidation States of Cd and Hg

6.9.4.2.1 Compounds with donor atom C

(i) Carbonyl complexes

In a most remarkable reaction, a solution of $Hg(SO_3F)_2$ in liquid SbF_5 at 80 °C absorbs gaseous CO (500–800 mbar) to yield colorless bis(carbonyl)mercury(II) undecafluorodiantimonate(V), $[Hg(CO)_2][Sb_2F_{11}]_2$ (recrystallization from magic acid, HSO_3F/SbF_5!); similarly, the corresponding dimercury(I) compound, $[Hg_2(CO)_2][Sb_2F_{11}]_2$, has been obtained also.[77,78] The Hg^{II} compound is thermally stable up to 160 °C; the Hg_2^{I} compound decomposes earlier. In the IR and Raman spectra of $[Hg(CO)_2][Sb_2F_{11}]_2$ the ν(CO) vibrations appear at $2,278\,cm^{-1}$ and $2,281\,cm^{-1}$, respectively (force constant f_r $21.0 \times 10^2\,N\,m^{-1}$); these are so far the highest ν(CO) values for any metal carbonyl complex. An IR band at $335\,cm^{-1}$ is assigned to ν_{as}(HgC). Evaluation of the ^{13}C-MAS-NMR spectrum of the ^{13}C-labeled isotopomer yields $\delta(^{13}C)$ 168.8 ppm, and the extraordinarily high $^1J(^{199}Hg,^{13}C)$ of 5,219 Hz. X-ray structure analysis (195 K; $P2_1/n$, $Z = 2$) reveals a centrosymmetric, slightly kinked $[Hg(CO)_2]^{2+}$ cation (r(Hg—C) 208.3, r(C—O) 110.4 pm; α(Hg—C—O) 177.7°), with the counteranions on general positions. Secondary bonds F···Hg (259.5 pm and 269.1 pm) complete the coordination around Hg to distorted octahedral and link the lattice constituents; contacts F···C shorter than the sum of the van der Waals' radii contribute to the stabilization of the compound. The collected data suggest a relatively weak, σ-only Hg—C bond with no π-back bonding, and therefore a strong C—O bond.

(ii) Acetylides

Compounds $A_2Cd(C{\equiv}CH)_4$ (A = Rb and Cs) (space group $I\,4_1/a$, isotypic to $K_2Cd(C{\equiv}CH)_4$), obtained from the acetylides AC_2H and $Cd(SCN)_2$ in liquid NH_3, contain complex anions with symmetry $\bar{4} - S_4$.[79] Also, an ammoniate $K_2Cd(C{\equiv}CH)_4{\cdot}2NH_3$ has been prepared and its structure determined (r_{av}(Cd—C) 224.0 pm (average), r_{av}(C≡C) 119.0 pm). A neutral heteroleptic Cd complex $[Cd(C{\equiv}CPh)_2tmen]$ (tmen = tetramethylethylendiamine) has been obtained by reacting $Cd[N(SiMe_3)_2]$ with Li-phenylacetylide PhC≡CLi and tmen in toluene, and its structure solved: Cd has a distorted tetrahedral environment with r_{av}(Cd—C) 214.1 pm (average), r_{av}(C≡C) 120.8 pm and a wide α(C—Cd—C) 142.8°; in contrast, the bite-angle of the tmen ligand is small, α(N—Cd—N) 76.16° (r_{av}(Cd—N) 245.4 pm).[80] In a related Hg compound $[Hg(C{\equiv}CPh)_2phen]$ (phen = 1,10-phenanthroline), the angle α(C—Hg—C), 165.6°, is even wider and tends to a linear arrangement.[81] The long-known, uncomplexed $Hg(C{\equiv}CPh)_2$ and also $Hg(C{\equiv}CSiMe_3)_2$ have been prepared in a crystalline form appropriate for X-ray structure analyses.[82] Both of these compounds crystallize in huge unit cells, with eight and five independent quasi-linear molecules, respectively, with r_{av}(Hg—C) 200 pm in both cases, and slightly different r_{av}(C≡C), 119 pm and 122 pm, respectively. The peculiarity in both structures is aggregation of these eight and five molecules by 'mercuriophilic' interaction, i.e., weak attraction between the Hg atoms with Hg···Hg distances in the ranges 375 up to 425 pm, and 376–407 pm, respectively. With a new value for the van der Waals' radius of Hg of 200 pm,[83,84] the limit for attraction between Hg atoms would be at a distance of ~400 pm. Closer inspection reveals that there are also intermolecular contacts $Hg\cdots C_2$ of 330–370 pm (sum of the van der Waals' radii of Hg and C ~ 370 pm). Thus, aggregation of the molecules is probably a cooperative effect of both Hg···Hg and $Hg\cdots C_2$ interactions.

For $Hg(C{\equiv}CPh)_2$ and for other symmetrical, as well as asymmetrical, alkynyl mercury compounds R′—Hg—C≡CR and R′—Hg—C≡C—Hg—R′, multinuclear NMR measurements (^1H, ^{13}C, ^{199}Hg) have been performed;[85] especially both the solvent and temperature dependencies of the $\delta(^{199}Hg)$ data of $Hg(C{\equiv}CPh)_2$ have been carefully measured. Also, $Hg(C{\equiv}CSiMe_3)_2$, other silylalkynyl mercurials $R'{-}Hg{-}C{\equiv}CSiMe_3$, and various trimethylsilyl mercury compounds have been studied by ^{13}C, ^{29}Si, and ^{199}Hg NMR.[86] The $\delta(^{199}Hg)$ values proved to be remarkably sensitive to changes in R′, but also in the more remote substituents R of the alkynyl ligands; also the coupling constants $^1J(^{199}Hg,^{13}C{\equiv})$ span a wide range, from 650 to almost 3,000 Hz.

(iii) Cyanides

Investigations of cyanides and cyano complexes of Cd and Hg have augmented tremendously since about 1990, after detection of inclusion compounds of $Cd(CN)_2$. A thorough review on transition-metal cyanides especially emphasizes the chemistry of inclusion compounds of both the Hofmann type (frameworks dominated by planar $Ni(CN)_4$ building blocks) and the cyanocadmate type (frameworks with tetrahedral $Cd(CN)_4$ units).[87] The structures of these inclusion compounds, but also of cyanides themselves, often topologically resemble the structures of minerals; this aspect ('mineralomimetic chemistry') is dealt with in a simultaneous survey.[88] A more generic review of framework structures, with a section on cyanide inclusion compounds, is also to be mentioned.[90]

The structure of $Cd(CN)_2$ (and of the isomorphous $Zn(CN)_2$) has been determined by state-of-the-art techniques;[91] $Cd(CN)_2$ adopts the *anti*-cuprite structure (cuprite Cu_2O, space group $P\bar{4}3m$) with two interpenetrating, independent, diamond-type frameworks (with respect to the composition frameworks related to the high-cristobalite (Hc) form of SiO_2). This space group implies two independent Cd atoms with ordered orientation of the CN bridges, i.e., distinct CdC_4 and CdN_4 entities (r(Cd—C) 209.9(5), r(Cd—N) 219.6(4), r(C—N) 116.2(5) pm). However, ^{113}Cd MAS NMR of $Cd(CN)_2$ displays five signals with different intensities, assigned to CdC_4, CdC_3N, CdC_2N_2, $CdCN_3$, and CdN_4 species (upfield sequence), indicating static disorder of the CN groups aligned between adjacent Cd atoms; the species CdC_2N_2 seemingly has some preference compared with a purely statistical distribution.[92] Consequently, the space group should be changed to $Pn3m$, allowing for orientational disorder, as has been confirmed by a redetermination of the structures of $Zn(CN)_2$ and $Cd(CN)_2$ (r_{av}(Cd—C,N) 216.9(9), r_{av}(C—N) 114.3(19) pm).[93]

As mentioned above $Cd(CN)_2$ itself, and related materials with partial or full substitution of Cd by other transition or post-transition metals, e.g., Zn or Hg, form a huge and still-increasing number of inclusion compounds $Cd(CN)_2{\cdot}x\ G$ (G = guest molecule). In just three papers, no fewer than twenty such clathrates and their structures are described.[93–95] Basically, in the clathrates one of the two frameworks of the mother-structure is retained as the host lattice, and its voids are filled with the guest molecules. In most of the cases the host lattice resembles one of the H-, L-cristobalite, H- or L-tridymite forms of SiO_2; a case with a framework intermediate between H- and L-cristobalite has also been found.[96] A systematic representation of these and of other clathrates structurally related to clay and zeolithe minerals is already developed.[88] A special case is met with $Cd(CN)_2{\cdot}2/3\ H_2O{\cdot}t\text{-}BuOH$, in which tetrahedrally and octahedrally coordinated Cd (ratio $Cd_{tet}{:}Cd_{oct} = 2{:}1$) form a honeycomb framework with pseudohexagonal channels hosting the guest molecules *t*-BuOH.[97–99] Below 240 K a phase transition with doubling of the unit cell occurs, obviously due to ordering of the guest molecules and of the hydrogen-bond system between the H_2O coordinated to Cd_{oct} and the *t*-BuOH molecules.[99] Phase transitions of clathrates at low temperatures with ordering of the guest molecules (e.g., $HCCl_3$, $HCBr_3$, and the like) have also been observed by means of temperature-dependent IR, Raman, and ^2H NMR spectrometry.[100] A short survey of the most important clathrate types involving $Cd(CN)_2$ is provided by Table 1 (modified after ref. 88). Vibrational spectra of benzene clathrates of the type $Cd(ND)_nM(CN)_4{\cdot}2\ C_6H_6$ (ND heterocyclic N-donor such as pyrazine or adenine, $n = 1$, 2; M = Cd, Hg) have been discussed.[101,102]

Table 1 Types of $Cd(CN)_2$ and related clathrates, space groups and examples.

Clathrate	*Host lattice*	*Space group*	*Examples for G*
$Cd(CN)_2 \cdot G$	Hc[a]	$Fd3m$	CCl_4, CMe_4
$Cd(CN)_2 \cdot 0.5\ G$	Hc	$Fd3m$	i-Bu_2O
$Cd(CN)_2 \cdot G$	Lc	$P4_1(4_3)2_12$	$CHCl_2CH_2Cl$
$Cd(CN)_2 \cdot G$	H/Lc	$I4_1/amd$	CH_2BrCH_2Br
$Cd(CN)_2 \cdot 0.5\ G$	Ht	$P6_3/mmc$	n-$Bu_2O \cdot H_2O$
$Cd(CN)_2 \cdot 2/3\ H_2O \cdot G$	special type	$Cmmm$ (r.t.) $Pbcm$ (<230 K)	t-BuOH
$[CdZn(CN)_4] \cdot 2\ G$	Hc	$Fd3m$	CCl_4
$[CdHg(CN)_4] \cdot 2\ G$	Hc	$Fd3m$	CCl_4

[a] Hc high cristobalite, Lc low cristobalite, H/l intermediate between Hc and Lc, Ht high tridymite.

$Hg(CN)_2$ in the solid state has a structure ($I\bar{4}2d$; neutron diffraction), completely different from that of $Cd(CN)_2$: Almost-linear molecules (r(Hg—C) 201.9, r(C—N) 116.0 pm (corrected for thermal motion); α(C—Hg—C) 175.0°) are arranged such that four secondary bonds N···Hg (274.2 pm) yield the often-occurring $2+4$ coordination around Hg.[103] Analysis of the ^{199}Hg MAS NMR spectrum of $Hg(CN)_2$ has yielded the chemical shift and shielding tensor parameters.[104]

Several quantum-chemical studies have been performed on $Hg(CN)_2$ and related species, applying different approaches with consideration of relativistic effects in order to get MO schemes and energies as a basis for discussion of bonding, valence XPS,[105] UPS,[106] XANES and EXAFS spectra.[41] The latter study also showed $Hg(CN)_2$ to be dissolved in H_2O in molecular form (r(Hg—C) 202, r(C—N) 114 pm), and obviously not to be hydrated, a remarkable finding insofar as solvates of $Hg(CN)_2$ with various donor molecules are well known.[2] However, in contrast to $Cd(CN)_2$ (see above), $Hg(CN)_2$ as such does not form clathrates.

Also, in complex compounds of the types $AHg(CN)_2X$ or $A_2Hg(CN)_2X_2$ (cf. ref. 2), almost unperturbed $Hg(CN)_2$ units are present. In a recent example, $[NH_3Et]_2Hg(CN)_2Cl_2$, ($A2/a$), the $Hg(CN)_2$ molecules (r(Hg—C) 206.4, r(C—N) 111 pm) are inserted in half of the meshes of a near-tetragonal net of Cl^- anions with weak Cl···Hg interactions (distances 2×290.1, 2×343.2 pm).[107] In a comproportionation reaction $Hg(CN)_2$ and $Hg(OAc)_2$ (OAc = acetate) readily form crystalline Hg(CN)(OAc). The structure ($P2_1/c$) contains two independent molecules with unidentate OAc and almost linear arrangements NC—Hg—OAc (r_{av}(Hg—C) 201.8, r_{av}(Hg—O) 206.3, r_{av}(C—N) 115 pm; α_{av}(C—Hg—O) 174.2°); secondary bonds O···Hg and N···Hg (range ~260–280 pm) yield a distorted $2+4$ coordination around Hg. IR and Raman bands below 500 cm^{-1} have been assigned to skeletal valence and deformation modes. $\delta_{iso}(^{199}Hg)$ of this compound lies upfield from that of $Hg(CN)_2$.[104]

In an admirable microwave study of methylmercury cyanide, H_3CHgCN (five isotopomers), the structural parameters have been obtained with high precision (data for substitution structure: $r_s(H_3C$—Hg) 205.63(1), r_s(Hg—CN) 203.69(2), r_s(C—N) 115.70(2) pm); the dipole moment is high, $\mu = 4.69(4)$ D.[108]

The tetrahedral $Cd(CN)_4$ building block present in $Cd(CN)_2$ and its clathrates also occurs in $K_2Cd(CN)_4$, crystallizing in the spinel structure ($Fd\bar{3}m$); here, the anion has full tetrahedral symmetry ($\bar{4}3m - T_d$), with r(Cd—C) 222.5(3) and r(C—N) 111.3(3) pm.[109]

From $K_2Cd(CN)_4$, $CdCl_2$, and $[PPh_4]Br$ under controlled conditions (pH, solvent mixture, temperature), $[PPh_4]_3[Cd_2(CN)_7]$ ($R\bar{3}c$) is obtained with the anion analogous to disilicate $Si_2O_7^{6-}$; this anion has staggered conformation and a disordered bridging CN group,[110] as required by crystallography. This reaction is the first step to catenation and the formation of oligomeric and polymeric cyanocadmates. As a consequence, the end member of this catenation exists in $[SbPh_4][Cd(CN)_3]$ with a chain anion $_\infty{}^1[Cd(CN)_3]^-$, analogous to the ino-silicate $_\infty{}^1[SiO_3]^{2-}$ in pyroxenes.[111] Further analogies between cyanocadmates and silicates are discussed in the survey already mentioned.[88] Recently, polycyano-polycadmate host clathrates, including the methylviologen (1,1′-dimethyl-4,4′-bipyridinum) dication, have been obtained which adopt 3-D framework structures related to zeolithes with different kinds of cavities, depending on the guest molecules; altogether a dozen such structures have been classified into five structural types on the basis of the shapes of the cavities (cages, channels, 3-D cavities).[89]

The long-known $K_2Hg(CN)_4$ and related compounds are still the object of structural studies. Thus, a neutron-diffraction study confirmed the spinel structure of $K_2Hg(CN)_4$ at room temperature (298 K) with exactly tetrahedral anions, $Hg(CN)_4{}^{2-}$ (r(Hg—C) 215.2, r(C—N) 114.9 pm).[112]

Remarkably, the Hg—C bonds are shorter than the Cd—C bonds in the respective cyano-spinel;[109] the probable reason is relativistic bond contraction with the Hg atom.

Also known for some time is a phase transition at low temperature (111 K), observed in studies with various methods (NQR, elasticity measurement by ultrasound, Raman spectrometry);[112] temperature-dependent neutron diffraction showed the phase transition to be caused by an antiphase rotation of adjacent anions around the threefold axis ([111] in the cubic cell) and to lower the symmetry from cubic to rhombohedral ($R\bar{3}c$). As shown by inelastic neutron scattering, this phase transition is driven by a low-frequency rotatory soft mode (0.288 THz $= 9.61\,\mathrm{cm}^{-1}/298\,\mathrm{K}$);[113] a more recent NQR study revealed a small hysteresis and hence first-order character of this transition.[114] This rhombohedral structure is adopted by $Rb_2Hg(CN)_4$ already at room temperature (r_{av}(Hg—C) 218.6, r_{av}(C—N) 114.0 pm for two independent cyano groups), and the analogous phase transition to the cubic structure occurs at 398 K.[115]

$K_2Hg(CN)_4$ and the crown ether dibenzo-18-crown-6 in aqueous ethanol yield the crystalline $[K(C_{20}H_{24}O_6)]_2[Hg(CN)_4]\cdot 2H_2O$; the structure contains two independent potassium-crown complexes and a distorted tetrahedral $Hg(CN)_4$ entity (r_{av}(Hg—C) 218.4, r_{av}(C—N) 112.3 pm) which coordinates to one of the complexed K ions through one of the CN ligands (slight lengthening of the C—N bond).[116]

For $K_2Hg(CN)_4$ in aqueous solution, ^{199}Hg NMR indicates deshielding on complexation ($\delta(^{199}\mathrm{Hg})$ −502 vs. −1021 ppm for $Hg(CN)_2$; reference 90% $HgMe_2$/10% C_6F_6).[117]

Quaternary cyanomercurates $NR_4[MHg(CN)_4]$ (R = Et, Pr; M = Li, Na, K, Cu) at higher temperatures adopt cubic framework structures ($F\bar{4}3m$) topologically related to cristobalite, with tetrahedral surroundings of both M and Hg and ordered cyano groups (M—NC—Hg); the cations are located in the cavities.[118,119] These compounds undergo reversible phase transitions (first order, displacive) to tetragonal ($I\bar{4}$) studied by DTA/DSC, X-ray diffraction, Raman and MAS NMR spectrometries, with transition temperatures depending on R and M.[120]

The thermal behavior and degradation of the sulfonium tetracyanometallates $(R_2R'S)[M(CN)_4]$ (R = R′ = Me and R = Me, R′ = Ph; M = Cd, Hg) and the degradation products (IR spectra) have been studied.[121,122]

(iv) Fulminates

In contrast to cyanides, for fulminates just a handful of papers has appeared in the period to be reviewed and only one is relevant here, namely on the structure of a tetrafulminatomercurate $[AsPh_4]_2[Hg(CNO)_4]$.[123] Seemingly the compound is quite stable, since the authors mention that the crystals used for X-ray structure analysis were 35 years old! The compound ($C2/c$) contains distorted tetrahedral anions (site symmetry $2 - C2$) with one angle α(C—Hg—C) widened to 118.4° and the opposite angle compressed to 101.8° (packing effects); the two independent Hg—C bonds are significantly different (average 218.7 pm) and the Hg—C—N—O groups nearly, but not fully, collinear. Recent DFT calculations with a quasirelativistic pseudopotential for mercury yielded structural parameters and vibrational frequencies of the free $[Hg(CNO)_4]^{2-}$ anion (idealized symmetry $\bar{4}3m - T_d$) which agree pretty well with the experimental data.[124]

6.9.4.2.2 *Compounds with donor atoms Si and Ge*

Recently, the crystal structure of bis(trimethylsilyl)mercury $Hg(SiMe_3)_2$ (by reaction of Me_3SiCl with Na/Hg) has been redetermined.[125] The most remarkable finding is the formation of dimers by "mercuriophilic" attraction with a distance r(Hg···Hg) of 314.6 pm, i.e., shorter than twice the van der Waals' radius of Hg (see the discussion in Section 6.9.4.2.1(i)); the axes of the two quasilinear molecules in the dimers are approximately perpendicular to each other. Otherwise, the bond lengths are r(Hg—Si) 249.13(18) and r(Si—C) 186.6(8) pm; the angles α(Hg—Si—C), 111.9°, are widened and α(C—Si—C), 107.4°, compressed.

In $Li_2Hg(SiMe_3)_4$ and $Li_2Hg(SiMe_2Ph)_4$ (simplified from the respective disilyl mercury compounds and lithium metal), both crystallizing in $C2/c$, the basically tetrahedral ate species are distorted by interaction with, and linking by, lithium.[126] The Hg—Si bonds (r_{av}(Hg—Si) 254.4 pm and 252.1 pm, respectively) are slightly longer than in $Hg(SiMe_3)_2$, as might be expected.

NMR data for $Hg(SiMe_3)_2$ in different solvents have been compiled and discussed,[86,117] as well as data for asymmetric mercurials $RHgSiMe_3$[86] and for compounds with simple SiH_3 and mixed silyl groups ($SiMe_{3-x}R_x$); even data for the ate complexes $LiHg(SiMe_3)_3$ and $Li_2Hg(SiMe_2Ph)_4$

and for germyl species $Me_3SiHgGeH_3$ and $Hg(GeH_3)_2$ are presented.[117] Substitution of one $SiMe_3$ group in $Hg(SiMe_3)_2$ by alkyl groups R increases the shielding of the Hg nuclei (negative shift of $\delta(^{199}Hg)$); a similar effect is brought about by substitution with SiH_3 and even more strongly with GeH_3. The extremes on the $\delta(^{199}Hg)$ scale for silyl mercury compounds are $Li_2Hg(SiMe_2Ph)_4$, (1,681 ppm, the least shielded) and $Hg(SiCl_3)_2$ (−1,177 ppm in dimethoxyethane DME, the most shielded).[117] As a rule of thumb the coupling constants $^1J(^{199}Hg,^{29}Si)$, where observed, also increase with increasing shielding (maximum 3,864 Hz for $Hg(SiCl_3)_2$).

In recent years, the chemistry of compounds with tris(trimethylsilyl)silyl groups $Si(SiMe_3)_3$ ("hypersilyl" group[127]) has been expanded. For bis(hypersilyl)cadmium and -mercury, $M[Si(SiMe_3)_3]_2$ (M = Cd, Hg), the crystal structures have been solved and low-frequency vibrational spectra measured and discussed.[128] In the isomorphous compounds ($P\overline{1}$, $Z = 1$) the molecules, since centrosymmetric, have an exactly linear arrangement Si—M—Si and staggered conformation. Again, the Hg—Si bonds (246.9(2) pm) are significantly shorter than the Cd—Si bonds (250.4(1) pm) (relativistic bond contraction), the Si—Si bonds show only small scatter (r_{av}(Si—Si) 233.2 pm); in both compounds the very similar angles α(Si—Si—Si) are widened (total average 112.5°) at the expense of the angles α(M—Si—Si) (106.3°), probably as a consequence of steric interaction (compare the contrasting findings with $Hg(SiMe_3)_2$).

^1H, ^{13}C, and ^{29}Si NMR, as well as UV/Vis data (λ_{max}, ε_{max}), have been reported for all $M[Si(SiMe_3)_3]_2$ (M = Zn, Cd, Hg) (also the crystal structure for M = Zn, isomorphous with the above compounds).[129] The ^{29}Si resonances move to lower field (decreasing shielding) in the series Zn > Cd > Hg: as expected, more pronounced for Si immediately bound to M; the UV absorption maxima move to lower wavenumbers. For M = Hg alone $\delta(^{199}Hg)$ and $^1J(^{199}Hg,^{29}Si)$ have been reported; as compared with $Hg(SiMe_3)_2$ δ moves downfield (987 vs. 499 ppm, deshielding) and ^1J decreases (432 vs. 981 Hz) under the same conditions.[117]

From CdI_2 and $LiTt(SiMe_3)_3$ (Tt = Si, Ge) in the presence of thf, the tris(μ-iodo)bis[tris(trimethylsilyl)tetrylcadmate] $[Li(thf)4][(Me_3Si)_3TtCdI_3CdTt(SiMe_3)_3]$ are obtained (IR and ^1H NMR data); an X-ray structure analysis of the Ge compound (*Cmcm*, $Z = 4$) has been performed.[130] In the anion (symmetry $mm2 - C_{2v}$) one of the bridging I atoms, the Cd, germanium, and two of the Si atoms are all lying in the same mirror plane, with the remaining two I atoms in the mirror plane orthogonal to the first one. The bond length r(Cd—Ge) is 253.3 pm (no reference data are given) and the distances in the symmetrical bridges r(Cd—I) 293.1 pm and 295.3 pm, respectively. The angles around Cd deviate considerably from the ideal tetrahedral angles (α_{av}(germanium—Cd—I) 124.7 and α_{av}(I—Cd—I) 90.8°) caused by the steric demands of the $Ge(SiMe_3)_3$ ligands.

6.9.4.2.3 Compounds with donor atom N

The large group of compounds with cadmium– and mercury–nitrogen bonds can be subdivided into two sections, one with amide ligands derived from molecules with acidic hydrogen or electropositive leaving groups attached to nitrogen, the other one with amine ligands just coordinated to the metal, with the option of further metal substitution on the bonded ligands. In the former case isolated mononuclear, but also oligonuclear complexes may be formed; in the latter case progressive substitution may lead to formation of 2-D or 3-D networks. With amides nitrogen is often three-coordinate, but secondary bonds between N and the metals, sometimes additional metals, can make things more complicated; with amine complexes tetra-coordinate nitrogen is always present.

Analogous considerations also apply to ligands with phosphorus and the other elements of the pentel group.

A special situation is met in systems containing Cd or Hg combined with cyano-complexes of other elements. In these cases, the coordination sphere of Cd or Hg is fully or partly made up of the N-ends of cyano-groups C-bonded to another metal.

(i) Amides

Among the simplest metal amides are the cyanamides $CdCN_2$[131] (from $CdCl_2$ and H_2NCN/NaOH in aqueous solution at pH 12.5/350 K)[132] and $HgCN_2$ (from $HgCl_2$ and H_2NCN/NaOH in aqueous solution).[37] In $CdCN_2$ ($R\overline{3}m$ or $R3m$, $Z = 3$; from X-ray powder data) Cd is surrounded by six equidistant N atoms (r(Cd—N) 238.0 pm) of the N—C—N groups, which are aligned along the threefold axes and symmetrical in $R\bar{3}m$, but asymmetrical in $R3m$.[132] The authors prefer the noncentrosymmetric structure with reference to the IR spectrum, but the arguments for this choice are not convincing.

The structure of $\mathrm{HgCN_2}$ ($Pbca$, $Z = 8$; from combined X-ray and neutron powder data)[37] contains zigzag chains $_{\infty}^{1}[\mathrm{Hg(NCN)_{2/2}}]$ (Hg atoms bonded to both ends of NCN: $\mu_{1,3}$-NCN bridges) with r_{av}(Hg—N) 206.5 pm, r_{av}(C—N) 122.2 pm, and α_{av}(Hg—N—C) 117.5. The fragments N—Hg—N and N—C—N are almost symmetrical and only slightly bent; thus, the compound is rather to be considered as a carbodiimide than as a cyanamide. Four secondary bonds N···Hg (r_{av}(Hg···N) 278.5 pm) between adjacent chains complete the coordination sphere of Hg to distorted octahedral (2 + 4). As shown by X-ray diffraction and Raman spectrometry, $\mathrm{HgCN_2}$ decomposes under pressure (diamond-anvil cell), starting at about 1.9 GPa, to give first rhombohedral α-Hg ($R\bar{3}m$) and then tetragonal β-Hg ($I4/mmm$) ($p \geq 7$ GPa).[133]

From the same educts, but under controlled-pH conditions (pH kept constant at ~6) a second, monoclinic form of $\mathrm{HgCN_2}$ is obtained ($\mathrm{HgCN_2}$(II), $P2_1/a$, $Z = 4$; again from combined X-ray and neutron powder data).[134] In this case again zigzag chains are found, but now with two Hg atoms covalently bonded to one end of the N—C—N fragment ($\mu_{1,1}$-NCN bridges) (r_{av}(Hg—N) 208.1 pm) with the consequence of clearly different C—N bonds (r(C—N) 135.3/112.0 pm; single/triple bond), i.e., $\mathrm{HgCN_2}$(II) is a true cyanamide; the N—C—N fragment deviates considerably from linearity (α(N—C—N) 160.7°). The interlocked arrangement of the chains to form layers also leads to four secondary bonds N···Hg, involving the 'free' ends of the N—C—N entities ($265 \leq r(\mathrm{Hg\cdots N}) \leq 296$ pm). Quantum-chemical calculations at three different levels always indicate $\mathrm{HgCN_2}$(II) to be less stable than the orthorhombic $\mathrm{HgCN_2}$(I), but a transition $\mathrm{HgCN_2(II)} \rightarrow \mathrm{HgCN_2H(I)}$ on heating is not observed prior to decomposition (~230 °C). To conclude, $\mathrm{HgCN_2}$(II) seems to be a metastable phase formed under kinetic control, with a high barrier to conversion into the thermodynamically stable $\mathrm{HgCN_2}$(I).

On diffusion of separated dilute aqueous solutions of $\mathrm{HgCl_2}$ and $\mathrm{H_2NCN}$ through a ceramic filter, besides the above $\mathrm{HgCN_2H}$(II) also two new crystalline phases $\mathrm{Hg_2(NCN)Cl_2}$ and $\mathrm{Hg_3(NCN)_2Cl_2}$ are formed; the former crystallizes in $P2_1/c$ ($Z = 4$), the latter in $Pca2_1$ ($Z = 4$).[135] Both compounds contain zigzag chains $_{\infty}^{1}[\mathrm{Hg(NCN)_{2/2}}]$, like those in $\mathrm{HgCN_2H}$(I), linked by additional Hg atoms to form 2-D networks $_{\infty}^{2}[\mathrm{Hg_3(NCN)_2}]^{2+}$, with 20-membered rings. The Hg—N bonds are similar in both cases, with a larger scatter in the latter one (r_{av}(Hg—N) 207.0 pm and 210.5 pm, respectively). In the first case the N—C—N entity has carbodiimide character (r_{av}(C—N) 123 pm); in the other one two independent N—C—N groups are also different in bonding, the one tending to carbodiimide (r_{av}(C—N) 122 pm), the other one to cyanamide (r(C—N) 113 pm and 128 pm). In both compounds two additional $\mathrm{Cl^-}$ ions form secondary bonds to the linking Hg atoms (r(Hg···Cl) 296.9 pm and 285.6 pm, respectively); in the first one an additional, exactly linear $\mathrm{HgCl_2}$ molecule is occluded in the meshes of the network. Thus, the formulae should reasonably have been written $[\mathrm{Hg_3(NCN)_2}]\mathrm{Cl_2{\cdot}HgCl_2}$ and $[\mathrm{Hg_3(NCN)_2}]\mathrm{Cl_2}$, respectively.

Homo- and heteroleptic complexes of Cd alone[136,137] and of Cd and Hg[138] with the ligand dicyanamide (dca) $\mathrm{N(CN)_2}^-$, homologous to cyanamide $\mathrm{NCN^{2-}}$, have been studied in various solvents (formation constants of the complexes $[\mathrm{M(dca)}_n]^{(n-2)}$ (M = Cd, Hg; $1 \leq n \leq 4$)), with the result that the complexes of Hg are more stable than those of Cd. Otherwise, obviously no studies on the isolated compounds $\mathrm{M(dca)_2}$ or on homoleptic complexes derived therefrom have been published.

Some heteroleptic Cd-dca complexes with exciting structures have been studied very recently, the simplest being the coordination polymer $[\mathrm{Cd}(\mu_{1,5}\text{-dca})_2(\mathrm{py})_2]_n$ (py = pyridine; $C2/m$, Z = 2).[139] Here, double end-to-end dicyanamide bridges N—C—N—C—N link the octahedral Cd centers to form chains or flat ribbons, with the py ligands in *trans*-position at Cd (barbed-wire like) (bond lengths $r(\mathrm{Cd{-}N_{dca}})$ 233.8 and $r(\mathrm{Cd{-}N_{py}})$ 231.7 pm); the dca bridges are bent (angle at the central N atom α(NC—N—CN) 123.4°) and all of the angles between adjacent Cd—N bonds very close to 90°. The individual chains are interlocked into a 2-D arrangement. Similar chains are formed when py is replaced by N-coordinated 4-aminobenzoic acid (aba) as a ligand in $\{[\mathrm{Cd}(\mu_{1,5}\text{-dca})_2(\mathrm{aba})_2]{\cdot}2\ \mathrm{H_2O}\}_\mathrm{n}$ ($P2_1/c$, $Z = 4$), with $r_{\mathrm{av}}(\mathrm{Cd{-}N_{dca}})$ 236.6 and $r(\mathrm{Cd{-}N_{aba}})$ 237.7 pm; here, the chains are linked to sheets by twin hydrogen bonds involving the carboxylic groups of aba and $\mathrm{H_2O}$ molecules.[140]

Replacement of the two py ligands in the above complex by the bidentate 2,2′-bipyridyl ligand (bipy) forces its *cis*-coordination at Cd and consequently an all-*cis* arrangement of the four bridging dca ligands in the polymeric $[\mathrm{Cd(dca)_2(bipy)}]_n$ ($C2/c$, Z = 4), yielding an undulating chain.[141] The comparable bonds have similar lengths as before ($r_{\mathrm{av}}(\mathrm{Cd{-}N_{dca}})$ 232.5 and

r(Cd—N$_{bipy}$) 232.2 pm); since the bite-angle of the bipy ligand is only 70.4°, all other angles around Cd deviate more or less from the expected 90° or 180°. Again the chains are interlocked into an efficiently space-filling arrangement. Further replacement of bipy by the very similar 1,10-phenanthrolin (phen) to yield [Cd(dca)$_2$(phen)]$_n$ ($P2_1/c$, Z = 4) changes the structure completely.[141] The Cd(phen) fragments are now linked to one adjacent fragment by a double, and to two others by single ($\mu_{1,5}$-dca)-bridges, to create a very peculiar 2-D network. Due to the structural difference of the dca linkers, the Cd—N$_{dca}$ bond lengths scatter considerably ($224.6 \leq r$(Cd—N$_{dca}$) ≤ 248.1 pm, r_{av}(Cd—N$_{dca}$) 232.4 pm), whereas the Cd—N$_{phen}$ bonds (r_{av}(Cd—N$_{phen}$) 233.2 pm) are close to the Cd—N$_{bipy}$ bonds. Stacking of the layers is such as to allow π—π interaction between the phen ligands.

With the bidentate ligand 1,3-bis(4′-pyridyl)propane (bpp) in place of two py ligands, other highly interesting structures are created. From Cd(NO$_3$)$_2$, Na(dca), and bpp in methanol–water, two different forms of crystals (columns, blocks) with the same composition [Cd(dca)$_2$(bpp)]$_n$ are deposited and manually separated; under the mother liquor the columns disappear after some time, leaving exclusively the block crystals (transformation of a metastable to a thermodynamically stable phase).[142] The columns ($C2/c$, Z = 4) contain chains with double ($\mu_{1,5}$-dca) bridges similar to those in [Cd(dca)$_2$(py)$_2$]$_n$, but with additional, arc-shaped, end-to-end bpp bridges between adjacent Cd centers. The arcs force the Cd(dca)$_2$Cd units (12-membered rings) into boat conformation and the chains as a whole into sinusoidal form. The chains interdigitate into layers. The stable phase (block crystals; $Fddd$, $Z = 16$) contains cisoidal chains as in [Cd(dca)$_2$-(bipy)]$_n$, but with arc-shaped bpp bridges to Cd centers in two adjacent chains, yielding undulating layers. In addition, neighboring layers interpenetrate by means of their protruding arc bridges, creating a 3-D framework.

Cd and Hg complexes of tricyanamide N(CN)$_3$ are unknown, but the isoelectronic tricyanomethanide C(CN)$_3^-$ (tcm) forms some compounds with highly interesting structural chemistry. Cd[C(CN)$_3$]$_2$ and Hg[C(CN)$_3$]$_2$, isomorphous to Zn[C(CN)$_3$]$_2$ ($Pmna$, $Z = 2$),[143–145] adopt a structure with two interpenetrating, equivalent 3-D frameworks which are topologically related to rutile (TiO$_2$), i.e., with octahedrally coordinated metal particles, carbon atoms with trigonal-planar surrounding, and CN groups as connectors between the coordination centers.

Reaction of Cd(NO$_3$)$_2$, K(tcm), and NaBPh$_4$ in methanol (MeOH) yields crystalline Cd(tcm)[B(OMe)$_4$]·1.6 MeOH ($P6_122$, $Z = 6$),[144] in which Cd is surrounded by three N atoms of tcm in T-shape (r(Cd—N) 240.0 pm and 239.6 pm) and two bidentate B(OMe)$_4$ ligands (r(Cd—O) 235.6 pm and 239.6 pm), giving an overall coordination number of seven (3 N, 4O). B(OMe)$_4$ further links the Cd particles to helical chains connected by tcm groups. The solvate molecules MeOH are hosted in the helical channels.

From Cd(NO$_3$)$_2$, (Me$_4$N)(tcm), and hexamethylenetetramine (hmt) in H$_2$O, crystals of [Cd(tcm)(hmt)(H$_2$O)](tcm) ($P2_1/c$, $Z = 4$)[145] are obtained. In the structure two different Cd atoms, both on inversion centers, are octahedrally coordinated to two *trans* hmt and four tcm ligands, and to two H$_2$O, hmt, and tcm ligands each, respectively; the Cd—N bonds to tcm are shorter than those to hmt (r_{av}(Cd—N) 228.4 pm and 244.0 pm). These two complex units are joined in alternating sequence to chains with hmt and tcm bridges; the third N atoms of the μ–tcm's provide links to Cd atoms in two adjacent chains, creating a 3-D connectivity. A further tcm entity is not involved in the framework, but is acceptor for a hydrogen bond from an H$_2$O ligand; hydrogen bonds from H$_2$O are also directed to N atoms of hmt not coordinated to Cd. Again, the overall connectivity pattern is related to the rutile topology.

The acidification of N—H bonds in amines and stabilization of the amide anion resulting on dissociation can be achieved by a variety of groups, which all have electron-withdrawal properties in common. These anions can then act as N-donors towards Cd or Hg.

A highly variable group of amines, and amides derived therefrom, are secondary silylated amines HNR(SiR′$_3$), where R can be an organic substituent, but also a silyl group, and R′ again an organic group. The steric requirements of R and R′ often strongly influence the structures of the Cd and Hg amides obtained from salts of these metals and the substituted amides.

Simple amides of this type are the bis(trimethylsilyl)amides M[N(SiMe$_3$)$_2$]$_2$ (M = Cd and Hg) the essential thermodynamic data of which have been determined in calorimetric measurements of the heats of hydrolysis in dilute H$_2$SO$_4$.[146] Evaluation of the measured data yielded the standard enthalpies of formation $\Delta H^0{}_f = -854(21)\,\mathrm{kJ\,mol^{-1}}$ and $-834(9)\,\mathrm{kJ\,mol^{-1}}$ for M = Cd and Hg, respectively. Using subsidiary data, the average thermochemical bond energies $\overline{E}$–(Cd—N) 144 and $\overline{E}$(Hg—N) 108 kJ mol^{-1} were also obtained, i.e., the Cd—N bonds are considerably stronger than the Hg—N bonds.

Both trimethylsilylamides $M[N(SiMe_3)_2]_2$ (M = Cd and Hg) have been studied in the gas phase by electron diffraction. The diffraction data are best interpreted assuming monomers with linear N—M—N cores and two planar $M—NSi_2$ groups in staggered conformation.[147,148]

A series of amides of the type $M[NR(SiMe_2R')]_2$ with group 12 metals has been prepared from the metal chlorides MCl_2 and the respective Li amide, and studied by mass spectrometry, ^1H and ^{13}C NMR spectrometry, and X-ray structure analyses.[149] In the case of the Cd compounds the mass spectra show the molecular cation M^+ and the fragments $M—L^+$ (L = the respective amide ligand); with the Hg compounds usually M^+ and $M—Me^+$ are found. For the Hg compounds with R′ = Me and R = Ph and with Me and i-Pr 2,6-substituted phenyl groups, as well as with $R' = NMe_2$, crystal structure analyses have been performed; in all cases the N—Hg—N fragment is almost or exactly linear, depending on the real crystallographic symmetry, and the Hg—N bonds are short with only a small scatter ($199.4 \leq r$(Hg—N) ≤ 202.9 pm, r_{av}(Hg—N) 201.5 pm).

Mixing of red $CdCp^*_2$ (Cp* = pentamethylcyclopentadienide) and of $Cd[N(SiMe_3)_2]_2$ (colorless) yields yellow, crystalline $Cp^*Cd[N(SiMe_3)_2]$, actually as the dimer, as shown by X-ray structure analysis at −73 °C ($P2_1/a$, $Z = 4$).[150] As is often the case with Cd amides, the N atoms link the Cd atoms in slightly asymmetric bridges (r_{av}(Cd—N) 229.3 pm) to form a distorted Cd_2N_2 square. The Cp* ligands are η^1-bonded to Cd (r_{av}(Cd—C) 222.2 pm); thus, the coordination around Cd is distorted trigonal-planar. An orange solution of $Cp^*Cd[N(SiMe_3)_2]$ in benzene gives the same ^1H NMR spectrum as the mixture of the educts $CdCp^*_2$ and $Cd[N(SiMe_3)_2]_2$, showing that these three components are engaged in a Schlenk-type equilibrium.

Upon reaction of $Cd[N(SiMe_3)_2]_2$ with the cyclohexylamide $[\{Sb(NCy)_3\}_2Li_6]$ (Cy = cyclohexyl) in tetrahydrofuran (thf), the complicated heterometallic complex amide $[\{Sb(NCy)_3\}\{Cd[N(SiMe_3)_2]\}_3]\cdot[Li\{N(SiMe_3)_2\}\cdot thf]$ is produced.[151] In the Cd-containing part, a pyramidal Sb atom is surrounded by three Cd atoms with three bridging μ_3-NCy ligands; this SbN_3Cd_3 core of the complex can be considered as a defective heterocubane, with one missing corner opposite to Sb (r_{av}(Sb—N) 205 pm, α_{av}(N—Sb—N) 87.9°; r_{av}(Cd—N) 226 pm, α_{av}(N—Cd—N) 78.1°). A highly irregular trigonal-planar coordination around the Cd atoms is completed by terminal $N(SiMe_3)_2$ ligands (r_{av}(Cd—N) 208 pm).

In a remarkable disproportionation reaction, dimercury(I) diacetate $Hg_2(OOCCH_3)_2$ and N,N,N′-tris(trimethylsilyl)benzamidine $Ph\text{-}C(NSiMe_3)[N(SiMe_3)_2]$ give the mercury(II) N,N′-bis((trimethylsilyl)benzamidinate $Hg[Ph\text{-}C(NSiMe_3)_2]_2$ and mercury.[152] The crystals ($P\bar{1}$, $Z = 2$) contain molecules with a nearly centrosymmetric skeleton, although they have no crystallographically imposed symmetry. The ligands are bonded to Hg through one N-donor atom each (r_{av}(Hg—N) 207.0 pm) in an almost linear arrangement; the other two N atoms form secondary bonds N···Hg (r_{av}(Hg···N) 271.9 pm). The C—N bonds in the coordinated amidinate tend to single and double bonds, respectively.

The fairly acidic dimesylamine $HN(SO_2Me)_2$ reacts with $Hg(NO_3)_2$ and $Hg_2(NO_3)_2$ in aqueous solution to form the sparingly soluble dimesylamides $Hg[N(SO_2Me)_2]_2$ and $Hg_2[N(SO_2Me)_2]_2$; the former can be recrystallized to give single crystals appropriate for a structure analysis.[153] Both amides, the latter under disproportionation, add donor molecules—*inter alia* the O-donors dimethyl sulfoxide (dmso) or hexamethylphosphoric triamide (hmpa)—to give $Hg[N(SO_2Me)_2]_2\cdot 2$-dmso and $Hg[N(SO_2Me)_2]_2\cdot$hmpa, respectively. In the structures of $Hg[N(SO_2Me)_2]_2$ ($I4_1/a$, $Z = 8$), and of the latter compounds ($P\bar{1}$, $Z = 1$; $P2_1/c$, $Z = 4$), the molecules contain nearly or exactly linear N—Hg—N groups with nonsignificantly different Hg—N bonds (total r_{av}(Hg—N) 206.6 pm). In the solvates, two dmso molecules (r(Hg—O) 261.2 pm) and one hmpa molecule (r(Hg—O) 246.2 pm) complete the coordination sphere of Hg to distorted square planar and T-shaped, respectively. In the solvate-free $Hg[N(SO_2Me)_2]_2$, intermolecular secondary O···Hg bonds (r(Hg···O) 282.5 pm) create weakly bonded dimers. In all of the three compounds, additional intra- and intermolecular O···Hg distances are around or beyond the sum of the van der Waals' radii (300 pm).

Organomercurials with one dimesylamide ligand $R—Hg—N(SO_2Me)_2$ have been obtained by reaction of the appropriate chloride RHgCl with $AgN(SO_2Me)_2$ and characterized by ^1H and ^{13}C NMR spectrometry.[154] The crystal structure of $Ph—Hg—N(SO_2Me)_2$ has been solved ($Pbca$, $Z = 8$); it contains molecules with slightly bent C—Hg—N groups (r(Hg—C) 204.0 and r(Hg—N) 209.1 pm, (C—Hg—N) 172.7°). Two similar intra- and intermolecular secondary O···Hg bonds, respectively (r(Hg···O) 296.1 pm and 297.6 pm), assisted by pairs of intermolecular C—H···O bonds, link the molecules to a 1-D polymer. Thus, the Hg atoms get an unusual distorted 2 + 2 coordination.

Various substituted sulfonylurea derivatives, partly in use as diabetes drugs, have been coordinated to Cd and Hg. Besides the IR and ^1H NMR spectra of several species, the structures of one each of the Cd and Hg compounds have been solved.[155] In the Cd complex three ligands act as bidentate N,O-donors, yielding an approximately trigonal-prismatic surrounding; in the Hg compound two monodentate ligands are bonded to give a strictly linear symmetric N—Hg—N fragment (r(Hg—N) 205.2 pm), with two pairs of intramolecular secondary O···Hg bonds (r_{av}(Hg···O) ~ 297 pm).

Some relation to sulfonylureas has saccharine (1,2-benzisothiazol-3(2H)-one 1,1,dioxide) which, as an anion (sac), with $CdCl_2$ in aqueous medium readily forms tetraaquabis(saccharinato-N)-cadmium(II) dihydrate $[Cd(sac)_2(H_2O)_4]\cdot 2H_2O$.[156] In the crystal structure ($P2_1/c$, $Z = 2$), the complex molecules occupy inversion centers and therefore adopt an all-*trans* octahedral configuration, with r(Cd—N) 232.3 pm and r(Cd—O) 227.9 pm and 234.2 pm, respectively, and minor deviations from 90° of the angles between adjacent bonds. The coordinated H_2O molecules are involved in a hydrogen-bonding network. Comparisons with other saccharinato complexes of lighter transition metals have been drawn.

Examples of Cd and Hg complexes with other cyclic sulfonamides, e.g., *p*-nitrobenzoxasulfamate, derived from the respective *o*-aminophenol, should also be mentioned. IR spectra and crystal structures of the compounds $[Cd(nbs)_2(H_2O)_4]$ and $[Hg(nbs)_2(H_2O)_4]$ (nbs = *p*-nitrobenzoxasulfamate) have been reported.[157] In the Cd complex ($P\bar{1}$, $Z = 1$) Cd has a centrosymmetric, almost perfectly octahedral surrounding, with very similar Cd—N and Cd—O bonds (r(Cd—N) 231.0, r(Cd—O) 230.3 pm and 230.9 pm) and angles between adjacent bonds close to 90°; a system of intermolecular hydrogen bonds with the coordinated H_2O molecules as donors holds the structure together. In the Hg complex, the Hg atoms (on a twofold axis) surprisingly adopt a basically pentagonal–bipyramidal coordination with a clearly bent N—Hg—N axis (r(Hg—N) 207.3 pm, α(N—Hg—N) 167.0°), and three H_2O molecules (r(Hg—O) 249.2 pm and 266.4 pm) and two O atoms from nitro groups in neighboring molecules (secondary bonds r(Hg···O) 321.6 pm) in the equatorial plane. The weak secondary bonds, and again numerous hydrogen bonds, link the molecules to a 3-D network.

A yellow complex $\{Hg[PhN_3C_6H_4N_3(H)Ph](NO_3)\}$, obtained from $Hg(NO_3)_2$ and the monoanion derived from *ortho*-bis(phenyltriazeno)benzene $PhN_3(H)C_6H_4N_3(H)Ph$, exhibits interesting structural features ($P2_1$, $Z = 2$):[158] The ligand strongly coordinates to Hg, with an N atom directly bonded to the central benzene ring (r(Hg—N) 210.1 pm), while opposite to this Hg—N bond a monodentate NO_3 ligand is similarly strongly bonded (r(Hg—O) 211 pm), giving an almost linear N—Hg—O fragment (α(N—Hg—O) 174.6°). As expected, two more N-donors of the ligand form secondary bonds with Hg (r(N···Hg) 266.2 pm and 285.0 pm), such that both covalent and secondary bonds are almost coplanar. These roughly planar complexes are stacked in columns in such a way that Hg gets contact with the terminal Ph rings of two neighboring molecules, with clear tendency to η^2 coordination (r(C···Hg) 340/341 pm and 381/410 pm); these arene–metal interactions obviously afford the main contribution to the cohesion of the lattice constituents.

Interesting complexes of Cd and Hg have been prepared with pentaazadienide ligands $[R{-}N{=}N{-}N{-}N{=}N{-}R]^-$ (obtained from the respective diazonium salts and NH_3 in aqueous solution); especially, the pyridine solvates $[Cd(R{-}N_5{-}R)_2py_2]$ (red; R = *p*-ethoxyphenyl) and $[Hg(Tol\text{-}N_5\text{-}Tol)_2py]$ (dark yellow, Tol = *p*-tolyl) have been obtained by recrystallization of the sparingly soluble primary products from pyridine (py).[159] Both of the compounds crystallize in $P\bar{1}$ ($Z = 2$), but with different structures. In the Cd complex, the two R—N_5–R ligands coordinate bidentate (N1,N3)-η^2 with unsystematically different Cd—N bond lengths (r_{av}(Cd—N) 237 pm) and small bite-angles (α_{av}(N—Cd—N) 52.7°); in the zigzag N_5 chain the terminal bonds tend to be shorter than the central ones; the py ligands coordinate in the *cis*-position (r_{av}(Cd—N) 233 pm). In the Hg complex the two ligands bind monodentate, with the central N atoms as donor to form a bent arrangement (r_{av}(Hg—N) 209.8 pm), α(N—Hg—N) 163.5°); the py ligand (r(Hg—N) 249.0 pm) coordinates in such a way that the overall coordination around Hg becomes T-shaped planar, with a tendency to trigonal planar.

Structurally surprising compounds have been obtained upon reaction of Cd halides CdX_2 with silylated phosphoranimines $R_3P{=}NSiMe_3$ in the presence of alkali-metal fluoride MF (formally yielding the imide $R_3P{=}N^-$ as an intermediate), to give the tetrameric phosphoraniminato species $[CdX(NPR_3)]_4$ (X = Cl, Br, I, R = Et; X = I, R = Me) as shown by EI mass spectrometry.[160] For X = Br, R = Et reactions with organolithium reagents LiR′ (R′ = Me, $C{\equiv}CSiMe_3$) smoothly give the substituted $[CdR'(NPR_3)]_4$. These complexes have further been characterized by IR and ^1H, ^{13}C, ^{31}P, and ^{29}Si NMR spectrometries, where applicable. Crystal-structure analyses have been performed for the complexes with X = Cl, Br, I, R′ = $C{\equiv}CSiMe_3$ and R = Et (mostly as solvates with dichloromethane or toluene). Although different in the space groups, they all contain molecules with heterocubane cores Cd_4N_4. The differences in the Cd—N bond lengths are nonsystematic and nonsignificant (overall average r_{av}(Cd—N) 227.6 pm); in all cases the angles between adjacent Cd—N bonds in the cube are slightly below 90° around the four-coordinate Cd (α_{av}(N—Cd—N) 88.9°), and over 90° around N (α_{av}(Cd—N—Cd) 91.0°). Consequently, the angles between the terminal bonds Cd—X or N—P and the edges of the cube are over or below ~125°, respectively, as expected. Recrystallization of the raw material with X = I, R = Et from CH_2Cl_2/MeCN gives small amounts of $[Cd_4I_4(OSiMe_3)(NPEt_3)_3]$, probably as a consequence of partial hydrolysis of the silylated starting material. The structure analysis shows that in the heterocubane core a μ_3-$OSiMe_3$ ligand has replaced a $NPEt_3$ group leading to a clear distortion of the cube, with long Cd—O bonds (r_{av}(Cd—O) 231.5 pm) and shorter Cd—N bonds (r_{av}(Cd—N) 224.6 pm) adjacent to the Cd—O bonds. A comparison of these heterocubanes with others containing lighter transition metals has appeared.[161]

An analogous reaction of Cd acetate $Cd(O_2CCH_3)_2$ with $Me_3SiNPEt_3$ in excess yields the heterocubane $[Cd(O_2CCH_3)(NPR_3)]_4$ (CH_2Cl_2 solvate after recrystallization; $C2/c$, $Z = 4$), with crystallographic symmetry $2 - C_2$ of the tetranuclear complexes.[162] The acetate groups bind as asymmetric bidentate ligands (r_{av}(Cd—O) 232.0 pm and 237.8 pm), leading to five-coordinate Cd. As a consequence the heterocubane core is more distorted (the angles at the corners vary between 87.3° and 92.6°) than in the previous examples with four-coordinate Cd; the Cd—N bonds are almost unaffected (r_{av}(Cd—N) 228.0 pm).

(ii) Ammine and organic amine complexes

Ammine complexes and their condensation products. Ammine complexes of Cd, or fragments thereof, are scarce in the literature. Fragments *trans*-$[Cd(NH_3)_2]$ have been mentioned as part of octahedral CdN_6 constituents of the interwoven 2-D networks in *trans*-$Cd(NH_3)_2\{Ag(CN)_2\}_2]_n$, but no structural data have been given (see also Section 6.9.4.2.3(iii)).[163] The fragments $[Cd(NH_3)_5]$ and $[Cd(NH_3)_3]$ (*mer* configuration) with Cd—N distances $229 \le r$(Cd—N) ≤ 247 pm and $225 \le r$(Cd—N) ≤ 239 pm, respectively, occur in the structure of $[Cd(NH_3)_5][Cd(NH_3)_3][Re_4Te_4(CN)_{12}]$, bound to the heterocubane anion by bridging CN groups (see Section 6.9.4.2.3(iii)).[164] $[Cd(NH_3)_6](ClO_4)_2$ has also been studied: It crystallizes in the anti-K_2PtCl_6 type ($Fm\bar{3}m$, $Z = 4$), with strictly octahedral cations (r(Cd—N) 237.8(13) pm) and disordered anions.[165]

There is good news from the field of ammine–mercury complexes. For the first time the structures of compounds with the ammine–mercury cations $[Hg(NH_3)_2]^{2+}$ and $[Hg(NH_3)_4]^{2+}$ have been solved from single-crystal X-ray data.[166] An aqueous solution of $HgCl_2$ and NH_4Cl at 60 °C dissolves $[Hg(NH_2)]Cl$ to some extent; upon cooling the supernatant, crystals of $[Hg(NH_3)_2][HgCl_3]_2$ deposit. In its structure ($Pmna$, $Z = 2$), the linear cations $[Hg(NH_3)_2]^{2+}$ (symmetry $2/m - C_{2h}$) have short Hg—N bonds (r(Hg—N) 207.2 pm) and a pair of equivalent Cl atoms (r(Cl···Hg) 317.6 pm) in the same mirror plane, and two pairs of more remote equivalent Cl atoms (r(Cl···Hg) 342.3 pm) in two neighboring mirror planes. Thus, the overall coordination number of Hg rises to an unusual $2 + 2 + 4$. The T-shaped planar anion $[HgCl_3]^-$ can be considered as a distorted $HgCl_2$ molecule (r(Hg—Cl) 235.8 pm and 236.9 pm, α(Cl—Hg—Cl) 167.68°) plus a more distant Cl^- anion (r(Hg—Cl) 280.0 pm); however, Cl···Hg contacts (r(Cl···Hg) 297.1 pm and 333.8 pm) from neighboring $[HgCl_3]^-$ entities generate a highly distorted octahedral environment of Hg. The bubbling of gaseous NH_3 into an aqueous solution of $Hg(ClO_4)_2$ under cooling yields $[Hg(NH_3)_4](ClO_4)_2$. In the structure ($P2_1/c$, $Z = 4$) all constituents lie on general positions; as a consequence the Hg—N bonds in the complex cation $[Hg(NH_3)_4]^{2+}$ are independent, but not significantly different (r_{av}(Hg—N) 226.6 pm). Yet, the basically tetrahedral coordination is severely distorted, in that two opposite angles α(N—Hg—N) are strongly widened (115.4° and 125.0°), i.e., the tetrahedron is flattened. Interionic distances N···O of 289 pm to 328 pm suggest hydrogen bonds, also indicated by the position and profile of the ν(NH) bands in the IR spectrum. IR and Raman bands at 436 cm^{-1} and 407 cm^{-1} are assigned to the valence vibrations of the HgN_4 entities.

Another old problem finally solved!? The long-known 'mercury amidochloride' ('infusible precipitate'), $HgNH_2Cl$, has been obtained as single crystals appropriate for X-ray structure analysis under hydrothermal conditions (160 °C).[167] Basically the earlier suggested structure with chains ${}_{\infty}^{1}[Hg(NH_2)_{2/2}]^+$ or ${}_{\infty}^{1}[(NH_2)Hg_{2/2}]^+$ (polymeric dimercurio-ammonium ion) has been confirmed, but now in a space group of higher symmetry ($Pmma$, $Z = 2$) with Hg in an inversion center. The Hg—N bonds (r(Hg—N) 207.5 pm) are very similar to those in $[Hg(NH_3)_2][HgCl_3]_2$; the angle at the ammonium center is slightly less than required for a tetrahedral surrounding (α (Hg—N—Hg) 107.9°). Four equivalent Cl particles complete the coordination around Hg to distorted octahedral

(r(Cl···Hg) 309.3 pm) and link the octahedra to layers by edge sharing; the layers are connected by hydrogen bonds N—H···Cl (H atoms located).

The next step of mercuration of the ammonium ion and generation of a network $_\infty[(\mathrm{NH})\mathrm{Hg}_{3/2}]^+$ is realized in $\mathrm{NH_4[Hg_3(NH)_2](NO_3)_3}$ (simply from aqueous solutions of $\mathrm{Hg(NO_3)_2}$ and $\mathrm{NH_3}$).[168,169] The structure ($P4_132$, $Z=4$) can be considered to be built up of $\mathrm{HNHg_3}$ tetrahedra (r(Hg—N) 207.0 pm, α(Hg—N—Hg) 112.2°) sharing the Hg corners to give a 3-D framework. The nitrate and ammonium ions occupy voids in the framework, such that secondary bonds between $\mathrm{NO_3}^-$ and Hg ($282.2 \leq r(\mathrm{O}\cdots\mathrm{Hg}) \leq 344.0$ pm) and hydrogen bonds between $\mathrm{NH_4}^+$ and $\mathrm{NO_3}^-$ are formed. Thermal analysis (DTA, TG, combined with mass spectrometry) and temperature-dependent X-ray powder diffractometry show $\mathrm{NH_4[Hg_3(NH)_2](NO_3)_3}$ to decompose essentially in one step above 270 °C to gaseous products ($\mathrm{H_2O}$, $\mathrm{NH_3}$, $\mathrm{N_2}$, $\mathrm{N_2O}$) and solid $\mathrm{[Hg_2N](NO_3)}$ (decay to HgO and $\mathrm{N_2O}$ above 380 °C). The latter can also be prepared by hydrothermal synthesis (180 °C) from $\mathrm{Hg(NO_3)_2}$ and $\mathrm{NH_3}$.

This deceptively simple-looking $\mathrm{[Hg_2N](NO_3)}$ ($P4_32_12$, $Z=20$!) adopts a complex framework structure with three independent tetrahedral $\mathrm{NHg_4}$ entities (r_{av}(Hg—N) 205.3 pm) corner-linked to two different types of helical strands running parallel to the tetragonal c-axis, which in turn are interlocked into the 3-D framework. The $\mathrm{NO_3}^-$ anions occupy the largest of three different types of cages and contact the Hg atoms of the framework, forming numerous secondary bonds O···Hg.

To conclude: structural data for carefully studied representatives of mercury–nitrogen compounds are now available, starting from $\mathrm{[Hg(NH_3)_2]^{2+}}$ (formally two $\mathrm{H_3NHg}$ tetrahedra with the Hg corner in common) and going through stepwise, increasing mercury substitution of the ammonium unit with formation of coordination polymers $_\infty[\mathrm{NH}_{4-n}\mathrm{Hg}_{n/2}]^+$ of increasing dimensionality. Irrespective of the degree n of mercuration, the Hg—N bonds retain almost the same length with $r(\mathrm{Hg—N}) \approx 207$ pm, the differences, if significant, being due to type and number of secondary bonds to Hg.

Organic amine complexes. An immense number of aliphatic and aromatic mono- and oligofunctional amines, as well as nitrogen-containing heterocycles, have been used as ligands in complexes of Cd and Hg. In organic ligands N-donor functions can be combined with other donors like O, S, Se and/or Te, and so on, and other ligands can compete; thus a highly complex and often unpredictable coordination chemistry without frontiers becomes possible, even with relatively simple ligands, e.g., cysteine. Therefore, only a selection of representative examples of Cd and Hg complexes can be offered here.

The thermodynamic parameters (formation constants, enthalpies ΔG^0 and ΔH^0, entropy terms $T\Delta S^0$) for complexation of $\mathrm{Cd^{II}}$ by open-chain N-donor ligands in dmso solution have been determined by potentiometric and calorimetric techniques under controlled conditions.[26] n-Butylamine, ethylenediamine (en), diethylenetriamine (dien), and various methyl derivatives of the latter two have been used for complexation. Mononuclear complexes CdL_n, with the polyamines as chelating ligands L, are formed; with the ligands en ($n \leq 3$) and dien ($n \leq 2$) all these species CdL_n have higher formation constants and higher absolute values of ΔH^0 in dmso than in water, i.e., they are more stable in dmso. Increasing methylation and thus increasing steric requirements of the N-donors decrease the stability, to the extent that the fully methylated ligands only form the species CdL with low stability. On the whole, the complexes are enthalpy stabilized, whereas the entropy changes counteract the complexation.

The crystal structure of a tris(ethylenediamine)cadmium dibenzohydroxamate hydrate $\mathrm{[Cd(en)_3](ONH(OC)Ph)_2 \cdot H_2O}$ ($Fdd2$, $Z=16$) has been briefly described without giving structural data.[170] From the given crystallographic data, the bond lengths in the distorted octahedral core $\mathrm{CdN_6}$ of the cation can be calculated ($235.4 \leq r(\mathrm{Cd—N}) \leq 238.4$ pm, r_{av}(Cd—N) 237.2 pm). Similar averaged data (r_{av}(Cd—N) 238 pm) for the $\mathrm{[Cd(en)_3]^{2+}}$ are given in another source.[171]

^{113}Cd NMR spectra of a series of $\mathrm{[Cd(en)_3]^{3+}}$ salts with different inorganic anions in $\mathrm{H_2O}$, en, and dmso as solvents have shown the ^{113}Cd chemical shifts (around 350 ppm/re aqueous $\mathrm{Cd(ClO_4)_2}$) to be practically independent of the changes of solvent, concentration and counterion.[172] However, increasing ring size in the chelate complexes with the diamine ligands $\mathrm{H_2N(CH_2)}_n\mathrm{NH_2}$ ($2 \leq n \leq 4$) causes an increase in shielding (up to 230 ppm in the series), as does methylation of the amino group. ^{113}Cd NMR data of complexes with several pyridine, dipyridine, and 1,10-phenanthroline derivatives, both in solution and as solids, have also been reported in this paper.

The effects of sterically more demanding ligands related to en are obvious for Cd complexes with N′-isopropyl-2-methylpropane-1,2-diamine (npda) or 2-amino-2,5-dimethyl-4-azahexane $\mathrm{i\text{-}PrNH(CH_2)CMe_2NH_2}$. From $\mathrm{Cd(ClO_4)_2}$ and excess npda, solid $\mathrm{[Cd(npda)_3](ClO_4)_2}$ has been obtained,[173] which in aqueous solution dissociates to $\mathrm{[Cd(npda)_2(H_2O)_2]^{2+}}$ + npda; this solution absorbs CO_2, even from the air, to give the dinuclear complex $[Cd(npda)_2(O_2CO)Cd(npda)_2(H_2O)](ClO_4)_2 \cdot H_2O$ with an asymmetric μ-carbonato bridge.[174] In the structure ($P2_1$, $Z = 2$), both Cd centers have a distorted octahedral surrounding CdN_4O_2 with two bidentate npda ligands ($230.9 \leq r(Cd—N) \leq 240.7$ pm, $r_{av}(Cd—N)$ 236.6 pm) each, the bidentate/monodentate carbonato bridge ($r(Cd—O)$ 217.2, 276.8/223.8 pm), and an H_2O ligand ($r(Cd—O)$ 235.1 pm). The bite-angles involving the bidentate μ-O_2CO ligand and in the four chelate rings are as small as $\alpha(O—Cd—O)$ 51.5° and, as expected, $\alpha_{av}(N—Cd—N)$ 74.9°, respectively.

Recent structural studies of dien complexes of light transition-metal saccharinates (sac) also comprise a respective Cd compound, namely $[Cd(dien)_2] \cdot sac)_2$.[175] This complex is obtained by reaction of $[Cd(sac)_2(H_2O)_4] \cdot 2\,H_2O$ in MeOH with dien. In the crystal structure ($P\bar{1}$, $Z = 2$), the cation $[Cd(dien)_2]^{2+}$ Cd has a strongly distorted octahedral environment, with Cd—N bonds varying in the range $232.7 \leq r(Cd—N) \leq 243.1$ pm ($r_{av}(Cd—N)$ 237.7 pm) and with the bonds between Cd and the tertiary N atoms being the longest; the bite-angles in the chelate rings are between 72.6° and 75.8°. The sac anions are linked to the cation only by hydrogen bonds N—H···O.

A related study deals with complexes formed from $Cd(NO_3)_2$ and α,ω-diamino-azaalkanes $H_2N(CH_2)_mNH(CH_2)_nNH_2$ (L), with increasing chain length leading to increasing chelate-ring size in the complexes.[176] The compounds $[CdL_2](NO_3)_2$ are prepared by simply mixing $Cd(NO_3)_2$ in MeOH with the amine in the appropriate molar ratio and then partial evaporation. In the structure of the first compound with 1,5-diamino-3-azapentane = dien ($m = n = 2$) ($I4_1/acd$, $Z = 16$; huge cell!) the cation $[Cd(dien)_2]^{2+}$ (symmetry $2 - C_2$) again clearly deviates from octahedral coordination, with the bonds Cd—1 N and Cd—5 N much shorter ($r_{av}(Cd—N)$ 233.8 pm) than Cd—3 N ($r(Cd—N)$ 243.1 pm); the bite-angles are close together at ≈74.0°. For 1,6-diamino-3-azahexane ($m = 2$, $n = 3$) as a ligand with the structure ($P2_1/c$, $Z = 4$), the cation is still distorted with bonds Cd—1 N and Cd—6 N ($r_{av}(Cd—N)$ 235.7 pm) shorter than Cd—3 N ($r_{av}(Cd—N)$ 240.6 pm); the bite-angles in the five-membered chelate rings (≈74.4°) are smaller than those in the six-membered rings (≈83.0°), of course. Finally, in the case of L = 1,7-diamino-4-azaheptane ($m = n = 3$) the bonds between Cd and the terminal and central N-donors approach each other ($r_{av}(Cd—N)$ 236.8 pm and 239.4 pm, respectively) and the bite-angles scatter considerably, with an average of 84.9°. As a result, the distortion of the octahedral surrounding of Cd and the strains in the chelate rings are reduced.

The ligand 1,4,7-triazacyclononane (tacn) or [9]aneN_3, formally derived from dien by ring closure with a CH_2CH_2 group, has been used for complexation of Cd to yield $[Cd(tacn)_2](ClO_4)_2$ and $[Cd(tacn)_2](BPh_4)_2 \cdot 2$ dmso.[177] In both compounds ($P\bar{1}$, $Z = 2$ and $Z = 1$, respectively) the complexes have crystallographically imposed centrosymmetry, with approximately trigonally elongated octahedra CdN_6 ($r_{av}(Cd—N)$ 236.3 pm and 236.2 pm, respectively) and average bite-angles of 75.7°.

An easily accessible hexadentate derivative of tacn, namely 1,4,7-tris(*o*-aminobenzyl)-1,4,7-triazacyclononane (tabtacn), forms a 1:1 complex $[Cd(tabtacn)](ClO_4)_2 \cdot 0.5\,H_2O$ ($Pc2_1n/Pna2_1$, $Z = 4$) with a distorted trigonal prismatic CdN_6 core. The Cd—N bonds to the N donors in both the tacn moiety and in the aniline pendant arms are very similar in a rather narrow range ($r_{av}(Cd—N)$ 237 pm).[178] Both solution and solid-state ^1H, ^{13}C, and ^{113}Cd NMR spectra have been measured and analyzed with respect to details of the stereochemistry and to dynamics in solution.

Systematic studies by potentiometric and calorimetric measurements have been performed of the complexation of Cd and polyazacycloalkanes $(CH_2CH_2NH)_k$ or [3k]aneN_k with increasing ring size ($6 \leq k \leq 11$).[179] Both mononuclear ($6 \leq k \leq 8$) and dinuclear ($8 \leq k \leq 11$) complexes are formed, with the mononuclear species showing increasing stability in the series $3 \leq k \leq 5$ (literature data) and decreasing stability for $6 \leq k \leq 8$; the formation constants of the dinuclear complexes increase continuously for $8 \leq k \leq 11$. The dinuclear complex $Na[CdCl_2([30]aneN_{10})Cd](ClO_4)_3$ has been isolated and its structure solved ($Pbna/Pbcn$, $Z = 4$): the complex has symmetry $2 - C_2$, with both independent Cd atoms on the twofold axis; one of the Cd atoms has a distorted octahedral environment CdN_4Cl_2, the other one approaches trigonal-prismatic coordination CdN_6 ($r_{av}(Cd—N)$ 240 pm, $r(Cd—Cl)$ 253.5 pm).

A survey of transition-metal polyazacycloalkane complexes in general, with data also for Cd and Hg species in particular, has been published.[180] Structural, ^1H and ^{13}C NMR, UV/vis, and conductivity data of several transition-metal complexes, including Cd and Hg complexes, with derivatives of the 16-membered ligand 1,9-dithia-5,13-diazacyclohexadecane have been compiled and compared. In particular, conversion between configurational isomers and exchange processes in solution have been discussed.[181]

Condensation of diethylenetriamine (dien) and glyoxal, OCH—CHO, gives a hexazapentacyclooctadecane (hapcod, $C_{12}H_{22}N_6$; three linearly fused six-rings plus two five-rings), which forms complexes with Cd salts.[182] The Cd halides CdX_2 (X = Cl, Br, I) and the ligand in MeOH yield the complexes $[CdX_2(hapcod)]$, partly as MeOH solvates. Their structures, albeit in three different space groups, have in common that the complexes adopt crystallographic symmetry $2 - C_2$. Basically, Cd has tetrahedral coordination, with two X ligands (r(Cd—X) 246.8, 258.6, 277.4 pm, for X = Cl, Br, I, respectively) and two N-donors from the ligand (r(Cd—N) 236.9, 233.6, 237.2 pm); the angle between these Cd—N bonds is widened to ≈120°, giving space for approach of two additional more remote N-donors (secondary bonds, r(Cd···N) 262.5, 273.6, 273.9 pm). Two N atoms of the ligand are not involved in complexation.

The formally comparable complex with $Cd(NO_3)_2$, $[Cd(O_2NO)_2(hapcod)]$ ($C2/c$, $Z = 4$),[183] has a deviating structure in that Cd is eight-coordinate, with two concentric tetrahedra of primary and secondary bonds, respectively. Thus, nitrate acts as an aniso-bidentate ligand with strongly asymmetric coordination (r(Cd—O) 233.1, r(Cd···O) 259.3 pm) and the primary and secondary Cd—N bonds from the pentacyclic ligand are even more different (r(Cd—N) 230.8, r(Cd···N) 267.6 pm). With $Cd(BF_4)_2$ the complex $[Cd(hapcod)_2](BF_4)_2$ ($P2_1/n$, $Z = 4$) is obtained.[183] Again Cd is eight-coordinate, with two pairs of clearly different primary Cd—N bonds from the two independent hapcod ligands (r_{av}(Cd—N) 237.4 pm and 243.8 pm) and two complementary pairs of secondary bonds (r_{av}(Cd···N) 274.6 pm and 270.2 pm). The nitrato complex in aqueous solution behaves as a 1:2 electrolyte (conductance measurements) indicating almost full dissociation; the complicated, time-dependent ^{13}C NMR spectrum (D_2O solution) suggests solvolysis reactions, obviously also occurring in solution of the complex $[Cd(hapcod)_2]^{2+}$. Combined ^{13}C and ^{113}Cd NMR studies of $[Cd(hapcod)_2]^{2+}$ in dmso-d_6 solution suggest fast partial and full exchange of the hapcod ligand by solvent molecules.

Complexation of Cd with a series of polyamine macrocycles, but also related open-chain polyamines, comprising or attached to the 2,2′-bipyridine (bipy) and 1,10-phenanthroline (phen) moieties, has been studied by combined UV/vis spectrometry and potentiometry.[24] Formation constants and distribution diagrams of the species present have been evaluated. As a result the thermodynamic stabilities, i.e., the formation constants, are lower for the bipy- and phen-containing ligands than those for Cd complexes with aliphatic oligoaza macrocycles containing the same number of N donors. The probable reason is loss of flexibility of the ligands caused by the size and stiffness of the inserted heteroaromatic moieties.

Complexes of transition metals, including Cd, with 17- and 20-membered N,O-donor macrocycles containing the dien and related fragments, have been prepared.[184] Conductances and formation constants in MeOH and crystal structures, *inter alia* of a complex obtained from $Cd(NO_3)_2$ and a ligand L with the dien group, a pyridine ring, and two ether O donors, have been determined. In this $[CdL(NO_3)]_2[Cd(NO_3)_4]$ ($C2/c$, $Z = 4$), the cation contains Cd in eight-coordination with four unsystematically varying Cd—N bonds to the N donors of the dien and py moieties ($237.1 \leq r(\text{Cd—N}) \leq 244.1$ pm), two Cd—O bonds to ether O donors (r(Cd—O) 244.7 pm and 252.1 pm), and two rather different Cd—O bonds to a bidentate NO_3 ligand (r(Cd—O) 250.3 pm and 268.5 pm). For comparison, relevant structural data for eight-coordinate Cd and for the other transition metals under discussion in this paper from the Cambridge Structural Data Bank (CSD) are presented.

A flood of papers, dealing with mostly heteroleptic Cd complexes with heterocyclic/heteroaromatic N donors, has been published. Often minor changes in the substitution pattern of the N-heterocyclus induce severe structural changes in the environment of Cd (coordination number, topology) and/or in the arrangement and linking of the building blocks of a crystal structure. Some examples with nitrogen-dominated coordination spheres or structure-commanding effect of the heterocyclus are selected to be dealt with here.

A coordination dominated by pyridine has been found in the complex bis(thiosaccharinato)-trispyridine cadmium $[Cd(tsac)_2(py)_3]$ ($C2/c$, $Z = 8$).[185] In a distorted octahedral coordination the py ligands are bound in *mer*-configuration with the donor atoms of the tsac ligands in a (pseudo)-plane approximately perpendicular to the plane $Cd(py)_3$; surprisingly, the tsac anions are bound to Cd in different modes, one as a monodentate S-coordinated ligand, the other one as a bidentate N,S-chelate ligand. The bond lengths Cd—N(py) scatter ($234.8 \leq r(\text{Cd—N}) \leq 247.8$ pm), the bond Cd—N(tsac) 259.6 pm is even longer; the Cd—S bonds are 259.9 pm and 277.9 pm for the mono- and bidentate tsac ligands, respectively.

The seemingly very similar pyridine derivatives 2- and 4-acetylpyridine (acpy) and 4-bromopyridine (4-Brpy), together with azide N_3^-, produce structurally completely different Cd complexes.[186] The compounds are simply prepared by mixing $CdSO_4$ with the ligands (in excess) in aqueous-alcoholic media. In $[Cd(2\text{-acpy})(N_3)_2]_n$ ($P2_1/a$, $Z = 4$), centrosymmetric dinuclear units $[(acpy)Cd(N_3)_2Cd(acpy)]$ with chelate acpy ligands and a pair of μ-1,1 azide bridges are linked by two pairs of μ-1,3 N_3 bridges to form a 2-D network with pseudosquare meshes and the dinuclear units as knots; Cd has a distorted octahedral coordination. In $[Cd(4\text{-acpy})_2(N_3)_2]_n$ ($P2_1/a$, $Z = 2$), Cd (on an inversion center) has an environment of two axial N-coordinated acpy ligands and fourequatorial azide ligands, which as μ-1,3 bridges provide the links to four neighboring Cd centers; thus, a simple 2-D network with pseudosquare meshes is generated. Finally, with the ligand 4-Brpy a compound with a more complicated composition $[Cd_3(4\text{-Brpy})_4(N_3)_6]_n$ is obtained. Also the structure ($P\bar{1}$, $Z = 1$) is much more complicated than before. First, there are two kinds of nonequivalent Cd atoms on an inversion center and in general position, respectively, both with pseudo-octahedral surroundings; second, μ-1,1 and μ-1,3 azide bridges join the Cd atoms to di-, tri-, and tetranuclear subunits and finally to a 2-D network with meshes of three different sizes. The bond lengths Cd—N(azide) span wide ranges in the 2-acpy and 4-Brpy complexes ($226.2 \leq r(\text{Cd—N}) \leq 237.7$ pm and $227.8 \leq r(\text{Cd—N}) \leq 236.9$ pm, respectively), but are much the same in the 4-acpy complex (r(Cd—N) 232.3 pm and 232.6(4) pm); for all of the complexes the Cd—N(py) bonds do not differ significantly ($232.2 \leq r(\text{Cd—N}) \leq 235.1(4)$ pm.

The ligand 1,2-bis(4-pyridyl)ethane (bpe) $NC_5H_4CH_2CH_2C_5H_4N$ and $Cd(NO_3)_2$ form the coordination polymer $[Cd(O_2NO)_2(\mu\text{-bpe})_2Cd(O_2NO)_2(\mu\text{-bpe})]_n$.[187] In its structure ($P2_1/n$, $Z = 4$) two bpe units bridge two Cd atoms to form a cyclic structural element which is linked to the next one by another bpe unit, thus giving chains. Each Cd is coordinated by two aniso-bidentate nitrato ligands and one pyridyl moiety in one plane, with two more pyridyl groups in an axial position to yield an overall pentagonal-bipyramidal coordination. In this case the nitrato ligands are bound in an almost symmetrical manner (r_{av}(CdO) 244.3 pm) and the Cd—N(py) bonds show little variance (r_{av}(Cd—N) 233.0 pm).

Cd adopts similar seven-coordinate topologies in complexes prepared from $Cd(NO_3)_2$ and the bifunctional pyridine ligands 1,4-bis(4-pyridylmethyl)benzene (bpmb) $(NC_5H_4CH_2)C_6H_4(CH_2C_5H_4N)$ and its tetrafluoro analog $(NC_5H_4CH_2)C_6F_4(CH_2C_5H_4N)$, with two aniso-bidentate nitrato ligands and three py moieties in a T-shaped arrangement.[188] The minor changes in the ligands cause great differences in the overall structures: the common substructures are chains, e.g., $[Cd(O_2NO)_2(\mu\text{-bpmb})]_n$, but in the first case two of these chains are linked by bpmb ligands to double chains (ladder), while in the second case one chain is alternately linked to two neighboring chains and eventually to a 2-D network with a brickwork pattern. To make things even more complicated, in both cases these polymeric ladder and brickwork structures, respectively, interpenetrate each other; closer inspection reveals that in the latter case three independent partial structures are interlocked to form thick sheets.

A pyridine derivative related to dien with respect to the number and distribution of N-donor atoms, namely bis(2-pyridylmethyl)amine (bpma), also gives comparable complexes with Cd, e.g., $[Cd(bpma)_2](ClO_4)_2$ with potentially three isomers (including a pair of enantiomers). As shown by the structure analysis ($C2/c$, $Z = 4$), a distorted octahedral *fac*-isomer with symmetry $2 - C_2$ has been isolated, necessarily with both enantiomers in the crystal lattice. No significant difference in the two kinds of Cd—N bonds (r_{av}(Cd—N) 235.0 pm) is observed.[189] Solid-state ^{13}C NMR spectra of this complex and related Mn and Zn complexes have been discussed.

Reaction of bpma with $Cd(ClO_4)_2 \cdot 6\,H_2O$ in acetonitrile, MeCN, yields a complicated compound $[Cd(bpma)(NCMe)(OH_2)(OClO_3)][Cd(bpma)_2](ClO_4)_3 \cdot (MeCN)$ with two different complex cations, both with six-coordinate Cd.[190] In the first complex the four N-donor atoms are arranged in the equatorial plane of a distorted octahedron, with the Cd—NCMe bond being the shortest (226.3 pm) and the other three in a narrow range 228.1–232.1 pm; H_2O and the monodentate $OClO_3^-$ ligand occupy the axial positions (r(Cd—O) 231.3 pm and 247.8 pm, respectively). In the second cation Cd adopts a pseudotrigonal prismatic coordination with clearly longer Cd—N bonds (r_{av}(Cd—N(py) 236.2, r_{av}(Cd—N(amine) 239.5 pm). The tetradentate ligand tris[(2-pyridyl)methyl]amine (tpma) forms the complex $[Cd(tpma)_2](ClO_4)_2 \cdot$toluene, with eight-coordinate Cd and much longer, unsystematically scattering Cd—N bonds ($249.1 \leq r(\text{Cd—N}) \leq 263.0$ pm). The complexation equilibria in MeCN—d_3 have been studied by ^1H NMR spectrometry and coupling constants $J(^{111/113}\text{Cd},^1\text{H})$ reported.

Pyridine derivatives with additional donor functions and sterically demanding substituents have been used with the intention of producing complexes of Cd (and of other metals) with low coordination number; one of these ligands is the tridentate, planar-bonding 2,6-bis[(2,6-dimethylphenylimino)methyl] pyridine (pydim; a Schiff base derived from 2,6-pyridine dialdehyde), which with $Cd(BF_4)_2$ and thiocyanate gives a dinuclear complex $[(pydim)Cd(\mu\text{-NCS-S,N})]_2(BF_4)_2$ with N-dominated coordination sphere.[191] As centrosymmetric ($P2_1/c$, $Z = 2$), the complex has an antiparallel μ-1,3 NCS double bridge with Cd—N and Cd—S bonds (224.6 pm and 255.5 pm, respectively); the Cd—N(py) bond is clearly shorter than the Cd—N(imino) bonds (225.6 pm and 245.0 pm, respectively). Remarkably, the arrangement of these ligands leaves space for a secondary bond Cd···F (254.4 pm) to the counterion BF_4^-.

A further pyridine-based ligand, that is, 2,6-bis(1-salicyloylhydrazonoethyl)pyridine (a Schiff base derivative of 2,6-diacetylpyridine, abbreviated H_4daps), as a pentadentate mono- H_3daps^- or dianion H_2daps^{2-}, respectively, forms several structurally interesting Cd complexes, which all have an almost planar pentagonal CdN_3O_2 environment in common. Hepta-coordination is achieved by the addition of two more ligands in axial positions, e.g., in the neutral complexes $[Cd(H_2daps)(H_2O)_2]$, $[Cd(H_2daps)(H_2O)(i\text{-}PrOH)]$, $[Cd(H_3daps)Cl(MeOH)]\cdot 2\,H_2O\cdot MeOH$, and in the anion of $NMe_4[Cd(H_2daps)Cl(H_2O)]$; in $[Cd(H_3daps)Cl]\cdot 0.25\ H_2O\cdot MeCN$ only hexa-coordination is achieved.[192]

The ligand pyrazineformamide N(4)-methylthiosemicarbazone (Hpyztsc, from cyanopyrazine and N(4)-methylthiosemicarbazide under reducing conditions) acts as a tridentate N,N,S-chelate ligand towards Cd to give $[Cd(pyztsc)_2]$ (as a MeCN solvate).[193] The two almost-planar ligands are arranged in *mer*-configuration, each with the planes roughly perpendicular to each other. The Cd—N bonds to the central N(imine) donors are substantially shorter (r_{av}(Cd—N) 231.3 pm) than to the N donors of the pyrazine rings (r_{av}(Cd—N) 250.4 pm); the Cd—S bonds are 257.5 pm on average. Remarkably, the second N atom of pyrazine does not coordinate to Cd, but is involved in hydrogen bonding; thus the coordination behavior of this pyrazine derivative is rather that of a pyridine-containing ligand.

Naked pyrazine (pyz) acts as a bidentate bridging ligand between Cd centers in $[Cd(pyz)(H_2O)_2MoO_2F_4]$ ($P3_221$, $Z=3$).[194] However, the dominating structural features are octahedral *trans*-$Cd(pyz)_2(H_2O)_2F_2$ and *cis*-MoO_2F_4 units that share fluoride vertices to form helical chains along the threefold screw axes. Linking of the helices is achieved by pyz bridges (along twofold axes), as mentioned above, with bond lengths r_{av}(Cd—N) 232.5 pm. The Cd—OH_2 and Cd—F bonds are quite similar (227.1 pm and 226.2 pm, respectively). As a consequence of the symmetry of the structure nonlinear optical behavior is expected, and indeed second harmonic generation (SHG) is observed.

Hydrido-(1-pyrazolyl)borates $[H_{4\text{-}n}B(C_3H_3N_2)_n]^-$, in short $[H_{4-n}B(pz)_n]^-$, often with more or less bulky substituents in 3- and/or 5-positions of the pz ring, have been used for the preparation of mononuclear complexes with controlled coordination sphere about a metal.[195] With Cd as a metal center different coordination numbers and geometries can be realized, depending on the pyrazolylborate used, but also on the co-ligands.

Unsubstituted dihydridobis(1-pyrazolyl)borate, for instance, gives a mononuclear, severely distorted tetrahedral complex $[Cd\{H_2B(pz)_2\}_2]$ (*Pbca*, $Z=8$).[196] The four independent Cd—N bonds vary significantly (r_{av}(Cd—N) 221.5 pm); the intraligand (bite-) angles are both slightly over 90°, but the interligand angles vary considerably in the range 106.9° to 131.7°, obviously due to the molecular packing.

With the sterically more demanding t-Bu-substituted tripode ligand tris(3-t-Bu-pyrazolyl)borate and $CdCl_2$, $[CdCl\{HB(3\text{-}t\text{-}Bupz)_3\}]$ is obtained with nearly threefold rotational symmetry (true symmetry $m-C_s$ in *Pnma*). The Cd—N bonds do not differ significantly (r_{av}(Cd—N) 224.3 pm) and the Cd—Cl bond is 235.5 pm.[197]

$[CdI\{HB(3\text{-}t\text{-}Bupz)_3\}]$ adopts the same site symmetry, but in $P\bar{4}2_1m$ ($Z=4$). The Cd—N bonds are almost the same (r_{av}(Cd—N) 224.7 pm) as in the chloro complex, and the Cd—I bond length is 267.3 pm.[198] With the further methyl-substituted ligand, the compounds $[CdMe\{HB(3\text{-}t\text{-}Bu\text{-}5\text{-}Mepz)_3\}]$ ($I\bar{4}3d$, $Z=16$) and $[Cd(O_2NO)\{HB(3\text{-}t\text{-}Bu\text{-}5\text{-}Mepz)_3\}]$ ($P2_1/n$, $Z=4$) have been prepared. The former takes the symmetry $3-C_3$ (r(Cd-N) 231.1, r(Cd-C) 207.4 pm); the latter occupies a general position in the lattice (r_{av}(Cd—N) 224.2 pm) and has an almost symmetrical bidentate nitrato ligand (r_{av}(Cd—O) 228.4 pm), as indicated in the formula. Finally, a complex with two i-Pr substituents in 3,5-positions of the pz moieties of the ligand has been presented, namely $[CdI\{HB(3,5\text{-}i\text{-}Pr_2pz)_3\}]$ ($P2_1/m$, $Z=2$; symmetry of the complex again $m-C_s$). The bond lengths are r_{av}(Cd—N) 222.0 and r(Cd—I) 262.2 pm.

For $[Cd(NCS)\{HB(3\text{-}t\text{-}Bupz)_3\}]$ IR spectra indicate N-coordinated thiocyanate, which is confirmed by the crystal-structure analysis ($Pna2_1$, $Z=4$).[191] The three independent Cd—N(pz) bond lengths are all very similar (r_{av}(Cd—N) 222.4 pm), and the Cd—NCS bond is clearly shorter (r(Cd—N) 210.7 pm).

Five-coordinate Cd complexes have been realized by combined ligation of dipode and tripode pyrazolylhydridoborates, e.g., in $[\{HB(3,5\text{-}Me_2pz)_3\}Cd\{H_2B(3,5\text{-}Me_2pz)_2\}]$, $[\{HB(3\text{-}Phpz)_3\}Cd\{H_2B(pz)_2\}]$, and $[\{HB(3\text{-}Phpz)_3\}Cd\{H_2B(3,5\text{-}Me_2pz)_2\}]$; the crystal structure of the latter has been solved ($P\bar{1}$, $Z=2$).[199] The Cd—N bonds to the dipode ligand are clearly shorter (r_{av}(Cd—N) 224.8 pm) than those to the tripode ligand (r_{av}(Cd—N) 234.2 pm); they are arranged in a severely distorted, square-pyramidal geometry. Highly irregular five-coordination is also observed in the dithiocarbamate complex [{HB(3,5-Me_2pz)$_3$}Cd{S_2CNEt_2}] ($P2_1/c$, $Z=4$), with strongly scattering Cd—N bonds (224.9–235.1 pm) and an asymmetrically bonded dithiocarbamate ligand ((*r*(Cd—S) 254.0 pm and 270.8 pm). ^{1}H and particularly ^{113}Cd NMR data for these and a series of other pyrazolylhydridoborate complexes with varying coordination numbers and environments have been measured and discussed. In the four-coordinate complexes the Cd nuclei are much more deshielded than in the five- and six-coordinate species, the ^{113}Cd shift ranges of which overlap substantially.

Substitution of boron in the pyrazolylhydridoborates by carbon gives neutral pyrazolylmethanes, which on coordination to Cd yield cationic complexes completely analogous to the neutral complexes with pyrazolylhydridoborates. The structure of a representative of a tris(pyrazolyl)methane Cd complex, namely [{HC(3,5-Me_2pz)$_3$}$_2$Cd](BF_4)$_2$, has been elucidated ($R\bar{3}$, $Z=3$; trigonal setting).[200] The cation has symmetry $\bar{3}-C_{3i}$, i.e., all six Cd—N bonds are equivalent (*r*(Cd—N) 232.1 pm) and span a trigonally elongated octahedron with an intraligand bite-angle of 80.0°. The analogous neutral pyrazolylhydridoborate complex crystallizes in the same space group and adopts the same symmetry; both Cd—N bonds and bite-angles are much the same (*r*(Cd—N) 234.8 pm, α(N—Cd—N) 82.7°).[201] At the same time, the structure of [{HB(3,5-Me_2pz)$_3$}$_2$Cd] has been described in the same space group ($R\bar{3}$, $Z=2$), but with two independent, slightly differing molecules in the rhombohedral unit cell;[202] the structural data are moderately precise due to disorder, but on the average they match the above data properly, as do ^{1}H NMR data.

Interestingly, the homoleptic tris(pyrazolyl)methane and -hydridoborate complexes undergo conproportionation reactions to yield mixed-ligand complexes, as is also shown by ^{1}H, ^{13}C, and ^{113}Cd NMR spectrometries of the respective solutions; surprisingly, tris(pyrazolyl)methane and -hydridoborate complexes with the same substitution pattern have similar ^{113}Cd shifts, irrespective of the different charge, but change in the substitution also changes the $\delta(^{113}\mathrm{Cd})$ values considerably.[200]

Homoleptic complexes have been obtained also with tetrakis(1-pyrazolyl)borates, e.g., [{B(pz)$_4$}$_2$Cd] and [{B(3-Mepz)$_4$}$_2$Cd] (both $P2_1/c$, $Z=2$); in both compounds' structure analyses the ligands have been shown to coordinate trihapto, i.e., with one pz ring free. In both cases Cd has a distorted octahedral environment, with averaged structural data very similar to those for the tris(1-pyrazolyl)hydridoborate complexes.[201] Variable-temperature ^{1}H NMR studies of these and of mixed complexes with tris- and bis(1-pyrazolyl)hydridoborates indicate fluxional behavior (coalescence temperatures and barriers for the dynamic processes are given).

Cd (and Hg) complexes with bis- and tris(1-pyrazolyl)methanes and -ethanes, as well as with bis(1-triazolyl)methane, have been prepared and studied by conductance measurements (H_2O, dmso, and dimethylformamide (dmf) solutions), IR, far-IR, ^{1}H, and ^{13}C NMR spectrometries.[203] The Cd halides form complexes of the type [$CdLX_2$]; complexes of the types [CdL_2](ClO_4)$_2$ and [CdL_3](BF_4)$_2$ are obtained from the respective Cd salts.

Complex formation in the system aqueous Hg^{2+}/1,2-ethanediamine (en) as a function of the pH has been studied by potentiometry. The data have been discussed on the basis of a system of coupled equilibria comprising [Hg(en)$_2$]$^{2+}$, [Hg(en)(enH)]$^{3+}$, [Hg(en)]$^{2+}$, and [Hg(enH)]$^{3+}$, depending on the pH value.[204–206]

The crystal structures of ethylenediamine mercury(II) dibromide and iodide have been reported.[207] Both compounds are coordination polymers with centrosymmetric en bridging the Hg centers. In the first compound (*Pbam*, $Z=2$), Hg is bonded to two N donors in the *trans*-position (*r*(Hg—N) 219 pm) and to four Br atoms (*r*(Hg—Br) 301.2 pm), forming a distorted octahedron. In the second, Hg is bonded to two N atoms (*r*(Hg—N) 234 pm and 235 pm) and to two I atoms (*r*(Hg—I) 269.1 pm and 274.0 pm), forming a distorted tetrahedron.

Stepwise formation constants have been determined in the system Hg^{2+}/Cl^-/diethylenetriamine (dien) and related systems by potentiometry. Thermodynamic parameters have been calculated and the contribution of the entropy term to complex stability discussed.[208]

The reactions of mercury(II) salts with oligo-amines afford informative examples for the fact that counterions induce the formation of a distinct complex or select a distinct complex in an equilibrium to crystallize with. Thus, Hg^{II} acetate with dien under exactly the same reaction conditions, in the presence of ClO_4^- or PF_6^-, yields the dinuclear complex [Hg_2(dien)$_3$](ClO_4)$_4$ or the mononuclear species [Hg(dien)(H_2O)](PF_6)$_2$, respectively, both characterized by IR, ^{1}H, and ^{13}C NMR spectrometries, by fast-atom bombardment (FAB) MS, cyclovoltammetry, and X-ray structure analyses.[209] In the first compound ($Pna2_1$, $Z=4$), one Hg adopts five-coordination with one tridentate and one bidentate dien ligand, which with the remaining N-donor binds to the second tetrahedral Hg center. Similarly to the Cd dien complexes, the central Hg—N bonds to the secondary N donors are longer than those to the primary N donors (NH_2 groups), whereby differences due to different coordination numbers have to be considered. The Hg—N bond in the bridge between the coordination centers is exceptionally short (217.4 pm). In the second complex ($P2_12_12_1$, $Z=8$), the two independent, tetrahedral, cationic entities have very similar structures, with r_{av}(Hg—N) 230.8 pm and 235.7 pm, respectively, for the two kinds of Hg—N bonds to primary and secondary N donors; the Hg—OH_2 bonds (214.1 pm) are much shorter than all the different Hg—N bonds in both complexes.

In a way related are the complexes formed by Hg salts and multicrown dendrimers of different generations (dendrimers with a polypropylene amine interior of different volume and benzo[15]-crown-5 ether periphery), studied by extraction methods using radioactive $^{203}Hg^{2+}$.[210] Up to 12 Hg^{2+} ions were found to be bound per dendrimer molecule, obviously in the amine-dominated interior, not in the crown-ether periphery.

The 1:2 complex of Hg^{2+} with the tacn derivative mono-N-(4-vinylbenzyl)-1,4,7-triazacyclononane copolymerizes with *p*-divinylbenzene to give an Hg-templated polymer which, after demetalation with 6 N HCl, is a highly selective gathering material for Hg^{2+} in competition with other transition metals like Cd^{2+}, Ag^{+}, Pb^{2+}, Cu^{2+}, and Fe^{3+} at low pH values.[211]

The crystal structure of hexakis(pyridine)mercury(II) trifluoromethanesulfonate $[Hg(py)_6](O_3SCF_3)_2$ has been determined both at ambient and low temperatures (183 K; $P\overline{1}$, $Z=2$; no phase transition). In the complex cation the six Hg—N bonds form tetragonally elongated octahedra (two long bonds in *trans*-position, four shorter ones in the equatorial plane), with the distortion more pronounced at low temperature (r_{av}(Hg—N 249.8 pm vs. 241.9 pm).[212] Thermoanalysis (TG, DSC, also of $[Hg(py)_6](ClO_4)_2$) also suggests that two molecules are more weakly bound than the others; in the further thermal degradation py molecules leave in pairs via the intermediate $[Hg(py)_2](O_3SCF_3)_2$. Electronic effects are discussed as a reason for the distortion; contributions of packing effects are ruled out.

A wealth of structures of Hg complexes with py, e.g., $[Hg(py)_2]X_2$ (X = Cl, Br, I), $[Hg(py)_4](ClO_4)_2$, $[Hg(py)_4](ClO_4)_2\cdot 2$ py, but also with other N heterocycles, e.g., $[Hg(pyridazine)]X_2$, $[Hg(pyrimidine)]X_2$, $[Hg(pyrazine)]X_2$, and with other N-donor ligands, has been determined and dealt with in a recent dissertation.[213]

As with Cd, the tri- and tetradentate ligands bis- and tris(2-pyridylmethyl)amine (bpma and tpma) have been used for complexation of Hg. Thus, $[Hg(bpma)_2](ClO_4)_2$ (as toluene solvate) has been prepared and its structure elucidated ($P\overline{1}$, $Z=2$). Differing from the $[Cd(bpma)_2]^{2+}$ cation, $[Hg(bpma)_2]^{2+}$ approaches a trigonal prismatic coordination with similar Hg—N bonds (r_{av}(Hg—N) 238.8 pm), except for one rather long Hg—N(py) bond (255.7 pm); a weak interaction with one of the counterions (secondary Hg···O bond) could be the reason for this deviation.[214] $Hg(ClO_4)_2$ and bpma (ratio 1:1) in MeCN give $[Hg(bpma)(NCMe)](ClO_4)_2$ in crystals appropriate for structure determination ($P2_1/c$, $Z=4$). In this case, the N donors of bpma and MeCN are arranged in an equatorial pseudoplane with a short Hg—NCMe bond (222.6 pm), a longer bond in the *trans*-position (240.1 pm), and two similar Hg—N(py) bonds (about 222 pm); the strongly distorted octahedral coordination is completed by two secondary Hg···O bonds (270 pm and 290 pm). The complexation equilibria in MeCN-d_3 solution have been studied by ^1H NMR spectrometry, and possible mechanisms of slow rearrangements discussed.

$Hg(ClO_4)_2$ and tpma in acetone yield $[Hg(tpma)_2](ClO_4)_2$; $HgCl_2$ and tpma in MeCN give $[Hg(tpma)Cl](HgCl_4)$. The former ($P2_1/n$, $Z=2$) has an eight-coordinate centrosymmetric cation, best described as a bicapped trigonal antiprism, with very similar, long Hg—N bonds ($256.0 \le r$(Hg—N)≤ 259.5 pm, r_{av}(Hg—N) 257.8 pm). The latter ($P\overline{1}$, $Z=2$) contains five-coordinate Hg in a distorted trigonal bipyramid, with the chloro ligand opposite to the amine N in axial positions. As expected for a lower coordination number, the Hg—N bonds in both of the two independent complex cations are shorter than before, namely r_{av}(Hg—N(py)) 239.4 and r_{av}(Hg—N(amine)) 243.4 pm; the Hg—Cl distances in the cations (average 235.4 pm) are close to those in $HgCl_2$. ^1H and ^{13}C NMR studies of solutions help to identify the species present in the equilibria; under conditions which slow down the exchange processes, ^{199}Hg,^1H and ^{199}Hg,^{13}C couplings become observable[215] (cf. also ref. 190).

In the presence of $Hg(SCN)_2$, pyridine-2,6-dicarbaldehyde and 2,6-bis(2-aminothiophenoxymethyl)pyridine undergo a metal-templated cyclocondensation to give immediately the 1:1 complex of $Hg(SCN)_2$ and the macrocyclic, 18-membered diimine (Schiff base). The structure analysis shows that the $Hg(SCN)_2$ molecule is strongly asymmetrically located in the macrocyclic ring, close to its Schiff-base segment, with the S—Hg—S axis nearly perpendicular to the pseudoplane of the ring; the two sulfur donors in the ring form only long, secondary bonds to Hg. Thus, Hg adopts a peculiar 2(S)+3(N)+2(S) coordination (distances r_{av}(Hg—SCN) 246.4, r_{av}(Hg—N) 266.6, r_{av}(Hg···S) 312.8 pm).[216] This complex and related others have been further characterized by IR, ^{1}H, and ^{13}C NMR and FAB mass spectrometries.

Simple mixing of $Hg(ClO_4)_2$ in MeOH and 2,4,6-tris(4′-pyridyl)-1,3,5-triazine (tpt) in tetrachloroethane $C_2H_2Cl_4$ produces the structurally highly interesting compound $[Hg(tpt)_2](ClO_4)_2 \cdot 6\text{-}C_2H_2Cl_4$ ($Pa\bar{3}$, $Z=4$), in which Hg (site symmetry $\bar{3}-C_{3i}$) adopts an almost perfect octahedral coordination, with six equivalent Hg—N bonds to six tpt ligands (r(Hg—N) 244.3 pm) and angles deviating only slightly from 90° (α(N—Hg—N) 88.8/91.2°). As each tpt coordinates to three Hg centers a wide-pore 3-D framework $_\infty^3[Hg(tpt)_{6/3}]^{2+}$ is generated, with the counteranions and solvate molecules located in its large voids.[217] Possible relationships of this type of framework to simple inorganic AX_2 structures are discussed.

(iii) N-coordinating cyanometallates

As mentioned in the introductory part of Section 6.9.4.2.3, compounds are known in which Cd or Hg is coordinated to the N-ends of cyano groups C-bonded to another element.

To start with a relatively simple case, $Rb[Cd\{Ag(CN)_2\}_3]$ (from RbCl, $AgNO_3$, $Cd(NO_3)_2$, and NaCN in H_2O) is discussed. In its structure ($P312$, $Z=1$), Cd and the rod-like N-coordinating NC—Ag—CN units create three independent, interpenetrating, 3-D frameworks; Cd (symmetry $32-D_3$) has trigonally distorted octahedral coordination (r(Cd—N) 232.4 pm). Rb occupies one of two types of trigonal channels.[218]

From $CdCl_2$, $K[Ag(CN)_2]$ (ratio 1:2), and NH_3 at pH 10 (citrate buffer), colorless crystals of $[Cd(NH_3)_2\{Ag(CN)_2\}_2]$ ($P4_2/mbc$, $Z=4$) are formed. Therein, *trans*-$Cd(NH_3)_2$ entities ($2/m-C_{2h}$) are linked by slightly bent NC—Ag—CN units to form a puckered 2-D network with large, 24-membered meshes. Two of these networks (transformed into each other by the 4_2 operation, i.e., they are perpendicular) interpenetrate.[163] Similar corrugated sheets occur in [*trans*-Cd(4-Mepy)$_2\{Ag(CN)_2\}_2$]·(4-Mepy) (4-Mepy = 4-methylpyridin) ($Ibca$, $Z=16$; all atoms in general positions); but here, they are pairwise interwoven in the same layer. The intercalated 4-Mepy molecules are located in the meshes of this layer.[219] From the same reaction medium, [Cd(4-Mepy)$_4\{Ag_2(CN)_3\}$][$Ag(CN)_2$] ($C2/m$, $Z=2$) crystallizes after some days. Here, the Cd(4-Mepy)$_4$ units ($2/m-C_{2h}$) are linked by almost linear NC—Ag—(C,N)—Ag—CN rods to form chains, which in turn are arranged in layers. Inserted between the chains or into the layers are linear $[Ag(CN)_2]^-$ anions.[219]

4,4′-Bipyridyl (4bipy) in place of 4-Mepy, under otherwise the same conditions, produces [*trans*-Cd(4bipy)$_2\{Ag(CN)_2\}_2$] ($P2_1/c$, $Z=2$); with pyrazine (pyz), $K_2[Cd(CN)_4]$, and $AgNO_3$ (1:2:1) [*trans*-Cd(pyz)$\{Ag_2(CN)_3\}\{Ag(CN)_2\}$] ($P2/c$, $Z=2$) is generated. In the former, 4bipy acts as a linker between layers $_\infty^2[Cd\{Ag(CN)_2\}_{4/2}]$ to form a 3-D framework, with two of these interpenetrating each other. In the latter, Cd and $\{Ag_2(CN)_3\}$ form nearly linear chains in one direction, which are linked to a 2-D network with rectangular meshes by $\{Ag(CN)_2\}$, and linkage of these nets to a 3-D framework is achieved by pyz. Here, even three identical 3-D frameworks interpenetrate one another.[220]

Finally, a highly complex structure is created when *trans*-Cd(4-ampy)$_2$ (4-ampy = 4-aminopyridine) and Cd(4-ampy)(ame)$\{Ag(CN)_2\}$ units (ame = 2-aminoethanol) are linked by bridging μ-$\{Ag(CN)_2\}$ groups to form a 2-D network with rhombus meshes and almost linear chains. These antiparallel chains in pairs embrace the nets.[221]

Cd^{2+} and hexacyanometallates $[M(CN)_6]^{3-}$ (M = Fe, Co) join to build up interesting framework structures in $NMe_4Cd[M(CN)_6] \cdot 3H_2O$ ($I4$, $Z=10$). Two different kinds of Cd centers (octahedral and square pyramidal, respectively) are linked by octahedral $M(CN)_6$ units to form primarily slightly puckered 2-D networks with nearly square meshes; in addition, 3-D linkage of these nets is achieved by CN bridges between $M(CN)_6$ groups and square-pyramidal Cd in adjacent nets. Thus, the two Cd centers get $Cd(OH_2)_2N_4$ and CdN_5 coordinations (r_{av}(Cd—N) 229.5, r_{av}(Cd—O) 237.1, and r_{av}(Cd—N) 224.4 pm, respectively, for M = Fe).[222]

Together with Cd, $Fe(CN)_6$ also acts as a layer builder in $[Cd(tren)]_2[Fe(CN)_6] \cdot 3H_2O$ (tren = tris(2-aminoethyl)amine) ($P2_1/n$, $Z=2$). Here, two Cd(tren) fragments (with tetradentate tren) and two Fe centers are linked by two μ_3-CN to form a tetranuclear, heterometallic unit with a central square Cd_2N_2 entity; this tetranuclear unit is the building block of a 2-D layer. A further μ-CN group augments the coordination polyhedron of Cd to a distorted pentagonal bipyramid ($232.6 \leq r$(Cd—N) ≤ 265.3 pm).[223]

Minor changes in one of the reagents can induce drastically different structures. Thus, if $[Fe(CN)_6]^{4-}$ is replaced by $[Fe(CN)_5(NO)]^{2-}$ in the reaction with $[Cd(tren)]^{2+}$, the simple-looking $[Cd(tren)][Fe(CN)_5(NO)]$ ($P2_1/n$, $Z=2$) is formed. Here, two [Cd(tren)] (with tridentate tren!) and two $[Fe(CN)_5(NO)]$ units join to a tetranuclear, centrosymmetric ring $Cd_2Fe_2(CN)_4$ (CN on the edges), which is linked to two adjacent rings by the pendant arms of the tren ligand to form a shelf-type polymer. In the similarly prepared $[Cd(tren)][Pd(CN)_4]$ ($P2_12_12_1$, $Z=4$), the [Cd(tren)] units (tetradentate tren) are linked by $[Pd(CN)_4]$ groups (cisoid) to a battlement-like chain or ribbon. Finally, $[Pt(CN)_6]^{2-}$ in place of $[Pd(CN)_4]^{2-}$ simply links two [Cd(tren)] units to a discrete, trinuclear, centrosymmetric cation $[(tren)Cd(NC)Pt(CN)_4(CN)Cd(tren)]^{2+}$, with $[Pt(CN)_6]^{2-}$ as counterion ($P2_1/c$, $Z=4$).[224]

A rather complex structure is built up when reacting the heterocubane $[Re_4Te_4(CN)_{12}]^{4-}$ with $CdSO_4$ in aqueous ammonia to yield $[Cd(NH_3)_5][Cd(NH_3)_3][Re_4Te_4(CN)_{12}]$ ($P\bar{1}$, $Z=2$) (cf. Section 6.9.4.2.3.ii). One *mer*-$Cd(NH_3)_3$ group links three heterocubane clusters via μ-CN bridges, and vice versa, to form a double-strand chain, and to each of these linked clusters a further terminal $Cd(NH_3)_5$ group is bound by a μ-CN bridge ($236 \leq r$ (Cd—NC) ≤ 243 pm).[164]

Back to simplicity: $Hg(NO_3)_2$ in aqueous HNO_3 with $K[B(CN)_4]$ gives $Hg[B(CN)_4]_2$ ($P\bar{3}m1$, $Z=1$), with Hg in an almost perfect octahedral environment HgN_6 (symmetry $\bar{3}m - D_{3d}$) but with relatively long Hg—N bonds (r(Hg—N) 236.4 pm, α(N—Hg—N) 89.2/90.8°). This compound undergoes comproportionation with metallic Hg to yield the simple dimercury(I) compound $Hg_2[B(CN)_4]_2$. IR and Raman spectra of both compounds have been discussed, and assignments suggested; strangely enough, vibrations of the HgN_6 entities have not been mentioned. A compilation and comparison of structural data of 10 compounds with the HgN_6 core, of different topologies and symmetries, has been included.[225]

6.9.4.2.4 Compounds with donor atom P

Phosphides and amides are closely related, as a synthetic route is based on metathesis of metal amides, especially the respective trimethylsilyl amides, with the appropriate free acidic phosphine or an anion derived therefrom. Reaction of metal halides and trisilylphosphines is an alternative for preparing metal phosphides.

(i) Phosphides

A reaction of the first type, in a broad sense, uses the mixture obtained from n-BuLi and the phosphinic acid $(mes)_2P(H){=}O$ (mes = 2,4,6-trimethylphenyl) in thf/hexane to which the Cd amide $Cd[N(SiMe_3)_2]_2$ is added; a mixed amide-phosphinite is obtained, namely $[\{MeSi)_2N\}Cd\{(mes)_2PO\}_2Li\cdot 2\ thf]$. The structure analysis (153 K) reveals that the two phosphinite ligands act as a double bridge between Cd and Li to give a six-membered, twisted ring with two independent Cd—P bonds (r_{av}(Cd—P) 259.4 pm); the exocyclic Cd—N bond is rather short (213.6 pm).[226]

In a metathesis reaction $M[N(SiMe_3)_2]_2$ (M = Cd, Hg) and $HP(SiMe_3)_2$ (ratio 1:2) give the dimers $\{M[P(SiMe_3)_2]\}_2$ in good yield;[227,228] methanolysis of the Cd compound gives Cd_3P_2 (potential semiconductor).[227] In their structures (both in $P\bar{1}$, $Z=1$, similar unit-cell volumes), the centrosymmetric dinuclear units have almost symmetric bridges μ-$P(SiMe_3)_2$ for M = Cd (r_b(Cd—P) 257.5 pm and 261.2 pm), but strongly asymmetric bridges for M = Hg (r_b(Hg—P) 241.0 pm and 324.6 pm); the terminal M—P bonds are shorter, as expected (r_t(Cd—P) 246.9 and r_t(Hg—P) 240.2 pm). The Hg compound can also be considered to be a monomer, with an almost linear P—Hg—P axis and secondary P···Hg bonds perpendicular to this axis.[228] A similar structural situation is met in the homologous compound $[Hg(P{-}t\text{-}Bu_2)_2]_2$ (linear P—Hg—P axis, r_{av}(Hg—P) 244.7 pm; secondary P···Hg bonds r(P···Hg) 316 pm).[229] Temperature-dependent ^1H and ^{31}P NMR spectrometries show the Cd compound to persist as a (fluxional) dimer in solution; kinetic parameters are given and possible pathways for the bridging-to-terminal site exchange of the phosphido ligands discussed. In contrast, the Hg compound in solution is a monomer under all conditions studied.[228]

The above-mentioned $[Hg(P{-}t\text{-}Bu_2)_2]_2$ has been obtained in a phosphide-transfer reaction between $HgMe_2$ and $Ga(P{-}t\text{-}Bu_2)_3$. If $CdMe_2$ and $Ga(P{-}t\text{-}Bu_2)_3$ are reacted, the product is the trimeric $[MeCd(P{-}t\text{-}Bu_2)_2]_3$ with a six-membered Cd_3P_3 ring in twist-boat conformation and exocyclic Cd—Me bonds; thus, Cd achieves near-planar, three-coordinate geometry. The Cd—P bond lengths in the ring are all similar (r_{av}(Cd—P) 258.5 pm); in solution these Cd—P bonds obviously level, as only one sharp single line (with $^{111/113}$Cd satellites) is observed in the ^{31}P{^{1}H} NMR spectrum.[229]

Upon reaction of $M[N(SiMe_3)_2]_2$ ($M = Cd$, Hg) with the bulky phosphide $LiP(SiPh_3)_2$, the stable monomeric complexes $M[P(SiPh_3)_2]_2$ are produced (one single ^{31}P resonance). The crystal structure of $Cd[P(SiPh_3)_2]_2$ ($C2/c$, $Z = 4$) contains centrosymmetric molecules with an exactly linear P—Cd—P group (r(Cd—P) 242.7 pm). In spite of the strong steric shielding this molecule retains some Lewis acidity, as shown by monitoring its reaction with py or PMe_3 by ^{31}P NMR spectrometry (estimation of formation constants of the complexes $Cd[P(SiPh_3)_2]_2{\cdot}L$).[230]

With the sterically less demanding phosphide $LiPPh_2$ in thf, $Cd[N(SiMe_3)_2]_2$ reacts to give the product $[Li(thf)_4]_2[Cd_4(PPh_2)_{10}]$. In the adamantoid complex anion μ-PPh_2 ligands are located in front of all of the edges of the Cd_4 tetrahedron, and terminal PPh_2 ligands complete the coordination around Cd to distorted tetrahedral. The Cd—P bond lengths in the bridges vary unsystematically (r_{av}(Cd—P) 265.7(20) pm), as do the terminal Cd—P bonds (r_{av}(Cd—P) 260.9(12) pm).[231] At room temperature the ^{31}P{^{1}H} NMR spectrum shows a single resonance which splits at lower temperatures (also $^{111/113}$Cd satellites appear), indicating the freezing of an intramolecular exchange of terminal and bridging phosphide ligands.

Reaction of $CdCl_2$ with Ph_2PSiMe_3 in the presence of $P(n\text{-}Pr)_3$ also leads to an adamantoid species $[Cd_4Cl_4(PPh_2)_4(PPr_3)_2]$ ($C2/c$, $Z = 4$). The molecules have crystallographically imposed symmetry $2 - C_2$, with two bridging PPh_2 ligands on opposite edges of the Cd_4 tetrahedron on the twofold axes; two more μ-PPh_2 and two μ-chloro ligands are related by symmetry, as are pairs of terminal PPr_3 and Cl ligands. Two of the μ-PPh_2 bridges are necessarily the other two *de facto* symmetric (r_{av}(Cd—P) 253.8 pm), whereas the μ-Cl bridges are clearly asymmetric. Remarkably, the terminal Cd—PPr_3 bonds are longer (r(Cd—P) 260.9 pm) than the bridging ones, in contrast to the terminal Cd—Cl bonds.[232]

CdI_2 and $P(SiMe_3)_3$ in dimethoxyethane (dme) react to give simply $[CdI_2\{P(SiMe_3)_3\}]_2$, a near-centrosymmetric dinuclear species with an almost square core Cd_2I_2 and two terminal I and $P(SiMe_3)_3$ ligands, respectively ($P2_12_12_1$, $Z = 4$, general positions only). The four Cd—I bonds in the central Cd_2I_2 unit are all independent, but very similar (r_{av}(Cd—I) 287.5 pm); also the terminal Cd—I and Cd—P bonds show minor differences (r_{av}(Cd—I) 271.5 and r_{av}(Cd—P) 255.5 pm).[233] Upon reaction of $[CdI_2\{P(SiMe_3)_3\}]_2$ with n-Bu_4NI in thf $[n\text{-}Bu_4N]_2[Cd_4I_8\{P(SiMe_3)_2\}_2]$ is formed, again with an adamantoid anionic complex unit ($Pna2_1$, $Z = 4$, general positions only). A tetrahedral Cd_4 core is bridged on two opposite edges by μ-$P(SiMe_3)_2$ ligands, four μ-iodo ligands are placed on the other edges, and four terminal iodo ligands are bound to each of the Cd corners, completing a tetrahedral coordination of Cd. Although crystallographically independent, the chemically equivalent bonds are very similar throughout. Thus, both of the μ-$P(SiMe_3)_2$ bridges are nearly symmetric, with nonsignificant differences in the Cd—P bonds (r_{av}(Cd—P) 250.7(3) pm); out of the four μ-I bridges only one is significantly asymmetric (r_{av}(Cd—I) 285.4(9) pm), and the terminal Cd—I bonds show minor scatter (r_{av}(Cd—I) 273.2(10) pm).[233]

(ii) Phosphine complexes

A series of Cd phosphine complexes $(Et_3P)_2Cd_2X_4$ and $(R_3P)_2CdX_2$ ($R_3P = Ph_3P$, Bu_3P, Et_3P, 1-phenyldibenzophosphole (dbp), 1-phenyl-3,4-dimethylphosphole (dmpp); X = Cl, Br, I) have been prepared and studied by IR, solution and solid-state CP/MAS spectrometries (^{31}P{^{1}H} and ^{113}Cd{^{1}H}), and partly by X-ray structure analyses.[234] Both $(Ph_3P)_2CdI_2$ and $(dbp)_2CdI_2$ ($P2_1/a$, $P2_1/c$, $Z = 4$) own distorted tetrahedral coordination around Cd, with similar Cd—P and Cd—I bond lengths, respectively ($260.3 \leq r$(Cd—P)≤ 265.3 pm, $271.8 \leq r$(Cd—I)≤ 273.1 pm). On the basis of the temperature dependences of ^{31}P{^{1}H} NMR spectra of some $(R_3P)_2CdX_2$ species, kinetic and thermodynamic data for the equilibria $(R_3P)_2CdX_2 \rightleftharpoons (R_3P)CdX_2 + R_3P$ have been determined. For the compounds $(Et_3P)_2Cd_2X_4$ NMR spectra suggest dinuclear symmetric entities with double halide bridges, and for solid $(Bu_3P)_3Cd_2X_4$ a structure $(Bu_3P)_2Cd(\mu\text{-}X)_2CdX_2(PBu_3)$, with four- and five-coordinate Cd, is proposed.

In a thorough work with an extensive literature survey, crystal structures, vibrational and ^{31}P NMR spectra of several phosphine complexes of mercury(II) halides HgX_2 are presented.[235] In the dibenzophosphole complex $(dbp)_2HgBr_2$, Hg adopts a distorted tetrahedral coordination (r_{av}(Hg—P) 250.2, r_{av}(Hg—Br) 261.1 pm) (cf. the related Cd complex in the previous paragraph), with slightly shorter Hg—P and Hg—Br bonds, respectively, than in the comparable

$(Ph_3P)_2HgBr_2$.[236] $[(Ph_3P)HgBr_2]_2$ can be described as two edge-sharing tetrahedra around Hg centers, with asymmetric, double μ-Br bridges $[(Ph_3P)HgBr(\mu\text{-}Br)_2HgBr(PPh_3)]$ (r_{av}(Hg-P) 242, r_{av}(Hg—Br_t) 250.2, r_{av}(Hg—Br_b) 275.7 pm); the analogous $[(Ph_3P)HgI_2]_2$ adopts a comparable structure (r_{av}(Hg—P) 247.2, r_{av}(Hg—I_t) 267.8, r_{av}(Hg—I_b) 291.4 pm) with even more asymmetric μ-I bridges.[237] Finally, in the dimethylphosphole complex $[(dmpp)HgI_2]_2$ with a similar overall structure, the terminal bonds are shorter, but the μ-I bridges longer and less asymmetric than before (r_{av}(Hg—P) 245.4, r_{av}(Hg—I_t) 263.9, r_{av}(Hg—I_b) 295.6 pm).[235] The seemingly analogous $[(Bu_3P)HgI_2]_2$ adopts a different structure, approximately given by the formula $[(Bu_3P)_2Hg(\mu\text{-}I)_2HgI_2]$; the $(Bu_3P)_2Hg$ fragments (r_{av}(Hg—P) 239.2, α_{av}(P—Hg—P) 161.5°) tend to linearity, the μ-I bridges are strongly asymmetric, and the terminal Hg—I bonds of the HgI_2 fragment the shortest in this entity (r_{av}(Hg—I_t) 268.8 pm). Thus, the complex can formally be considered to contain $[(Bu_3P)_2Hg]^{2+}$ and $[HgI_4]^{2-}$ ions, connected by two secondary I···Hg bonds.[235] $[(Pr_3P)HgI_2]_2$ has a similar structure, but the separation of the constituents is less pronounced.[238] IR and Raman data, as well as findings from solution and solid-state ^{31}P NMR spectra, have been correlated with structural data.[235]

An insight into the equilibria present in solutions of several complexes of the type $(R_3P)_2HgX_2$ ($X = ClO_4$, CF_3COO) is provided by electrospray mass spectrometry (ES MS) (cf. Section 6.9.2.1.8).[239] In all cases the principal ions $[(R_3P)_2HgX]^+$ are observed, even if these ions and other ionic constituents of the equilibria are known to be labile on the NMR timescale. In the presence of excess R_3P the principal ions $[(R_3P)_3HgX]^+$ appear. Also fragments of collisionally activated decomposition (CAD, can be influenced and controlled to some extent) are detected, e.g., $[(R_3P)HgX]^+$.

In a paper on complexes of mercury(II) halides with the sterically demanding ligand tris(2,4,6-trimethoxyphenyl)phosphine (tmpp), a selective literature survey of the field of HgX_2–PR_3 complexes has been given.[240] In particular, tmpp complexes with HgX_2 (X = Cl, Br, I) and P:Hg ratios 1:1, 2:1, and 2:3, and their vibrational and solution ^{31}P NMR spectra, are presented and discussed. Crystal structures of the monomeric complexes $(tmpp)HgX_2$ (X = Br, I) and of $(tmpp)(HgI_2)_2$ have been reported. The first two compounds have basically the same structures (albeit in different space groups), with three-coordinate Hg (short Hg—P bonds of about 243 pm, two different terminal Hg—X bonds); two secondary O···Hg from the OMe groups in *o*-positions of the organic substituents have also to be considered. In $(tmpp)(HgI_2)_2$ Hg tends to be two-coordinate, with even shorter Hg—P and terminal Hg—I bonds (240.8 pm and 261.9 pm); two fragments (tmpp)(HgI) are linked by a dinuclear bridge, described in some detail with the formula $[(tmpp)(HgI)(\mu\text{-}I)HgI(\mu\text{-}I)_2HgI(\mu\text{-}I)(HgI)[(tmpp)]$, or with some simplification in the shorter $[(tmpp)(HgI)(\mu\text{-}Hg_2I_6)(HgI)[(tmpp)]$. The secondary O···Hg contacts are shorter than before.

Again a distorted tetrahedral coordination of Hg is achieved in the 1,1-bis(diphenylphosphino)ferrocene (dppf) complex with HgI_2. Both Hg—P in the dppf chelate ring and terminal Hg—I bonds (averages 256.5 pm and 277.6 pm, respectively) are clearly longer than in the previous examples; all angles around Hg are close to the value for a tetrahedron. Nonlinear optical properties of the material have been studied.[241]

A completely different structural situation is met with the mixed phosphine complex $[Hg\{OP(O)CF_3(OH)\}_2(PMe_3)_3]$, obtained from $[Hg\{P(CF_3)_2\}_2(PMe_3)_2]$ (for formation and properties of this compound see ref. 242) in a multistep hydrolysis in the presence of PMe_3.[243] In a trigonal-planar fragment $Hg(PMe_3)_3$ (r_{av}(Hg—P) 246.7 pm), the coordination is expanded to distorted trigonal bipyramidal by two O donors of the phosphinic acid ligands in axial positions. These units are linked to polymers by rather short hydrogen bonds (O—H···O).

6.9.4.2.5 Compounds with donor atoms As and Sb

A Cd—Sb compound with potential application in semiconductor technology has yet to be mentioned. CdI_2 and tetraethyldistibine, Sb_2Et_4, in thf react to give crystalline $Sb_2Et_4{\cdot}2\ CdI_2$ after some time. The crystal structure is made up of molecules $(I_2Cd)Sb(Et_2)Sb(Et_2)(CdI_2)$, with the central Sb_2Et_4 moiety (r(Sb—Sb) 278.4 pm) in skew conformation and the terminal Cd centers in trigonal-planar coordination (r_{av}(Cd—I) 275.1, r_{av}(Cd—Sb) 282.2 pm). Intermolecular secondary bonds I···Cd expand the coordination to distorted trigonal bipyramidal and link the molecules to chains, which in turn are covalently connected by the Sb_2Et_4 linkages to form a 2-D network.[244]

6.9.4.2.6 *Frameworks made up of Cd, Hg, and P, As, Sb*

In recent years a great variety of ternary and/or quaternary systems containing Cd or Hg, one of the pentels (Pn = P, As, Sb), and a halogen or a halogenometalate have been prepared by heating a metal halide, e.g., HgX_2 or Hg_2X_2, with an elemental pentel, and if desirable, an additional metal M′ or a halide thereof. A typical example is the deceptively simple-looking $(Hg_2P)_2HgBr_4$, obtained as a bright yellow, crystalline material by heating $HgBr_2$, red phosphorus, and mercury in the appropriate ratio in a sealed ampoule at 300 °C for several days.[245] In the structure ($P2_1$, $Z = 2$), a cationic 3-D framework with tridymite-like topology is built up by corner-sharing tetrahedra PHg_4 corresponding to the Niggli formula ${}_{\infty}{}^{3}[PHg_{4/2}]^{+}$; in pseudohexagonal channels of this framework, chains of apex-sharing trigonal bipyramids $HgBr_5$ (${}_{\infty}{}^{1}[HgBr_3Br_{2/2}]^{2-}$) are running along the 2_1 axes. The cationic framework can be considered as a coordination-polymeric tetramercurio-phosphonium complex, i.e. a metallo-onium complex. Another, related example is $[Hg_2Sb]GaCl_4$ (*Pbcn*, $Z = 8$), with a framework of low-cristobalite topology and cavities hosting the isolated anions.[246]

In these structures the PnM_4 (M = Cd, Hg) tetrahedra can fully or partly be replaced by Pn_2M_6 groups (trigonally elongated octahedra with a Pn_2 core), as is found in $[Hg_6P_4][M'X_6]X$,[247] in $[Hg_6As_4][M'X_6]X$,[248,249] in $[Hg_6Sb_4][M'X_6]X$,[250] or in the phases $[Hg_6Pn_4X_3][SnX_3]$[251] and $[Hg_7Pn_4X_3][SnX_3]$.[252]

A further modification can be achieved by combining Hg, Hg_2, and Hg_3 groups as linkers between Pn atoms, as is the case with $[Hg_{11}As_4](GaBr_4)_4$.[253] Here Hg and As form corrugated layers ${}_{\infty}{}^{2}[AsHg_{3/2}]$, which are linked in one crystallographic direction alternately by Hg_2 and Hg_3 sticks, thus creating two types of channel with different cross-sections and filled by the isolated anions as guests.

A review on mercury and cadmium pentelide halides has appeared,[254] with emphasis on discussion of the structures, based on the Zintl–Klemm concept, and their relationship to the electronic properties.

6.9.4.2.7 *Compounds with donor atom O*

In many closely related compounds of Cd and Hg with all-oxygen or oxygen dominated coordination spheres, the metals adopt different coordination numbers and geometries—even independent metals in the same structure. As a rule, in the rare isostructural Cd and Hg compounds, Hg possesses the more distorted coordination.

As the structures of comparable or analogous Cd and Hg compounds are often different, they are dealt with separately.

(i) Cadmium

In a simple triple oxide Sr_3CdPtO_6 ($R\bar{3}c$, $Z = 6$, trigonal setting), Cd has a trigonal-prismatic (r(Cd—O) 232.8 pm), but Pt an octahedral six-coordination; these polyhedra share opposite triangular faces to form columns ${}_{\infty}{}^{1}[Cd_{trip}O_{6/2}Pt_{oct}O_{6/2}]^{6-}$ along the three-fold axes in a hexagonal rod packing arrangement.[255]

In contrast, Cd in $[Cd(H_2O)_6](ClO_4)_2$ ($P\bar{3}m1$, $Z = 1$) ($[Hg(H_2O)_6](ClO_4)_2$ has the same structure [256]) has an almost perfect octahedral surrounding (r(Cd—O) 227.7 pm, α(O—Cd—O) 87.69°);[257] the Cd—O bond length of $[Cd(H_2O)_6]^{2+}$ in aqueous solution is only slightly different (229.2 pm).[258] Quantum-chemical calculations (SCF, effective core potentials, relativistic effects) for the hexaaqua complexes $[M(H_2O)_6]^{2+}$ (M = Zn, Cd, Hg) give results for *inter alia* bond lengths and vibrational frequencies that are in reasonable agreement with experimental data.[259]

Another structure with reference character is that of $[Cd(thf)_4(BF_4)_2]$ ($P2_1/n$, $Z = 2$), with a centrosymmetric octahedral complex unit (r(Cd—O) 221.9 pm and 226.3 pm) and, rather unusual, strongly coordinated BF_4 ligands in axial positions (r(Cd—F) 230.7 pm).[200]

Hydroxo complexes of Cd are rare. In one example, two μ-OH groups link two Cd centers to a distorted square $Cd_2(OH)_2$ (r_{av}(Cd—O) 222.5 pm); otherwise two tetradentate N,S-donor ligands complete the coordination sphere of Cd. Remarkably, in a reaction with CO_2 the two μ-OH groups are replaced by one μ-carbonato group.[260]

Towards Cd the *cis*-$[Cr(OH)_2(en)_2]^{+}$ unit acts as a chelating ligand and yields heterometallic Cd(μ-OH)$_2$Cr moieties as components in structures. Examples are the straight cationic chain

$_\infty^1[Cd(\mu\text{-}Cl)(H_2O)_2\{Cr(\mu\text{-}OH)_2(en)_2\}]^{2+}$ with a —Cd—Cl— backbone, the kinked neutral chain $_\infty^1[Cd_2(\mu\text{-}Cl)_2Cl_3(H_2O)_3\{Cr(\mu\text{-}OH)_2(en)_2\}]$ with both bridging and terminal chloro ligands, and the isolated centrosymmetric pentanuclear complex $[Cd_3(\mu\text{-}Cl)_4Cl_4(H_2O)_3\{Cr(\mu_3\text{-}OH)(\mu\text{-}OH)(en)_2\}_2]$ with a triply bridging OH group.[261]

These μ_3-OH groups also occur in heterocubanes, e.g., $[C_6F_5CdOH]_4$ with a Cd_4O_4 core and tetrahedral Cd.[262] Alkoxyl groups can replace OH groups in heterocubanes as in $[MeCdO\text{-}t\text{-}Bu]_4$.[263] Use of 2-methoxyethanolate as a ligand can induce formation of a heterocubane with a Cd_4O_4 core as before, of a diheterocubane with two Cd corner-linked cubes (Cd_7O_8 entities), or a heterododecahedrane (Cd_6 octahedron with μ_3-O in front of each of the octahedral faces: Cd_6O_8 core).[264] A Cd_4O_4 core with a strongly shielded periphery is obtained with the hydrate of di-2,2′-pyridyl ketone (*gem*-diol) as a ligand.[265] A certain shielding of a Cd_4O_4 core is also achieved by the oxide of a bora-bicyclooctane $C_8H_{14}BO$ in $[MeCd(OBC_8H_{14})]_4$.[266]

Cadmium phenoxides (phenolates) with bulky substituents like Ph or *t*-Bu in 2,6-positions seemingly do not form heterocubanes, but do add slim donor molecules. Thus, thf adducts $[Cd(OC_6H_3R_2)_2(thf)_2]$ ($R = t\text{-Bu}$,[267] Ph[268]), with short Cd—O(phenoxide) (205.8/207.4 pm) and long Cd—O(thf) bonds (249.8/230.7 pm), are accessible; however, in the *t*-Bu compound the CdO_4 core is planar, but it is strongly distorted tetrahedral in the Ph compound. Also planar is the central CdO_2S_2 moiety in $[Cd(OC_6H_3t\text{-}Bu_2)_2(tht)_2]$ (tht = tetrahydrothiophen) with *r*(Cd—O) 210.2 and *r*(Cd—S) 276.8 pm.[268] With the stronger N-donor py $[Cd(OC_6H_3t\text{-}Bu_2)_2(py)_3]$ is obtained, with five-coordinate Cd intermediate between square pyramidal and trigonal bipyramidal (r_{av}(Cd—O) 219.2, r_{av}(Cd—N) 235.4 pm).[268] ^{113}Cd NMR data for the above mentioned species in solution are given.[268]

Consequently, addition of a further phenoxide ligand should be possible, and this has indeed been realized in the anion of the compound $[K(thf)_6][Cd(OC_6H_3t\text{-}Bu_2)_3]$, with planar three-coordinate Cd (r_{av}(Cd—O) 207.1 pm).[269]

Numerous compounds of Cd with mono- and difunctional carboxylic acids have been prepared and studied. Special ^{113}Cd solid-state NMR studies on single crystals of some simple Cd carboxylates have been reported, with a short review of the structural chemistry of these compounds.[270,271]

Special emphasis has been laid on structural studies of Cd compounds with dicarboxylic acids, because these combinations form coordination polymers of differing dimensionalities depending on the carboxylate component and on coligands coordinated to Cd. The simplest compound of this type, namely Cd oxalate CdC_2O_4, adopts a 3-D framework structure, with CdO_6 octahedra linked by oxalate groups.[272] Further interesting structures containing Cd, oxalate and other components have been described recently.[273,274]

The monoanion of aspartic acid $HOOCCH_2CH(NH_2)COOH$ (aspH) and Cd together with nitrate give $Cd(aspH)NO_3$, with a seven-coordinate, all-oxygen environment of Cd in a layer structure.[275] A similar coordination is found in the chain structure of the Cd salt of acetylenedicarboxylic acid, $[Cd\{C_2(COO)_2\}(H_2O)_3]\cdot H_2O$.[276] In a template reaction Cd acetate, terephthalic acid H_2tp, and $[Ph_3PCH_2Ph]Cl$ give the polymeric $[Ph_3PCH_2Ph][Cd(tp)Cl]\cdot 2\,H_2O$, forming a twofold interpenetrating 3-D framework with giant rhombic channels (about 33 × 23 Å).[277] Under hydrothermal conditions Cd^{2+}, biphenyl-4,4′-dicarboxylate (bpdc), and 1,2-bis(4′-pyridyl)ethane (bpe) join to a polymeric compound $[Cd(bpdc)(bpe)(H_2O)]$, with a threefold interpenetrating 3-D framework with different large voids.[278] A layer structure is built up by Cd and the anion of 4,4′-oxydibenzoic acid ($HOOC\text{-}C_6H_4\text{-}O\text{-}C_6H_4\text{-}COOH$) (Cd is five-coordinate).[279] The Cd(phen) fragment and adipic or pimelic acid ($HOOC(CH_2)_nCOOH$, $n = 4$ and 5, respectively) primarily form chains with seven-coordinate Cd (slightly different geometries), which join to layers due to π—π interaction between the phen ligands.[280]

To finish the topic of carboxylate-dominated Cd complexes, a representative of three closely related species is briefly discussed. $Cd(NO_3)_2$ and the betaïne-type ligand triphenylphosphoniopropionate $Ph_3P(CH_2)_2CO_2$ (tpp) in H_2O combine to the dinuclear complex $[\{Cd(tpp)_2(NO_3)\}_2](NO_3)_2$, with a centrosymmetric tetrakis(μ-carboxylato-*O,O′*) dicadmium core, the apical sites being occupied by chelating nitrato ligands; the nitrato groups can be replaced by chloro ligands and the extracomplex NO_3^- by ClO_4^-.[281]

Various Cd compounds with inorganic oxo-anions have been studied. A model system for the application of solid-state MAS NMR spectrometry is the β'-form of tricadmium phosphate $Cd_3(PO_4)_2$, obtained by heating of the hydroxyapatite phase $Cd_{10}(PO_4)_2(OH)_2$. The structure of $Cd_3(PO_4)_2$ contains nine crystallographically independent Cd atoms and six PO_4 groups. Each Cd has a primary five-coordination, but varying secondary coordinations. The ^{31}P MAS NMR spectrum exhibits the required number of six narrow resonances with similar intensities; in the ^{113}Cd MAS NMR spectrum eight narrow lines are observed, one being an overlap of two signals in view of the much higher intensity. The ^{31}P signals have been assigned to the different PO_4 groups on the basis of bond-valence calculations.[282] In a related study of a series of mixed Cd—Pb hydroxyapatites by combination of X-ray powder diffraction and ^{31}P MAS NMR spectrometry, the site-occupancy analysis indicated a clear preference of Cd for one of the two possible sites.[283]

Certain Cd phosphonates are interesting materials, because of their layer structure and the potential for intercalation of guest molecules. As an example, the structure of Cd 2-aminoethylphosphonate $Cd(O_3PC_2H_4NH_2)$ has been solved *ab initio* from X-ray powder data with Rietveld refinement. Corrugated layers formed by Cd and the phosphonate ends of the ligands are connected by coordination of the amino ends to Cd atoms in the adjacent layers (pillared layer structure). ^{31}P and ^{113}Cd MAS NMR data are correlated with the structural facts.[284] Similarly, the layers in $Cd_2(OH)(O_3PC_2H_4CO_2)$, containing two differently coordinated Cd atoms and μ_3-OH groups, are linked by the carboxylate ends. ^{113}Cd MAS NMR spectra of this material and of the related $Cd_3(O_3PC_2H_4CO_2)_2\cdot 2H_2O$ indicate that the latter contains Cd in three different sites.[285] In a logical next step diphosphonates, e.g., *p*-xylenediphosphonate in the compound $Cd_2(O_3PCH_2C_6H_4CH_2PO_3)\cdot 2H_2O$, can be used as both builder in the layers and linker between them.[286]

Two simple Cd arsenates have been described, namely $Cd_2As_2O_7$, with a ditetrahedral anion [287], and $CdAs_2O_6$, with both Cd and As in octahedral environment.[288]

Out of the Cd compounds with oxoanions of elements of group 16, the trimorphic $CdSO_3$ is to be mentioned, with different six-coordinate Cd in each of the three phases.[289]

With diammonium ions $[H_3N(CH_2)_nNH_3]^{2+}$ $(2 \leq n \leq 6)$ as counterions, several linear and layered polymeric Cd sulfates are generated. In the chain anion ${}_{\infty}^{1}[CdCl_{4/2}(SO_4)_{2/2}]^{2-}$ $(n = 2)$, octahedral units are linked by both μ-chloro and μ-sulfato bridges; a similar structural situation is met in the compounds with ${}_{\infty}^{1}[CdX_{4/2}(SO_4)_{2/2}]^{2-}$ anions (X = Cl, Br; $n = 6$). A layered structure of the anion ${}_{\infty}^{2}[Cd_2(H_2O)_2(SO_4)_3]^{-}$ $(n = 3)$ is achieved by linking two different octahedral CdO_6 units by SO_4 bridges exclusively.[290]

Also $CdSeO_3$ exists in two polymorphic forms, with octahedral and trigonal-prismatic coordinations, respectively; in the hydrate $CdSeO_3\cdot 4/3\ H_2O$ a coordination polyhedron intermediate between these two forms occurs.[291] Two mixed Cd selenites have been described: in $LiCd_2(SeO_3)_2(OH)$ a 3-D framework contains columns as subunits with linked CdO_6 and CdO_7 groups and inserted $Cd_2(\mu\text{-}OH)_2$ squares as sub-subunits.[292] In $Cd_3(SeO_3)(CO_3)(OH)_2$ buckled sheets are built up by connected CdO_6 octahedra, and linked to a 3-D network by SeO_3, CO_3, and square anti-prisms CdO_8.[293]

A Cd compound $Cd_3(SeO_3)_2(SeO_4)$, with both selenite and selenate, has been presented. The 3-D network with channels running along the *b* axes in $P2_1$ $(Z = 2)$ contains three independent CdO_x polyhedra $(x = 6, 8)$, three independent SeO_3 pyramids, and one SeO_4 tetrahedron.[294] It should be mentioned that this compound is isotypic with the analogous mercury compound.[295]

Finally, in $K_2Cd(SeO_4)_2\cdot 2H_2O$ the SeO_4 groups act as bridging ligands to link octahedral CdO_6 units to chains ${}_{\infty}^{1}[Cd(OH_2)_2(SeO_4)_{4/2}]^{2-}$ (the H_2O ligands are in the *trans*-position).[296]

(ii) Mercury

Among others, a 1:1 complex of $Hg(NO_3)_2$ with the aza-crown-ether 1-aza-4,7,10-cyclododecane has been prepared and structurally studied. The coordination sphere of Hg (2 + 6 coordinate) is oxygen dominated, with a Hg—ONO_2 bond (216.6 pm) being the shortest, followed by the Hg—N bond to the N-donor of the macrocyclic ring (218.4 pm); all other Hg—O bonds (two chelating NO_3 ligands, three O-donors of the crown-ether) are much longer, in the range 254.1–290.6 pm.[297]

More recent reports on Hg^{II} phosphates are rather rare. The structure of mercury(II) diphosphate $Hg_2P_2O_7$ has been solved; it contains two different six-coordinate Hg atoms: one of them lying in an axially compressed octahedron (2 + 4 coordination, average bond lengths 213.2 pm and 258.3 pm, respectively), the other one in an expanded octahedron (4 + 2, averages 228 pm and 249 pm).[298] The polyphosphate $Hg(PO_3)_2$ has been obtained from HgO in an acidic polyphosphate melt and contains polymeric anions ${}_{\infty}^{1}[PO_2O_{2/2}]^{-}$ and Hg in distorted octahedra, which in turn are linked to chains ${}_{\infty}^{1}[HgO_2O_{4/2}]$ $(217.5 \leq r(\text{Hg—O}) \leq 250.3\ \text{pm})$.[299]

Mercury(II) arsenate $Hg_3(AsO_4)_2$ has three independent Hg particles with coordination numbers five and seven, but each of them has two short Hg—O bonds $(206 \leq r(\text{Hg—O}) \leq 214\ \text{pm})$ in a nearly linear arrangement; linking of these polyhedra including the AsO_4 tetrahedra leads to a 3-D network.[300]

Heating of the dimercury(I) compound $Hg_2As_2O_6$ gives a mercury(II) compound of the same composition, crystallizing in the $PbSb_2O_6$ structure type with $[As_2O_6]^{2-}$ layers and Hg in a pseudo-octahedral environment (r(Hg—O) 235.3 pm).[301]

The structure of the long-known basic sulfate, formally $HgSO_4{\cdot}2HgO$—with respect to its structure better written as $[Hg_3O_2](SO_4)$—has been reinvestigated ($P3_121$, $Z = 3$). The slightly corrugated hexagonal layers ${}_{\infty}{}^{2}[Hg_3O_2]^{2+}$ (r_{av}(Hg—O) 209.2 pm), or the other way round ${}_{\infty}{}^{2}[OHg_{3/2}]^{+}$, can be considered as a typical case of a coordination polymeric trimercurio-oxonium complex (metallo-onium complex); the disordered $SO_4{}^{2-}$ anions are located in the meshes of the layers and donate secondary bonds to the Hg atoms.[302]

Mercury(II) selenite $HgSeO_3$ has been found to crystallize in a perovskite-like structure with axially compressed, corner-sharing HgO_6 octahedra ($2+4$ coordination).[303] The hydrate $HgSeO_3{\cdot}0.5\ H_2O$ adopts a different structure, with five- and seven-coordinate Hg in a 3-D framework containing cavities in which the H_2O molecules are located.[304] Formally related but structurally different is an ammonia-containing $HgSeO_3{\cdot}NH_3$, which *de facto* is an ammine complex with an almost linear H_3N—Hg—O fragment with short bonds (209.9 pm and 212.9 pm, respectively); the overall coordination around Hg is octahedral $2+4$.[305]

Two new modifications of $HgSeO_3$ have been structurally studied. Hydrothermal treatment of $HgSeO_3$ yields $(HgSeO_3)_3HgSe$, with Se in two different oxidation states; the structure contains pyramidal Hg_3Se groups (trimercurio-selenonium groups; (r_{av}(Hg—Se) 248.9 pm).[306] In the basic selenite $HgSeO_3{\cdot}HgO{\cdot}1/6\,H_2O$, HgO_x polyhedra ($x = 6$, 7) are linked to a 3-D framework with channels running in one crystallographic direction.[307] Also an acidic mercury(II) selenite is known, namely $Hg_3(HSeO_3)_2(SeO_3)_2$, with a layer structure and medium-strong interlayer hydrogen bonds;[308] in this Hg^{II} compound the distortion of the polyhedra around the metal is more pronounced than in the corresponding Cd compound $Cd_3(HSeO_3)_2(SeO_3)_2$.[309]

The compound $Hg_3Se_3O_{10}$ with both selenite and selenate has already been mentioned.[295] The selenates $HgSeO_4$ and $[Hg_3O_2](SeO_4)$ are isotypic with the corresponding sulfates (for the latter see above), but $HgSeO_4{\cdot}HgO$ crystallizes in a hitherto unknown structure type with kinked chains ${}_{\infty}{}^{1}[HgO_{2/2}]$, SeO_4 tetrahedra, and again HgO_x polyhedra ($x = 6$, 7) which have O atoms in common with the above structural units.[310]

In this context, Hg compounds with anions containing chromium and tungsten can be mentioned. Thus, the triple oxide Pb_2HgCrO_6 can be described as containing isolated $CrO_4{}^{2-}$ tetrahedra and nearly linear $HgO_2{}^{2-}$ dumbbells (r(Hg—O 200.6 pm), which form layers of composition $[HgCrO_6]^{4-}$. These are intercalated with corrugated pseudohexagonal Pb^{2+} layers.[311] $HgWO_4$, prepared in aqueous medium, has been shown by neutron powder diffraction (Rietveld refinement) to consist of chains of edge-sharing HgO_6 and WO_6 octahedra; Hg on an inversion center forms two short collinear Hg—O bonds (200.6 pm).[312] $HgWO_4$ prepared under high-pressure/high-temperature conditions (300 MPa/973 K) contains chains of edge-sharing WO_6 octahedra, but layers of strongly distorted, corner-sharing HgO_6 octahedra (centrosymmetric O—Hg—O entities, r(Hg—O) 204.4 pm).[313]

6.9.4.2.8 Compounds with donor atoms S, Se, and Te

The detection of metal-binding proteins, especially of Cd- and Hg-binding metallothioneins or of the *mer*R protein, induced numerous studies of model compounds of Cd and Hg with more or less simple sulfur- and selenium-containing ligands.

(i) Cd and Hg chalcogenido complexes

The simplest possible coordination compounds of Cd and Hg with chalcogen donors are the anions $MCh_2{}^{2-}$. Multinuclear NMR studies of these species (Ch = Se, Te) in NH_3 or en solutions with [K(2.2.2-cryptand)]$^{+}$ counterions have been reported.[314] Structural studies[315], also combined with new multinuclear NMR measurements, have been performed.[316]

(ii) Cd and Hg thiolate and selenolate complexes

Cd thiolates and selenolates tend to form μ-S- or μ-Se-bridged dinuclear species, even with bulky organic groups, e.g., 2,4,6-tri-t-butylphenyl.[317,318] With some ligand combinations, heterocubanes with Cd_4S_4 core or oligonuclear species derived from heterocubanes are formed.[319,320]

With simple Hg thiolates the structures of bis(ethanethiolato)mercury $Hg(SEt)_2$[321] and of the cysteamine complex $[Hg\{S(CH_2)_2NH_3\}_2]Cl_2$[322] have reference character, as only weak or no secondary bonds are present, and therefore the central S—Hg—S entities can be considered to be unperturbed. In mercury bis(tri-t-butoxysilanethiolate) $Hg[SSi(o\text{-}t\text{-}Bu)_3]$, with a strictly linear S—Hg—S unit, two weak intramolecular O···Hg interactions obviously do not affect the bonding in this unit.[323]

As for thiolato complexes $[M(SR)_3]^-$ (M = Cd, Hg), the anion $[Hg(SPh)_3]^-$ can be mononuclear[324] or dinuclear $[Hg_2(SPh)_6]^{2-}$,[325] depending on the counterion; the methanethiolato complex is also dinuclear $[Hg_2(SMe)_6]^{2-}$ in the solid.[326] Further mononuclear trithiolato complexes of Cd and Hg with bulky organic groups have been described.[23,327–330] Correlations between structures and solid-state ^{113}Cd and ^{199}Hg NMR data have been worked out.[329,331] Ligand-exchange processes in dissolved thiolate complexes of Hg have been studied by ^{13}C NMR spectrometry.[332]

Reviews on mercury—thiolate complexes and their bio-relevance[333] and complexes with sterically hindered thiolate ligands have been published.[334]

The benzeneselenolates of mercury, $[Hg(SePh)_2]$ and $(Bu_4N)[Hg(SePh)_3]$, both adopt simple structures, with mononuclear complex entities which posses near-linear Se—Hg—Se and near trigonal-planar $HgSe_3$ cores, respectively.[335]

Interesting molecular mercury zinc sulfides $Hg[SZn(3\text{-}Ph\text{-}5\text{-}Mepz)_3BH]_2$ and $PhHg[SZn(3\text{-}Ph\text{-}5\text{-}Mepz)_3BH]$ (pz = pyrazole) have been obtained and structurally studied.[336]

(iii) Cd and Hg chalcogene clusters

Adamantoid systems $[(\mu\text{-}ChR)_6(MX)_4]^{2-}$ (Ch = S, Se, Te; R usually Ph; M = Cd, Hg; X = halogene) have been prepared and studied by X-ray structure analyses, heteronuclear NMR and vibrational spectrometries, and partly by UV/vis spectrometry.[337–341] Meanwhile, the systems have been expanded to superadamantoid clusters with four fused adamantoid subunits $[M_{10}Ch_4(ChPh)_{12}(PPh_3)_4]$[342,343] and related clusters,[344] and finally to nanoclusters with up to 32 metal atoms in one cluster.[345,346]

(iv) Cd and Hg polychalcogenide complexes

The field of polysulfide complexes has been reviewed earlier.[347] A more recent survey covers polychalcogenide complexes in general,[348] and in a review on ate complexes also further examples of anionic polychalcogenide species are dealt with.[349]

6.9.4.2.9 Compounds with halides as donor atoms

A huge number of studies have been done in the past on cadmium and mercury halides and their complexes, and there is still research interest in the field, sometimes yielding surprising results. And simple-looking systems, on closer inspection, turn out to be rather complex.

(i) Mercury fluoride systems

The ternary fluorides M_2HgF_4 (M = Rb, Cs), obtained by heating the alkali-metal fluorides MF with Hg_2F_2 under carefully controlled conditions, crystallize in the well-known K_2NiF_4 type, with octahedra sharing four corners to form layers $_\infty^2[HgF_2F_{4/2}]^{2-}$ and the cations M^+ embedded between these layers.[350]

In the fluoride phase $HgFeF_5 \cdot 2H_2O$, *trans*-$Hg(OH_2)_2F_4$ octahedra and FeF_6 octahedra share F-corners to form layers connected by hydrogen bonds.[351] Similarly, *trans*-$Hg(OH)_2F_4$ octahedra and FeF_6 octahedra share F corners, but the $Hg(OH)_2F_4$ octahedra also share the OH corners to form the layers in $Hg_2FeF_5(OH)_2 \cdot H_2O$.[352]

In $Hg_3AlF_6O_2H$, Hg on an inversion center is eight-coordinate (distorted cube), with two short Hg—O bonds (214.6 pm) and two sets of Hg—F interactions (252.6 pm and 267.0 pm); linking of these polyhedra and of AlF_6 octahedra generates OHg_3 units (trimercurio-oxonium groups).[353]

(ii) Cd and Hg halide complexes

Halogenocadmates can occur as simple tetrahedral anions CdX_4^{2-},[354] or they form the backbone of chain polymers $_\infty^1[CdL_2Br_{4/2}]^{2-}$ (L = N-donor ligand).[355] Isolated dinuclear complexes as in $[\{Me_3Si\}_3Ge\text{-}Cd(\mu\text{-}I)_3Cd\text{-}Ge\{SiMe_3\}_3]$ with a triple iodo bridge,[356] and heterocubanes with Cd_4X_4 cores[357] or derivatives or fragments thereof[358] are also encountered.

Solvation of the higher mercury(II) halides in donor solvents has been studied by X-ray diffraction on these solutions (large-angle X-ray scattering, LAXS), X-ray diffraction on complexes isolated from the solutions, and vibrational spectrometries; a paper (and references cited therein) on the halides HgX_2 in dimethylthioformamide is typical for this kind of multimethod approach.[359] Systematic studies of frequency shifts of the mercury halides HgX_2 in various solvents afforded the basis for a new scale of donor strengths.[360]

Chloromercurates adopt an incredible diversity of structures, as has been discussed in one review.[361] The sobering *facit* of this critical discussion: "The configuration of the anion cannot be determined from the stoichiometry. It is still not possible to predict, even for simple stoichiometries, the form that will be adopted in the solid state." Two more recent examples support this view. $CsHgCl_3$ does not adopt the simple perovskite-type structure assumed for a long time, but a complicated lattice with three different distorted octahedra $HgCl_6$ (2 + 2 + 2 coordinate), even with bent $HgCl_2$ moieties, and only at pressures above 3.5 GPa, is the structure forced to perovskite.[362] Even minor changes in the countercation of chloromercurates can alter the structure of the anion, as is shown for the compounds with the isomeric 2-, 3-, and 4-chloropyridinium cations.[363] The diversity of structures of chloro- and bromomercurates has once more been demonstrated in a series of very recent (2002) papers.[364–368]

Iodomercurates can adopt the simple forms of tetrahedra HgI_4^{2-}or bitetrahedra $Hg_2I_6^{2-}$, even in overall complicated structures.[369,370]

6.9.4.2.10 Compounds with pseudohalides

In recent years research in the field of transition-metal thiocyanates and selenocyanates received a new impetus, because of the partly interesting physical properties of such crystalline species. A review on Cd and Hg thiocyanate systems collects and sorts results of this endeavor.[371] The nonlinear optical (NLO) properties of Cd thiocyanate and selenocyanate systems and criteria for the design of NLO crystals (crystal engineering), especially, have been discussed afterwards.[372] Further contributions to the field have also been described.[373,374]

The structure of mercury chlorothiocyanate has been re-determined.[375]

6.9.4.2.11 Compounds with hydrido ligands

After earlier indications of the existence of mercury hydrides[376] and the proof that MeHgH exists,[377] several organomercury hydrides RHgH and their deuterated isotopomers with simple aliphatic substituents, phenyl, fluorophenyl, and substituted fluorophenyl ligands have been prepared from the respective chlorides and $NaBH_4$ in aqueous solution, and thoroughly studied by mass spectrometry and ^1H NMR spectrometry.[378,379] Correlations between chemical shifts $\delta(\mathit{H}HgR)$, coupling constants $^1J(^{199}Hg,^1H)$, and the electron-withdrawing nature of the R groups have been established. Quantum-chemical calculations considering relativistic effects have yielded optimized structures and ^1H chemical shifts; the latter have been compared with experimental data.[53]

6.9.4.3 Lower Oxidation States of Cd and Hg

6.9.4.3.1 Compounds with formal oxidation states intermediate between +2 and +1

(i) Compounds with triangulo-Hg_3^{4+} entities

As mentioned in Section 6.9.3, nature produces the minerals terlinguaite $(Hg_3)HgO_2Cl_2$[61–63] and kuznetsovite $(Hg_3)AsO_4Cl$,[64–66] both with the *triangulo*-Hg_3^{4+} entities in which the Hg atoms formally possess the oxidation number +4/3; in the former compound the Hg—Hg bonds are the same accidentally, in the latter by symmetry (270.3 pm and 265.8 pm, respectively). Meanwhile, further arsenates and phosphates with analogous compositions to kuznetsovite have been synthesized;[66] as for the overall average of the Hg—Hg bonds, the value 266.9 pm is given. The phosphate $(Hg_3)_3(PO_4)_4$[380] and the isotypic arsenate $(Hg_3)_3(AsO_4)_4$,[381] as well as the phosphate $(Hg_3)_2(HgO_2)(PO_4)_2$,[380] all contain this unusual constituent.

Independently, *triangulo*-Hg_3 compounds with stabilizing chelating diphosphine and diarsine ligands have been prepared;[382–387] crystal-structure analyses have been solved (the Hg—Hg bonds, ≈280 pm, are longer than before), and careful multinuclear NMR spectra measured and analysed.

(ii) Mixed-valence compounds with Hg^{2+} and $Hg_2{}^{2+}$

A deceptively simple-looking compound, Hg_2OI contains 2-D networks built up from kinked —Hg—O— chains which are linked by Hg_2 dumbbells;[388] this network can be described in brief as ${}_{\infty}{}^{2}[OHg_{2/2}(Hg_2)_{2/2}]^{+}$. Quite a similar network is found in one of the hydrolysis products of $Hg_2(NO_3)_2$, namely $Hg_4O_2(NO_3)_2$, with the above mixed-valence mercurio-oxonium units as building blocks.[389] A product of the partial hydrolysis of $Hg(ClO_4)_2$ treated with elemental Hg, namely $(Hg_2)Hg(OH)_2(ClO_4)_2$, can be isolated; this basic chlorate(VII) ($C2/c$, $Z = 4$) contains chains with alternating Hg and Hg_2 groups between OH groups: ${}_{\infty}{}^{1}[(OH)Hg_{1/2}(Hg_2)_{1/2}]^{+}$.[390]

6.9.4.3.2 Compounds with oxidation state +1

(i) Dimercury(I) compounds

The crystal structures of Hg_2F_2[350] and Hg_2Cl_2 (neutron diffraction)[391] have been redetermined (r(Hg—Hg) 251.0, r(Hg—F) 213.3 pm; r(Hg—Hg) 259.55, r(Hg—Cl) 236.22 pm). $[Hg_2(OH_2)_2][SbF_6]_2 \cdot 4\,HF$ obtained from the dimercury(I) carbonyl complex, mentioned in Section 6.9.4.2.1(i), in super-acid has been studied by X-ray diffraction (r(Hg—Hg) 249.2, r(Hg—O) 214.8 pm).[392]

The crystal structure of dimercury(I) bis(tricyanomethanide), $Hg_2\{C(CN)_3\}_2$, has been solved (2-D network).[393] Further hydrolysis products of $Hg_2\{NO_3)_2$ have been structurally elucidated.[394–396] Several dimercury(I) phosphates and arsenates have been thoroughly studied (X-ray diffraction, vibrational spectra, thermal analyses).[397–399] The methanesulfonate $Hg_2(O_3SMe)_2$ has basically molecular units, with monodentate O_3SMe ligands and secondary O···Hg bonds (r(Hg—Hg) 251.4, r(Hg—O) 220.5 pm).[400] The molybdates $Hg_2Mo_2O_7$, Hg_2MoO_4 (two modifications), and the tungstate Hg_2WO_4 have been prepared by solid-state reactions and structurally studied.[401,402]

In an $Hg_2{}^{2+}$ asymmetrically complexed by two crown-ethers of different ring size, an extremely high coupling constant ${}^{1}J({}^{199}Hg,{}^{199}Hg)$ of 284 kHz between the magnetically inequivalent Hg nuclei has been observed.[403]

${}^{199}Hg$ MAS NMR and vibrational spectra of several inorganic dimercury(I) compounds have been measured and discussed.[404]

Reasonably stable compounds of Hg_2 groups bound to silyl groups have been obtained, e.g., $Hg_2\{Si(SiMe_2SiMe_3)_3\}_2$, with a straight Si—Hg—Hg—Si arrangement (r(Hg—Hg) 265.7, r(Hg—Si) 248.5 pm).[405]

Interaction of Hg_2 groups with electron-rich aromatic rings has been observed in the structure of $[Hg_2(C_6Me_6)](AlCl_4)_2$ (r(Hg—Hg) 251.5 pm).[406]

As mentioned at the end of Section 6.9.3, reviews of the crystal chemistry of mercury minerals with lower oxidation states and with oxo-centered building blocks have been published[72,73] and the structural role of $Hg_2{}^{2+}$ and $Hg_3{}^{4+}$ groups discussed.[407]

(ii) Dicadmium(I) compounds

Only a few dicadmium(I) compounds are known so far. The very first structurally characterized is $Cd_2(AlCl_4)_2$, which contains Cd_2 groups in a trigonally elongated octahedron of chloro ligands

(r(Cd—Cd) 257.6 pm) (see the Hg—Hg distances above!).[408] In an independent study the results have basically been confirmed (r(Cd—Cd) 256.2 pm).[409]

A Cd_2 complex with one of the tris(pyrazolyl)borate ligands mentioned in Section 6.9.4.2.3(ii) has been identified in solution by its large coupling constant $^1J(^{113}Cd,^{111}Cd)$ of 20.626 kHz; also a Cd^{II} hydride complex has been detected by NMR.[410]

6.9.4.3.3 Subvalent mercury compounds

Compounds such as $Hg_3(AsF_6)_2$, $Hg_3(SO_3F)_2$, and $Hg_4(AsF_6)_2$ in liquid SO_2 have been studied by ^{199}Hg NMR, with large coupling constants $^1J(^{199}Hg,^{199}Hg)$ for the Hg_3^{2+} ion observable only below −40 °C.[411] Structure analyses of the silvery-shining compounds $HgMF_6$ ($M = Nb$, Ta) reveal that the Hg atoms are arranged in hexagonal layers sandwiched between layers of the anions.[412] Completely different structures, with almost-linear Hg_3^{2+} ions (r(Hg—Hg) 256.9 pm) and also nearly linear Hg_4^{2+} ions (r(Hg—Hg) 259.3 pm and 263.0 pm), have been found for $Hg_3(MF_5)_2SO_4$ ($M = Nb$, Ta) and for $Hg_4(Ta_2F_{11})_2$, respectively.[413]

Comprehensive Coordination Chemistry II
ISBN (set): 0-08-0437486

Volume 6, (ISBN 0-08-0443281); pp 1253–1292

6.10
Appendix to Volume 6

JON A. McCLEVERTY
University of Bristol, Bristol, UK
and
THOMAS J. MEYER
Los Alamos National University, Los Alamos, New Mexico, USA

This appendix provides access to original chapters from Comprehensive Coordination Chemistry (published in 1987) that are relevant to this volume of Comprehensive Coordination Chemistry II (CCC2) but that are not cited by a specific chapter in CCC2.

For further details please see the end of the Preface under the General Information tab.
