Volume 6
Transition Metal Groups 9 - 12

Introduction to Volume 6

This volume is concerned with fundamental developments in the coordination chemistry of the elements of Groups 9–12 since 1982. The individual chapters cover the coordination chemistry of cobalt, iridium, nickel, palladium, platinum, copper, silver and gold, zinc and cadmium, and mercury. Unfortunately, because of factors beyond the Editors' control, the manuscript for the proposed chapter on rhodium was not available in time for publication.

Each author has selected material in such a way as to give the most effective review of discoveries and new interpretations. The style of coverage mainly uses formal oxidation state (highest to lowest) and the nature of the ligand donor atom (C, Group 5, Group 6, halides, H, mixed donor atoms) to define progression through this chapter. Uni- up to polydentate ligands (cyclic and acyclic) and mono- through oligo- to polynuclear species are covered with an emphasis on compounds for which full structural characterization is available.

Throughout this volume it has been the intention not only to highlight the fundamental developments in this field, but also to indicate the very important connections between these fundamentals, and developments in other related fields, with cross-references to the later volumes. For example, if one regards a metallo-protein, or a metallo-enzyme, as a highly elaborated coordination complex, the metal site of which is comprised of one or more metals and their ligating atoms, then the study of the chemistry of the metal centers in such species can be regarded as bio-coordination chemistry. Furthermore, in order to gain insight into metallobiosites for which the structure is not known, it is possible to consider simulating the immediate coordination environment of that metallobiosite through the use of synthetic analogues derived from small-molecule compounds. Our understanding of the bio-coordination chemistry of cobalt, nickel, copper, and zinc has advanced considerably since 1982 and generic issues relating to this chemistry appear in Volume 8.

Application of coordination compounds in medicine, materials chemistry, and as catalysts are mentioned and are cross-referenced to a fuller discussion in Volume 9. Comment is made on application of complexes in nanotechnology, and on the molecular modeling of complexes. The material cannot be totally comprehensive because of space limitations, but is selected in such a way to give the most effective review of discoveries and new interpretations.

Since 1982 there have been enormous developments in metal-based chemistry, particularly the emergence of supramolecular chemistry – "chemistry beyond the molecule," molecular architecture, and molecular engineering. *Comprehensive Supramolecular Chemistry* was published in 1996, a survey which contains much of interest to coordination chemists. Consequently in this volume review material relating to supramolecular systems is mainly restricted to developments since 1990.

There has been a considerable expansion of the literature in the period under review. In 1982 CAS abstracted 16,095 publications in the CA inorganic section and this number rose to 21,579 abstracts in 2001 – a total of 401,312 abstracts were published in the period 1982–2001 [Source: CAplus database on STN]. Although these numbers refer to inorganic chemistry as a whole they nevertheless give an indication of the probable corresponding increase in papers relating specifically to coordination chemistry and clearly indicate the enormity of the task undertaken by the authors of the chapters in this volume. As the Volume Editor I cannot thank them enough for their dedication and diligence in preparing such detailed and stimulating reviews.

Introduction to Volume 5

This volume presents a survey of significant developments in the chemistry of Groups 7 and 8 of the transition metals since the publication of *Comprehensive Coordination Chemistry* (CCC) in 1987. The material for each element is organized by oxidation state of the metal and also by the nature of the ligands involved, with additional sections covering special features of the coordination chemistry and applications of the complexes.

Manganese, Technetium, and Rhenium

The coverage for manganese and rhenium is from 1982, whereas for technetium the earlier literature is included, as technetium did not feature in CCC (1987). The biological role of manganese has been a significant driving force for recent studies of its coordination chemistry and this area is treated in some detail, as are the uses of manganese complexes for selective oxidations. For technetium much of the literature is closely linked to the applications of 99m–Tc complexes in diagnostic nuclear medicine and the development of first- and second-generation agents is placed in the context of the reported coordination chemistry. The potential role of radioactive rhenium complexes for therapy is a comparatively recent theme, and is again placed against the backdrop of a systematic account of the fundamental coordination chemistry of the element.

Iron, Ruthenium, and Osmium

The coverage for iron commences in 1984–1985 and aims to provide a broad-based introduction to important advances in the chemistry of this element over the past 20 years. A comprehensive coverage of the chemistry of iron over this period would be impossible and the authors have done an admirable job in selecting the most important papers in the primary literature and have made extensive reference to the review literature to give as broad an overview as possible. Similar constraints apply to the coverage of ruthenium and osmium in both high and low oxidation states. However, the coverage in these two chapters gives an excellent overview of the primary literature since 1982 and leads the reader naturally to the important review literature for these elements.

It would be invidious to pick any particular area of activity in the chemistry of these elements for particular attention, but very significant advances have been made in many aspects of the coordination chemistry of iron, ruthenium, and osmium. Our understanding of the roles which iron can play in biological systems and the subtle chemical control over iron metabolism has increased enormously since 1987 and they represent beautiful aspects of applied coordination chemistry. Much iron coordination chemistry is designed to further understand biomimetic aspects. In low-oxidation-state ruthenium chemistry, renewed interest in photovoltaic cells is generating a resurgence in $\{Ru(bpy)_3\}$ chemistry. In high-oxidation-state ruthenium and osmium chemistry, the utilization of complexes as increasingly selective catalytic or stoichiometric oxidizing agents shows no sign of abating.

Finally, we would like to thank the authors involved with these elements for their fortitude in approaching such a potentially enormous task with good humor and a positive attitude.

Description

This is the sequel of what has become a classic in the field, Comprehensive Coordination Chemistry. The first edition, CCC-I, appeared in 1987 under the editorship of Sir Geoffrey Wilkinson (Editor-in-Chief), Robert D. Gillard and Jon A. McCleverty (Executive Editors). It was intended to give a contemporary overview of the field, providing both a convenient first source of information and a vehicle to stimulate further advances in the field. The second edition, CCC-II, builds on the first and will survey developments since 1980 authoritatively and critically with a greater emphasis on current trends in biology, materials science and other areas of contemporary scientific interest. Since the 1980s, an astonishing growth and specialisation of knowledge within coordination chemistry, including the rapid development of interdisciplinary fields has made it impossible to provide a totally comprehensive review. CCC-II provides its readers with reliable and informative background information in particular areas based on key primary and secondary references. It gives a clear overview of the state-of-the-art research findings in those areas that the International Advisory Board, the Volume Editors, and the Editors-in-Chief believed to be especially important to the field. CCC-II will provide researchers at all levels of sophistication, from academia, industry and national labs, with an unparalleled depth of coverage.

6.1.1 INTRODUCTION

6.1.1.1 Introductory Remarks and General Scope

Since the publication of the first edition of this volume, the field of cobalt coordination chemistry has continued to grow apace. Historically, cobalt has been a popular metal for coordination chemists, driven in part by the generally inert and diamagnetic nature of the trivalent oxidation state that has permitted detailed studies in solution and in the solid state by key physical methods.

Even after all these years subsequent to the first edition of *Comprehensive Coordination Chemistry* (*CCC*, 1987), cobalt has maintained its appeal, as is evident in Figure 1. A survey of the chemical literature (1900–2001) revealed that 60% of the ca. 30,000 articles on Co coordination chemistry have appeared since the early 1980s. Clearly, this level of activity presents a daunting task for reviewers with a brief to cover that particular period, and hence this review necessarily is selective in capturing the present state of Co coordination chemistry and its impact. The nature of information retrieval has also changed significantly since the early 1980s, notably through the availability of on-line computer-based data retrieval, which permits and indeed demands a distillation of the field without exhaustive referencing. Subsequently, partly in a bid to capture the field as widely as possible, we have chosen to make use of secondary references along with primary references. This has been essential, given the space available, and we trust the following presents a representative "taste" of the more recent coordination chemistry literature of Co.

In the period since the mid-1980s, great advances have been made in our understanding of transition metal ions in biological systems, and Co chemistry has been an unexpected beneficiary. At the time of the first volume, little was known about the biological chemistry of Co aside from the cobalamin (Vitamin B_{12}) cofactors. Since then, advances in molecular biology and protein expression coupled with the emergence of even more sophisticated structural and spectroscopic methods have led to the identification of at least eight distinctly different, Co-dependent (non-corrin) proteins. In parallel, the substitution of Co for spectroscopically silent ions (e.g., zinc) in metalloproteins has been an invaluable tool in the determination of active site structure and mechanism. In Section 6.1.3, we discuss the multifarious aspects of biological Co chemistry; most of these are very recent indeed.

The view taken in the analogous chapter in the first edition of this publication[1] was that Co coordination chemistry could be captured under the concepts of *synthesis*, *structure*, and *reactivity*. What has changed since that time is not the correctness of these generalizations, but rather the growth of their sophistication and the rise of a further key concept—*applications*, particularly in the areas of catalysis and (bio)technology. In Section 6.1.4 we hope to alert the reader to the wide range of uses of particular Co compounds that have emerged since the early 1980s. It is noteworthy that a number of these compounds, synthesized at the turn of the twentieth century, were ahead of their time given that the scientific areas in which they ultimately found application, particularly biology, were then still in their infancy.

Cobalt chemistry has become more targeted, with much published work directed towards an application, albeit long-term, or else towards elucidation of an existing problem making use of growing synthetic and instrumental sophistication. The era of synthesis and characterization as an art in itself is passing for Co chemistry; it seems that chemical research itself, not just the electrons

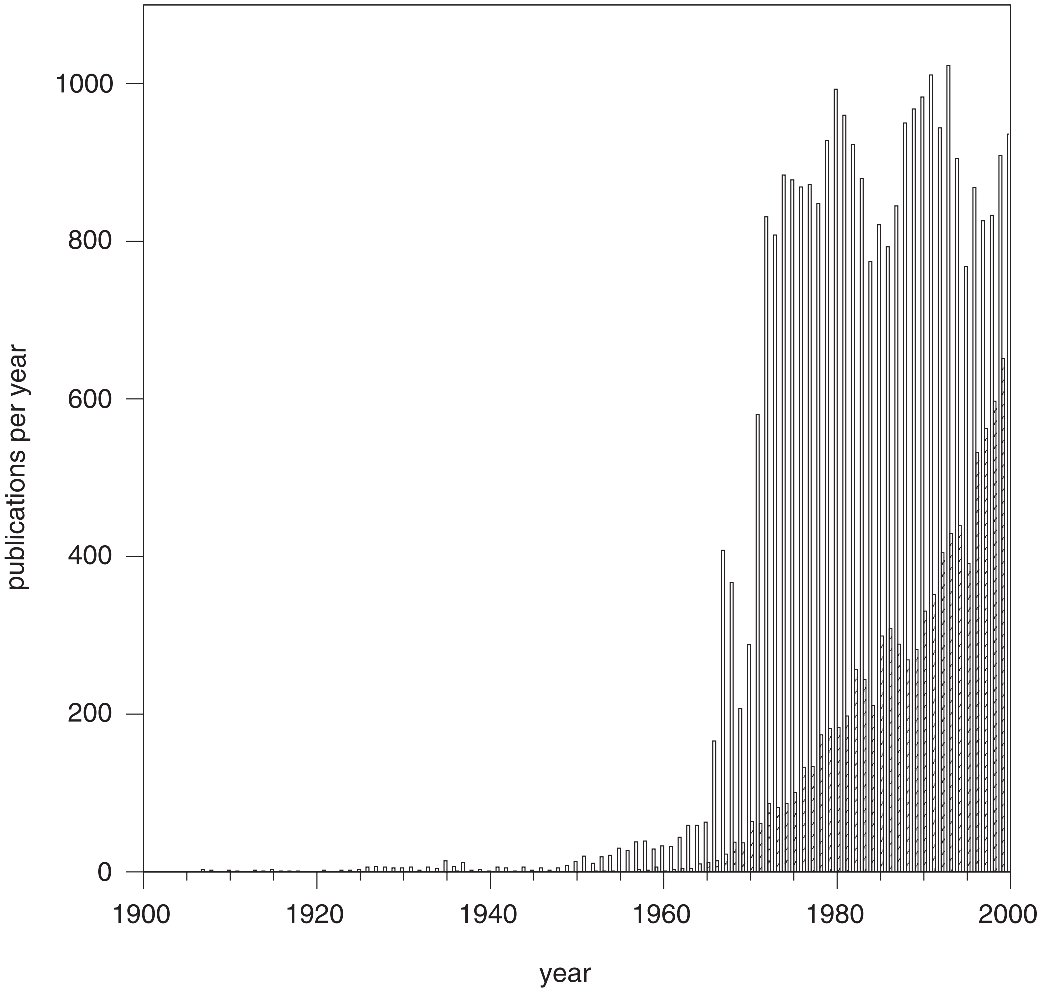

Figure 1 Publications per year featuring cobalt complexes (unshaded bars) and publications reporting at least one crystal structure of a Co-containing complex (shaded bars).

and nuclei that underpin its achievement, must have a "spin". The changing times are reflected in focused reviews of the field. Well over 1,000 reviews and books featuring aspects of Co coordination chemistry have appeared during the past two decades.

It is appropriate to identify our approach to developing the present review in the context of the Co chapter in *CCC*(1987). The first-edition chapter on Co featured a focused discussion and tabulation of synthetic methods, and many of these basic methods are still employed in synthesis today. Consequently, to avoid repetition, there will be diminished description here where prior appropriate methods have been provided, and only newer developments featured. The last two decades feature the development of many mixed-donor and sophisticated multidentate and macrocyclic ligands, which found limited coverage in the previous edition, and these will be discussed in more detail herein. Reaction kinetics and mechanism were also described thoroughly in the previous edition. We shall not reiterate this material, since the core mechanisms of many reactions involving Co compounds are now adequately defined.

Structural aspects were discussed, but not heavily, in the first edition. The complexity of new compounds (and macromolecules) now being investigated has driven many of the technological advances in X-ray crystallographic data collection and structure solution over the last two decades. Small-molecule (m.w. $< 1{,}000\,\mathrm{g\,mol^{-1}}$) structure determinations are now routinely carried out, and Co complexes constitute a significant proportion of these. Indeed, the incorporation of crystal structures in most papers reporting new synthetic coordination chemistry is now a standard feature; much more so than at the time of *CCC*(1987) (Figure 1). Inevitably, most of the new compounds described herein have been the subject of crystal structure determinations, rather

than being identified solely through the use of "sporting" physical methods. Nevertheless, advanced instrumentation, including high-field NMR and electrospray-ionization MS, has augmented the range of physical techniques, so that structural assignment in solution has become more firmly based, as an important complement to solid state structural determination. The very complexity of many new molecules required us to adopt a different approach to reporting compared with *CCC*(1987), with extensive reliance here on line drawings, as distinct from tables, to illustrate effectively the complexes described.

Apart from *CCC*, regular general reviews of Co chemistry have appeared in the period 1984–1998 in *Coordination Chemistry Reviews*.[2–9] These provide distilled supplementary reading covering a large part of the preceding two decades. Organometallic chemistry in particular is further served by an annual survey, which has appeared in the 1980s and 1990s in *Organometallic Chemistry*; several recent examples of these are cited in Table 1 along with a selection of reviews and monographs also featuring Co chemistry.[10–62]

6.1.1.2 Synthesis, Reactivity, and Structure

There are relatively few key synthetic reagents for entry into Co coordination chemistry. Of these, simple compounds are dominant: for low-valent Co chemistry, $Co_2(CO)_8$; for cobalt(II) and cobalt(III) chemistry, the simple CoX_2 ($X = $ halide) salts in hydrated or anhydrous forms. More sophisticated reagents for synthesis have been developed during the last century, but sophistication also frequently involves specificity; the "boutique" precursor, with limited general application. Occasionally, a general concept can be identified as overarching a suite of synthons. For example, an aspect of trivalent Co chemistry that has attracted attention over recent decades is the introduction of labile leaving groups into an inherently inert system. The capacity to have available, in designated coordination sites, ligand molecules that can be readily replaced by other nucleophiles is a sophistication that was not previously so readily achieved. The range of reactivities found for coordinated ligands in Co^{III} chemistry is vast, and the simple hydrolysis rates from the pentaamminecobalt(III) core (Table 2) adequately defines the spectrum from seriously inert to highly labile leaving groups.[63]

One of the earlier employed labile ligands was perchlorato, but the dangers in working with this strongly oxidizing anion are well documented and its use as a ligand in compounds bearing oxidizable (organic) ligands is frowned upon these days, if tolerated at all. Indeed, the establishment of the labile, non-oxidizing trifluoromethanesulfonato ($CF_3SO_3^-$) ligand over the last two decades has obviated the need to employ notorious perchlorato complexes as synthons.[64] More elaborate leaving groups, such as $^-OTeF_5$,[65] have subsequently appeared. Further, the develop-

Table 2 $[Co(NH_3)_5X]^{(3-n)+}$ aquation rate constants for anionic and neutral leaving groups (X^{n-}, $n = 0$–3, at 25 °C); selective lability of coordination sites in complexes of this inherently inert metal offers synthetic opportunities.

X^{n-}	$k_{obs}(s^{-1})$	X	$k_{obs}(s^{-1})$
PO_4^{3-}	1.5×10^{-9}	NH_3	5.8×10^{-12}

FSO_3^-	2.2×10^{-2}	$OC(CH_3)_2$	$\sim 4 \times 10^{-2}$
$CF_3SO_3^-$	1.5×10^{-2}	$NH_2SO_2C_6H_4CH_3$	$\sim 1 \times 10^{-1}$
ClO_4^-	$\sim 1 \times 10^{-1}$	N_4O ($N_3^- + NO^+$)	$\gg 10^{-1}$

ment of solvated complexes, where weakly coordinating solvent molecules such as sulfolane or acetone occupy key substitution sites, has expanded the armory of synthons. Chemical treatment of a normally robust ligand to generate a very short-lived intermediate, such as azide with NO^+ forming an N_4O entity that rapidly decomposes to release N_2 and N_2O and leave a "naked" coordination site, provides yet another route which has been established for some decades but not heavily exploited.[63]

Reaction mechanisms in Co chemistry continue to attract interest, and the level of sophistication and depth of understanding of reactions has grown. The elucidation of reaction mechanisms in Co chemistry has benefited from the application of high pressure to provide activation volumes, which in concert with reaction volume information allows a full volume profile analysis.[66] A parallel advance has been the study of electrode reactions at high pressures.[67] Study of self-exchange reactions for a series of $Co^{III/II}$ systems has provided mechanistic insight into heterogeneous electrode redox reactions, including establishing a simple relationship with the homogeneous self-exchange process. Nevertheless, in light of the ample treatment of this area of Co chemistry in *CCC*(1987), mechanistic studies will receive a limited coverage in this chapter, which by no means reflects the contribution of this area to our control of the element's chemistry. It simply reflects the fact that space within this review, unlike the scope and breadth of Co coordination chemistry, is limited.

There are now many on-line and CD-ROM databases of important structural and thermodynamic data of relevance to Co chemistry. The Cambridge Structural Database is the first port of call when seeking complete structural information (molecular dimensions) of any carbon-containing Co complex, and we shall not attempt to duplicate this invaluable resource through the tabulation of structural data. Complex formation constants of relevance to this review (mostly with divalent Co) are to be found in Martell's *Critical Stability Constants*, which is updated regularly and checked rigorously, or in focused reviews. For this reason, no tables of thermodynamic data will be presented. Specific redox potentials (for example $Co^{III/II}$ couples) may be found within a range spanning more than 2 V, and although some examples will be mentioned, no attempt will be made here to assemble a "representative" table of redox potential data. The reader is referred to either compendia such as the *Encyclopedia of Electrochemistry of the Elements* or to the original papers, which often themselves present focused collections of electrochemical potentials.

6.1.2 METAL COMPLEXES

The bulk of this chapter is devoted to the descriptive coordination chemistry of Co with a diversity of ligands, addressed separately for the key Co^{II} and Co^{III} oxidation states as well as for each of low-valent and high-valent cobalt. Throughout the chapter, ligand types are treated separately. Given the omnipresence of mixed-ligand complexes, we have tackled this problem by focusing on a particular class of ligand while other ligands that complete the coordination sphere are viewed as "spectators".

6.1.2.1 Co^{-I}, Co^{0}, and Co^{I}

Of the known low-valent forms of Co, Co^{-I} is rarely met while the coordination chemistries of the more commonly encountered zero- and monovalent Co are dominated by four-coordinate tetrahedral complexes. For Co^{I} (d^8), coordination numbers from three to six are known but with the extremities very rarely found, and four-coordinate tetrahedral (paramagnetic) and five-coordinate trigonal bipyramidal (diamagnetic) most common. Traditionally, the low oxidation state compounds are susceptible to oxidation in air and the tendency toward the formation of cluster compounds is strong. Low-valent Co chemistry remains dominated by carbonyl chemistry, although increasing numbers of examples of low-valent compounds with no carbonyl groups are appearing, as is evident from the following sub-sections.

6.1.2.1.1 Carbon

The chemistry of the low-valent Co—C bond is extensive, and dominantly the regime of organometallic chemistry, which is covered in the companion *Comprehensive Organometallic Chemistry* series; hence the coverage here will be limited. There are few examples of carbon-only compounds of cobalt, a notable exception being the buckminsterfullerene cations $[Co_n(C_{60})_m]^+$ (where n, m range up to 5); these form by a combination of laser vaporization and molecular beam approaches. One example is the $[Co(C_{60})_3]^+$ ion, which appears to adopt a planar structure with the Co surrounded by three C_{60} molecules.[68] In the $[CoC_{60}]^+$ ion, the metal assists gas phase reactions to produce metallated $[CoC_{60}(CH_2)_n]^+$ ($n=1$–5) species.[69]

(i) Cyanides

Organocyanocobaltate(I) chemistry has been reviewed.[70] Mononuclear and polynuclear forms are known, and CN^- continues to appear regularly as a co-ligand, as it does in other Co oxidation states, and examples of it as co-ligand appear throughout the review.

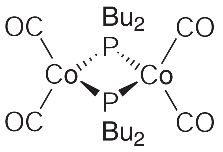
(ii) Carbonyls

The diversity and depth of studies in this field is exceptional, and a detailed exposure cannot be provided here. Aspects of this chemistry appear in detail in the companion series *Comprehensive Organometallic Chemistry*. Here, we will concentrate on compounds that are CO-rich, and attempt to provide an overview of their chemistry.

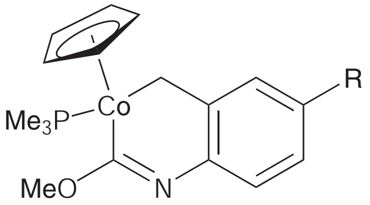
Small Co metal clusters Co_n^- ($n=2$–8) react with CO, with sequential addition leading to the saturated Co species $[Co_2(CO)_7]^-$, $[Co_3(CO)_{10}]^-$, $[Co_4(CO)_{12}]^-$, $[Co_5(CO)_{13}]^-$ and $[Co_6(CO)_{15}]^-$.[71] This points towards one of the features of low-valent Co carbonyls; a tendency to form stable clusters. Reactivity of Co_n^- with O_2 is higher but leads to cluster fragmentation, whereas N_2 is essentially unreactive. Entry into carbonyl chemistry of low-valent Co is frequently via the well-known dimer $Co_2(CO)_8$. A range of reactions commencing with this compound has been developed, as follows.

(a) Simple substitution reactions. Direct substitution in $Co_2(CO)_8$ produces a range of dinuclear compounds. Reaction with phosphines or arsines readily produces derivatives such as $Co_2(CO)_6L_2$ where the core stereochemistry is retained. Substitution with some rearrangement may also occur; for example, reaction with $(t\text{-Bu})_2PH$ by heating in toluene yields the phosphido bridged compound (**1**).[72] Whereas $\{Co_2(CO)_6\}$ complexes of alkynes $R–C{\equiv}C–R'$ formed from substitution in $Co_2(CO)_8$ have been known for some time and are reasonably stable to attack by nucleophiles and electrophiles, when heated with an alkene they react in a regiospecific $[2+2+1]$ cycloaddition to form a cyclopentenone.[73]

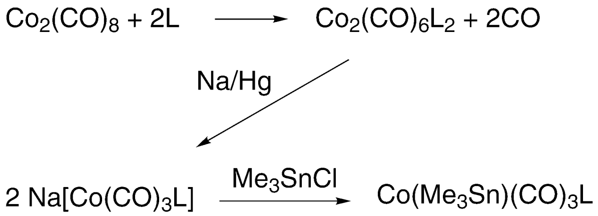
(b) Cleavage reactions. These reactions involve monomer formation through cleavage of the Co—Co bond. Reaction of $Co_2(CO)_8$ in liquid SO_2 in the presence of AsF_5 leads to Co—Co bond cleavage and yields monomeric $[Co(CO)_4(SO_2)]AsF_6$, providing a simple route to cationic Co^{I} sulfur dioxide complexes.[74] Tetra-coordinated monomeric Co^{I} is readily obtained via reductive cleavage of the Co—Co bond in $Co_2(CO)_8$ and also in substituted derivatives such as $Co_2(CO)_6L_2$ ($L=$ a phosphine, phosphite or arsine), under a nitrogen atmosphere. Subsequently, pentacoordinated Co^{I} can be achieved by addition of entities such as trimethyltin (Equation (1)).[75] One example is the trigonal bipyramidal arsine complex $Co(Me_3Sn)(CO)_3(AsPh_3)$, where the carbonyl ligands occupy the equatorial positions.[75,76]



(**1**)



(**2**)

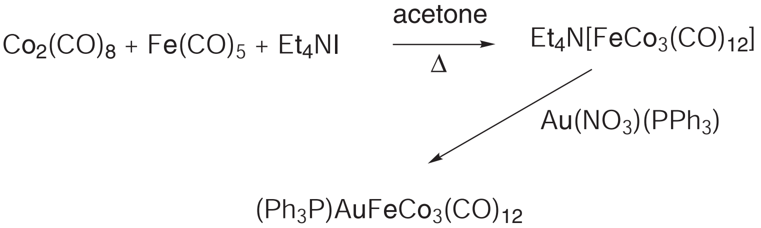


(1)

Mononuclear acyl Co carbonyl complexes $ROC(O)Co(CO)_4$ result from reaction of $Co_2(CO)_8$ with RO^-.[77] These also form via the carbonylation of the alkyl precursor. The $ROC(O)Co(CO)_4$ species undergo a range of reactions, including CO ligand substitution (by phosphines, for example), decarbonylation to the alkyl species, isomerization, and reactions of the coordinated acyl group involving either nucleophilic attack at the C or electrophilic attack at the O atom.

(c) Cluster formation. Clusters with at least three metals are accessible. The dimer $Co_2(CO)_8$ reacts in THF at −15 °C with $B_2H_6{\cdot}THF$ to form $[(CO)_4Co(BH_2)]{\cdot}THF$.[78] This is a useful synthetic reagent, mainly because it is a very active reducing agent which can condense with metal fragments to yield clusters, as illustrated by the formation of the "tailed" cluster $(CO)_9Co_3C(CH_2)_nOH$ ($n = 4$, 5), where the Co atoms form a commonly encountered equilateral triangular arrangement.

Mixed-metal clusters are also accessible from $Co_2(CO)_8$. For example, the following reaction (Equation (2)) leads to a purple–black Au–Fe–Co cluster with a trigonal bipyramidal array of metals, via a long-known mixed Co–Fe red–brown colored cluster intermediate.[79]



(2)

Likewise, reaction of $Co_2(CO)_8$ with $Ru(CO)_5$ yields $[RuCo_3(CO)_{12}]^-$, which can be reacted with HCl to form the hydride-containing cluster $HRuCo_3(CO)_{12}$.[80] A trinuclear mixed-metal cluster featuring a μ_3-S^{2-} ion, $(\mu_3\text{-S})Co_2Fe(CO)_9$, is formed from reaction of $Co_2(CO)_8$, $Fe(CO)_5$, and C_2H_5SH, where $[Co(CO)_4]^-$ and S^{2-} are intermediate species.[81] Clusters such as this have reactive M—M bonds useful for further synthesis, but do not undergo total fragmentation.

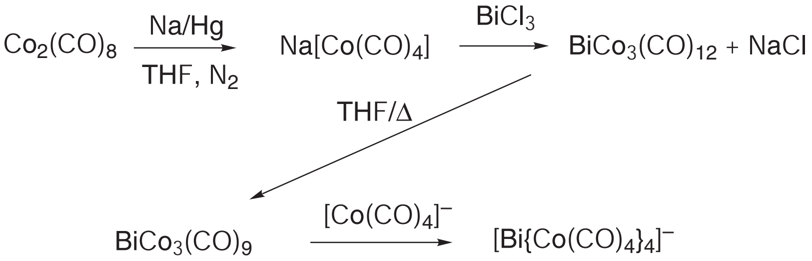
The $(\mu_3\text{-X})Co_3(CO)_9$ core, which has three tetrahedral $\{Co(CO)_3\}$ units each bonded to a central entity in a trigonal array, is a common cluster geometry, as are analogs with Co substitution. A recent example of such a structure is via the reaction of $Co_2(CO)_8$ with $(C_6F_5)_2S$, which yields $(\mu_3\text{-S})Co_3(C_6F_5)(CO)_8$.[82]

These types of clusters represent some of the more modest sizes and geometries detected in homo- and hetero-metal carbonyl clusters. From dimetallic up to pentadecametallic clusters have been defined by crystal structures, and assembly of the metal centers in these clusters adopt a number of well-defined arrangements.[83] Redox activity in these polymetallic clusters is anticipated and has been observed. Routes to large carbonyl polymetal clusters have been reviewed.[83,84]

Water-soluble carbonyls are relatively rare. A route to such a species involves reaction at room temperature of the sulfonated phosphine $P(PhSO_3)_3{}^{3-}$ as its water-soluble Na^+ salt with $Co_2(CO)_8$ in a two-phase water/toluene mixture, whereupon the product forms in the aqueous phase in high yield.[85]

Complex clusters incorporating multiple-bridging groups such as O^{2-}, CCl, and CCO_2 have been known for some time, with clear synthetic routes available.[86] Typical species include $(\mu_3\text{-CCl})Co_3(CO)_9$, $(\mu_3\text{-CCO}_2)Co_3(CO)_9$, and $Co_4(\mu_4\text{-O})[(\mu_3\text{-CCO}_2)Co_3(CO)_9]_6$. Substitution of further carbonyls can lead to chiral clusters.

Main-group cobalt carbonyl clusters are well known, with neutral clusters such as $Sn\{Co(CO)_4\}_4$ and anionic clusters such as $[Bi\{Co(CO)_4\}_4]^-$ reported.[87] Synthesis proceeds for the former as follows (Equation (3)):



(3)

(d) Photochemical reactions. Photoreactivity is exhibited by many carbonyl complexes. Photosubstitution reactions, where a CO ligand is commonly replaced, are assumed to proceed by an associative mechanism. A simple example is given in the reaction below (Equation (4)).[88]

$$Co(CO)_3(NO) + PPh_3 \longrightarrow Co(CO)_2(NO)(PPh_3) + CO \qquad (4)$$

Photooxidation of $Co_2(CO)_8$ is a complex reaction, with major products being the simple monomers $Co(O_2)(CO)_n$ ($n = 1$, 2) with the dioxygen bound side-on (η^2).[89] The same products arise from reaction of Co atoms with CO and O_2 at 10–12 K.

(e) Other reactions. Reduction reactions from a higher oxidation state offer an alternative route to low-valent Co compounds. For example, cobalt(II) chloride serves as a precursor for generation of $[Co(CO)_4]^-$ by treatment with $NaBH_4$ or Na_2S under a CO atmosphere.[90] This, in turn, catalyzes the double carbonylation of aryl halides (RX) to give RCOCOOH in the presence of $Ca(OH)_2$.

Dendrimers incorporating Co carbonyls and other organocobalt species have been the subject of a recent review.[91] This sets the scene for a likely growth of interest in such systems in the future.

(iii) Alkyls and aryls

The field of alkyl and aryl Co complexes in low formal oxidation states has been extensively studied, and is frequently associated with cluster chemistry.[92] Alkyl and aryl ligands, with or without additional functionality, are often co-ligands with π acceptors such as carbonyls and/or phosphines, e.g., $(MeOCOCH_2)Co(CO)_3(PPh_3)$.[93] A simple example of a cluster is $(RC)Co_3(CO)_9$, where the triangular $\{Co(CO)_3\}_3$ moiety is capped by the η^3-alkyl fragment, which occupies the apex of a distorted Co_3C tetrahedron.

Cobalt incorporation in a ring is one less common way in which Co–alkyl bonding is observed. One interesting example is the cobaltadihydroquinoline (**2**).[94] This arises from reaction of $(Cp)Co(PMe_3)(CO)$ (Cp = cyclopentadienyl anion) with an aryl isocyanide (CNR) and CH_2ClI in benzene, which first forms the carbenoid cation $[(Cp)CoCH_2CI(PMe_3)(CNR)]^+$, then yielding the cobaltadihydroquinoline on addition of KOH to a methanolic solution. A crystal structure defines a slightly distorted octahedral environment for the Co center.

(iv) Other carbon-bonded ligands

Complexation of CO_2 to Co demands a somewhat different approach. C-bound η^1-CO_2 is invariably a co-ligand with multidentate unsaturated N-donor ligands, particularly imines, and discussion of this area is deferred until Section 6.1.2.1.3(v). Close analogs which bind Co are carbonyl sulfide (COS) and carbon disulfide (CS_2).[95] The latter has been characterized in a η^2-C,S coordination mode to cobalt. These undergo reductive cleavage to produce sulfido and thiocarbonyl ligands.

The first transition metal isonitrilate complex reported was the tetrahedral Co^{-I} complex $[Co(C{\equiv}NPh^*)_4]^-$ where $Ph^* = 2,6\text{-}Me_2C_6H_3$,[96] characterized by a crystal structure analysis. Oxidation yields the zerovalent dimer $Co_2(C{\equiv}NPh^*)_8$, which features two bridging isonitrile groups.

6.1.2.1.2 Silicon

Silicon–cobalt bonds are essentially exclusive to low-valent cobalt. The companion series *Comprehensive Organometallic Chemistry* provides a coverage. Although monomers such as $Co(CO)_4(SiEt_3)$ are known, silyls tend to be found more often in clusters; for example, reaction of $Na[Co(CO)_4]$ in THF at −5 °C with $MeSiHCl_2$ yields $MeSiCo_3(CO)_9$.[97] Typically, Si–hydride and Si–halogen bonds can be replaced by Co carbonyl units, such as in the reaction of SiH_4 with $Co_2(CO)_8$ in dry hexane in a sealed tube, which forms $SiCo_4(CO)_{14}$.[98] A recently characterized simple cluster with a silicon-bonded chelate is (μ-$PhSiCH_2CH_2SiPh$) $Co_2(CO)_6$, formed from substitution in $Co_2(CO)_8$.[99]

6.1.2.1.3 Nitrogen

The most commonly encountered N-donor ligands, the amines, are not usually associated with Co in its low oxidation states. However, unsaturation coupled with chelation opens up many opportunities for the stabilization of monovalent Co with N donors such as imines, porphyrins, and pyrazoles.

(i) Amines

The monovalent Co chemistry of amines is sparse. No structurally characterized example of low-valent Co complexed exclusively to amines is known. At low potentials and in non-aqueous solutions, Co^I amines have been identified electrochemically, but usually in the presence of co-ligands that stabilize the reduced complex. At low potential, the putative monovalent $[Co(cyclam)]^+$ (cyclam = 1,4,8,11-tetraazacyclotetradecane) in NaOH solution catalyzes the reduction of both nitrate and nitrite to give mixtures of hydroxylamine and ammonia.[100] Mixed N-donor systems bearing π-acceptor imine ligands in addition to amines are well known, but these examples are discussed separately in Section 6.1.2.1.3.

(ii) Pyridine and oligopyridines

The π-acceptor ability of these unsaturated ligands offers more extensive low-valent Co chemistry than found with amines. Photochemical irradiation of $[Co(py)_6](BPh_4)_2$ (py = pyridine) results in reduction to the Co^I complex with the anion as the electron donor.[101] The same Co^I complex has been found to catalyze the cyclotrimerization of but-2-yne and hex-1-yne at room temperature,[101] and to reduce CO_2 at atmospheric pressure forming a carbonyl complex.[102] The formally monovalent $[Co(bpy)_3]^+$ and $[Co(phen)_3]^+$ complexes (bpy = 2,2′-bipyridine; phen = 1,10-phenanthroline) have been well characterized. The crystal structure of $[Co(bpy)_3]Cl$ is known[103] and the coordination geometry is almost identical to that of the divalent analog $[Co(bpy)_3]Cl_2$, suggesting considerable electron delocalization stabilizing this rare low-valent CoN_6 compound.

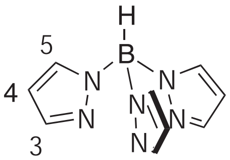
The $[Co(terpy)_2]^+$ ion (terpy = 2,2′;6′,2″-terpyridine) has been found to catalyze the reduction of CO_2 when the divalent precursor is immobilized on electrode surfaces. The vinyl-substituted terpy analog was electropolymerized to give a film that reduced the overpotential for CO_2 reduction in DMF and MeCN by more than 1 V.[104] The activity of this surface-confined species was superior to that of the complexes in solution.[105] Similarly, in water, the $[Co(terpy)_2]^{2+}$ ion immobilized and reduced *in situ* within a Nafion film also catalyzes the reduction of CO_2[106] and H^+ ions.[107]

(iii) Porphyrins

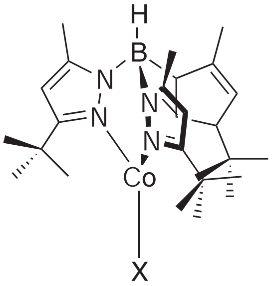
Most recent advances in the area of low-valent Co porphyrin chemistry involve their use as reduction catalysts of organic substrates, and this work appears in Section 6.1.4.3.

(iv) Pyrazole and related ligands

By far the most studied pyrazole-containing ligand is the symmetrical monoanionic tripod hydridotrispyrazolylborate, Tp (**3**). Substituents introduced at each of the 3-, 4- or 5-positions (3,5-Me_2Tp[108], 3-*i*Pr,4-BrTp[109]) have led to a number of sterically encumbered threefold symmetric complexes and some remarkable Co coordination chemistry has ensued. Hydride substitution at the B atom is also possible by organic groups such as *p*-bromophenyl, which enables further functionalization of the ligand.[110]



(**3**)



(**4a**) X= CO
(**4b**) X=N_2
(**4c**) X=H
(**4d**) X=C_2H_4

The diamagnetic (3-*t*Bu,5-MeTp)Co$(CO)_2$ has been prepared and structurally characterized.[111] In solution it spontaneously loses CO to give the paramagnetic (3-*t*Bu, 5-MeTp)Co(CO) (**4a**). In the presence of CO, the two complexes are in equilibrium. A Mg reduction of (**4a**) yielded the dimer [[(3-*t*Bu,5-MeTp)Co](μ-CO)$]_2$·Mg$(THF)_4$.[112] The crystal structure of this compound shows a linear CO bonding mode. However, in the crystal structures of the di mononuclear neopentyl analogs [(3-npTp)Co$]_2$(μ-N_2) and (3-npTp)Co(CO) the CO and N_2 ligands are bent away from the pseudo-threefold axis of the complex by about 30°.[112] Hydrogenation of the mononuclear dinitrogen complex (**4b**) produced the hydride (**4c**), whereas reaction with ethylene yields the corresponding olefin complex (**4d**), all of which were structurally characterized (Figure 2).[113]

(v) Imines

Polyimines of low-valent Co are now well represented, particularly with macrocyclic or mixed-donor ligands. The monovalent Co complex (**5**) of the 14-membered macrocyclic hexamethyl diimine (hmd), may be generated electrochemically from its divalent precursor. Furthermore,

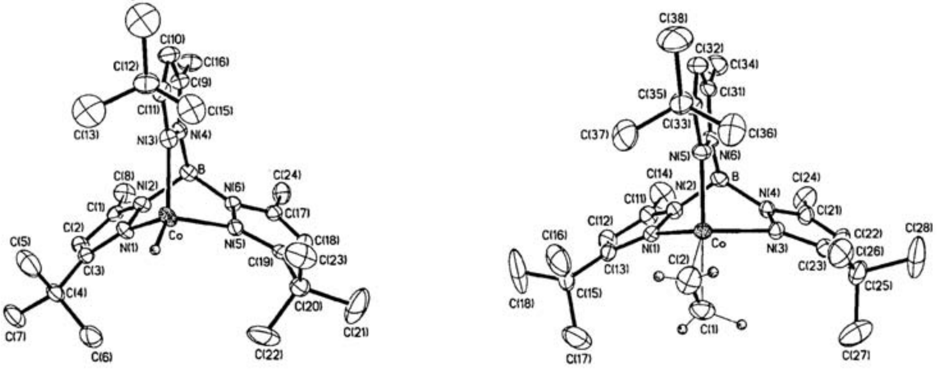


Figure 2 Crystal structures of the monovalent hydrido (**4c**) (left) and ethylene (**4d**) (right) complexes of *i*-Pr-5-MeTp (reproduced with permission of the American Chemical Society from *Organometallics*, **1999**, *18*, 300–305).

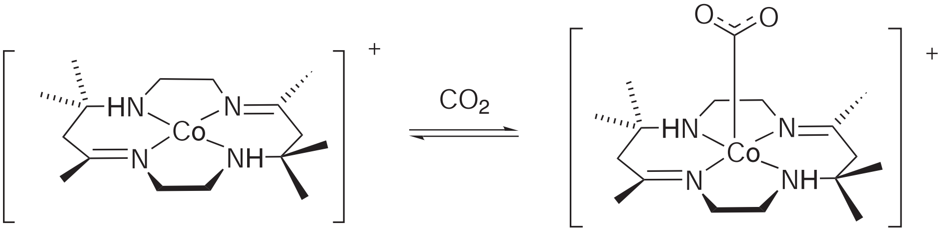
cyclic voltammetry of $[Co(hmd)]^{2+}$ in 0.1M Et_4NClO_4-DMSO in the presence of CO_2 showed a pronounced anodic shift in the $Co^{II/I}$ potential, indicating a large CO_2 binding constant for the monovalent complex.[114] Subsequently it was found that (**5**) rapidly forms a purple 1:1 adduct (**6**) with CO_2 in MeCN ($K_a=1.2\times10^4$ M^{-1}).[115] In ultrapure MeCN, (**6**) slowly reacts to give $[Co(hmd)]^{2+}$, CO, and HCO_3^-.



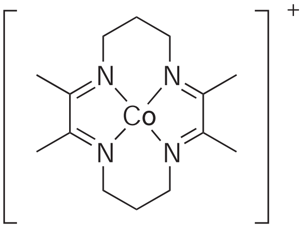
(**5**) (**6**)

The dinuclear complex $[Co_2(hmd)_2(\mu\text{-}CO_2H)](ClO_4)_3$ and the monomeric carbonyl $[Co(hmd)(CO)](ClO_4)$ were crystallized and structurally characterized. The structure of the dinuclear complex finds both Co ions in a square pyramidal environment, with axial sites occupied by the bridging ligand. A μ-η^1:η^1 coordination mode (Co–C(OH)O–Co) was defined involving a distorted trigonal planar C atom. The thermodynamics and kinetics of complex formation between pulse radiolytically generated (**5**) and the species H^+, CO_2, and CO were also studied in aqueous formate solutions.[116] Subtle stereochemical influences were revealed in parallel investigations of the N-based *meso* and *rac* diastereomers of (**5**) and (**6**), the *rac* isomer having both amine H atoms *syn* to the coordinated CO_2. Although the *meso* and *rac* isomers have identical $Co^{II/I}$ redox potentials, their CO_2 binding constants in DMSO differ by a factor of 100 (*rac* being more stable) indicating that steric effects are at work.[117] The effects of solvent dielectric constant and electrolyte were also explored. A similar, but independent, CO_2 binding study was published soon after,[118] also incorporating the thermodynamics and kinetics of binding CO and H^+ to the *rac* and *meso* isomers of the same complex. Hydrogen bonding was also found to be a factor in stabilizing (**6**).[119] The solution structures of the five-coordinate (**6**) and its six-coordinate solvated adduct were examined with XANES and EXAFS together with the related (**5**), $[Co(hmd)(CO)]^+$, $[Co(hmd)]^{2+}$, and $[Co(hmd)(CO_3)]^+$. The edge position of (**6**) and $[Co(hmd)]^{2+}$ are the same, whereas the edge position for six-coordinate $[(MeCN)Co(hmd)(CO_2)]^+$ shows significant metal-to-CO_2 charge transfer consistent with a Co^{III} C-bound carboxylate.[120] The pressure dependence of this five- to six-coordinate equilibrium was studied,[121] with high pressures favoring the six-coordinate form.

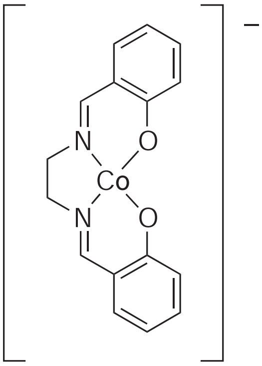
Photoreduction of CO_2 using *p*-terphenyl as a photosensitizer and a tertiary amine as a sacrificial electron donor is efficiently catalyzed by $[Co(hmd)]^{2+}$ using continuous and flash photolysis, and charge separated species (Co^I and terphenyl cation) were identified.[122] Similarly, photoreduction of $[Co(hmd)]^{2+}$ by several bis-bipyridyl Ru^{II} photosensitizers leads to Co^I-mediated reduction of CO_2.[123] The tetramethyl-tetraimine (tmt) relative $[Co(tmt)(NCMe)_2]^{2+}$ also undergoes facile one-electron reduction in MeCN to give the corresponding monovalent species (**7**), which is a potent Lewis acid toward a variety of monodentate ligands (pyridine; 2,6-lutidine; 1-Me-imidazole; Br^-).

Electrogenerated monovalent Co complexes of the well-known open chain N_2O_2 Schiff base ligands salen (**8**), salphen (**9**), and their substituted derivatives undergo oxidative additions with alkyl halides. Reactions of the complex with substrates within the series RBr (R = Pr, Bu, *t*-Bu) proceed at different rates. The reaction occurs by an inner-sphere alkyl-bridged electron transfer, with a $Co^{I}\cdots R^{+}\cdots X^{-}$ transition state, which is sensitive to distortions of the complex in different configurations.[124]

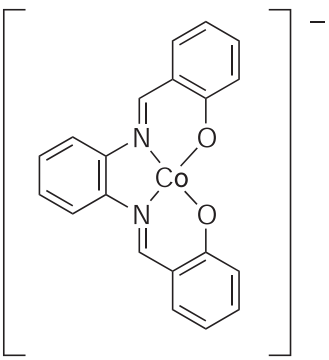
A crystal structure of the CO_2 derivative of (**8**), $K[Co(salen)(\eta^1\text{-}CO_2)]$, has been reported in which the Co—C bond is 1.99 Å, the C—O bonds are both equivalent at 1.22 Å and the O–C–O angle is 132°.[125] Carboxylation of benzylic and allylic chlorides with CO_2 in THF-HMPA was achieved with (**8**) electrogenerated by controlled-potential electrolysis,[126] in addition to reductive coupling of methyl pyruvate, diethyl ketomalonate and *p*-tolylcarbodiimide via C—C bond formation. Methyl pyruvate is transformed into diastereomeric tartrates concomitant with oxidation to the divalent Co(salen) and a free-radical mechanism is proposed involving the homolytic cleavage of the Co—C bond. However, reaction with diphenylketene (DPK) suggests an alternative pathway for the reductive coupling of CO_2-like compounds.



(**7**)



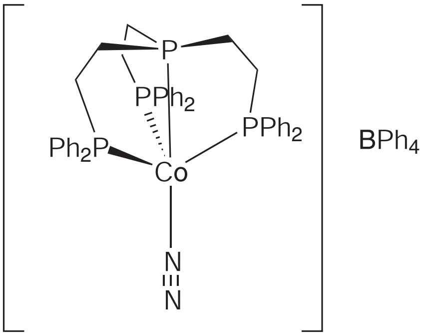
(**8**)



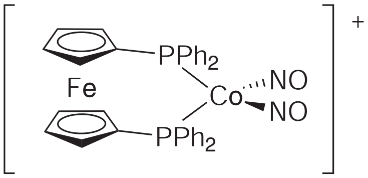
(**9**)

(vi) Dinitrogen

The dinitrogen coordination chemistry of Co is restricted to low oxidation states and phosphine co-ligands appear to be a requirement. The formally monovalent hydrido complex $CoH(N_2)(PPh_3)_3$ when reacted with Et_2Mg, then BuLi, gives $[Co(N_2)(PPh_3)_3]Li(Et_2O)_3$ or $[Co(N_2)(PPh_3)_3]Li(THF)_3$ depending on the solvent used.[127] The complexes possess threefold symmetry with the N_2 ligand bridging Co and Li with an N—N bond length of ca. 1.18 Å. In contrast to the hydrido precursor, the ligated N_2 in $[Co(N_2)(PPh_3)_3]^-$ is attacked by conc. H_2SO_4 to afford N_2H_4 and NH_3, providing the first examples of this conversion involving N_2 coordinated to Co. Also, $CoH(N_2)(PPh_3)_3$ catalyzes oligomerization and cyclization reactions of alkynes under mild conditions.[128] The Mg reduction of (3-*t*Bu, 5-MeTp)CoX (X = Cl, I) in an N_2 atmosphere yields (3-*t*Bu,5-MeTp)$Co^I(N_2)$ (**4b**) as an intermediate, which upon exposure to O_2 yielded the superoxo Co^{II} analog.[129] Heterogeneous reactions of the monovalent tripodal phosphine complex $[(dppep)Co(N_2)]BPh_4$ (**10**) with gaseous C_2H_2, C_2H_4, CH_2O, CH_3CHO, and CO lead to N_2 displacement and either 1:1 complexes or C—H bond cleavage at cobalt. The latter case ultimately results in either H_2 elimination or hydrogen transfer from metal to the coordinated ligand.[130]



(**10**)



(**11**)

The symmetrical dimer $[(Me_3P)_3CoH]_2(\mu\text{-}N_2)$ is formed by protonation of the dinitrogen cobaltate precursor and its crystal structure is reported.[131] The complex reversibly binds N_2, forming the monomer $CoH(N_2)(PMe_3)_3$.

(vii) Nitrosyl

Nitrosyl is now well established as a ligand for low-valent cobalt. The distorted tetrahedral $[Co(NO)_2(py)_2]^+$ has been prepared and structurally characterized.[132] In contrast to bis-phosphine analogs, the bis-pyridine complex decomposes rapidly in solution unless stabilized by excess pyridine. This was correlated with structural parameters, most notably the compressed ON–Co–NO coordination angle. Electrochemistry of the four-coordinate $[Co(P(OEt)_3)_2(NO)_2]^+$ in MeCN at Pt or Hg electrodes reveals two consecutive reductions and a single oxidation process. The less negative reductive wave yields a stable neutral species in the absence of oxygen.[133] The novel pseudo-tetrahedral complex (**11**) also bears two P donors and two NO ligands, but a ferrocenyl group bridges the two phosphines.[134] The interaction between the two metallic centers bridged by the two Cp–PPh_2 linkers was studied by ^{57}Fe Mössbauer spectroscopy and cyclic voltammetry.

The doubly bridged nitrosyl complex $[(Cp)Co]_2(\mu\text{-}NO)_2$ has attracted a considerable amount of interest with regard to its electronic ground state. *Ab initio* calculations carried out on this d^9-d^9 species predicted a triplet ground state 280 cm^{-1} lower in energy than the singlet state, and the authors suggested that the magnetic properties of the compound be more closely examined.[135] In response, experimental reinvestigation of the magnetic susceptibility of the complex found that the compound is actually diamagnetic in the solid state (from 5 K to 280 K) and in benzene solution (in the range 303–327 K).[136]

Coordinated nitrosyl can participate in further chemistry, as illustrated in the following example. Methylation of $[(Cp)Co(NO)]^-$ with MeI in THF at $-40°$ gives (Cp)Co(Me)(NO) which in the presence of PPh_3 undergoes NO migratory insertion to give $(Cp)Co(N(O)Me)(PPh_3)$. The ethyl, isopropyl, and *p*-methyl-benzyl analogs behave similarly.[137]

(viii) Nitriles and azides

These are adequate ligands for low-valent Co, but their chemistry is somewhat limited. Dicobalt hexacarbonyl complexes of propargyl acetates and acetylenic acetals couple efficiently with diethylaluminum cyanide to produce the corresponding complexed propargyl nitriles and cyanohydrins.[138] Electron-poor dipolarophiles such as alkynes, alkenes, and nitriles undergo 1,3-dipolar cycloadditions with azido Co complexes to give five-membered heterocycles such as triazoles (from nonterminal alkynes), triazolines (from alkenes), and tetrazoles (from nitriles).[139] Tetracyanoethylene is an effective one-electron oxidant and also is capable of forming sigma-bonded complexes such as (Cp)Co(CO)(TCNE).[140,141]

6.1.2.1.4 Phosphorus

Most work done on the coordination chemistry of phosphorus ligands bonded to Co lies within the realm of organometallic chemistry where the P donor is in the minority of non-C-bonded ligands. Examples such as these where the principal ligands are CO, Cp, and olefins, will not be discussed here. Tertiary phosphines (trialkyl and triaryl) and phosphite esters dominate the examples of phosphorus coordinated to Co, as they are excellent ligands for low-valent Co. Of the monodentate P donors, PMe_3, PEt_3, $P(i\text{-}Pr)_3$, $P(ch)_3$, and PPh_3 are the most commonly encountered examples.

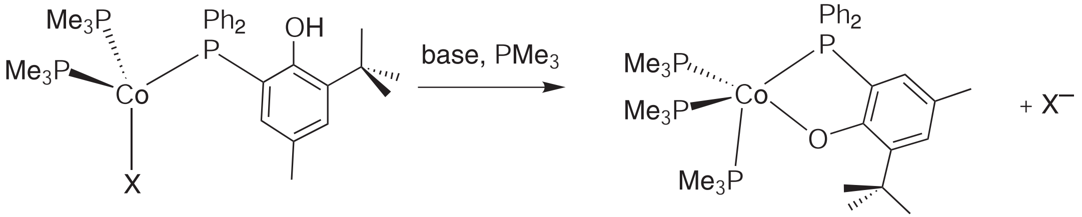
(i) Monodentate phosphines

The simple tetrahedral complex $[Co(PMe_3)_4]PF_6$ reacts with formaldehyde to give the trigonal bipyramidal derivative $[Co(CO)(PMe_3)_4]PF_6$ where the CO ligand is in an equatorial position. Curiously, the BPh_4^- salt reacts to give the axially bound CO isomer in addition to the *cis*-octahedral Co^{III} dihydrido species $[CoH_2(PMe_3)_4]^+$.[142] Reaction of $[Co(PMe_3)_4]^+$ with O_2 in MeCN yields the octahedral divalent phosphine oxide complex *trans*-$[Co(MeCN)_2(OPMe_3)_4]^{2+}$ and its X-ray crystal structure was determined.[143] The dioxygen complex $[Co(PMe_3)_4(O_2)]^+$ (with $\overline{\nu}_{O\text{-}O} = 880\ cm^{-1}$) was identified as an intermediate.

The tetrahedral halide-bridged monovalent compounds $[Co(PPh_3)_2X]_n$ (X = Cl, Br) or $[Co(PPh_3)X]_n$ (X = Cl, I), may be prepared by reduction of CoX_2 with $NaBH_4$ in the presence of PPh_3.[144] The $[Co(PPh_3)_2Br]_n$ analog reacts further with PPh_3 to form paramagnetic tetrahedral monomeric $Co(PPh_3)_3Br$. Although $Co(PPh_3)_3Cl$ is formally a homolog of its illustrious Rh^I analog $Rh(PPh_3)_3Cl$ (Wilkinson's catalyst), their structures and reactivities are in no way similar. Unlike the square planar diamagnetic Rh complex, $Co(PPh_3)_3Cl$ is tetrahedral and paramagnetic.

Nevertheless, the $Co(PPh_3)_nX$ compounds are excellent synthons for a variety of low-valent phosphine complexes, as the Co—P bonds are quite stable, allowing the investigation of ligand addition and substitution reactions at the remaining coordination site(s). For example, the first Co^I siloxide complex $Co(PPh_3)_3(OSiMe_3)$ was synthesized and characterized structurally by reaction of $Co(PPh_3)_3Cl$ with trimethylsilanolate.[145] The paramagnetic tetrahedral $Co(PMe_3)_3Br$ reversibly binds ethylene in a variety of solvents (toluene, acetone, and MeOH) to give the diamagnetic $CoBr(C_2H_4)(PMe_3)_3$ species.[146] By contrast, reaction of $Co(PMe_3)_3Br$ with diphenylacetylene yields different mononuclear diamagnetic Co-alkyne species depending on the solvent; $CoBr(C_2Ph_2)(PMe_3)_3$ forms in toluene, whereas in acetone the salt $[Co(PMe_3)_3(C_2Ph_2)]Br$ is also present. MeCN is also found to be a competitive ligand in these systems.[147] Homologs of the form $[Co(PMe_3)_3(RC{\equiv}CR_1)]^+$ ($R = Ph$, $R_1 = Me$, pentyl; R, $R_1 = Me$) were also prepared from $Co(PMe_3)_3Br$.[148] The alkyne ligand acts as a four-electron donor but is weakly bound. Reaction of $HC{\equiv}CPh$ in excess with $Co(PMe_3)_3Br$ and $NaBPh_4$ in MeOH gave the phosphonium salt $[Me_3P(CH_2CH(OMe)Ph)]BPh_4$, which was characterized in the solid state by X-ray diffraction and in solution by ^1H and ^{31}P NMR.[149] Addition of aryl halides (ArX) to $Co(PPh_3)_3Me$ yield ArAr and ArMe when Ar = 4-toluyl, but exclusively ArMe for 1- and 2-bromonaphthalene and 4-bromobiphenyl.[150]

In the four-coordinate complexes (**12**) (X = Cl, Br) the phenol phosphine is coordinated as a monodentate.[151] In the presence of base, the phenolate O atom deprotonates and coordinates to give (**13**). The five-membered chelate ring in this complex is resistant to protonation, and ring-opening is not observed even in the presence of CO or C_2H_4.



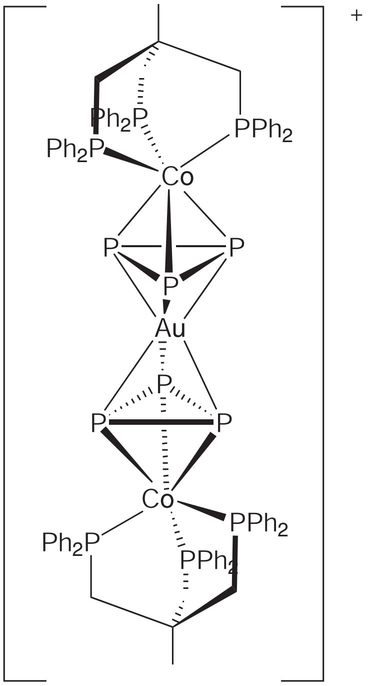
(**12**) (**13**)

At least partial substitution of other inherently strong ligands by phosphines can be achieved. Trialkylphosphines substitute partially into arylisocyanide complexes $[Co(CNR)_5)]^+$, with monosubstitution and at best disubstitution observed, influenced by the steric bulk of the phosphine.[152]

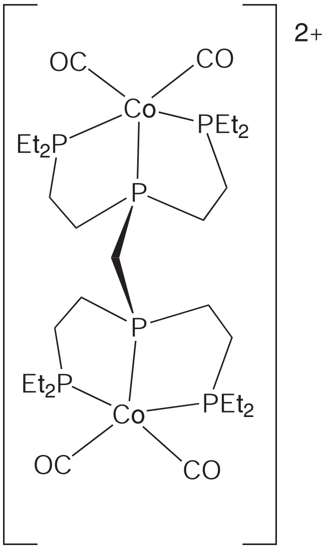
(ii) Multidentate phosphines

There is a wide range of examples extant, but a selection illustrates recent chemistry sufficiently. There are many Co complexes, both monomers and clusters, of the facially coordinating tridentate phosphine triphos (1,1,1-tris((diphenylphosphino)methyl)ethane) and its dimethylphosphino (mtriphos) or diethylphosphino (etriphos) analogs. The novel mixed P-ligand complex $Co(triphos)(P_3)$ reacts with $AuCl(PR_3)$ ($R = Me$ or Ph) and $Au_2Cl_2(Ph_2PCH_2PPh_2)$ in the presence of $TlPF_6$ to give the P_3-bridged compound (**14**). The Au atom is sandwiched between the two cyclic P_3 units of each $Co(triphos)(P_3)$ moiety.[153] Similarly, treatment of $Co(triphos)(P_3)$ with Cu^I and Ag^I salts affords $[M\{Co(triphos)(P_3)\}_2]^+$ ($M = Cu$, Ag).[154] The protonated form $[Co(triphos)(P_3H)]CF_3SO_3$, also containing an η^3-coordinated P_3 unit, reacts with $Pt(PPh_3)_2$ to give the trinuclear compound $[((triphos)Co)_2(P_6H_2)PtPPh_3](CF_3SO_3)_2$.[155] In this compound, the P_6 fragment bears a P—P bond between two different P_3 moieties and this novel ligand is stabilized by coordination to three metal–ligand fragments.

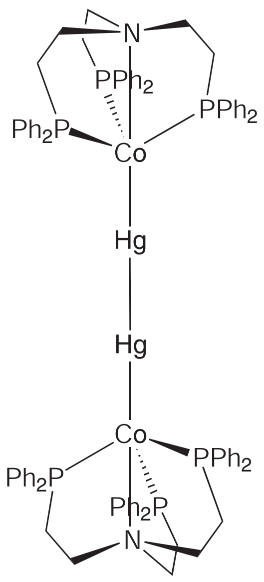
The dinucleating hexaphosphine eHTP binds as a bridging bis-tridentate ligand and several dicobalt complexes have been isolated, such as (**15**).[156] The solution conformational behavior of (**15**) was examined with NMR, which identified a number of solvent- and temperature-dependent shifts of the methylene bridge and chelate ring proton resonances.[157] Chemical shift changes for the P–CH_2–P proton resonances were assigned to CO shielding from different rotational conformers, whereas variations in the chelate ring resonances were attributed to trigonal–bipyramidal/square–pyramidal coordination geometry changes. In the same study, reduction of (**15**) with the naphthalenide anion produced the zerovalent Co—Co-bonded dimer $Co_2(CO)_2(eHTP)$. In dry



(**14**)



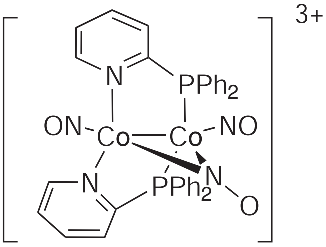
(**15**)



(**16**)

MeCN, the divalent analog Co_2Cl_4(eHTP) undergoes P oxidation (by dioxygen) at each donor atom to produce the corresponding hexaphosphine oxide.[158]

A rather unusual Co–Hg–Hg–Co moiety was stabilized by the NP_3 tripod tris(2-diphenylphosphinoethyl)amine (tdppea) in (**16**).[159] The complex is converted to the monomer $[Co(tdppea)(CO)]^+$ by reaction with either CO or CO_2 at room temperature and atmospheric pressure. The five-coordinate mixed tri-/dimethylphosphite complex $Co(P(O)(OMe)_2)(P(OMe)_3)_4$ has been reported along with its Rh and Ir analogs.[160] There is a range of other ligands incorporating both P and N donors. One deceptively simple example is 2-(diphenylphosphino)pyridine (dpppy), whose chemistry has been reviewed.[161] The dpppy ligand can chelate in both a simple fashion, as in the tetrahedral monomer $[Co(dpppy)(NO)_2]^+$, and in a bridging mode, as in the dimer (**17**).[162]



(**17**)

Diphosphinoamines ($X_2P–NR–PX_2$) are examples of a more unusual potentially chelating diphosphine. The dimer $Co_2(F_2PN(CH_3)PF_2)_3(CO)_2$ has three of these ligands bridging symmetrically between the two tetrahedral Co centers, which also carry a terminal CO group; this molecule can undergo reduction with $LiEt_3BH$ in THF to form a stable mixed valence ($d^9–d^{10}$) radical anion.[163]

6.1.2.1.5 Arsenic

Low-valent arsine complexes of Co are few and these bear mostly C ligands such as CO (see Section 6.1.2.1.1 for an example).

6.1.2.1.6 Oxygen

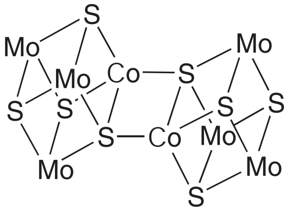
Stable low-valent Co is not often found with simple O-donor ligands such as water, hydroxide, dioxygen, and oxoanions. Carboxylate anions are also not frequently met as ligands in low-valent Co chemistry. One interesting compound, however, is the Co cluster-substituted carboxylic acid μ_3-$[(CO)_9Co_3]CCOOH$, which can perform its function as a carboxylate ligand; for example, it reacts with $Co(OAc)_2$ in THF to yield $Co_2[(CO)_9Co_3CCOO]_4(THF)_2$.[164] This class of compound catalyzes the selective hydrogenation of 2-butenal.

6.1.2.1.7 Sulfur

(i) Sulfides

Sulfide-capped triangular Co clusters are a well-known feature in organometallic systems. A number of examples will serve to illustrate this. The simple monomeric phosphine complex $(Ph_3P)_2CoBr_2$ reacted with Na_2S yields the symmetric cluster $Co_6S_8(PPh_3)_6$, where the six Co atoms form a distorted octahedral core with each octahedral face bridged by a μ^3-S^{2-} atom.[165] Each Co is identically surrounded by four S and one P atom in a distorted square–pyramidal environment. In a quite different approach, reaction of $CoCl_2$, 2-aminobenzenethiol (Habt), $NaOCH_3$, and P(*t*-Bu)$_3$ in the absence of air with following addition of Li_2S yields a cluster of this type, $Co_3(\mu_3$-$S)(abt)_3(P(t$-$Bu)_3)$.[166] The paramagnetic sulfide-capped cluster $Co_3(CO)_9(\mu_3$-$S)$ has been developed as a reagent for the synthesis of $Co_3(CO)_7(\mu$-$SR)(\mu_3$-$S)$ species via reaction with organic compounds possessing S—S or S—H bonds.[167]

The heteronuclear cluster $[Mo_3CoS_4(H_2O)_{10}]^{4+}$ has been reported, where the Co is formally zerovalent.[168] The core structure (**18**) features two edge-linked cubane units with Co—S bridging the two clusters.



(**18**)

(ii) Thioethers

Multidentate thioethers are readily introduced into the coordination sphere of low-valent cobalt. As an example, the tridentate thioethers 1,3,5-trithiacyclohexane and tris(methylthio)methane both replace three facially arranged carbonyl ligands in $Co_3(CO)_9(\mu$-$CPh)$, leaving the cluster otherwise intact.[169]

(iii) Thiolates

In organometallic systems in particular, clusters with bridging alkylthiolates are well known, as exemplified by $Co_2(Cp)_2(\mu$-$SCH_3)_2$, which undergoes reactions with alkyne-cobalt complexes to yield trinuclear clusters.[170]

(iv) Thiocarbamates

Dithiocarbamates in stable low-valent Co systems are rare and usually restricted to organometallic systems. An example is the heteronuclear metal cluster $WCo_2(\mu_3$-$S)(\mu_3$-$SCNEt_2)(CO)_4(S_2CNEt_2)$, characterized by a crystal structure, and formed by reaction of $Co_2(CO)_8$ with $W(CO)(PhCCPh)(S_2CNEt_2)_2$ and subsequent rearrangement in solution following carbonyl loss from an intermediate.[171] The three metals are arranged in a triangular array, bicapped by the sulfido and thiocarboxamido anions. Each Co is also bonded to two terminal carbonyl groups, the remaining ligands binding to the tungsten center.

(v) Thioureas

A rare example of thiourea coordination to low-valent Co is of a disubstituted thiourea as bridging ligand, observed in the cluster $Co_3(CO)_7(\mu_3\text{-}S)(\mu\text{-}\eta_2\text{-}PhNC(S)NHCH_2Ph)$ which is formed by reaction of $Co_2(CO)_8$ with the thiourea.[172] The crystal structure of the product defines a tetrahedral Co_3S core with all carbonyls in terminal positions and the deprotonated thiourea bridging two Co centers via the S and an amido N.

6.1.2.1.8 Halogens

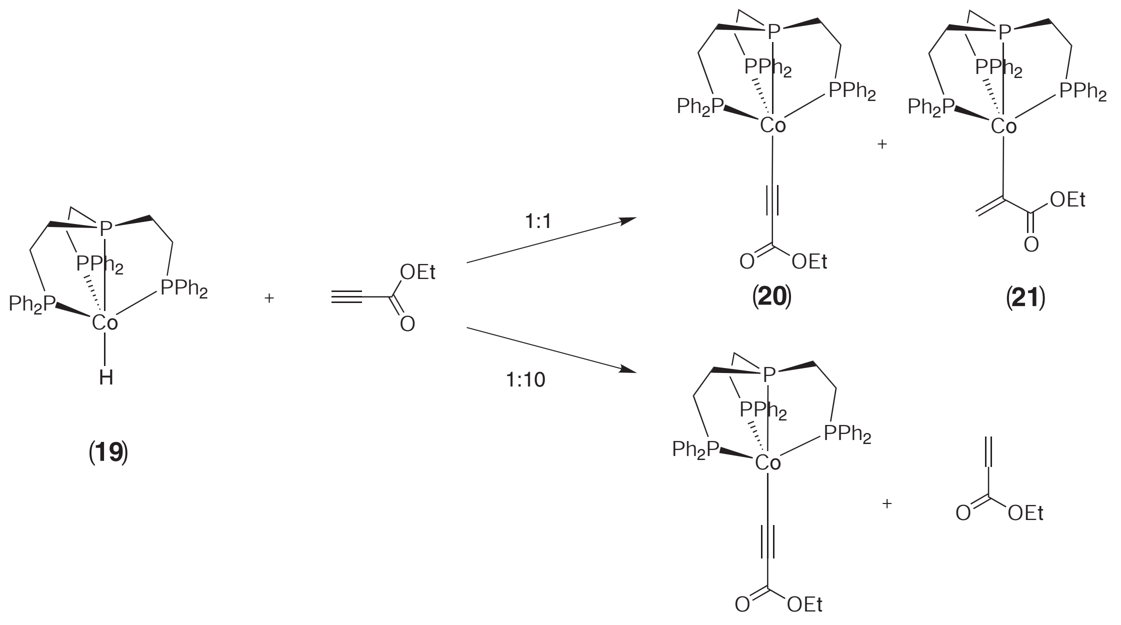
Compounds containing Co and only halogen ligands are extremely rare in low oxidation states. However, halogen is a common companion ligand in low-valent Co chemistry, particularly to phosphorus (see Section 6.1.2.1.4), where they are often the leaving group in substitution reactions. Of course, the effectiveness of a leaving group is determined by its stability in isolation, so it is no surprise that halides play a similar role across all oxidation states of Co coordination chemistry.

6.1.2.1.9 Hydrogen

(i) Hydrides

Cobalt compounds with hydride as the sole ligand are not usually observed, and hydride compounds, at least in isolable form, include other companion ligands. However, using a time-of-flight atom-probe field ion microscope, the interaction between hydrogen and Co atoms in an external electric field led to the Co hydrides CoH, CoH_2, and CoH_3,[173] although these species have no extended stability. Recent advances in the chemistry of hydrides in general have been reported in a monograph.[174]

The effect of stoichiometry, substituent, and temperature were investigated in reactions between the hydride HCo(tdppep) (**19**) and a number of alkynes.[175] The σ-acetylide complex (**20**) and the σ-alkenyl (**21**) are formed from the stoichiometric reaction with ethyl propiolate. However, when a ten-fold excess of ethyl propiolate is used, the acetylide complex is formed quantitatively and one equivalent of alkyne is hydrogenated to alkene. Forcing conditions and a large excess of



alkyne were required to form the analog (tdppep)Co(C$\equiv$CPh). The electrochemical behavior of these Co^I σ-acetylides was also reported.

Unsually short NMR T_1 relaxation values were observed for the metal-bonded H-ligands in $HCo(dppe)_2$, $[Co(H_2)(dppe)]^+$ (dppe = 1,2-bis(diphenylphosphino)ethane), and CoH(CO)$(PPh_3)_3$.[176] A theoretical analysis incorporating proton–metal dipole–dipole interactions was able to reproduce these T_1 values if an $r_{Co\text{-}H}$ distance of 1.5 Å was present, a value consistent with X-ray crystallographic experiments. A detailed structural and thermodynamic study of the complexes $[H_2Co(dppe)_2]^+$, $HCo(dppe)_2$, $[HCo(dppe)_2(MeCN)]^+$, and $[Co(dppe)_2(MeCN)]^{2+}$ has been reported.[177] Equilibrium and electrochemical measurements enabled a thorough thermodynamic description of the system. Disproportionation of divalent $[HCo(dppe)_2]^+$ to $[Co(dppe)_2]^+$ and $[H_2Co(dppe)_2]^+$ was examined as well as the reaction of $[Co(dppe)_2]^+$ with H_2.

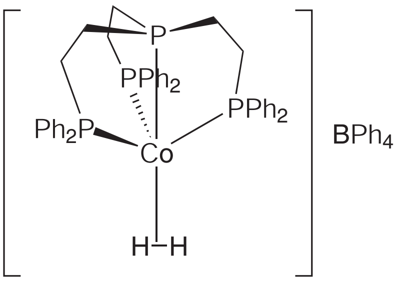
The electrochemical behavior of monovalent phosphite ester Co hydrides of the type $HCo(PR_3)_4$ ($PR_3 = P(OEt)_3$, $PPh(OEt)_2$, $PPh_2(OEt)$) in CH_2Cl_2 and MeCN was examined.[178] Cyclic voltammetry in CH_2Cl_2 identified a reversible single electron oxidation to $[HCo(PR_3)_4]^+$, followed by a second irreversible oxidation, for all the ligands employed. In MeCN, the behavior was similar, but stability of the compounds in this solvent was diminished. Bulk electrolysis gave a new Co^{II} hydride, $[HCo(P(OEt)_3)_4]BPh_4$.

The monovalent hydride $HCo(PPh(OEt)_2)_4$ is a versatile synthon and catalyst. Photoirradiation of $HCo(PPh(OEt)_2)_4$ generates the coordinatively unsaturated complex $HCo(PPh(OEt)_2)_3$ which catalyzes H transfer from secondary alcohols to carbonyl compounds.[179] Intermediate coordination of the carbonyl compound to $HCo(PPh(OEt)_2)_3$ was proposed. The rate-determining step involves hydride transfer to the carbonyl carbon at the stage of transformation of the hydrido aldehyde/ketone complex into its alkoxo derivative. A kinetic analysis showed that aldehydes reacted considerably faster than ketones, attributable to steric repulsion hindering approach by the Co complex to the carbonyl group. Reaction of $HCo(PPh(OEt)_2)_4$ with $p\text{-}MeC_6H_4N_2^+$ affords the paramagnetic $[HCo(PPh(OEt)_2)_4]^+$. When reacted with NO^+, the dinitroso complex $[Co(NO)_2(PPh(OEt)_2)_2]^+$ is formed and protonation with $HBF_4\cdot Et_2O$ to give the dihydrogen complex $[Co(H_2)(PPh(OEt)_2)_4]^+$ occurs.[180] Reaction of the monovalent HCo(tdppea) (hydrido monomer of (**16**)) with CS_2, SCNPh, or OCNPh affords the corresponding η^2-bonded sulfide, isothiocyanate, or isocyanate.[181]

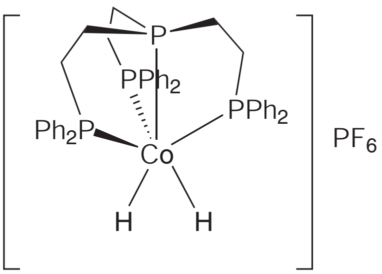
$HCo(N_2)(PPh_3)_3$ has been shown to promote C—O bond cleavage selectively in allylic and vinylic trimethylsilyl ethers, resulting in $Co(OSiMe_3)(PPh_3)_3$ and free olefin at room temperature.[182] The mechanism of C—O bond cleavage involves insertion of the olefinic double bond into the Co—H bond, followed by β elimination of the Me_3SiO group from the transition metal complex. The same group reported that C—O bonds in aryl and alkyl carboxylates ($R'CO_2R$) are selectively cleaved by the same complex.[183] The reaction products are accounted for by assuming insertion of the ester C$=$O bond into the Co—H bond, followed by abstraction of the β alkoxo group by Co. Other derivatives prepared include $Co(OCH(CF_3)OEt)(PPh_3)_3$ (from trifluoroacetic acid) and $Co(OPh)(PPh_3)_3$ from (phenyl acetate). Borohydride is well known to form non-classical η^2-bonded complexes through a pair of bridging H atoms. The diamagnetic monovalent $Co(terpy)(H_2BH_2)$ undergoes rapid exchange between its terminal and bridging H atoms, as shown by NMR.[184]

(ii) Dihydrogen

Dihydrogen is an effective and usually η^2-bonded ligand, as exemplified here. The remarkably stable η^2–H_2 complex $[Co(tdppep)(H_2)]PF_6$ (**22**) was prepared via three routes: protonation of the hydride HCo(tdppep) by a strong acid; displacement of N_2 by H_2 in $[(Co(tdppep)(N_2)]PF_6$; or H_2 addition to the 16-electron fragment $[Co(tdppep)]^+$.[185] X-ray crystallography identified a trigonal–bipyramidal geometry with the H_2 ligand presumably *trans* to the bridgehead P donor, although the actual position of the H_2 ligand was not resolved. The complex catalytically isomerizes dimethyl maleate to dimethyl fumarate. However, an unusual counter-ion dependence was seen for the reaction with H_2 and two salts of the dinitrogen complex (**10**) in the solid state.[186] With BPh_4^- as the counter ion, the classical dihydro distorted octahedral complex $[(tdppep)Co(H)_2)]BPh_4$ (**23**) results (characterized by its X-ray crystal structure), rather than the non-classical $[(tdppep)Co(\eta^2\text{-}H_2)]PF_6$ (**22**).[185] Both reactions are reversible upon treatment with N_2. In solution the complexes are indistinguishable and consistent with a η^2-bonded H_2 ligand.



(**22**)



(**23**)

6.1.2.2 Co^{II}

Cobalt(II) is a key oxidation state, and the range of compounds extant is truly vast. Four-coordinate tetrahedral and six-coordinate octahedral complexes, in particular, abound, with five-coordinate trigonal bipyramidal complexes also common. However, three- to eight-coordinate compounds have been reported, with examples at the extrema sparse, and their formation is usually particularly dependent on ligand topology. Traditionally, the complexes of this d^7 paramagnetic ion are considered to be labile and ligand exchange facile.

6.1.2.2.1 Carbon

(i) Cyanides

Cyanide complexes have a venerable history (see *CCC*(1987)),[1] and find utilization in many industrial processes including as synthetic catalysts e.g., Co cyanides on inorganic supports catalyze alkylene oxide polymerization,[187] molecular magnetic materials, in electroplating, and in mining. Their pharmacology and toxicology is well explored

(f) Mononuclear. Given the long history of cyanide complexes, it is not intended to cover simple complexes to any marked extent. One interesting example is the characterization of the well-known anion $[Co(CN)_5]^{3-}$ formed inside Zeolite Y by treatment of the Co zeolite first with CsCl and then with methanolic NaCN.[188] This encapsulated complex has been shown to reversibly bind dioxygen in the zeolite lattice with high selectivity, whereas the usual reaction is irreversible formation of a dioxygen-bridged dimer. The simple aquapentacyanocobaltate(II) ion is an efficient catalyst for photolytic hydrogen evolution.[189] In aprotic solutions, a synthetic, spectroscopic and X-ray structural study has identified the existence of species with from one to five cyanide ions coordinated to cobalt.[190] The $Li_3[Co(CN)_2]\cdot 3DMF$ species was isolated and structurally defined, and a salt of $[Co(CN)_4]^{2-}$ was also isolated.

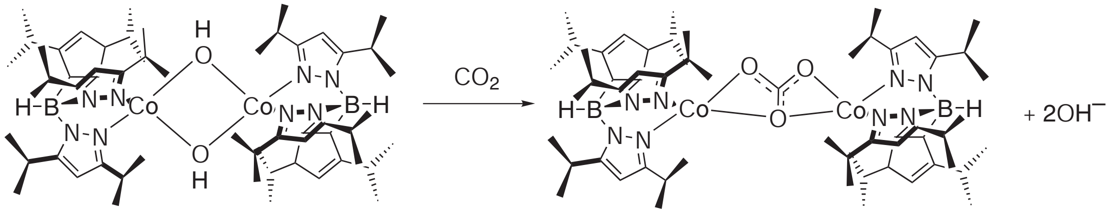
(g) Oligonuclear and polymeric. The Co–Co linked dimer $[Co_2(CN)_{10}]^{6-}$, which is readily prepared in liquid ammonia as solvent, reacts with water to yield a number of products identified by ^{59}Co NMR, including $[HCo(CN)_5]^{3-}$.[191] Monomeric species such as $Li_3[Co(CN)_5]\cdot 3DMF$ can form and may be isolated from aprotic solvents. Cyanide features as a bridging ligand as well as a terminal monodentate in polymetallic species. A recent example of a mixed-metal Co^{II}/Mn^{II} dimer arises from reaction of trans-Mn(CN)(CO)(dppm)$_2$ (dppm = bis(diphenylphosphino)methane) with $CoCl_2$ in THF, which leads to the μ-cyano complex $Cl_2(THF)Co^{II}(\mu\text{-}NC)Mn^{II}(CO)(dppm)_2$, defined by a crystal structure which shows the Co^{II} center is pseudo-tetrahedral.[192]

(ii) Carbonyls

Cobalt(II) carbonyls are rarely met, except as transient redox products from stable lower-valent precursors.

(iii) Carbon dioxide

Carbon dioxide is activated by metal complexes, including Co$^{\mathrm{II}}$, to undergo a range of reactions: oxidative coupling with unsaturated substrates; insertion into M—X bonds; and insertion into M—M′ bonds. The Co(dmg)$_2$(H$_2$O)$_2$ complex reacts with CO$_2$ to form Co(dmg)$_2$(H$_2$O)(CO$_2$H) bearing a Co—C bond.[193] Insertion of CO$_2$ into the core of the substituted Tp di(μ-hydroxo)dicobalt(II) complex (**24**) leads to the bridged carbonato complex (**25**).[194] Electrochemical reduction of CO$_2$ is activated by Co$^{\mathrm{II}}$(cyclam) and analogs, promoting the two-electron reduction in aqueous acid to form CO and H$_2$O.[195] Coordination of CO$_2$ to the reduced complex as intermediate is implicated.



(**24**) (**25**)

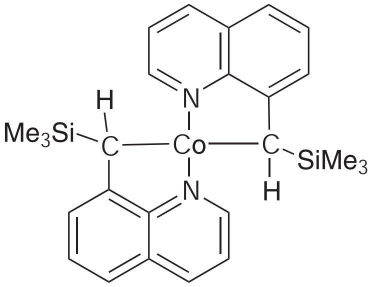
(iv) Alkyls and aryls

No attempt to cover the coordination chemistry of unsaturated cyclic anions such as cyclopentadienyl is made here, due to their coverage in the companion series on *Comprehensive Organometallic Chemistry*. The only example to be mentioned here, because it is the first example of a high-spin Co$^{\mathrm{II}}$ organometallic complex, is Co(Cp)(Tp).[196]

Simple alkyl and aryl σ-bonded complexes are conveniently prepared by reaction of an alkylating reagent with a halocobalt(II) precursor. All-alkyl systems are rare, but the pentamethylcobaltate(II) anion is known.[197] More typically, the coordination sphere of the metal contains additional co-ligands, particularly with P, S, or N donors. Some examples that reflect the style of reactions extant appear below.

Reaction of Li(2-((Me$_3$Si)$_2$C)pyridine) with CoCl$_2$ in ether yields the thermally stable bis cobalt(II) dialkyl complex, which is planar with *trans*-disposed C,N-chelates.[198] The strained four-membered rings are reflected in a C—Co—N angle of 69.6(2)°, while Co—C and Co—N distances are 2.094(6) Å and 1.919(4) Å respectively. Earlier, related chemistry produced the tetrahedral ion with only Co—C bonds, [Co(CH(SiMe$_3$)$_2$)$_4$]$^{2-}$, and an ion [CoCl(CH(SiMe$_3$)$_2$)$_2$]$^{-}$, , with two Co—C bonds and a rare trigonal planar geometry.[199]

Examples with S- and P-donor companion ligands abound. The thioether-containing complex Ph(ttb)CoCl (ttb = tris((*tert*-butylthio)methyl)borate) can be reacted with either Me$_2$Mg or MeLi in THF to yield the alkylcobalt(II) compound Ph(ttb)CoMe in high yield.[200] The high-spin divalent tetrahedral complexes Co(pnp)X (pnp = $^{-}$N(SiMe$_2$CH$_2$PPh$_2$)$_2$; X = Cl, Br) are conveniently prepared from CoX$_2$ and Li(pnp),[201] and subsequently react with alkylating reagents to form low-spin square–planar Co(pnp)R (R = alkyl) compounds. Treatment of CoCl$_2$ with organolithium precursor compounds yields low-spin Co$^{\mathrm{II}}$ dialkyls which include (**26**).[202]



(**26**)

Bis(aryl)cobalt(II) compounds have been prepared by reaction of R′MgX (where $R' = C_6H_{6-n}Cl_n$; $n = 2$–4) with $Co(PR_3)_2Cl_2$.[203] They undergo both thermally and oxidatively induced decomposition, with the corresponding biphenyl a product. The reactions of alkyl-cobalt complexes have been reviewed recently, and include thermolysis, photolysis, oxidation, and reduction reactions.[25] Homolysis of the Co—C bond is a feature of reactions.

6.1.2.2.2 Nitrogen

All known types of N-donor ligands are found in complexes with divalent Co, so our treatment of this topic will be selective in an endeavor to provide an overview of this vast area. There is a crossover in stability of divalent Co complexes going from hard amine donors (almost all being oxygen sensitive) to the highly unsaturated polyimines, which are rather difficult to oxidize. Divalent Co forms a variety of N-donor complexes of all electronic ground states (high and low spin) depending on the ligand field strength and symmetry.

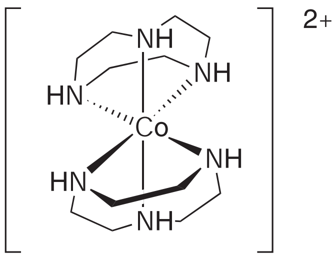
(i) Amines

(h) Monodentate. The simplest classical amine complex is the hexaammine. The $[Co(NH_3)_6]^{3+/2+}$ redox potential is −0.04 V (vs NHE) making the $[Co(NH_3)_6]^{2+}$ ion air sensitive as well as substitution labile. Nevertheless, the divalent hexaammine complex has been thoroughly characterized. The X-ray crystal structure of $[Co(NH_3)_6]Cl_2$ has been reported at both 294 K and 128 K, revealing six crystallographically identical Co—N bonds of 2.170(2) Å in the room-temperature structure and no phase change at lower temperature.[204] By contrast, differential scanning calorimetric study of $[Co(NH_3)_6](ClO_4)_2$ and $[Co(NH_3)_6](BF_4)_2$ found that these complexes were polymorphic between 100 K and 300 K.[205] In solution, the changes in Co—N bond length upon reduction from Co^{III} to Co^{II} have been studied with EXAFS. The bond length changes report on the inner sphere reorganizational energy of the complex, and this allowed the calculation of outer sphere electron transfer cross reaction rates using semi-classical theory that were in excellent agreement with experiment.[206]

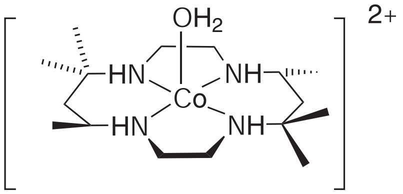
(i) Multidentate. The ethane-1,2-diamine (en) complex of Co^{II} represents this category of ligands well. Crystal structures of the air-sensitive $[Co(en)_3]^{2+}$ with simple anions have been known for some time. A hydrothermal reaction of $CoBr_2$ with Na_3SbS_3 and en led to the isolation of $[Co(en)_3]CoSb_4S_8$ comprising $[Co(en)_3]^{2+}$ cations and infinite $[CoSb_4S_8]^{2-}$ layers which form a novel open framework structure.[207] Low-dimensional structures of the type $[Co(en)_3]Sb_2S_4$ and $[Co(en)_3]Sb_4S_7$ have also been reported.[208]

Although somewhat more stable than its hexaammine relative, the air-sensitive $[Co(en)_3]^{2+}$ is still substitutionally labile and racemizes rapidly in solution. Chiral discrimination in its (racemic) solutions has been observed in outer sphere electron transfer reactions with optically active oxidants including $[Co^{III}(EDTA)]^-$,[209,210] $[Cr(ox)_3]^{3-}$,[211,212] Co^{III} oxalate, malonate, and acetylacetonate (acac) complexes.[213]

(j) Macrocyclic. Like most divalent amines of Co, the bis macrocyclic $[Co(tacn)_2]^{2+}$ (tacn = 1,4,7-triazacyclononane) complex (**27**) is a high-spin, air-sensitive complex. Its crystal structure and spectroscopy have been reported.[214] When fewer than six N-donors are present, divalent Co complexes become more stable. Electrochemical oxidation of the putative five-coordinate complex (**28**) $[(H_2O)Co(teta)]^{2+}$ (teta = *meso*-5,5,7,12,12,14-hexamethyl-1,4,8,11-



(**27**)

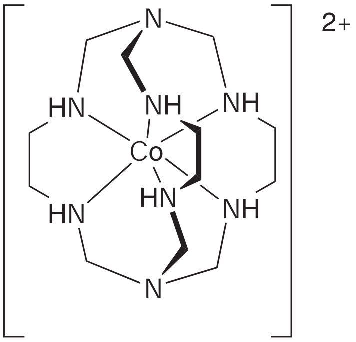


(**28**)

tetraazacyclotetradecane) has been studied, and the effect of ligands *trans* to the aqua ligand upon oxidation of the complex was examined.[215] The *trans*-Co(teta) $(OSO_2CF_3)_2$ complex has been structurally characterized, providing a rare example of triflate coordinated to divalent Co.[216]

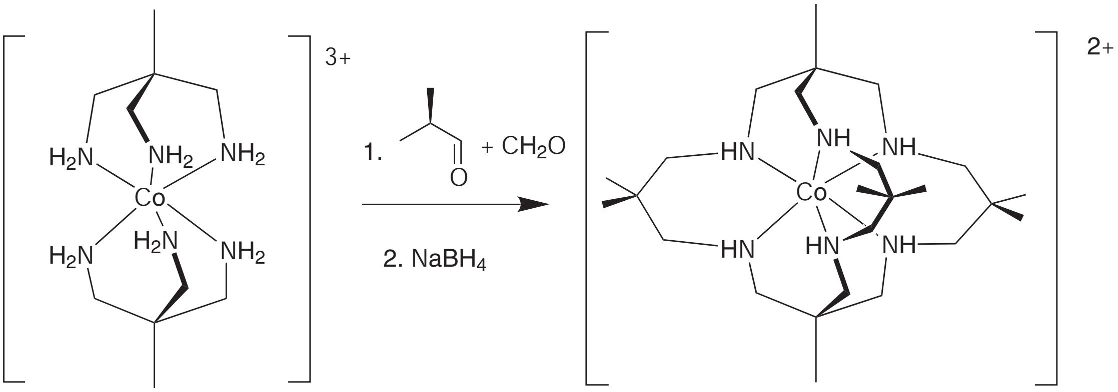
In methanolic MeCN, the resulting photoreduced Co^{II} complex of the unsubstituted (cyclam) analog of (**28**) mediates electron transfer in the reduction of CO_2 to CO and formate with *p*-terphenyl as the photocatalyst and tertiary amines as sacrificial electron donors.[217] Similarly, photoreduction of CO_2 to formate can be achieved by the same complex using phenazine as the photosensitizer, the Co complex as electron mediator, and Et_3N as an electron donor.[122] The multi-step photoreduction of O_2 to H_2O_2 is achieved with $[Co(cyclam)(OH_2)_2]^{2+}$ (and various C-methylated analogs) generated *in situ* by oxidative quenching of photoexcited $[Ru(bpy)_3]^{2+}$.[218]

The remarkable physical properties exhibited by the divalent macrobicyclic cage complex $[Co(sep)]^{2+}$ (**29**) are unparalleled in Co chemistry.[219] The complex, characterized structurally, is inert to ligand substitution in its optically pure form and resists racemization in stark contrast to its $[Co(en)_3]^{2+}$ parent. The encapsulating nature of the sep ligand ensures outer sphere electron transfer in all redox reactions. For example, unlike most divalent Co amines, the aerial oxidation of (**29**) does not involve a peroxo-bound intermediate.



(**29**)

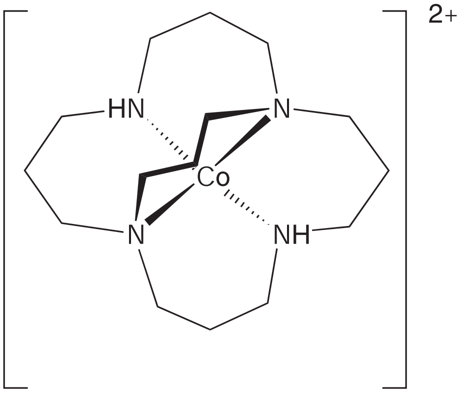
Larger cavity cages have been reported by reaction of $[Co(tame)_2]^{3+}$ (**30**) (tame = 1,1,1-tris (aminomethyl)ethane) with paraformaldehyde and isobutyraldehyde leading to the expanded octamethylated cage (**31**), with distinctly different properties to any other hexaamine.[220] Foremost, the $Co^{III/II}$ redox potential of (**31**) is more than 1 V positive of the couple found in the smaller cavity cage (**29**). In fact, (**31**) is resistant to oxidation by O_2 and H_2O_2; a unique feature in Co hexaamine chemistry. N-Based diastereomers were crystallized and characterized structurally. Controlled potential electrolysis of these isomers led to the observation of two distinctly different Co^{III} complexes; one yellow and the other a most unusual blue in color.



(**30**) (**31**)

Smaller macrobicycles and macrotricycles bearing less that six N-donors are also known. These ligands comprise tertiary or secondary amines and are derived from insertion of one or more straps between pairs of potentially bridgehead N-donors contained within a small ring macrocycle, and in this sense they may be considered analogs of the well-known azacryptands. The inability to offer six N-donors, and the presence of tertiary amines in these ligands leads to the preference for divalent over trivalent Co.

The small bowl-shaped tetraamine 3^5-adamanzane (1,5,9,13-tetraazabicyclo[7.7.3]nonadecane) comprises the 16-membered macrocyclic tetraamine ([16]aneN_4) with one pair of diagonally opposite N atoms linked by a trimethylene bridge. The crystal structure of its Co^{II} complex (**32**) reveals a distorted tetrahedral CoN_4 array, with the metal ion slightly too large to be bound symmetrically within the confines of the small cavity (Figure 3).[221] Solution behavior is more complicated. The tetrahedral complex exhibits limited stability in aqueous solution, although its electronic spectrum is essentially the same as its pseudotetrahedral [16]aneN_4 parent, with five- and six-coordinate Co^{II} complexes being formed in the presence of coordinating anions (Cl^-) and solvents. Kinetic analysis showed that Cl^- ions accelerate extrusion of the Co^{2+} ion from the small cage.



(**32**)

(ii) Pyridine and oligopyridines

(k) Monodentate. Pyridine complexes of Co^{II} may take several forms depending on the method of preparation. Blue tetrahedral $[Co(py)_4]^{2+}$ is well known in addition to the polymeric halide-bridged six-coordinate $\{Co(py)_2X_2\}_n$ species in the solid state. Investigations of the solution equilibria between these four- and six-coordinate species are well documented. The tetrahedral $[Co(py)_4]^{2+}$ ion has been shown to catalyze the aromatization of 1,4-dihydropyridine[222] and also

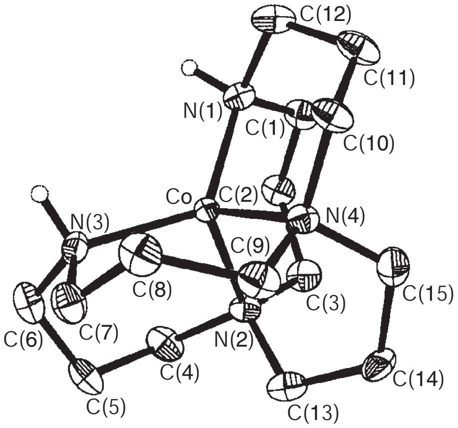


Figure 3 View of complex (**32**) with alkyl H-atoms omitted (reproduced with permission of the American Chemical Society from *Inorg. Chem.*, **2001**, *40*, 2323–2334).

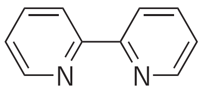
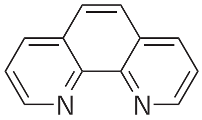
1,3-dipolar cycloadditions.[223] More recently, the crystal structure of a novel square planar form $[Co(py)_4]Cl(PF_6)$ has been reported.[224] The formation and low-energy collision-induced dissociation of $[Co(py)_6]^{2+}$ and derivative complexes has been investigated by electrospray ionization mass spectrometry.[225]

Halopyridinecobalt(II) complexes have been explored in detail, and exhibit either distorted octahedral or tetrahedral geometries, depending on ligands involved. The preparation and characterization of dihalotetrakis(3,5-dimethylpyridine)cobalt(II) complexes with chloro, bromo and iodo ligands have been reported.[226] The crystal structure of the elongated octahedral chloro complex defines the chloride ions in a *trans* disposition with Co—Cl distance of 2.455(2) Å, with Co—Br and Co—I being 2.63 Å and 2.88 Å respectively. The difluoro analog has also been characterized separately, with an equivalent structure and Co—F distance of 2.016(3) Å.[227] IR spectroscopy shows clear differences between the coordinated chloride complex and a pyridinium tetrachlorocobaltate(II) species. In a related study, halocobalt(II) complexes of 2-, 3- and 4-methylpyridine have been examined,[228,229] and molecular mechanics studies supplemented crystal structural studies. A correlation between solid-state structure and thermal properties was defined. In the dibromobis(2-bromopyridine) cobalt(II) complex,[230] a slightly distorted tetrahedral geometry was defined by a crystal structure analysis. A series of four- or six-coordinate 2-, 3- and 4-methylpyridine compounds of formula CoL_2X_2 or CoL_4X_2 ($X = Br$, I) have been prepared and their thermal stability examined.[231] Dibromobis(2,4-dimethylpyridine)cobalt(II) and bromotetrakis(2,4-dimethylpyridine)cobalt(II) have been prepared and characterized by X-ray crystal structures.[232] The former exhibits tetrahedral geometry and the latter the more rarely observed five-coordinate square pyramidal geometry. Thermal decomposition occurs with release of pyridines from the former in one step at 335 °C, whereas three successive steps releasing one (at 130 °C), one (at 193 °C), and two (at 360 °C) pyridines are observed for the latter. Thermal decomposition of a large series of $Co(Rpy)_2X_2$ (Rpy = substituted pyridine, $X = Cl$, Br) has been probed by thermogravimetric analysis,[233] with pyridine loss a primary process prior to halide loss. The temperature and pressure effects on the equilibrium between octahedral $Co(Mepy)_4X_2$ and tetrahedral $Co(Mepy)_2X_2$ (Mepy = 3-methylpyridine; $X = Cl$, Br) has been probed.[234] Higher pressure favors the octahedral species, whereas higher temperature favors the tetrahedral species.

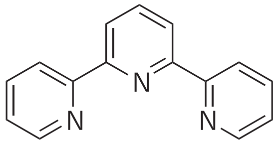
(l) Multidentate. Complexes of the bidentate bpy (**33**) and phen (**34**) ligands share many common features. The $[Co(bpy)_3]^{2+}$ and $[Co(phen)_3]^{2+}$ ions typically possess high-spin ($S = 2$) electronic ground states, but they are close to the high/low-spin crossover, in contrast to their (exclusively) high-spin hexaamine relatives. The crystal structures of $[Co(phen)_3]^{2+}$ with a number of simple and more complex anions have been reported, including perchlorate[235], antimony tartrate,[236] benzene-1,2-dioxyacetate[237] and octa- and nonanedioate.[237] The latter two dicarboxylate salts inhibit the growth of *Candida albicans*.



(**33**)



(**34**)



(**35**)

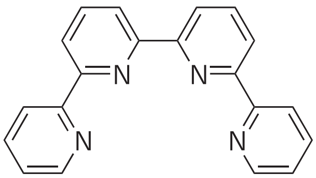
An interesting study of the $[Co(bpy)_3][MCr(ox)_3]$ system (ox = oxalato dianion) found that when $M = Na^+$ the Co^{II} complex is high spin, but when $M = Li^+$, the compound assumes a low-spin electronic ground state due to contraction of the counter ion network surrounding the bpy complex.[238] Optical spectroscopy and magnetic susceptibility studies reveal that $[Co(bpy)_3][LiCr(ox)_3]$ exhibits temperature-dependent spin-crossover behavior. A related system, $[Co(bpy)_3][MCr(ox)_3](ClO_4)$, where M is a divalent transition metal ion, has been investigated. The separate cationic and anionic tris-chelate complexes within this network are necessarily homochiral.[239]

Encapsulation of $[Co(bpy)_3]^{2+}$ within zeolite frameworks has also been shown to have a remarkable influence on the electronic spin state of the complex.[240] Distortions imparted on the tris-chelate complex by the confines of the zeolite "supercage" are found to be responsible for stabilizing the unusual low-spin electronic ground state.[241,242] The $[Co(bpy)_3]^{3+/2+}$ couple has been measured for the encapsulated complex and it has been found that the complexes remain within the zeolite and do not exchange with the bulk solution.[243] Electrochemistry of $[Co(bpy)_3]^{3+/2+}$ immobilized within a sol–gel has also been studied.[244]

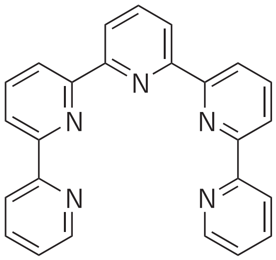
The structural and magnetic properties of divalent Co complexes of the tridentate terpy (**35**) are distinctly different. The high-spin/low-spin equilibrium of $[Co(terpy)_2]^{2+}$ has attracted considerable attention and a marked anion dependence has been identified. In the solid state, $[Co(terpy)_2]I_2$ exhibits a temperature-dependent magnetic moment coupled with temperature-dependent Co—N bond lengths.[245] At 295 K, the intermediate magnetic moment (μ_{eff} 3.2 B.M.) and Co—$N_{central,distal}$ bond lengths (1.942(7) Å and 2.104(5) Å) are consistent with a high/low-spin equilibrium in the solid state. On cooling to 120 K, the bond lengths (1.912(5), 2.083(4) Å) and magnetic moment (μ_{eff} 2.2 B.M.) reflect an exclusively low-spin electronic ground state. By contrast, $[Co(terpy)_2](ClO_4)_2$ exhibits a much higher room-temperature solid state magnetic moment (4.2 B.M.) and longer Co—$N_{central,distal}$ bond lengths (2.03 Å and 2.14 Å).[246] In the nitrate salt the Co—N bond lengths are longer again.[247] Solid state optical and EPR spectroscopy have also been used to study the temperature and anion dependence of this spin equilibrium.[248] The structurally imposed Co—$N_{central}$ bond compression of the terpy ligand directs the Jahn–Teller enforced tetragonal elongation along one of the N_{distal}–Co–N_{distal} axes of the complex to remove the orbital degeneracy of the ^2E (O_h) electronic ground state.

In solution, $[Co(terpy)_2]^{2+}$ is also in a high-spin/low-spin equilibrium. Ultrasonic absorption measurements determined the spin equilibrium relaxation time in both water and MeOH solution to be less than 2 ns.[249] Electron-donating functional groups such as methoxyl appended to the terpy ring result in a shift towards the high-spin form of the complex,[250] as does replacement of one pyridyl ring with a pyrazole.[251]

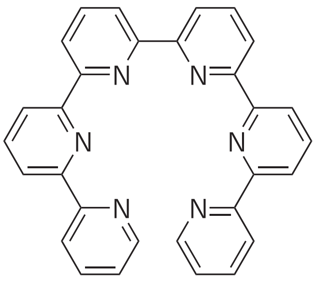
Further extension of the terpy structure generates a novel class of oligopyridines that typically behave quite differently from the mono-, bi-, and terpyridyl analogs. Steric repulsion between the two distal pyridyl rings disfavors planarity of oligopyridines larger than terpy, and enforces a helical conformation. Mononuclear and dinuclear Co^{II} complexes of quaterpyridine (**36**), and its substituted derivatives,[252,253] and quinquepyridine[222,254] (**37**) have been reported where the distinctly non-planar helically disposed ligand occupies the equatorial coordination sites of the six- or seven-coordinate ion. In solution the Co^{II} 4′,4‴-di-(*p*-chlorophenyl)quinquepyridine complex is typically mononuclear but can be crystallized as either a 1:1 (Figure 4) or 2:2 (helical) complex.[255,256] Double helical, homometallic, oligonuclear complexes of Co^{II} predominate when at least six donor atoms can be provided by the ligand i.e., sexipyridine (**38**) and higher oligomers. In these cases, pairs of tridentate (terpy-like) chelates are forced to bind separate Co^{II} centers. The introduction of a second bridging bis-tridentate oligopyridine completes the six-coordinate geometry of the two Co^{II} centers. For example, (**38**) forms a double helical 2:2 ($[Co_2L_2]^{4+}$) complex with each ligand binding in a bridging bis-tridentate manner.[257] A substituted derivative of septipyridine forms a double helical 2:2 complex comprising two $[Co(terpy)_2]^{2+}$ moieties with each strand containing a single non-coordinated pyridyl ring; one central and the other terminal (Figure 4).[258] The nonadentate novipyridine forms a trinuclear double helicate $[Co_3L_2](PF_6)_6$ as shown by mass spectrometry and elemental analysis.[259]



(**36**)



(**37**)



(**38**)

The linear bis-bidentate ligand bis(pyridylpyrazolyl)borate (**39**) ligand reacts with $Co(OAc)_2$ in MeOH to yield a discrete cyclic nanostructure $[Co_8L_{12}(PF_6)]^{3+}$.[260] This complex was characterized intact by ESMS, with the anion apparently trapped in the central cavity, a concept supported by the crystal structure of the perchlorate analog (Figure 5). Other oligopyridine ligands complexed with divalent Co include the tripodal tris(2-pyridylmethyl) amine (**40**),[261] and the novel dinucleating bis(2-pyridylmethyl)amine dimer (**41**).[262]

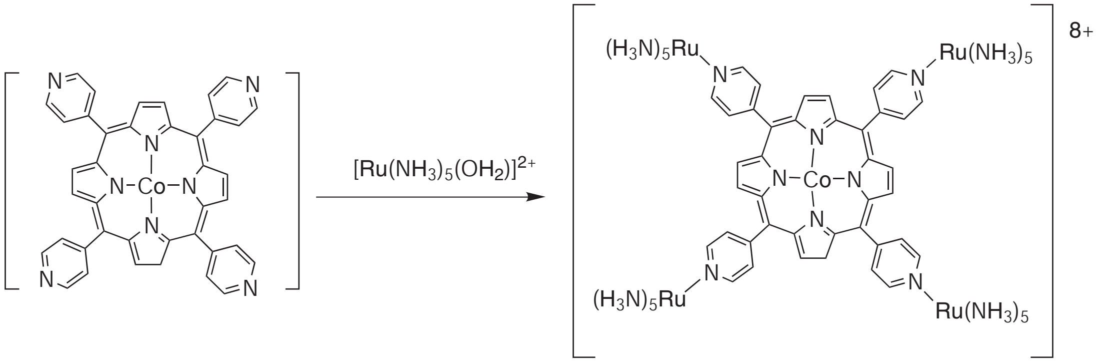
(41)

(iii) Porphyrins

Cobalt complexes of these compounds and their properties have been widely studied for some time. Substituted porphyrin complexes of divalent Co catalyze a wide variety of useful inorganic and organic transformations. The catalytic four-electron reduction of dioxygen to water in aqueous solution close to its thermodynamic potential is of great importance to fuel cell and battery technology. However, the two-electron reduction of O_2 to H_2O_2 is a more common and much less useful side reaction. Anson, Collman, and co-workers have published a series of papers using bridged dicobalt "face-to-face" porphyrins, some of which are efficient catalysts of the four-electron reduction of O_2 to H_2O.[263,264] Participation of both Co ions in O_2 binding (in a sandwich configuration) and in inner sphere electron transfer was implicated. Later, a superoxo-bridged dicobalt co-facial porphyrin complex, an intermediate in the four-electron reduction, was isolated and characterized.[265]

Anson and co-workers have shown that two Co ions were not necessary for four-electron O_2 reduction.[266] The *meso*-substituted complex porphyrin Co(TPyP) (**42**) complex bears four active pyridyl donors which readily react with four equivalents of $[Ru(NH_3)_5(OH_2)]^{2+}$ to produce the tetra-ruthenated derivative. The four Ru centers are sufficiently remote that their $Ru^{III/II}$ potentials coincide. Under steady state conditions $[Co(TPyP)]\{Ru(NH_3)_5\}_4]^{8+}$ (**43**) adsorbed onto a pyrolytic graphite working electrode catalyzes the reduction of dioxygen (Figure 6).



(42) **(43)**

Of the total current passed, 72% results in complete reduction to H_2O, while the remainder generates H_2O_2.[267] Catalytic activity was somewhat lower when the complex was confined to a Nafion polyelectrolyte film coated on a graphite electrode.[268] The roles of the Ru and Co centers in catalysis were elucidated by varying the number of Ru centers and their ancillary ligands. A tri-(pentaammine)ruthenated analog was also an efficient four-electron catalyst,[269] although the di-, mono-, and non-ruthenated analogs could only act as two-electron reductants. It was established[268] that (**43**) is a (homogeneous) two-electron O_2 reduction catalyst in solution, illustrating the importance of a rapid supply of electrons to the complex (adsorbed to an electrode surface) to ensure complete reduction before dissociation of the intermediate peroxo-bound form. This foreshadowed the fact that the four-electron reduction did not involve redox cycling of the four peripheral Ru centers in parallel. Subsequently it was established that Ru^{II}–pyridine π-back bonding (ultimately into the $Co^{II}-O_2$ reaction center) was the key factor in determining two- or four-electron reduction at the Co center of the porphyrin. Attachment of $\{Os(NH_3)_5\}^{3+}$ groups to the pyridyl rings (in a η^2 fashion, not involving the N-donor) instead of $\{Ru(NH_3)_5\}^{3+}$ led to

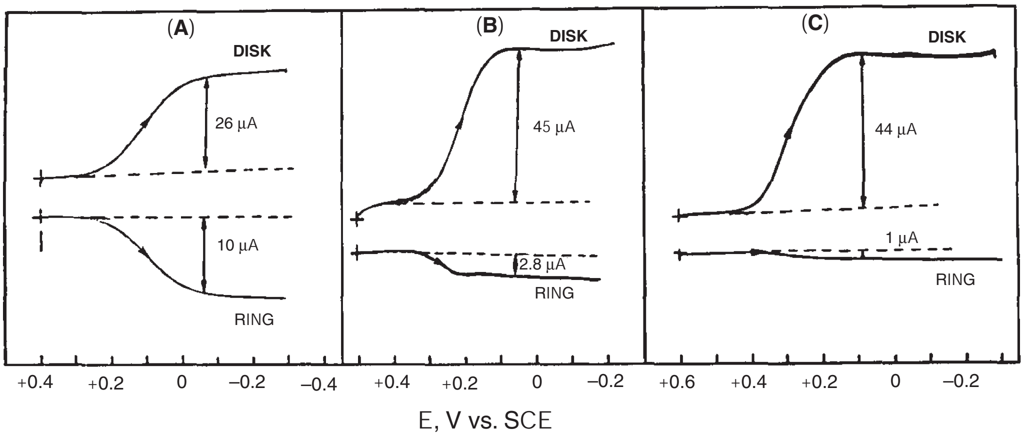


Figure 6 Steady state rotating ring-disk voltammograms of (A) compound (**42**); (B) compound (**43**) and (C) a Ru-bridged polymer of (**43**) each adsorbed to a graphite working electrode. Disk current shows reduction of O_2 while ring current reveals the presence of H_2O_2 simultaneously reoxidised at the ring anode poised at +1.0 V (reproduced with permission of the American Chemical Society from *Acc. Chem. Res.*, **1997**, *30*, 437–444).

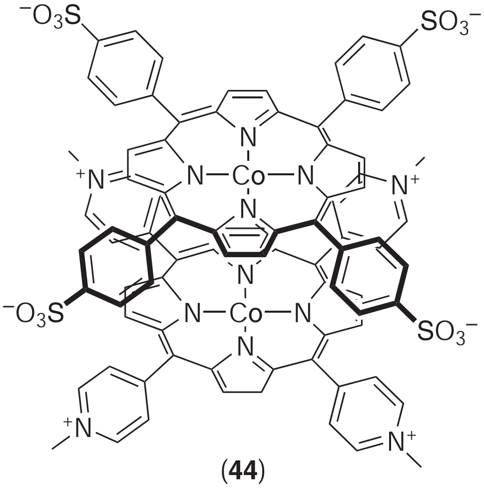
significant (30%) four-electron O_2 reduction at a potential more positive than the $Os^{III/II}$ couple, thus ruling out participation of the peripheral subunits in electron transfer.[268]

More recently, even simpler non-covalently linked porphyrin dimers, self-assembling through hydrophobic[268] or electrostatic[270] interactions have been shown to achieve the four-electron reduction of O_2 to H_2O. The Co^{II} complex of the parent porphine ligand and its tetra-methyl derivative Co(TMP) aggregate in aqueous solutions, and in the absence of bulky *meso*-substituents, can form cofacial dimers in solution and on electrode surfaces reminiscent of the covalently linked analogs.[271] The porphyrin ion pair (**44**) comprising $[Co(TMpyP)]^{4+}$ (Mpy = 4-methylpyridinium) and $[Co(TSpP)]^{4-}$ (Sp = 4-sulfonatophenyl) similarly spontaneously dimerizes to form an active four-electron O_2 reduction catalyst.[270] The inter-planar separation (~3.1 Å) is close to that required for O_2 insertion between the Co centers of the cofacial assembly.



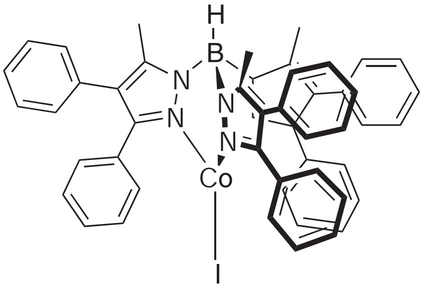
(**44**)

These studies have led to the development of other Co porphyrins with potential applications in a variety of areas with the common theme of catalyzing the efficient reduction of O_2. These systems are explored in Section 6.1.4.

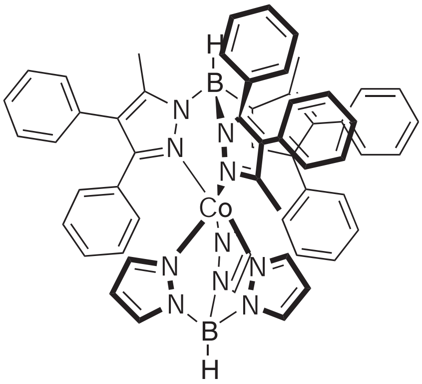
(iv) Imidazole, pyrazole, and related ligands

The fact that imidazole (Him) residues are particularly popular transition metal binding sites within metalloproteins is a major driving force for investigations of this heterocycle. The divalent oxidation state is preferred for the hexakisimidazolecobalt ion, and a number of complexes of this class have been characterized structurally including $[Co(Him)_6]^{2+}$,[272,273] $[Co(Meim)_6]^{2+}$,[274] and $[Co(vinyl\text{-}im)_6]^{2+}$.[275] The structures of simple tetrahedral complexes $Co(Him)_2(OAc)_2$ and its propionate analog were determined, and were found to be very similar to their Zn^{II} analogs. The implications of these results are relevant to Co^{II}-substituted Zn proteinases. Ternary complexes such as $[Co(ATP)(Him)]^{2-}$ were studied by potentiometric pH titration as a simple model for competition between ligating groups of biological relevance. The Him ligand was found to form more stable adducts than NH_3 at physiological pH, as proton competition for Him was negligible at pH 7.4, unlike NH_3.[276] Some examples of multidentate imidazole-containing ligands that have been complexed with Co^{II} include histamine (4-(2′-aminoethyl)imidazole) and its glycyl and sarcosyl derivatives, which, when reacted with Co^{II} in aerated aqueous solution, form mixtures of O_2 adducts that were studied by potentiometry, NMR, and spectrophotometry.[277]

Monomeric, pseudo-tetrahedral complexes of the type $Co(Tp')L$ and dinuclear centrosymmetric five-coordinate complexes of the form $Tp'Co(L)_2CoTp'$ (Tp' = 3-*i*Pr,4-BrTp; 3-*t*Bu,5-MeTp; L = NCS^-, NCO^-, and $N_3{}^-$) have been synthesized.[278] The ligand-field spectral data for the monomeric complexes indicate a strong, trigonally distorted tetrahedral ligand field. In an elegant study, the tris-trisubstituted 3,4-Ph_2,5-MeTp reacts with CoI_2 to form the pseudotetrahedral (3,4-Ph_2,5-MeTp)CoI (**45**). Steric effects from the 4-Ph group on the 3-Ph group prevent the formation of bis (octahedral) complexes, whereas the isomeric ligand (3,4-Ph_2-5-Mepz)(3-Me-4,5-Ph_2pz)$_2$B does form an octahedral complex (**46**), with (unsubstituted) Tp as the ancillary tridentate ligand.[279]

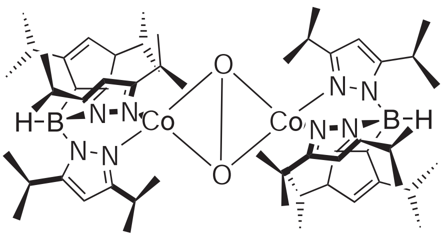


(**45**)

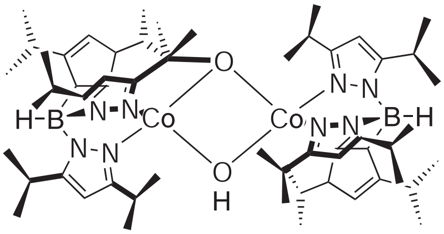


(**46**)

Compounds of the $[Co(3\text{-}t\text{Bu},5\text{-MeTp})X]^{n+}$ family have been found to exhibit a number of remarkable properties in the coordination and stabilization of small molecules and ions in the labile fourth coordination site.[280] The iodo derivative (3-*t*Bu,5-MeTp)CoI has been prepared and its X-ray crystal structure reported.[281] Reduction of (3-*t*Bu,5-MeTp)CoX (X = Cl, I) under N_2 generates the monovalent N_2 complex (**4b**) which upon reaction with O_2 yields the novel divalent side-on bound superoxo complex (3-*t*Bu,5-MeTp)Co(O_2) which was structurally and spectroscopically characterized ($r_{\text{O-O}}$=1.262(8) Å, ($\nu_{\text{O-O}}$=961 cm^{-1}).[129] This complex is stable in the solid state, but decomposes in solution to give $[(3\text{-}t\text{Bu},5\text{-MeTp})Co]_2(\mu\text{-OH})_2$.[282] The dioxygen-bridged dimer $[(3\text{-}t\text{Bu},5\text{-MeTp})Co]_2(\mu\text{-}O_2)$ is an intermediate and can be prepared independently by reaction of $[(3\text{-}t\text{Bu},5\text{-MeTp})Co]_2(\mu\text{-}N_2)$ with oxygen[282] or from reaction of the monovalent carbonyl (**4a**) with oxygen.[283] This later study showed that, at low temperature, the dimer is in equilibrium with its monomer. The crystal structure of $[(3\text{-}t\text{Bu},5\text{-MeTp})Co](\mu\text{-}O_2)$ was also determined. An independent study found that reaction of the 3,5-diisoproyl dihydroxo-bridged dimer (**24**) with a stoichiometric amount of H_2O_2 generates the unusual planar, side-on bound peroxo-bridged dinuclear complex $[(3,5\text{-}i\text{Pr}_2\text{Tp})Co]_2(\mu\text{–}\eta^2\text{:}\eta^2\text{-}O_2)$ (**47**) on the basis of two intense absorptions attributable to $O_2{}^{2-} \rightarrow Co^{II}$ LMCT transitions in the UV-visible spectrum and a low energy $\bar{\nu}_{\text{O-O}}$ vibration in the resonance Raman spectrum.[284] This group had previously identified a similar $\mu\text{–}\eta^2\text{:}\eta^2$ binding mode in a peroxo-bridged dicopper(II) oxyhemocyanin model complex. Compound (**47**) is highly reactive and decomposes by hydroxylation of one of its isopropyl groups (at the secondary C atom) to give a novel μ-alkoxo-μ-hydroxo dinuclear compound $Co_2(\mu\text{-OH})(\mu\text{-3-OCMe}_2\text{-5}i\text{Prpz})(3,5\text{-}i\text{Pr}_2\text{pz})_2\text{BH})(3,5\text{-}i\text{Pr}_2\text{Tp})$ (**48**) where the deprotonated hydroxyl group and a hydroxo ligand bridge the two Co ions.

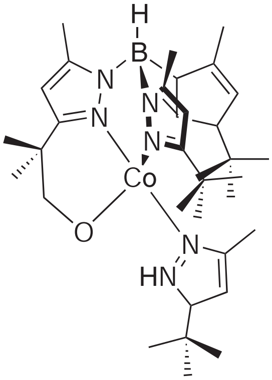


(**47**)



(**48**)

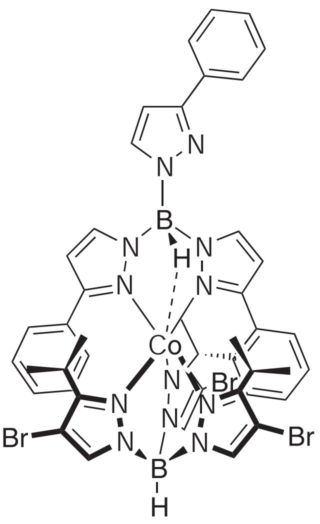
Somewhat similar observations were made separately in a study of the heterogeneous reaction between solid (3-*t*Bu,5-MeTp)CoH (**4c**) and O_2 which led to hydroxylation of one *t*-butyl group and coordination of the resulting deprotonated hydroxymethyl group.[285] The complex was crystallized as the mononuclear (((3-(OCH_2)Me_2C)pz)(3,5-*t*Bu_2pz)$_2$BH)Co(3-*t*Bu,5-MepzH) adduct (**49**) which exhibited a trigonal bipyramidal CoN_4O coordination geometry. In solution, the reaction with O_2 proceeds via a spectroscopically observable hydroperoxide (HOO^-) which decomposes to give (3-*t*Bu,5-MeTp)Co(OH) and (3-*t*Bu,5-MeTp)Co(O_2).



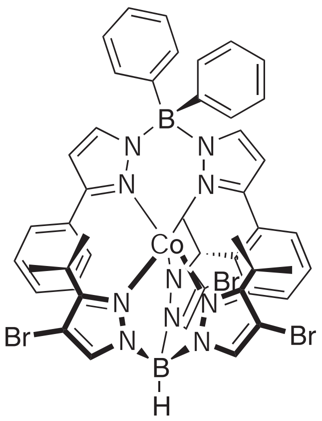
(**49**)

A number of other homo-substituted (threefold-symmetric) Tp derivatives have been complexed with Co^{II}. The 15-electron four-coordinate alkyl complex (3,5-*i*Pr_2Tp)Co(CH_2CH_3) was prepared and structurally characterized. Despite bearing a ligand with β H-atoms, the complex is resistant to β-hydride elimination.[286] The same group subsequently reported an extended series of these compounds including (3,5-*i*Pr_2Tp)CoR where $R = \eta^3$-allyl, η^1-*p*-methylbenzyl and η^1-1-α-naphthylmethyl.[287] Independently, the paramagnetic analogs (3-*t*Bu,5-MeTp)CoR (R = Me, Et, *n*-Bu) were prepared, and the related (3-*t*BuTp)Co(Me) complex was structurally characterized.[113] Like the di-isopropyl analog, these alkyls are thermally stable and show no tendency to β-eliminate. When the alkyl complexes are reacted with CO, homolytic cleavage of the Co—C bond is found instead of migratory insertion. The crystal structure of the fluorinated Tp complex (3-CF_3,5-MeTp)Co(η^2-NO_3)(MeCN) reveals a distorted octahedral N_4O_2 coordination sphere.[288] This complex catalyzes the oxidation of cyclohexane by cumene hydroperoxide to give a 1:1 mixture of cyclohexanol and cyclohexanone at a rate 50% faster than the nonfluorinated complex.

Octahedral bis-Tp complexes bearing different substituents on the separate Tp ligands have been prepared by sequential ligand substitution. The tetrahedral Co(3-*i*Pr,4-BrTp)Cl reacts with Tp or 3-*i*Pr,4-BrTp to form the corresponding hetero-bis-Tp complex Co(3-*i*Pr,4-BrTp)(Tp) and the symmetrical Co(Tp)$_2$.[109] However, reaction with the bulkier 3-PhTp leads to the coordination of only two pyrazolyl groups in (**50**) featuring an agostic B—H—Co interaction, as shown by X-ray crystallography. A similar agostic B—H—Co interaction was identified in the bis-pyazolyl-dihydroborate analog Co(3-*i*Pr,4-BrTp)((3-Phpz)$_2$$BH_2$). Substitution of both hydrides by phenyl groups leads to Co(3-*i*Pr,4-BrTp)((3-Phpz)$_2$$BPh_2$) (**51**) which is strictly five-coordinate. By comparison, the Co(3-*i*Pr,4-BrTp)((3-Ph-pz)$_4$B) adduct is tetrahedral.



(50)



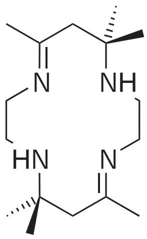
(51)

The synthesis of heterosubstituted Tp ligands (lacking a C_3 symmetry axis) has enabled a systematic investigation of substituent effects on both structure and reactivity of their Co complexes. The homo- (3-PhTp) and hetero- ((3-Phpz)$_2$(3-*t*Bupz)BH) trisubstituted ligands were complexed to Co^{II}. Four- or five-coordinate complexes ensued, depending on the steric demands of the substituents.[289] The {(3-PhTp)Co} moiety is able to coordinate two additional ligands such as NCS$^-$, pyrazole (Hpz) and MeOH, whereas the more sterically demanding {((3-Phpz)$_2$ (3-*t*Bupz)BH)Co} unit forms tetrahedral complexes. Crystal structures of the five-coordinate (3-PhTp)Co(NCS)(Hpz) and four-coordinate ((3-Phpz)$_2$(3-*t*Bupz)BH)Co(NCS) were reported. The structures of the asymmetric hexacoordinate complexes ((3,5-Me$_2$pz)(3,5-Ph$_2$pz)BH)Co (η^2-NO$_3$)(THF) and ((3,5-Ph$_2$pz)BH$_2$)((3,5-Ph$_2$pz)$_2$(3,5-Me$_2$pz)BH)Co were established by X-ray crystallography.[290] An agostic H—Co interaction in the former (2.035 Å) was identified. The symmetrical analog ((3-Ph,5-MeTp)Co(η^2-NO$_3$)(THF) was also investigated for comparison. The symmetrical bis-bidentate coordinated tetrahedral Co((3-Ph$_2$pz)$_2$BH$_2$)$_2$ (CoN$_4$) and octahedral mixed ligand complexes (3-PhTp)Co((3-Ph$_2$pz)$_2$BH$_2$) (CoN$_5$H) have been isolated and characterized structurally.[291] The presence of an adjacent phenyl substituent prevents participation of the nitrile group as a bridging ligand, thus avoiding coordinative polymerization in the tetrahedral CoN$_4$ complex Co((3-Ph,4-CNpz)$_2$BH$_2$)$_2$.[292]

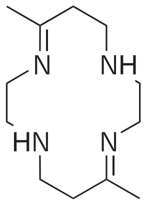
A Co *K*-edge X-ray absorption spectroscopic study of Co(Tp)$_2$, Co(3,5-Me$_2$Tp)$_2$, and Co(3,4,5-Me$_3$Tp)$_2$ was undertaken at 295 K and 77 K to investigate the ground electronic states of the complexes. EXAFS analysis indicates that the three complexes are all structurally similar, with Co—N bond lengths consistent with high-spin ground states, and these are unchanged upon cooling from 295 K to 77 K. However, the complexes are gradually converted from high-spin to low-spin state with increasing pressure, with Co(3,4,5-Me$_3$Tp)$_2$ showing the greatest change in spin state of the three complexes.[293] Heterodinuclear pyrazole-bridged complexes were reported by the reaction of (mes)Ru(pz)$_2$(Hpz), as one example, with CoCl(3-*i*Pr,4-BrTp) to give (mes)Ru(μ-pz)$_2$(μ-Cl)Co(3-*i*Pr,4-BrTp).[294]

(v) Imines and oximes

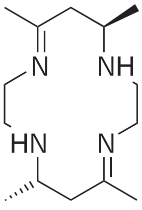
Imines, either acyclic or macrocyclic but invariably multidentate, have a rich coordination chemistry that has been investigated at length. The π-accepting ability of imine donors results in the stabilization of lower oxidation states relative to their saturated amine analogs, and there exist many air-stable divalent imine complexes of Co, in contrast to amine relatives. The hexamethyl-diene (**52**) has been the most intensively studied ligand of this class, particularly when complexed with Co. In addition, Co complexes of the dimethyl (**53**),[295,296] tetramethyl (**54**),[297] pentamethyl (**55**)[298] and octamethyl (**56**)[299] macrocyclic dienes are also known. In the presence of bidentate chelates such as amino acids[297] or carbonate[300], *cis* configurational isomers are formed, whereas monodentate ligands usually lead to *trans* isomers.[297]



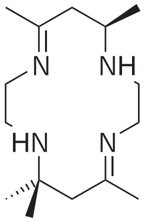
(**52**)



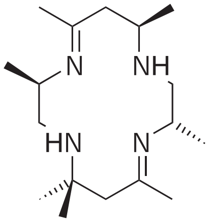
(**53**)



(**54**)

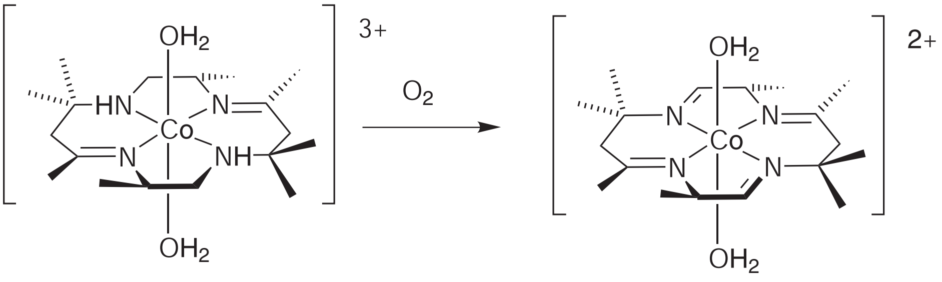


(**55**)



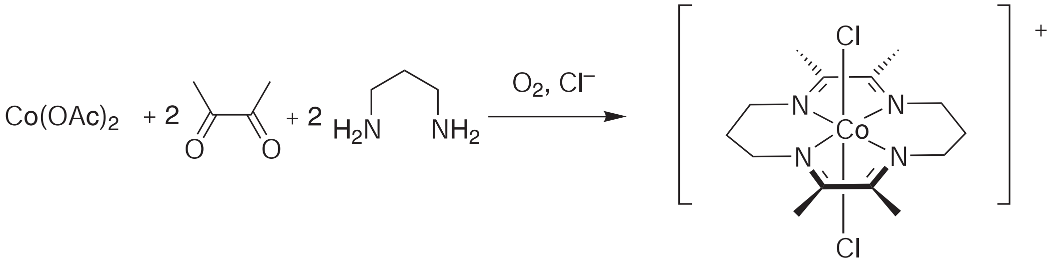
(**56**)

In an interesting variation, aerial oxidative dehydrogenation of the trivalent octamethyl diene complex (**57**) generates the divalent tetraimine complex (**58**).[301]



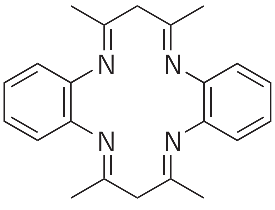
(**57**) (**58**)

The macrocyclic tetraene 2,3,9,10-Me_4[14]tetraene (tmt) may be synthesized by a metal-directed condensation between trimethylenediamine (tn) and 2,3-butanedione in the presence of $Co(OAc)_2$, ultimately resulting in the *trans*-dichloro Co^{III} complex $[Co(tmt)Cl_2]^+$ (**59**).[302]

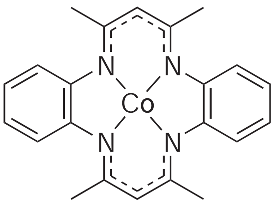


(**59**)

The 14-membered tetraaza-annulenes (such as tmtaa (**60**)) are somewhat similar to porphyrins in that they are highly conjugated, tetradentate dibasic acids. The crystal structure of the *trans*-dipyridyl adduct of (**61**) reveals coordination by the four macrocyclic N donors and the two axial pyridines. The macrocycle exhibits its characteristic non-planar (saddle-shaped) conformation.[303] Complex (**61**) undergoes three reversible one-electron oxidations (0.01, 0.55, and 1.04 V vs. SCE) and one low potential reduction (−1.65 V).[304] Oxidation of the complex by controlled-potential electrolysis resulted in an absorbance shift of the visible band from 595 nm to 543 nm after removal of the first electron, but removal of the second electron produced little change in the spectrum. This two-electron oxidized species exhibited an isotropic EPR spectrum consistent with a ligand-centered radical. Reduction to the monovalent complex resulted in a visible maximum shift to 629 nm. Divalent pyridyl and trivalent superoxo adducts were also examined. The potential uses for Co complexes of tetraaza-annulenes to bind and reduce O_2 was recognized some time ago, and a large class of substituted analogs of (**61**) was patented for this purpose.[267]

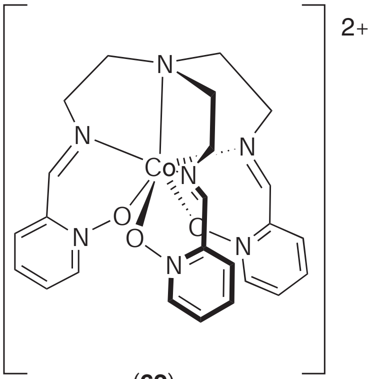


(60)

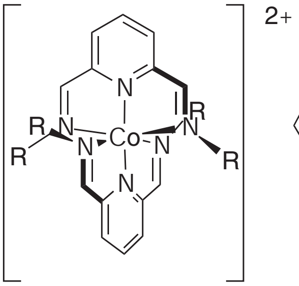


(61)

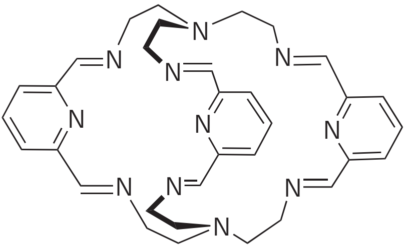
Divalent Co forms a trigonally symmetric seven-coordinate complex (**62**) with the N_4O_3 pyridine N-oxide trenpyo.[305] The effect of spin state on the electron-transfer properties of the six-coordinate $[Co(pdci)_2]^{2+}$ family (**63**) (R = *t*-Bu, *i*-Pr, *p*-tol, Bz) was studied.[306] The reversible $Co^{III/II}$ and $Co^{II/I}$ potentials were correlated with the solvent dielectric constant and H-bonding acceptor ability. Although no correlation was found between the N-substituent type and either the electron transfer rate constant or half-wave potentials, some correlation did exist between the substituent type and the magnetic moment of the central divalent complex. Much later, the use of Co complexes of this class as propylene oligomerization catalysts in the presence of polymethylaluminoxane was patented.[307] Dinucleating cryptands derived from the 2:3 condensation of tris(2-aminoethyl)amine (tren) and various dialdehydes (1,3-benzenedicarbaldehye, 2,5-furyldialdehyde and 2,6-pyridinedicarbaldehyde (**64**)) have been prepared and Co^{II} complexes have been reported.[308]



(62)

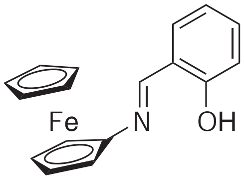


(63)

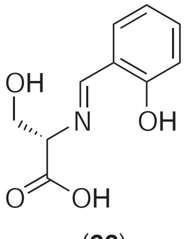


(64)

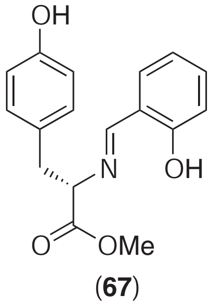
Salicylaldehyde condenses with primary amines (RNH_2) to form bidentate monobasic ligands of the form *o*-$(HO)C_6H_4CH{=}NR$. In a novel example, a ferrocenylamine adduct Hsalfc (**65**) results in the bis complex $Co(salfc)_2$.[309] The serine derivative (**66**) as its Co^{II} complex $Co(salser)_2$ is an efficient catalyst for conversion of a number of secondary alcohols to their corresponding ketone in the presence of O_2 and 2-methylpropanal[310] or ethyl 2-oxocyclopentanecarboxylate.[311] This versatile catalyst also oxidizes hydrocarbons such as cyclohexane to cyclohexanol and cyclohexanone (1:9).[312] The tyrosine analog (**67**) (as its methyl ester) $Co(saltyr)_2$ oxidizes benzylic substrates to their ketone.[313] The requirement of an aliphatic aldehyde or ketone in these processes is such that an active Co^{III}-superoxo species (identified in EPR experiments) is formed.[314] Electrochemical oxidation of the 1-(3′-aminopropyl)pyrrole analog $Co(salappr)_2$ in MeCN produces a conducting polymeric film at the electrode surface, which is catalytically active in the electroreduction of O_2 and CO_2.[315]



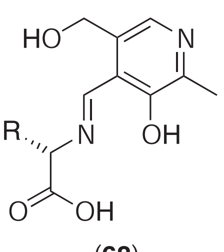
(65)



(66)



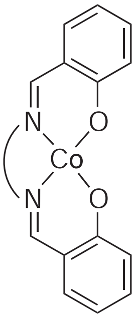
(67)



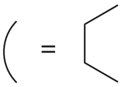
(68)

Pyridoxal is a biologically important aromatic aldehyde also bearing an *ortho* hydroxyl group. A variety of tridentate Schiff base ligands incorporating amino acids have been prepared from this aldehyde (H_2pdxaa) (**68**) and also from salicylaldehyde (H_2salaa), and their Co complexes bind O_2.[316] Coordinating solvents are required to activate the Co(pdxaa) and Co(salaa) complexes for O_2 binding, unless amino acids with coordinating side groups (e.g., aa = histidine) are present. Either 1:1 or 2:1 Co:O_2 adducts are formed dependent on the bulk of the amino acid side groups, which hinder dimerization and enhance reversibility. The reaction of H_2pdxphe with Co^{II} in the presence of H_2O_2 generates $[Co(pdxphe)_2]^-$ which is converted to the novel asymmetric complex where one phenyl alanine α-C atom has been hydroxylated, while the other bears a hydroperoxo group.[317] Schiff base complexes derived from sulfanilamide, homosulfanilamide, and *p*-amino-ethyl-benzenesulfonamide coupled with heterocyclic and aromatic aldehydes were investigated for their ability to inhibit three isozymes of carbonic anhydrase (CA, one bovine and two human enzymes). Unusually, several of the free ligands were more active against the membrane-bound bovine CA than the human isozymes, which contrasts with other known CA inhibitors. However, metal complexes of these Schiff bases (including Co^{II}) showed a reverse activity.[318]

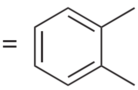
The divalent Co(salen) complex (**69a**) is one of the most versatile and well-studied Co coordination compounds. It has a long and well-documented history and we shall not restate this here. Recent applications of (**69a**) as both a synthetic oxygen carrier and as a catalyst for organic transformations are described in Sections 6.1.3.1.2 and 6.1.4.1 respectively. Isotropic shifts in the ^{1}H NMR spectrum of low-spin Co(salphn) (**69b**) were investigated in deuterated chloroform, DMF, DMSO, and pyridine.[319] Solvent-dependent isotropic shifts indicate that the single unpaired electron, delocalized over the tetradentate π-electron system in $CHCl_3$, is an intrinsic property of the planar four-coordinate complex. The high-spin/low-spin equilibrium of the 3-carboxy derivative of Co(salen) was studied by variable-temperature magnetic susceptibility measurements and EPR spectroscopy in a number of substituted pyridine solutions.[320] In the five-coordinate 2-methylpyridine adduct, a quartet ground state was found, whereas the 4-methylpyridine adduct is low-spin (doublet).

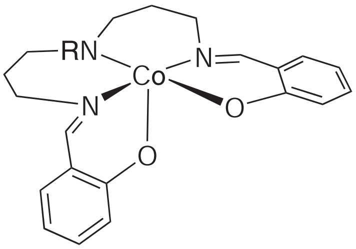


(**69a**)



(**69b**)

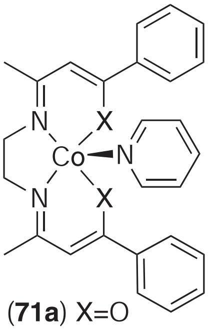




(**70a**) R=H
(**70b**) R=Me

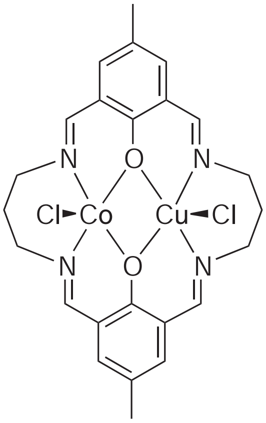
Divalent cobalt complexes of the pentadentate Schiff base H_2saldtn bearing a bis(trimethylene) triamine linker and its N-methyl derivative H_2salMedtn have also been intensively investigated. A study of the structures, electrochemical behavior, and O_2 reactivity of the complexes Co(saldtn) (**70a**), Co(salMedtn) (**70b**) and aromatic-substituted analogs has been reported.[321] A linear correlation was found between the $Co^{III/II}$ redox potential and $\log K_{O2}$ values. Electronic and steric factors of the Co—O_2 complexes with aromatic and N-substituted derivatives of (**70a**) were examined with regard to their ability to catalyze phenol oxidation.[322] The conversion of 2′-hydroxychalcones to flavanones occurs in MeOH in the presence of O_2.[323] Compound (**70b**) catalyzes the oxidation of 1-hexene by O_2 to give a mixture of 2-hexanone and 2-hexanol.[324] The more commonly encountered auto-oxidation, Wacker-type (peracids) and peroxylmetallocycle mechanisms do not apply in this case.[325] Rather, reaction of (**70b**) with H_2O_2 (generated *in situ* by oxidation of the primary alcohol solvent, or as a reagent) results in a hydroperoxy radical Co complex as the active species, which attacks the olefin double bond. Ultimately the alkyl hydroperoxide decomposes to give the ketone and secondary alcohol products. By contrast with the en-based system, the dien-linked analog Co(saldien) adopts a trigonal bipyramidal structure, with *trans* imine groups.[326]

An EPR study of the monomeric O_2 adducts of the Schiff base complexes of Co(bzacen)(py) (**71a**) and the thiobenzoyl analog Co(Sbzacen)(py) (**71b**) characterized the five-coordinate mono (pyridine) precursors and the six-coordinate O_2 adducts.[327] Increased covalency in the Co—S bonds was seen in the EPR parameters, indicative of π-backbonding. Substituent effects on the aromatic rings had no effect on the EPR spectra, but these were reflected in the observed redox potentials. Furthermore, the S-donors stabilize the Co ion in lower oxidation states, which was consistent with destabilization of the O_2 adducts.

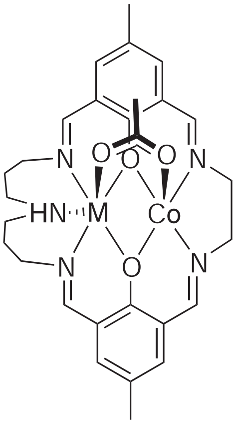


(**71a**) X=O
(**71b**) X=S

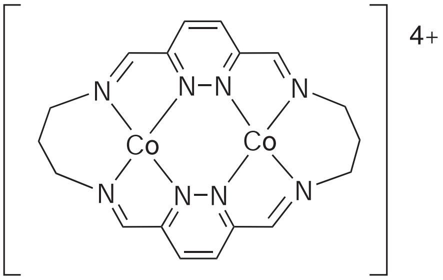
Ditopic macrocyclic imines may be formed by condensation of 2,6-diformyl-4-methylphenol with tn. Heterodinuclear complexes such as (**72**) have been made, with both metal ions in square pyramidal coordination geometries.[328] Variable-temperature magnetic susceptibility data (4.2–385 K) were complicated and fit to an expression derived from a Hamiltonian that included axial and rhombic single-ion zero-field effects, spin–orbit coupling for the Co ion, and an isotropic exchange interaction. The two metal binding sites may be tailored for different metal ions if individual diamine linkers are used. For example, a heterobinucleating ligand comprising salen and saldtn units has been made and the isomorphous series of compounds (**73**) (M^{II} = Mn, Fe, Co) has been characterized.[329] The thiocyanate derivatives are similar except the SCN^- ligand forms part of a one-dimensional zigzag coordination polymer (N-bound to M^{II}, S-bound to Co). Interestingly, magnetic susceptibility experiments reveal that the Co^{II} ions (in the N_2O_2 site) in the acetate structures are high spin, whereas in the thiocyanate structure they are low spin. The M^{II} ions in the six-coordinate site are all high spin. Replacement of 2,6-diformyl-4-methylphenol with 3,6-diformylpyridazine leads to a dinucleating macrocycle, with two independent, but closely spaced, N_4 donor sets and the structure of its dicobalt(II) complex (**74**) was reported.[330] Single-electron reduction generates a mixed valent complex exhibiting a NIR intervalence transition.



(**72**)

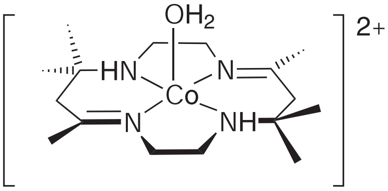


(**73**)

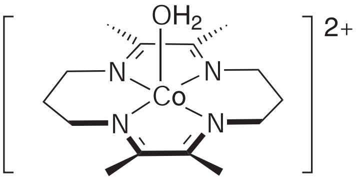


(**74**)

Low-spin square pyramidal divalent complexes of the form $[Co(hmd)(X)]^{n+}$ (X = OH_2 (**75**) and $OClO_3^-$) have been structurally characterized.[331] The rate of outer-sphere ($[Co(OH_2)_6]^{3+}$) and potentially inner-sphere ($[Co(OH_2)_5Cl]^{2+}$) oxidation of $[Co(hmd)]^{2+}$ has been investigated and variations in reactivity by more than four orders of magnitude were found.[332] Other oxidants studied included $[Ru(bpy)_3]^{3+}$[333] and the novel hydroperoxopentaaquachromium(III) ion.[334] Oxygenation of (**75**) gives the trivalent peroxo-bridged dimer $[\{(H_2O)(hmd)Co\}_2(\mu\text{-}O_2)]^{4+}$, which may be deoxygenated in acidic solution.[335] In an electrochemical study, the O_2 and O_2^- coordination chemistry of the $[Co(hmd)]^{2+}$ system in DMSO was investigated.[336] The divalent complex forms an adduct with O_2 ($K_a = 54\,M^{-1}$), which is reduced at potentials more positive than the formal potential of the O_2/O_2^- couple owing to the high affinity of the divalent complex for superoxide. The reduction and oxidation kinetics of $[(hmd)Co(OOH)]^{2+}$ by a variety of inner and outer sphere electron transfer agents has been reported.[337] The unusual S-bonded sulfite complex $[(H_2O)Co(hmd)(SO_3)]^+$ has been characterized structurally and found to undergo photoisomerization to its O-bound linkage isomer. A mechanism involving Co^{II} and the SO_3^{2-} was proposed.[338]



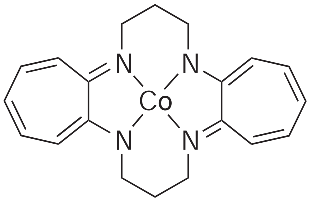
(**75**)



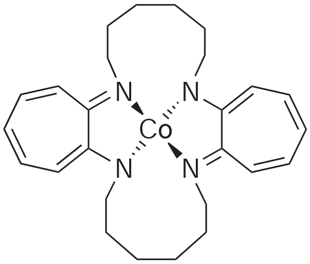
(**76**)

The tmt complex (**76**) reacts slowly with O_2 but this reaction may be catalyzed by Fe_{aq}^{2+} in acidic aqueous solution. A kinetic study revealed first-order dependence on complex, O_2, and Fe_{aq}^{2+} which leads to the trivalent Co complex and H_2O as products,[339] bypassing hydrogen peroxide as an intermediate. Formation of the intermediates $[(tmt)CoOOFe]^{4+}$ then $[(tmt)Co(OOH)]^{2+}$ was proposed to account for these observations. However, adsorption of (**76**) on graphite electrodes makes the complex an active catalyst for the reduction of O_2 to H_2O_2 in a single voltammetric step.[340] By comparison, (**75**) exhibits two separate voltammetric steps in the reduction of O_2 at more negative potentials. In a study somewhat related to these oxygenation reactions, the catalytic auto-oxidation of azide by (**76**) in the presence of dioxygen was observed.[341]

Air-sensitive divalent Co complexes of the tropocoronand ligand TC^{2-} in addition to larger ring relatives were prepared in an extensive investigation. The square–planar 14-membered Co(TC) (low-spin) complex (**77**) changes to tetrahedral (high spin) for the 20-membered analog (**78**).[342] The dihedral angle between the two five-membered aminotroponiminate chelate rings increases from 9° (pseudo-planar) to 85°, which was attributed to torsional strain within the polymethylene linker chains of the macrocycle.

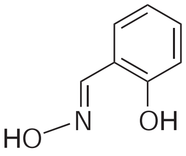


(**77**)

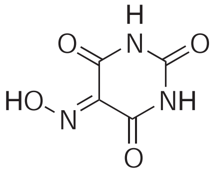


(**78**)

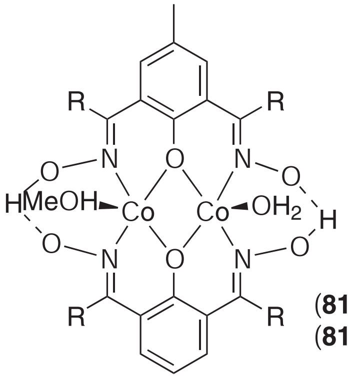
In contrast with the Schiff base salen, salicylaldehyde oxime (**79**) (salox) complexes of Co have received comparatively little attention, but a series of bis-bidentate divalent complexes of the form *trans*-$Co(salox)_2(DMSO)_2$ have been reported.[343] The heterocyclic bidentate oxime violurate (1H,3H-pyrimidine-2,4,5,6-tetrone 5-oximate, Hvi) (**80**) and its *N*-methyl (mvi) and *N*,*N*′-dimethyl (dmvi) derivatives form high-spin divalent $[Co(vi)]^+$ and $Co(vi)_2$ complexes, whereas $[Co(vi)_3]^-$ is low spin.[344] The mixed-ligand $Co(dmvi)_2(phen)$ complex is also low spin. The crystal structure of *cis*-$Co(pxo)_2Br_2$ (pxo = 2-acetylpyridine-1-oxide oxime) is isostructural with the Ni^{II} relative.[345] The dichloro complex also adopts a *cis* configuration. The tridentate dioximes 2,6-diformyl-4-methylphenol dioxime and 2,6-diacetyl-4-methylphenol dioxime (Hdampo) form binuclear complexes of the type (**81a**) and (**81b**) respectively.[346] Cobalt oxide nanoparticles were prepared by pyrolysis of $Co(pao)_2$ (Hpao = pyruvic acid oxime, Me(HOOC)C=NOH). Electron microscopy showed the products were nanocrystalline with various morphologies (rod-like or quantum dot).[347]



(**79**)



(**80**)

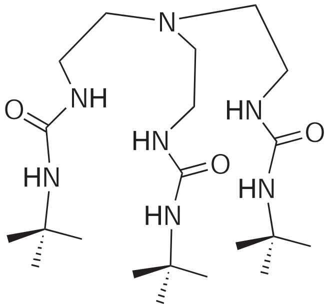


(**81a**) R=H
(**81b**) R=Me

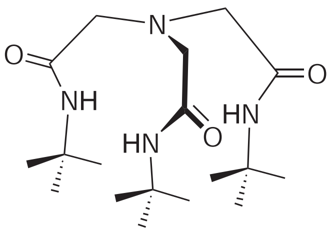
(vi) Amides

N-Containing heterocycles bearing carbonyl functional groups adjacent to the ring heteroatom(s) are ubiquitous in nature. As N-deprotonation accompanies coordination, they may be considered formally as amide ligands. A number of divalent Co complexes of purines and pyrimidines showing a variety of coordinating modes have been studied, such as 5-chlorouracil (monodentate, tetrahedral $[Co(ur)(OH_2)_3]^+$)[348] and cytosine (bis-bidentate, $Co(cyt)_2Cl_2$).[349] A range of divalent 4-oxopteridine Co complexes with substituents at the 2-, 6- and 7-positions of the bicyclic ring system have been prepared. Electronic and IR spectral data on the series of complexes indicate that all are coordinated to Co via the O atom in the 4-position and the pyrazine ring N in the 5-position.[350]

The tren derivative (**82**) was used to synthesize monomeric complexes with terminal hydroxo ligands. Trigonal bipyramidal complexes of the trianionic ligand with both divalent and trivalent hydroxocobalt were reported; the latter is a rare example of a trigonal bipyramidal, paramagnetic Co^{III}.[351] A feature of their structures is the presence of intramolecular H bonds from the urea cavity of the ligand to the coordinated hydroxo O atom, which results in an unusually long Co—O bond (Figure 7). The tripodal tetradentate triamide (**83**) is structurally similar to tren, and the ligand enforces an unusual trigonal pyramidal coordination geometry on divalent metal ions, including Co (Figure 7).[352]



(**82**)



(**83**)

(vii) Nitrosyl

The structures of the oxime complex $Co(NO)(dmg)_2$ (**84**) and its diphenylglyoxime analog exhibit strongly bent Co—NO groups, which are easily oxidized to the corresponding nitro compound.[353] A mechanistic study of NO transfer from $Co(NO)(dmg)_2$ to hemoglobin established that the reaction involves NO association with the protein subsequent to dissociation of NO from the Co complex.[354] This mechanism is also consistent with the observation of nitrato complexes in reactions

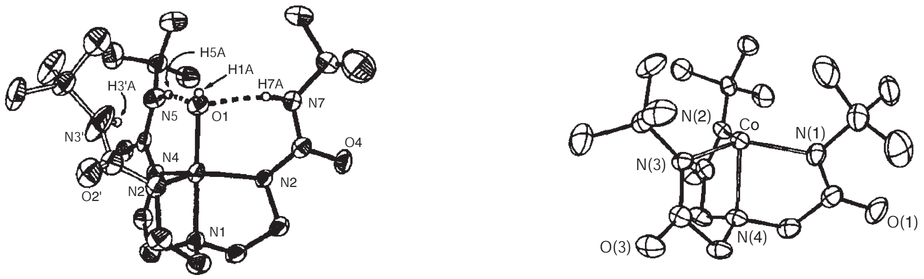


Figure 7 Tripodal triamide complexes of (left) (**82**) with hydroxocobalt(III) (divalent complex is similar) (reproduced with permission of the American Chemical Society from *Inorg. Chem.*, **2001**, *40*, 4733–4741) and (right) (**83**) with Co^{II} (reproduced with permission of the American Chemical Society from *Inorg. Chem.*, **1998**, *37*, 1527–1532).

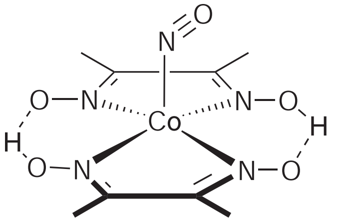
of these metal nitrosyls with O_2. This process is also relevant to the oxidation of oxymyoglobin (MbO_2, Fe^{II}) to metmyoglobin (Mb^+, Fe^{III}) by $Co(NO)(dmg)_2$, where the free NO released from the Co complex oxidizes the heme.[355] Nitrate formation accompanying the production of Mb^+ is proposed to arise from isomerization of the initially formed peroxynitrite ion. Furthermore, the $Co(dmg)_2$ product is an effective trap for the O_2 released from MbO_2. The 8-quinolinolate (qn) complexes $Co(qn)_2$ and $Co(NO)(qn)_2$ react with NO forming $Co(NO_3)(qn)_2L$ (L = py, DMF), releasing N_2O.[356]



(**84**)

(viii) Nitriles, azide, cyanates, and thiocyanates

These rod-shaped ligands share a sterically efficient terminal N-donor and their divalent Co chemistry is well established. They will be discussed here only with selected examples. $[Co(NCMe)_6](TFPB)_2$ ($TFPB^-$ = tetrakis(3,5-bis(trifluoromethyl)phenyl)borate)) has been synthesized and characterized in the solid state along with a number of other divalent transition metal analogs.[357] As a result of the extremely poor coordinating ability of the anion and facile loss of MeCN ligands from the cation, the salt is an excellent source of "naked" Co^{2+} ions. Thermolysis up to 100 °C leads to the loss of one MeCN and formation of a η^2-bound nitrile, whereas above 130 °C decomposition occurs with loss of MeCN and abstraction of fluoride from the anion to form CoF_2.

Reactions of nitriles may be promoted by the presence of divalent Co. The conversion of sterically unhindered nitriles RCN (R = Me, Et, *n*-Pr, *n*-Bu) into the corresponding amidines $RC(NH_2){=}NH$ occurs in the presence of $Co(NO_3)_2.6H_2O$ and the ketoxime $Me_2C{=}NOH$. The metal free amidinium ions were crystallized as their nitrate salts.[358]

The well-known tetrahedral $[Co(NCS)_4]^{2-}$ ion has continued to attract attention from analytical chemists, physical chemists, and spectroscopists. The inelastic electron tunneling (IET) spectrum of $(Me_4N)_2[Co(NCS)_4]$ was compared with IR and Raman spectra of the same complex.[359] The vibrational bands due to the Me_4N^+ were prominent in all three spectra, but Co-ligand stretches were absent from the IET spectra. The lowest ${}^4A_2 \rightarrow {}^4T_2$ electronic transition was strong in the IET spectrum but absent from the IR spectrum. The electric dipole allowed ${}^4A_2 \rightarrow {}^4T_1$ electronic transition was observed in both the IET and IR spectra and no fine structure was observed. Complex formation equilibria between Co^{II} and SCN^- were studied calorimetrically in both aqueous solution and in micellar solution of the surfactant Triton X-100. The formation of $[Co(NCS)_3]^-$ is virtually negligible in any of the solutions examined, whereas $[Co(NCS)]^+$ is formed only in the aqueous phase and $[Co(NCS)_4]^{2-}$is formed mainly in micelles as ion pairs.[360] The $[Co(NCS)]^+$ ion was also identified as a major species in an independent study involving conductivity and visible absorption spectroscopy of DMSO–water solutions of $Co(NCS)_2$.[361]

The intense blue color of $[Co(NCS)_4]^{2-}$ has been exploited as a spectroscopic signal for a number of analytical methods for determining Co^{II} in solution. A method for the determination of trace concentrations (1–15 μg) of Co^{II} as its NCS^- complex was reported by fixing the complex on a coagulated material composed of anion and cation exchange resins, followed by colorimetry (using a densitometer).[362] Methods for simultaneously determining Fe^{II} and Co^{II} have been reported that are applicable to a disparate range of samples (e.g., blood and steel) involving complexation of Co with NCS^- and chelation of Fe with *N*-phenylcinnamohydroxamic acid (HPCHA) to form their respective blue $[Co(NCS)_4]^{2-}$ and red $[Fe(NCS)_2(PCHA)_2]^-$ complexes, which extract quantitatively into EtOAc from dilute HCl solution.[363] Spectrophotometric detection of tamoxifen citrate,[364] lignocaine,[365] mefloquine,[366] mebeverine,[367] the surfactant Pluronic F-68,[368] trazodone.HCl and amitriptyline.HCl[369] have also been reported through their association with divalent Co-NCS^- adducts.

Octahedral coordination of N-bonded thiocyanate was achieved in $[Co(NCS)_6]^{4-}$ accidentally as a polyammonium salt while trying to coordinate a tetraamine.[370] Thiocyanate is frequently met as a co-ligand in Co chemistry. A recent example where both monodentate and bridging thiocyanate occur is the trinuclear Co^{II} complex $[Co_3(amt)_6(SCN)_6]\cdot 2H_2O$ (amt = 4-amino-3,5-dimethyl-1,2,4-triazole), where bridging between pairs of antiferromagntically coupled Co centers involves both an SCN^- and two amt ligands.[371] The complex forms simply from reaction of $Co(NCS)_2\cdot 6H_2O$ in water with the amt ligand. A general method for synthesis of anionic thiocyanate Co complexes (such as $[Co(NCS)_4]^{2-}$), as well as neutral mixed-ligand species, by oxidation of a sacrificial Co anode has appeared.[372]

Azide appears as both an effective monodentate and bridging ligand. As an example, the one-dimensional 1,3-azido bridged coordination polymer is defined by the structure of $[Co(py)_4(N_3)]PF_6$.[373] A μ-1,1 bridging mode has been observed for N-bound cyanate in conjunction with di-2-pyridyl ketone in an unusual tetranuclear dicubane-Co^{II} complex where two vertices are missing from the core. Ferromagnetic coupling between the Co centers was found.[374]

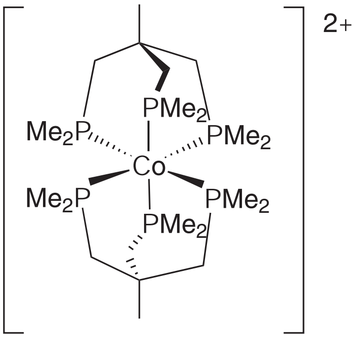
6.1.2.2.3 Phosphorus

(i) Monodentate phosphines

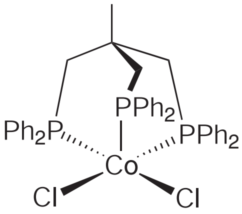
Examples of monodentate phosphines appear as companion ligands in other parts of the review, and only limited additional examples will be presented here. The reactivity of $Co(NO_2)_2$ toward a variety of monodentate phosphines such as PMe_3, PEt_3, PMe_2Ph, $PMePh_2$, and PPh_3 has been investigated.[375] For PMe_3 and PMe_2Ph, five-coordinate square–pyramidal $Co(NO_2)_2(PR_3)_3$ complexes were isolated, but for PEt_3 only the pseudo-octahedral, formally trivalent $Co(NO)(NO_2)_2(PEt_3)_2$ was obtained. The analogs $Co(NO)(NO_2)_2(PMe_3)_2$ and $Co(NO)(NO_2)_2(PMe_2Ph)_2$ were prepared indirectly from the dinitro precursor by reaction with NO gas. The resultant Co^{III} species contain both O-bonded and N-bonded NO_2. Reactions of R_3PI_2 (R = Et, Pr, Bu, $PhMe_2$, Ph_2Me, Ph_2Pr, Ph, *m*-MeC_6H_4), with unactivated Co metal in dry ether produce $[PR_3I][Co(PR_3)I_3]$ in quantitative yield,[376] and the X-ray crystal structure of $[PPh_3I][Co(PPh_3)I_3]$ is reported. However, the reaction with $PPhMe_2$ is more complicated and generates the Co^{III} compound $Co(PPhMe_2)_2I_3$ as an additional product. The simple tetrahedral complex $CoCl_2(PPh_3)_2$ bound to a polymer support catalyzes the oxidation of alcohols to aldehydes (e.g., benzyl alcohol to benzaldehyde, 86% yield) and the preparation of anhydrides from reaction of acid chlorides with carboxylic acids.[377]

(ii) Multidentate phosphines

Chelating phosphines are effective ligands for Co^{II}. The $[Co(mtriphos)_2]^{2+}$ cation (**85**) was formed by controlled potential electrolysis of its trivalent relative and characterized by EPR and spectrophotometry.[378] This divalent CoP_6 species has a low-spin electronic ground state with a large Jahn-Teller distortion. The $Co^{III/II}$ electron self-exchange reaction is very fast ($\sim 10^4 M^{-1} s^{-1}$), which is consistent with other low-spin/low-spin $Co^{III/II}$ couples. The nephelauxetic effect of the P donors is responsible for stabilizing the low-spin state in Co^{II}.



(**85**)

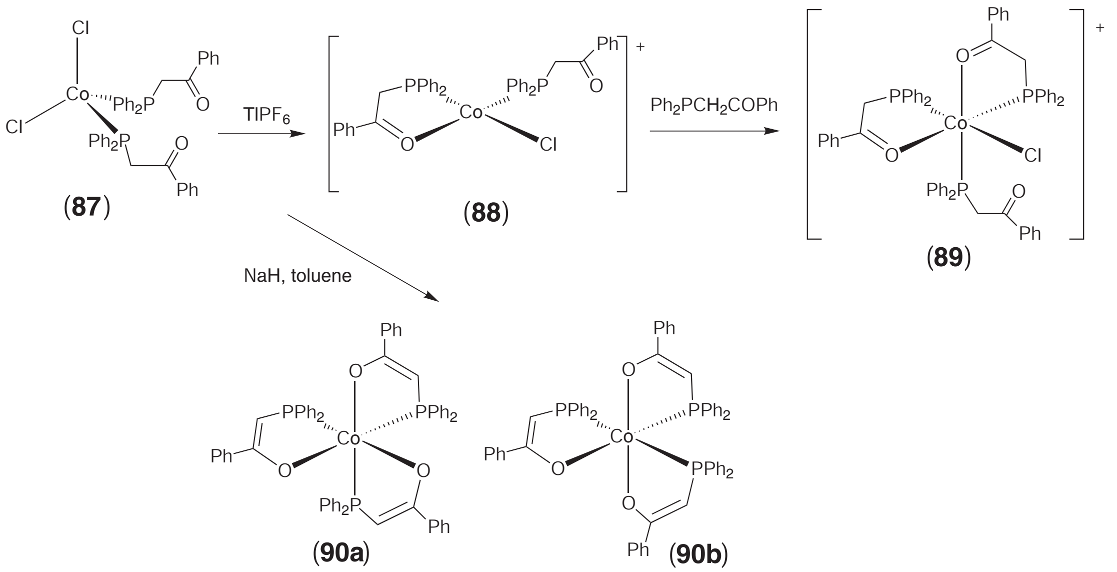


(**86**)

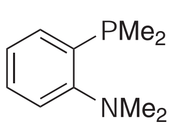
The bi- and tridentate phosphines dppp (1,3-bis(diphenylphosphino)propane) and dppep (bis(2-diphenylphosphinoethyl)phenylphosphine) have been complexed with Co and their divalent four- and five-coordinated thiophenolate complexes $Co(dppp)(SPh)_2$ and $Co(dppep)(SPh)_2$ have been isolated and structurally characterized.[379] Somewhat related to dppp is the bidentate silane $Ph_2PCH_2SiMe_2CH_2PPh_2$, which forms high-spin, pseudo-tetrahedral dihalocobalt(II) complexes.[380]

The five-coordinate triphos complex (**86**) undergoes selective substitution of its Cl groups on activation with KPF_6 in the first substitution step and by $TlPF_6$ in the second. This enabled the synthesis of mixed-ligand complexes of the type $[Co(triphos)(L)(L')]^{2+}$, e.g., the divalent hydride $[Co(triphos)H(PEt_3)]^+$.[381] Homo-disubstituted compounds $Co(triphos)L_2$ are directly accessible from $Co_{aq}{}^{2+}$ as the starting material.[382] Depending on the reaction conditions, a variety of products including $[(triphos)Co(S_2CPEt_3)]^{2+}$, $[(triphos)Co(S_2C(H)PEt_3)]^{2+}$, and $[(triphos)Co(\mu\text{-}CS_2)Co(triphos)]^{2+}$ are obtained from the reaction of the $[Et_3P][CS_2]$ adduct with $Co_{aq}{}^{2+}$ and triphos. Triphos may also be substituted by its diethylphosphino analog (etriphos).[383] Reaction of the template $\{(triphos)Co\}^{2+}$ with potentially bridging ligands (L) generates dinuclear $[(triphos)Co(L)Co(triphos)]^{n+}$ species. When L is oxalate, a biscobalt(II) complex is formed, whereas when L is the dianion derived from 2,5-dihydroxy-1,4-benzoquinone, two-electron transfer within the dimetallic unit occurs and a biscobalt(III) complex results.[384] Single-electron reduction of the dinuclear $[(triphos)Co(L)Co(triphos)]^{2+}$ complexes (L = dianion of tetrahydroxybenzene or tetrahydroxyanthracene) by cobaltocene gave the corresponding mixed-valence monocation $[(triphos)Co(L)Co(triphos)]^+$.[385] The tetrahydroxybenzene bridged system exhibits a strong metal–metal interaction leading to delocalized class-III behavior while the extended tetrahydroxyanthracence bridging ligand leads to only partial electron localization. Reaction of the pseudo-tetrahedral complex (η^2-triphos)$CoCl_2$ with O_2 yields the mixed phosphine/phosphine oxide ligands triphos-O and triphos-O_2, the latter being formed in quantitative yield using catalytic amounts of the Co precursor.[386] Complexes of triphos-O and triphos-O_2, proposed as intermediates in the oxygenation reaction, were isolated and fully characterized structurally.

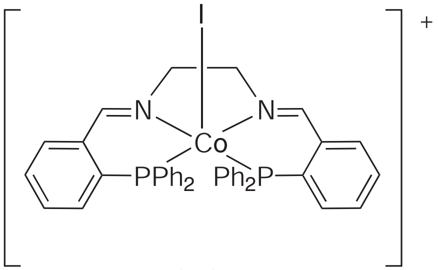
The coordination chemistry and catalytic applications of chelating P,O-donor ligands (phosphine esters, ketophosphines and phosphinocarboxylates) has been reviewed.[387] A variety of divalent complexes of keto-phosphine ligands of the form $CoX_2(Ph_2PCH_2C(O)Ph)_2$ (X = Cl, Br, I) have been investigated.[388] These complexes exhibit tetrahedral–octahedral equilibria in MeOH, but this does not involve coordination of the keto O atom, but instead by the solvent. The crystal structure of the pseudotetrahedral complex (**87**) was reported with the ligand binding as a monodentate P-donor. When reacted with $TlPF_6$, the square planar Co^{II} complex (**88**) is formed initially and then is transformed in solution to the six-coordinate (**89**). Reaction of (**87**) with bases (NaH, NaOMe, $K[OSiMe_3]$) in toluene or THF at 0 °C gives deprotonated tris-P,O-chelated octahedral cobalt(III) enolates of the form $Co(Ph_2PCHC(O)Ph)_3$ where *fac* (**90a**) and *mer* (**90b**) isomers are observed.[388] The potentially tridentate ligand benzylbis(2-ethoxyethyl)phosphine (L) reacts with $CoCl_2$ to give the monodentate P-coordinated tetrahedral $CoCl_2L_2$ complex, but when reacted with $CoCl_2.6H_2O$ and $AgCF_3SO_3$ the *trans*-(P,O)-$CoL_2(O_3SCF_3)_2$ complex is the result.[389]



The P-N chelate (**91**) (dapdmp) exhibits a variety of coordination geometries in complexes with divalent Co. Pseudotetrahedral Co(dapdmp)X$_2$ (X = Cl, Br, I, NCS), low-spin five-coordinate [Co(dapdmp)$_2$X]$^+$ (X = Cl, Br, I), planar [Co(dapdmp)$_2$]$^{2+}$ and pseudo-octahedral Co(dapdmp)(NO$_3$)$_2$ were all identified.[390] The tetradentate P$_2$N$_2$ Schiff base complex (**92**) is formed by reacting the free ligand with CoI$_2$. The iodo complex is low spin and square pyramidal.[391]



(**91**)



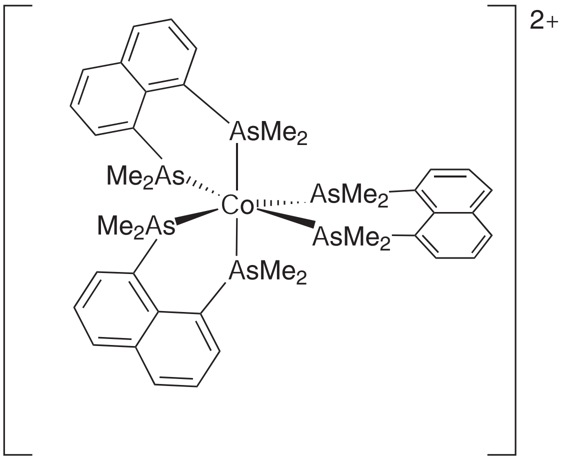
(**92**)

Tetrahedral, high-spin halo(amidodiphosphine)cobalt(II) complexes Co(L)X where X = Cl, Br, I and tridentate L = $^-$N(SiMe$_2$CH$_2$PPh$_2$)$_2$ have been described.[392] Amongst a range of reactions with organic halides studied, they undergo a one-electron oxidation reaction with PhCH$_2$X to yield five-coordinate cobalt(III) complexes Co(L)X$_2$.[201]

6.1.2.2.4 Arsenic

(i) Monodentate and multidentate arsines

Arsenic is an obvious replacement for phosphorus particularly in multidentate ligands, and some limited examples will suffice to define this fact. The rigid aromatic diarsine nas (1,8-naphthylenebis(dimethylarsine)) forms a divalent tris bidentate complex [Co(nas)$_3$]$^{2+}$ (**93**) upon reaction with Co$_{aq}$$^{2+}$ (Cl$^-$, Br$^-$ and ClO$_4$$^-$ salts), but similar treatment of CoI$_2$·6H$_2$O gave the five-coordinate [Co(nas)$_2$I]I.[393] Mixed donor As-chelate complexes of Co^{II} have been reported. The ligand *o*-C$_6$H$_4$(AsMe$_2$)(PMe$_2$) forms only 2:1 ligand:Co complexes such as [CoL$_2$X]$^+$ (X = Cl, Br, I), which are low spin and five-coordinate in solution.[390] By comparison, *o*-C$_6$H$_4$(AsR$_2$)(CO$_2$H) (R = Et, cyclohexyl and *p*-tolyl) reacts with Co(OAc)$_2$ to give the neutral bis complex of the ligand monoanion CoL$_2$.[394] Electronic spectra and magnetic susceptibility measurements are consistent with a pseudo-tetrahedral geometry.



(**93**)

6.1.2.2.5 Oxygen

Oxygen-donor ligands represent, along with nitrogen, the most likely to be met in Co^{II} chemistry. The variety of ligands reported is extensive.

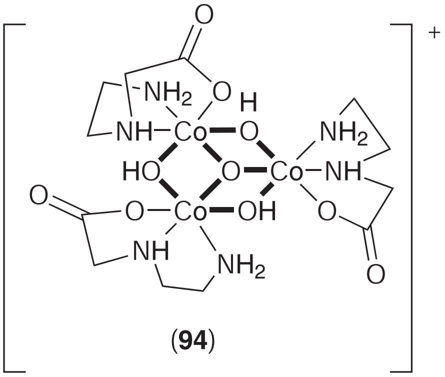
(i) Aqua, hydroxo, and oxo

Water and its successively deprotonated forms hydroxide and oxide are classical ligands for Co in both its di- and trivalent oxidation states. Whereas H_2O is typically found as a monodentate ligand, hydroxide may be monodentate or else bridge two metals (μ_2), and oxide can be any of monodentate, dibridging (μ_2) or tribridging (μ_3), with tetrabridging (μ_4) rare but known. Acidity of any ligand is enhanced by the influence of additional coordinated metal ions. Indeed, the fully deprotonated oxo ligand is only encountered in divalent Co chemistry as a bridging ligand; terminal oxo complexes do not feature.

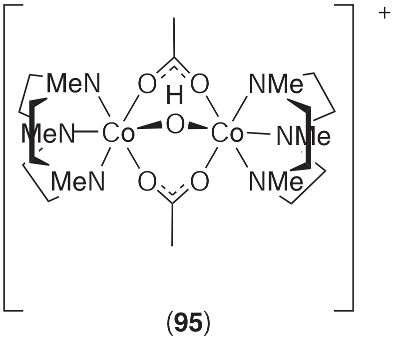
The chemistry of the aqua ions has been extensively covered in a monograph with that title.[395] The hexaaquacobalt(II) ion undergoes exchange rapidly[396] and often serves as an entry point into the chemistry of both Co^{II} and Co^{III}. Although commonly found as a monodentate, several examples of water as a bridging ligand between two Co^{II} centers have appeared. An example is $Co_2(\mu\text{-}OH_2)(\mu\text{-}OOCCCl_3)_2(OOCCCl_3)_2(tmen)_2$ (where tmen = *N,N,N′,N′*-tetramethylethane-1,2-diamine).[397] This dimeric structure with a bridging aqua ligand is stabilized by intramolecular hydrogen bonding.

Apart from water, hydroxide and oxide are well-established ligands for Co^{II}. This includes the latter ions adopting bridging modes. An example of a complex featuring both the (μ_2-OH) and (μ_3-O) ligands is the cluster (**94**).[398] The dicobalt complex (**95**) bears both bridging hydroxide and acetate ligand and is stabilized by the trimethylated 1,4,7-triazacyclononane ligand.[399] The substituted Tp dimer (**24**) reacts with one equivalent of H_2O_2 to give the reactive trivalent μ-oxo dimer (**96**), which was isolated and characterized structurally.[400] The polymeric trimethylacetate complex $[Co(OH)_n(OOCCMe_3)_{2-n}]_m$ is transformed upon recrystallization from non-polar aromatic solvents into discrete clusters such as $Co_6(\mu_3\text{-}OH)_2(\mu\text{-}OOCCMe_3)_{10}(HOOCCMe_3)_4$, where each hydroxide ions bridge three Co centers.[401] A cluster featuring μ_4-oxo groups is also reported.

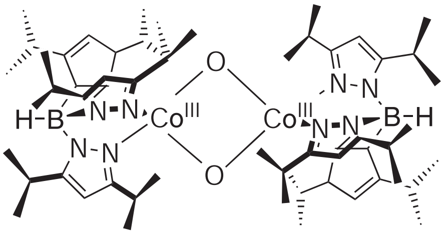
Perhaps the highest nuclearity complex containing divalent Co ever structurally characterized is the cluster $Co_{24}(\mu_3\text{-}OH)_{14}(\mu\text{-}OH)_4(\mu_3\text{-}OMe)_2(\mu_3\text{-}Cl)_2Cl_4(mph)_{22}$ (Hmph = 2-methyl-6-hydroxypyridine), which has a high-spin ground state and indications of superparamagnetic behavior.[402] It self-assembles from reaction of the sodium salt of Hmph with $CoCl_2$ in methanol. Polyiron oxo chemistry offers another class of readily prepared clusters in which Co^{II} plays a cameo role as a core metal, as in the cluster $Fe_{16}CoO_{10}(OH)_{10}(OBz)_{20}$, where Co occupies a center of symmetry of the compact $Fe_{16}CoO_{10}(OH)_{10}$ core, surrounded by the twenty coordinated benzoates.[403] Large



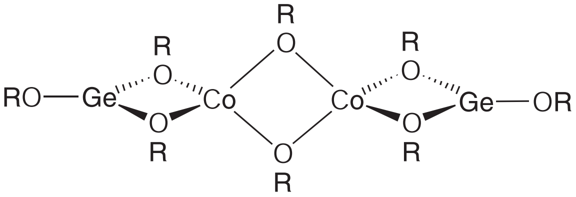
(**94**)



(**95**)



(**96**)



(**97**)

clusters are accessible via thermal "dimerization" of smaller clusters, as exhibited by heating $Co_4(\mu_3\text{-}OH)_2(OOCCMe_3)_6(EtOH)_6$ in decalin, which forms an octanuclear oxo-bridged cluster with ethanol loss.[404] An unusual cluster where oxo groups play a key structural role forms when $Co(OAc)_2$ is heated with $Me_3SiNPEt_3$ at 180 °C and recrystallized from diethyl ether.[405] The blue crystals obtained are of $[Co_7(\mu_4\text{-}O)_2(OOCCH_3)_8(NCO)_2(HNPEt_3)_4]\cdot 2OEt_2$, where the Co centers are arranged in a $\{Co(Co)_6\}$ octahedron with two μ_4-oxo ions and four bridging acetates linking the octahedral central Co to the six peripheral Co centers, four of which have a distorted trigonal bipyramidal geometry while the other two adopt tetrahedral coordination.

Definitive structural characterization of Co in a solid state oxide lattice has been achieved for a single crystal of partially Co^{II}-exchanged zeolite A.[406] Dehydration at high temperature and low pressure for two days afforded the characteristic color change from light pink to deep blue. Exposure to H_2S gas gave a black crystal whose X-ray structure was determined. Four Co^{II} ions were found recessed into the large cavity of the zeolite at six-oxygen ring sites, each coordinated to three framework oxygens (Co—O 2.24(1) Å) and to one H_2S sulfur (Co—S 2.60(2) Å)

A pH-controlled interconversion from a dicobalt(II) complex where each Co carries a single monodentate hydroxo group to a compound with a shared μ-hydroxo group has been reported; a pendant arm dinucleating polyimine macrocycle completes the coordination sphere of the two Co ions.[407] The process features interchangeable coordination geometries, as the yellow–green μ-hydroxo compound is octahedral and the purple dihydroxo compound trigonal prismatic.

(ii) Dioxygen

Dioxygen can bind reversibly to several classes of Co^{II} complexes including porphyrins, peptides, Schiff bases, and macrocyclic polyamines. Diverse physical studies of dioxygen binding have been reported. Thermodynamics and kinetics of dioxygen binding to Co^{II} have been well studied, as exemplified by a recent study involving macrocyclic tetraamines.[408] Binding to Co^{II} complexes of tetraimine "lacunar" macrocycles is typically fast and differences in dissociation rates define dioxygen affinity (see Section 6.1.3.1.3). Dioxygen complexes of particularly μ-phenoxo and μ-alkoxo bridged dimetal complexes of compartmental ligands has appeared recently.[409] Dioxygen binding to Co^{II} porphyrins has also been observed and the catalytic reduction of dioxygen to water has been a motivating force driving their study (see Section 6.1.2.2.2).

(iii) Neutral oxygen donors

Apart from water as the ubiquitous neutral solvent donor for cobalt(II) chemistry, other neutral O donors are known, including alcohols, ketones, amides, and sulfoxides. The complex $[Co(DMSO)_6]$ $[CoCl_4]$ has been characterized by an X-ray structure, which confirmed monodentate O coordination around the octahedral Co center.[410] Formally neutral molecules such as amine N-oxides and nitrosoalkanes are effective ligands. A ligand such as nitrosomethane (MeNO) can be considered to benefit from resonance forms such as $H_3C—N^+—O^-$, where its capacity as an O-donor ligand would be clearly enhanced. This ligand has been characterized in $[Co(MeNO)_4]^{2+}$, whereas pyridine-*N*-oxide (pyo) exists in the octahedral complex $[Co(pyo)_6]^{2+}$. The same ligand forms a range of ionic complexes with cobalt(II) halides, including the tetrahedral anion $[Co(pyo)I_3]^-$.[411] The triarsine oxide tetrahedral complex ion $[Co(OAsR_3)_4]^{2+}$ was prepared by light-catalyzed decomposition of tetrakis(alkylisocyanide)-bis (triarsine)cobalt(II) in dichloromethane.[412]

(iv) Alkoxides and aryloxides

Cobalt(II) alkoxides are known and monomeric forms are part of a wider review.[413] The interest in these compounds pertains to a potential role in catalysis. For example, a discrete cobalt(II) alkoxide is believed to form *in situ* from a chloro precursor during reaction and performs the catalytic role in the decomposition of dialkyl pyrocarbonates to dialkyl carbonates and carbon dioxide.[414] A number of mononuclear alkoxide complexes of cobalt(II) have been characterized by crystal structures, as exemplified by $[CoCl(OC(t\text{-}Bu)_3)_2\cdot Li(THF)]$.[415] The Co ion in this structure and close relatives has a rare distorted trigonal–planar coordination geometry due to the extreme steric crowding around the metal.

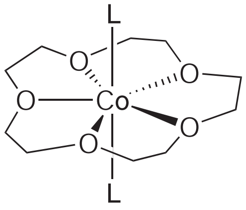
Polymeric forms have also been reported. One example, which also includes germanium heteroatoms terminating the chain, is the oligomer $(RO)Ge(RO)_2Co(RO)_2Co(RO)_2Ge(OR)$, (**97**) where each Co center is surrounded by four bridging *tert*-butoxide ions.[416] These form via a photochemically induced labile solvent complex, or else through thermally induced substitution into carbonyl compounds.

(v) Ethers

(m) Acyclic. Ether oxygens are not considered strong donors for cobalt. Nevertheless, simple ethers can be the sole occupant of the Co^{II} coordination sphere, as exhibited in the crystal structure of the $[Co(THF)_6]^{2+}$ ion.[417] Ethers are met as a component donor group in mixed-donor polydentates; an example is the N,O,N-donor bis(pyrazolylethyl)ether,[418] which binds meridionally to Co^{II}. The weak character of the ether bond is illustrated in the reaction of benzylbis(2-ethoxyethyl)phosphine (bbp) with $CoCl_2$.[389] Reacted alone, the tetrahedral $Co(bbp)_2Cl_2$ forms with the ligand a P-bound monodentate; however, when $Ag(O_3SCF_3)$ was included, the octahedral *trans*(P),*trans*(O),*trans*(O)-$Co(bbp)_2(O_3SCF_3)_2$ forms where the ligand is P,O-chelated and in addition the weak ligand triflate is also bound. However, ^{31}P NMR suggests the solution structure is different, with a dimer believed to form.

(n) Macrocyclic. Crown ethers also do not form strong complexes with Co^{II}, and crown ethers with pendant groups carrying strong donors tend to coordinate Co ion via the pendant donors rather than involve the ether oxygens. A measure of the poor capacity of the ether oxygen as a donor is exemplified in the structure of $[Co(ONO_2)(OH_2)_5](NO_3)\cdot H_2O\cdot$(18-crown-6), the product of an attempted crown ether complexation, where the ether oxygens are only linked by hydrogen bonding to coordinated water molecules.[419] However, syntheses leading to ether coordination have appeared, usually in non-aqueous media. Reaction of 15-crown-5 with anhydrous $CoCl_2$ in acetonitrile yields the blue cation $[Co(15\text{-crown-}5)(MeCN)_2]^{2+}$, with the ether surrounding the Co as part of a rare pentagonal bipyramidal structure with apical acetonitrile donors.[420] Hydration leads to replacement of the acetonitrile groups by water, while retaining the intact ether coordination. An ethanol analog is also known, as well as 18-crown-6 complexes. Complexes of $Co(ClO_4)_2$ with 16-crown-5 and a lariat ether derivative 15-(2,5-dioxahexyl)-15-methyl-[16-crown-5] have been prepared and the latter structurally characterized.[421] The Co ion is again heptacoordinated with five crown ether O atoms in the equatorial plane (average Co—O 2.20(2) Å), with a pendant-arm oxygen and a water molecule in apical sites. One novel approach involves reaction of

$Co_2(CO)_8$ with HCl gas in the presence of 15-crown-5 and water in toluene. This led to a complex species which included seven-coordinate pentagonal bipyramidal Co^{II} centers (**98**) which included the metal ion in the macrocyclic polyether.[422]



(**98**)

(vi) Ketones and esters

Monoketones are poor ligands. Di-2-pyridylketone ($(py)_2C{=}O$) accommodates this deficiency in an unusual way when it reacts with $Co(OAc)_2$ to form clusters, including $[Co_4(HQ)_4(OAc)_4]\cdot H_2O$, where the monodeprotonated hydrated gem-diol form of the ketone (HQ^-) (Equation (5)) binds as an ionic ligand.[423] This cluster adopts a tetranuclear cubane shape with four deprotonated O atoms of the diol occupying the alternating vertices to the Co ions.

$$(py)_2C{=}O + H_2O \rightleftharpoons (py)_2C(OH)_2 \rightleftharpoons (py)_2C(O^-)(OH) + H^+ \tag{5}$$

The well-established chemistry of β-diketones has been widely reported previously. These monoanionic enolate chelates readily form complexes with cobalt. A more elaborate recent example is a pyridine with *t*-Bu–CO–CH_2–CO arms attached in the 2- and 6-positions, which acts as a pentadentate tritopic chelator when reacted with Co^{2+} to form the octanuclear cluster $Co_8O_2L_6$.[424] Polyvinyl ketone forms coordination polymers with Co^{II} and other divalent ions which exhibit 1:2 metal:ketone stoichiometry, suggesting the coordination is β-diketone-like.[425] Alkylation of β-diketones at the central C atom has been achieved through reaction of their Co^{II} or Co^{III} complexes with alkyl halides; for example, the adamantyl group has been introduced into pentane-2,4-dione (Hacac) by this route.[426]

The β-ketoesters $[RC(O^-){=}CHC(O)OR]^-$ are close analogs which also chelate effectively. A useful general method for synthesis of Co^{II} compounds of these molecules has been reported, which uses the lithium, caesium, or trimethylsilyl enolate of the β-ketoester reacting with a Co^{II} salt in tetrahydrofuran.[427]

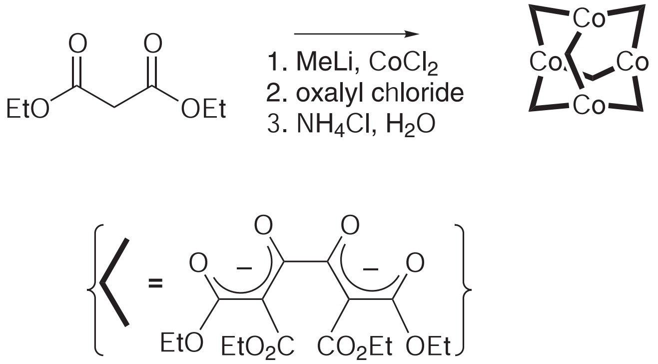
(vii) Amides

Divalent Co complexes of N-bound amides are discussed in Section 6.1.2.2.2. Examples of simple O-bound amides consist of acetamides (H_2NCOCR_3), *N*-alkylacetamides ($R'_3CNHCOCR_3$), *N*,*N*-diakylacetamides ($(R'_3C)_2NCOCR_3$), dimethylformamide (Me_2NCHO) and *N*-alkylpyrrolidones. As an example, acetamide forms an octahedral complex *trans*-$[Co(acetamide)_4(OH_2)_2]^{2+}$, where the Co—O(amide) distance lies in the range 2.10–2.13 Å.[428]

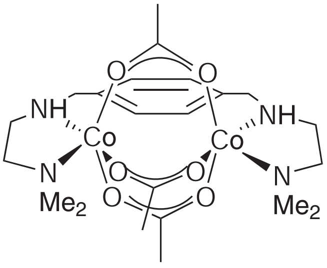
(viii) Carbonates, carbamates, and carboxylates

Carbonate is a well-established ligand, but its coordination diversity continues to surprise. Elaborate bridging modes have been reported for carbonate; for example, a μ_4-carbonato-bridged Co^{II} compound $[Co_2(2,2'\text{-bipyrimidine})(OH_2)_2(\mu\text{-}CO_3)(\mu\text{-}OH)]^+$ has been characterized.[429]

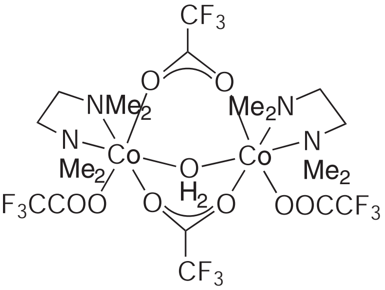
Acetate remains the classical carboxylate ligand, with the capacity to bind in monodentate (μ_1), bidentate chelate (μ_2), or bridging (μ_1:μ_1) modes. Whereas early chemistry featured simple μ_1 coordination, more frequent examples of bridging coordination are now appearing. A typical example is the dinuclear complex with three acetate bridges, $Co_2L_2(OOCCH_3)_3$ (L = bis[(2-dimethylaminoethyl)iminomethyl]benzene,[430] (**99**) where the geometry around each Co is a trigonal bipyramid. Elaborate oligomeric complexes based on heptanuclear Co^{II} fragments supported by carboxylates have been reported, and three heptanuclear cages characterized structurally, including $Co_7(OH)_2(OOCCMe_3)_4(chp)_8(H_2O)_{0.25}$ (chp = 6-chloro-2-pyridonate).[431] The alternate use of phthalate leads to a tridecanuclear cage. Complex (**100**) features both bridging and terminal carboxylates, and reflects the differing reactivities of the two coordination modes, since it undergoes carboxylate exchange reactions with other simple monocarboxylates featuring selective terminal carboxylate substitution by bulky carboxylates.[432] A tetracobalt(II) cluster featuring only oxygen donor anionic ligands can be formed in a relatively straightforward self-assembly reaction (Equation (6)).[433]



(6)



(**99**)

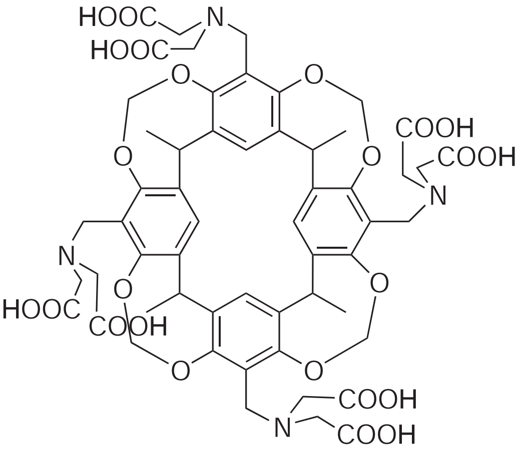


(**100**)

Simple polycarboxylates are well known ligands, and but a few examples appear here. Succinate features in an example of a three-dimensional ferrimagnetic Co^{II} carboxylate, $Co_5(OH)_2(C_4H_4O_4)_4$ which has a three-dimensional array of layers of edge-sharing Co octahedral pillared by succinate ions, the Co octahedra forming 12-membered rings within the layers.[434] This was prepared, in a typical example of hydrothermal reactions for this class of compound, by reacting $CoCl_2$, succinic acid, KOH and water in a 2:3:8:120 ratio in a sealed vessel at 180° for 72 h. Citrate, a member of a class of carboxylic acids found in biological fluids, has a key role in several biochemical processes in lifeforms ranging from bacteria to humans. Previously, its interaction with Co has not been well elucidated, but the synthesis from aqueous solution of a 1:2 Co:citrate mixture at pH 8, and subsequent spectroscopic and structural characterization of octahedral $[Co(citrate)_2]^-$ has now appeared.[435] It may offer a source of bioavailable cobalt.

Pyromellitate, the tetracarboxylate of benzene, forms red crystals of formula $[Co_2(C_6H_2(COO)_4)_4]\cdot 18H_2O$ from aqueous silica gel, and feature infinite chain-like polyanions with $[Co(OH_2)_4[C_6H_2(COO)_4)]_2]_n{}^{2n-}$ stoichiometry where Co is in an octahedral environment of four waters and two *trans*-disposed carboxylates.[436]

An example of a cage molecule based on resorcinarene and carrying polycarboxylate pendants is shown in (**101**). When the ligand was treated in dilute aqueous acid with $CoCl_2$ and the pH raised to ~6 with carbonate ion, $[Co_4L_2]^{8-}$ was formed and characterized by a crystal structure.[437] The two resorcinarene molecules are linked by four octahedral Co^{II} ions each bound to an iminodiactetate unit from separate resorcinarenes, creating an oblate spherical cavity big enough to encapsulate small molecules.



(**101**)

Organic carbamates ($RNHCOO^-$) commonly display monodentate coordination, as exemplified in the structurally characterized tetrahedral $Co(bmc)_2Cl_2$,[438] (bmc = *N*-(benzimidazoyl-2-yl)-O-methylcarbamate). An unusual route to a carbamato complex involves the reaction of $Co_2(CO)_8$ in the presence of a fourfold excess of the stable radical species tmpo, which yields the blue $Co_4O(OOCNC_9H_{18})_6$ cluster, presumably via a $Co(CO)_2(tmpo)$ intermediate, with the nitroxyl radical serving as oxidant.[439]

(ix) Oxoanions of N, S, P, and the halogens

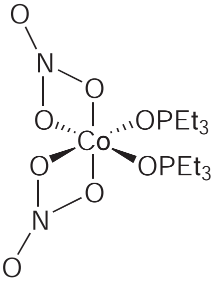
The oxoanions of these elements represent an extensive set of potential ligands, characterized by a dominant, but not exclusive, tendency towards O bonding. Practically every known oxoanion has been introduced into the Co coordination sphere during the last century.

(o) Nitrogen oxoanions. Nitrate and nitrite both bind to Co^{II}, as monodentate or bidentate ligands. Nitrate is found as a monodenate co-ligand in a wide range of structures, as exemplified by octahedral *trans*-$Co(cb\text{-}im)_4(NO_3)_2$ (cb-im = 4′-cyanobenzyl-1-imidazole)[440] It is also met in mononuclear complexes as a bidentate chelate, as in the distorted octahedral $[Co(bpa)_2(NO_3)](NO_3)$ (bpa = bis(2-pyridyl)amine).[441] An example featuring both monodenate and bidentate nitrate in the same complex ion is $Co(ddae)(NO_3)_2$ (ddae = bis(2-(3,5-dimethyl-1-pyrazolyl)ethyl)ethylamine);[442] the Co—O (monodenate) distance is 2.060(8) Å whereas the Co—O (chelate) distances are longer at 2.172(8) Å and 2.216(8) Å, reflecting strain in the four-membered ring.

Syntheses of many nitrato complexes are straightforward, such as by reaction of hydrated cobalt(II) nitrate with stoichiometric amounts of ligand in alcohol, although whether nitrate is incorporated into the coordination sphere or simply acts as a counterion is hard to predict. Perhaps some of the more interesting compounds appearing including coordinated nitrate are the so-called "molecular ladders"; a simple example is $[Co(NO_3)_2(4,4'\text{-bpy})_{1.5}]_\infty$ as MeCN or $CHCl_3$ solvates.[443] This polymeric structure comprises 4,4′-bpy ligands bridging Co centers forming both the rungs and side rails of the ladder, with chelated nitrates completing the Co coordination sphere. The solvent molecules are enclathrated in the large square hydrophobic cavities of the structure.

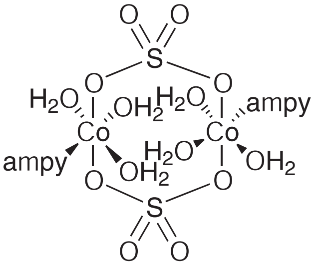
Although the bulk of work with NO_2^- as a ligand features Co^{III}, nitrite can also be O- or N-bonded to Co^{II}, and both modes have been observed in complexes formed by the reaction of several PR_3 compounds with $Co(NO_3)_2$, as well as in mixed nitro/nitroso complexes.[375] The product $Co(NO)(NO_2)(PEt_3)_2$ reacts with dioxygen to form $Co(NO_3)_2(OPEt_3)_2$, a distorted octahedral structure with bidentate nitrate and *cis* phosphine oxides (**102**).

(p) Sulfur oxoanions. The various oxoanions of sulfur are known to bind effectively to Co^{II}, and a few examples will suffice to define the chemistry. Sulfate is reported to bind as either a monodentate or bidentate chelate to divalent Co. Sulfate in a bridging role to Co^{II} has also been observed, as the 2-aminopyrimidine (ampy) complex (**103**), where two bridging sulfates and the two Co^{II} centers form an eight-membered ring.[444] A μ_3-coordination mode for sulfate has been observed in the product of the reaction of $Co(CF_3COO)_2$ with $SOCl_2$ in dimethoxyethane (dme)

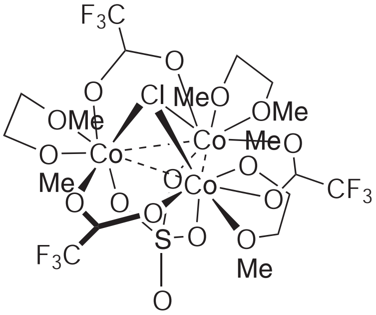


(**102**)

under a nitrogen atmosphere, the cluster $Co_3Cl(CF_3COO)_3(SO_4)(dme)_3$.[445] The Co ions occupy corners of an equilateral triangle, each in a distorted octahedral environment which includes a sulfate ion acting as a tripod ligand bridging to each Co center (**104**). Sulfite is formed as a chelate bound through two O donors when SO_2 is reacted with $[\{(triphos)Co\}_2(\mu\text{-}Cl)_2]^{2+}$; likewise, CO_2 and CS_2 form CO_3^{2-} and CS_2O^{2-} chelates in metal-assisted oxidations.[446]



(**103**)



(**104**)

(q) Phosphorus oxoanions. Phosphate and its protonated forms, as well as polyphosphates, have been well characterized in complexes with divalent cobalt, being involved in monodentate, chelate, and bridging coordination modes. It is usually met with other companion ligands; even simple compounds such as $Na_2Co(H_2PO_4)_4{\cdot}2H_2O$ finds Co in an octahedral environment comprising four dihydrogen phosphates and two aqua ligands.[447] Anhydrous compounds featuring only phosphate ligands such as $Na_4Co_3(PO_4)_2(P_2O_7)$ have appeared, albeit as structurally complex polymeric solids.[448]

Apart from inorganic phosphates, analogs with C—P bonds, the phophonates (RPO_3^{2-}) and phosphinates ($R_2PO_2^-$), are known ligands for Co^{II}. They may be present as the sole ligand; for example, diphenylphosphinate forms the polymeric $[Co(R_2PO_2^-)_2]_\infty$ where the metal is tetrahedrally bound with double phosphinate bridges.[449]

Recently, highly branched macromolecular polyamidoamine dendrimers have been prepared with Co^{II} bound where the metal ions have additional exchangeable coordination sites.[450] These macromolecules show a capacity for catalyzing the hydrolysis of phosphate esters, presumably via intermediate bound phosphoester species.

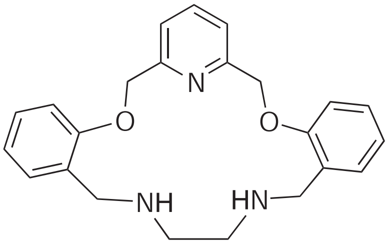
(r) Halogen oxoanions. The suite of oxoacids HXO (hypohalous), HXO_2 (halous), HXO_3 (halic), and HXO_4 (perhalic) in principle all form anions capable of coordination to cobalt. Of all possibilities, perchlorate is the best known of the halogen oxoanions, although it is a weak ligand and met more often as a counter ion. As mentioned in Section 6.1.1.2, ClO_4^- complexes are potentially hazardous due to their inherent thermal instability particularly in coexistance with organic ligands. Nevertheless, there are many examples of it found as a ligand for Co^{II}, for example in tetrakis(2,6-diethylphenylisocyanide)bis(perchlorato)cobalt(II).[451] Also, a Co^{II} corrinate derived from Vitamin B_{12} has been isolated and structurally characterized with a coordinated axial perchlorato ligand bound to the face opposite the one used for nucleotide binding in cobalamin.[452]

(s) Other oxoanions. Transition metal oxoanions can also act as ligands. As an example, the trans-$Co(py)_4(HCrO_4)_2$ complex of Co^{II} with hydrogenchromate(VI) and pyridine has been characterized by an X-ray structure.[453] The complex efficiently oxidizes benzyl halides to aldehydes.

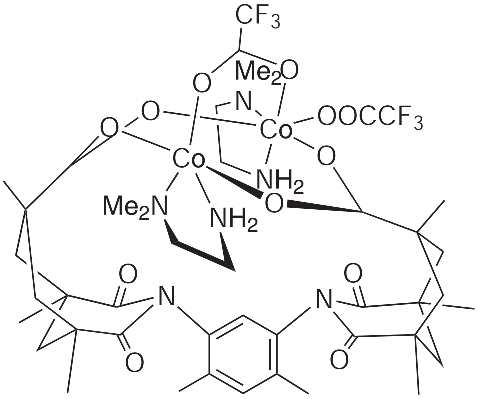
(x) Mixed O, N Donors

Mixed O, N donor molecules are truly extensive and structurally diverse, and only a few selected examples will be presented. In line with other 2-substituted pyridine analogs reported in this chapter, it is worthwhile noting the chemistry of 2-pyridone (or 2-hydroxypyridine, Hopy), which can form O-bonded monodentate complexes such as $Co(Hopy)_4(NO_3)_2$, but as the monoanion is an effective chelate ligand, forming $Co(opy)_2$ and $Co(bpy)(opy)_2$ compounds.[454] An unusual solid state melt reaction with $Co(OAc)_2$ yields the dodecanuclear cluster Co_{12} $(OH)_6(OAc)_6(opy^-)_{12}$.[455]

Polydentate ligands resulting from the Schiff base condensation of primary amines and aldehydic phenols have a venerable history; the products are, when deprotonated, strong ligands for Co^{II} (see Section 6.1.2.2.2). While this chemistry is sufficiently well established to need little discussion, one recent example illustrates the sometimes unexpected outcomes of supposedly straightforward syntheses. Reaction of $Co(OAc)_2$ with salpnH_2 (the propane-1,2-diamine analog of salen) yields a Co^{II} trimer where the two end Co ions are tetracoordinated by the salpn ligands but the phenolic oxygens all bridge to the central Co ion and each terminal Co is also linked to the central Co by a bridging acetate.[456] Macrocyclic polyether–polyamine ligands are an extensive family, which have been widely exposed in the literature. One example is the mixed donor macrocycle (**105**), which forms a $[Co(L)(NO_3)](NO_3)$ complex with all five macrocycle donors coordinated in addition to a chelated nitrate, giving a rare example of seven-coordinate Co^{II}.[457]



(**105**)



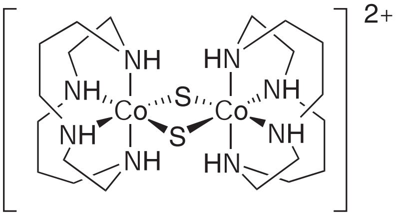
(**106**)

Mixed-donor ligands featuring carboxylate groups appear throughout this chapter. One example of a polycarboxylate-derived ligand is the convergent dicarboxylate ligand formed from Kemp's triacid and xylenediamine, shown as a dinuclear complex in (**106**) with diamine and trifluoroacetate co-ligands. The cobalt(II) complex of this with 2,9-dimethyl-1,10-phenanthroline as co-ligand adopts a highly distorted trigonal bipyramidal geometry. However, in the presence of alkali metal ions the structure adopts an unusual distorted trigonal pyramidal form.[458] Since binding of the alkali metal also leads to significant changes in the visible spectrum, this complex functions as a metallochromoionophore. The participation of this ligand and other carboxylates in dinuclear cobalt(II) binding had been demonstrated earlier,[459] when seeking models of non-heme dinuclear proteins.

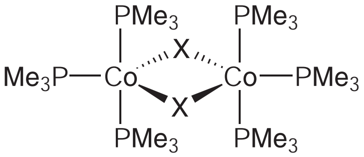
6.1.2.2.6 Sulfur

(i) Sulfides

Sulfide is a well-established ligand for Co. In addition to S^{2-}, the protonated form SH^- is known as a ligand, with a linear polymer of $[Co(cyclam)(SH)]^+$ cations, where the SH^- acts as a bridging group, forming from reaction of $Co(ClO_4)_2 \cdot 6MeCN$ with SH^- in the presence of the cyclam macrocycle.[460] Further, the bridged dinuclear complex $[\{(cyclam)Co\}_2(\mu\text{-}SH)_2]^{2+}$ forms on varying the Co:S ratio, and $[\{(cyclam)Co\}_2(\mu\text{-}S)_2]^{2+}$ (**107**) results if disulfide $S_2{}^{2-}$ is used instead of SH^-, with all products defined by X-ray crystallography. Not only bridging sulfide, but selenide and telluride also, are found in $\{(Me_3P)_3Co\}_2(\mu\text{-}X)_2$ (X = S, Se, Te), featuring a planar Co_2X_2 metallocycle (**108**).[461] These form in a number of ways, including oxidation of $Co(Me_3P)_3Cl$ with Te, Se, or S.



(**107**)

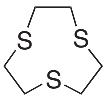


(**108**)

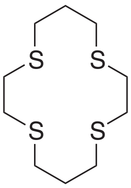
(ii) Thioethers

Thioethers lack the capacity to neutralize positive charge and display weak σ-donor properties. Consequently, they do not readily displace strong donor solvents (water) or strongly bonding anions (such as halides) from the coordination sphere. As a consequence, many thioether complex syntheses employ aprotic or alcoholic solvents and precursor complexes with weakly bound solvents (such as DMSO or acetone) or anions (such as $CF_3SO_3^-$). Despite the synthetic challenges, a wide range of complexes has been reported, particularly with the cyclic polythioethers, where the macrocyclic effect overcomes many of the above difficulties.

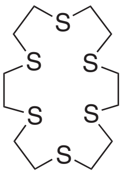
A range of polythioether macrocycles is known, along with mixed thioether–ether and thioether–amine analogs. Macromonocyclic ligands and their Co complexes have been known for some time, with the three most frequently encountered ligands being [9]aneS_3 (**109**), [14]aneS_4 (**110**) and [18]aneS_6 (**111**). Crown thioether chemistry has been reviewed.[462] The most intensively studied cyclic thioether is (**109**), which forms bis-ligand complexes of both Co^{II} and Co^{III}, both six-coordinate, the former Jahn–Teller distorted low-spin.[463] The Co^{II}—S distances range from 2.240(7) Å to 2.356(6) Å. The purple Co^{II} complex may be oxidized reversibly to Co^{III} (+0.68 V) and reduced reversibly to the green Co^{I} (−0.29 V), stabilized by π delocalization. The S_6 crown thioether (**111**) forms a low-spin octahedral complex by reaction with cobalt(II) picrate in refluxing acetone/acetonitrile for a short period, and is one of the few examples of a structurally characterized divalent CoS_6 complex.[464] A $Co^{II}S_6$ Jahn–Teller distorted octahedral complex with Co—S distances in the range 2.251(1)–2.479(1) Å was found.[465] The $Co^{III/II}$ couple (+0.84 V) shifts to a slightly more positive potential (+0.89 V) if the ring size is increased to 24 atoms with additional methylene groups. A much more rapid $Co^{III/II}$ self-exchange electron transfer in the CoS_6 systems compared with CoN_6 analogs ($\sim 10^5$-fold faster) has been assigned for the S ligands to both extensive delocalization of metal electron density over the ligands and a small reorganization of the coordination sphere with oxidation state change due to comparable Co—S distances in the di- and trivalent oxidation states.



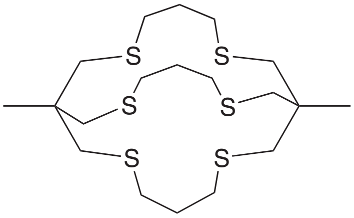
(**109**)



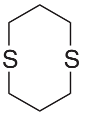
(**110**)



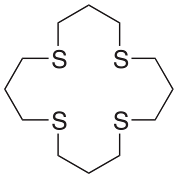
(**111**)



(**112**)



(**113**)



(**114**)

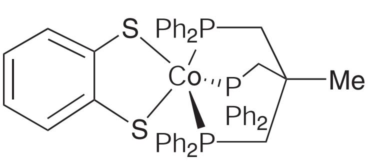
The S_6 macrobicyclic cage (**112**), when complexed to divalent Co, also exhibits four short and two long Co—S bonds in a distorted octahedral environment.[466] Smaller cyclic thioethers such as (**113**) and [16]aneS_4 (**114**) react with $Co(BF_4)_2$ in acetonitrile in the absence of air to form square–pyramidal CoS_4N complexes, with the solvent completing the coordination sphere.[467] A wide range of mixed-donor ligands incorporating thioethers have appeared as ligands for Co^{II}, but their coordination chemistry is generally not unusual. One example of a mixed S,O-macrocycle characterized by a crystal structure is $[Co([20]aneS_4O_2)]^{2+}$.[468]

(iii) Thiolates

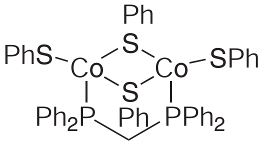
Thiolates (RS^-) represent an extensive family of ligands, and include chelating forms. Thiolates are known to act as monodentate donors, but often act in a bridging role. There is a clear biological interest, through participation of thiolates (cysteine residues) as donors in many metalloproteins both as terminal S donors and bridging ligands in, for example, Fe–S clusters.

Cobalt(II) alkylthiolates of the types $[Co(SR)_4]^{2-}$, $[Co_2(SR)_6]^{2-}$, and $[Co_4(SR)_{10}]^{2-}$ have been reported and structurally characterized.[469] Tetrahedral, dark green $[Co(SR)_4]^{2-}$ ions are fairly well known and studied. The PhS^- complex can be formed by reaction of $Co(S_2COC_2H_5)_3$ with K(PhS) and isolated as the Ph_4P^+ salt.[470] Reaction of $CoCl_2$ with sodium 2-aminobenzenethiolate and Et_4NCl in MeOH yields the tetrahedral $(Et_4N)_2$ $[Co(SC_6H_4NH_2)_4]$, where coordination is through the S (Co—S 2.295(2) Å) and not the N atom.[471] The electronic spectrum implies an equilibrium in solution between the tetrahedral form characterized in the solid state and an octahedral form. A new mixed halide–thiolate cluster complex of cobalt(II) arises from reaction of NaSPh and Et_4NCl with $CoCl_2$ in methanol.[472] The $[Co_4(SPh)_6Cl_4]^{2-}$ cluster ion crystal structure shows the four Cl ions bind to different Co centers and define a tetrahedron, whereas the S-donors are arranged in an irregular octahedron. Each Co center exhibits distorted tetrahedral symmetry, while the core itself consists of a distorted Co_4 tetrahedron.

More complex coordination modes can arise if other potential donors are in appropriate positions. For example, reaction of anhydrous $CoCl_2$ with tris(*t*-butoxy)silanethiol (tbstH) in acetonitrile in the presence of Et_3N as base yields $Co(tbst)_2(MeCN)$, where the $tbst^-$ chelates through the S and one of the O atoms to form a trigonal bipyramidal structure.[473] Chelated dithiolates also form complexes with Co^{II}; the classical chelator *o*-$C_6H_4S_2{}^{2-}$ binds in a complex with a $Co^{II}S_2P_3$ donor set, with a tripodal phosphine occupying the other sites (**115**).[474] The 2,3-disulfanylmaleonitrile chelate binds in a square–planar $Co^{II}S_4$ arrangement with stacking in the crystal allowing for S atoms to interact axially with another Co center.[475]



(115)

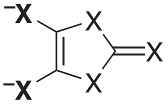


(116)

Thiolates often bind in concert with other strong donors. An unusual example is the dimeric $Co_2(dppm)(\mu\text{-}SPh)_2(SPh)_2$, which displays terminal and bridging modes for the thiolate, as well as bridging by the diphosphine ligand in (**116**).[476] Clusters $[Co_3(\mu\text{-}SR)_6(PEt_3)_3]^+$ involving thiols and phosphines form readily from the reaction of an alkylthiolate with cobalt(II) acetate in the presence of excess PEt_3.[477] The three cobalts form a triangle, with six symmetrically bridging thiolates and a terminal phosphine on each cobalt. The cluster can be oxidized or reduced in one-electron steps.

Thiolates coupled with other donors are effective chelators. Pyridine-2-thiolate (pyt) forms four-membered chelate rings to Co^{II} in $Co(pyt)_2$ compounds which are conveniently formed by anodic oxidation at a Co electrode in an acetonitrile solution of the ligand.[478] These are able to be oxidized further to tris(pyt)cobalt(III) compounds. The ligand 2-methyl-1-[methyl-(2-pyridin-2-ylethyl)amino]propane-2-thiolate (pyat) forms distorted tetrahedral cobalt(II) complexes Co(pyat)X- (X = Br, SCN), where pyat acts as an N_2S-tridentate, the first examples of this type defined by crystal structures.[479] Four-coordination appears to persist in solution regardless of solvent, and only one diastereomer is detected and predicted by molecular mechanics due to a favorable conformation of the ligand. It is suggested the complexes are structural mimics of metalloproteins such as peptide deformylase, which possess a His_2Cys site. Cobalt(II) binding to thiolates in biological molecules has been probed. Interaction of a 34-amino acid peptide derived from α-fetoprotein with cobalt(II) and zinc(II) has been examined by UV–visible and CD spectroscopy, and coordination by two thiolate (from cysteine) and two imine (from histidine) donors with similar protein conformations is implied.[480] The Co ion acts in the opposite way to the zinc in the sense that the former catalyzes the loss of the anti-growth form of the peptide whereas with the latter there is stabilization.

1,1-Dithiolates ($R_2C{=}CS_2^{2-}$) and analogs dithiocarbimates ($RN{=}CS_2^{2-}$), trithiocarbonates ($^-S–CS_2^{2-}$), and dithiocarbonates ($^-O–CS_2^{2-}$) were introduced in *CCC*(1987) (Section 47.8.10),[1] and will not be exhaustively reviewed here. The dithiolates and their selenium analogs have continued to attract attention because of potential applications of their complexes as superconducting materials; the first molecular superconductor was a nickel dithiolate complex. One extensively studied family of ligands is 1,3-dithiole-2-thione-4,5-dithiolate (dmit) and its isologs (**117**).[481,482] Although work has concentrated on Ni and Pd chemistry, complexes such as $[Co(dmit)_2]^{2-}$ have been reported, along with mixed-ligand species such as $[Co(Cp)(dmit)]^-$.



(**117**) [X = S, Se]

(iv) Dithioacids and thiosemicarbazones

The dithioacid family of ligands includes dithiocarbamates ($R_2N–CS_2^-$), xanthates ($RO–CS_2^-$), thioxanthates ($RS–CS_2^-$) and dithiocarboxylates ($R–CS_2^-$), which have been described in *CCC*(1987, Section 47.8.10).[1] The ligands are prepared by addition of a suitable nucleophile to the carbon center in CS_2, usually in the presence of a base. It has been established for some decades that they bind to Co almost exclusively as bidentate chelates, including S-donors acting as bridging ligands in dinuclear systems.

Chelating thiosemicarbazone ($RNH–CS–NH–N{=}CR'R''$, Htsc) complexes of Co^{II} were briefly mentioned in *CCC* (1987, Section 47.8.6), with tetrahedral, trigonal bipyramidal, and octahedral forms known for compounds of empirical formula $Co(Htsc)_2X_2$ ($X = Cl^-$, Br, I^-), the geometry influenced by R groups present. Chelation as an *S*,*N*-bidentate is dominant, but not exclusive, with *N*,*N*-bidentate known. Since the last edition, driven by potential medical applications as fungicides and antimicrobials, more extensive examples of thiosemicarbazone cobalt(II) complexes have appeared, with 1, 2, 3, or 4 donors coordinated, almost invariably including the S and usually a N atom as donors. The ligands commonly bind in an N-deprotonated (thiolene) form, although neutral coordination (as a thione) can occur.[483] Reported complexes are typically mononuclear, although coordination polymers have been proposed. Octahedral coordination has been proposed in most cases, though tetrahedral and trigonal bipyramidal geometries have been suggested. For example, octahedral $Co(mftsc)_2X_2$ and tetrahedral $Co(mftsc)X_2$ (with mftsc = 5-methyl-2-furaldehyde thosemicarbazone) have been reported, with coordination through both the S and azomethine N atoms supported.[484]

Ligands of higher denticity have appeared. Tridentate coordination as an S,N,O-donor is reported for the cobalt(II) complex of salicylaldehyde N(4)-cyclohexylthiosemicarbazone, with four- or five-coordinate complexes proposed where additional sites are occupied by heterocyclic bases.[485] A mixed ligand complex $Co(stsc)(amN)_3$ where stsc = salicylaldehyde thiosemicarbazone and amN is an aromatic amine has been reported, with the stsc bound as an S,N,O-tridentate dianion.[486] Methyl 2-pyridyl ketone thiosemicarbazone forms a bis(tridentate)cobalt(II) complex with N_4S_2-coordination, from spectroscopic evidence and by analogy to the crystal structure of the copper(II) analog.[487] Tridentate S_2N-binding is proposed in octahedral cobalt(II) complexes of 2-acetyl thiophene thiosemicarbazone, involving the azomethine N, cyclic thioether S and thiol S.[488] The complexes proved effective as fungicides against several species. Vanillin thiosemicarbazone (vtsc), as the $[Co(vtsc)_2(H_2O)_2]^{2+}$ complex, also displays fungicidal activity.[489] Tetradentate (N_2S_2-donor) examples bound to cobalt(II) of the form benzil-bis(4-alkylthiosemicarbazone) have been proposed, where the dianion forms apparently octahedral $Co(dtc)(OH_2)_2$.[490]

Introduction of an organometallic moiety has been achieved by coupling ferrocenecarbaldehyde with thiosemicarbazide, with the resulting thiosemicarbazone (fctsc) forming the presumably octahedral cobalt(II) complex $Co(fctsc)_2Cl_2$,[491] which showed antibacterial activity. Acetylferrocene thiosemicarbazone complexes of Co were reported earlier,[492] including a species of the same form as that given above.

The cobalt(II) complexes may be readily oxidized to cobalt(III) species. For example, use of different cobalt(II) salts in syntheses have been reported to direct the formation of either tetrahedral cobalt(II) species or oxidized octahedral cobalt(III) species.[493] Also, μ-peroxodicobalt(III) complexes of 2,6-diacetylpyridine-bis(N(4)-azacyclic thiosemicarbazones) form by rapid reaction of the cobalt(II) complex in organic solvents with oxygen; the kinetics have been probed in detail.[494]

Fungicidal activity of cobalt(II) and other divalent metals of tsc compounds have been observed, and is usually greater than for the free ligand.[495] Broad antimicrobial activity has been reported for the cobalt(II) complex of acetophenone-4-(2′-carboxy-5′-sulfophenyl)-3-thiosemicarbazone.[496]

(v) Thioureas

Thiourea ($H_2NC(S)NH_2$, tu), as typically an S-bound monodentate ligand, has been commonly observed. The simple S-bound tetrahedral tetrakis(thiourea)cobalt(II) ion has been defined by an X-ray crystal structure.[497] The S-coordination of thiourea has also been defined in high-spin, octahedral cobalt(II) complex $Co(phen)(tu)(H_2O)Cl_2$.[498] A similar coordination mode is observed in aqua(thiourea)(semicarbazidediacetato)cobalt(II).[499] Cobalt(II)-coordinated thiourea has also been defined in a crystal structure of Co(tsd)(tu) (tsd = thiosemicarbazide diacetate).[500] Digestion of $[Co_2(CNCHMe_2)_{10}]^{4+}$ in ethanol with an excess of thiourea produces octahedral monomers *trans*-$[Co(CNCHMe_2)_4(tu)_2]^{2+}$,[501] rather than the presumed initial cleavage and addition product $[Co(CNCHMe_2)_5(tu)]^{2+}$, assigned to a preference for a structure with two strongly σ-bonding ligands in *trans* dispositions. Lability of the thiourea cobalt(II) systems has been probed in a study of ^{60}Co exchange in $Co(SCN)_2(tu)_2$.[502]

Substituted thioureas have been extensively studied over the decades. Reaction of CoX_2 (X = Cl, Br) with substituted phenylthioureas yield a range of complexes involving halide and thiourea as ligands, characterized by spectroscopy and thermogravimetric analysis.[503] Both $[Co(Rtu)_4(OH_2)_2]^{2+}$ (Rtu = thiourea, phenylthiourea, allylthiourea) and $[Co(Rtu)_2(OH_2)_4]^{2+}$ (Rtu = diphenylthiourea) have been prepared and characterized as low-spin octahedral species.[504] The octahedral bis(phenylthiourea)bis(dithiolate)cobalt(II) complex, one of a number of complexes of phenylthiourea, chlorophenylthiourea and bis(diphenylphospinothioyl)methane prepared and characterized,[505] proved the most biologically active of those tested.

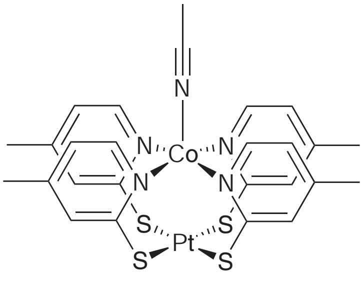
Chelated species are less common. The substituted thiourea *N*-ethoxycarbonyl-*N*-[3-(*p*-anisyl) pyrazol-5-yl]thiourea (eatu) acts as a monoanionic O,S-chelate to cobalt(II), forming $Co(eatu)_2$.[506] Whereas ethylenethiourea (etu) has been observed to act as a S-donor monodentate in $Co(etu)_2X_2(H_2O)_2$ (X = Cl, Br), it binds as an S,N-chelate in $Co(etu)_2(OOCCH_3)_2$.[507] Both violet octahedral and blue tetrahedral cobalt(II) compounds $Co(pptu)_2Cl_2$ and $Cp(pptu)Cl_2$ respectively were prepared with bidentate *N*-2-(5-picolyl)-*N*′-phenylthiourea (pptu) chelated.[508] Refluxing Co powder with thiourea in 4-methylpyridine provides a route to isothiocyanates, which form by decomposition of thiourea to ammonium thiocyanate[509] with one product, $Co(pic)_4(NCS)_2$, characterized by a crystal structure.

(vi) Mixed S, N and S, O ligands

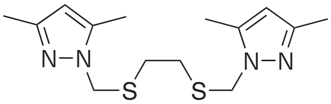
Ligands with S donors in addition to N and or O donors bound to Co^{II} are reasonably large in number. For example, the 4-amino-3-alkyl-1,2,4-triazole-5-thione can bind Co^{II} as a chelate employing the primary amine and thione substituents on the five-membered ring,[510] whereas the trifluoromethyl ligand (afmt) forms $[Co(afmt)_2(H_2O)_2](NO_3)_2$, defined as the all-*trans* isomer by a crystal structure.

The simple ligand 4-methylpyridine-2-thiolate (pyt) participates in a lantern-type heteronuclear complex $(MeCN)Co(pyt)_4Pt$ where the four thiolate groups bind Pt^{II} in its preferred square–planar arrangement while the four pyridine groups and the acetonitrile bind the Co^{II} center in a square–pyramidal geometry (**118**).[511] The complex forms readily by reaction of $[Pt(pt)_4]Cl_2$ with $CoCl_2$ in basic solution, and the complex characterized was obtained following recrystallization from acetonitrile. The complex has a close Co—Pt distance of 2.573(2) Å, enforced by the short donor separation in the bridging ligands.

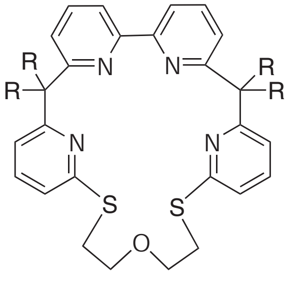
An unusual *S*,*N*-chelate is the anion $R'NH{-}PR_2{-}S^-$, which has no carbon atoms amongst the four-membered chelate ring atoms, and forms a tetrahedral bis Co^{II} "spirocyclic" complex.[512] Higher denticity ligands also feature in the literature. A dipyrazoyl-dithioether ((**119**), bddh) forms a simple octahedral *cis*-α-$Co(bddh)(NCS)_2$ complex.[513] The ketal coronand (**120**) forms a complex with Co^{II} which leads to a change in orientation of the bipyridyl unit from *anti* in the free ligand to *syn* in the complex.[514] One example of a simple S,O chelate reported is the dianion of 2-mercaptophenol (spo). This forms strong complexes of the type $[Co(spo)_2]^{2-}$, clearly defined in a crystal structure determination.[515]



(118)



(119)



(120)

6.1.2.2.7 *Halogens*

(i) Halides

Halides are common coligands, partly because Co^{II} halides feature as a common entry point into Co chemistry. As such, examples are scattered throughout the chapter.

(t) Mononuclear. Cobalt(II) with halide ligands alone occurs in the well-known tetrahedral $[CoX_4]^{2-}$. Electrochemical oxidation of Co in a HX/acetonitrile solution containing a neutral tertiary phosphine provides a route to crystalline $[CoX_4]^{2-}$ as the phosphonium salts.[516] The same complex anion has also been reported with rhenocene cations, as $[Cp_2Re]_2[CoBr_4]$, characterized by a crystal structure.[517] The 1,5-pentanediammonium form of $[CoCl_4]^{2-}$ has also appeared.[518] Apart from $[CoCl_4]^{2-}$, the ions $[Co_2Cl_6]^{2-}$ and $[CoCl_3(MeCN)]^{-}$ have been structurally characterized as counterions to a Co^{II} crown ether complex cation.[420]

Speciation of halocobalt(II) compounds in solution has been examined. Absorption spectra of $CoCl_2$ and $CoBr_2$ in aqueous halide solutions (up to 5 M) were measured over the temperature range 25–90 °C and used to probe speciation in solution.[519] At low temperatures and halide concentrations, octahedral aquahalo complexes dominate, with a transformation to tetrahedral $[CoX_4]^{2-}$ complexes occurring as temperature and halide ion concentration rises. Thermodynamic data for all complexation reactions were determined, and geological implications discussed. Octahedral/tetrahedral transformations have also been probed in the molten state, with addition of halide ion (Cl, Br) to cobalt(II) in ammonium/calcium nitrate melts leading to apparently tetrahedral species with at least two halide ions coordinated to the Co ion.[520] From spectroscopic studies, extraction of cobalt(II) halides from aqueous solution with quaternary ammonium chloride and bromide salts is thought to involve formation of dinuclear anionic complexes.[521] The kinetics of complex formation reactions for cobalt(II) with halide ions (Cl, Br, I) have been studied,[522] and an associative interchange mechanism proposed.

The simple tetrahedral $[CoX_4]^{2-}$ ions can undergo substitution, with neutral species such as $Co(L^+)Cl_3$ reported [$L^+ = $(1H-benzimidazol-2-ylmethyl)-(ethyl)ammonium-N-3)],[523] as well as the long-established CoL_2Cl_2 species with neutral ligands such as monoimines.

Mixed ligand halocompounds abound, and only a few illustrative examples of simple complexes appear here. Octahedral dihalotetra(imine)cobalt(II) complexes of the simple monoimines butyraldoxime and acetaldoxime with the halogens chloride or bromide were prepared and characterized by X-ray structures, which revealed stabilization arising from intra- and in one case inter-molecular hydrogen bonding.[524] Decomposition occurs, however, in a moist atmosphere. Cobalt(II) chloride and bromide reacted with aminopyridines yielded complexes that were characterized by a range of physical methods, with the propeller-shaped octahedral complex $Co(3\text{-aminopyridine})_4Cl_2$ characterized by a single crystal X-ray structure.[525]

Surface complexation to form a tetrahedral $Co(L)X_2$ species is proposed to account for the adsorption of cobalt(II) chloride and bromide from acetone and ethanol solution onto silica gel modified with 3-amino-1,2,4,-triazole,[526] supported by electronic and ESR spectroscopy.

(u) Oligonuclear and polymeric. Halides are well established as bridging ions in a wide range of coordination polymers, and feature in this role as one of several ligands in often complicated structures. The facile formation of triangulo–trihalocobalt(II) moieties, similar to Ti, V, Fe, and Ni homologs, and their structural characterization represents an interesting sub-class, featuring compounds such as $[Co_3Cl_5(tmen)_3]^+$.[527] One apical halide is readily replaced by hydroxide.

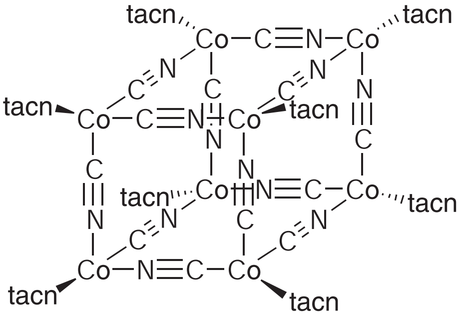
6.1.2.3 Co^{III}

Trivalent Co is one of the most thoroughly investigated ions in transition metal chemistry. The overwhelmingly inert and mostly diamagnetic complexes encountered offer ease of handling and facile spectroscopic characterization, which have assisted to drive the field. Six-coordinate octahedral geometry is particularly dominant in this oxidation state, with nitrogen donors particularly favored. Nevertheless, a range of other coordination numbers (from four to seven) and geometries has been observed. Despite a century of exploration, cobalt(III) chemistry continues to reward and surprise the investigator.

6.1.2.3.1 Carbon

(i) Cyanides

Cyanide has an extended history as a ligand for Co^{III}, and only some aspects will be mentioned here. The $[Co(CN)_6]^{3-}$ ion is well known, and mononuclear Co^{III} complexes with a mixture of cyanide and other ligands abound in the literature; some examples appear elsewhere in this chapter. The pentacyanocobalt(II) ion reacts in solution with air to form peroxo-bridged (and, on oxidation, superoxo-bridged) Co^{III} dimers $[\{(CN)_5Co\}_2 (\mu\text{-}O_2)]^{5-/6-}$. With Co^{III}-cyanide complexes usually C-bound, one important paper reports the isolation of the elusive isocyano complex $[Co(NH_3)_5(NC)]^{2+}$, formed through a selenium-abstraction reaction involving N-bound selenocyanate.[528] One other interesting recent example is the $[Co(dbsq)(CN)_4]^{2-}$ octahedral ion, which includes the chelated radical anion of 3,5-di(*tert*-butyl)-1,2-semiquinone (dbsq).[529] The complex was characterized by a crystal structure and by ESR spectroscopy, and was formed by reaction of the Co^{II} tetramer $[Co(dbsq)_2]_4$ with $Bu_4N(CN)$ in THF via a cyanide-induced redox reaction. The coordinated cyanides display the usual essentially linear Co—CN bonds with average Co—C distances of 1.89(2) Å. An interesting example of bridging cyanide occurs in the trivalent Co cluster $[Co_8(tacn)_8(CN)_{12}](OTs)_{12}$ (**121**), which forms from boiling equimolar mixtures of $[Co(tacn)(OH_2)_3](OTs)_3$ and $Co(tacn)(CN)_3$ in water.[530] The tridentate tacn ligands cap the "external" coordination sites of each Co ion situated at a vertex of the cube.



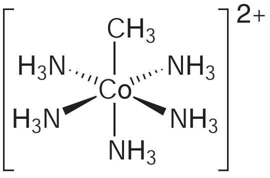
(**121**)

(ii) Carbonyls

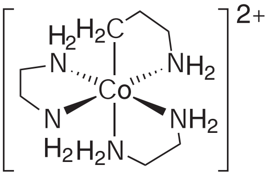
High-valent Co complexes incorporating carbonyl ligands are rare, and those extant are outside the scope of this review. The companion series *Comprehensive Organometallic Chemistry* covers this area.

(iii) Alkyls and aryls

The Co^{III}–alkyl bond was established some time ago with the characterization of simple complexes with Co—CH_3 or other Co—R groups. Incorporation of R^- as an axial ligand in Co^{III} porphyrins, Schiff base and bis(dimethylgloximato) compounds were early types defined, and examples continue to appear. This is a key feature of cobalamin (B_{12}) model complexes and a review of this area appears in Section 6.1.3.1.1. The deceptively simple isoelectronic alkyl homologs of $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$, (**122**)[531] and (**123**), have appeared since the first edition of *CCC*.[532,533]



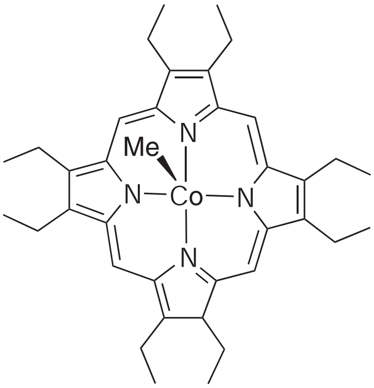
(**122**)



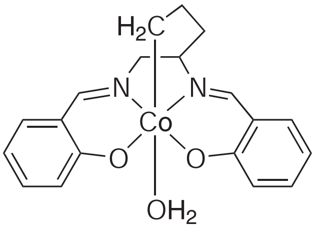
(**123**)

Introduction of several CH_3^- ligands into the Co^{III} coordination sphere is facilitated with phosphine ligands in other sites. For example, the octahedral $[Co(CH_3)_2(PMe_3)_4]^+$ is known, and the Co—C bonds are sufficiently stable to be unaffected by phosphine exchange in THF with the chelate dmpep ($Me_2PCH_2CH_2PMe_2$), which results in $[Co(CH_3)_2(PMe_3)_2(dmpep)]^+$.[534]

Trivalent five-coordinate methyl (**124**) and six-coordinate (*trans*) methyl pyridyl complexes of the octaethylporphyrin dianion (OEP) have been reported.[535] In (**124**) the square–pyramidal geometry results in an axial Co—C distance of 1.973 Å and the Co is displaced 0.10 Å out of the porphyrin plane towards the methyl group. The latter complex, with a pyridine *trans* to the methyl ligand, finds the Co ion centered in the plane of the porphyrin and with a Co—C distance of 2.018 Å; the elongation reflecting a strong mutual *trans* effect of the Me and py axial ligands. This is relevant to the methyl transfer ability of these complexes as B_{12} mimics (Section 6.1.3.1.1), as base coordination in the site *trans* to the Me ligand accelerates Co—C homolysis in the natural systems. The ethyl analog of (**124**) has also been characterized.[536]



(**124**)

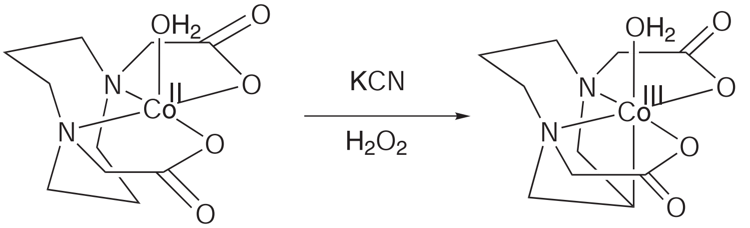


(**125**)

Introduction of a pendant coordinated alkyl chain to Co(salen) has been achieved through condensation of salicylaldehyde with the branched ethylenediamines $H_2NCH((CH_2)_nCl)CH_2NH_2$ ($n = 2–5$). Complexation to Co^{II}, reduction to Co^I, and subsequent intramolecular alkylation results in the novel complex (**125**).[537] Oxidative addition of several alkyl halides to the Co^I compound generated on reduction of divalent $[Co(pabo)(Hpabo)]^{2+}$ (Hpabo = 2-(2′-pyridylethyl) amino-3-butanone oxime) led to the alkylcobalt(III) compounds $[RCo(pabo) (Hpabo)]^+$.[538] A pseudo-octahedral geometry was defined by several crystal structures, with Hpabo and pabo acting as bi- and tridentates respectively, and the alkyl group occupying the remaining site.

A series of trivalent organocobalt complexes of the form $[RCo(cyclam)(OH_2)]^+$ have been reported, where R = Me, Et, Pr, CH_2Cl, CH_2Br, CH_2OMe, and CH_2Ph.[539] These compounds are photosensitive, decomposing to Co^{II} and carbon-centered radicals when irradiated with visible light. These carbon-centered radicals abstract hydrogen atoms from thiols (C_2H_5SH, cysteine, or glutathione), generating thiyl radicals.[540] In the absence of light, the alkyl complexes are air-stable in acidic aqueous solutions whereas the benzyl complex undergoes rapid homolysis of the Co—C bond. Visible light photolysis of the methylcobalt(III) complex causes nicking of supercoiled DNA; the complex is inactive in the absence of light, implying a photo-initiated radical mechanism.[541]

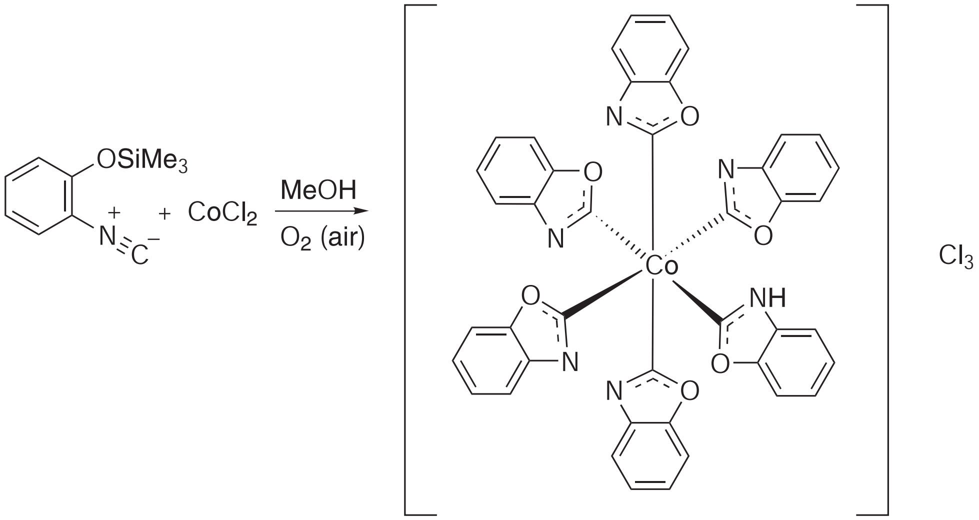
Reaction of the 1,5-diazacyclooctane-*N*,*N*′-diacetate complex (**126**) with H_2O_2 in the presence of KCN forms an octahedral complex (**127**) containing the now pentadentate ligand coordinated through a deprotonated carbon atom in addition to the N_2O_2 donors. A particularly short Co—C distance (1.941(4) Å) was found.[542] The cyclic thioether 1,4-diaza-7-thiacyclodecane was prepared recently, and, in addition to the anticipated N_2S-bonded Co^{III} complex, a C-bonded form involving the anion 1,4-diamino-7-thiacyclodecan-8-ide was described.[543]



(**126**) (**127**)

Carboranes also offer the capacity for Co^{III}—C bond formation. Perhaps the best-known example of a mixed cyclopentadienyl–metallocarborane sandwich complex is the cobalt(III) compound (Cp)Co(1,2-$C_2B_9H_{11}$), which serves as a precursor for other species.[544]

Ylide compounds of cobalt(III) have been reported, but are usually traditional organometallic compounds. For example, the cobalt(III) ylide complex $[(Cp)Co(CH_2PMe_3)(PMe_3)Br]^+$ made from a labile Co^I precursor has been described.[545] Reaction of *o*-C_6H_4 ($OSiMe_3$)(NC) with $CoCl_2$ in methanol in the presence of air affords an octahedral Co^{III} complex ion (**128**) with a monocarbene ligand producing a $Co^{III}C_6$ environment.[546] This is similar to the analogous oxazolidin-2-ylidene chemistry.[547] The monoanionic tricarbene ligand hydrotris(3-ethyl-imidazoline-2-yliden-1-yl)borate (triset) forms the Co^{III} complex $[Co(triset)_2](BF_4)$.[548] From its crystal structure, the hexacarbene complex does not display M—C multiple bonding, which might have been expected with an electron-rich stabilized carbene and a high-valent metal.



(**128**)

6.1.2.3.2 Silicon and tin

There appear to be no well-characterized Co^{III}—Si bonded compounds. Interactions with silicates, particularly on surfaces, are through oxygen atoms. The use of the complex $[Co(en)_2(LL)]Cl_3$ (where $LL = (MeO)_3SiCH_2CH_2CH_2NHCH_2CH_2NH_2$) permits bonding of the substitution-inert CoN_6 species to a silica surface.[549]

There are few well-established examples of Co^{III}—Sn bonds. Stannanes R_3SnH react with OEP complexes (**124**) or the divalent Co(OEP) to form $Co(OEP)SnR_3$.[550] This is also accessible from R_3SnCl and $[Co^I(OEP)]^-$. The structure shows a square-pyramidal Co displaced 0.777 Å out of the porphyrin plane and towards the Sn, which is 2.510(2) Å distant from the Co^{III} center.

6.1.2.3.3 Nitrogen

(i) Amines

The trivalent Co coordination chemistry of amines is simply immense. Amines, both mono- and multidentate, are typically thermally and air stable, often commercially available, easily derivatized, and are well matched to the electronic needs of trivalent Co. Space does not permit a discussion of all categories of amines that have been investigated since *CCC*(1987) nor their limitless permutations when bound to mostly six-coordinate Co. Much of the synthetic and mechanistic work that underpins Co amine chemistry has long been known and will not be restated here. The emphasis here will be on novelty rather than breadth. That is, recent innovative aspects of the structure, reactivity, and applications of selected, but representative, collections of these simple but ever-present compounds will be our focus.

(v) Monodentate. The hexaamminecobalt(III) ion is the simplest closed-shell octahedral coordination compound of the first transition series. With only 84 electrons and effectively no conformational isomers, the $[Co(NH_3)_6]^{3+}$ ion has been an ideal subject for computational chemists. Quantum mechanical calculations have dealt with vibrational[551–553] and electron transfer[554–559] properties of this ion. Ligand field[560] and molecular mechanics[561–563] calculations have also been reported.

The $[Co(NH_3)_6]^{3+}$ ion is inert to substitution reactions, like most Co^{III} compounds, and it possesses a high positive charge and 18 strong hydrogen bond donors. These features result in the complex ion having a strong tendency for ion pairing, and a number of investigations of the association between the complex and inorganic anions have been reported.[564–571] Liquid crystalline phases containing the $[Co(NH_3)_6]^{3+}$ ion have also been studied.[572,573] Second sphere coordination of $[Co(NH_3)_6]^{3+}$ through NH···O bonding to ionophores such as crown ethers are also well known.[574,575] The affinity of $[Co(NH_3)_6]^{3+}$ for DNA and RNA has been the subject of a considerable amount of attention but discussion of this topic is deferred until Section 6.1.3.1.4.

However, there are a number of other miscellaneous biological roles played by this complex. The $[Co(NH_3)_6]^{3+}$ ion has been shown to inhibit the hammerhead ribozyme by displacing a Mn^{2+} ion from the active site.[576] However, $[Co(NH_3)_6]^{3+}$ does not inhibit ribonuclease H (RNase),[577] topoisomerase I,[578] or hairpin ribozyme,[579] which require activation by Mg^{2+} ions. The conclusions from these studies were that an outer sphere complex formation between the enzyme and $Mg_{aq}{}^{2+}$ is occuring rather than specific coordination of the divalent ion to the protein. These results are in contrast to DNase I inhibition by the same hexaammine complex. Inhibition of glucose-induced insulin secretion from pancreatic cells by $[Co(NH_3)_6]^{3+}$ has been found.[580] Intracellular injection of $[Co(NH_3)_6]^{3+}$ into a neurone has been found to cause characteristic changes to the structure of its mitochondria, and this offers a simple technique to label neuronal profiles for examination of their ultrastructures.[581]

The solid state chemistry of various $[Co(NH_3)_6]^{3+}$ salts has been investigated. Phase transitions[582] and conformational changes[583] have been studied by variable temperature crystallography. The thermal decomposition of a number of $[Co(NH_3)_6]^{3+}$ salts has been reported.[584–587]

Outer-sphere electron transfer reactions involving the $[Co(NH_3)_6]^{3+/2+}$ couple have been thoroughly studied. A corrected $[Co(NH_3)_6]^{3+/2+}$ self-exchange electron transfer rate ($8 \times 10^{-6}\,M^{-1}\,s^{-1}$ for the triflate salt) has also been reported,[588] which is considerably faster than an earlier report. A variety of $[Co(NH_3)_6]^{3+/2+}$ electron transfer cross reactions with simple coordination compounds,[589] organic radicals,[590,591] metalloproteins,[592] and positronium particles (electron/positron pairs)[593] as redox partners have been reported.

The simplest member of the hexakis-alkyamines, $[Co(MeNH_2)_6]^{3+}$, possesses a prominent UV ligand-to-metal charge transfer transition.[594] The hexaamine and a number of $[Co(MeNH_2)_5X]^{2+}$ (X = halide) analogs exhibit photoactivity, with ligand substitution, i.e., release of $MeNH_2$, occurring upon either excitation into the N → Co or X → Co LMCT bands. Incorporation of these complexes into thin films of the copolymer of glycidyl methacrylate and ethyl acrylate gave a photosensitive material that underwent base-initiated crosslinking upon exposure to 254 nm radiation.[594,595] This property may be utilized for pattern delineation at the 1–2 μm level. Higher hexakis-alkylamines of Co are yet to be synthesized.

(w) Multidentate. The $[Co(en)_3]^{3+}$ ion is one of the most commonly encountered coordination compounds in undergraduate teaching laboratories as both a precursor [596,597] and as a product.[598] The chirality of the $[Co(en)_3]^{3+}$ complex ion is central to many studies of its chemistry, and it has been the subject of many fundamental investigations that have dealt with the influence of a chiral molecule on its environment and its spectroscopy. There are numerous X-ray crystal structures of both racemic[599–609] and resolved[610–614] $[Co(en)_3]^{3+}$ salts of both simple and complex anions. A novel isotopic crystallographic study[615] found that deuteration of $([Co(en)_3](C_2O_4)I)_2 \cdot 3H_2O$ led to crystallization of $([Co(d_4\text{-}en)_3]I_2 \cdot D_2O)_2(C_2O_4)$ as a racemate in a centrosymmetric space group whereas the nondeuterated analog crystallized in an acentric space group. The isotope effect on the strength of intermolecular H bonding was held responsible for this unusual phase transformation.

It is usually found that the conformation of the three chelate rings in $[Co(en)_3]^{3+}$ is such that each C–C vector lies approximately parallel (*lel*) with respect to the molecular C_3 axis. This has been examined with a number of experimental and theoretical methods including NMR and IR,[616] vibrational circular dichroism[617] spectroscopy as well as molecular mechanics calculations.[618]

Ion-pairing constants of $[Co(en)_3]^{3+}$ with simple inorganic anions have been reported[571,619] and the rotational correlation times of ion-paired complexes with lanthanoid complex anions have been studied.[620] More specifically, and fundamental to the resolution of racemic $[Co(en)_3]^{3+}$ mixtures, are diastereoselective ion pairing investigations with chiral anions such as tartrate. This has continued to be a major focus of investigation with a variety of theoretical,[621] chromatographic[622–625] and spectroscopic techniques including circular dichroism[626] and NMR.[627]

The adsorption[628] and ion exchange[629–631] reactions of chiral $[Co(en)_3]^{3+}$ with clays have been studied. When the $[Co(en)_3]^{3+}$ ion exchanges with lamellar clays such as fluorhectorites, it increases the interplanar separation of the lamellae and influences the selectivity for intercalation of small molecules and atoms (H_2, D_2, Ne, and O_2) within the clay over larger ones such as isobutane and neopentane.[631]

The $[Co(en)_3]^{3+}$ ion has been shown to be a useful template for the synthesis of unusual cobalt, aluminum, gallium, and magnesium phosphates exhibiting framework,[632–637] layered[638–641] and chain[642] structures, as well as for the hydrothermal synthesis of novel zeolites[643,644] and other framework structures such as molybdenum phosphates.[645]

A number of electrochemical studies of the $[Co(en)_3]^{3+/2+}$ couple have been reported, investigating the effects of pressure[646,647] and solvation[648,649] on the redox potential and electron transfer rate. The self-exchange $[Co(en)_3]^{3+/2+}$ electron transfer rate has been determined, and its pressure dependence investigated.[650] Outer sphere electron transfer cross reactions of the $[Co(en)_3]^{3+}$ ion with a variety of cationic,[651] neutral,[652] and anionic[653,654] coordination compounds in addition to reduced viologens,[590,655] flavins, and polymer-immobilized reductants[656,657] have been studied, with the rates of electron transfer usually conforming to predictions from Marcus theory. Ion pairing with potential redox partners may lead to ion pair charge transfer (IPCT) transitions. Excitation into the IPCT transition leads to photoinduced electron transfer between the paired ions. Examples of this include $[Co(en)_3]^{3+}$ paired with tetraphenylborate[658] and a number of cyanometallate anions.[659] As a result of its high isotopic abundance, the technique of ^{59}Co NMR has been used as a sensitive probe for the chemical environment of the metal ion. Studies of $[Co(en)_3]^{3+}$ within micelles[660] and surfactants[661] are known.

There are many variations on the simple tris(bidentate) structure of $[Co(en)_3]^{3+}$, such as expansion of the chelate ring size to six and seven (propane-1,3- and butane-1,4-diamine) or the introduction of alkyl groups and fused rings for chirality and rigidity (propane-1,2-diamine and *meso* and *rac*-cyclohexane-1,2-diamine). These analogs, although yielding interesting chemistry, will not be explored here.

Tridentate amines come in a variety of forms. Diethylenetriamine (dien) (**129**) and its bis-trimethylene homolog ditn (**130**) may adopt either facial or meridional coordination modes. Furthermore, the *fac*-$[Co(dien)_2]^{3+}$ complex may exist as either the centrosymmetric *meso* or dissymmetric *rac* isomer where the secondary amines are *trans* or *cis* respectively.[662] However, there are some triamines that coordinate exclusively in a facial configuration due to stereochemical requirements of the ligand. Some examples include the symmetrical tripods tame[663] (**131**), *cis,cis*-cyclohexane-1,3,5-triamine (tach)[664] (**132a**) (including its 2,4,6-trihydroxy analog, taci[665] (**132b**)) and triazatrishomobenzene (**133**).[666]

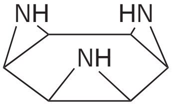
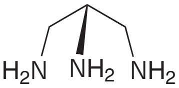
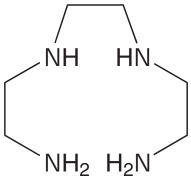
(**132a**) R=H
(**132b**) R=OH



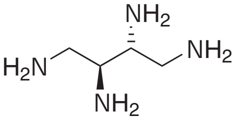
(**133**)



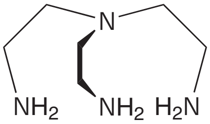
(**134**)



(**135**)



(**136**)



(**137**)

The less symmetrical and more rigid propane-1,2,3-triamine (trap) (**134**) has also been complexed with Co^{III}.[667] Even more isomers arise with linear tetraamines such as triethylenetetraamine (trien)[668] (**135**) or its branched homolog *rac*-butane-1,2,3,4-tetraamine[669] (**136**) when bound to Co^{III}, and this number proliferates when the amine is asymmetric. The tripodal tris(2-aminoethyl)amine (tren) (**137**) may bind as tri- or tetradentate to Co in various oxidation states;[670,671] the latter binding mode resulting in a single stereoisomer. There are simply too many combinations of these amines and their co-ligands to do justice to their chemistry in this review. A review of trivalent Co amine chemistry is available, which covers this area in greater detail than space permits herein.[672]

(x) Macrocyclic. There are many potential rewards for synthetic efforts devoted to the closure of open chain multidentate amines to afford their macrocyclic analogs. Enhanced complex stability (particularly upon conversion to the divalent state) and greater stereochemical control are the two most obvious benefits. Additionally, the ring may provide a scaffold onto which extra functional groups may be attached to give so-called pendent arm macrocycles. General reviews concerned with complexation and structural aspects of N-functionalized polyazamacrocycles (of various sizes, in complexes with a range of metal ions) have appeared.[673,674]

The smallest macrocyclic amine is the facially coordinating tridentate 1,4,7-triazacyclononane (tacn or [9]aneN_3) (**138a**). The $[Co(tacn)_2]^{3+}$ ion exhibits physical properties typical of other hexaamines, and the complex has been thoroughly characterized.[463,675] Like other macrocyclic amines, the outer sphere electron transfer reactions involving the $[Co(tacn)_2]^{3+/2+}$ couple with proteins[676] and simple coordination compounds[677] as well as its electrochemistry[678] have been well studied.

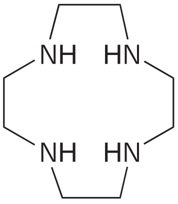
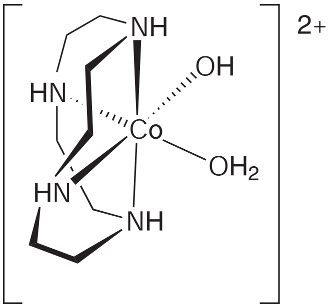
In contrast to its secondary amine parent, the *N*-trimethylated derivative (**138b**) (tmtacn) has a distinct preference for 1:1[679] or 2:2[399] metal:ligand stoichiometries as a consequence of steric effects of its methyl groups. Face-sharing octahedral, bridged dinuclear complexes of the type $[\{(\text{tmtacn})\text{Co}\}_2(\mu\text{-X})_3]^{n+}$ (where $X = OH^-$, Cl^-, Br^-, AcO^-) are known where the metals can be in either their di- or trivalent states (or mixed valence).[399,680] The sterically encumbered tris-isopropyl (**138c**) and isobutyl (**138d**) analogs of tacn have been reported and complexed with Co.[681] Mononuclear complex formation is favored in these cases.

A vast array of hexadentate, threefold symmetric tris-*N*-substituted derivatives of tacn have been reported incorporating a variety of pendent groups such as those seen in (**138e**),[682] (**138f**),[683] (**138g**),[684] (**138h**),[685,686] (**138i**),[652] (**138j**),[687,688] (**138k**)[689] and (**138l**),[690] each of which has been complexed with Co^{III} and characterized. Wieghardt and co-workers have identified many interesting trisubstituted tacn derivatives featuring phenolate or thiophenolate ligating groups that, when complexed with Co^{III}, are capable of stabilizing ligand-centered radicals. Examples include homo- and heterotrisubstituted tacn ligands such as tris(3,5-di-*tert*-butyl-2-hydroxybenzyl), tris(3-*tert*-butyl-5-methoxy-2-hydroxybenzyl), diacetate-(3,5-di-*tert*-butyl-2-hydroxybenzyl), diacetate-(2-mercaptobenzyl), diacetate-(3,5-di-*tert*-butyl-2-mercaptobenzyl), dimethyl-(3-*tert*-butyl-5-methoxy-2-hydroxybenzyl), and di-isopropyl-(3,5-di-*tert*-butyl-2-hydroxybenzyl) where Co^{III}-phenoxyl or Co^{III}-phenylthiyl radicals are formed upon oxidation of the complex.[691–693] Pendent arms bearing donors capable of bridging two metal centers (alkoxides, phenolates, and thiophenolates) have been reported and the degree of magnetic coupling mediated by the bridging ligand has been studied.[694,695] Mono-*N*-substituted derivatives of tacn in complexes with Co^{III} include 2-aminoethyl[696] and the versatile ethylene-bridged bis-macrocycle 1,2-bis(1,4,7-triaza-1-cyclononyl)ethane (dtne),[697] which is capable of both mononuclear and dinculear complex formation.

The Co^{III} coordination chemistry of the 12-membered macrocyclic tetraamine 1,4,7,11-tetraazacyclododecane (**139**) (cyclen or [12]aneN_4) has been extensively studied. A feature of this macrocycle, like tacn, is that its small ring size restricts its mode of coordination. All known Co^{III} cyclen complexes exhibit *cis*-N_4X_2 coordination geometries, where the macrocycle folds to leave a pair of *cis* coordination sites available for other ligands, although *N*-based isomers are known. There has been a particular focus on the reactivity of the $[Co(cyclen)(OH_2)(OH)]^{2+}$ ion (**140**) towards polyphosphate and phosphate ester hydrolysis, and its relevance to biomimetic chemistry (see Section 6.1.3.1.3). Attachment of active substituents to the cyclen N donors may be achieved with standard alkylation procedures. A number of Co complexes of tetra-*N*-substituted cyclen derivatives bearing both coordinating (2-carbamoylethyl[698]) and non-coordinating (2-cyanoethyl[699]) pendent arms have been reported. The incorporation of C substituents on the ring instills chirality in the ligand and its complexes. Examples of this approach include a homochiral C-tetraethyl cyclen Co complex which forms diastereomeric pairs of complexes with bidentate coordinated amino acids such as methionine[700] and methyltyrosine.[701]



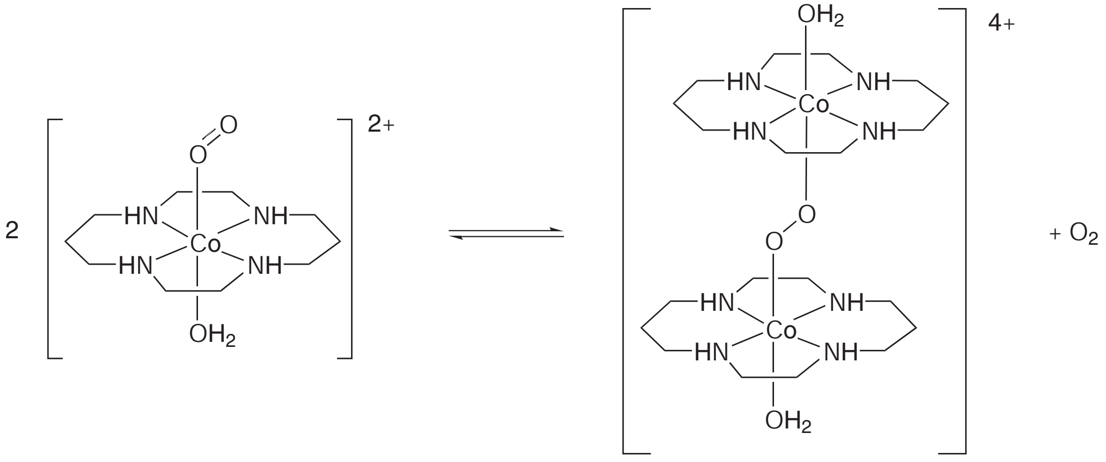
(**139**)



(**140**)

The 14-membered macrocycle 1,4,8,11-tetraazacyclotetradecane (cyclam or [14]aneN_4), unlike cyclen, is capable of encircling most transition metal ions and in the case of Co^{III} the *trans* configuration is much preferred by comparison with the folded *cis* isomer. Electrochemical reduction of *cis*-$[Co(cyclam)(OH)_2]^+$ in 3M NaOH leads to rapid isomerization to the *trans* form, and the relative stabilities of the *trans* and *cis* isomers of the di- and trivalent complexes were determined from a thermodynamic cycle.[702] This preference for *trans* orientation of the non-macrocyclic donors has enabled the isolation and investigation of many Co complexes without the complications of isomerization. Some novel examples include *trans*-$[Co(cyclam)(O_2^{-\bullet})(OH_2)]^{2+}$

(**141**), which exists in equilibrium with its peroxo-bridged dinuclear analog (**142**).[703] The mononuclear hydroperoxo analog was found to accelerate the rate of I^- oxidation (to I_3^-) by three orders of magnitude relative to H_2O_2.[704]



(**141**) (**142**)

Due to their ease of synthesis (from the cation-templated condensation reaction of ethylenediamine and acetone), C-methylated analogs of cyclam such as *meso* and *rac* 5,5,7,12,1214-hexamethylcyclam (tet*a* (**143a**) and tet*b* (**143b**) respectively) have been extensively studied, where the stereogenic C-atoms in the 7- and 14-positions of the ring lead to distinctly different coordination chemistries. The racemic ligand (**143b**) has been resolved and its resulting chiral Co^{III} complexes have been investigated.[705] A number of crystallographic[706,707] and spectroscopic[100,708] studies of these ligands in complexes with Co^{III} have been reported. The steric effects of the C-methyl groups influence the reactivity and stereochemistry of their resulting Co complexes significantly relative to the unsubstituted cyclam parent. The unusual hydroperoxocobalt complex [Co(tet*a*)(MeCN)(OOH)]$(ClO_4)_2$ has been isolated and structurally characterized.[709] The O—O stretch in the IR spectrum appears at 815 cm^{-1} and photolysis of an acidic aqueous solution of the complex results in homolytic splitting of the Co—O bond, yielding the diaqua complex as a product. The reaction of aminomethylmalonate with *cis*-$[Co(tet\textit{b})Cl_2]^+$ in DMSO in the presence of Et_3N yielded a novel 2-iminocarboxylato complex via oxidative decarboxylation of the malonate ligand. The reaction is specific for Co^{III} complexes containing C–Me-substituted cyclic tetraamines.[710]

A remarkable variety of methylated analogs are known and their Co^{III} complexes have all been synthesized and characterized. Examples include 5,7-dimethylcyclam (*meso* isomer) (**144**),[711,712] 5,12-dimethylcyclam (*meso* (**145**) and *rac* isomers),[713,714] 5,5,7-trimethylcyclam (**146**),[711] 5,7,12,14-tetramethylcyclam (**147**),[715] 1,5,8,12-tetramethylcyclam (**148**)[716] and 3,10-C-*meso*-3,5,7,7,10,12,14,14-octamethylcyclam (**149**).[717]

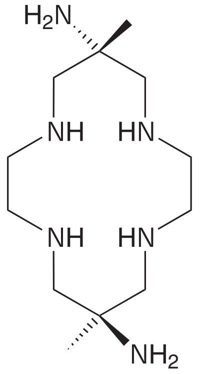
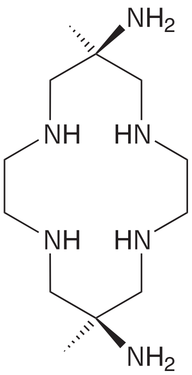
Ligating pendent arms have been attached to the cyclam ring to give penta- and hexadentate coordinated cyclams coordinated to Co. *N*-functionalization of the macrocycle is synthetically more straightforward, although the resulting (tertiary) amine donors are less effective ligands due to the increased steric effects of the pendent group. An example of this that has been complexed to Co^{III} is the hexadentate 5,12-dimethyl-7,14-diphenyl-4,11-diacetatocyclam.[718]

Actually, C-substituted cyclams are more common in the coordination chemistry of Co, with ligating pendent groups typically attached to the trimethylene ring C atoms. The synthetic strategies are many and varied. An unusual example concerns conversion of *trans*-$[Co(teta)Cl_2]^+$ to its 5-hydroxymethyl analog by aerial oxidation of the precursor in refluxing MeOH containing Et_3N.[719] 5-Aminomethyl-2,5,10,12-tetramethylcyclam was prepared by nucleophilic addition of $MeNO_2$ to the imine precursor, followed by reduction of the pendent nitromethyl group.[720] The chlorocobalt(III) complex of this pentaamine ligand was characterized structurally and rapid base hydrolysis of the chloro ligand was reported.

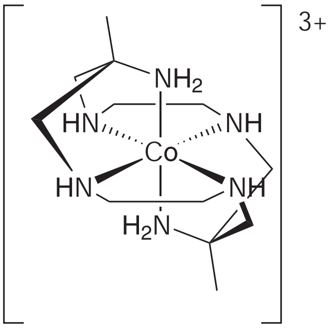
The *trans*[721] (**150**) and *cis*[722,723] (**151**) isomers of the hexadentate ligand 6,13-diamino-6,13-dimethylcyclam (also known as diammac) have been complexed with Co^{III} and characterized structurally, spectroscopically, and electrochemically. The ligands are synthesized by a metal-directed condensation reaction between $[Cu(en)_2]^{2+}$, $EtNO_2$, and formaldehyde, followed by reduction of the nitro groups. Each isomer may coordinate in but one hexadentate configuration, thus the isomers [Co(*trans*-diammac)]$^{3+}$ (**152**) and [Co(*cis*-diammac)]$^{3+}$ (**153**) provide a unique example of *trans*/*cis* isomerism at a metal center predetermined by ligand stereochemistry. In [Co(*trans*-diammac)]$^{3+}$, the Co—N bond lengths are amongst the shortest reported for a Co^{III} hexaamine, and this leads to unusually high-energy electronic maxima and a particularly negative $Co^{III/II}$ redox potential.[721] By contrast, the structural,[723] spectroscopic, and electrochemical[722] properties of [Co(*cis*-diammac)]$^{3+}$ are typical of other hexaamines such as $[Co(en)_3]^{3+}$. A rapid $Co^{III/II}$ self-exchange electron transfer rate was determined[721] for [Co(*trans*-diammac)]$^{3+}$ and, coupled with its particularly negative $Co^{III/II}$ redox potential, it was found to efficiently catalyze the reduction of H^+ when adsorbed in its divalent form to a Hg working electrode.[724]



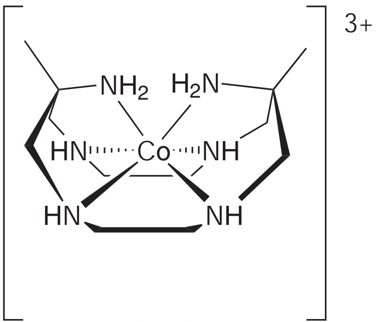
(**150**)



(**151**)

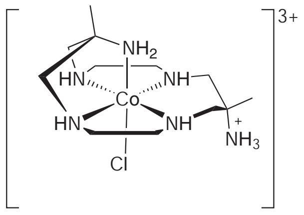


(**152**)

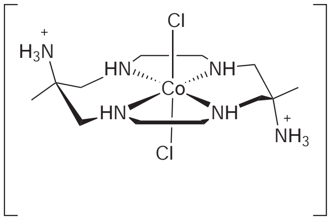


(**153**)

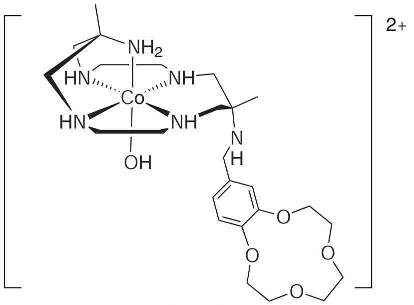
Other coordination modes of *trans*-diammac have been identified where one (**154**) or both (**155**) primary amines are free from the metal.[721,725] An extension of this concept involves attachment of active functional groups such as crown ethers selectively at one primary amine to generate ditopic ligands capable of electrochemically sensing alkali metal ions through their inductive effect on the $Co^{III/II}$ redox potential. One example is provided by (**156**); further, the 15-crown-5 and 18-crown-6 analogs were also prepared.[726]



(154)

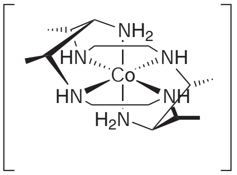


(155)

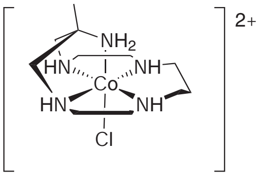


(156)

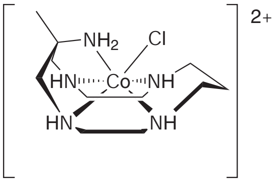
Some diammac analogs complexed with Co^{III} include 6,13-diamino-6,13-diethylcyclam (*trans* and *cis* isomers),[727] and the isomeric *meso*-5,7,12,14-tetramethyl-6,13-diaminocyclam (**157**) (*trans* isomer). The 6-amino-6-methyl analog (ammac) may only occupy five coordination sites and its greater degree of flexibility leads to *trans* (**158**)[728,729] and *cis* (**159**)[730] coordination modes when bound to Co^{III}. The ability to isolate non-interconverting isomeric forms of these pentaamine Co^{III} complexes has enabled the investigation of steric and electronic effects on the rates of reactions at the sixth coordination site such as base hydrolysis of coordinated Cl^-[728,730,731] and nitrito to nitro linkage isomerism.[732] The introduction of ferrocyanide as a ligand (N bound to Co) into the sixth coordination site of these Co complexes results in a novel class of dinuclear mixed valent compounds (**160**) exhibiting a prominent $Fe^{II} \rightarrow Co^{III}$ metal-to-metal charge transfer transition in the visible region of the spectrum.[733,734] A number of other examples of mono-C-substituted cyclam ligands coordinated to Co^{III} include 5-(4′-imidazolyl)cyclam,[735] and 6-amino-6-(4′-aminobenzyl)cyclam.[736–738]



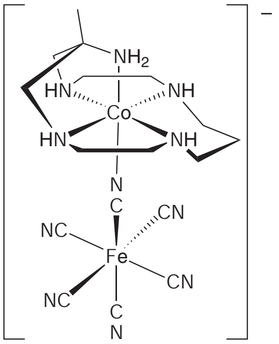
(157)



(158)



(159)



(160)

Sargeson and co-workers pioneered the metal template syntheses of a class of ligands that effectively encapsulate the metal ion within a macrobicyclic N_6 array or secondary amines. Most of this work focused on $[Co(en)_3]^{3+}$ as a template onto which two "caps" were attached using Mannich reactions involving formaldehyde and a potentially tribasic nucleophile such as NH_3 or $MeNO_2$, leading to the sepulchrate (sep) (**161**)[739] and substituted sarcophagine (sar) (**162a**)[740] Co^{III} cage complexes, respectively (Equation (7)). The initial reports of this chemistry focused on (**161**) and its Co^{II} analog. Remarkable physical properties of this system were reported,[219] including an unusually inert divalent complex. The $[Co(sep)]^{3+/2+}$ self-exchange rate constant was found to be several orders of magnitude greater than that of the $[Co(en)_3]^{3+/2+}$ parent. Moreover, the cage redox couple is reversible.

The C-capped $[Co(sar)]^{3+}$ (**162a**) (and its various homo- and hetero-disubstituted derivatives) exhibit very similar structural[741] and physical properties, although the sar class of ligands has the advantage of being isolable as the metal-free base,[742] in contrast to sep which is unstable in the absence of Co. A number of electrochemical investigations of $[Co(sep)]^{3+}$ and $[Co(sar)]^{3+}$ (and its substituted analogs) have appeared.[743,744] The facile and reversible one-electron redox chemistry of these complexes has led to their employment as electron relays in the photoinduced oxidation of coordination compounds such as $[Ru(bpy)_3]^{2+}$[745–747] and organic photosensitizers such as

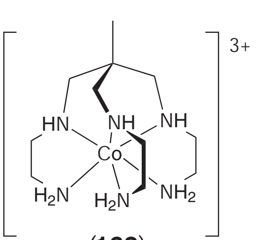
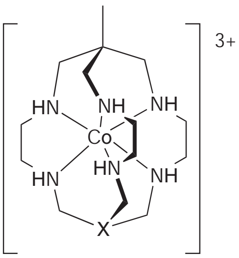
anthracene.[748,749] Outer sphere electron transfer between divalent Co cages and metalloproteins such as plastocyanin[750] and cytochrome *c*[751] has been demonstrated. The amino substituents of $[\mathrm{Co(NH_2)_2sar}]^{3+}$ have been used to attach a variety of functional groups through either reductive alkylation[752,753] or amide coupling.[754]

Other "capping" reagents and templates have been employed to create Co cages with different substituents, donor atoms, and chelate ring sizes. The acyclic hexaamine complex $[\mathrm{Co(sen)}]^{3+}$ (**163**) offers one set of facially coordinated primary amines when bound to $\mathrm{Co^{III}}$ and this template has been used to synthesize a number of similar cages bearing an inert methyl group at one cap. By analogy with the chemistry employed in the synthesis of $[\mathrm{Co(sep)}]^{3+}$, the group 15 hydrides $\mathrm{NH_3}$,[219] $\mathrm{PH_3}$,[755] and $\mathrm{AsH_3}$[756] with $\mathrm{CH_2O}$ have been used as capping reagents for $[\mathrm{Co(sen)}]^{3+}$ to form their respective cages (**164a–c**). Synthesis of the P- and As-capped cages required anhydrous conditions (and paraformaldehyde), and the P-oxide analog of (**164b**) was also isolated from the synthesis of its phosphine cage precursor.[755] The longer As—C bonds in (**164c**) induce a conformational change (*lel*$_3$ to *ob*$_3$) in the ethylenediamine chelate rings of the cage relative to their precursor conformers.[756] The $\mathrm{Co^{III}}$ complex of the hexadentate ligand *N*,*N*′,*N*″″-tris(2′-aminoethyl)-1,4,7-triazacyclononane (**165**) also offers three facially coordinated primary amines, and this complex reacts with formaldehyde and either $\mathrm{NH_3}$ or $\mathrm{MeNO_2}$ to give the corresponding tricyclic cages (**166a–c**).[682]



(**163**)



(**164a**) X=N
(**164b**) X=P

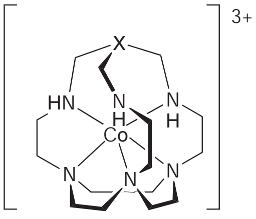
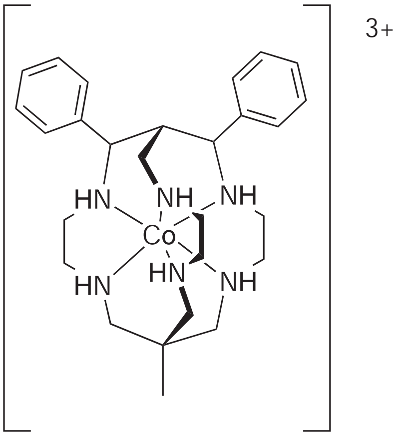
(**165**)



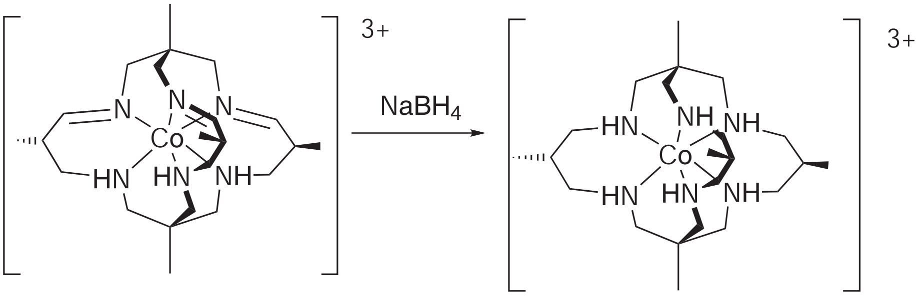
(**166a**) X=N
(**166b**) X=C-NO$_2$
(**166c**) X=C-NH$_2$

The use of formaldehyde with carbon acids including higher aldehydes, ketones, and esters has seen the expansion of this chemistry to incorporate many other substituents into the cap of the cage. *N*-benzylation of 4-methylpyridine enhances the acidity of the methyl group sufficiently to enable its employment as a carbon acid. The pyridyl-capped cage (**162h**) results.[757] Condensation of the diketone dibenzoylmethane with $[Co(sen)]^{3+}$ and formaldehyde leads to a diphenyl-substituted diimine cage, which may be reduced to the corresponding amine (**167**), with stereogenicity induced at the reduced imine C atoms.[758] Methyl aryl ketones ($ArCOCH_3$) are also sufficiently acidic to enable their use as capping reagents for $[Co(sen)]^{3+}$ in combination with paraformaldehyde, which leads to the corresponding aroyl-substituted cage (Ar = phenyl, naphthyl, phenanthryl, anthracenyl, anthroquinonyl).[759] These compounds have been proposed as candidates for DNA intercalation[760] and also as photosensitizers.



(**167**)

Variations on the basic bicyclo-eicosane (20-membered) $[Co(sar)]^{3+}$ cage structure were a later development. Instead of capping the $[Co(en)_3]^{3+}$ or $[Co(sen)]^{3+}$ templates, "strapping" reactions involving the threefold cross linking of $[Co(tame)_2]^{3+}$ (**30**) with combinations of aldehydes have been achieved, albeit in poorer yields. The first example of this approach involved the synthesis of the pentamethyl expanded bicyclo-tricosane (23-membered) triimine cage (**168**) with formaldehyde and propionaldehyde as the strapping reagents, followed by imine reduction to the hexamine (**169**). The hexamine exhibits contrasting physical properties with its smaller-cavity $[Co(sar)]^{3+}$ relatives (**162**) such as an anodically shifted Co$^{III/II}$ redox potential, elongated Co—N bond lengths and red-shifted electronic maxima.[761] Substitution of priopionaldehyde with isobutyraldehyde in this synthesis leads to further stabilization of divalent Co. The ensuing octamethylated hexamine analog of (**169**) (with *gem*-dimethyl groups on each strap), is as stable in the divalent oxidation state as compound (**31**), and the trivalent complex is only accessible through using controlled potential electrolysis.[220]



(**168**) (**169**)

(ii) Pyridine and oligopyridines

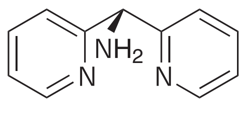
(y) Monodentate. No trivalent Co complexes bearing six pyridine ligands are known. The *trans*-$[\mathrm{Co(py)_4(OH_2)_2}]^{3+}$ and $[\mathrm{Co(py)_4(OH)_2}]^{+}$ complexes are known, but they are highly reactive in acidic chloride solution to ligand substitution and ultimately to reduction to the divalent state.[762]

(z) Multidentate. There are many parallels between the coordination chemistries of the bidentate ligands 2,2′-bipyridine (bpy) and 1,10-phenanthroline (phen). Both ligands form five-membered chelate rings comprising a pair of pyridyl N-donors, and they stabilize the trivalent forms of their Co complexes relative to the unknown $[\mathrm{Co(py)_6}]^{3+}$ analog. This can be attributed to the chelate effect but also to the elimination of H···H repulsion in the pyridyl complex through the formation of covalent C—C bonds in their place. Both $[\mathrm{Co(bpy)_3}]^{3+}$ and $[\mathrm{Co(phen)_3}]^{3+}$ are well-characterized, stable low-spin complexes. The crystal structures of both $[\mathrm{Co(phen)_3}](\mathrm{ClO_4})_3$ and $[\mathrm{Co(bpy)_3}](\mathrm{ClO_4})_3$ have been reported.[763] The $[\mathrm{Co(bpy)_3}]^{3+}$ ion has been crystallized with a number of paramagnetic complex anions and the magnetic and spectroscopic properties of these systems have been studied.[764,765] Furthermore, it is found that the inert chiral Co$^{\mathrm{III}}$ complex induces the crystallization of chiral, anionic three-dimensional coordination polymers of oxalate-bridged metal complexes of the form $[\mathrm{M^{II}_2(ox)_3}]_n^{2n-}$ or $[\mathrm{M^{I}M^{III}(ox)_3}]_n^{2n-}$.[764]

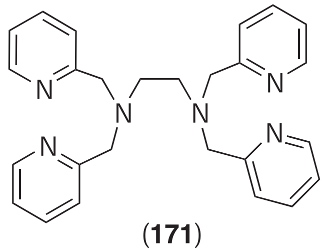
Outer sphere electron transfer reactions involving these complexes have been extensively investigated. The high Co$^{\mathrm{III/II}}$ redox potentials of the bpy and phen complexes make them ideal one-electron oxidants. The pressure-dependence of their redox potentials have been examined, with substantial (ca. 200 mV) negative shifts being found at high pressure (10 kbar).[766] Outer sphere reactions of $[\mathrm{Co(bpy)_3}]^{3+}$ and $[\mathrm{Co(phen)_3}]^{3+}$ with simple coordination compounds have revealed a number of interesting features. Reaction with $\mathrm{Cr_{aq}}^{2+}$ led to a variety of products including $[\mathrm{Cr_2(bpy)(OH)_2(OH_2)_6}]^{4+}$, $\mathrm{Co_{aq}}^{2+}$, $[\mathrm{Co(bpy)(OH_2)_4}]^{3+}$, in addition to uncomplexed (intact) bpy and reduced bpy.[767] The kinetics of oxidation of a series of $[\mathrm{Ru(NH_3)_5X}]^{2+}$ complexes (X = substituted pyridine) by $[\mathrm{Co(bpy)_3}]^{3+}$ have been studied,[768] with the electron transfer rates being correlated with Hammett sigma parameters of the pyridyl substituents. Oxidation of the $[\mathrm{Cr(bpy)_3}]^{2+}$ and $[\mathrm{Cr(phen)_3}]^{2+}$ ions by their Co$^{\mathrm{III}}$ analogs were found to be significantly non-adiabatic,[651] a result confirmed in other outer sphere reactions involving these oxidants where a large driving force is operant.[769] A number of other studies of electron transfer with Co$^{\mathrm{II}}$ [589,770] and ferrocene[771] have appeared. Outer sphere electron transfer reactions between proteins and polypyridylcobalt complexes are discussed in Section 6.1.3.1.5.

Chiral recognition of Δ-$[\mathrm{Co(phen)_3}]^{3+}$ has been observed in a modified β-cyclodextrin.[772] Chiral discrimination has also been seen in photoinduced energy transfer from luminescent chiral lanthanoid complexes[773] to $[\mathrm{Co(phen)_3}]^{3+}$ and between photoexcited $[\mathrm{Ru(bpy)_3}]^{2+}$ and $[\mathrm{Co(phen)_3}]^{3+}$ co-adsorbed on smectite clays.[774] The $[\mathrm{Co(bpy)_3}]^{3+}$ ion has been incorporated into clays to generate ordered assemblies and also functional catalysts. When adsorbed onto hectorite, $[\mathrm{Co(bpy)_3}]^{3+}$ catalyzes the reduction of nitrobenzene to aniline.[775] The ability of $[\mathrm{Co(phen)_3}]^{3+}$ to bind to DNA has been intensively studied, and discussion of this feature is deferred until Section 6.1.3.1.4.

The structures of Co complexes of the tridentate terpy invariably exhibit a compression of the Co—N$_{\mathrm{central}}$ coordinate bonds relative to the Co—N$_{\mathrm{distal}}$ bond lengths, as a consequence of restraints imposed by the meridionally disposed pair of five-membered chelate rings. This is clearly seen in the $[\mathrm{Co(terpy)_2}]\mathrm{Cl_3}$ crystal structure[776] where the Co—N$_{\mathrm{central,distal}}$ bond lengths are 1.86 Å and 1.93 Å respectively. Like their amine analogs, there are countless examples of more complicated mixed-donor pyridyl-based ligands complexed with Co and these examples cannot be covered in a review of this breadth. Some miscellaneous examples of mixed-donor polypyridyl-amine complexes of Co$^{\mathrm{III}}$ include di(2-pyridyl)methanamine (**170**),[777] and *N*,*N*,*N*′,*N*′-tetrakis (2-pyridylmethyl)ethylenediamine (**171**).[778]



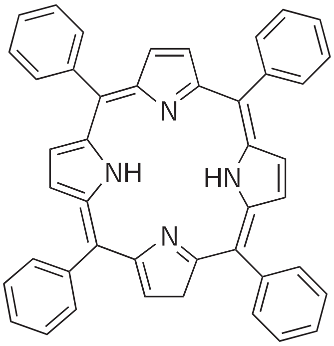
(**170**)



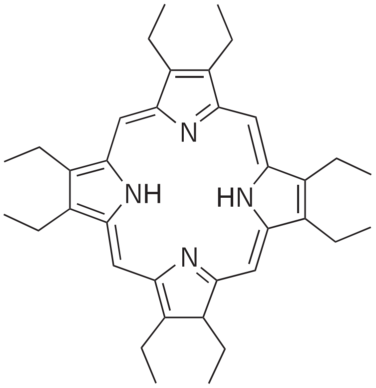
(**171**)

(iii) Porphyrins, corrinoids, and polypyrroles

Trivalent complexes of porphyrins (like their divalent analogs) have found many uses in sensor technology and catalysis. *Meso*-tetraphenylporphyrin (H_2TPP) (**172**), the most common of all synthetic porphyrins, has been used extensively in this regard. The $\{Co^{III}(TPP)\}$ moiety has been incorporated into a chemically modified, heat-treated glassy carbon electrode to produce an amperometric sensor for hydrazine operating at 0.5 V vs. Ag/AgCl, incorporated into a flow injection analysis system.[779] A substituted analog Co(TmapP) (Tmap = 4-trimethylammonium-phenyl) also exhibited catalytic electro-oxidation of hydrazine in solution.[780]



(**172**)

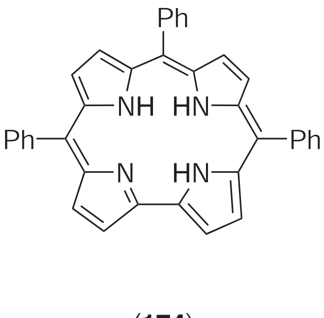


(**173**)

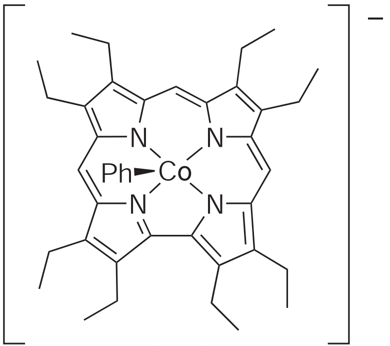
It has been shown that Co^{III} porphyrins are effective oxygenation catalysts. Alkyl- and aryl-substituted Co complexes of the dianions of H_2TPP and H_2OEP (**173**) undergo dioxygen insertion reactions to form alkyl(aryl) peroxy intermediates, which have been isolated and characterized.[781] The alkylperoxy complexes ultimately break down to release the corresponding alcohol. Peroxidation of fatty acids and esters (linoleic acid, methyl linoleate, and linolenic acid) has been achieved with Co(TPP)Cl as a precursor, which initiates an auto-oxidative radical-chain reaction in oxygen-saturated MeCN solution. Another transformation catalyzed by a Co porphyrin is the oxidation of $CH_2{=}CHCH{=}CHCO_2Et$ to $MeCH_2COCH{=}CHCO_2Et$ catalyzed by Co(T (2,6-Cl_2Ph)P).[782]

A detailed chemical and electrochemical investigation of the oxidation and coupled chemical reactions of alkyl substituted trivalent Co(TPP)R (R = Bu, Et, Me, Ph) found that one- or two-electron oxidation of the Co^{III} σ-bonded complexes led to R group migration to give the *N*-aryl or *N*-alkyl Co^{II} porphyrins.[783] The rates of migration (from Co to N) in the series varied by six orders of magnitude. Determination of the Co—C bond dissociation enthalpies and entropies revealed that the Co^{IV}—C bond in the singly oxidized species is significantly weaker than the Co^{III}—C bond of the precursor. A high-valent $Co^{IV}{=}O$ intermediate was postulated as the active species in the catalytic hydroxylation of alkanes by an electron-deficient Co^{III} porphyrin in the presence of *m*-chloroperbenzoic acid with high regioselectivity.[784] Co(TPP)(NO_2)(py) is capable of oxo-transfer catalysis, involving a pentacoordinate Co(TPP)(NO_2) intermediate which can stoichiometrically oxidize allyl bromide.[785] Both radical and nonradical oxo-transfer steps are involved in the mechanism, suggesting a peroxynitro intermediate in the reaction of reduced Co(TPP)(NO) with dioxygen. Kinetics of the reaction of the porphyrin complex Co(TTP)Cl with a range of substituted imidazoles (R-im) has shown that Co(TTP)(R-im)Cl is formed rapidly, then undergoes slower interconversion by rate-determining chloride ionization to the cationic complex [Co(TTP)(R-im)]Cl, a process sensitive to hydrogen-bonding interactions.[786]

The ring-contracted analogs of the porphyrin family (corroles) and their hexahydro derivatives (corrins) have attracted a considerable amount of attention because of their biological relevance (the Co–corrin moiety is found in co-enzyme B_{12}, see Section 6.1.3.1.1) and also due to their potential use in optoelectronics and catalysis. By analogy with their porphyrin relatives, substituents on the corrole ring may be found at the *beta* (pyrrole) or *meso* (methine) positions. An important distinction between these ligands is that the smaller ring corrole is a tribasic acid, in contrast to its dibasic porphyrin analogs. The 5,10,15-triphenylcorrole (H_3TPC) (**174**) may be synthesized in one pot by reaction of benzaldehyde with an excess of pyrrole (the same reagents used in the synthesis of H_2TPP).[787] The crystal structure of Co(TPC)(PPh_3) was also reported.



(**174**)

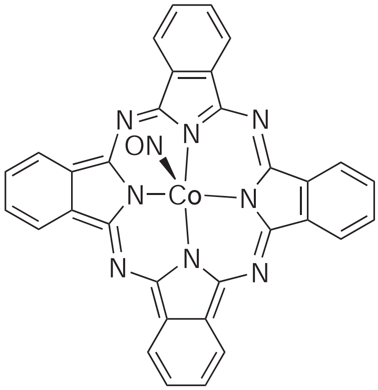


(**175**)

In the tris-pentafluorophenyl analog (TFPC), in contrast to other Co corroles, aromatic amines can substitute PPh_3 to form six-coordinate trivalent bis(amine) complexes.[788] Bis-chlorosulfonation of TFPC occurs regioselectively to give the 2,17-(pyrrole)-bis-chlorosulfonated derivative fully characterized as its triphenylphosphinecobalt(III) complex.[789] The amphiphilic bis-sulfonic acid was also obtained.

Electrochemical oxidation of the Co^{III} complex of the octamethylcorrole trianion (OMC) identified two reversible, ligand-centered responses, and two metal-centered reductions, depending on solvent.[790] Similarly, the octaethyl analog $[PhCo(OEC)]^-$ (**175**) undergoes sequential facile ligand-centered oxidations and the crystal structures of the one and two-electron oxidised complexes PhCo(OEC) and $[PhCo(OEC)]ClO_4$ have been determined.[791] A number of *meso*-phenyl substituted derivatives of OMC were reported and spectroscopic measurements indicated the maintenance of ligand planarity despite the insertion of the bulky aromatic groups.[792] The structures of a number of alkylcobalamin complexes have been investigated by molecular mechanics calculations, and it was concluded that the structure of the ground state is influenced by the same factors that control the strength of the Co—C bond in these compounds.[793] A density functional theory analysis of these complexes has been reported and the results from this study are consistent with experimentally observed structural and magnetic data for the ground state electronic configurations of these compounds.[794] Dimeric corrole complexes of Co have been investigated bearing bridges such as anthracene.[795] This and other "face-to-face" Co–corrole dimers are capable of catalyzing the four-electron reduction of O_2 to water.[796]

Co–corrins are also efficient catalysts of a number of (bio)organic transformations including the oxidation of quinols,[797] raising the possibility of their use as catalytic generators of oxygen-based radicals for targets such as DNA. The nitrosyl phthalocyanine complex Co(Pc)(NO) (**176**) reacts with pyridine in air at high pressure to give the nitro complex $Co(Pc)(py)(NO_2)$ which is an oxidant for the stoichiometric and catalytic oxidation PPh_3 to Ph_3PO (in an inert atmosphere) regenerating the nitrosyl complex.[798]



(**176**)

(iv) Imidazole, pyrazole, and related ligands

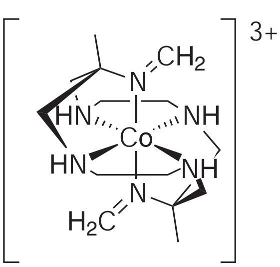
These heterocyclic unsaturated ligands share similar coordination chemistry with trivalent Co. The isomers imidazole (Him) and pyrazole (Hpz) are monodentate ligands in their neutral state. Upon deprotonation, they gain the ability to act as bridging ligands. Oxidation of $[Co(Him)_6]^{2+}$ with H_2O_2 generates the trivalent octahedral complex.[799] The first three pK_a values of the $[Co(Him)_6]^{3+}$ ion were determined to be 8.65, 9.88, and 10.63. The pK_a values of coordinated imidazole itself (or as part of a histidyl residue) have been determined for $[Co(NH_3)_5(Him)]^{3+}$,[800] $[Co(en)_2(Him)(OH_2)]^{3+}$[801] and in the peptide histidylglycylglycine complex Co(hisglygly)$(NH_3)_2$.[802] In these cases, the imidazole pK_a is in excess of 10. The Co^{III} complex of the peptide N-(2-(4-imidazolyl)ethyl)pyridine-2-carboxamide (PyepH), a molecule resembling part of the metal-chelating portion of the antitumor drug bleomycin, has been prepared.[803] Electrochemical reduction of the compound in DMF or MeOH gives rise to an unstable Co^{II} species. The photoactive Co complex showed high capacity for DNA cleavage under UV illumination.[804] The imidazole group was found to be capable of bridging two Co centers in both trinuclear and tetranuclear analogs of this system.[805] The imidazole-bridged binuclear and trinuclear ammine complexes $[\{(H_3N)_5Co\}_2(im)]^{5+}$ and *cis*-$[(H_3N)_4Co\{(im)Co(NH_3)_5\}_2]^{7+}$ have been synthesized, and the crystal structure of the latter complex reported.[806]

Studies of the reactivity of imidazole coordinated to Co^{III} have identified some interesting chemistry. The imidazole ligand in *cis*-$[Co(en)_2Cl(Him)]^{2+}$ may be nitrated (at the 4-position) under mild conditions with a $HNO_3-H_2SO_4$ nitrating mixture, whereas the pyridine analog cannot be nitrated without complex decomposition.[807] Nucleophilic displacement of the nitro group of the coordinated ligand by Cl^- was also found. Treatment of $[Co(NH_3)_5(Him)]^{3+}$ with $Br_{2(aq)}$ in acetate or phosphate buffer between pH 4 and 6 results in exclusive formation of the oxidized $[Co(NH_3)_5(2,4,5\text{-oxo-im})]^{2+}$ complex (2,4,5-oxo-im = conjugate base of imidazolidine-2,4,5-trione, or parabanic acid). A mechanism involving a tetrabrominated imidazole intermediate was proposed.[808] Chlorination results in the same product. An unusual linkage isomerization of $[Co(NH_3)_5(4\text{-Meim})]^{3+}$ (from adjacent to remote methyl group isomer) was observed and a mechanism involving a largely dissociative transition state was proposed.[809]

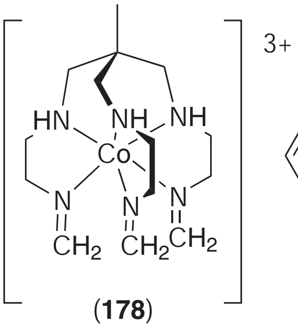
There are relatively few reports of trivalent Tp complexes by comparison with mono- and divalent systems. One interesting example involved transmetallation (from Sn to Co) in the reaction of $TpSnCl_3$ with $[Co(CO)_4]^-$ to give a mixture of products from which $[Co(Tp)_2]$[*trans*-$[(CO)_4Co(Cl_2Sn)_2Co(CO)_3]$ was isolated and characterized by X-ray crystallography.[810]

(v) Imines

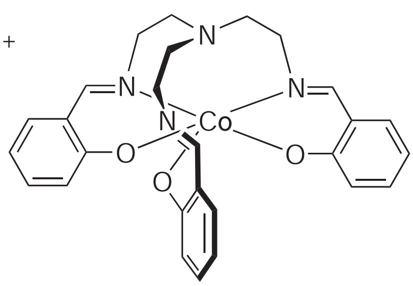
Cobalt(III)-directed reactions, where the metal either directs the stereochemistry or activates the coordinated precursor, have played an important role in the development of imine coordination chemistry. Mixed donor imines coordinated to Co^{III} have been produced by metal-templated reactions. Anation of $[Co(NH_3)_5(OH_2)]^{3+}$ by 5-bromo-2-oxopentanoate at pH 5 gives two major products, the 2-oxo-2-cyclopropylethanoato complex and the 5-hydroxy-2-oxopentanoato complex, both which were converted to tetraammine-iminocarboxylato chelates by attack of an adjacent deprotonated ammine ligand.[811] The tridentate monoimine analog of dien (dienim) is formed directly by condensation of acetaldehyde with ethylenediamine in the presence of $CoCl_2$ and H_2O_2, and isolated as the *mer*-[Co(dienim)(en)Cl]$ZnCl_4$ complex.[812] A series of α-amino acid complexes $[Co(en)_2(H_2NCH(R)CO_2)]^{2+}$ ($R = CH_2OH$, CH_2SMe, CMe_2SMe, CH(Me)OH) react with $SOCl_2$ in DMF, undergoing β-elimination to give the related imine complex or else reacting further to give chelated isothiazole-3-carboxylato complexes.[813] Intramolecular condensation between *N*-bound aminoacetaldehyde and the terminal primary amine of coordinated trien (**135**) leads to the imine, $[Co(tetraenim)Cl]^{2+}$; the (hydrated) carbinolamine intermediate was also identified. The carbinolamine results from condensation of the aldehyde with the most acidic coordinated amine *trans* to Cl^- and this species is unable to dehydrate until after ligand rearrangement that permits formation of a planar imine *N*-donor.[814] Methylene imines coordinated to Co ((**177**)[815] and (**178**)[756]) have been isolated from reactions of hexaaminecobalt(III) precursors with formaldehyde in anhydrous solvent. These imines are highly reactive towards nucleophiles and are rapidly hydrolysed in neutral aqueous solution, but are stable in strong acid. The trigonally symmetric potentially heptadentate triacid trensal forms charge neutral complexes with most trivalent metal ions, including Co^{III} (**179**), although the apical tertiary amine does not coordinate in this case.[816]



(**177**)

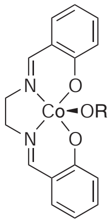


(**178**)

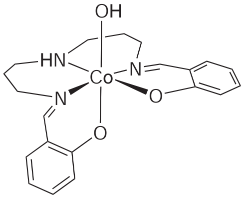


(**179**)

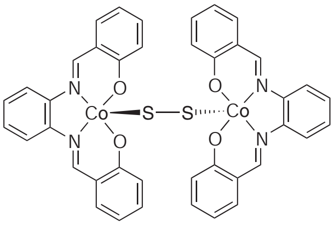
Complexes of imine ligands formed from salicylaldehyde have been widely investigated. Oxygenation of Co(salen) (**69a**) in alcoholic (ROH) solution involves a rate-determining proton transfer from ROH to the coordinated O_2 ligand, ultimately affording the corresponding alkoxycobalt(III) complex (**180**), which may be hydrolyzed to the hydroxocobalt(III) derivative in water.[817] The rate of oxidation of Co(salen) in MeOH solution is increased rapidly in the presence of Bu_3SnCl, leading to $[Co(salen)Cl][BuSn(OMe)Cl_2]$ where the trivalent Co moiety may be considered a ligand for the Sn complex.[818] The coordinatively saturated Co(saldtn)(OH) complex (**181**) catalyzes the selective aldol condensation between dibenzoylmethanes and formaldehyde in methanol to give 1,1,3,3-tetrabenzoylpropanes, which undergo a retro-Claisen reaction to give 1,3-dibenzoylpropanes in CH_2Cl_2.[819] The complex of the substrate anion is the reactive species.



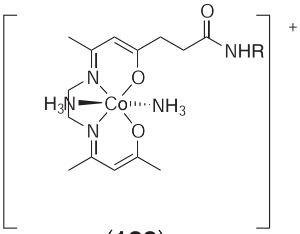
(**180**)



(**181**)



(**182**)



(**183**)

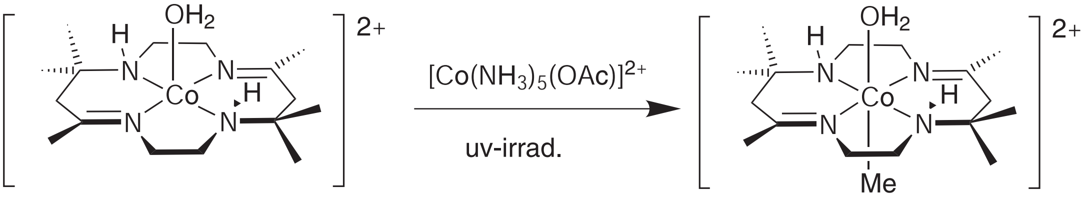
Spectroelectrochemistry of the trivalent peroxo-bridged dimer $\{(DMSO)(salen)Co\}_2(\mu\text{-}O_2)$ in DMSO has been investigated.[820] Two-electron, controlled-potential oxidation liberates O_2 leaving the solvated complex $[Co(salen)(DMSO)_2]^+$, while reduction produces the divalent compound. By analogy with the dioxygen/peroxide chemistry of these systems, treatment of Co(salphn) (**69b**) with elemental S in THF or pyridine gives the tetrasulfide complexes $\{(L(salphn)Co\}_2(S_4)$ (L = THF, py), whereas in the presence of Na^+ in THF the trivalent μ-persulfido complex (**182**) $[(salphn)Co(\mu\text{-}S_2)Co(salphn)Na(THF)_2]BPh_4$ results. A S—S distance 1.962(9) Å was determined from its crystal structure.[821] Removal of the Na^+ ion (not shown here), which bonds with the O donors and the bridging persulfide, leads to decomposition of the complex.[822]

Complexes based on (**183**) ($[Co(acacen)(NH_3)_2]^+$ with a peptide spacer attached to one of the methyl groups) have been patented as potential agents that bind to surface histidine residues on proteins.[823,824] The potential uses for this are as bactericides, antimicrobial or antiviral agents, as reducing agents, or for protein labeling. Inhibition of proteins such as carbonic anhydrase, thermolysin,[825] α-thrombin[826] and a zinc finger-containing transcription factor[827] was demonstrated by this class of compound. The activity of these compounds was found to be dependent on the amino acid residues in the linker. The structure and spectroscopy of the 3-chloro derivative of the parent complex *trans*-$[Co(acacen)(NH_3)_2]^+$ were reported separately.[828]

The kinetics of electron transfer (both heterogeneous and homogeneous) involving trivalent Co complexes of hmd[590,829] and tmt[830,831] have been well studied. $[Co(hmd)(OH_2)_2]^{3+}$ undergoes photoreduction in an aqueous acidic solution using $[Ru(bpy)_3]^{2+}$ as photosensitizer and phenol as the sacrificial electron donor.[832] Ligand substitution reactions of *trans*-$[Co(hmd)X_2]^{n+}$ at the labile (X) sites have been thoroughly investigated. Examples of leaving groups (X) include halide[833–835] and aqua.[836]

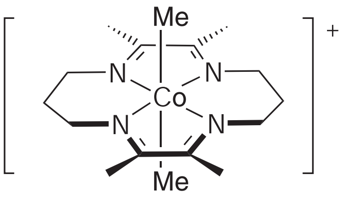
The UV irradiation of a mixture of $[Co(NH_3)_5(OAc)](ClO_4)_2$ with the divalent precursor (**184**) in 0.1 M $HClO_4$ yields the methyl complex *rac*-$[MeCo(hmd)(OH_2)]^{2+}$ (**185**). The complex was crystallized and its structure has been determined.[837] The alkyl homologs $[RCo(hmd)(OH_2)]^{2+}$

(R = Et, Pr), prepared independently, undergo unimolecular homolysis (effectively the reverse process) and the activation enthalpy for these processes were determined.[838]

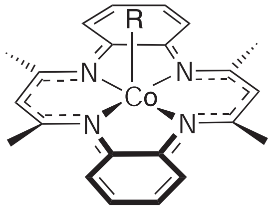


(**184**) (**185**)

Methylation of $[Co(tmt)]^{2+}$ with MeI leads to the potent methyl carbanion donor *trans*-$[Co(tmt)Me_2]^+$ (**186**). Reaction of this complex with variety of methyl–lead(IV) compounds in MeCN is rapid, leading to the same monomethylcobalt(III) product, but resulting in different methylated Pb derivatives depending on the reaction stoichiometry and Pb compound.[839] The same complex rapidly transfers Me groups to Zn^{2+} and Cd^{2+} in MeCN,[840] or Pb^{2+} and Sn^{2+} in water.[302,841] The kinetics of Co—C bond formation in the reactions with primary alkyl and substituted primary alkyl radicals has been found to be influenced more by the structure of the macrocycle than by the nature of the radicals.[842]

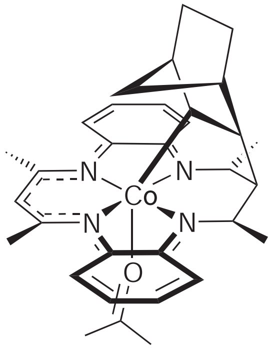


(**186**)

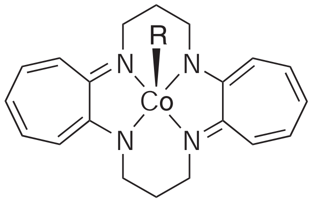


(**187**)

The alkyl complexes RCo(tmtaa) (**187**) (R = Me, Et, or Ph), were synthesized and studied by cyclic voltammetry.[843] Two anodic waves, assigned to single-electron, ligand-centered, oxidative processes were observed that were only moderately influenced by the R group. Two cathodic waves were found. Growth of thin films by electropolymerization on a Pt electrode was achieved during which the Co—C bond remained intact. An interesting example of an axially bound alkyl group is provided by the norbornyl complex (**188**), prepared by reacting Co(tmtaa) with norbornene in the presence of dioxygen. The crystal structure of this novel pendent arm macrocyclic complex was reported.[844,845] In contrast to the saddle-shaped tmtaa complexes, the 6,13-dimethyl analog adopts a planar conformation when bound to Co^{II}, stabilizing the Co^{I} oxidation state by 250 mV and destabilizing the trivalent state by 160 mV relative to the tmtaa complex.[846]



(**188**)



(**189**)

Cobalt complexes of the fused 7-membered ring unsaturated analogs of the dibenzo-[14] tetraazaannulenes, the tropocoronands (H_2TC), have also been reported. The crystal structure of five-coordinate ClCo(TC) has been determined ((**189**) where R = Cl).[847] The alkyl derivatives RCo(TC) (R = Et, Pr) were prepared, but were diamagnetic in contrast to the chloro precursor. The alkyl complexes homolyze in solution either on exposure to light or at elevated temperatures in the dark, to afford the corresponding divalent tropocoronand complex and an alkyl radical.[848] Five-coordinate thiolate and nitrosyl derivatives have also been prepared.[849]

(vi) Oximes

Although oxime complexes of Co share many of the physical properties of their imine relatives, the presense of an ionizable OH group attached to the coordinated N=C group leads to these ligands binding in their anionic forms. For this reason, the trivalent oxidation state is preferred in the Co coordination chemistry of oximes.

The hexadentate so-called clathrochelates are formally derived from $Co(dmg)_3$ with borate "caps" at either end; the archetypal example being the trivalent (**190**). Like the hexaamine analog $[Co(sep)]^{3+}$ cage, the encapsulated metal ion is insulated from its surrounding solvent. Furthermore, the low charge of the complex decreases outer sphere (solvent, ion pairing) contributions to electron transfer and a number of structural and electron transfer investigations have been reported for these systems.[850–852] Increasing the bulk of the oxime substituents (diphenglyoxime, cyclohexanonedioxime) decreases further the outer sphere contributions to electron transfer leading to an enhancement of the $Co^{III/II}$ self-exchange rate.[853] Further, Co complexes bearing a variety of different caps including ferrocenylborate,[854] butylborate,[855] phenylborate,[856] and trichlorostannate(IV)[857] have been reported.

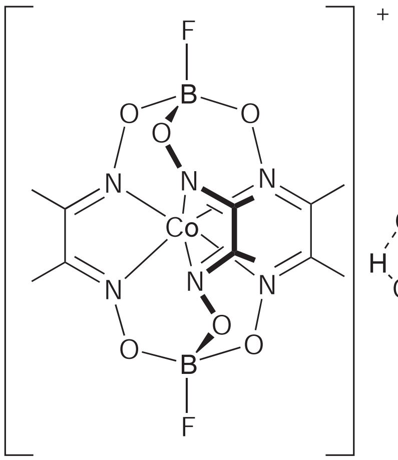
A variety of 4-substituted-1,2-benzoquinone-2-oximes (Me, Cl, Br) (analogs of the green pigment ferroverdin) form tris bidentate Co^{III} complexes, that are mixtures of *fac* and *mer* isomers.[858] Another ferroverdin analog, 1-phenyl-2-(hydroximino)-1,3-butanedionate, forms a tris-bidentate Co^{III} complex which has been synthesized and characterized structurally.[859] A trigonally symmetric (*fac*) isomer was observed. The hexadentate tripodal trioxime $MeC(CH_2NHCMe_2C(Me){=}NOH)_3$ (H_3tox) was synthesized from the triamine tame (**131**) and 2-chloro-2-methyl-3-nitrosobutane.[860] The complex with Co^{III} was crystallized in both its tripositive (fully protonated) and singly deprotonated dipositive forms. Attempts to cap $[Co(H_3tox)]^{3+}$ with aqueous borate and phenyl boronate were unsuccessful, resulting instead in partial ligand hydrolysis. Oxamide oxime forms a trigonally symmetric tris-bidentate Co^{III} complex $[Co\ (H_2oxao)_3]I_3$ and its structure was determined by single crystal X-ray diffraction.[861] The bis-bidentate (N,O) complexes *trans*-$Co(HQ)Q(L)_2$ (H_2Q = 2-oximinopropionic or 2-oximino-3-phenylpropionic acids; L = monodentate aromatic N-donor) were reported.[862] Extension of this ligand by addition of a glycyl residue produces the tridentate ligand N-(2-oximinopropionyl) glycinate and its bis Co^{III} complex (*mer* isomer) was also characterized.[863]

One of the most commonly encountered oxime ligand systems involves the cooperative coordination of two bidentate dmg anions. When coordinated in a *trans* configuration internal hydrogen bonding between *cis*-disposed protonated and deprotonated oxime groups (N–O–H ⋯ O–N) leads to a 14-membered pseudo-macrocyclic CoN_4 array, as seen in the structures of *trans*-$[Co(dmg)_2X_2]^+$ ((**191**) X = H_2O[864] and py[865]). There has been a substantial effort devoted to the biomimetic chemistry of cobalamins (B_{12}) using polyoxime ligands, and a discussion of this area is to be found in Section 6.1.3.1.1.

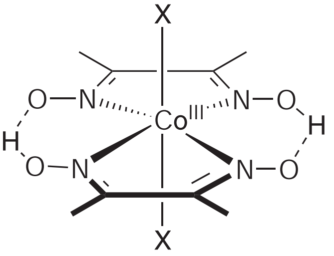
Alkyl Co oxime complexes have been used as chain transfer catalysts in free radical polymerizations.[866,867] Regioselective hydronitrosation of styrene (with NO in DMF) to PhCMe=NOH is catalyzed by $Co(dmg)_2(py)Cl$ in 83% yield.[868,869] Catalytic amounts of the trivalent $Co(dmg_2tn)I_2$ (**192**) (X = I) generate alkyl radicals from their corresponding bromides under mild reaction conditions, allowing the selective preparation of either saturated or unsaturated radical cyclization products.[870]

(vii) Amides

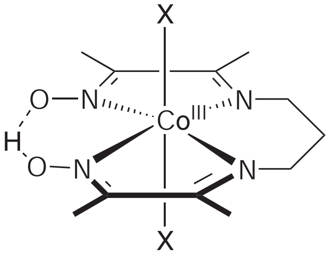
Amides offer both O and N-donors for Co coordination. N-bound amides are accessible through hydrolysis of their corresponding coordinated nitrile or by linkage isomerization of the *O*-bound form. The preparation of an extensive series of pentaamminecobalt(III) complexes of (monodentate-coordinated) amides of the form $RCONH_2$ (R = H, Me, CF_3, CH_2Cl, CH_2F, $CH{=}CH_2$, Ph,



(**190**)

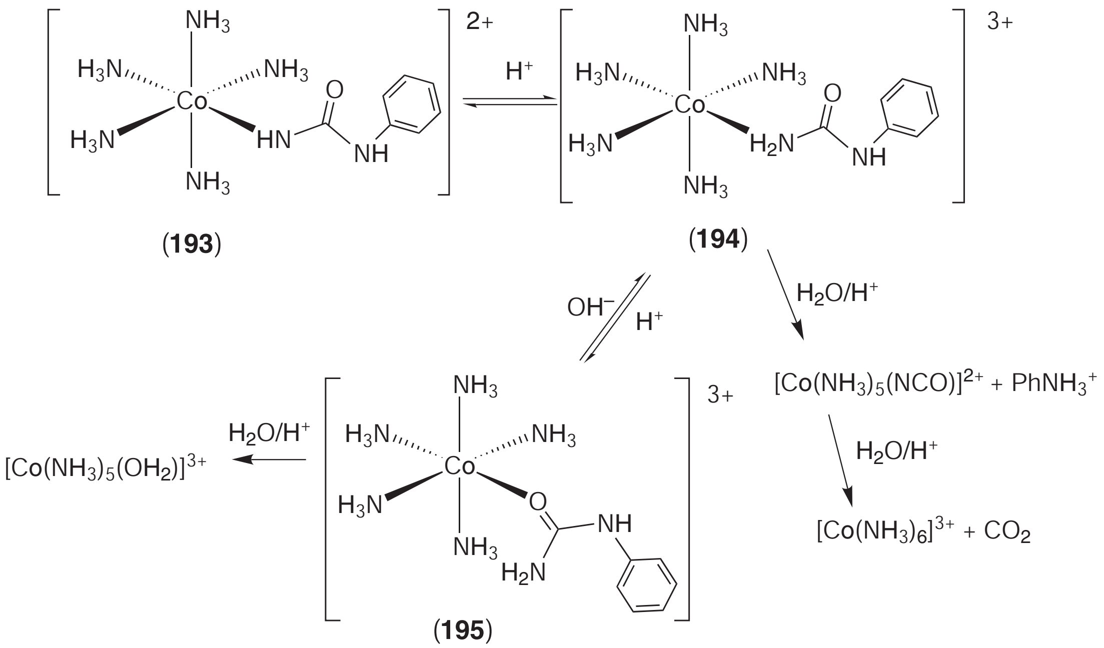


(**191**)



(**192**)

p-C_6H_4F, *o*-$C_6H_4NO_2$) has appeared.[871] N-Bound amides are quite acidic (pK_a < 4) and are able to be isolated in both their neutral (enol) $[(H_3N)_5CoNH{=}C(OH)R]^{3+}$ and monoanionic (amidate) $[(H_3N)_5CoNHCOR]^{2+}$ forms. For example, the N-bound amidate form of the phenylurea complex (**193**) is stable, whereas the protonated form (**194**) spontaneously undergoes linkage isomerization to the *O*-bound isomer (**195**). This reaction is in competition with ligand hydrolysis via $[Co(NH_3)_5(NCO)]^{2+}$ to give $[Co(NH_3)_6]^{3+}$.[872] Interestingly, (**195**) does not undergo hydrolysis but instead ligand substitution (aquation) occurs to give $[Co\ (NH_3)_5(OH_2)]^{3+}$ and unbound urea.

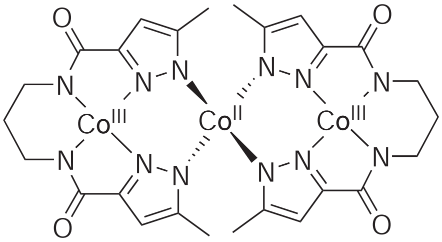


(**193**) (**194**) (**195**)

Addition of $[Co(en)_2(gly)]^{2+}$ to a solution of $SOCl_2$ in DMF followed by hydrolysis resulted in oxidation and formylation of the glycinato ligand. The *N*-formyloxamato complex and elemental S were identified as products.[873] Multidentate amides met as peptides, for example, invariably bind through at least one deprotonated peptide N atom. A number of mixed ligand Co^{III} complexes of the dipeptide gly–gly have been prepared. The peptide coordinates in a meridional configuration, and the crystal structure of *mer*-Co(gly–gly)(en)(NCS) was reported.[874] The corresponding nitro complex undergoes a condensation reaction at the N terminus with CH_2O to give an unusual 1,3-oxazine, which is coordinated through carboxylato O, peptide N, and imine N atoms.[875] The dipeptides (H_2dipep = L-met-gly, gly-L-met, L-met-L-ala and L-ala-L-met) have been complexed with Co. A number of compounds of the form $[Co(dipep)_2]^-$,

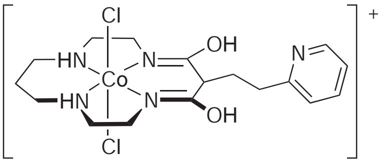
$[Co(dipep)(en)]^+$ and *cis*-$[Co(dipep)(NH_3)_2]^+$ were prepared and characterized by NMR and CD spectroscopy.[876] The dipeptides coordinate through the terminal and peptide N atoms, the carboxylate and the S atom of the side chain. The complexes $Co(dipep)(NO_2)_3$ (H_2dipep = gly-gly, gly-L-ala, gly-L-val, gly-L-nva, gly-L-leu, β-ala-gly) were prepared and interproton NMR coupling over five bonds of the peptide was identified.[877] The crystal structure and CD absorption spectum of the tripeptide complex $Co(NH_3)_2$(L-ala-gly-gly) has been reported. The sole methyl side chain on the tetradentate ligand (at the N terminal end) is in an equatorial position.[878] Proline residues attached to either end of dien result in the pentadentate ligand H_2prodien, which was characterized structurally, as well as with CD spectroscopy, as its complex $[Co(prodien)(OH_2)]^+$.[879] The ^{15}N NMR spectra of a number of dipeptide, tripeptide, and tetrapeptide complexes of Co^{III} were measured. Coordination of oligopeptides resulted in large upfield shifts for both amine and deprotonated amide nitrogens, and specific *trans* effects were also identified.[880]

The novel tetrabasic ligand 1,3-bis(5-methylpyrazole-3-carboxamido)propane forms a trinuclear Co^{III}–Co^{II}–Co^{III} complex (**196**). The tetradentate diamide-pyrazolyl chelates encircle the terminal trivalent metal ions while the central divalent Co is in a distorted tetrahedral environment provided by the four bridging pyrazolyl rings.[881]

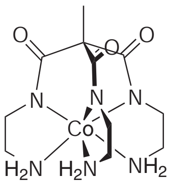


(**196**)

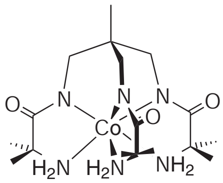
The Co^{III} complexes of the macrocycle 5,7-dioxocyclam and a pendent pyridylethyl derivative (**197**) have been structurally characterized.[882] The ligands bind in their enol tautomeric forms in the complexes when isolated from acidic solution, as shown by X-ray crystallography and IR spectroscopy. The tripodal triamides (**198**) and (**199**) have been synthesized and their Co complexes exhibit a pronounced cathodic shift of their $Co^{III/II}$ redox couples relative to the hexaamine analog $[Co(sen)]^{3+}$ (**163**).[883] The crystal structure of (**198**) was reported. Amide analogs of the macrobicyclic $[Co(sar)]^{3+}$ cages (**200**), using ester groups as capping fragments, have been synthesized.[884,885] Alternatively, homologous cages derived from tris(cyclohexane-1,2-diamine)cobalt(III) undergo oxidative dehydrogenation to give diamide complexes where one of the cyclohexyl rings has undergone aromatization.[886]



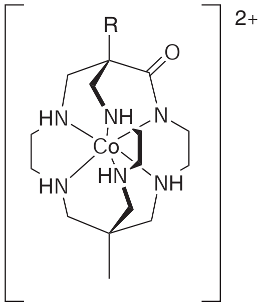
(**197**)



(**198**)

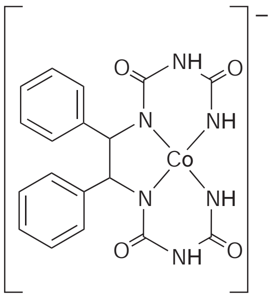


(**199**)

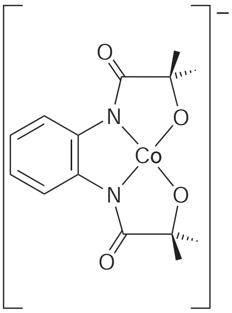


(**200**)

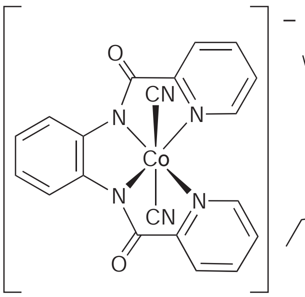
Examples of paramagnetic ($S = 1$) trivalent Co complexes are unusual, but multidentate amide ligands provide a significant proportion of known examples. The square planar tetraamide amide complex (**201**) bears a ligand formally derived from a pair of biuret molecules bridged by a 1,2-diphenylethyl moiety.[887] The crystal structure reveals that the Co—N bonds are on average shorter than those found in diamagnetic (octahedral) Co^{III} amide complexes. Similarly, (**202**) is square planar, as shown by an X-ray crystal structure.[888] A spin triplet ground state was also identified in the solid state. An octahedral diamagnetic complex is formed upon addition of two equivalents of pyridine to an aqueous solution, but no adduct forms in aprotic solvents.



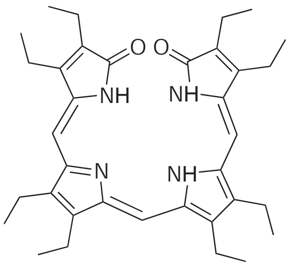
(**201**)



(**202**)



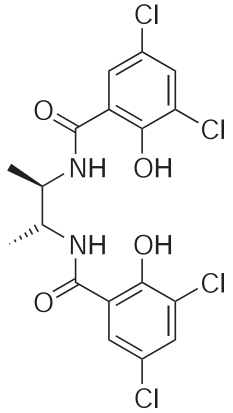
(**203**)



(**204**)

The dianionic tetradentate ligand 1,2-bis(pyridine-2-carboxamido)-benzenate (bpc) is non-innocent. The anion (**203**) can be oxidized to Co(bpc$_{ox}$)(CN)$_2$ which has a $S=1/2$ ground state, and the crystal structure of the complex has been determined.[889] The open chain tetradentate octaethylbilindione (**204**) (H$_3$OEB) bears a tetrapyrrole unit found in biliverdin, an intermediate in heme catabolism and a commonly found pigment. Carbonyl groups at opposite ends of the open chain porphyrin relative forbid the adoption of planar conformations by this ligand in contrast to porphyrins themselves.[890] Instead, the tetrapyrrole ligand adopts a helical conformation; the monomeric Co(OEB) complex has been characterized by X-ray crystallography and spectroscopic techniques. The compound exhibits a rich electrochemistry, with four electrochemically reversible redox states [Co(OEB)]^n ($n=-2$, -1, 0, and $+1$).[891] The monopositive complex has also been characterized structurally, and spectroscopic evidence indicates that it is a divalent complex of the 2-electron oxidized ligand, i.e., [Co^{II}(OEB$_{ox}$)]$^+$. A ligand-centered radical has been observed upon reaction of this compound with pyridine to give the [Co^{III}(OEB$^{-\bullet}$)(py)$_2$]$^-$ species.[892]

Epoxidation of norbornene with *t*-BuOOH or PhI as terminal oxidant catalyzed by the Co^{III} complex of (**205**) was explored.[893] Co catalysis is associated with the Co^{III}- to Co^{II}-driven formation of *t*-BuOO radicals. By contrast, there is no evidence for radical intermediates in Co catalysis with PhIO and an oxo-cobalt(IV) species was postulated instead in this case. The chiral square planar complex of 2,4-bis((*R*)-2-methylbutyramido)-2,4-dimethylpentan-3-one and other close relatives were prepared and characterized by NMR and X-ray crystallography.[894] Asymmetric epoxidation of styrenes with these complexes and PhIO were achieved in varying yields with modest enantiomeric excess. The pyridyl-substituted pentadentate ligand, N,N′-bis(2-(2′-pyridyl)ethyl)-2,6-pyridinedicarboxamide (H$_2$py$_3$p), when complexed with Co^{III}, catalyzes the selective oxygenation of phenols to the corresponding *p*- or *o*-quinones.[895] Crystal structures of the [Co(py$_3$p)X]$^{n+}$ (X = H$_2$O, $n=1$; X = OH$^-$, *t*-BuOO$^-$, $n=0$) complexes have been reported.[896] The *t*-butylperoxo complex oxidizes alkanes such as cyclohexane via homolytic scission of the O—O bond. The *t*-BuO$^\bullet$ radicals liberated abstract an H atom from cyclohexane and the cyclohexyl radical reacts with O$_2$ to give a mixture of cyclohexanol and cyclohexanone. The bis(pyr-



(**205**)

azolylethyl) analog H_2pypz$_2$p has also been synthesized and its analogous pentadentate coordinated Co^{III} complexes have been reported.[897] By contrast, the pentadentate coordinated complex $[Co(pypz_2p)(OH_2)]^+$ is converted quantitatively to the bis-bidentate $[Co(pypz_2p)_2]^-$ in solution. The influence of the strong field amide N-donors is the driving force for this transformation.

(viii) Nitrosyl

Bound nitrosyl can display either a linear or bent geometry. The ^{15}NO NMR shifts for five-coordinate Co^{III} complexes with Schiff base or dithiocarbamato basal ligands and bent apical nitrosyl ligands have been reported.[898,899] As in C-nitroso groups, bent ^{15}NO ligand resonances are strongly deshielded (by 500–800 ppm) relative to comparable linear nitrosyls, and both ^{59}Co and ^{15}NO shielding was found to decrease with the Co—N—O angle.

Nitrosyl complexes of Co porphyrins have attracted considerable attention. As an example, Co(TPP)(NO), and some methoxy and nitroaromatic homologs, were prepared and the Co—NO bonding interaction was probed using cyclic voltammetry and reflectance IR spectroelectrochemistry. These experiments revealed $\bar{\nu}_{N\equiv O}$ vibrations for the one- and two-electron oxidized complex; the latter being consistent with an effectively σ-bonded nitrosyl.[900] An extended series of Co(TPP)(NO) analogs bearing an even greater variety of aromatic substituents was reported by reaction of the precursor Co porphyrin with NO or with $NOBF_4$, then reduction with cobaltocene. The complexes are diamagnetic, display $\bar{\nu}_{N\equiv O}$ bands around 1,690 cm^{-1} and possess a bent nitrosyl ligand (Co—N—O ~120°).[901] Spectroelectrochemical IR experiments showed that the complexes undergo a reversible one-electron oxidation of their porphyrin ring and a one-electron reduction of the Co center.[902] An accurate crystal structure of Co(OEP)(NO) was determined in order to probe apparent structural distortions found in the Fe analog.[903] The Co—N vector was within 2° of perpendicular to the porphyrin plane, whereas the Fe—N vector was tilted by more than 6°. Equatorial M—N(porphyrin) bond length asymmetry was seen in both structures, which was correlated with the axial M—N(O) tilt angle. Subsequent theoretical studies confirmed this structural correlation.[904]

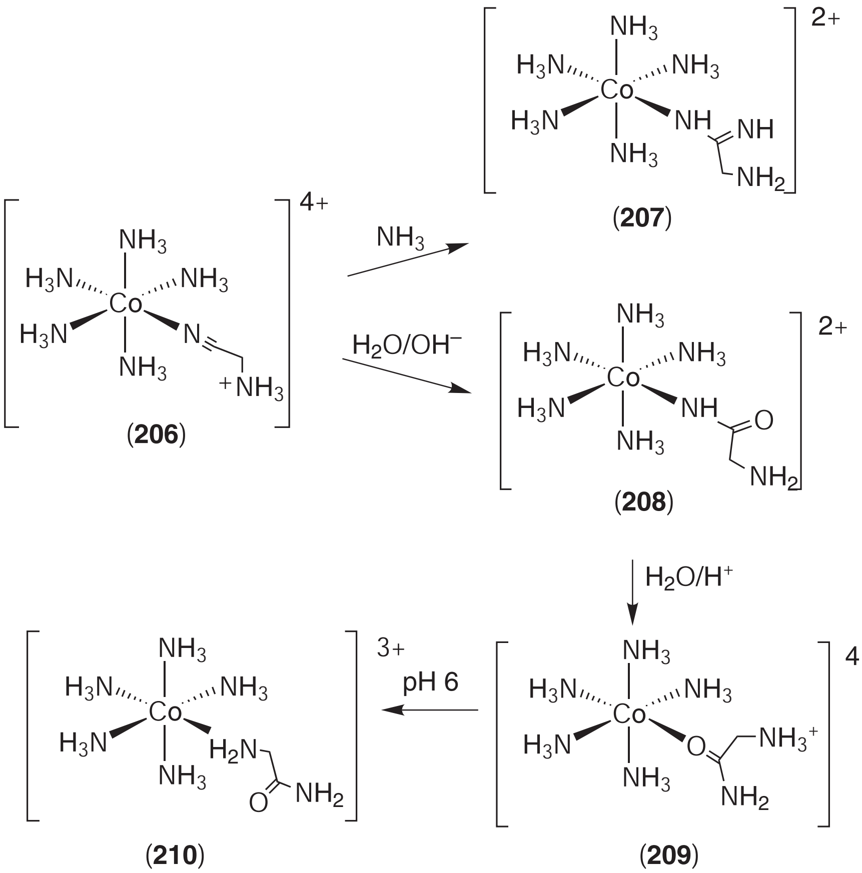
Coordination of NO to the divalent tetrasulfonated phthalocyanine complex $[Co(TSPc)]^{4-}$ results in a complex formally represented as $[(NO^-)Co^{III}(TSPc)]^{4-}$ ($k_f = 142\ M^{-1}s^{-1}$, $K_a = 3.0 \times 10^5\ M^{-1}$). When adsorbed to a glassy carbon electrode, $[Co(TSPc)]^{4-}$ catalyzes the oxidation and reduction of NO with catalytic currents detectable even at nanomolar concentrations. Electrochemistry of the same complex in surfactant films has also been studied.[905] Bent nitrosyl complexes of the paramagnetic trivalent tropocoronand complex Co(NO)(TC) ((**189**), R = NO) have also been reported.[849]

(ix) Nitriles, azides, isocyanides, cyanates, and thiocyanates

Nitrile coordination chemistry of Co has attracted attention as the influence of the trivalent metal ion greatly enhances the reactivity of the C≡N bond toward nucleophilic attack, especially hydrolysis. Amine complexes of Co^{III} have been popular scaffolds upon which to perform these reactions. Following syntheses of the pentaamminecobalt(III) complexes of 2- and 4-nitrobenzonitrile, base hydrolysis of the coordinated nitrile to the corresponding carboxamides was investigated. Rate constants for nitrile hydrolysis for these and a number of other substituted aromatic nitrile analogs were correlated with the Hammett substituent parameters.[906] The N-bonded nitrile complexes $[Co(tetren)(NCR)]^{3+}$ (R = Me, Ph, p-$MeOC_6H_4$; tetren = linear tetraethylenepentaamine) were prepared and the kinetics of base hydrolysis were studied. The reactions involved displacement of the nitrile to give the hydroxopentaamine as opposed to nucleophilic attack at the nitrile carbon, i.e., the corresponding carboxamido complex is not formed.[907]

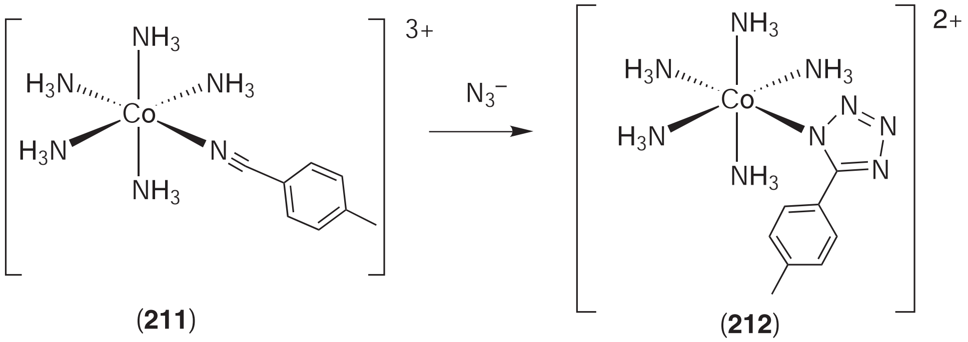
The ammonioacetonitrile complex (**206**) reacts with NH_3 to produce the amidine-bonded aminoacetamidine (**207**) complex, whereas in aqueous base it hydrolyzes to the amido-*N*-bonded glycinamide complex (**208**).[908] Acid-catalyzed linkage isomerization to first the *O*-bound form (**209**) precedes formation ultimately of the amino-bonded isomer (**210**) as the stable product upon deprotonation of the free amine above pH 6.

The 1,3-dipolar cycloadditions of N_3^- with coordinated nitriles (**211**) may result in formation of 5-substituted tetrazole complexes (**212**). Some examples include $[Co(NH_3)_5(N_4R)]^{2+}$-(R = *p*-methylphenyl, *p*-chlorophenyl, *p*-nitrophenyl (N1 bound), *m*-formylphenyl (*N*2 bound)).



(206) (207) (208) (209) (210)

The kinetics of the reaction is first order in both nitrile complex and azide.[909] NaN_3 reacts with $[Co(tetren)(NCMe)]^{3+}$ at pH 5.7 to give the 5-methyltetrazolato complex $[Co(tetren)(N_4CMe)]^{2+}$. The reaction is biphasic, involving the initial rapid formation of the *N*1-bonded tetrazole followed by the slow linkage isomerization to the N2-bonded complex.[907]



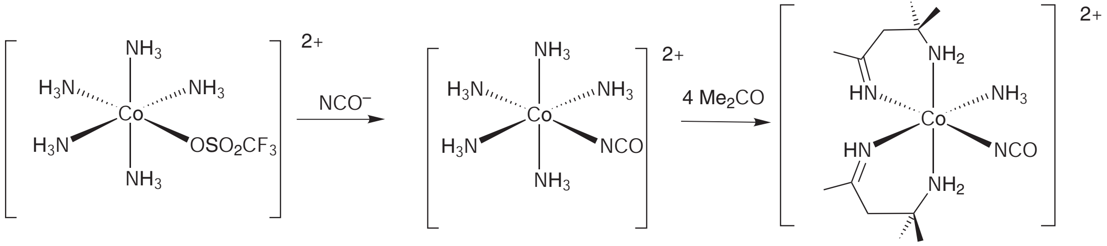
(211) (212)

The ambidentate isomers 3-cyanopyridine and 4-cyanopyridine have been complexed to the pentaamminecobalt(III) moiety and their corresponding linkage isomers $[(H_3N)_5Co(NCpy)]^{3+}$ and $[(H_3N)_5Co(pyCN)]^{3+}$ have been prepared.[910] Their electron transfer cross reactions with $[Fe(CN)_5(OH_2)]^{3-}$ were investigated and were found to proceed in two stages. In the first stage, pyCN-bridged Fe^{II}–Co^{III} dinuclear complexes are formed as intermediates, but their fate depends on the linkage isomer present that undergoes rapid inner-sphere electron transfer. The binuclear $(H_3N)_5Co^{III}(NCpy)Fe^{II}(CN)_5$ complex undergoes inner-sphere electron transfer followed by complex dissociation, whereas the $(H_3N)_5Co^{III}(pyCN)Fe^{II}(CN)_5$ isomer simply dissociates to its reactants without electron transfer taking place. For the latter systems, outer-sphere electron transfer is more competitive. The Cr^{II} reduction of the nitrile-bonded pentaamminecobalt(III) complexes of 3- and 4-cyanobenzoic acid has also been studied.[911] The reaction between Cr^{II} and $[(H_3N)_5Co(NCCH_2I)]^{3+}$ gave the unusual dinuclear complex $[(H_3N)_5Co(NCCH_2)Cr(OH_2)_5]^{5+}$ as the only product.[912] The Hg^{II} analog was also prepared.

The potentially bridging 2-cyano-acetylacetonato anion has been complexed with Co in its N-bound form to give $[Co(NH_3)_5(NCC(C(O)Me)_2)]^{2+}$. The bridged dicobalt(III) complex $[(H_3N)_5Co(\mu\text{-}NCC(C(O)Me)_2)Co(tn)_2]^{5+}$ was also prepared.[913] Inner-sphere electron transfer between $[Co(NH_3)_5(NCC(C(O)Me)_2)]^{2+}$ and Cr^{II} was verified by blocking the acac coordination site with a non-reducing metal ion, which inhibited reaction with divalent Cr. The cyanoborane complexes $[Co(NH_3)_5(NCBH_2R)]^{3+}$ ($R = Et_3N$, py, PPh_3) were prepared from the triflatopentaammine precursor in acetone; further, the syntheses of some alkane nitrile analogs were described as well as the kinetics of their base-catalyzed hydration reactions.[914]

Coordinated azide complexes have been widely reported. The azido complex $[Co(NH_3)_5(N_3)]^{2+}$ has been well explored. Amongst its applications, it is an efficient photoinitiator of polymerization of 2-hydroxyethyl methacrylate (HEMA).[915] The interaction of Me_3SiN_3 with *mer*-$CoMe_3(PMe_3)_3$ gives the octahedral $CoMe_2(N_3)(PMe_3)_3$ complex. This azido complex and its trigonal bipyramidal carbonyl derivative $Co(N_3)(CO)_2(PMe_3)_2$ were characterized structurally.[916]

The complex $[Co(NH_3)_5(OSO_2CF_3)]^{2+}$ undergoes triflate substitution by cyanate and condensation with acetone to form the unusual bis-bidentate imine complex (**213**)[917] in a reaction reminiscent of the classic Curtis condensation of acetone with ethylenediamine. Apart from the novelty of the synthesis, the reported crystal structure was only the second of a CoN_6 complex bearing a cyanate ligand.



(**213**)

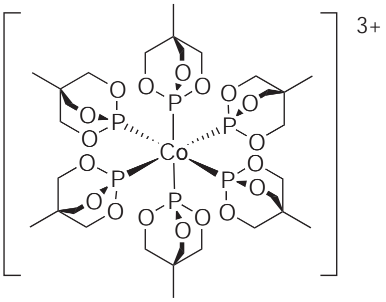
The coordination chemistry of the ambidentate SCN^- and its linkage isomerism when bound to Co^{III} has been reviewed.[19] With Co^{III}, the *N*-bound isomer is thermodynamically stable and commonly observed, and the Co–NCS unit (typical Co—N 1.90 Å) is usually linear, although some deviations from strict linearity are sometimes found in practice. A more unusual monomeric complex is *mer*-$Co(NCS)_3(PMe_3)_3$, formed via reaction of $Co(NCS)_2(PMe_3)_2$ with NO, where a disproportionation leads to the CoN_3P_3 species as well as $[Co(NO)_2(PMe_3)_2]$ $[Co(SCN)_4]$.[918]

6.1.2.3.4 Phosphorus

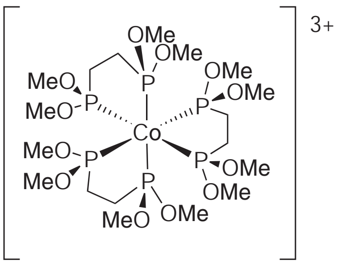
Phosphorus ligands bound to cobalt are met more broadly in the parallel *Comprehensive Organometallic Chemistry* series, but some representative examples not also including Co—C bonded species are presented here.

(i) Mono- and bidentate phosphines

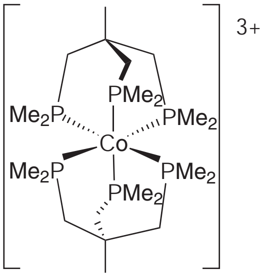
The bicyclic phosphite ester $P(OCH_2)_3CMe$ and the bidentate bis-diphosphite $((MeO)_2PCH_2CH_2\text{-}P(OMe)_2)$ form trivalent CoP_6 complexes of the form (**214**) and (**215**). A photophysical study observed emission from the $^3T_{1g}$ electronic state in both complexes.[919] Photolysis of (**215**) in aqueous solution at 300 K results in photoaquation. An NMR investigation reported the longitudinal relaxation times (T_1) of ^{59}Co and ^{31}P nuclei across a series of $CoP_6{}^{3+}$ complexes (where P was $P(OMe)_3$ or a mono or bicyclic phosphite ester).[920] The magnitude of T_1 decreased as the symmetry of the ligands was lowered and the $^{59}Co–^{31}P$ coupling constants decreased as the exocyclic group in the monocyclic phosphite ligand was enlarged.



(214)



(215)



(216)

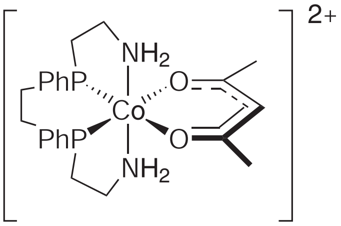
The reaction of *trans*-$[Co(acac)_2(PPh_3)_2]PF_6$ with PR_3 (R = Me or Et) in MeOH yields *trans*-$[Co(acac)_2(PR_3)_2]PF_6$. These *trans* complexes are stable in dry solvents, but are rapidly hydrolyzed in wet MeOH to give *trans*-$[Co(acac)_2(PR_3)(H_2O)]^+$ and isomerize to *cis*-$[Co(acac)_2(PR_3)_2]^+$ in the presence of a catalytic amount of activated charcoal.[921] The *cis* isomers did not undergo aquation under similar conditions. X-ray crystal structure analyses showed that the Co—P bonds in the *trans* isomers were longer by approximately 0.07 Å than those of the corresponding *cis* isomers. The Co—O bonds *trans* to the phosphine ligands were also longer than those of the mutually *trans* Co—O bonds, owing to the strong *trans* influence of phosphine ligands. In a comprehensive systematic study a larger number of monodentate phosphine bis(acac)cobalt(III) complexes were prepared. The observed ratios of the *cis* and *trans* isomers of $[Co(acac)_2(P(R_nPh_{3-n})_2]^+$ depend upon the bulkiness (R = Me or Et) and basicity of the phosphine.[922] The *trans* isomers exhibit a strong absorption band in the expected *d–d* transition region, which was assigned to a charge transfer transition between the Co^{III} ion and a phosphine ligand, whereas the *cis* isomers exhibit the first *d–d* band split into two components by the lower symmetry ligand field. Other systems studied included *trans*-$[Co(acac)_2(H_2O)(P(R_nPh_{3-n})]^+$, *trans*-$[Co(acac)_2(amine)(PMe_2Ph)]^+$, and *trans*-(P,P)-$Co(acac)(CN)_2(P(R_nPh_{3-n}))_2$. The crystal structures of a number of these complexes were subsequently reported.[923]

Five-coordinate complexes of the form $Co(PR_3)_2X_3$ (X = Cl, Br; $PR_3 = PMe_3$, PEt_3, PMe_2Ph, PEt_2Ph, $PEtPh_2$) were prepared by oxidation of their divalent $Co(PR_3)_2X_2$ precursors at low temperature.[924] The intensely colored, paramagnetic ($\mu_{eff} = 2.9–3.3$ B.M) Co^{III} complexes were formulated as trigonal-bipyramidal species on the basis of vibrational and UV-visible spectroscopic data. Coordinate bond lengths for $Co(PEt_3)_2X_3$ and $Co(PEt_2Ph)_2X_3$ were obtained by Co and Br K-edge EXAFS spectroscopy and average values of Co—P 2.30, Co—Cl 2.20, and Co—Br 2.36 Å were obtained.

The bidentate phosphine dppe (1,2-bis(diphenylphosphino)ethane) and the aminophosphine eddp (2-aminoethyl-diphenylphosphine) form mixed ligand (N, P, O) complexes such as Co(acac)(edpp)$_2$ and Co(acac)(en)(dppe). A preference for *trans* N–Co–P and P–Co–P configurations over N–Co–N was found for the bis(edpp) complexes.[925]

(ii) Multidentate phosphines

The tripodal phosphine mtriphos (1,1,1-tris(dimethylphosphinomethyl)ethane) forms a stable trivalent complex (**216**) that has been characterized by X-ray diffraction.[119] The Co—P bond distances (2.291(9)–2.357(7) Å) are longer than those normally found in Co^{III}–phosphine complexes. A number of trivalent CoP_4X_2 and CoP_3X_3 ($X = Cl^-$ and Br^- but not I^-) complexes have been prepared incorporating chelating phosphines such as the bidentate o-$C_6H_4(PPh_2)_2$, the tridentate $PhP(CH_2CH_2PPh_2)_2$, and the tripodal $P(CH_2CH_2PPh_2)_3$ and linear $Ph_2PCH_2CH_2PPhCH_2CH_2P(Ph)CH_2CH_2PPh_2$ tetraphosphines.[926] Mixed donor P,N,O-ligands such as o-$C_6H_4(CH{=}NCH_2CH_2PPh_2)(OH)$ have been prepared by standard Schiff base condensation reactions.[927] On deprotonation these ligands coordinate as tridentates to give trivalent bis complexes of the form $[CoL_2]^+$. The distortions in the free ligand predispose it for coordination in a *fac* geometry to Co with *cis*-PPh_2 groups, as shown by X-ray crystallography. Another example is the linear P_2N_2 tetradentate which forms *cis*-α- (**217**) and *cis*-β-$[Co^{III}(L)(aa)]^{n+}$ (aa = oxalate or acetylacetonate) complexes.[928]



(**217**)

6.1.2.3.5 Arsenic

(i) Monoarsines and multidentate arsines

The Co coordination chemistry of As donors is less developed than that of phosphorus, although there are obvious parallels between the two. Treatment of Me_3AsI_2 with Co metal powder gives both trivalent ($[CoI_3(AsMe_3)_2]$) and divalent ($[AsMe_3I][CoI_3(AsMe_3)]$) complexes as products.[929]

$CoAs_6$ complexes bearing chelating tertiary arsines are well known. Preparation of the homoleptic $CoAs_6$ and $CoAs_3P_3$ complexes $[Co(o\text{-}C_6H_4(AsMe_2)_2)_3]^{3+}$ and $[Co(o\text{-}C_6H_4\ (PMe_2)(AsMe_2))_3]^{3+}$ have been described,[930] and the X-ray structure of $[Co(o\text{-}C_6H_4\ (AsMe_2)_2)_3](BF_4)_3$ reveals a Co ion coordinated (Co—As 2.365(2)–2.395(2) Å) within an approximately D_3 symmetrical ligand field. The Co^{III} complexes of a variety of the bi-($o\text{-}C_6H_4(AsMe_2)_2$) tri-(MeAs ($o\text{-}C_6H_4AsMe_2)_2$, $MeC(CH_2AsMe_2)_3$) and tetradentate (($As(CH_2CH_2CH_2AsMe_2)_3$) arsines have appeared and their ^{59}Co NMR spectra studied.[931] The characteristic chemical shift range for $CoAs_6$ complexes was identified as about −350 ppm to +200 ppm relative to $[Co(CN)_6]^{3-}$. Solvent effects were identified in the $CoAs_6$ chromophores, but these were diminished in $CoAs_3I_3$ and $CoAs_4I_2$ complexes.

The CD spectra of a series of *cis*-$[CoX_2(o\text{-}C_6H_4(AsMe_2)_2)_2]^+$ complexes (X^- = Cl, OH, NO_3, NO_2) were reported,[932] and the absolute configurations of the resolved enantiomers were inferred. In a related study the chiral and diastereomeric octahedral Λ-*cis*-α and Δ-*cis*-β Co complexes of the linear tetraarsine $Me_2As(CH_2)_3As(Ph)(CH_2)_2As(Ph)(CH_2)_3AsMe_2$ gave complex CD spectral patterns for their *d–d* electronic transitions, and the conclusions of this study were that CD of complexes of such soft donor atoms are not useful for establishing absolute configuration.[933] A number of bidentate chelate complexes of the saturated diarsines dmae (1,2-bis(dimethylarsino)ethane) and dmap (1,3-bis(dimethylarsino)propane) have been reported including *trans*-$[CoX_2(dmap(e))_2]^+$ (X^- = Cl, Br, I), *cis*-$[CoX_2(dmap)_2]^+$ (X^- = Cl, Br), $[Co(CO_3)(dmap(e))_2]^+$, and $[Co(acac)_{3-n}(dmap)_n]^{n+}$ ($n = 0, 1, 2$).[934] Isomerization of *cis*-$[CoCl_2(dmap)_2]^+$ to the *trans* isomer in MeOH is one hundred times faster than that reported for *cis*-$[CoCl_2(o\text{-}C_6H_4\ (AsMe_2)_2)_2]^+$ at the same temperature. The crystal structure of *trans*-$[CoCl_2(dmap)_2]ClO_4$ was subsequently reported.[935]

Trivalent Co complexes of the mixed donor amino arsine emda (2-aminoethyl)dimethylarsine) have been synthesized.[936] Examples include *trans*(X,X), *cis*(As,As)-$[CoX_2(edma)_2]^+$ (X^- = Cl, Br, and I), *trans*(As,As)- and *trans*(As,N)-$[Co(acac)(edma)_2]^{2+}$, *trans*(As,N)-$[Co(CO_3)(edma)_2]^+$, $[Co(acac)_2(edma)]^+$, and *fac*-$[Co(edma)_3]^{3+}$. The *fac*-$[Co(edma)_3]^{3+}$ complex was resolved and the absolute configuration of the $(+)_{490}$ CD isomer was assigned as Λ on the basis of the CD spectrum. Racemization of this complex was first order in both complex and hydroxide ions. The crystal structure of $[Co(acac)_2(emda)]ClO_4$ has been reported.[937]

Uncomplexed chirotopic tertiary As atoms are known to undergo slow inversion and so chiral polyarsines may be resolved into their enantiomeric and diastereomeric forms. The mixed donor tetradentate ligand (R^*,S^*)-1-[(2-dimethylarsinophenyl)methylarsino]-2-[(2-aminophenyl)methylphosphino]benzene was prepared stereoselectively and the crystal structure of its dichlorocobalt (III) complex was reported.[938,939] The same group reported the syntheses of the chiral tetraarsine 1-(chloromethyl)-1,1-bis(((2-dimethylarsinophenyl)methylarsino)methyl)ethane and the hexaarsine 1,1,1-tris(((2-dimethylarsinophenyl)methylarsino)methyl) ethane;[940] the latter providing the first example of a chiral hexaarsine.[940] The three diastereomers of the tetraarsine bind to Co^{III} stereoselectively.

6.1.2.3.6 Oxygen

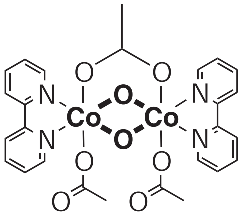
(i) Aqua, hydroxo, and oxo

H_2O, HO^- and O^{2-} are all accessible and well-studied ligands for cobalt(III). The hexaaquacobalt(III) ion is only stable in concentrated acids of non-reducing anions, being a powerful oxidant which oxidizes water. It has been characterized in the solid state as an octahedral ion with Co—O 1.873(5) Å.[941] Due to its instability, it is not a very useful entry point into synthetic cobalt(III) chemistry. Invariably, coordinated water is consequently found in mixed-ligand cobalt(III) complexes. The pK_a of water is reduced substantially on coordination, and the highly polarized aqua ligand is deprotonated around neutral pH to form hydroxo complexes. For trivalent (inert) cobalt, which does not tend to undergo subsequent oligomerization reactions, this is usually a reversible process. Further deprotonation to an isolated oxo ligand is rare, with this ligand found in metal-bridging environments where the presence of several metal ion centers promotes its formation. Of historical significance is the report of the crystal structure of Werner's hexol cation $[Co\{Co(OH)_2(NH_3)_4\}_3]^{6+}$, where the core Co^{III} is surrounded by six bridging hydroxides linked to three distal Co^{III} centers, obtained serendipitously when attempting to grow crystals of carbonatopentamminecobalt(III) nitrate from water.[942] Another compound from the Werner collection characterized structurally recently is the (μ-amido) (μ-hydroxo)(μ-superoxo)hexaamminedicobalt(III) complex.[943] Hydroxo-bridged complexes reported prior to 1988 have been reviewed in detail,[944] and will not be covered here.

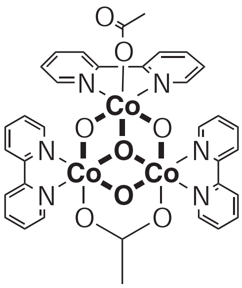
Although there is a tendency to associate coordinated water with Werner-type complexes, where it is extensively established, organometallic aqua ions are known.[945] The simple $[(Cp^*)Co(OH_2)_3]^{2+}$ has been established, and is prepared via Equation (8). The lower pK_a is 5.9, similar to values in aminecobalt(III) compounds, and reversible deprotonation and dimerization has been identified as part of the reactions of the aqua ion.[946]

$$[CpCo^{II}Cl]_2 \xrightarrow[(-C_2Cl_4)]{C_2Cl_6} [CpCo^{III}Cl_2]_2 \underset{HCl}{\overset{H_2O}{\rightleftharpoons}} 2\,[CpCo^{III}(OH_2)_3]^{2+} \overset{OH^-}{\rightleftharpoons} [\{CpCo\}_2(\mu\text{-}OH)_3]^+ \tag{8}$$

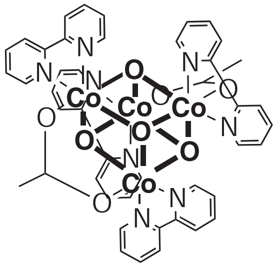
Multiple bridging involving the oxo and hydroxo anions is well established with Co^{III}. A number of bridging modes can be considered as possible, and examples of most will be exemplified below. Although well established in iron chemistry, the mono-bridged oxygen analog is not well established in Co chemistry. Dihydroxy-bridged systems, however, are well known; an example is $(en)_2Co(\mu\text{-}OH)_2Co(edda)$, which also features different ligand sets around each octahedral Co center.[947] The trihydroxy-bridged systems are less commonly reported, but examples exist; a simple one is the structurally characterized $[\{(tacn)Co\}_2(\mu\text{-}OH)_3]^{3+}$.[948] Two examples of μ_3-oxo in a cobalt(III) complex are in the partial cubane $[Co_3L_3(\mu\text{-}OH)_3(\mu_3\text{-}O)]Cl$ (L = ethylenediamine-*N*-acetate)[949] and in the cubane $Co_4(\mu_3\text{-}O)(\mu\text{-}OAc)_4(py)_4$.[950] Another compound with μ_3–oxo bonding arises from reaction involving salicylaldoxime, leading to a species with a triangular $\{Co_3(\mu_3\text{-}O)(\mu_2\text{-}OPh)\}$ core.[951] A μ_3-O coordination mode is found in $[Co_4O_4(OAc)_2(bpy)_4]^{2+}$,[952] where each Co is in a distorted octahedral environment. The red dicobalt (**218**), green–black partial cubane tricobalt (**219**) and brown cubane tetracobalt (**220**) structures have all been characterized by X-ray crystallography, and their synthesis is straightfor-



(**218**)



(**219**)



(**220**)

ward. The first two form via reaction in 3:1 MeOH:H_2O and the latter through "dimerization" in DMSO, as in Equations (9–11).

$$\mathrm{Co(OAc)_2 + bpy\ (1{:}1\ ratio)} \xrightarrow[50^\circ C]{H_2O_2} \mathrm{[Co_2(OH)_2(OAc)_3(bpy)_2]^+} \tag{9}$$

$$\mathrm{Co(OAc)_2 + bpy\ (3{:}2\ ratio)} \xrightarrow[50^\circ C]{H_2O_2} \mathrm{[Co_3(O)(OH)_3(OAc)_2(bpy)_3]^+} \tag{10}$$

$$\mathrm{[Co_2(OH)_2(OAc)_3(bpy)_2]^+ + 2Li_2O_2} \xrightarrow[70^\circ C]{DMSO} \mathrm{[Co_4(O)_4(OAc)_2(bpy)_4]^+} \tag{11}$$

Further, a μ_4-O is reported in the structurally more complex cluster $Co_8O_4(OBz)_{12}$-$(MeCN)_3(H_2O)$, where the $Co^{III}{}_4O_4$ cubane bridges through each of four μ_3-O groups in the core to a Co^{II} five-coordinate site, making the oxo groups μ_4-O by this attachment (Figure 8).[953]

Heteronuclear bridged systems featuring hydroxo and or oxo ligands are also known. An example of this category is the hydroxo-bridged heterotrinuclear complex ion $[Cu\{(HO)_2Co(en)_2\}_2]^{2+}$, where the Cu^{II} is surrounded by four bridging hydroxides linking in pairs from two octahedral Co^{III} centers.[954] Another related example, where in this case the central metal is in an octahedral environment, is the series $[M^{II}\{(HO)_2Co(en)_2\}_3]^{5+}$ (M = Ni, Zn, Mg), prepared by reaction of $[Co(en)_2(OH_2)_2]^{3+}$ with MCl_2 in water at pH ~8.[955] Yet another, where the concept is extended to the central metal ion being an eight-coordinated ion, is the series $[M^{III}[(HO)_2Co^{III}(NH_3)_4]_4]^{7+}$ (M = Ce, Y, La, Pr, Gd).[956]

Oxo ligands find their fullest expression in polyoxometallates, dominantly of high-valent Mo and W. Polyoxometallates have been extensively reviewed.[957–959] An example of a polyoxometallate cluster incorporating cobalt(III) is $[CoW_{12}O_{40}]^{5-}$. This has the Co^{III} in an unusual tetrahedral geometry, as in the Co^{II} analog from which it can be oxidized reversibly.[960] The trivalent complex is a strong oxidizing agent.

(ii) Dioxygen, superoxide, and peroxide

The interaction of dioxygen with Co centers has its roots in the very beginning of Co chemistry. Biorelevance is a theme that retains a sturdy interest in these systems to the present time (see Section 6.1.3.1.3). Dioxygen can bind reversibly to Co complexes where they retain their integrity as monomers. Further, binding which generates a dimer can be reversible, as observed with $[Co(terpy)(bpy)X]^{2+}$ in polar non-aqueous solvents where X is a labile group such as trifluoromethanesulfonate or 4-chloro-3-nitrobenzenesulfonate.[961] Peroxide ($O_2{}^{2-}$) as a bridging

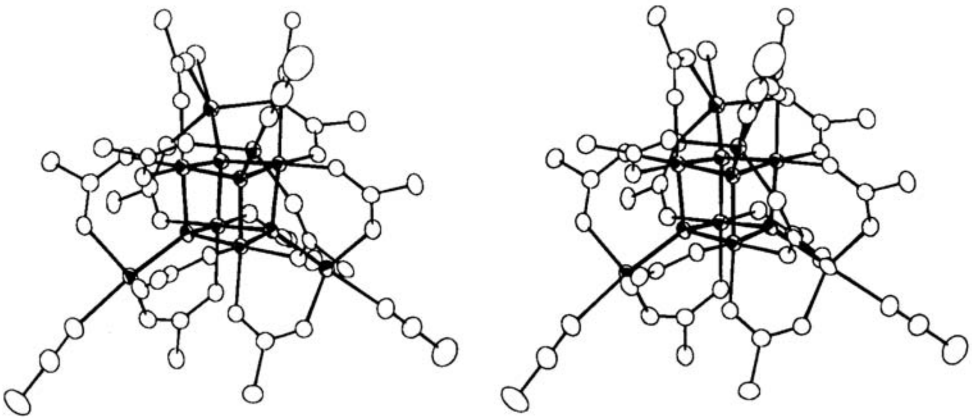


Figure 8 Stereoview of the $[Co_8O_4(OBz)_{12}(MeCN)_3(OH_2)]$ cluster, with phenyl rings and H-atoms omitted (reproduced with permission of the American Chemical Society from *Inorg. Chem.*, **1995**, *34*, 4160–4166).

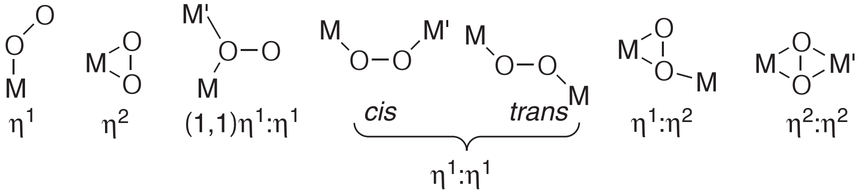
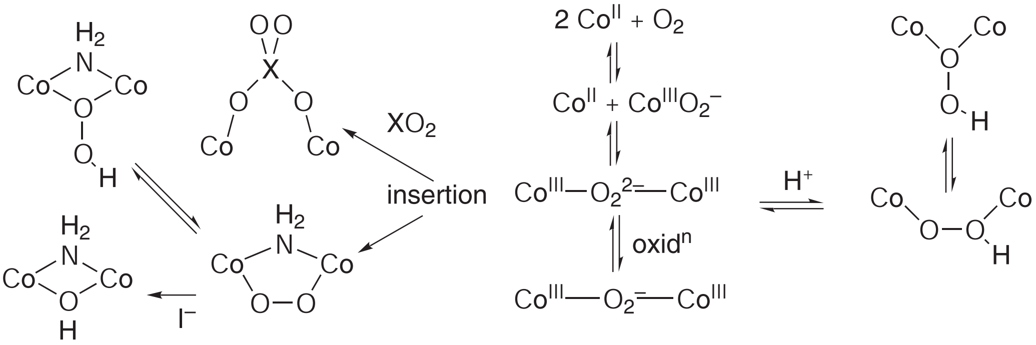
ligand between two cobalt(III) centers is an enduring theme in Co chemistry, as is superoxide (O_2^-). The commonly brown μ-peroxo complexes are usually easily oxidized to the typically green μ-superoxo complexes, as defined in the first edition.

Dioxygen and its ions can bind in mononuclear and dinuclear structures in a number of ways,[962] as illustrated in Scheme 1. The typical reaction of dioxygen with Co compounds involves a number of these binding forms, outlined in Scheme 2. Mononuclear Co^{III}–peroxo complexes are relatively rare, but yellow trigonal bipyramidal complexes $[Co(O_2)L_2]^+$ (L = chelating phosphines dppe or dppp) have been characterized structurally where the O_2^{2-} is bonded to the Co in the side-on η^2 form (Co—O 1.858(7)–1.881(4) Å), with O—O stretching frequencies (~870 cm^{-1}) consistent with Co^{III}–peroxo speciation.[963]



Scheme 1



Scheme 2

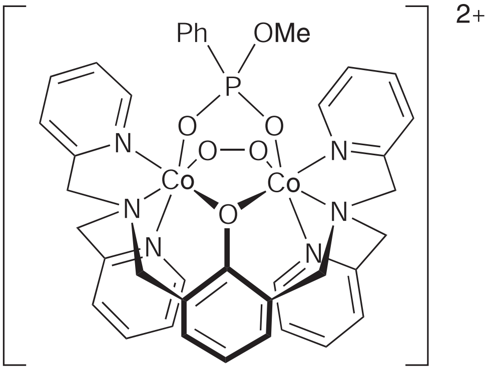
Dioxygen anions (peroxide and superoxide) in a bridging mode are more common. As representative examples, a selection of structurally characterized dicobalt dioxygen complexes is collected in Table 3. It is notable that the type of companion ligands influences the bridged dioxygen moiety. For example, the presence of a polyamine with unusually short Co—N distances has an effect on the superoxide O—O distance, which is shorter than in the simple decaammine analog.[964] Raman spectroscopy provides one method for monitoring behavior in solution for both superoxo and peroxo compounds, with the position of the strong Raman-active O_2 vibration reflecting bond strength. Multiple bridging also influences both Raman and structural parameters. A rare

Table 3 Some structurally characterized dicobalt dioxygen complexes.

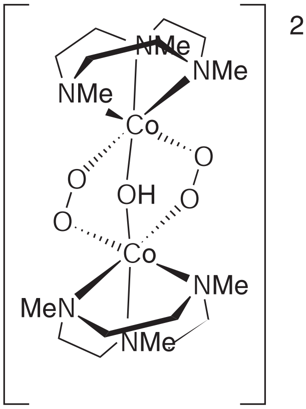
Dioxygen unit	*Other bridging groups*	*Other ligands*	*References*
cis-μ-peroxo	Ph_2PO_2, phenoxo	polyimine/amine	966
cis-bis(μ-superoxo)	hydroxo	polyamine	967
cis-μ-peroxo	acetato, alkoxo	polyimine/amine	968
trans-μ-peroxo		bpy, terpy	961
trans-μ-superoxo		polyamine	964
cis-μ-peroxo	hydroxo	imidazole/thioether	969
cis-μ-peroxo	thiolate	polyamine	970
trans-μ-peroxo		polyamine/imine	971
trans-μ-superoxo		polyamine/imine	971
cis-μ-peroxo	thiosulfato	polyamine	972
trans-μ-peroxo		aminosugar	973

example of a $\mu_3(\eta^1,\eta^2)$-peroxo bridge between Co^{III} and Pb^{II} has been reported in a macrocyclic polyimine compartment ligand where phenoxo groups link metals in each compartment.[965]

Examples are tending to be more sophisticated and complex in form. For example, a dinuclear complex featuring a bridging phosphinate and phenolate in addition to peroxide (**221**) has been reported,[966] as a model for phosphodiester systems. Apart from dicobalt(III) systems, a mixed-valence $Co^{II,III}$ di-μ-superoxo complex (**222**) has been prepared.[967] Transition between the three redox states $Co^{II,II}$, $Co^{II,III}$, and $Co^{III,III}$ is electrochemically reversible.



(**221**)



(**222**)

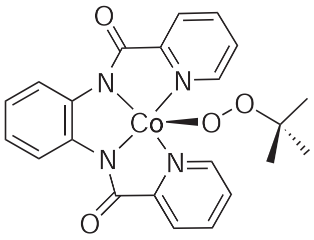
A detailed study of the reaction of the Co^{II} complex of 1,4,7,10,13-pentaazapentadecane ([15]aneN_5) with dioxygen to form Co^{III} complexes has been reported.[974] Formation equilibrium constants for the superoxo ($2.2 \times 10^7\,M^{-1}$) and peroxo ($1.2 \times 10^{20}\,M^{-2}$) were calculated, as well as ligating properties of superoxide and peroxide towards $[Co[15]aneN_5(OH_2)]^{3+}$ ($10^{12}\,M^{-1}$ and $2 \times 10^{37}\,M^{-2}$ respectively), defining the strength of the dioxygen anion complexes. The formation constant with superoxide is similar to a value of $10^8\,M^{-1}$ deduced for the transient superoxo complex of Co^{II}(EDTA).[975] The mechanism of the superoxo monomer $[Co(CN)_5(O_2)]^{3-}$ decomposition in aqueous solution has been examined,[976] and involves partial decomposition to a pentacyanocobaltate intermediate which binds an undissociated dioxygen-bound monomer to form the dimer $[\{(NC)_5Co\}_2(\mu\text{-}O_2)]^{6-}$. This in turn hydrolyzes to form $[Co(CN)_5(OH)]^{3-}$ and $[Co(CN)_5(OOH)]^{3-}$.

(iii) Neutral oxygen donor ligands

In the same way that H_2O is an excellent monodentate ligand for Co^{III}, simple alcohols ROH are known to bind effectively to cobalt(III) as monodentate ligands. They can be conveniently introduced into the coordination sphere where other sites are occupied by amines through simply dissolution of the trifluoromethanesulfonatocobalt(III) precursor in the pure alcohol,[977] or less readily by reaction of the halocobalt(III) complexes with silver ion in the alcohol, and are reasonably inert to substitution. Introduction of polyalcohols is possible through the same paths; for example, the complex $[Co(tacn)(inisotol)]^{2+}$ has been reported, albeit with the hexahydroxycyclohexane (inisotol) monodeprotonated and hence a superior ligand to the neutral alcohol.[978]

(iv) Alkyl peroxides

A number of alkylperoxy Co^{III} complexes including mainly polyimine ligands have been prepared, exemplified by (**223**).[979] Hydroxylation of saturated hydrocarbons, preferentially at the more nucleophilic C—H bonds, yields alcohols, ketones, and *t*-butylperoxo products, whereas olefins form epoxides if they carry no allylic H atoms.



(**223**)

β-Diketonate cobalt(III) complexes with alkyl peroxo adducts have been prepared recently and characterized structurally, and their value in hydrocarbon oxidation and olefin epoxidation examined.[980] Compounds Co(acac)$_2$(L)(OO*t*-Bu) with L = py, 4-Mepy and 1-Meim, as well as the analog of the first with dibenzoylmethane as the diketone, were prepared. A distorted octahedral geometry with the monodentates *cis* is consistently observed, and the Co—O bond distance for the peroxo ligand lies between 1.860(3) Å and 1.879(2) Å.

(v) Ketones and esters

The monoketone bis(2,2′,*N*,*N*′-bipyridyl)ketone forms a [Co^{III}L$_2$]$^+$ complex on reaction with [Co(NH$_3$)$_4$(CO$_3$)]$^+$ in water.[981] As reported for a quite different Co^{II} complex, the ketone is hydrated to form the gem diol which binds as a monodeprotonated O-donor along with the two pyridine groups in a tridentate chelate, with very little distortion from octahedral observed in the complex. This appears to represent a facile route for this type of inherently poor donor to achieve coordination. Chelated β-diketonate anions are long-studied examples of O-donor chelates, and continue to be examined. A simple example is the *cis*-[Co(acac)$_2$(NH$_3$)$_2$]$^+$ (acac = 2,4-pentanedionate), structurally characterized and utilized to produce molecular mechanics force field parameters for β-diketones bound to Co^{III}.[982]

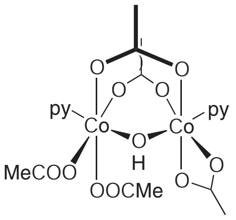
Amino acid esters act as chelates to Co^{III}; for example, the β-alanine isopropyl ester is known as both a chelate and as an *N*-bonded monodentate,[983] and the mechanism of hydrolysis of the ester, which is activated by coordination, to yield chelated β-alanine has been closely examined.

(vi) Carbonates, carbamates, and carboxylates

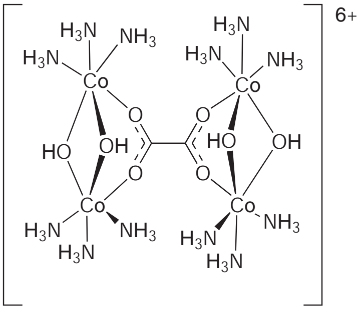
Carbonate is a well-known ligand for Co^{III}, and can adopt monodentate, chelate, and bridging roles. Recent structurally characterized examples, obtained from prolonged aerial oxidation of a solution of cobalt(II) nitrate and ammonium carbonate in aqueous ammonia, are chelated carbonate in [Co(NH$_3$)$_4$(η^2-CO$_3$)]$^+$ and bridging carbonate in [(NH$_3$)$_3$Co(μ-OH)$_2$(μ-CO$_3$)Co(NH$_3$)$_3$]$^{2+}$.[984] The four-membered chelate ring is strained, with the internal O—Co—O angle typically near 70°. The protonated form, hydrogen carbonate (HCO$_3^-$), is usually met as a monodentate; however, chelation has now been reported in the crystal structure of the bicyclic tetraamine complex of (**32**), [Co(adz)(HCO$_3$)]$^{2+}$, where protonation appears to occur at the non-coordinated O atom.[985]

Carbamates (R$_2$NCOOR′) may be *O* or *N* bonded. Base-promoted isomerization of carbamates from the O- to the deprotonated *N*-bound form in pentaamminecobalt(III) complexes have been defined.[986]

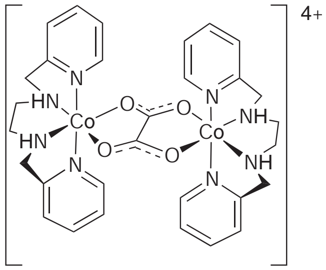
Carboxylates (RCOO$^-$) in simple form or as components of more elaborate polydentate ligands, are commonly met as strong ligands in cobalt(III) chemistry. Monocarboxylate anions can adopt roles as monodentate, bidentate, or bridging anions. Complexes are usually relatively inert to substitution, with hydrolysis of acetato slower than halo ligands. Acetato complexes can be prepared simply by substitution reactions, replacing coordinated solvents and labile anionic groups such as trifluoromethanesulfonate. Acetate in its three possible coordination modes appears in the one dinuclear complex (py)(η^1-OAc)$_2$Co(μ-OH$_2$)(μ-O,O-OAc)$_2$Co(η^2-OAc)(py) (**224**).[987] A range of other examples where carboxylates form one of a suite of ligands or one of the donor groups in polydentate ligands is met elsewhere in this chapter. Simple $[Co(NH_3)_5(OOCR)]^{2+}$ ions with long-chain alkyl R groups have been examined for use as catalysts in dishwashing and laundry detergents.



(**224**)



(**225**)



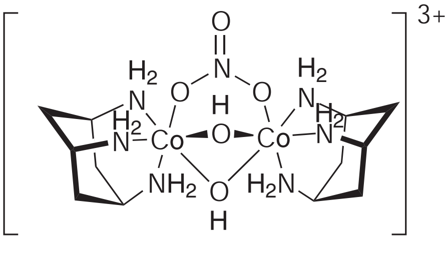
(**226**)

The classical chelating diacid, oxalic acid, has been studied for many years. It has the potential to bind through any combination ranging from one to four oxygen atoms, including bonding to up to four separate metal ions. The latter arrangement is achieved in the cluster (**225**).[988] More recently, a simple dinuclear μ_4-oxalato complex where the ligand chelates a cobalt(III) on each side has been reported (**226**).[989]

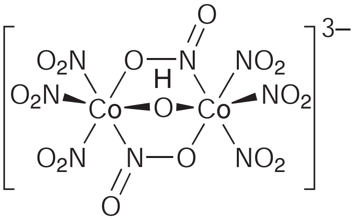
An interesting example of the detailed rearrangement chemistry possible on Co^{III} is the study of pentaamminecobalt(III) complexes of malonamic and phthalamic acids, which can bond through the carboxylate group or else the deprotonated amide nitrogen.[990] The former complexes are readily prepared directly from the amidic acids, whereas the latter form from base hydrolysis of precursors such as (for malonamato-*N*) cyanoacetate-*N*. The *N*-bound compounds undergo in water the usual amide-*N* to amide-*O* rearrangement but, concurrently, an amide-*N* to carboxylate-bonded rearrangement.

(vii) Oxoanions of N, S, P, and the halogens

(aa) Nitrogen oxoanions. The best-known nitrogen oxoanions are nitrate (NO_3^-) and nitrite (NO_2^-). The ambidentate nature of the latter as a monodentate ligand is well known, with *O*-bound (nitrito) and *N*-bound (nitro) isomerism on cobalt(III) well studied, but still producing new insights.[732] Complexes incorporating nitrite are readily formed; for example, reaction of hydrated $Co(ClO_4)_2$ with ethylenediamine and $NaNO_2$ in aqueous solution in air affords the yellow, crystallographically defined *trans*-$[Co(en)_2(NO_2)_2](ClO_4)$.[991] Of course, the anion with nitrite as the sole ligand, $[Co(NO_2)_6]^{3-}$, is well known, and the nitro ligands are readily displaced by, for example, amines and cyanide, as well as rapidly forming a range of mixed aquanitro complexes is aqueous solution, as defined from solution NMR studies.[992] The nitrate and nitrite anions can also act as bidentates and in bidentate bridging modes. Chelated nitrate is exemplified in the complex of the tripodal ligand *N*-(2-aminoethyl)-*N*,*N*-bis(3-aminopropyl)amine (abap), $[Co(abap)(O_2NO)](ClO_4)_2$,[993] where the O—Co—O angle is reduced to 66.1° while the other angles around the plane that includes the nitrate and Co are expanded to as much as 99.9° to compensate. The nitrate ion has been characterized in a bridging mode along with two hydroxide ions (**227**), formed via a tris(alcohol) intermediate.[978] For nitrite, the μ_2-*N*,*O* bridging mode is found in the dimer (**228**).[994]

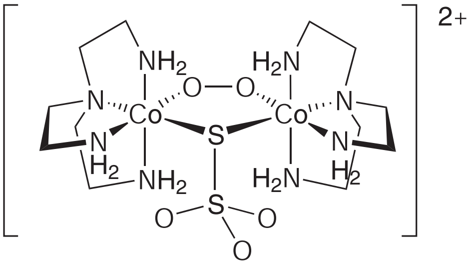


(**227**)



(**228**)

(bb) Sulfur oxoanions. The sulfur oxoanions all can form complexes with cobalt(III) via simple substitution reactions in solution, and are usually *O*-bound in form. However, S coordination is found in the thiosulfate ion ($S_2O_3^{2-}$), which can act as a *O*,*S*-chelate in simple complexes such as $[Co(en)_2(S_2O_3)]^+$,[995] and adopt a bridging mode as in the dinuclear complex (**229**).[970] Coordinated *S*-bound thiosulfato in $[Co(NH_3)_5(S_2O_3)]^+$ can be cleanly oxidized by peroxomonosulfate to produce the coordinated $S_2O_5^{2-}$ ion.[996]



(**229**)

Sulfito (SO_3^{2-}) complexes may also be *S*- and *O*-bound; a solution NMR study of sulfite reacting with several simple aquaaminecobalt(III) complexes has identified both monodentate *O*- and *S*-bound linkage isomers.[997] The SO_3^{2-} ion has been characterized in both monodentate[998] and bridging modes.[999] The *S*-bonded coordination of monodentate sulfite was established in a crystal structure of $[Co(hmd)(OH_2)(SO_3)]^+$.[338] The photochemistry is complex, and involves photoisomerization to *O*-bound sulfite as well as photoredox formation of Co^{II}, with secondary photolysis yielding Co^{I}. The reverse *O* to *S* linkage isomerization is usually observed spontaneously in solution, as exemplified by the reaction of $[Co([16]aneN_5)(OSO_2)]^+$ ($[16]aneN_5 = 1,4,7,10,13$-pentaazacyclohexadecane);[1000] the *O*-sulfito complex is also rapidly cleaved to the aqua compound in acidic solution. The trinuclear complex $Ni\{Co(en)_2(SO_3)_2\}_2$ (and other M^{II} analogs) has the sulfite ions *S*-bound to Co^{III} and O bound to the central Ni atom.[1001] Thermolysis in air of several of the mixed-metal compounds above 750 °C yielded spinel oxides. Reaction of $CoCl_2$ with $Na_2S_2O_4$ in aqueous ammonia in air yields similar type of complex, the mixed oxidation state trinuclear complex $[Co^{II}[(O_3S)_3Co^{III}(NH_3)_3]_2]^{4-}$, where the central Co^{II} lies in an octahedral CoO_6 environment provided by six O atoms of bridging sulfito groups.[999] The reactions of sulfur(IV) in solution (as SO_3^{2-}/HSO_3^-) with aquaaminecobalt(III) complexes has been reviewed.[1002]

The sulfate ion, well known as a monodentate and simple bidentate ligand, has been observed also as a bridging ligand, as exemplified in $[(en)_2Co(OS(O_2)O)_2Co(en)_2]^{2+}$.[1003] The *cis*-bis($\mu$-sulfato) bridge undergoes hydrolysis to *cis*-$[Co(en)_2(OSO_3)(OH_2)]^+$ in acidic solution, hydrolyzing further with loss of coordinated sulfate in aqueous base to the dihydroxo complex.

The use of *O*-bound $CF_3SO_3^-$ as a labile leaving group was established with the reported syntheses of complexes with one, two, and three triflato groups, namely $[Co(NH_3)_5(OSO_2CF_3)]^{2+}$, *cis*-$[Co(en)_2(OSO_2CF_3)_2]^+$, and *fac*-$Co(dien)(OSO_2CF_3)_3$.[1004] These are readily formed by reaction of the corresponding chloro complexes with the anhydrous triflic acid eliminating HCl, and this permits introduction of a wide range of neutral and ionic ligands into the coordination sphere in substitution reactions.[64]

(cc) Phosphorus oxoanions. Monophosphate (PO_4^{3-}), diphosphate ($P_2O_7^{4-}$) and triphosphate ($P_3O_{10}^{5-}$) and their various protonated forms have been coordinated to cobalt(III) in a range of complexes. The cis-$[CoL(OH)(OH_2)]^{2+}$ (L = tetraamine) ions are rapidly anated by phosphate to form $CoL(PO_4)$, with a chelating phosphate.[1005] Coordinated polyphosphates are stable to hydrolysis except where a cis-coordinated hydroxy group exists, but hydrolytic cleavage can be catalyzed by addition of two molar equivalents of another hydroxyaquacobalt(III) complex, which form bridging intermediates with a coordinated nucleophile available for attack. Those with 3-aminopropyl(amine), 6-(4-amino-2-azabutyl)-6-methyl-1,4-diazacycloheptane and trien (**135**) "spectator" tetraamine ligands bound in the other sites have proved particularly effective.[1006,1007]

Mono-, di-, and polyesters of phosphates have also been bound as ligands. Acidity of the remaining phosphate acid sites rises as ester groups are introduced, facilitating the ligation of the esters. Interest in the esters of phosphate is high because of their biological relevance (after all, DNA can be considered from a basic chemical viewpoint as simply an oligomeric phosphate diester). Further examples of this chemistry are provided in Section 6.1.3.1.3.

Trimethylphosphate, despite being neutral, is known to form the simple complex $[Co(NH_3)_5(OP(OMe)_3)]^{3+}$; this reacts with nucleophiles $X^{n-} = S_2O_3^{2-}$, I^- and SCN^- in that order of reactivity to produce $[Co(NH_3)_5(O_2P(OMe)_2)]^{3+}$ and MeX up to 150-fold faster than in the absence of coordination.[1008] Both hydroxide and water are ineffective in this reaction, with simple ligand hydrolysis occurring more rapidly than any reaction.

(dd) Halogen oxoanions. The halogen oxoanions are *O*-donor ligands for Co^{III}. Perchlorato complexes are the type most likely to be met, since the weak, labile perchlorato ligand serves as a good leaving group for further chemistry. For example, perchloratocobalt(III) porphyrins bind acetylene reversibly in anhydrous dichloromethane.[1009] Despite this, the hazards of these thermally unstable perchlorato complexes have been well documented and their use is not recommended.

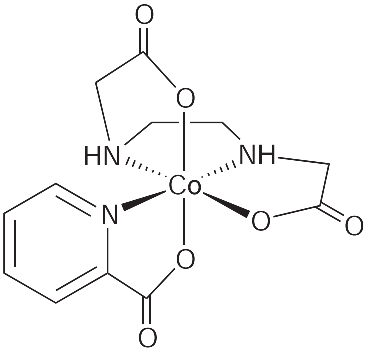
(ee) Other oxoanions. There have been other oxoanions, including metal-centered anions, reported as ligands for Co^{III}. An example is the coordination of molybdate ion in $[Co(NH_3)_5(OMoO_3)]^+$ via reaction of the aquacobalt complex and molybdate.[1010] The rapid hydrolysis kinetics supports Mo—O and not Co—O bond cleavage, unfortunately limiting synthetic usefulness of this compound.

(viii) Mixed O, N ligands

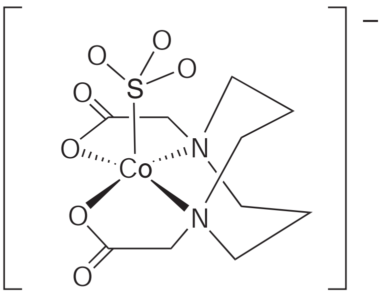
The variety and extent of research devoted to ligands carrying both O- and N-donors is simply immense. The type of cobalt(III) systems extant include amino acids, amino alcohols, amino ethers, amino phosphates, amino phenolates, as well as amide and imine analogs of these. These are met as simple chelates or more elaborate polydentates. Here, we highlight a strictly limited selection of examples to illustrate the type of systems reported; no attempt at exhaustive review has been made.

(ff) Aminoacids. Simple aminoacid complexes have been studied for decades, with strong interest in their stereochemical and chiroptical properties. An example of a well-characterized complex featuring only aminoacids in the coordination sphere is the *mer*-$Co(gly)_2(\beta\text{-ala})$, which has been characterized with glycinato and β-alaninato ligands chelated and in a trans(O5) arrangement, as one of several isomers isolated.[1011] Column chromatography using ionic resins usually features as the best mode of separation of geometric isomers of this type.

The best known of the synthetic polyaminoacids is the tetraanion EDTA, and a wide range of analogs of the N_2O_4 donor set have subsequently appeared.[1012] An example is the propionate analog EDTP. The additional methylene in each carboxylate arm and ensuing twist-boat six-membered chelate rings with Co^{III} [1013] lower the ligand field strength of the chelate as reflected in visible absorption maxima, which shift from bands at 18,630 and 26,040 cm^{-1} for EDTA to 18,000 cm^{-1} and 24,800 cm^{-1} for EDTP. The tetradentate analog EDDA $((^-O_2CCH_2)NHCH_2CH_2NHCH_2CO_2^-)$ has been structurally characterized as *uns-cis-mer*-Co(EDDA)(pic) (**230**).[1014] Intramolecular reaction of a Co^{III} EDDA complex leading to a macrocyclic aminoacid involves a precursor complex of tetradentate EDDA and a bidentate diamine bearing two 3-chloropropyl groups. This undergoes efficient intramolecular alkylation in basic solution to form the 1,4-bis(carboxymethyl)-1,4,8,11-tetraazacyclotetradecane complex.[1015] The smallest member of the carboxymethylated en family is the N_2O-donor monoacetate EDMA



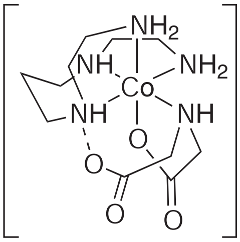
(**230**)



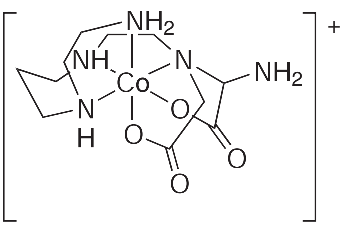
(**231**)

(($^-O_2CCH_2$)$NHCH_2CH_2NH_2$), which forms a bis complex *mer*-$[Co(EDMA)_2]^+$.[1016] This undergoes isomerization in aqueous base to a mixture of other forms.

The *N*,*N*′-substituted ligand (**231**) forms an unusual square-based pyramidal Co^{III} complex with SO_3^{2-} in the axial site, presumably stabilized by the strong *trans* influence of the SO_3^{2-} ligand.[998] The enzyme inhibitor α-aminomalonic acid ($^-O_2CCH(NH_2)CO_2^-$, ama), when reacted with $[Co(2,3,2\text{-tet})Cl_2]^+$ (2,3,2-tet = *N*,*N*′-bis(2′-aminoethyl)propane-1,3-diamine) under various conditions, undergoes halide substitution to produce both the simple $[Co(2,3,2\text{-tet})(N,O\text{-ama})]^+$ (**232**) and other species which underwent metal-directed condensations involving the acidic carbon and a nitrogen of the polyamine, such as (**233**).[1017]

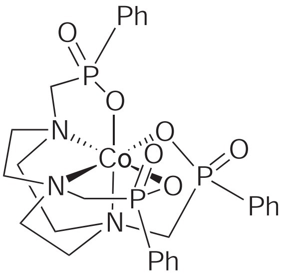


(**232**)

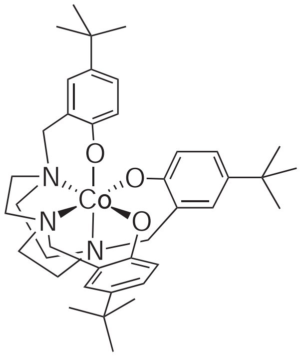


(**233**)

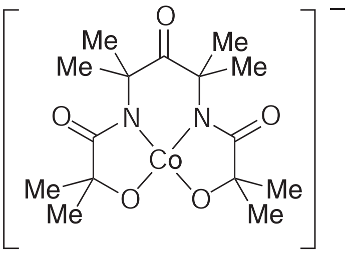
(gg) Aminophosphates. Phosphate and phosphite groups can be attached to amines conveniently through reaction with haloalkylphosphates or analogs. One example features a pendant triazamacrocycle, which acts as a hexadentate ligand to form octahedral complexes (**234**) with both Co^{III} and Co^{II}.[1018]



(**234**)



(**235**)



(**236**)

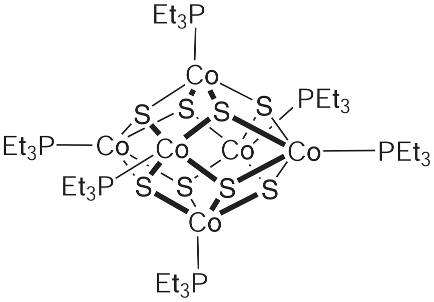
(hh) Aminophenolates. An *N*-pendant phenolate ligand based on tacn (**235**) readily forms a 1:1 complex with Co^{III}.[1019] Further, this reacts with Fe^{2+}_{aq} or Fe^{3+}_{aq} to form mixed trinuclear complexes $(CoL)_2Fe$ where the Fe is sandwiched between two sets of three phenolate oxygens which bridge between the cobalt(III) and iron(II)/(III) centers. Macrocyclic ligands featuring amine and phenolate donor groups, particularly with side-by-side compartments where phenolate ions act as bridging donors to two metal ions, abound.

(ii) Amidoalcoholates. The methylated diamidedialcoholate (**236**) forms another example of the rare square planar cobalt(III) geometry,[1020] with steric congestion presumably blocking facile entry to the axial sites.

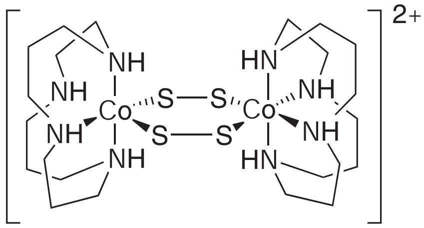
6.1.2.3.7 Sulfur and selenium

(i) Sulfides and selenides

Sulfide is a strong ligand, but compounds containing S^{2-} as the only ligand are rare. One example is the compound $M_9Co_2S_7$, formed in a melt with $M_2(CO_3)$ (M = K, Rb, Cs) and S, where both Co^{III} and Co^{II} centers are present in trigonal planar CoS_3 units.[1021] More typically, sulfide is a companion ligand in mixed-ligand systems. These are often clusters, as exemplified by the mixed oxidation state (formally 4Co^{III}, 2Co^{II}) diamagnetic cluster $Co_6S_8(PEt_3)_6$ (**237**).[1022] This type of cluster spontaneously self-assembles from reaction of metal salt, chalcogen, and ancillary ligand.



(237)



(238)

A Co^{III} compound containing only selenium as a ligand, $[Co_3(Se_4)_6]^{3-}$, has also been reported, prepared by reaction of $CoCl_2{\cdot}6H_2O$ with Li_2Se_6 in DMF at 100 °C.[1023] This trimer includes $Se_4{}^{2-}$ as a linear chelating fragment, bound in bidentate and bridging arrangements; the average of Co^{III}—Se distances reported was 2.37 Å.

Apart from S^{2-}, the disulfide ion $S_2{}^{2-}$ is an effective ligand. Reaction of the hexakis(acetonitrile) adducts of CoX_2 ($X = BPh_4{}^-$ or $ClO_4{}^-$) with $S_2{}^{2-}$ or $S_4{}^{2-}$, with a tetraaza macrocycle also present, yields the dimer $[\{([15]aneN_4)Co\}_2(\mu\text{-}S_2)_2]^{2+}$ (**238**) where the two Co^{III} centers are bridged by two disulfido groups, forming a six-membered Co_2S_4 ring.[1024]

(ii) Thioethers and selenoethers

The acyclic and macromonocyclic polythioethers were well illustrated in *CCC* (1987 Section 47.8.3.2).[1] Only a few recent examples will be given of this chemistry here.

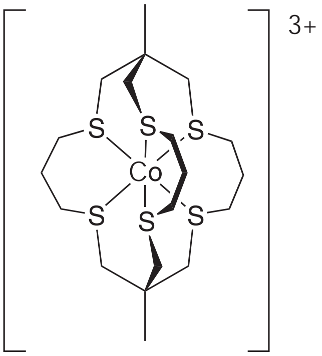
(jj) Acyclic. The simple dimethylsulfide complex ion $[Co(NH_3)_5(SMe_2)]^{3+}$ was prepared from reaction of Me_2S with the trifluoromethanesulfonato precursor complex in sulfolane at 80 °C.[1025] It is hydrolyzed slowly in aqueous acid, but undergoes rapid base-promoted hydrolysis, with Co—S cleavage.

Linear thioethers of the type $MeS(CH_2)_nS(CH_2)_mS(CH_2)_nSMe$ ($n = m = 2$; $n = 2$, $m = 3$) form octahedral dihalo tetrathioether complexes by air oxidation of a solutions of CoX_2 (X = Cl, Br, I) and the ligand in nitromethane.[1026] In addition, $[Co(MeSCH_2CH_2SMe)_2X_2]^+$ and a Co^{III}S$_6$ compound comprising one each of the tetradentate and bidentate ligands were prepared.

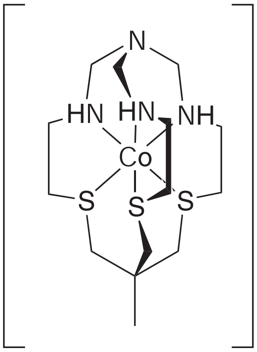
Apart from well-established thioether chelates, coordination of selenium analogs has also now appeared. The chelate 2,5-diselenahexane reacts with CoX_2 (X = Cl, Br, or I) in an aprotic solvent in the presence of dry air and $NaBPh_4$ to form the air-stable Co^{III} complex $[Co(CH_3SeCH_2CH_2SeCH_3)_2X_2]BPh_4$, as a mixture of *cis* and *trans* isomers.[1027]

(kk) Macrocyclic. The macromonocyclic polyethers and their Co^{III} complexes have been known for some time, with ttcn ($[9]aneS_3$) (**109**) and $[14]aneS_4$ (**110**) classic examples. The mixed-ligand complex $[Co(tacn)(ttcn)]Br_3$ offers the opportunity to compare the thioether and aza macrocycles within the one compound.[1028] Average Co—S and Co—N distances were 2.247 Å and 1.961 Å respectively, and the complex displayed reversible Co$^{III/II}$ and Co$^{II/I}$ couples near 0.0 V and −1.15 V vs NHE respectively. Larger macrocycles with more thioether donors have been reported; a recent example is the octahedral Co^{III}S$_6$ system with 1,4,7,11,14,17-hexathiacycloeicosane ($[20]aneS_6$) coordinated.[1029] More recently, the synthetically demanding organic chemistry leading to macrobicyclic polythioethers has been developed. The hexathia macrobicyclic tricosane cage complex of Co^{III} has subsequently been reported (**239**).[466] Metal-directed condensations of CH_2O and $MeNO_2$ (or NH_3) with their corresponding acyclic hexadentate Co^{III} complexes lead to their corresponding mixed-donor cage complexes, for example (**240**)[1030] and (**241**).[1031] The asymmetric CoN_4S_2 cage is also known.[1032] The electrochemical and magnetic properties of these mixed-donor complexes are quite distinct from their Co^{III}N$_6$ relatives (**161**) and (**162**). For example, the divalent CoN_3S_3 cage complex is low spin in contrast to its high-spin hexamine relatives. The octadentate ligand tetrakis((2-aminoethyl)thiamethyl)methane, with four identical

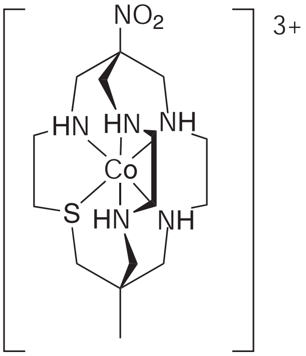
aminothioether arms, can similarly be capped to form an N_3S_3 cage with an exocyclic N,S chelate.[1033] The tri- and divalent Co cage complexes have been characterized.



(**239**)



(**240**)

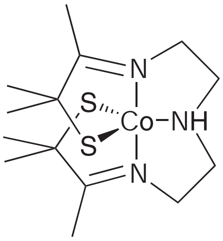


(**241**)

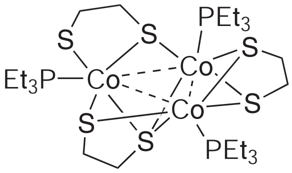
(iii) Thiolates

Thiolates are strong ligands and a rich coordination chemistry with cobalt(III) exists. Normally, thiols are employed directly in synthesis, and this is the usual entry into their coordination chemistry. However, alternative approaches do appear from time to time, and recently the cobalt-mediated direct thiolation of an aromatic ring in bidentate phenyl(2-pyridyl)diazene using dithiocarbamate ion to produce a coordinated tridentate thiolate has been reported.[1034]

A reactive five-coordinate thiolate cobalt(III) complex (**242**) was prepared to model the active site of nitrile hydratase, a cobalt(III) or iron(III) metalloenzyme promoting the conversion of nitriles to amides.[1035] The synthesized complex is facile in its uptake and release of azide and thiocyanate, indicating that ligand displacement in the presence of an appropriate non-leaving group environment is not too slow for catalytic paths in non-redox active Co metalloenzymes. Other model compounds for nitrile hydratase feature new octahedral Co^{III} complexes with carboxamido nitrogen (Co—N 1.91 Å) and thiolate sulfur (Co—S 2.23 Å) donors.[1036] Hydrogen peroxide, or even air and activated charcoal, readily converts the sulfides to sulfinato groups.



(**242**)



(**243**)

Chelation of *iso*-maleonitriledithiolate (imdt) has been structurally characterized in the octahedral cobalt(III) complex *trans*-$[Co(imdt)_2(P(n\text{-}Bu)_3)_2]^-$, formed via reaction of cobalt(II) ion with K_2(imdt) in the presence of the phosphine.[1037] Simple chelating thiolates such as $^-SCH_2CH_2S^-$ not only form mononuclear compounds, but participate in bridging in clusters such as $[Co_3(SCH_2CH_2S)_3(PEt_3)_3]^{3+}$ (**243**).[1038]

When electrochemical oxidation of Co metal is carried out in an acetonitrile solution of phosphinothiol ligands, tris(phosphinothiolate)cobalt(III) compounds are formed.[1039] The octahedral P,S-chelated $Co(2\text{-}(Ph_2P)\text{-}6\text{-}(Me_3Si)C_6H_3S)_3$ compound has been characterized structurally.

Thiolates are candidates for oxygenation reaction leading to sulfenates (RSO^-) and sulfinates ($RSO_2{}^-$). Oxygenation by H_2O_2-urea of the cobalt(III) complex of the N_2S_2 ligand bis(carboxamido-*N*)dithiolato with *tert*-butyl isocyanide in the axial sites produced the first (carboxamido-*N*) bis(sulfenato-*S*)cobalt(III) complex, in a reaction asserted to model oxygenation of nitrile hydratase thiolate ligands.[1040] Oxidation of thiolates to sulfinates has been achieved in the cobalt(III) complex of *N*,*N*′-(3-mercapto-3-methyl-butyryl)-*o*-phenylenediamine with axial *t*-butyl isocyanide groups, yielding an octahedral product defined by a crystal structure.[1041] The two oxidized thiolates (now SO_2 groups) lie *trans* to two deprotonated carboxamido N atoms; there is some structural resemblance to Co nitrile hydratases, where thiolate oxidation has been proposed for enzyme activity. Oxidation of thiolates to sulfinates by H_2O_2 has also been described for the mononuclear octahedral CoN_3S_3 complex of the trianion of *N*,*N*′,*N*-tris(2-thiobenzyl)-1,1,1-tris(aminomethyl)ethane, whereas a related thiolate-bridged dinuclear dicobalt(III) complex is resistant to oxidation.[1042] The *cis,cis,cis*-$[Co(pyet)_2]^+$ complex (pyet = 2-((2-pyridylmethyl)amino)-ethanethiol) is converted to sulfenato and sulfinato complexes by molecular oxygen alone in the presence of activated charcoal.[1043]

Tri-*tert*-butoxidesilanethiolate forms complexes with both Co^{II} and Co^{III}. Reaction of the thiol with a Co^{II} ammine in water yields a dimer which undergoes oxidation in an ammonia-saturated atmosphere to form octahedral $[Co(SSi(O\text{-}t\text{-}Bu)_3)_2(NH_3)_4]^+$, the first silanethiolate characterized structurally.[1044]

(iv) Thiocarbamates

Thiocarbamate (tc, $RHNCSO^-$) is a monodentate ambidentate ligand, and both oxygen- and sulfur-bonded forms are known for the simple pentaamminecobalt(III) complexes. These undergo redox reactions with chromium(II) ion in water via attack at the remote O or S atom of the S- and O-bound isomers respectively, with a structural *trans* effect suggested to direct the facile electron transfer in the former.[1045] A cobalt-promoted synthesis utilizing the residual nucleophilicity of the coordinated hydroxide in $[Co(NH_3)_5(OH)]^{2+}$ in reaction with MeNCS in $(MeO)_3PO$ solvent leads to the O-bonded monothiocarbamate, which isomerizes by an intramolecular mechanism to the S-bound isomer in water.[1046]

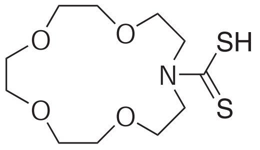
The dithioacid ligands dithiocarbamates ($R_2N–CS_2^-$), xanthates ($RO–CS_2^-$), thioxanthates ($RS–CS_2^-$), and dithiocarboxylates ($R–CS_2^-$), appeared in *CCC* (1987, Section 47.8.10). Dithiocarbamato (dtc^-) ligands are usually bidentate chelates, although monodentate coordination is known. Their chemistry, and that of the related xanthates and thioxanthates, has been extensively examined in the past, and recent chemistry has been more limited. A long-established, facile route to distorted octahedral $Co(dtc)_3$ is via reaction of $Na^+R_2NCS_2^-$ with $CoCl_2$ in the presence of oxygen. The four-membered planar chelate ring is characterized by a small bite angle, typically below 80°.[1047]

Cobalt(III) complexes of formula *cis*- and *trans*-$[Co(dtc)L_4]^{2+}$ and $[Co(dtc)_2L_2]^+$ where dtc = dimethyl-, diethyl- or piperidino-dithiocarbamate were prepared with phosphites $P(OMe)_3$, $P(OEt)_3$ and 4-ethyl-2,6,7-trioxa-1-phophabicyclo[2.2.2]octane as ligands L.[1048] Whereas Co—P bonding is found, as defined in the crystal structures of each of the two forms of complexes isolated, a linkage isomer in which the phosphite is O bound was detected for the bis(dithiocarbamate) compounds.

The dinuclear dialkyldithiocarbamate precursor $[Co_2(dtc)_5]^+$ reacted with diamine mustards *N*,*N*- and *N*,*N*′-bis(2-chloroethyl)ethylenediamine (bce, dce) and their non-chlorinated analogs yield $[Co(dtc)_2(diamine)]^+$.[1049] The bce and dce compounds were prepared and tested as potential hypoxia-selective cytotoxins, but did not prove of value as potential bioreductive anticancer drugs, partly due to their redox instability.

Examples in organometallic systems are known. Reaction of thiuram disulfides, $(R_2NCS_2)_2$, with $Co(Cp)(CO)_2$ produces dithiocarbamato pseudo-octahedral cobalt(III) complexes $Co(Cp)(dtc)_2$ with one chelated and one monodentate dtc, also accessible via Co(Cp)I(dtc).[1050] Fluxional behavior, including monodentate–chelate exchange, was observed for some complexes in temperature-dependent NMR studies. The Co(Cp)I(dtc) complex was defined in a crystal structure.

A mixed cobalt(III)–copper(I) one-dimensional polymer featuring Cu_3Br_3 units linking to tris(dithiocarbamato)cobalt(III) complexes through two of three interligand chelate sites forms readily from reaction of $Co(S_2CNR_2)_3$ with CuBr.[1051] With CuI, a novel and more complex infinite double-stranded polymer featuring CuI_2Cu and Cu_6I_6 linkers results. Dithiocarbamate pendant to a polyether macrocycle (**244**) is an unusual example of a simple chelating ligand. This reacts as the sodium salt with aqueous $CoSO_4$ to form a tris(dtc)cobalt complex.[1052] This complex has the potential to bind appropriate metal ions in the three pendant polyether cavities.

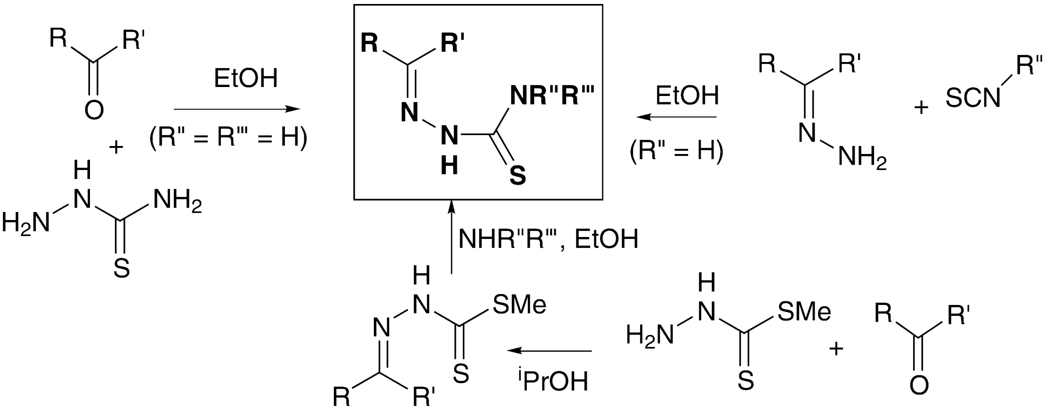


(**244**)

(v) Thiosemicarbazones

Thiosemicarbazone (RNH–CS–NH–N=CR′R″, tsc) complexes of cobalt(III) have been extensively studied since the early 1980s and continue to attract attention, gaining particularly from an interest in their biological activity and potential cytotoxicity. A truly extensive range of tsc compounds has now been reported, although structural definition of their complexes widely relied on basic analytical and spectroscopic techniques up to the late 1980s, when X-ray crystal structural studies of tsc compounds became more common. A review of thiosemicarbazone and *S*-alkyldithiocarbazate complexes has appeared.[1053]

The ligands are synthetically quite accessible through a number of routes (Scheme 3). Co^{II} complexes are formed in an inert atmosphere, with oxidation through to Co^{III} readily achieved in air. The ligands are poorly soluble in water, but their complexes are more soluble, enhancing their value in pharmacological applications. Various complexes have exhibited antitubercular, antileprotic, antiviral, antimalarial, and antitumor activity,[1053] with complexes of tridentate ligands usually exhibiting higher activity.



Scheme 3

Primarily, studies with structural characterization are discussed below. Typically, tsc ligands displaying *N*,*S*-bidentate, or else tridentate coordination for ligands carrying additional functionality, have been described. The *mer*-bis(tridentate) distorted octahedral geometry occurs as the dominant form of cobalt(III) complexation reported, as evident from the selected examples following. Pyridine-2-carbaldehyde thiosemicarbazone ($pcts^-$) acts as a tridentate ligand, binding through one S and two N atoms in $[Co(pcts)_2](NCS)$, as defined by a crystal structure.[1054] Redox activity and reaction with cell thiols is believed to be involved in the cytotoxicity of metal complexes of this ligand against some melanoma and erythroleukemia cells. Methyl pyruvate and α-ketoglutaric acid thiosemicarbazides form bis(tsc)cobalt(III) complexes, the crystal structure of the latter determined wherein the ligand acts as a tridentate in a distorted octahedral geometry.[1055] The octahedral cobalt(III) ion $[Co(datsc)_2]^+$, where tridentate ligand coordination occurs as defined by a crystal structure, is formed following reaction of dimethyl-2-acetylpyridine-*N*-oxide thiosemicarbazone (datscH) with $CoCl_2$.[1056] The potentially tridentate ligand 2-pyridineformamide N(4)-methylthiosemicarbazone (pntscH) forms following Na reduction of 2-cyanopyridine in dry methanol in the presence of the semicarbazide. The $[Co(pntsc)_2](ClO_4)$ has the thiolato S and both the pyridine and imine N atoms bound.[1057] The neutral octahedral *mer*-

Co(kbtsc)(Hkbtsc) has the 2-ketobutyric acid thiosemicarbazone (H_2kbtsc) bound as both a mono- and di-anion, with small differences between the two forms found in the crystal structure.[1058]

A range of S,N,O-donor ligands bound to Co have appeared. Pyridoxal (3-hydroxy-5-(hydroxymethyl)-2-methylpyridine-4-carbaldehyde) thiosemicarbazone (hhtsc) also forms an octahedral *mer*-$[Co(hhtsc)_2]^+$ ion, where the tridentate binding of the ligand has N-donors *trans* and S and O donors *cis*.[1059] However, for the phenylpyruvic acid thiosemicarbazone (H_2pptsc) dianion bound as an *S*,*N*,*O*-tridentate in the octahedral *mer*-$[Co(pptsc)_2]^-$, the S donors are *cis*-disposed and the N- and O-donor pairs each *trans*.[1060] Tridentate S,N,O-chelation of octahedral cobalt(III) by pyruvic acid thiosemicarbazone dianion (patsc) in *mer*-$[Co(patsc)_2]^-$, of 5-formyluracil thiosemicarbazone (ftsc) in $[Co(ftsc)_2]_2(SO_4)$, and of glyoxylic acid thiosemicarbazone (gatsc) in $[Co(OH_2)_6][Co(gatsc)_2]\cdot 3H_2O$ are also defined by crystal structures.[1061–1063] The patsc compound displays an electrochemically reversible $Co^{III/II}$ couple. The $[Co(ftsc)_2]^+$ compound exhibited low activity against human leukemic cell lines.

Both the 2-furfural thiosemicarbazone and semicarbazone Co complexes proved potent in their cytotoxicity against a wide range of cancer cell lines, with suppression associated with DNA nicking and fragmentation rather than base alkylation, intercalation, or crosslinking.[1064] Potent antineoplasticity or cytotoxicity is displayed by a range of heterocyclic thiosemicarbazones and thioureas and their Co complexes.[1065] Cytotoxicity was also established both *in vitro* and in tissue cultures for $[Co(qtsc)_2]X$ (qtsc = *S*,*N*,*N*-tridentate quinoxaline-2-carboxaldehyde thiosemicarbazone; X = Cl, Br).[1066] The cobalt(III) complex of 3-acetylisoquinoline thiosemicarbazide displays less antifungal activity than the 2-acetylpyridine analog.[1067]

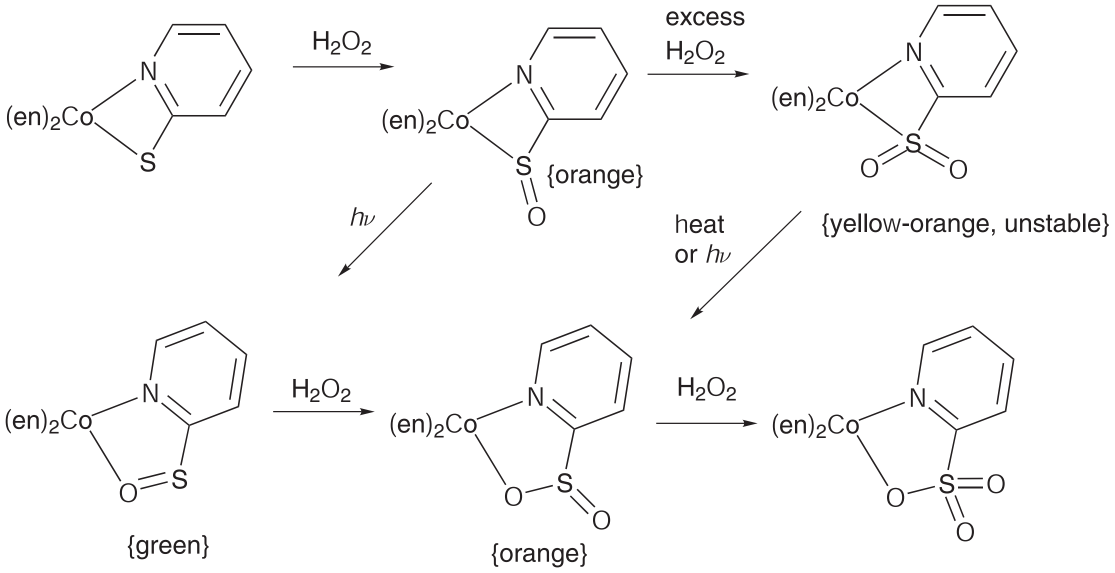
(vi) Thioureas and selenoureas

Thiourea (tu) dominantly forms *S*-bonded complexes with octahedral cobalt(III), with the *trans*-bis(thiourea)cobalt(III) moiety common along with multidentate N- and O-donors in other sites. These are readily prepared; for example, reaction of *trans*-$[Co(dmg)_2(OH_2)_2]^+$ with thiourea at pH 3–4 in hot aqueous solution yields the bis(thiourea) complex on slow cooling.[1068] Alternatively, in a one-pot reaction, heating an alkaline mixture of cobalt(II) and dimethylglyoxime in air to ~80 °C, lowering the pH to 1–2, then treating with thiourea produces the same complex. Further, the selenourea analog forms identically. The *trans* arrangement of the two-coordinated thiourea molecules has been confirmed by a crystal structural characterization of the dimethylglyoxime cobalt(III) complex cation $[Co(dmg)_2(tu)_2]^+$,[1069] and of the methylglyoxime analog $[Co(mg)_2(tu)_2]^+$. The ability of the former compound to stimulate the biosynthetic capacities of micromycetes is also noted. Further, the *trans*-bis(thiourea)bis(α-furylglyoximato)cobalt(III) nitrate has been characterized by a crystal structure analysis, with thiourea S-bonded.[1070] Thiourea is a co-ligand along with 1,2-cyclohexanedione dioxime (cdd) in $[Co(cdd)_2(tu)_2]_2(SiF_6)$, for which a crystal structure defines the octahedral geometry with the thioureas in a *trans* disposition.[1071] A detailed study of the kinetics of substitution by thiourea and other neutral ligands in *trans*-$[Co(salen)(OH_2)_2]^+$ indicates very rapid substitution by the first ligand followed by a slower second substitution.[1072]

Thiourea has the potential to bind through either the S or the amine N atoms, and the existence of linkage isomers may be anticipated. The ambidentate ligands thiourea, NO_2^- and SO_3^{2-}, in interactions with *cis*- and *trans*-$[Co(en)_2(OH_2)_2]^{3+}$ ion, display *N,S*-, *O,N*- and *O,S*- linkage isomerization processes, followed by ^{59}Co NMR studies.[1073] Equivalent reactions have been reported for the bis(2,2′-dipyridyl) and bis(1,10-phenanthroline) analogs.[1074] With *mer*-$Co(dien)Cl_3$ in aqueous solution, *mer*-$[Co(dien)(tu)_3]^{3+}$ forms with both *S*- and *N*-bound thiourea (tu) isomers detected, amongst other analogs.[1075]

(vii) Mixed donor sulfur and selenium ligands

There are growing and diverse numbers of examples of polydentate ligands which feature S-donors in concert with N, O, or P-donors. One simple, but interesting, example is 2-pyridinethiolate (pt). This ligand can bind as a monodentate, a chelate and in bridging modes as a versatile electron-rich ligand, and its coordination chemistry has been reviewed.[1076,1077] The restricted "bite" of the N,S four-membered ring chelate has obvious structural effects. The *mer*-$Co(pt)_3$ complex has been reported, with intraligand S—Co—S angles below 73° and *trans* S—Co—S angles around 166°.[1078] The complex is able to be formed in several ways; via transmetallation from a Zn^{II} cluster of the ligand with Co^{II} in methanol, by base-promoted ligand substitution in tris (acetylacetonate)cobalt(III), or by reaction of the ligand salt with $Co(ClO_4)_2$ in acetone in air. Typically, across a range of structures for this ligand and close analogs, Co—S and Co—N distances are ~2.28 Å and ~1.92 Å respectively, with the S—Co—N angle near 73°. Mixed ligand complexes of pt with diamines form by reaction of both diamine and 2,2′-dipyridyldisulfide with $Co(ClO_4)_2$ in ethanol.[1079] One of the products, $[Co(en)_2(pt)]^{2+}$, spontaneously resolves upon recrystallization, i.e., as a conglomerate. The ligand, when chelated in $[Co(en)_2(pt)]^{2+}$, also undergoes a series of stepwise oxidation reactions from thiolato to sulfenato, sulfinato, and sulfonato ligands, with some S,O-isomerization reactions also possible.[1080] This is outlined in Scheme 4.

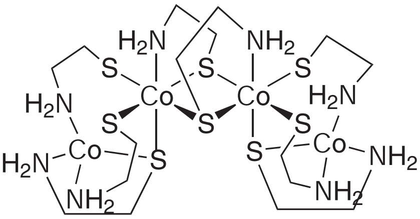


Scheme 4

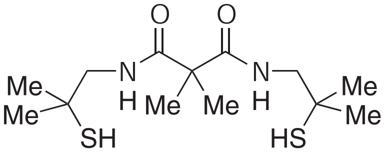
Chelation of pt to Co^{III} has been observed in the complex $[Co(mpyct)_2(PBu_3)_2]^+$, which has a $CoN_2S_2P_2$ donor set, with the two phosphines in apical sites around an elongated ocatahedron.[1081]

The selenium analog of pt, 2-pyridineselenolate (ps), is known and a series of $[Co(ps)_{3-n}(en)_n]^{n+}$ complexes have been prepared and characterized.[1082] Oxidation by peracetic acid produced seleninato ($^-SeO_2$) and selenonato ($^-SeO_3$) complexes, which were shown by structural studies to undergo change from Se to O coordination, relaxing in the process from a four- to a five-membered chelate ring system.

The *N*,*S*-chelate 2-aminoethanethiolate (aet^-) forms stable cobalt(III) complexes, including clusters where the S can take on a bridging role. Reaction of $[Co(NH_3)_5Cl]^{2+}$ with $Ni(aet)_2$ in water for several hours affords the black tetranuclear compound $Co_4(aet)_8$, which features aet^- in simple chelate and bridging roles (**245**).[1083] The simple monomeric complex $[Co(aet)_2(en)]^+$ has been reported;[1084] when heated in water at 50 °C, the trimer $Co\{Co(aet)_3\}_2$ is one product, with the central Co surrounded by six bridging S atoms.



(**245**)



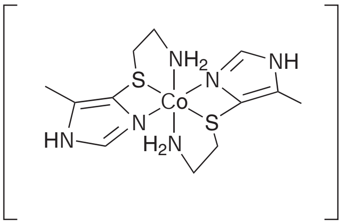
(**246**)

Novel Co^{III} surfactants containing aminothioether ligands have been described.[1085] These involve $[Co(en)_2(NH_2CH_2CH_2SR)]^{3+}$ monomers (R = 6-, 8- or 12-carbon alkyl chain) and $[(en)_2Co(NH_2CH_2CH_2S\text{-}(CH_2)_n\text{-}SCH_2CH_2NH_2)Co(en)_2]^{6+}$ dimers ($n = 8$, 12). The aminothiol chelate in $[Co(en)_2(SCH_2CH_2NH_2)]^{2+}$ is oxidized first to a coordinated sulfenate complex and then, more slowly, to a coordinated sulfinate using oxo diperoxo complexes $MO(O_2)_2$ and $MO(OH)(O_2)_2$- (M = W, Mo).[1086] Oxygen atom transfer from peroxide to the coordinated S acceptor is involved. The sulfinate–carboxylate chelate in the cobalt(III) complex *trans*(*t*-N,S)-[Co(tren)-$(S(O)_2CH(CH_3)COO)]^+$ photolyzed with visible light undergoes irradiation-induced desulfurization and yields an organic peroxide complex which was characterized by a crystal structure.[1087]

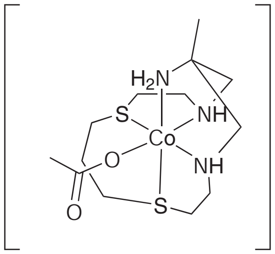
The di-N-carboxamido dithiolato N_2S_2 ligand (**246**) forms an unusual square–planar Co^{III} complex which mimics the active site of cobalt-containing nitrile hydratases.[1088] Hexacoordination of Co^{III} is only achieved with addition of strong ligands like cyanide and isocyanides in axial sites, which occurs along with an expansion of the Co–donor distances in the equatorial plane, as defined by EXAFS studies.

Reaction of the thiol group in $HSCH_2CH_2NH_2$ with a haloalkane carrying an additional functional group can produce a range of new tridentate ligands. An example is the 5-methylimidazolyl terminated (ati), which readily forms a *fac*-$Co(ati)_2$ complex (**247**) by oxidation of a Co^{II}–ligand mixture, with all equivalent donor types in *trans* arrangements.[1089] This type of chemistry is convenient and straightforward, with the sodium salt of the thiol in dry alcohol very reactive when presented with, particularly, iodo- or bromoalkanes. Reaction of a dithiol usually leads to dithioethers, and elaboration of the chemistry is reasonably straightforward.

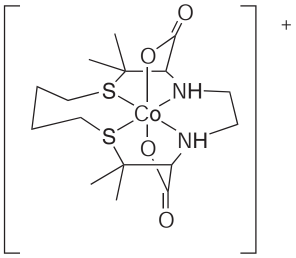
Macrocycles featuring multiple N,S donors have been reported. The saturated macrocycle $[18]aneN_2S_4$ readily forms a Co^{II} complex upon reaction with $Co(NO_3)_2\cdot 6H_2O$ in ethanol, and this is oxidized in air to the Co^{III} complex,[1090] which has all six donors bound in an octahedral form but showing a small tetrahedral distortion of the four S-donors out of the best S_4 plane. Metal-directed $CH_2O/EtNO_2$ cyclization of a diaminodithioether, followed by Zn/HCl reduction leads to an amino-appended N_2S_2 macrocycle which has been complexed as a pentadentate to Co^{III} (**248**).[1091,1092] A somewhat similar ligand, but carrying two carboxylate pendants, binds octahedral Co^{III} with a $N_2S_2O_2$ chromophore (**249**), the two *O*-pendants in *trans* dispositions.[1093]



(**247**)



(**248**)



(**249**)

A suite of S_2P_2-donor ligands $H_3CS(CH_2)_2PPh(CH_2)_nPPh(CH_2)_2SCH_3$ ($n = 2$ or 3) has been coordinated to Co^{III} to give distorted octahedral $[Co(SPPS)Cl_2]^+$ compounds, with a range of geometric isomers identified.[1094] Both Co—S and Co—Cl bond elongation is observed when these are located *trans* to a phosphine. Chelated acetyacetonato ligands were also introduced in place of chloro ligands, forming a mixture of *cis*-α and *cis*-β isomers. A related example, but with the donor locations inverted, is the $Me_2P(CH_2)_2S(CH_2)_3S(CH_2)_2PMe_2$ (mtdmp) ligand, which reacts with *trans*-$[Co(py)_4Cl_2]Cl$ to afford, after addition of $NaPF_6$, the green *trans(Cl,Cl)*-$[Co(mtdmp)Cl_2](PF_6)$.[1095]

6.1.2.3.8 Halogens

(i) Halides

Halides are ubiquitous co-ligands for cobalt(III), and are met throughout this review. Anation of (solvent)cobalt(III) complexes by halide has been examined from time to time. An example is substitution of coordinated acetonitrile in $[Co(L)(MeCN)_2]^{3+}$ (L = tetraaza-macrocycle) by Cl^- and Br^-.[1096] A mechanism involving interchange from within tight ion pairs was proposed. Halo-bridged polymeric complexes are well known with both classical and organometallic complexes.

An example of an unusual cobalt(III) complex is the $[\{(Cp^*)Co\}_2(\mu\text{-}X)_3]^+$ ion (X = Cl, Br, I),[946] with three bridging halide ions present.

6.1.2.3.9 Hydrogen

(i) Hydrides

Limited examples of cobalt(III) hydrides are extant, and they tend to be quite reactive species. Equilibration of $[Co(bpy)_3]^+$ with acid produces the trivalent hydrido complex $[HCo(bpy)_2(OH_2)]^{2+}$ and free (protonated) bpy.[1097] A mechanism was proposed in which bpy radical generation (bpyH) via outer-sphere reduction of the protonated bipyridinium monocation by the monovalent Co complex is rate determining. The hydrido complex results from reaction of the Co^{II} complex with the radical bpyH. Reaction of divalent (**75**) (*meso* and *rac* isomers) with pulse radiolytically generated H• generates the trivalent hydride $[HCo(hmd)]^{2+}$;[118] a kinetic and thermodynamic analysis is reported. Mixtures of the porphyrin complex Co(TMeOPP) and alkyl radicals such as $\cdot C(Me)_2CN$ and $\cdot C(Me)(CH\ (Me)_2)CN$ react with alkenes and alkynes to form alkyl and vinyl complexes and with alkyl halides and epoxides to form alkyl and β-hydroxyalkyl complexes. The intermediate trivalent hydride HCo(TMeOPP) is implicated, which adds to unsaturated substrates or, in its deprotonated from, reacts as a nucleophile $[Co(TMeOPP)]^-$ with alkyl halides and epoxides.[1098] Sequential one-electron electrochemical reduction of the hexaamine $[Co(tacn)_2]^{3+}$ leads to an unstable monovalent complex, which undergoes protonation at a mercury electrode to afford the hydride. The trivalent hydride is believed to decompose via disproportionation to H_2 and a Co^{II} species.[1099]

6.1.2.4 Co^{IV} and Co^{V}

The chemistry of high-valent Co is not extensive. Whereas there are now several examples of Co^{IV}, the higher oxidation state Co^{V} has not been well established. Since Co^{IV} has a d^5 ground state, electron paramagnetic resonance spectroscopy offers an effective way of identification.[1100] Early studies proposed Co^{IV} complexes formed with some dithiocarbamato, Schiff base, and dimethylglyoximato complexes.[1101] $[Co(dtc)_3]^+$ ions form from oxidation of the well-known Co^{III} precursors, and magnetic moments (~2.5 B.M) support the d^5 Co^{IV} assignment. Delocalization of electron density onto the ligands is an issue in nominally Co^{IV} compounds, with the extreme alternative representation being a Co^{III}–ligand radical species. Consequently, the development of a wide range of stable well-characterized Co^{IV} compounds remains unattained, because the metal is likely to oxidize its bound ligand(s) or to oxidize solvents in which the complex is formed. A brief coverage of some more recent examples follows.

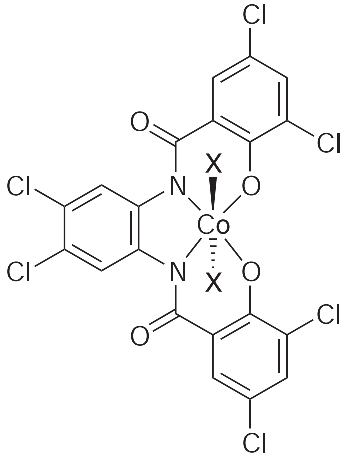
6.1.2.4.1 Carbon

The simple methylidyne compound $[HC{\equiv}Co]^+$ has been formulated as a Co^{IV} species.[1102] The norbornyl anion (nor), as the lithium salt, reacts with $CoCl_2$ to produce the brown, paramagnetic tetrahedral $Co(nor)_4$. This can undergo both reduction (to $[Co(nor)_4]^-$) and oxidation (with $AgBF_4$) to what appears to be $[Co(nor)_4]^+$, a diamagnetic tetrahedral compound. This remains one of the very few established examples of Co^{V}.

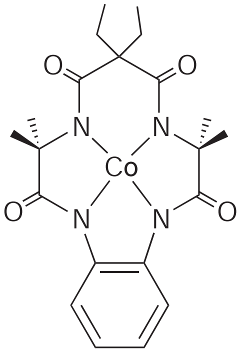
The alkyl complex $[Co(4\text{-}CNpy)(dmg)_2(R)]^+$ has been reported.[1103] The cyclopentadienyl complex $[(Cp)(PPh_3)Co(C_4Ph_4)]^+$ has been detected in frozen haloalkane solvent,[1104] but has no long-term stability.

6.1.2.4.2 Nitrogen

N donor ligands for tetravalent Co must be carefully designed in order to prevent disproportionation (ligand dehydrogenation/Co reduction). A key feature is that no H atoms must be present on the C atoms adjacent to the coordinated N-donor. A range of multidentate amide ligands capable of stabilizing high oxidation states of Co have been reported. The Co^{IV} complex (**250**) (X = 4-*t*-Bu-pyridine) of the dioxo-salphn analog was prepared by Ce^{IV} oxidation of the trivalent analog. The presence of four ionizable donor atoms enables the ligand to stabilize this high formal oxidation state and the compound was characterized structurally.[1105] The frozen solution EPR spectrum (10 K) of the complex exhibits an eight-line pattern from hyperfine coupling (16 G) of the single unpaired electron to the Co nucleus ($I = 7/2$), centered at $g = 2.011$. The emergence of three visible maxima in the spectrum of this complex not seen in the precursor was also indicative of metal-centered oxidation. Two sequential reversible electrochemical oxidations of the Co^{III} complex were observed 0.39 V and 0.84 V more positive than the Fc/Fc^+ reference. The square–planar tetravalent complex (**251**) has been reported along with its 4,5-dihalobenzo analogs.[1106] EPR data in toluene at 5.9 K are consistent with a single unpaired electron residing on the metal center. The complex slowly oxidizes H_2O, yielding the trivalent complex. Replacement of the *gem* dimethyl groups of (**251**) with spiro-cyclohexyl moieties and attachment of methoxyl aromatic substituents results in an effective one-electron oxidant in cyclohexane solutions. A number of charge transfer salts of this tetravalent complex with single electron reductants such as ferrocene, *N*,*N*′-tetramethyl-*p*-phenylenediamine and Mg(TPP) were isolated.[1107] Reaction with PhSH gave PhSSPh and with Bu_3SnH gave the tributyltin dimer, while the reduced trivalent monoanionic complex precipitates quantitatively following reaction.



(**250**)



(**251**)

6.1.2.4.3 *Oxygen*

A high-valent oxocobalt porphyrin complex has been suggested as the reactive hydroxylating intermediate for alkane hydroxylation involving an electron-deficient Co^{III} porphyrin and μ-chloroperbenzoic acid.[784] The bis(tridentate) coordinated Co complex (**252**) undergoes electrochemical oxidation to a Co^{IV} species.[1108] EPR spectroscopy identified a single unpaired electron with a characteristic eight-line hyperfine coupling pattern due to the ^{59}Co nucleus ($I = 7/2$).

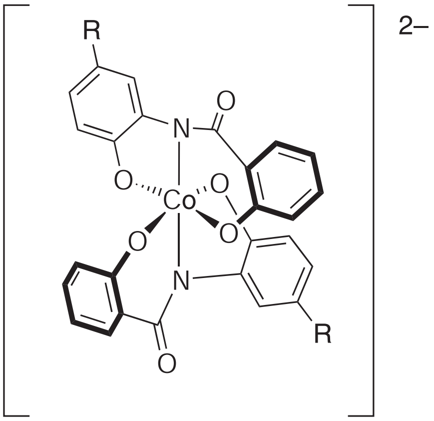
6.1.3 BIOLOGICAL CHEMISTRY OF COBALT

At the time of the first volume of *CCC*(1987), the biological chemistry of cobalt was almost exclusively concerned with the cobalamins. The field has expanded and developed markedly since then. New cobalt-containing proteins have been characterized and applications of traditional cobalt coordination compounds in biology developed. These developments are illustrated below in some detail, as the field was not reviewed in the first edition.

6.1.3.1 Metalloproteins and Cofactors

6.1.3.1.1 *Cobalamins (B_{12})*

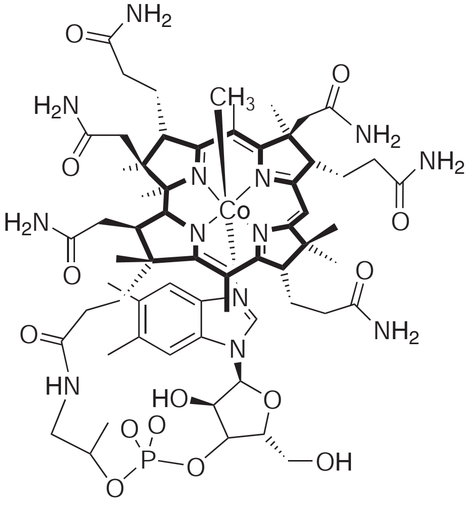
Cobalamin chemistry is the best-established area of cobalt biological chemistry. The 15-membered tetraazamacrocyclic corrin ring (incorporating four pyrrole residues) is the binding site for



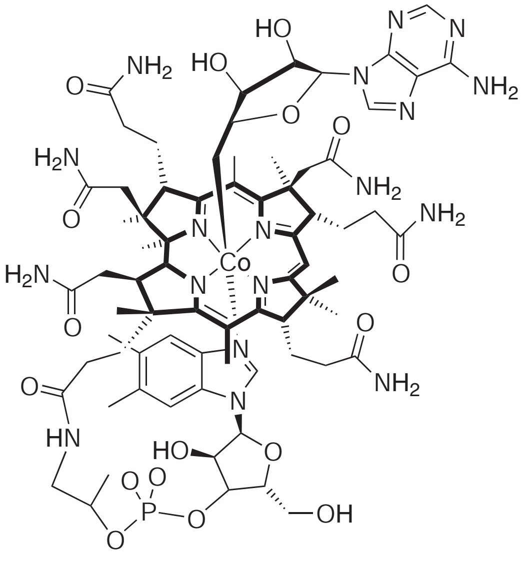
(252)

Co within all compounds of the so-called cobalamin (or B_{12}) family. The biological functions of cobalamin cofactors are defined by their axial substituents; either a methyl or an adenosyl group. Both cofactors participate in biosynthesis; the former in methyl transfer reactions while the latter is a free radical initiator, abstracting H atoms from substrates. Decades after their initial characterization, the fascination with the biological chemistry of cobalamins remains.[1109]

In mammals and in the majority of bacteria, cobalamin regulates DNA synthesis indirectly through its effect on a step in folate metabolism, catalyzing the synthesis of methionine from homocysteine and 5-methyltetrahydrofolate via two methyl transfer reactions. This cytoplasmic reaction is catalyzed by methionine synthase (5-methyltetrahydrofolate-homocysteine methyltransferase), which requires methyl cobalamin (MeCbl) (**253**), one of the two known coenzyme forms of the complex, as its cofactor. 5′-Deoxyadenosyl cobalamin (AdoCbl) (**254**), the other coenzyme form of cobalamin, occurs within mitochondria. This compound is a cofactor for the enzyme methylmalonyl-CoA mutase, which is responsible for the conversion of *L*-methylmalonyl CoA to succinyl CoA. This reaction is involved in the metabolism of odd chain fatty acids via propionic acid, as well as amino acids isoleucine, methionine, threonine, and valine.



(253)



(254)

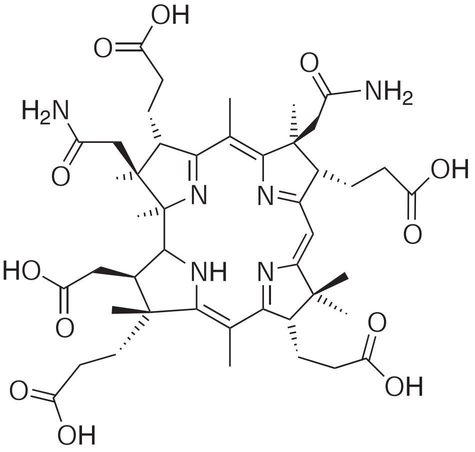
As Co-containing organometallic compounds, cobalamins are unique in nature, and they have a genetic history of more than four billion years. Their biosynthesis, absorption, transport, and metabolism have been well documented in organisms of both marine and terrestrial origin.[1110–1112]

Mammalian intestinal absorption requires the presence of two receptors and two transporters, which is itself a unique feature. Specific transporters such as intrinsic factor, transcobalamin, and haptocorrin have been characterized,[1113] as well as a number of receptors for passage across cell membranes. A number of biochemical studies on cell uptake[1114] and receptors[1115,1116] of cobalamins have been reported. Genetic disorders that impair the synthesis, transport, or transmembrane passage of cobalamins and their consequences have been reviewed.[1117,1118]

The mechanistic and structural chemistry of B_{12} may be separated into (i) investigations of cobalamin cofactors both apart from and in complex with their enzymes, and (ii) biomimetic model complexes, both structural and functional.

(i) B_{12} cofactors

Naturally, the biosynthesis of cobalamins themselves require delivery of Co ions at a particular point in the reaction scheme. Cobaltochelatase catalyzes the ATP-dependent insertion of Co^{II} into the corrin ring during the biosynthesis of coenzyme B_{12} in *Pseudomonas denitrificans*. Cobaltochelatase is a heterodimeric enzyme (140 KDA and 450 KDA subunits each inactive in isolation), and the two components have been isolated and purified to homogeneity.[1119] The reaction product is divalent cobyrinic acid, demonstrating that hydrogenobyrinic acid and its diamide (**255**) are precursors of AdoCbl.



(**255**)

The structures of cobalamins both in isolation and as cofactors in complex with an enzyme have been probed with a variety of techniques including X-ray crystallography[1120–1124] and EXAFS,[1125,1126] in addition to spectroscopic methods such as NMR[1127] and EPR[1128] and also via molecular mechanics calculations.[793] As one example, an NMR study of some cobalamins and their cobinamide analogs (lacking the axially coordinated dimethylbenzamidazole) has been reported.[1129] Hydrogen bonding interactions involving the aqua ligand in aquacobalamin previously identified crystallographically persist in solution. In the cobinamides, removal of the axial benzimidazole produces characteristic changes in the amide nitrogen and proton chemical shifts of the proximal side chains.

Reduction of aquacobalamin with Zn/AcOH gives the five-coordinate hydrido complex, which reacts with ethylene to give EtCbl.[1130] The same compound may be prepared by using the ethylating agent $[Et_3O]BF_4$ in aqueous solution.[1131] The interactions of MeCbl with the complex anions $[Pt(CN)_4]^{2-}$, $[PtCl_4]^{2-}$, and $[Pt(SCN)_4]^{2-}$ have been investigated by UV–visible and ^1H NMR spectroscopy.[1132] At least three Pt binding sites on MeCbl were identified, one of which is located on the methyl ligand side of the macrocycle, and is implicated in methyl transfer in the presence of a Pt^{IV} complex. The reaction of MeCbl with I_2 in MeOH forms a stable charge transfer complex. In water this species reacts resulting in cleavage of the Co—C bond.[1133] The mechanism involves electron transfer from MeCbl to I_2 to generate a $MeCbl^{+\cdot}$ radical, which undergoes a chloride-induced heterolytic cleavage to yield the Cbl radical and CH_3Cl. The EtCbl analog was also studied. The solution structure of the glutathionyl analog GsCbl, which has been found to be a substrate for MeCbl formation in the presence of *S*-adenosylmethionine and a thiol reductant, was investigated by multinuclear NMR,[1127] establishing *S*-coordination by the ligand. Interactions between cobalamins and NO have been investigated with absorption and EPR spectroscopy.[1134,1135] Marked spectral changes are seen upon reaction of divalent cobalamin with NO, which are consistent with NO-effected oxidation to the trivalent state.[1134] This trivalent Co–NO complex is stable, but transfers its NO ligand to hemoglobin concomitant with reduction to the divalent state. Homolytic cleavage of the trivalent Co–C(Me or Ado) also resulted in the reduction of the Co. Nitrosylcobalamin had diminished ability to serve as a cofactor for methionine synthase, and observation that aquacobalamin could quench NO-mediated inhibition of cell proliferation suggests that interactions between NO and cobalamins may have important biological consequences.

A mechanistic study of dealkylations of a variety of adenosylcobalamins was conducted in acidic solution resulting in competitive homolytic and acid-induced hydrolytic Co—C bond scission pathways.[1136] Two hydrolytic mechanisms were identified; one involving initial depurination followed by elimination from the organometallic intermediate, while the second involved ring-opening protonation at the ribofuranosyl oxygen. These reactions were sensitive to substituents on the adenosyl ligand. The limiting homolytic Co—C bond dissociation rate was found to be insensitive to alkyl ligand substituents.

Sonolytically generated ·OH radicals lead to Co—C bond cleavage in MeCbl in oxygenated aqueous solution.[1137] Under anaerobic conditions, H· scavenging by O_2 is circumvented and reduction to divalent MeCbl occurs instead, which after protonation releases methane. A bioconjugate of cobalamin and the alkylating agent chlorambucil behaves similarly, which suggests that sonorelease of an active alkylating agent from a bioconjugate may be a viable and less toxic alternative method for the selective release of anticancer drugs.[1138] The rate of Co—C bond dissociation in micellar solutions of BzCbl have been studied as a function of detergent concentration and pH.[1139]

5-Methyltetrahydromethanopterin:co-enzyme M methyltransferase (MtrA) is a membrane-associated corrinoid-dependent enzyme that uses a methyl transfer reaction to drive an energy-conserving Na^+ ion pump. The purified enzyme exhibits a rhombic EPR signal indicative of a base-on divalent cobalamin, and was inactive in this form. One-electron reduction with Ti^{III} citrate generates the active monovalent species, and reaction with 5-methyltetrahydromethanopterin leads to methyl group transfer to the Co complex. The reaction is reversible upon reincubation with tetrahydromethanopterin.[1140] The structural properties of the soluble deletion mutant of MtrA (lacking the C-terminal hydrophobic tail) have also been studied.[1141] However, the expressed apoprotein was devoid of its Co prosthetic group and incorrectly folded. Unfolding with guanidinium chloride and successful refolding proceeded with Ti^{III} citrate, suggesting that the monovalent cobalamin is the species that binds to the apoprotein. EPR spectroscopy of the divalent reconstituted protein revealed that the Co is bound in its base-off form and that a His residue is coordinated.

Although the system is catalytically inactive, adeninylethylcobalamin (AdoEtCbl) undergoes Co—C bond cleavage to the enzyme-bound hydroxocobalamin upon interaction with the apoprotein of diol dehydratase.[1142] These results imply that the C—Co bond of AdeEtCbl is activated by the enzyme and undergoes heterolysis in contrast to homolysis of the C—Co bond of AdoCb1 in the normal catalytic process. Diol dehydratase undergoes suicide inactivation by the physiological substrate glycerol, which causes irreversible cleavage of the Co—C bond in the cofactor, which remains tightly bound to the enzyme. Recombinant proteins co-purified to homogeneity exist as an A_2B_2 tetramer; a reactivating factor for the glycerol-inactivated holoenzyme that exchanges the enzyme-bound, adenine-lacking cobalamin for free adenosylcobalamin.[1143]

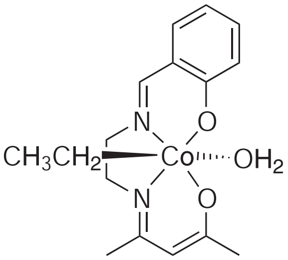
Methionine synthase forms a ternary complex with homocysteine and 5-methyltetrahydrofolate prior to catalyzing a methyl group transfer from the MeCbl cofactor to homocysteine, generating the monovalent cofactor and methionine. The trivalent MeCbl cofactor is restored by methyl transfer from 5-methyltetrahydrofolate to produce tetrahydrofolate prior to release of both products. In cobalamin-dependent methionine synthase, the cofactor may be converted to its EPR-active (but biologically inactive) divalent form. In acid frozen solutions the axial dimethylbenzimidazole substituent is protonated and hence not coordinated.[1128] Reduction of the inactive divalent cofactor to its monovalent form during turnover may be achieved by flavodoxin (from *E. coli*) but not with the corresponding ferrodoxin.[1144] EPR spectroscopy revealed that binding of flavodoxin to divalent cobalamin methionine synthase results in a change in the coordination number of the Co from five to four with loss of the coordinated His residue. Methionine synthase exists in two different conformations that interconvert in the divalent cobalamin oxidation state. In the primary turnover conformation, the enzyme reacts with homocysteine and methyltetrahydrofolate but is unreactive toward adenosylmethionine and flavodoxin. In the reactivation conformation, the enzyme is active toward adenosylmethionine and flavodoxin but unreactive toward methyltetrahydrofolate, and a model has been proposed where these conformational changes control access to the cobalamin cofactor and regulate cobalamin reactivity in methionine synthase.[1145] An additional cobalamin-dependent enzyme that has been characterized is the Fe–S protein CO dehydrogenase.[1146]

Oxidative addition of gaseous or liquid halogenated organic pollutants may be achieved with cobalamins immobilized on solid state supports in the presence of reductants, and this application has been patented.[1147] In DMF solution containing tetrabutylammonium bromide and acetic acid, Vitamin B_{12} itself mediated the reduction of CH_2Cl_2 in the presence of styrene to give cyclopropylbenzene in quantitative yields with high efficiency.[1148] A pathway involving formation and electroreductive cleavage of a chloromethylene–Co^{III} intermediate to liberate a chloromethylene radical, which then attacks styrene, was suggested. The reaction is highly sensitive to solvent and the presence of water as a proton donor leads to 1-chloro-3-phenylpropane as a byproduct.

(ii) B_{12} model complexes

There are many biomimetic model Co complexes of the cobalamins.[1149] The primary criterion for an effective B_{12} model has been that the complex may be reduced to the monovalent state and undergo facile oxidative addition to generate a stable alkylcobalt(III) complex. The two main classes of B_{12} model complexes that have been investigated are Co oximes and Schiff base complexes. The former class shares the planar CoN_4 array of their biological analogs whereas the majority of effective Schiff base B_{12} model complexes comprise equatorial *cis*-N_2O_2 donor sets.

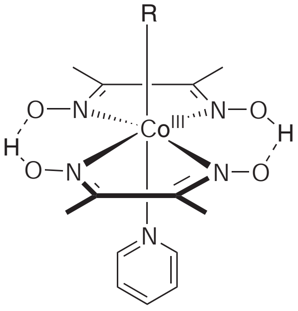
The stabilization of axially coordinated alkyl groups by trivalent Co complexes of the tetradentate Schiff base salen, and analogs, is a feature that has prompted many studies relevant to B_{12} biomimetic chemistry. The mixed aldehyde/ketone Schiff base complex *trans*-EtCo(salacacen)-(OH_2) (**256**) exhibits a number of structural features (elongated Co—OH_2 bond, non-planar CoN_2O_2 moiety) that are desirable in a B_{12} model complex.[1150] A variety of salen complexes bearing secondary alkyls or a bulky diamine in the equatorial position were synthesized and characterized. The complexes RCo(salen)(4-picoline) (R = *n*-Pr, *i*-Bu) are six-coordinate and their coordination geometry is similar to that seen in 5′-deoxyadenosylcobalamin.[1151] By contrast, the bulkier EtCo(Me_4salen) (derived from 2,3-dimethylbutane-2,3-diamine) offers a rare example of a five-coordinate square–pyramidal geometry for this class of compound coupled with a highly reactive Co—C bond. The template syntheses of $[RCo(bzacen)(L)]^+$ (bzacen = benzoylacetone condensed with ethylenediamine, R = Me, Et, L = py_2, en) has been described.[1152] The presence of an alkenyl substituent on the ethylenediamine bridge of Co(salen) leads to an interesting pendent alkyl complex. The overall reaction mechanism involves oxidation of the divalent precursor to give the alkoxycobalt(III) analog followed by attack on the double bond by the metal and ultimately addition to the carbocation by the alcohol.[1153]



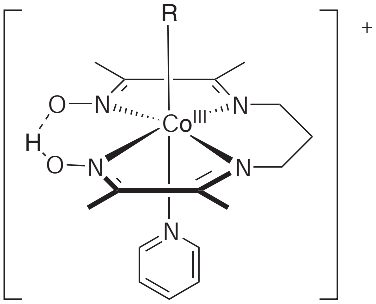
(**256**)

Tridentate Schiff base analogs (bearing a single aromatic residue and a diamine) are capable of stabilizing alkyl ligands. The primary amine of *N*-methylethylenediamine (Me-en) condenses with *o*-hydroxyacetophenone in the presence of Co^{II} to produce the complex Co(MesalMeen)(Me-en), which after reduction to the monovalent state may undergo oxidative addition with MeI to give $[MeCo(salMeen)(Me\text{-}en)]^+$.[1154] The dimethylamino analogs Co(MesalMe$_2$en)(N_3)(*o*-(MeCO)-C_6H_4O) and Co(MesalMe$_2$en)(SCN)(*o*-(MeCO)C_6H_4O) have also been reported.[1155]

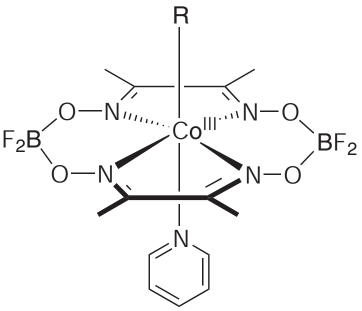
Like their macrocyclic imine counterparts, Co oximes complexes are capable of stabilizing alkyl groups in their axial coordination sites. Alkyl complexes containing bis-dioxime bidentate and mixed imine–oxime tetradentate ligands of Co have been extensively studied as B_{12} model complexes. The crystal structures of the organocobalt bis-glyoximato (Hglo = HO—N=CHCH=N—OH) complexes, *trans*-RCo(glo)$_2$(py) (R = Me, Et, *i*-Pr) have been reported.[1156] The coordinate bond lengths in the *trans* (py)–Co–R group both increase with increasing alkylation of R due to both steric bulk (Co—C) and σ-donating strength of the alkyl group (*trans* influence on Co—N). In comparison, the structures of the dimethylglyoxime analogs RCo(dmg)$_2$(py) (**257**) are less sensitive to alkyl group variations. Dealkylation may be achieved through protonation, and reactions of an extensive homologous series of RCo(dmg)$_2$(py) complexes (R = Me, CH_2Cl, $CHCl_2$, Et, $CHMe_2$, Bu, $(CH_2)_2CH{=}CH_2$, $CH_2CHMeCH{=}CH_2$) with trifluoroacetic acid (Htfa) were studied by NMR. The reactions are stepwise; the first acid equivalent results in reversible protonation of the complex, the second proton releases the pyridine ligand while irreversible alkyl protonation occurs in excess acid.[1157] The *cis*-Co(dmg)$_2$(tfa)$_2$ product was structurally characterized. The synthesis and characterization of the diphenylglyoximate series *trans*-RCo(dpg)$_2$(L) were reported (dpg = diphenylglyoxime, R = Cl, Me, Et, CH_2Cl or *i*-Bu; L = py, 3,5-lutidine, γ-picoline, P(OMe)$_3$).[1158] The crystal structure of MeCo(dpg)$_2$(py) found that the Co—C bond length was little affected by the methyl-to-phenyl substitution. Mixed oxime complexes such as (N$_3$)Co(dmg)(dpg)(py) have only recently been described.[1159]



(**257**)



(**258**)



(**259**)

The *trans* dihalo (Cl$^-$ and Br$^-$) Co^{III} complexes of the linear tetradentate dmg$_2$tn react with alkylating agents and NaBH$_4$ and ultimately pyridine to give the so called "Costa-type" B_{12} model complexes [RCo(dmg$_2$tn)(py)]$^+$ (**258**) in good yields (R = Et, $CHMe_2$, CH_2CMe_3, CH_2CF_3, CH_2CO_2Me, CH_2Ph, CH_2SiMe_3).[1160] The X-ray crystal structures of the R = CH_2CMe_3 analog shows that the dmg$_2$tn ligand is more distorted from planarity than bis(dmg) cobaloxime relatives, and the Co—N bonds are longer. The carbonyl complex Co(dmg$_2$tn)(CO) may also be used as precursor to the homologs [RCo(dmg$_2$tn)L]$^+$ (R = CH_2OMe, CH_2SMe CH_2Cl, CH_2NO_2, CH_2CN, L = monodentate ancillary ligand).[1161] Axial Co—N bond lengthening was observed with increasing electron-donating ability of the R group. Introduction of alkyl substituents onto the trimethylene linker has been studied.[1162] Dimethylation of the central CH_2 group results in a complex with greater rates of py ligand dissociation. This is correlated with the crystallographically determined structure, which shows that the planar py ligand leans away from the more sterically demanding $CH_2CMe_2CH_2$ moiety compared with the dmg$_2$tn complex. The tetramethylene-bridged analogs [RCo(dmg$_2$bn)(OH$_2$)]$^+$ were prepared in an effort to increase ligand-effected distortions that ultimately lead to a weakening of the Co—C bond, as seen in coenzyme B_{12} through folding of the equatorial corrin ring. Although the crystal structure of [EtCo(dmg$_2$bn)(OH$_2$)]$^+$ exhibits somewhat elongated Co—C and C—O bonds and an extended Co—C—C bond angle (119.3(5)°) the N$_4$ array is effectively planar,[1163] in contrast to the Cu^{II} relative. The structure of the [EtCo(dmg$_2$bn)(Him)]$^+$ analog has also been reported, although two different ligand conformations were identified within the asymmetric unit.[1164] It has been noted that imidazole, once deprotonated, may form μ-imidazolato dimers and such species have been identified by NMR and crystallography.[1165] Near-IR FT-Raman spectroscopy was used to investigate the influence of electronic and steric effects on the Co—Me stretching frequency. It was found that for the series MeCo(dmg$_2$tn)L, the Co—C frequency decreased (from 505 cm^{-1} to 455 cm^{-1}) with increasing electron-donating character of L.[1166] The ethylmethyl glyoxime analog

$[(Bz)Co(emg_2tn)(OH_2)]^+$ has been shown to perform an unusual Co-to-C migration of the axial alkyl group upon photolysis, with the benzyl group attacking one of the oxime C atoms.[1167]

1,5,6-Trimethylbenzimidazole (Me_3Bzm) is an appropriate analog for the axial 5,6-dimethylbenzimidazole ligand in cobalamins. The complexes $[RCo(dmg_2tn)(Me_3Bzm)]^+$ (R = Me, Et and CF_3CH_2) have been characterized structurally and the rates of substitution of the axial benzimidazole ligand were determined.[1168] The comparable crystal structures of $[MeCo(dmg_2tn)L]^+$ (L = 1-Meim, 1,2-Me_2im) show the steric influence of the 2-Me group, which extends the axial Co—N bond length from 2.042(2) Å to 2.100(4) Å, while the Co—C bond length is unaffected.[1169] Novel 3-membered metallocycles (Co—C—N) have been formed by attack of a halomethyl axial ligand on the oxime ligand.[1170,1171] An example of this is illustrated in Figure 9.

The tridentate 2-(2-pyridylethyl)amino-3-butanone oxime (Hpeab) is also an effective ligand for the formation of B_{12} model complexes with Co^{III}.[538] Compounds of the general formula $[RCo(peab)(Hpeab)]^+$ (R = Me, Et, CH_2CF_3, *n*-Bu and CH_2Cl) have been synthesized. Crystal structures show that Hpeab binds as a bidentate, while the peab anion coordinates as a tridentate, including the pyridyl group in the coordination sphere. The axial geometry in $[MeCo(peab)(Hpeab)]^+$ is closer to that found in methylcobalamin than has been reported for other B_{12} models.

An electrochemical study of the diaqua bis(dioxime), tetradentate dmg_2tn and macrocyclic $dmg_2(BF_2)_2$ (**259**) Co complexes has been reported.[1172] Both tetradentate ligands stabilize the divalent oxidation state relative to the bis(dmg) analog, with the trimethylene link in dmg_2tn being more effective in this role. The acyclic and macrocyclic diphenylborinic acid adducts $dmg_2(BPh_2)$ and $dmg_2(BPh)_2$ have also been reported.[1173] Cyclic voltammetry and spectroelectrochemistry of the (**256**) series (R = *i*-Pr, neopentyl, *i*-Bu, Et, Bz, Me, $HO(CH_2)_2$, CH_3COOCH_2 and CF_3CH_2) was explored.[1174] A marked influence of axial group bulk on the reactivity of the lower oxidation was found, and this was attributed to their ability to form stable bisalkyl complexes. The series $[LCo(dmg_2tn)Cl]^+$ (L = py, 4-CNpy-, 4-Brpy-, 4-MeOpy, 4-Me_2Npy) and $[Co(dmg_2tn)(py)_2]^+$ were also synthesized. As L becomes more basic, the first $Co^{III/II}$ potential is shifted cathodically, although ligand substitution reactions following reduction complicate the voltammetry.[1175]

The Co complexes of the *o*-phenylenediamine-linked dioxime $Hdmg_2Ph$ bearing a variety of monodentate ligands (halides and pseudo halides) in the axial coordination sites have been synthesized.[1176] B_{12} model complexes $[RCo(dmg_2Ph)(L)]^+$ (R = Me, Et, Me_2CH, Bz, ch; L = py, H-im, or PPh_3) were prepared by the oxidative addition reactions of the alkyl halide to the *in situ*-generated monovalent dibromo complex.

Replacement of the axial pyridine by phosphine has been achieved with the synthesis of the complexes $[MeCo(dmg_2tn)L]^+$ (L = $P(OMe)_2Ph$, $P(OEt)Ph_2$, $PEtPh_2$, $P(OMe)_3$, $P(p\text{-}Me_2NC_6H_4)_3$, $P(CH{=}CH_2)Ph_2$, $P(CHMe_2)Ph_2$, $PCyPh_2$, $P(CH_2CH_2CN)Ph_2$, PPh_3), which were characterized by ^1H NMR spectroscopy and crystallography for the trimethyl phosphite and triphenyl phosphine derivatives. The phosphine/phosphite ligand dissociation rates are twice as fast as bis(dmg) analogs, and vary by four orders of magnitude across the series.

In contrast with the role of cofactor B_{12} in methionine synthase (methyl group transfer to a thiol), functional B_{12} model complexes have provided a formidable challenge. Several oxime alkyl-cobalt (structural) B_{12} models when reacted with arene- and alkanethiolates lead only to

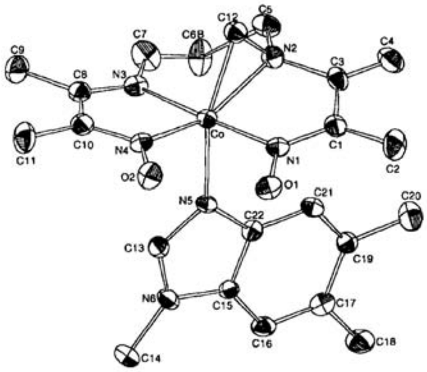


Figure 9 Pendent alkyl complex resulting from intramolecular attack of the chloromethyl axial ligand in $[((ClCH_2)Co(dmg_2tn)(Me_3Bzm)]$ on the coordinated tetradentate dioxime (reproduced with permission of the American Chemical Society from *Inorg. Chem.*, **1997**, *36*, 3854–3860).

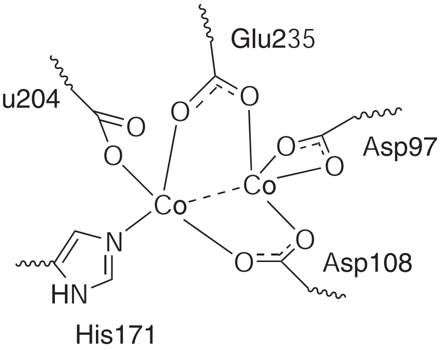
thiolate coordination *trans* to the alkyl group.[1177] An example is *trans*-$[(EtS)Co(dmg)_2(Me)]^-$ which exhibits a particularly long Co—S bond consistent with the strong *trans* influence of alkyl ligands.

6.1.3.1.2 Non-corrin proteins

(i) Native cobalt-dependent proteins

Aside from B_{12} cofactors, there are at this time eight known Co-dependent proteins, in addition to so-called chaperone proteins that are involved in Co transport and uptake.[1178] Methionine aminopeptidase (MetAP) represents the first Co-containing (non-corrin) protein to be characterized by X-ray crystallography. The enzyme is present in prokaryotes and eukaryotes and its function is to hydrolyze N-terminal methionine residues from polypeptides. Since the enzyme is isolated as the apoprotein, the identity of the native metal ion has not been established absolutely. However, MetAP from *Salmonella typhimurium* is active upon addition of Co^{2+}, but not divalent Mg, Mn, or Zn. The crystal structure of MetAP from *E. coli* revealed a pair of Co^{II} ions bridged by two carboxylate residues (Glu235 and Asp108). Each metal is in a square–pyramidal coordination environment (**260**) which includes a weak Co—Co bonding interaction.[1179] The vacant *trans* sixth coordination sites may be for substrate binding, or for coordination of a hydroxo ligand that itself is the active nucleophile. More recently, the crystal structure of MetAP from the thermophile *Pyrococcus furiosus* has been reported and a pair of Co ions were again revealed at the active site.[1180] MetAP from other organisms as well as different metalloproteases (leucine (Zn_2) and proline (Mn_2) aminopeptidase) also employ a pair of transition metals at their active sites.



(**260**)

Proline dipeptidase cleaves dipepetides where proline is adjacent to the N-terminal residue. The enzyme is a homodimer, with one Co ion tightly bound in each subunit. However, it has been shown that an additional Co^{II} ion must be added (per subunit) for activity. This second ion is relatively weakly bound and may be substituted by Mn^{II} with somewhat attenuated activity. Curiously, the active site ligands identified in metallohydrolases such as MetAP are conserved in this enzyme despite a generally low sequence similarity.

Nitrile hydratase from various organisms has been well studied and even employed in industrial processes requiring the large-scale hydrolysis of nitriles to amides. The active site structure is believed to comprise two peptide N-donors and three cysteine thiolates bound to Co^{III} on the basis of a high sequence similarity with a structurally characterized Fe^{III} nitrile hydratase. The role of the Co^{III} ion is thought to be that of a Lewis acid that activates a hydroxo ligand for attack on the nearby nitrile. A number of biomimetic systems have recently been studied in an effort to better understand the properties of this enzyme.[1040,1041,1181–1183]

Glucose isomerase catalyzes the conversion of D-glucose to D-fructose and has also been used extensively on an industrial scale.[1184] Some, but not all, enzymes of this family require Co specifically, while others can function with other divalent ions. Environmental and health issues limit the concentrations of Co in culture media during D-fructose production and other metal ions are being sought as substitutes. Although the active site structure remains unknown, EXAFS, optical and EPR spectroscopy has suggest a low-spin divalent Co ion, bound by N and O-donors only (no S-donors).

Other less well-characterized Co-containing proteins include methylmalonyl–CoA carboxytransferase (or transcarboxylase); this is a complex multi-subunit enzyme comprising three different types of subunit, two of which contain Co.[1185] A catalytically important high-spin divalent Co ion has been identified, but only the Co-free (biotin-containing) subunit has been structurally characterized. The Co–porphyrin containing aldehyde decarbonylase acts on fatty aldehyde substrates and is an important energy source in many organisms.[1186] The rearrangement of L-lysine to L-β-lysine is catalyzed by lysine 2,3-aminomutase in the presence of pyridoxal phosphate, an Fe–S cluster and either divalent Co or Zn.[1187] Although there are similarities with B_{12} chemistry (activation by S-adenosylmethionine leading to an adenosyl-bound cofactor) no cobalamins are present nor do they activate the enzyme. Furthermore, the Co ions are not bound within the Fe–S cluster as shown by EPR spectroscopy. Bromoperoxidase specifically requires Co for activity (oxidative C—Br bond formation), but the ion is weakly bound and as yet the essential role of the metal in this enzyme is not well understood.[1188]

(ii) Cobalt-modified proteins

Apart from its natural occurrence, Co may find its way into other proteins either adventitiously or deliberately. A study was undertaken where the blood, serum, and plasma of workers occupationally exposed to Co were analyzed for the element.[1189] When separated by gel electrophoresis under denaturing conditions, the Co fractions in all blood, serum, and plasma samples showed a similar protein pattern. A variety of proteins of differing size were found to bind Co in fractions collected at pH 5, whereas only hemoglobin was found in the pH 7 fractions. The conclusions were that *in vivo* Co is bound to plasma proteins, perhaps albumin and hemoglobin.

(II) Active site structure and spectroscopy. Due to its well-understood coordination chemistry, characteristic spectral properties, lability and compatible ionic radius and charge, divalent Co is a useful active site substituent for spectroscopically silent metal ions such as Zn^{II} and Cu^{I}, and Co substitution has been used as a structural probe of protein active sites. The paramagnetic NMR shifts induced by divalent Co substituted for the native diamagnetic metal ion at the active site is a useful tool in the interpretation of NMR spectra of the protein. The binding of L- and D-phenylalanine and carboxylate inhibitors to Co^{II}-substituted carboxypeptidase A in the presence of pseudohalogens N_3^-, NCO^-, and NCS^- was studied by ^1H NMR.[1190] The proton signals of the bound histidine residues were sensitive to the interactions between the inhibitors and the metal. Enzyme–inhibitor complexes with characteristic NMR features were identified. L–Phe formed a 1:1 complex, whereas D–Phe bound stepwise, first to a non-metal site and then to the Co ion forming a 2:1 complex. The carboxylates CH_3COO^- and $PhCH_2COO^-$ also formed 2:1 adducts stepwise with the enzyme, but 2-phenylpropionate gave a 2:1 complex without any detectable 1:1 intermediate. The pseudohalides N_3^-, NCO^-, and NCS^- generated complexes directly with the Co^{II}:L–Phe adduct but indirectly with the D–Phe and carboxylate inhibitor, 2:1 complexes displacing the inhibitor from the metal. Inhibitor binding constants have also been determined from ^{13}C NMR T_1 and T_2 measurements on the ^{13}C-enriched amino acid inhibitors,[1191] and EPR spectroscopy has been employed as well to gain insight to the active site structure.[1192] Substitution of Cu^{I} by Co^{II} in blue copper proteins has also been achieved for the purpose of NMR investigations. Assignment of the ^1H NMR spectrum of *Pseudomonas aeruginosa* Co-substituted azurin has been made with contact-shifted signals from amino acid residues as distant as 10 Å from the metal being achieved.[1193] Resonances due to the five amino acid residues known to reside at the metal binding site of oxidized (Cu^{II}) azurin (His46, His117, Cys112, Met121 and Gly45) were identified. However, there are metal-dependent differences; most notable being that Met121 appears to be only weakly interacting with the metal ion in the Co protein whereas Gly45 is apparently strongly bound to Co in contrast to the native Cu protein. Overall, a distorted tetrahedral N_2OS geometry for the Co ion was assigned. Metal ion-induced conformational changes in *Serratia* protease (one Zn ion per native protein, replaced by Co) were investigated by small-angle X-ray scattering. The protein is an elongated ellipsoid of approximately 110 × 40 × 40 Å with a large cleft in its central region. Comparisons of the native (Zn) enzyme with the apoenzyme show small but significant differences in their radii of gyration, maximum particle dimensions, and intraparticle pair-distance distributions.[1194]

The Zn^{II} ion of angiotensin-converting enzyme (ACE) has been replaced by Co^{II} to give an active, chromophoric enzyme and inhibitor binding has been identified spectroscopically. Visible and MCD spectroscopy were used to characterize the catalytic metal binding site in the

Co-substituted enzyme and in a number of enzyme-inhibitor complexes.[1195] The visible absorption spectrum of Co ACE exhibits a single weak broad maximum (525 nm) in contrast to the spectra of enzyme-inhibitor complexes, which display red-shifted and more intense maxima (525–637 nm). The presence of S—Co charge-transfer bands in the spectra of the tetrahedral Co ACE-inhibitor complex confirm direct ligation of the thiol group. The optical spectrum of Co-substituted *Aeromonas* aminopeptidase is perturbed by the presence of equimolar concentrations of D-amino acid hydroxamates and acyl hydroxamate inhibitors. D-Valine and D-leucine hydroxamate each produces a splitting of the characteristic 527 nm maximum of the Co enzyme to give three new maxima between 570 nm and 480 nm, whereas hydroxamates of L-valine and L-leucine produce little change in the spectrum.[1196] Conversion of yeast Cu^{I}-thionein to the Co^{II} derivative has been achieved. The optical spectrum of the Co protein is virtually identical to those of Co-substituted metallothioneins originating from vertebrates. Characteristic charge transfer bands and *d–d* transitions led to the proposal of a tetrahedral Co-thiolate coordination with three bridging cysteine S-donors.[1197] Superoxide dismutase has a crucial role in defense against cytotoxic $O_2^{-\cdot}$. It contains both Zn^{II} and Cu^{II} binding sites and these have been replaced by Co^{II} in all three combinations, i.e., $Co^{II}-Co^{II}$; E–Co^{II}, and Co^{II}–E where E represents a vacancy at either the Cu or Zn binding site.[1198] The cobalt-protein derivatives have been characterized by optical absorption, CD, and fluorescence spectroscopy. The Co^{II}–Co^{II} protein exhibits an optical spectrum corresponding to the sum of the spectra of the other two derivatives, although the CD spectra were not additive, suggesting that the presence of Co^{II} in one site strongly affects the geometry of the neighboring site. Fluorescence spectra illustrated that Co^{II} ions exert a different quenching effect on tyrosine emission, depending on whether they are located in the Zn^{II} or in the Cu^{II} site.

(mm) Activity and inhibition. There are many Zn-dependent enzymes that retain their catalytic activity or that are equally sensitive to inhibition upon substitution by divalent Co. Although the chelating ligand *N*,*N*-diethyldithiocarbamate anion is an inhibitor of (Zn-dependent) bovine carbonic anhydrase (CA), no removal of Zn could be detected even at a very high concentrations of anion. At identical pH values a larger inhibitory effect was found for the Co-substituted enzyme, but Co^{II} was removed from the protein by the ligand at pH less than 7. However, Co ion remained bound at pH 10, and a five-coordinate Co^{II} ion was observed spectroscopically.[1199] The kinetics of complex formation between Co^{II}-substituted CA and OCN^-, SCN^-, and CN^- has also been studied.[1200] Formation of a 1:1 complex occurs exceedingly quickly and the explanation for this observation was that the anion enters a vacant coordination site on the metal, effecting a change in coordination number of the Co ion from 4 to 5. Reversible amide inhibition of Co-substituted CA by iodoacetamide, urethane, and oxamate has been reported,[1201] and visible spectroscopy indicated coordination of the inhibitors to the metal with a deprotonated *N*-bound amide being the final product with O-bound linkage isomer intermediates being found in some cases.

Streptomyces griseus aminopeptidase specificity was studied using amino acid 4-nitroanilide substrates. The zinc enzyme hydrolyzes leucine 4-nitroanilide at a ten-fold faster rate than the Co enzyme, the Co enzyme hydrolyzes alanine 4-nitroanilide at a more than 20-fold faster rate than the zinc enzyme.[1202] Activity of the bacterial enzyme *N*-succinyl-L-diaminopimelic acid desuccinylase was completely abolished following dialysis of the enzyme against metal chelators, but restored on addition of Co^{II} or Zn^{II}. The binding constants for both metals were similar and the Co enzyme was about twice as active as the Zn homolog.[1203] The enzyme is highly specific for its natural substrate, and given its essential role in bacterial growth it is an ideal target for the development of inhibitors with antibacterial potential. Divalent Co inhibits the Ca^{2+}–Mg^{2+}–ATPase activity of sealed muscle sarcoplasmic reticulum vesicles, of solubilized membranes, and of the purified enzyme. Inhibition by Co^{II} is likely due to free $Co_{aq}{}^{2+}$ binding to the enzyme, which is reversible on addition of Ca^{2+} in millimolar concentrations, indicating that the Ca binding site is the one targeted by Co.[1204] The kinetic and spectral properties of native (Zn) and Co-substituted D-lactate dehydrogenase (a flavin-dependent enzyme) have been compared.[1205] Optical and MCD spectra are consistent with high-spin tetrahedral Co and the metal appears to be involved in substrate binding and reduction. The Zn-containing protein farnesyltransferase catalyzes the addition of a farnesyl isoprenoid to a conserved cysteine in peptide or protein substrates. Substitution of Zn by Co has no effect on catalytic activity, but reveals through optical spectroscopy a thiolate ligand at the active site as part of a pentacoordinate or distorted tetrahedral coordination sphere.[1206] Furthermore, the thiolate charge transfer band intensity is enhanced upon substrate binding, which was indicative of the formation of a second Co–thiolate bond corresponding to the thiolate group of the peptide substrate. Acetylpolyamine amidohydrolase exhibits activity in both its native (Zn) form and upon Co substitutions, although the pH optima are different.[1207]

Co-for-Zn substitution in alcohol dehydrogenase from *Saccharomyces cerevisiae* revealed a 100-fold increase in activity and a higher resistance of the modified protein to the inhibitory action of other divalent transition metals,[1208] making the Co-modified enzyme suitable for biotechnological applications.

The introduction of redox activity through a Co^{II} center in place of redox-inactive Zn^{II} can be revealing. Carboxypeptidase B (another Zn enzyme) and its Co-substituted derivative were oxidized by the active-site-selective *m*-chloroperbenzoic acid.[1209] In the Co-substituted oxidized (Co^{III}) enzyme there was a decrease in both the peptidase and the esterase activities, whereas in the zinc enzyme only the peptidase activity decreased. Oxidation of the native enzyme resulted in modification of a methionine residue instead. These studies indicate that the two metal ions impose different structural and functional properties on the active site, leading to differing reactivities of specific amino acid residues. Replacement of zinc(II) in the methyltransferase enzyme MT2-A by cobalt(II) yields an enzyme with enhanced activity, where spectroscopy also indicates coordination by two thiolates and two histidines, supported by EXAFS analysis of the zinc coordination sphere.[1210]

Divalent Co substitution in copper amine oxidase revealed 19% of the native specific activity (for $MeNH_2$) and 75% of the native reactivity toward phenylhydrazine. The major cause of this was a 68-fold increase in K_m for O_2. These investigations support the idea that electrons flow directly to bound O_2 without the need for a prior metal reduction and that the Cu does not redox cycle but simply provides electrostatic stabilization during reduction of O_2 to $O_2^{-\bullet}$.[1211]

6.1.3.1.3 Biomimetic chemistry

(i) Dioxgen binding

Although the natural O_2 storage and transport proteins hemoglobin and myoglobin bear no Co ions, there have nonetheless been many Co-containing functional models of these proteins reported in the literature. The key to a successful O_2 carrier is reversibility. That is, the metal must not undergo spontaneous auto-oxidation to generate superoxide or peroxide species, nor must the coordinated O_2 ligand be attacked by protons or reductants that may assist this process.

Some 6,13-disubstituted macrocyclic Co(tmtaa) (**60**) complexes were prepared by Busch and co-workers and their O_2 binding affinities were determined.[1212] The complexes slowly undergo oxidation, but the ligand remains intact. This group has made many contributions to the field of O_2 binding through a class of macrobicyclic ligands often referred to as the cyclidenes (or lacunar macrocycles). Examples of 14-, 15-, and 16-membered macrocycles bound to divalent Co have been reported. For example, the planar [14]cyclidene complex has a small cavity which is only capable of partially protecting a bound O_2 from attack by solvent. This is in contrast to the deep saddle-shaped cavities of the 15- and 16-membered homologs. Some Co complexes of the [16]cyclidene family ((**261**) is an example) bind O_2 reversibly at low temperature with an enhanced affinity and lower rate of auto-oxidation compared to the [14]cyclidene analogs, both features attributed to the more exposed O_2 ligand in the smaller macrocycle. Dioxygen affinity decreases monotonically with the length of the polymethylene bridging group from octamethylene to tetramethylene and no binding occurs with a trimethylene bridge.[1213] The X-ray crystal structure of the Co–dioxygen adduct of (**261**) $[Co(MeMeC_6\text{-}[16]cyclidene)(Me\text{-}Im)(O_2)](PF_6)_2$ (Figure 10) reveals that the conformation of the ligand in the six-coordinate complex is crucial in protecting the O_2 ligand. Subsequently, the kinetics of O_2 binding to the vacant coordination site of the divalent complex were found to proceed with a very low activation barrier at rates comparable with the biological oxygen carriers myoglobin and hemoglobin.[1214] An interesting discovery was that ionizable Me groups on the cyclidene ligand enhance the rate of auto-oxidation of the divalent O_2 adduct, which prompted the synthesis of unsubstituted cyclidenes and their Co complexes.[1215] A lower O_2 binding constant was observed to the unsubstituted cyclidene complex, although the rates of dioxygen binding were as fast as those of the Me-substituted analogs, which pointed to differences in the complex dissociation rates as being responsible for the disparate O_2 affinities. Molecular dynamics calculations have been used to examine solution conformations of these complexes.[1216]

The ability of the ubiquitous Co(salen) complex and its tetradentate Schiff base analog complexes to bind O_2 reversibly has been central to most investigations of its coordination chemistry. A density functional computational investigation has been carried out on the O_2 carriers

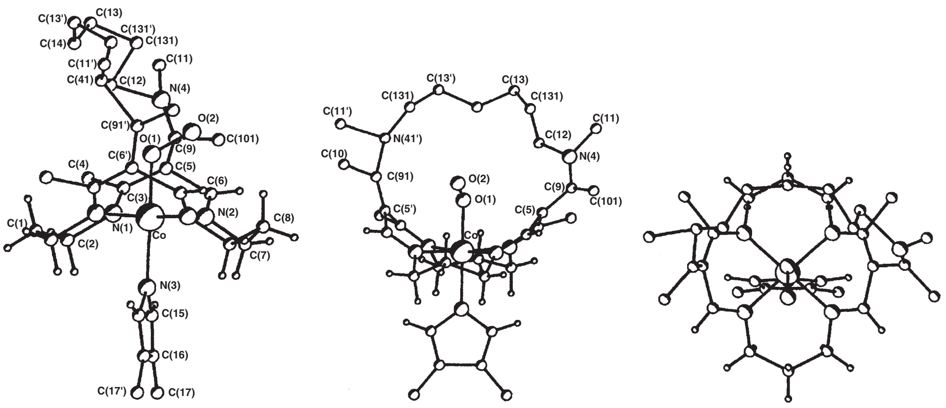


Figure 10 Three views of the Co-O_2 adduct of (**261**), with a disordered N-methylimidazole as the sixth ligand (reproduced with permission of the American Chemical Society from *Inorg. Chem.*, **1994**, *33*, 910–923).

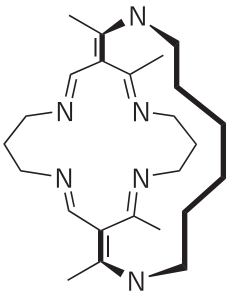
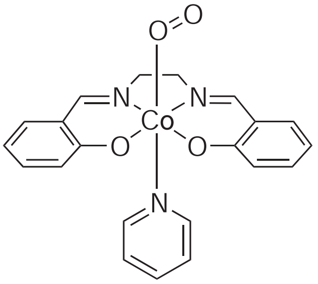
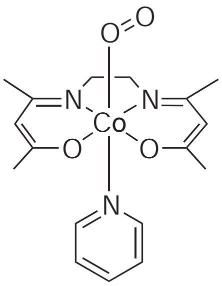
$(O_2)Co(salen)(py)$ (**262**) and $(O_2)Co(acacen)(py)$ (**263**).[1217] The calculated geometries and O_2 binding energies were consistent with experiment. The inclusion of effects due to the basis set superposition error and zero point correction attenuate the calculated binding energy. Magnetic susceptibility measurements showed that 22% of divalent Co(salen) exists as the high-spin ($S = 3/2$) $Co(salen)(py)_2$ complex in pyridine solution at 295 K and that lower temperatures favor the high-spin species.[1218] In DMF-d^7 temperature-dependent NMR experiments, the formation of antiferromagnetically coupled dimers at low temperature was indicated. The pressure dependence of the high-spin-low–spin spin equilibrium was studied at room temperature for the six-coordinate 3-carboxy derivatives of $Co(salen)L_2$, where L is a coordinating solvent. The high-spin-low–spin crossover was observed with near-edge XANES spectroscopy.[1219] The pressures required to induce a spin transition were less than 1.1 GPa for L = pyridine, 4-tert-butylpyridine and H_2O (which are known to also undergo thermal spin crossover) and 6.5–9.0 GPa for L = 3-methylpyridine, which is normally high-spin at all temperatures.



(**261**)



(**262**)



(**263**)

The single-electron reduction and oxidation of Co(salen) is solvent dependent as a result of the available coordination sites perpendicular to the CoN_2O_2 plane.[1220] Furthermore, substituents on the phenyl rings modulate the observed redox potentials and subsequently the O_2 binding constants. Hammett correlations are obtained.[1221] Potentiometric titrations were performed to determine the O_2 binding constants and species distribution as a function of pH for a variety of Schiff base Co complexes.[1222]

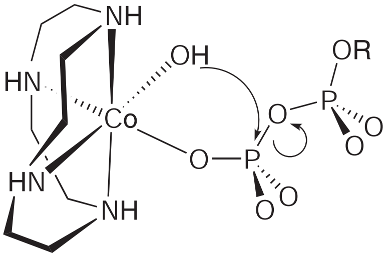
The Co(salen) complex may be prepared *in situ* inside zeolite Y (but not zeolite 5A) by reaction of the free ligand with the Co^{II}-exchanged zeolite (a "ship in a bottle" approach).[1223] When reacted with pyridine, 1:1 O_2 adducts are formed that are too large to exit the interior of the material and although the O_2 complex formation constants are smaller, auto-oxidation is attenuated significantly within the zeolite cavity. Similar experiments were performed to compare the reactivity of Co(salen) within cubic (zeolite Y) and hexagonally symmetric (EMT) cavities.[1224] An analogous approach has been reported using porous organic matrices to encapsulate Co(salen) and its O_2 adduct.[1225] Further, an oxygen-sensitive membrane incorporating Co(salen) has been prepared via sol–gel methods with poly(*N*-vinylpyrrolidone) as the mediation agent.[1226]

Well-dispersed silica and polymer/Co(salen) segments at a molecular level were obtained. Non-destructive immobilization of Co(salen) complexes within silica aero- and xerogels was also achieved with the sol–gel method using silylether-appended salen.[1227]

The mononuclear O_2 adduct L(salchn)Co(O_2) (L = various substituted pyridines) bearing a fused cyclohexyl ring has been investigated by EPR spectroscopy.[1228] The effect of the basicity of the solvent *trans* to the dioxygen ligand on the g and A values was studied and discussed in terms of the degree of Co—O_2 back bonding. 1-Hydroxy-2-naphthaldehyde may be considered as a benzo-salicylaldehyde and Co complexes of its corresponding npthn analogs have been prepared with 2–6 methylene groups connecting the two N donors.[1229] Reversible O_2 binding occurs with the ethylenediamine analog Co(npthn) complexes in DMF, although the reaction is considerably more exothermic than for Co(salen).

(ii) Polyphosphate and phosphate ester hydrolysis

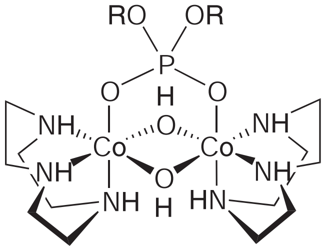
The biomimetic catalysis of polyphosphate hydrolysis by Co^{III} amines has received a great deal of attention. A number of tetraaminecobalt(III) complexes are known to be effective in this role. A stereochemical requirement is a *cis*-octahedral tetraamine complex where a pair of adjacent reactive coordination sites are present; one for a highly polarized hydroxo ligand (the nucleophile) and the other for the polyphosphate (the substrate). ATP,[1230–1232] cAMP (adenosine 3′,5′-cyclic monophosphate),[1233], triphosphate,[1234,1235] and pyrophosphate hydrolysis have been shown to be catalyzed by the macrocyclic complex $[Co(cyclen)(OH_2)(OH)]^{2+}$ (**140**). Monodentate coordination of a terminal phosphate group to produce a species of the type $[Co^{III}(cyclen)(OPO_3PO_2R)(OH)]^{n+}$ (**264**) is followed by rapid intramolecular phosphate hydrolysis involving the *cis*-coordinated hydroxo ligand resulting in the $[Co(cyclen)(OPO_3)(OH)]^-$ ion as a product.



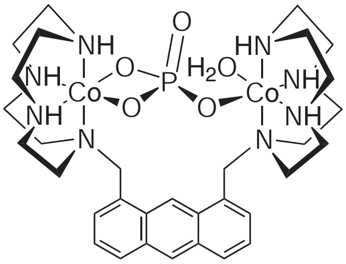
(**264**)

Phosphate monoester, diester,[1236] and triester[1237] hydrolysis is also catalyzed by this versatile ion, and it is known that the amine spectator ligands also influence the observed rates significantly.[1238] Measurable rate increases of up to 10^7-fold have been reported with Co^{III} polyamine catalysts.[1239] The large difference in reactivity of monodentate hydroxyethylphosphate where a *cis*-hydroxy group is also bound, compared with the chelated ester occupying both sites, points to the role of the coordinated nucleophile in hydrolysis of the phosphoester.[1240] With additional aquahydroxy-cobalt(III) tetraamines present, however, ester hydrolysis is significantly accelerated, pointing to a dinuclear intermediate forming. Indeed, a product of this hydrolysis has been characterized as $[(trpn)Co(OP(O_2)O)Co(trpn)]^{3+}$, supporting this view (trpn = tris(3-aminopropyl)amine).

Understanding the cooperative hydrolysis of phosphoesters by two metal ions, the presumed mechanism in endonucleases, is a current focus of attention, prompting study of dinuclear systems. Diester coordination can involve both terminal O atoms as donors, as exemplified in the bridged dinuclear complexes (**265**).[1241] Ester cleavage is promoted in basic solution via nucleophilic attack by a deprotonated bridging hydroxide. The Co···Co separation (2.9 Å) in the dimer is much shorter than in dinuclear phosphodiesterases.[1242] The diester is hydrolyzed by a mechanism involving double Lewis acid activation and attack from a neighboring bridging oxo ligand, with an exceptional 10^{12}-fold rate acceleration reported. The hydrolysis of methyl aryl phosphate diesters bound to Co^{III} in the dinuclear ion $[\{(tame)Co\}_2\ (\mu\text{-}OH)_2(\mu\text{-}O_2P(OAr)(OMe))]^{3+}$ is base catalyzed, and sensitive to the basicity of the aryloxy leaving group and to variation of the "spectator" amine ligand.[1243] Further rate enhancements have been observed in carefully designed dinuclear Co^{III} cyclen complexes capable of binding monoester[1244] or diester[1245] substrates within a pocket between the pairs of reactive *cis* aqua/hydroxo ligands on each metal (**266**). A triply bridged dinuclear complex with a bridging phenylphosphonate ester has also been examined as a model of phosphodiester cleavage.[966]



(**265**)



(**266**)

DNA (phosphodiester) hydrolysis has also been examined with $[Co(cyclen)(OH_2)(OH)]^{2+}$ as the active species.[1239,1246] Significant rate enhancement of linear[1247] and supercoiled[1248] double-stranded polydeoxyribonucleotide hydrolysis is observed by immobilizing the Co complex on a polystyrene support. Wider exploration of reactions with DNA follow.

6.1.3.1.4 DNA binding, intercalation, and scission

The humble $[Co(NH_3)_6]^{3+}$ ion is an extremely effective hydrogen bond donor, and its high charge density ensures a strong association with oligonucleotide duplexes both large and small. These ion pairing interactions can influence the helical structure of DNA and its relatives considerably.[1249] The oligonucleotide–$[Co(NH_3)_6]^{3+}$ interaction has been studied with a wide variety of physical techniques including crystallography,[1250–1255] electron microscopy,[1256,1257] atomic force microscopy,[1258] circular dichroism,[1259,1260] vibrational spectroscopy,[1261,1262] NMR,[1263–1265] and light scattering.[1266,1267] Condensation of DNA[1268,1269] is affected by the presence of this ion. It has been found that $[Co(NH_3)_6]^{3+}$ effects the conversion of B- (right-handed) to Z-DNA (left-handed) or B- to A-DNA (conformationally distinct right-handed helices) depending on the DNA sequences, and a number of spectroscopic and theoretical[1270] studies have investigated this phenomenon. Marked changes in the helical structure of the oligonucleotide such as bending and photosensitized cleavage of the helix have been observed.[1271,1272]

The interaction of chiral $[Co(en)_3]^{3+}$ with DNA and small oligonucleotides has been extensively studied. A ^{1}H NMR investigation revealed distinctly different chemical environments of the nucleotide protons of a dodecanucleotide in the presence of the different enantiomers, and concluded that Δ-$[Co(en)_3]^{3+}$ binds with the dodecamer in the major groove, near the center of the duplex and binds more strongly than the corresponding Λ isomer.[1273] This interaction has been investigated with molecular dynamics simulations, and this study identified key H-bonding interactions responsible for the diastereoselectivity.[1274] A ^{59}Co and CD spectroscopic study[1275] of the interaction between the Δ- and Λ-$[Co(en)_3]^{3+}$ with DNA identified a similar sequence selectivity (guanine) to that seen for $[Co(NH_3)_6]^{3+}$, and both enantiomers were found to induce a B-to-A DNA conversion in G-rich regions while leaving other sections of the duplex in the B conformation.[1276] However, Δ-$[Co(en)_3]^{3+}$ binds more strongly to right-handed, guanine-rich DNA than Λ-$[Co(en)_3]^{3+}$. The reverse is true for left-handed DNA. The two enantiomers bind in an indistinguishable manner to AT-rich DNA. These findings were subsequently supported by 2D NMR experiments.[1277] The B–Z DNA transformation in poly (dG-dC)(dG-dC) DNA, known to be assisted by $[Co(NH_3)_6]^{3+}$, has also been achieved with $[Co(en)_3]^{3+}$.[1260] DNA has been shown to co-precipitate rapidly with $[Co(en)_3]^{3+}$ at trace concentrations whereas charge neutral and anionic complexes are left in solution.[1278]

The $[Co(phen)_3]^{3+}$ complex is photoactive and a powerful oxidant in its excited state. The ion has no H-bonding groups and hence is considerably more hydrophobic[1279] than hexaamine relatives. These properties have proven particularly useful. Aryl and alkyl substituted $[Co(phen)_3]^{3+}$ complexes have received a great deal of attention due to their ability to intercalate within the helical structure of DNA through a combination of electrostatic and hydrophobic forces. The chirality of the tris-chelate complex is crucial in determining the degree of association between the complex and

DNA. A key paper by Barton and Raphael[1280] reported that (right-handed) B-DNA associates strongly with Δ-$[Co(4,7\text{-}Ph_2\text{-}phen)_3]^{3+}$ but not with its Λ enantiomer. Upon irradiation DNA nicking was achieved, which was attributed to photooxidation by the Co^{III} complex when closely bound to the helix activating strand scission. The area of DNA intercalation by $[Co(phen)_3]^{3+}$ and other similar complexes has received a great deal of attention subsequently.[1281] The DNA double helix has been shown to be an efficient conduit for intermolecular electron transfer between photoexcited $[Ru(phen)_3]^{2+}$ and $[Co(phen)_3]^{3+}$, where both complexes are intercalated within the double helix.[1282] This concept was extended to the same intermolecular electron transfer reaction on the surface of starburst dendrimers.[1283] Electrochemical methods have been employed to quantify the association constants between the Co complex and various oligonucleotides,[1284–1286] and to gauge the effect of DNA binding on the rate of diffusion of the Co complex.[1287] The concept of association between the DNA double helix and the complementary $[Co(phen)_3]^{3+}$ unit has been extended to DNA-modified electrodes with potential biotechnological applications.[1288–1293] Adsorptive transfer stripping voltammetry at a hanging mercury drop electrode has been used to detect conformational changes of DNA due to binding of DNA intercalators.[1294]

The molecules bleomycin A_2 and B_2, (**267a**) and (**267b**), comprise a potent chemotherapeutic agent for the treatment of cancer. The anti-cancer activity lies in the drug's ability to achieve DNA strand scission in tumor cells through the production of peroxyl species. A single bleomycin molecule is capable of cleaving both strands of DNA in the presence of its required cofactors $Fe_{aq}{}^{2+}$ and O_2 without dissociating from the helix. There are a number of N donors (in bold) that participate in binding the Fe cofactor and produce hydroperoxide as a ligand that initiates strand cleavage. Substitution of Co for Fe enables interactions between the drug and DNA fragments to be investigated by NMR spectroscopy. Conformational properties of the $HO_2\text{-}Co^{III}$-bleomycin A_2 (**267a**) (Form I) and Co^{III}-bleomycin (Form II) complexes bound to DNA oligomers were examined by NMR.[1295] Form I binds in slow exchange to the oligomers $d(GGAAGCTTCC)_2$ and $d(AAACGTTT)_2$, whereas Form II binds with DNA in fast exchange on the NMR time scale. The association constant of Form II with $d(GGAAGCTTCC)_2$ (pH 7.4, 25 °C) is $1.7 \times 10^5\ M^{-1}$. A later 2D NMR study of the complex formed between Co-bleomycin and other oligonucleotides gave a well-defined picture, which found that the bithiazole tail of bleomycin is partially intercalated between T19 and A20 of the duplex and that the metal binding domain is poised for abstraction of the T19 H4′ in the minor groove.[1296] The interaction between the Co^{III} complex of a bleomycin functional model (AMPHIS-NET) and the oligonucleotide $d(CGCAATTGCG)_2$ were examined by 2D NMR methods and molecular dynamics calculations.[1297] The 1:1 cobalt(III) complex of AMPHIS-NET binds in the minor groove of the oligonucleotide at the central AATT site. Cross peaks also indicate that the metal binding moiety of the Co^{III}–AMPHIS-NET complex interacts with the oligonucleotide two base pairs beyond the central AATT site in the minor groove.

(**267b**) R = $CH_2CH_2NHC(NH_2)NH_2$

6.1.3.1.5 Biological electron transfer

Association of $[Co(NH_3)_6]^{3+}$ with acidic amino acid residues on the surface of proteins has been exploited in the "promotion" of electron transfer reactions of redox active proteins at electrode surfaces.[1298,1299] The $[Co(phen)_3]^{3+}$ and $[Co(bpy)_3]^{3+}$ ions are particularly attractive high-potential, single-electron, outer-sphere oxidants lacking any potential hydrogen bonding sites. The oxidation of blue copper proteins with $[Co(phen)_3]^{3+}$ and $[Co(bpy)_3]^{3+}$ has been studied in a series of papers from Sykes and co-workers,[1300–1305] and other groups.[1306–1309] Reactions of the Co^{III} complexes with ferrocytochromes,[1310–1318] Fe–S clusters,[1319] molybdoenzymes,[1320] and galactose oxidase[1321] have also been reported. Enantioselective oxidation of ferrocytochrome *c* by optically pure $[Co(bpy)_3]^{3+}$ was interpreted as evidence for the closeness of approach of the Co^{III} complex to a hydrophobic, and inherently chiral, pocket of the protein.[1322] Like the bpy and phen homologs, the $[Co(terpy)_2]^{3+}$ ion has been used as a single-electron oxidant of a number of biological targets.[1305,1323] With the $[Co(phen)_3]^{3+/2+}$ couple, the $[Co(terpy)_2]^{3+/2+}$ system has been used as a high potential mediator in redox potentiometry of biological redox centers.[1324]

6.1.3.1.6 Medicinal chemistry

Co porphyrins have been found to play interesting and varied roles in medicine. Co protoporphyrin and *meso*-substituted porphyrins administered subcutaneously to normal adult rats led to decreases in food intake and sustained decreases in body weight, while direct injection of the compound into the brain produced similar changes in food intake and body weight, but requiring about 1–2% of the parenteral dose.[1325] Similar effects were observed with genetically obese rats, chickens, and dogs. These studies demonstrate that porphyrins can act on the central nervous system to regulate appetite and to produce long-sustained diminutions in body weight and content of fat in animals; pharmaceutical compositions for these porphyrins for the treatment of obesity have been patented.[1326]

The high CN^- affinity of trivalent $[Co(TSpP)]^{4-}$ has led to its investigation as a potential cyanide antidote either alone or in various combinations with the cyanide antagonists $NaNO_2$ and $Na_2S_2O_3$.[1327] The study found that administration of $[Co(TSpP)]^{4-}$ alone protects against the lethal effects of cyanide, and that the complex adds to the protection provided by $Na_2S_2O_3$ and/or $NaNO_2$. Co protoporphyrin administered in conjunction with organ transplantation has been found to enhance organ survival. Inhibition of cytotoxicity *in vitro* and prolongation of graft survival in therapy of heart allograft recipients has been demonstrated.[1328] It is known that $CoCl_2$ is a potent inducer of heme oxygenase *in vivo* in animals, so the possibility of the biosynthesis of Co protoporphyrin was examined in human hepatoma cells by incubating them with $CoCl_2$ and protoporphyrin and δ-aminolevulinate, the precursor of protoporphyrin.[1329] Both types of treatment led to a potent induction of heme oxygenase mRNa, with Co protoporphyrin formation demonstrated in cells incubated with the metal and δ-aminolevulinate, which demonstrated that incorporation of Co into the porphyrin is necessary for induction, and indicated that the role of $CoCl_2$ (as its porphyrin complex) was to activate the heme oxygenase gene via a heme-responsive transcription factor.

The therapeutic potential of sarcophagine cage complexes in general has been reviewed.[760] For Co cages, in particular (**162**), the irreversible nature of coordination means that the metal is a spectator in systems examined to date. Most of the uses for this class of Co complex in biology relate to the nature of the substituents introduced at the cap. Long alkyl substituents result in complexes that exhibit surfactant-like properties and these have been found to exhibit antiparasitic activity.[1330–1332] The anthracenyl-substituted (cationic) Co cage (unlike anthracene itself) associates strongly with DNA and irradiation of the intercalated complex at 254 nm leads to single-strand cleavage of DNA.[1333]

6.1.4 INDUSTRIAL AND ANALYTICAL APPLICATIONS OF COBALT COMPLEXES

6.1.4.1 Organic Transformations

The use of transition metal compounds in organic synthesis, where they may be involved in stoichiometric reactions or catalytic reactions, has grown consistently, as recent reports illustrate.[1334–1337]

Catalysts for promoting organic transformations are as diverse as are the reactions they catalyze, and there are a growing number of examples featuring Co extant in the literature. Nevertheless, Co features less commonly than some other metal ions, but may find application in a range of characteristic organic reactions such as alkylation, conjugate addition, oligomerization, acylation, rearrangement, and functional group synthesis. It remains true to say that applications of Co compounds in catalysis are limited relative to other metals such as palladium and ruthenium, and this presents an area for future development of the chemistry of the element. This section does not aim to be exhaustive in its coverage, but to give examples of applications and recent developments in the field; some examples have appeared already for selected complexes throughout the review.

Both heterogenous and homogenous catalysts featuring Co have been reported. The macromolecular heterogenous catalysts are outside the scope of this report, which concentrates on molecular systems. However, it is noted that surfaces can promote reactions in concert with molecular systems. For example, surface reactions between $Co_2(CO)_8$ and an inorganic oxide involves disproportionation and tight ion pair formation, leading to catalytically active $Mg[Co(CO)_4]_2$.[1338] Further, surfaces may be templated with organic molecules capable of binding metal ions strongly, providing modified surfaces for catalytic activity,[1339] or else complex ions may be intercalated in layered inorganic solids such as double hydroxides.[1340] Intercalation of phthalocyanines and porphyrins of cobalt(II), as well as polyoxometallates including cobalt(II), has been established in these anionic clays. Photocatalysis by transition metal complexes has been widely studied also.[1341] Amongst systems identified, cobalt(III) complexes of oxalate and dithiooxalate feature in their use for hydrogen generation from thiols, which also leads to disulfides.

6.1.4.1.1 Oxidations

Cobalt(III)–alkylperoxo complexes find use in the oxidation of hydrocarbons.[1342,1343] Since they release ROO· and RO· radicals upon mild heating in solution, they are effective oxidants under mild conditions, and produce catalytic systems in the presence of excess ROOH. Aliphatic C—H bond oxidation by $Co^{II}OOR$ ($R = Co^{II}$, alkyl, H) complexes including a hydrotris(pyrazolyl) borate ligand have also been reported, with homolysis of the peroxo O—O bond believed to be important in oxygenation of the C—H bond.[1344]

Regioselective hydroperoxygenation of $\alpha,\beta,\gamma,\delta$-unsaturated carbonyl compounds with O_2 and triethylsilane was achieved with a Co^{II} porphyrin complex, to give the corresponding γ-hydroperoxy-α,β-unsaturated carbonyl derivative in good yield.[1345] The same group extended this range of reactions to include other conjugated olefins such as styrene and acrylic esters.[1346] 4-Aryl-substituted derivatives of Co(TPP) catalyze the oxidation[1347] or epoxidation[1348] of organic substrates such as alkenes, allylic or benzylic substrates, alcohols, and hydrocarbons at ambient conditions in the presence of O_2 and 2-methylpropanal.

The 4-methoxy derivative of the Schiff base complex Co(salphn) (**69b**) catalyzes the mild epoxidation of olefins in one atmosphere of O_2 in the presence of a cyclic ketone reductant.[1349] The catalytic dioxygenolysis of 3-methylindole to 2-(*N*-formylamino)acetophenone has been investigated within a series of electronically and sterically designed Co(salen) (**69a**) complexes. The cathodic shifts in the $Co^{III/II}$ redox potential and steric bulk each slow the reaction.[1350] Substituted anilines undergo oxidation by *t*-butyl hydroperoxide in the presence of Co(salen) analogs to give the corresponding nitrobenzene.[1351] A Co(salen)(OO-*t*-Bu) intermediate was implicated in the mechanism. The catalysis of phenol oxidation reactions was investigated using Co(salen) analogs, particularly coniferyl and sinapyl alcohols as substrates. This oxidation of monomeric and dimeric lignin model compounds was also studied with a view to its relevance to practical pulp bleaching conditions.[1352]

Complexes of the Co(salen) family are capable of mediating the electrocatalytic reduction of O_2 to H_2O_2.[1353] The reduction potential is pH dependent, irreversible, and diffusion controlled. The biphenyl-derived dimer of Co(salphn) (joined at the 4-positions of the two *o*-phenylenediamine rings) adsorbs onto a graphite electrode and also catalyzes the reduction of O_2 which is believed to involve axial coordination of O_2.[1354] An electrochemical investigation of the cyclohexane fused analog Co(salchn) identified a reversible $Co^{III/II}$ response in deoxygenated non-aqueous solution in addition to O_2 reduction waves on aeration. An XPS analysis of an anodically formed film of the complex on a platinum electrode identified the Co complex in its trivalent oxidation state. In aerated solution, catalytic oxidation of alkenes such as cyclohexene and 4-methyl-1-cyclohexene was observed.[1355]

Cobalt(II) bis(1,3-diketone) complexes find use for the conversion of olefins into alcohols, ketones, and paraffins, by contacting the olefins with an oxygen-containing gas in the presence of the Co catalysts.[1356] Cobalt catalysts supported on or incorporated into other materials are also recognized as effective heterogeneous catalysts. Co(salen) can be incorporated into the intercrystalline cavities in zeolites, and catalyzes the oxidation of cyclohexene with aqueous peroxide to form cyclohexane-1,2-diol, 2-cyclohexenol and 2-cyclohexenone.[1357] Crosslinked polystyrene is an efficient support for thiosemicarbazone cobalt (II) complexes.[1358] This functionalized polymer, when 10% crosslinked, shows potential as a catalyst for the epoxidation of cyclohexene and styrene. It is also able to catalyze the decomposition of peroxide. Polymer-immobilized EDTA was prepared by redox initiation with sodium EDTA and ceric ion of copolymerization of methacrylic acid and acrylonitrile. The Co complex proved useful for the peroxidation of benzaldehyde, in a selective and high-yielding reaction.[1359] Immobilization of a Co^{III} complex on chemically modified silica has recently been described, and efficiently oxidized alkylaromatics with air and without requiring a solvent.[1360] Immobilized catalysts present the opportunity for more environmentally friendly industrial processes to be developed.

6.1.4.1.2 Carbonylation and formylation

Hydroformylation promoted by metal compounds is sufficiently extensive to attract annual reviews of work in the field.[52,1361,1362] However, Co catalysts form a smaller subset. Of the more established Co catalysts, $Co_2(CO)_8$ continues to be well studied. The equilibrium reaction pertinent to hydroformylation (Equation (12)), has been recently reviewed.[1363]

$$Co_2(CO)_8 + H_2 \rightleftharpoons 2\,HCo(CO)_4 \tag{12}$$

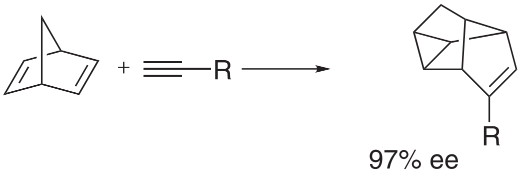
The attainment of regio- and enantioselectivity are continuing challenges, which form the basis of investigations of new catalytic systems. For example, novel mixed-metal catalysts such as $(CO)_2Co(\mu\text{-}CO)(\mu\text{-}HC{\equiv}CBu)Rh(CO)_2$ promote the stereospecific synthesis of *Z*-only BuC(CHO) = $CHSiMe_2Ph$ from 1-hexyne and $HSiMe_2Ph$.[1364]

A recent example where $Co_2(CO)_8$ serves as a precatalyst is in the preparation of linear and branched aldehydes via propylene hydroformylation in supercritical CO_2 (93–186 bar; 66–108 °C). Cyclohexane carbaldehyde is produced from cyclohexene using $Co_2(CO)_8$ and an acid RCOOH, or else is successful with another established Co catalyst, $Co(OOCR)_2$, assumed to form *in situ* in the former case. Oligomerization of aldehydes such as n-butanal is achieved with $Co_2(CO)_6L_2$ as catalyst (L = CO, PR_3).[1364]

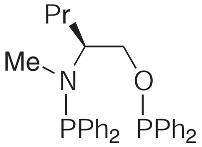
High yielding and chemoselective hydrocarbonylation of benzyl chloride and bromide and substituted analogs in a mixed organic/aqueous NaOH two-phase system occurs in the presence of $Co_2(CO)_8$ as catalyst and polyethylene glycol as phase transfer agent.[1365] Proposed intermediates in the catalysis are species such as η^1- and η^3-benzylacetylcobalt carbonyls. Polynuclear $Co_4(CO)_{11}(SMe_2)$ promotes the hydroformylation of alkenes to aldehydes.[1366] Carbonylation of organic halides to form esters with $Co(PPh_3)_mX_n$ compounds as catalyst has been examined,[1367] with yields of up to 80% established in a two-phase benzene aqueous NaOH system with tetrabutylammonium bromide as phase transfer agent. Anhydrous $CoCl_2$ with $[PhEt_2N][BH_3]$ is a useful reagent for hydroboration and carbonylation of alkenes to dialkylketones, after oxidation with H_2O_2/NaOH.[1368] The oxidative carbonylation of aromatic primary amines employs Co(salen) as a catalyst, and produces ureas in high yields, including cyclic ureas.[1369]

6.1.4.1.3 Cycloadditions and asymmetric synthesis

Asymmetric, enantioselective, and regiospecific synthesis is of particular importance for sophisticated syntheses of relevance to the pharmaceutical industry and other industries demanding "boutique" chemicals. The field is attracting continuing effort, and the type of reaction where Co catalysts appear are diverse and activity strong, so it is only possible to give a flavor of the field here. An example is in the Diels–Alder reaction (Equation (13)), which occurs in high yield and with 97% enantiomeric excess where the CoI_2/Zn catalyst incorporating the aminophosphine–phosphinite ligand (**268**) is employed.[1370]

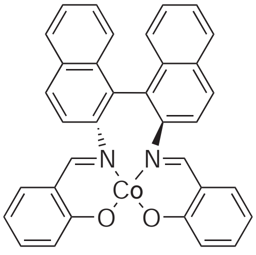


(13)

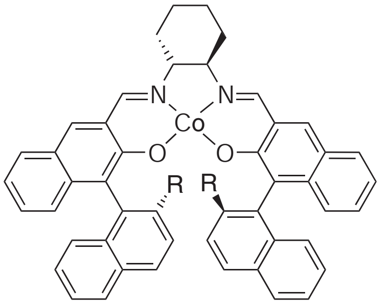


(**268**)

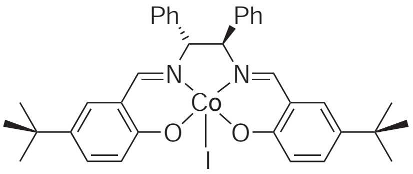
The potential of chiral Co(salen) analogs in asymmetric N, S, and P oxidations has been realized and the preparations of a number of these compounds have been patented.[1371] Chiral Schiff base complexes derived from 2,2′-diamino-1,1′-binaphthalene or 1,2-diaminocyclohexane and various salicylaldehydes have been synthesized and complexed with cobalt (**269**).[1372] The crystal structure of Co(phsaldpen) (derived from 2-hydroxybenzophenone and *rac*-1,2-diphenylethylenediamine) has been determined where the two Ph groups on the chelate ring occupy axial positions and hinder access to the apical coordination sites.[1373] The $\mathrm{Co^{III/II}}$ couple is ca. 300 mV anodically shifted relative to Co(salen). The *meso* isomer was also prepared. Chiral tridentate Schiff base complexes have also been exploited as catalysts for stereoselective cycloaddition reactions.[1374] Cyclopropanecarboxylates were obtained with excellent enantioselectivity (>95% ee) from reaction of styrene derivatives and *t*-butyl α-diazoacetate, using the advanced chiral $\mathrm{Co^{II}}$–salen complex (**270**).[1375] Chiral trivalent Co (salen)(OAc) analogs immobilized on the mesoporous siliceous material (MCM-41) achieve hydrolytic kinetic resolution of racemic epoxides (epichlorohydrin, 1,2-epoxyhexane, epoxystyrene and epoxycyclohexane) to their diols.[1376]



(**269**)

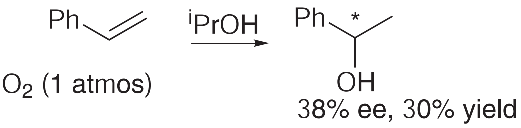


(**270**)

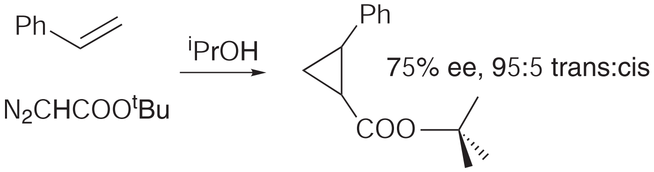


(**271**)

Catalysts of the Co(salen) family incorporating chiral centers on the ligand backbone are useful in asymmetric synthesis and the field has been reviewed.[1377,1378] In two examples, the hydroxylation reaction (Equation (14)) involving (**269**) proceeds with 38% ee,[1379] whereas the cyclopropanation reaction with (**271**) (Equation (15)) proceeds with 75% ee and with 95:5 *trans:cis*.[1380] A Co(V) salen carbenoid intermediate has been suggested in these reactions.



(14)



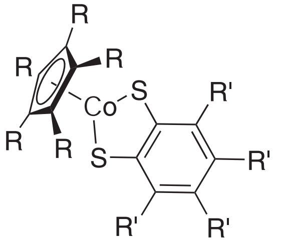
(15)

Optically active β-ketoiminato cobalt(III) compounds based on chiral substituted ethylenediamine find use as efficient catalysts for the enatioselective hetero Diels–Alder reaction of both aryl and alkyl aldehydes with 1-methoxy-(3-(*t*-butyldimethylsilyl)oxy)-1,3-butadiene.[1381] Cobalt(II) compounds of the same class of ligands promote enantioselective borohydride reduction of ketones, imines, and α,β-unsaturated carboxylates.[1382]

6.1.4.1.4 Other catalytic reactions

A selected assortment of other organic transformations not discussed above is given here. Catalysis of the condensation reaction between *p*-nitrobenzaldehyde and *p*-aminotoluene by thiourea complexes of cobalt(II) and zinc(II) has been observed, and activation by substrate coordination to the complex in the activated state is implied.[1383] Reductive nitrosation of olefins, α,β-unsaturated and α,β,γ-unsaturated carbonyl compounds have been reported with Me_3CONO and Et_3SiH in the presence of Co^{II} porphyrin catalysts to give the respective acetophenoximes, α-hydroxyimino and γ-hydroxyimino-α,β–unsaturated carbonyl compounds in good yields. The potential role of cyclodextrins functionalized with polyamines as enzymes models and chiral receptors has been reviewed.[1384] Their application as artificial hydrolases is exemplified by the 900-fold enhancement of hydrolysis of *p*-nitrophenyl acetate by a cyclodextrin carrying an appended cyclen macrocycle bound to a cobalt(III) ion, which also carries two *cis*-coordinated water molecules.[1385] These two adjacent sites provide the opportunity for both substrate binding and provision of a coordinated nucleophile for attack of the ester group. The potential of metal complexes, including those of cobalt, as synthetic nucleases has been reviewed.[1386]

Isomerizations are another category of reaction where Co complexes act as catalysts. Mixed S,P donor complexes $Co(SCN)_2(PR_3)_2$ catalyze the isomerization of 1-butene to 2-butene in the presence of $NaBH_4$, with $CoH(SCN)(PR_3)_2$ proposed as the active species.[1366] A cyclopentadienyl complex (**272**) is active in the isomerization of quadricyclene to norbornadiene.



(**272**)

Rearrangement of trivalent (5-hexenyl)Co(salen) proceeds via a radical chain process leading to the isomeric cyclopentylmethyl complex.[1387] The efficiency with which this rearrangement occurs is dependent on the presence of trace impurities or O_2. The selective reaction of alcohols (ROH) with arylglyoxals (ArCOCHO) to give α-aryl-α-hydroxyacetic esters $ArCH(OH)CO_2R$ is catalyzed by compounds of this family.[1388]

6.1.4.2 Polymerization

Polymerization employing Co complexes as catalysts or else polymers incorporating functionality that includes Co ions represent aspects of polymerization reactions of interest here. Cobalt-mediated free-radical polymerization of acrylic monomers has been reviewed.[55] Co^{II} porphyrins act as traps for dialkylcyanomethyl radicals.[1098] Alkyl complexes of Co(TMesP)

(Mes = mesitylene) have been shown to initiate and control living free radical polymerization of poly methyl acrylates and block copolymers of methyl and butyl acrylate.[58,1389,1390] Oxygen transfer polymerization, using the reversible oxygen carrier Co(TPP)(py), which serves as both oxygen supplier and a fully recoverable initiator, has been reported.[1391] Vinyl monomers are converted under mild conditions to polymeric peroxides. Similarly, Co(TPP) in the presence of O_2 has been found to catalyze the room-temperature free radical polymerization of styrene and methyl methacrylate.[1392] The same group reported the oxidative polymerization of indene with Co(TPyP), leading to the formation of poly(indene peroxide) with narrow polydispersity.[1393] Dual behavior of Co(TPyP) as a dioxygen carrier as well as an initiator was implicated in this study.

Dichloro(2,6-bis(imino)pyridine)cobalt(II) has been characterized by X-ray diffraction.[1394] Upon treatment with methylaluminoxane, a highly active ethylene polymerization catalyst for production of highly linear polyethylene is produced that yields polymer of MW up to 600,000. Poly(salicylaldehyde acrylate) crosslinked with divinylbenzene has been derivatized with thiosemicarbazone, semicarbazone oxime, and ethylenediamine, and their formation of coordination polymers with cobalt(II) probed.[1395] Novel metal halide-complexed polymer films, including that of cobalt(II), were prepared with poly(arylene ether phosphine oxide).[1396] Metal complexation to the polymer was defined by IR and ^{31}P NMR studies. Imprinted polymers have been prepared which use a cobalt(III) imine complex as the template in a surface grafting technique, and their use for reversible dioxygen binding explored.[1397] Polymer materials with immobilized metal complexes of defined structures such as these have potential for application in catalysis, gas storage, and sensor technology.

6.1.4.3 Electrocatalysis and Analytical Sensors

Electrocatalysis employing Co complexes as catalysts may have the complex in solution, adsorbed onto the electrode surface, or covalently bound to the electrode surface. This is exemplified with some selected examples. Cobalt(I) coordinatively unsaturated complexes of 2,2′-dipyridine promote the electrochemical oxidation of organic halides, the apparent rate constant showing a first order dependence on substrate concentration.[1398,1399] Catalytic reduction of dioxygen has been observed on a glassy carbon electrode to which a cobalt(III) macrocycle tetraamine complex has been adsorbed.[1400,1401]

Recent studies on Co porphyrin chemistry have focused on their use as catalysts of reactions involving coupled electron and atom transfer, where the substrate is typically coordinated in a coordination site axial with respect to the CoN_4 plane. Coupled with glucose oxidase, (GO), $[Co(TMpyP)]^{4+}$ adsorbed into a Nafion film was used to monitor O_2 depletion (through glucose oxidation during GO turnover), and the voltammetric current from the porphyrin was used to determine glucose concentrations.[1402] Independently, Kadish and co-workers have investigated the reactions of monovalent $[Co^{I}(TMpyP)]^{3+}$ with O_2 to give a superoxo–Co^{II} complex that is stable in DMF solution. In oxygenated DMF solution, electrogenerated monovalent $[Co(TMpyP)]^{3+}$ catalyzes the epoxidation of cyclohexene.[1403] Although monovalent $[Co(TPP)]^{-}$ was inactive, the single-electron reduced complex generated chemically, electrochemically, and using pulse radiolysis and assigned as a π-radical, catalytically reduces CO_2 to CO and HCO_2^{-}.[121] Fluorination of the porphyrin results in an anodic shift of the potential at which catalysis occurs.

The consequences of polychlorination of porphyrins on redox properties of complexes has been investigated.[1404] The highly chlorinated porphyrin β-octachloro-*meso*-tetrakis(3,5-dichloro-2,6-dimethoxyphenyl)porphyrin exhibits a substantial anodic shift for reduction of over 0.5 V and a smaller shift for oxidation versus the unchlorinated precursor. Contrastingly, small potential shifts for the octabromo-substituted 5,10,15,20-tetraphenylporphyrinate arise from the dominance of macrocycle "ruffling" over electronic effects. In the polychloro complex, distortion does not compensate fully for electron-withdrawing effects of the Cl substituents.

Flow-injection spectrophotometric analysis of cobalt(II) has been developed employing pyridoxal 4-phenylthiosemicarbazone as chelating agent in strongly acidic medium, forming an intense yellow-colored 1:2 complex ($\lambda_{max} = 430$ nm, $\varepsilon_{max} = 1.35 \times 10^4$ M^{-1} cm^{-1}), with very few interferences at the low pH used, and detection down to 0.4 μg mL^{-1}.[1405] Direct, simple spectrophotometric analysis of Co down to similar levels has also been reported using 2′-hydroxyaceto--hydroxyacetophenone thiosemicarbazone,[1406] amongst a number of analogous studies. A sophisticated flow-injection method that allows for the simultaneous detection of Co and Ni via complexation with 2-hydroxybenzaldehyde thiosemicarbazone has been described.[1407] This relies on different formation rates of the two complexes. This technique has also been applied to determination of Co and Fe simultaneously.[1408]

A cobalt(II)–ethanolamine complex sorbed onto Dowex-50Wx2 resin serves as a heterogenous catalyst for luminol chemiluminescence, and was developed as a flow-through sensor for hydrogen peroxide and glucose.[1409] Electoactive Co complexes may play a key role in the analytical detection of compounds electrochemically. For example, nitrate in vegetables has been detected accurately in the mg/kg range by forming a complex with thiocyanate and nitric oxide, generated chemically from nitrate ion, and employing polarographic analysis.[1410]

6.1.4.4 Environmental

There is a range of environmental activities employing or dealing with cobalt; this is a growing area, and only a very few selected examples follow to identify the breadth of the field. In their monovalent oxidation state, Co porphyrin complexes are effective dechlorination catalysts of chlorinated hydrocarbons. Electropolymerization of a pyrrole-substituted *meso*-tetraphenylporphyrin (TPP) complex of Co onto a carbon support produces a catalyst that can reductively dechlorinate benzyl chloride[1411] and other organic halides.[1412] Similarly, Co(TPP) adsorbed onto a graphite foil electrode has been used as a sensor for the catalytic dechlorination of organic pollutants when reduced to its monovalent state. The aim of this work was to screen toxic organohalogen pollutants in environmental monitoring situations.[1413] Catalytic electrochemical reduction of *trans*-1,2-dibromocylohexanes is also achieved with Co porphyrins at potentials more than 1 V positive than in the absence of catalyst.[1414] Nitrotoluene reduction is catalyzed by Co hematoporphyrin as a preliminary step to enhance biodegradability of these waste products.[1415]

The treatment of waste water containing sulfide ions by catalytic aerial oxidation in the presence of a Co^{II} tetrasulfophthalocyanine catalyst removed over 95% of sulfide over a period of several hours.[1416] Removal by precipitation of cobalt(II) from waste water in the presence of other complexing agents was achieved by the addition of *N*,*N*-diethyl-*N*′-benzoylthiourea. The use of substituted thioureas can be applied to removal of other heavy metals also.[1417] The very low toxicity of several halo(2,3-dimethylpyrazolone-5-thione)cobalt(II) complexes allowed their use in the development of granulated slow-release fertilizers using collagen hydrolyzate as the organic filler, to deliver Co as a micronutrient.[1418]

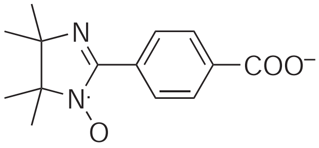
6.1.4.5 Technology

Cobalt complexes find application commercially, or else have been developed for commercial use, in a surprising range of tasks. Even the simplest of complexes may be employed. It has been found that $[Co(NH_3)_6]^{3+}$ salts with oxidizing anions (nitrate, nitrite, and perchlorate) may be used as gas generants for the rapid inflation of automobile airbags.[1419] These compounds are proposed as alternatives to highly toxic sodium azide, which is the most widely used gas generant in this application. Upon detonation, in the presence of co-oxidizers, $[Co(NH_3)_6]$ $(NO_3)_3$ liberates gaseous N_2, O_2, and water vapor which inflate the airbag. The same complex cation may be induced to release ammonia on heating at an appropriate stage of electrographic image formation, enhancing image contrast and density markedly.[1420] In testimony to its versatility, $[Co(NH_3)_6]^{3+}$ also finds application in a peroxide-free bleaching mixture in concert with polyoxyethylene lauryl ether and sodium carbonate.[1421] More elaborate complexes have been patented to enhance the bleaching effect of peroxide, as distinct from replacing it, including Co complexes with tripodal ligands and polyamide–polyamine dendrimers. At the other extreme, fabric dyes of dark green Co complexes with glyoxal anil arylhydrazones have appeared.[1422] Potential uses of Co coordination complexes are diverse. A quite different application, making use of cobalt's redox chemistry, uses (pyridine)bis(dialkylglyoximato)cobalt(III) chloride complexes along with acetylene black as cathodes in an effective rechargeable conducting polymer battery where poly(*p*-phenylene sulfide) anodes and $LiClO_4$-propylene carbonate electrolyte also feature.[1423] The complex Co (TMeOPP) (MeOP = 4-methoxylphenyl) has been incorporated into the cathode of an Al–O battery (where Al is the anode) with the goal being the use of this technology as a power source in spacecraft.[1424]

Somewhat unanticipated applications can arise. For example, a process for the production of ultrapure hydrogen peroxide for the electronics industry has been patented recently,[1425] which uses the macrobicyclic hexamine complex (**29**) supported on an inert material for dioxygen reduction. Cobalt(III) EDTA has been patented as a component in polymers to produce flame-retardant plastics,[1426] and simple hexa(alkylamine)cobalt (III) complexes have been examined as new photoinitiators for deep-UV resist materials, via efficient photoredox decomposition which releases free amine to initiate crosslinking.[594] Some other, and by no means exhaustive, examples of developing technological applications are presented below.

Inorganic crystal engineering employing self-assembly processes promises to lead to the future development of planned solids which may have application as molecular-scale devices such as molecular wires. A recent example is $[Co^{II}_2(4,4'\text{-bpy})_3(NO_3)_4]_\infty$ in solids where the pseudo-octahedral metal provides an appropriate junction in "molecular ladder" structures.[1427] Other mixed organic–inorganic composite materials have been developed relying on the differing stereochemistries around two metal centers; for example $Co(bpy)Mo_3O_{10}$ has chains of edge-sharing Mo-based polyhedra where octahedral CoN_2O_4 units link these to form a two-dimensional covalent network.[1428]

Molecular magnets are a rapidly expanding field, where some Co compounds are finding a role.[1429] A series of $Co^{II}_2(OH)_3X$ compounds, where X is an exchangeable organic radical anion produce new metal–radical magnets which feature stacks of Co^{II} hydroxide layers interlayered with organic radicals. The imino-nitroxide radical (**273**) is an example that produces a successful system.



(**273**)

Other molecular magnets have been based on polycyano metal complexes. For example, the Prussian Blue analog $Co^{II}_3[Fe^{III}(CN)_6]_2 \cdot nH_2O$, which is prepared by substitution of hexacyanoferrate(III) into the $Co^{2+}{}_{aq}$ coordination sphere, is a species with a significant photomagnetic effect.[1430] A stable Co^{III}–NC–Fe^{II} pair arises via internal electron transfer. Solids with intermediate stoichiometries can be formed, such as $Rb_{1.8}Co_4[Fe(CN)_6]_{3.3} \cdot 13H_2O$. Further, polynuclear species such as $[Cr^{III}(CN)_3[(CN)Co^{II}L]_3]^{3+}$ where L is a pentaamine ligand, have been prepared and magnetic properties examined. Yet another family of magnetic materials are clusters based on polyoxometallates.[1431] Mixed-metal clusters such as $[Co^{II}_4(H_2O)_2(PW_9O_{34})_2]^{10-}$ and $[WCo^{II}_3(H_2O)(Co^{II}W_9O_{34}]_2]^{12-}$ have been examined, with ferro- and anti-ferromagnetism found in selected examples.

Diagnostic processes in medicine and pharmaceutical applications featuring metal complexes are expanding rapidly.[1432,1433] Of radionuclides of possible value, ^{55}Co complexes have potential for use in positron emission tomography since they undergo β^+ decay with a suitable half-life and energy. To date, however, it has been studied very little. Likewise, cobalt-based drugs are not a high-profile area of development currently, although there are some advances. Cobalt(III) complexes of macrocyclic polyimines have been patented for use as anti-inflammatory agents, due to their superoxide coordination chemistry which is, in effect, antioxidant behavior.[1434]

New solid state materials are a major research target. Most, such as Co nanocrystals, Co nitride films, and zirconia-supported cobalt, do not involve formal coordination compounds, and are outside the scope of this review. One interesting application of a Co compound, however, has appeared recently. Carbon nanoflasks, a new form of fullerene-type carbon, use $Co(CO)_3NO$ as the source of carbon in their synthesis.[1435] Upon decomposition, the $Co(CO)_3NO$ yields fcc Co particles, of from several nanometers to hundreds of nm in size. The cobalt-filled carbon flasks have tube-neck widths of from 50 nm to over 100 nm, whereas the body of the flask ranges from 100 nm to 500 nm, but can reach over 1 mm. Following acid treatment of the sample to remove cobalt, opened and empty carbon flasks are readily obtained. Sol–gel glasses, based on metal oxides/hydroxides that dissolve in ROH partially forming alkoxides[1436] do not feature Co as a metal, partly at least because the Co^{III} aqua ion is a powerful oxidant which oxidizes water, and partly because appropriate oligomerization does not apply. However, a major blue pigment as a colorant is the cubic spinel $CoAl_2O_4$, where the cobalt(II) lies in a CoO_4 tetrahedron. In another example, a transparent glass with Mg–Al spinel nanocrystallites doped with tetrahedrally coordinated Co^{2+} operates as a new saturable absorber Q switch for Er:glass lasers.[1437] A novel route to Co_3O_4 thin films on glass substrates has been established by firing at 500 °C the tributylammonium salt of $[Co(EDTA)]^-$ adhered to the glass.[1438] Pillared clays are an area of growing interest, and Co compounds find application in this field; for example, montmorillonites expanded with small amounts of $[Co^{III}_3(H_2NCH_2CH_2O)_6](ClO_4)_3$ and an aluminum compound (final Si:Co ratio from 38 to 128) and calcinated by firing at 500 °C in air proved to be significantly enhanced in thermal stability.[1439]

6.1.5 CONCLUSION

At the beginning of the twenty-first century, it is still true to say that Co remains a firm favorite for traditional Werner-type coordination chemistry, with perhaps less emphasis on organometallic chemistry than is the case with other transition metals. However, Co coordination compounds are appearing in greater diversity than before and ever more examples of polynuclear systems are appearing. Although the basic synthetic routes established for decades have remained as entry points into Co chemistry, the application of these routes with a wider range of potential ligands and the development of more "boutique" reagents has expanded the possible and encompassed some of the (at least previously considered) impossible. Statements such as "no examples of this type exist" and "it is very unlikely that these can be prepared" simply spur research; it seems that often examples do not exist or are thought unlikely simply because effort has not been spent sufficiently, rather than there being an inherent chemical barrier. After all, that simple polyamine coordination complexes including cobalt(III)–carbon bonds could be easily prepared was not anticipated several decades ago, yet examples continue to expand. Given the growth in chemistry since the early 1980s generally, it is dangerous to predict the paths Co chemistry will travel in the next few decades. However, it takes no great foresight to suggest, broadly, that biologically relevant and advanced materials chemistry of Co will grow more significant in this time. Retrospection and prognostication aside, Co remains today an enticing and rewarding center for coordination chemistry.

6.2
Iridium

L. J. YELLOWLEES and K. G. MACNAMARA
University of Edinburgh, UK

6.2.1 INTRODUCTION

The coordination chemistry of iridium has continued to flourish since 1985/86. All common donor atoms can be found bound to at least one oxidation state of iridium. The most common oxidation states exhibited by iridium complexes are I and III, although examples of all oxidation states from $-$I to VI have been synthesized and characterized. Low-oxidation-state iridium species usually contain CO ligands or P donor atoms, whereas high-oxidation-number-containing coordination compounds are predominantly hexahalide ones.

Complexes of Ir^{III} have over half the referenced entries in this chapter. The Ir^{III} metal center has a d^6 electronic configuration, and most of the Ir^{III} compounds have a coordination number of six with a geometry based on the octahedron. All the compounds have low-spin $(t_{2g})^6$ configuration, and a majority are colorless or pale yellow. Donor atoms to Ir^{III} are many and various, with nitrogen being the most frequent. The second most common oxidation state is Ir^{I} with a d^8 electronic configuration, usually found in a square-planar arrangement. Most donor atoms bind to Ir^{I} and oxidative addition reactions feature regularly. Ir($-$I), Ir^{0}, Ir^{II}, Ir^{IV}, Ir^{V} and Ir^{VI} coordination compounds are more unusual.

The most common use of iridium coordination compounds remains in the catalysis field, although interest is developing in the luminescent properties of iridium compounds. The wide range of accessible oxidation states available to iridium ($-$I) to (VI) is reflected in the diverse nature of its coordination compounds.

6.2.2 IRIDIUM(VI)

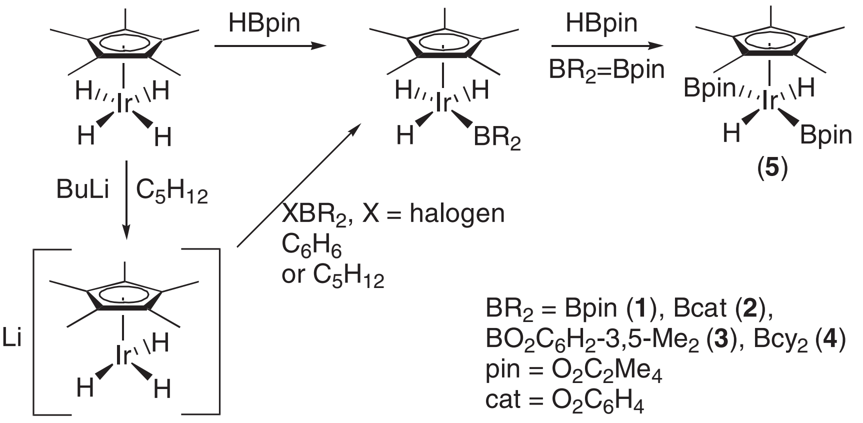
Laser-ablated iridium atoms react with O_2 to give the linear dioxide OIrO and the side-bound dioxygen adduct $(O_2)IrO_2$ as primary reaction products.[1] IR spectra and DFT calculations in solid argon show that the $(O_2)IrO_2$ species is best formulated as a peroxide with iridium in the +6 oxidation state, providing the first example of an Ir^{VI} oxo complex. There are other references to Ir^{VI}, in the main as part of perovskite structures under high oxygen pressures.[2,3]

6.2.3 IRIDIUM(V)

Iridium(V) complexes, although not common, take a variety of forms, including polynuclear and multidentate structures as well as five-, six- and seven-coordinate species, some of which are stable and have been characterized by X-ray crystallography.

6.2.3.1 Boron Ligands

A series of Ir^V boryl polyhydrides, $cp^*IrH_2XBR_2$ (X = H and BR_2 = Bpin (**1**) (pin = $O_2C_2Me_4$), Bcat (**2**) (cat = $O_2C_6H_4$), $BO_2C_6H_2$-3,4-Me_2 (**3**); Bcy (**4**), X = Bpin and BR_2 = Bpin (**5**)) have been prepared and isolated by Hartwig and Kawamura according to Reaction Scheme 1.[4] The X-ray crystal characterization of (**1**) is reported. (**1**) to (**5**) react regiospecifically with alkanes to produce free functionalized products.



Scheme 1

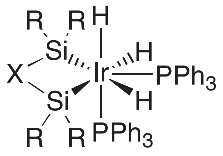
The crystal and molecular structure of $(PPh_3)_2(CO)(H)Ir(\mu^3\text{-}B_3H_7)$ have been reported.[5] The structure is interpreted as a capped octahedral, 7-orbital, 18-electron d^4, Ir^V complex in which the metal–borane bonding occurs predominantly via three two-electron, two-center Ir—B bonds.

6.2.3.2 Silyl and Stannyl Ligands

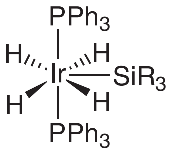
The neutral Ir^V complex, $cp^*Ir(H)_2(SiEt_3)_2$, has been studied by neutron diffraction and its structural characteristics compared to those of the isomorphous Rh analogue.[6] The significant differences are longer metal–ligand distances and larger bond angles for the Ir species.

The dihydrobis(trialkylstannyl)–iridium(V) complex $[cp^*Ir(H)_2(SnMe_3)_2]$ was prepared by reaction of Me_3SnH and $[(cp^*Ir)_2Cl_4]$ or $[cp^*Ir(C_2H_4)_2]$.[7] The hydrido-carbonyl equivalent, $[cp^*Ir(H)(CO)(SnMe_3)]$, was prepared by the reaction of Me_3SnH and $[cp^*Ir(CO)_2]$.

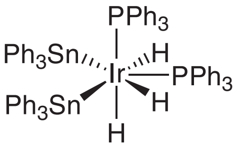
The pentahydride, $IrH_5(PPh_3)_2$, reacts with chelating silanes with loss of H_2 to form the seven-coordinate, distorted pentagonal-bipyramidal, silyl polyhydride complexes IrH_3(disil)$(PPh_3)_2$(disil = dmsb (**6**), tids (**7**)) with monodentate silanes to give $Ir(H_4(SiR_3)(PPh_3)_2$ (R = Et (**8**), Ph (**9**)), and with triphenyltin hydride to give $IrH_3(SnPh_3)_2(PPh_3)_2$ (**10**), all examples of Ir^V.[8] A crystal structure has been obtained for (**6**).



(**6**) X = C_6H_4, R = Me
(**9**) X = O, R = ^{i}Pr



(**7**) R = C_2H_5
(**10**) R = C_6H_5



(**8**)

6.2.3.3 Nitrogen, Phosphorus, Arsine, and Stibine Ligands

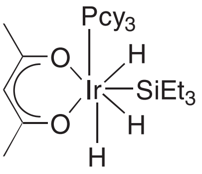
Oxidation of $(PPh_4)_2[Ir(NH_3)Cl_5]$ with $PhI(OAc)_2$ in CH_2Cl_2 affords the Ir^V amido complex $(PPh_4)[Ir(NH_2)Cl_5]$.[29]

From the precursor complex, cp*Ir(Me)$_3$(otf) (**11**), a series of trisubstituted phosphine, arsine, and stibine (L) Ir^V complexes have been prepared, of the type [cp*(L)IrMe$_3$](otf) (L = PMe$_3$ (**12**), PEt$_3$ (**13**), PPh$_3$ (**14**), AsEt$_3$ (**15**), AsPh$_3$, SbPh$_3$ (**16**).[9] Metathesis of the triflate anion of (**16**) for the tetraphenylborate anion afforded [cp*(SbPh$_3$)IrMe$_3$][BPh$_4$], which was characterized by single-crystal X-ray diffraction analysis. (**12**) was identified as a potential model for the proposed intermediate in the methane carbon–hydrogen bond activation pathway by cp*(PMe$_3$)Ir(Me)(otf). Reaction of (**11**) with excess dppm afforded *cis*-[(η^2-dppm)$_2$IrMe$_2$][OTf], characterized by single-crystal X-ray diffraction.

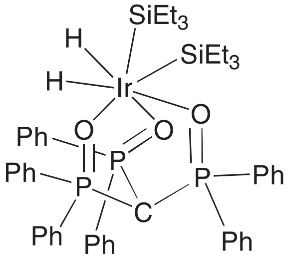
6.2.3.4 Oxygen Ligands

Quantitative yields of the green Ir^V complex Ir(O)(mes)$_3$ (**17**) were obtained by the interaction of trimesityliridium(III) and trimethylamine oxide, or by the interaction of dioxygen with Ir(mes)$_3$ and Ir(mes)$_4$.[10] The molecular structure of (**17**) was determined by X-ray crystallography and is distorted tetrahedral, with Ir=O and Ir—C bond lengths of 1.725(9) Å and 1.989–2.034(12) Å, respectively.

The acetyloacetonato (acac) ligand acts as a stabilizing ligand for the Ir^V complex Ir(acac)H$_3$-(SiEt$_3$)(Pcy$_3$) (**18**).[11] In solution the hydride ligands are equivalent, and analysis of variable temperature ^{1}H NMR spectra gives values of $\Delta H^\dagger$ and $\Delta S^\dagger$ of 12.33 ($\pm$0.76) kcal mol^{-1} and 1.45 ($\pm$1.84) cal K^{-1} mol^{-1}, respectively. Ir^V can be stabilized by the O-donor, tris(diphenyloxophosphoranyl)methanide, as (**19**).[12]



(18)



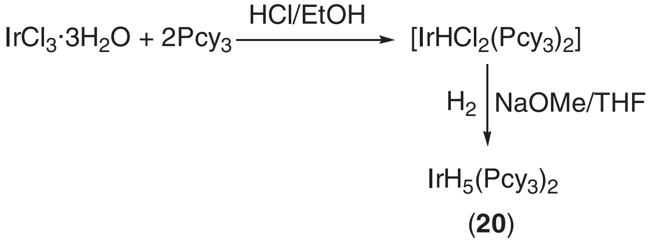
(19)

6.2.3.5 Halide Ligands

The deep red complex Cs[IrF$_5$Cl] was isolated from a mixture of complexes [IrF$_n$Cl$_{6-n}$]$^-$, prepared by treatment of [IrCl$_6$]$^{2-}$ with BrF$_3$ in liquid HF.[13] The IR and Raman spectra of [IrF$_5$Cl]$^-$ may be assigned according to point group C_{4v}. The interaction of IrF$_6$ and ZnS or B$_2$S$_2$ at elevated temperatures yields the Ir^V complex, [SF$_4$]$^+$[IrF$_6$]$^-$.[14]

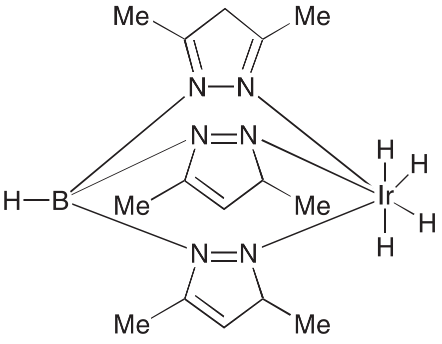
6.2.3.6 Hydrogen Ligands

The polyhydrido phosphine Ir^V complex, IrH$_5$(Pcy$_3$)$_2$ (**20**), was prepared by Reaction Scheme 2 in good yield (75–85%).[15] Treatment of [Ir(μ-OMe)(cod)]$_2$ with Pcy$_3$ in methanol gives (**20**) and *mer*-IrH$_3$(CO)(Pcy$_3$)$_2$.[622]

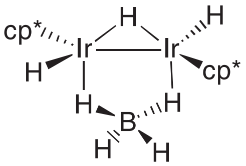


Scheme 2

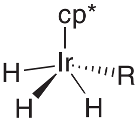
The tetrahydride Ir^{V} complex, Tp^*IrH_4 (**21**), $Tp^* = HB(3,5\text{-}Me_2pz)_3$, has been prepared in very high yield from the hydrogenation of $Tp^*Ir(C_2H_4)_2$ (**22**) under forcing conditions (C_6H_{12}, 90 °C, 2 atm, 3 days).[16] A later preparation of (**21**) was by the photolysis of $[Ir(\eta^2\text{-coe})H_2(Tp^*)]$ in MeOH.[17] (**21**) is proposed to have face-capped octahedral structures (C_{3v}), with each of the three Ir—H bonds *trans* to an Ir—N bond and the fourth hydride capping the IrH_3 face. However, density functional geometry optimizations and couple cluster calculations on Tp^*IrH_4 demonstrate that a C_s edge-bridged, octahedral, tetrahydride structure and a C_1 η^2-dihydrogen, dihydride structure are local minima, and the C_{3v} structure is a local maximum (second-order saddle point).[18] NMR and IR experimental data support the assignment of the C_s and C_1 structures to (**21**). Heating (**22**) in neat $HSiEt_3$ at 80 °C gives the very stable compound $Tp^*IrH_3(SiEt_3)$ (**23**). A crystal structure of (**23**) shows C_{3v} symmetry in which the $SiEt_3$ group caps the IrH_3 face.[19]



(**21**)



(**24**)



(**27**)

The reaction of $LiBH_4$ with $[(cp^*Ir)_2(\mu\text{-}H)_3]PF_6$ (**24**) gave the borohydride-bound dimer $[(cp^*Ir)_2H_3BH_4]$ (**25**).[20] Hydrolysis of (**25**) yielded the Ir^{IV} dimer $[cp^*IrH_3]_2$. (**24**) reacts with $LiEt_3BH$ to give the mononuclear salt $(cp^*IrH_3)[Li(THF)_x]$, which hydrolyzes to the Ir^{V} complex, cp^*IrH_4 (**26**). Deprotonation of (**26**) with Me_3CLi in the presence of pmdeta (pmdeta $= Me_2N(CH_2CH_2NMe)_2Me$) gives $cp^*IrH_3[Li(pmdeta)]$, which reacts with $Me_3SiO_3SCF_3$, Me_3SnCl, and Ph_3SnBr to yield the novel Ir^{V} polyhydrides cp^*IrH_3R (**27**) ($R = SiMe_3$, $SnMe_3$, $SnPh_3$). The X-ray structure of (**27**), $R = SnPh_3$, shows it to have the expected four-legged piano stool geometry. Reaction of (**24**) with PMe_3 gives the monohydride-bridged Ir^{III} dimer, $[(cp^*Ir(PMe_3)H)_2(\mu\text{-}H)]PF_6$ and $LiEt_3BH$.[21] Protonation of the dimer with HBF_4 gives the Ir^{V} complex, $[cp^*Ir(PMe_3)H_3]BF_4$ (**28**).

A large number of complexes of the type $[cp^*Ir(L)H_3]BF_4$, where L = various phosphine and phosphite ligands, have been prepared from the neutral iridium dihydrides, $cp^*Ir(L)H_2$ with $HBF_4{\cdot}Et_2O$.[22] The ^1H NMR spectra of the cations in the hydride region at low temperature display AB_2X spin systems ($X = {}^{31}P$), which are simplified to AB_2 spin systems in the $^1H\{^{31}P\}$ spectra. A neutron diffraction study and crystal structure determination has also been undertaken for (**28**). Treatment of $[cpIrH_2(P(CHMe_2)_3)]$ with $HBF_4.OEt_2$ gives the Ir^{V} species $[cpIrH_3(P(CHMe_2)_3]BF_4$.[23]

6.2.3.7 Mixed-donor-atom Ligands

6.2.3.7.1 C/Si

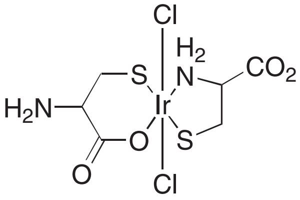
The Ir^{III} complex, $cp^*Ir(PMe_3)(Me)(otf)$, reacts with $H_2Si(mes)_2$ by oxidative addition of a C—H bond of a mesityl group to the Ir^{III} center to give the Ir^{V} species (**29**).[24] (**29**) isomerizes to an iridium silylene complex, $[cp^*Ir(PMe_3){:}Si(mes)_2(H)](otf)$, over 9 hours. $cp^*Ir(PMe_3)(Me)(otf)$ also undergoes oxidative addition with $HSiPh_3$ to give $cp^*Ir(PMe_3)(Ph)SiPh_2(otf)$. Replacing the triflate group with the less strongly coordinating anion (NaBAr or $LiB(C_6F_5)_4(Et_2O)_{2.5}$) gave (**30**), which has been characterized by X-ray crystallography.

6.2.4 IRIDIUM(IV)

Iridium(IV) complexes are less common when compared to Ir^{III} or Ir^{I}. There are examples of N, P, As, Sb, O, S, Se, Te, and halide ligands, often prepared by oxidation from an Ir^{III} salt. "Recent developments" (in 1991) in the chemistry of the platinum metals in high oxidation states were addressed by Levason, including complexes of Ir^{IV} and Ir^{V}.[25]

6.2.4.1 Boron Ligands

The complex catalytic polarographic hydrogen wave of the Ir^{IV}–cystine complex (**31**) has been investigated in 1.2 M HCl.[26,27]



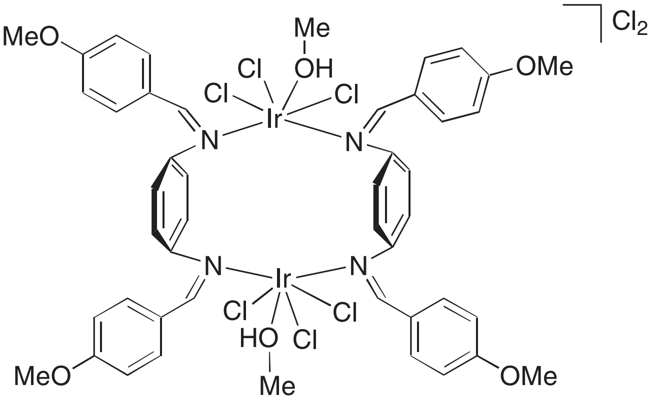
(**31**)

6.2.4.2 Nitrogen, Phosphorus, Arsine, Stibine, Sulfur, Selenium, and Tellurium Ligands

The Ir^{IV} complexes *trans*-$[IrL_2Cl_4]$ (L = py, PEt_3, PEt_2Ph, $PEtPh_2$, $AsEt_3$, $AsMe_2Ph$, SMe_2, SMe_2), and *cis*-$[Ir(L\text{-}L)Cl_4]$ (L-L = Me*S*CH_2CH_2*S*Me, Me*Se*CH_2CH_2*Se*Me, bpy, or phen) have been prepared by oxidation of the Ir^{III} analogues by Cl_2 or HNO_3.[28,29] Similarly, the dark green Ir^{IV} complexes *trans*-$[IrL_2Br_4]$ (L = py, PEt_3, PMe_2Ph, $AsEt_3$, $AsMe_2Ph$, SMe_2) have been obtained by the oxidation of the Ir^{III} salts by Br_2 or HNO_3. The complexes *trans*-$[IrL_2Cl_4]$ (L = PPh_3, $AsPh_3$, $SbPh_3$) have been obtained directly from the reaction of $IrCl_3 \cdot nH_2O + 2L$, followed by the chlorination of the intermediate, $[(IrL_2Cl_3)_n]$. The synthesis of dark green *cis*-Ir(L-L) Br_4, where L-L = bpy or phen and *cis*-IrL_2X_4 (L = py or $SbMe_3$, X = Cl or Br), is also described. The Ir^{IV} complexes are characterized by elemental analysis, IR and UV-vis spectroscopy, and cyclic voltammetry. The crystal structures of *trans*-$[Ir(AsEt_3)_2Br_4]$ and the dark purple, air-sensitive complex *cis*-$Ir(phen)Cl_4$ have been determined. The UV-vis spectra are interpreted as LMCT transitions, that is, $X^- \rightarrow Ir^{IV}$ transfers. Electrochemical studies show a reversible $Ir^{IV/III}$ couple, with the reduction occurring at more positive values for the *cis* than for the *trans* complexes.

The Ir^{IV} complex $(NH_4)[Ir(NH_3)Cl_5]$ has been prepared by the oxidation of the Ir^{III} analogue with Cl_2 at 330 °C, and its structure determined from powder diffraction studies.[30]

The binuclear complex $[Ir(PBA)Cl_2(MeOH)_2]_2Cl_2$ (**32**) (PBA = *N,N′*-*p*-phenylenebis(anisalidene-imine)) has been prepared and characterized.[31]



(**32**)

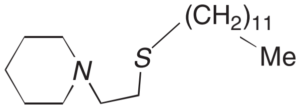
The 17-electron, dihydrido complexes of Ir^{IV}, $Ir(H)_2(Cl)_2(P^iPr_3)_2$, (**33**), and $Ir(H)_2(Cl)_2(Pcy_3)_2$, (**34**), have been prepared by the reaction of $(NH_4)_2IrCl_6$ with PR_3 in refluxing ethanol containing conc. HCl.[32–34] Both crystal structures reveal a slightly distorted octahedral geometry, with the three pairs of ligands in the *trans* configuration. Solid (**35**) is stable, but in $CDCl_3$ displays dihydride/dihydrogen dynamic equilibrium, as shown in Reaction Scheme 3.

$$\underset{\textbf{(33)}}{2[IrH_2Cl_2(P^iPr_3)_2]} \rightleftharpoons \underset{\textbf{(35)}}{2[IrHCl_2(P^iPr_3)_2].H_2}$$

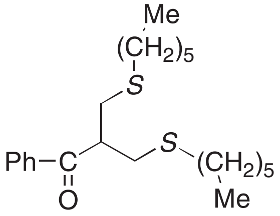
Scheme 3

Photolysis of (**35**) at 404 nm gives geometrical isomers, as determined by UV-vis and NMR spectroscopy. If (**35**) is irradiated in the presence of H_2, then $[IrH_3Cl_2(P^iPr_3)_2]$ is formed via an oxidative addition reaction.[35] The ^1H NMR shows the hydride chemical shifts at extremely high field ($\delta = -49.0$ (t) ppm and -47.9 (t) ppm for (**33**) and (**34**), respectively). Magnetic moment values of (**33**) and (**34**) were in agreement with a spin-paired d^5 electron configuration; however, they showed a significant reduction of their μ_{eff} after crystallization.[36] The IR spectra, X-ray powder diffraction patterns in the solid state, and NMR and EPR spectra in solution are reported. The rhombic EPR signals, at 110 K and in the solid state, of (**33**) and (**34**) are detailed.[37]

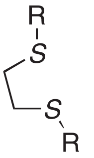
The complexes $IrLCl_4$, where L = (**36**), (**37**), (**38**), (**39**), and IrL_2Cl_4, where L = (**40**) or (**41**), show electrochemical reductions at more anodic potentials than their keto- or aminosulfide analogues.[38,39] Similar *Se* complexes of the type $IrLCl_4$ ($L = MeSeC_3H_6SeMe$, $PhSeC_3H_6SePh$, $MeSeC_2H_4SeMe$, $PhSeC_2H_4SePh$) are attained by oxidation of the Ir^{III} anion with Cl_2 in CCl_4.[40]



(**36**)

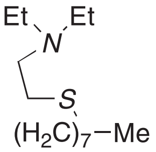


(**37**)

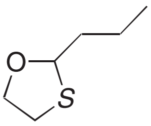


R = Et, CH2Ph

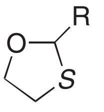
(**38**)



(**39**)



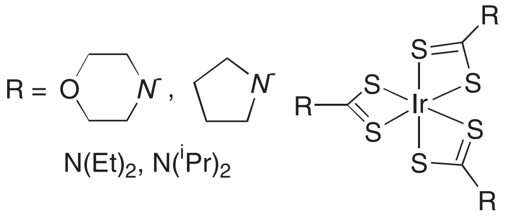
(**40**)



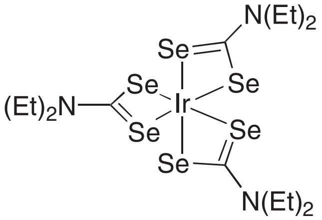
R = (CH2)7Me, iPr

(**41**)

The Ir^{IV} complexes $[Ir(RR'dtc)_3]^+$, (**42**), and $[Ir(Et_2dsc)_3]^+$, (**43**), (HRR′dtc = morpholino-, pyrrolidinocarbodithioic acid, HS_2CNEt_2, $HS_2CN(^iPr)_2$; Hdsc = HSe_2CNEt_2) were prepared electrolytically from their Ir^{III} analogues.[41] Voltammetric studies revealed a reversible $Ir^{IV/III}$ process (**42**) is indefinitely stable, whereas (**43**) slowly dimerizes and undergoes an internal redox reaction to give $[Ir_2(Et_2dsc)_5]^+$ and oxidized ligand.



(**42**)



(**43**)

The paramagnetic complexes $[IrCl_4(SeCl_4)_2]$ and $[IrCl_4(TeCl_4)_2]$ have been prepared and show effective magnetic moments characteristic of the Ir^{IV} oxidation state.[42] IR and ^{35}Cl NQR (Nuclear Quadruple Resonance) data indicate heteronuclear structures for the complexes with chloride bridges.

6.2.4.3 Oxygen Ligands

Complexes of Ir^{IV} with iminodiacetic acid $(HN(CH_2COOH)_2)$, nitrilotriacetic acid $(N(CH_2COOH)_3)$, and *trans*-1,2-cyclohexanediaminetetraacetic acid (L) have been studied by spectroscopic methods.[43]

The electronic adsorption spectra for the complexes $[Ir(OH)_6]^{n-}$, where $n = 0$–2, have been resolved and peak maxima locations, molar extinction coefficients, oscillator strengths, and band half-widths calculated.[44] Bands have been assigned in the main part to be one-electron MLCT transitions. Spectrophotometrically determined rate constants for the OH reduction of the Ir^{VI} and Ir^{V} complexes at 25 °C in 3M NaOH are $(2.59 \pm 0.09) \times 10^{-3}\,s^{-1}$ and $(1.53 \pm 0.05) \times 10^{-4}\,s^{-1}$ respectively. The activation energy for the reduction, $Ir^{V} \rightarrow Ir^{IV}$, is $17.5\,kcal\,mol^{-1}$. Cyclic voltammetry and potentiostatic coulometry of $[Ir(OH)_6]^{2-}$ in 3M NaOH on a Pt electrode show that during the electro-oxidation compounds of Ir^{V} and Ir^{VI} are formed.[45]

The decay of zinc tetrakis(*N*-methylpyridinium-4-yl)porphyrin π-radical cations in the presence of poly(styrenesulfonate) and Ir^{IV} oxides or $[Ir(OH)_6]^{2-}$ has been studied at high pH.[46] The hexahydroxide species was found to be very reactive.

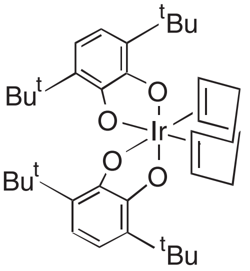
The aqueous solution chemistry of Ir in its higher oxidation states III, IV, and V has been explored by Sykes *et al.*[47,48] Chemical and electrochemical oxidation of $[Ir(H_2O)_6]^{3+}$ gives a brown-green Ir^{V} product, which undergoes chemical and electrochemical reduction to a blue and a purple Ir^{IV} complex. ^{17}O NMR studies are consistent with double- and single-bridged dimeric structures, with likely formulas $[(H_2O)_4Ir(\mu\text{-}OH)_2Ir(H_2O)_4]^{6+}$ for the blue complex and $[(H_2O)_5Ir(\mu\text{-}O)Ir(H_2O)_5]^{6+}$ for the purple one.

The reaction of $[Ir(H_2O)_6]^{4+}$ with Cl^- ions has been studied at various temperatures, giving stability constants and the thermodynamic parameters ΔH^o, ΔG^o, and ΔS^o for the substitution reactions.[49]

The aquation of $[IrCl_6]^{2-}$ to $[Ir(H_2O)Cl_5]^-$ and $Ir(H_2O)_2Cl_4$ has been found to activate the complex toward the oxidation of insulin in acidic solutions, with measured rate constant of 25,900 and 8,400 $L\,mol^{-1}\,s^{-1}$, respectively.[50] The oxidation reaction proceeds via an outer-sphere mechanism.

The Ir^{IV} anion, $[Ir(H_2O)Br_5]^-$, oxidises ascorbic acid at 20.0 °C.[51] This reaction is first order with respect to ascorbic acid concentration and first order with respect to the Ir^{IV} anion. Comparison of hexabromo-, hexachloro, aquopentachloro-, and di-aquotetracholoiridium(IV) reactions with ascorbic acid shows that replacing a halide ion with a water molecule increases the standard reduction potential of the Ir^{IV} complex and increases the rate of reaction.

(cod)bis(3,6-di-tert-butylcatecholateo)iridium(IV), (**44**), has been prepared by the reaction between $[Ir(cod)Cl]_2$ and the cobaltocenium salt of 3,6-di-tert-butyl-1,2-semiquinone in DCM.[52] Single-crystal X-ray studies show the catecholate C—O lengths to be slightly shorter at the *trans* position to the olefin groups. Cyclic voltammetry results show two reversible couples; an oxidation at −0.092 V and a reduction at −0.636 V vs. Fc^+/Fc.



(**44**)

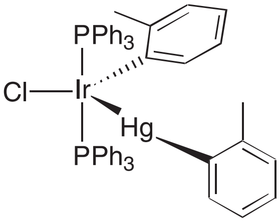
X-ray techniques have shown the compound $Ba_5AlIr_2O_{11}$ to have the two Ir centers in an octahedral coordination bound to AlO_4 tetrahedra, giving $[Ir_2AlO_{11}]^{10-}$ units.[53]

6.2.5 IRIDIUM(III)

A significant number of Ir^{III} complexes arise from the oxidative addition reactions of Ir^{I} species. Such reactions may proceed via routine addition, whereas some proceed by ligand expulsion in conjunction with oxidative addition. Complexes containing Ir^{III} have a low-spin d^6 electronic configuration, and are usually to be found with an octahedral-based ligand set.

6.2.5.1 Mercury Ligands

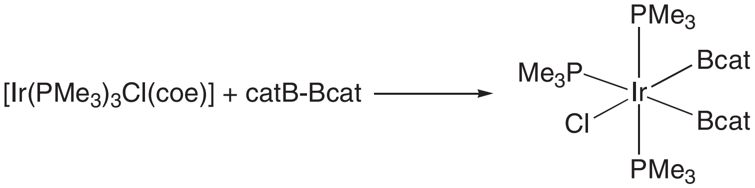
Reaction between $IrHCl_2(PPh_3)_2$ and Hg(*o*-tolyl)$_2$ yields the red complex (**45**), in which the Ir—Hg bond has been confirmed by $^{31}P-^{199}Hg$ coupling in ^{31}P NMR spectroscopy. Addition of CO and I_2 gives [Ir(*o*-tolyl){Hg(*o*-tolyl)}Cl(CO)$(PPh_3)_2$] and [Ir(*o*-tolyl)Cl(HgI)$(PPh_3)_2$], respectively.[54]



(**45**)

6.2.5.2 Boron Ligands

The bis(boryl) complex *mer-cis*-[Ir$(PMe_3)_3$Cl(Bcat)$_2$], (**46**), cat = 1,2-$O_2C_6H_4$, is formed according to Reaction Scheme 4.[55] The *mer-cis* geometry of (**46**) is confirmed by X-ray crystallography and NMR spectroscopy. Reaction of [IrCl$(PEt_3)_3$] with (Bcat)$_2$ yields [IrCl$(PEt_3)_2$(Bcat)$_2$]. X-ray crystallography reveals that the Ir center has a Y-shaped geometry, with a narrow B—Ir—B angle of 76.6(6)° and *trans* PEt_3 groups.[56]



(**46**)

Scheme 4

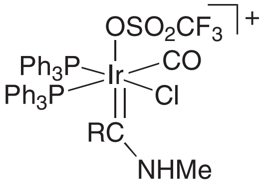
6.2.5.3 Carbon Ligands

Reaction of $[Ir(CO)_2I_2]^-$ with $C_6H_{13}I$ yields the structurally characterized species Ph_4As-[Ir $(CO)_2I_3(C_6H_{13})$], which shows *fac,cis* geometry for the anion.[57] The oxidative addition reaction is first order in both reactants. The structurally determined species $[Ir(CO)_5Cl][Sb_2F_{11}]_2$, formed from reaction of *mer*-$Ir(CO)_3(SO_3F)_3$] with SbF_5/HSO_3F, has a cation of C_{4v} symmetry with long Ir—C bonds (2.02(2) Å) and short C—O bonds (1.08(2) Å).[58] The vibrational spectrum is assigned with the help of density functional calculations.[59] Reaction of IrF_6 in SbF_5/CO yields $[Ir(CO)_6][Sb_2F_{11}]_3$, in which the Ir^{III} center is strictly octahedral.[58]

Reaction of [Ir(CH_3)(CH=CHNEt$_3$)(C≡C(*p*-$C_6H_4CH_3$)(CO)$(PPh_3)_2$]ClO_4 with aqueous HCl gives [Ir(C(CH_3)=CH(*p*-$C_6H_4CH_3$)(CH=CHNEt$_3$)(Cl)(CO)$(PPh_3)_2$]ClO_4 and [Ir(CH=CHNEt$_3$)-(Cl)$_2$(CO)$(PPh_3)_2$]ClO_4 plus *cis*-CH_3CH=CH(*p*-$C_6H_4CH_3$), via an intramolecular coupling reaction.[60]

The ionic iridium(III) carbene complex (**47**) is prepared from the reaction of [IrHCl(O_3SCF_3)-(CO)$(PPh_3)_2$] with [RC≡NMe](O_3SCF_3).[61] Addition of Na(barf) (barf = B(3,5-C_6H_3 $(CF_3)_2)_4$) to [Ircp*$(PMe_3)(CH_3)(OSO_2CF_3)$] in CH_2Cl_2 yields the structurally determined species

[Ircp*(PMe_3)(CH_3)($ClCH_2Cl$)](barf), (**48**), which confirms the linkage of CH_2Cl_2 to Ir through one Cl atom (Ir—Cl = 2.462(3) Å).[62] Complex (**48**) can thermally activate CH_4 and terminal alkanes at 10 °C, and can induce C—H activation reactions in functionalized substrates. The X-ray structural determinations of [Ircp*$(CO)_2$I]BF_4 and [Ircp*$(PMe_3)_2$Cl]PF_6 are reported.[63,64] [$IrCl_2$(CO)- ($PMe_2Ph)_3$]ClO_4 reacts with KOH to give [$IrCl_2(CO_2H)(PMe_2Ph)_3$], which is more basic than [$IrCl_2(CO_2H)(CO)(PMe_2Ph)_2$].[65]



R = Ph, 4-MeC_6H_4, 4-EtC_6H_4, Me

(**47**)

Reaction of [Ir(acac)$(PMe_3)_2$] with 3-vinyl-1-cyclopropene yields complex (**49**), rearranging on heating to give (**50**) initially and finally (**51**), which has been identified by X-ray crystallography.[66] Reaction between *mer*-[$(Me_3P)_3Ir(H)_2Cl$] and 2-ethynylpyridine in H_2O, or *mer*-[$(Me_3P)_3$Ir(H)(Ph)(Cl)] and 2-ethynylpyridine and Tl(PF_6) in CH_2Cl_2, leads to formation of (**52**), which has been structurally characterized.[67] The coordinatively unsaturated complexes $Ir(H)_2X(PBu_2{}^tPh)_2$ (X = Cl, Br, I, N_3, N═C═$NSiMe_3$, $NHC(O)CH_3$, $OC(O)CF_3$, OSO_2CF_3, $OC(O)CH_3$, SPh, OPh, F) bind CO.[500] The initial product eliminates HX, where X = $OC(O)CH_3$, SPh, OPh, and F. The reaction of $Ir(H)_2(F)$-$(PBu_2{}^tPh)_2$ with CO in a glass vessel yields crystalline [$Ir(H)_2(CO)_2(PBu_2{}^tPh)_2$][$SiF_5$].[500]

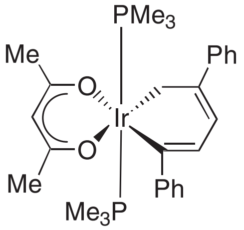
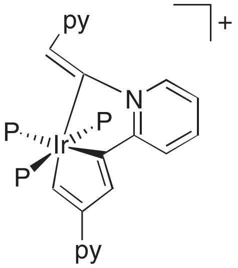
(**50**)



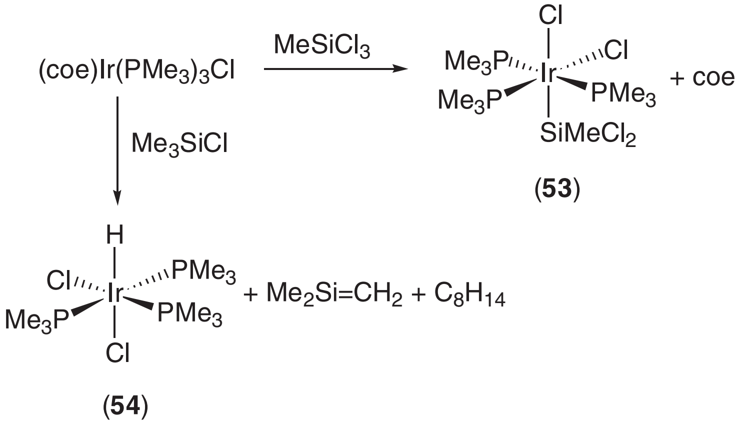
(**51**)



(**52**)

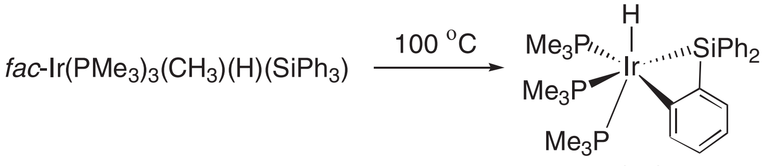
6.2.5.4 Silicon Ligands

The crystallographically characterized complex *mer*-$Ir(PMe_3)_3(Cl)_2(SiMeCl_2)$, (**53**), which contains a short Ir—Si bond, is prepared by Reaction Scheme 5.[68] Reaction with Me_3SiCl yields the Ir—H complex (**54**).



Scheme 5

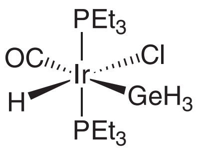
The facial complexes $(PMe_3)_3Ir(CH_3)(H)(SiR_3)$, (**55**), (R = EtO, Ph, Et) result from the oxidative addition of the corresponding silane to $MeIr(PMe_3)_4$.[69] On heating (**55**) in which R = OEt and Ph, reductive elimination of methane forms iridasilacycles, as shown in reaction Scheme 6. The structure of compound (**55**) in which R = Ph is confirmed by single-crystal diffraction studies.



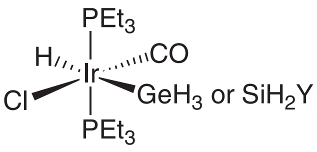
(**55**)

Scheme 6

The methyl analogue *fac*-$(PMe_3)_3Ir(o\text{-}C_6H_4SiMe_2)(H)$ can also be prepared from the reaction of $Ir(PMe_3)_4Cl$ with $LiSiMe_2Ph$ at room temperature in THF.[507] Reaction of $IrCl(^{13}CO)(PEt_3)_2$ with GeH_4 gives (**56**) as the major product and (**57**) as the minor product, as confirmed by ^{13}C NMR spectroscopy.[70] If SiH_3Y (Y = H, Cl, Br, I) is used in place of GeH_4, then (**57**) is the only product formed. Reaction with SiH_2F_2 gives the product in which the hydride is *cis* to the $SiHF_2$ group.



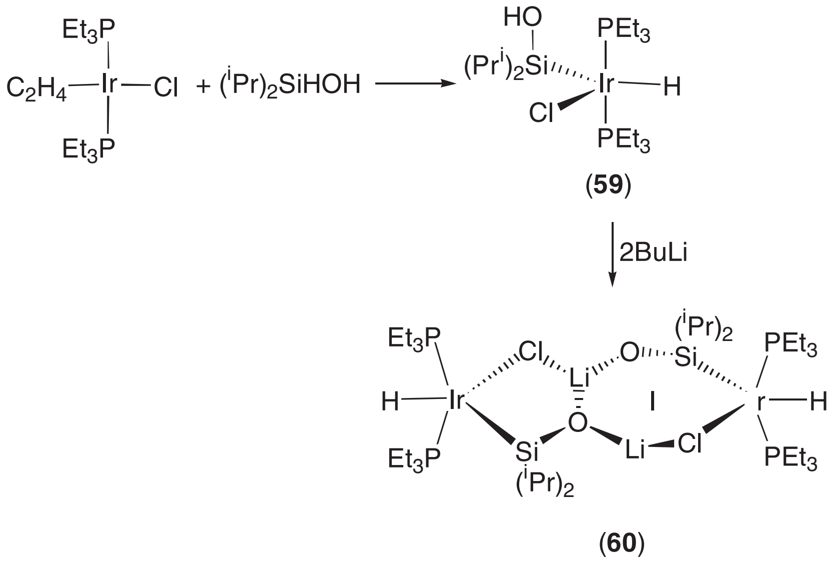
(**56**)



(**57**)

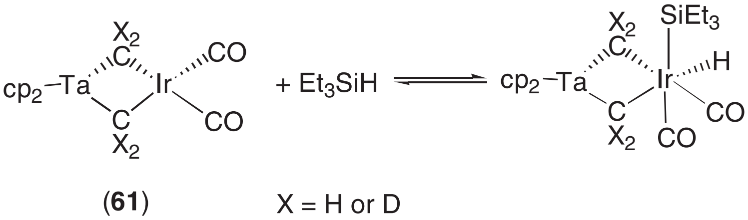
Oxidative addition of $SiXRR'_2$ (X = H, D; R = H, D, Cl, Ph; R′ = Ph, ^tBu) to $Ir(H)(PMe_3)_4$ yields $[Ir(H)(X)(PMe_3)_3(SiRR'_2)]$. The complexes with X = H, R = H, R′ = Ph; X = H, R = Cl, R′ = ^tBu and X = H, R = R′ = Ph have been characterized by single-crystal X-ray diffraction techniques.[71] $Ir(H)_2(SiEt_3)(cod)L$, (**58**), (L = PPh_3, $AsPh_3$) complexes are prepared from $[Ir(OMe)(cod)]_2$, $HSiEt_3$, and L.[72] The products are active catalyst precursors for the dehydrogenative silylation of alkenes. The complex (**58**), L = $AsPh_3$, has been characterized by X-ray diffraction.[73]

Reaction Scheme 7 shows the synthesis of $[Ir(PEt_3)_2(H)(Cl)(Si(^iPr)_2OH)]$, (**59**), and $[Ir(PEt_3)_2(H)(Cl)(Si(^iPr)_2OL)]_2$, (**60**), which have been characterized by single-crystal diffraction studies.[74] (**59**) has a trigonal-bipyramidal structure with *trans* PEt_3 groups. In (**60**) the $Ir_2Si_2Cl_2O_2Li_2$ core is almost planar, with three-coordinate Li. The dinuclear compound is stable with respect to 12-crown −4. but reacts with H_2O to regenerate (**59**).



Scheme 7

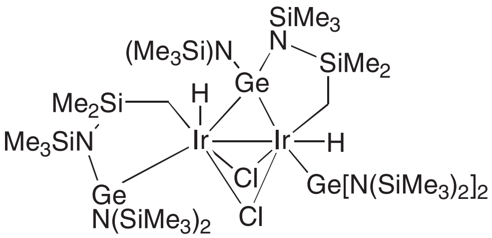
The complex $[IrH_5\{P(CHMe_2)_3\}_2]$ reacts with neohexene to form $IrH\{P(CHMe_2)_3\}_2$, which undergoes an oxidative addition reaction with halo(methyl)silanes.[75] Reaction with $MeSiCl_3$ yields the structurally characterized species $[Ir(SiCl_2Me)Cl(H)\{P(CHMe_2)_3\}_2]$ The mixed-metal binuclear complex (**61**) reacts with Et_3SiH according to reaction Scheme 8.[76] Kinetic isotope studies revealed an electron-donating effect of β-deuterium on oxidative addition reactions.



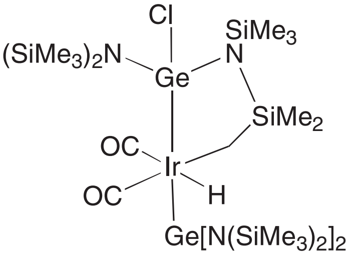
Scheme 8

6.2.5.5 Germanium Ligands

Treatment of $[Ir(coe)_2Cl]_2$ with $Ge\{N(SiMe_3)_2\}_2$ leads to (**62**).[77] If the reaction proceeds in the presence of CO, then (**63**) results. Both product species have been characterized by X-ray crystallography.



(**62**)



(**63**)

Reaction of Na_3IrCl_6 with Me_4NGeCl_3 in aqueous HF yields $(Me_4N)_3[Ir(GeF_3)_5Cl]$.[78] Reaction of $IrBr_3$ with $GeBr_2$ in 6M HBr gives $[Ir(GeBr_3)_nBr_{6-n}]^{3-}$ ($n = 1$, 2, 3), with the species $[Ir(GeBr_3)_2Br_4]^{3-}$ labile to substitution.[79]

6.2.5.6 Tin Ligands

The photocatalytic activity of $[Ir(SnCl_3)_5H]^{3-}$ in the dehydrogenation of methanol to give dimethoxymethane and dihydrogen is described.[80,81] *Trans*-$[IrClH(SnCl_3)_4]^{3-}$ and *trans*-$[IrCl_2(SnCl_3)_4]^{3-}$ catalyze the dehydrogenation of 2-propanol *via* the dissociation of one $SnCl_3^-$ ligand.[82] The synthesis of substitutionally inert $[IrBr(SnBr_3)_5]^{3-}$ is described.[79,83] Oxidative addition of two molar equivalents of $HSnR_3$ ($R = Ph$, ^nBu) to $Ir(XR')(tfb)(Pcy_3)$, $XR' = OMe$, OEt, O^iPr, OPh, S^nPr; tfb = tetrafluorobenzobarrelene, gives $[IrH_2(SnR_3)(tfb)(Pcy_3)]$, (**64**), and $R'XSnR_3$.[84] The structure of (**64**), where $R = Ph$, has been determined by X-ray crystallography and has been shown to catalyze the addition of $HSnP_3$ to phenylacetylene.

6.2.5.7 Nitrogen Ligands

6.2.5.7.1 Ammine

The synthesis of chloride-free $[Ir(NH_3)_6](NO_3)_3$ from an acidic solution of $IrCl_3$ is detailed.[85] A high-yield preparation of $[Ir(NH_3)_6]Cl_3$ from $IrCl_3$and NH_3 is reported.[86] This publication also describes procedures for the synthesis of *mer*-$[Ir(NH_3)_3Cl_3]$, *cis*-$[Ir(NH_3)_4Cl_2]Cl\cdot 1/2H_2O$,

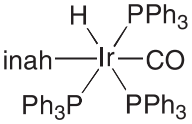
Table 1 Rate constants and activation energies for H_2O exchange.

Complex	$K(s^{-1})$	$E_a(\text{kcal mol}^{-1})$
trans-$[Ir(NH_3)_4(OH_2)_2]^{3+}$	$k(90\,°C) = 1.73(7)\ x10^{-6}$	693(17)
trans-$[Ir(NH_3)_4(OH)(OH_2)]^{2+}$	$k(90\,°C) = 7.6(7)\ x10^{-3}$	403(8)
trans-$[Ir(NH_3)_4(OH_2)Cl]^{2+}$	$k(60\,°C) = 6.20(8)\ x10^{-5}$	475(55)

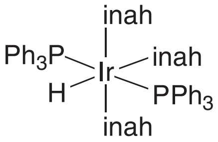
trans-$[Ir(NH_3)_4Cl_2]Cl{\cdot}H_2O$, $[Ir(NH_3)_5Cl]Cl_2$, *trans*-$[Ir(NH_3)_4(OOCCH_3)Cl]CF_3SO_3$, $[Ir(NH_3)_5(OOCCH_3)](ClO_4)_2$, and $[Ir(NH_3)_5(OH_2)](ClO_4)_3$, and their characterization by electronic and IR spectroscopy. The rate constants and activation energies for the exchange of a water ligand in 1M $HClO_4$ were measured as in Table 1.[87]

The equilibrium reaction between *cis*-$[Ir(NH_3)_4(OH_2)_2]^{3+}$ and *cis,cis*-$[(H_2O)(NH_3)_4Ir(\mu\text{-}OH)Ir(NH_3)_4(OH_2)]^{5+}$ and $[(NH_3)_4Ir(\mu\text{-}OH)_2Ir(NH_3)_4]^{4+}$ has been studied using spectrophotometry and IE-HPLC. Complementary studies on the en complexes are also presented.[88] The photocalorimetric (366 nm) enthalpies of aquation at 25 °C are 17.4 kcal mol^{-1} and 2.3 kcal mol^{-1} for $[Ir(NH_3)_5X]^{2+}$ ($X = Cl^-$, I^-), respectively.[89] The reaction of $[Ir(NH_3)_5(OH_2)](ClO_4)_3$ in aqueous $HClO_4$ solution at 130–200 °C results in the release of Ir metal.[90] In alkaline solutions (0.1–0.01M NaOH), $[Ir(NH_3)_5(OH_2)]Cl_3$, $[Ir(NH_3)_5X]X_2$, and *trans*-$[Ir(NH_3)_4X_2]ClO_4$ (X = Cl, I) are reduced to Ir^0 by NH_3 at 170 °C.[91]

Complexes (**65**) and (**66**) result from the reaction of $IrCl_3$ with inah and PPh_3 (inah = isonicotinic acid hydrazide).[92] Reaction of Tröger's base (tb) (**67**) with $IrCl_3$ yields dark violet $tb{\cdot}2IrCl_3$ (68).[93] (**68**) was not catalytically active towards the hydrosilylation of alkynes.

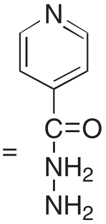


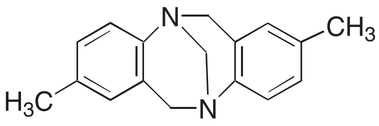
(**65**)



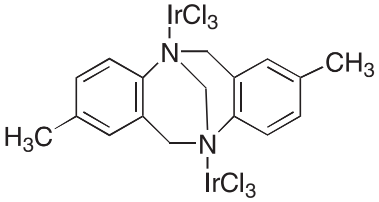
(**66**)

inah =



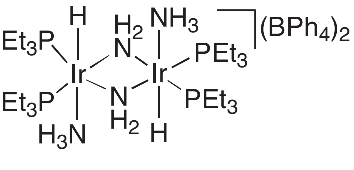


(**67**)

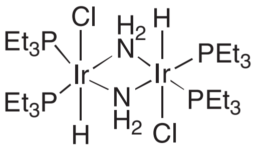


(**68**)

The binuclear species (**69**) and (**70**) are prepared from the reaction of $[Ir(PEt_3)_2(C_2H_4)_2Cl]$ with liquid NH_3, followed by treatment with $NaBPh_4$ or pyridine, respectively. Both structures are determined by X-ray crystallography and show Ir—Ir distances of 3.33 Å and 3.34 Å, respectively.[94]



(**69**)

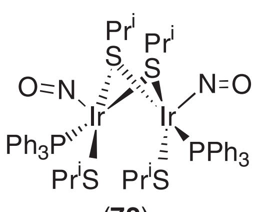


(**70**)

6.2.5.7.2 Nitrosyl

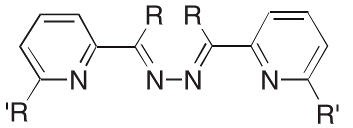
Reaction of [Ir(Me)$_2$cp*(L)], L = PPh$_3$, PMePh$_2$, PMe$_2$Ph, PMe$_3$, with NOBF$_4$ in CH$_2$Cl$_2$ affords [Ir(Me)$_2$cp*(NO)]BF$_4$ and [Ir(Me)cp*(NO)L](BF$_4$)$_2$, (**71**).[95] EPR spectroscopy shows that the reaction proceeds through the Ir^{IV} intermediate. Electrochemical or chemical reduction of (**71**) yields the EPR-active species [Ir(Me)cp*(NO)L](BF$_4$), in which the unpaired electron is partially delocalized on the Ir nucleus.

[Ir(NO)Cl$_2$(PPh$_3$)$_2$] reacts with NaSH to yield the square-pyramidal Ir^{III} complex [Ir(NO)(SH)$_2$(PPh$_3$)$_2$], with a bent nitrosyl ligand[747], and reaction with NaSPr^i affords the binuclear Ir^{III} species (**72**). Complex (**72**) contains two square-pyramidal Ir^{III} centers, each with a bent nitrosyl ligand. Reaction of (**72**) with benzoyl chloride gives the mixed-valent Ir^I—Ir^{III} species [Ir(NO)(PPh$_3$)(μ-SPr^i)$_3$IrCl$_2$(PPh$_3$)], characterized by X-ray diffraction.[747] [Ir(NO)(S-mes)$_2$(PPh$_3$)] converts to the structurally determined binuclear Ir^{III} complex [{IrCl(μ-5-C$_6$H$_2$-Me$_2$*C*H$_2$)(PPh$_3$)}$_2$(μ-mesSSmes)] on treatment with benzoyl chloride.[747] *Trans*-Ir(mes)$_2$(PMe$_3$)$_2$ reacts with NO to form the structurally characterized complex Ir(mes)$_2$(NO) (PMe$_3$)$_2$, with a bent IrNO moiety.[456]



(**72**)

The nitrile species [Ir(NO)(MeCN)$_3$(PPh$_3$)$_2$](PF$_6$)$_2$ and [Ir(CO)(MeCN)(PPh$_3$)$_2$]PF$_6$ combine with paa, mpaa, and dppn, L (**73**), to give [Ir(NO)L(PPh$_3$)$_2$]$^{2+}$ and [Ir(CO)L(PPh$_3$)$_2$]$^+$, respectively, in which L is bound in a bidentate fashion.[96] The IR stretching frequencies ν_{NO} and ν_{CO} are 1,800 cm^{-1} and 1,900 cm^{-1}, respectively.



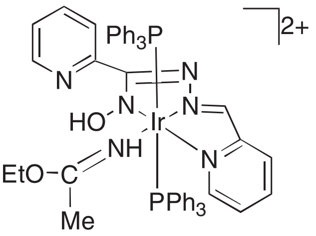
dppn, R = CH, R' = H

paa, R = R' = H

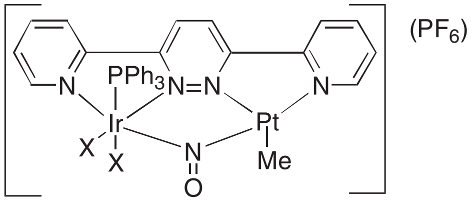
mpaa, R = H, R' = Me

(**73**)

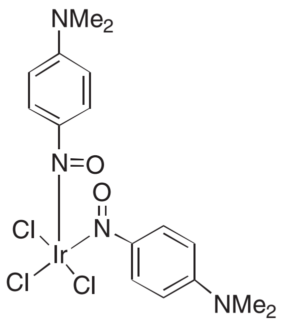
Reaction of [Ir(NO)(paa)(PPh$_3$)$_2$](PF$_6$)$_2$ with MeCN and EtOH yields the structurally determined species (**74**).[97,98] The tridentate N$_3$ ligand is considered to be formed by the intramolecular insertion of NO into a methinic C—H bond of the paa ligand. The OH group is strongly hydrogen bonded intramolecularly with the uncoordinated pyridyl N atom. Treatment of the linearly bonded NO species [Ir(NO)(dppn)(PPh$_3$)$_2$](PF$_6$)$_2$ (dppn = 3,6-bis(2′-pyridyl)pyridazine) with X$^-$ (X = Cl, I) affords the bent-NO-containing species [Ir(NO)X(dppn)(PPh$_3$)](PF$_6$), which reacts with [PtCl(Me)(DMSO)$_2$] or [PtI(Me)(cod)] to give heterodinuclear (**75**), bridged by NO and dppn.[99] Nitrosoarene complexes of type (**76**) were investigated using XPS and IR spectroscopy.[100] The binding mode of the NO group could be identified using these techniques.



(**74**)



(**75**)



(**76**)

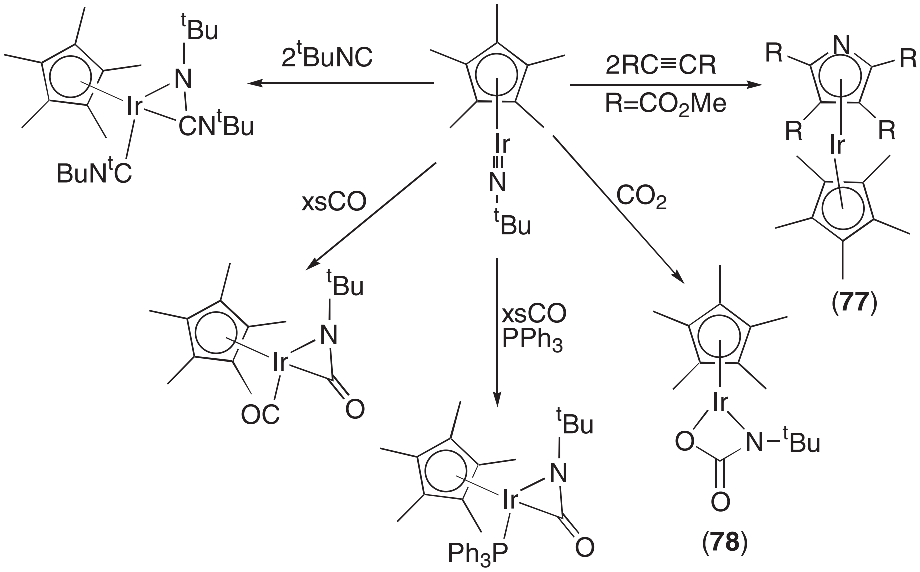
6.2.5.7.3 Nitrile

The complexes $[IrXH(P^iPr_3)(NCCH_3)_3]BF_4$ ($X = Cl$, H) are prepared from $[IrCl(coe)_2]_2$ and $[Ir(OMe)(cod)]_2$, and readily dissociate one CH_3CN ligand *trans* to H.[101] Ethene inserts reversibly into the Ir—H bond, yielding $[IrCl(Et)(P^iPr_3)(NCCH_3)_3]BF_4$ and $[Ir(Et)_2(P^iPr_3)(NCCH_3)_3]BF_4$. Similar reactions occur with propene. The complexes $[Ir(H)(\text{—}C{\equiv}CPh)(NCPh)(CO)(PPh_3)_2]ClO_4$ and $[Ir(\text{—}CH{=}CH\text{—}CH{=}CH)(CO)(NCMe)(PPh_3)_2]ClO_4$ were studied by X-ray absorption techniques. Ir L_{III}edge X-ray absorption spectroscopy confirmed the low-spin state of the Ir^{III} center. The bond distances, Ir—C and Ir—N, determined from EXAFS, are reciprocally proportional to the IR frequencies $\nu_{C\equiv O}$ and $\nu_{C\equiv N}$.[102]

6.2.5.7.4 Nitride

The Ir(III,IV,IV) complex $[Ir_3N(SO_4)_6(OH_2)_3]^{4-}$ undergoes ligand substitution of the three H_2O ligands with azide, Cl^-, Br^-, and NCS^-. The three H_2O ligands, one on each metal, are all equivalent towards substitution.[103] The rate constant for the reaction with azide is 17.3×10^{-4} $M^{-1}s^{-1}$.

The monomeric terminal imido complexes cp* IrNR ($R = {}^tBu$, $SiMe_2{}^tBu$, 2,6-$Me_2C_6H_3$, 2,6-${}^iPr_2C_6H_3$) were prepared from $[cp^*IrCl_2]_2$ and four equivalents of LiNHR in THF.[104] All four product species were structurally characterized by X-ray diffraction and exhibit short Ir—N distances (1.712(7) − 1.759(3) Å) and nearly linear Ir—N—C (Si) angles. Some reactions of cp^*IrN^tBu are highlighted in Reaction Scheme 9. Complexes (**77**) and (**78**) have been studied by single-crystal X-ray diffraction.



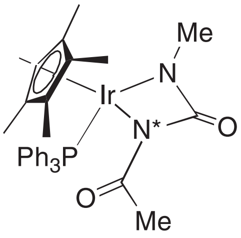
Scheme 9

6.2.5.7.5 Urea

The structure of $[Ircp^*(PPh_3)N(Me)C(O)NC(O)Me]$, (**79**), has a piano-stool-type configuration.[105] The two N—C bond lengths in the iridacycle are 1.348(5) Å and 1.413(5)* Å, the difference arising from the different substituents on the N atoms.

6.2.5.7.6 Nitrite

The rate-limiting step in Reaction Scheme 10 was determined to be conversion of *trans*-$[Ir(NO_2)_4Cl_2]^{3-}$ to $[Ir(NO_2)_6]^{3-}$. The kinetics were studied gravimetrically between 80 °C and 126 °C.[355] Addition of Cu^{2+} ions to the solution had a positive effect on the formation



(79)

of $[Ir(NO_2)_6]^{3-}$, whereas Ni^{2+}, Fe^{3+}, and Al^{3+} all had negative effects.[107] *Fac*-$[Ir(NO_2)_3(OH_2)_3]$ and $[Ir(NO_2)_3Cl_3]$ have been characterized by UV-vis, IR, and ^{15}N NMR spectroscopy.[108] The complex $[Ir(NO_2)_6]^{3-}$ may be precipitated by $\{C_5H_5N(CH_2)_{15}CH_3\}Cl$ but not by $AgNO_3$, whereas $[Ir(CN)_6]^{3-}$ is precipitated by both species.[109]

$$[IrCl_6]^{3-} + 6NO_2^- \longrightarrow [Ir(NO_2)_6]^{3-} + 6Cl^-$$

Scheme 10

6.2.5.7.7 Cyanide

Heating the double salts $[Ir(OH_2)(NH_3)_5][Cr(CN)_5X]$ (X = CN, NO) under N_2 results in expulsion of H_2O and formation of $[(NH_3)_5IrNCCr(CN)_4X]$. Thermogravimetric measurements yield activation energies of 5576.5 ± 21 kcal mol^{-1} and 536.8 ± 21 kcal mol^{-1} for X = CN and NO, respectively, and indicate an S_N1 dissociative mechanism.[110] Analogous studies on $[Ir(NH_3)_5\ (OH_2)]_2[M(CN)_4]_3$ (M = Ni, Pd, Pt) give activation energies of 452.3, 496, and 387.2 kcal mol^{-1} for Ni, Pd, and Pt, respectively.[111]

The mixed-metal complexes $M_3[(M'Ir^{III}(CN)_6]_2{\cdot}13H_2O$ ($M = Cd^{2+}$, Pd^{2+}, $M' = Cr^{3+}$; $M = Co^{2+}$, $M' = Co^{3+}$) are characterized by X-ray crystallography, IR spectroscopy, and thermal gravimetric analyses. The 3+ metal centers are octahedral and linked to M^{2+} metals by cyanide bridges.[112]

6.2.5.7.8 Pyridine

The complexes $[Ircp^*(Cl)_2L]$ (L = py, 2-,3-,4-methyl pyridine, 3,4-ethylpyridine) have been prepared and characterized by IR spectroscopy.[113] The synthesis of *trans*-$[Ir(4\text{-}X\text{-}py)_4Cl_2]NO_3$, X = H, Me, is described and the structure of *trans*-$[Ir(py)_4Cl_2]{\cdot}Ag(NO_3)_2$ is reported.[114] Two distinct crystalline dimorphs of *fac*-$[Ir(py)_3Cl_3]$ have been identified by their IR spectra and powder diffraction patterns.[115] In solution, one converts irreversibly to the other. Reaction of *trans*-$[Ir(py)_4Cl_2]Cl$ with $K_2C_2O_4$ in aqueous ethanol yields the structurally characterized complex *mer*-$[Ir(py)_3Cl(C_2O_4)]$, which converts to *mer*-$[Ir(py)_3Cl_3]$ on recrystallization from boiling conc. HCl.[116]

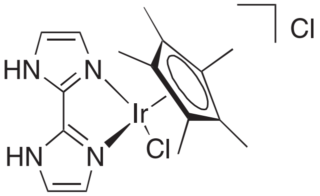
6.2.5.7.9 Phthalimide

The complexes *fac*-$[IrL_3X(OH_2)]$, HL = phthalimide, X = bpy, phen, have been prepared and characterized by IR and UV-vis spectroscopy, electronic conductance and magnetic measurements.[117]

6.2.5.7.10 Imidazole

The complex $[imH][IrCl_4(im)_2]$, imH = imidazole, is prepared by the reaction of either H_2IrCl_6 or $IrCl_3$ with imidazole and HCl.[118] X-ray diffraction confirmed the *trans* geometry around the Ir center and showed that the im ligands are nearly perpendicular to one another (84°). The complex is stable in aqueous solution pH = 7.4, as confirmed by ^1H NMR studies.

The synthesis of (**80**) from $[Ircp^*Cl_2]_2$ and 2,2′-biimidazole has been detailed.[119] The X-ray structure of (**80**) shows the expected three-legged piano-stool arrangement round the Ir center.



(**80**)

6.2.5.7.11 *Pyrazole*

The syntheses of [cp*Ir(Cl)$_2$(pz)Rh(tfb)], [cp*Rh(Cl)$_2$(pz)Ir(tfb)], and [cp*IrCl(pz)$_2$Rh(tfb)] have been reported; these complexes contain Ir^{III}/Rh^{I}, Rh^{III}/Ir^{I}, and Ir^{III}/Rh^{I}, respectively.[120]

The acetone ligand in $[IrH_2(Me_2CO)(Hpz)(PPh_3)_2]BF_4$, (**81**), can be replaced by CO, $P(OMe)_3$, CH_3CN, or Hpz.[121] The reaction of $[IrH_2(Hpz)_2(PPh_3)_2]BF_4$ with KOH yields $[IrH_2(pz)(Hpz)(PPh_3)_2]$, from which the pz ligand can be replaced by Cl^- or CH_3COO^-. Treatment of (**81**) with KOH affords $[\{IrH_2(\mu\text{-pz})(PPh_3)_2\}_2]$, which gives $[IrH_2(Hpz)(PPh_3)_2]BF_4$ on addition of HBF_4 in diethyl ether. All species are characterized by ^1H and $^{31}P\{^1H\}$, NMR, and IR spectroscopy.

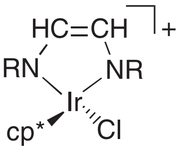
The Ir^{III} cationic pyrazole derivative $[Ir(PPh_3)_2(CO)(dmpzH\text{-}N)(H)_2]BF_4$ has been characterized by X-ray crystallography, and shows a roughly octahedral Ir^{III} center with *trans* P ligands and *cis* H ligands.[532]

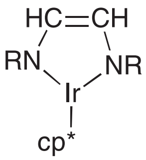
6.2.5.7.12 *Chelate–ethylenediamine*

The crystal structures of *mer*-$[Ir(en)(enH)Cl_3]Cl{\cdot}H_2O$ and *mer*-[Ir(en)(en*)Cl$_3$] show that the coordination geometry of Ir is almost identical in the two complexes, with the only difference being in the conformation of the unidentate en* and enH^+ groups.[122] Density functional theory and *ab initio* calculations have been performed on the two complexes and the calculated confirmations agree well with the X-ray diffraction values.[123] The enH^+ ligand is stabilized via intramolecular N—H···Cl hydrogen bonds.

The complexes $[Ir(en)]^{3+}$ and $[Ir((\pm))chxn)_3]^{3+}$, chxn = *trans*-1,2-diaminocyclohexane, can be used as structure-directing agents in the synthesis of aluminophosphates.[124] The compound $[Ir(chxn)_3][Al_2P_3O_{12}]$ contained the two isomers $\Lambda(lel_2ob)\text{-}[Ir(S,S\text{-}chxn)_2(R,R\text{-}chxn)]^{3+}$ and its mirror image $\Delta(lel_2ob)\text{-}[Ir(R,R\text{-}chxn)_2(S,S\text{-}chxn)]^{3+}$, whereas $[Ir(en)_3][Al_3P_4O_{16}]$ is composed of $\Delta,\Lambda\text{-}[Ir(en)_3]^{3+}$ only. Crystallization of a racemic mixture of $[Ir(en)_3]^{3+}$ from water gave an excess of the (+) enantiomer.[125]

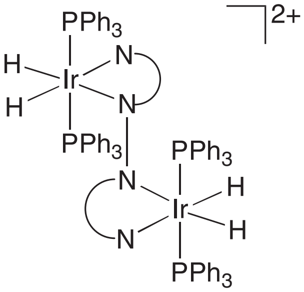
The reaction of $[Ircp^*Cl_2]_2$ with dab, dab = 1,4-bis(2,6-dimethylphenyl)-1,4-diaza-1,3-butadiene, in MeOH yields $[Ircp^*Cl(dab)](PF_6)$, (**82**), on addition of Bu_4NPF_6.[126] Reduction of (**82**) with $NaBH_3CN$ affords [Ircp*(dab)], (**83**). X-ray diffraction studies on (**82**) and (**83**) reveal that (**83**) is better considered as an ene-1,2-diamido Ir^{III} species.



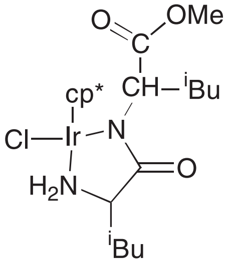


R = 2,6-Me$_2$-C$_6$H$_3$

(**82**) (**83**)



(**85**)



(**86**)

Treatment of $[IrH_2(Me_2CO)_2(PPh_3)_2]X$, X = PF_6, SbF_6, with L, L = paa or mpaa yields the mononuclear species $[IrH_2L(PPh_3)_2]X$, (**84**).[127] The X-ray structure of (**84**), L = mpaa, X = SbF_6, reveals the PPh_3 ligands in a *trans* position and *cis* hydrido ligands. Further reaction of (**84**) with $[IrH_2(Me_2CO)_2(PPh_3)_2]X$ affords the binuclear species $[\{IrH_2(PPh_3)_2\}_2(\mu\text{-N-N})]X_2$, (**85**), and reaction with $CuCl_2{\cdot}2H_2O$, $[PdCl_2(PhCN)_2]$, or $[PtMe_2(DMSO)_2]$ gives the heterobimetallic complexes. All species are characterized by elemental analysis, conductivity measurements, IR and ^1H and ^{31}P NMR spectroscopy.

The tris chelate compounds $[Ir(ArNNNAr)_3]$, Ar = p-C_6H_4X, X = H, Me, Cl, were prepared from $(NH_4)_2IrCl_6$ and excess 1,3-diaryltriazene and Et_3N.[128] The intensely colored compound formed from the reaction of Ir^{III} with dbpmp, dbpmp = 3,5-dibromopyridinylazo-5-methoxyphenol, and salicylic acid, $\lambda_{max} = 588$ nm ($\varepsilon = 1.96 \times 10^5$ L mol^{-1} cm^{-1}), has been used for Ir detection in compounds and metal ores.[129] The kinetic and mechanistic studies of H_2O substitution at $[Ircp^*(A\text{-}B)(OH_2)]^{2+/1+}$ (A-B = D/L-proline anion, picolinic acid anion, [(−)-(1*R*,2*R*)-1,2-diaminocyclohexane][(+)-(1*R*,2*R*)-1,2-diphenylethylenediamine], phen, bpy) support an I_d mechanism with a second-order rate constant dependent on A-B and incoming ligand L, L = py, dimethyl sulfide thiourea Br^-, I^-, N_3^-, NO_2^-, SCN^-.[130] The structure of the perchlorate salt of the complex, where A-B = 1,2-diaminocyclohexane, is reported.

The crystal structure of chloro-pentamethylcyclopentadienyl-*S*-leucyl-*S*-leucyl methyl ester-iridium(III), (**86**), indicates that the Ir—N(NH_2-linkage) is longer (2.129 Å) than that to the deprotonated peptide N atom (2.090 Å).[131]

6.2.5.7.13 α-diimine

Reaction of $[Ircp^*Cl_2]_2$ with chiral imine ligands and $NaSbF_6$ gives diastereomeric mixtures of $[cp^*IrCl(imine)](SbF_6)$, imine ligands L_1–L_6 (**87**).[132] The X-ray structures of the complexes of L_1, L_2, and L_3 are reported and contain the metal center in a pseudo-octahedral environment. Addition of $AgSbF_6$ yields the solvated complexes on precipitation of AgCl; these are active Diels–Alder catalysts. A similar reaction between $[Ircp^*Cl_2]_2$ and NN*H or ON*H (**88**) affords the chiral complexes $[Ircp^*(NN^*)Cl]$ and $[Ircp^*(ON^*)Cl]$, respectively.[133] The structures of the R_M,S_C diastereomers is given. In solution, the compounds epimerize in a first-order reaction.

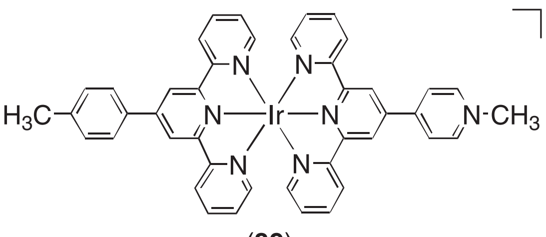
(**88**)

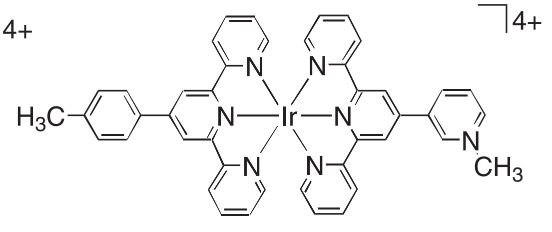
Derivatives of bpy and phen are the most common α-diimine ligands for Ir^{III}. A review by Sauvage, Barigelletti *et al.* in 2000 concentrates on the synthesis and luminescent properties of such compounds, including bidentate and tetradentate ligands with both N and C donor sites.[134] The emissive states are either charge transfer or ligand centered, depending on the ligand set. $[IrN_6]^{3+}$ complexes are found to be strong photooxidants, while the tris-cyclometalated $[IrN_3C_3]$ complexes are strong photoreductants.

The synthesis and characterization of *cis*-$[Ir(diimine)(hdpa)Cl_2]Cl$, diimine = bpy, phen, hdpa = 2,2′-dipyridylamine, is reported.[135] Emission studies suggest that it is the Ir(diimine) chromophore which is responsible for the phosphorescent behavior. The microwave-assisted synthesis and characterization (spectroscopic and electrochemical) of $[Ir(diimine)_3]^{3+}$ and $[Ir(diimine)_2Cl_2]^+$, diimine = bpy, 4,4′-Me_2-bpy, 4,4′-Ph_2-bpy, phen, 4,7-Ph_2-phen, 2,2′-biquinoline, is described.[136]

Complexes (**89**) and (**90**) emit around 520 nm, with (**90**) having the greater emission intensity.[137] Emission is quenched by Cl^-, Br^-, and I^- ions, but not by NO_3^-, SO_4^{2-}, $H_2PO_4^-$, PF_6^-, or BF_4^- ions.

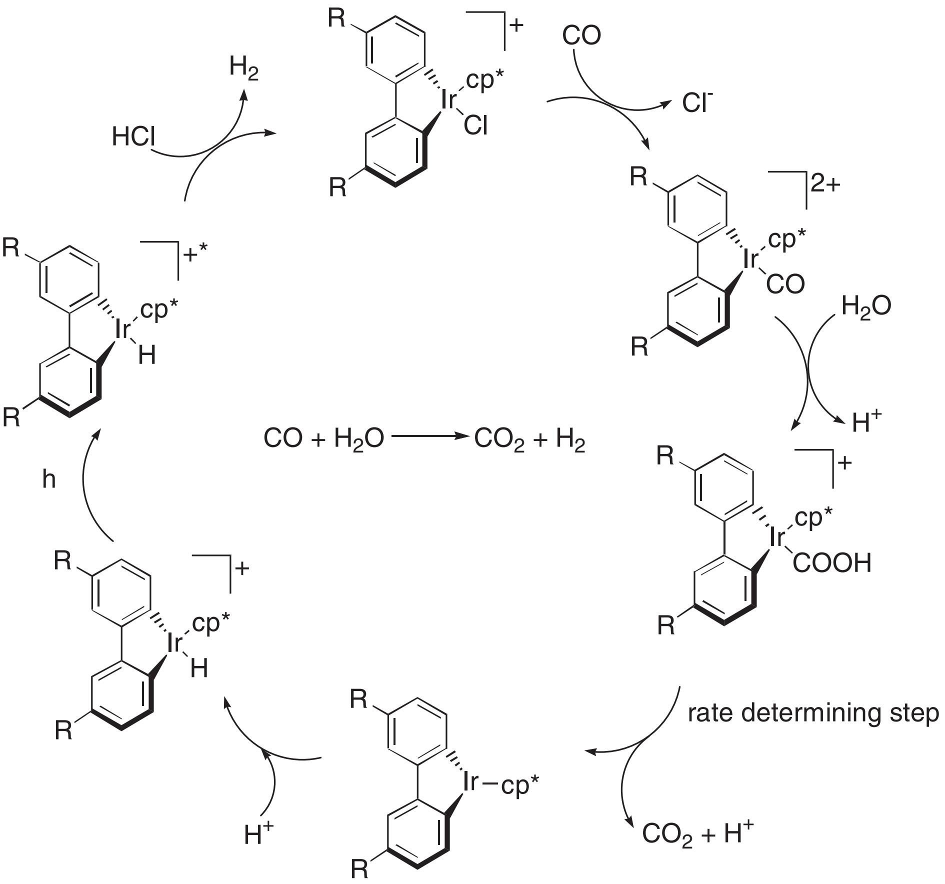


(**89**)



(**90**)

The synthesis of [Ircp*Cl(bpy-cd)]Cl, where bpy-cd is a β-cyclo-dextrin attached at the 6 position to a bpy ligand, is detailed.[138] The complexes $[Ircp^*(diimine)X]^+$, X = Cl, H, diimine = bpy, phen, are active catalysts for the light-driven water-gas-shift reaction.[139] The hydride complexes luminesce at 77 K and room temperature, whereas the chloride complexes do not.[140] The three-legged piano-stool arrangement of the ligands in $[Ircp^*(bpy)Cl]^+$ and $[Ircp^*(4,4'\text{-}COOH\text{-}bpy)Cl]^+$ is confirmed by X-ray crystallography.[141,142] Further mechanistic studies on the catalytic cycle shown in reaction Scheme 11 indicate that Cl^- is substituted by CO and the rate-determining step involves loss of CO_2 and H^+ to leave the Ir^I species, which readily binds H^+ to yield the Ir^{III}–hydride species.[143]



Scheme 11

Photoactivation of the hydride complex in the presence of HCl results in the release of H_2 and generation of the starting material. Extension of this work includes the electrochemical study of the $Ir^{III/I}$ reduction process in $[Ircp^*LCl]^+$, L = bpy and phen derivatives, in anhydrous CH_3CN. When pyrrole-substituted bpy or phen ligands are used, then films may be grown on glassy carbon electrodes via oxidative polymerization reactions. The polymer films are electrocatalytically active in the hydrogen-generation process.[144]

$[IrL_2Cl_2]^+$ complexes, L = 4,4′-Me_2-bpy, bipyrimidine, biquinoline, 2-phenylazopyridine, have been studied by fast-atom bombardment mass spectroscopy in thioglycerol, glycerol, and tetraglyme matrices.[145] One or two chloride ligands are substituted by thioglycerol ligands in a thioglycerol matrix.

The functionalized polypyridine ligands (**91**) have been used to form a series of Ir^{III} complexes of general formula $[Ir(ppy)_2(\mathbf{91})]^+$, (**92**), where ppy = monoanion of 2-phenylpyridine, (**170**).[146] The crystal structures of (**92**), where (**91**) = d and i, are reported.[146,147] The complexes have an irreversible oxidation process primarily based on Ir—C σ-bonds, and a reversible reduction process primarily based on the polypyridine ligand. The redox and absorption properties are insensitive to X, whereas the luminescence properties may be fine-tuned by varying X.[146] Direct binding of the substituent X onto the pyridine ring, as in (**91e**), results in absorption maxima shifts as well as luminescence shifts.[148] Binuclear complexes $[(ppy)_2Ir(\mu\text{-}L\text{-}OC(O)C_6H_4C(O)O\text{-}L)Ir(ppy)_2](PF_6)_2$, $[(ppy)_2Ir(\mu\text{-}L\text{-}OC(O)\text{-}L(ppy)_2](PF_6)_2$ and $[(ppy)_2Ir(\mu\text{-}L\text{-}OC(O)\text{-}L)Re(CO)_3Br]BF_6$, where L = (**91k**), have also been synthesized and characterized.[149] The redox behavior of the binuclear compounds indicates that the metal-based orbitals interact only weakly, but the two chelating halves of the bridging ligands exhibit electronic interactions. Photo-induced energy transfer across the ester linkage occurs with low efficiency.[149]

Determination of stability constants towards outer-sphere association reactions for *cis*-$[Ir(phen)_2Cl_2]X$, X = Cl^-, Oac^-, $HCOO^-$, gives the following decreasing order: $Cl^- > Oac^- > HCOO^-$.[150]

The maximum zero-field splitting in the ligand-centered luminescence of $[Ir(5,6\text{-}Me_2\text{-}phen)_2Cl_2]^+$ in glycerol is $3 \pm 0.5\,cm^{-1}$, compared to $<1\,cm^{-1}$ for $[Ir(phen)_3]^{3+}$.[151]

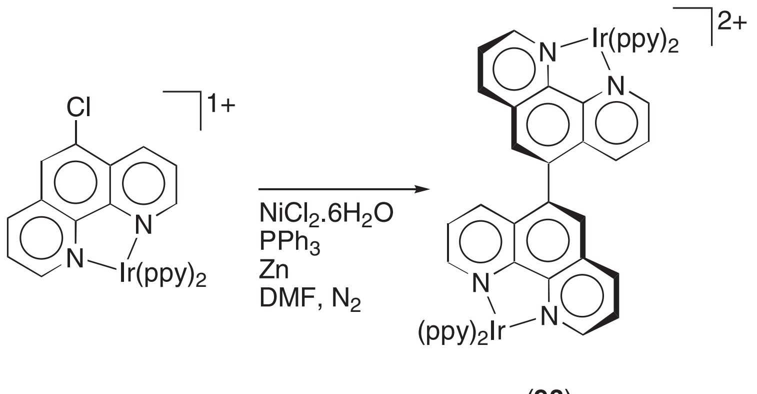
The solution structure of $[Ir(bpy)H_2(PRPh_2)_2]X$, R = Me, Ph, X = PF_6, BF_4, CF_3SO_4, BPh_4, as determined from NMR studies, is compared to solid-state structure.[152] The main difference between the two structures is the location of the counter ion X. In solution, X is positioned on the side of the bpy ligand remote from the Ir, whereas in the solid state X is found close to one of the pyridine rings and one hydride ligand. Theoretical calculations at the QM/MM (B3PW91/UFF) level support the experimental results.

The complex $[(cp^*)IrCl(2,2'\text{-}bpy\text{-}4,4'\text{-}COO(CH_2)_3\text{-}pyrrole)]ClO_4$ has a typical three-legged piano-stool structure, with short Ir–cp* distances due to the strong π-acceptor properties of the bpy ligands.[540]

6.2.5.7.14 Binuclear complexes

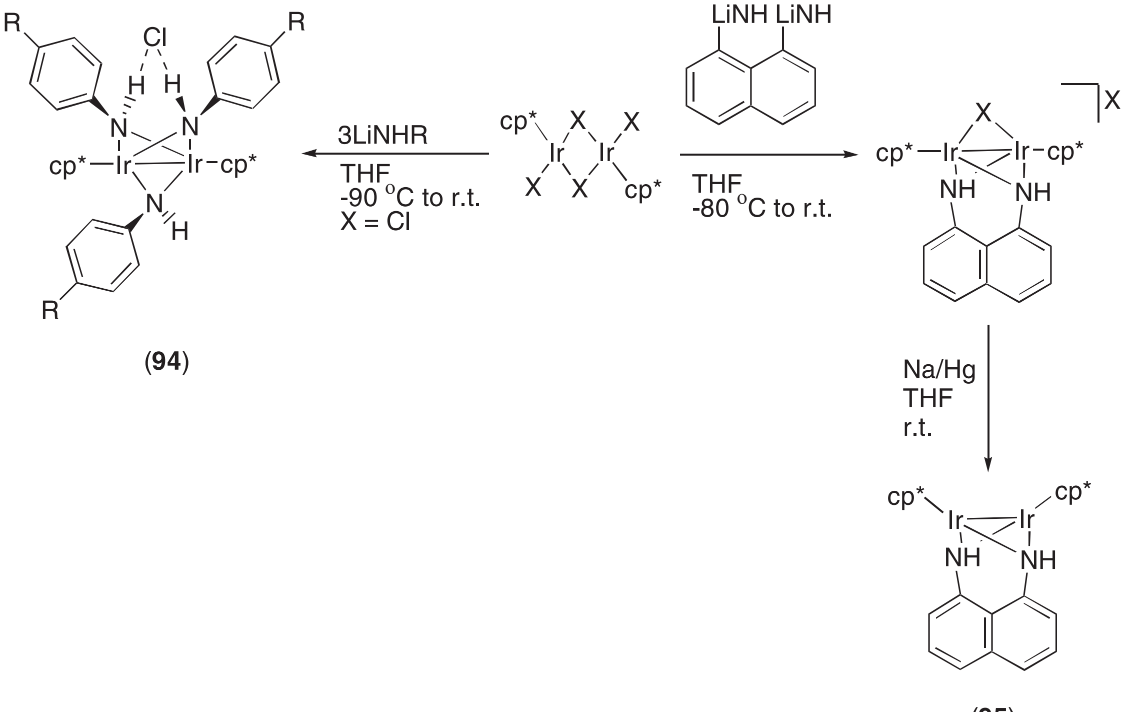
The binuclear Ir complex (**93**) is produced from the direct coupling reaction of the Ir-bound 5-chloro-phen ligand as shown in reaction Scheme 12.[153] The nonplanar structure of the bridging ligand results in the electronic isolation of the two Ir centers. Hence both metal centers and ligands are oxidized and reduced, respectively, in two-electron processes.

Amido-bridged binuclear complexes of Ir^{III} and Ir^{II} are prepared by Reaction Scheme 13.[154] The molecular structures of (**94**) (R = Me) and (**95**) are reported. Dark red (**95**) has a single Ir—Ir bond (2.584(1) Å) and is diamagnetic.



(**93**)

Scheme 12



(**94**)

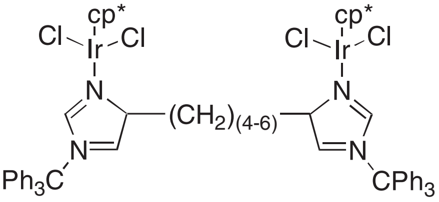
(**95**)

Scheme 13

The reaction of *fac*-$[IrH_2(NCCH_3)_3(P^iPr_3)]BF_4$ with Kpz gives $[Ir_2(\mu\text{-}H)(\mu\text{-}pz)_2\text{-}H_3(NCCH_3)(P^iPr_3)_2]$, (**96**), which has been characterized by single-crystal X-ray diffraction.[155] The complex is rigid on the NMR timescale. The CH_3CN ligand is easily replaced by C_2H_4, CO, Hpz. Reaction of (**96**) with $CHCl_3$ gives CH_2Cl_2 and $[Ir_2(\mu\text{-}H)(\mu\text{-}pz)_2H_2Cl(NCCH_3)(P^iPr_3)_2]$. The bridged Ir_2 bis[imidazol-4-yl]alkene compounds (**97**) are obtained from the reaction of $[cp^*IrCl_2]_2$ with the CH_2-bridged bis-imidazoles.[156]

6.2.5.7.15 *N_3 ligands*

Reaction of dien, dien = diethylene-triamine, with $IrCl_3{\cdot}1.5H_2O$ yielded $[Ir(dien)_2]Cl_3$.[157] Separation of the *mer*-isomer was effected by chromatography on SP-Sephadex, with an X-ray structure



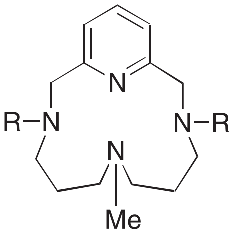
(97)

determination confirming the geometric form of the isolated species. Protonation of $[Ir(HBpz*_3)(CO)_2]$, pz* = 3,5-dimethylpyrazol-1-yl, by $HBF_4{\cdot}OEt_2$ affords $[Ir(\eta^3\text{-}HBpz*_3)(H)(CO)_2]BF_4$, (**98**).[158] NaOMe and ^{n}BuLi attack a carbonyl carbon of (**98**), giving the methoxycarbonyl and acyl hydrides, respectively. Photolysis of a benzene solution of $[IrH_2(HBpz*_3)(coe)]$ in the presence of $P(OMe)_3$ gives $[Ir(HBpz*_3)(H)(C_6H_5)(P(OMe)_3)]$.[159] When the reaction is carried out in diethyl ether or *tert*-butyl acrylate, then $[Ir(HBpz*_3)H_2(P(OMe)_3)]$ and $[Ir(HBpz*_3)H_2(CH_2{=}CHCOO^tBu)]$ result, respectively. Mechanistic studies suggest that the primary photoproduct is $[Ir(HBpz*_3)H_2]$.

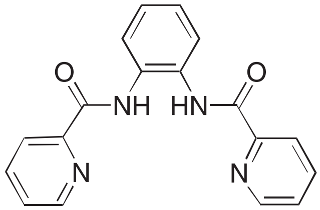
Combined Mössbauer and vibrational spectroscopic studies of $[Ir(tpy)_2](ClO_4)_3]$, tpy = 2, 6-bis(2-pyridyl)pyridine, in the solid state reveal the presence of three structural units: (i) mononuclear bis-tpy; (ii) oligomeric species with two bidentate and two bridging monodentate tpy ligands bound through terminal pyridine rings; and (iii) the same as (ii), except that the monodentate tpy ligands are bound through the central *N*-pyridine atoms.[160] The X-ray structure of $[Ir(tpy)_2](PF_6)_3$ is reported.[161] The family of complexes $[Ir(tpy)_2](PF_6)_3$, $[Ir(^tBu\text{-} tpy)_2](PF_6)_3$, $[Ir(ttpy)_2](PF_6)_3$, and $[Ir(ttpy)(Metpy)](PF_6)_3$, ^{t}Butpy = 4′-(3,5-di-*tert*-butylpheyl)tpy, ttpy = 4′-tolyltpy, Metpy = 4′-methyltpy, have long-lived excited states, 1.2, 6.8, 9.5, 5.8 μs, respectively, at 293 K in deareated acetonitrile.[160] The complexes all show a ligand-based reduction. Linkage of a tetraaryl–porphyrin group containing H_2, PH_2, Au, PAu or Zn, PZn at the 4′-position of tpy gives rise to multicomponent arrays PH_2—Ir, PZn—Ir—PAu, where Ir is the $[Ir(tpy)_2]^{3+}$ moiety.[162] The triad PZn—Ir—PAu yields on irradiation the charged, separated, excited state PZn^+—Ir^-—PAu, which has a lifetime of 450 ns. The complexes $[Ir(tpy\text{-}R)(4'\text{-}C_6H_4\text{-}NCS\text{-}p\text{-}tpy)](PF_6)_3$, R = H, C_6H_5, $C_6H_4\text{-}CH_3\text{-}p$, $C_6H_4\text{-}Cl\text{-}p$, have been synthesized.[163] All complexes exhibit intense, long-lived, yellow emission in CH_3CN at 298 K, and green emission in low-temperature alcohol glass. The complex R = H has been used as a luminescent label for proteins.

6.2.5.7.16 N_4 ligands

Reaction of $IrCl_3{\cdot}3H_2O$ with (**99**) in aqueous EtOH affords *cis*-[IrCl(H)(**99**)]PF_6.[164] The *cis* arrangement of Ir-bound (**99**) is confirmed by X-ray crystallography. The analogous reaction with (**100**) yields *trans*-[IrCl(Et)(**100**)]PF_6 as determined by X-ray crystallography.[165]

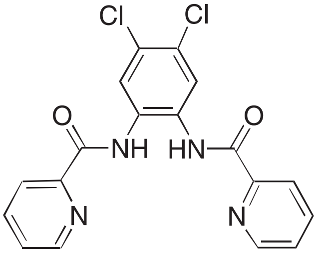


R = H (**99**)
R = Me (**100**)



H_2bpb

(**101**)

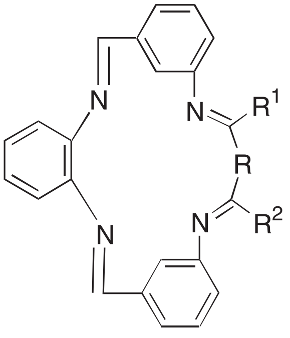


H_2bpc

(**102**)

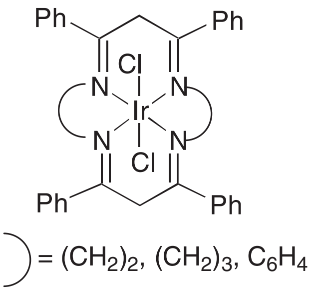
Treatment of $Na_2[IrCl_6]$ with H_2bpb (**101**) and H_2bpc (**102**) gives $Na[Ir(bpb)Cl_2]$ and $Na[Ir(bpc)Cl_2]$, respectively.[166] Both complexes undergo reversible, one-electron, ligand-based oxidations at +0.21 V and +0.31 V vs. ferrocenium/ferrocene, respectively, in CH_3CN.

The macrocyclic ligands (**103**) react with $IrCl_3$ in anhydrous EtOH to produce [Ir(**103**)Cl_2]Cl, characterized by IR, UV-vis, and NMR spectroscopy.[167] Both *cis*- and *trans*-[Ir(cyclam)Cl_2]Cl result from the reaction of $IrCl_3$ or $Ir(thtp)_3Cl_3$, thtp = tetrahydrothiophene, with cyclam, cyclam = 1,4,8,11-tetrahydrodecane.[168] X-ray powder diagrams assign the *cis*- and *trans*-isomers as (*R,R,R,R*/*S,S,S,S*) and (*R,R,S,S*) configurations, respectively. The synthesis of the 14–16 membered, tetraazamacrocylic-bound Ir complexes (**104**) is described. IR, UV/vis, ^1H NMR spectroscopic studies are detailed for all complexes.[169]



R = CH_2, R^1 = R^2 = Me
R = CH_2, R^1 = Me, R^2 = Ph
R = Nil, R^1 = R^2 = Me, Ph

(**103**)



(**104**)

Successive oxidation of $[Ir(pc)(py)]_2$ with I_2 yields the mixed-valent species $[\{Ir(py)(pc)\}_2]I$ initially and then *trans*-[Ir(py)I(pc)].[170] The latter compound has been characterized by X-ray crystallography. The spectrum of the mixed-valent material is reported. Reaction of $[Ir(pc)]_2$ with NO in py yields nitrosyl intermediates, which immediately oxidize in air to give [Ir(py)-(NO_2)pc].[171] The structurally characterized species pnp-*trans*-[Ir$(NO_2)_2$(pc)], pnp = bis(triphenyl-bis(triphenylphosphine)iminium, is formed by air oxidation of $[Irpc]_2$ in CH_2Cl_2 and pnp(NO_2), and contains *N*-bound NO_2 ligands.[171] In alkaline solution $[Ir(pc)]_2$ is oxidized by air to give deep blue $[Ir(OH)_2(pc)]^-$, which may be acidified by HX (X = F, Cl, Br, I) yielding black-green H[IrX_2pc].[172] Further oxidation by Cl_2, Br_2, dibenzoyl peroxide results in oxidation of the pc ligand, affording [IrX_2pc]. $[IrX_2pc]^-$ exhibits three one-electron reduction processes. $[Irpc]_2$ reacts in methanol with excess $[^nBu_4N]OH$ to give $[^nBu_4N]$*trans*-[Ir(OH)(OMe)pc], which has been characterized by X-ray crystallography.[173]

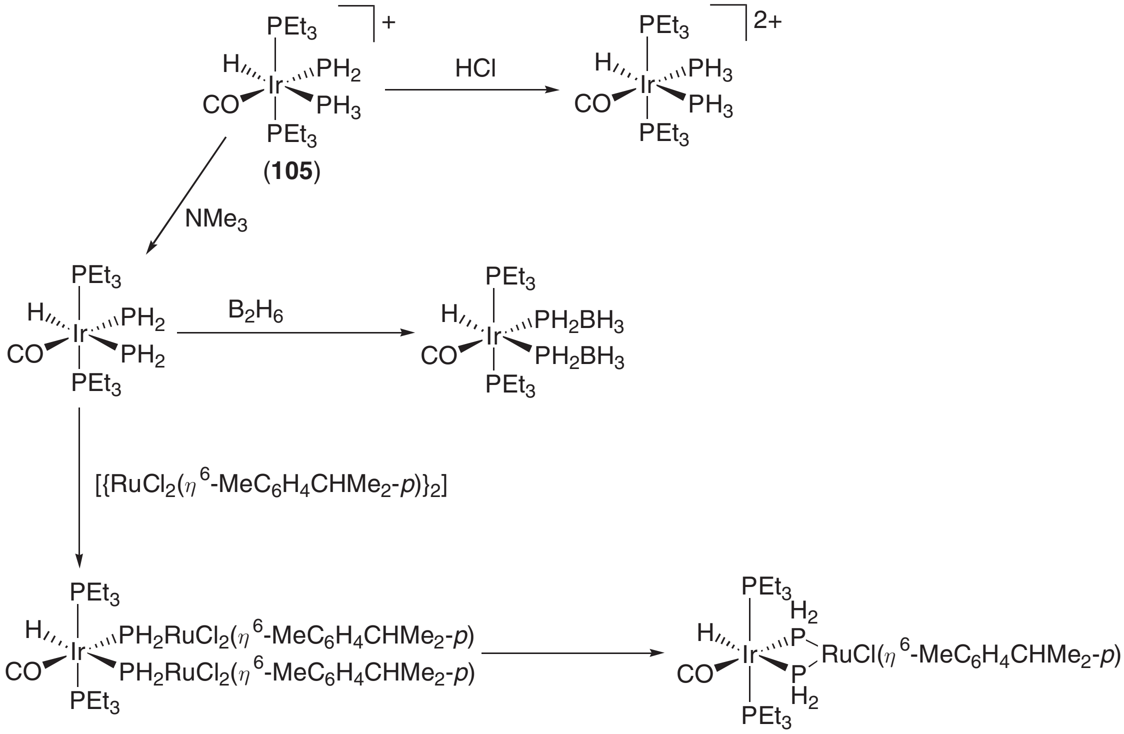
6.2.5.8 Phosphorus Ligands

6.2.5.8.1 Monodentate ligands

The X-ray structures of *cis*-$[IrH(EH)(PMe_3)_4]^+$, E = O, S, confirm the *cis*-geometry of the Ir center.[174] In the complex where E = O, the O—H group points towards the hydride ligand, whereas when E = S the S—H group points away from the hydride ligand. The structure *cis*-$[IrH(OH)(PMe_3)_4]^+$ has also been determined by a neutron diffraction study at 20 K.[175] The X-ray structure of *trans,mer*-$[IrCl_2(PMe_3)_3(PMe_2Ph)]ClO_4$ has been determined.[176] Low-temperature $^{31}P\{^1H\}$ NMR studies show that at $-75\,^\circ C$ in d_6-acetone there is restricted rotation about the Ir—PMe_2Ph bond, and two rotamers can be identified. At $45\,^\circ C$ the rotamers are in fast exchange. The single-crystal diffraction study of $[IrCl_2(CO)(PEt_3)_2(SOCl)]$ identifies *trans*-PEt_3 groups, *cis*-Cl ligands, and a Cl—S—O angle of $106.5(4)\,^\circ$.[177]

The structure of *cis*-$[Ir(H)Cl(PEt_3)_4][B(cat)_2]$, $B(cat)_2$ = bis(benzene-1,2-diolato)borate, exhibits one long Ir—P bond *trans* to the hydride ligand and a short Ir—P bond opposite chloride, in agreement with the relative *trans* influence of these ligands.[178] The crystal structures of the series of complexes *mer*-$[Ir(PMe_2Ph)_3Cl_nH_{3-n}]$ reveal that the Ir—P (but not Ir—Cl) distances decrease by ca. 0.04 Å per unit increase in hydride content.[179–182] Replacement of PMe_2Ph ligands by P^iPr_3 results in similar trends, although the bulkier P^iPr_3 ligand gives longer Ir—P bonds.[183,184]

The reactions of (**105**) are summarized in reaction Scheme 14. In all cases the products were identified by ^1H and ^{31}P NMR spectroscopy.[556]



Scheme 14

Reaction of *mer*-$IrCl_3P_3$ (P = $PBuPh_2$, $PMePh_2$, PEt_2Ph) with $RuCl_2P'_3$ (P′ = PPh_3, $P(C_6H_4CH_3\text{-}p)$) yields $PP'ClRu(\mu\text{-}Cl)_3IrPP'Cl$.[185] ^{31}P NMR spectroscopy shows that the PMe_2Ph ligands in *mer*-$[IrCl_2(OH_2)(PMe_2Ph)_3](ClO_4)$ rapidly exchange and that the H_2O ligand *trans* to PMe_2Ph dissociates.[186] Treatment of $[IrL_2(MeCN)P_3]^+$, (**106**), L = H, Me, P = PMe_2Ph, with $HBF_4{\cdot}OEt_2$ in MeCN gives *cis,mer*-$[IrL(MeCN)_2P_3]^{2+}$.[187] If the reaction of (**106**) with $HBF_4{\cdot}OEt_2$ is carried out in the absence of MeCN, then the product species *cis,mer*-$[IrH(MeCN)_2P_3]^{2+} + [IrH_4P_3]^+$ and *mer*-$[IrMe(OEt_2)(MeCN)P_3]^{2+}$ (**107**) result for L = H and Me, respectively. The latter product (**107**) in the presence of H_2O yields *mer*-$[IrMe(H_2O)(MeCN)P_3](BF_4)_2$, which has been characterized by X-ray crystallography.

The H_2O ligand in *trans,mer*-$[IrCl_2(OH_2)(PMe_2Ph)_3]ClO_4$ (**108**) is readily substituted by NH_3 and PH_3.[188] The resulting PH_3-containing species may be deprotonated to give the structurally characterized product *trans,mer*-$[IrCl_2(PH_2)(PMe_2Ph)_3]$. Replacement of H_2O by H_2S in (**108**) gives the structurally determined species *trans,mer*-$[IrCl_2(SH)(PMe_2Ph)_3]$. Reaction of $[Ir(CO)Cl(R)(X)(PPh_3)_2]$ with C_2H_2 and PPh_3 yields *cis,trans*-$[Ir(R)(\text{-}CH{=}CH^+\ PPh_3)_2(CO)(PPh_3)_2]^{2+}$, R = H, CH_3, X = Cl, I, which gives *cis,trans*-$[IrCl(\text{-}CH{=}CH^+\ PPh_3)_2(CO)(PPh_3)_2]^{2+}$ on treatment with HCl.[189] The latter product has been characterized by X-ray diffraction.

The species $[Ir(H)Cl(PMe_3)_4]^+$ would be expected to adopt the *trans* geometry on electronic and steric grounds; however, it is the *cis* conformation which is found experimentally.[190] Quantum-mechanical calculations suggest that there is little energy difference between the two structures, but the *cis*-form is favored by the higher entropy of this lower-symmetry arrangement. Oxidative addition to $[Ir(CO)_3(PEt_3)_2]BF_4$ and $[Ir(CO)_2(PH_3)(PEt_3)_2]BF_4$ yields a variety of octahedral Ir^{III} complexes, which are characterized by ^1H, ^{13}C, ^{19}F, and ^{31}P NMR spectroscopy.[575] Addition of H^+ to the metal center of the ortho-cyclometalated complexes $[Ir[P(OC_6H_3Me\text{-}o)(OC_6H_4Me\text{-}o)_2](cod)L]$, L = $P(OC_6H_4Me\text{-}o)_3$, $PMePh_2$, PMe_2Ph, PMe_3, is stereoselective and occurs *trans* to L, which isomerizes on heating to the thermodynamically stable isomer of $[IrH(OC_6H_3Me\text{-}o)(OC_6H_4Me\text{-}o)_2(cod)L]^+$ in which the hydride is *trans* to the cyclometalated phosphite ligand.[191] A further isomer, where the proton attacks the ortho-metalated C atom, is detected by UV-vis, ^1H, and ^{31}P NMR spectroscopy.

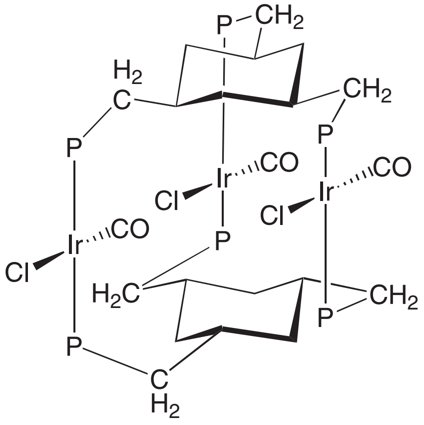
The complexes $[IrCl(PPh_3)_2S]$, $[IrCl(diphos)S]$, and $[IrCl(diphos)PPh_3]$ (diphos = $Ph_2PCH_2CH_2PPh_2$, S = solvent) react with H_2 at 30 °C, 1 atm of H_2 in $EtOH/C_6H_6$, to form stable dihydrido Ir^{III} complexes.[192] Computation of thermodynamic parameters reveals that the enthalpy of formation of the dihydrido complexes is more exothermic for the Ir^I complexes than for the analogous Rh^I complexes.

The complexes $IrCl(CO)P_2$ ($P = PMePh_2$, PMe_2Ph, PMe_3) oxidatively add RBr, $R = CH_2CO_2Et$, CH_3CHCO_2Et, $CH_3CHCOCH_3$, $EtCHNO_2$, to give $IrBrClR(CO)P_2$.[193] CH_2I_2 and CH_2ClI give $IrClI(CH_2Y)(CO)P_2$, $Y = I$, Cl, respectively. In all cases the final compounds contain *trans* tertiary phosphine ligands.

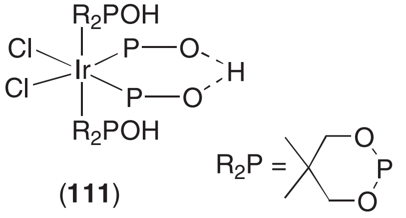
Trans-$[Ir(CO)X(PEt_3)_2]$, $X = Br$, Cl, reacts with ZH_3 ($Z = P$, As, Sb) in toluene to give $[Ir(CO)XH(PEt_3)_2(ZH_2)]$ (**109**).[194] The X-ray structure of (**109**), with $X = Cl$, $Z = As$, is detailed. Treatment of (**109**), $X = Br$, $Z = P$, with HCl yields $[Ir(CO)BrH(PEt_3)_2(PH_3)]^+$ and then $[Ir(CO)BrClH(PEt_3)_2]$, and with H_2Se gives $[Ir(CO)BrH(PEt_3)_2(SeH)]$.

Reaction of $[Ir(cod)Cl]_2$ with PPh_3 and $AgBF_4$ gives $[Ir(\eta^4\text{-}1,5\text{-cod})(PPh_3)_2]BF_4$ which gives $[IrH_2Q_2(PPh_3)_2]BF_4$ on treatment with H_2 and Q ($Q = Me_2CO$, H_2O).[195]

Treatment of $Ir(PPh_3)_2(CO)Cl$ with tdppmcy yields the trinuclear complex $[Ir(CO)Cl]_3(tdppmcy)_2$, (**110**).[196] $[Ir(CO)Cl]_3(tdppmcy)_2$ reacts with H^+, H_2, and H^- to give $[Ir(CO)ClH]_3(tdppmcy)_2]^{3+}$, $[Ir(CO)(Cl)H_2]_3(tdppmcy)_2$, and $[Ir(CO)H_3]_3(tdppmcy)_2$, respectively.

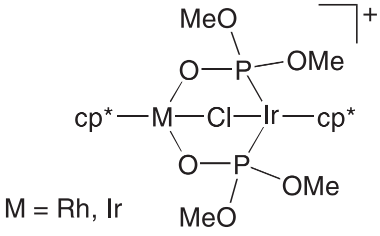


(**110**)

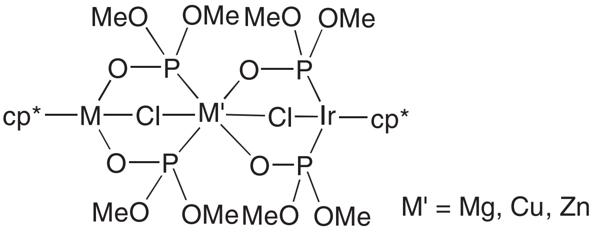


(**111**)

Reaction of the secondary phosphite 5,5-dimethyl-1,3-dioxa-2-phosphorinane $\overline{OCH_2CMe_2CH_2O\text{-}}$ $\overline{P}(O)H$, R_2POH, with $[IrCl(coe)_2]_2$ affords the product species $[IrCl_2(R_2POHOPR_2)(R_2POH)_2]$, (**111**), $[IrH(R_2POHOPR_2)_2(R_2POH)]$, and $[IrCl(R_2POHOPR_2)_2(R_2POH)]$.[197] Heating the phosphite with $Ir(acac)(coe)_2$ in toluene produces $[Ir(acac)(R_2POHOPR_2)_2]$. The synthesis of mixed phosphite/phosphine or arsine hydride complexes $IrHCl_2[PPh(OEt)_2]L_2$ and $IrHCl_2P(OEt)_3L_2$ ($L = PPh_3$, $AsPh_3$) has been described.[198] The hydride ligand may be substituted by the hydrazine ligands $RNHNH_2$, $R = H$, Me, Ph, $C_6H_4NO_2$-4, giving $[IrCl_2(RNHNH_2)\{PPh(OEt)_2\}L_2]^+$ and $[IrCl_2(RNHNH_2)\{P(OEt)_3\}L_2]^+$, respectively. The multinuclear complexes (**112**) and (**113**) have been synthesized from the anion $[Ircp^*Cl\{PO(OMe)_2\}_2]^-$ and spectroscopically characterized.[199,200]



(**112**)

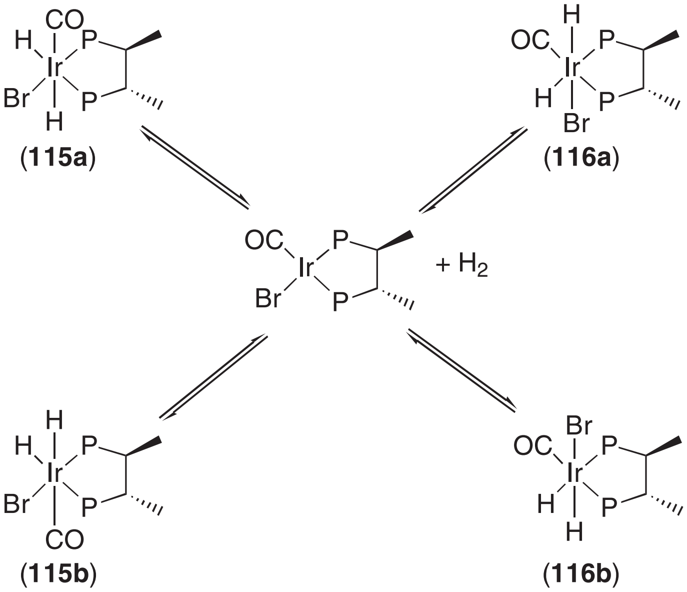


(**113**)

6.2.5.8.2 *Bidentate ligands*

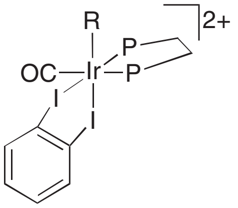
The complex $[Ir(\mu\text{-}OCH_3)(\eta^4\text{-}1,5\text{-cod})]_2$ reacts with bis(diphenyl-phosphino)methane, dppm, to give $[IrH(\eta^1,\eta^3\text{-}C_8H_{12}\}dppm]$, the structure of which has been confirmed by single-crystal X-ray studies.[201] A reaction mechanism has been proposed as a result of deuteration experiments. The family of complexes Li[Ir(P-P)I_4], Li(**114**), P-P = dppe or *cis*-1,2-bis(diphenylphosphino) propane, has been synthesized.[202] The salt Ph_4As(**114**), P-P = dppe, has been characterized by X-ray crystallography.

Oxidative addition of H_2 and Ph_3SiH to IrBr(CO)(chiraphos), where chiraphos = 2*S*,3*S*-bis (diphenylphosphino)butane, leads to stable kinetic (**115a**,**115b**), followed by thermodynamic (**116a**,**116b**) diastereomers as shown in reaction Scheme 15.[203] The crystal structure of *cis*-$[IrH_2(chiraphos)_2]BF_4$ has been reported.[204]

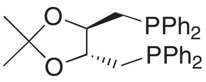


Scheme 15

Oxidative addition of silanes to IrX(CO)(dppe), X = Br, CN, proceeds stereoselectively under kinetic control with hydride binding *trans* to CO and Si *trans* to P(dppe).[205] When X = Br the kinetic product isomerizes to the thermodynamically stable species, with H *trans* to Br and Si *trans* to P(dppe). NMR studies of H_2 addition to IrBr(CO)(dppe) have proved sensitive to para-enriched H_2.[206] The complex $[Ir(CH_3)(CO)(CF_3SO_3)_2(dppe)]$, when dissolved in CH_2Cl_2 under 1 atmosphere of H_2, yields CH_4 and $IrH(CO)(CF_3SO_3)_2(dppe)$ (**117**).[207] The complex (**118**) proves to be an effective hydrogenation catalyst for ethane and 1-hexane. The cationic complexes (**118**) and (**119**) have been shown to polymerize isobutylene, norborene, styrene, and β-pinene.[208] Reaction of (**119**) with H_2 yields $[IrH_2(CO)_2dppe]^+$.[209] Labeling and NMR studies show that the reaction involves conversion of coordinated CF_3 to CO. The synthesis of monomeric carboxylato(diphosphine)iridium(III) complexes has been described (diphosphine = diop (**120**), binap (**121**), and bdpp (**122**)).[210] Some of theses complexes catalyze the asymmetric hydrogenation of prochiral imines to amines.



(**118**) R = CH_3
(**119**) R = CF_3



diop

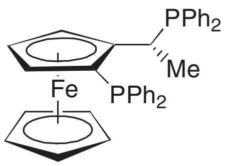
bdpp

(**122**)



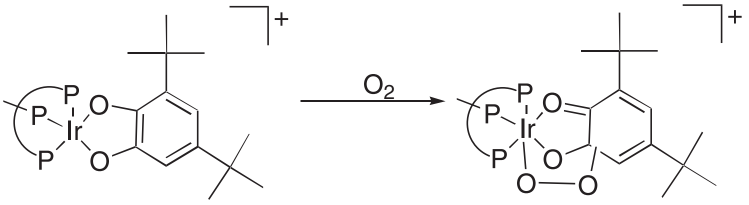
(*R*)-(*S*)-PPFPPh$_2$

(**123**)

The diphosphine ligand (*R*)-(*S*)-PPFPPh$_2$ (**123**) binds to Ir^I to form the dinuclear species *cis* and *trans*-[Ir$_2$(μ-Cl)$_2$((*R*)-(*S*)-PPFPPh$_2$)$_2$] which oxidatively adds H$_2$O to give [(*R*)-(*S*)-PPFPPh$_2$)$_2$-Ir$_2$Cl$_2$(H)$_2$(μ-OH)$_2$].[211] The X-ray structure of the *syn*-*trans* isomer has been determined.

6.2.5.8.3 Tridentate ligands

Oxidation of 3,5-di-tert-butyl catechol to 3,5-di-tert-butyl-*o*-benzoquinone by O$_2$ is catalyzed by the Ir^{III} catecholate complex (**124**).[212] The authors suggest that formation of the dioxygen adduct, as in reaction Scheme 16, is an important step in the process.



(**124**)

Scheme 16

The structure of [IrH$_2$X(cyttp)], X = Cl, I, cytpp = PhP(CH$_2$CH$_2$CH$_2$PR$_2$)$_2$, R = cyclohexyl, confirms an octahedral arrangement around Ir with the cytpp ligand taking up a *mer*-configuration around the metal.[213] Diastereoisomers were characterized by NMR spectroscopy.[214] [IrCl(CO)(Htriphos)] undergoes oxidative addition reactions with H$_2$, HCl, and Cl$_2$ to give [IrH$_2$(CO)(Htriphos)]$^+$, [IrHCl(CO)(Htriphos)]$^+$, and [IrCl$_3$(Htriphos)], respectively.[608]

6.2.5.8.4 Arsine and antimony ligands

Reaction of [IrCl(C$_2$H$_4$)$_2$]$_2$ and As^{i}Pr$_3$ yields *trans*-[IrCl(C$_2$H$_4$)(As^{i}Pr$_3$)$_2$], which on UV irradiation in MeCN gives [IrHCl(CH:CH$_2$)(MeCN)(As^{i}Pr$_3$)$_2$], the molecular structure of which has been determined by X-ray crystallography.[215] The reaction of [IrCl(coe)$_2$]$_2$ with Sb^{i}Pr$_3$ in the presence of H$_2$ affords *cis,mer*-[IrH$_2$Cl(Sb^{i}Pr$_3$)$_3$], which gives [IrH$_2$Cl(CO)(Sb^{i}Pr$_3$)$_2$] on treatment with CO.[216] Five co-ordinate [IrCl(C$_2$H$_4$)$_2$(SbR$_3$)$_2$] (**125**) results from the reaction of [IrCl(C$_2$H$_4$)$_2$]$_2$ with SbR$_3$ (R = ^{i}Pr, Me, Ph), and the X-ray structure of (**125**), where R = ^{i}Pr, confirms a distorted trigonal-bipyramidal geometry around Ir, with one stibine ligand and the two ethene ligands in the equatorial plane. The synthesis and characterization of [Ir(tetras)X$_2$]X, tetras = As(*o*-C$_6$H$_4$-AsMe$_2$)$_3$, X = Cl, Br, I, and *fac*-[Ir{MeC(CH$_2$AsMe$_2$)$_3$}Cl$_3$] have been detailed and the crystal structure of [Ir(tetras)(CO)Cl](BF$_4$)$_2$ reported.[217] All complexes undergo an irreversible Ir^{III}/Ir^I oxidation. The synthesis of *trans*-[IrCl(=CR$_2$)(Sb^{i}Pr$_3$)(P^{i}Pr$_3$)], R = C$_6$H$_5$, *p*-C$_6$H$_4$Me, is reported.[218]

6.2.5.9 Oxygen Ligands

6.2.5.9.1 Monodentate ligands

The single-crystal X-ray structure of *trans,mer*-[IrCl$_2$(OH$_2$)(PMe$_2$Ph)$_3$](ClO$_4$) exhibits a long Ir—O bond (2.189 Å) and a short Ir—P bond (2.249 Å) *trans* to it.[219] At room temperature the phosphine ligands are equivalent (^{31}P NMR) via the five co-ordinate square-pyramidal intermediate [IrCl$_2$(PMe$_2$Ph)$_3$]$^+$. Water exchange on [Ir(OH$_2$)$_6$]$^{3+}$ proceeds by an associative interchange mechanism, as determined by ^{17}O NMR studies, whereas it goes by an interchange mechanism on the deprotonated species [Ir(OH$_2$)$_5$(OH)]$^{2+}$.[220] Analogous studies on [Ircp*(OH$_2$)$_3$]$^{2+}$ showed that H$_2$O exchange was 10^{14} times faster than for [Ir(OH$_2$)$_6$]$^{3+}$ and proceeds by a dissociative mechanism.[221] The structure of [Ir(OH$_2$)$_6$]F$_3$·3H$_2$O has been studied by X-ray crystallography and NMR spectroscopy.[222] The aqua complexes [Ircp*(PMe$_3$)-R$_F$(OH$_2$)]X (R$_F$ = CF(CF$_3$)$_2$, X = BF$_4$, B(Ar$_F$)$_4$; R$_F$ = CF$_2$CF$_3$, CF$_2$CF$_2$CF$_3$, X = CF$_3$SO$_3$) and

$[Ircp^*(PPh_3)(CF_2CF_2CF_3)(OH_2)]BF_4$ have been synthesized and their molecular structures determined by single-crystal X-ray diffraction studies.[223] The complexes form hydrogen bonds from the H_2O ligands to the counterions or to additional outer-sphere water molecules. The dinuclear aqua ions $[(H_2O)_4Cr(\mu\text{-}OH)_2Ir(OH_2)_4]^{4+}$ and $[(H_2O)_4Rh(\mu\text{-}OH)_2Ir(OH_2)_4]^{4+}$ have been synthesized from oxygen-free alkaline media.[224]

The syntheses of Δ,Λ-$[(en)_2Ir(\mu\text{-}OH)_2Ir(en)_2](ClO_4)_4$, (**126**), and Δ,Λ-$[(H_2O)(en)_2Ir(\mu\text{-}OH)Ir(en)_2(OH)](S_2O_6)_{1.5}(ClO_4)_4 \cdot 2.75H_2O$, (**127**), have been reported.[225] The crystal structure of (**127**) shows that the terminal OH and H_2O ligands interact by a very short, symmetric H bond (2.429(9) Å). The thermodynamics and kinetics of the equilibrium reaction between (**126**) and (**127**) were studied spectrophotometrically at different pH values.

The binuclear complex $[H(binap)Ir(\mu\text{-}OMe)_2(\mu\text{-}Cl)IrH(binap)]Cl$ catalyzes the hydrogenation transfer from methanol to alkynes via the five co-ordinate intermediate [IrHCl(OMe)(binap)].[226]

The phosphate diesters $(O_2P(OR)_2)$, ethyl-4-nitrophenyl phosphate and bis(4-nitrophenyl)phosphate in *cis*-$[(en)_2Ir(OH)(O_2P(OR)_2]^+$, react intramolecularly with the *cis*-OH group at pH 8 to liberate nitrophenolate.[227]

Phenols react with $[Ir(cod)(PMe_3)_3]Cl$ to yield *mer*-$[(Me_3P)_3Ir(OAr)(H)(Cl)]$ (**128**).[228] The structure for (**128**), where Ar = 2,4-dimethylphenyl, is given. Carboxylic acids react with $[Ir(cod)(PMe_3)_3]Cl$ to afford *mer*-$[(Me_3P)_3Ir(OC(O)R)(H)Cl]$, (**129**), with the structures of (**129**) reported where R = Ph (**130**), C_6H_4OH-2. (**130**) reacts with $Tl[PF_6]$ to form *mer*-$[(Me_3P)_3Ir(\eta^2\text{-}O_2CC_6H_5)(H)][PF_6]$, which has been crystallographically characterized.[229]

Addition of CO to $Ir(SO_3F)_3$ dissolved in HSO_3F gives crystals of *mer*-$[Ir(CO)_3(SO_3F)_3]$.[230] IR spectroscopy and X-ray structural determination confirm the *mer* configuration. In solution (HSO_3F) there is evidence (IR and NMR) of a mixture of *mer*- and *fac*-isomers.

The X-ray structure of $[Ir(CO)(CH_3)(SO_4)(P(p\text{-tolyl})_3)_2]$, (**131**), shows that the phosphine ligands are *trans* to one another and the SO_4^{2-} is chelated to the Ir^{III} center.[231] Carbonylation of (**131**) yields $[Ir(CO)_3(P(p\text{-tolyl})_3)_2]^+$, which has also been characterized by single-crystal diffraction studies, and $[Ir(CO)_3(C(O)Me)(P(p\text{-tolyl})_3)_2]$.

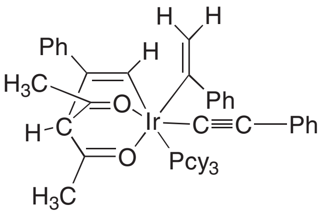
The complex $[Ircp^*(PMe_3)(CH_3)(otf)]$, otf = OSO_2CF_3, reacts with aliphatic C—H bonds (RH) and silane Si—H bonds (SiR_3H) to yield $[Ircp^*(PMe_3)(R)(otf)]$ and $[Ircp^*(PMe_3)(R)\{SiR_2(otf)\}]$, respectively.[232] Treatment of *trans*-$[Ir(CO)(PPh_3)_2Cl]$ (i) with HBF_4 gives $[Ir(CO)(PPh_3)_2Cl(H)(BF_4)]$; (ii) with Me_3OBF_4 yields $[Ir(CO)(PPh_3)_2Cl(Me)(BF_4)]$; and (iii) with Ag(otf) affords $[Ir(CO)(PPh_3)_2(otf)]$.[233] Further treatment of $[Ir(CO)(PPh_3)_2(otf)]$ with H(otf) results in the formation of *trans,cis*-$[Ir(PPh_3)_2(otf)_2(CO)(H)]$. The rate constant for solvolysis of $[Ir(NH_3)_5(otf)](otf)_2$ to $[Ir(NH_3)_5S](otf)_3$, where S = H_2O, MeOH, DMSO, DMF, CH_3CN, py, is relatively independent of solvent.[234] No simple relationship between rate constant and solvent properties was found. Base hydrolysis and aquation reactions of $[Ir(NH_3)_5(otf)]^{2+}$ have also been investigated.[235] The reaction between $[cp^*(PMe_3)Ir(otf)_2]$ and $[(PPh_3)_2Pt(HC{\equiv}CPh)]$ or $[(PPh_3)_2Pt(C_2H_4)]$ yields $[cp^*(PMe_3)Ir(\mu\text{-}H)(\mu\text{-}\eta^2,\eta^1\text{-}PhC{\equiv}C)Pt(PPh_3)_2](otf)_2$ and $[cp^*(PMe_3)Ir(\mu\text{-}H)(\mu\text{-}\eta^2,\eta^1\text{-}H_2C{=}CH)Pt(PPh_3)_2](otf)_2$, respectively, with the latter product characterized by X-ray diffraction studies.[236]

6.2.5.9.2 Bidentate ligands

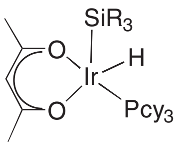
The series of complexes $[Ir(acacX)_n(acac)_{3-n}]$, where acacX = $CH_3COCXCOCH_3$ and X = F, Cl, Br, I, n = 1, 2, 3, has been prepared.[237–239] The molecular structures of $Ir(acac)_3$, $Ir(acacCl)_3$, $Ir(acacBr)_3$, and $Ir(acacI)_3$ have been determined. In the presence of Pcy_3, $[Ir(acac)(coe)(Pcy_3)]$ (**132**) reacts with H_2, RC=CH, R = Ph, cy, Me_3Si, or $HSiR_{3'}$, where $R_{3'}$ = Et_3, Ph_3, HPh_2, to give $[Ir(acac)H_2(Pcy_3)_2]$, $[Ir(acac)H(C_2R)(Pcy_3)_2]$, and $[Ir(acac)H(SiR_3)(Pcy_3)]$, respectively.[240] In the absence of Pcy_3, the addition of three equivalents of $PhC{\equiv}CH$ yields $[Ir\{\kappa^3\text{-}CH{=}C(Ph)CH[C(O)CH_3]_2\}(C_2Ph)(CPh{=}CH_2)(Pcy_3)]$, (**133**), which has been structurally characterized. The structure of (**134**), R = Et, has been confirmed by X-ray crystallography.

Trans oxidative addition of CH_3I to [Ir(acac)(cod)] affords the structurally determined complex $[Ir(acac)(cod)(CH_3)^I]$.[241] The reaction of $[(Npet)_2Ir]Cl$, Npet = {*o*-(diphenylphosphino)benzylidene}ethylamino, with tetrachloro-*o*-quinone yields the structurally characterized product (**135**).[242] The synthesis and characterization of the water-soluble complex (**136**) have been described.[243]

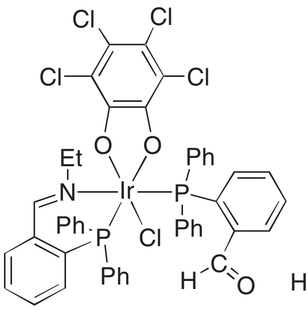
The preparation and characterization of five co-ordinate [(triphos)Ir(cat)]Z, H_2cat = 9,10-phenanthrenecatechol, 1,2-naphthalenecatecol, 3,5-di-tert-butylcatechol, 4-methylcatechol, 4-carboxycatechol Et ester, tetrachlorocatechol, Z = BPh_4, PF_6, have been reported.[244] All compounds



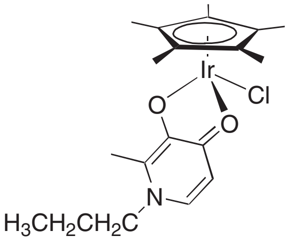
(133)



(134)



(135)



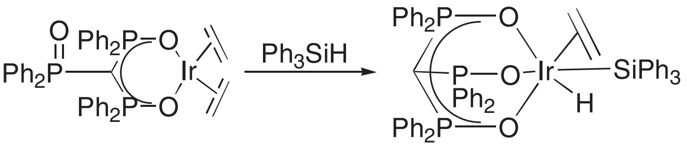
(136)

undergo electron-transfer reactions, and paramagnetic states have been studied by EPR spectroscopy. Most of the compounds react with O_2 to give [(triphos)Ir(OO)(sq)]Z, Hsq = semiquinone derivative. The O_2 adducts are also redox active.

The synthesis and characterization of tris-chelate Ir^{III} complexes of 2-(acetylamino)benzoic acid, 2-(benzoylamino)benzoic acid, 2-[(2-aminophenylamino)carbonyl]benzoic acid, maleanilic acid, malea-1-naphthalanilic acid, and 2-[(phenylamino)carbonyl]benzoic acid have been described.[245]

6.2.5.9.3 *Tridentate ligands*

The complex $[(\eta^2\text{-triso})Ir(C_2H_4)_2]$, (**137**), (triso = $C(Ph_2PO)_3{}^-$), undergoes oxidative addition with Ph_3SiH to form the η^3-triso complex $[Ir(triso)(C_2H_4)H(SiPPh_3)]$, (**138**), according to Reaction Scheme 17.[246,247] Both compounds catalyze the hydrosilylation of ethene.[248]



(137) **(138)**

Scheme 17

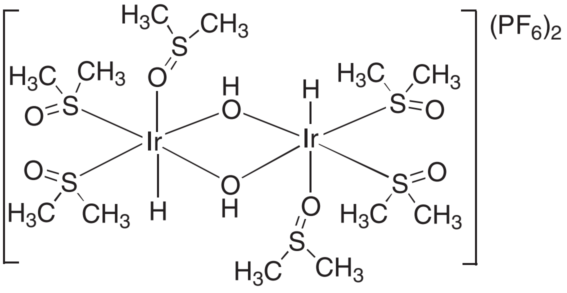
6.2.5.9.4 *Trinuclear complexes*

The structure of the trinuclear complex $[Ir_3(\mu_3\text{-O})(\mu\text{-}CH_3COO)_6(OH_2)_3](NO_3)_2$ has been determined.[249] The average Ir—Ir distance is measured at 3.34 Å. Addition of HCl gave $[Ir_3(\mu_3\text{-O})(\mu\text{-}CH_3COO)_6(OH_2)Cl_2]$. The trinuclear species are paramagnetic, with a magnetic moment equivalent to one unpaired electron per Ir_3 unit. The species $[Ir_3(\mu_3\text{-O})(\mu\text{-}CH_3COO)_6(OH_2)_3]^{2+}$ can be electrochemically reduced to the $Ir^{III}/Ir^{III}/Ir^{III}$ form.[250] The related complex $[Ir_3(\mu_3\text{-O})(\mu\text{-}CH_3COO)_6(py)_3]^+$, (**139**), has two reversible one-electron oxidation waves at +0.68 V and +1.86 V vs. Ag/AgCl in acetonitrile/0.1 M $[Bu_4N][PF_6]$.[251] The compound (**139**) has a featureless visible spectrum, whereas the mono-oxidized species $(\mathbf{139})^+$ has bands at 688, 1,093, and 1,400 nm which have been assigned to transitions involving orbitals based on the μ_3-O bridging ligand.

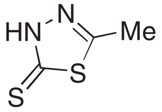
6.2.5.10 Sulfur and Selenium Ligands

6.2.5.10.1 *Monodentate ligands*

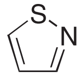
Treatment of $[Ir(coe)_2(O{=}CMe_2)_2]PF_6$ in acetone with DMSO followed by water yields the structurally characterized species (**140**), in which both *O*- and *S*-bonded DMSO ligands are present.[636] Reaction of $IrCl_3$ with ligand L, (**141**), in ethanol yields $IrLCl_3(OH_2)$, in which (**141**) binds to the metal center through the terminal S donor atom.[252]



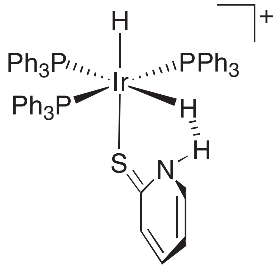
(140)



(141)



(142)



(143)

SF_4 reacts with *trans*-$Ir(CO)(X)(PEt_3)_2$, X = Cl, Br, in CD_2Cl_2 at 180 K to afford thermally stable $[Ir(CO)FX(PEt_3)_2(SF_3)]$.[253] The SF_3 ligand shows reversible fluxional behavior (200–300 K), as studied by ^{19}F and ^{31}P $\{^1H\}$ NMR spectroscopy.

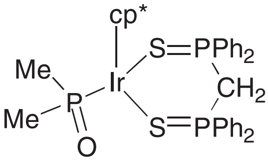
The isothiazide ligand, (**142**), and its 3- and 5-methyl derivatives form the tris complexes $IrCl_3(isothiazole)_3$ in which isothiazole and the 5-methyl derivative bind through the S atom, whereas 3-methylisothiazole binds through the N atom.[254]

The crystal structure of $[IrCl_4(SCl_2)_2](SCl_3)$ shows that the SCl_2^- ligands adopt a *cis* position around the metal.[255] Oxidation of *trans*-$Na_7[Ir(SO_3)_4Cl_2]\cdot 5H_2O$ by $Ce(SO_4)_2$ or $KMnO_4$ results in formation of $S_2O_6^{2-}$ and SO_4^{2-}.[256] Reaction of $IrH_3(PPh_3)_3$ with HBF_4 in the presence of pyridinethione, SpyH, affords $[IrH_2(\eta^1\text{-SpyH})(PPh_3)_3]BF_4$ (143).[257] A further SpyH can replace one PPh_3 ligand, giving $[IrH_2(\eta^1\text{-SpyH})_2(PPh_3)_2]BF_4$. The structures of both Ir—SpyH compounds and $[IrH(CO)(\eta^1\text{-SpyH})_2(PPh_3)_2]BF_4$ are reported and all show NH···HIr proton–hydride interactions, as shown in (**143**). The related complexes $[IrH(\eta^1\text{-SpyH})(\eta^2\text{-Spy})(PPh_3)_2]BF_4$, $[Ir(H)_2(\eta^1\text{-SpyH})_2(Pcy_3)_2]BF_4$, and $[IrH(\eta^1\text{-SpyH})_2(\eta^2\text{-Spy})(Pcy_3)]BF_4$ also exhibit the proton–hydride interaction.[258–260] NMR studies indicate that such interactions are maintained in solution.

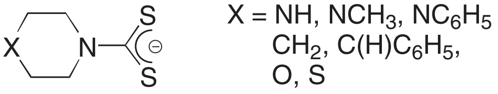
Reaction of $[Ircp^*Cl_2]_2$ with $(MeS)_2CH_2$ and $AgBF_4$ gives $[Ircp^*Cl(\eta^2\text{-}(MeS)_2CH_2)]BF_4$, whereas treatment with $(PhS)_2CH_2$ leads to $[Ircp^*Cl_2(\eta^1\text{-}(PhS)_2CH_2]$, characterized by X-ray crystallography.[261]

6.2.5.10.2 *Bidentate ligands*

Treatment of $[Ircp^*Cl_2]_2$ with $dppmE_2$ and $TlBF_4$ ($dppmE_2 = Ph_2P(E)CH_2P(E)Ph_2$, E = S, Se) gives $[Ircp^*Cl(dppmE_2)](BF_4)$ (**144**).[262,263] Further reaction with NaH leads to the deprotonation of $dppmE_2$ and formation of $[Ircp^*\{\eta^3\text{-}(EPPh_2)_2CH\}]^+$. $P(OMe)_3$ can displace the chloride ligand in (**144**) to produce $[Ircp^*(P(OMe)_3)(dppmE_2)]^{2+}$, which gives $[Ircp^*(PO(OMe)_2)(dppmE_2)]^+$ on treatment with NaI. The structure of (**145**)BF_4 has been determined. The analogous chemistry of the $(EPPh_2)_2NH$ ligands is described, with the crystal structure of $[Ircp^*Cl\{\eta^2\text{-}(SePPh_2)_2N\}]$ detailed.[264] The $\eta^2\text{-}(SePPh_2)_2N$ ligand binds in a bidentate Se, Se′ manner.



(145)

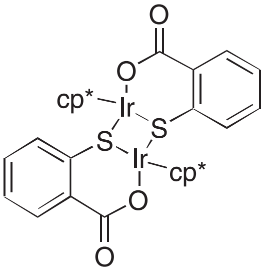


(146)

The synthesis and characterization of $[Ir(S_2P(Me_2\text{-}C_6H_3\text{-}2,4)_2)_3]$ and $[Ir(S_2CNMeR)_3]$, R = cyclohexyl, are reported.[265,266] Further tris dithiocarbamate (**146**) Ir^{III} complexes have been prepared and characterized by UV-vis spectroscopy.[267] The complex $[Ircp^*(1,2\text{-}C_6H_4S_2\text{-}S,S')]$ has been prepared and characterized by X-ray structural analysis.[268]

6.2.5.10.3 Binuclear complexes

The complex [Ir(μ-^{t}BuS)(CO)L]$_2$ reacts with dihalomethane to yield [IrX(μ-^{t}BuS)(CO)L]$_2$(μ-CH$_2$), X = I, L = CO, P(OMe)$_3$, PPh$_3$, PPh$_2$Me, PMe$_3$; X = Br, L = PPh$_3$.[269] The crystal structure of the product in which X = I and L = P(OMe)$_3$ has been determined and shows an Ir—Ir separation of 3.1980(4) Å. Reaction of [Ircp*Cl$_2$]$_2$ with two molar equivalents of thiosalicylic acid (HSC$_6$H$_4$COOH, H$_2$tsal) and excess base gives [cp*Ir(tsal)]$_2$ (**147**).[270]



(**147**)

6.2.5.10.4 Tridentate ligands

Reaction of [Ircp*Cl$_2$]$_2$ with AgBF$_4$ and (SPPh$_2$)$_3$CH in CH$_2$Cl$_2$ or Me$_2$CO to which Et$_3$N is added yields [Ircp*(η^3-(SPPh$_2$)$_3$C]BF$_4$, which has been structurally characterized.[271] The Ir^{III} complexes [Ircp*L^3](PF$_6$)$_2$ (L^3 = MeC(CH$_2$ER)$_3$, E = Se, R = Me; E = Te, R = Me, Ph) have been prepared and characterized by IR and multinuclear NMR spectroscopy.[647]

6.2.5.10.5 Halide ligands

A review of preparative methods for the synthesis of Ir–fluoro complexes is available.[272] Addition of I$_2$ to [Ir((*R*)-(*S*)-PPFP(Xyl)$_2$)cod]BF$_4$ in THF yields [IrI((*R*)-(*S*)-PPFP(Xyl)$_2$)(η^3,η^2-C$_8$H$_{11}$)]BF$_4$, which has been characterized using X-ray crystallography.[273] When the same reaction is carried out in CH$_2$Cl$_2$, then the structurally characterized product [Ir((*R*)-(*S*)-PPFP(Xyl)$_2$)^{I}(H)(C$_8$H$_{11}$I)]$^+$ is isolated. Abstraction of iodide from Ir(CF$_3$)(Cl)^{I}(CO)(PPh$_3$)$_2$ by AgSbF$_6$ in CH$_3$CN yields [Ir(CF$_3$)Cl(MeCN)(CO)(PPh$_3$)$_2$](SbF$_6$) (**148**).[274] The CH$_3$CN group can be displaced with CN-*p*-tolyl or H$^-$ to give [Ir(CF$_3$)Cl(CN-*p*-tolyl)(CO)(PPh$_3$)$_2$]$^+$ and [Ir(CF$_3$)HCl(CO)(PPh$_3$)$_2$], in which the CF$_3$ and H ligands are mutually *trans*. Addition of excess NaBH$_4$ to (**148**) affords *trans*-[Ir(CF$_3$)H$_2$(CO)(PPh$_3$)$_2$]. The X-ray structure of *cis*-[Ir(CO)$_2$I$_4$]$^-$(C$_{11}$H$_{12}$N)$^+$ has been reported.[275]

The complex *mer*-[IrCl$_3$(PEt$_2$Ph)$_3$] readily substitutes the Cl$^-$ ligand *trans* to PEt$_2$Ph with CN$^-$, to give the structurally characterized species *trans,mer*-[IrCl$_2$(CN)(PEt$_2$Ph)$_3$].[276] Extended irradiation by white light gives the *cis,mer*-[IrCl$_2$(CN)(PEt$_2$Ph)$_3$] isomer, which has also been analyzed by X-ray diffraction.

The reaction of [IrBr$_2$cp*]$_2$ with [Re(μ-Br)(CO)$_3$(C$_4$H$_8$O)] yields the structurally characterized complex [cp*Ir(μ-Br)$_3$Re(CO)$_3$].[277] In solution the complex is in dynamic equilibrium with [cp*Ir(μ-Br)$_3$Ircp*][(CO)$_3$Re(μ-Br)$_3$Re(CO)$_3$]. The preparation of [cp*Ir(μ-Cl$_3$)Ru(PPh$_3$)$_2$Cl] has been published.[278]

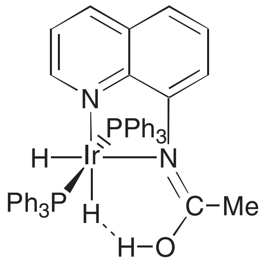
IrCl$_3$ reacts with excess active magnesium (Mg*) or Et$_2$Mg to form the inorganic Grignard reagents [Ir(MgCl)$_3$] and [IrMgCl·MgCl$_2$], respectively.[279] Hydrolysis or alcoholysis of THF solutions of the inorganic Grignard delivers finely divided X-ray amorphous Ir.

6.2.5.11 Hydrogen Ligands

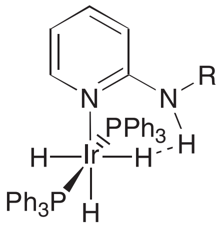
The complex Ir(H)$_2$Br(CO)(dppe), formed via the oxidative addition of H$_2$ to [IrBr(CO)(dppe)], has the hydrogen ligands in a *cis* configuration *trans* to Br$^-$ and one of the P-donor atoms, as determined by X-ray crystallography.[280] [Ir(PMe$_3$)$_4$]PF$_6$ undergoes oxidative addition of H$_2$O to yield stable *cis*-[IrH(OH)(PMe$_3$)$_4$]PF$_6$ (**149**).[281] Exchange reactions of (**149**) with D$_2$O and MeOH afford *cis*-[Ir(H)(OD)(PMe$_3$)$_4$PF$_6$ and *cis*-[IrH(OMe)(PMe$_3$)$_4$]PF$_6$ (**150**), respectively.[282] (**149**) and

(**150**) have been crystallographically characterized, with (**149**) showing a much smaller Ir—O—H angle (91(±7) °) compared to Ir—O—CH_3 (119.4(±0.9) °) in (**150**). The complexes $[IrH(H_2)bqL_2]^+$, L = PPh_3, Pcy_3 and $[IrH_2(H_2)_2(Pcy_3)_2]^+$, have been synthesized and characterized by ^1H NMR spectroscopy.[283]

The structurally characterized iminol complex $[IrH_2L'(PPh_3)_2]SbF_6 \cdot 2H_2O$, (**151**), contains an O—H···H—Ir proton–hydride bond calculated at 1.58 Å.[284] A series of related complexes replacing the amide Me group by ^{n}Bu, *p*-tolyl, Ph, *p*-FC_6H_4, 3,4-$F_2C_6H_3$ show a similar H···H interaction in common with complexes (**152**).[285] (**152**) exhibits an intramolecular N—H···H—Ir hydrogen bond (1.80 Å), as evidenced by ^1H NMR studies.[286] Replacement of one hydride ligand by a fluoride results in the complex $[Ir(H)_2F(PPh_3)_2(pyNHR)]$, which shows N—H···F—Ir hydrogen bonding.

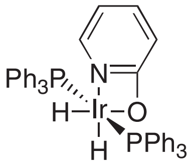


(**151**)

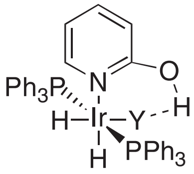


R = Ph, H

(**152**)



(**153**)



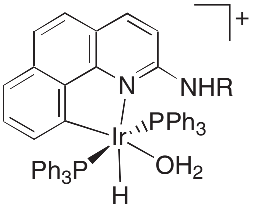
(**154**)

Treatment of $[IrH_5(PPh_3)]_2$ with 2-hydroxy-pyridine in benzene yields the structurally determined complex (**153**), which reacts with HY (Y = Cl, Br, I) to give (**154**).[287]

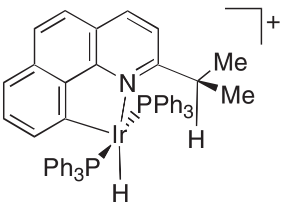
NMR studies indicate that the rotamer of (**154**), in which the *trans* H and Y ligands are transposed, is also formed. Replacement of 2-hydroxypyrdine with 2-aminophenyl pyridine (pyNHPh) gives the complexes $[Ir(PPh_3)_2(H)_2Y(pyNHPh)]$, Y = F, Cl, Br, I, which show analogous hydrogen-bonding interactions to (**154**). The N—H···H—Ir hydrogen bonds are stronger than N—H···Cl—Ir bonds.

Synthesis of the complex $[Ir(PPh_3)_2(H)(OH_2)(bqNH_2)]^+$ has been detailed.[288] The H_2O ligand may be readily substituted by F^-, which has an intramolecular NH···F—Ir hydrogen bond. Treatment with HBF_4–Et_2O yields $[Ir(PPh_3)_2(H)(FH)(bqNH_2)]^+$, which exhibits Ir—F—H···NH_2 intramolecular bonding.

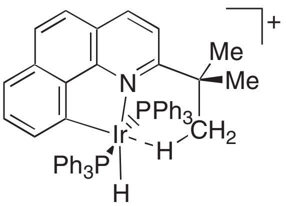
The synthesis and structural determination of (**155**), R = ^{i}Pr, have been reported. The structure shows hydrogen bonding between the hydrogen of the NHR group and the lone pair of electrons on the water oxygen.[289] Replacing the H_2O ligand in (**155**), R = H, by fluoride gives the structurally determined complex $[IrH(F)(PPh_3)_2(bq\text{-}NH_2)]$, with an H···F distance of 1.813 Å. A DFT study of the intramolecular hydrogen-bonded compounds has been detailed.[290] Reaction of (**155**), R = H, with H_2 yields $[Ir(H)_2(bq\text{-}NH_3)(PPh_3)_2]BF_4$, as characterized by ^1H NMR spectroscopy.[291] Replacing the NHR pendant arm in (**155**) by ^{t}Bu and ^{i}Pr results in complexes (**156**) and (**157**), respectively, which have been studied by X-ray crystallography.[292] Note that for the ^{t}Bu derivative an agostic interaction is observed, which is absent in the ^{i}Pr compound. Calculations (B3PW91/UFF) suggest that weak ligand–ligand interactions, such as parallel aromatic stacking between P—Ph and bq ligands, is important. Similar proton–hydride interactions are discussed for sulphur-bound ligands.[258–260]



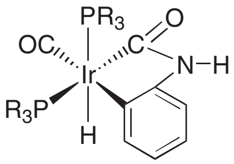
(**155**)



(**156**)



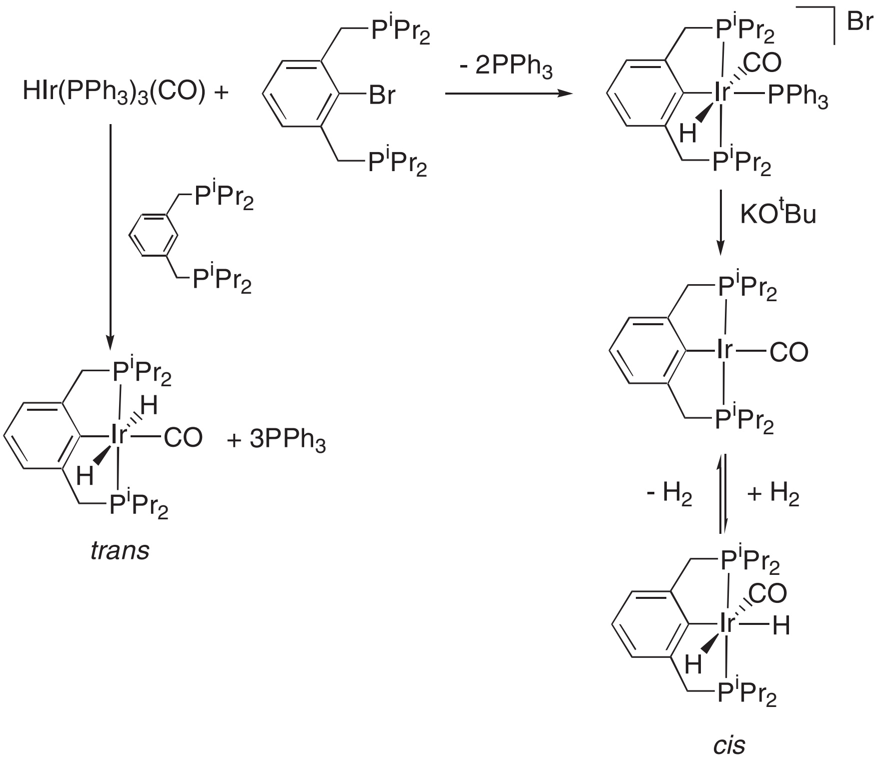
(**157**)



(**158**)

The reaction of $IrCl_3 \cdot 3H_2O$ with Pcy_3 and PPh_3 gives $[IrHCl_2(Pcy_3)_2]$ and $[IrHCl_2(PPh_3)_3]$, respectively.[293] Further reaction of $[IrHCl_2(PPh_3)_3]$ with NaOEt in THF under H_2 yields *fac*-[$IrH_3(PPh_3)_3$]. The carbonylation reaction of *trans*-$Ir(PR_3)_2(CO)(NHAr)$, R = Ph, Ar = Ph, *o*-tolyl, *p*-tolyl, *p*-C_6H_4Cl, 2,6-$C_6H_3Me_2$, 3,5-$C_6H_3Me_2$; R = Me, Et, Ar = Ph, yields the hydride complex (**158**).[517,520]

The *cis* and *trans* isomers of H_2IrCOL ($L = C_6H_3(CH_2P(^iPr_2))_2$) are prepared from $HIr(PPh_3)_3(CO)$, according to reaction Scheme 18.[294] Under H_2 pressure the *cis* form isomerizes into the *trans* species. Electrophiles such as [Ph_3C]BF_4, PhC(O)Cl, CS_2, and MeI directly attack the hydride ligands of the *trans* isomer. Addition of H_2 to [$Ir(CO)ClP_2$] to afford [$Ir(CO)Cl(H)_2P_2$] is 45 times faster for the $P = PPh_2(C_6H_4SO_3K\text{-}m)/H_2O$ system than for the $P = PPh_3$/toluene system.[295]



Scheme 18

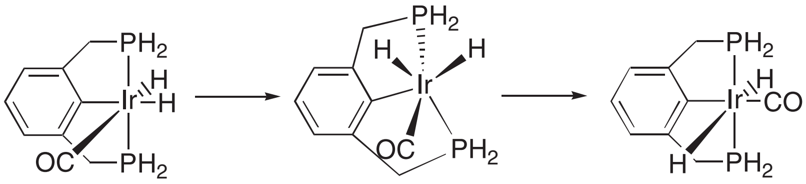
Thermolysis of *trans*-[$Ir(H)(OCH_3)(C_6H_5)(PMe_3)_3$] yields *trans*-[$Ir(H)_2(C_6H_5)(PMe_3)_3$] and formaldehyde.[296] Extensive mechanistic studies show that the β-hydride elimination process does not follow the usual pathway. Me_3NO selectively abstracts the proton from [$IrH(CO)(PPh_3)_2L(A)$]$^{0,1+,2+}$, $A = C_2Ph$, Cl, CH_3CN; $L = CH_3CN$, Cl, ClO_4, to give the *trans* elimination product [$Ir(CO)(PPh_3)_2A$]$^{0,1+}$.[297] The rate-determining step is found to be formation of $(PPh_3)_2L(A)(CO)Ir$—H—ON + Me_3, where L = A = Cl. The rate varies with A and L.

Flash photolysis reactions of [$Ir(H)_2Cl(L)(PPh_3)_2$], L = CO, PPh_3, in deareated benzene, proceed by ligand, L, dissociation to give [$Ir(H)_2Cl(PPh_3)_2$], followed by rapid H_2 elimination to yield $IrCl(PPh_3)_2$, which reacts with CO or PPh_3 to form [$IrCl(CO)(PPh_3)_2$] and [$IrCl(PPh_3)_3$], respectively, with rate constants of 25×10^8 M^{-1} s^{-1} and 13×10^7 M^{-1} s^{-1}.[298]

Heating (at 100 °C), or photolysis by visible light, of the 1:1 mixture of [$IrH_3(PPh_3)_3$]:C_{60} in toluene gives a product whose UV-vis spectrum is characteristic of η^2-coordinated C_{60}.[299]

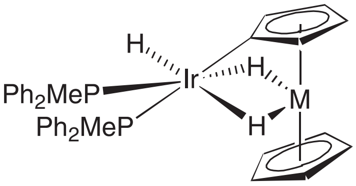
Density functional theory (B3LYP) has been used to investigate the mechanism of the *cis*-*trans* isomerization in $Ir(H)_2(CO)(C_6H_3\{CH_2P(H_2)\}_2)$.[300] The preferred mechanism involves two consecutive trigonal twists in which the complex passes through a distorted octahedral intermediate, as shown in reaction Scheme 19.

Intramolecular hydrogen exchange in $IrX(H)_2(\eta^2\text{-}H_2)(PR_3)_2$, X = Cl, Br, I; R = H, Me, has been studied using density functional calculations (B3LYP).[301] The two lowest-energy processes are rotation of the H_2 ligand and oxidative addition of the η^2-H_2 to form an intermediate Ir^V tetrahydride, which undergoes rapid reductive elimination to interchange the dihydrides and the dihydrogen.



Scheme 19

Reaction of $[IrH_5(PEt_3)_2]$ with "$RhClL_2$", $L = PEt_3$ or $L_2 =$ diphos, gives $[L_2Rh(\mu\text{-}H)(\mu\text{-}Cl)\text{-}IrH_2(PEt_3)_2]$.[302] The X-ray structure of the complex in which $L = PEt_3$ confirms a square-planar geometry around Rh and octahedral coordination to Ir. The Rh—Ir distance is 2.898(1) Å, and the asymmetrically bridging Cl^- ligand is closer to Rh. The X-ray structures of bimetallic complexes (**159**), where M = Mo and W, show that the Mo—Ir distance of 2.641(1) Å is significantly shorter than the W—Ir distance at 2.706(1) Å.[303]



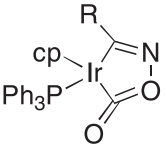
(159)

The preparation and NMR characterization of $[(\text{triphos})(H_{3-x})Ir(\mu\text{-}H)_xHgR](CF_3SO_3)$, R = n-$C_{12}$-$H_{25}$, $PhCH_2$, 2,4,6-$Me_3C_6H_2$, Ph, 4-ClC_6H_4, 2,4,6-$Cl_3C_6H_2$, in CD_2Cl_2 at −80 °C have been described.[304] The structures of complexes *cis*-$[IrH(H_2)Cl_2(P^iPr_3)_2]$, (**160**), and $[Ir(H)_2Cl(P^tBu_2Ph)_2]$, (**161**), have been studied by neutron diffraction.[305] (**161**) contains a planar H_2IrCl fragment in a Y shape, with an H—Ir—H angle of 73 °. ECP *ab initio* calculations show that the *cis* form of (**160**) is more stable than the *trans* configuration, with the Ir—H_2 interaction stronger in the *cis* form. The structure of $[IrCl_2(NH_3)H(PCy_3)_2]$ has been reported.[306]

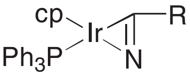
6.2.5.12 Mixed-donor-atom Ligands

6.2.5.12.1 C/N

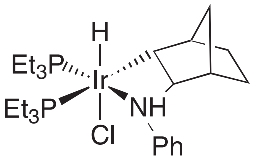
Thermolysis of (**162**), R = p-ClC_6H_4, p-FC_6H_4, results in loss of CO_2 and the formation of the kinetically stable side-bonded nitrile (**163**).[307] The crystal structure of (**163**) in which R = p-Cl-C_6H_4 has been determined. The insertion product from the reaction of $[Ir(PEt_3)_2(C_2H_4)Cl]$ with aniline and norbornylene is $[Ir(PEt_3)_2(NHPhC_7H_{10})(H)Cl]$, (**164**), which has been characterized by NMR spectroscopy and single-crystal X-ray diffraction.[308] Decomposition of (**164**) proceeds via two competing pathways to give either norbornylene and a reactive Ir intermediate, or *exo*-2-(phenylamino)norbornane.



(162)



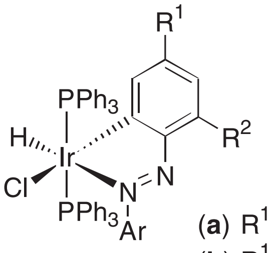
(163)



(164)

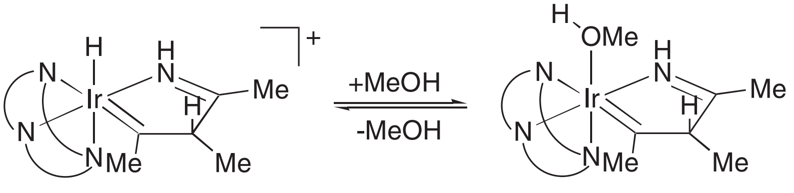
The synthesis and X-ray structural determination of a stable Ir^{III} hydride/alkylidene complex, (**165**), has been reported, in which the tridentate N_3 ligand is Tp^{Me2}.[309] The complex undergoes reversible hydride migration onto the electrophilic carbene atom, as shown in reaction Scheme 20.

The X-ray structures of two ortho-metalated compounds, (**166**), have been discussed.[310] Weak interactions between the hydride ligand and C—H protons of the PPh_3 groups are recorded.



(**166**)

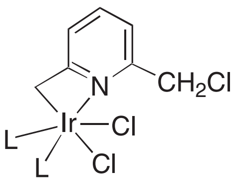
(**a**) R^1 = MeO, R^2 = H, Ar, *p*-$MeOC_6H_4$
(**b**) R^1 = H, R^2 = Cl, Ar = Ph



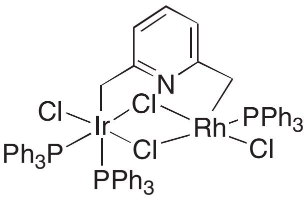
(**165**)

Scheme 20

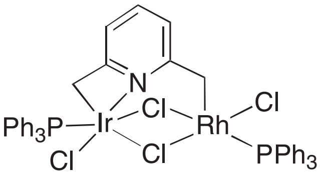
Oxidative addition of $[Fe\{\eta^5-C_5H_4(2-C_5H_4N)\}\{\eta^5-C_5H_4PPh_2\}]$ to $[Ir(cod)Cl]_2$ results in the structurally characterized species $[Ir(H)\{Fe(\eta^5-C_5H_3(2-C_5H_4N))(\eta^5-C_5H_4PPh_2)\}(cod)]PF_6$, which contains the PNC-bound derivative of ferrocene.[311] The syntheses and structures of (**167**), (**168**), and (**169**) are described.[312]



(**167**)

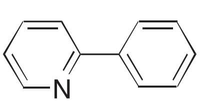


(**168**)

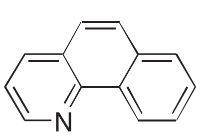


(**169**)

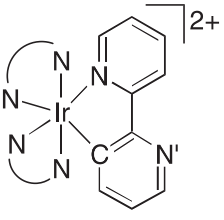
The most frequently reported mixed C/N-donor ligands are the 2-phenylpyridine anion, ppy (**170**), orthometalated 2,2′-bipyridine, C3N′bpy (**171**), and derivatives, for example (**172**).



ppyH
(**170**)



Benzo[h]quinoline bqH
(**172**)



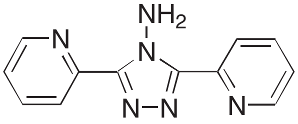
N⌒N = bpy
(**173**)

Complexes of the type$[Ir(L)_2(S)_2](otf)$ have been prepared by reaction of $[Ir(L)_2Cl]_2$ with Ag(otf) in solvent S, L = ppy or ptpy, S = H_2O pr CH_3CN.[313] The complexes were characterized by ^1H and ^{13}C NMR spectroscopy, UV-vis absorption and emission spectroscopy, and cyclic voltammetry.

The species $[Ir(bpy)_2(C3N'bpy)]^{2+}$ (**173**) protonates at pH < 3, giving $[Ir(bpy)_2(C3N'Hbpy)]^{3+}$, (**174**).[314] In strong acid (pH < 1.7), the one-electron reduction product of (**174**) reacts directly with H^+ to give H_2. At higher pH, reduction of (**173**) is followed by disproportionation and then reaction with H^+ or H_2O to yield H_2. In all cases the reduction site is *N*,*N*′-bound bpy.

Rate-constant data are reported. Pulse radiolysis of (**173**) or (**174**) in water plus 2-propanol produces the monoreduced species. Addition of small amounts of poly(styrenesulfonate), PSS, to the solution enhances decay of the monoreduced from of (**173**) and (**174**) and catalyzes the formation of H_2.[315] If colloidal Pt is added to the system, then the decay rate of $(\mathbf{173})^-$ is further enhanced. The order of the reaction with respect to [Pt] changes from one at low [(**173**)] to nearly two upon increasing the concentration of (**173**), which suggests that adsorption of (**173**) onto Pt is important.[316] Similar physical measurements have been reported for the system containing (**173**) or (**174**), tetramethoxybenzene or dimethoxybenzene (DMB), and PSS.[317] Immobilization of (**173**) and $[Ru(bpy)_3]^{2+}$ in a rigid porous SiO_2 matrix results in H_2 evolution when the matrix/aqueous DMB system is irradiated by an N_2 laser or Hg lamp.[318]

The complex $[Ir(ppy)_2(dpt\text{-}NH_2)]PF_6$ (**175**), dpt-NH_2 = 4-amino-3,5-bis(2-pyridyl)-4*H*-1,2,-4-triazole, (**176**), has been synthesized and characterized.[319] A reversible, one-electron oxidation of (**175**) is assigned to removal of an electron from an Ir $d\pi$-based orbital. (**175**) luminesces at room temperature and 77 K. The complex (**175**), when immobilized in a polymeric matrix, acts as an oxygen sensor.[320]



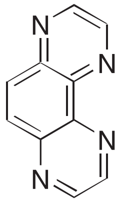
dpt-NH_2

(**176**)

Further optical oxygen sensors which have been developed are those of $[Ir(LH)(L)](PF_6)_2$ and $[Ir(L)_2]PF_6$, LH = 2,6-bis(7′-methyl-4′-phenyl-2′-quinolyl)pyridine, immobilized in a polymeric matrix[321], and $[Ir(ppy)_3]^{3+}$ immobilized in fluoropolymer film.[322]

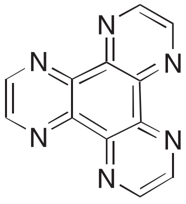
Reactions of $IrCl_3{\cdot}H_2O$ with 2-(*p*-tolyl)pyridine(ptpy) and 3-methyl-2-phenylpyridine(mppy) gave $[Ir(ptpy)_2Cl]_2$ and $[Ir(mppy)_2Cl]_2$, respectively.[323] Treatment with bpy afforded [Ir $(ptpy)_2$-bpy]Cl and $[Ir(mppy)_2bpy]Cl$. All complexes were characterized by UV-vis, emission spectroscopy, and cyclic voltammetry.

The electrochemical and spectroscopic properties of $[Ir(ppy)_2Cl]_2$, $[Ir(bq)_2Cl]_2$, $[Ir(ppy)_2$-(NN)]Cl, and $[Ir(bq)_2(NN)]Cl$, NN = bpy or phen, have been reported.[324] The binuclear species have metal-centered oxidations, and the monomers NN-based reductions. The mixed-ligand monomers exhibit dual emissions from MLCT states associated with both ortho-metalated (higher-energy) and NN ligands.[325,326] Reaction of Hppy with $Ir(acac)_3$ gives *fac*-$[Ir(ppy)_3]$.[327] Similar reactions of phenyl-ring-substituted Hppy, namely 4R-Hppy, where R = Me, Pr, ${}^tBu$, F, MeO, yields *fac*-$[Ir(R\text{-}ppy)_3]$. The structure of $[Ir(Me\text{-}ppy)_2Cl]_2$ has been detailed.[328] Electrochemical studies on $[Ir(ppy)_2(tap)]^+$ and $[Ir(ppy)_2(hat)]^+$, tap = (**177**), hat = (**178**), show two reversible reductions on the tap or hat ligand and an irreversible oxidation.[329]



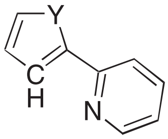
tap

(**177**)



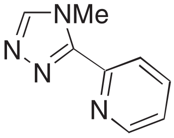
hat

(**178**)



Hthpy

(**179**)



4mptr

(**180**)

$[Ir(ppy)_2hat]^+$ exhibits dual emission at 77 K. The bimetallic complex $[(ppy)_2Ir(\mu\text{-hat})\text{-}Ru(bpy)_2]^{3+}$ has three reversible reduction waves; the first two involve the bridging hat ligand, and the third process is attributed to a bpy-based process.[330] The complex also has an irreversible oxidation. Low-energy ($\sim$19,000 cm^{-1}) bands are assigned as $Ru^{II} \rightarrow$ hat π^* transitions.

Reaction of $[Ir(CO)(CH_3CN)(PPh_3)_2]PF_6$ with bqH (**172**) gives the structurally characterized product *trans*-$[Ir(H)(CO)(bq)(PPh_3)_2]PF_6$, in which the CO ligand is *trans* to the orthometalated

C(3) cation of the ppy ligand.[331] The comparable species [Ir(H)(OH_2)(bq)(PPh_3)$_2$]SbF_6, has a similar structure.[332]

The syntheses and characterization of [Ir(ppy)$_2$NN]$^+$ and [Ir(thpy)$_2$NN]$^+$, NN = bpy, en, Hthpy = 2-(2-thienyl)pyridine, **(179)**, in which the thpy ligand is C/N bound, are detailed.[333]

The lowest-energy excited states of [Ir(ppy)$_2$NN]$^+$ and [Ir(thpy)$_2$NN]$^+$ may be assigned to either a $^3(\pi-\pi^*)$ state on the C/N ligand or a ^{3}MLCT Ir → bpy transition, depending on the environment of the complex. In the solid phase, a crystalline [Rh(ppy)$_2$bpy]PF_6 lattice, the $^3(\pi-\pi^*)$ transition is at lowest energy, but the ^{3}MLCT state is lowest in solution.[334] The ortho-metalated complex [Ir(ppy)$_2$(4mptr)]PF_6, 4mptr = 4-methyl-3-(pyridin-2-yl)-1,2,4-triazole, (**180**), has been synthesized and characterized by X-ray crystallography, NMR spectroscopy, electrochemical measurements, UV-vis absorption and emission spectroscopy.[335] The *cis* ppy ligands have *trans* Ir—N bonds, and the 4mptr ligand coordinates through the pyridine nitrogen and *N*2 of the triazole ring. The complex has an irreversible oxidation (Ir based) and a reversible reduction (ppy based), and emits at room temperature (broad band at 582 nm) and at 77 K (highly structured band at 471 nm).

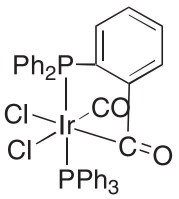
The complex *fac*-[Ir(Fppy)$_3$], Fppy = 2-(4,5-difluorophenyl) pyridine, has been used as a phosphorescent dye in polymer-based, organic, light-emitting diodes.[336] The maximum external quantum efficiency reached is ~1.8%. Endothermic energy transfer from CBP (4,4′-*N*,*N*′-dicarbazole-biphenyl) to [Ir(F′ppy)$_2$(pic)], [Ir(ppy)$_2$(acac)], or [Ir(F′ppy)$_2$(acac)], F′ppy = 2-(4,6-difluorophenyl) pyridine, leads to blue electroluminescence with an external quantum efficiency of 5.7%.[337,338] Replacing CBP for 3-phenyl-4-(1′-naphthyl)-5-phenyl-1,2,4-triazole results in a 19% external quantum efficiency for [Ir(ppy)$_2$(acac)].[339] The X-ray structures of *fac*-[Ir(F″ppy)$_3$], where F″ppy = 3-$C_6H_4(CF_3)$-py-CF_3-5, 4-C_6H_4F-py-CF_3-5, 2-C_6H_4F-py-CF_3-5 and 3-$CH_3OC_6H_4$-py-CF_3-5, are reported.[340] The complexes exhibit fully reversible reduction and oxidation waves. Most complexes show good electroluminescence efficiencies, with the peak emission maximum dependent on substituent. The electrochemiluminescence efficiencies of [Ir(ppy)$_3$] in CH_3CN, CH_3CN/H_2O (1:1), and aqueous 0.1 M KH_2PO_4 with tri-*n*-propylamine are 0.33, 0.0044, 0.00092, respectively, using [Ru(bpy)$_3$]$^{2+}$ with an efficiency of 1.0 as the standard.[341]

The syntheses, photophysical and electrochemical properties of [Ir(ppy)$_2$(phen-NS-5)]PF_6, (**181**), [Ir(ppy)$_2$(phen-NHCOCH$_2$I-5)]PF_6, (**182**), and [Ir(ppy)$_2$(phen-NH$_2$-5)]PF_6 are reported.[342] Complexes (**181**) and (**182**) have been used to label amine- and sulfhydryl-modified oligonucleotides and human serum albumin to give luminescent bioconjugates.

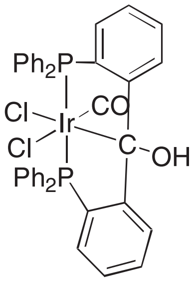
Reaction of [M(ppy)$_2$Cl]$_2$ with [M′(cod)Cl]$_2$ affords the binuclear species [(ppy)$_2$M(μ-Cl)$_2$-M′(cod)], M = M′ = Rh, Ir, M = Rh, M′ = Ir. Treatment of [Ir(ppy)$_2$Cl]$_2$ with [(PR_3)$PtCl_2$]$_2$, R = Bu, Et, produces [(ppy)$_2$Ir(μ-Cl)$_2$Pt(PR_3)Cl].[343]

6.2.5.12.2 C/P

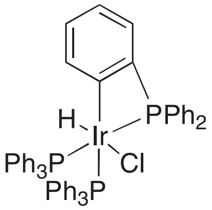
Bis-chelating C/P donor ligands on Ir^{III} are formed from the electrophilic addition of dichlorocarbene ligands to triphenylphosphine ligands.[344] The X-ray crystal structures of (**183**) and (**184**) confirm the metallacycle ligand arrangement. Reaction of [IrCl(coe)$_2$]$_2$ with PPh_3 gives [IrCl(PPh_3)$_3$], which yields (**185**) after heating in cyclohexane.[345]



(183)



(184)

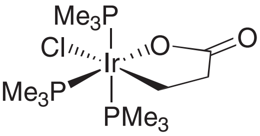


(185)

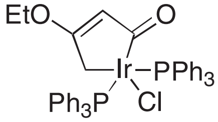
6.2.5.12.3 C/O

[Ir(coe)(PMe_3)$_3$Cl] undergoes oxidative addition with β-propiolacetone to yield the structurally characterized complex *mer*-[($CH_2CH_2CO_2$)Ir(PMe_3)$_3$Cl], (**186**).[346] The structure of the stable

16-electron α-acyl ester endolate Ir^{III} complex (**187**) has been reported.[347] Complex (**187**) adds CO and CH_3CN reversibly.



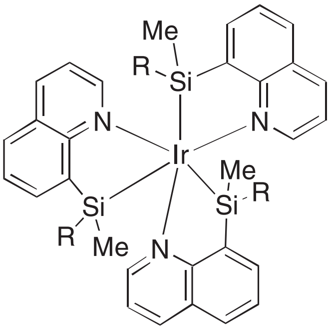
(**186**)



(**187**)

6.2.5.12.4 Si/N

The luminescence lifetimes of ΔRRR, ΛSSS, ΔRRS, and ΛSSR diastereomers (**188**), R = Ph, show that the symmetric forms are longer lived by a factor of two than the less symmetric species and are solvent dependent.[348] The X-ray structure of R = Me confirms the *fac* arrangement of the Si/N ligands.[349]

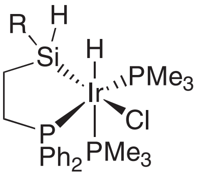


(**188**)

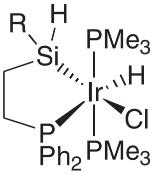
6.2.5.12.5 Si/P

Reaction of $[Ir(cod)Cl]_2$ with an excess of $PPh_2CH_2CH_2SiMe_2H$ (Si/P) in THF affords $Ir(PPh_2CH_2CH_2SiMe_2)_2Cl$, whereas when two molar equivalents of the (Si/P) ligand are used, then the compound $[Ir(PPh_2CH_2CH_2SiMe_2)(cod)(H)(Cl)]$ is isolated.[350] Both Ir^{III} complexes have been characterized by X-ray diffraction, and show shorter equatorial bonds in the five co-ordinate species compared to the six coordinate complex.[351] When $[Ir(CO)(PMe_3)_4]Cl$ is heated in toluene with $PPh_2CH_2CH_2Si(mes)H_2$ the *cis*-$[Ir(PPh_2CH_2CH_2SiH(mes))(Cl)(H)(PMe_3)_2]$ complex results, and may be photolyzed to the structurally determined *trans* form in which the Cl ligand is *trans* to Si donor atoms.[352] The Cl ligand may be replaced in the *cis* form by metathesis with MeLi or EtMgBr. Heating $[Ir(PPh_2CH_2CH_2SiH(mes))(R)(H)(PMe_3)_2]$ (R = Me, Et) leads to the reductive elimination of RH. Thermolysis of $[Ir(PPh_2CH_2CH_2SiMe_2)(Et)(H)(PMe_3)_2]$, $Ir(Si/P)_2(PMe_3)$-(Et)(H), affords a 1:1 mixture of $[Ir(Si/P)(PMe_3)_2(C_2H_4)]$ and $[Ir(Si/P)(PMe_3)_2(H)_2]$.[353]

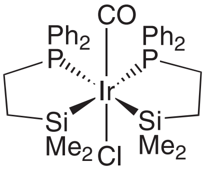
Photolysis of complex (**189**), R = mesityl, causes geometric isomerization to (**190**), with the structure (**190**) established by single-crystal diffraction studies.[354] Reaction of $Ph_2P(CH_2)_2Si(Me)_2$-$Si(Me)_2(CH_2)_2PPh_2$ with *trans*-$[Ir(PPh_3)_2(CO)Cl]$ yields complex (**191**) via an oxidative addition reaction to the Si–Si linkage.[355]



(**189**)



(**190**)

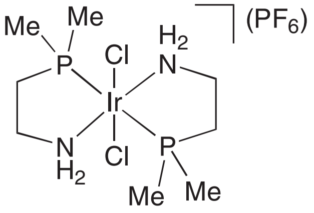


(**191**)

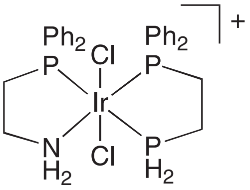
6.2.5.12.6 N/P

Reaction of $[IrCl(cod)]_2$ and *o*-$Ph_2PC_6H_4NHR$, R = CH_2Ph, Et, yields the *P*-bound species $[IrCl(cod)(o\text{-}Ph_2PC_6H_4NHR)]$.[356] Treatment with $AgClO_4$ affords the N/P-chelated complex $[Ir(cod)(o\text{-}Ph_2PC_6H_4NHR)]ClO_4$. Reaction of $[IrCl(coe)_2]_2$ with *o*-$Ph_2PC_6H_4NHR$ gives $[IrHCl(o\text{-}Ph_2PC_6H_4NR)(o\text{-}Ph_2PC_6H_4NHR)]$, which forms $[IrHCl(o\text{-}Ph_2PC_6H_4NHR)_2]Cl$, (**192**), on addition of HCl. The structure of (**192**), where R = CH_2Ph, shows that the H and Cl groups are in the axial positions and the chelate ligands have a mutual *cis* geometry.[356]

The structure of $[IrCl_2(edmp)_2]PF_6$, (**193**), edmp = (2-aminoethyl)dimethyl phosphine, confirms that the coordination geometry around the Ir center is approximately octahedral.[357] If the edmp ligand is replaced by edpp, edpp = (2-aminoethyl)diphenylphosphine, then the isomeric form (**194**) may be isolated and structurally characterized. The X-ray crystal structure of *fac*-$[Ir(edmp)_3]Cl_3\cdot 5H_2O$ has also been reported.[358]



(**193**)

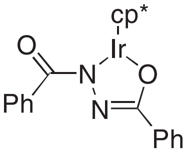


(**194**)

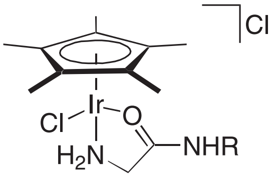
Treatment of $[IrCl(CO)_2(p\text{-toluidene})]$ with azine phosphines of type *Z*, *E*-$PPh_2CH_2C(^tBu){=}N\text{-}N{=}C(Q)R$, Q = H, Me, R = an organic group, activates aryl, heterocyclic, alkenyl, or aliphatic C—H bonds to give cyclometalated Ir^{III} hydrides.[359]

6.2.5.12.7 N/O

The complex cp*Ir[OC(Ph) =NNCOPh], (**195**), was obtained from the reactions of cp^*IrN^tBu or $[cp^*Ir(\mu\text{-}OH)_3Ircp^*]OH$ with $(PhCONH)_2$.[360] X-ray structural analysis suggests that the product species should be considered as an electronically unsaturated Ir^{III}, 16-electron complex with normal oxide and amido bonds. The synthesis of the chiral half-sandwich complexes (**196**) and (**197**) has been detailed.[361]



(**195**)



R = H, CH_2CO_2Et

$R^1 = H, R^2 = CH_2CO_2Me$
$R^1 = H, R^2 = CH_2CO_2Et$

(**197**)

The biologically important 2-hydroxyiminocarboxylic acid ligands chelate to Ir^{III} centers to give (**198**), where R = CH_3, $D_o = P(OMe)_3$, PMe_3, PEt_3, PPr_3, PPh_3, py; R = CH_2Ph, $D_o = PEt_3$, PPh_3, py. The structure of (**198**), where R = CH_3, P = PMe_3, has been determined by X-ray crystallography.[362] Further related complexes, from the same laboratory and characterized by single-crystal diffraction studies, are (**199**), (**200**), and (**201**).[363]

Reaction of H_3IrCl_6 and 1,2-naphthoquinone-1-oxime (1-nqoH) (**202**) and py yields the structurally characterized species $[pyH][Ir(1\text{-nqo})(py)Cl_3]$.[364] In the absence of py, $[Ir(1\text{-nqo})_3]$ results. The spectral properties of the complexes $[Ir(N/O)_2Cl_2]Cl$, where N/O ligands are as (**203**), have been reported.[365] Tris chelates of (**204**), $[Ir(\mathbf{204})_3]Cl_3$, bound through O and N*, have been characterized by IR and UV-vis absorption studies.[366,367]

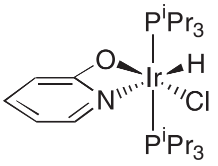
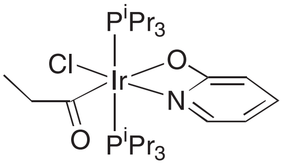
(204)

The synthesis and characterization of [cp*Ir(aa)(PPh_3)]BF_4, Haa = *L*-analine, *L*-proline (pro), have been described.[368] The crystal structure of [cp*Ir(pro)Cl] (**205**) has been detailed. Reaction of (**205**) with HC≡CCMe_3 in the presence of NEt_3 gives the structurally characterized species [cp*Ir(pro)(C≡CCMe_3)], which has the *R* configuration at the Ir center.[369] In chloroform the complex epimerizes to the *S* form by an intramolecular mechanism.[370] The structures of the py-containing complexes (**206**) and (**207**) have been reported.[371,372]



(206)



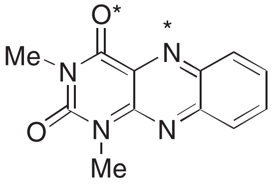
(207)

The guanylurea complexes [Ir(Gu)$_2$Cl$_2$]Cl and [Ir(Gu)$_3$]Cl$_3$, Gu = $H_2NC(:NH)NHC(:O)NH_2$, have been prepared and characterized by IR and UV-vis absorption spectroscopy.[373] The X-ray structure of [Ir(cp*)(DMA)Cl]PF_6, DMA = 1,3dimethylalloxazino, (**208**) confirms that the O* and N* atoms are the chelate donors for binding to Ir^{III}. The complexes can be electrochemically reversibly reduced, and spectroelectrochemical studies (IR, UV-vis, EPR) confirm that the redox site is centered on the DMA ligand.[374] The complex cation [cp*Ir(bigOH)]$^+$, big = bis(1-methylimidazol-2-yl)glyoxal, bigOH = (**209**), has been structurally characterized as its PF_6 salt.[375] The donor atoms of bigOH are denoted by an *.

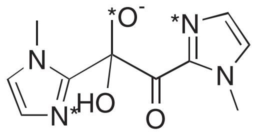
The binuclear complex [cp*Ir(μ-H)(μ-S^{i}Pr)$_2$Ircp*](otf), (**210**), has been studied by X-ray crystallography.[376] (**210**) reacts with nitrosobenzene to give the paramagnetic, structurally determined species (cp*Ir(μ-PhNO)(μ-S^{i}Pr)$_2$Ircp*]$^+$, in which the nitrosobenzene acts as a μ-η^1:η^1-*N*,*O* ligand. Reaction of 3-hydroxy-2-methyl-4(1H)-pyridine with [cp*IrCl$_2$]$_2$ gave the trinuclear complex (**211**), which has been characterized by X-ray crystallography.[377]

6.2.5.12.8 N/S

The complex IrL$_3$, HL = 8-quinolinethiol (**212**), has been prepared from an aqueous solution of $(NH_4)_3[IrCl_6]$ and NaL. An X-ray diffraction study confirms the *mer* configuration about the Ir

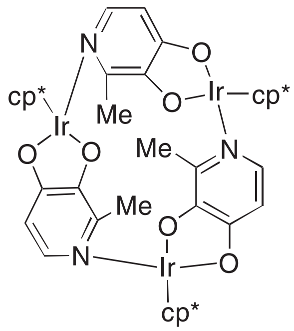


(**208**)



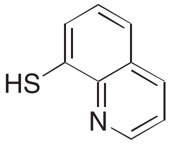
bigOH

(**209**)

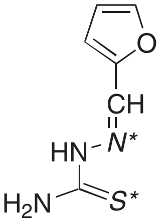


(**211**)

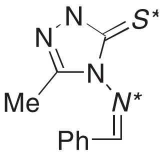
center.[378] The 4-methyl derivative has an analogous structure.[379] The redox chemistry of Ir complexes bound to (**212**) and its 2-, 4-, 5-, 6-, and 7-methyl derivatives shows a reversible one-electron reduction and a one-electron oxidation involving the ligand.[380]



(**212**)



(**213**)



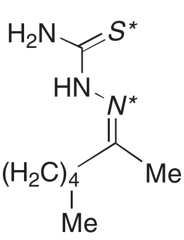
(**214**)

Reaction of $[IrCl(cod)]_2$ with $LiNHC_6H_4$-*o*-SMe gives $[Ir(Me)(SC_6H_4NH)(cod)]$ by oxidative addition of the S—Me bond.[381] The octahedral complex $[Ir(HL)_2X_2]X$, X = Cl, Br, HL = 2-furfuralthiosemicarbazone, (**213**) has been prepared and characterized by UV-vis, IR spectroscopy, and magnetic measurements.[382]

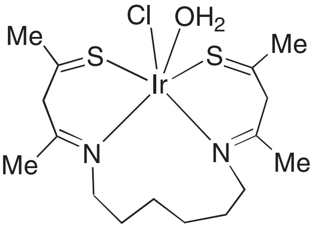
K_3IrCl_6 reacts with cystine (H_2L) to give $[Ir(HL\text{-}O,S)(HL\text{-}N,S)Cl(OH_2)]$ and $[Ir(HL\text{-}N,S)Cl(OH_2)(OH)]$, which have been characterized by XPS, IR spectroscopy, and TGA.[383]

The complex IrL_3, HL = 3-methyl-4-benzylideneimino-5-mercapto-1,2,4-triazole (**214**), which binds through the indicated S and N in a bidentate manner, has been prepared and characterized by physicochemical techniques.[384]

The synthesis and characterization of $[Ir(N/S)_3]Cl_3$, N/S = thiosemicarbazones of methyl *n*-hexyl ketone and methyl *n*-pentyl ketone (**215**), have been described.[385] The complex $[IrL(Cl)(OH_2)]$ (**216**), H_2L = *N*,*N*′-hexylenebis(monothioacetylacetonimine), has been prepared and characterized by UV-vis, IR, and ^1H NMR spectroscopy.[386]



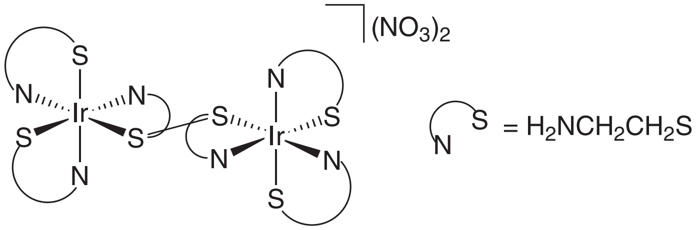
(**215**)



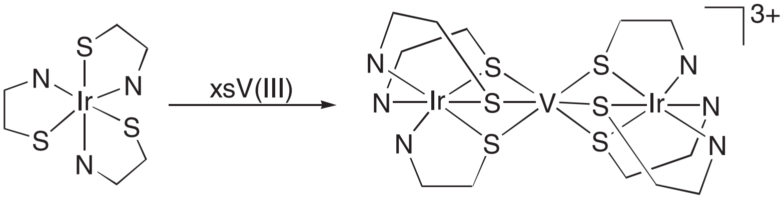
(**216**)

The synthesis of the Cu^I/Ir^{III} Cu_4Ir_4 S/N-bridged polynuclear complex $[Cu\{Ir(aet)_3\}_2\{Ir_2(aet)_4(cysta)\}]^{6+}$, Haet = $H_2NCH_2CH_2SH$, cysta = cystamine, has been discussed.[387] Treatment of an aqueous solution of *fac(S)*-$[Ir(aet)_3]$ with HNO_3 gave the structurally characterized complex $[Ir_2(aet)_4(cysta)](NO_3)_2$, (**217**).[388]

Reaction of *fac(S)*-$[Ir(aet)_3]$ with VCl_3 gave $[V\{Ir(aet)_3\}_2]^{3+}$ according to Reaction Scheme 21.[389] The structure of (**218**)$(ClO_4)_3$ confirms the linear-type structure. Cyclic voltammetric studies of (**218**) show irreversible oxidation and reduction processes.



(**217**)

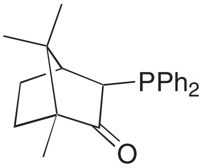


(**218**)

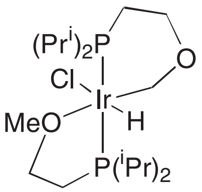
Scheme 21

6.2.5.12.9 P/O

Reaction of (1*R*)-endo-(+)-3-diphenylphosphinocamphor, (**219**), with $IrCl_3{\cdot}3H_2O$ gives *mer,trans*-$[IrCl_3($**219**$)_2]BF_4$.[390] In the complex ligand, (**219**) binds once in a unidentate manner through the P donor atom and again in a bidentate fashion through P and O. Treatment of $[IrCl(coe)_2]_2$ with $^iPr_2PCH_2CH_2OMe$ affords the structurally determined hydridoiridium(III) complex (**220**), which reacts with H_2 and HCl to give $[IrH(Cl)(X)\{\kappa(P)\text{-}^iPr_2PCH_2CH_2OMe\}\{\kappa^2(P,O)\text{-}^iPr_2PCH_2CH_2OMe\}]$, $X = H$ and Cl, respectively.[391]



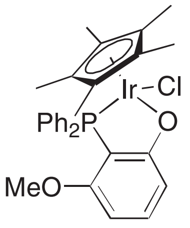
(**219**)



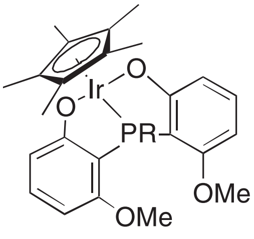
(**220**)

Reaction of (**220**) with $HC{\equiv}CCO_2Me$ yields $[IrCl(C{\equiv}CCO_2Me)(CH{=}CHCO_2Me)\{\kappa(P)\text{-}^iPr_2PCH_2CH_2OMe\}\{\kappa^2(P,O)\text{-}^iPr_2PCH_2CH_2OMe\}]$. The phosphine ether ligand $cy_2PCH_2CH_2OCH_3$ coordinates to Ir^{III} in a bidentate manner through both P/O bonds (PO) and C/P (OCH_3) orthometalated linkages (CP) in [IrClH(PO)(CP)], (**221**).[391] Reaction of (**221**) with H_2 yields $[IrCl(H)_2(PO)P]$, where $P = \eta^1$-(P) coordination of $cy_2PCH_2CH_2OCH_3$.[392] NMR studies show that the two ether O donors and the two *cis* H ligands are involved in fast exchange processes. Treatment of (**221**) with HCl and CO yields $[IrH(Cl)_2(PO)P]$ and [IrH (CO)Cl(CP)(P)], respectively.[393] The structure of *mer*-$[Ir(Cl)_3(PO)(P)]$, in which the P donor atoms are in a *cis* configuration, is detailed.

Reaction of $[cp^*IrCl_2]_2$ with 2,6-dimethoxyphenyl(diphenylphosphine), mdmpp, gives (**222**), and with tris(2,6-dimethoxyphenyl)phosphine, tdmpp, gives (**223**).[394] Addition of tcne to a CH_2Cl_2 solution of (**222**) yields the structurally characterized complex (**224**), in which tcne has inserted into a C—H aromatic bond.[395] The complex (**223**) reacts with one molar equivalent of tcne to give (**225**), and with two molar equivalents to give (**226**); both have been analyzed by X-ray crystallography.[396]

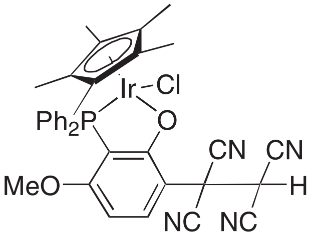


(222)

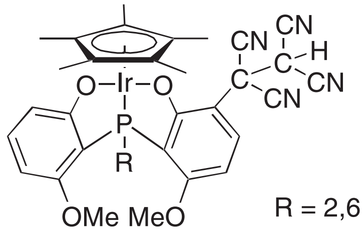


R = 2,6-$(MeO)_2C_6H_3$

(223)

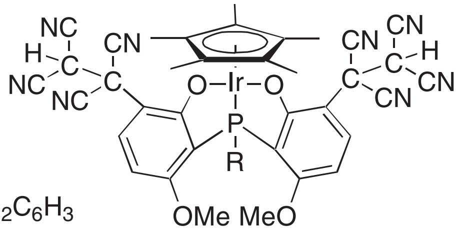


(224)



R = 2,6-$(MeO)_2C_6H_3$

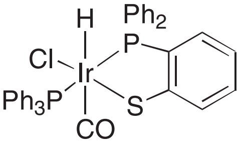
(225)



(226)

6.2.5.12.10 *P/S*

Treatment of *trans*-[IrCl(CO)$(PPh_3)_2$] with two equivalents of $Ph_2P–CH_2CH_2–SR$ (R = Me, Et), P-SR, in CH_2Cl_2/MeOH affords $[Ir(CO)(P\text{-}SR)_2]^+$, whereas reaction at 70 °C gives $[IrH(CO_2Me)(P\text{-}SR)_2]^+$.[397] A single-crystal X-ray diffraction study of $[IrH(CO_2Me)(P\text{-}SEt)_2]BPh_4$ reveals an octahedral geometry around Ir, with *trans* P atoms and *cis* S atoms. Reaction of $[Ir(CO)(P\text{-}SEt)_2]^+$ with HY (Y = Cl, BF_4) yields *trans*-$[IrH(CO)(P\text{-}SEt)_2]^{2+}$ and *cis*-$[IrH(CO)(P\text{-}S\ Et)_2]^{2+}$, respectively. The crystal structure of (**227**) has been reported.[398]



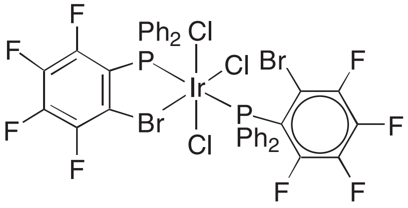
(227)

6.2.5.12.11 *P/Br*

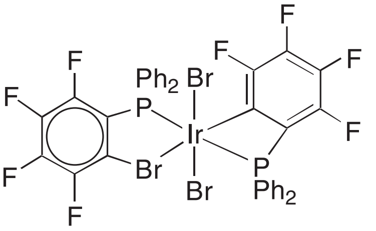
Replacement of one phosphine ligand in [$IrCl_3(\eta^2$-L)(η^1-L)], (**228**), L = $PPh_2C_6F_4Br$-*o*, by PR_3, $PR_3 = PMePh_2$, P(*p*-$MeC_6H_4)_3$, $P(OMe)_3$, $P(OPh)_3$, gave [$IrCl_3(\eta^2$-L)(PR_3)].[399] Electrochemical reduction of (**228**) at −1.5 V results in the formation of [$IrBr_2(\eta^2$-L)L2], [$IrCl_2(\eta^2$-L)L2] (**229**), and [$IrClBr(\eta^2$-L)L2], where L2 = $PPh_2(C_6F_4)$.

6.2.5.12.12 *O/S*

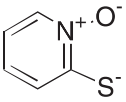
The synthesis of *fac*-L_3, L = PT = 2, mercaptopyridine-1-oxide (**230**), 3Me-PT, and 4Me-PT, and their characterization by UV-vis, IR, ^{1}H NMR spectroscopy, has been reported.[400] The ligand HS-CH_2-CH(OH)-CH_2-OH, HL, binds to Ir^{III} in a bidentate manner, coordinating through the S atom and the primary alcohol O atom to form IrL_3.[401]



(228)



(229)

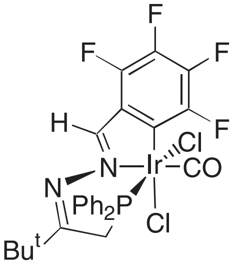


(230)

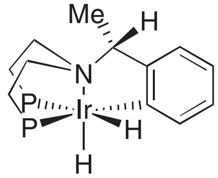
6.2.5.12.13 *Multidentate ligands*

Theoretical studies of catalytic alkane-dehydrogenation reactions by [(PCP′)IrH$_2$], PCP′ = η^3-C$_6$H$_3$(CH$_2$PH$_2$)$_2$-1,3 and [cpIr(PH$_3$)(H)]$^+$, suggest that they proceed through similar steps in both cases; namely: (i) alkane oxidation, (ii) dihydride reductive elimination, (iii) β-H transfer from alkyl ligand to metal, (iv) elimination of olefin.[402] The calculated barriers to steps (i), (ii), and (iv) are more balanced for the PCP′ system than for cp(PH$_3$).

The cyclometalated dichlorocarbonyliridium(III) complex [IrCl$_2$(CO){PPh$_2$CH$_2$C(^{t}Bu)=N-N=CH-(C$_6$F$_4$)}], (**231**), has been characterized by ^{1}H, ^{31}P, ^{13}C, ^{19}F NMR spectroscopy, and a single-crystal diffraction study.[403]



(231)



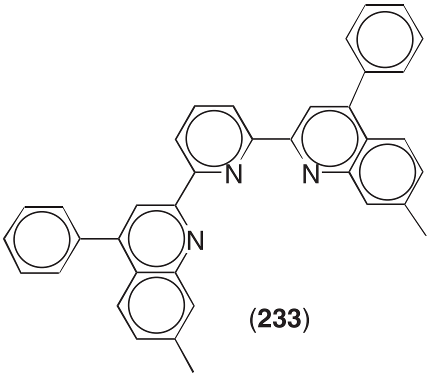
(232)

The crystal structure of (**232**) is reported. Ir complexes bound to the multidentate ligand as in (**232**) have proved successful in the enantioselective reduction of α,β-unsaturated ketones to allylic alcohols.[404]

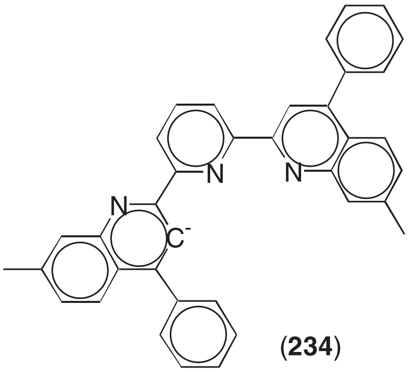
The terdentate cyclometalated complexes [Ir(L)(L$^-$)]$^{2+}$ and [Ir(L$^-$)$_2$]$^+$, L = 2,6-bis(7′-methyl-4′-phenyl-2′-quinoyl)pyridine (**233**), L$^-$ = monoanion of L (**234**), luminesce at 77 K in MeOH/EtOH (λ_{max} = 592 nm, τ = 20 μs) and at room temperature in deoxygenated acetonitrile (λ_{max} = 620 nm, τ = 325 ns).[405] Both compounds undergo four reversible, ligand-centered, one-electron reduction processes.

The electrochemical behavior of an aqueous/ethanol solution of [Ir(sat)$_2$]Cl, satH = salicylaldehyde thiosemicarbazone (**235**), has been studied on mercury. A two-electron, ligand-based reduction at −1.09 V vs. SCE (independent of pH) is observed at fast scan rates.[406]

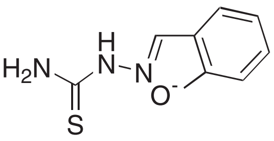
Bis(8-quinolyl)methyl silane NSiHN, (**236**), reacts with [Ir(coe)$_2$Cl]$_2$ to give [Ir(NSiN)-(coe)(H)Cl], which reacts with PPh$_3$ to give [Ir(NSiN)(PPh$_3$)(H)Cl], and with half a molar equivalent of LiB(C$_6$F$_5$)$_4$ to afford [(NsiN)(H)(coe)Ir(μ-Cl)Ir(coe)(H)(NsiN)]B(C$_6$F$_5$)$_4$.[407] The crystal structures of the three Ir(NSiN) complexes are reported.



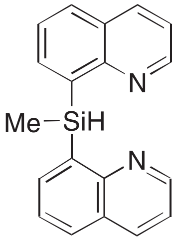
(233)



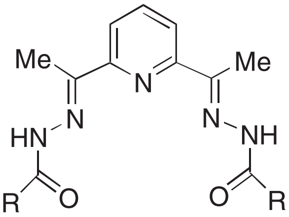
(234)



(235)



(236)

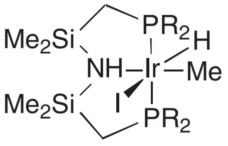


(237)

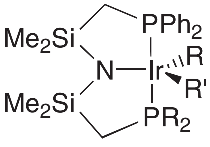
Reaction of $IrCl_3{\cdot}3H_2O$ with hydrazones (**237**), R = Ph, *o*-ClC_6H_4, *p*-$NO_2C_6H_4$, $PhCH_2$, $PhOCH_2$, gave complexes of formula $[Ir(\mathbf{237})Cl_2]Cl$ and $[Ir\{(\mathbf{237})\text{-}H_2\}Cl(OH_2)]$.[408]

The crystal structure of *fac-exo-(R)*-$[IrH_2\{C_6H_4C^*H(Me)N(CH_2CH_2PPh_2)_2\}]$ confirms a distorted octahedral geometry at Ir, with the PNP donor atoms bound facially, the two hydride ligands *cis* to one another, and an *ortho*-C atom of the phenyl substituent occupying the final coordination site.[604] Reaction of dpba and daba with $IrCl_3$ gives octahedral $IrCl_3$(dpba) and $IrCl_3$(daba), respectively.[664]

$[\{R_2PCH_2SiMe_2)_2N\}Ir(coe)]$, R = Ph, $CHMe_2$, ${}^iPr$, undergoes oxidative addition reactions with MeI to give five-coordinate $[\{(R_2PCH_2SiMe_2)_2N\}Ir(Me)I]$, which reacts with H_2 to produce (**238**).[409,410] The X-ray structure of (**238**), R = ${}^iPr$, shows that the addition of H_2 has occurred across the Ir—N bond. The structure of the closely related complex $[Ir(H)_2I\{NH(SiMe_2CH_2PPh_2)_2\}]$ has also been reported.[411] Reaction of $[Ir(R)X\{N(SiMe_2CH_2PPh_2)_2\}]$ (**239**), R = Me, Ph, X = I; R = CH_2Ph, X = Br, with LiR′, R′ = CH_3, CH_2CMe_3, CH_2SiMe_3, Ph, CH_2Ph, generates $[Ir(R)R'\{N(SiMe_2CH_2PPh_2)_2\}]$, (**240**).[412] The crystal structure of (**240**) with R = R′ = CH_2Ph shows a distorted trigonal-bipyramidal structure, as does (**239**) with R = CH_2CMe_3 and X = Cl.[413]



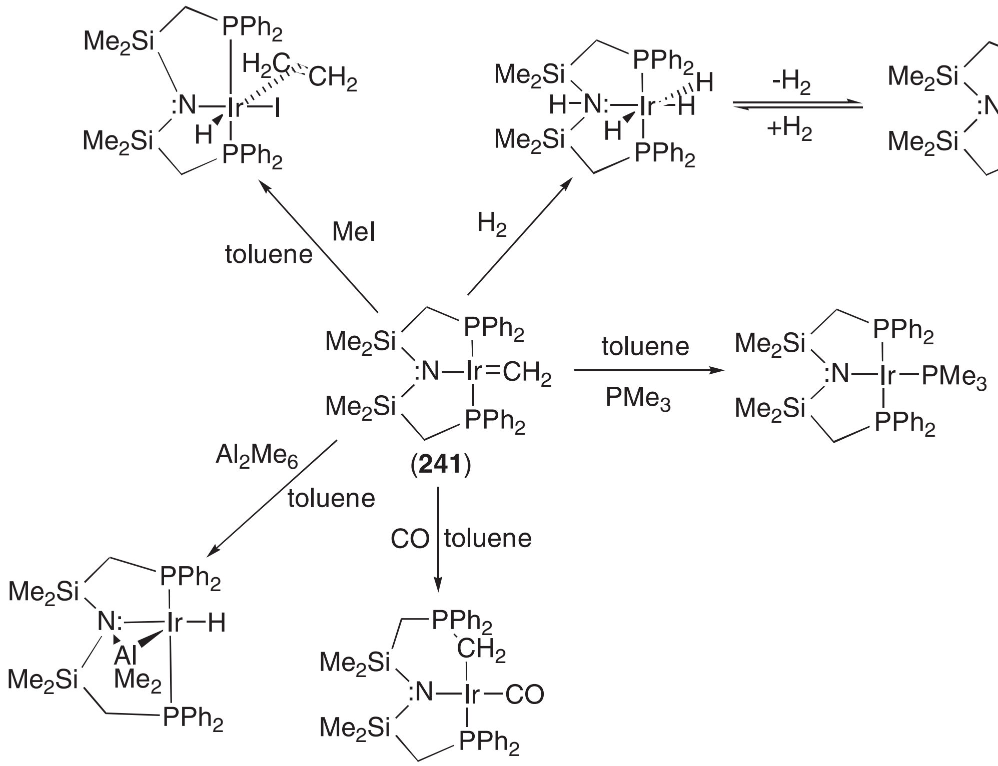
(238)



(240)

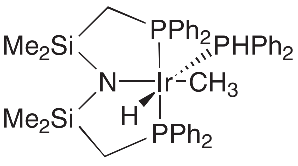
Treatment of (**239**), R = Me, with KO^{t}Bu in toluene results in formation of the coordinatively unsaturated complex $[Ir{=}CH_2\{N(SiMe_2CH_2PPh_2)_2\}]$, (**241**). A summary of the reactions of (**241**) is given in Reaction Scheme 22. Possible mechanisms have been probed using NMR spectroscopy.[414]

The dark purple complex $[Ir(CH_3)(PPh_2)\{N(SiMe_2CH_2PPh_2)\}]$, (**242**), has been synthesized by treatment of (**239**) with $LiPPh_2$.[415] A toluene solution of (**242**) exposed to 1 atm of H_2 produced (**243**) and (**244**); prolonged exposure to H_2 resulted in formation of (**244**) only. (**243**) thermally

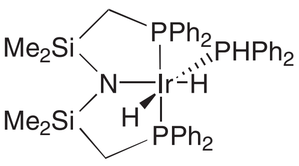


Scheme 22

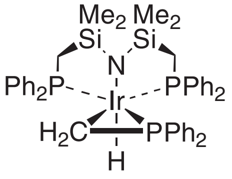
decomposes to *fac*-[Ir(η^2-CH_2PPh_2)H{N($SiMe_2CH_2PPh_2$)$_2$}], (**245**), which has been structurally characterized by X-ray analysis.[416] Further heating of (**245**) produces [Ir($PMePh_2$){N($SiMe_2$-CH_2PPh_2)$_2$}].



(**243**)

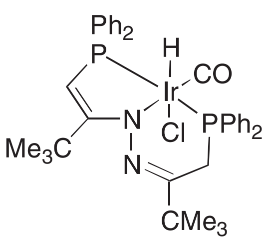


(**244**)

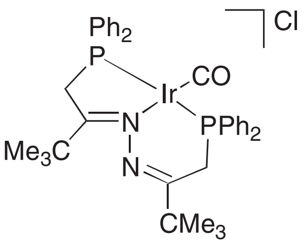


(**245**)

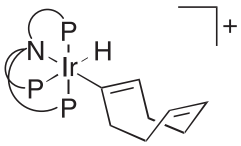
Reaction of the azine diphosphine *Z,Z*-$Ph_2PCH_2C(^tBu){=}N\text{-}N{=}C(^tBu)CH_2PPh_2$ with [IrCl-$(CO)_2$(*p*-toluidene)] gives the coordinatively saturated hydride (**246**).[417] Complex (**246**) dissolves in MeOH or EtOH, isomerizing to give (**247**). Isolation of (**247**) and dissolution in benzene or CH_2Cl_2 results in reversion to (**246**). (**247**) reacts with alkenes, alkynes, and H_2. Reaction of $[Ir(cod)Cl]_2$ and np_3 ($np_3 = N(CH_2CH_2PPh_2)_3$) in the presence of $NaBPh_4$ yields the structurally characterized cation (**248**).[418]



(**246**)



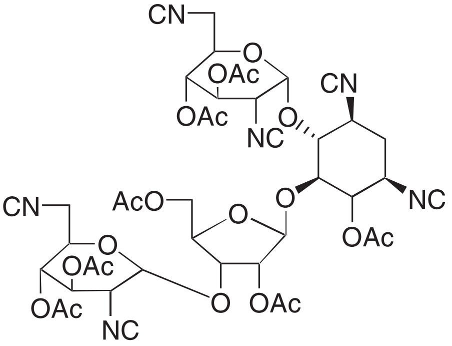
(**247**)



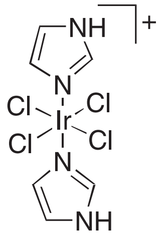
(**248**)

6.2.5.13 Biological Complexes

The hexanuclear Ir^{III} complex $[L\{IrCl_2cp^*\}_6]$, in which L is based on the amino glycoside neomycin B (**249**), has been characterized by IR, ^{13}C, and ^{31}P NMR spectroscopy, and by FAB MS.[419] The *in vivo* antitumor and antitrypanosomal effects of $[IrY_4Cl_2]^+$ complexes, Y = primaquine, mepacrine, amodiaquine, lepidine, plasmoquine, pentaquine, and isopentaquine, have been reported.[420] Similar studies of 27 complexes of general formula $[IrY_3]$, where Y = dithiocarbamate or xanthate derivatives, found that the most active compounds have Y = pyrolidine dithiocarbamate.[421]



(249)



(250)

Dialysis experiments and DNA thermal denaturation studies of bisimidazoletetrachloroiridate(III), (**250**), suggest poor binding of (**250**) to DNA, with no formation of interstrand crosslinks.[422]

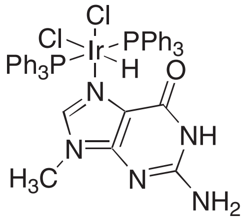
The DNA binding of $[cp^*Ir(dppz)(Aa)]^{n+}$, dppz = dipyrido[3,2-a:2′,3′-c]phenazine, Aa = S-coordinated amino acid or peptide, has been investigated by UV-vis spectroscopy, 2D-NOESY, and gel electrophoresis. The complexes intercalate into DNA adjacent to T_2 from the major groove. The X-ray structural data for $[cp^*IrCl(dppz)](CF_3SO_3)_4$ and $[\{cp^*Ir(9\text{-}EtG)(Phen)](CF_3SO_3)_2$, where GH = guanine, are reported.[423]

Treatment of $[cp^*Ir(OH_2)_3](CF_3SO_3)_2$ with adenine (AH) and 9-ethyladenine (9-EtA) results in formation of the structurally determined species $[\{cp^*Ir(A)\}_4](CF_3SO_3)_4$ and $[\{cp^*Ir(9\text{-}EtAH\text{-}1)\}_3](CF_3SO_3)_3$, where A and 9-EtAH-1 are bridging, bidentate ligands.[424] Analogous trimers were also formed from $[cp^*Ir(OH_2)_3]^{2+}$ and 5′-AMP^{2-} (5′-$AMPH_2$ = adenosine-5-monophosphate) or 5′-ATP^{4-} (adenosine-5′-triphosphate), whereas tetramers $[\{cp^*Ir(B)(OH_2)\}_4]^{4+}$ resulted when B = guanine or hypoxanthine (HXH). The structure of the tetramer B = G is detailed.

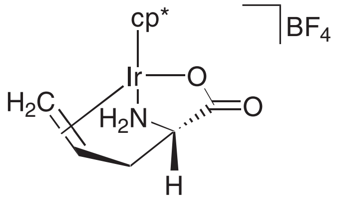
K_3IrCl_6 reacts with amino acids to give $K[Ir(HL)_2Cl_4]$, HL = α-alanine (Hal), L-methionine, $K[Ir(Hal)(al)Cl_3]$, *cis*-$K[Ir(gl)_2Cl_2]$ (Hgl = glycine), and $[Ir(Hgl)_3(gl)Cl_2]$. IR and UV-vis spectroscopy indicate binding through O- and N-donor atoms to the Ir center.[425] Reaction between $IrCl_3$ and Schiff bases yields complexes $[Ir(SB)_3]$, $[Ir(SB')Cl(OH_2)_2]$, $[Ir(SB'')Cl_2]_n$, and $[Ir(SB''')Cl(OH_2)]_n$, where SBH = Schiff base derived from anthranilic acid and benzaldehyde, acetophenone, vanillin, cinnamaldehyde, or *m*-hydroxyacetophenone; $SB'H_2$ = Schiff base derived from anthranilic acid and salicylaldehyde or *o*-hydroxyacetophenone; $SB''H$ = Schiff base derived from *p*-aminobenzoic acid and benzaldehyde, acetophenone, vanillin cinnamaldehyde, or *m*-hydroxyacetophenone; and $SB'''H_2$ = Schiff base derived from *p*-aminobenzoic acid and salicylaldehyde or *o*-hydroxyacetophenone.[426] The complexes with Schiff bases derived from anthranilic acid showed antifungal activity, but only weak antiviral activity.

Reaction of $[(PPh_3)_2Ir(Cl)(N_2)(H)(FBF_3)]$ with 9-methylguanine (9-MeG) affords $[(PPh_3)_2Ir(Cl)(H)(9\text{-}MeG)]$, and crystallization from methanol gives the structurally characterized species $[(PPh_2)_3Ir(Cl)_2(H)(9\text{-}MeG)]BF_4$, (**251**).[427] Treatment of $[(PPh_3)_2Ir(Cl)(N_2)(H)(OSO_2C_4F_9)]$ with 9-MeG yields $[(PPh_3)_2Ir(Cl)(N_2)(H)(9\text{-}MeG)]C_4F_9SO_3$ and $[(PPh_3)_2Ir(Cl)(OH_2)(H)(9\text{-}MeG)]C_4F_9SO_3$.

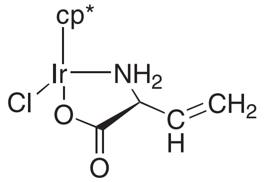
The X-ray structure of $[cp^*Ir(CNR)Cl_2]$, CNR = 1,3,4,6-tetra-*O*-acetyl-2-deoxy-2-isocyano-α, β-D-glucose, has been determined.[428] The synthesis of chiral complexes of Ir^{III} with α-amino acid anions, L-L′, of general formula $[cp^*Ir(Cl)(L\text{-}L')]$ (**252**), and their NMR spectroscopic characterization, have been detailed. The X-ray structures of (**252**), L-L′ = L-proline and $[cp^*Ir(Cl)(L\text{-}His\text{-}OH)]Cl$, His = histidine, are described.[429] C-allylglycinate binds in a terdentate manner in (**253**), which has been characterized by X-ray diffraction studies.[430] C-vinylglycinate forms complex (**254**).



(251)



(253)



(254)

Reaction of $[cp^*IrCl_2]_2$ with L′,L′ = N-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-thiocarbamate and β-D-glucopyranosylthiourea (**255**), L^2, yields $[cp^*IrCl_2L']$ (**256**) and $[cp^*Ir(Cl)_2L^2]$, respectively.[431] Treatment of $[cp^*IrCl_2]_2$ with 2-hydroxyiminocarboxylates affords complex (**257**), where, X = I, Cl; R^1 = Me, CH_2Ph, Ph; R^2 = H, Me.[432] The synthesis and characterization of (**258**) and (**259**) have been reported, including the X-ray diffraction study of (**259**).[433] Reactions of $[cp^*IrCl_2]_2$ with *N*,*N*-dimethyl-2-hydroxyiminopropionic acid and *N*-(2-hydroxyiminopropionyl)-amino acids gave complexes (**260**) and (**261**), respectively. The crystal structures for complexes (**261**), R = CH_2CO_2H and $C(H)(CH_2Ph)(COOH)$, are given.[434]

$C(H)(CH_2C_6H_5)(COOH)$

The series of complexes $[cp^*IrCl_2L]$, where L = H_2NRCO_2Me, R = CH_2, $C(H)(CH_3)$, $C(H)(CH_2CH{=}CH_2)$, CH_2CH_2, have been prepared and characterized. The complexes undergo ester-exchange reactions with CD_3OD.[435] The ligands (**262**) and (**263**) form complexes $[cp^*IrCl(\mathbf{262})]$ and $[cp^*IrCl(\mathbf{263})]$ by reaction with $[cp^*IrCl_2]_2$. The structure of $[cp^*IrCl(\mathbf{263})]$ establishes the bidentate binding of (**263**) to Ir via the N and hydroxyl O atoms.[436] The complexes $[Ir(H)_2(aa)(PPh_3)_2]$, aa = L-alaninate, L-valinate, L-prolinate, L-phenylalaninate, have been synthesized and characterized. Reaction with $HC{\equiv}CPh$ gives *trans,mer*-$[IrH(C{\equiv}CPh)_2(PPh_3)_3]$.[437]

$[(ppy)_2Ir(\mu\text{-}Cl)]_2$ reacts with sodium salts of L′, where L′ = glycinate, L-alaninate, L-valinate, D-Leucinate, L-prolinate, and L-phenylalaninate, to give $[(ppy)_2IrL']$, (**264**). The crystal structure of (**264**), L′ = L-prolinate, is described.[438] The X-ray diffraction analysis of (**265**) shows a five-membered and a seven-membered chelate ring.[439] The synthesis and characterization of [cp*IrCl(L)], where L = 2-amino-2-deoxy-D-gluconic acid, have been detailed.[440] Reaction of $[cp^*IrCl_2]_2$ with the pyrazine derivative desoxyfructosazin, pfz, gives the water-soluble complex $[cp^*(Cl)_2Ir(pfz)Ir(Cl)_2cp^*]$, (**266**).[441] The dinuclear complex (**267**) has been prepared and characterized.[442]

6.2.5.14 Catalytic Complexes

A review of the photocatalyzed reduction of CO_2 and water-gas-shift reaction by Ir^{III} complexes containing bpy or phen has been published by Ziessel.[443] Lohrenz and Jacobsen have written a review article on C—H activation by cationic Ir^{III} complexes.[444] An extensive review by Sutin, Creutz, and Fujita on photo-induced generation of H_2 and reduction of CO_2 using polypyridine complexes of Co^{III}, Rh^{III}, Ir^{III}, Ru^{II}, and Re^{I} is available.[445]

The complex $[Ir(OH_2)_2Cl(OAc)AA]^+$, AA = α-amino acid, has been identified as the active catalytic species in the oxidative decarboxylation and deamination of α-amino acids by lead tetraacetate.[446] $[Ir(ClO_4)(CO)(PPh_3)_2]$, (**268**), dehydrogenates $HOCH_2CH{=}CHPh$ under nitrogen to give $[Ir(H)_2(ClO_4)(CO)(PPh_3)_2]$, which then reacts with a further $HOCH_2CH{=}CHPh$ to give $PhCH{=}CHMe$, (**268**), and H_2O. Under an atmosphere of hydrogen, (**268**) catalyzes the isomerization of $HOCH_2CH{=}CHPh$ to $PhCH_2CH_2CHO$, followed by hydrogenation to $Ph(CH_2)_3OH$.[447] The complexes [cpIrCl(4,4′-X_2-bpy)]Cl, X = COOH, COO^iPr, Br, NO_2, NMe_2, $[cp^*Ir(bpy)D]^+$, D = H, Cl, and $[cp^*Ir(phen)D]^+$ are successful water-gas-shift catalysts.[448–450] The reaction is accelerated when X = an electron-withdrawing group, and is inhibited by electron-donating groups.

The oxidation of 1-hexane by O_2 catalyzed by $[Ir(CH_3CN)_{5\text{-}x}Cl_x(NO_2)]^{z\text{-}x}$, $x = 0$, 1, 2, has been studied in CH_3CN under pressurized O_2 at 1.5 atm and 100 °C.[451] When $x = 0$ the product of the reaction is 1,2-epoxy-hexane, whereas when $x = 1$ then 2,3-epoxy-hexane results. In the presence of the olefin activator $[Pd(PhCN)_2Cl_2]$, the species in which $x = 2$ oxidizes 1-hexane to 2-hexane. $IrCl_3$ catalyzes the oxidation of maltose and lactose by *N*-bromoacetamide in $HClO_4$, and the oxidation of mallibiose and cellobiose by *N*-bromosuccinimide in $HClO_4$.[452,453] Addition of $[Hg(Oac)_2]$, which acts as a Br^- scavenger, to the solution accelerates the reaction. Theoretical studies of C—C and C—H bond activation by $[cp^*Ir(PMe_3)CH_3]^+$ on cyclopropane have been investigated with density functional calculations (B3LYP).[454]

The binuclear complexes $[IrL(H)I_2]_2$, L = diphosphine, e.g., diop (**120**), binap (**121**), bdpp (**122**), are effective catalysts in the asymmetric hydrogenation of prochiral amines.[455]

6.2.6 IRIDIUM(II)

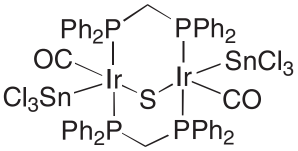
There are few Ir^{II}-containing complexes detailed in the literature. The monomeric compounds are all reported to be either EPR active, or to have a magnetic moment in agreement with their paramagnetic d^7 electronic configuration. More common are binuclear compounds with Ir^{II}–Ir^{II} single metal bonds, which are diamagnetic. The metal–metal bond may be unsupported or bridged by a variety of donor-atom ligands. Most binuclear species are strongly absorbing in the visible region of the spectrum.

6.2.6.1 Carbon Ligands

The synthesis and structure of *trans*-$Ir(mes)_2(SEt_2)_2$ (**269**) are reported.[456] Paramagnetic (**269**) reacts with phosphines and amines to give *trans*-$Ir(mes)_2X_2$, where $X = PMe_3$, PMe_2Ph, PEt_2Ph, py, and 4-tert-butylpyridine, and with CO to give the Ir^I compound $Ir(mes)(CO)_2(SEt_2)$.

6.2.6.2 Tin Ligands

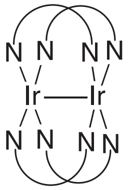
The binuclear complex (**270**) contains two Ir^{II} centers, with an Ir–Ir distance of 2.878 Å.[457]



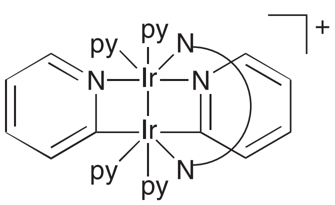
(**270**)

6.2.6.3 Nitrogen Ligands

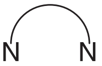
The first crystallographically characterized, inorganic, Ir^{II} binuclear complex was reported in 1987 by Cotton and Poli.[458] Dark green $[Ir_2(form)_4]$, (**271**), has D_4 symmetry and a very short metal–metal distance (2.524(3) Å). In the same year Cotton and Poli published details of a related complex, (**272**), with a metal–metal bond distance of 2.517(1) Å.[459] The Ir^{II} complex $Ir_2(cod)(\mu\text{-form})_2(O_2CCF_3)_2(H_2O)$, when treated with excess Et_3OBF_4 at room temperature in MeCN, gives the dication $[Ir_2(cod)(\mu\text{-form})_2(MeCN)_3](BF_4)_2$ but, when heated to reflux, gives the thermal substitution product $[Ir_2(\mu\text{-form})_2(MeCN)_6](BF_4)_2$.[460]



(**271**)



(**272**)

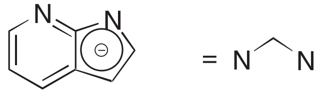


= form = $CH(N\text{-}p\text{-}C_6H_4Me)_2$

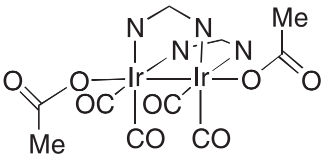
Oro *et al.* have synthesized binuclear Ir^{II} compounds from $[Ir_2\{\mu\text{-}1,8\text{-}(NH)_2C_{10}H_6\}(CO)_2(PPh_3)_2]$ by reaction with I_2, MeI or CH_2I_2.[461] The X-ray structure of the binuclear cation $[Ir_2(\mu\text{-}1,8\text{-}(NH)_2C_{10}H_6)(CH_3CN)_2(CO)_2(P^iPr_3)_2]^{2+}$ shows a short intermetallic distance.[462] Oxidation of $[\{Ir(\mu\text{-aza})(CO)_2\}_2]$ (aza = 7-azaindolate), (**273**), by silver acetate yields the diamagnetic, binuclear Ir^{II}-containing complex (**274**) or the solvated equivalent $[\{Ir(\mu\text{-aza})(CO)_2(S)\}_2]^{2+}$, (**275**) (S = acetone or acetonitrile) when oxidized by $AgBF_4$.[463] Other binuclear Ir^{II} compounds are synthesized from $[\{Ir(\mu\text{-aza})(CO)_2\}_2]$ by reaction with halogens (Cl_2, Br_2, I_2) and chlorinated hydrocarbon solvents.

A dark red, amido-bridged complex is prepared from Na/Hg reduction of $[cp^*Ir\{(\mu^2\text{-NH})_2\text{-}C_{10}H_6\text{-}1,8\}(\mu^2\text{-Br})Ircp^*]Br$ yielding (**276**), a diamagnetic complex with an Ir^{II}—Ir^{II} metal bond

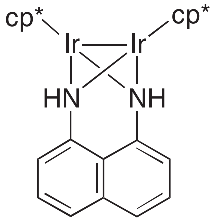
(2.584(1) Å.[464] A purple-black, mixed-valence Ir^{II}–Ir^{I} binuclear compound, $[\{Ir(cod)(\mu\text{-}L)\}_2]BF_4$ (L = pz, 4-Mepz), is synthesized from the reaction of $[Ir(cod)(\mu\text{-}L)]_2$ with $NOBF_4$.[465] The binuclear cationic radical exhibits an EPR spectrum showing hyperfine coupling to two equivalent Ir. Cyclic voltammetry studies have shown a reversible, one-electron oxidation.[466]



(273)



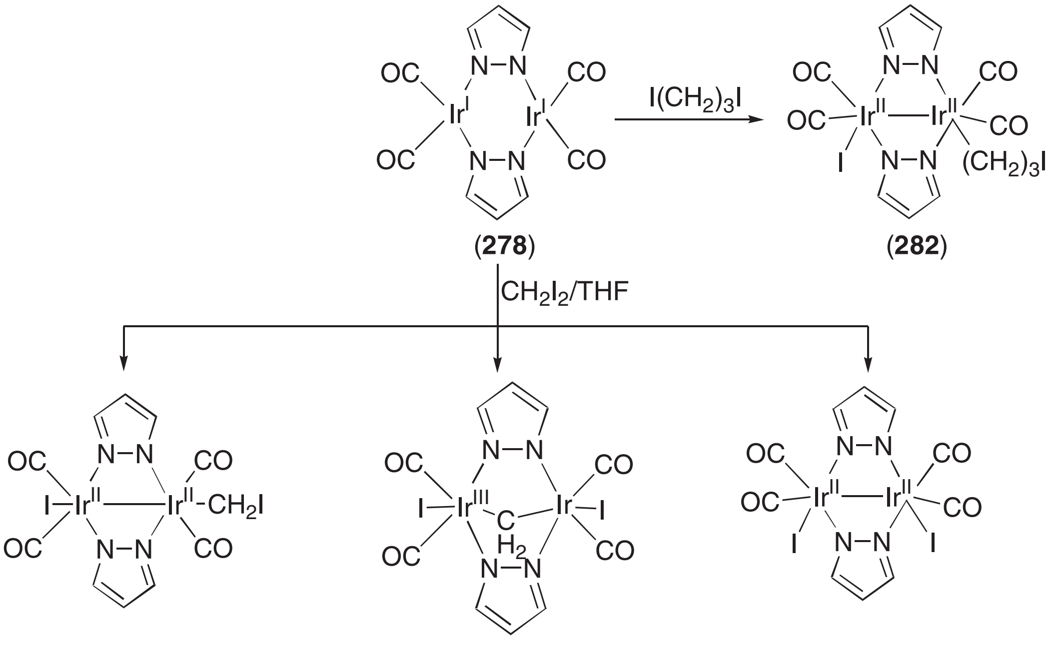
(274)



(276)

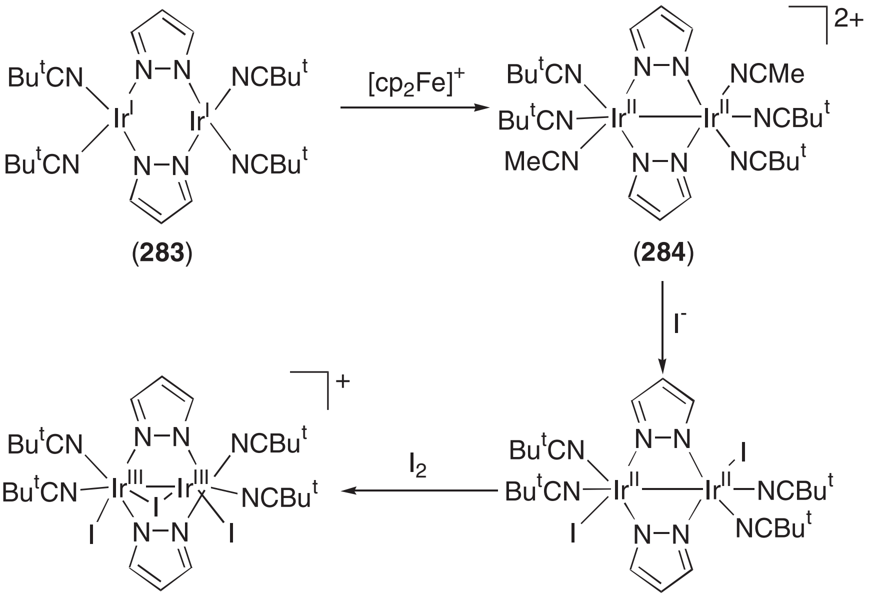
The energetics of the oxidative addition of I_2 to the Ir^I complexes $[Ir(\mu\text{-}L)(CO)_2]_2$ ($L = S^tBu$, 3,5-Me_2pz, 7-aza) have been studied using the results of reaction-solution calorimetric measurements, X-ray structure determination, and EHMO calculations.[467] One equivalent of I_2 gives the Ir^{II} complexes $[Ir(\mu\text{-}L)I(CO)_2]_2$, (**277**). The enthalpies of reaction were found to be -528.3 ± 20.6, -638.4 ± 16, and -864.8 ± 41.6 kcal mol^{-1} for $L = S^tBu$, 3,5-Me_2pz, 7-aza, respectively, and are consistent with a decrease of the strain associated with the formation of 3-, 4-, and 5-membered rings. The Ir—Ir bond distances are 2.638(1) Å and 2.637(1) Å for (**277**), $L = S^tBu$ and 3,5 Me_2pz, respectively.

Reaction of the Ir^I complex $[Ir(CO)_2(\mu\text{-}pz)_2]_2$, (**278**), with CH_2I_2 in THF gave a 7:2:1 mixture of complexes (**279**), (**280**), and (**281**).[468] Treatment of (**278**) with $(ICH_2)_2$ gave (**280**) exclusively, and with $I(CH_2)_3I$ gave (**282**).



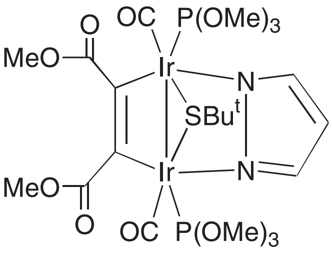
The binuclear complex $[\{Ir(\mu\text{-}pz)(NCBu^t)_2\}_2]$, (**283**), oxidizes readily with $[cp_2Fe]^+$ to give the Ir^{II}—Ir^{II}-bonded dication (**284**), which adds I^- yielding the neutral complex (**285**).[469] Reaction of (**283**) with I_2 gives (**285**) directly, which reacts with further I_2 to yield the Ir^{III} complex (**286**).

Dma (dimethyl acetylenedicarboxylate, $MeO_2CC{:}CCO_2Me$), acts as a bridging ligand in the Ir^{II} complex $[Ir_2(\mu\text{-}pz)(\mu\text{-}SBu^t)(\mu\text{-}dma)(CO)_2\{P(OMe)_3\}_2]$, (**287**).[470] X-ray diffraction studies show the crystals of (**287**) to be monolithic, space group $P21/n$. Oxidative addition of iodine to (**287**) gives (**288**). Complexes (**287**) and (**288**) have been characterized by X-ray crystallography. (**287**) has an Ir—Ir bond (2.614(2) Å), whereas there is no Ir—Ir interaction in (**288**) (3.626(2) Å). The

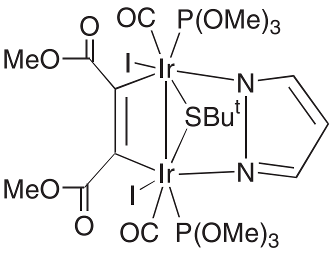


(**283**) (**284**) (**286**) (**285**)

bridging framework remains unaltered between the two species. The related complexes of type $[Ir_2(\mu\text{-pz})(\mu\text{-SBu}^t)(CO)_2\{P(OMe)_3\}_2{}^I(R)]$, where $R = {}^-CH_3$ or ${}^-CH_2I$, have been prepared.[471]



(**287**)



(**288**)

Monomeric Ir^{II}-containing complexes have been isolated for sterically demanding porphyrin-type ligands (por). Wayland *et al.*[472] generated Ir^{II} tetrakis(2,4,6-trisalkylphenyl)porphyrin by photolysis of the Ir–Me derivative in C_6D_6 according to Reaction Scheme 23.

$$(\text{por})\text{Ir-Me} \xrightarrow{h\nu,\ \lambda > 350\ \text{nm}} (\text{por})\text{Ir(II)} + \text{Me}''$$

Scheme 23

The Ir^{II} dimer $[Ir(oep)]_2$ (oep = octaethylporphyrin) has been prepared in low yield by photolysis of (oep)IrCH$_3$ in C_6D_6.[473] This preparation has been improved by Chan *et al.*[474], as shown in Reaction Scheme 24, where TEMPO = 2,2,6,6-tetramethyl-1-piperidinyloxy, free radical. The dimer undergoes several organometallic reactions, including oxidative addition of alkyl C—H bonds and alkene insertions.[475]

$$2\text{Ir(oep)H} + 2\text{TEMPO} \longrightarrow \text{Ir}_2(\text{oep})_2 + 2\text{TEMPOH}$$

Scheme 24

Successive oxidation of bis$[Ir(py)(pc)]_2$ (pc = phthalocyaninato(2-)) with iodine yields the mixed-valence Ir^{III}–Ir^{II} compound $[Ir(py)(pc)]_2I$ initially, and then the Ir^{III} monomer

$[Ir(py)I(pc)]\cdot py$.[476] [Ir(pc)] reacts in MeOH with excess Bu_4NOH to yield $Bu_4N[Ir(pc)(OMe)(OH)]$, which is characterized by X-ray diffraction.[477]

6.2.6.4 Phosphorus Ligands

One-electron oxidation of *trans*-$Ir(R)(CO)(PPh_3)_2$ ($R = CH_3$, CH_2CN, C_6H_5) in 1,2-dichloroethane containing PPh_3 produces stable $[Ir(R)(CO)(PPh_3)_3]$,[478] according to Reaction Scheme 25.

$$Ir(R)(CO)(PPh_3)_2 + PPh_3 \rightleftharpoons Ir(R)(CO)(PPh_3)_3 \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [Ir(R)(CO)(PPh_3)_3]^+$$

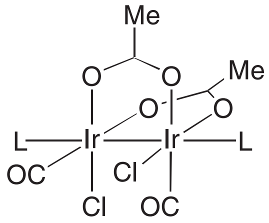
Scheme 25

The radical Ir^{II} complex $[Ir(CO)Cl(PPh_3)_3]BF_4$ is formed by the thermal and photoreaction of $[Ir(NO)(CO)Cl(PPh_3)_2]BF_4$ with PPh_3 and the dissociation of NO.[479] The structure of $Ir_2(Tc\text{-}bim)_2(CO)_2(CH_3CN)_2[P(OEt)_3]_2$, with an unsupported metal–metal bond, is reported.[480] The dimer is prepared via electro-oxidation of the monomeric Ir^I salt from an electrolyte-free acetonitrile solution. The phosphido-bridged di-iridium complex $[(CO)(PEt_3)ClIr(\mu\text{-}Pcy_2)_2IrCl(PEt_3)(CO)]$ is characterized by single-crystal X-ray crystallography and contains a single Ir^{II}—Ir^{II} bond (2.762(1) Å).[481]

Reactions of the Ir^I complexes (**289**) and (**290**) with H_2 and subsequent reaction of the dihydride products with dimethyl acetylenedicarboxylate, $MeO_2CC{:}CCO_2Me$ (dma), give the Ir^{II} complexes (**291**), (**292**), (**293**), and (**294**), as shown in Reaction Scheme 26.[482] The X-ray crystal-structure determination of (**294**) confirms the double insertion of the alkyne into each of the Ir—H bonds of (**293**).

6.2.6.5 Oxygen Ligands

The one-step reaction of $H_2[IrCl_6]$ with $MeCO_2Li$ under O_2 in a mixed solvent of acetic acid and acetic anhydride yields the Ir^{II} binuclear complex $[Ir_2(\mu\text{-}O_2CMe)_2Cl_2(CO)_2]$.[483] Crystal-structure determinations of $[Ir_2(\mu\text{-}O_2CMe)_2Cl_2(CO)_2L_2]$, (**295**), where L = MeCN, DMSO, and py, are reported. The one-electron oxidation product for (**295**), L = py, is EPR active at 77 K; the odd electron occupies the $\delta_{Ir-Ir}{}^*$ orbital.

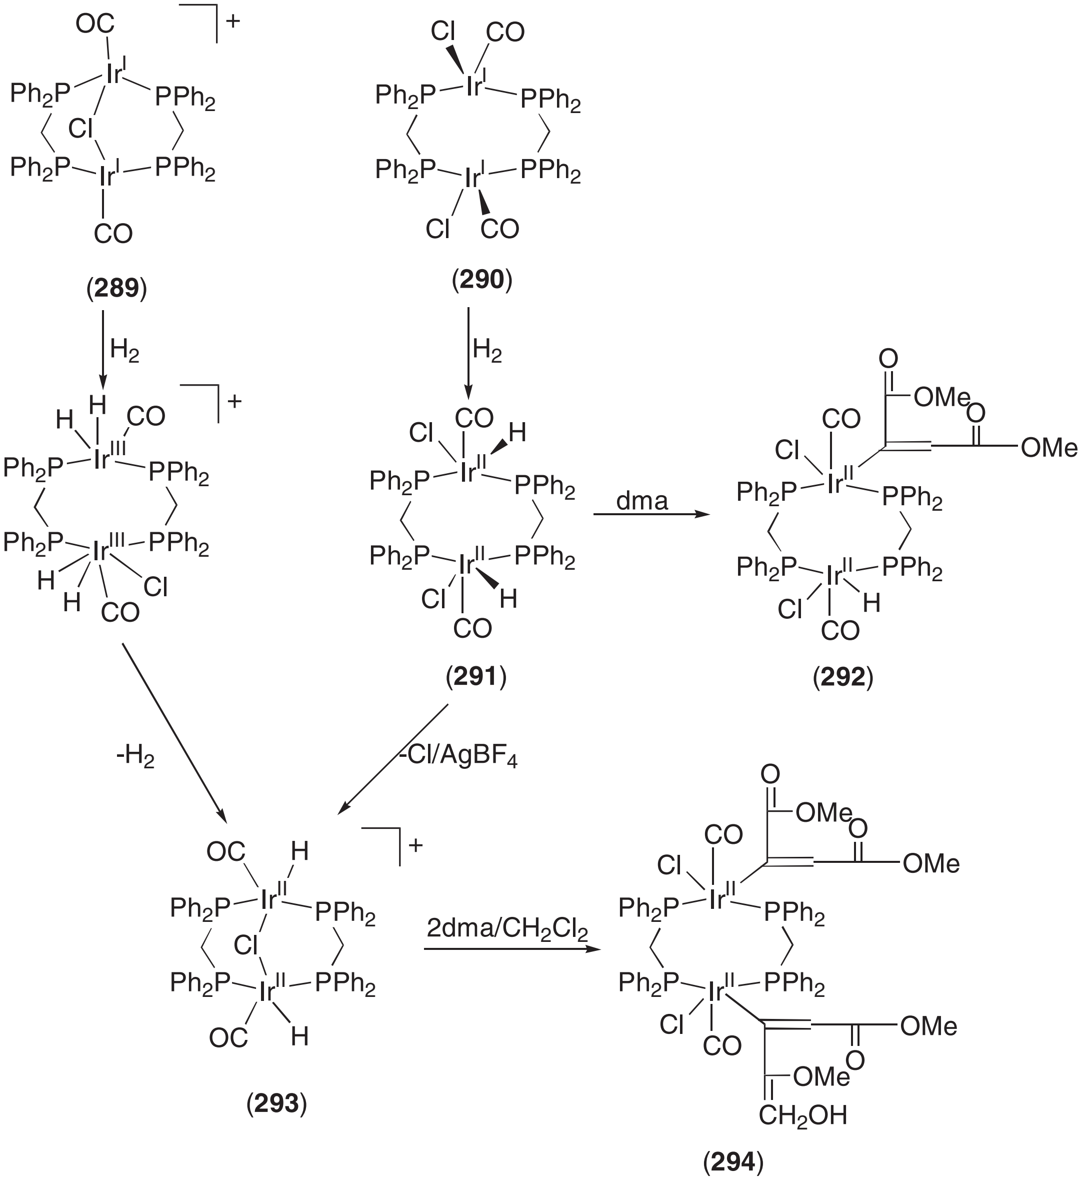


(**295**)

6.2.6.6 Sulfur Ligands

Reduction of $[cp^*IrCl(\mu\text{-}SR)_2Ircp^*Cl]$ ($R = Pr^i$, cy) with excess Na/Hg affords the dark red, binuclear Ir^{II} complexes $[cp^*Ir(\mu\text{-}SR)_2Ircp^*]$.[484] X-ray diffraction studies of R = cy confirm the two SR^- bridging units supporting the Ir^{II}–Ir^{II} single bond. The bitetrahedral structure of $[(PPh_3)_2Ir(\mu\text{-}S)_2Ir(PPh_3)_2]$, (**296**), is confirmed by single-crystal X-ray diffraction.[485] (**296**) reacts with H_2 to give the binuclear Ir^{III} species $[Ir(PPh_3)_2(H)]_2(\mu\text{-}S)_2$, which reacts further with H_2 to give $[Ir(PPh_3)_2(H)](\mu\text{-}S)(\mu\text{-}SH)(\mu\text{-}H)$.

The dark red Ir^{II} binuclear complex $[Ir(CO)(P(p\text{-}tolyl)_3)(mnt)]_2$, formed via one-electron oxidation of $[Ir(CO)(P(p\text{-}tolyl)_3(mnt)]^-$ by ferrocenium, contains chelating mnt ligands bridging the Ir—Ir bond.[639] The X-ray crystal structure shows square-pyramidal geometry at each Ir, and an Ir—Ir bond length of 2.706(2) Å.



Scheme 26

6.2.6.7 Halide Ligands

The electronic spectra of $[Ir_2(tmb)_4L_2]^{2+}$ binuclear compounds (L = Cl, Br, I) have intense $d\sigma \rightarrow d\sigma^*$ transitions between 37,000 cm^{-1} and 30,000 cm^{-1}.[486] Ir^{II}–Ir^{II} stretching vibrations are observed between 140 cm^{-1} and 116 cm^{-1}, from which Ir_2 force constants are evaluated.

Reaction of equimolar amounts of $Ir(OMe)_2(cod)_2$ and I_2 in CH_2Cl_2 affords the dark red, dimeric species $[(cod)^{I}Ir(\mu\text{-}I)_2Ir^{I}(cod)]$ (**297**), which has been characterized by single- crystal X-ray diffraction.[487]

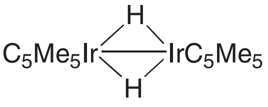
6.2.6.8 Hydrogen Ligands

Electrochemical oxidation of $IrH(CO)(PPh_3)_3$ in CH_2Cl_2 yields the Ir^{II}-containing cation $[IrH(CO)(PPh_3)_3]^+$, which is characterized by IR and EPR spectroscopy.[488] EPR data suggest the cation has a square-pyramidal geometry, in agreement with DFT calculations. Further one-electron oxidation gives the stable Ir^{I} species $[Ir(CO)(PPh_3)_3]^+$ according to reaction Scheme 27.

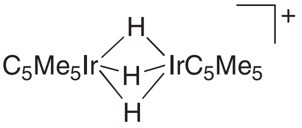
$$[IrH(CO)(PPh_3)_3]^+ - e^- \longrightarrow [IrH(CO)(PPh_3)_3]^{2+} \longrightarrow [IrH(CO)(PPh_3)_3]^+ + H^+$$

Scheme 27

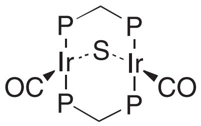
The binuclear Ir^{II} dihydride complex $[(C_5Me_5)Ir(\mu\text{-}H)]_2$, (**298**), has been structurally characterized.[489] (**298**) can abstract a proton from acidic organic compounds to give (**299**), can catalytically cleave C—C bonds in 1,2-diols, and can act as a catalyst for Michael addition reactions.[490] Oxidative addition of dihydrogen to the sulphido-bridged complex (**300**) affords the Ir^{II}/Ir^{II} dihydride species (**301**), which rearranges to give (**302**).[491]



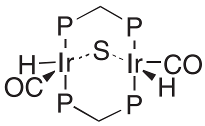
(**298**)



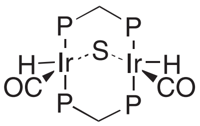
(**299**)



(**300**)



(**301**)



(**302**)

6.2.6.9 Mixed-donor-atom Ligands

6.2.6.9.1 C/P

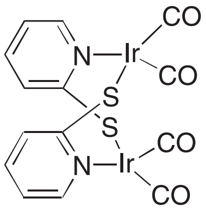
The orange-red, divalent Ir complex $[Ir(C_5H_4PPh_2)_2CO]_2^{2+}$ was synthesized following the chemical oxidation of $[Ir(C_5H_4PPh_2)CO]_2$ by either $[Fe(cp)_2]BF_4$ or $AgPF_6$.[492] The Ir^{II} complex was characterized by IR (ν_{CO}) and NMR spectroscopy.

6.2.6.9.2 N/P

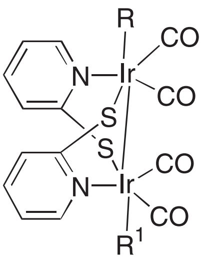
The Ir^{II} complex $[Ir(PN^tBu)_2]^{2+}$, $PN^tBu = O\text{-}Ph_2PC_6H_4\text{-}CH{=}N^tBu$, formed via one-electron oxidation of $[Ir(PN^tBu)_2]^+$, exhibits a rhombic EPR signal.[751]

6.2.6.9.3 N/S

Photochemical oxidative addition of (**303**) with I_2 MeI or CH_2I_2 gives dinuclear Ir^{II} complexes (**304**).[493] The crystal structure of (**304**), R = I, R′ = CH_2I, is reported.



(**303**)



(**304**)

6.2.6.10 Biological Complexes

The *in vivo* antitumor and trypanocidal effects of dimeric $[Ir^{II}_2(CH_3COO)_4(L)_n]^0$ (L = classical organic antimalarial drugs, $n = 1, 2$) are reported.[494] The dimeric complexes are characterized by IR spectroscopy. Further studies of monomeric Ir^{II} complexes, $Ir^{II}L_2$, where L = alkyl or aryl dithiocarbamates and xanthates, reveal no clear relation between antitumor and antitrypanosomal actvities.[495] Structure-activity data for the Ir^{II} complexes is presented.

6.2.6.11 Catalytic Complexes

An Ir^{II} intermediate in the carbonylation of ethanol, stabilized by the isoquinoline cation, has been isolated and characterized.[496] $IrCl_3 \cdot 3H_2O$ is the catalyst precursor and HI the promoter. The intermediate analyzes as $(C_9H_8N)[Ir(CO)_2I_3(COC_2H_5)]$. The magnetic moment is measured at 1.33 B.M., which is indicative of Ir^{II}.

6.2.7 IRIDIUM(I)

The geometry of most Ir^I complexes is based on the square-planar arrangement of ligands that arises from the d^8 electronic configuration. Vaska's compound, $[Ir(CO)Cl(PPh_3)_2]$, and derivatives thereof, and $[Ir(cod)Cl)]_2$ plus analogues prove to be the most useful Ir^I starting materials. Five-coordinate, trigonal-pyramidal structures also feature among Ir^I coordination compounds. Most Ir^I compounds are yellow or colorless, and all are diamagnetic. Common tools for characterization are NMR and IR spectroscopy.

6.2.7.1 Carbon Ligands

6.2.7.1.1 Isocyanide

$[Ir_2(\mu\text{-}CNR)_2(CNR)_2(Me_2PCH_2PMe_2)_2]$ ($R = 2,6\text{-}Me_2C_6H_3$) reacts with CO_2 to form $[Ir_2(CN(CO_2)R)_2(CNR)_2(Me_2PCH_2PMe_2)_2]$, which decomposes in CH_2Cl_2 to give $[Ir_2(\mu\text{-}CO)(\mu\text{-}H)(C(O)NHR)_2(CNR)_2(Me_2PCH_2PMe_2)_2]Cl$, (**305**), which is structurally characterized.[497] Labeling studies with $^{13}CO_2$ show that the μ-CO ligand in (**305**) is derived from CO_2. The binuclear complexes $[Ir_2(\mu\text{-}CNR)(CNR)_4(PMe_2CH_2PMe_2)_2](PF_6)_2$, (**306**), ($R = 2,6\text{-}Me_2\text{-}C_6H_3$, ^tBu) have been synthesized.[498] The X-ray structure of $R = 2,6\text{-}Me_2\text{-}C_6H_3$ reveals an A-frame structure and an Ir—Ir bond (2.7850(7) Å) bridged by a CNR ligand. Reaction with H_2 yields $[Ir_2(\mu\text{-}H)_2(CNR)_4(PMe_2CH_2PMe_2)_2](PF_6)_2$. Kinetic measurements reveal the reaction as first order in [(**306**)] and zero order in $[H_2]$.

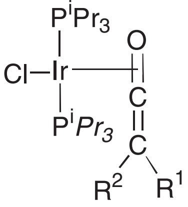
The electronic absorption spectrum of orange $[Ir(CNBu^t)_4]^+$ shows a $dz^2 \rightarrow pz$ transition around 420 nm, whereas blue $[Ir_2(tmb)_4]^{2+}$ (tmb = 2,5-diisocyano-2,5-dimethylhexane) absorbs strongly at 625 nm due to a $d\pi^* \rightarrow p\sigma$ transition.[499]

6.2.7.1.2 Carbonyl

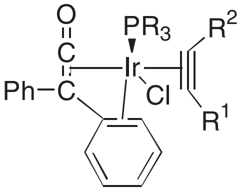
The X-ray crystal structure determination of *trans*-$[Ir(CO)_2(P^tBu_2Ph)_2][SiF_5]$ indicates an approximate square-planar geometry for the Ir cation.[500] The deviation of the C—Ir—C angle (162.7°) from 180° is indicative of the strong backbonding from the Ir^I into the CO π^* orbitals. The complexes $IrH(CO)_2(P^tBu_2Ph)$ and $IrH(CO)(P^tBu_2Ph)_2$ are characterized by multinuclear NMR and IR spectroscopy.

6.2.7.1.3 Alkyls and aryls

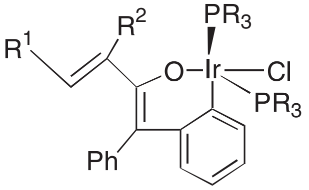
Benzene addition to $Ir(P^iPr_3)_2Cl$ is an exothermic reaction (22 kcal mol^{-1}), while addition to $Ir(P^iPr_3)_2(CO)Cl$ is endothermic (-5 kcal mol^{-1}).[501] The reaction enthalpies of substitution reactions to complexes containing the $Ir(P^iPr_3)_2Cl$ fragment are supplied. Reaction of $Ir(P^iPr_3)_2Cl$ with 2-pyridyl esters gives a μ^2 (C,O)-bound ketene, (**307**), where $R^2 = R^1$ = aryl or R^2 = aryl, R′ = alkyl.[502] (**307**) ($R^1 = R^2 = Ph$) reacts with alkynes to form a ketene–alkyne complex, (**308**), which ultimately yields the five-coordinate Ir^{III} species (**309**).[503]



(**307**)

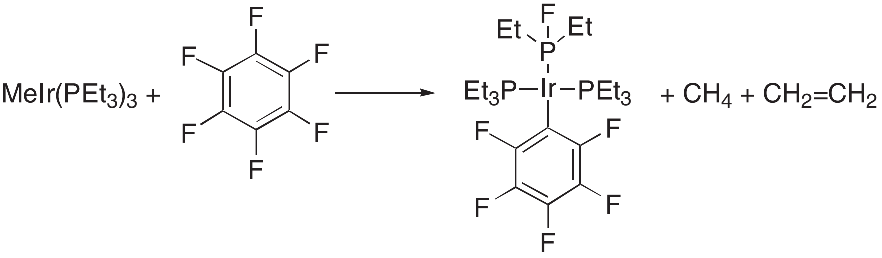


(**308**)



(**309**)

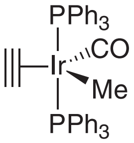
Reaction of hexafluorobenzene with $MeIr(PEt_3)_3$ results in C—F and P—C bond cleavage and P—F bond formation, according to reaction Scheme 28.[504] An X-ray crystallographic study of (**310**) reveals a distorted square-planar arrangement of Ir.



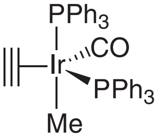
(**310**)

Scheme 28

A theoretical evaluation of C—X (X = F, Cl, Br, I) bond activation in CX_4 by an Ir^I complex is detailed by Su and Chu.[505] Reaction of $C_2(CO_2Me)_2$ with *trans*-$MeIr(CO)(PPh_3)_2$ affords a kinetic isomer (**311**), identified by NMR and IR spectroscopy, which converts to the thermodynamic isomer (**312**), characterized by ^{31}P and ^1H NMR, IR spectroscopy, and X-ray crystallography.[506]



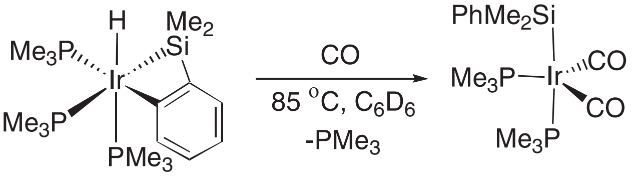
(**311**)



(**312**)

6.2.7.2 Silicon Ligands

The Ir^I silyl complex $Ir(PMe_3)_2(CO)_2(SiMe_2Ph)$, (**313**), is formed by reaction Scheme 29 and is characterized by X-ray crystallography.[507] This result shows that metalation of silyl ligands can be a facile, reversible process.



(**313**)

Scheme 29

6.2.7.3 Nitrogen Ligands

6.2.7.3.1 Pyridine

The bis pyridine complex [Ir(cod)py$_2$][PF$_6$], (**314**), is prepared by the reaction of [IrCl(cod)]$_2$ with pyridine in the presence of NH$_4$PF$_6$.[508] Best yields were achieved from a water/acetone (1:1) solvent system. Reaction of (**314**) with equimolar amounts of P(C$_6$H$_{11}$)$_3$ affords the substituted, air-stable species [Ir(cod){P(C$_6$H$_{11}$)$_3$}py][PF$_6$].

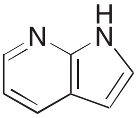
The reaction of [IrCl(cod)]$_2$ with K$^+$ form$^-$ (form = CH(N-*p*-C$_6$H$_4$Me)$_2$) in PhMe yields [Ir(form)(cod)]$_2$,[509] which on addition of two equivalents of AgOCOCF$_3$ produces (cod)Ir(μ-form)$_2$Ir(OCOCF$_3$)$_2$(H$_2$O), (**315**), containing an Ir$^{\text{I}}$ → Ir$^{\text{III}}$ dative bond.[510] The H$_2$O ligand in (**315**) can be replaced by other donor ligands, and the crystal structure of (cod)Ir(μ-form)$_2$-Ir(OCOCF$_3$)$_2$py (**316**) is reported. Cyclic voltammetric studies of (**315**) and (**316**) reveal that one-electron reduction of the Ir$^{\text{III}}$ center is rapidly followed by loss of H$_2$O and py, respectively.

The synthesis, structure, and electrochemistry of Ir$^{\text{I}}$ dinuclear complexes [Ir(μ-L)(cod)]$_2$ (L = 2-aminopyridinato (ap) and 2-anilinopyridinato (anp)) are reported, in which the square-planar Ir$^{\text{I}}$ centers are 3.0998 Å and 3.0681 Å apart, respectively.[511] Both complexes may be reversibly oxidized to the mixed-valent species. The frozen EPR spectrum of the mono-oxidized anp species shows a rhombic signal with no resolved hyperfine splitting.

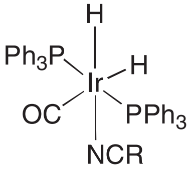
Preliminary data on the preparation of monomeric and dimeric Ir$^{\text{I}}$ species [IrCl(cod)(Haza)], (Haza = 7-azaindolate(1H-pyrrole[2,3-*b*]pyridine), (**317**)), [IrCl(CO)$_2$(Haza)], and [{Ir(μ-aza)(cod)}$_2$] are given.[512] The high-scale synthesis of pure [{Ir(μ-aza)(cod)}$_2$] is reported later;[513] it reacts with CO to afford the highly oxygen-sensitive binuclear complex [{Ir(μ-aza)(CO)$_2$}$_2$], in which the head-to-tail arrangement of the bridging aza ligands is non-interconvertible.

6.2.7.3.2 Nitriles

Reaction of [Ir(CO)(PPh$_3$)$_2$(ClO$_4$)] with the unsaturated nitriles L (PhCN=CHCN, *cis* and *trans* CH$_3$CH=CHCN, and CH$_2$=CHCH$_2$CN) produces [Ir(L)(CO)(PPh$_3$)$_2$]ClO$_4$, (**318**), where L is co-ordinated through the N atom.[514,515] (**318**) reacts through with H$_2$ to give the Ir$^{\text{III}}$ complex *cis*-[Ir(H)$_2$L(CO)(PPh$_3$)$_2$]ClO$_4$, (**319**). Both (**318**) and (**319**) show catalytic activity for the hydrogenation of L to PhCH$_2$CH$_2$CN or CH$_3$CH$_2$CH$_2$CN at 100 °C under 3 atm of H$_2$. In the absence of H$_2$, CH$_2$=CHCH$_2$CN isomerizes to CH$_3$CH=CHCN.



(**317**)



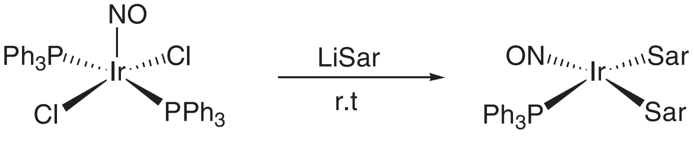
(**319**)

6.2.7.3.3 Nitride

The heterobimetallic, nitrido-bridged compounds (R$_3$SiO)$_3$V≡N—Ir(CO)(PPh$_3$)$_2$, (**320**), (R = Me, Et) were synthesized by condensation reactions between V(NSiR$_3$)(OSiR$_3$)$_3$ and IrF(CO) (PPh$_3$)$_2$ and should be considered as adducts of [(R$_3$SiO)$_3$V≡N:]$^-$ and [Ir(CO)(PPh$_3$)$_2$]$^+$.[516] Oxidative addition of MeI, O$_2$, H$_2$ to (**320**) gives the Ir$^{\text{III}}$ compound, which retains the V≡N—Ir moiety. However, the nitrido linkage may be cleaved at Ir by silyating reagents ClSiMe$_3$, ClSiEt$_3$, or HSiEt$_3$.

6.2.7.3.4 Nitrosyl

A series of square-planar Ir$^{\text{I}}$ complexes, [Ir(NO)(Sar)$_2$(PPh$_3$)], (**321**), (ar = C$_6$H$_2$Me$_3$-2,4,6 (mes), C$_6$H$_3$Me$_2$-2,6, and C$_6$H$_2{}^{\text{i}}$Pr$_3$-2,4,6) are prepared according to reaction Scheme 30, and all contain a linear nitrosyl ligand ($\nu_{NO} = 1{,}802\text{–}1{,}825\,cm^{-1}$).[747] The X-ray diffraction study of (**321**) with ar = mes is reported.

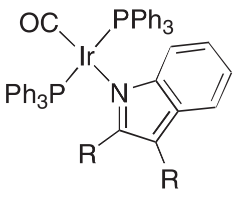


(**321**)

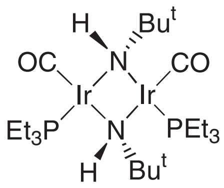
Scheme 30

6.2.7.3.5 *Amides*

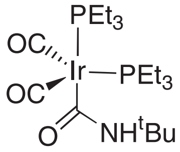
The reaction of Vaska's compound with the lithium salts of aryl amides yields *trans*-$Ir(PPh_3)_2(CO)(NHAr)$, (**322**), (ar = C_6H_5, *p*-C_6H_4Me, *o*-C_6H_4Me, 3,5-$C_6H_3Me_2$, 2,6-$C_6H_3Me_2$, *p*-C_6H_4Cl, *p*-$C_6H_4NO_2$).[517] Single-crystal X-ray diffraction studies of (**322**), ar = *p*-$C_6H_4NO_2$[518] and ar = 3,5-$C_6H_3Me_2$,[517] are reported and show a virtually planar Ir center, with the plane of the amido phenyl ring perpendicular to the square plane around Ir^I. All of the complexes except (**322**) with ar = *p*-$C_6H_4NO_2$ undergo rapid reactions with CO. The related complex (**323**) forms from a similar reaction of Vaska's compound with Li indolyl.[519] The X-ray crystal structure of (**323**) (R = Me) is reported. (**323**) is unreactive towards CO and protic acids, but reacts with triflic acid at the 3-position of the ring to give an indolenine cation. Reaction of *trans*-$Ir(PR_3)_2(CO)Cl$ (R = Me, Et) and LiNHPh in THF gives *trans*-$Ir(PR_3)_2(CO)(NHPh)$, (**324**).[520] Benzene solutions of *trans*-$Ir(PEt_3)_2(CO)(NHBu^t)$ readily convert to the dimer species (**325**) when heated.



(**323**)



(**325**)



(**326**)

(**325**) reacts with CO to give the carbamoyl complex (**326**), and with PhC≡CH to give the bisalkynyl complex *trans*-$Ir(PEt_3)_2(CO)H(C{=}CPh)_2$.

The bridged amido complex $[Ir\{\mu\text{-}NH(p\text{-tolyl})\}]_2(CO)_4$ is prepared according to Reaction Scheme 31.[521] The X-ray crystal structure reveals each Ir^I center to be in a roughly square-planar geometry, with an angle between the two Ir planes of 124.6 °. The structure contains a single Ir—Ir bond of 2.933 Å. The bridging amido ligands undergo deprotonation by ^tBuLi in a stepwise manner, as shown in reaction Scheme 32.[522]

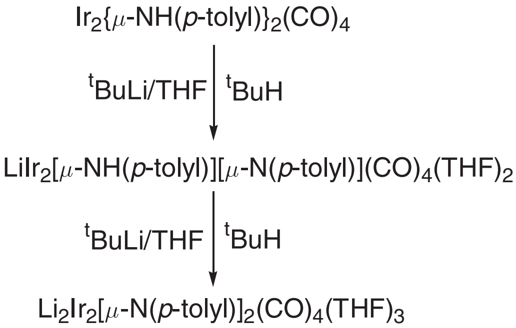
$$2Ir(CO)_2Cl(NH_2\text{-}p\text{-tolyl}) + 2NaOR \longrightarrow Ir_2(\mu\text{-}NH\text{-}p\text{-tolyl})_2(CO)_4 + NaCl + ROH \ (R = Me, Et, Ph)$$

Scheme 31

(**327**) reacts with $(PPh_3)AuCl$ to generate the tetranuclear complex (**328**).

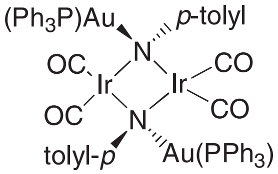
6.2.7.3.6 α-*diimines*

$[Ir(cod)Cl]_2$ reacts with α-diimines LL (derived from glyoxal and biacetyl) to yield cationic $[Ir(cod)LL]^+$.[523] If the reaction is carried out in the presence of $SnCl_2$, then the pentacoordinate $Ir(SnCl_3)(cod)LL$ species results. The compounds are active catalysts in the homogeneous hydrogen transfer from isopropanol to cyclohexanone or to acetophenone followed by hydrogenation to phenylethanol.[524] α,β-unsaturated ketones are reduced to saturated ketones and alcohols. Reaction pathways are discussed.

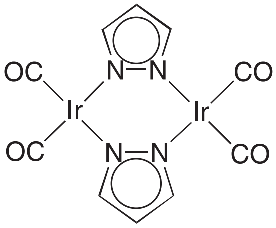


(**327**)

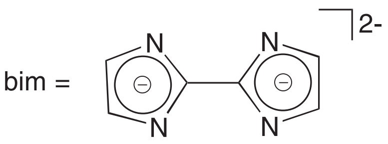
Scheme 32



(**328**)



(**329**)



(**334**)

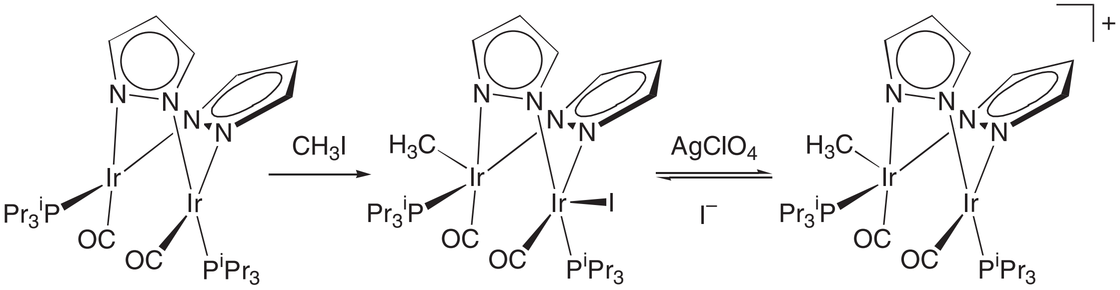
6.2.7.3.7 *Pyrazole and derivatives*

The pyrazole ligand may be found bridging a variety of binuclear Ir compounds and mixed-metal Ir species. Reaction of $[Ir(\mu\text{-pz})(cod)]_2$ (pz = pyrazole) with CO yields the yellow, stable, binuclear complex $[Ir(\mu\text{-pz})(CO)_2]_2$, (**329**), with an Ir—Ir distance of 3.506 Å.[525] Substitution of Me groups in the 3- and 5-positions of pz gives an analogous complex $[Ir(\mu\text{-dmpz})(CO)_2]_2$ (dmpz = 3,5-dimethyl pyrazole), having an Ir—Ir distance of 3.245 Å. The structure of the mixed-metal compound $[Me_2Ga(\mu\text{-pz})_2Ir(cod)]$ is also detailed. The structure of $[Ir(\mu\text{-dmpz})(CO)(Ph_2POC_6H_4CH_3)]_2$ contains two square-planar Ir^I centers with an Ir—Ir distance of 3.307 Å.[526]

Electrochemical studies of $[Ir(\mu\text{-pz})(cod)]_2$ in CH_2Cl_2 reveal two one-electron oxidations. The position of the second oxidation depends on the nature of the supporting anion. Addition of CH_3CN to the solution causes the second oxidation process to shift to the same potential as the first wave, due to the strong complexation of two CH_3CN ligands.[527] Comparative studies on $[Ir(\mu\text{-L})(cod)]_2$ (L = pz, 3-methylpyrazole (mpz), and dmpz) in THF shows that the first oxidation potential shifts to more negative potentials with increasing substitution.[528]All three compounds exhibit an irreversible reduction. Electrogenerated chemiluminescence is observed by pulsing the working electrode between the anodic and cathodic peak potentials.

The electronic absorption and emission spectra and emission lifetimes of $[Ir(\mu\text{-L})(CO)_2]_2$ (L = pz, mpz and dmpz) have been determined.[529] The intense low-energy absorption band around 400 nm is assigned to a $dz^2 \rightarrow pz$ electronic transition. The three complexes all emit around 740 nm at 300 K and 670 nm at 77 K. The dimer excited states are stabilized relative to monomer levels by strong metal–metal bonding.

The Ir^I–Ir^{III} mixed-valent, pyrazole-bridged species $[Ir_2(\mu\text{-pz})_2(CH_3)(CO)_2(P^iPr_3)_2]ClO_4$, (**330**), is formed according to reaction Scheme 33.[530] The X-ray diffraction data indicated that (**330**) contains a square-planar Ir^I center and a nearly regular square-pyramidal Ir^{III} center, connected via a weak metal–metal bond of 2.8694 Å. The two very different ν_{CO} stretching vibrations confirm the different Ir oxidation states.



(330)

Scheme 33

The IR- and ^{1}H NMR-characterized, hetero-binuclear, pyrazole-bridged complex [(C_5Me_5)-Rh(μ-Cl)$_2$(μ-pz)Ir(tfb)] (tfb = tetrafluorobenzo[5.6]bicyclo[2.2.2]octa-2,5,7-triene)] contains the unusual combination of oxidation states Rh^{III}–Ir^{I}.[531] The reaction of Ir(PPh$_3$)$_2$ (CO)(dmpz) with Au(tht)X (tht = tetrahydrothiophene, X = Cl, Br) affords the Ir^I–Au^I derivative Ir(PPh$_3$)$_2$(CO)(μ-dmpz)AuX, whereas reaction with Au(tht)Cl$_3$ gives an unstable, yellow, bimetallic intermediate IrAu(PPh$_3$)$_2$(CO)(dmpz)Cl$_3$, which readily decomposes to (Audmpz)$_n$ and Ir(PPh$_3$)$_2$(CO)Cl$_3$.[532]

The heterodinuclear complex [(η^6-p-cymene)(pz)Ru(μ-pz)$_2$Ir(CO)$_2$] was prepared by reacting [(η^6-p-cymene)Ru(pz)(Hpz)] with [Ir(acac)(CO)$_2$]$^-$ (p-cymene = p-isopropylmethylbenzene, acac = acetylacetate).[533] The X-ray structure of the protonated BF$_4$$^-$ salt confirms two bridging pz ligands with no intermetallic interaction, and a further protonated Hpz ligand bound to the Ru^{II} center.

The donor–acceptor complexes [Ir(μ-dmpz)(CO)(PPh$_2$\{O(CH$_2$)$_2$R\})]$_2$ exhibit photo-induced electron-transfer rate constants of $10^{12}\,s^{-1}$ and charge recombination rates slower than $2 \times 10^{10}\,s^{-1}$ when R = pyridine and 4-phenylpyridine.[534] Further studies on these complexes revealed that recombination reactions were temperature dependent and slower for the deuterated acceptors.[535]

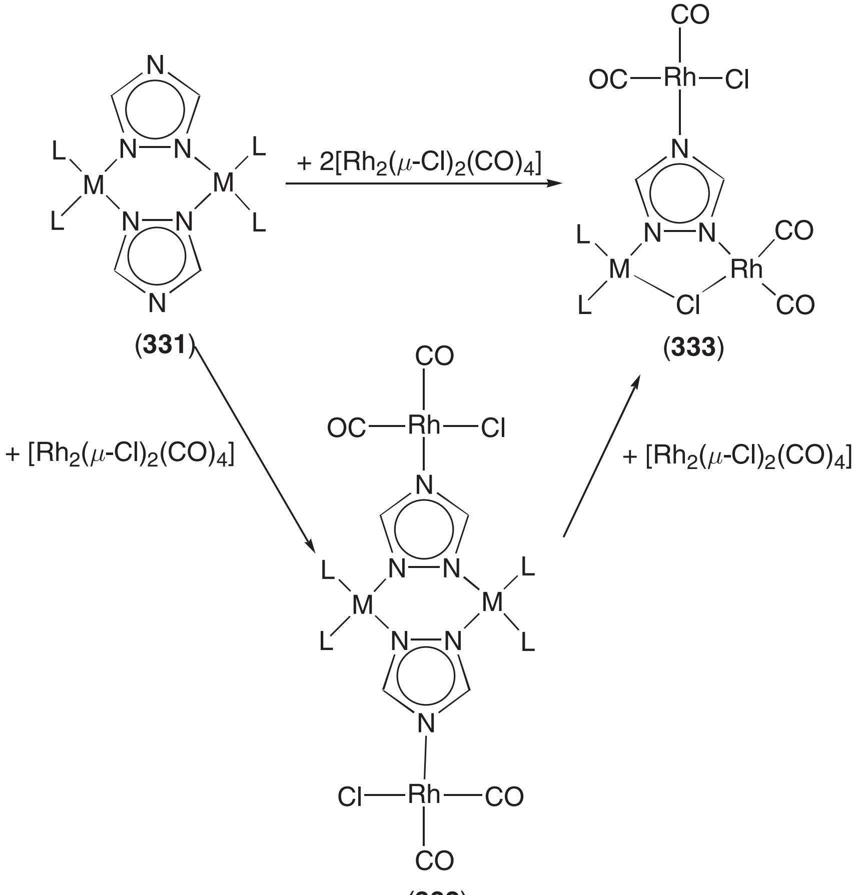
The binuclear complexes of formula [M$_2$(μ-tz)$_2$(L$_2$)$_2$], (**331**), (tz = triazolate, M = Rh, Ir, L$_2$ = diolefin, (CO)$_2$, or (CO)(PPh$_3$)) have been prepared.[536] Reaction with [Rh(μ-Cl)$_2$ (L$_2$)$_2$] yields the tetranuclear compounds [Rh$_2$Ir$_2$(μ^3-tz)$_2$Cl$_2$(L$_2$)$_4$], (**332**), and the trinuclear mixed-metal complex [Rh$_2$Ir(μ^3-tz)(μ-Cl)ClL$_2$(CO)$_4$], (**333**), (L = cod) according to Reaction Scheme 34.

The anionic ligand 2,2′-bi-imidazolate (2-) (bim) (**334**) has been reported to bridge Ir^I and Rh^{III} centers to form binuclear and tetranuclear complexes, [(η-C$_5$Me$_5$)pyRh(bim)Ir(tfb)](ClO$_4$) and [\{(η-C$_5$Me$_5$)(PR$_3$)Rh(bim)Ir(tfb)\}$_2$](ClO$_4$)$_2$ (R = Ph, OEt).[537] Oligomerization reactions of the planar anion [Ir(CO)$_2$Tcbim]$^-$ (H$_2$Tcbim = 4,4′,5,5′-tetracyano-2,2′-biimidazole), studied as a function of concentration, revealed that at 10^{-3} M dimerization resulted, with a concomitant growth of a strong ($\varepsilon = 18{,}500\,M^{-1}cm^{-1}$) absorption band at 475 nm.[538] At higher concentrations (10^{-2} M), further oligomerization was observed. The chemistry of Tcbim and its complexes with Ir^I was reviewed in 1987 by Rasmussen.[539]

6.2.7.3.8 Bis-chelating Ligands

The structurally characterized complex [cp*Ir(4,4′-(COOH)$_2$-bpy], cp* = pentamethyl cyclopentadienyl, bpy = 2,2′-bipyridine, has a five-coordinate Ir^I center.[540] The bpy mean plane makes an angle of ca. 75° with the cp* mean plane. The π-acceptor properties of the bpy ligand lead to unusually short Ir–cp* distances. The black compound [IrCl(CO)(bpy)] is formed when a mixture of [IrCl(C$_8$H$_{14}$)$_2$]$_2$, (**335**), and bpy in CH$_2$Cl$_2$ is exposed to an atmosphere of CO, and it exhibits a single ν_{CO} stretching frequency of 1,996 cm^{-1}.[541] If (**335**) is reacted with an excess of bpy, then the hydride complex IrH(bpy)$_2$·CH$_2$Cl$_2$ is formed, with a ν_{Ir-H} stretch at 2,114 cm^{-1}. The donor–acceptor properties of several derivatized bpy and 1,10-phenanthroline (phen) ligands (N$\cap$N) were characterized in [Ir(N$\cap$N)(CO)$_2$](PF$_6$) by analyzing the symmetric ν_{CO} stretching vibration.[542] The 2,2′-dipyridylamine ligand (Hdipy), and its deprotonated form (dipy), coordinate to Ir(CO)$_2$ and Ir(diolefin) fragments.[543]

The cationic [Ir(cod)(bnda)](BF$_4$) complex (bnda = 2,2′-diamno-1,1′-binaphthyl), (**336**), catalyzes the enantioselective hydrogenation of (Z)-α-acetamidocinnamic acid to acetamidodihydrocinnamic

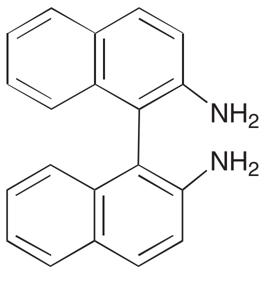


(**332**)

Scheme 34

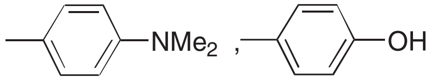
acid at room temperature under 35 atm of H_2.[544] The bnda complex is prepared by the reaction of $[IrCl(cod)]_2$ with $AgBF_4$, followed by treatment with bnda.

bnda =



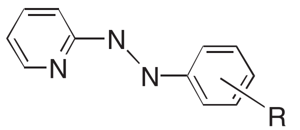
(**336**)

R = cyclohexyl,



(**337**)

N∩N =



(**338**)

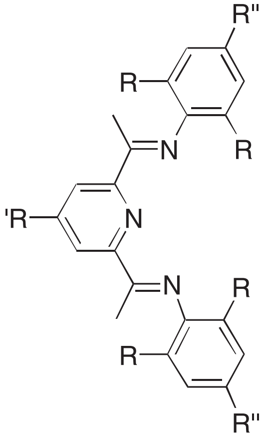
1 R = *p*-Cl
2 R = *m*-Me

$[IrCl(cod)]_2$ reacts with α-diimines derived from glyoxal (R—N=CH—CH=N—R) (LL), R = (**337**), in acetone containing PPh_3 and $AgBF_4$ to yield the pentacoordinate complexes of general formula $[Ir(cod)(LL)(PPh_3)](BF_4)$.[545] Exposure to CO results in displacement of cod by two CO ligands. $[Ir(CO)(LL)(PPh_3)_2]ClO_4$ results from the reaction of *trans*-$[Ir(OClO_3)(CO)(PPh_3)_2]$ with LL.

The structure and properties of azopyridine chelates (N∩N) (**338**) of iridium, [Ir(cod)(N∩N)X] (X = Cl, Br, I), are detailed.[546] The dark blue compounds [Ir(cod)(N∩N^1)Cl] and [Ir(cod)(N∩N^2)I] are characterized by X-ray crystallography and show a square-pyramidal geometry. The intense color has been assigned to an electronic transition primarily localized on the Ir–(N∩N) fragment. The complexes do not undergo oxidative addition reactions, in contrast to their bpy analogues.

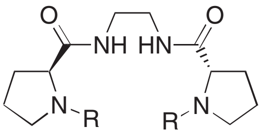
6.2.7.3.9 Polydentate N-donor ligands

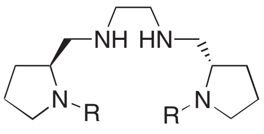
The tridentate N-donor ligand (**339**) forms square-planar $\mathrm{Ir^I}$ chloro complexes through coordination to the three N-donor atoms.[547] Attempts to exchange directly the chloride ligand for hydride and methyl ligands were unsuccessful. However, routes were developed to the reactive methoxide and triflate complexes, which proved to be excellent starting materials for the synthesis of $\mathrm{Ir^I}$ and $\mathrm{Ir^{III}}$ methyl compounds. The structure, bonding, and thermodynamics of the methoxy species were analyzed by DFT methods. The X-ray crystal structure of the $\mathrm{Ir^I}$ methoxy species shows square-planar geometry at the metal center.



(339)

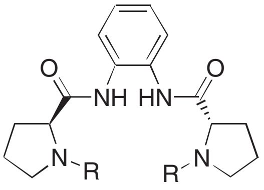
The tetradentate ligands (**340**) and (**341**) form 1:1 metal:ligand complexes with $[\mathrm{IrCl(cod)}]_2$.[548] The complexes were tested in the asymmetric hydrogenation of prochiral olefins, providing enantioselectivities up to 36%. The multitopic ligands L, (**342**) and (**343**), bind to $\mathrm{Ir^I}$ to form [IrL] species which have been characterized by elemental analysis, mass spectrometry, IR and NMR spectroscopy.[549] The complexes show enantioselectivities of up to 30% for the hydrogenation of prochiral olefins under mild reaction conditions.

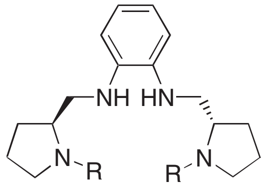




R = H, Benzyl

(340) **(341)**





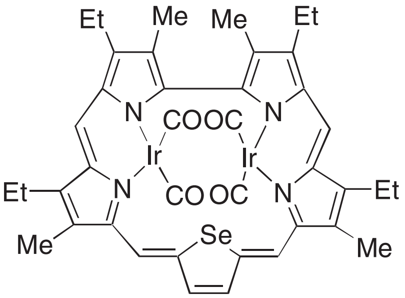
R = H, Benzyl

(342) **(343)**

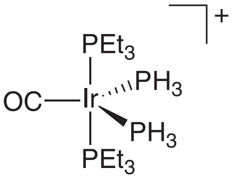
The theoretical study of complexes [IrLCl], $[\mathrm{cpIrCl}]^{1-}$, and $[\mathrm{IrCl_2(PH_3)_2}]^{1-}$, where L is a tridentate chelating ligand, has resulted in the establishment of criteria for selecting tridentate chelating ligands for the stabilization of hydridoalkyl complexes [(Me)Ir(L)(H)Cl].[550]

The *bis*-$\mathrm{Ir^I}$ complex (**344**) of the selena sapphyrin ligand has been synthesized and characterized by X-ray diffraction studies.[551] The pairs of bound N atoms in (**344**) are bent towards the $\mathrm{Ir^I}$ centers, and the respective pyrrole rings are twisted from the macrocyclic plane. The coordination geometry around the Ir is close to square-planar, and the Ir—Ir distance is 4.233 Å. The Se center is not involved in bonding to the Ir centers.

The triazenide-bridged Ir/Rh complexes, general formula $[\mathrm{RhL_m}(\mu\text{-RNNNR})_2\mathrm{IrL_n}]$, (**345**), $\mathrm{L_m}$ = cod, $(\mathrm{CO})_2$, $(\mathrm{CO})(\mathrm{PPh_3})$, $(\mathrm{CO})\{\mathrm{P(OMe)_3}\}$, $\mathrm{L_n} = (\mathrm{CO})_2$, $(\mathrm{CO})(\mathrm{PPh_3})$, $(\mathrm{CO})\{\mathrm{P(OMe)_3}\}$, $\mathrm{R = C_6Me_4Me}$-*p*, are electrochemically and chemically oxidized by one electron to form paramagnetic monocations.[552] The X-ray structure of (**345**), $\mathrm{L_m}$ = cod, $\mathrm{L_n} = (\mathrm{CO})_2$, confirms the square-planar geometry of the Ir center. EPR studies of the monocations show coupling to both $^{103}\mathrm{Rh}$ and $^{191,193}\mathrm{Ir}$ whose magnitude depends on the ancillary ligands at the two metals.



(344)



(346)

6.2.7.4 Phosphorus Ligands

6.2.7.4.1 Monodentate Ligands

Reactions of Vaska-type compounds $[Ir(CO)X(PR_3)_2]$, where X = halide and R = alkyl, aryl, commonly yield Ir^{III}-containing complexes and are considered in the appropriate Ir^{III} section. The structure and chemistry of analogues of Vaska's compound will be addressed here. *Trans*-$[IrCl(CO)\{P(C_6H_4\text{-}p\text{-}Me)_3\}_2]$, characterized by X-ray crystallography, is structurally similar to Vaska's compound.[553] The structures of *trans*-$[IrCl(CO)\{P(C_6H_{11})_3\}_2]$ and $[Ir(cod)(py)\{P(C_6H_{11})_3\}](PF_6)$ show approximate square-planar geometry at Ir, with distortions due to the size of the $P(C_6H_{11})_3$ ligand.[554,555]

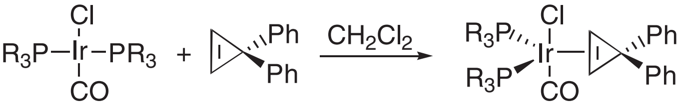
The initial product of reaction of $[Ir(CO)X(PEt_3)_2]$, X = Cl or Br, at 180 K with PH_3 is identified by ^1H and ^{31}P NMR spectroscopy as (**346**), which converts to (**105**) at 230 K.[556]

The molecular conformation of *trans*-$[(^tBu)_2PPh]_2Ir(CO)Cl$ has been investigated by $^{31}P\{^1H\}$ NMR spectroscopy and reveals four diastereoisomers: two major conformations in which the phenyl groups are mutually *anti* and orientated on the same side or opposite sides of the coordination plane, and two minor isomers in which the two phenyl groups are *syn* to the CO ligand.[557]

The electron density at the Ir nucleus of the series *trans*-$(Ph_3P)_2Ir(CO)(X)$, *trans, cis*-$(Ph_3P)_2(H)_2Ir(CO)(X)$ (X = Cl or *pz-N*, *pz-N*-H = 3,5-dimethyl-, 3,5-dimethyl-4-nitro-, 3,5-bis(trifluoromethyl)pyrazole) and *trans*-$(Ph_3P)_2(CO)Ir[\mu$-3,5-dimethyl-pyrazole-*N,N′*$)]AuX'$ (X′ = Cl, Br), studied by ^{193}Ir and ^{197}Au Mössbauer spectroscopy, is affected by the substituents on the heterocycle and the density of ligand X, but not by the presence of conformers.[558] Electronic effects are transmitted from Au to Ir.

The study of rapid, intermolecular ligand exchange between square-planar complexes *trans*-$Ir(CO)L_2X$ (X = Cl or Me, L = PPh_3, P(*p*-tolyl)$_3$, or $PMePh_2$) by variable-temperature ^{31}P NMR spectroscopy indicates that the reaction proceeds through dissociation of phosphine from the metal center and a subsequent associative substitution with other complexes.[559,560] Ligand exchange between square-planar Ir and Pt complexes is slow.

A series of $Ir(CO)Cl(PR_3)_2(\eta^2$-3,3-diphenylcyclopropane) complexes ($PR_3 = PMe_3$, PMe_2Ph, $PMePh_2$, PEt_3) is prepared according to reaction Scheme 35.[561]



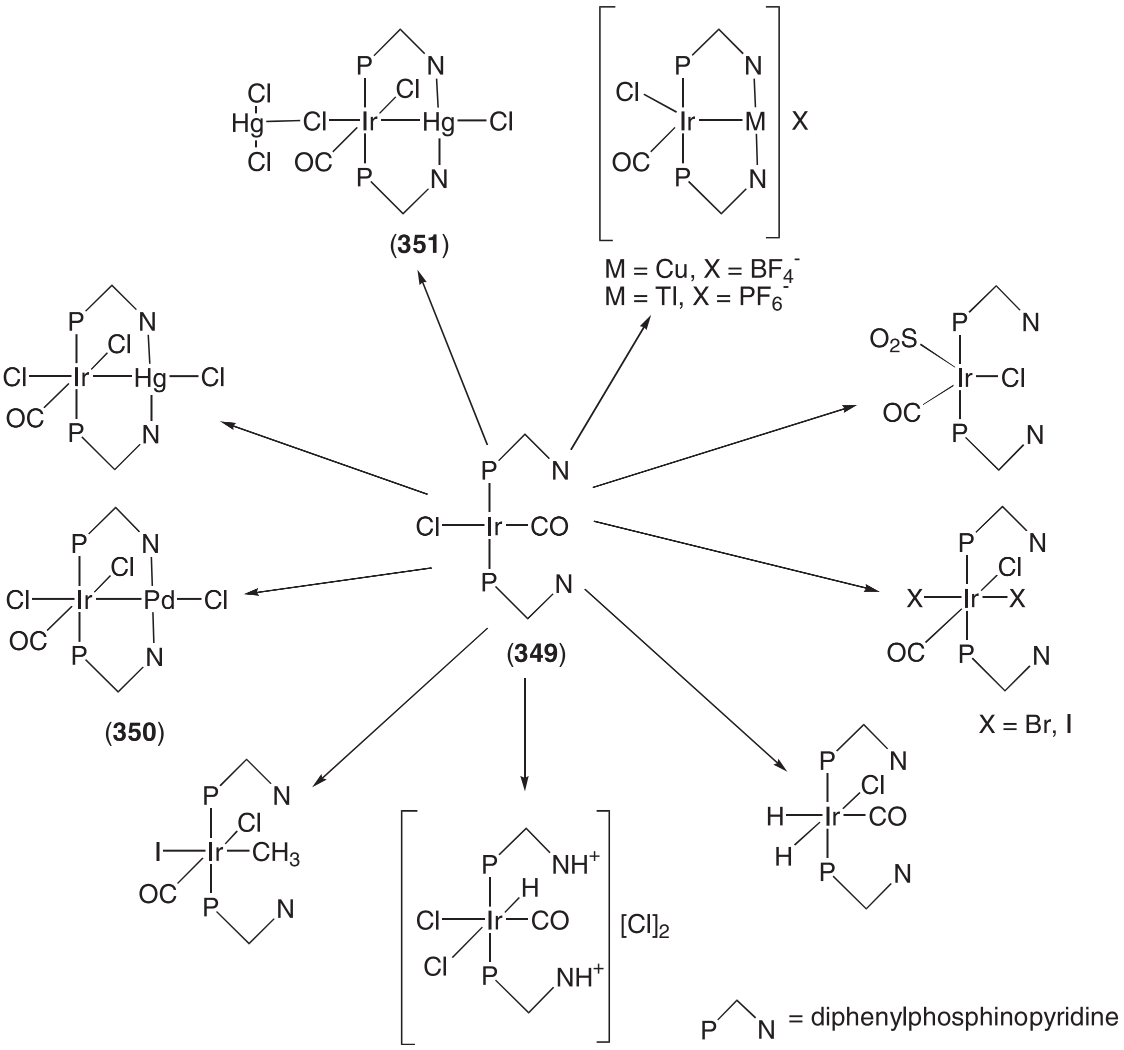
(347)

Scheme 35

The X-ray structure of (**347**), $PR_3 = PMe_3$, confirms the trigonal-bipyramidal structure, with the olefin and phosphine ligands lying in the equatorial plane. The equilibrium between free and bound olefin depends on the size of the tertiary phosphine. Further reaction of (**347**) with $IrCl(CO)(PMe_3)_2$ results in formation of a bimetallic iridacyclobutene complex by a second-order process.

Trans-IrCl(CO)$(PPh_3)_2$ reacts with tppts (tppts = *m*-sulfonatophenyl sodium diphenyl phosphine; tppms is the potassium analogue) to give the water-soluble complex *trans*-IrCl(CO)$(tppts)_2$ in good yield (71%).[562] The hydroxo analogue *trans*-Ir(CO)(OH)$(tppms)_2$, (**348**), has excellent solubility in water. Reaction of (**348**) with H_2 yields *fac*-Ir(CO)$(H)_3(tppms)_2$ in H_2O, but 1:1 *fac/mer* mix when the reaction is carried out in DMSO.[563] The tppms complexes of Ir have very similar spectroscopic characteristics to the PPh_3 analogue, and similar reactions in toluene. However, weak acid/base equilibria are evident for aqueous solutions of tppms, which are not observed in nonaqueous solvents. Hydrogen adds to *trans*-Ir(CO)ClL_2 (L = tppms, tppts) in H_2O and has a similar kinetic deuterium isotope effect to its PPh_3 analogue in toluene, indicating a common mechanism. Increasing the pH of the aqueous solution decreases the rate of H_2 addition, which is ascribed to protonation/hydrogen bonding to the Ir center.[564] Further studies of the complexes reveal that $[Ir(CO)(tppms)_3]^+$ is stable in H_2O but forms $[Ir(CO)(DMSO)(tppms)_2]^+$ in DMSO. $[Ir(CO)_2(tppms)_3]^+$ reacts with CO in DMSO to give $[Ir(CO)_3(tppms)_2]^+$, but there is no reaction in H_2O. Reaction of *trans*-Ir(CO)ClL_2 with excess L in H_2O produces $[Ir(CO)L_3]Cl$; however, there is no reaction in DMSO.[565]

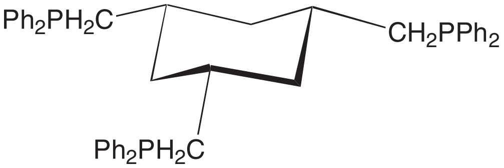
Vaska's analogue *trans*-$[Ir(CO)Cl(Ph_2Ppy)_2]$, (**349**), (Ph_2Ppy = 2-diphenylphosphinopyridine) has two monodentate, P-bound Ph_2Ppy ligands. (**349**) undergoes a variety of reactions according to Reaction Scheme 36.[566] The X-ray crystal structures of (**350**) and (**351**) are given. Complex (**349**) acts as a precatalyst in the hydroformylation of styrene at 80 °C and under 80 atm of CO/H_2.



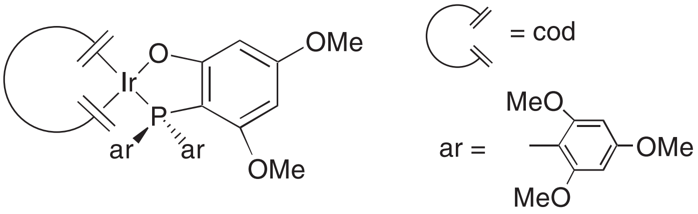
Scheme 36

The steric and electronic effects of phosphine ligands on the binding of small molecules to Ir^I were probed by studying reactions of O_2, SO_2, and CH_3I with *trans*-$Ir(CO)(Cl)(PR_3)_2$, where $PR_3 = P(^iPr)_3$ and $P(^tBu)_2Me$, compared to $PR_3 = PPh_3$, $P(p\text{-tolyl})_3$, and Pcy_3. Increasing phosphine size inhibits O_2 reaction, but not SO_2 reaction.[567]

Treatment of *cis,cis*-1,3,5-tris[(diphenylphosphanyl)methyl]-cyclohexane (tdppmcy), (**352**), with $Ir(PPh_3)_2(CO)Cl$ in toluene gives the trinuclear complex $[Ir(CO)Cl]_3$ $(tdppmcy)_2$, (**353**), in which tdppmcy ligands act as bridging ligands to each of the Ir centers.[568] Addition of H^+, H_2, and H^- to (**353**) yields $\{[Ir(CO)ClH]_3(tdppmcy)_2\}^{3+}$, $[Ir(CO)ClH_2]_3(tdppmcy)_2$, and $[Ir(CO)H_3]_3$ $(tdppmcy)_2$, respectively.



(**353**)



(**354**)

The structure of *trans*-$[IrCl(COp)(^iPr_3P)]$ confirms a Vaska-type geometry of Ir.[569] The structure of $[Ir\{P(C_6H_5)_2CH_3\}_4](BF_4)$ has been reappraised and found to belong to the space group R*c*, and not to *C*2/*c* as previously reported.[570,571] The bond lengths and angles do not differ significantly from the earlier report. The structure of $[Ir(PPh_3)_2(cod)](PF_6)$ reveals a square-planar geometry at Ir, but different Ir—P bond lengths at 2.367(2) Å and 2.326(3) Å.[572]

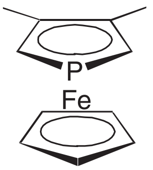
Treatment of $[Ir(coe)_2Cl]_2$ with PEt_3 in THF at room temperature yields $[Ir(PEt_3)_3Cl]$.[573] Heating the solution to 80 °C gives $IrH_2Cl(PEt_3)_3]$.

$[Ir(MeCN)(CO)\{P(CH_2Ph)_3\}_2]ClO_4$ reacts with CO to give $[Ir(CO)_x\{P(CH_2Ph)_3\}_y]ClO_4$ ($x = 1$, 2, 3, $y = 3$, 2) and with X ($X^- = NCS^-$, $^-C{:}CPh$) to give $[IrX(CO)\{P(CH_2Ph)_3\}_2]$; both have been characterized by IR spectroscopy.[574] The trigonal-bipyramidal species $[Ir(CO)_3$ $(PEt_3)_2]BF_4$ reacts with PH_3 to form $[Ir(CO)_2(PH_3)(PEt_3)_2]BF_4$.[575] Both Ir species undergo oxidative addition reactions with HX (X = Cl, Br, I) and SiH_3Br.

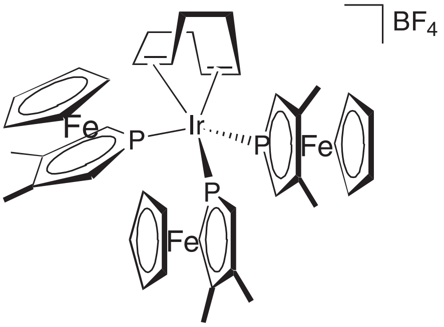
A series of complexes $[IrCl(cod)L]$ and $[Ir(cod)L_2]^+$ ($L = P(C_6H_4OMe\text{-}o)_3$, $PMe_2(C_6H_4OMe\text{-}o)$, $PMe_2(C_6H_4OMe\text{-}o)$, $PPh_2(C_6H_4OMe\text{-}o)$, $PPh_2(C_6H_4NMe_2\text{-}o)$, $PMe(C_6H_4OMe\text{-}o)_2$, $PPh_2(C_6H_4\text{-}OCHMe_2\text{-}o)$) have been synthesized and characterized by ^1H and ^{31}P NMR spectroscopy.[576] The *O*-containing ligands bind in a monodentate fashion, whereas the *N*-containing ligand chelates to the Ir center.

Reaction of $[Ir(cod)Cl]_2$ with two molar equivalents of $P(C_7H_7)_3$ yields the highly symmetric complex $IrCl[P(C_7H_7)_3]$, in which the phosphorus ligand acts as a tetradentate ligand.[577] The X-ray crystal structure of the Rh analogue reveals Rh at the center of a trigonal bipyramid, with Cl and P in the axial positions and three double bonds forming the equatorial plane. However, reaction of $[Ir(cod)Cl]_2$ with an excess of tmpp (tmpp = tris(2,4,6-trimethoxyphenyl)phosphine) in the presence of KBF_4 yields the air-unstable, mono-demethylated complex (**354**).[578] If the reaction is carried out in CH_3CN under a CO atmosphere, then *trans*-$[Ir(CO)_2(tmpp)_2](BF_4)$ results, which has been characterized by X-ray crystallography and shows the expected square-planar geometry at Ir.

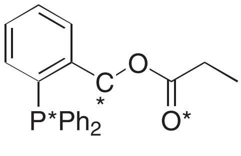
A further reaction of $[Ir(cod)Cl]_2$ with 3,4-dimethylphosphaferrocene, (**355**), yields the trigonal-bipyramidal complex $[Ir(\mathbf{355})_3(cod)]BF_4$, (**356**).[579] (**356**) reacts with H_2 under pressure to give $[Ir(355)_4H_2]^+$. Reaction of $[Ir(cod)Cl]_2$ with *o*-diphenylphosphinobenzoic acid ethyl ester (dpes), (**357**), yields [IrCl(cod)(dpes)], where dpes is acting as a monodentate P-donor-atom ligand.[580] When dpes is reacted with $[Ir(cod)_2]BF_4$, then the structurally determined species $[Ir(cod)dpes(H)](BF_4)$ results, in which the dpes is a tris-chelating ligand with P*, C*, and O* donor atoms.



(355)



(356)



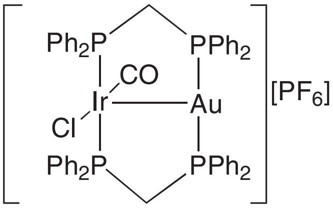
dpes

(357)

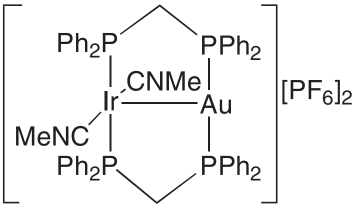
The crystal structure of $[IrCl(tcep)_3]$ (tcep = tris(cyanoethyl)phosphine) as an MeCN solvate shows a distorted square-planar coordination geometry.[581] The structure of $[Ir(cod)(py)(P(2,\text{-}6\text{-}(OMe)_2\text{-}C_6H_3)_3)]PF_6$ shows approximately square-pyramidal geometry at the Ir atom, with one of the methoxy groups of the phosphine ligand weakly bound in the apical position (Ir–O, 2.724 Å).[582] The related complex $[Ir(cod)(py)(P(4\text{-}OMe\text{-}C_6H_4)_3)]PF_6$ reveals a square-planar coordination of Ir.[583] Increasing the steric bulk of the phosphine ligands gives rise to distorted geometries around the Ir center. The binuclear Ir^I complex $[Ir_2(CO)_2(dmpm)_2\text{-}(\mu\text{-}CO_3)]$ is characterized by single-crystal X-ray diffraction and shows a weakly interacting Ir···Ir bi-square-planar geometry.[748]

The synthesis of bimetallic, group 6 metal(0)–iridium(I) complexes bridged by dppm (dppm = $Ph_2PCH_2PPh_2$), of general formula $[(OC)_3M'(\mu\text{-dppm})_2M(CO)X]$ (M′ = Cr, Mo, W, M = Rh, Ir, X = Cl, Br, I, CO), by two independent routes is detailed by Shaw *et al.*[584] The complexes are characterized by $^1H\text{-}\{^{31}P\}$ and $^{31}P\{^1H\}$ NMR and IR spectroscopy.

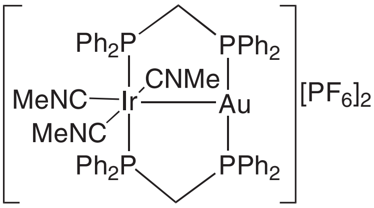
The Ir^I–Au^I complex (**358**) yields (**359**) and (**360**) following treatment with two or three equivalents of MeCN, respectively.[585] Red (**359**) has a nearly planar $Ir(CNCH_3)_2P_2$ unit connected to a linear AuP_2 unit and an Ir–Au distance of 2.944(1) Å, as determined by X-ray crystallography. Yellow (**360**) has a similar structure, with a MeCN ligand added to Ir on the Ir–Au axis and an Ir–Au distance of 2.817(1) Å. (**359**) absorbs strongly at 492 nm, and has a fluorescence maximum at 540 nm and a phosphorescence band at 668 nm. In contrast, (**360**) has a strong visible absorption and a broad emission at 580 nm. Detailed assignment of the luminescent states of $[AuIr(CO)Cl(\mu\text{-dppm})_2][PF_6]$ has been made following analysis of emission, photoemission, and phosphorescence spectroscopic data.[586]



(358)

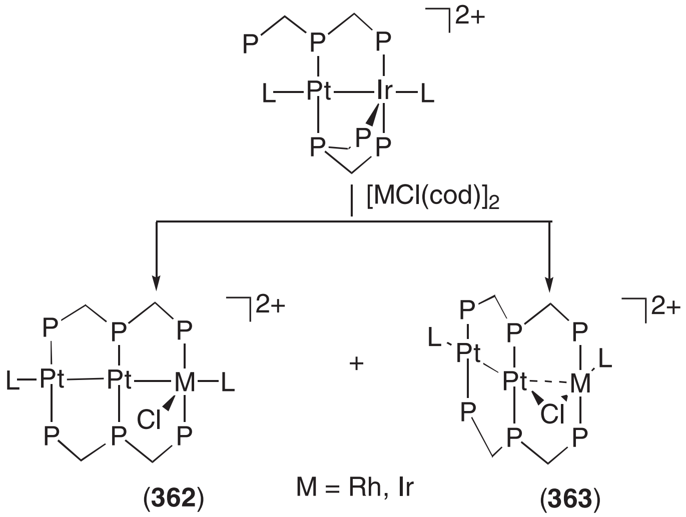


(359)



(360)

The dark green Ir/Pt acetylide complex $[(RC{\equiv}C)Pt(\mu\text{-dppm})_2(\mu\text{-}C{\equiv}CR)IrCl]$, (**361**), was synthesized from $[IrCl(coe)_2]_2$ and *trans*-$[Pt(C{\equiv}CR)_2(dppm)_2]$ (R = Ph, *p*-tolyl).[587] Reaction of (**361**) with H_2 and CO yields $[(RC{\equiv}C)_2Pt(\mu\text{-dppm})_2(\mu\text{-}H)IrH(Cl)]$ and $[(RC{\equiv}C)Pt(\mu\text{-dppm})_2(\mu\text{-}C{\equiv}CPh)Ir(CO)Cl)]$, respectively. Treatment with large cations gives the red cationic species $[(RC{\equiv}C)Pt(\mu\text{-dppm})_2(\mu\text{-}C{\equiv}CPh)Ir(CO)]^+$, which reacts with H_2 affording $[(RC{\equiv}C)Pt\text{-}(\mu\text{-dppm})_2(\mu\text{-}C{\equiv}CPh)(\mu\text{-}H)IrH(CO)]^+$. The Pt/Ir heterotrinuclear complexes (**362**) and (**363**) are prepared according to reaction Scheme 37, where P^P^P = bis((diphenylphosphine) methyl)-phenylphosphine and L = $(2,6\text{-}Me_2)C_6H_4NC$.[588] The X-ray structure shows a linear Pt–Pt–Ir geometry in (**362**) and an asymmetric A-frame in (**363**).



Scheme 37

The X-ray crystal structure of $[IrCl(PF_3)_2]_2$ confirms a binuclear species with bridging chloride ligands. The solid-state structure has intramolecular Ir—Ir distances of 2.942 Å, intermolecular Ir—Ir interactions of 3.271 Å, and infinite zigzag chains of Ir atoms. Other related complexes containing $PF_2(NMe_2)$, $PF(O_2C_6H_4)$, and $OC(NMePF_2)_2$ were synthesized, but only $[\{IrCl[OC(NMePF_2)_2]\}_2]$ shows evidence for extended metal–metal interactions.[589]

Oxidative addition to $[Ir_3(\mu\text{-}PPh_2)_3(CO)_3(dppm)]$ and $[Ir_3(\mu\text{-}PPh_2)_3(CO)_4(^tBuNC)_3]$ gives $[Ir_3(\mu\text{-}PPh_2)_3(CO)_3(dppm)XY]$ (X = I, Y = I, OH; X = H, Y = Cl) and $[Ir_3(\mu\text{-}PPh_2)_3(CO)_4(^tBuNC)_3(R)]X$ (RX = MeI, BzBr, HCl, I_2, $HgCl_2$), respectively.[590] In both cases reaction occurs at one Ir center. The structures of $[Ir_3(\mu\text{-}PPh_2)_3(CO)_4(^tBuNC)_3(CH_3)]I$ and $[Ir_3(\mu\text{-}PPh_2)_3(CO)_3(dppm)\,I(OH)]$ are reported.

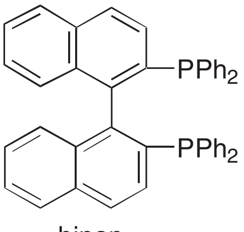
6.2.7.4.2 Polydentate ligands

The 1,2-bis(dicyclohexylphosphino)ethane (dcpe) bidentate ligand forms the mononuclear, square-planar Ir^I complexes $[Ir(cod)(dcpe)]BPh_4$, $[Ir(dcpe)_2]BPh_4$, and $[IrCl(CO)(dcpe)]$, which have been characterized by IR, ^1H, and $^{31}P\{^1H\}$ NMR spectroscopy.[591] Products of reaction with CO are discussed.

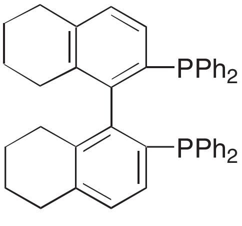
The structure of $[Ir(cod)(dppf)]PF_6$ shows approximately square-planar geometry at Ir, and the cp rings of the dppf ligand are close to parallel and staggered.[592] The systems $[Ir(cod)(LL)]ClO_4$, where LL = dppf, 1-diphenylphosphino-2-(*N*,*N*-dimethylamino)methyl ferrocene and 1,6-diferrocene-2,5-diazahexane, catalytically trimerize PC≡CH to 1,3,5-triphenylbenzene.[593] The electrochemistry of $[Ir(dppf)_2]BPh_4$ shows two one-electron reductions at −1.560 V and −1.755 V vs. ferrocenium/ferrocene.[753]

The complexes $[Ir(binap)(cod)]BF_4$, binap = (**364**), and $[Ir(H_8\text{-}binap)(cod)]BF_4$, H_8-binap = (**365**), are selective catalysts in the enantioselective hydrogenation of prochiral 1,2-benzocycloalkanes to their corresponding alcohols.[594] The structure of $[(binap)Ir(\mu\text{-}Cl)_2Ir(binap)]$, (**366**), contains two slightly distorted square-planar Ir centers (Ir···Ir distance 3.322(2) Å), with a 126° angle between the coordination planes.[595] The complex is a catalyst precursor for the asymmetric hydroamination of norborene with aniline. Complex (**366**) and $[Ir_2(\mu\text{-}Cl)_2\{(R)\text{-}(S)\text{-}ppf\text{-}PPh_2\}_2]$, (*R*)-(*S*)-ppf-$PPh_2$ = (*S*)-1-(diphenylphosphino)-2-[(*R*)-1-(diphenylphophino)ethyl]ferrocene, react with $Li(C_6H_5NH_2)$ to ultimately yield the binuclear, aminato-bridged complexes (**367**) and (**368**), which have been characterized by X-ray crystallography.[596] However, neither of the complexes shows catalytic activity in the hydroamination of olefins.

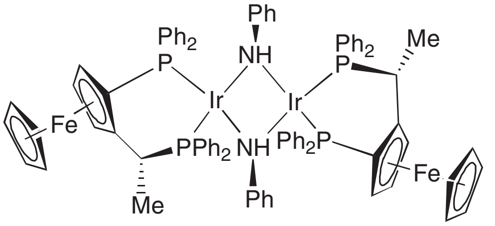
The potential tripodal ligand (**369**), R = H or Me, coordinates to Ir^I centers only via two P atoms in a *trans* geometry, leaving the third P center dangling but in fast exchange with the metal-bound phosphines.[597] The complex [Ir(CO)(mes)dppe], (**370**), dppe = 1,2-bis(diphenylphosphino) ethane, displays a slight tetrahedral distortion from square planarity.[598] If (**370**) is heated in a benzene solution under C_2H_4, then the five-coordinate species $[Ir(\eta^2\text{-}C_2H_4)\,(CH_2C_6H_3(CH_3)_2)(CO)(dppe)]$ is formed. (**370**) undergoes stereospecific oxidative reactions with SiH_2Ph_2 and H_2.



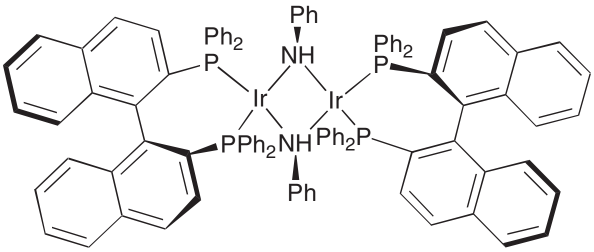
(364)



(365)

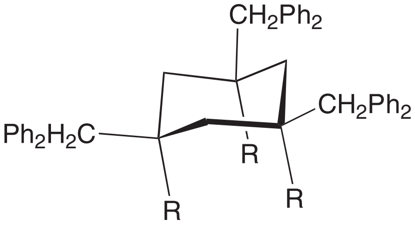


(367)



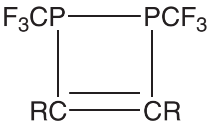
(368)

The photochemical carbonylation of benzene by $IrH(CO)_2(dppe)$ is shown to proceed via the square-planar intermediate Ir(H)(CO)(dppe).[599] Equimolar quantities of $[Ir(CO)_3(PPh_3)_2]ClO_4$ and $MeN(P(OMe)_2)_2$ yield the crystallographically characterized $[Ir(CO)(MeN(P(OMe)_2)_2)(PPh_3)_2]ClO_4$, in which the Ir center has a distorted trigonal-bipyramidal geometry with a CP_4 donor-atom set.[600] The axial sites are occupied by one PPh_3 ligand and by one end of the $MeNP(OMe)_2)_2$ ligand. Related complexes $[Ir(MeN(P(OMe)_2)_2(PPh_3)_2]ClO_4$ and $[Ir(MeN(P(OMe)_2)_2)_2(PPh_3)]ClO_4$ are characterized by NMR spectroscopy.

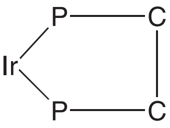


(369)

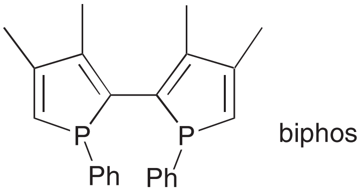
Reaction of *trans*-$[IrCl(N_2)(PPh_3)_2]$ with (**371**), R = CF_3, $SiMe_3$, Ph, at low temperature results in N_2 evolution and η^1-binding of the diphosphines to Ir, which transforms to the metallacycle (**372**) at room temperature.[601] The chiral ligand biphos, (**373**), reacts with $[Ir(cod)Cl]_2$ and $AgBF_4$ to form racemic $[Ir(biphos)(cod)]BF_4$, which proves to be catalytically inactive in the hydrogenation of α-acetoamidocinnamic acid.[602] If the reaction between a single crystal of enantiomerically pure biphos ligand and $[Ir(cod)Cl]_2$ is carried out at −78 °C, then enantiomerically pure $[Ir(biphos)(cod)]BF_4$ results.



(371)



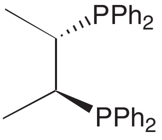
(372)



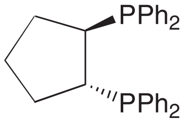
(373)

Other chiral diphosphine ligands (**374**), (**375**), (**376**), and (**377**) bind to iridium with little diastereoselectivity.[603] The complexes are characterized by ^1H and $^{31}P\{^1H\}$ NMR spectroscopy.

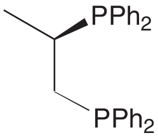
All the [Ir(diphosphine)$_2$]Cl complexes undergo a quasi-irreversible, two-electron reduction process followed by a chemical reaction.



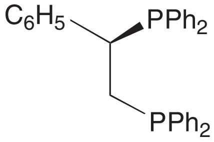
(374)



(375)



(376)



(377)

The optically pure ligands $C_6H_5C^*H(Me)N(CH_2CH_2PPh_2)_2$ (*R*)-(+)- and (*S*)-(-)-pnp, in the presence of [Ir(cod)(OMe)]$_2$ and propan-2-ol, selectively reduce α,β-unsaturated ketones to optically pure allylic alcohols.[604]

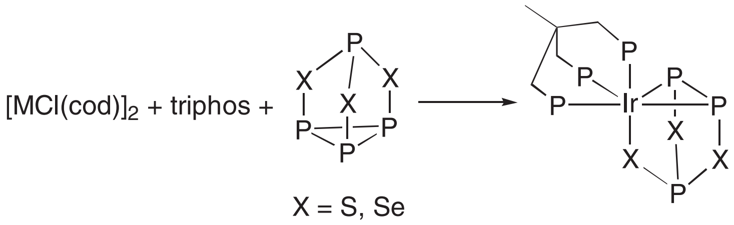
The aqueous biphase hydrogenation of dimethyl itaconate is accomplished with an Ir-(*R*)-(*R*)-3-benzyl(*p*-sulfonate)-2,4-bis(diphenylphosphino)pentane complex.[605]

Luminescent Ir complexes of diphosphine and diphosphinite calix[4]arene show emission maxima at 619 nm and 597 nm, respectively, at 77 K.[606] The emission lifetimes are perturbed by addition of Li^+, Na^+, and UO_2^{2+}.

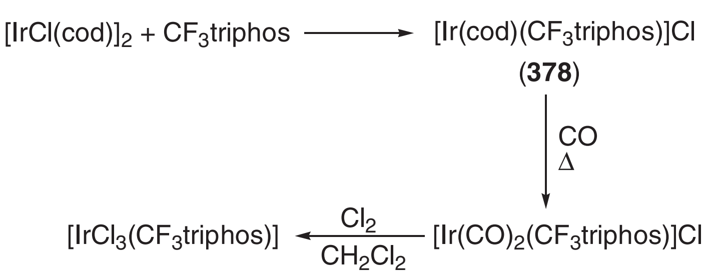
The reaction of P_4X_3 (X = S, Se) with [IrCl(cod)]$_2$ in the presence of triphos (triphos = 1,1,1-tris((diphenylphosphino)methyl)ethane) yields the compounds [(triphos)Ir(P_3X_3)]$\cdot C_6H_6$ according to Reaction Scheme 38.[607] The crystal structure of X = S shows that the compounds contain the (triphos)Ir moiety replacing a basal P atom of the cage.

The X-ray structure of [IrCl(CO)(triphos)] confirms the trigonal-bipyramidal geometry of the Ir center, with the three phosphorus atoms occupying one axial and two equatorial positions and the Cl ligand in the remaining axial position.[608]

The tridentate ligand CF$_3$triphos (CF$_3$triphos = $CH_3C\{CH_2P(m\text{-}CF_3\text{-}C_6H_4)_2\}_3$) reacts with [Ir(Cl(cod)]$_2$ to form [Ir(cod)(CF$_3$triphos)]Cl, (**378**), and with [Ir(CO)Cl(PPh$_3$)$_2$] to afford [IrCl(CO)(CF$_3$triphos)].[609] The CF$_3$triphos complexes are more stable than the triphos analogues. The complex [IrCl$_3$(CF$_3$triphos)] is synthesized according to reaction Scheme 39.



Scheme 38

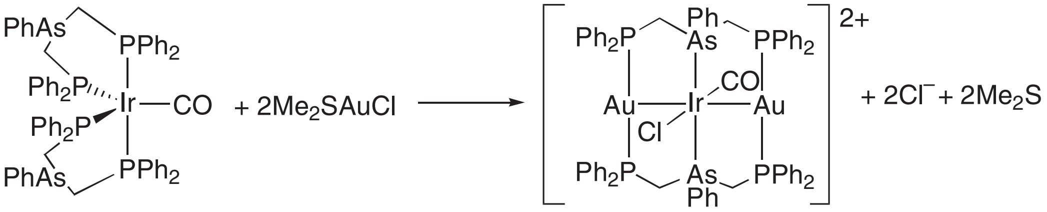


Scheme 39

6.2.7.5 Arsine and Stibene Ligands

Reaction of [IrCl(C$_2$H$_4$)$_2$]$_2$ with As^{i}Pr$_3$ yields *trans*-[IrCl(C$_2$H$_4$)(As^{i}Pr$_3$)$_2$], (**379**), which gives *trans*-[Ir(Cl)(CO)(As^{i}Pr$_3$)$_2$] and *trans*-[IrCl(N$_2$)(As^{i}Pr$_3$)$_2$] on reaction with CO and Ph$_2$CN$_2$, respectively.[610] The mixed As/P compound [IrCl(C$_2$H$_4$)(P^{i}Pr$_3$)(As^{i}Pr$_3$)] is also reported.

The red, trimetallic Au_2Ir species (**380**) is formed according to reaction Scheme 40.[611] The structures of (**380**) and (**381**) have been determined by X-ray crystallography. (**380**) shows significant Au–Ir interactions.



(**381**) (**380**)

Scheme 40

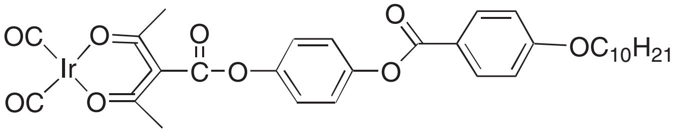
Reaction of $[IrCl(C_2H_4)_2]_2$ with SbR_3 ($R = {}^iPr$, Me, Ph) yields the five-coordinate complexes $[IrCl(C_2H_4)_2(SbR_3)_2]$ (**382**).[612] The complex (**382**) $R = {}^iPr$ has been characterized by X-ray crystallography and reveals one stibene and two olefinic ligands in the equatorial plane. NaC_5H_5 replaces the Cl ligand by C_5H_5, and ethene may be substituted by different alkynes. Reaction of $[IrCl(coe)_2]_2$ with Sb^iPr_3 gives *trans*-$[IrCl(coe)(Sb^iPr_3)_2]$, which rearranges in hexane to *anti,exo*-$[IrHCl(\eta^3\text{-}C_8H_{13})(Sb^iPr_3)_2]$.[613]

6.2.7.6 Oxygen Ligands

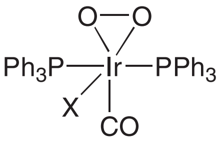
6.2.7.6.1 Monodentate Ligands

Reaction of *trans*-$MeOIr(CO)(PPh_3)_2$ with tcne (tetracyanoehylene) gives the structurally determined trigonal-bipyramidal complex $MeOIr(CO)(PPh_3)_2(tcne)$, in which the tcne and CO ligands occupy axial sites.[614] The tcne ligand is η^2-bound, with the olefinic bond parallel to the equatorial coordination plane. The structures of square-planar *trans*-$Ir(CO)(OH)(Pcy_3)_2$, *trans*-$Ir(CO)(OCH_2C_6H_5)(P(p\text{-tolyl})_3)_2$, and *trans*-$Ir(CO)(O\text{-}p\text{-}C_6H_4CH_3)(P(p\text{-tolyl})_3)_2$ are reported.[615]

The square-planar complex (**383**) shows a monotropic smectic A-phase, and the X-ray diffraction study of the yellow form shows that the whole molecule adopts an extended rod-like shape with an all-*trans* conformation of the decycloxy chain.[616]



(**383**)



(**384**)

The complex *cis*-$IrCl(CO)_2(OPhVpy)$, OPhVpy = *trans*-4-alkoxy-4′-stilbazole), is mesomorphic and shows nematic and smectic phases below 140 °C.[617,618]

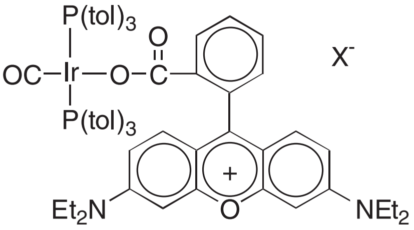
The electrochemical investigation on an Hg electrode of the interaction between $[Ir(Me_2\text{-}phen)(cod)]$ and O_2 gives evidence of formation of an unstable adduct.[619]

Reaction of *trans*-$[Ir(CO)X(PPh_3)_2]$, X = halogen, is $10^8 - 10^9$ times faster with singlet oxygen than with triplet oxygen and yields the same product species (**384**) in both cases.[620]

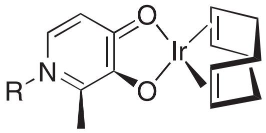
The rate constants for the ${}^1O_2$ reaction do not vary significantly with different ligands (X = F, Cl, Br). The reaction of *trans*-$[Ir(CO)(CH_3CN)(PPh_3)_2]^+$ with ${}^1O_2$ is slightly slower than for the halide analogues.[621] The peroxo compounds do not react with alkenes.

The reaction of $[Ir(\mu\text{-}OR)(cod)]_2$ (**385**), R = Me, Et, Ph, with Pcy_3 yields $[Ir(OR)(cod)(Pcy_3)]$, which undergoes alkoxy exchange with phenol and $HC{\equiv}CPh$.[622] The latter species has been characterized by X-ray diffraction. Reaction of (**385**) with the chelating triphosphine ligand ttp $\{C_6H_5P[CH_2CH_2CH_2P(C_6H_5)_2]_2\}$ or cyttp$\{C_6H_5P[CH_2CH_2CH_2P(C_6H_{11})_2]_2\}$ yields the monomeric species $[Ir(OR)ttp]$ and $[Ir(OR)(cyttp)]$, respectively.[623] Sulfur dioxide insertion reactions lead to the metal sulfonates, for example [Ir($SO_2OC_6H_5$)(ttp)·SO_2]. Alkoxyiridium complexes *trans*-ROIr(CO)(PPh_3)$_2$, (**386**), R = Me, Ph, ^{t}Bu, ^{i}Pr, react with R′X, R′ = Me, $CH_3C(O)$, $C_6H_5C(O)$, $C_6H_5CH_2C(O)$, HC(O), X = Cl, I, H, to give esters, ROR′, but not ethers.[624] Mechanistic studies on β-hydrogen elimination from (**386**) showed this process to be reversible, and it is followed by an associative displacement of the co-ordinated ketone or aldehyde by $PPh_3$to yield [Ir(CO)(PPh_3)$_3$H].[625]

The rhodamine B-bound complex of Ir^I (**387**) shows only minor alterations in the absorption spectrum of bound rhodamine B as opposed to free dye; however, its fluorescence is strongly quenched.[626] Fluorescence is intense when the rhodamine dye is attached to an Ir^{III} center. The authors conclude that the excited-state quenching mechanism is via electron transfer.



(387)



(389)

The yellow, air-stable, binuclear species [Ir(OMe)(cod)]$_2$ is a useful precursor in Ir alkoxy chemistry and may be prepared according to reaction Scheme 41.[627]

$$[IrCl(cod)]_2 + 2KOH + 2MeOH \longrightarrow [Ir(OMe)(cod)]_2 + 2KCl + 2H_2O$$

Scheme 41

The mixed-metal μ-oxo compounds [$cp_2M{=}O{-}M'(PPh_3)_2(CO)$]$^+$ (M = Mo, W; M′ = Rh, Ir) have been prepared by solvent displacement from [M′(CO)(PPh_3)$_2$(CH_3CN)]$^+$ by $cp_2M{=}O$, and the resulting complex is best described as having a dative interaction of the oxo-ligand with the unsaturated M′ center.[628] ^{1}H NMR studies show that the $cp_2M{=}O$ units rapidly exchange with solvent and with excess $cp_2M{=}O$.

6.2.7.6.2 Bidentate ligands

Diffuse reflectance spectra of racemic mixtures of Ir(CO)$_2$L (L = *R*- and *S*-trifluoroacetylcamphorate) in the solid state reveal absorbance in the 440–610 nm region, which is attributed to Ir—Ir interactions.[629] The crystal structure of the related compound, where L = trifluoroacetylcarvonate, has an Ir—Ir distance of 3.290(1) Å.[630] The bis(ethene) complex [Ir(acac)(C_2H_4)] undergoes a monosubstitution reaction with PR_3 (PR_3 = P^{i}Pr$_3$, PPh_3, ^{i}Pr$_2$PCH$_2$CH$_2$OMe, ^{i}Pr$_2$PCH$_2$CO$_2$Me) to yield [Ir-(acac)(C_2H_4)(PR_3)], (**388**).[631] The X-ray structure of (**388**) with PR_3 = P^{i}Pr$_3$ is reported. UV irradiation of (**388**), where PR_3 = ^{i}Pr$_2$PCH$_2$CO$_2$Me, in the presence of excess P^{i}Pr$_3$, gives a hydrido(vinyl)iridium-(III) complex. Reaction of [Ir(acac)(C_2H_4)(P^{i}Pr$_3$)] with $CH_2{=}CHR$ (R = CN, OC(O)Me, C(O)Me) affords [Ir(acac)($CH_2{=}CHR$)(P^{i}Pr$_3$)], which undergoes C—H activation on photolysis.

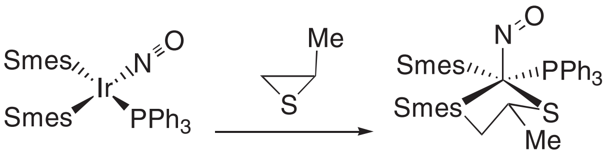
The five-coordinate complexes Ir(CO)(PPh_3)$_2$L, where HL = β-diketone, *N*-benzoyl-*N*-phenylhydroxylamine, salicylaldehyde, 8-hydroxyquinoline, 2-hydroxybenzophenone, 2-hydroxy-8-methoxybenzophenone, were prepared from [Ir(CO)(PPh_3)$_2$Cl].[632] The resulting compounds all underwent oxidative addition reactions with Br_2. Reaction of [(cod)$_2$IrCl]$_2$ with N-substituted 3-hydroxy-2-methyl-4-pyridine gives the bichelated complex (**389**).[633]

The dimeric Ir^I complexes [(dfepe)Ir(μ-X)]$_2$, (**390**), (dfepe = $(C_2F_5)_2PCH_2CH_2P(C_2F_5)_2$, X = O_2CCF_3, OTf) have been synthesized, and for (**390**) with X = O_2CCF_3 have been characterized by X-ray crystallography.[634] The structure revealed a hinged dimeric geometry, with a large interplanar angle of 82.7° defined by the two four-coordinated metal centers and an Ir—Ir distance of 4.307 Å. Both dimer species are reactive towards H_2 and alkane C—H bonds.

6.2.7.7 Sulfur Ligands

6.2.7.7.1 *Monodentate Ligands*

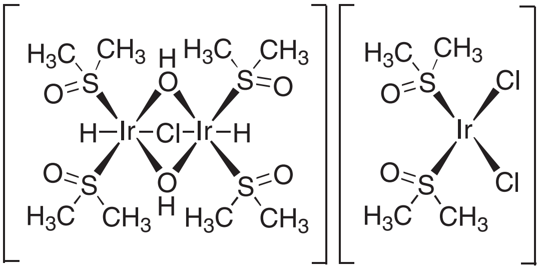
The square-planar Ir^I thiolate complex (**391**) has been prepared by the reaction of $[Ir(NO)Cl_2(PPh_3)_2]$ with NaSmes (mes = $C_6H_2Me_3$-2,4,6).[635] reaction of (**391**) with propylene sulfide affords the Ir^{III} complex (**392**), as shown in Reaction Scheme 42. The X-ray structure of (**392**) confirms the square-pyramidal geometry of the Ir center and the bent nature of the Ir—N=O linkage.



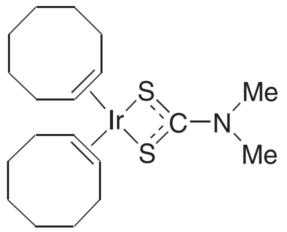
(**391**) (**392**)

Scheme 42

The synthesis and structure of square-planar $[IrCl(DMSO)_3]$ is reported.[636] All the DMSO ligands are S-bonded to the Ir center with a short Ir—S bond (2.1957(9) Å), *trans* to Ir—Cl. Addition of H_2O to $[IrCl(DMSO)_3]$ yields complex (**393**), as characterized by X-ray crystallography.



(**393**)



(**394**)

The equilibrium constants for SO_2 binding to *trans*-$Ir(CO)L_2X$ (L = PPh_3, P(*p*-tolyl)$_3$, Pcy_3; X = Cl, Br, Me) show that SO_2 is binding as a Lewis acid and is enhanced by electron-donating groups on Ir.[637] Increasing the steric bulk of the phosphine reduces the equilibrium constant for SO_2 binding. Reaction of SO_2 with $[Ir(CO)(OR)L_2]$ (R = H, Me, ^{t}Bu, L = PPh_3, P(*p*-tolyl)$_3$) results in insertion of the SO_2 into the iridium–methoxy bond to form an oxygen co-ordinated OS(O)OMe ligand. The X-ray structure of $[Ir(CO)(OS(O)OMe)(SO_2)(PPh_3)_2]$ reveals Ir in a square-pyramidal environment, with the SO_2 ligand in the apical site and *trans* PPh_3 ligands.

The syntheses of several Ir complexes containing phosphine sulfide ligands of the type $[Ir(cod)L_2]_n^{n+}$ and $[Ir(CO)_2L_2]_n^{n+}$ (L = Me_3PS, Et_3PS, Ph_3PS; L_2 = $MeP(S)(S)PMe_2$, $Et_2P(S)(S)PEt_2$, $Ph_2P(S)(S)PPh_2$) and their characterization by elemental analysis, IR and ^{31}P NMRspectroscopy, and conductance studies have been reported.[638]

6.2.7.7.2 *Bidentate ligands*

Acetonitrile solutions of $IrLL'(mnt)^{n-}$ (mnt = maleonitriledithiolate, n = 1, L = L′ = CO, $P(OPh)_3$; n = 1, L = CO, L′ = PPh_3; n = 2, L = CO, L′ = CN) and methyl viologen (MV^{2+}) exhibit outer-sphere electron-transfer behavior ranging from optical $[Ir(CO)_2(mnt)]^-$ to thermal $[Ir(CO)(CN)(mnt)]^{2-}$.[639] The structure of MV^{2+} $[Ir(CO)_2(mnt)]_2$ is reported and shows a cation–anion separation in the range 3.2–3.6 Å, with a square-planar Ir^I anion. The structure of (**394**) reports an essentially planar arrangement of the IrS_2CNMe_2 chelate system, as is the coordination plane defined by Ir, S atoms, and the two midpoints of the olefinic bonds.[640]

The synthesis and characterization (NMR, IR, UV-vis spectroscopy) of a series of complexes $IrLL'(Et_2dtc)$ (**395**) ($L = L' = CO$, PPh_3, $P(OPh)_3$; $L = CO$, $L' = PPh_3$, $L + L' = $ cod, dppe, dpfpe; dtc = *N,N'*-diethyldithiocarbamate) have been detailed.[641] The single-crystal structure of (**395**), $L = CO$, $L' = PPh_3$, has been determined. All of the complexes emit in the solid state at 77 K, with complexes (**395**), $L = CO$, $L' = PPh_3$, $L + L' = $ dppe, and $L = L' = P(OPh)_3$ emitting in CH_2Cl_2 at 293 K. Benzene solutions of (**395**), $L = CO$, $L' = PPh_3$, and $L + L' = $ dppe react with O_2 yielding $IrLL'(Et_2dtc)(O_2)$, which will lose O_2 on irradiation.

6.2.7.7.3 *Tridentate ligands*

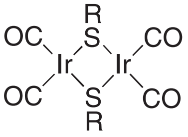
The half-sandwich complex $[Ir([9]aneS_3)(cod)]^+$, $[9]aneS_3 = 1,4,7$-trithiacyclononane, synthesized from $[Ir(cod)Cl]_2$ and $[9]aneS_3$, reveals a five-coordinate Ir center with $[9]aneS_3$ bound facially via all three S-donor atoms.[642] Further single-crystal studies of $[Ir([9]aneS_3)(L_2)]PF_6$, $L = C_2H_4$, C_8H_{12}, C_4H_6, also show distorted five-coordinate geometries.[643]

6.2.7.7.4 *Binuclear complexes*

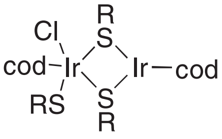
Reaction of $[Ir(cod)Cl]_2$, (**396**), with HSR–NEt_3 ($R = C_6F_5$) yields the dinuclear complex $[Ir(\mu\text{-}SR)(cod)]_2$, and further reaction with CO gives the structurally determined complex (**397**), $[Ir(\mu\text{-}SR)(CO)_2]_2$.[644] Both Ir centers in (**397**) are square planar, with the dihedral angle between the two IrS_2 planes being 114.05° and an Ir—Ir distance of 3.066(1) Å. However, reaction of (**396**) with HSR gives (**397**) and the mixed-valence complex (**398**), $[(cod)Cl(SR)Ir(\mu\text{-}SR)_2I(cod)]$, which contains an octahedral Ir^{III} center bridged by two SR^- linkages to a square-planar Ir^I center. In (**398**) the dihedral angle is 151.99° and the Ir—Ir distance 3.660 Å. Extension of the work yields the trimetallic compound $[Ir_3(\mu\text{-}SR)_3(\mu\text{-}CO)(CO_4)(PPh_3)_2]$[645], which contains an asymmetric Ir_3S_3 ring with one Ir—Ir bond (2.665(1) Å) doubly bridged by CO and SR^-. The molecular structures of $[Ir(SR)(CO)(PPh_3)_2]$ and $[Ir(SR)(\eta^2\text{-}O_2)(CO)(PPh_3)_2]$ are also reported.

6.2.7.7.5 *Bimetallic complexes*

The red, mixed-metal compound $[(cod)Ir(\mu\text{-}SPPh_2)_2Pt(S_2CN^iPr_2)]$, prepared by the reaction of $[Ir(cod)Cl]_2$ with $(NH_2{}^iPr_2)[Pt(S_2CN^iPr_2)(Ph_2PS)_2]$, has been characterized by X-ray crystallography.[646] The structure reveals that both bridging ligands bind to the Ir center through the S atoms, with a Pt–Ir separation of 4.2728(8) Å.



(**397**)



(**398**)

6.2.7.8 Selenium and Tellurium Ligands

Reaction of $[Ir(cod)Cl]_2$ with two molar equivalents of L^3($L^3 = MeC(CH_2ER)_3$, E = Se, R = Me; E = Te, R = Me, Ph) and two molar equivalents of NH_4PF_6 in CH_2Cl_2 affords the species $[Ir(cod)(L^3)][PF_6]$, (**399**), which have been characterized by analysis, IR and multinuclear NMR spectroscopy.[647] The crystal structures of (**399**), E = Se, R = Me and E = Te, R = Ph, reveal distorted square-pyramidal geometries and greater π-donation by the E = Te ligand. Single-crystal X-ray diffraction studies of *cis*-$[(PPh_3)_2Ir\{Te(2,4,6\text{-}{}^tBu_3\text{-}C_6H_2)\}(CO)]$, formed from the reaction of $[(PPh_3)_2Ir(CO)Cl]$ and $(2,4,6\text{-}{}^tBu_3\text{-}C_6H_2)TeLi(THF)_3$, confirm the *cis*-geometry of the PPh_3 ligands.[648]

6.2.7.9 Halide Ligands

Reaction of $[IrCl(CO)L_2]$ ($L = PMe_3$, PEt_3, PPh_3) with Me_3SiX ($X = Br, I$) affords $IrX(CO)L_2$ and Me_3SiCl.[649] The phase-transfer-catalyzed, hydrogen-transfer reduction of 2-propanol has been realized using KF on alumina, $[Ir(cod)Cl]_2$, and 18-crown-6 as phase-transfer agent.[650]

A theoretical and structural analysis of $[Ir_2(\mu\text{-}Cl)_2L_4]$, where $L_4 = (PF_3)_4$, $(PH_3)_4$, $(cod)_2$, $((C_2F_5)_2PC_2H_4P(C_2F_5)_2)_2$, debates the factors which determine the degree of bonding between the coordination planes of the two metal centers.[651] One driving force would appear to be the attractive metal/metal interactions resulting from donor–acceptor interactions between the $d_z{}^2$ and p_z orbitals of the two metal atoms.

6.2.7.10 Hydrogen Ligands

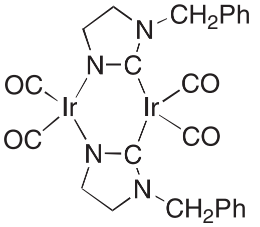
A detailed review of the stereochemistry of H_2 oxidative addition and dihydride-transfer reactions involving Ir^I complexes of the type $IrX(CO)P_z$ has been published by Deutsch and Eisenberg in 1988.[652] The addition reaction of H_2 to $[Ir(bpm)(CO)_2](BPh_4)$ (bpm = bis(pyrazol-1-yl)methane) has been studied using parahydrogen NMR, and reveals a series of products containing metal-hydride linkages.[653] Reaction of 2-phenyl-1-methylenecyclopropane with $IrH(CO)(PPh_3)_3$ at room temperature yields $Ir(\eta^1{:}\eta^2\text{-}CH_2CH(Ph)CH{=}CH_2)(CO)(PPh_3)_2$, which has been characterized by X-ray crystallography.[654] When the same reaction is carried out at 50 °C, then the product species are 2-phenyl- and 1-phenyl-1,2-butadiene and $Ir(\eta^1{:}\eta^2\text{-}C_6H_4CH(Me)\ CH{=}CH_2)(CO)(PPh_3)_2$, whose structure has been confirmed by X-ray crystallography.

6.2.7.11 Mixed-donor-atom Ligands

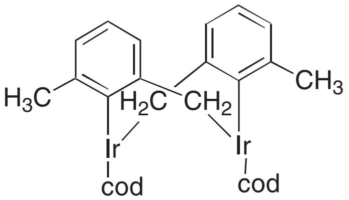
6.2.7.11.1 C/N

$[Ir(cod)Cl]_2$ reacts with lithium *N*-benzyl-2-imidazolate (LiBzim) to yield $[Ir_2(\mu\text{-}Bzim)_2(cod)_2]$ and then with CO to give the structurally characterized species (**400**), in which one Ir co ordinates to two N atoms of the imidazole ring and the other Ir to two C atoms.[655]

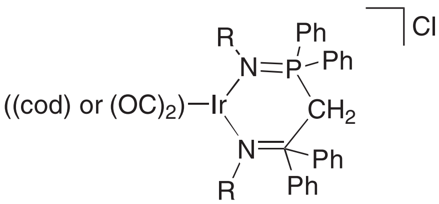
Reaction of $[Ir(cod)Cl]_2$ with (6-methyl-2-pyridyl)methyl lithium yields the binuclear species $[(cod)Ir(\mu\text{-}CH_2\text{-}py\text{-}6\text{-}Me\text{-}C, N)]_2$, (401).[656] The Ir centers in (**401**) are 3.5889(3) Å apart, indicating little metal–metal interaction. Treatment of (**401**) with PPh_2Et yields $[(cod)Ir(PPh_2Et)_2(CH_2\text{-}py\text{-}6Me)]$, which contains the monodentate, carbon-bound pyridylmethyl ligand.



(**400**)



(**401**)

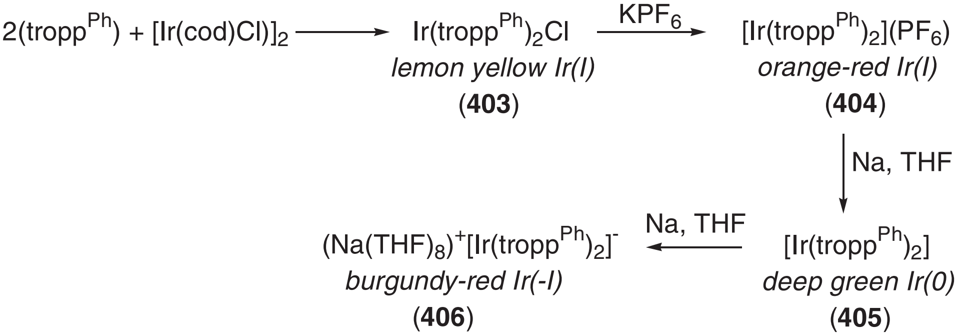


(**402**)

Reaction of $[Ir(cod)Cl]_2$ with LiL ($L = CH_2PPh_2{=}N\text{-}C_6H_4\text{-}CH_3\text{-}4$, $CH(PPh_2{=}N\text{-}C_6H_4\text{-}R\text{-}4)_2$, $R = CH_3$, NO_2, affords $[Ir(L)(cod)]$, in which ligand L is co-ordinated as a σ-N, σ-C chelate.[657,658] The structure of $[Ir(CH(PPh_2{=}N\text{-}C_6H_4\text{-}CH_3\text{-}4)_2)(cod)]$ is reported as containing a four-membered Ir—N—P—C metallacycle and one pendant iminophosphorane moiety. Further reaction with an excess of CO results in replacement of cod by $(CO)_2$. When $[IrL(cod)]$ or $[IrL(CO)_2]$, where $L = CH(PPh_2{=}N\text{-}C_6H_4\text{-}R\text{-}4)_2$, is treated with HCl, then product (**402**) results.

6.2.7.11.2 C/P

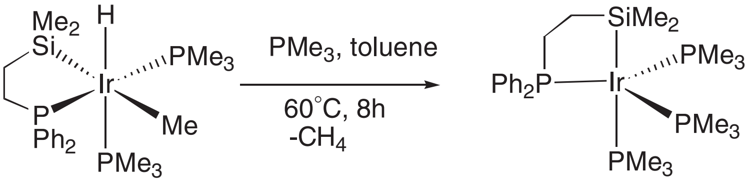
The monomeric Ir^I C/P-donor-atom compounds $[Ir(tropp^{Ph})_2]^+$, $tropp^{Ph}$ = dibenzotropyl-idenyl phosphine, are synthesized via reaction Scheme 43.[755] The X-ray structural study of (**404**) shows a similar geometry to its one-electron reduced analogue, (**405**). Complex (**404**) reacts with $NaBH_4$ to give $[IrH(tropp^{Ph})_2]$, which can be further protonated with acid to give the Ir^{III} dihydride $[IrH_2(tropp^{Ph})_2]^+$, (**407**).[756] (**407**) may also be produced via the oxidative addition reaction of (**404**) with H_2. The X-ray structure (**407**) (PF_6) is reported.



Scheme 43

6.2.7.11.3 Si/P

The reddish-orange complex (**408**) is formed by the reductive elimination of methane according to Reaction Scheme 44.[659] X-ray crystal structure analysis revealed that (**408**) adopts a slightly distorted, five-coordinate, trigonal-bipyramidal geometry, with the silyl ligand occupying an axial site. Further work on the related complexes $L_nIr(R)(H)$ ($L_n = \{\mu^2\text{-(mes)-}HSi(CH_2)_2PPh_2\}(PMe_3)_2$) led to the formation of the Ir^I intermediate L_nIr, which reacted with MeOH to generate $Ir(H)_2\{\mu^2\text{-(mes)(OMe)}Si(CH_2)_2PPh_2\}(PMe_3)_2$.[660] Thermolysis of $HMePhSi\text{-}SiMe_3$ in the presence of $Ir(PPh_2CH_2CH_2SiMe_2)(PMe_3)_3$ yields $HMe_2SiSiMe_2Ph$.[661]



(**408**)

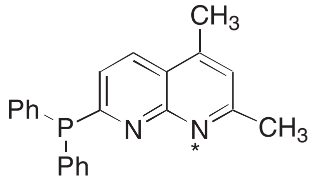
Scheme 44

6.2.7.11.4 N/P

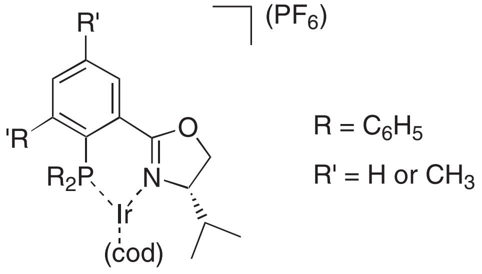
The binuclear complex $[\{Ir(cod)Cl\}_2(\mu\text{-dpnapy})]$, formed from a 1:1 reaction of $[\{Ir(cod)Cl\}_2]$ and dpnapy, (**409**), contains the mixed-donor bridging ligand dpnapy, which binds to the two Ir centers through the P and terminal N* sites with no interaction between the two Ir centers.[662] Monochelated complexes such as *trans*-$[Ir(CO)(dpnapy)_2Cl]$, *cis*-$[Ir(CO)_2(dpnapy)Cl]$, and $[Ir(cod)Cl(dpnapy)]$ all involve coordination through the P atom. Pfaltz *et al.* report the synthesis and structure of square-planar Ir^I complexes containing P/N bidentate ligands (**410**).[663] The cationic complexes (**410**) catalyze the enantioselective hydrogenation of imines, with the highest selectivity achieved in weakly coordinating solvents such as CH_2Cl_2.

The mixed-donor tridentate ligands bis[2-diphenylphosphino)ethyl] benzylamine (dpba) and bis[2-(diphenylarsino)ethyl] benzylamine (daba) form square-planar complexes with IrCl and $IrPPh_3$ moieties.[664]

The coordinatively flexible P/N-donor ligand PN_n (**411**) reacts with $[IrCl(cod)]_2$ in the presence of $AgPF_6$ to yield $[Ir(cod)(PN_n)](PF_6)$, (**412**).[665] The X-ray structure of (**412**) $PN_{n=1}$, R = H, complex confirms the *cis* geometry of the ligand attached via N and P donor atoms to a square-pyramidal Ir^I cod fragment with a long ethereal oxygen—Ir bond in an apical position. The Ir^I

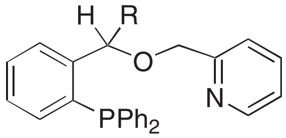


dpnapy
(**409**)

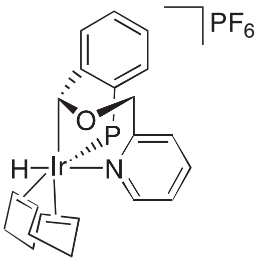


(**410**)

species undergoes intramolecular C—H bond activation at the benzylic position to give the structurally characterized Ir^{III} hydrido alkyl species (**413**). The structure of the related Ir^{I} complex, $PN_{n=1}$, Me, has no obvious interaction between the Ir and the O atom.[666]

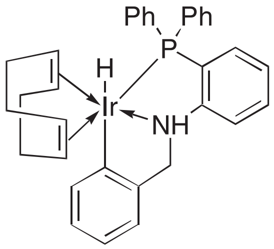


PN_n ligand
(**411**)

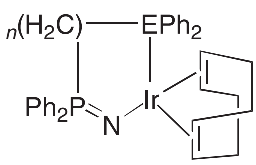


(**413**)

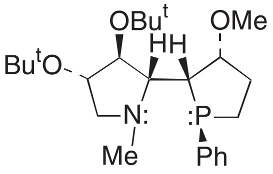
Treatment of $[Ir(cod)Cl]_2$ with the iminophospheranophosphine ligands, L, $Ph_2P^*QP(Ph_2){:}NR$ ($Q = CH_2$, CH_2CH_2, 1,2-C_6H_4, $R = p$-C_6F_4CN, $C_6H_2F(NO_2)_2$, $C_6H_3(NO_2)_2$) yields $[Ir(cod)L]^+$, in which L binds through the N atom and the P* atom of the ligand.[667] Reaction of $[Ir(cod)(THF)_2]$-ClO_4 with $L = Ph_2PC_6H_4NHC(O)Ph$ or $Ph_2PC_6H_4C(O)NHPh$ yields $[Ir(cod)L]ClO_4$, where L is acting as a P, N bidentate ligand.[668] Treatment of $[Ir(cod)Cl]_2$ with $Ph_2PC_6H_4NHR$ ($R = CH_2Ph$) yields $[IrCl(cod)(Ph_2PC_6H_4NHR)]$, (**414**); here the amine moiety is uncoordinated.[669] If $AgClO_4$ is added to (**414**), then the bis P/N-chelated species $[Ir(cod)(Ph_2PC_6H_4NHR)]$ is generated, which when heated gives (**415**).



(**415**)



(**416**)



P*-N-1
(**417**)

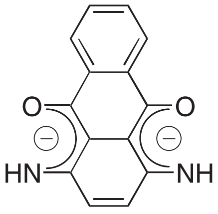
Oxidation of one phosphorus in $Ph_2PCH_2PPh_2$ and on $Ph_2PC_2H_4AsPh_2$ with Me_3SiN_3 gives the mixed-donor ligands $Me_3SiN{=}PPh_2CH_2PPh_2$ and $Me_3SiN{=}PPh_2C_2H_4AsPh_2$, respectively.[670] These ligands react with $[Ir(cod)Cl_2]_2$ to form the metallacycles (**416**), where $E = P$, $n = 1$ and $E = As$, $n = 2$.

The chiral ligand P*-N-1 (**417**) reacts with [Ir(cod)Cl] in the presence of $NaBPh_4$ to yield [Ir(P*-*N*-1)(cod)]BPh_4, which contains a stereogenic phosphorus in addition to five contiguous stereoisomers in the ligand backbone.[671] The binuclear complex $[I(CO)_2Ir(\mu\text{-}Ph_2Ppy)_2CdI_2]$, (**418**), ($Ph_2Ppy = $ 2-diphenylphosphinopyridine), characterized by X-ray crystallography, reveals an Ir–Cd distance of 2.784(1) Å.[672] The Ir center binds to the P-donor atoms and is in a distorted octahedral geometry. A solid sample of (**418**) excited with UV light emits at 739 nm, with a lifetime of 6.48 μs at room temperature.

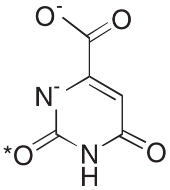
6.2.7.11.5 N/O

A review of dinuclear complexes of Ir^I bridged via 2-pyridone ligands (N/O donor atoms), by Rawson and Winpenny, has been published in 1995.[673]

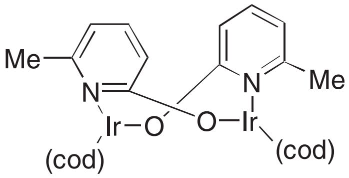
The 1,4-diaminoanthraquinolate ligand (1,4-da), (**419**), forms the binuclear complexes $[Ir_2(\mu\text{-}1,4\text{-da})L_2]$ ($L_2 = $ cod, $(CO)_2$, $(CO)(PPh_3)$), which undergo oxidative addition reactions with MeI and I_2.[674] The crystal structure of $[NEt_3H][Ir(cod)(HL)]$, HL = (**420**), exhibits square-planar Ir bound to the N^- and O^- of (**420**). The solid-state structure shows intermolecular, hydrogen-bonded dimers through the NH proton and the carbonyl oxygen (O*) atom.[675] Additional hydrogen bonding also exists amongst cation protons, solvent protons, and the ligand.



(**419**)



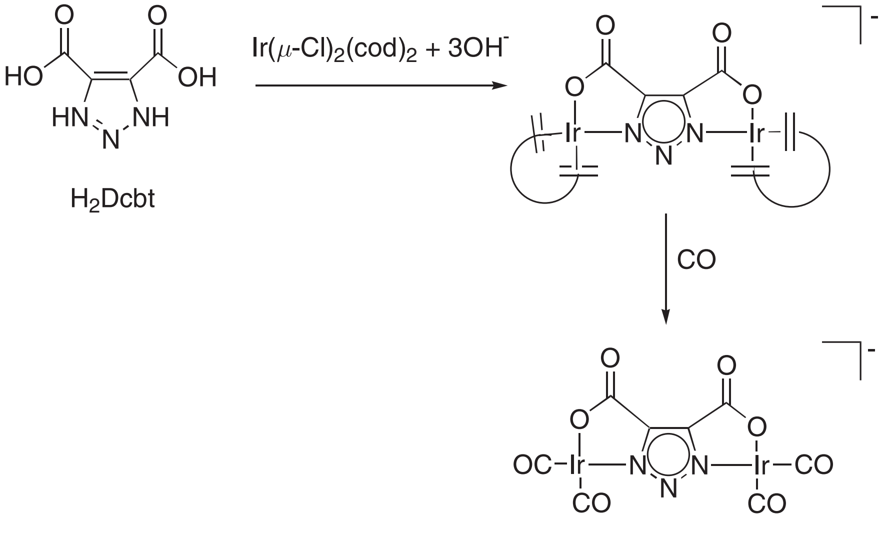
(**420**)



(**422**)

Reaction of $[Ir(cod)Cl]_2$ with NaL (L = 2-oxypyridinate (hp) or 6-methyl-2-oxypyridinate (mhp) yields $[Ir(cod)(\mu\text{-}L)]_2$ (**421**).[676] The structure of (**421**), L = hp (**422**), reveals an Ir—Ir distance of 3.2412(1) Å. $[Ir(cod)(hp)]_2$ undergoes a one-electron, quasi-reversible oxidation at +0.332 V vs. Ag/AgCl. Reaction with Cl_2 gives the structurally characterized Ir^{III} complex $[Ir(cod)(Cl)_2(hp)]$. $[Ir(cod)(mhp)]_2$ is isostructural.[677] Assignment of the ^1H NMR spectra is given.

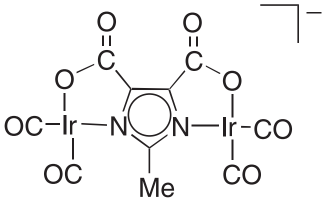
The binuclear complex (**423**) is formed via reaction Scheme 45. Electrochemical oxidation of $[NR_4]$(**423**) (R = Pr, Bu) yields the metal-centered, partially oxidized, conductive material $[NR_4]_{0.5}$, (**423**).[678] An EXAFS study indicates that the coordination sphere of the Ir is preserved upon oxidation. The color of the dinuclear complexes $[Ir_2L(CO)_4]^-$ (L = dcbi, 4,5-dicarboxyimidazole, dcbmi, 4,5-dicarboxyl-2-methylimidazole) depends on the cation (NMe_4^+, $NHEt_3^+$, NEt_4^+, NBu_4^+) and is caused by intermolecular stacking interactions of the Ir metal.[679]



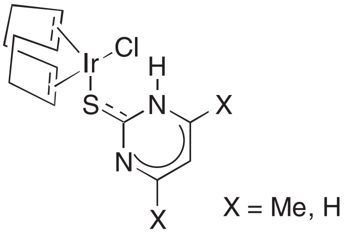
(**423**)

Scheme 45

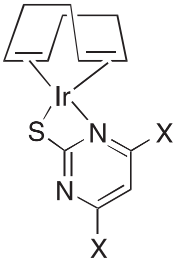
The structure of $[Ir_2dcbmi(CO)_4]^-$ (**424**) is reported.[680] The binuclear compounds were all oxidized around +0.1 V vs. SCE, with the oxidation potential dependent on the solvent.[681] Oxidation of $[NBu_4][Ir_2(dcbmi)(CO)_4]$ results in growth of a conducting film on the surface. The partially oxidized material $[NBu_4]_{0.5}[Ir_2(dcbmi)(CO)_4]$ has been characterized by X-ray photoelectron spectroscopy.



(**424**)



(**425**)



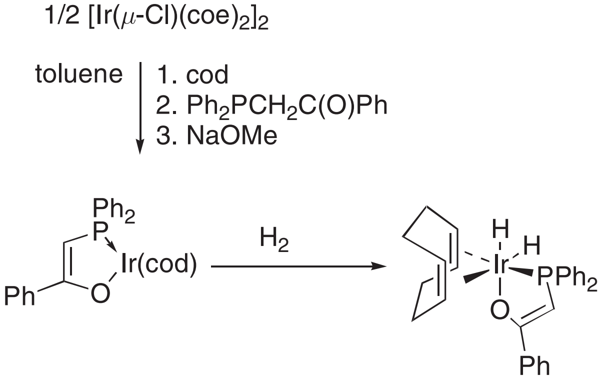
(**426**)

6.2.7.11.6 *N/S*

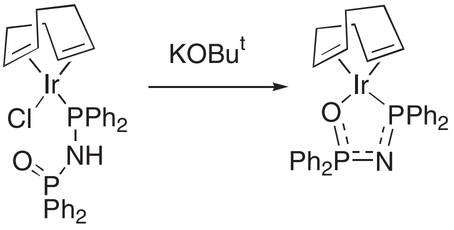
The mono- and bidentate complexes (**425**) and (**426**), respectively, form from the reaction of $[Ir(cod)Cl]_2$ with mercaptopyrimidine.[682] (**426**) reacts with CO, yielding the dicarbonyl analogue through displacement of cod. One CO ligand may be replaced by PPh_3, but further addition of PPh_3 results in a five-coordinate species.

6.2.7.11.7 *P/O*

Reaction Scheme 46 yields mixed P/O-donor ligand Ir^I complexes, which have been characterized by ^1H NMR spectroscopy.[683] Reaction of $[Ir(cod)Cl]_2$ with $Ph_2PNHP(O)Ph_2$ yields the monodentate, P-bound complex $[Ir(cod)(Cl)(Ph_2\mathit{P}NHP(O)Ph_2)]$ (**427**), which gives the bidentate, P/O-bound species $[Ir(cod)(Ph_2PNP(O)Ph_2)]$, (**428**) according to reaction Scheme 47.[684] Complex (**428**) undergoes a *cis* addition reaction with MeI to give $[IrI(Me)(cod)\ (Ph_2PNP(O)Ph_2\text{-}\mathit{P,O})]$, the structure of which has been characterized by X-ray crystallography.



Scheme 46

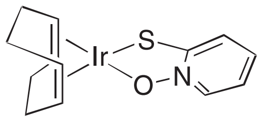


(**427**) (**428**)

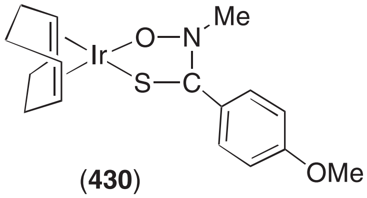
Scheme 47

6.2.7.11.8 O/S

The X-ray structure of (**429**) confirms the square-planar environment of the Ir center and the planar nature of the S/O ligand.[685] The related complex (**430**) shows similar Ir—O (2.030(7) Å) and Ir—S (2.279(3) Å) distances to (**439**); however, the olefinic bonds are much longer in (**430**) than in (**429**): 1.52 Å and 1.38 Å, respectively.[686]



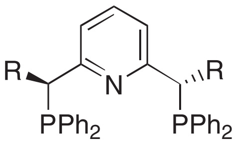
(**429**)



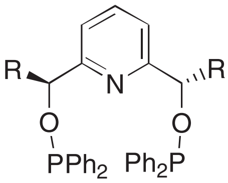
(**430**)

6.2.7.11.9 Multidentate ligands

Reaction of $[Ir(cod)Cl]_2$ with tridentate diphosphine ligands, PNP, (**431**), (**432**), (**433**), and (**434**) yields the complexes $[Ir(PNP)(cod)]^+$, which prove to be active catalysts for the hydrogenation of imines.[687]

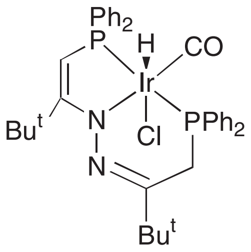


(**431**) R = H
(**433**) R = CH_3

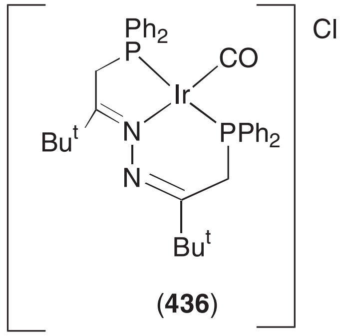


(**432**) R = H
(**434**) R = CH_3

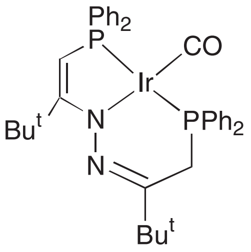
The Ir^{III} species (**435**) isomerizes reversibly in polar solvents (EtOH, MeOH) to give the Ir^I cation (**436**), which reacts rapidly with alkenes, alkynes, CO, and dihydrogen. The product species have all been characterized by $^1H\{^{31}P\}$ and ^1H NMR spectroscopy.[688,689] Treatment of (**435**) with NEt_3 gave the neutral Ir^I species (**437**), which reacts with H_2 to give a *cis*-Ir^{III} species, and with olefins and acetylenes to give five-coordinated Ir^I adducts.[690] All species are studied using ^1H, ^{13}C, and ^{31}P NMR spectroscopy.



(**435**)



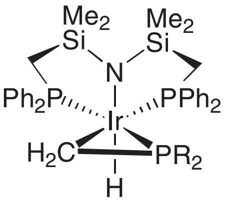
(**436**)



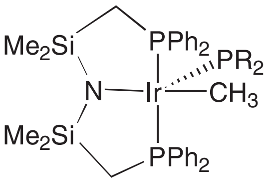
(**437**)

Reaction of $[Ir(coe)(N(SiMe_3CH_2PPh_2)_2]$ with excess 1,3-butadiene yields the structurally characterized, five-coordinate complex $[Ir(C_4H_6)[N(SiMe_2CH_2PPh_2)_2]$, which contains the P_2N ligand coordinated in a quasi-facial manner, and the 1,3-butadiene bound in a s-*cis*-η^4-π mode.[691]

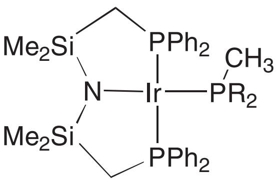
The thermal and photochemical reactions of Ir^{III} complexes (**438**) and (**439**), respectively, yield the same product species (**440**), $R_2 = Ph_2$, Me_2, HPh.[692] Kinetic studies indicate that the reaction involves the direct reductive transfer of the methyl to the phosphide via a three-centered transition state. The crystal structures of (**438**) and (**439**) ($R_2 = Ph_2$) are reported.



(438)



(439)



(440)

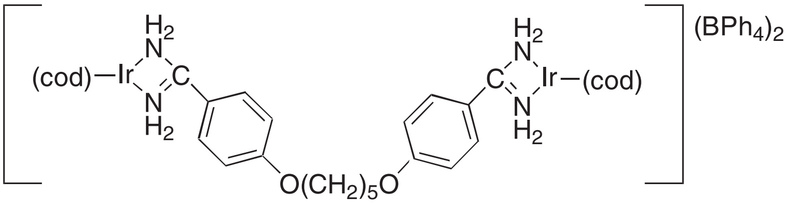
The complexes $[Ir(cod)dap][IrCl_2(cod)]$, $[IrCl(CO)(dap)]$, and $[Ir(cod)(dap)]ClO_4$, containing the tridentate ligand dap (dap = 2,6-diallylpyridine), have been characterized by IR and ^1H NMR spectroscopy.[693]

6.2.7.11.10 *Biological complexes*

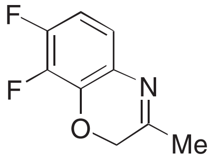
The chloro bridges in $[Ir(cod)Cl]_2$ are cleaved by α-amino acid esters to yield [(cod)Ir(Cl)(L)] (L = GlyOEt, *L*-AlaOMe, *L*-ValOMe).[694]

Prochiral aryl and dialkyl ketones are enantioselectively reduced to the corresponding alcohols using whole-cell bioconversions, or an Ir^I amino sulfide catalyst prepared *in situ*.[695] Comparative studies show that the biocatalytic approach is the more suitable for enantioselective reduction of chloro-substituted ketones, whereas reduction of α,β-unsaturated compounds is better achieved using the Ir^I catalyst. An important step in the total synthesis of brevetoxin B involves hydrogenation of an ester using $[Ir(cod)(py)\{P(cy)_3\}]PF_6$.[696]

Several transition-metal complexes were evaluated for their *in vitro* antifilarial activity, with (**441**) proving the most active towards infective larvae of *Molinema dessetae*.[697] The study of the antimetastatic properties of Rh^I and Ir^I derivatives of $[Mchel(L\text{-}L)]^{+/0}$, chel = pyridinalimine, acac; L-L = 1,5-hexadiene, cod, norbornadiene, reveals that the Rh^I complexes were more active than the Ir^I species.[698] The same group reports a higher anti-inflammatory activity on carrageenin paw edema in rats for $[Ir(cod)Cl]_2$ than for $[Rh(cod)Cl]_2$.[699]



(441)



(442)

The *in vitro* trypanocidal and antitumor activities of [Ir(cot)L], cot = cyclotetraene, derivatives of dithiocarbamates and xanthates, have been investigated.[700] The Ir complexes were characterized by IR spectroscopy, and MO calculations (Hückel) were performed on the ligands. Similar studies were performed on [Ir(nbr)L], nbr = norbornadiene, L = derivatives of alquil and aryl xanthates;[701] and also on $[Ir_2(cod)_2L]X_2$, where L = 2-hydroxystilbamidine, X = Cl, NO_3, ClO_4, BPh_4, and $[Ir(cod)L_{2'}]X$, where L′ = benznidazole, R_o-2516, nifurtimox, niridazole. The complex $[Ir_2(cod)_2(2\text{-hydroxystilbamidine})](BPh_4)_2$ showed the highest activity, as studied by optical microscopy of rats' kidneys.[702]

The key intermediate for the antibacterial agent levofloxcin, (*S*)-(−)-7,8-difluoro-2,3-dihydro-3-methyl-4H-1,4-benzoxazin, was prepared by the asymmetric hydrogenation of (**442**) by the catalyst system made *in situ* from $[Ir(cod)Cl]_2$, biphosphine and bismuth(III) iodide.[703] The product was isolated in 96% yield, with an enantiomeric purity of 90% for the biphosphine (2*S*,4*S*)-BPPM,(2*S*,4*S*)-N-(*t*-butoxy-carbonyl)-4-(diphenylphosphino)-2-[(diphenylphosphino)methyl]-pyrrolidine.

$Ir(CO)_2$(aniline-dithiocarbamate) shows a moderate activity against Ehrlich ascites at 50 mg kg^{-1}.[704] The synthesis of air-unstable $[Ir_2(\mu\text{-}L)(cod)_2]$, where $H_2L = RiSSH_2$(1,2-*O*-isopropylidene-2,5-dithio-α-*D*-ribofuranose, $XySSH_2$(1,2-*O*-isopropylidene-3,5-dithio-α-*D*-xylofuranose), is described.[705]

6.2.7.12 Catalytic Complexes

Table 2 details Ir^I complexes which are active catalysts in the given reactions. For more detailed descriptions of catalytic systems, see relevant section in series.

Table 2 Iridium(I)-based catalyst systems.

$[Ir(cod)(PPh_3)_2]ClO_4$	Oligomerization of phenylacetylene to 1,3-diphenylbut-1-yn-3-ene	719
$[Ir(cod)(PPh_3)(PhCN)]ClO_4$	Oligomerization of phenylacetylene to 1,3,5-triphenylbenzene	
$[Ir(cod)(PPh_3)_2]PF_6$	Oligomerization of phenylacetylene to (*Z*) 1,4-diphenylbut-1-yn-3-ene	
$[Ir(cod)(PPh_2R)_2]X$, $R = Me$, $X = BF_4$, PF_6, and $R = Ph$, $X = BF_4$	Deuterium exchange into aromatic substrates	720
$[Ir(cod)Cl]_2 + (4R, 5R\text{-mod-diop}) + {}^nBu_4NI$	Asymmetric hydrogenation of *N*-(α-methylbenzylidene)benzylamine, 2,3,3-trimethylindolenine	721
$[Ir(cod)Cl]_2 +$ bcpm + (a) ${}^nBu_4NI$ or NiI_3 (b) phthalimide + other imides or amides	Asymmetric hydrogenation of imines	722
	(i) Asymmetric hydrogenation of cyclic ketimines	723
	(ii) Asymmetric hydrogenation of 1-aryl-3,4-dihydro-6, 7-dimethoxyisoquinoline	724
$[Ir(cod)Cl]_2 + (R)$-binap + 3,4,5,6-tetrafluorophathalimide	Asymmetric hydrogenation of 1-benzyloxymethyl-3,4-dihydro-6, 7-dimethoxyisoquinodine	725
$[IrCl(CO)_3]_n$	Cycloisomerization of enynes	726
$IrCl\{HN(CH_2CH_2PPh_2)_2\}$	Hydrogenation of cyclohexene	727
$IrCl\{HN(CH_2CH_2AsPh_2)_2\}$		728
(a) $[Ir(cod)I(NNR^*)]$	Asymmetric hydrogen transfer from propan-2-ol to prochiral ketones	729
(b) $Ir(cod)(chiraphos)]^+$ or $[Ir(cod)(prophos)]^+$		730
$[Ir(cot)_2Cl]_2 + NNN$	Hydrogen transfer to PhCOMe	731
$[Ir(cod)L_2{}^P]PF_6$	Migration of double bond in allyl silanes	732
(a) $[Ir(cod)Cl]_2 + NN$	Hydrogenation of alkyl aryl ketones	733
(b) $[Ir(cod)Cl]_2 +$		734
(c) $[Ir(cod)(NN^*)Cl]_2 + (NS)$		735

Table 2 continued

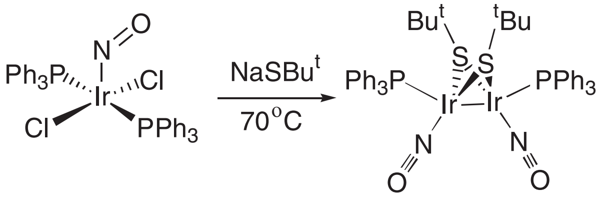
Catalyst system	*Catalyzed reaction*	*References*
$[Ir(cod)(PPh_3(PhCN)]BF_4$	Hydrogenation of double bond of vinyl epoxides	736
$[Ir(cod)Cl]_2 + (R)$-dipof	Hydrosilylation of ketones	737
$[Ir(dppe)(CO)Br]$ and $[Ir(PPh_2Me)_2(CO)Cl]$	Dimerization and cyclotrimerization of acetylenes	738
$[Ir(cod)(Pcy_3)(py)]PF_6 +$ catecholborane	Hydroboration of olefins	739
$[Ir(CO)Cl(PPh_3)_2]$	Hydrosilylation of 1-alkynes	740
$IrH(CO)_2(dppe)$ or $IrBr(CO)(dppe)$ or $IrCl(CO)(PPh_3)_2$	Photochemical carbonylation of benzene	741
$[Ir(dmp\text{-}S)(cod)]^+$	Water-gas-shift reaction	742
$[Ir(cod)Cl]_2 +$ bdpop+ KOH, Et_3N or NaOMe	Asymmetric transfer hydrogenation of ketones	743
$[Ir(CO)Cl(PPh_3)_2]$	Decarbonylation of formate esters	744
$[Ir(cod)Cl]_2 +$ binap + benzylamine	Hydrogenation of imines	745
$[Ir(cod)(Ph_3P{=}S)_2]ClO_4$	Hydrogenation of olefins	746

6.2.8 IRIDIUM(0)

There are few reported coordination compounds of Ir^0. Monomeric Ir^0 species are paramagnetic (d^9 electronic configuration), and binuclear compounds are diamagnetic with a metal–metal bond.

6.2.8.1 Nitrogen Ligands

The dark brown Ir^0 complex $[Ir(NO)(\mu\text{-}SBu^t)(PPh_3)]_2$, (**443**), is prepared according to Reaction Scheme 48.[747] (**443**) contains two tetrahedral Ir^0 centers with a linear nitrosyl ligand ($\nu_{NO} = 1{,}646\ cm^{-1}$ and $1{,}676\ cm^{-1}$), and is diamagnetic.



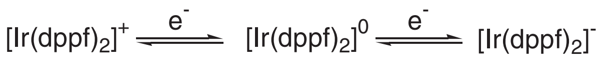
(443)

Scheme 48

6.2.8.2 Phosphorus Ligands

6.2.8.2.1 Monomeric complexes

The dark brown complex $[Ir(dppf)_2]$ (**444**), dppf = 1,1′-bis(diphenylphosphineoferrocene), is generated by either the one-electron reduction of $[Ir(dppf)_2]^+$ (**445**) or by the comproportionation reaction of (**445**) and (**446**), as shown in Reaction Scheme 49.[753] The geometrical environment of the Ir center in (**444**) is between the highly distorted, square-planar $[Ir(dppf)_2]^+$ and the slightly irregular tetrahedral geometry of $[Ir(dppf)_2]^{1-}$. Complex (**444**) exhibits an EPR signal in toluene at 120 K in keeping with its d^9 electronic configuration.[754]



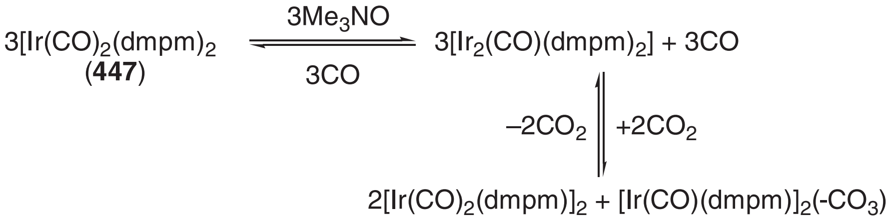
$$[Ir(dppf)_2]^+ \xrightleftharpoons{e^-} [Ir(dppf)_2]^0 \xrightleftharpoons{e^-} [Ir(dppf)_2]^-$$

(445) **(444)** **(446)**

Scheme 49

6.2.8.2.2 *Dimeric complexes*

The dimer $[Ir(CO)_2(dmpm)]_2$, (**447**), (dmpm = bis(dimethylphosphino)methane) is prepared via the reaction of $[Ir(cod)Cl]_2$ and dmpm in toluene at 0 °C.[748] (**447**) reacts with Me_3NO and then further with CO_2 to produce a binuclear Ir^I complex (Reaction Scheme 50).



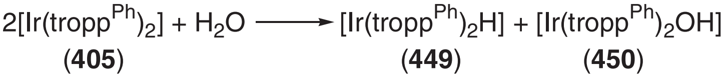
Scheme 50

The Ir^{II}–Ir^0 mixed-valence complex $Ir_2\{MeN[P(OEt^{F3})_2]_2\}_3Cl_2$, (**448**), ($OEt^{F3} = OCH_2CF_3$) is prepared by treatment of $[Ir\ Cl(cod)]_2$ with three equivalents of $MeN(P(OEt^{F3})_2$.[749] X-ray diffraction analysis of (**448**) reveals the Ir^0 center coordinated to two bridging P atoms and one bidentate P_2 ligand, and the Ir^{II} center bound to the other end of the two bridging ligands and two terminal chloride ligands. The iridium metal centers are connected via a single metal–metal bond.

6.2.8.3 Mixed-donor-atom Ligands

6.2.8.3.1 *C/P*

The mixed-donor-atom Ir^0-containing species $[Ir(tropp^{Ph})_2]$, (**405**), is prepared according to Reaction Scheme 43.[755] The single-crystal X-ray structure of (**405**) reveals the two P centers of each $tropp^{Ph}$ ligand are coordinated in *trans* positions, and the Ir center deviates significantly from square-planar geometry. The deep green, paramagnetic d^9 complex has a magnetic moment of 1.7 B.M. (**405**) reacts with H_2O to give the Ir^I hydride and hydroxide species (**449**) and (**450**), respectively, as shown in reaction Scheme 51.[756]



$$\underset{\textbf{(405)}}{2[Ir(tropp^{Ph})_2]} + H_2O \longrightarrow \underset{\textbf{(449)}}{[Ir(tropp^{Ph})_2H]} + \underset{\textbf{(450)}}{[Ir(tropp^{Ph})_2OH]}$$

Scheme 51

The high-resolution EPR spectra of the 17-electron complex (**446**) have been studied in combination with pulse ENDOR and ESEEM techniques.[750]

6.2.8.3.2 *N/P*

The mixed-donor bidentate ligand *O*-$Ph_2PC_6H_4$-CH=NR (R = Et, ^{i}Pr, ^{t}Bu) (PNalkyl) binds to Ir^I giving $[(PNalkyl)_2Ir]^+$, which undergoes reversible electron transfer to the Ir^0 species at around −1.50 V vs. SCE.[751] The Ir^0 complex shows an axial EPR signal at 100 K ($g\| = 2.032$, $g\perp = 1.999$), with no appreciable coupling to ^{193}Ir.

6.2.9 IRIDIUM (-I)

Coordination compounds of d^{10}, diamagnetic, Ir(-I) are very rare and are almost always synthesized via reduction of the parent Ir^I d^8 complex. The synthesis, characterization, and chemical properties of highly reduced metal carbonyl anions, including Ir, have been reviewed by Ellis in 1990.[752]

6.2.9.1 Phosphorus Ligands

Chemical or electrochemical reduction of $[Ir(dppf)_2]^+$, (**445**), in THF yields the Ir^0 complex (**444**) and the dark red Ir(-I) d^{10} species $[Ir(dppf)_2]^{1-}$, (**446**), according to Reaction Scheme 49.[753] The crystal structure of $[Na(THF)_5][Ir(dppf)_2]\cdot THF$ shows that the Ir(-I) center is bound to two chelated dppf molecules in a slightly distorted tetrahedral environment. Reduction of Ir^I to Ir^0 to Ir(-I) causes a stepwise decrease of the Ir—P bond lengths of 0.04 Å and 0.05 Å, respectively, with a concomitant increase of the bite angle of diphosphine from 94.3° in (**445**) to 102.3° in (**446**).[754]

6.2.9.2 Mixed-donor-atom Ligands

6.2.9.2.1 C/P

X-ray structural studies of the diamagnetic anion (**406**) confirm that the Ir(-I) center is in a distorted coordination geometry intermediate between square planar and tetrahedral, with the P donor atoms in a *cis* position. The metal–ligand bond distances do not show significant changes among (**404**), (**405**), and (**406**). The $Ir^I/^0$ and $Ir^0/(-I)$ redox couples are measured at easily accessible potentials and are solvent dependent.

6.3.1 INTRODUCTION

The basic properties of nickel and the coordination chemistry of nickel reported until 1983 have been comprehensively described in *Comprehensive Coordination Chemistry* (*CCC*, 1987). Hence, work published prior to 1983 will not be mentioned here, and the reader should generally refer to the respective chapters of *CCC*—only at some points specific reference to *CCC* is given. Also, the basic geometric preferences and the electronic and spectromagnetic properties of nickel in its various oxidation states will not be recapitulated, since an excellent overview is included in the first edition and only selected recent advances are added in this second edition.

Coordination chemistry in general—and the coordination chemistry of nickel in particular—has flourished since the early 1980s, stimulated by, *inter alia*, the discovery of an increasing number of fascinating nickel centers in metalloprotein active sites, the use of nickel in catalysis, and the booming interest in materials with specific physical properties related to magnetism, nonlinear optics, superconductivity, etc. As a consequence, an enormous amount of work dealing with nickel coordination compounds has appeared in the literature, and a comprehensive review is a mission impossible. We have tried to mention most of the important areas, but some unbalanced coverage is inevitable and we apologize in advance for all those studies that—albeit certainly important—we have overseen or omitted. Except for some isocyanide complexes, compounds in which Ni—C bonds play a dominant role are not included in this compilation.

For many years, the coordination chemistry of nickel has been included in annual reviews.[1–10]

6.3.2 RELEVANCE IN BIOINORGANIC CHEMISTRY AND MATERIALS CHEMISTRY

6.3.2.1 Nickel in Biology

In 1975, Zerner discovered that urease is a nickel enzyme, and the role of Ni in biology has been rapidly expanding since then.[11–18] The list of nickel-dependent enzymes includes urease, *E. coli* glyoxalase I (*E. coli* Glx I), [NiFe]-hydrogenase, methyl-CoM reductase (MCR), CO dehydrogenase (CODH), and acetyl CoA synthase (ACS), all of which have been crystallographically characterized. In addition, a Ni-containing superoxide dismutase (NiSOD) has been reported,[19] and some enzymes such as peptide deformylase are active with Ni while not known to naturally occur as a Ni enzyme.[20–22] Ni proteins are characterized by their diversity with respect to structure and function: urease and *E. coli* Glx I are nonredox enzymes that catalyze the hydrolysis of urea or the second reaction step in α-keto aldehyde detoxification (i.e., the isomerization of the glutathione adduct of the α-keto aldehyde), whereas [NiFe]-hydrogenase, MCR, CODH, ACS, and NiSOD are involved in various redox chemistries.

The dinuclear active site of urease (**1**) has been studied in great detail[23–29] and has inspired manifold model studies—hence a separate section, Section 6.3.4.12.7, is dedicated to the coordination chemistry related to urease. *E. coli* Glx I is the first example of a Ni-dependent isomerase and contains a single Ni^{II} ion coordinated by two histidines, two axial carboxylates of glutamic acid, and two water molecules (**2**).[30–32] It is not active with Zn bound, which is believed to result from the inability of the Zn-substituted enzyme to bind a second aqua ligand and to adopt a six-coordinate structure.

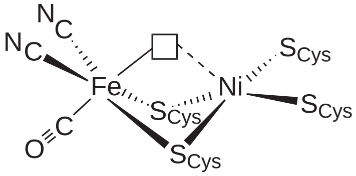
(3)



(4)

Nickel is found in thiolate/sulfide environment in the [NiFe]-hydrogenases and in CODH/ACS.[33] In addition, either a mononuclear Ni-thiolate site or a dinuclear cysteine-S bridged structure are assumed plausible for the new class of Ni-containing superoxide dismutases, NiSOD (**3**).[34] [NiFe]-hydrogenase catalyzes the two-electron redox chemistry of dihydrogen. Several crystal structures of [NiFe]-hydrogenases have demonstrated that the active site of the enzyme consists of a heterodinuclear Ni—Fe unit bound to thiolate sulfurs of cysteine residues with a Ni—Fe distance below 3 Å (**4**).[35–39] This heterodinuclear active site has been the target of extensive model studies, which are summarized in Section 6.3.4.12.5.

CODHs catalyze the reversible dehydrogenation of CO and H_2O to CO_2 and has many functions important to the global carbon cycle.[33,40] *Inter alia*, phototropic anaerobes have the ability to use CO as their carbon and energy source, which is based on the oxidation of CO to CO_2 catalyzed by CODHs. Some CODH enzymes also participate in the synthesis or disassembly of acetyl CoA. These so-called CODH/ACS enzymes thus have a dual role and contain two metal-containing active sites connected by a hydrohopic channel: the metallocluster found in the CODH subunit reduces CO_2 to CO, and that in the ACS subunit uses the formed CO and a methyl group to assemble acetyl CoA. Both sites contain nickel. Two structures of CODH enzymes appeared in 2001 and revealed that—contrary to previous assumptions—the Ni is completely integrated in the Fe/S cluster (**5a**, **b**).[41,42] This has been proposed to allow the Ni ion to formally remain in the EPR silent Ni^{II} oxidation state even in the CO-reduced state, despite the fact that the Ni is the likely site of CO binding. Indeed, one of the two structures shows a fifth ligand bound to Ni (**5b**), but the overall structures of the clusters differ significantly, possibly indicating considerable rearrangement between different oxidation states.

The crystal structure of a CODH/ACS enzyme was reported only in 2002.[43,44] It reveals a trio of Fe, Ni, and Cu at the active site (**6**). The Cu is linked to the Ni atom through two cysteine-S, the Ni being square planar with two terminal amide ligands. Planarity and amide coordination bear some resemblance to the Ni porphinoid in MCR. A two-metal ion mechanism is likely for acetyl CoA synthesis, in which a Ni-bound methyl group attacks an adjacent Cu—CO fragment with formation of a Cu-acyl intermediate. A methylnickel species in CODH/ACS has been identified by resonance Raman spectroscopy.[45]

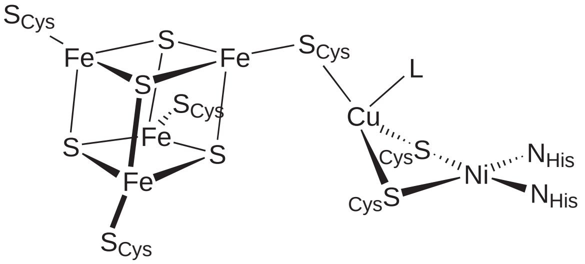
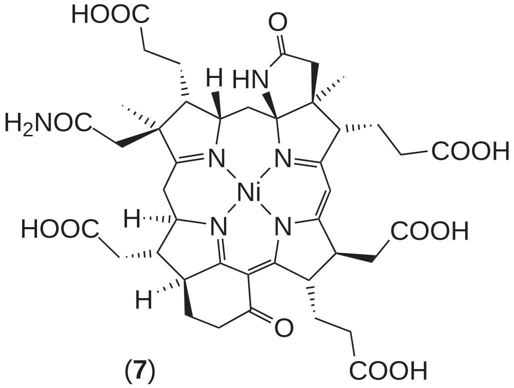
(5b)



(6)



(7)

MCR catalyzes the final chemical step in methane formation by strictly anaerobic methanogens (methanoarchaea).[46] The reaction involves a formal two-electron reduction of a methylthioether, methyl-coenzyme M (H_3C-S-CoM), by N-7-mercaptoheptanoylthreonine phosphate (HTP-SH, coenzyme B, CoB-SH) to yield methane and the mixed disulfide CoM—S—S—CoB. The key component is an unusual Ni tetrahydrocorphinoid cofactor (F_{430}, (**7**)),[47,48] and the assumed mechanism involves an intermediate Ni—CH_3 species. The redox chemistry of F_{430} has been the subject of numerous EPR studies (both on the enzyme and on model systems) as well as quantum chemical studies, where Ni^{I}, Ni^{II}, and Ni^{III} states have been characterized and proposed as intermediates in the catalytic cycle.[49–51] Model systems for MCR are mentioned in the respective chapters dealing with Ni–porphyrin and Ni–tetraazamacroclic complexes as well as in Section 6.3.4.11.7.

6.3.2.2 Nickel in Materials Chemistry

Nickel plays a prominent role in several areas of materials chemistry. However, in this review only in cases where Ni coordination chemistry is central to the physical properties will this relevance be mentioned specifically, and compounds are usually ordered according to their respective donor set. Some topical interplay between Ni coordination chemistry and materials science exists in the use of Ni-containing alkoxides for the synthesis of ceramic materials by MOCVD and sol–gel processes,[52] the preparation and nanoscopic dendrimers incorporating Ni,[53,54] the construction of 3D hybrid inorganic–organic porous materials with Ni coordination units,[55,56] and the fabrication of supported Ni catalysts and Ni nanostructures through nanotechnology.[57,58] The relevance of Ni complexes with dithiolene-type ligands in the areas of, *inter alia*, conducting and magnetic materials is mentioned in Section 6.3.4.7.10. Paramagnetic high-spin Ni^{II} has found particular attention in the field of molecular magnetism, culminating in the recent discovery of the first single molecule magnets based on Ni^{II} centers.[59–61] Magnetic properties of some prominent classes of polynuclear Ni^{II} compounds are presented in Section 6.3.4.13.

6.3.3 COMPLEXES OF NICKEL(III) AND NICKEL(IV)

6.3.3.1 Introduction

There is increasing interest in high-valent Ni, both because of the relevance of Ni^{III} in some bioinorganic sites and because of the high reactivity of the high-valent species. An account of the chemistry of Ni^{III} and Ni^{IV} has been published,[62] and the redox chemistry of nickel has been reviewed.[63] In particular, the general steric and electronic requirements and the methods of study of Ni^{III} and Ni^{IV} complexes have previously been summarized—hence these aspects will not be covered here. Also, the mechanisms and kinetics of electron transfer reactions of Ni^{III} and Ni^{IV} complexes have been reviewed.[64]

Ligands used to fulfill the requirements for stabilizing Ni^{III} and Ni^{IV} states are particularly deprotonated amides and oximes as well as certain macrocyclic N-donor ligands. Since many studies of Ni^{II} complexes include reports on the electrochemical Ni^{II}/Ni^{III} redox potentials, the reader should also refer to the respective Ni^{II} sections when looking for individual ligand sets. Section 6.3.3 does not give an exhaustive compilation, but instead focuses on selected examples where the high-valent Ni states have been the central aspect of the work. Since dinuclear (and oligonuclear) complexes that incorporate Ni^{III} (or even Ni^{IV}) are usually prepared from the respective Ni^{II} compounds, these systems are not covered here (with few exceptions), and the reader should refer to the respective section of the Ni^{II} part for some further information.

6.3.3.2 Cyano Complexes

The Ni^{III} complex *trans*-$[Ni(CN)_4(H_2O)_2]^-$ can be generated in aqueous solution by the oxidation of $[Ni(CN)_4]^{2-}$, either by bulk electrolysis or chemically.[65] Chlorine oxidation of aqueous solutions of $[Ni(CN)_4]^{2-}$ has been the subject of a detailed kinetic study.[66] Three parallel paths were found, determined by the species present in Cl_2/H_2O solutions (Cl_2, Cl_2O, HOCl). The fastest reaction is oxidation by Cl_2O ($1.3 \times 10^7\,M^{-1}\,s^{-1}$ at 25 °C, $\mu = 0.10\,M$), the formation of which is catalyzed by acetic acid. The reaction is proposed to proceed via Cl^+ transfer, affording a transient Ni^{IV} species.

trans-$[Ni(CN)_4(H_2O)_2]^-$ is moderately stable at low concentrations in acidic solutions, but decays rapidly in base. The base decomposition is slower in the presence of excess cyanide.[67] The interaction of axially bound water with Ni^{III} has been investigated using electron spin echo envelope modulation with different pulse sequences.[68,69] Cyclic voltammetry of $[Ni(CN)_4(H_2O)_2]^-$ gives a formal reduction potential of 1.19 V (vs. NHE) for the $[Ni^{III,II}(CN)_4]^{1-/2-}$ couple. Although it is a strong oxidizing agent, $[Ni(CN)_4(H_2O)_2]^-$ coordinates excess cyanide to form $[Ni(CN)_6]^{3-}$, which gives an anisotropic EPR spectrum at −190 °C, with $g_\perp = 2.081$ and $g_\parallel = 2.010$. At −35 °C the frozen EPR spectrum collapses to an isotropic signal, because the six cyanides become equivalent due to dynamic Jahn–Teller distortion.[67]

In addition, the labile aqua species *trans*-$[Ni^{III}(CN)_4(H_2O)_2]^-$ is a useful source of various tetragonally elongated Ni^{III} complexes through the displacement of the axial water ligands. Ni^{III} complexes that have been prepared via this intermediate include $[Ni(CN)_4(NCO)_2]^{3-}$, $[Ni(CN)_4(Cl)_2]^{3-}$, $[Ni(CN)_4(NCCH_3)_2]^-$, $[Ni(CN)_4(py)_2]^-$, $[Ni(CN)_4(N_3)_2]^{3-}$, $[Ni(CN)_4(\text{imidazole})_2]^-$, $[Ni(CN)_4(NH_3)_2]^-$, $[Ni(CN)_6]^{3-}$, and $[Ni(CN)_4(bpy)]^-$. The products can be detected and analyzed using EPR spectroscopy, indicating a variety of tetragonally elongated complexes with two equivalent axial donor ligands.[67]

Cyanide binds to a series of Ni^{III} complexes with $\{N_3O_2\}$ chelate ligands, and EPR spectra of the adducts indicate quasi-axial symmetry with a g pattern typical of low-spin, six-coordinate complexes with axial elongation and with a $^2A_1$ ground state. No direct spin interaction of the unpaired electron with the carbon atom of the cyanide takes place.[70]

6.3.3.3 Complexes with N-donor Ligands

6.3.3.3.1 Complexes with nonmacrocyclic N-donor ligands

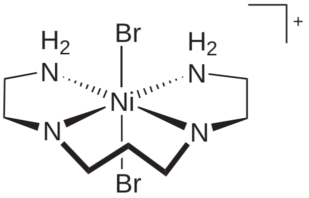
In CCl_4 suspension, chlorine oxidation of $[Ni(\text{diamine})_3]Cl_2$ affords unstable orange $[Ni(\text{diamine})_3]Cl_3$ (diamine = en, 1,3-propanediamine, 1,2-cyclohexanediamine, 1,2-diamino-2-methylpropane, *N*-methylethanediamine); some of these species are stable for a few weeks in a glove-box.[71] They have been characterized by EPR, IR, and diffuse reflectance electronic spectroscopy. EXAFS analysis of solid samples suggests a very slight shortening of the Ni—N distance on passing from Ni^{II} to Ni^{III}, although larger Debye–Waller factors are evident, possibly because of disorder induced by the Jahn–Teller effect in the low-spin d^7 systems.

Halogen oxidation of Ni^{II}–diamine complexes in solution is known to give either genuine Ni^{III} complexes $\{[NiX(diamine)_2]X_2\}_n$ or Ni^{II}/Ni^{IV} mixed valence species $\{[Ni^{II}(diamine)_2][Ni^{IV}X_2(diamine)_2]X_4\}_n$. For the chlorination of $[NiCl_2(en)_2]$, both products have finally been characterized, after much dispute in the literature over the nature of these materials.[72] Either *trans*-$[Ni^{III}Cl_2(en)_2]Cl$ or the mixed-valence compound $\{[Ni^{II}(en)_2][Ni^{IV}Cl_2(en)_2]Cl_4\}_n$ are obtained, depending upon the conditions. $\{[Ni^{III}Cl(en)_2]Cl_2\}_n$ has been synthesized by anodic electrocrystallization from a solution of $[Ni_2(\mu\text{-}Cl)_2(en)_4]Cl_2$ (prepared *in situ* in MeOH, in the presence of excess LiCl). It has a one-dimensional (1D) structure with symmetrical halogen bridges,[73] as does $\{[NiX(R,R\text{-}1,2\text{-cyclohexanediamine})_2]X_2\}_n$.[74] Useful structural information for the mixed-valence species $\{[Ni^{II}(en)_2][Ni^{IV}Cl_2(en)_2]Cl_4\}_n$ is forthcoming from nickel and chlorine EXAFS.[75] The chloro-bridged 1D Ni^{II}/Ni^{IV} mixed-valence complexes $[NiL][NiCl_2L]Cl_4$ (L = 3,7-diazanonane-1,9-diamine)[76] and $\{[Ni^{II}(en)_2][Ni^{IV}Cl_2(en)_2]Cl_4\}_n$[77] have also been analyzed using XPS and EPR, respectively.

The X-ray determination of the crystal structure of $[Ni^{III}Br_2(en)_2]Br$ shows a centrosymmetric cation, with $d(Ni—N) = 1.944$ Å and $d(Ni—Br) = 2.635$ Å.[78] The long Ni—Br bond is as expected for this d^7 $(d_{z^2})^1$ complex, while the Ni—N bonds have shortened considerably upon oxidation. Data obtained from EXAFS measurements are quite consistent with these findings: $d(Ni—N) = 1.915$ Å; $d(Ni—Br) = 2.582$ Å.[79] Bromine oxidation of $[NiBr_2(en_2)]$ affords discrete $[Ni^{III}Br_2(en)_2]Br$, whereas with $[NiBr_2(R,R\text{-}1,2\text{-cyclohexanediamine})_2]$, the product is the 1D Ni^{III} complex $\{[NiBr(R,R\text{-}1,2\text{-cyclohexanediamine})_2]Br_2\}_n$. Since both Ni^{II} complexes, in MeOH solution, exhibit virtually identical CVs, it is proposed that the different solid-state structures for the two complexes are caused purely by strong NH· · ·Br· · ·HN bonding in the 1D complex.

In most such chains, the bridging halogen atoms are distorted from the neighboring two Ni atoms due to strong electron-phonon interaction, giving rise to the mixed-valent Ni^{II}/Ni^{IV} 1D sequences or Peierls distorted charge density wave (CDW) states. In the case of stronger on-site Coulomb interaction, however, the Ni^{III} state or spin density wave state (SDW) becomes more stable, where the bridging halogens are located at the midpoints between neighboring two Ni atoms. This has been verified for several quasi-1D Ni^{III} complexes $\{[NiX(R,R\text{-}1,2\text{-cyclohexanediamine})_2]Y_2\}_n$ (X = Cl, Br, and mixed halides; Y = Cl, Br, mixed halides, NO_3, BF_4, ClO_4).[80] Strong antiferromagnetic coupling in $\{[NiX(diamine)_2]X_2\}_n$ accounts for the observed diamagnetism. Work on the electronic structures of the quasi-1D halogen-bridged Ni^{III} complexes has been reviewed, emphasizing the strong electron-correlation.[81]

The octahedral Ni^{III} complex (**8**) has been obtained serendipitously and the structure of the perchlorate salt was determined.[82] It features short equatorial Ni—N bonds of 1.952(5)–1.972(6) Å.



(**8**)

The structure of the Ni^{III} complex $[Ni(bpy)_3]^{3+}$ has been determined.[83] It contains a $\{NiN_6\}$ center, and there is a significant shortening of the Ni—N bond lengths upon going from Ni^{II} to Ni^{III}. While the EPR data have been interpreted in terms of tetragonal elongation with the single electron in a d_{z^2} orbital, the structure shows two axial bonds 0.09 Å shorter than the average of the other four. Crystal packing forces have been assumed a more likely reason than dynamic in-plane distortion for this finding.[84] Cyclic voltammetry and spectroscopic techniques have been used to study the electrochemical oxidation of $[Ni(bipy)_3]^{2+}$ in liquid sulfur dioxide. Four successive oxidations were observed, the first two of which were attributed to oxidation of the metal center. The procedure for separation and purification of the very strong solid oxidant $[Ni(bipy)_3](AsF_6)_4$ has been described.[85]

The complexes (**9**) are readily oxidized and the Ni^{II}/Ni^{III} conversion is reversible.[86] The Ni^{III} species obtained chemically by oxidation with $[Fe(CN)_6]^{3-}$ is relatively stable and does not bind

CO or react with H^-. It has a $(d_{z^2})^1$ ground state. The Ni^{III} complex of (**10**) is described in Section 6.3.3.8.2. The tridentate bis-amide ligand (**11**) forms complexes $[Ni^{II}(\mathbf{11})_2]^{2-}$, $[Ni^{III}(\mathbf{11})_2]^-$, and $[Ni^{IV}(\mathbf{11})_2]$ with the metal ion in three consecutive oxidation states.[87] Redox potentials are 0.05 V and 0.51 V (vs. SCE) for the Ni^{II}/Ni^{III} and Ni^{III}/Ni^{IV} transitions, respectively. X-ray crystallography of the Ni^{II} and Ni^{IV} species reveals that the nickel is coordinated in tetragonally compressed geometry in both cases, with the expected decrease of the $Ni—N_{amide}$ (2.131(8) Å vs. 1.946(8) Å) and $Ni—N_{py}$ (1.994(7) Å vs. 1.846(8) Å) bond lengths upon oxidation. The Ni^{III} complex has $S = 1/2$ with the unpaired electron in a d_{z^2} orbital, while the Ni^{IV} compound is diamagnetic.

Ni^{III} Schiff base complexes have been produced by electrochemical oxidation of Ni^{II} complexes derived from naphthaldehyde, and identified by EPR spectroscopy.[88]

6.3.3.3.2 *Complexes with macrocyclic N-donor ligands*

Macrocyclic N-donor ligands continue to dominate Ni^{III} coordination chemistry. Their chemistry makes for a big part of the redox chemistry of Ni, although it has been shown that the cyclic nature of an N-donor ligand is not crucial for thermodynamic stabilization of Ni^{III}.[89,90] Several reviews have appeared in the field,[63,91–93] also dealing with kinetic aspects of redox reactions of Ni^{III} macrocyclic complexes.[64,94] $E_{1/2}(Ni^{II}/Ni^{III})$ values for various Ni-macrocyclic complexes and general trends of the oxidation potential are summarized in Section 6.3.4.10.1(iii) for tacn-type ligands and in Section 6.3.4.10.2(iii) for larger N-macrocycles.

$[Ni([9]aneN_3)_2]^{3+}$ (**12**) is a strong oxidant and exhibits a quasi-reversible one-electron redox process with a formal redox potential of +0.95 V (vs. NHE).[95] The trivalent complex exhibits UV and magnetic data consistent with a low-spin d^7 configuration of a Jahn–Teller distorted octahedral $\{Ni^{III}N_6\}$ center, which has been confirmed by the X-ray crystal structure of the dithionate salt of $[Ni([9]aneN_3)_2]^{3+}$.[84] Similarly, for the Ni sandwich complexes with (*R*)-2-methyl-1,4,7-triazacyclononane it was found that $E_{1/2} = +0.94$ V (vs. NHE) and that the $\{NiN_6\}$ chromophore is retained in both oxidations states, +2 and +3.[96] The Ni^{III} complex shows only slight decomposition at pH 3 and is indefinitely stable in acetonitrile. The potentials for the $[LNi]^{3+/2+}$ couple are generally more negative for complexes containing the pure σ-donor tacn than those of a ligand containing three tertiary amine donors and pendant π-acceptor ligands that stabilize the +2 oxidation state; e.g., the difference is −400 mV compared to 1,4,7-tris(2-pyridylmethyl)-1,4,7-triazacyclononane bearing three pyridine N atoms.[97] Reinvestigation of the structure reported before as the Ni^{III} complex of 1,4,7-triazacyclononane-*N*,*N*′,*N*″-triacetate[98,99] failed to confirm the presence of Ni and indicated a Co complex instead.[100]

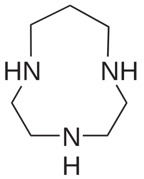
The Ni^{II} sandwich complexes of 1-thia-4,7-diazacyclononane ([9]aneN_2S),[101] 7-aza-1,4-dithiacyclononane ([9]aneNS_2),[102] 1-oxa-4,7-diazacyclononane ([9]aneN_2O), and related tridentate macrocycles can all be oxidized to the corresponding Ni^{III} species. $[Ni([9]aneN_2S)_2]^{3+}$ and $[Ni([9]aneN_2O)_2]^{3+}$ were found to exhibit a distorted stereochemical arrangement with the S and O heteroatoms, respectively, occupying the axial sites of an elongated octahedron.[101] $E_{1/2}$ values for the Ni^{II}/Ni^{III} redox couple indicate that the relative stability of the trivalent complex decreases along the series [9]aneN_3 > [9]aneN_2S > [9]aneNS_2 > [9]aneS_3 > [9]aneN_2O, which is assumed to be controlled by the strength of the metal–ligand interactions. Spectroscopic data confirm that these oxidations are metal-centered.[103] The effect of ring size and medium on the $Ni^{II/III}$ redox couple potential for complexes of triazamacrocyclic ligands has been investigated: in the series of complexes $[Ni([9]aneN_3)_2]^{2+}$, $[Ni(\mathbf{13})_2]^{2+}$, and $[Ni(\mathbf{14})_2]^{2+}$, according to voltammetric techniques the Ni^{III} state becomes more difficult to attain the larger the macrocyclic ring.[104]

The kinetics formation of $[Ni([9]aneN_3)_2]^{3+}$ have been studied in great detail. *Inter alia*, the volume of activation for peroxodisulfate oxidation of $[Ni([9]aneN_3)_2]^{2+}$ has been determined ($-25.8 \pm 2.3\,cm^3\,mol^{-1}$),[105] and the kinetics of this reaction have been determined as a function of peroxodisulfate concentration and temperature.[106] The reaction is first-order in both reagents (second-order rate constant $1.13\,mol\,dm^{-3}\,s^{-1}$ at 298 K), and the activation energy is $38 \pm 1.8\,kJ\,mol^{-1}$. In mixed solvents, the rate is slower.

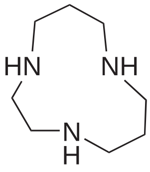
The inner shell activation barriers to electron transfer in the $[Ni([9]aneN_3)_2]^{2+/3+}$ couple have been studied,[107] and the entropy changes associated with the two half reactions $[Ni^{III}([9]aneN_3)_2]^{3+} + e^- \rightleftharpoons [Ni^{II}([9]aneN_3)_2]^{2+}$ and $[Ni^{III}L]^0 + e^- \rightleftharpoons [Ni^{II}L]^-$ (L = 1,4,7-triazacyclononane-*N*,*N′*-*N″*-triacetate) have been determined through investigation of the temperature dependence of the $E_{1/2}(Ni^{III}/Ni^{II})$ parameter over the 0.1–3.5 M concentration range of the background electrolyte (NaCl).[108] Molecular mechanics calculations have been performed on complexes $[Ni([9]aneN_3)_2]^{2+/3+}$ to resolve the discrepancy between experimental inner-shell activation enthalpies and values predicted using the harmonic oscillator model.[109] It is found that most of the inner-shell barrier derives from M—N bond stretching.

A large amount of work has been devoted to the mechanism and kinetics of electron transfer reactions with $[Ni([9]aneN_3)_2]^{3+}$,[64,110] including studies of the oxidation of excess thiocyanate[111] and of hydrogen peroxide[112] by $[Ni([9]aneN_3)_2]^{3+}$. Also, reactions of $[Ni([9]aneN_3)_2]^{3+}$ with NO_2^- and NO have been studied in aqueous solution at 25 °C. NO_2^- reacts to form $[Ni([9]aneN_3)_2]^{2+}$ and NO_3^-, with electron transfer from NO_2^- to $[Ni([9]aneN_3)_2]^{3+}$ proposed as the rate determining step. NO was found to react either via an outer-sphere-electron transfer reaction or via a pathway which leads to destruction of the complex.[113] UV–visible spectroscopy and stopped-flow techniques have been used to investigate the base promoted decomposition of $[Ni([9]aneN_3)_2]^{3+}$ in aqueous solution. It has been suggested that the reaction is initiated by deprotonation of $[Ni([9]aneN_3)_2]^{3+}$ with the N-deprotonated species then decomposing further to yield $Ni(aq)^{2+}$ and $[Ni([9]aneN_3)(H_2O)_3]^{2+}$. The reaction has been postulated to proceed via mono- and bimolecular pathways.[114] Electron transfer reactions of $[Ni(\mathbf{14})_2]^{2+}$ have also been studied.[115]

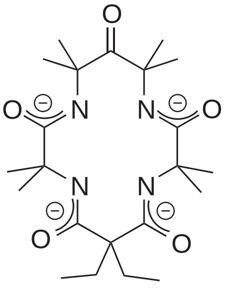
Studies on the oxidative chemistry of Ni complexes with larger macrocycles, in particular with tetraazamacrocycles, are countless. Pulse radiolysis continues to be one of the methods used for generating azamacrocyclic Ni^{III} species.[116,117]



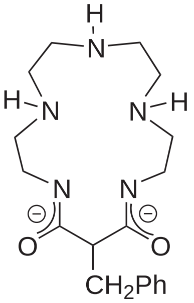
(13)



(14)



(15)



(16)

Aliphatic tetraazamacrocycles are well known to be effective in stabilizing Ni in higher oxidation states due to the very strong in plane σ-interactions which raise the energy of the (metallic) antibonding orbital from which the electron is extracted on oxidation. Table 1 lists characteristics

Table 1 Structurally characterized azamacrocyclic Ni^{III} complexes.

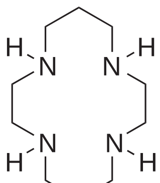
Complex	*Structure*	*d(Ni—N)* (Å)	*d(Ni—X)* (Å)	*References*
$[Ni(tacn)_2]^{3+}$	Tetragonally distorted; octahedral	1.964(5)–2.111(5)		126
trans-$[Ni(\mathbf{17})(NO_3)_2]^+$	Axially elongated; octahedral	1.970(2)–1.978(2)	(X = O); 2.110(2), 2.114(2)	127
trans-$[Ni(\mathbf{17})(NCS)_2]^+$	Axially elongated; octahedral	1.965(2), 1.979(2)	(X = N); 2.081(3)	128
trans-$[Ni(\mathbf{18})Cl_2]^+$	Axially elongated; octahedral	1.983(2), 2.011(2)	(X = Cl); 2.4721(6)	129
trans-$[Ni\{H_2(\mathbf{19})\}Cl_2]^{3+}$	Axially elongated; octahedral	1.970(14)–2.007(14)	(X = Cl); 2.401(6), 2.430(6)	130
trans-$[Ni(\mathbf{20})Br_2]^+$	Axially elongated; octahedral	1.869(12), 1.969(14)	(X = Br); 2.664(1)	131
$[Ni(\mathbf{16})(H_2O)]^+$	Axially elongated; octahedral	N_{amide} (equatorial): 1.893(3), 1.887(5); N_{amine} (equatorial): 1.961(5), 1.965(4); N_{amine} (axial): 2.067(4)	(X = O); 2.340(4)	132
$[Ni(\mathbf{15})]^-$	Distorted square-planar (significantly nonplanar tetraamido ligand)	1.824(4)–1.849(4)		125

of structurally characterized azamacrocyclic Ni^{III} complexes. All of them have an axially elongated octahedral geometry, except for $[Ni(\mathbf{15})]^-$ which is distorted square planar with the Ni atom sitting 0.09 Å above the mean plane of the N-donor atoms. Dioxa tetraaza macrocycles with amide sites such as (**16**) are often used for stabilizing Ni^{III}.[118–123] The tetraamide macrocycle (**15**) is particularly well suited to stabilize nickel in the +3 oxidation state and features short Ni—N bonds.[124,125] The purple complex $[Ni(\mathbf{15})]^-$ has a very low affinity for axial ligands in solution: only addition of cyanide gives a color change to yellow, with the resulting EPR spectrum being rhombic. The use of ^{13}CN confirms binding of a single cyanide.[125]

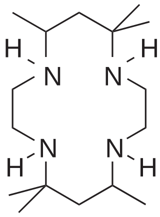
Typically, the Ni—Cl and Ni—N bonds shorten on passing from the Ni^{II} to the Ni^{III} state, e.g., by about 0.09 Å in the case of *trans*-$[Ni(\mathbf{18})Cl_2]^+$.[129] For this particular compound, quasi-reversible oxidation occurs at +1.14 V (vs. SCE) and the EPR spectrum ($g_\perp = 2.121 > g_\parallel = 2.019$) is indicative of axial symmetry. More sterically congested tetraazamacrocyclic ligands can promote the low-spin square planar geometry of the Ni^{II} complexes in aqueous solution and thus can make the Ni^{II}/Ni^{III} redox potential more anodic, as expected given the increasing difficulty experienced by the metal ion in coordinating axial coligands. This has been demonstrated for, *inter alia*, Ni complexes of a series of sterically congested cyclam derivatives (e.g., (**21**), (**22**) and various cyclohexane appended cyclam systems).[133] Ligands with pendant arms bearing potentially coordinating groups have been employed in order to circumvent the need for additional external ligands for stabilizing the Ni^{III} state (compare Section 6.3.4.10.2). However, in the case of some hexaazamacrocyclic ligands, the hydroxyethyl or cyanoethyl pendant arms have been found to not coordinate.[134] It should be mentioned that Ni complexes of hexaaza macrotricyclic ligands have also been investigated in detail with respect their Ni^{II}/Ni^{III} redox chemistry.[135,136]

The electrochemical behavior of the Ni^{II} complex of (**23**) reveals that the *cis*-octahedral Ni^{II} species $[Ni(\mathbf{23})H_{-1}(H_2O)]^+$ rapidly rearranges to a nominally square planar form upon oxidation to Ni^{III} at ~+0.6 V vs. SCE, which is reversible upon reduction.[137] Ligand (**24**) with a weakly-binding sulfonamide moiety readily supports Ni^{III}: on treatment of the Ni^{II} complex in H_2O with $S_2O_8^{2-}$, *trans*-$[Ni(\mathbf{24})Cl_2]^+$ is generated.[138] Indirect evidence suggests that the Ni^{III} species is more stable than the complex with parent cyclam.

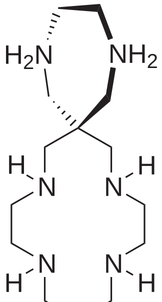
With respect to the ring size, it has been stated that neither the redox potentials nor the half-lives of the Ni^{III} species are directly correlated to the cavity of the macrocyclic ligand, but the redox potentials are dependent on solvation effects.[139] The effect of fused benzene rings and ring conformation has been monitored.[140] In Ni complexes of fluorine-containing cyclams (**25**) the higher oxidation state becomes successively destabilized with respect to Ni^{II}, while the lower oxidation state (i.e., Ni^I) becomes successively stabilized.[141]



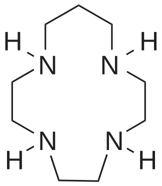
(17)



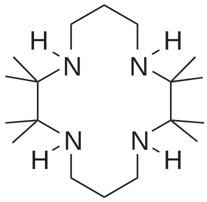
(18)



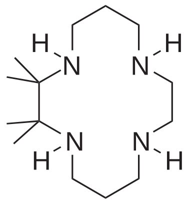
(19)



(20)



(21)



(22)

A violet transient forms when acid $[Ni(\mathbf{17})]^{3+}$ solutions are added to water buffered at pH 7 ± 1. The color originates from a band at 539 nm, with a high extinction coefficient (1330 ± 100) assigned to a Ni^{III} complex of monodeprotonated cyclam (pK_a of $[Ni(\mathbf{17})]^{3+}$ secondary amine: 7.1 ± 0.1).[142] The latter undergoes decay by a second-order rate process, probably transfer of an electron from the amido nitrogen to a second Ni^{III} center, giving a Ni^{II}–cyclam radical complex which undergoes loss of a proton to give a Ni^{II} complex of the monoimine macrocycle. This is believed to be the general pathway of decomposition of Ni^{III} complexes with ligands having secondary N-donors.[143,144] Systems with tertiary tetraaza macrocyclic ligands may be kinetically stabilized in aqueous solution.[145]

The kinetics and mechanism of chloride and bromide substitution of diaquonickel(III) complexes with several ligands of the cyclam type have been studied. The data reveal a reversible process yielding $[NiL(H_2O)X]^{2+}$ and are consistent with a dissociative mechanism, sterically more demanding axial groups substantially increasing the rate. In addition, a rearrangement step is observed subsequent to the formation of the monohalide complex.[146]

Trivalent Ni complexes of tetraazamacrocycles are powerful single-electron oxidizing species, and much work has been carried out on the mechanism and kinetics of such reactions. Only selected examples can be mentioned here. These include the kinetics of reduction by Ti^{III} in aqueous solution, where an outer-sphere mechanism is favored,[147] the kinetics of the reduction of a range of eight Ni^{III} macrocycle complexes by reagents such as Fe^{II},[148] the reactions of Ni^{III} tetraazamacrocyclic complexes with iodide,[149] the kinetics of the reaction of $[Ni(cyclam)]^{2+}$ in acidic aqueous solution with alkyl hydroperoxides,[150] and the kinetics of reduction of $[Ni(cyclam)(H_2O)_2]^{3+}$ and species $[Ni(cyclam)X(H_2O)]^{2+}$ (X = Cl, Br) by SO_2 in acid media.[151] In the latter case, only ${SO_3}^{2-}$ and ${HSO_4}^{-}$ were detected; no evidence was found for ${S_2O_6}^{2-}$, which would be expected if ${SO_3}^{-}$ were an important intermediate. Halide ions accelerated the reaction. A mechanism involving insertion of S^{IV} into Ni^{III}—X bonds was proposed.

Studies have been carried out on the methylated complex $[H_3C\text{-}Ni^{III}(\mathbf{17})(H_2O)]^{2+}$, which is obtained from the reaction of methyl radicals (generated by pulse radiolysis) with $[Ni(\mathbf{17})]^{2+}$. The volumes of activation are consistent with the coherent formation of Ni—C and Ni—OH_2 bonds, as expected for the generation of a Ni^{III} complex from a square planar Ni^{II} precursor.[152] The kinetics of reactions of $[H_3C\text{-}Ni^{III}(\mathbf{17})(H_2O)]^{2+}$ involving homolysis, O_2 insertion and methyl transfer to Cr^{II}(aq) have been determined, and intermediates have been considered relevant as models for biological systems.[153] Comparing different alkyl radicals, rate constants for the formation of σ-bonded organonickel(III) cations are most favorable for methyl radicals, and least favorable for secondary alkyls.[154]

Complexes such as [Ni(**16**)] are known to stoichiometrically interact with O_2 to give 1:1 adducts and subsequently the autoxidized Ni^{III} species (compare Section 6.3.4.10.2(v)).[155] Such systems have been tested for the Ni^{III}-catalyzed cleavage of DNA (see Section 6.3.4.10.2(v)). It has been suggested that Ni^{II} macrocycle complexes with rather low Ni^{II}/Ni^{III} reduction potentials can be active inhibitors of aldehyde autoxidation.[156]

Oxidation of encapsulated complexes with hexadentate sarcophagine-type ligands to the Ni^{III} cations was achieved by controlled potential coulometry in acetonitrile, or Ce^{IV} oxidation in aqueous solution; [(**26**)]$(CF_3SO_3)_3$ could be isolated as a pure solid and is a strong oxidant (+0.90 V vs. NHE).[157] Since the Ni^{II} complex could be resolved into its enantiomers by fractional crystallization as bis((+)-tartrato)diantimonate salts, the optically pure Ni^{III} cations were obtained from these. The electron self-exchange rate between enantiomeric forms in the two oxidation states was measured using a stopped flow circular dichroism technique ($k_{ct} = 5{,}300 \pm 300\,dm^3\,mol^{-1}\,s^{-1}$ at 298 K, $I = 0.2$ M). The rate constant and the activation parameters are consistent with only minor rearrangements of the coordination spheres on electron transfer.

The redox behavior of Ni^{II} tetraazaannulene complexes can be tuned by the appropriate choice of substituents bound to the ligand scaffold.[158] It is interesting to note that in a series of Jäger-type Ni^{II} complexes, both the type (**27**) and type (**28**) systems give reversible oxidation, while (**29**) does not.[159]

6.3.3.4 Complexes with Ligands Containing Phosphorus, Arsenic, and Antimony

The three main types of Ni^{III} complexes with P- and As-donor ligands are $[NiX_3L_2]$, $[NiX_3(L–L)]$, and $[NiX_2(L–L)_2]^+$. Although the five-coordinate Ni^{III} complexes with phosphine or arsine ligands have long been known, more detailed investigations have been carried out since the early 1980s. Some 25 examples of this class have been described in a report which includes an account of their spectral and magnetic properties,[160] and high-valent Ni complexes with P- and As-donor ligands have been reviewed.[161]

A new method for synthesis of type $[NiL_2X_3]$ phosphine complexes involves reaction of reagent grade metal powders with phosphoranes or arsanes in ether according to Equation (1).[162,163] The Ni^{III} complex is formed quantitatively without use of an additional oxidizing agent. However, the procedure leads to products whose composition is very dependent on L and X; in the case of L = phosphane, the products include square planar $[NiI_3(PR_3)]^-$ ($R \neq Me$), $[NiBr_2(PMe_2Ph)_2]$, and five-coordinate $[NiI_3(PR_3)_2]$ ($PR_3 = PMe_3$, PMe_2Ph), as well as $[NiBr_4(PR_3)_2]$ ($PR_3 = PPh_2Pr$, PMe_2Ph) which appears to be $[PBrR_3][NiBr_3(PR_3)]$.[164] Nickel K-edge EXAFS data, supplemented by bromine K-edge data, have been used to obtain structural information relating to the complexes $[Ni(PR_3)_2X_3]$ ($PR_3 = PEt_3$, PMe_2Ph; X = Cl, Br). These studies confirmed the occurrence of rare trigonal bipyramidal geometry for these Ni^{III} complexes,[165] in accordance with X-ray crystallographic results for $[NiI_3(PMe_3)_2]$[166] and $[NiI_3(AsMe_3)_2]$ (**30**).[162]

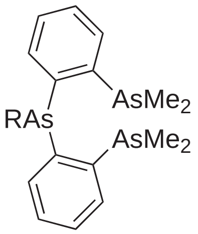
(32)



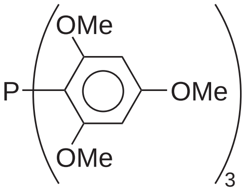
(33)
R = Me, Ph

In contrast to the $[NiX_3(PR_3)_2]$ complexes, $[NiX_3(L–L)]$ with bidentate phosphines L–L lose X_2 on heating and revert to the Ni^{II} species. Various Ni^{III} complexes $[NiCl_3(L–L)]$ have been obtained by Cl_2 or NOCl oxidation of the corresponding $[NiCl_2(L–L)]$.[160] Nitric acid oxidation of $[NiI_2(\mathbf{31b})]$ leads to *trans*-$[NiI_2(\mathbf{31b})]^+$; corresponding Ni^{III} diphosphine complexes could not be made by this route.[167] EXAFS results are available for Ni^{II}, Ni^{III}, and Ni^{IV} complexes[168] of *o*-$C_6X_4(EMe_2)_2$ (X = H, E = P, As; X = F, E = As) and the crystal structure of tetragonal $[NiBr_2(\mathbf{31d})_2]BF_4$ has been determined. The polarized optical spectrum of the d^7 Ni^{III} complex $[NiCl_2(\mathbf{31a})_2]PF_6$ at 19 and 298 K is consistent with an energy level ordering $xy > z^2 > xz > yz > x^2–z^2$,[169] in agreement with the crystal structure which showed the four P atoms of the didentate ligands occupying the equatorial plane and two chloride atoms occupying *trans*-axial positions.[170] UV–visible spectra of these $^2A_{2g}$ ground state Ni^{III} complexes are very characteristic, consisting of a weak feature at ca. $(12–14) \times 10^3\,cm^{-1}$, further *d–d* bands ca. $20{,}000\,cm^{-1}$, and charge transfer transitions ca. $25{,}000\,cm^{-1}$.

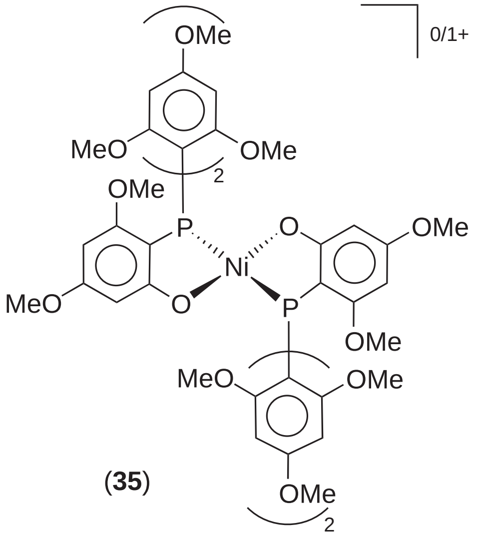
The electrochemistry of $[NiX\{P(CH_2CH_2PPh_2)_3\}]^+$ (X = Cl, Br, I) shows reversible oxidation to the corresponding Ni^{III} species and irreversible oxidation to the corresponding Ni^{IV} species.[171] In general, the chemistry of Ni^{IV} with P- and As-donor ligands is less extensive than that of Ni^{III}. Most Ni^{IV} complexes are of the $[NiCl_2(L–L)_2]^{2+}$ type. Since these $t_{2g}{}^6$ species are EPR silent, convincing evidence for the Ni^{IV} formulation usually comes from the UV–visible spectra which are very similar to those of the corresponding Co^{III} compounds. Pseudo-octahedral Ni^{IV} complexes of the type $[NiX_2(\mathbf{31})_2][ClO_4]_2$ (X = Cl or Br) have been prepared and characterized, and electrochemistry as a function of L has been studied.[172] A combination of EXAFS and electronic spectroscopy have been used to determine the structure of such tetragonally distorted, pseudo-octahedral Ni^{IV} complexes, e.g., $[NiCl_2(\mathbf{31a})_2]^{2+}$ (d(Ni—Cl) = 2.26 Å, d(Ni—P) = 2.22 Å), and $[NiCl_2(\mathbf{31b})_2]^{2+}$ (d(Ni—Cl) = 2.27 Å, d(Ni—As) = 2.36 Å).[172,173]

Five-coordinate Ni^{II} arsine complexes of the ligands (**31**)–(**33**) of formulas $[Ni(L^3)(L^2)]^{2+}$ (L^3 = tridentate (**33**), L^2 = bidentate (**31d**), (**32**)) and $[Ni(L^3)_2]^{2+}$ (the latter are also five-coordinate with a single "dangling" $AsMe_2$ group) have been studied electrochemically.[174] All complexes showed two oxidations and two reductions in CV experiments in CH_3CN. The second oxidation process was only reversible (at $100\,mV\,s^{-1}$) for $[Ni(L^3)_2]^{2+}$, and scan rates in excess of $500\,mV\,s^{-1}$ or temperatures ($\leq 0\,°C$ were necessary to obtain reversible behavior for this process with $[Ni(L^3)(L^2)]^{2+}$. The second process is irreversible in CH_2Cl_2 for $[Ni(L^3)(L^2)]^{2+}$, presumably because of the need to coordinate a sixth donor atom to stabilize the formally low-spin d^6 Ni^{IV}. Overall, the arsine donor sets stabilize (on the voltammetric timescale) all Ni oxidations states from 0 to +4 (compare Sections 6.3.6.3 and 6.3.6.5.4).

When $[Ni(CH_3CN)_6](BF_4)_2$ is treated with four equivalents of (**34**), the orange diamagnetic complex $[\mathbf{35}]^0$ forms.[175] This has a remarkably mild Ni^{II}/Ni^{III} couple at −0.07 V, and the Ni^{III} complex is readily prepared by ferrocenium oxidation in acetone. The crystal structure of the Ni^{II} complex shows square planar $\{NiP_2O_2\}$ coordination with two additional methoxy-O residing above and below the plane, but the Ni—OMe distances preclude any bonding interaction. However, the Ni^{III} complex has distorted octahedral geometry with these methoxy-O coordinated (mean d(Ni—P) 2.223(3) Å; mean $d(Ni—O^-)$ 1.918(5) Å; mean d(Ni—OMe) 2.192(1) Å).



(34)



(35)

6.3.3.5 Complexes with O-donor Ligands

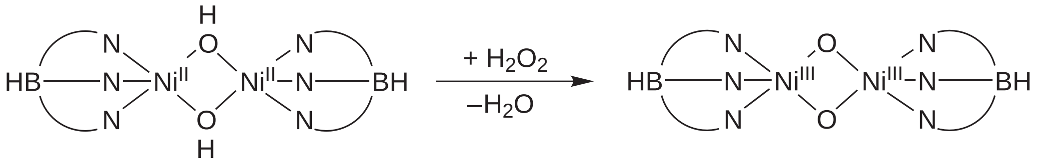
The low-spin $\{Ni^{III}O_6\}$ compound $[Ni(bipyO_2)_3]^{3+}$ ($bipyO_2$ = 2,2′-bipyridyl-1,1′-dioxide) is the product of constant-potential electrolysis of the Ni^{II} salt.[176] Its violet solutions show a rhombic EPR spectrum indicative of a Jahn–Teller-distorted $(d_{z^2})^1$ ground state.

$S_2O_8^{\,2-}$ has been used to oxidize Ni^{2+}(aq) in the presence of molybdate ion. The Ni^{IV} product obtained was crystallized as $(NH_4)_6[NiMo_9O_{32}]\cdot 6H_2O$ and its crystal structure (determined independently by two groups) revealed a severely distorted octahedral $\{O_6\}$ environment for the Ni atom, with an average Ni—O bond length of 1.876(5) Å or 1.872(2) Å.[177,178]

An EXAFS study of β-NiO(OH) indicates that the Ni^{III} sites experience Jahn–Teller distortion, with four Ni—O bonds at 1.87 Å and two at 2.03 Å; in the η-phase containing Ni^{III} and Ni^{IV} this is absent.[179]

Reaction of $NiCl_2\cdot 6H_2O$ with Bu^tCO_2H and KOH is reported to form a nonanickel cluster $[Ni_9(Bu^tCO_2H)_4(\mu_4\text{-}O)_3(\mu_3\text{-}OH)_3(Bu^tCO_2)_{12}]$, which contains both Ni^{II} and Ni^{III}.[180]

High-valent nickel complexes with oxo-bridges, in particular the $Ni^{III}_2(\mu\text{-}O)_2$ core, are of interest in the context of O_2 activation and subsequent C—H oxidation. A first example of a bis(μ-oxo) core in Ni^{III} chemistry was found for (**36**) incorporating tris(pyrazolylborato) ancillary ligands. When the bis(μ-hydroxo)nickel(II) complex (**37**) was reacted with H_2O_2 at low temperatures, the bis(μ-oxo)nickel(III) complex (**36**) could be isolated and structurally characterized (Equation (2)).[181,182] (**36**) contains five-coordinate Ni ions with a slightly distorted square pyramidal geometry. It decomposes within 1 h at room temperature via oxidation of the tris(pyrazolylborato) ligand, with H-atom abstraction being the rate-determining step (compare also Section 6.3.4.4.6).

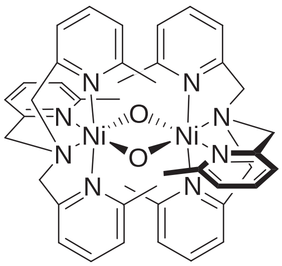


(37) **(36)**

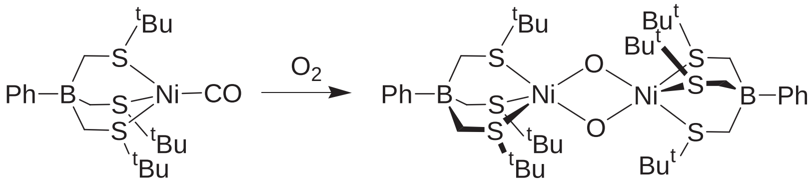
(2)

In a similar fashion, the bis(μ-oxo)nickel(III) complex (**38**) with six-coordinate metal ions was prepared at −90 °C from the respective bis(μ-hydroxo)nickel(II) species.[183] Reaction with excess H_2O_2 afforded a unique bis(μ-superoxo)nickel(II) species. Average Ni—O and Ni—N bond lengths are significantly shorter for the Ni^{III} complex (1.871 Å and 2.143 Å, respectively) compared to the Ni^{II} starting material (2.081 Å and 2.185 Å, respectively). (**38**) decomposes at −20 °C via partial hydroxylation of the ligand methyl groups.

Oxygenation of the Ni^{I} complex (**39**) leads to O_2 activation and O-O bond rupture with formation of a deep purple bis(μ-oxo)nickel(III) complex (**40**) supported by thioether ligands.[184] Its electronic structure has been investigated by spectroscopic and DFT methods.[185]

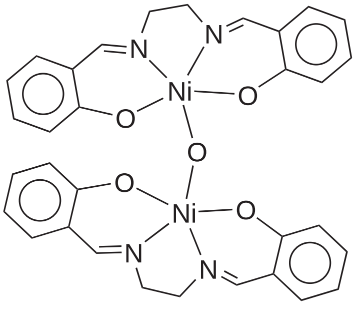


(38)



(39) **(40)**

A thermally stable singly oxo-bridged dinickel(III) complex [$\{Ni^{III}(salen)\}_2O$] (**41**)) incorporating two high-spin d^7 ions has been prepared from the respective [Ni^{II}(salen)] precursor and O_2.[186] The Ni—O—Ni linkage is not linear (angle 146.3(2)°) and the Ni^{III}—O distances are short (1.870(8) and 1.841(7) Å), while the Ni—O_{salen} and Ni—N_{salen} distances are substantially longer than for related Ni^{II} species. (**41**) shows a reversible redox process at $E_{1/2}$ +1.05 V vs. SCE.

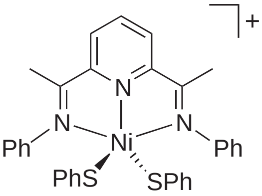


(41)

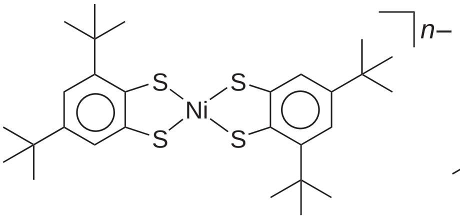
6.3.3.6 Complexes with Ligands Containing S- and Se- donors

Interest in high-valent nickel complexes with sulfur and selenium ligands is fired by the discovery of nickel–sulfur centers in numerous hydrogenase enzymes. These have remarkably low redox potentials (ca. −0.39 V to −0.64 V vs. SCE with a dependence of −60 mV/pH unit) for the formal couple Ni^{II}/Ni^{III}. Thiolate donors are known to stabilize the high-valent Ni^{III} state, and thus there has been much interest in the synthesis of biomimetic complexes with alkyl- and arylthiolate ligands. Since many studies of Ni^{II} complexes with ligands containing S-donors report redox properties and evidence for the oxidized species, the reader should also refer to the chapter dealing with Ni^{II} thiolate complexes if looking for particular ligand systems. Only selected examples are mentioned here, where the high-valent species have been investigated in detail. Ni^{III} complexes with mixed $\{N_xS_y\}$ ligands are described in Section 6.3.3.9.2.

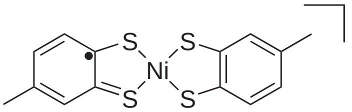
Optimum conditions for the preparation of the Ni^{III} complexes of 1,2-dithiolate have been reported.[187] In many cases, suitable *monomeric* $\{Ni^{III}S_x\}$ complexes are unstable with respect to oligomerization and autoredox decomposition (formation of disulfide) reactions. Bulky ligands, or a large excess of ligand, may be used to avoid oligomerization. In general, "Ni^{III}" complexes with arylthiolato ligands are more easily accessible due to the lower redox potential of aliphatic thiolates. Typical examples are (**42**), (**44**)[188] (as well as the parent bis(benzenedithiolate)nickel(III))[189] and [Ni(3,5-Bu$^t_2$bdt)$_2$]$^{0,1-,2-}$ (**43**).[190] In any case it has to be rigorously proven that Ni^{II} → Ni^{III} oxidation is indeed metal centered and not ligand based. (**42**) is readily prepared by oxidation of the respective Ni^{II} complex with $[Fe(CN)_6]^{3-}$ and is much more stable than the analogous terpy compound.[191] The single unpaired electron resides in the d_{z^2} orbital, and CN$^-$ can be bound to give a six-coordinate adduct.



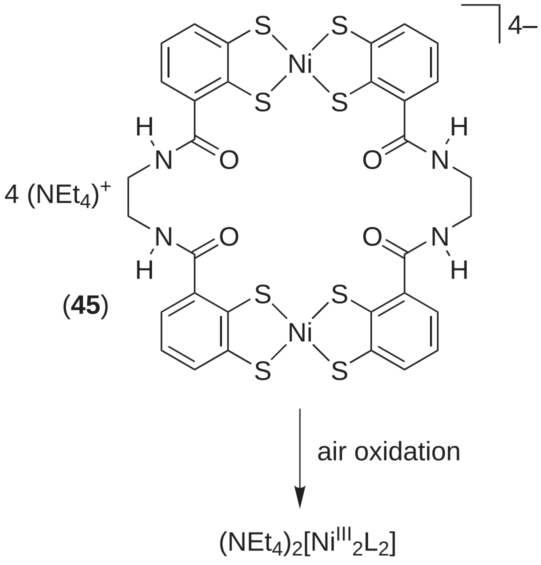
(**42**)



(**43**)
$n = 0, 1, 2$



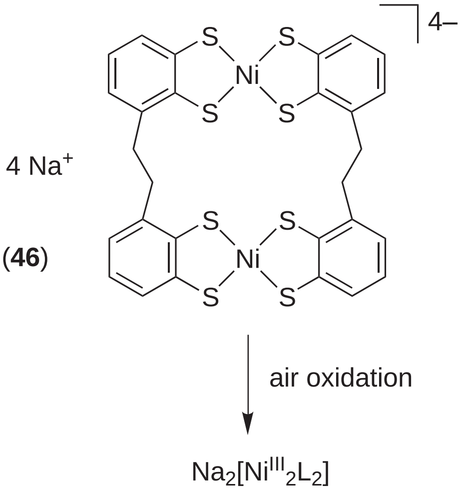
(**44**)



(**45**)

$(NEt_4)_2[Ni^{III}_2L_2]$

(**47**)



(**46**)

$Na_2[Ni^{III}_2L_2]$

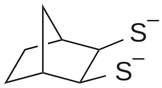
(**48**)

(**43**) is one of the few cases where three formal oxidation states could be crystallographically characterized.[190] According to cyclic voltammetry, the redox potentials for [Ni(3,5−Bu$^t_2$bdt)$_2$]$^{0,1-,2-}$ are −0.61 V and +0.355 V (in THF, vs. NHE). The Ni—S distances decrease only slightly, but significantly, upon going from Ni^{II} (2.175(1)/2.171(2) Å) to "Ni^{III}" (2.135(2)–2.145(2) Å) and "Ni^{IV}" (2.124(1)/2.127(1) Å), and based on various spectroscopic evidence it has been suggested that oxidation concerns electrons which reside in orbitals having $\{NiS_4\}$ character with significant Ni contribution. More recent findings, however, indicate that these systems should be regarded as Ni^{II} complexes with a singlet diradical character due to strong antiferromagnetic coupling of the two benzosemiquinone π-radicals,[192] in accordance with earlier results for (**44**).[188]

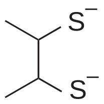
Dinuclear Ni^{II} complexes with bis(benzenedithiolate) ligands (**45**) and (**46**) are electrochemically oxidized to the respective dinickel(III) species (**47**) and (**48**) at −0.785 mV and −1.130 mV (vs. Cp_2Fe/Cp_2Fe^+), respectively, or chemically by air.[193] (**47**) has been structurally characterized and reveals slightly shortened average Ni—S bonds (2.152 Å vs. 2.166 Å in (**45**)).

The square planar complexes [Ni(**49a**)$_2$]$^{2-}$ and [Ni(**49b**)$_2$]$^{2-}$ show reversible waves at very low potentials of around −0.76 V (vs. SCE) in their cyclic voltammogram, assigned to the Ni^{II}/Ni^{III} couple.[194,195] The red-brown Ni^{III} species [Ni(**49a**)$_2$]$^-$ can be generated simply by exposing solutions of the Ni^{II} complex to air. Its EPR characteristics ($g_{\parallel} = 2.14 > g_{\perp} = 2.05$) suggest a less common $(d_{xy})^1$ ground state. No evidence has been found for axial ligation to Ni^{III} on dissolution in acetonitrile, pyridine or DMF. Presumably, the two bridging methylene groups, which hinder the axial sites, prevent this, and they are also responsible for the unusual stability of the complex. While cyclic voltammetry of [Ni(**49c**)$_2$]$^{2-}$ shows a reversible Ni^{II}/Ni^{III} wave at around the same potential as for [Ni(**49a**)$_2$]$^{2-}$, the cyclohexyldithiolate complex decomposes on exposure to air.[196] Similarly, the [NiL$_2$] complexes with ethane-1,2-dithiolate (edt) and ligand (**49b**) are less robust, but the $E_{1/2}$ value of [Ni(edt)$_2$]$^{2-}$ with 0.75 V, and the EPR parameters of [Ni(**49b**)$_2$]$^-$ ($g_{\parallel} = 2.187 > g_{\perp} = 2.042$) are in close agreement with those of complex [Ni(**49a**)$_2$]$^-$.[197]

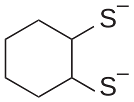
Square planar Ni^{II} complexes (**50a**) and (**50b**) of the quinoxaline-2,3-dithiolate ligand are oxidizable in chemically reversible, electrochemically quasi-reversible processes to yield Ni^{III} species, also featuring the $(d_{xy})^1$ configuration.[198] Interestingly, the difference in protonation state makes for a 0.20 V difference in oxidation potential ((**50a**): +0.12 V; (**50b**): +0.32 V vs. SCE), consistent with the less basic S-donors in the thione form.



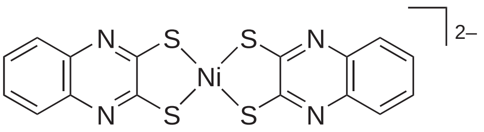
(49a)



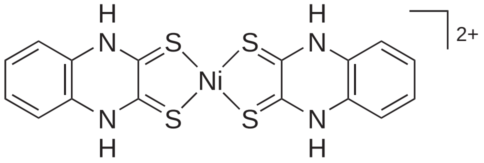
(49b)



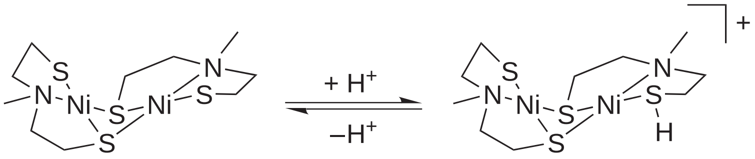
(49c)



(50a)



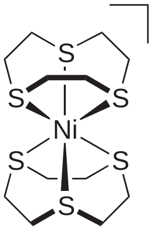
(50b)



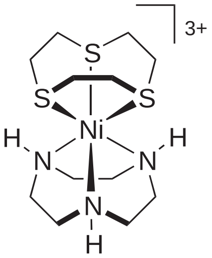
(51) **(52)**

In combination with their inherent redox activity, Ni-bound thiolates may also become protonated, which is of relevance to the reactivity of the Ni/Fe hydrogenase active site. For example, the dinuclear Ni^{II} thiolate complex (**51**)[199] is reversibly protonated at a single terminal thiolate-S upon addition of $[H(OEt_2)_2]\{B[3,5\text{-}(CF_3)C_6H_3]_4\}$ to give (**52**).[200] While (**51**) shows an irreversible one-electron oxidation at +390 mV (vs. NHE in CH_2Cl_2), oxidation of (**52**) is shifted anodically to +960 mV and a cathodic process is observed at −550 mV.

[Ni([9]aneS$_3$)$_2$]$^{2+}$ shows a reversible oxidation at +0.97 V (vs. Cp_2Fe/Cp_2Fe^+). Spectroelectrochemistry and EPR spectroscopy of ^{61}Ni-enriched samples confirms that the oxidation is metal centered.[201] Chemical oxidation to give deep orange [Ni([9]aneS$_3$)$_2$]$^{3+}$ (**53**) is achieved by dissolving [Ni([9]aneS$_3$)$_2$]$^{2+}$ in 70% $HClO_4$ or 98% H_2SO_4, and the product was isolated as [Ni([9]aneS$_3$)$_2$][H_5O_2]$_3$[ClO_4]$_6$. The single-crystal X-ray structure of this complex confirms octahedral homoleptic thioether coordination, where the Ni—S bond lengths (2.3129(25) Å) for the Ni^{III} complex cation are considerably shorter than those for the corresponding Ni^{II} complex cation, thereby confirming its formulation as a mononuclear Ni^{III} thioether complex cation.[201] The mixed complex [Ni([9]aneN$_3$)([9]aneS$_3$)]$^{2+}$ is electrochemically oxidized at 0.86 V (vs. Cp_2Fe/Cp_2Fe^+), or chemically oxidized by $NOPF_6$. The Ni^{III} species (**54**) shows an axial EPR spectrum with $g_{\perp} = 2.106$ and $g_{\parallel} = 2.063$.[202]



(53)



(54)

Some mixed valence polynuclear thiolate complexes such as $[Ni_4(SC_3H_7)_8Br]$ and $[Ni_4(SC_3H_7)_8I]$ have been prepared and characterized by single-crystal X-ray methods.[203]

The work on nickel complexes with dithiolene-type ligands such as dmit, mnt, dddt, etc., is extensive, usually focusing on magnetic or (super)conducting properties. In salts containing anions such as $[Ni(dmit)_2]^-$ or $[Ni(mnt)_2]^-$, the metal is usually formulated as Ni^{III}. The reader is referred to previous publications for some selected Ni^{III} complexes[204–209] An example of a structurally characterized neutral complex (formally Ni^{IV}) is (**55**), which shows a noticeably nonplanar $\{NiS_4\}$ central moiety, possibly due to an unusual conformation of the seven-membered rings.[210] Generally, the influence of the charge state of the complexes on the Ni—S bond lengths is quite small, i.e., 2.12–2.13 Å for neutral complexes vs. 2.13–2.15 Å for monovalent anions. The question whether the unpaired electron resides mainly on the metal or on the ligand had been investigated in great detail. Since the monoanions possess a single electron in their HOMO, interanion interactions are possible and a wide range of structures and properties in the solid state are found.[211] Here, this field will not be covered comprehensively. Some recent work can be found elsewhere.[212–221] As many studies deal with Ni–dithiolene complexes in different oxidation states, the reader should refer to the respective Ni^{II} section (Section 6.3.4.7.10), where more detailed information is given, also on complexes formally involving Ni^{III} and Ni^{IV}.

New work on high-valent Ni–dithiocarbamates involves the Ni^{III} species (**56**),[222–228] (**57**),[226–230] and (**58**)[230] as well as the Ni^{IV} species (**59**).[225] The structure of the type (**59**) Ni^{IV} compound $[Ni(S_2CNEt_2)_3][C_3(CN)_5]$ has been reported.[231] The Ni atom of the cation has a distorted octahedral geometry with $d(\text{Ni—S}) = 2.246(2)\text{–}2.257(2)$ Å. The type (**59**) complex $[Ni^{IV}(\mathbf{60})_3]^+$ can be oxidized three times at the outer ferrocenyl units, where the second and third one-electron couple occur at the same potential.[232] EPR spectra of high-valent Ni-dithiocarbamate complexes have been interpreted in detail,[233] and the photochemistry of Ni^{IV} dithiocarbamate complexes has been reviewed.[234] Soft X-ray-induced photoreduction of the Ni^{IV} complex $[Ni(S_2CNEt_2)_3](BF_4)$ results in square planar Ni^{II} species.[235]

Xanthate complexes $[Ni^{II}(S_2COR)_3]^-$ can be oxidized electrochemically at rather mild potentials (−0.10 V to −0.16 V vs. SCE) in acetonitrile to yield the trivalent species (**61**). However, these are unstable and disproportionate readily according to: $2\,[Ni^{III}(S_2COR)_3] \rightarrow 2\,[Ni^{II}(S_2COR)_2] + ROCS{\cdot}SS{\cdot}CSOR$.[236,237] The reaction, examined kinetically (k(first order) $= 1.0 \times 10^{-3}\,s^{-1}$ at 253 K), prevents the isolation of pure samples. It is suggested that Ni^{III} systems (**61**) can formally be described as resonance hybrids of Ni^{III}/S^- and Ni^{II}/S. Oxidation of (**62**) gives solvated Ni^{II} and $ROCS{\cdot}SS{\cdot}CSOR$.[237] The octahedral anion $[Ni(thioxanthate)_3]^-$ is oxidized electrochemically to the Ni^{III} species; it does, however, decompose at room temperature to the dimer $[Ni_2(SEt)_2(CS_3)_2]^{2-}$ which has thiolato bridges and one CS_3 group chelated to each nickel.[238]

The reaction of $[Ni(S_2COEt)_2]$ with Li_2Se and Se or with Li_2Te and Te gives complexes $[Ni_4Se_4(Se_3)_5(Se_4)]^{4-}$ and $[Ni_4Te_4(Te_2)_2(Te_3)_4]^{4-}$, respectively, in a spontaneous assembly reaction. Structures were verified by single-crystal X-ray crystallography, and $[Ni_4Se_4(Se_3)_5(Se_4)]^{4-}$ was found to possess a Ni_4Se_4 cubane core, while $[Ni_4Te_4(Te_2)_2(Te_3)_4]^{4-}$ has a Ni_4Te_4 cubane core. Ni—Se bond lengths vary from 2.338(7) Å to 2.442(8) Å, while Ni—Te bond lengths vary from 2.492(2) Å to 2.667(2) Å.[239,240] Each Ni atom is located in a distorted octahedral environment, and is coordinated by three chalcogenide atoms in the cubane framework and by three chalcogenide atoms in the rings that bridge to the other three Ni atoms. Both compounds are diamagnetic and have been formulated as Ni^{IV} species, mainly based on charge balance considerations.

6.3.3.7 Halide Complexes

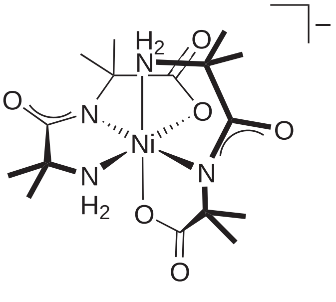
High valent nickel fluorides have attracted attention because of their possible involvement in the electrochemical fluorination of organic compounds (Simon's process), which is particularly efficient if nickel is used as the anode. $[XeF_5]_2[NiF_6]$ (prepared from NiF_2, KrF_2, anhydrous HF, and XeF_6) has been structurally characterized and contains octahedrally coordinated Ni^{IV} (d(Ni—F) = 1.77 Å); it is decomposed in a laser beam at 77 K to XeF_4, F_2, and NiF_x ($x = 2$–3).[241] Also, O_2^+ salts dissolve in anhydrous HF affording O_2F, which oxidizes NiF_2 to $[NiF_6]^{2-}$ salts.[242] The thermodynamically unstable fluorides NiF_4 and NiF_3 have been obtained by the addition of F^- acceptors such as BF_3 and XF_5 (X = As, Sb, Bi) to solutions of $[NiF_6]^{2-}$ in anhydrous HF at low temperature.[243–245] At −65 °C, the tan solid NiF_4 is precipitated; this is converted back to $[NiF_6]^{2-}$ quantitatively on treatment with F^- donors (XeF_6 or KF). Dry NiF_4 decomposes above −60 °C to black NiF_3 with loss of F_2. When $K_2[NiF_6]$ is the precursor, a pyrochlore form that contains small amounts of potassium, $K_{0.1}NiF_3$, is obtained. When K^+ is present at 20 °C, a hexagonal tungsten bronze-type phase (H-NiF_3) is precipitated. Suspensions of NiF_4 in anhydrous HF decompose to a rhombohedral form of genuine NiF_3 (called R-NiF_3). The latter was shown by XAS at the nickel K-edge and UV–visible studies to have a mixed-valent composition $Ni[NiF_6]$.[246] The three forms of NiF_3 differ in thermal stability, the pyrochlore form being the most stable (it loses F_2 at 138 °C). R-NiF_3 thermally decomposes at 353–373 K to give Ni_2F_5.[247] NiF_4 is an extremely powerful oxidant; it converts $[MF_6]^-$ to MF_6 (M = Pt, Ph), while NiF_3 fluorinates perfluoropropene and oxidizes Xe to XeF_6. Solutions of $[NiF_6]^{2-}$ in anhydrous HF, when treated with three equivalents of BF_3, give yellow solutions with extreme oxidizing power; these probably contain solvated Ni^{III}.[248] NiF_4 and R-NiF_3 have been employed for the fluorination of organic compounds.[249]

6.3.3.8 Complexes with Bioligands

6.3.3.8.1 Complexes with peptides, amino acids, and related ligands

Ni^{III} peptide complexes have been studied and characterized using chemical and electrochemical oxidation, redox stoichiometry, substitution reactions, UV–visible spectral shifts and EPR.[250] The complexes were found to be six-coordinate with tetragonal distortion. The Ni^{III}/Ni^{II} electron transfer reactions are usually rapid (with good Marcus correlation)[251] and it was generally found that Ni^{III} peptides will add a second peptide or other chelating agents to form stable bis-peptide or ternary complexes. The reduction potentials of bis(dipeptido)nickelate(III) complexes are significantly lower than for mono(tripeptido)nickel(III) complexes, with E° values of 0.66 V for $[Ni^{III}(H_{-1}G_2)_2]^{2-}$ and 0.34 V for $[Ni^{III}(H_{-1}Aib_2)_2]^-$ (HAib = α-aminoisobutyric acid). C-methyl substitution has little effect on the potentials of the mono(tripeptido) complexes, but a large effect on the potentials of the bis(dipeptido) complexes.

Oxidation of blue bis(dipeptide)nickel(II) complexes yields violet-black solutions of Ni^{III} species, in most cases characterized *in situ* by means of EPR spectroscopy. These low-spin compounds rearrange in acid and then decompose to Ni^{II} species.[252] The low-spin Ni^{II} complex with the dipeptide of α-aminoisobutyric acid, $[Ni^{II}(H_{-1}Aib_2)_2]^{2-}$, can be oxidized to produce a dark olive green tetragonally compressed Ni^{III} complex, $[Ni^{III}(H_{-1}Aib_2)_2]^-$ (**63**) that was found to be very stable in neutral and basic solutions.[253] Acid catalyzes the decomposition to give Ni^{II}, Aib_2, and oxidized peptide fragments. A novel method, based on the influence of ^{61}Ni on the room temperature EPR spectra of Ni^{III} complexes, was applied to this nickel/α-aminoisobutyric acid system to measure the electron transfer self-exchange rate constants.[254] The exchange rate decreases when pyridine replaces one of the axial H_2O.



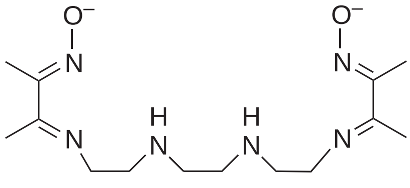
(**63**)

The kinetics and mechanism of the oxidation of $[Co(edta)]^{2-}$ by four bis(dipeptide)nickel(III) complexes, $[Ni(H_{-1}GG)_2]^-$, $[Ni(H_{-1}GA)_2]^-$, $[Ni(H_{-1}AG)_2]^-$, and $[Ni(H_{-1}AA)_2]^-$ (GH = glycine, AH = (*S*)-alanine), have been investigated at 25.0 °C and in 0.10 M perchlorate media.[255] The reactions are first order in each reagent and have a complex dependence on pH. The dominant pathway over the pH range 4–10 involves the acid-catalyzed formation of a precursor complex through which electron transfer takes place. There is indirect evidence for a strong hydrogen-bonding interaction between the N-terminal amine hydrogen atoms of a coordinated dipeptide ligand and the carboxylate oxygen atoms of the probe complex. The bis(dipeptide) ligands are arranged meridionally around the Ni^{III} to produce a chiral center, and the complexes with optically active dipeptides exist as diastereomers which are readily separated by chromatography.[255]

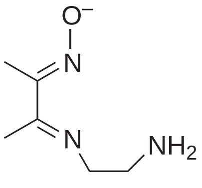
Bis(tripeptido)nickelate(III) complexes of Gly_3, GlyAlaGly, and GlyGlyAla, formed by the addition of excess tripeptide to solutions of (tripeptido)nickel(III), have been observed in solution and characterized by means of electronic spectra, EPR, reduction potentials, and rate measurements. Coordination was found to be a function of pH, with $\{N_5O\}$ coordination occurring at pH 6–11.[256] Ni^{III} peptide complexes undergo a variety of substitution and rearrangement reactions in acidic solution. The terminal $N_{peptide}$ bonds to Ni in $[Ni(H_{-3}Gly_4)(H_2O)_2]^-$ and $[Ni(H_{-3}Gly_4a)(H_2O)_2]^-$ (Gly_4a = tetraglycinamide) break rapidly in acid with first-order rate constants of 0.1–15 s^{-1} as the hydrogen ion concentration increases (0.004–1.0 M). However, the other three equatorial Ni^{III}—N bonds are relatively inert to substitution. EPR spectra at room temperature and in frozen aqueous glasses have allowed to characterize several protonated species for these complexes and for Ni^{III} tripeptide complexes.[257] These peptide complexes also undergo substitution reactions with a series of polypyridine and polyamine ligands such as 1,2,-diaminoethane, 1,10-phenanthroline, etc. to yield stable ternary complexes.[258] In diluted acid, phen chelates to an axial and an equatorial site while terpy coordinates to two axial sites and one equatorial site of the Ni^{III} ion.

6.3.3.8.2 Complexes with oximes and related ligands

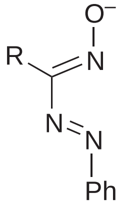
Oximes have long been known to stabilize both Ni^{III} and Ni^{IV} in their complexes. There has been a great deal of work on the electron transfer kinetics and the reactions of high-valent Ni-oxime complexes, in particular with tris(dimethylglyoximato)nickelate(IV) or complexes of ligand (**64**) as oxidizing agent. This work is not described in detail here, but the reader should refer to a recent review.[64] *Inter alia*, kinetics of disproportionation of the Ni^{III} complexes of (**64**) have been recorded over a pH range and the disproportionation path has been established.[259] Likewise, The reaction of Ni^{IV} complexes $[Ni(\mathbf{65})_2]^{2+}$ and $[Ni(\mathbf{64})]^{2+}$ with sulfite have been investigated in aqueous solution as a function of pH.[260] Below pH ca. 5, the process is a single step two-electron transfer, but above this pH, the initial one-electron transfer is distinctly faster. The stoichiometry varied depending on whether oxidant or reductant was present in excess; both dithionate and sulfate were formed. The mechanism is inner-sphere, although probably with initial formation of a H-bonded adduct. In the reactions of $[Co(edta)]^{2-}$ with chiral Ni^{IV} oxime complexes, significant enantiomeric excess has been observed, indicative of ion-pairing before outer-sphere electron transfer.[261] The Ni^{II}/Ni^{III} redox potential in the $[Ni(\mathbf{66})_3]^-$ complex is very low, ~0.1 V vs. SCE in acetonitrile. Azooxime stabilizes effectively a higher oxidation state of Ni, and $[Ni(\mathbf{66})_3]$ with trivalent Ni can be easily obtained.[262]



(64)

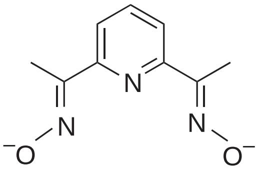


(65)



(66)

(67)



(68)

While quinones are not effective for stabilizing high oxidation states of Ni, their monooximes have been found to act as good N,O-bidentate ligands towards Ni^{III}. $[Ni^{II}(\mathbf{67})_3]^-$ occur as equilibrium mixtures of *fac* and *mer* isomers in MeCN solution and display the reversible Ni^{II}/Ni^{III} couples *fac*-$[Ni(\mathbf{67})_3]^-$/*fac*-$[Ni(\mathbf{67})_3]$, and *mer*-$[Ni(\mathbf{67})_3]^-$/*mer*-$[Ni(\mathbf{67})_3]$.[263] The former couple has a higher (by approximately 0.12 V) formal potential. These potentials are also sensitive to the substituent R, and the range 0.3–0.7 V vs. SCE is covered by the complexes studied. *fac*-$[Ni(\mathbf{67})_3]$ is spontaneously transformed into the *mer* form in solution. For R = Me, the rate constant is estimated to be 0.02 s^{-1} at 258 K. The dark-colored $[Ni(\mathbf{67})_3]$ chelates behave as one-electron paramagnets and in frozen solution they display rhombic EPR spectra ($g = 2.04$, 2.14, 2.19). Upon reduction, *mer*-[Ni(**67**)$_3$] is reconverted into the equilibrium mixture of *fac*- and *mer*-[Ni(**67**)$_3$]$^-$.[263]

The Ni^{IV} complex with 2,6-diacetylpyridine dioxime, [Ni(**68**)$_2$], is one of the prototype Ni^{IV}–oxime systems and has been studied extensively. The corresponding Ni^{III} complex is much less accessible and cannot be isolated (its Ni^{III} formulation is established by a broad, nearly isotropic EPR signal with an average *g*-value of 2.086).[264] However, two-electron reduction of [Ni(**68**)$_2$] by, *inter alia*, Fe^{II}, Sn^{II}, I$^-$, or U^{IV} to give the Ni^{II} species entails pairs of one-electron steps.[265] [Ni(**68**)$_2$]$^{2-}$ has a very low Ni^{II}/Ni^{III} redox potential of -0.735 V in DMF (vs. SCE).

6.3.3.8.3 Complexes with porphyrins and related ligands

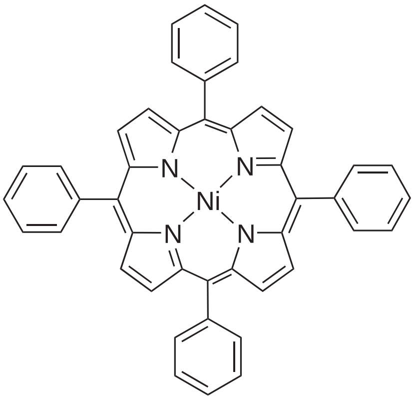
The catalytic cycle of F$_{430}$ is postulated to involve reduction of the Ni^{II} resting state to Ni^{I} followed by formation of a methyl–Ni^{III} transient from which methane is formed (compare Section 6.3.4.11.7). The latter Ni^{III} species prompts the current interest in high-valent Ni–porphyrin compounds.[266–268] The question whether the tetrapyrrole ligand of F$_{430}$, which is unusual in its ability to stabilize Ni^{I}, can also give rise to high-valent Ni^{III}, has been tackled in many ways, including theoretical and model studies. DFT calculations suggest that Ni^{III} is indeed accessible, the special architecture of F$_{430}$ allowing occupation of the $d_{x^2-y^2}$ orbital.[269] The electronic spin density profiles of this $(d_{x^2-y^2})^1$ Ni^{III} species can be deceptive and closely mimic Ni^{I} species.

Redox properties of Ni porphyrins have been extensively studied and detailed reviews of the oxidative chemistry of nickel porphyrins,[268] of their electrochemistry in nonaqueous media,[270] and of the electronic structure description of high-valent metalloporphyrins based on quantum chemical calculations[271] have appeared. Ni porphyrins can be oxidized in up to three one-electron transfer steps,[272] depending upon the solvent, although the third oxidation is not always observed. The existing body of information for oxidized Ni porphyrins and hydroporphyrins suggests the existence of Ni^{III} cations, Ni^{II} porphyrin π cation radicals, and dications comprised of Ni^{III} porphyrin π dications. In most cases, the initial oxidations and reductions involve the porphyrin π-system, but examples where the first electron is removed from the central metal ion to give a Ni^{III} species[273–275] are well documented in the literature. However, there still exist no structures of authentic Ni^{III} porphyrins.

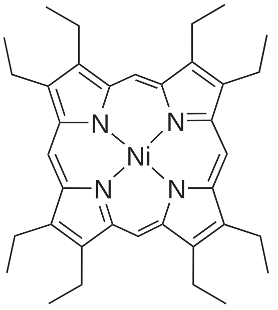
As a general pattern, the site of oxidation, i.e., Ni^{III} vs. Ni^{II} π cation radical, is controlled by the relative ordering of the Ni *d*-orbitals and the highest occupied porphyrin orbital (HOMO). Axial ligation of the Ni^{II} itself makes it easier to oxidize the metal.[274,275,280] Ni^{III} porphyrin complexes are paramagnetic and normally low spin with one unpaired electron; there appear to be no examples of Ni^{III} porphyrines with a high spin, $S = 3/2$, ground state. Particularly relevant to Ni^{III} porphyrins, which are typically hexacoordinated, are the tetragonally distorted energy schemes: for the compressed case, the unpaired electron resides in the $d_{x^2-y^2}$ orbital with an EPR signal in which $g_\perp < g_\parallel$. In the tetragonally elongated configuration, the unpaired electron is found in the d_{z^2} orbital with $g_\perp > g_\parallel$. In porphyrins, the ground state configuration is further confirmed by the EPR hyperfine interactions with the four pyrrole nitrogens in the case of the half-occupied $d_{x^2-y^2}$ orbital or with the axial ligands if the d_{z^2} orbital is half occupied. As in the case of the high spin Ni^{II} macrocycles, population of the $d_{x^2-y^2}$ orbital in Ni^{III} porphyrins will require an expansion of the Ni—N distances relative to low spin Ni^{II}. Hence, the conformational flexibility of the porphyrin necessary to accommodate this core expansion can control whether the $d_{x^2-y^2}$ orbital or d_{z^2} orbitals are occupied in Ni^{III} complexes.[268]

Oxidation of [Ni^{II}(TPP)] can give a Ni^{III} cation or a Ni^{II} π cation radical, depending on the anion and the solvent. ClO$_4^-$ or PF$_6^-$ anions can coordinate and thus stabilize the Ni^{III} form at low temperatures, while Ni^{III} was not formed when Br$^-$ or water were added. Oxidation in the presence of ligands L such as thf, pyridine, or acetonitrile all yielded Ni^{III} species at low temperatures of the form [Ni^{III}(TPP)L$_2$]$^+$ with the unpaired electron in the d_{z^2} orbital.[273] These are stable under inert atmospheres for extended periods. [Ni^{II}(OEP)] only yields the π cation radical under the same experimental conditions that affords [Ni^{III}(TPP)]$^+$.[276] A resonance Raman study clearly distinguished between the two types of oxidation products and further supported the Ni^{II} π cation radical and Ni^{III} cation assignments.[277] When the effects of solvent, counterion and peripheral substituents on the sites of oxidation by pulse radiolysis at RT were studied on a microsecond timescale, it was found that [Ni(TTP)] was oxidized to [Ni^{III}(TPP)]$^+$ in several protic and aprotic solvents whereas addition of 10% water to CH$_2$Cl$_2$ yielded the π cation radical.[278]

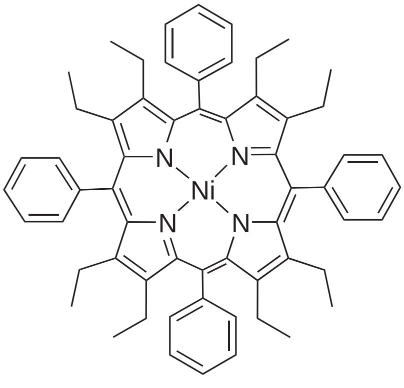
Apparently, the different sites of oxidation are controlled by a combination of solvent and charge interactions. It has been speculated that the broad, room temperature EPR signal of $[Ni(TPP)]^+$ results from mixing of the metal *d* and porphyrin π cation radical orbitals.[273] Since OEPs are easier to oxidize than TPPs, it is perhaps not surprising that [Ni(OEP)] is simply oxidized to a π cation radical at all temperatures in the presence of weak ligands such as ClO_4^- or PF_6^-, whereas $[Ni^{II}(TPP\cdot)]^+$ undergoes the electronic isomerization to $[Ni^{III}(TPP)]^+$ at low temperatures which also favor ligation of the Ni. Both $[Ni^{II}(TPP\cdot)]^+$ and $[Ni^{II}(OEP\cdot)]^+$ form Ni^{III} species in the presence of stronger ligands such as ethers, imidazoles, pyridines, alcohols, nitriles, and cyanides which lower the oxidation potentials of the Ni. Addition of CO or PPh_3 to solutions of $[Ni^{II}(TPP\cdot^+)]$ results only in reduction back to $[Ni^{II}(TPP)]$, while addition of CN^- produces the short-lived Ni^{III} species $[Ni(TPP)(CN)_2]^-$ with a $(d_{x^2-y^2})^1$ ground state and ultimately results in reduction.



[Ni(TPP)]



[Ni(OEP)]



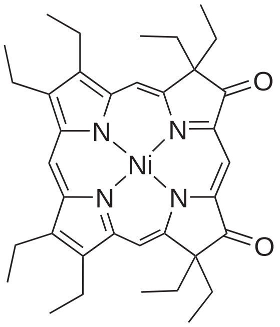
[Ni(OETPP)]

The radiolytic technique has also been applied to the reaction of alkyl radicals R with Ni^I porphyrins anions.[279] In analogy with the postulated reaction of Ni^IF_{430} to form $CH_3Ni^{III}F_{430}$, short lived R-Ni^{III} products have been detected.

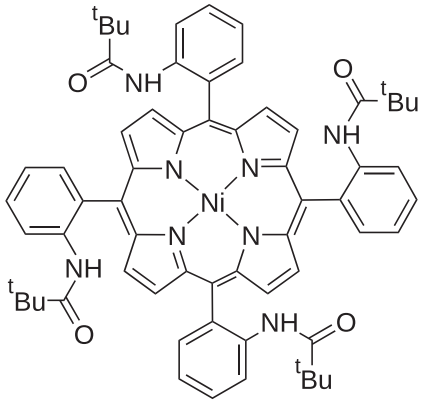
Electrochemistry and spectroscopy of the π cation radical of *meso*-tetraalkylchlorin (tetramethyl) and various porphyrins (tetramethyl, tetraethyl, and tetra-*n*-propyl) indicate that these do not convert to Ni^{III} at low temperatures.[280] Optical evidence reveals, however, that oxidation of the π cation radical of [Ni(*p*Et$_2$N)(TPP)] leads to a Ni^{III} cation radical which can be further oxidized to a Ni^{III} porphyrin dication. Similar studies have been carried out for various other derivatives of *meso*-tetraarylporphyrins such as *N*-oxides of TPP and 5,10,15,20-tetramesitylporphyrin (TMP). Addition of trifluoroacetic acid (TFA) to the *N*-oxide of [Ni^{II}TMP] at $-25\,^\circ C$ in CH_2Cl_2 results in $[Ni^{III}(TMP)]^+$ with a rhombic EPR spectrum, $g = 2.40$, 2.12, and 2.04.[281]

In general, porphyrins that are easy to oxidize, such as the *meso*-tetraalkylporphyrins and hydroporphyrins should all be oxidized to π cation radicals and this trend is indeed observed. It is not until these molecules are doubly oxidized that evidence of Ni^{III} is found. The exceptions to this general trend are the β-dioxo- and trioxoporphyrins (i.e., hydroporphyrins with an additional two or three electron-withdrawing keto groups at the β positions, e.g., (**69**)).[274,275] It was suggested that the β-dioxo- and trioxoporphyrins have a greater capacity to stabilize Ni^{III} than the porphyrin ring, due to the greater tendency of the former compounds to bind axial ligands and thereby relieve the strain of ruffling. Upon two electron-oxidation of Ni β-monooxoporphyrin in CH_3CN, a paramagnetic species with $g_{av} = 2.243$ and a broad line width of 160 G was observed at low temperatures and assigned to a dication comprised of a Ni^{III} π cation radical.[274] Hydroporphyrins invariably are easier to oxidize as the number of double bonds decreases in the order hexahydroporphyrin > tetrahydroporphyrin (bacteriochlorin and isobacteriochlorin) > dihydroporphyrin (chlorin) > porphyrin.[282]

When multiple peripheral substituents, as in [Ni(2,3,5,7,8,10,12,13,15,17,18,20-dodecaphenylporphyrin)], [Ni(5,10,15,20-tetra(*t*-butyl)porphyrin)], [Ni(2,3,7,812,13,17,18-tetracyclohexenyl-5,10,15,20-tetraphenylporphyrin)], and [Ni(OETPP)], cause the macrocycles to become nonplanar,[283,284] the HOMOs of the porphyrins are destabilized and the molecules become easier to oxidize.[283,285] In accord with the general discussion above, these compounds are oxidized to π cation radicals and remain so even at low temperatures in CH_2Cl_2. However, upon addition of



(69)



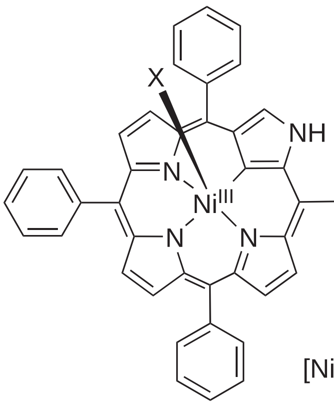
(70)

N-donor bases to these nonplanar Ni^{II} porphyrin π cation radicals, all the compounds exhibit EPR spectra at 110 K characteristic of Ni^{III} cations with an electron in the d_{z^2} orbital. Contradiction between the EPR and the other spectroscopic and structural data has been suggested to result from antiferromagnetic coupling of the unpaired electron in the $d_{x^2-y^2}$ orbital of the high spin Ni^{II} with the unpaired electron of the porphyrin radical, i.e., the high spin Ni^{II} radical becomes a pseudo Ni^{III}.[286] Similarly, the structure of a dipyridine adduct of a Ni^{II} octaethyloxophlorin radical has been reported which displays stereochemical parameters typical of high spin Ni^{II} but has a magnetic moment of $2.5\,\mu_B$, i.e., one unpaired electron. Here again, antiferromagnetic coupling between the unpaired electrons of the high spin Ni^{II} and porphyrin radical has been invoked.[287] DFT calculations and geometry optimizations have been carried out in order to predict the metrics of, e.g., the tetragonally elongated $[Ni^{III}(TPP)(py)_2]^+$ and tetragonally compressed $[Ni^{III}(TPP)(CN)_2]^-$.[288] For the latter, a planar molecule was predicted (using a porphine rather than TPP skeleton) with equatorial Ni—N distances of 2.06 Å and axial Ni—C bonds of 1.92 Å, consonant with a tetragonally compressed configuration and the $d_{x^2-y^2}$ orbital occupancy observed experimentally.

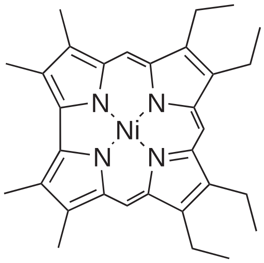
The "picket fence" Ni^{II} complex [Ni(TpivPP)] ((**70**); TpivPP = *meso*-α-α-α-α-tetrakis-(*o*-pivalamidophenyl)porphyrin) is reversibly oxidized by three electrons in two steps and generates as final product $[Ni(Tipvv)]^{3+}$ which was characterized as a Ni^{IV} cation radical in solution by both UV–visible and EPR spectroscopy.[289]

Oxidation of the recently synthesized Ni^{II} tetraphenylcarbaporphyrins ("confused" porphyrins in which one pyrrole ring is inverted to form a Ni—C bond) clearly yield Ni^{III} species of the type $[Ni^{III}(CTPP)X]$ which show line broadening upon substitution of ^{61}Ni ($I = 3/2$) and hyperfine interactions with a variety of counterions.[290] The orbital occupancies of the Ni^{III} vary with ligand field strength. For Br^- and I^- complexes, the EPR data supports d_{z^2} occupancy whereas for NO_3^-, a molecular orbital comprised of $d_{x,y}$ and $d_{x^2-y^2}$ is suggested.

The Ni complex of corrole (octaalkyl derivative (**71**)) is a $S = 1/2$ low-spin Ni^{II} species with a ligand-centered π-cation radical, as evidenced by the isoptropic EPR signal at $g = 2.01$.[291,292]



$[Ni^{III}(CTPP)X]$



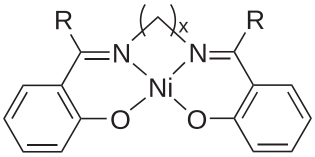
(71)

6.3.3.9 Complexes with Mixed Donor Set Ligands

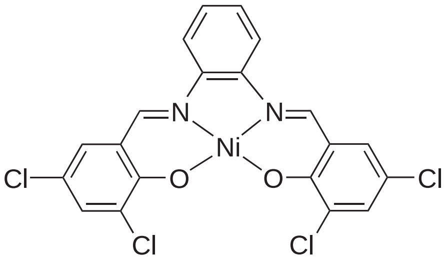
6.3.3.9.1 *Complexes with mixed {N,O} ligands*

Ni complexes with salen-type $\{N_2O_2\}$ ligands (**72**) have received considerable attention with respect to their oxidation. The tetradentate salen ligands are intrinsically noninnocent, but the solvent was found to play a determining role in controlling the final oxidation site, since $Ni^{II} \rightarrow Ni^{III}$ oxidation of salen complexes $[Ni^{II}(L)]$ proceeds with the simultaneous coordination of two solvent molecules in axial positions to give six-coordinate species $[Ni^{III}(L)(S)_2]^+$ (S = solvent). Hence, oxidation to Ni^{III} occurs in strong donor solvents (such as DMF or DMSO), whereas in poorly coordinating solvents ligand oxidation or oxidative polymerization at the electrode surface takes place.[293,294] For example, electrochemical oxidation of (**73**) in DMF or DMSO gives a Ni^{III} complex that interacts with a range of pyridines. According to EPR and electronic spectroscopy, genuine Ni^{III} complexes $[Ni(L)(py)_2]^+$ ($g_{av} = 2.12$) form with less basic pyridines, but with more basic pyridines (proton affinity > 945 kJ mol^{-1}) intramolecular electron transfer from the ligand to Ni^{II} occurs, giving species $[Ni^{II}(L^{\bullet -})(py)_2]^+$ ($g = 2.00$).[295,296] Cyclic voltammetry of complexes (**72**) in DMSO reveals a single, one-electron quasi-reversible oxidation wave at between +0.7 V and +1.0 V.[294] In cases of metal-centered oxidation, EPR spectra of the electrochemically-oxidized complexes in frozen matrices show rhombic patterns characteristics of Ni^{III}, and the complexes invariably have a low-spin $^2A_1$ ground state, usually with $(d_{z^2})^1$ occupation. In order to reduce solvent influence, complexes (**74**) with $\{N_3O_2\}$ ligands bearing an additional backbone N-atom have been prepared. By changing the length of the backbone carbon bridge, structures can be controlled: in dien-based ligands, steric constraints prevent coordination of the backbone-N, while in trien-based systems the ligand acts as a pentadentate. An inverted ground state, $(d_{x^2-y^2})^1$, has been detected for the pyridine adducts in the latter case.[70]

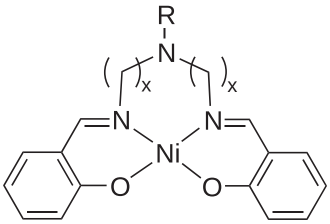
The Ni^{III} state is more easily attained with the {NOS} donor-set ligand (**75a**) ($E_{1/2} = +0.75$ V vs. SCE) compared to the $\{NO_2\}$ analogue (**75b**), the latter showing only an ill-defined anodic response.[297]



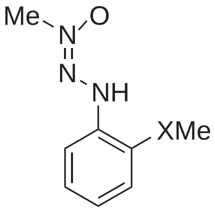
(**72**)



(**73**)



(**74**)



(**75a**) X = S
(**75b**) X = O

6.3.3.9.2 *Complexes with mixed {N,S} ligands*

In view of the low Ni^{II}/Ni^{III} redox potential of [NiFe] hydrogenase, the search for low-potential Ni^{II}/Ni^{III} complexes not only with pure S-donor but also with mixed {N/S} environment has been of major interest, and significant advances in this field have been reported.[298,299] Various mononuclear systems are listed in Figure 1 according to their redox potentials (usually in DMF). Homodinuclear Ni_2 and heterodinuclear NiM complexes with {N/S} donor ligands, in particular

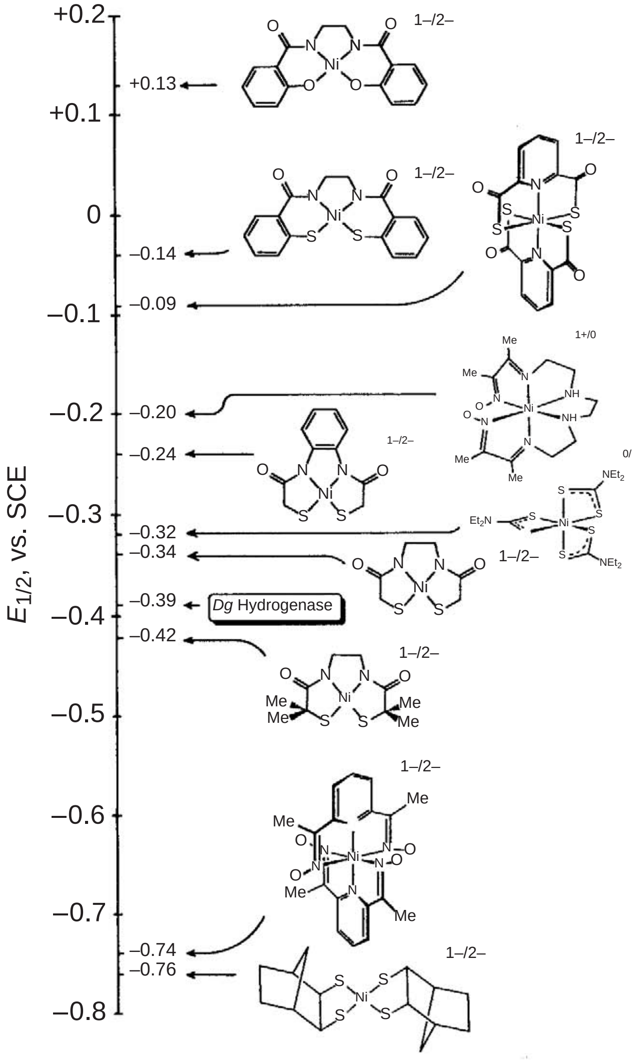


Figure 1 Comparative display of low-potential $Ni^{II/III}$ redox couples[298] (reprinted with permission from ref. 298; © 1991, American Chemical Society).

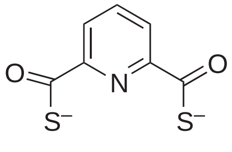
those with thiolato bridges, have been intensively studied with respect to their redox properties. These dinuclear compounds are not included here, but the reader should refer to Sections 6.3.4.12.4 and 6.3.4.12.5 for some further information.

A leading factor that influences the potentials is the presence of anionic (polarizable) ligands. The potentials are lowered in the following series: $ArO^- > ArS^- > RS^-$.[298]

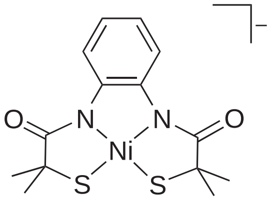
The oxidation of $[Ni^{II}(\mathbf{76})_2]^{2-}$ with I_2 in MeOH affords $[Ni^{III}(\mathbf{76})_2]^-$, in which the tetragonally distorted octahedral geometry with an essentially planar $\{NiS_4\}$ fragment and a *mer*-configuration observed for Ni^{II} is preserved.[264] The Ni—N and Ni—S distances decrease by 0.01 and 0.04 Å upon oxidation. Cyclic voltammetry of the Ni^{II} complex shows a reversible oxidation at −0.085 V (SCE) and the EPR spectrum of the ^{61}Ni-enriched Ni^{III} species demonstrates the $(d_{z^2})^1$ ground state.

Complex (**77**) has been obtained by electrolysis of the respective Ni^{II} species ($E_{1/2} = -0.78$ V vs. Cp_2Fe/Cp_2Fe^+ in DMF) and represents the first Ni^{III} complex with aliphatic thiolato donors that could be characterized crystallographically.[300] The overall square planar structure is retained, but the Ni—N and Ni—S distances shorten by 0.023 Å and 0.057 Å, respectively, upon oxidation. While (**77**) is EPR-silent, its pyridine adduct shows an axial spectrum ($g = 2.313$, 2.281, 2.000) with N-hyperfine coupling of the *z*-component, indicative of a $(d_{z^2})^1$ ground state.

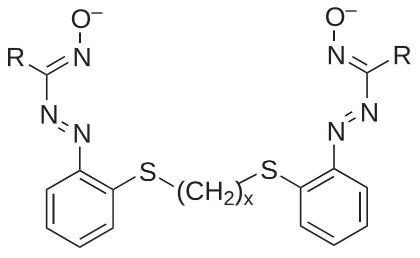
Selected further ligand scaffolds that give relatively stable Ni^{III} complexes with thioether or thiolate coordination are (**78**),[301] (**79**),[302] and (**80**).[303] The latter can stabilize Ni^{III} and Ni^{IV}, where the Ni^{IV} species is prepared by oxidation with HNO_3.



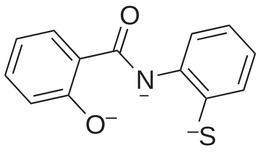
(76)



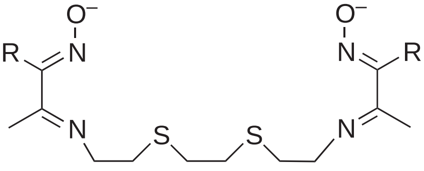
(77)



(78)



(79)



(80) R = Me,Ph

6.3.3.9.3 *Complexes with miscellaneous ligands*

Square planar, diamagnetic Ni complexes of type (**81**) have been shown to be best described as Ni^{II} species with singlet diradical character due to strong antiferromagnetic coupling of the two benzosemiquinone π-radicals.[192] Hence, these compounds are mentioned in the respective Ni^{II} sections. For (**82**), oxidation from the dianion to the monoanion occurs by air, and the monoanion is stable in the solid and in solution. X-ray crystallography reveals that the distorted square planar structures with *cis* orientation of the two *o*-mercatophenolato ligands is retained upon oxidation, but the Ni—S distances shorten by ~0.035 Å and the Ni—O distances by ~0.025 Å.[304]

The hybrid phosphin or arsin/thio- or selenoether ligands (**83a,b**) are less effective at stabilizing high oxidation state Ni than diphosphines or diarsines.[188] Octahedral complexes [Ni(**84**))$_2$] and $[Ni(\mathbf{85})_2]^{2+}$ containing mixed hard/soft donor sets undergo a reversible Ni^{II}/Ni^{III} oxidation at +0.66 V (in methanol) and at +0.93 V (in propylene carbonate), respectively. The Ni^{III} species can be generated chemically by oxidation with $(NH_4)_2[Ce(NO_3)_6]$ at low temperature; they retain the stereochemistry of the Ni^{II} species and have a $(d_{z^2})^1$ ground state.[305] Compared to the related 1,4,7-triazacyclononane systems, the sandwich complex $[Ni(\mathbf{86})_2]^{2+}$ shows a surprisingly low Ni^{II}/ NiI^{III} potential of $E_{1/2} = +0.27$ V (vs. Cp_2Fe/Cp_2Fe^+).[306]

The dinuclear complex $[Ni_2\{P(o\text{-}C_6H_4S)_3\}_2]^{2-}$ (**87**) undergoes two reversible electrochemical oxidations at −0.57 V and −0.05 V (in DMF, vs. SCE) to give the $Ni^{II}Ni^{III}$ and the $Ni^{III}Ni^{III}$ species, both of which are thermally stable. Chemical oxidation of (**87**) by $[Cp_2Fe]BF_4$ yields the robust thiolato-bridged mixed-valent (**88**), concomitant with substantial structural change.[307] (**88**) is assigned class II behavior according to Robin and Day. Related mononuclear systems such as $[(2\text{-}PhC_6H_4S)Ni\{P(o\text{-}C_6H_4S)_2(Ph)\}]^-$ cannot be oxidized to a stable Ni^{III}–thiolate species.

Five-coordinate Ni^{III} complexes (**89**) have been prepared by oxidation of the square planar Ni^{II} precursor complexes [Ni(L)X] with either X_2 or CuX_2, and the crystal structure of the iodo derivative has been determined. The geometry at Ni is best described as square pyramidal, with the Ni atom displaced approximately 0.34 Å out of the basal plane towards the apical I atom. EPR confirms the Ni^{III} oxidation state, in which the unpaired electron of the low-spin d^7 system is situated in the d_{z^2} orbital.[308,309] In aqueous solution full dissociation of both X anions occurs, while in acetone solution dissociation is not significant. The redox couple $[Ni^{II}\{NCN\}(H_2O)]^+$/ $[Ni^{III}\{NCN\}(H_2O)_n]^{2+}$ in water is +0.14 V (vs. SCE).

The salt $[NBu_4][Ni(C_6Cl_5)_4]$ is the first homoleptic Ni^{III} organometallic; it has square planar coordination of nickel.[310] The first examples of organonickel(IV) complexes to be isolated and characterized are six-coordinate $[Ni(Me)I(L)(PEt_3)_2]$ (**90**), which have been obtained via oxidative addition of MeI to $[Ni(L)(PMe_3)_3]$.[311,312] X-ray crystallography confirmed that the phosphine ligands are mutually *trans* and the methyl group is *trans* to the phenolate-O. These complexes are surprisingly stable, surviving at room temperature under argon for days. Their decomposition in

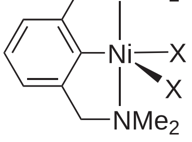
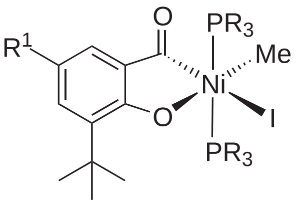
(87) **(88)**

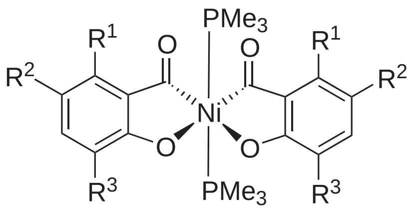
solution (with C—C bond formation between the methyl and aryl groups) is catalyzed by [Ni(PEt_3)$_4$]. Similarly, a bis(acylphenolato) complex of Ni^{IV} is accessible by reaction of [Ni(L)(PMe_3)$_3$] with CH_2I_2, I_2, or diiodoethane at −70 °C, which results in a dismutation reaction with formation of [Ni(L)$_2$(PMe_3)$_2$] (**91**) and [NiI_2(PMe_3)$_2$].[312,313] Again, these Ni^{IV} complexes are thermally stable and surprisingly air stable. X-ray crystallography shows the two phosphine ligands mutually *trans*, the acyl groups mutually *cis*. Interestingly, while the precursor Ni^{II} complexes are acid sensitive, the Ni^{IV} complex is not. Since organonickel(IV) species are of obvious interest in considering mechanisms for Ni-catalyzed coupling reactions, reductive coupling reactions of (**90**) have been studied.[314]



(89)

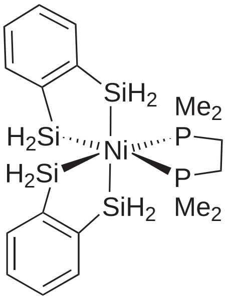


(90)

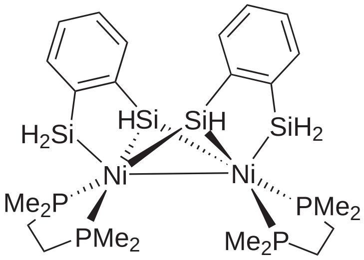


(91)

Complex (**92**) has been obtained from the reaction of 1,2-disilylbenzene and [Ni(dmpe)$_2$] at 80 °C.[315] The reaction is assumed to proceed via oxidative addition of Si—H bonds and subsequent elimination of H_2, and some intermediates have been detected spectroscopically. (**92**) is described as a Ni^{IV} species, but care has to be taken, since a related hexasilylpalladium complex, initially formulated as Pd^{VI},[316] should better be viewed as Pd^{II} with two side-on bound Si—Si bonds.[317,318] The same is valid for a related dinuclear (μ-silylene) (silyl)nickel complex (**93**), formulated as Ni^{III}.[319]



(92)



(93)

The formally Ni^{IV} complex [*commo*-1,1′-$Ni(B_{11}H_{11})_2]^{4-}$ should be mentioned, which has been isolated (as the Cs^+ and Ph_3PMe^+ salts) and characterized by ^{11}B and ^1H NMR spectroscopy.[320]

6.3.4 COMPLEXES OF NICKEL(II)

6.3.4.1 Advances in Structural Trends and Spectroscopy of Nickel Complexes

The electronic spectra and spectromagnetic properties of nickel complexes have been exhaustively described in *CCC* (1987)—in particular for Ni^{II}. Hence, the present discussion will be restricted to selected examples of more recent work and emerging new methods.

6.3.4.1.1 General structural features

Typical Ni—L bond lengths have been extracted from the Cambridge Structure Database (CSD) and listed in tabular form.[321] Also, Ni^{II}—L bond lengths from the CSD have been analyzed by the BDBO technique, which is related to the bond valence model (BVM) where the total bond order is equal to the oxidation state of any atom.[322] Selected mean Ni—L distances from the CSD source are collected in Table 2.

Ni has a smaller radius in square planar geometry than in tetrahedral, which is assumed to result from the non-Aufbau electron filling in d^8 square planar species.[322] The well-known thermal octahedral $\rightleftharpoons$ square planar transformation of Ni^{II} coordination compounds has been

Source: See *et al.*[322]

discussed in detail, particularly with respect to its dependence on thermal stabilities of the initial and final complexes, the electronic and steric properties of the ligands, and the equatorial–axial interactions of the ligands.[323]

Rules and trends for the *trans*-influence in mixed planar Ni^{II} complexes have been reviewed by considering structure data for 19 planar Ni^{II} complexes with mono- and bidentate ligands, [Ni(*trans*-XY)(*cis*-ZZ′)].[324] The Ni—X bond lengths primarily depend on the *trans*-influence of the ligand Y which increases in the order of donor strength O- $<$ N- $<$ P- $<$ C-ligated group. The influence of the *cis*-ligands ZZ′ is smaller. Whenever both hard and soft ligands are present in planar Ni^{II} complexes, a structure with a hard and a soft ligand in the *trans*-position is favored. This rule is substantial for the steric course of reactions yielding planar Ni^{II} complexes.

While tetrahedral Ni^{II} generally is paramagnetic, four-coordinate square planar Ni^{II} is usually assumed to have a closed-shell (diamagnetic) ground state, which results from the large antibonding σ-interaction of the four ligands with the $d_{x^2-y^2}$ metal orbital. This is not always true, however, since paramagnetic square planar Ni^{II} complexes (**94**) with a triplet ground state have been discovered.[325,326] Also, the lack of ligand field bands $<10{,}000\,\mathrm{cm}^{-1}$ is no longer an essential feature of planar Ni^{II} complexes, since planar compounds (**94**) show ligand field bands at 7,300–7,500 cm^{-1} (vs. $\sim$6,600 cm^{-1} for the tetrahedral species). While the structure of type (**94**) complexes in the solid state (planar or tetrahedral) depends on the R and R′ substituents ((**94a**) and (**94e**): planar; (**94b**): two isomers, one planar and one tetrahedral; (**94f**): tetrahedral), all compounds are predominantly tetrahedral in solution.[326,327] The ligand field spectra of the planar triplet complexes have been interpreted and well reproduced by extended AOM calculations.[328] However, there has been some dispute about the origin of the paramagnetism of these square planar d^8 complexes, and *s*–*d* orbital mixing[328,329] as well as the small chelate bite angle (which lowers the energy difference between $d_{x^2-y^2}$ and d_{xy}, Figure 2)[330] have been claimed as the determining factors. Both the angular overlap model (AOM) extended by *s*–*d* mixing of central metal orbitals and the cellular ligand field (CLF) model are able to rationalize the experimental findings.[331] The importance of *s*–*d* mixing is emphasized by a study employing AOM in its molecular orbital oriented form (MO-AOM).[332]

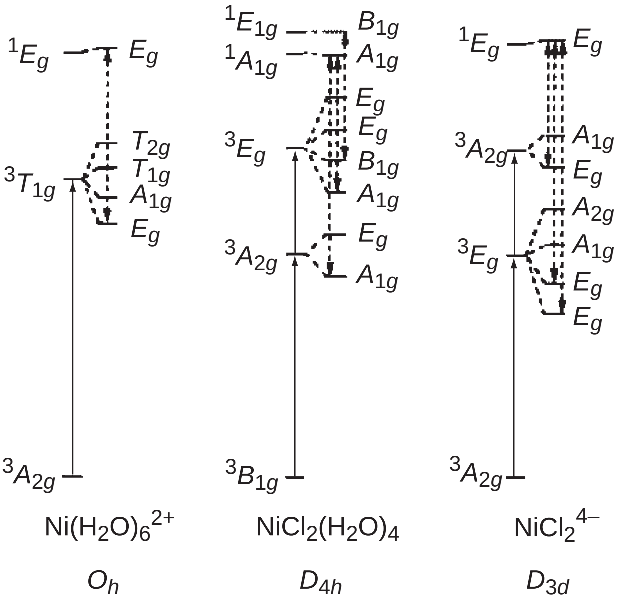
6.3.4.1.2 Electronic absorption spectroscopy

Published *d–d* spectral assignments for seven tetragonal Ni^{II} complexes [Ni{N$_4$}X$_2$] with equatorial N$_4$ donor set have been analyzed within the CLF framework, which appears to reproduce the experimental data better than any other ligand field approach.[333] Five out of seven spectra were shown to require reassignment due to unreasonable e_π(X) values. An essentially linear correlation exists between e_σ(N) and the equatorial Ni—N bond length over the range 2.0–2.3 Å.[333–335] Equatorial and axial parameters are coupled inversely: as e_σ(N) decreases, e_σ(X) and e_π(X) increase, in accordance with Pauling's electroneutrality principle.[333]

The middle band of the three spin-allowed transitions of octahedral Ni^{II} complexes ($^3A_{2g} \rightarrow {}^3T_{2g}$, $^3A_{2g} \rightarrow {}^3T_{1g}(F)$, $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ in O_h symmetry) is often found to be split into two components (in particular in spectra of Ni^{II} complexes with halide or O-donor ligands), which is usually assigned to spin–orbit coupling of $^1E_g(D)$ with $^3T_{1g}(F)$. All crystal field states of interest are summarized in Scheme 1. The vibronic structure is also affected by coupling of the energetically excited states, and this has been analyzed in more detail by low-temperature, polarized single-crystal spectra and a quantitative time-dependent theoretical model (Figure 3).[336] It rationalizes band positions, intensities, and the unusual vibronic progression, which is shown to arise from efficient intersystem crossing between the two excited states. This model linking point group symmetry, electronic states and potential energy surfaces is also illustrated in an educational paper and visualized in an electronic publication.[337]



Scheme 1 Electronic states involved in the absorbtion bands in the region of the first singlet–triplet intersection for octahedral, tetragonal and trigonal complexes of nickel(II).[336] Solid arrows denote spin-allowed absorbtion transitions, dotted arrows connect pairs of interacting levels. (reprinted with permission from ref. 336; © 1998, American Chemical Society).

6.3.4.1.3 NMR spectroscopy

The NMR paramagnetic relaxation enhancement of the high-spin Ni^{II} ($S = 1$) ion is strongly dependent on the rhombicity in the zero-field splitting (zfs) tensor, and much work has been devoted to the role of the zfs interactions and the interpretation of nuclear magnetic relaxation dispersion (NMRD) data.[338–340] Since electronic relaxation times for high-spin Ni^{II} are quite short (typically 10^{-10}–10^{-12} s), reasonably sharp and well-resolved signals can be observed in favorable cases. This is particularly true for pseudotetrahedral and pentacoordinate species, but less so for octahedral Ni^{II} where relaxation times are usually longer and resonances are consequently broader. A theory of the paramagnetic shift in pseudotetrahedral complexes of Ni^{II} based on the AOM has been developed, and it has been shown that the shifts are sensitive to delocalization of spin only from the metal $d_{\pm 1}$ orbitals (which are an equal mixture of d_{xz} and d_{yz}).[341]

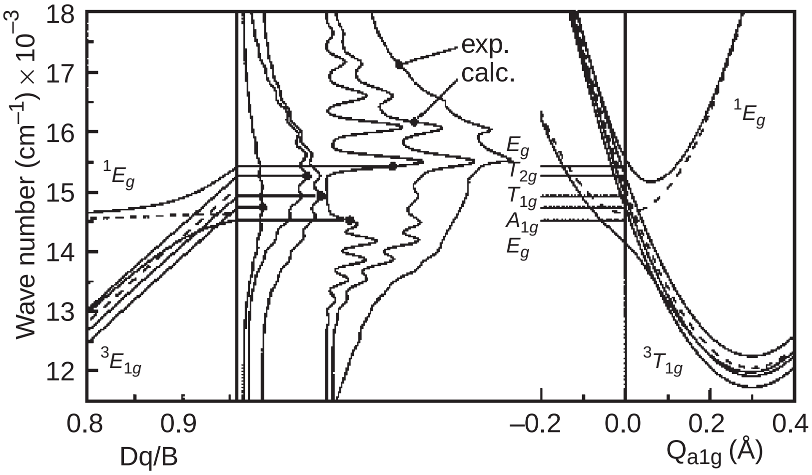


Figure 3 Crystal field states (left-hand panel) and potential energy surfaces (right-hand panel) for an octahedral complex of nickel(II) in the $^3T_{1g}/^1E_g$ energy range. Calculated spectra for the transition to each electronic state are shown in the central panel. Lines with markers connect electronic states and their corresponding calculated spectra. The total calculated spectrum (calc.) is obtained as the sum of the four individual spectra and is compared to the experimental spectrum of $Ni(H_2O)_6{}^{2+}$ measured at 5 K[336] (reprinted with permission from ref. 336; © 1998, American Chemical Society).

Selected applications of 1D-NMR spectroscopy in paramagnetic Ni^{II} chemistry include the conformational characterization of [14]aneN_4 complexes through ^1H NMR relaxation studies,[342] the identification of organometallic σ-aryl complexes of heteroporphyrins,[343] a ^{13}C NMR study of inversion processes of (*meso*-2,3-butanediaminetetraacetato)nickelate(II),[344] the use of solid-state ^{13}C CP/MAS NMR for defining the coordination and ligand conformation in weakly paramagnetic (β-imonocarbonylenolato)nickel(II) complexes,[345] and the determination of isotropic paramagnetic shifts in the NMR of N and C nuclei in nickel complexes.[346]

If the fine structure is not observable due to line broadening, 2D ^1H NMR spectroscopy of paramagnetic Ni^{II} complexes is a useful tool for signal assignment and for deducing structural information.[347] While COSY experiments have been successfully employed for characterizing octahedral Ni^{II} complexes,[348] a problem may arise from the antiphase structure within the multiplet of COSY cross-peaks, which leads to dramatic cancellation of intensities every time the J splitting is not resolved. Since this often happens in paramagnetic systems, other 2D experiments such as HOHAHA and EXSY have also been tested.[349]

While mononuclear octahedral Ni^{II} complexes often show relatively broad signals, nuclear relaxation enhancement and sharp signals may be observed in related dimer species.[350,351] This has been taken advantage of for a detailed NMR investigation of a series of weakly ferromagnetically spin-coupled dinuclear octahedral Ni^{II} centers.[352]

6.3.4.1.4 EPR spectroscopy

Standard EPR spectroscopy at X-band (~9 GHz; microwave quantum energy 0.3 cm^{-1}) or Q-band (~35 GHz, 1.2 cm^{-1}) has often failed to excite transitions in the spin-triplet manifold of non-Kramers ($S=1$) Ni^{II} systems unless the symmetry about the metal ion is high, because the magnitude of the zfs may be larger than the available microwave quantum. High-frequency/high-field EPR has now become a valuable tool to overcome this difficulty by the combination of sufficiently high-mm/sub-mm frequencies and magnetic fields, and hence the EPR signals of $S=1$ systems with large zfs have become available.[353,354] This has been applied to pseudo-octahedral Ni^{II} ions with $\{N_6\}$[355] or $\{N_2O_4\}$[356] donor sets (magnetically diluted by doping in a diamagnetic Zn^{2+} host) as well as to pseudotetrahedral $[Ni(PPh_3)_2X_2]$ (X = Cl, Br).[354] For $[Ni(PPh_3)_2Cl_2]$, analysis of the two-dimensional (2D) field-frequency data set yielded spin-Hamiltonian parameters in agreement with, but with much higher accuracy than, powder magnetic susceptibility and magnetization measurements. A high value for the axial zfs parameter, $D \approx +13\,cm^{-1}$, was determined and its sign corroborated by considering which transitions are detectable and which not. The $|D|$ value for $[Ni(PPh_3)_2Br_2]$ is much less (~5 cm^{-1}) due to greater covalency, while the magnitude of $|D|$ for $[Ni(PPh_3)_2I_2]$ ($\sim 27\,cm^{-1}$, due to the high spin–orbit coupling of iodine) was still too high and outside the available field and frequency range, thus precluding resonance observation.

Double quantum transitions have been analyzed in high-field EPR studies of Ni^{II} complexes with $\{N_6\}$[355,357] and $\{N_4O_2\}$[357] donor set.

6.3.4.1.5 XAS at the nickel K-edge

While X-ray absorption spectroscopy has proven extremely valuable for analyzing the active site structures of Ni-containing metalloenzymes such as [Fe,Ni] hydrogenases,[358] it has found only scattered use in classical Ni coordination chemistry. However, it is a valuable tool for assigning Ni oxidation states, since it has been reported that the shift in energy of the Ni K-edge absorption towards higher values correlates with the increase in the oxidation state of Ni from +2 to +4. The inflection point energy of the Ni pre-edge structure shifts approx. 1 eV per unit change in valency.[359] For example, the Ni K-edge position in the X-ray absorption spectrum of rhombohedral NiF_3 indicates that the compound has a mixed-valence composition $Ni^{II}[Ni^{IV}F_6]$.[360] However, the edge energy cannot be used to determine formal oxidations states without specific information regarding the nature of the ligand environment.[361] For example, the edge energy shift that occurs upon oxidation is small or nonexistent in the case of complexes with many S-donor atoms, in accordance with XPS spectra revealing the involvement of the S-donors in the redox chemistry of such species.

Although not very prominent, nickel K-edge EXAFS data have been used to investigate Ni—L distances, in particular for the determination of the coordination environment of Ni in artificial metallopeptides. Examples include the Ni^{II} complex of a cyclic tetracysteinyl peptide which was shown to possess a distorted planar NiS_4 core,[362] and the structural characterization of metallopeptides designed as scaffolds for Ni^{II}/Fe_4S_4 bridged assemblies.[363] Comparison of EXAFS data of synthetic Ni complexes and Ni metalloproteins, e.g., [FeNi] hydrogenase, indicates whether the complexes are good structural models of the biological sites.[361,364,365] Use of the XANES region extends the structural information, in particular with respect to coordination geometry. The edge energy, edge slope and the maximum absorbance of the edge region of the spectra are useful in determining the number of hard vs. soft donor sites. However, predictions become difficult in complexes with a larger number of S-donor atoms (i.e., low edge energy).[361] Application of Ni EXAFS for obtaining first coordination sphere structural data of classical Ni coordination compounds has been reported in several cases where no single crystals could be grown.[366–371] Peaks in the Fourier transform (FT) of Ni K-edge XAFS data at approximately twice the Ni—L distance ($2R$) have been interpreted to arise from multiple scattering pathways involving the central Ni ion in linear L—Ni—L units. Hence, while such peak at $2R$ is observed for square planar *trans*-$[NiBr_2(PEt_3)_2]$, it is absent for tetrahedral $[NiBr_2(PPh_3)_2]$.[372]

Application of element-specific L absorption spectra and the "white light" sum role to a series of Ni complexes appears to be an excellent tool for quantitatively determining the number of 3*d* vacancies.[373]

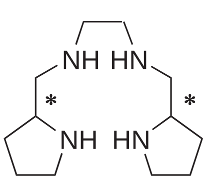
6.3.4.1.6 ^{61}Ni Mössbauer spectroscopy

While ^{61}Ni Mössbauer spectroscopy has proven valuable in solid-state chemistry, its application to problems in coordination chemistry is very rare. The parent ^{61}Co nucleus ($t_{1/2} = 99$ min) serves as the radiation source. A bioinorganic model compound with a NiS_4 core has been investigated by ^{61}Ni Mössbauer spectroscopy in order to gain further evidence for a postulated formal Ni^{IV} oxidation state.[374]

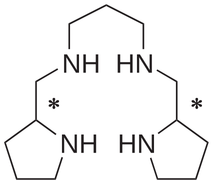
6.3.4.1.7 Molecular modeling of nickel complexes

Molecular mechanics calculations have become a well established tool in the area of coordination chemistry, including the coordination chemistry of nickel[375–379] where they are often applied for the analysis or the prediction of structures,[380] the computation of isomer or conformer ratios and metal ion selectivities,[381,382] and for simulating spectroscopic properties in combination with AOM calculations or by hybrid quantum mechanics/molecular mechanics (QMMM) methods.[383,384] Details of the various approaches, e.g., the incorporation of *d*-electron stabilization energy contributions by, *inter alia*, hybrid cellular ligand field/molecular mechanics methods,[385] are found in the given references, although only a few selected examples can be cited here. MM techniques have also been applied for the computational analysis of bioinorganic nickel sites.

A crucial point is the use of a reliable force field, and various parameters for Ni^{II} have been developed and employed successfully.[379,386–392] As an example, molecular mechanics calculations (MOMEC87 program) have been used to predict the isomer distributions of Ni^{II} complexes of chiral (**95**) and (**96**), and isomer ratios were in good agreement with observed ratios.[393]



(95)



(96)

The possible conformations of six-membered Ni^{II} chelate rings have been identified by cluster analysis of all such chelate structures contained in the CSD. While most chelate rings are in the expected chair conformation, around 10% adopt the high-energy boat form due to ligand constraints. However, these structures were well reproduced by molecular mechanics calculations, irrespective of the starting conformation.[380,394,395] In the case of some 16-membered tetraaza and tetrathia macrocycles the occurrence of high-energy conformations is attributed to artifacts of the metal incorporation mechanism.

Optimizing a MM model (MOMEC95, force field[396]) with regard to axial Ni···H and Ni···C interactions in a set of structurally characterized bis(diamine)nickel(II) complexes has allowed the deduction of a van der Waals radius for low-spin Ni^{II} of 1.35 Å.[397]

In a comparative study, the semiempirical PM3(tm) method was shown to be less effective than molecular mechanics for modeling the structures of Ni^{II} complexes with tetraaza macrocycles.[398] In contrast, local DFT calculations (VWN5 method), coupled with appropriately large basis sets, accurately describes the geometries of the isomers of $[Ni(cyclam)]^{2+}$.[399]

6.3.4.2 Carbonyl Complexes

While *cis*-$[PtCl_2(CO)_2]$ is reasonably stable, related carbonyl complexes of the lighter homologue Ni^{II}, such as $[NiCl_2(CO)]$ and $[NiCl_2(CO)_2]$, are detectable only at very low temperature in solid argon matrices.[400,401] However, the anionic compound $[Ni(C_6F_5)_4]^{2-}$ has proven a valuable starting material for a convenient entry to the chemistry of square planar Ni^{II} carbonyl chemistry.[402] The halide-bridged dinuclear species (**97**) reversibly bind CO giving rise to the isolable derivatives (**98**). The chloro complex (**98a**) reacts with AgC_6F_5 to give (**99**). *cis*-$[Ni(C_6F_5)_2(thf)_2]$ reacts with CO at −78 °C to give isolable (**100**), which has been crystallographically characterized. The high ν(CO) stretching frequencies (2,156 cm^{-1}, 2,130 cm^{-1}) are consistent with the CO acting as mainly a σ-donor with negligible π-backbonding. (**100**) easily decomposes above −40 °C by reductive elimination of C_6F_5—C_6F_5.

(100)

6.3.4.3 Cyano and Other Pseudohalide Complexes

6.3.4.3.1 Cyano complexes

The structure of $Na_2[Ni(CN)_4]\cdot 3H_2O$ has been redetermined and the charge distribution analyzed by multipole refinements.[403] The structure contains practically square planar $[Ni(CN)_4]^{2-}$ ions, which are stacked on top of each other in almost linear chains. The bonding in $[Ni(CN)_4]^{2-}$ has been investigated by MO calculations, confirming the expected σ-donation from cyanide orbitals and π-backbonding from the Ni d_{xy} orbitals.[404] Its electronic spectrum has been analyzed and the MO energy sequence deduced.[405] Ground state energies and electronic transitions have been calculated by the ZINDO technique.[406] MCD results confirm the conventional $3d \rightarrow a_{2u}\{Ni4p_z,p^*(CN)\}$ assignment of the intense UV bands at 3.2–4.5 μm^{-1} and suggest an $a_{1g}(z^2) \rightarrow e_u$ assignment of the band at 5.0 μm^{-1}.[407]

Formation of $[Ni(CN)_4]^{2-}$ from the reaction of $[NiL_2]^{2+}$ (L = ethylendiamine derivative) proceeds via a stable $[LNi(CN)_2]$ intermediate.[408] Formation of the intermediate is first order in CN^-, while the subsequent reaction is second order. The pH dependence, however, is different in each case. Oxidation of $[Ni(CN)_4]^{2-}$ by aqueous chlorine to form *trans*-$[Ni^{III}(CN)_4(H_2O)_2]^{2-}$ follows distinct Cl_2O, Cl_2, and HOCl pathways (with the first being the fastest) and proceeds through formation of a highly reactive Ni^{IV} intermediate.[409] The ability of the $[Ni(CN)_4]^-$ unit to bind to other metal ions through the cyanide N atoms has been extensively used for the construction of high nuclearity cyanide-based compounds. Since these are important in the field of molecular magnetism, they are mentioned in Section 6.3.4.13.2. One selected class is described here, since it incorporates various forms of cyanonickelate(II). The reaction between $[Ni(H_2O)_6]^{2+}$ and $[(Me_3tacn)Cr(CN)_3]$ in aqueous solution generates $[(Me_3tacn)_8Cr_8Ni_6(CN)_{24}]^{12+}$, a cube of eight Cr^{3+} ions with each square face spanned by a $[Ni(CN)_4]^{2-}$ unit.[410] In the course of cluster formation the cyanide ligands reorient from the Cr^{III}—C≡N to the more stable Cr^{III}—N≡C—Ni^{II} bridging arrangement. Use of NiI_2 in a similar reaction gives $[(Me_3tacn)_8Cr_8Ni_5(CN)_{24}]I_{10}$ with a Ni^{2+} ion missing from one of the cube faces.[411] If this latter cyanide-rich cluster is reacted with additional $[Ni(CN)_4]^{2-}$ in aqueous solution, $[(Me_3tacn)_{10}Cr_{10}Ni_9(CN)_{42}][Ni(CN)_4]_3$ is formed, which incorporates square pyramidal (**101**) and trigonal bipyramidal $[Ni(CN)_5]^{3-}$ (**102**) and square planar $[Ni(CN)_4]^{2-}$ units in a single compound.[411] $[Ni(CN)_4]^{2-}$ has long been known to react with excess cyanide to generate $[Ni(CN)_5]^{3-}$, and while the latter species favors a square pyramidal coordination geometry, a slightly distorted trigonal bipyramidal structure lies close in energy. The structure of $[(Me_3tacn)_{10}Cr_{10}Ni_9(CN)_{42}][Ni(CN)_4]_3$ is claimed to support that this distortion from an ideal trigonal bipyramid is not a consequence of packing forces, but represents a local minimum structure for the free $[Ni(CN)_5]^{3-}$ ion.[411] Magnetic measurements now document the low-spin character of trigonal bipyramidal $[Ni(CN)_5]^{3-}$, which is well established for the square planar form and for $[Ni(CN)_4]^{2-}$.

The reaction of $K_2[Ni(CN)_4]$ with $B(C_6F_5)_3$ followed by treatment with Ph_3CCl gives (**103**), which has a highly delocalized negative charge in the anion.[412] (**103**) is an active cocatalyst for the Cp_2ZrMe_2-mediated olefin polymerization. An extremely bent cyanide coordination with a very acute angle Ni—N≡C of around 111.2(2)° has been observed for the preorganized dinickel(II) site (**104**), where the short Ni—Ni distance is constrained by the dinucleating ligand scaffold.[413]

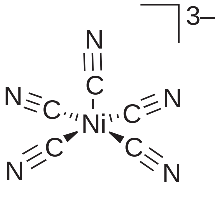
Application of $[Ni(CN)_4]^{2-}$ as a tumor imaging agent has been reported.[414]

6.3.4.3.2 Fulminato, cyanato, thiocyanato, and related pseudohalide complexes

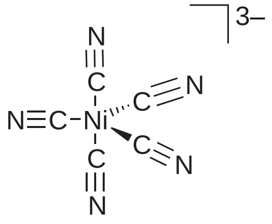
Nickel–azide coordination chemistry has received particular attention with respect to magnetic properties and molecular magnetism. Therefore, Ni^{II}/N_3^- systems are covered in a separate section (Section 6.3.4.13.1).

The crystal structure of $[N(C_3H_7)_4]_2[Ni(CNO)_4]$ containing the square planar tetrafulminato nickel(II) anion has been determined.[415] Due to the large cations separating the anions, this high-energy fulminato species is not explosive. C≡N (114.0(5) pm and 113.6(5) pm) and N—O distances (126.0(4) pm and 126.2(4) pm are in the usual range for fulminato complexes, and the M—C≡N—O units are almost linear. Based on spectroscopic and magnetic studies, bridging fulminato ligands have been proposed in a dimeric Ni^{II} complex.[416]

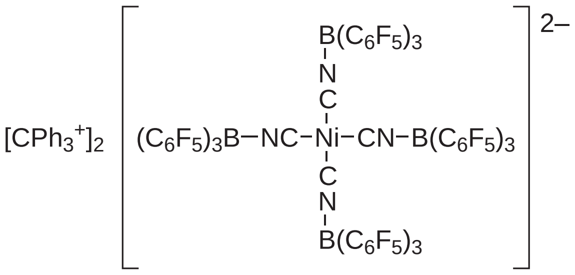
The cyanato ligand generally tends to bind through its N atom to Ni^{II} and acts as an N-bound terminal ligand in mononuclear complexes. Complexes of the type $[Ni(NCO)_2L_4]$ (L = py, H_2O)



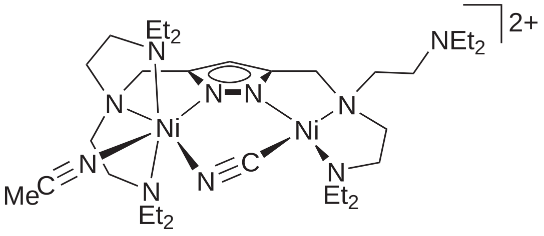
(**101**)



(**102**)

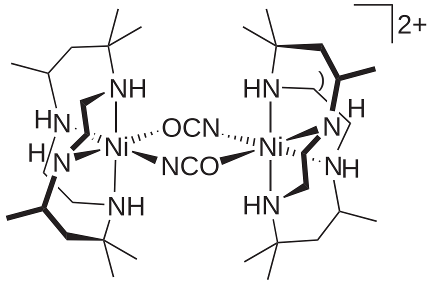


(**103**)

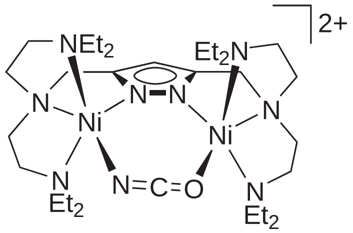


(**104**)

have been characterized structurally and spectroscopically.[417,418] In several cases, cyanato complexes are formed from urea complexes upon heating (see Section 6.3.4.12.7). The bridging ability of the cyanate ion is manifest in some di- and polynuclear complexes where end-to-end (μ-1,3) linkages have been detected due to the use of tetradentate ligands that leave two accessible coordination sites at the metal center. If these sites are disposed in the *cis* position, doubly bridged dinickel(II) species such as $[\{Ni(terpy)(H_2O)\}_2(\mu\text{-}NCO)_2](PF_6)_2$[419] and $[\{Ni(Me_6[14]aneN_4)\}_2(\mu\text{-}NCO)_2](ClO_4)_2$ (**105**)[420] result. Otherwise, 1D chains are obtained as in $[\{Ni(3,2,3\text{-}tet)(\mu\text{-}NCO)\}_n](ClO_4)_n$.[420,421] In all these cases, however, the cyanate binding is asymmetric with rather long Ni—O distances (>2.21 Å) and with very different bond angles ((Ni—O—C) = 122–132°) and ((Ni—N—C) > 150°). Bond angles of bridging SCN^- and $SeCN^-$ ligands are even more asymmetric (see below). Magnetic properties of cyanato bridged Ni^{II} complexes have been analyzed, revealing that the antiferromagnetic component of the coupling constant J is lower compared to the azido systems, as a consequence of the large Ni—O distance and the asymmetry of the ligand.[420]



(**105**)

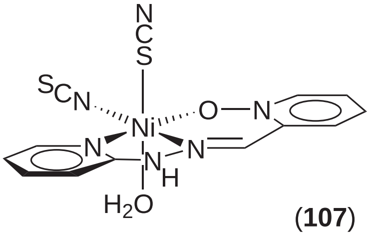


(**106**)

Enforced by the preorganized bimetallic array, a more symmetrical cyanato bridge has been observed in (**106**).[422] Triple μ-1,1,1-NCO linkages have been reported for heterobimetallic nickel/lanthanide systems.[423]

Thiocyanate is a common coligand found in Ni^{II} coordination compounds of multidentate chelate ligands.[424–431] A convenient method of preparing $Ni(NCS)_2$ has been reported, which serves as a starting material for the preparation of various Ni^{II}–thiocyanate compounds.[432] A detailed magnetic analysis reveals antiferromagnetic ordering of $Ni(NCS)_2$ at $T_c = 52 \pm 1$ K.[433] Solution studies show the presence of $[Ni(NCS)_n]^{(2-n)+}$ with $n = 1$–4 in DMA and $n = 1$–2 in DMSO.[434,435] In concentrated aqueous NaNCS, a value of $0.12 \pm 0.041\ mol^{-1}$ has been determined for the fourth consecutive binding constant.[436]

While SCN^- usually binds via its N atom to Ni^{II} (or it adopts a N,S bridging mode), rare S-coordination has also been observed.[437] (**107**) involves both N- and S-coordinated terminal thiocyanate, where the Ni—S—C angle is 98.3(1)°, whereas the Ni—N—C angle is 168.7(2)°. S bonding seems to be stabilized by intermolecular H bonding to the uncoordinated thiocyanato-N atom.



(107)

The $[Ni(NCS)_6]^{4-}$ ion is almost perfectly octahedral, with Ni—N distances of around 209.5 pm and N—Ni—N angles around 89.5°. The Ni—N—C and N—C—S entities are practically linear.[438,439] In $[Ni(NCS)_2L_2]$ where L is a R-substituted pyridine, stereochemistry and spin state depend on the type and positions of R.[431] While for 2-Me- and 2-Et-pyridine square planar complexes are observed, other pyridins lead to coordination polymers with pseudo-octahedral Ni^{II} due to N,S-bridging thiocyanate. Ni^{II} thiocyanato complexes have been studied quite intensively as hosts for inclusion compounds.[440–442]

Bridging thiocyanate has received attention as magnetic exchange mediator in polynuclear Ni^{II} complexes. Besides discrete dinuclear complexes (**108**)[443,444] and several trinuclear systems (**109**),[445,446] 1D chain compounds with single (**110**, **111**)[447,448] or double bridges (**112**, **113**)[449–452] and *cis* (**110**, **113**)[447,448,450] or *trans* (**111**, **112**)[449,451,452] orientation of the bridges have been characterized and their magnetic properties analyzed. The small bonding angle at the thiocyanate-S (around 100°) leads to orthogonality of the magnetic orbitals, and hence ferromagnetic coupling is usually observed.

Selenocyanate binds via its N atom to Ni^{II},[453,454] but is also able to bridge two Ni^{II} ions in the μ-1,3 mode. Compounds $[LNi(NCSe)_2(H_2O)]$ (L = tridentate amine, e.g., bis(3-aminopropyl) amine or (2-aminoethyl)(3-aminopropyl)amine) undergo deaquation to form dinuclear selenocyanate bridged species $[LNi(NCSe)(\mu\text{-}NCSe)]_2$ (**114**) upon heating.[453] In (**114**), the Ni—Se—C and Ni—N—C angles are around 95° and 170°.[455] Due to the resulting orthogonality, ferromagnetic superexchange is usually found for these compounds.[455,456]

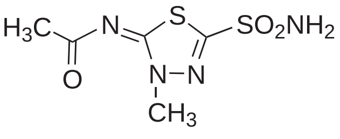
6.3.4.4 Complexes with Nonmacrocyclic Nitrogen Donor Ligands

6.3.4.4.1 Complexes with monodentate amino, amido, and imido ligands

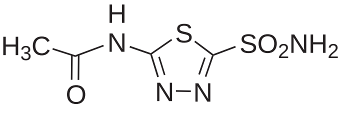
A combination of matrix isolation IR and DFT studies have shown that condensation of monomeric NiX_2 (X = Cl, Br) in solid N_2 matrices initially gives species $NiX_2\cdots(N_2)$ with a physisorbed type of interaction. These can be converted by photolysis into pseudotetrahedral $NiX_2(\eta^1\text{-}N_2)_2$ (**115**) moieties with end-on bound N_2 in a chemisorbed type of interaction below 10 K. On warming to ca. 20 K the chemisorbed species revert to the physisorbed state.[457]

Amines are very efficient donors for Ni^{II} ions. The most effective monodentate nitrogen-containing ligands are heterocyclic amines like imidazole (Im) or pyridine (py). Imidazole or substituted imidazoles may form classical complexes with six or fewer ligands bound to Ni^{II}. Powdered nickel dissolves in *N*-methylimidazole (*N*-MeIm) solutions of elemental sulfur to give red-colored salts $[Ni(N\text{-}MeIm)_6]S_8$.[458] The Ni atom is surrounded by six ligands with parameters very close to those found in the classical imidazole complexes. In the *trans*-$[Ni(NCS)_2(Im)_4]$ complex with a $\{NiN_6\}$ chromophore, the Ni^{II} ion exhibits axially distorted octahedral geometry with *trans* N-bonded thiocyanate ligands.[459] Structural studies on the $[Ni(NCS)_2\ (alkylpyridine)_n]$ complexes have shown that there is a direct relation between the size and the position of alkyl substituents and the structure of the complexes formed. While a simple pyridine ligand gives six-coordinate complexes, e.g., in $[NiCl_2(py)_4]$,[460] substituted pyridines may give complexes with coordination numbers from four to six.[461] Using 2,4-dimethylpyridine (2,4-dmepy) the $[Ni(NCS)_2(2,4\text{-}dmepy)_3]$ complex is obtained with five nitrogen atoms around the metal ion and with a geometry intermediate between a trigonal bipyramid and a tetragonal pyramid. The arrangement of the methyl substituents prevents coordination of a sixth ligand.

Methazolamide ((**116a**), Hmacm) and acetazolamide ((**116b**), H_2acm) contain two different nitrogen binding sites, the sulfoamide and thiadiazole nitrogen donors. The interaction of Hmacm with Ni^{II} ions and ammonia gives rise to $[Ni(macm)_2(NH_3)_4]$.[462] Two sulfonamido molecules occupy the axial positions by binding through the deprotonated sulfonamide N atoms, while four ammonia N atoms form the equatorial plane. A similar complex, $[Ni(Hacm)_2(NH_3)_4]$, is formed with H_2acm.[463] Hacm coordinates through its thiadiazole nitrogen with the Ni—N distance being shorter (2.150 Å) than in the case of the sulfonamide Ni—N bond (2.216 Å). The shorter distance for the thiadiazole ligand indicates the effect of the π-electron delocalization in the thiadiazole ring.



(**116a**) (Hmacm)



(**116b**) (H2acm)

In contrast to amino ligands, Ni^{II} coordination chemistry with amido or imido ligands is much less developed. Parent $[Ni(NH_2)_2]$ can be obtained by the reaction of $NiBr_2$ with KNH_2 in liquid NH_3.[464] In the solid state, it contains $[Ni_6(NH_2)_{12}]$ entities that consist of Ni octahedra surrounded by amide groups forming a cuboctahedron. There are at most weak $NH\cdots N$ bonds between the $[Ni_6(NH_2)_{12}]$ clusters. Reaction of $NaNH_2$ with $[Ni(NH_2)_2]$ gives $Na_2[Ni(NH_2)_4]\cdot 2NH_3$.[465] This compound contains planar $[Ni(NH_2)_4]^{2-}$ units that are oriented to form the ground and top of a prism capped by Na^+ and (at a greater distance) NH_3. Upon further reaction with $LiNO_3$, LiCl, or LiBr, $Li_3[Ni_4(NH_2)_{11}]\cdot NH_3$ is formed.[466]

Ni^{II}–amido complexes such as (**117**) react with small electrophiles by insertion either in the Ni—N bond (e.g., with CO_2 to form (**118**)) or in the N—H bond. With unsubstituted aryl groups (Ar = Ar′ = Ph), both a monomeric complex (**117**) or a dimeric species (**119**) is formed, depending on the amount of PMe_3 added. Using bulky borylamide ligands, an almost linear, two-coordinate Ni^{II} complex could be obtained and structurally characterized.[467] The N—Ni—N angle in (**120**) is 167.9°.

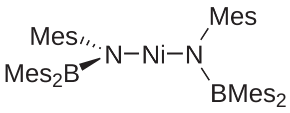
(**119**)



(**120**)
(Mes =
2,4,6-trimethylphenyl)

A first terminal imido complex of nickel (**121**) was prepared according to Equation (3).[468] The synthesis goes via the Ni^{II} amido compound (**122**) and uses the steric bulk of the arylimido group for stabilization. The Ni^{II} center in (**121**) is planar and three-coordinate. Reaction of (**121**) with CO or benzyl isocyanide leads to formal nitrene transfer with formation of (**124**) and (**125**), respectively. Further reaction with CO liberates the isocyanate and carbodiimide (Equation (4)).[469]

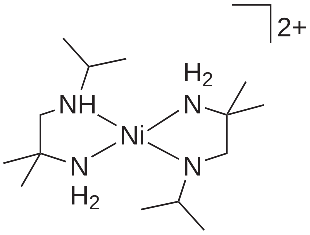
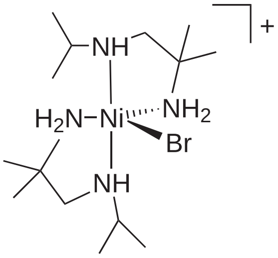
(4)

6.3.4.4.2 Complexes with chelating amino and amido ligands

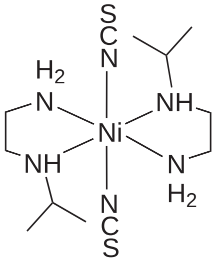
With *C*- and/or *N*-substituted diamines square planar or octahedral Ni^{II} complexes are usually formed. 2-Methyl-1,2-propanediamine may form both octahedral[470] or square planar complexes.[471,472] The *C*-substituted diamine complexes with Ni^{II} often exhibit solid-state yellow to green-blue thermochromism which is usually explained by the square planar to octahedral isomeric transformation.[473,474] The simultaneous substitution on diamine C and N atoms in *N*-isopropyl-2-methyl-1,2-propanediamine results in a set of three complexes $[NiL_2]Br_2 \cdot 3H_2O$ (**126a**), $[NiL_2Br]Br$ (**126b**) and $[NiL_2(NCS)_2]$[475] (**126c**) with square planar ($\{NiN_4\}$ chromophore), distorted trigonal bipyramid ($\{NiN_4Br\}$ chromophore), and *trans* octahedral ($\{NiN_6\}$ chromophore) geometry, respectively. In the pentacoordinate complex the secondary N atoms are coordinated in axial positions while the Br atom and two primary N atoms define the basal plane. The square planar complex (**126a**), on heating, undergoes an irreversible exothermic isomerization after dehydration into complex (**126b**)—a unique example of the change from square planar to a trigonal bipyramidal species (yellow to green thermochromism). The isocyanide complex exists only as a six-coordinate species in the solid state as well as in solution. The smaller size of the coordinating atom and a higher ligand field of the NCS^- ion compared to the bromide ion allows the steric hindrance caused by the bulky substituents to be overcome. *N*,*N*′-dimethyl-1,2-ethanediamine forms with $Ni(NO_3)_2$ octahedral complexes exhibiting *cis–trans* isomerization. *cis*-$[NiL_2(NO_3)_2]$ obtained from *cis*-$[NiL_2(H_2O)_2][NO_3]_2$ by heating may be transformed into *trans*-$[NiL_2(NO_3)_2]$ on heating to 150 °C or by the presence of humidity.[476]



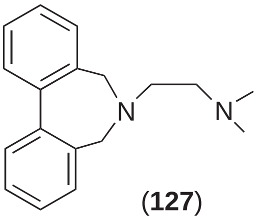
(**126a**)



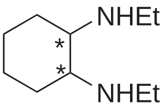
(**126b**)



(**126c**)



(**127**)



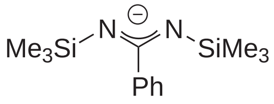
(**128**)

Equilibria between four-, five-, and six-coordinate complexes in solution are found in the case of ternary substituted $[Ni(diamine)(\beta\text{-kitenonate})]^+$ species for coordinating solvent with different donor strength.[477] Increasing of the solvent donor strength as well as increasing the electron-withdrawing abilities of the substituents at the diamine and β-kitenonate ligands favors the formation of the six-coordinate species.

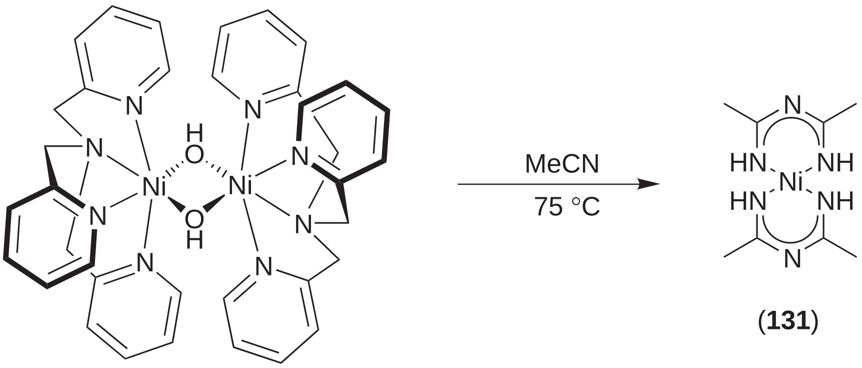
The heavily substituted diamine (**127**) forms with Ni^{II} a violet complex $[NiCl_2(\mathbf{127})]$.[478] The Ni atom is surrounded by two chlorine atoms and by two amino groups in a distorted tetrahedral geometry with a dihedral angle between the planes defined by Cl—Ni—Cl and N—Ni—N of 86.3°. The main reason for this unusual Ni–diamine complex structure is most likely the geometry of the resulting diazanickelacyclopentane ring that invariably shows a N—Ni—N angle ranging from 82° to 90°.

1,2-Cyclohexanediamines are simple analogues of 1,2-ethylenediamine[479,480] and much of their coordination chemistry is very similar. Ni^{II} complexes may be used to separate the stereoisomers of 1,2-cyclohexanediamine.[481] The complex composed of Ni^{II} and optically active *N*,*N*′-diethylcyclohexane-1,2-diamine (**128**) shows an ability to recognize the shape of molecules in terms of the configuration of the various OH groups in aldolases during the epimerization of D-glucose to D-mannose.[482]

Amidines, i.e., bifunctional nitrogen compounds of general formula R′NH—C(R)=NR′, exhibit various bonding modes, with small amidino ligands favoring formation of dimeric complexes.[483,484] N-silylated benzamidines with larger substituents usually form monomeric species.[485] Ligand (**129**) (*siam*, Me_3Si-NC(Ph)N—$SiMe_3^-$) forms two complexes with Ni^{II} ion, [Ni(*siam*)$_2$] and [Ni(*siam*)(H*siam*)Br].[486] The complex [Ni(*siam*)$_2$] shows a distorted tetrahedral environment around the Ni^{II} ion. The distortion arises from the amidine groups resulting in the dihedral angle between the planes defined by atoms involved in the formation of two chelates, NNNi—NiNN, of 96.1°. The [Ni(*siam*)(H*siam*)Br] complex has a monodentately bound H*siam* ligand and a weakly distorted square planar geometry with a dihedral NNNi—NiBrN angle of 173.5°. [Ni(*siam*)$_2$] is very reactive towards CO_2: two moles of the starting complex can incorporate 5 mol of CO_2 that insert into five N—Si bonds ((**130**), Figure 4). *Siam* coordinated to metal ions can stabilize metal–carbon bonds similar to the cyclopentadienyl ligand.[487]



(**129**)



(**132**)

(**131**)

The square planar Ni^{II} complex (**131**) is formed upon reaction of MeCN with the dinuclear complex (**132**). A sequence of Ni-mediated hydrolytic transformations, MeCN → acetamide and NH_3 → acetamidine → *N*-acetimidoylacetamidine, is proposed.[488] While the *N*-acetimidoylacetamidine ligands are isoelectronic with acac, they have a much stronger ligand field.

From the reaction of [Ni(acac)$_2$] with a variety of oxalamidines, di- and oligonuclear complexes with oxalic amidinato bridging ligands and square planar Ni^{II} have been obtained (**133a**).[489] In contrast, the (Ph_3P)BrNi fragment can only coordinate to sterically less demanding oxalamidinates

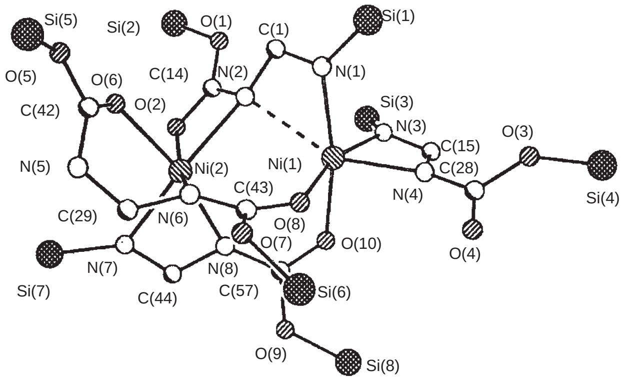


Figure 4 Crystal structure of (**130**)[486] (reproduced with permission of Elsevier from *Inorg. Chem. Acta*, **1998**, *281*, 181–189).

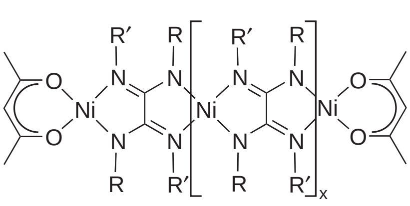
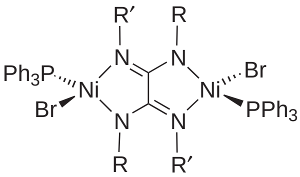
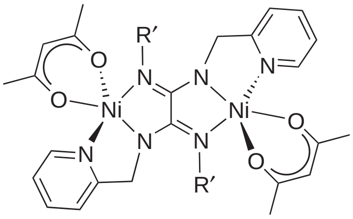
and gives tetrahedral coordination of the metal ion (**133b**).[490] Oxalamidines with additional donor atoms in the *N*-substituents have also been studied, e.g., in (**133c**).[490]



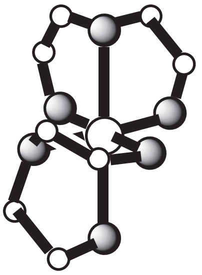
(133a)



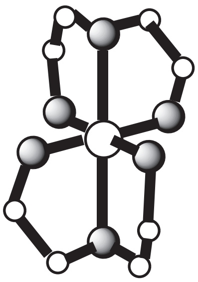
(133b)



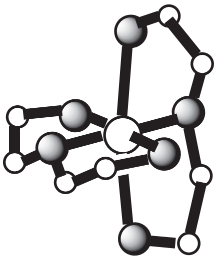
(133c)



(134a)
(u-*fac*)



(134b)
(s-*fac*)



(134c)
(*mer*)

Triamine ligands bind Ni^{II} to usually give octahedral complexes both in the equimolar and bis(ligand) species.[491,492] The bis-complexes of the tridentate diethylenetriamine (dien) can exist in three edge configurations: meridional (*mer*), symmetrical facial (s-*fac*), and unsymmetrical facial (u-*fac*) (**134**).[493] The difference in energy between them is very small (only few $kJ\ mol^{-1}$). Thus, even the thermal transformation in the solid state between different isomers is possible. $[Ni(dien)_2](SCN)_2$ undergoes a phase transition (162–180 °C, $\Delta H = 29.4\ kJ\ mol^{-1}$) from the low-temperature ordered form s-*fac*-$[Ni(dien)_2](SCN)_2$ to a high-temperature unordered *mer* isomer.[494] The latter isomer is metastable and transforms to the former one in the presence of humidity.

Dien is classified as an N-donor, polycentric, chelate and also chiral ligand.[495] In octahedral $[M(dien)_2]^{n+}$ complexes the configuration u-*fac* is chiral (C_2), the configuration s-*fac* is achiral (C_i) and the configuration *mer* is chiral due to nonplanarity of the central N atom. Different isomers can be obtained not only by thermal phase transition but also by appropriate complex synthesis.[496] Two particular complexes in this context are $[Ni(dien)_2]ca{\cdot}2H_2O$ (ca = chloranilate) and $[Ni(dien)_2][Ni(CN)_4]{\cdot}2H_2O$. In the former complex the $[Ni(dien)_2]^{2+}$ cation has nearly octahedral geometry. Two ligand molecules with terminal amino groups in *cis* and secondary amino groups in *trans* position define the s-*fac* configuration. The conformations of two independent chelate rings are enantiomeric with each other. In contrast, the metal ion in the $[Ni(dien)_2]^{2+}$ unit of the second compound shows distorted octahedral geometry, but the two tridentate ligands are coordinated meridionally.

N-(2-aminoethyl)-1,4-diazacycloheptane ((**135**), dachen) is a tridenate ligand incorporating a mesocyclic diamine and is termed "structurally reinforced."[497] Like other polyamine ligands with steric bulk disposed above and below the complex plane, dachen stabilizes the low-spin square planar Ni^{II}. In aqueous solution it exists as the octahedral $[Ni(dachen)(H_2O)_3]^{2+}$ cation, which upon reaction with ammonia yields the square planar complex $[Ni(dachen)(NH_3)]^{2+}$, a rare example of a monodentate ammine ligand in a low-spin Ni^{II} complex.[498]

The choice of tridentate amine has a critical impact on the coordination mode of the ambidentate nitrite ligand, NO_2^-.[499,500] Complexes with substituted tri- and tetraamines have shown that bulky substituents may prevent the formation of the μ-NO_2^- bridged polymeric complexes, and the intramolecular hydrogen network may stabilize N coordination of nitrite.

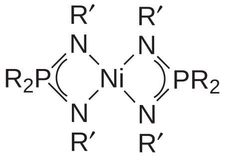
1,3,5-Triamino-1,3,5-trideoxy-*cis*-inositol (taci, (**136a**)) provides a rigid arrangement of three amino groups sterically constrained to facial coordination and hence is an effective chelator for Ni^{II}, much more effective than the related 1,3,5-triaminocyclohexane.[501] O-alkylated derivatives such as *all*-*cis*-2,4,6-trimethoxy-cyclohexane-1,3,5-triamine (tmca, (**136b**)) and *all*-*cis*-2,4,6-tribenzoxycyclohexane-1,3,5-triamine (tbca, (**136c**)) form particularly stable $[Ni(tmca)_2]^{2+}$ and $[Ni(tbca)_2]^{2+}$ complexes, which in the solid state show near octahedral coordination geometry with some trigonal distortion. The $\{NiN_6\}$ core has almost ideal D_{3d} point group symmetry.[502] A potentiometric study performed for the Ni^{II} tmca system shows potent binding ability of this ligand toward Ni^{II}. In comparison to the parent ligand (**136a**), the stability constant is larger by two orders of magnitude for the 1:1 complex and about five orders of magnitude for the 1:2 complex. A comparison with other triamines shows that tmca belongs to the most effective triamine ligands for Ni^{II} ions. The data suggest that the methyl groups located on the periphery of the complex generate a lipophilic surface, whereas the hydrophilic part of the molecule is mostly hidden in the inside. Compared with the parent (nonmethylated) ligand, tmca complexes are stabilized by a more favorable entropy of hydration. $[Ni(taci)(H_2O)_3]^{2+}$ is a valuable building block and can be attached to other moieties. Solvothermal reaction of $NiCl_2$, $Nb(OEt)_5$ and taci in a 1:1:1 ratio under alkaline conditions resulted in the formation of two Nb–Ni heteropolyoxometalate complexes $[Ni(taci)_2]_2\{trans\text{-}[Nb_6O_{19}][Ni(taci)]_2\}26H_2O$ and $[Na(H_2O)_6]_2\{cis\text{-}[H_2Nb_6O_{19}][Ni(taci)]_2\}18H_2O$. In both compounds, two $[Ni(taci)]^{2+}$ entities are each bonded to three Nb—O—Nb bridges of a central Nb_6O_{19} unit, resulting in the formation of an approximately C_{3v} symmetric NiN_3O_3 coordination geometry.[503]

Stability constants for complexes of *cis*-3,5-diaminopiperidine (dapi, **137a**) with several divalent metal cations have their maximum for Ni^{II}. $[Ni(dapi)_2]^{2+}$ forms directly in aqueous solution, and the centrosymmetric *trans* isomer was found exclusively in the solid state.[504] Ligands (**137b**) and (**137c**) bearing additional pyridine donors form six-coordinate complexes $[Ni(\mathbf{137b})Cl]^{+}$ and $[Ni(\mathbf{137c})]^{2+}$.

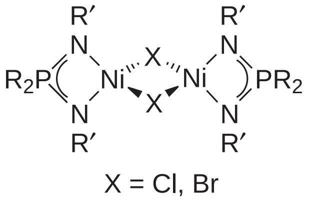
Phosphinoimidic amidato ligands give Ni^{II} complexes (**138a**) and (**138b**), depending on the size of the R and R′ substituents. For example, for $R = Bu^t$ and $R' = SiMe_3$, halogeno-bridged type (**138b**) complexes with tetrahedral $\{NiN_2X_2\}$ chromophores are formed. In the solid state, complexes (**138a**) can be either planar (e.g., $R = Pr^i$, $R' = Me$) or tetrahedral (e.g., $R = Ph$, $R' = SiMe_3$), while in solution an equilibrium planar (diamagnetic) $\rightleftharpoons$ tetrahedral (paramagnetic) is often observed. Higher temperatures shift the equilibrium towards the tetrahedral form.[505] Distorted tetrahedral structures in the solid state are also observed for type (**138a**) and (**138b**) complexes with $R = R' = Ph$ and $X = PPh_2$.[506]

Bis(8-quinolinyl)amide acts as a tridentate pincer ligand towards Ni^{II} to give the square planar complex (**139**).[507] A trigonal monopyramidal (TMP) coordination geometry around the Ni^{II} ion is rare.[508] The tripodal ligand $N[CH_2C(O)NHBu^t]_3$, which contains a tertiary amine and three amides with appended *t*-butyl groups is very efficient in forming TMP complexes with Ni^{II}. The orange nickel complex (**140**) has a TMP structure with the three deprotonated amide nitrogen donors coordinated equatorially.[509,510] The Ni^{II} ion lies nearly in the trigonal plane, displaced only 0.14 Å toward the vacant coordination site. (**140**) does not form trigonal bipyramidal species while dissolved in solvents, even in pyridine and water. The lack of reactivity can be explained by the nearly complete shielding of the vacant coordination site by the bulky amide substituents. This TMP ligand effectively stabilizes the divalent Ni^{II} state and leads to a high Ni^{II}/Ni^{III} redox potential.

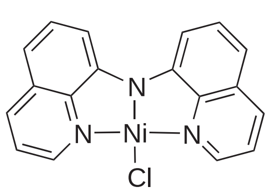
Tetraamine ligands (2*S*,3*S*)-1,2,3,4-tetraaminobutane (threo-form, *t*tab) and (2*S*,3*R*)-1,2,3,4-tetraaminobutane (erythro-form, *e*tab) (**141**) form oligonuclear and polymeric complexes with Ni^{II}. The solid-state structure of $[Ni_8(t\text{tab})_{12}]Br_{16}\cdot 17.5H_2O$ has been shown to contain discrete chiral $[Ni_8(t\text{tab})_{12}]^{16+}$ cubes with approximate *T* symmetry.[511] Ni^{II} complexes of the tripodal tetraamine ligand tren are well established. In the linear complex cation $[Ni_3(tren)_4(H_2O)_2]^{6+}$ (**142**)



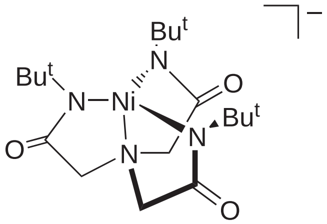
(**138a**)



(**138b**)



(**139**)



(**140**)

all Ni ions are six-coordinate, but with different coordination spheres.[512] Two of the tren ligands act as bridges, being only tridentate with respect to the central Ni^{II} and binding the outer Ni^{II} via the pendant primary amine. The higher homologues of tren, ((**143**)–(**145**)), also form octahedral type (**146**) and (**147**) complexes.[513] Variation of the lengths of the ligand arms leads to different chelate ring sizes, which causes distinct distortions of the octahedral coordination environment, of the strengths of bonds to monodentate coligands, and induces a slight shift in the UV–visible spectra.

The encapsulating hexadentate ligand (**148**) forms $[Ni(\mathbf{148})]^{2+}$ with a distorted octahedral geometry. This can be oxidized to a Ni^{III} species in which a substitution reaction by sulfate in the NiN_6 chromophore is observed.[514]

6.3.4.4.3 Complexes with chelating imine ligands

The discovery[515,516] that Ni^{II} (and Pd^{II}) complexes of bulky α-diimine ligands (**149a,b**) are active precatalysts for the polymerization of olefins (giving polyolefins with branched microstructure) has sparked an enormous activity in that field.[517–520] This includes theoretical work[521–526] and mechanistic studies[527–529] as well as numerous investigations regarding the effects of, *inter alia*, the cocatalyst (usually MAO or other aluminum alkyls),[530] the ligand structure,[531] etc. New developments include the covalent binding of the catalysts to a silica support via appropriate ligand modifications,[532] polymerization in aqueous media,[533,534] and the design of new ligand scaffolds, in particular nonsymmetric ones (e.g., in (**150**)–(**152**)).[535–539]

In the solid state, (**149a**) with $R^1 = R^2 = Pr^i$ and $R^3 = H$ is a dimer with two μ-bromo linkages and five-coordinate Ni^{II} ions.[540] Precatalysts (**152**) with very bulky 2,6-diphenylaniline substituents ($R = Bu^t$, OMe) adopt a chiral C_2 symmetry due to repulsive interactions between the sterically demanding groups.[541]

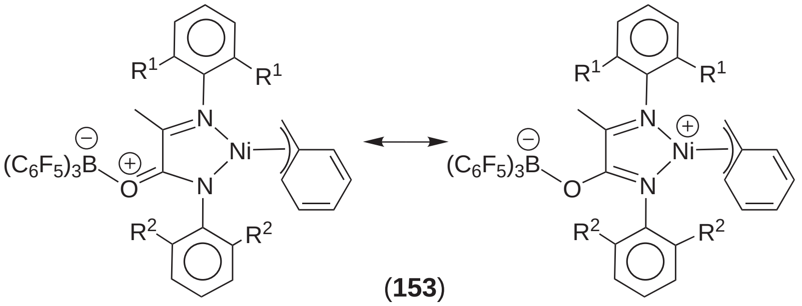
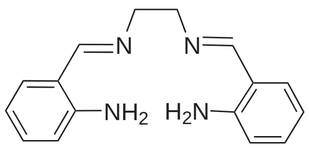
(152)

Ni catalysts for olefin polymerization incorporating α-iminocarboxamide ligands are activated by the formation of borane–carbonyl adducts (**153**).[542] Structure/reactivity relationships are similar to Brookhart's dimine catalysts.

While according to the Irving–Williams series octahedral Cu^{II} complexes are thermodynamically more stable than the corresponding Ni^{II} complexes, in the case of square planar geometry the ligand field stabilization effect is reversed and a higher stability is predicted for d^8 than for d^9 electron configuration. M(amben) complexes (where amben is the $\{N_4\}$ counterpart of salen, (**154**)) are approximately planar both for Cu^{II} and Ni^{II} ions.[543] In the reaction $[Cu(amben)] + NiX_2 \rightarrow [Ni(amben)] + CuX_2$ (in DMF) Ni^{II} replaces Cu^{II} irreversibly, but the rate is



(153)

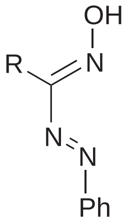


(154) (H_2amben)

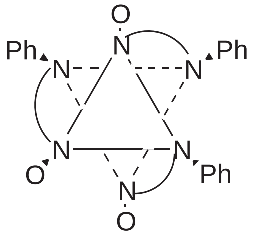
strongly dependent on the nature of X.[544] The order or reactivity was found to be: $ClO_4^- < Br^- < SCN^- \ll Cl^-$. The slow substitution with $X = ClO_4^-$ takes days, while with $X = Cl^-$ it proceeds within minutes. According to the kinetic data for the system [Cu(amben)]/$[Ni(DMF)_6]^{2+}/Cl^-$ the overall process consists of a Ni- and Cl-dependent step, followed by two Ni- and Cl-independent consecutive steps. The first step can be described as a second-order reaction between [Cu(amben)] and a chloro species assumed to be distorted tetrahedral $[NiCl_2(DMF)_2]$. This species initially reacts with the $\{N_2\}$ donor metalloligand [Cu(amben)] to form the binuclear intermediate $[Cu(amben)NiCl_2]$ which subsequently rearranges in two first-order steps to form [Ni(amben)].

6.3.4.4.4 Complexes with chelating nitrogen ligands incorporating oximes and related functions

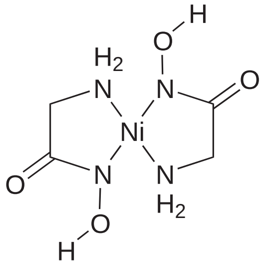
The oxime function is usually inserted close to another donor ensuring chelate formation, e.g., other donors like an oxime, amide, imine, or azo group. The insertion of an N-donor atom next to an oxime group results in efficient ligands for Ni^{II} ions. The arylazooximes with an aza function next to the oxime (H[**155**]) form complexes $[Ni^{II}(\mathbf{155})_3]^-$ (**156**; R = Me or Ph).[262] One of the ligands may be easily displaced by 2,2′-bipyridine or related ligands giving the octahedral $[Ni(\mathbf{155})_2(bipy)]$ complex. The crystal structure of $[NEt_4][Ni(\mathbf{155})](R{=}Ph)$ shows that the $\{NiN_6\}$ coordination sphere (chelates are meridionally bound) is severely distorted from octahedral symmetry with Ni—N_{oxime} bonds shorter than the Ni—N_{aza} distances and a distinct *trans* effect displayed by the Ni—N_{oxime} bond.



(155)



(156)



(157)

Bis(glycinohydroxamato)nickel(II) (**157**) forms a square planar complex where the ligand behaves as an $\{N_2\}$ chelate.[545] Ni^{II} complexes of imine oximes synthesized from corresponding alkyldione monoximes and amines show an unusual coordination. After almost 70 years the structure of the Pfeiffer complex (Figure 5) and the reaction leading to this structure was finally established.[546]

Amide N atoms next to an oxime moiety are strong donors and $\{N_{oxime},N_{amide}\}$ chelation usually results in square planar NiL_2 complexes.[547] Two oxime groups accompanied by two amine, amide, imine, or other donors are also powerful ligands. Such tetradentate dioximes form planar complexes. Deprotonated 3,6,6,9-tetramethyl-4,8-diaza-3,8-undecadiene-2,10-dione dioxime forms with Ni^{II} a slightly distorted square planar complex (**158**) with intramolecular hydrogen between the oxime oxygen atoms.[548]

A ring closing reaction involving coordinated amide groups is observed for (**159a**), which forms (**159b**) upon condensation with formaldehyde and methylamine.[549]

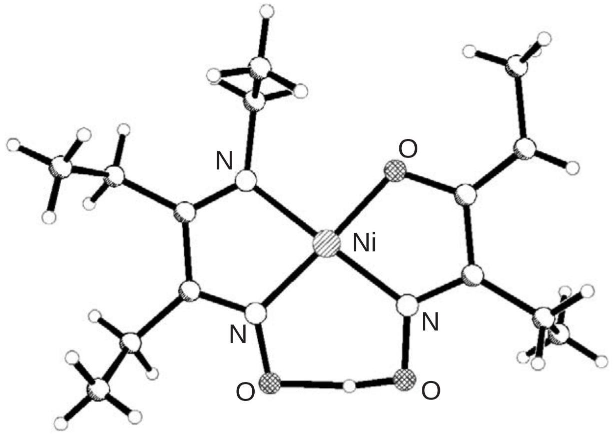


Figure 5 Crystal structure of Ni(hex)(eti).[546]

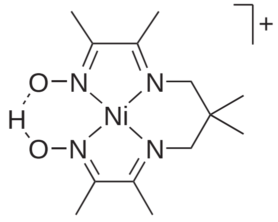
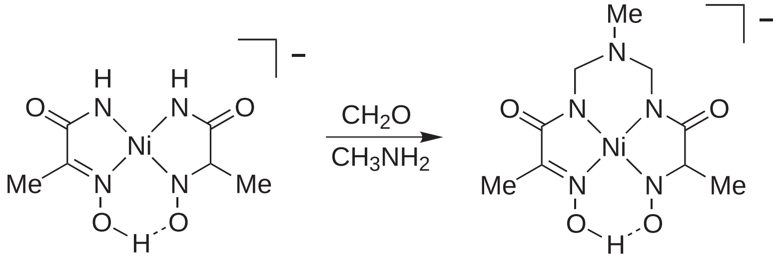


(**158**)



(**159a**) (**159b**)

Various tetradentate amide and oxime open chain ligands exhibit very high efficacy in the coordination to Ni^{II} ions. *N*,*N*′-bis(2-hydroxyiminopropionyl)-1,2-diaminoethane (H_2pen) and *N*,*N*′-bis(2-hydroxyiminopropionyl)propane-1,3-diamine (H_2pap) form very stable square planar Ni^{II} complexes ($NiH_{-1}L$) with very short hydrogen bonds between two oximic oxygen atoms (Figure 6).[550–552] This short hydrogen bond closes the planar complex structure into a pseudo-macrocyclic environment. The $NiH_{-1}L$ complex is very stable also in solution and it is the first major species formed with Ni^{II} above pH 6. The structure of Li[Ni(H_{-1}pen)]·4H_2O shows that the metal ion lies in the center of four N-donors of two deprotonated amides and two oxime groups. The coordination in $[Ni(H_{-1}pap)]^-$ is very similar to that of $[Ni(H_{-1}pen)]^-$; however, in the former complex there are alternating five-, six-, five-membered rings, whereas in the $[Ni(H_{-1}pen)]^-$ species all three fused chelate rings are five membered. This leads to noticeable shortening of the Ni—N bonds. The Ni—N_{amide} bonds being within the 1.803–1.816 Å range are

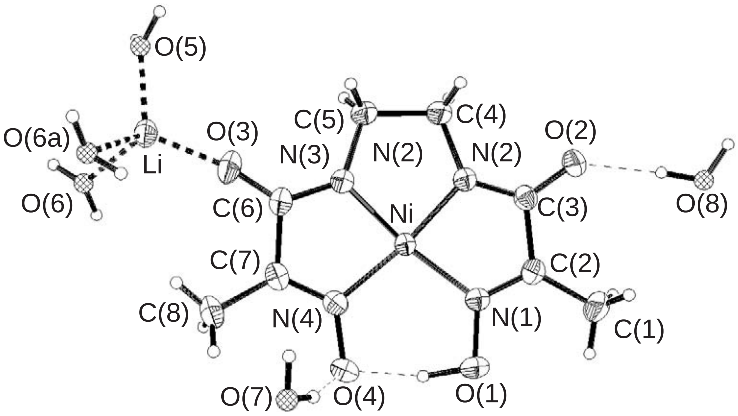


Figure 6 Structure and numbering scheme for the complex Li[Ni(H_{-1}pen)]·4H_2O.

distinctly shorter than those found for other amides including macrocyclic complexes (average 1.85–1.87 Å). Very similar behavior is shown by dithia dioxime ligands. The $\{S_2N_2\}$ coordination in the square planar Ni^{II} complex is stabilized by the short effective hydrogen bond between two oxime oxygen atoms.[553] A tetraoximic analogue of EDTA, ethylenedinitrilo-tetraacetamidooxime, which is potentially a six-coordinate ligand involves all four oxime nitrogen donors to coordinate the Ni^{II} together with two tertiary amine nitrogen donors.[554]

6.3.4.4.5 Complexes with chelating ligands incorporating N-heterocycles

N-heterocyclic compounds containing six-membered rings (pyridine and analogues) behave as excellent π-acceptors and in turn they provide a rather soft site for metal ion coordination. The π-excessive five-membered pyrazole is a poorer π-acceptor and a better π-donor and it acts as relatively hard donor site. Inclusion of six- and five-membered N-heterocycles like pyridine and pyrazole in one ligand system leads to very attractive coordination chemistry with variations of the electronic properties.[555] The insertion of a spacer (e.g., methylene groups) between two heterocycles, which breaks any electronic communication, makes the coordination properties even more manifold.

Pyrazolate as a ligand can exhibit various coordination modes, *inter alia*, monodentate, *exo*-bidentate, and *endo*-bidentate. Several review articles have been published in the field.[556–559] The use of pyrazole in the modeling of biological systems was also reviewed.[560,561] The most common application of pyrazole ligands is to use its *exo*-bidentate coordination mode linking two metal centers that may be identical or different (compare Section 6.3.4.12.6). Polypyrazolylborates and related ligands are covered in the subsequent section.

The bidentate ligand (**160**) forms a dimeric compound $[Ni(\mathbf{160})Cl_2]_2$ incorporating two chloride bridges,[562] where both metal centers are in a distorted trigonal bipyramidal $\{N_2Cl_3\}$ environment. Two pyrazole rings are linked by a short bridge, e.g., borate in (**161**), which prevents coordination to one of the pyrazole N atoms. Hence, (**161**) acts as a bidentate ligand and is very effective in metal extraction.[563] Substitution of the pyrazole rings by methyl groups may change distinctly the complex stability and selectivity in the metal extraction. The small Ni^{II} ion usually forms square planar complexes, but when both pyrazoles bear methyl substituents, steric hindrance causes the $[Ni(\mathbf{161})_2]$ species to be highly strained and less stable than complexes with larger metal ions. One pyrazole and one benzimidazole linked by a methylene group (**162**) forms $[Ni(\mathbf{162})_2(ClO_4)]^+$ with a chelating bidentate perchlorate.[564] The complex can have a Λ configuration with the chelate rings in boat conformation α, or a Δ configuration with the chelate rings in β-conformation. This conformational flexibility in the coordination of Ni^{II} is proposed to have implications for asymmetric catalysis.[565]

(163)

Bis(2-benzimidazolyl)ethane (**163**) forms mononuclear $[Ni(\mathbf{163})_2]^{2+}$ with the Ni^{II} ion surrounded by four N atoms in an almost perfect square planar geometry.[566]

The simple tris(biimidazolato)nickel(II) complex has been known for a long time. However, it is still a very attractive unit to build cation-mediated 1-, 2-, and 3-D superstructures.[567–569] The production of such molecular architectures by a one-pot molecular self-organization of the anionic building blocks $[Ni(Hbim)_3]^-$ (**164**) evolves from three basic factors: (i) the presence of three complementary binary hydrogen bonding sites, (ii) the occurrence of Δ and Λ optical isomers of the anionic nickel building blocks, and (iii) the identity of the counterions. Simplified self-organized superstructures are shown in (**164a**)–(**164d**).

Bis(1-pyrazolylmethyl)amine (**165**) acts as a tridentate ligand that forms [Ni(**165a**)$_2$]$^{2+}$ with almost octahedral geometry and *fac* coordination of the ligands.[570] A similar ligand with dimethyl-substituted pyrazoles (**165b**) forms [Ni(**165b**)(NO$_3$)$_2$] with the metal ion surrounded by two pyrazoles and one tertiary amine N atom as well as three nitrate O atoms (one of the nitrates acts as a bidentate ligand).[571] Two pyrazoles combined with one pyridine (**166**) results in [Ni(**166**)$_2$]$^{2+}$, which is an octahedral complex. The Ni—N$_{\text{pyridine}}$ bond is longer than

Ni—N$_{\text{pyrazole}}$.[572] Tridentate (**167**) forms five-coordinate [Ni(**167**)Cl$_2$] with trigonal bipyramidal geometry, while (**168**) forms octahedral [Ni(**168**)(H$_2$O)$_2$]Cl$_2$. The presence of the basic phenantroline allows the ligand to stabilize the Ni^{I} species as revealed by a quasi-reversible Ni^{II}/Ni^{I} wave at $E_{1/2} = -0.46$ V vs. AgCl/Ag$^+$ (for [Ni(**167**)Cl$_2$]).[573]

The combination of imidazole and pyrazole units leads to multidentate ligands useful for biological modeling. Potentially pentadentate (**169**) forms a six-coordinate Ni^{II} complex with a distorted octahedral {N$_4$O$_2$} geometry.[574] One of the ligand imidazole groups is not involved in the coordination and nitrate acts as bidentate ligand. A pyrazole moiety in Schiff base-type tetradentate N ligands may have a strong impact on the complex structure even if not directly bound to the metal ion. Increase of the polymethylene chain in *N*,*N′*-bis(5-aminopyrazol-4-ylmethylene)polymethylenediamine forces a gradual alteration of the configuration at the metal center from planar to tetrahedral.[575] Ni^{II} complexes (**170**) with $n = 2$ or 3 are square planar both in the solid state and solution, whereas in the case of (**170f**) with $n = 4$ the complex is diamagnetic in the solid state and a rapid (on the NMR timescale) equilibrium between planar ($S = 0$) and tetrahedral ($S = 1$) forms is observed in chloroform solution. Strong tetrahedral distortion from planar metal configuration is also evident from the X-ray crystal structure of (**170f**).

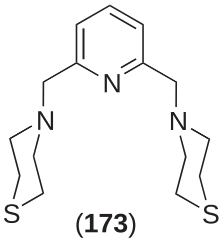
H(**172**)



(173)

Pyridine, which has a softer N-donor atom than pyrazole, is one of the most prominent coordinating units for the Ni^{II} ion. It has been combined with a variety of other donor systems forming very specific metal complexes. In the case of pyridine-substituted urea (**171**) an involvement of the pyridine nitrogen in metal ion binding induces Ni^{II} ion coordination to the urea N atom.[576] This N-coordination of urea is not enforced by the geometry of the ligand (in the related Zn^{II} complex the urea moiety exhibits the standard mode of binding via its oxygen donor). 4-Methyl-*N*-(pyridin-2-yl-ethyl)-benzenesulfonamide (H[**172**]) forms [Ni(**172**)$_2$] with the metal ion in a distorted square-planar environment defined by two pyridyl and two amide nitrogen atoms.[577]

Tridentate 2,6-bis(thiomorpholinomethyl)pyridine (**173**) forms only the 1:1 complex [Ni(**173**)(NO$_3$)$_2$] with Ni^{II}. However, the geometry around the metal center is octahedral due to coordination of two nitrates, one as a monodenate and the other as a bidentate ligand.[578]

Complexes with pyridine-2,6-diimine ligands, five-coordinate [NiX$_2$(**174**)] (X = Cl, Br) or six-coordinate [Ni(**174**)$_2$]X$_2$, were usually assumed to have innocent neutral ligands. The X-ray structure and spectroscopic characteristics of [Ni(**174**)$_2$](PF$_6$) confirm that the complex contains the neutral ligand ([**174**]^0) and a divalent nickel ion.[579] The cyclic voltamogram of this complex in CH$_2$Cl$_2$ shows three reversible one-electron-transfer processes at = 1.19 V, −1.30 V, and −1.82 V (vs. Fc$^+$/Fc), of which the first is a one-electron oxidation, while the other two correspond to two successive one-electron reductions. The spectroscopic data allow one to assign these processes as follows ([**174**]$^{1-}$ is a one-electron reduced radical form of [**174**]^0): [Ni^{III}(**174**)$^0{}_2$]$^{3+}$ $\rightleftharpoons$ [Ni^{II}(**174**)$^0{}_2$]$^{2+}$ $\rightleftharpoons$ [Ni^{I}(**174**)$^0{}_2$]$^+$ $\rightleftharpoons$ [Ni^{I}(**174**)^0(**174**)$^{1-}$]^0.

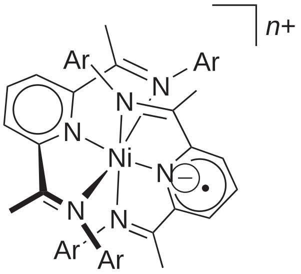
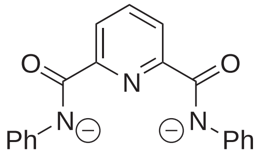
$[\mathrm{Ni^{II}}(\mathbf{174})^0{}_2]^{2+}$
$[\mathrm{Ni^{I}}(\mathbf{174})^0{}_2]^{+}$



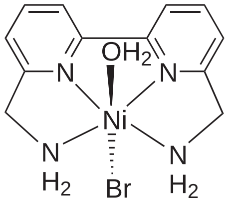
$[\mathrm{Ni^{I}}(\mathbf{174})^0(\mathbf{174})^{1-}]$



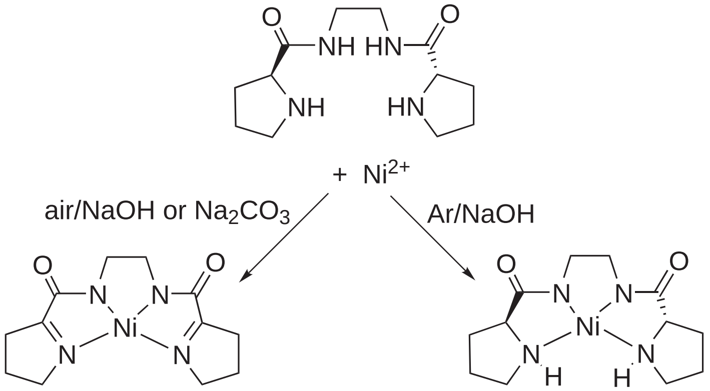
(**175**)

The addition of two amide nitrogen donors to a pyridine moiety in 2,6-bis(*N*-phenylcarbamoyl)pyridine (H_2[**175**]) allows stabilization of the higher oxidation states $\mathrm{Ni^{III}}$ and $\mathrm{Ni^{IV}}$ (see Section 6.3.3.3.1). In the $\mathrm{Ni^{II}}$ complex $[\mathrm{Et_4N}]_2[\mathrm{Ni}(\mathbf{175})_2]\cdot\mathrm{H_2O}$, the metal ion is coordinated by four deprotonated amide nitrogens in the equatorial plane and two pyridine nitrogens in the axial positions.[580] The arrangement of the ligands is meridional and the geometry of the $\{\mathrm{NiN_6}\}$ polyhedron is distinctly compressed.

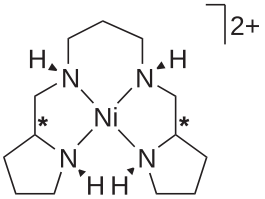
$\mathrm{Ni^{II}}$ complexes (**176**) of a tetradentate 2,2′-bipyridyl derivative feature unusual stabilities.[581] In the solid state, the complex contains a six-coordinate metal ion with bromide and water completing the coordination sphere. The low stability of the complex in aqueous solution results from the low ligand basicity and the unfavorable spacing of its donor groups as seen in the solid-state structure. Acyclic diamide–dipyridyl tetradentate ligands with two central amide groups form $\mathrm{Ni^{II}}$ complexes having the ability to cleave DNA in the presence of oxidants, as do $\mathrm{Ni^{II}}$ complexes with oligopeptides.[582] The same behavior is found for the pyrrolidine-based analogue (**177**). When its $\mathrm{Ni^{II}}$ complex is prepared in the presence of air, two amine groups undergo oxidative dehydrogenation.[583] The $\mathrm{Ni^{III/II}}$ reduction potentials of complexes with pyridyl- and pyrrolidine-based diamide ligands do not show any correlation with the ease of ligand oxidation.



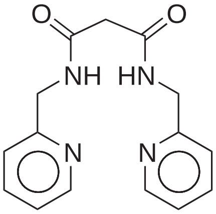
(**176**)



(**177**)



(**178**)



(**179**)

Racemic amino acids have been resolved via stereoselective coordination to the square planar chiral matrix complex (**178**).[584] The bisamidobispyridyl ligand (**179**) forms a square planar Ni^{II} complex with considerable tetrahedral twist due to repulsion of the *ortho* protons of the pyridyl rings.[585]

The terpyridine (terpy) unit is widely used to design multidentate ligands which are attractive for, *inter alia*, supramolecular chemistry.[586–588] The use of two covalently linked terpy moieties results in octahedral Ni^{II} monomeric complexes, but the length of the linker is critical for their stability. Complexes with (**180a,b**) are six-coordinate and relatively strain free, because the butane linker is optimal for complex stability.[589] The structure of the [Ni(**180a**)]$^{2+}$ cation is slightly bowed with the angle between the two mean terpyridine planes around 85°. For [Ni(**180b**)]$^{2+}$ this angle is close to 89°.

Tris(2-pyridyl) tripod ligands which use nitrogen, phosphorus, arsenic, or carbon as central bridging atoms are very useful tridentate ligands both in Ni^{II} coordination and organometallic chemistry.[590] Tripodal tris(2-pyridyl)amine (tpa, (**181a**)) forms centrosymmetric [Ni(**181a**)$_2$]$^{2+}$.[591] Similar to a pyrazole tripod (*vide supra*), tripodal pyridine ligands induce a strong ligand field due to relatively short Ni—N distances. An angular overlap study indicates that pyridines are moderately strong σ-donors and weak π-donors. A comparison of the amine, methyl, and phosphine analogues shows negligible, if any, conjugation of the π-system across the bridgehead atom.

(182)

The potentially heptadentate tripod tris{2-[(2-pyridylmethyl)amino]ethyl}amine (**182**) does not show any particular effect on the electronic or steric properties of its Ni^{II} complex in the solid or solution phase, although it is playing a part in enforcing six-coordination on the Ni^{II} ion in the gas phase.[592] Such a type of tripod ligand has interesting chiral properties. The tris-imidazole-based ligand tris[2-(((2-phenylimidazole-4-yl)methylidene)amino)ethyl]amine (H_3L) forms chiral [NiH$_3$L]X$_2$ complexes ((**183**); X = nitrate, acetate, or perchlorate). Each complex has an octahedral coordination environment for the metal ion, formed by six N atoms, and is either a Δ (clockwise) or a Λ (anticlockwise) enantiomorph, depending on the screw arrangement of the tripodal ligand around the nickel ion.[593] CD spectra and crystal structures provide strong evidence for spontaneous resolution of the chiral molecules.

Ni^{II} complexes with open-chain pyrrolic ligands bear certain similarities to Ni–porphyrins (compare Section 6.3.4.11.3). Ni^{II} complexes of various differently substituted 2,2′-bidipyrrins (**184**) are diamagnetic, despite the tetrahedral deviation from square planar coordination geometry.[594,595] The complexes are helical, and even the methyl terminated species are extremely stable towards racemization (no racemization after prolonged heating to >200 °C; *t*-butyl groups at the termini are sterically too demanding to give stable Ni^{II} complexes). In comparison to the related porphyrinato–Ni^{II} complexes, complexes (**184**) have a much smaller HOMO–LUMO gap due to a significantly raised HOMO, which gives rise to a red shift of the longest-wavelength UV–visible absorption. Ni^{II} complexes of α,ω-dimethyltripyrrins (**185**) are paramagnetic and their coordination geometry can best be described as distorted trigonal bipyramidal with one equatorial ligand missing. This is enforced by the terminal methyl groups of the tripyrrolic ligand which shield the fourth site of a putative square around the metal ion and force the coligand above or below the $\{NiN_3\}$ plane. A fifth ligand such as water can easily be accepted to give five-coordinate species.[596]

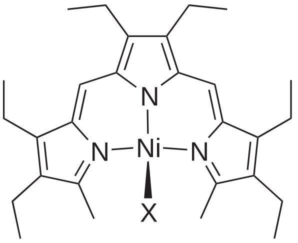
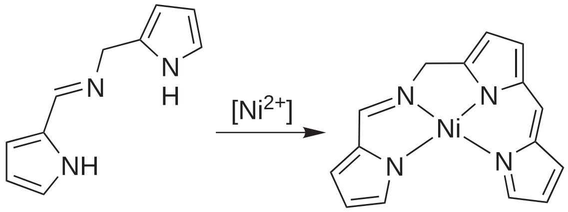
(**184**)



(**185**)



(**186**) (**187**)

A square planar Ni^{II} complex (**187**) of a tripyrrolic tetradentate ligand was obtained unexpectedly from the reaction of (**186**) with $Ni(OAc)_2$.[597] The reaction presumably proceeds via Ni-mediated partial cleavage of (**186**) to give 2-formylpyrrol and its subsequent condensation with a second equivalent of (**186**). The Ni^{II} complex of *meso*-phenyl-4,6-dipyrrin (**188**) is severely distorted from square planar (angle between the planes of the two dipyrrin ligands $\sim$40 °C) but still diamagnetic.[598]

Optical spectra of the Ni^{II} complex (**189**) show close similarity to those of Ni–phtalocyanines in the low-energy spectral region where the first π–π^* transition (Q band) occurs.[599,600] A reduction of the Ni—N distance causes a red shift of the Q band, as deduced from a comparison of (**189**) with the related mixed-ligand compound (**190**) and its pyridine adduct [(**190**)·2py].[600]

6.3.4.4.6 *Complexes with polypyrazolylborates and related tripodal ligands*

The family of poly(pyrazol-1-yl)borates has been widely used as supporting ligands in nickel coordination chemistry.[556,557] Complex (**191**) is an example, where unusual cysteine coordination is achieved at a tris(pyrazolylborate)nickel(II) template.[601] (**191**) undergoes rapid reaction with molecular oxygen to presumably form a sulfinate.

Properties of nickel poly(pyrazol-1-yl)borate complexes such as solubility, coordination geometry, etc., can be controlled by appropriate substituent groups on the pyrazol rings, in particular in the 3- and 5-positions. Typical complexes are those of octahedral (C_{3v}) symmetry (**192**)[602–604] and tetrahedral species (**193**). In the former case, two different tris(pyrazolyl)borate ligands may be involved to give heteroleptic compounds.[602,603] Substituents in the 5-position mainly provide protection of the BH group. Only few representative examples are discussed here.

Even in the case of bulky substituents in the 3-position of the pyrazoles (e.g., in (**194a**)), octahedral complexes may be formed. However, while [Ni(**194a**)$_2$] is octahedral in the solid state, it is five-coordinate in the melt or in solution. Upon heating, [Ni(**194a**)$_2$] rearranges to the thermally very stable complex [{HB(3-neopentyl-pz)$_2$(5-neopentyl-pz)}$_2$Ni], in which one of the neopentyl groups has migrated from the 3- to the 5-position.[604] This underscores the driving force toward octahedral structures in these compounds, even in the presence of steric bulk. The tendency for the stabilization of tetrahedral species (**193**) (with respect to conversion to (**192**)) increases with the hierarchy of steric hindrance as a function of the 3-R group: $\mathrm{H} < $ 2-thienyl $< \mathrm{Me} < \mathrm{Ph} < \mathrm{Pr^i} < \mathrm{Bu^t}$.[605,606] However, steric effects are not always straightforward: [Ni(**194a**)NCS] is monomeric while [Ni(**194b**)NCS]$_2$ is a dimer (with S-bridging),[606] but [Ni(**194a**)$_2$] could be isolated while [Ni(**194b**)$_2$] could not. Ligands (**194b–d**) exhibit similar coordination chemistry, although complexes derived from the cyclohexyl-substituted ligands show greater stability.[607] A distinction, however, is the reaction with oxalate, where either the simple oxalate-bridged dinuclear species [Ni(**194b**)]$_2$(C$_2$O$_4$)[602] or the unusual complex [Ni(**194d**)(3-cyclohexyl-4-Br-pz)](H)$_2$ is formed.[607]

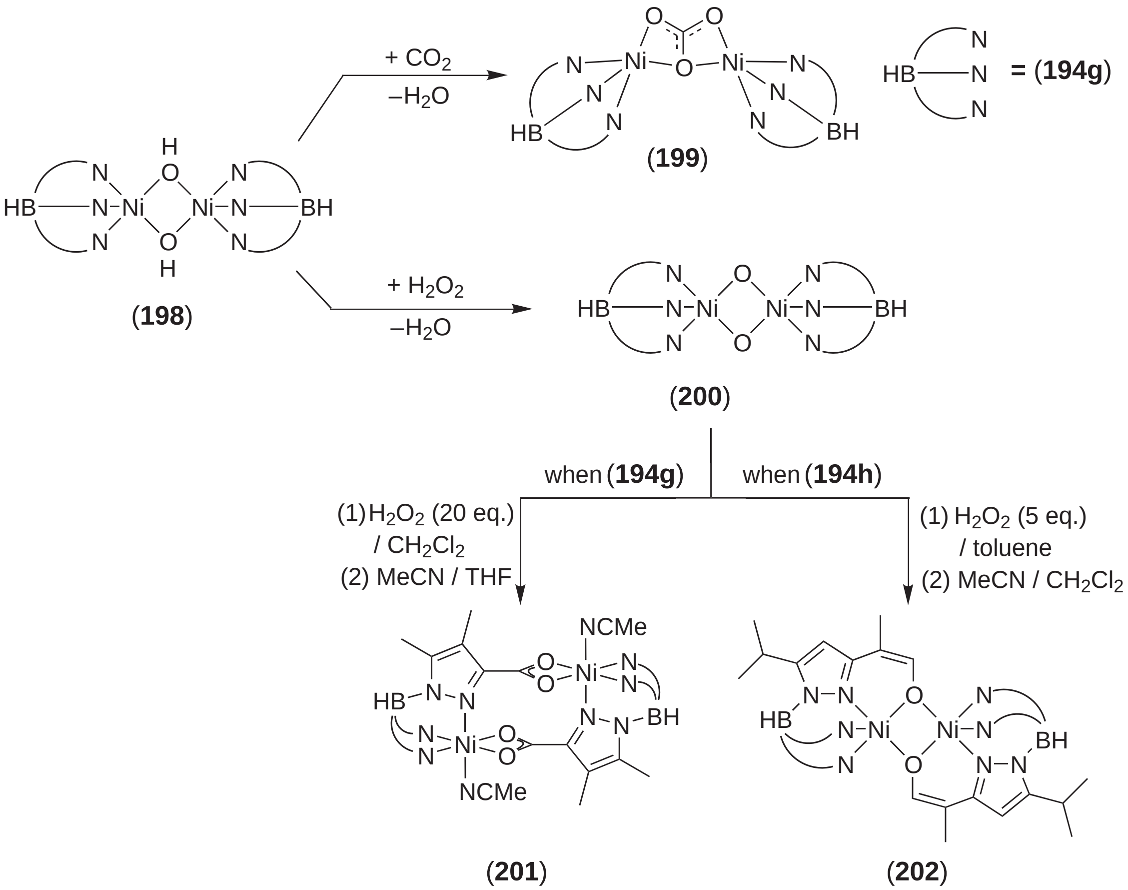
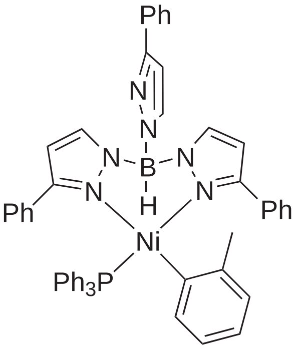
(**197**)

Very bulky (**194e**) coordinates monohapto in the Ni^{II} complex (**195**), both in solution and in the solid state.[608] Upon reaction of (**194e**) with *trans*-[Ni(CH$_2$R)Cl(PMe$_3$)$_2$], however, (**196**) is formed in low yields.[609] (**196**) is also accessible directly from NiCl$_2$ and (**194e**).[610,611] Treatment of (**194e**) with [NiCl$_2$(py)$_4$] gave the homoleptic complex (**197**).[609] In contrast to other complexes [Ni{H$_2$B(3-R-5-R′-pz)}$_2$] which are usually orange and square planar (hence diamagnetic),[612] (**197**) is pale blue and paramagnetic ($\mu_{eff} = 2.9\,\mu_B$). The X-ray crystal structure reveals that the square planar NiN$_4$ arrangement is complemented by two trans Ni···H—B interactions.

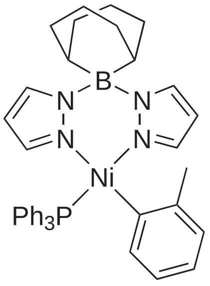
The dinuclear hydroxo-bridged Ni^{II} complex (**198**) fixes atmospheric CO$_2$ to give the μ-carbonato species (**199**).[613] A similar coordination mode of carbonate is also seen with ligand (**194c**).[607] Upon treatment with 1 N NaOH, the carbonato complex (**199**) is converted back to the hydroxo complex. When [Ni(**194g**)(OH)]$_2$ was reacted with H$_2$O$_2$ at low temperatures, the bis(μ-oxo)nickel(III) complex (**200**) could be isolated and structurally characterized.[181,182] Both [Ni(**194g**)(OH)]$_2$ and (**200**) contain five-coordinate Ni ions with a slightly distorted square pyramidal geometry. (**200**) decomposes within 1 h at room temperature via oxidation of the methyl substituents at the (**194g**) ligand, with H-atom abstraction being the rate-determining step. In the presence of excess H$_2$O$_2$, products (**201**) and (**202**) are formed, depending on the ligand employed.[182,614]

In square planar (**203**), the ligand (**194f**) acts as a bidentate. Despite the presence of the potentially coordinating third pyrazole group, (**203**) is an active catalyst for the alternating copolymerization of CO and ethylene.[615] Similar activity is displayed by complex (**204**), indicating that neither the borane H atom nor the noncoordinating pyrazole ring are essential for the catalysis.[616]





(203)



(204)

Tris(3-methyl-5-carboxyethylpyrazol-1-yl)borate forms the Ni^{II} complex (**205**) with three water molecules completing the octahedral geometry (Figure 7). The ester groups of the tripod ligand act as H-bond acceptors and stabilize the triaqua species, which is a structural model for enzymes of the vicinal oxygen chelate superfamily.[617] (2-Hydroxy-phenyl)bis (pyrazolyl)methanes act as tripod ligands.[618] For the unsubstituted ligand (**206**), the absence of steric bulk on the pyrazoles allows two ligands to coordinate to one metal ion in a tridentate fashion with the two phenoxy groups in *trans* position to each other. 3,5-Dimethyl substitution does not produce much bulk, but besides the [Ni(**206**)$_2$] species a dinuclear complex [Ni(**206**)$_2$NiCl$_2$] is also formed. Introduction of 3-isopropyl substituents prevents formation of the NiL_2 complex due to steric reasons, and oligonuclear species are formed instead.

The coordination mode of bis(imidazolyl)(pyrazolyl)borates towards Ni^{II} depends on the steric congestion around the boron center caused by substituents in the pyrazol 5-position. Complexes (**207**) or (**208**) have been obtained upon reaction with $Ni(NO_3)_2$.[619] The tripodal ligand

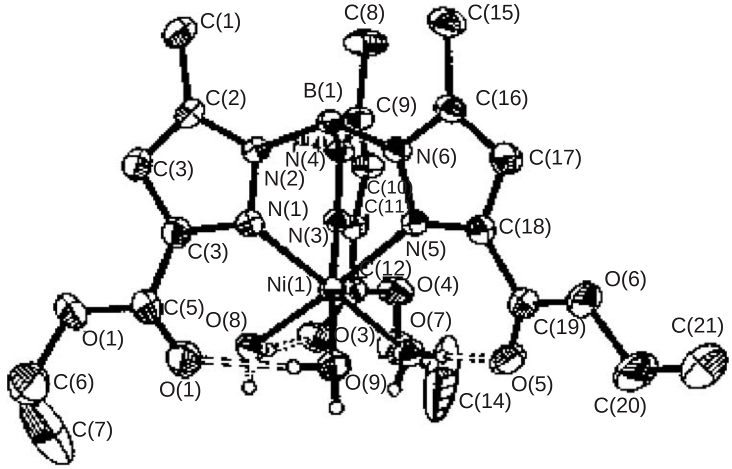


Figure 7 Molecular structure of (**205**)[617] (reproduced by permission of The Royal Society of Chemistry).

tris-(pyrazol-1-yl)methane forms $[Ni\{(pz)_3CH\}_2](NO_3)_2$ which has an octahedral geometry with slight trigonal distortion.[620] The pyrazol group acts as a moderately strong σ-donor and a weak out-of-plane π-donor. The tripod ligand produces a relatively strong ligand field, consistent with rather short Ni—N bond lengths (2.072–2.084 Å).

twist-boat conformation boat conformation

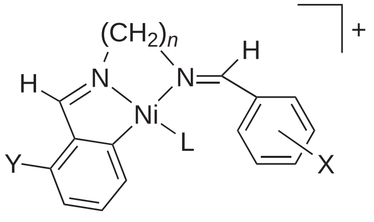
6.3.4.4.7 *Complexes of miscellaneous nitrogen ligands*

Tripodal polyamine ligands derived from amino acids are used to mimic metal–peptide systems relevant to metal pharmaceuticals[621] as well as for combinatorial screening of catalytically active metal complexes.[622] The Ni^{II} complex formed with *N,N*-bis(picolylamino)acylglycine is of octahedral structure with tetradentate ligand coordination.[623] The octahedral structure is typical for Ni^{II} complexes with tetradentate tripodal ligands based on bispicolylamine.[624] However, the glycine derivative forms a neutral complex with two chlorides coordinated in *cis* position to each other.

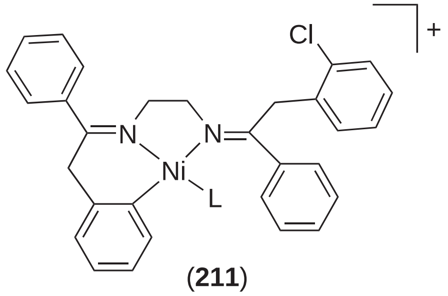
Classical metal complexes with 1,10-phenantroline (phen) or modified phen ligands are particularly attractive compounds for developing of new diagnostic and therapeutic agents that can recognize and cleave DNA.[625] However, Ni^{II} complexes with this family of ligands are less promising in this respect. A dipyridophenazine (dppz) complex of Ni^{II}, $[Ni(phen)_2(dppz)]^{2+}$, did not show any light-induced nuclease activity, probably because of the paramagnetic nature of the complex that would render the excited state of the molecule ineffective.[626]

The Ni coordination chemistry of aniline is receiving comparatively little attention because aniline forms relatively weak Ni—N bonds. The low stability is overcome by attaching aniline to effectively coordinating aza macrocyclic backbones (see also Section 6.3.4.10.2). 1,4-Bis(*o*-aminobenzyl)-1,4-diazacyclohexane (**209**) crystallizes as a diamagnetic planar [Ni(**209**)]$(ClO_4)_2$ complex.[627] The [Ni(**209**)]$^{2+}$ cation has two six-membered chelate rings with different conformations, boat and twist-boat. In coordinating solvents (py, DMF) or in the presence of coordinating anions (NCS^-), [Ni(**209**)]$^{2+}$ becomes blue and paramagnetic. In the neutral $[Ni(NCS)_2$(**209**)], the coordination by (**209**) is identical to that in the planar complex but with two axial N-bound NCS^- in *trans* position to each other.

Nickelacycles with anionic C—N—N tridentate ligands containing (5,5)-, (5,6)-, (5,7)-, and (6,5)-membered fused rings based on dibenzylidene diamines and 1,2-diphenylethylidene have been synthesized (**210**, **211**).[628] When the Ni—C bond is involved in a six-membered ring, neutral or ionic planar complexes show moderate ability to activate the insertion reaction in the ethylene oligomerization test. A promising application of metallodendriditic macromolecules is their use in homogenous catalysis. This stimulated the synthesis of Ni-coated carbosilane dendrimers with NCN-chelating aryldiamine anchor ligands $[2,6\text{-}(CH_2NMe_2)C_6H_3]^-$ (**212**).[629,630] The carbosilane support plays a pivotal role in an active site accessibility and catalytic activity of the nickelated dendrimers.



(210)



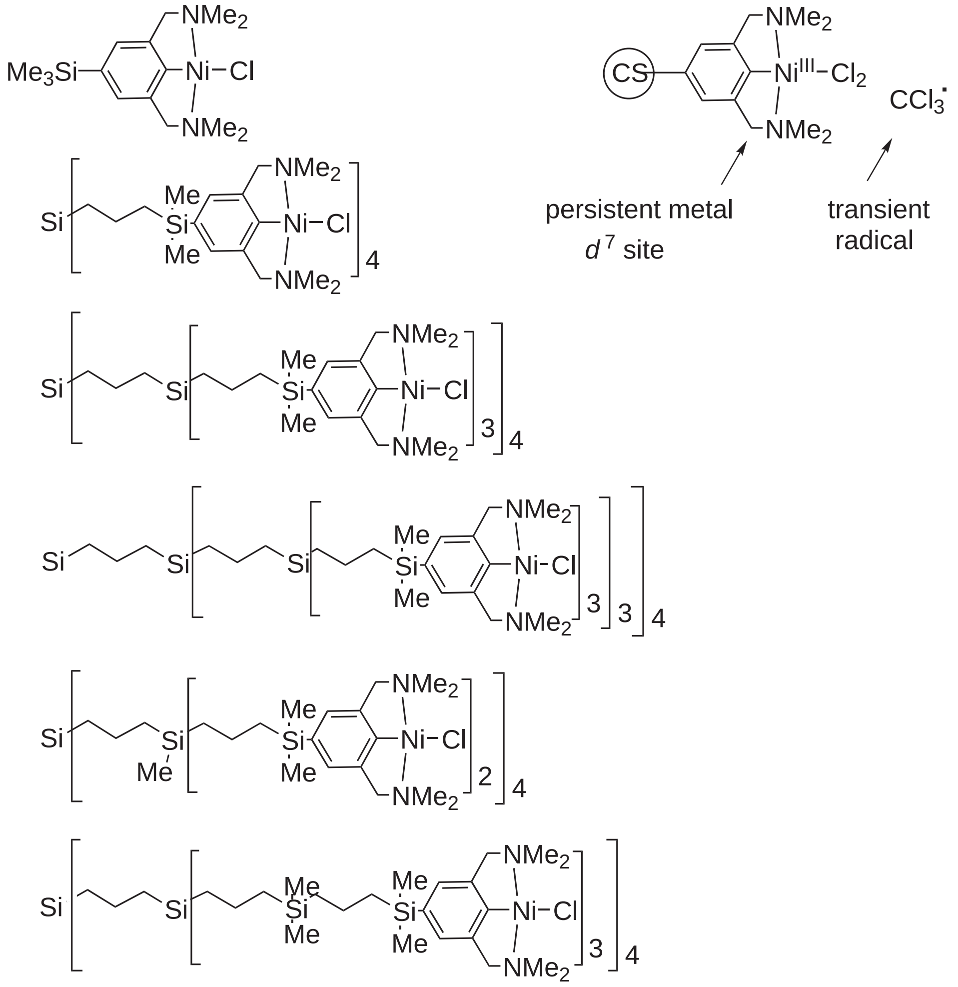
(211)

Thiazyldialkylamide $N{\equiv}SF_2(NR_2)$ can act as an N-donor ligand towards Ni^{II}, either terminal (**213**) or bridging (**214**).[631] Phosphaneiminato ligands (**215**) usually form heterocuban-type complexes $[NiX(NPR_3)]_4$ (X = Cl, Br, I) with a $\{Ni_4N_4\}$ skeleton.[632–634] These have shown some promising activity in olefin polymerization.[635] Neutral phosphaneimine $HN{=}PR_3$ also forms complexes with Ni^{II}, as was shown for the crystallographically characterized $[NiBr_2\{HNP(NMe_2)_3\}_2]$ with the metal atom in a distorted octahedral $\{Br_2N_2\}$ surrounding.[634]

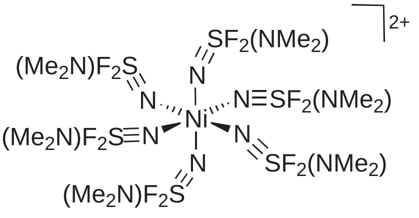
6.3.4.5 Complexes with Ligands Containing Phosphorus, Arsenic, and Antimony as Donor Atoms

6.3.4.5.1 *Complexes with mono- and oligodentate phosphine ligands*

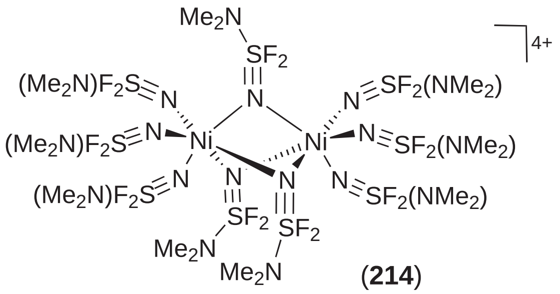
The Ni—P bond is one of the basic motifs in Ni-based catalysis and Ni organometallic chemistry. The earlier work on phosphine–nickel complexes has been reviewed.[636] The complex $[Ni(dppm)Cl_2]$ with the $Ph_2PCH_2PPh_2$ (dppm) ligand is square planar. Complexes of formula



(**212**)



(**213**)



(**214**)

$R_3P{=}N^-$

(**215**)

$[(dppm)_2MCl_2]$ are ionic for M = Pd, Pt with two phosphines bound as {P,P} chelates, while it is nonionic for M = Ni. It was assumed that in the nickel complex two phosphines are bound as monodentate ligands because of the four-membered ring strain. The X-ray structure has shown, however, that the complex is five-coordinate with both monodentate and bidentate dppm ligands and two chlorides completing the coordination.[637]

$[NiBr_2(PEtPh_2)_2]$ has pseudotetrahedral coordination[638] while $[Ni(N_3)_2(PEt_3)_2]$ has a *trans*-planar geometry;[639] charge-transfer photolysis of the latter gives dimeric $[\{Ni(N_3)_2\ (PEt_3)\}_2]$. In the square planar Ni^{II} complex [Ni(*cis*-dppen)Cl_2] (*cis*-dppen = *cis*-bis(diphenylphosphino)ethene), a slight tetrahedral distortion caused by crystal packing effects is observed.[640] The *cis*-dicyanide complex [Ni(*cis*-dppen)$(CN)_2$] has a similar structure, but comparison with the respective Pd^{II} and Pt^{II} complexes indicates that C—H···Ni repulsive contacts may also lead to small deviations from coplanarity.[641] The unsaturated nature of (dppen) gives rise to π-bonding interactions with the Ni—ligand bonds, which causes a very high stability of the *cis*-dicyanide complex. It is interesting to note that removal of coordinated chloride in [Ni(*cis*-dppen)Cl_2] by $AgBF_4$ followed by subsequent coordination of bis-(diphenylphosphino)amine (dppam) gives the five-coordinate complex [Ni(*cis*-ddpen)(dppam)Cl](BF_4).

The unsymmetrical triphosphine ligand $Ph_2P(CH_2)_3PPh(CH_2)_2PPh_2$ is a simple analogue of the well-known bidentate ligands $Ph_2P(CH_2)_nPPh_2$ ($n = 2, 3, 4, \ldots$). It is able to establish tridentate coordination to the Ni^{II} site of a square planar complex. Chiral tridentate phosphines $R_2P(CH_2)_3PPh(CH_2)_2PPh_2$ ($R = C_6H_5$, p-ClC_6H_4, p-FC_6H_4) form a series of diamagnetic [NiLX]X complexes. In the solid state the complex with X = I exhibits five-coordination with only a slight distortion of the square pyramid.[642] However, the Ni—I bond lengths reveal that the second apical iodide is only weakly bound to the nickel ion, which explains the square planar geometry found in solution.

The neopentane-based triphos ligands $RC(CH_2PPh_2)_3$ (**216**) are prominent scaffolds in Ni coordination chemistry, in particular for low-valent Ni^0 and Ni^I. These ligands can also be functionalized at the backbone R substituent, e.g., in [{$PhCH_2C(CH_2PPh_2)_3$}NiCl].[643] Treatment of $[Ni(H_2O)_6]^{2+}$ with triphos initially gives red-brown (**217**), which upon addition of further $[Ni(H_2O)_6]^{2+}$ yields the hydroxo-bridged dimeric (**218**). The dangling P atoms of the latter can be oxidized by polysulfide to give the P=S species.[644] An all-phosphorus environment for Ni^{II} is found the crystallographically characterized (**219**) which features a cyclic P_3 unit.[645,646] $Pt(PPh_3)_2$ inserts into one of the P—P bonds of (**219**) to give [(triphos)Ni(P_3)Pt$(PPh_3)_2$].[647]

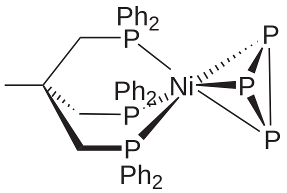
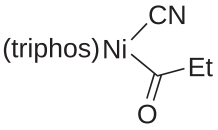
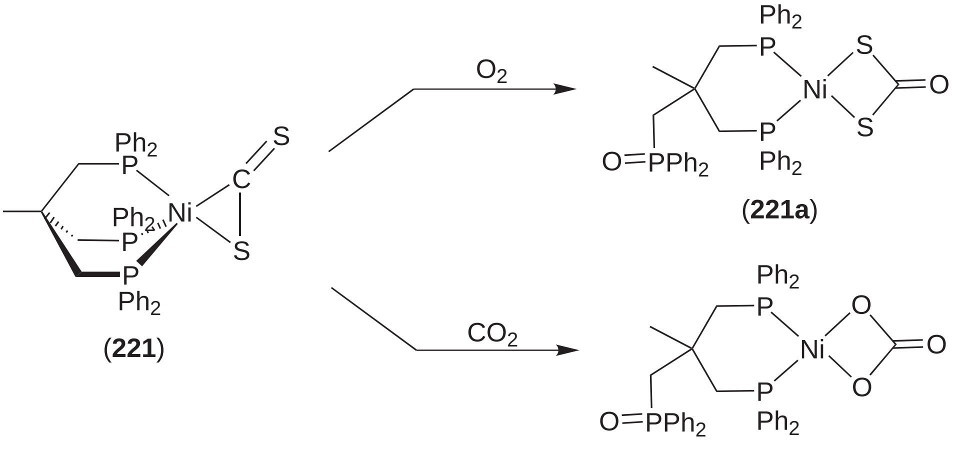
(**217**) (**218**)



(**219**)



(**220**)



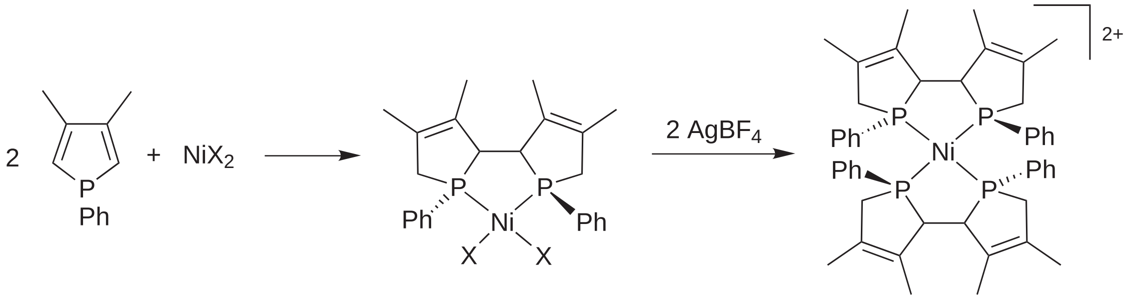
(**221**) (**221a**) (**221b**)

The (triphos)Ni^0 template reacts with ethyl cyanoformate to give (**220**).[648] The MO description and reactivity of the CS_2 complex (**221**) has been studied in some detail.[649] Treatment with O_2 gives the dithiocarbonate compound (**221a**),[650] while bubbling of CO_2 through a solution of (**221**) yields the carbonato complex (**221b**).[651] In both cases, one of the phosphine arms has been oxidized and is found dangling.

Reaction of [(triphos)Ni(S_2CS)] with $Ni(BF_4)_2$ and $NaBPh_4$ yields the dinuclear complex [(triphos)Ni(μ-CS_3)Ni(triphos)]$(BPh_4)_2$.[652]

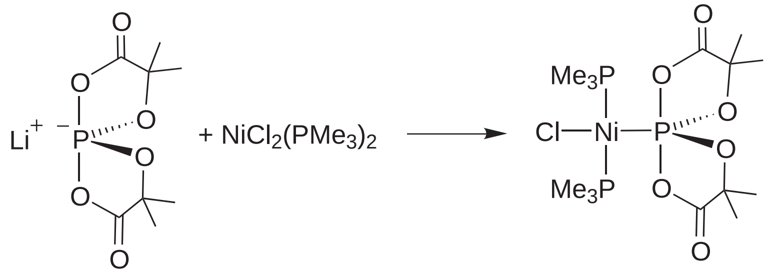
Thermolysis of 1-phenyl-3,4-dimethylphosphole in alcoholic solvents in the presence of $NiCl_2$ leads to the synthesis of the racemic biphospholene complex (**222**).[653,654] Upon reaction of the bromo derivative with $AgBF_4$, the meso and racemic diastereomers of (**223**) are formed, which can be separated by fractional crystallization.[655] In both (**222**) and (**223**) the coordination sphere is slightly distorted from square planar.

Metal–phosphoranide complexes have been known for many years.[656] The use of LiBu to deprotonate spirobicyclic phosphorane followed by the reaction of the lithiated species with $[NiCl_2(PMe_3)_2]$ gives *trans*-$[(PMe_3)_2\ \{(C_4H_6O_3)_2P\text{-}P\}NiCl]$ (**224**), which is a square planar species with *trans*-PMe_3 ligands.[657] The large steric demands of the phosphoranide ligand result in some angular distortion seen by bending of the phosphine ligands toward the chlorine.



(**222**)

(**223**)

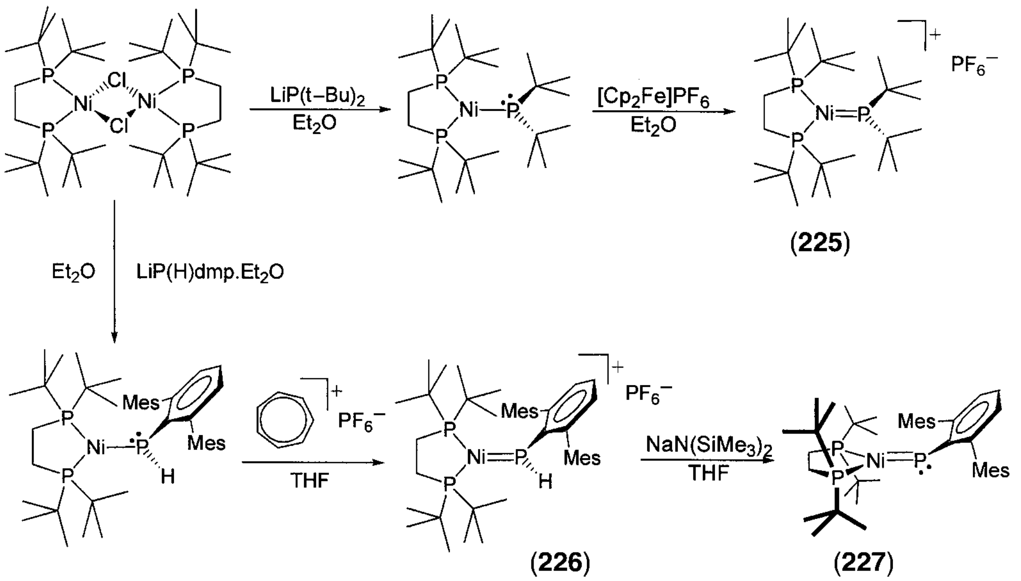


(**224**)

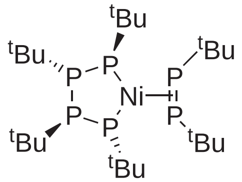
6.3.4.5.2 Complexes with phosphido and phosphinidene ligands

There are few well-characterized terminal phosphido complexes of nickel Ni^{II}. (**225**) and (**226**) have been obtained according to Equation (5).[658] The Ni—P bond length shortens considerably upon going from Ni^I to Ni^{II}, which is accompanied by planarization at P as required for in-plane Ni—P π-bonding. Deprotonation of (**226**) gives the bright green phosphinidene complex (**227**) ($\delta^{31}P = 970$ ppm). In (**227**), the Ni is distorted from planarity, the Ni—P bond length is similar to those in (**225**) and (**226**), and the Ni—P—Ar moiety is significantly bent (130.8° at P).

An unusual complex is (**228**), which forms upon reaction of $[NiCl_2(PMe_3)_2]$ with $K_2(Bu^tP)_2$.[659] Different mechanisms have been proposed for its formation, generally involving diphosphene Ni^0 intermediates.[660]



(5)



(228)

6.3.4.6.3 Complexes with mixed donor atoms involving phosphorus

Ni^{II} complexes with monodentate phosphines are countless. $P(CH_2OH)Ph_2$ is found in complex (**229a**) which forms upon reaction of $Na_2[Ni(CN)_4]$ with $PHPh_2$ and formaldehyde. One of the Ni—P bonds in (**229a**) is extremely long (2.400 Å), and (**229a**) readily dissociates one phosphine to give (**229b**).[661]

Hemilabile ligands containing a strongly coordinating donor center and one weakly binding donor center can be used to protect an active site metal center until it is required to effect a transformation of a substrate during a catalytically operating process. Polydentate ligands containing pairs of P and O or S donor atoms meet these requirements.[662–664] In Ni chemistry, hemilabile {P,O} ligands are prominent with a tertiary phosphorus atom, which is responsible for effective binding to the metal center, and a ketonic, carboxylic, oxidic, or alcoholic oxygen atom (or O atoms incorporated into ether moieties, both open chain and cyclic). These latter donors form only weak Ni—O bonds, which can be cleaved reversibly.[665] The earlier reviews devoted to the general chemistry of {P,O} ligands described most of the major achievements in the field.[662,666] A set of Ni^{II} complexes with various diastereoisomers of the P-containing macrocycle (**230**) has shown such flexibility of the Ni—O interactions.[667]

In square planar Ni^{II} complexes [Ni(Ph)(**231**)(PPh_3)] and *cis*-[Ni(**231**)$_2$], the bond lengths indicate considerable electron delocalization in the five-membered NiPCCO chelate rings.[668] The reaction of 3-diphenylphosphino-1,1,1-trifluoro-trifluoromethyl-2-propanol (**232**) with $[Ni(cod)_2]$ (cod = 1,5-cyclooctadiene) gives an active system for the formation of higher olefins from ethene. The reaction of $[Ni(cod)_2]$ with (**232**) in the presence of tricyclohexylphosphane results in complex (**233**), which has a square planar geometry.[669] The structure of the latter complex supports a nickel hydride mechanism in ethene oligomerization. Treatment of $[Ni(\eta^5\text{-}C_5Ph_5)X(CO)]$ complexes (X = I, Br) with phosphine-β-ketophosphorus ylide gives the {P,O} complex (**234**). This complex is a rare example of a keto-stabilized ylide nickel complex derived from the nucleophilicity of the oxygen atom.[670]

Ligands like diphosphine monoxides $Ph_2P(CH_2)_nP(O)Ph_2$, ((**235a**); $n = 1$–3) and pTol$_2$P-(CH$_2$)-P(O)pTol$_2$ consist of a soft phosphino group and hard phosphoryl group. With nickel they form cationic species with {P,O} chelation. Although X-ray structures are not available, the complexes seem to be monomeric species.[671] Biphosphine monoxides have been proven to behave as functionalized phosphines showing hemilabile behavior.[672] Se-containing $Ph_2PCH_2P(Se)Ph_2$ (**235b**) behaves very similarly to its O analog. It coordinates through the {P,Se} donor set forming $[Ni(\mathbf{235b})_2]Cl_2\cdot 2EtOH$ with square planar geometry.[673]

Ligands combining P-and S-donor atoms offer rich coordination chemistry since both P and S are excellent donors for a variety of metal ions, including Ni. Five main types of {P,S} ligands are usually distinguished: phosphino-thiols containing phosphine and thiol groups, phosphino-thioformamides, phosphino-dithioformates, diphoshine-monosulfides, and phosphino-thioethers. The coordination abilities of these ligands have been reviewed.[663]

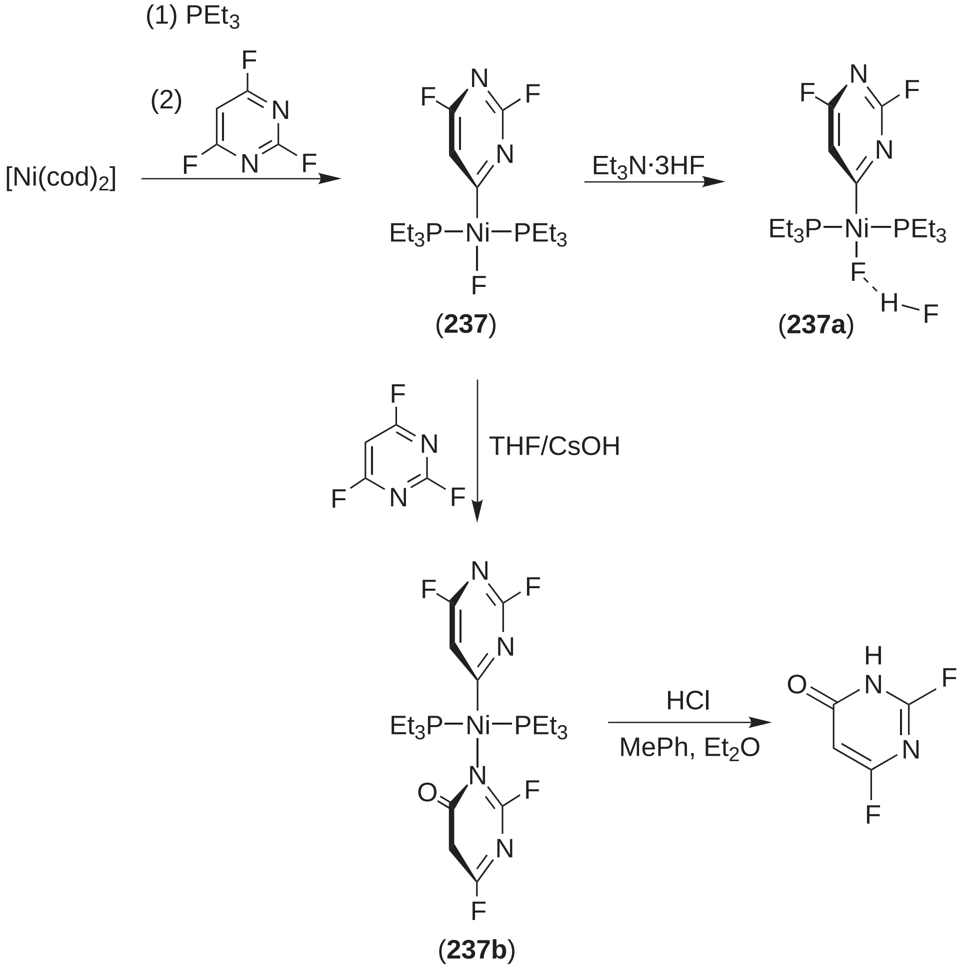
The coordination chemistry of phosphino-thiols and phosphino-thioethers towards nickel has been studied rather extensively. Phosphino-thiols (**236**) often give thiolate-bridged complexes like $[Ni(Ph_2PCH_2CH_2S)_2Ni(Ph_2PCH_2CH_2S)]^+$ and $[\{Ni(Et_2PCH_2CH_2S)_2\}_2Ni]^{2+}$.[674] The oligomerization reaction involves the isomerization of the original monomeric complex from the *trans*- to the *cis*-form as is also seen in the case of $[Ni(MePhPCH_2CH_2S)_2]$.[675] The formation of monomeric and dimeric complexes with $Ph_2PCH_2CH_2S^-$ is also likely.[305,676]

P-donor ligands are prominent spectator ligands that enable transformations at $\{NiP_x\}$ templates. When simple Ni^{II} salts are treated with thiols, different products are obtained depending on the bulkiness and basicity of the thiol ligand (compare Section 6.3.4.7). The presence of phosphines may induce the formation of monomeric complexes with mixed {P,S} coordination relevant to catalytic or biological sites. The complex $[NiBr_2(dippe)]$ (dippe = 1,2-bis(diisopropylphosphino)ethane) reacts with benzene- and polyfluorobenzene-thiolates yielding square planar complexes $[Ni(SR)_2(dippe)]$ ($R = C_6F_5$, C_6F_4H, C_6H_4F, or Ph).[677] These compounds further react with $CNBu^t$ yielding *cis*-$[Ni(SR)(CNBu^t)(dippe)](BPh_4)$, but they do not react with CO under the same conditions. The disphosphino complex also reacts with bidentate dithiocarbamate inducing its degradation and giving a square planar complex with dithiocarbonate $[Ni(S_2CO)(dippe)]$. Diphosphino complexes with bidentate dithiolates may be easily obtained starting from the corresponding bis(hydrosulfido) complexes $[Ni(dppe)(SH)_2]$ and the α-bromoketones (heterocycle–$C(O)CH_2Br$) (dppe = 1,2-bis(diphenyldiphosphino)ethane).[678] The resulting complexes $[Ni(dppe)(S_2C_2\text{–heterocycle})H]$ have slightly distorted square planar geometries around nickel and the metallo-1,2-dithiolate is ~6° from being coplanar with the heterocycle. In the monomeric $[Ni(dppp)(Se_2C_2(CN)_2]$ complex (dppp = 1,3-bis(diphenylphosphino)propane), the square planar geometry around the metal ion is formed by two bidentate ligands.[679]

New fluorinated azaheterocycles have been synthesized via C—F activation of fluorinated precursors by Ni.[680] The stepwise reaction of $[Ni(cod)_2]$ with PEt_3 and 2,4,6-trifluropyrimidine in hexane results in the fast and regioselective formation of the C—F activation product (**237**).[681] Addition of $Et_3N\cdot 3HF$ to (**237**) gives bifluoride complex (**237a**). Treatment with CsOH converts (**237a**) into (**237**) and (**237b**). Treatment of (**237**) or (**237a**) with the base in the presence of excess of 2,4,6-trifluoropyrimidine in THF results solely in (**237b**). Reaction of the latter with HCl liberates the oxygenated heterocycle. This set of reactions represents an interesting example of Ni-assisted C—F bond activation.

Several other methods for activation of C—F bonds with Ni–phosphine complexes have been reported.[682,683,2546,2577] Treatment of *trans*-$[NiF(2\text{-}C_5NF_4)(PEt_3)_2]$ ($C_5NF_4 =$ tetrafluoropyridyl) with HCl effects the formation of air-stable *trans*-$[NiCl(2\text{-}C_5NF_4)\ (PEt_3)_2]$. Reaction of this complex with an excess of HCl slowly gives 2,3,4,5-tetrafluoropyridine. The latter compound instantly reacts with $[Ni(cod)(PEt_3)_2]$ to form $[NiF(2\text{-}C_5NF_3H)\ (PEt_3)_2]$ via a C—F activation process.[684] Treatment of $[Ni(cod)_2]$ with trifluoroiodoethene or 1,1-dibromodifluoroethene in the presence of PEt_3 results in the formation of *trans*-$[NiI(CF{=}CF_2)(PEt_3)_2]$ (**238a**) and *trans*-$[NiBr(CBr{=}CF_2)(PEt_3)_2]$ (**239**), respectively.[685] Reaction of (**238a**) with $NaBAr'_4$ ($Ar' = 3,5\text{-}C_6H_3(CF_3)_2$) and acetonitrile gives complex (**238b**), treatment of (**238a**) with $NaBAr'_4$ in the presence of CO results in (**238c**) (which is stable in CH_2Cl_2), and the reaction of (**238a**) with BAr'_4 and Bu^tNC yields complex (**238d**). The highly electrophilic properties of the vinyl ligand cause that upon treatment of complex (**238d**) with PEt_3 and $NaBAr'_4$ the dicationic phosphonioethyl complex *trans*-$[Ni\{CF{=}CF\ (PEt_3)\}(CNBu^t)\text{-}(PEt_3)_2][BAr'_4]_2$ (**240**) is formed which features a phosphonioethenyl ligand bound to nickel.

A combination of P- and N- donors is another useful approach to potentially reactive (and catalytically active) Ni species. Similar to O- donors, N is a hard donor capable of stabilizing metal ions in higher oxidation states, whereas the soft donor P is best suited to stabilize medium or low oxidation states. A neutral bidentate {P,N} ligand combining a hard dimethylamino and a soft phosphine donor in *N*,*N*′-dimethyl-2-(diphenylphosphino)aniline (**241**) affords the neutral trigonal bipyramidal and the cationic square planar Ni^{II} complexes [$NiCl_2(PMe_2Ph)$(**241**)] and [$NiCl(PMe_2Ph)$(**241**)]PF_6, respectively.[686] The latter complex is an effective cocatalyst in propylene oligomerization.



Complexes [Ni(**242a**)$_2$]$(BF_4)_2$ and [Ni(**242b**)$_2$]$(BF_4)_2 \cdot MeCN$ with the imidazolylphosphine ligands adopt square planar structures with different configurations. In the former complex the two P atoms are in *cis*-position, whereas in the latter complex they are *trans* to each other.[687] The complex [Ni(**242a**)Cl_2] has a five-coordinate dimeric structure with chlorides bridging two Ni ions in the solid state and a monomeric square planar geometry [Ni(**242a**)(solv)$_2$]$^{2+}$ in aqueous and methanolic solutions. In the case of [Ni(**242b**)Cl_2], a planar structure is present both in the solid state as well as in solution. Steric bulk and the electronic nature of the substituents on the P atom have distinct influence on the stereochemistry of [Ni{P,N}$_2$]$^{2+}$-type complexes. It is also evident that imidazolylphosphine ligands have better donor abilities than related and well-known pyridylphosphines (**243**).[688]

Various phosphino oxazoline ligands were designed, and they can also be optimized via high-throughput catalyst screening for certain applications. In (**244**), a near square planar environment with two nitrogen atoms in a *cis* position relative to each other is observed.[689]

Chiral ligand self-recognition phenomena are well described for transition metals and diphosphine ligands.[690,691] Phosphinoaryl oxazoline ligands form two complexes (**245a**) and (**245b**).[692] Reaction of the paramagnetic complex (**245a**) ($R^1 = CH_2Pr^i$) with two equivalents of AgO_3SCF_3 in the presence of one further equivalent of the ligand yields a bright orange diamagnetic complex [(4*S*)(4′*S*)]-(**246**). Two arrangements T and C of the {P,N} ligands are possible for the square planar geometry. The latter is favored, since two π-accepting P centers are *trans* to the σ-donating N donors. The C arrangement was indeed found both in the solid state as well as in solution. The homochiral complex [(4*S*)(4′*S*)]-(**246**) is strongly preferred over the heterochiral [(4*R*)(4′*S*)] species due to a fitting of the two {P,N} ligands around the nickel center that is reminiscent of an intramolecular embrace. (**247**) is an example of a Ni^{II} complex with a chiral {P_2N_2} Schiff base ligand.[693]

(245b)

The oxidative addition of α-ketophoshorus ylides $Ph_3P{=}CR'C({=}O)R''$ to Ni^0 in the presence of a two-electron donor phosphine ligand leads to square planar complexes containing both a Ni—C σ-bond and a bidentate, three-electron donor {P,O} chelating ligand, e.g., [NiPh(**231**)(PPh_3)].[694] This and related complexes are convenient precursors for the active species responsible for the catalytic oligomerization of ethylene into olefins (Shell higher olefin process, SHOP). The α-iminophosphorus ylide $Ph_3P{=}CHC({=}NPh)Ph$ (**248**) reacts with [Ni(cod)$_2$] to produce the square planar complex (**249**) in which the tertiary phosphine is not bound to the Ni^{II},[695] but instead an intact ylide molecule is bound via the α-imino nitrogen. In the presence of PMe_3, PMe_2Ph, or $PMePh_2$ the complexes (**250a–c**) were obtained.

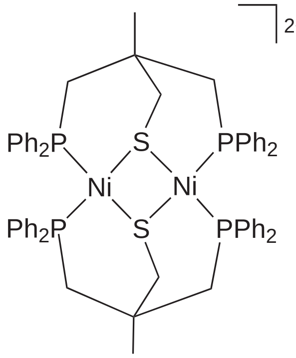
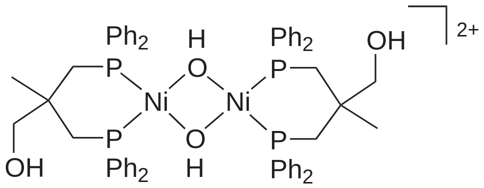
The coordination modes found in Ni^{II} complexes with 2-(diphenylphosphino)nicotinic acid and its methyl ester and 2-(diphenylphosphino)benzoic acid and its methyl ester are surprising.[696] The complex with the benzoic acid derivative shows the expected {P,O}coordination with a six-membered chelate ring (**252**), while the nicotinic acid analogue forms a four-membered chelate ring with {P,N} binding (**251**).

Various mixed tridentate ligands with {P,N,O/S/N} donor sets have been explored in Ni^{II} chemistry. For example, condensation of 2-(diphenylphosphino)aniline with substituted (5-chloro-, 5-nitro, 5-bromo-, 5-methoxy-, and 3-methoxy-) salicylaldehydes yields (**253**).[697] The deprotonated ligand coordinates through its {P,N,O} donor set in a square planar geometry with some distortion, which is probably due to the bulk of the phosphine group and to the bite angle of the {P,N} chelate.

Triphos-derived tridentate ligands with mixed donor sets have been developed and subsequently used in Ni coordination chemistry. Nickel(II) complexes include dinuclear compounds (**254**) and (**255**) with {P_2S} and {P_2O} ligands, respectively.[698]



(254)



(255)

6.3.4.5.4 *Complexes with ligands containing arsenic and antimony*

Multidentate arsine ligands stabilize a wide range of oxidation states and coordination geometries for nickel.[636] 1,2-Bis(dimethylarsino)tetrafluorobenzene, *o*-$C_6F_4(AsMe_2)_2$ (**257b**), forms high-spin tetragonal Ni^{II} complexes [Ni(**257b**)$_2X_2$] (X = Cl or Br), which remain six-coordinate in nonpolar solvents, while in the case of [Ni(**257b**)$_2$]I_2 the nickel environment is square planar and diamagnetic.[699] The Ni^{III} bromide complex *trans*-[Ni(**257b**)$_2Br_2$]BF_4 consists of a tetragonal cation with *d*(Ni—Br) = 2.543 and *d*(Ni—As) = 2.336 Å. However, EXAFS data have shown that the Ni^{II} complex with nonfluorinated benzene, [Ni(**257b**)$_2$]Br_2, is square planar. The octahedral geometry for this type of ligands is rather unusual, but is reminiscent of [Ni{*o*-$C_6F_4(PMe)_2$}$_2Cl_2$] for which both planar and octahedral forms are known.[700] The diarsine is a strongly coordinating ligand capable of stabilizing high oxidation states of nickel including Ni^{III} and Ni^{IV} (compare Section 6.3.3.4).[701,702]

Some Ni complexes containing arsenic donors or hybrid arsine–phosphine ligands were shown to exhibit unusual intra- and intermolecular dynamic behavior in solution.[703] NMR studies have shown that two five-coordinate Ni^{II} complexes containing either the tridentate (**256a**) or (**256b**) and the bidentate (**257**) undergo a rapid intramolecular donor-site exchange process in square pyramidal complexes.[704] Complex [Ni(**256a**)(**257a**)]$(ClO_4)_2$ adopts an unsymmetrical square pyramidal geometry with a mean basal Ni—As distance of 2.285 Å and an apical Ni—As distance of 2.400 Å. The complex [Ni(**256b**)(**257a**)]$(ClO_4)_2$ adopts a similar structure. There are two different mechanisms of ligand exchange dynamics. The low-energy donor-site process (i) shows a rapid exchange between square pyramidal enantiomers as one of the $AsMe_2$ groups of (**257a**) oscillates between the equivalent sites through the pseudotrigonal pyramidal transition state, while in the high-energy donor-site process (ii) both groups of (**257a**) spin over the three positions of a facial site on the complexes.

The reaction of square pyramidal [Ni(**256a**)$_2$]$^{2+}$ with either free (**257a**) or square planar [Ni(**257a**)$_2$]$^{2+}$ yields five-coordinate [Ni(**256a**)(**257a**)]$^{2+}$. In both reactions the ternary complex formation involves the detachment of (**256a**) from [Ni(**256a**)$_2$]$^{2+}$, which is the slow rate-determining process ($t_{1/2}$ = 105 min), followed by a rapid ligand reorganization.[705]

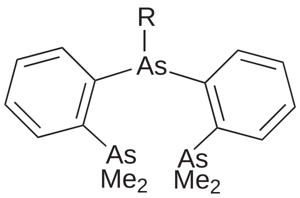
There are two structurally distinct conformers of [Ni(fdma)$_2Br_2$] (fdma = 1,1′-bis(dimethylarsino)ferrocene). The geometry around Ni^{II} in both forms is a tetragonally compressed octahedron. In one conformer the ferrocene moieties are parallel, while in the other they are approximately at right angles to each other (Figure 8).[706] Both conformers show staggered arrangements of the ferrocenyl rings and the Ni—As distances are rather long (2.588 Å).

[$(C_3H_5)Ni(EPh_3)_2$](PF_6) (E = P, As, Sb) are active catalysts for olefin oligomerization. The stibine species is the most active in the 1,4-polymerization of butadiene.[707,708]

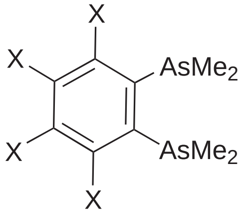
6.3.4.6 Complexes with Oxygen Donor Ligands

6.3.4.6.1 *Complexes with monodentate oxygen ligands and carboxylates*

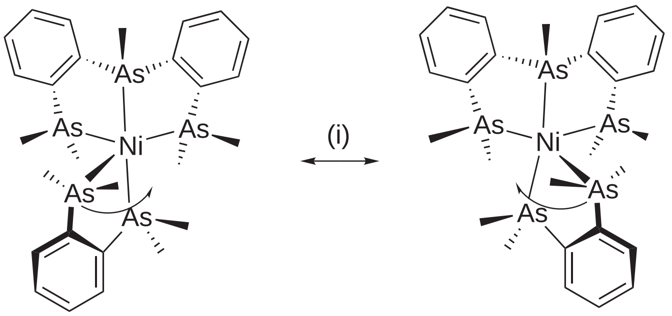
The geometry and bond distances of the [$Ni(H_2O)_6$]$^{2+}$ cation were thoroughly discussed.[709] As expected from ligand field theories, the metal–OH_2 bond reaches its minimum for Ni^{II} ions, which

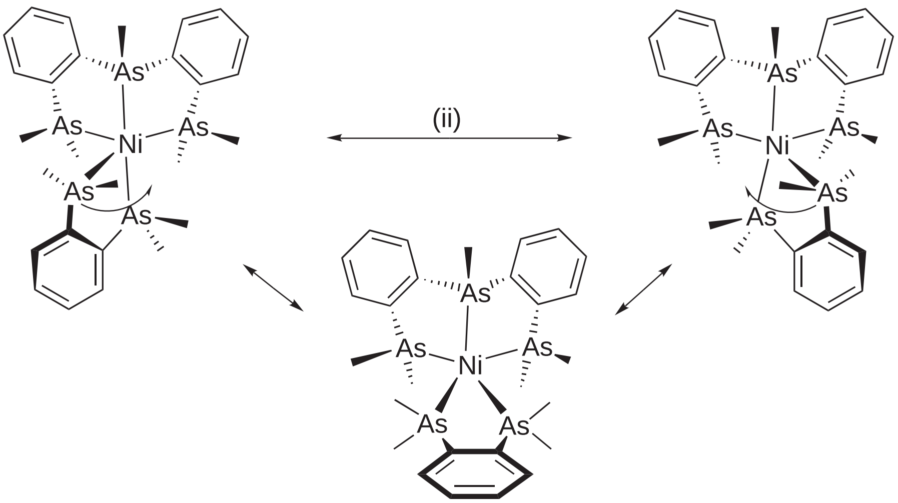


(**256a**) R = Me
(**256b**) R = Ph



(**257a**) R = H
(**257b**) R = F





is usually located in the center of symmetry in a distorted octahedron. The set of the hydrogen bonds formed between water molecules of the aquaion and the other ions (cations and anions present in the crystal) may form specific layers depending on their hydrophilic and hydrophobic character.[710–713] The mean Ni—O distance of the $[Ni(H_2O)_6]^{2+}$ cation is about 2.055 Å in both solid state and solution.[714]

The specific structure of $[(H_2O)_5Ni(py)]^{2+}$ was observed in the complexes with the second-sphere coordination of calix[4]arene sulfonate.[715] There are two different $[(H_2O)_5Ni(py)]^{2+}$ cations in the complex assembly. In one the hydrophobic pyridine ring is buried in the hydrophobic cavity of the calixarene with the depth of penetration into the calixarene cavity being 4.3 Å (Figure 9). The second independent $[(H_2O)_5Ni(py)]^{2+}$ cation is intercalated into the calixarene bilayer.

N,*N*-dimethylformamide binds Ni^{II} ion monodentately forming an octahedral cation.[716–718] The hexakis(*N*,*N*-dimethylformamide-*O*)nickel(II) complex is a useful starting reagent for the synthesis of various Ni^{II} complexes. Hexakis(dimethylsulfoxide)nickel(II) chloride or bromide with an octahedral $[Ni(Me_2SO)_6]^{2+}$ cation precipitates from a concentrated DMSO solution of the respective NiX_2 salt (X = Cl, Br).[719] The Ni—O distance in $[Ni(Me_2SO)_6]^{2+}$ is about 2.08 Å.[720–722] The 1,1,3,3-tetramethylurea solvated Ni^{II} ion is reported to be five-coordinated in

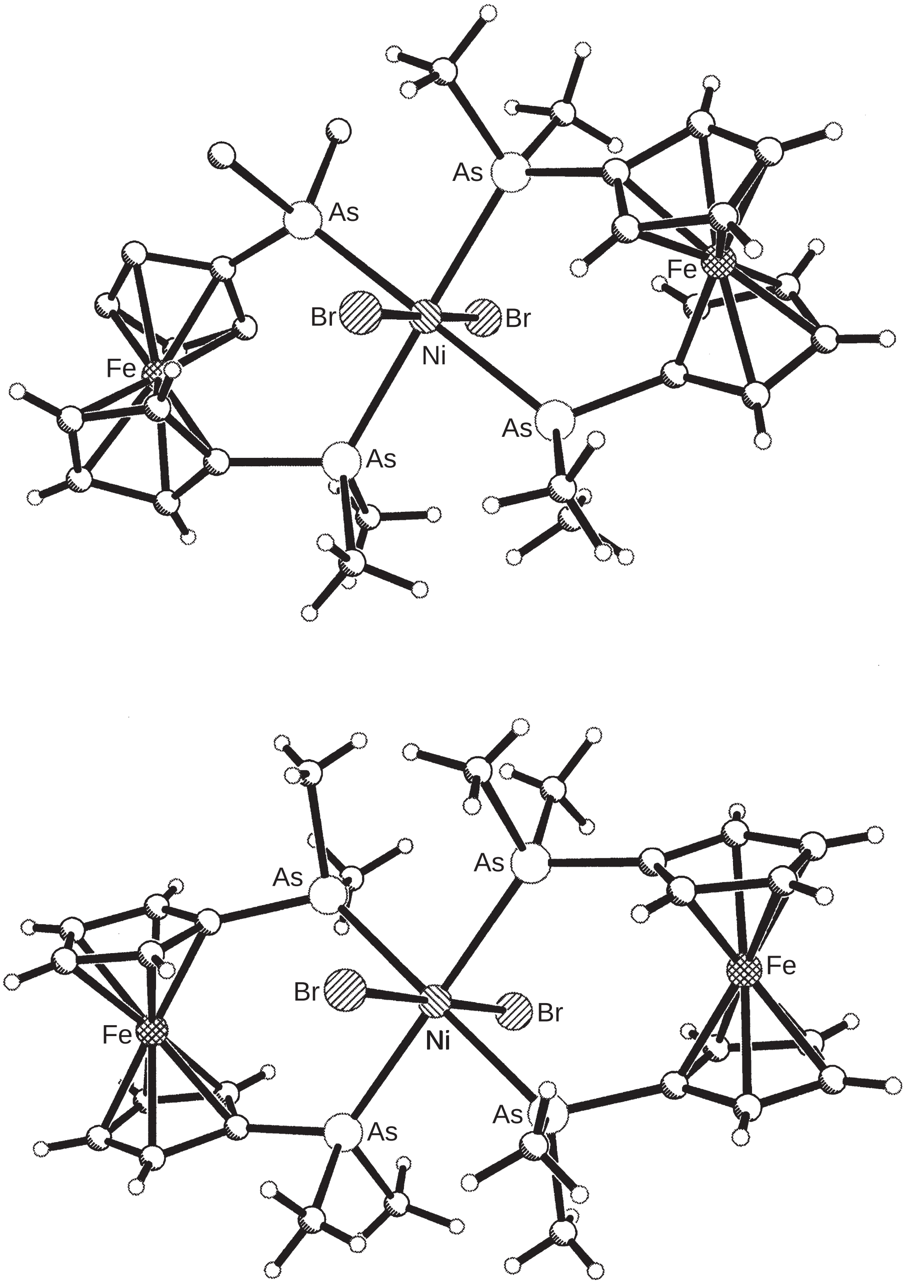


Figure 8 Planar and centrosymmetric “stepped” conformer of Ni(fdma)$_2$Br$_2$.[706]

solution with d(Ni—O) = 2.00(1) Å according to EXAFS.[723] For these O-donor solvent complexes, coordination numbers lower than six are generally ascribed to steric restrictions.

In general, monodentate coordination through O is not a very effective binding mode in the case of Ni^{II}. In many cases, however, the presence of hydrogen bonding networks may lead to interesting tertiary structures in the solid state. Squarate complexes were initially expected to be good materials for semiconductivity or magnetism studies. However, due to poor metal–ligand orbital overlap they do not exhibit the desired properties.[724–728]

In the complex of Ni^{II} with methoxycyclobutenedionate, [Ni(CH$_3$OC$_4$O$_3$)$_2$(H$_2$O)$_4$], the metal ion is six-coordinate with two 1-methoxycyclobutenedionate(−1) ligands, the methoxy substituent being oriented *cis* with respect to the ligating oxygen (Figure 10). The remaining sites are filled by water molecules, and monomers are linked by O—H···O hydrogen bonds to form arrays of stepped tapes.[728] The methoxy substituent, which has lone pairs that can move into

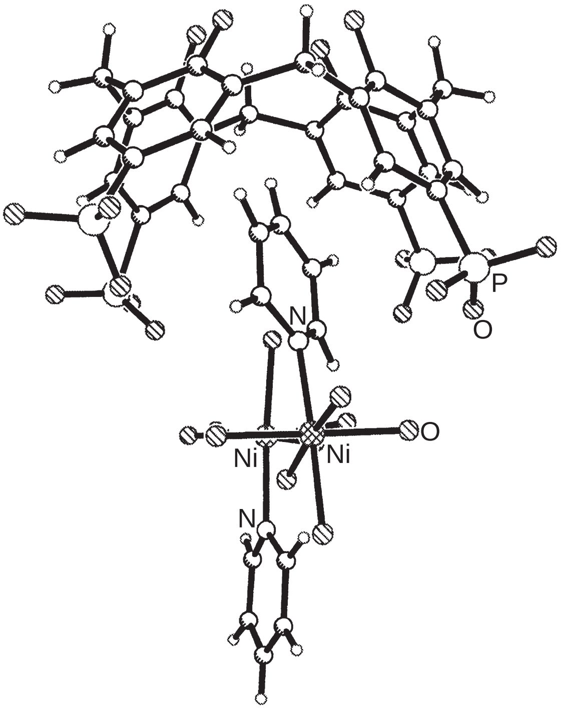

Figure 9 Complex assembly of $[(H_2O)_5Ni(py)]^{2+}$ and calix[4]arene sulfonate.[715]

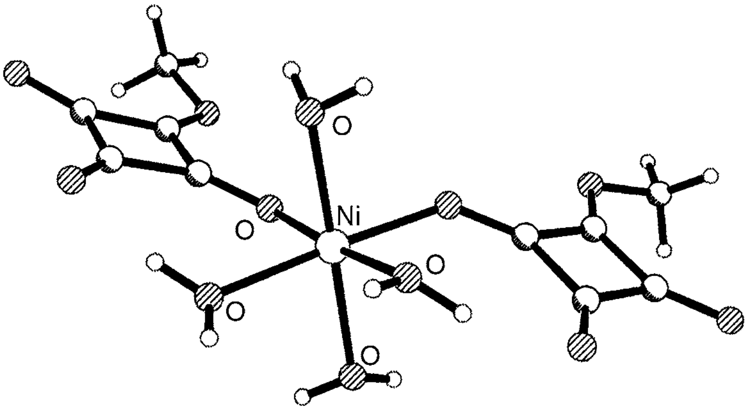

Figure 10 Molecular structure of $[Ni(CH_3OC_4O_3)_2(H_2O)_4]$.[728]

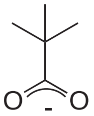
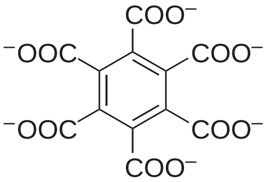
the ring, apparently causes an increase in the amount of delocalization. Thus, proper ring substituents may be used to synthesize metal–squarate complexes with desired solid-state structure and properties through formation of extensive three-dimensional (3D) hydrogen bond networks.[727]

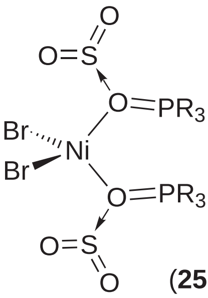
Ni^{II} complexes with carboxylates are numerous and no comprehensive list can be given here. For example, the Ni^{II} coordination chemistry of trimethylacetate (pivaloate, (**258**)**a**) has been covered in a review.[729] Quite often, the bridging ability of the carboxylate group is taken advantage of for the assembly of polynuclear cluster and supramolecules where, *inter alia*, magnetic properties are of particular interest (compare also Section 6.3.4.13.3). Perspectives in this regard are offered by the use of polycarboxylates like, for example, benzenehexacarboxylic acid (mellitic acid, (**258b**)). This forms a 2D coordination polymer [Ni_4(**258b**)$(OH)_2(H_2O)_6$] (incorporating dimer motifs of pseudo-octahedral $\{NiO_6\}$ linked through μ_3-OH) via a hydrothermal synthesis.[730]



(258a)



(258b)



(259)

Monodentate coordination of carboxylate in monomeric species is rather rare although well understood. The monomeric complexes usually formed have a very effective hydrogen bond system, especially when water is the additional ligand as it is seen in the tetraaquabis(maleato)-nickel(II) complex.[731] Neutron diffraction clearly shows the presence of a three-centered bifurcated donor hydrogen bond and reveals that the hydrogen network reduces the complex symmetry from O_h to C_i. Substituted benzoate often acts as a monodentate ligand coordinated through a single carboxylate-O to complete the coordination sphere of six-coordinate Ni^{II} complexes chelated by two molecules of, for example, 1,3-diaminopropane.[732,733]

Bis(trialkylphosphine oxide) complexes $[NiBr_2(O{=}PR_3)_2]$ reversibly bind SO_2 to give species formulated as (**259**).[734]

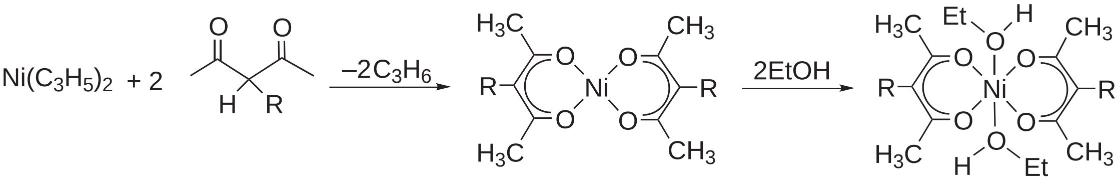
6.3.4.6.2 *Complexes with β-diketones and related ligands*

Acetylacetone (acac) and a variety of its derivatives have one of the most examined coordination chemistry among the chelate systems.[735,736] The parent acac may be substituted at various sites. Its methyl groups can be fluorinated, and the hexafluoroacetylaceconato ligand forms a stable octahedral complex having two co-ligands bound in *cis* positions.[737] The substitution of the methyl groups in the trimer $[Ni(acac)_2]_3$ by sterically more bulky groups results in the formation of a monomeric species containing square planar Ni^{II}.

The dibenzoylmethanate (DBM) ligand forms with Ni^{II} three polymorphic forms (light green, brown, and green).[738] The light green polymorph is metastable, and after recrystallization the brown stable polymorph is formed which is a square planar diamagnetic $[Ni(DBM)_2]$ species. When heated, the brown form transforms to a green form, which is trimeric $[Ni_3(DBM)_6]$ consisting of linear Ni_3 clusters and a Ni—Ni distance of 2.81 Å. Benzene stabilizes the trimeric structure at room temperature, forming the $[Ni_3(DBM)_6]\cdot 2(\text{benzene})$ inclusion compound. $[Ni(DBM)_2]$ may accept two pyridine-type molecules in the axial positions. The resulting $[Ni(py)_2(DBM)_2]$ complex has *trans* configuration and forms supramolecular structures.[739]

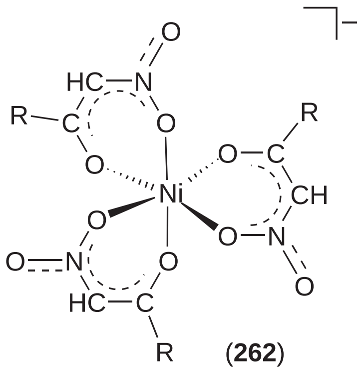
In the presence of diamines, the square planar Ni^{II}-bis(β-ketoenolate) unit forms ternary complexes with nearly octahedral geometry and *trans* configuration of two monodentately bound diamines (e.g., 1,2-diaminobenzene)[740] or with *cis* configuration of the chelating amines (e.g., 1,2-ethanediamine)[741] and two 1,3-diphenyl-1,3-propanedione molecules. The monomer–trimer isomerism can be also controlled by substitution at the C(3) position of the ligand. Such 3-substituted pentane-2,4-dione derivatives (**260**)[742] form monomeric square planar NiL_2 complexes (**261**). These dissolve readily in ethanol to give octahedral adducts (**261a**).[743] In the case of (**260c**), small amounts of green crystals were also formed and identified as the trimer [Ni(**260c**)$_2$]$_3$. Thus, the presence of electron-donating substituents in the 3-position of the pentane-2,4-dionato group favors the formation of the monomeric species, while in the presence of the electron-withdrawing phenyl group, both monomeric and trimeric complexes are possible.

Carbonylnitronate ligands $O_2NCHC(O)R^-$ form complexes similar to those of β-dicarbonyl ligands. The reaction of a Ni^{II} salt with benzoylnitromethane or alkyl nitroacetate gives, in the presence of a deprotonating agent, complexes in which the monoanion of the nitro derivative is coordinated to the metal center. When 1,8-bis(dimethylamino)naphthalene (DMAN) is used as the deprotonating agent, $(DMANH)[Ni(O_2NCHC(O)R)_3]$ is obtained.[744] In the case of $R = Ph$, the benzoylnitronate ligand is coordinated to Ni^{II} through its keto and one nitro oxygen (**262**).



(261) **(261a)**

(260a) R = –CH$_3$
(260b) R = –(CH$_2$)$_4$– CH=CH$_2$
(260c) R = –Ph

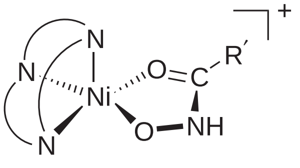


(262)

The reactions of Ni^{II} with acac-type ligands are complicated by the fact that β-diketones HL are subject to keto/enol tautomerism. The keto tautomer HK is in equilibrium with the enol from HE and both tautomers can dissociate to form the enolate E$^-$, so that the given metal can react with HK, HE, or E$^-$.[745] The β-diketone 3-(*N*-acetylamido)pentane-2,4-dione (Hamac) is highly soluble in water and strongly enolized ([enol]/[ketone] = 2.4). Kinetic studies have shown that the enol tautomer HE and the enolate E$^-$ are the reactive species to form [Ni(amac)]$^+$, with second-order rate constant $k_E > k_{HE}$. The kinetic data further suggest that formation of the first Ni—O bond is rate controlling and the acidity of the bound water is rate affecting.[746]

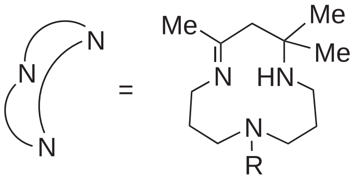
6.3.4.6.3 Complexes with deprotonated hydroxamic acids, catechols, and related ligands

Hydroxamic acids, RC(O)N(R′)OH, are important ligands especially when acting as siderophores for Fe^{III}[747] or inhibitors for enzymes.[748–750] The stability constants of Ni^{II} complexes of hydroxamic acid and derivatives thereof as well as the speciation in aqueous solution have been studied in great detail.[751–756] Although the hydroxamate ligand usually behaves as a bidentate ligand, it may also coordinate as a monodentate and bridging unit. The monodentate coordination is enforced if adjacent coordination sites are blocked, e.g., by porphyrins.[757] For coordination of hydroxamates via their N atoms see Section 6.3.4.4.4. Purely bidentate O-coordination was found in the ternary complex with the macrocyclic [12]aneN$_3$ ligand.[758] Upon addition of acetohydroxamic acid (HAh) to a solution of [Ni([12]-aneN$_3$-mc2)(μ-OH)]$_2$(PF$_6$)$_2$ ([12]ane N$_3$-mc2 = 2,4,4,9-tetramethyl-1,5,9-triazacyclododec-1-ene), the complex [Ni([12]aneN$_3$-mc2)(Ah)]PF$_6$ is obtained with pentacoordinate nickel (**263**). The hydroxamate oxygen atoms occupy two basal coordination sites. The Ni—O distances are shorter than those found for octahedral dinuclear complexes.[759] Bidentate and bridging modes can occur simultaneously in polynuclear complexes. The reaction of 2-(dimethylamino)phenylhydroxamic acid with NiSO$_4$ gives a heptanuclear complex, in which the hydroxamate moiety exhibits a variety of binding modes including the bidentate and bridging coordination.[760] In some metallacrowns the binding modes are even more spectacular showing the involvement of all hydroxamate donor atoms including the N atom.[761]



(263)

(R' = Me (Ah); Ph (Bh))



Another family of bidentate O-donor ligands are the 3-acytetramic acids.[762] Catechol complexes were reviewed in detail.[763] Although binary Ni^{II} catecholate compounds have been known for a long time, many studies explaining details of their electronic properties were published only recently.[764] $Ni(OAc)_2$ and catechol form two types of complexes depending on the crystallization rate: the paramagnetic six-coordinate $Na_2[Ni(cat)_2(H_2O)_2]$ and diamagnetic square planar $Na_2[Ni(cat)_2]$ or $Na_2[Ni(cat)_2]\cdot 2DMF$. Dissolution of the paramagnetic complex in hot DMSO generates the planar complex by removing water from the coordination sphere. In the paramagnetic species the nickel ion is located in a slightly distorted octahedral environment composed of two symmetry-equivalent catechol ligands in the equatorial plane and two axial water molecules. The bond lengths of the two catechol O atoms are identical for both ligands, with $d(Ni—O_{cat}) = 2.043$ Å and 2.045 Å. The $Ni—O_{water}$ bond is longer, at 2.162 Å. In the planar complex $Na_2[Ni(cat)_2]\cdot 2DMF$, the metal center is coordinated in a slightly distorted square planar fashion by two catecholates with distances $d(Ni—O_{cat}) = 1.858$ Å and 1.868 Å. Both paramagnetic and diamagnetic complexes are very sensitive toward oxidation. The oxidation of Ni–catechol complexes is a major reason for difficulties in their unambiguous assignment in the earlier work. The use of bis(catechol) ligands such as *N*,*N'*-bis(2,3-dihydroxybenzoyl)-1,7-diazaheptane (5-LICAM) gives monomeric Ni^{II} complexes. The yellow diamagnetic Ni^{II} complex with 5-LICAM (**264**) incorporates a square planar Ni^{II} bis(catecholate) entity (Figure 11).[765]

A variety of ternary complexes containing catecholate moieties are known. For example, in a trimeric Ni^{II} core the catecholate serves as a bidentate ligand to one Ni^{II} and also as a bridge between the two podal and the unique axial metal.[766]

Due to their magnetic properties, complexes of Ni^{II} with semiquinone- and quinone-type ligands have been studied more intensively than catecholates. $[Ni(3,6\text{-}DBSQ)_2]$ ((**265a**); 3,6-DBSQ = 3,6-di-*t*-butyl-1,2-benzosemiquinone) and $[Ni(3,5\text{-}DBSQ)_2]$ ((**265b**); 3,5-DBSQ = 3,6-di-*t*-butyl-1,2-benzosemiquinone) are monomeric square planar complexes.[767,768] The metal core is diamagnetic, while in $[Ni(3,6\text{-}DBSQ)_2]$ two SQ ligands are antiferromagnetically coupled with the value of $J(SQ–SQ) = -39.1\ cm^{-1}$. The mixed ligand complex $[Ni(3,6\text{-}DBBQ)(3,6\text{-}DBSQ)_2]$ is octahedral with high-spin Ni^{II} ($S = 1$) and two paramagnetic SQ ligands. There is only little temperature dependence of the magnetic moment from 4.57 μ_B at room temperature to 4.38 μ_B at 5 K. Thus, the exchange interactions between the SQ moieties strongly depend on the complex structure and accompanying ligands.[769,770] Quinone and semiquinone ligands are distinguishable by their bond lengths, with average Ni—O distances of 1.999 Å for SQ and 2.125 Å for Q oxygens.

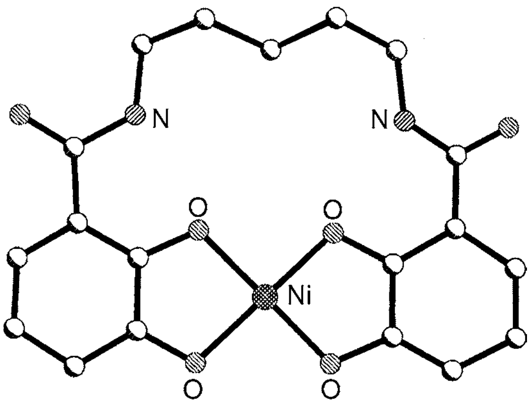


Figure 11 Molecular structure of (**264**).[765]

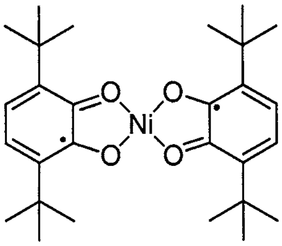
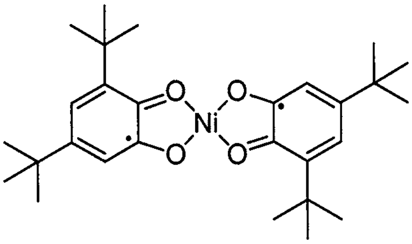
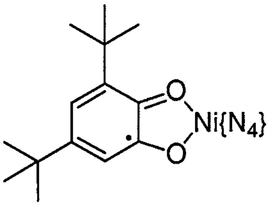


(265a)



(265b)

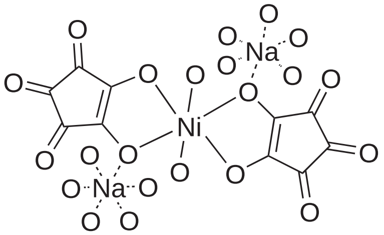


(266)

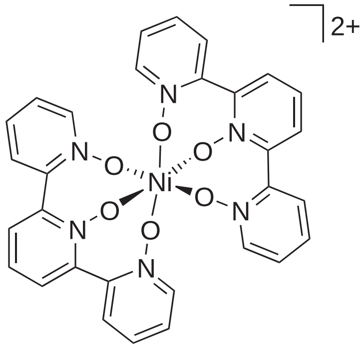
The ferromagnetic coupling between the Ni^{II} ion ($S=1$) and the SQ ($S=1/2$) in (**266**) ($\{N_4\}$ = *dl*-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane) is so strong that no evidence of population of the excited doublet state is observed at room temperature.[771] $[\{N_3\}Ni(TCSQ)(TCQ)]$ (TCQ = tetrachloroquinone, TCSQ = tetrachlorosemiquinone) exhibits an effective magnetic moment of $2.97\mu_B$ and is formulated as a Ni^I species ferromagnetically coupled to the TCSQ based on the bond lengths of the dioxolene moieties, although a Ni^{II} description cannot be completely ruled out.[772]

6.3.4.6.4 *Complexes with miscellaneous oxygen ligands*

Croconate, the monocyclic aromatic oxocarbon dianion $[C_5O_5]^{2-}$, is an analogue of squarate (*vide supra*) and may act as a bidentate ligand forming octahedral complexes like $Na_2[Ni(C_5O_5)_2(H_2O)_2]\cdot 4H_2O$ (**267**).[773] In this case the nickel atom is located at the inversion center and is surrounded by six oxygen atoms of which four are croconate O atoms and two are from water molecules. Sodium acts as an interconnecting cation to build up a 3D framework.



(267)

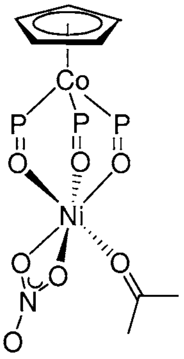


(268)

Tridentate oxygen ligands usually form $[NiL_2]$ complexes having pseudo-octahedral geometry. Terpyridine 1,1′,1″-trioxide ($terpyO_3$) gives monomeric $[Ni(terpyO_3)_2]^{2+}$ (**268**), which features a six-coordinate Ni center in a slightly distorted octahedron with typical Ni—O bond lengths (2.047–2.064 Å). The seven-membered chelate rings produce an unstrained structure that contains the ligand in facial coordination mode rather than the meridional arrangement typical for the parent terpyridine ligand.[774] DFT calculations, which agree well with the X-ray structure, show that no stable meridional arrangement can be constructed for this ligand without one metal–oxygen bond being cleaved. Terpyridine 1,1′-dioxide ($terpyO_2$) forms $[Ni(terpyO_2)_2](ClO_4)_2$ with the Ni^{II} center in an octahedral geometry and the two terpyridyl units in *mer* arrangement. The structure of the terpyridine monooxide complex is also meridional.

The oxydiacetate ligand (oda = $^-O_2C\text{-}CH_2—O—CH_2—CO_2^-$) is mainly acknowledged for its capacity to form bridges, which results in polymeric structures as described for polycarboxylates. It may also form, however, monomeric complexes with Ni^{II} featuring tridentate coordination.[775] In all complexes obtained, $[Ni(oda)(H_2O)_3]\cdot 1.5H_2O$, $[Ni(oda))phen)(H_2O)]\cdot 1.5\ H_2O$, and $[Ni(oda)(terpy)]\cdot 2H_2O$, oxydiacetate acts as a tridentate ligand being hinged in the first complex and almost planar in the other two. The hydrogen bond network is very extensive in the solid state leading to a very intricate packing scheme. Other multicarboxylate ligands with monodentate coordination usually serve as a bridge to form oligomeric or polymeric structures like it is found for $[Ni(H_2O)_5(\mu\text{-}C_6H_2(COO)_4)Ni(H_2O)_5]\cdot 6H_2O$.[776]

Kläui's tripodal metalloligand $L^{OMe} = (\eta^5\text{-}C_5H_5)Co[P(=O)(OMe)_2]_3$ has been used for the synthesis of an octahedral Ni^{II} complex (**269**).[777] Before crystallization from acetone, the dinuclear adduct $[Ni(\mu\text{-}L^{OMe})_2(\mu\text{-}NO_3)_2Ni(NO_3)]$ was isolated. The labile acetone ligand in (**269**) is easily replaced by various P- and N-donor ligands.

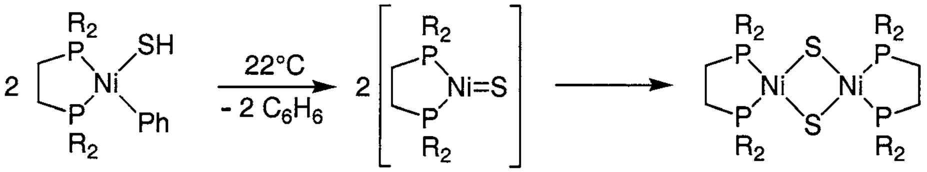


(**269**)

6.3.4.7 Complexes with Sulfur-, Selenium-, and Tellurium-containing Ligands

6.3.4.7.1 *Complexes with sulfido and monodentate thiol ligands*

Ni coordination compounds bearing SH^-, S^{2-}, $S_2{}^{2-}$, and H_2S are attractive targets as models for biological Ni/S systems. Further, nickel sulfides are of interest as promotors in hydrotreating catalysts, and nickel complexes can be employed in desulfurization reactions.[778] The latter desulfurizations are believed to proceed via intermediate terminal sulfido species. Evidence for the existence of a terminal Ni^{II} sulfido complex comes from the reaction depicted in Equation (6), where kinetic data are consistent with a unimolecular rate determining step involving the loss of benzene from (**270**) and formation of a terminal sulfido intermediate (**271**) to finally yield the bridged sulfido dimer (**272**) (which has a bent Ni_2S_2 core).[779] (**271**) can be trapped by nitrones.

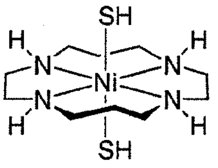


(6)

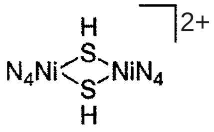
(**270**) (**271**) (**272**)

Complexes containing ligands such as SH^-, S^{2-}, $S_2{}^{2-}$, and H_2S usually tend to form the binary sulfides or to form oligonuclear S-bridged species. However, mononuclear Ni^{II} complexes with terminal SH ligands can be obtained by the proper choice of spectator ligands, and some selected examples are given here. Reaction of $[Ni(cyclam)](ClO_4)_2$ with KSH gives $[\{Ni(\mu\text{-}SH)_2\,(cyclam)\}_2][Ni(SH)_2(cyclam)](ClO_4)_2$, which contains a mononuclear *trans*-$Ni(SH)_2$ unit (**273**) and a dinuclear cationic $Ni_2(\mu\text{-}SH)_2$ fragment (**274**).[780] Treatment of $[Ni(cyclam)](ClO_4)_2$ with K_2S_2 instead of KSH gives (**275**).[781] A *cis*-$Ni(SH)_2$ moiety is found in (**276**), which is a valuable starting material for the synthesis of various S-bridged nickel complexes. A tetradentate bridging $S_2{}^{2-}$ ligand is found in the tetranuclear Ni^{II} complex (**277**).[782] The mercaptodithiotrinickel complex $[Ni_3(\mu_3\text{-}S)_2(SH)(PEt_3)_5]^+$ is a product of the reaction of H_2S and PEt_3 with $[Ni(C_2H_4)(PPh_3)_2]$.[783]

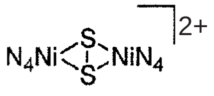
Two general classes of mononuclear $[Ni(SR)_4]^{2-}$ complexes are known, those containing monodentate thiolates[784,785] which adopt a flattened tetrahedral geometry in the solid state with Ni—S bond distances of 2.26–2.33 Å and S—Ni—S angles in the range 88–125°. In contrast, mononuclear $[Ni\{S\}_2]^{2-}$ complexes of chelating thiolates like ethane-1,2-dithiolate and analogues are diamagnetic and show square planar geometries. The latter complexes are discussed in the subsequent section.



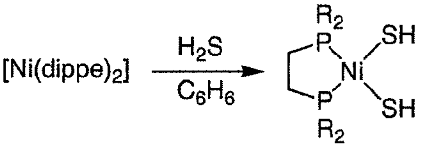
(273)



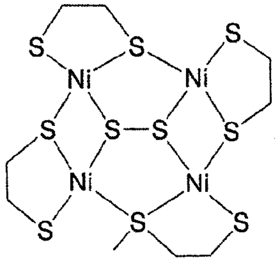
(274)



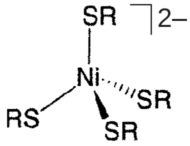
(275)



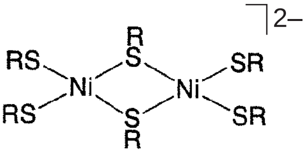
(276)



(277)



(278)



(279)

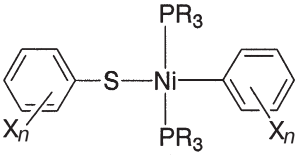
Nickel(II) complexes with monodentate thiolate ligands are unstable towards oligomerization or polymerization and autoredox decomposition reactions. Therefore the synthesis requires strictly oxygen-free conditions. A careful choice of solvent and the use of excess of thiolate prevent the precipitation of insoluble polymers. In this context some new syntheses have been reported which start usually from alkali thiolates and a Ni^{II} salt (e.g., $(NEt_4)_2[NiCl_4]$). The resulting $[Ni(SR)_4]^{2-}$ anions (**278**) have a tetragonally distorted tetrahedral coordination geometry which could be shown by means of several X-ray structures of $(NEt_4)_2[Ni(SR)_4]$ complexes ($R = Bu^t$,[786] C_6H_5,[787,788] p-ClC_6H_4,[789] p-PhC_6H_4[790]). The dissociation sequence of nickel complexes with arene thiolate ligands was studied in DMSO by spectrophotometric methods. Dissociation was found to proceed through generation of the diamagnetic species $[Ni(SR)_3(DMSO)]^-$ and $[Ni(SR)_2(DMSO)_2]$.[791]

In addition, the structures of various dimeric,[786] trimeric,[792–794] and oligomeric thiolate nickel complexes are known, in some cases with additional sulphido bridges. Among them are toroidal Ni^{II} thiolates $[Ni(SR)_2]_4$ containing S-bridged Ni tetragons,[795–798] $[Ni(SR)_2]_5$ containing S-bridged Ni pentagons,[796,799,800] various examples of $[Ni(SR)_2]_6$ hexagons,[801–807] a $[Ni(SR)_2]_8$ octagon ($R = CH_2CO_2Et$),[808] as well as $[Ni(SPh)_2]_9$ and $[Ni(SPh)_2]_{11}$ containing unique 9- and 11-membered ring systems, respectively.[809] In general, square planar geometries about the nickel centers are predominant. For example, the reaction of $[Ni(Me_6tren)Cl]Cl$ with p-$ClC_6H_4S^-$ (L) affords the salt $[Ni(Me_6tren)Cl]_2[(L)_2Ni(\mu\text{-}L)_2Ni(L)_2]$, the anion (**279**) showing a square planar geometry around each Ni^{II}.[810] For some species with bulky ligands, however, a tetrahedral geometry is found.[786,801] In many cases the oligonuclear Ni^{II}–thiolato complexes can be reversibly oxidized to give compounds with broken Ni oxidation states.[811] Oligomeric complexes with manifold different structures have been discovered including rings and clusters, where the electronic structures and the binding modes are of particular interest. For the pentanuclear star-like complex $[Ni_5(\mu_5\text{-}S)(\mu_2\text{-}SBu^t)]^-$[812] the MO diagram has been calculated.[813]

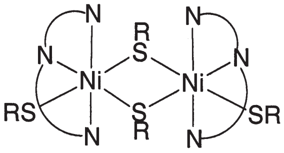
By oxidative addition of aryl sulphides to low-valent nickel complexes, a C—S bond cleavage occurs to form Ni^{II} thiolate complexes. For example, exposure of diaryl sulphides to $[(Bu^t_3P)_3Ni^0]$ leads to oxidative addition, with nickel inserting into the C—S bond (**280**).[814]

Similarly, exchange between the Ar and Ar′ groups in $[Ni(Ar)(SAr')(PEt_3)_2]$ occurs via reversible reductive elimination and oxidative addition involving C—S bond formation and cleavage at the nickel center to give a mixture of $[Ni(Ar')(SAr)(PEt_3)_2]$ and $[Ni(Ar)(SAr')(PEt_3)_2]$.[815]

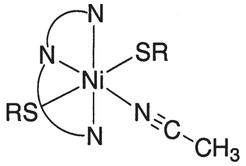
The reaction of thiolate ligands with $[Ni(terpy)Cl_2]$ in MeOH or MeCN affords different products depending on the basicity and bulk of the thiolate ligand employed. Thus, the reaction with PhSH yields the thiolate bridged dimer $[Ni(terpy)(SPh)_2]_2 \cdot 6CH_3OH$ (**281**), reaction with C_6F_5SH yields the solvated monomer $[\mathrm{Ni(terpy)(SC_6F_5)_2(CH_3CN)}]\cdot 3\mathrm{CH_3CN}$ (**282**), while the reaction with 2,4,6-$(\mathrm{Pr^i})_3\mathrm{C_6F_2SH}$ yields the pentacoordinate complex [Ni(terpy)(*S*-2,4,6-$(\mathrm{Pr^i})_3\mathrm{C_6F_2})_2$] (**283**).[816]



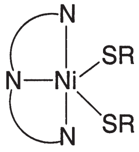
(280)



(281)



(282)



(283)

Complexes (**284**) can be protonated at the sulfur to give $[(\mathbf{284})\mathrm{H}]^+$.[817] Kinetic evidence suggests a simple equilibrium reaction for R = Ph, but more complicated kinetics for R = Et. In the latter case, the data are indicative of two coupled equilibria in which the initial protonation of the thiolate is followed by a unimolecular equilibrium reaction that is assumed to involve formation of an η^2-EtS-H ligand. Presumably, the more strongly *s*-donating EtS ligand makes the $\mathrm{P_3Ni}$ fragment sufficiently electron rich and hence the basicities of the S and the Ni become similar. This observation is relevant with respect to nickel-based hydrogenases.

6.3.4.7.2 Complexes with dithiol ligands

(**285**)–(**289**) are typical dithiol ligands forming dithiolate nickel complexes with five-membered chelate rings. The basic ligand is ethane-1,2-dithiolate ($\mathrm{edt^{2-}}$) (**285**), which forms complexes of the composition $[\mathrm{Ni}(\mathbf{285})_2]^{2-}$ and $[\mathrm{Ni_2}(\mathbf{285})_3]^{2-}$. Crystal and molecular structures of both compounds (as the $\mathrm{NEt_4}^+$, $\mathrm{Ph_4P}^+$, or $\mathrm{Ph_3MeP}^+$ salt) have been determined, revealing a square planar geometry around the nickel center,[197,787,818,819] and complexes of higher nuclearity have also been obtained.[782,820] Also characterized crystallographically are the $\mathrm{Ni^{II}}$ complexes with (**287**) ($(\mathrm{Et_4N})_2[\mathbf{290a}]$)[821,822] and (**288**) ($(\mathrm{PPh_4})_2[\mathbf{290b}]$).[196]

The K-edge spectra of $[Ni(\mathbf{287})_2]^{2-}$ and $[Ni(edt)_2]^{2-}$ are remarkably similar to each other and to those of natural hydrogenases.[196] Some complexes with ligand (**289**) ($R = NMe_2$, $R' = H$, Me, NMe_2) have been characterized using electronic and near infrared spectroscopy.[823] Complex $[Ni(\mathbf{289})_2]^{2-}$ served to study phase transformation behavior by microscopy and DSC.[824]

1,3-Propanedithiol (**291**) forms hexanuclear $[Ni_6(\mathbf{291})_7]^{2-}$ which can be viewed as composed of two $[Ni_3(\mathbf{291})_4]^{2-}$ subunits sharing a common ligand.[820] A study has been carried out on the thermodynamic characteristics of the formation of Ni^{II} complexes with 2,3-mercaptopropanesulphonate. The stability constants for both 1:1 and 1:2 complexes have been determined.[825] Dithiolate complexes with six-membered chelate rings are formed in the reaction of Ni^{II} with the ligands (**292**) (lipoic acid) and (**293**), the complexes having been characterized by potentiometric and spectroscopic methods.[826]

Seven-membered chelate rings are formed with biphenyl-2,2′-dithiolate and *o*-xylenedithiol (**294**). The latter gives trinuclear Ni^{II} complexes $[Ni_3(\mu_3\text{-}S)(\mathbf{294})_3]^{2-}$ and $[Ni_3(\mathbf{294})_4]^{2-}$.[827,828] The Ni^{II} is in a square planar $\{NiS_4\}$ environment, as it is in complex (**295a**). In the absence of excess ligand the mononuclear (**295a**) readily looses one ligand to form the dinuclear complex (**295b**). Oxidation by air causes complex decomposition instead of oxidation at the thiole ligand or oxidation to Ni^{III}.[829]

Upon reaction of Na_2edt with $NiCl_2$ and PPh_3 in methanol, C—S bond cleavage occurs and the mixed ligand complex $[Ni(PPh_3)(tpt)]$ (**296**) is formed. The crystal and molecular structure of this complex revealed a distorted square planar geometry for the nickel atom with tpt functioning as a tridentate ligand, and the fourth coordination site occupied by the phosphine ligand.[830]

A number of structures with S-rich dianion ligands have been determined (**297–299**).[831,832] For example, (**297**) can be synthesized by the reaction of $[Ni(CN)_4]^{2-}$ with polysulfide.[833] Upon further reaction with CS_2 or substituted acetylenes it forms perthiocarbonato and dithiolene complexes, respectively.

6.3.4.7.3 Complexes with thioether and mixed thioether/thiol ligands

Monodentate thioether ligands are relatively poor ligands towards Ni^{II}. However, several Ni^{II} complexes with polydentate thioether ligands are known, where the coordination capability is enhanced by chelation. In particular, complexes with macrocyclic thioether ligands, which are discussed in Sections 6.3.4.10.1(iii) and 6.3.4.10.3, are very stable.

(**300**)–(**302**) are selected Ni^{II} complexes with di-, tri-, and polydentate thioether ligands. Three type (**300**) Ni^{II} complexes with the bidentate ligands 1,2-bis(methylthio)ethane and 1,2-bis(ethylthio)ethane have been characterized by X-ray crystallography. Octahedral complexes are formed with the thioether ligands coordinating in a bidentate manner and two additional ligands (X = Br, SCN) in *trans*-position.[834] The reaction of a Ni^{II} salt with 3,6,9,12,15-pentathiaheptadecane affords a nearly perfect octahedral complex (**302**) with an additional water ligand.[835] An attempt to restrict the flexibility of the polythioether ligands without making use of macrocyclic ligands lead to the syntheses of complexes with ligand (**303**) and related ligands in which one donor is part of a thiane or a thiepane unit. The resulting Ni^{II} complexes show an octahedral coordination geometry. The S donors of the side arms form a NiS_4 plane, and the S-donor of the heterocycle coordinates in the axial position. In addition, one ClO_4^- ion or one water molecule occupies the sixth position.[836]

Ligands that provide a face-capping S_3 donor set comparable to trithiacyclononane (ttcn) are tetrakis((methylthio)methyl)borate (**304a**) and phenyl(tris((methylthio)methyl)borate) (**304b**). These ligands are more easily accessible than ttcn but show a comparable coordination behavior by forming complexes of the type $[L_2Ni]$.[837,838] They particularly stabilize Ni^{II}, but also higher oxidation states. Oxygenation of the Ni^{I} complex (**304c**)Ni(CO) leads to O_2 activation and O—O bond rupture with formation of a bi(μ-oxo)nickel(III) complex.[184] Attempted alkylation of [NiCl(**304c**)] with Me_2Mg or MeLi results in production of [Ni(κ^2-(**304c**))(η^2-CH_2SBu^t)] (**308**).[839] The reaction presumably proceeds via reduction of the starting complex and subsequent loss of the borato ligand, which then alkylates another [NiCl(**304c**)]. In contrast to other Ni–alkyl complexes, (**308**) does not react with CO. (**304d**) forms a square planar homoleptic Ni^{II} complex [Ni(**304d**)$_2$], while with the more bulky ligand (**304e**) B—C bond rupture takes place and the organometallic derivative [Ni(**304e**)(η^2-CH_2SBu^t)] with a structure analogous to (**308**) is yielded.[840]

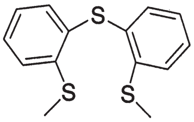
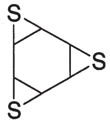
(305)



(306)



(307)

In complexes with ligand (**305**), hexacoordination of the nickel center is imposed.[841] Benzene trisulfide (BTS) (**307**) forms with Ni^{II} the octahedral complex $[Ni(BTS)_2](BF_4)_2$, BTS coordinating in a facial manner. A comparison of this system with other complexes containing thioether ligands was made, and BTS was shown to generate the strongest ligand field of any of the thioether ligands examined. This was ascribed to its rigid endodentate conformation.[842]

Another class of ligands is those with mixed thioether–thiolate donors. (**309**)–(**311**) are shown as a selection of Ni^{II} complexes of this class characterized by X-ray crystallography.[843,844]

Ligands (**312**)–(**319**) are usually synthesized by template reaction between $[Ni(C_6H_4S_2)_2]^{2-}$ and the corresponding dibromide linker, e.g., $(BrCH_2CH_2)_2S$. Even chiral ligands such as (**318**) (R' = Me, $HO(CH_2)_9$, $PhCH_2$) can be obtained.[845] The ligands can be displaced for complexation to other metals by treatment with aqueous HCl. Depending on the linker, the corresponding Ni^{II} complexes adopt various coordination geometries (Table 3) examined by crystallographic and spectroscopic methods.[846–850] For example, the Ni^{II} complex of (**312**) is the first five-coordinate Ni^{II} complex with all-sulfur coordination.

Table 3 Ni^{II} complexes of ligands (**312**)–(**319**).

Ligand	*R*	*Complex type*	*Coordination number*
(**312**)	—$(CH_2CH_2S)_nCH_2CH_2$— ($n=2$)	[NiL]	4

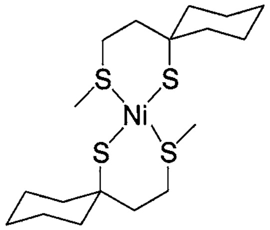
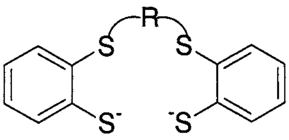
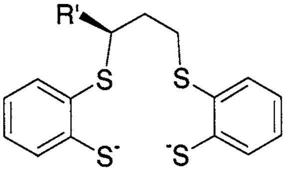
(**310**)



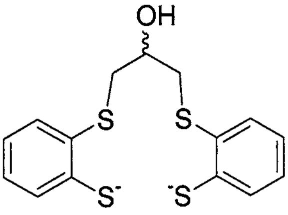
(**311**)



(**312–317**)



(**318**)



(**319**)

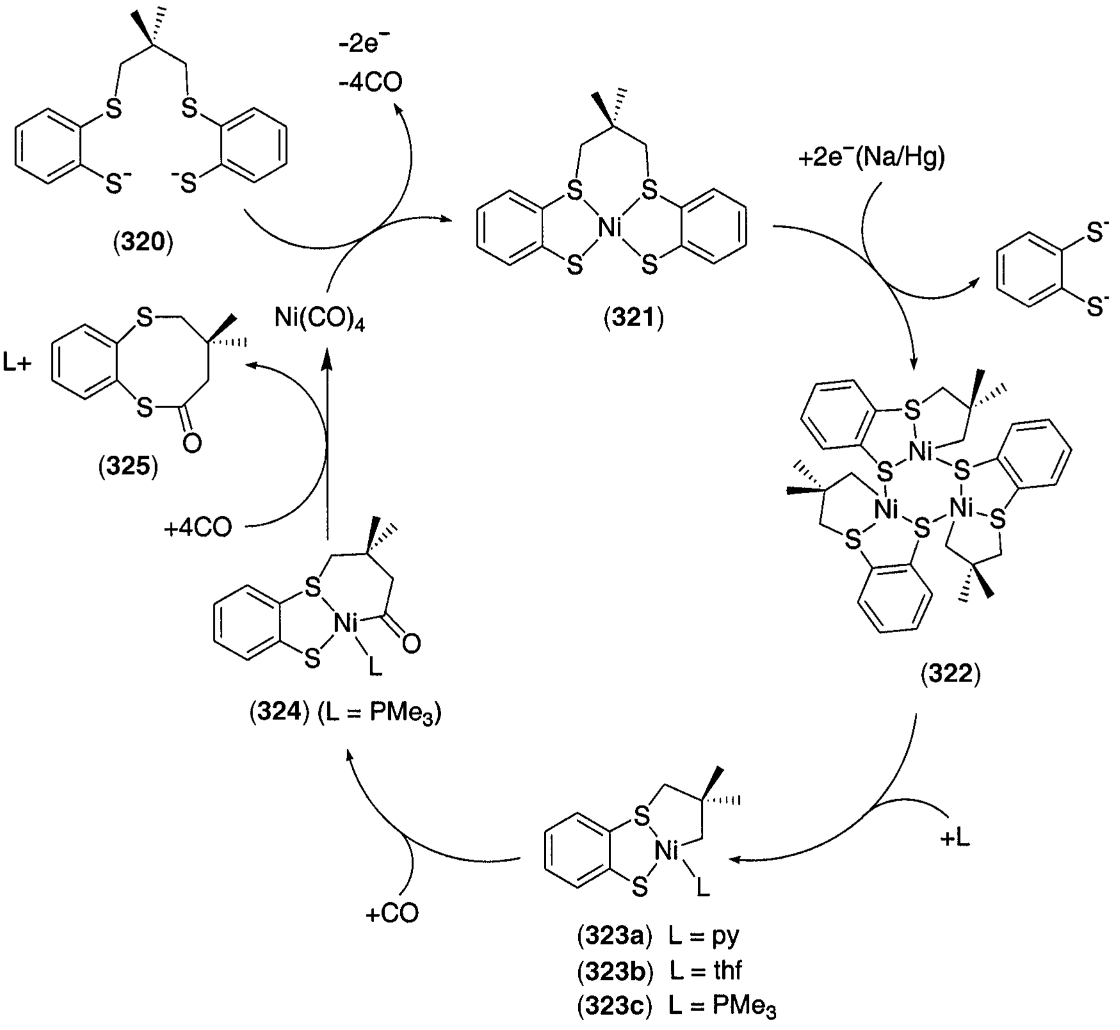
Nickel complexes of this group are of interest in biomimetic work. By means of ligand (**320**) the complete reaction cycle of acteyl CoA synthase could be executed (Scheme 2). Ligand (**320**) can also be synthesized by a template reaction. Upon reduction of the Ni^{II} complex (**321**) with Na/Hg, the ligand backbone is cleaved, resulting in a thermally stable trinuclear Ni^{II} alkyl thiolato complex (**322**).

Treatment of (**322**) with donor ligands L (L = Py, thf, PMe_3) affords the corresponding mononuclear complexes (**323**). Subsequent stoichiometric reaction with CO ultimately leads to formation of the cyclic thioester (**325**) and $Ni(CO)_4$. By reaction of (**323c**) with CO the intermediate Ni^{II} acyl thiolato complex (**324**) could be intercepted and fully characterized. The original complex (**321**) can be regenerated by reaction of $Ni(CO)_4$ with ligand (**320**). Hence, the reaction cycle that comprises the CODH sequence [Ni] → [Ni–alkyl] → [Ni–acyl] → [Ni] + thioester is closed.[851]

In order to obtain suitable precursors of Ni^{II} complexes $[LNiX]^{n-}$ that model the reactive sites of hydrogenases and CO dehydrogenases, compounds with the ligand L = bis(2-mercaptophenyl)-sulfide were synthesized ($X = SR^-$, PR_3, Cl^-, N_3^-). All these complexes (**326**) exhibit a distorted tetrahedral coordination geometry.[852,853]

With X = $HNPPr_3$ the new phosphorane imine complex (**326a**) was obtained. Spectroscopic and structural data indicate that the $HNPPr_3$ ligand favors an ylidic structure.[854]

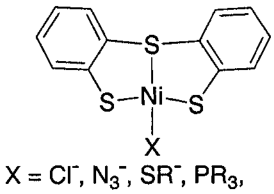
The exchange reaction of $LNiHNPPr_3$ (**326a**) with D_2 at 10 bar gave $LNiDNPPr_3$ and HD. This reaction can be followed by ^2H NMR spectroscopy. Similarly the exchange reaction of (**326a**) with D_2O gave $LNiDNPPr_3$ and HDO. These findings suggest a D_2 heterolysis caused by the concerted attack of the Ni^{II} center and the thiolate donor. Following Scheme 3 an exchange of H and D occurs, resulting in the formation of HD.[855]



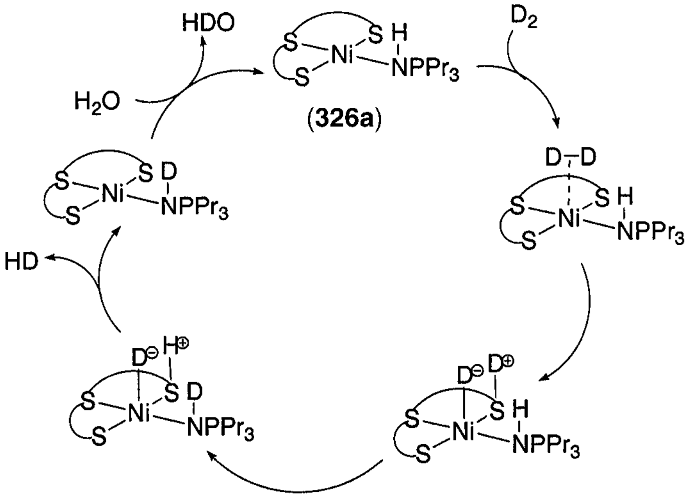
Scheme 2

The type (**326**) azido and amido complexes $NBu_4[\{S_3\}NiN_3]$ and $NBu_4[\{S_3\}Ni\{N(SiMe_3)_2\}]$ were found to react with CO, CO_2, and SO_2 under very mild conditions at temperatures down to −50 °C. Depending on the oxidation state of the N-donor ligands, addition or partial to complete desoxygenation of the oxides take place. The reaction between $NBu_4[\{S_3\}NiN_3]$ and CO gives $NBu_4[\{S_3\}Ni(NCO)]$. The reaction between $NBu_4[\{S_3\}Ni\{N(SiMe_3)_2\}]$ and CO, CO_2, and SO_2 affords selectively the complexes $NBu_4[\{S_3\}NiX]$ with X = CN^-, NCO^-, NSO^-. The silyl groups act as oxygen scavengers. Mechanisms are suggested which have in common the formation of reactive five-coordinate $NBu_4[LNiXX']$ intermediates. In these reactions highly activated X and X′ react with each other.[856]

The oxidation of nickel-bound thiolate by dioxygen has been explored for complexes of multidentate ligands including $S(CH_2CH_2S^-)_2$.[857] Reaction of the dithiole with $Ni(OAc)_2$ gives the thiolate bridged dimer $[Ni\{S(CH_2CH_2S^-)_2\}]_2$. Reaction of this with $(Et_4N)CN$ gives planar $Et_4N[Ni\{S(CH_2CH_2S^-)_2\}CN]$ (**327**), the crystal structure of which shows a highly distorted square

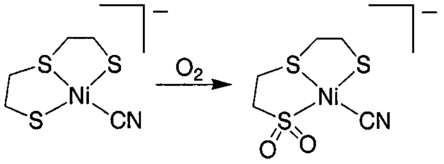


(326)

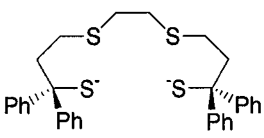


Scheme 3

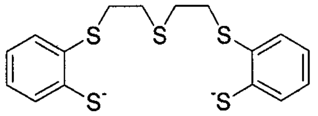
planar arrangement with *trans*-thiolates. (**327**) reacts with dioxygen to form a planar complex (**328**) of a mixed thiolate–sulfinate ligand. Isotopic labeling studies show that the two sulfinate atoms in each molecule derive mainly from a single O_2 molecule.



(327) (328)



(329)



(330)

The ligand (**329**) affords with $\mathrm{Ni^{II}}$ the dark violet square planar complex [Ni(**329**)].[858,859] Cyclic voltammetry shows that [Ni(**329**)] undergoes one-electron reduction at $-1.33\,\mathrm{V}$, which shifts to more positive potentials and becomes irreversible in the presence of CO. This together with IR spectroscopic data suggests that the corresponding $\mathrm{Ni^{II}}$ complex binds CO. Moreover the complex is catalytic for CO_2 reduction. Thus, the complex mimics two of the suggested reactions of the nickel site in [NiFe] CODH.

A nickel-promoted C—S bond cleavage has been reported,[860] which occurs when solutions of the $\mathrm{Ni^{I}}$ complex of (**330**) are electrogenerated. The product was identified by cyclic voltammetry and spectroscopy as $[\mathrm{Ni(C_6H_4S_2)_2}]^{2-}$. EPR and NMR evidence suggests a one-electron mechanism, involving reduction to a 19-electron $\mathrm{Ni^{I}}$ species, electron transfer, and concomitant C—S bond cleavage, extrusion of ethylene followed by a further one-electron reduction and extrusion of ethylene sulfide.

The olive green precursor to the S-rich $[\mathrm{Ni(S_2CPh)(S_3CPh)}]$, originally thought to be $[\mathrm{Ni^{IV}S(S_2CPh)_2}]_2$, has been identified as $[\mathrm{Ni(S_2CPh)_3}]^-$ and crystallographically characterized as the $[\mathrm{K(2,2,2\text{-}crypt)}]^+$ salt.[861]

6.3.4.7.4 Complexes with dithiophosphates and related ligands

With dithiophosphate ligands (also called phosphorodithioates), $\mathrm{Ni^{II}}$ forms complexes of the general formula $[\mathrm{Ni\{S_2P(OR)_2\}_2}]$ with the bidentate ligands forming four-membered chelate rings. The $\{\mathrm{NiS_4}\}$ core has a square planar structure as confirmed by three crystal structures of this complex type with $\mathrm{R = Pr^i}$,[862] cyclohexyl,[863] and the cyclic ligands with R—R = biphenyl and dimethylethylene.[864] In addition, a number of adduct complexes with N-donors have been characterized structurally (Table 4). In the case of monodentate amine ligands, the square planar

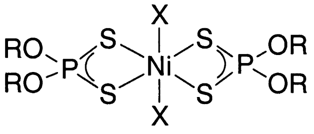
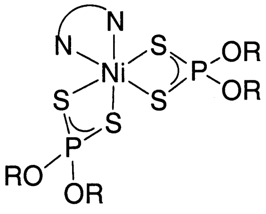
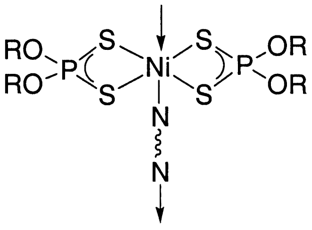
$\{NiS_4\}$ core is conserved giving *trans* octahedral complexes, while with bidentate amines *cis* octahedral complexes are obtained. Linear bidentate amines can result in a 1D chain like in compound (**341**) where 4,4′-bipyridine molecules bridge the square planar units.



L_2NiX_2



L_2NiX



$[L_2NiX]_n$

In compounds (**333**) and (**336**) the amines substitute one of the dithiophosphate ligands to form a $\{NiN_4S_2\}$ core with the second dithiophosphate ligand serving as a counterion. Coordination number 5 is rare, but is found for complex (**345**) where one of thiophosphates switched to a monodentate coordination,[879] and in compound (**346**) where only one additional phosphine adduct coordinates to Ni.[880]

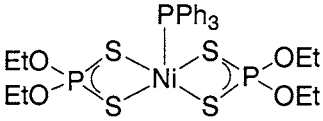
(345)



(346)

Stability constants of dithiophosphate nickel complexes have been determined by potentiometric and spectrophotometric measurements.[881] A number of binary and mixed ligand Ni complexes of dialkyl dithiophosphate and ammoniumethyl dithiophosphate were studied with respect to their thermal decomposition reactions by TG and DSC techniques in nitrogen and oxygen atmospheres.[882] The activation energies for the thermal decomposition were determined thermogravimetrically using different approaches to analyze the data.[883–885] The thermogravimetric and vapor pressure studies of a number of [NiL$_2$] complexes reveal that only for R = Et the thermal stability is high enough to allow gas chromatography of these compounds.[886] N-donor adduct complexes are unstable towards the loss of the N-donor upon heating.[887,888] Nickel complexes of dithiophosphates are not stable towards hydrolysis.[889] Hydrolysis can be followed by ^{31}P NMR spectroscopy.[890] The complex dissociation of bis(O,O′-dipropyl dithiophosphato) Ni^{II} in ethanol–water mixtures can be utilized for spectrophotometric detection of the alcohol content of alcoholic drinks.[891]

Various physicochemical methods have been used to investigate structural features and properties of the dithiophosphate Ni^{II} complexes,[892–894] among them IR, ^{1}H NMR, ^{31}P NMR, EPR, ENDOR,[895] electronic spectroscopy,[896] spectrophotometry,[897] magnetochemical studies, as well as cyclic voltammetry and coulometry.[898] The oscillator strength for the *d–d* transitions in planar [ML$_2$] complexes of D_{2h} symmetry were calculated within the framework of the vibronic mechanism and the AOM. General expressions were used to interpret the intensities and polarization of the *d–d* bands in the bis(diethyldithiophosphato) Ni^{II} spectra.[899] A theoretical *ab initio* (pseudopotential valence only) and UV–PE (He I and He II) spectroscopic examination of [M(S$_2$P{OEt}$_2$)$_2$] complexes (M = Ni, Pd, Pt) has been reported. The conclusions of this study are that the metal-based orbitals are more tightly bound in Ni than in Pd or Pt complexes. Ni ionization energies obtained by the Tamm–Dancoff method deviate from Koopman's theorem. The dominant nickel–ligand interaction is of σ-character, the d_{xz} and d_{yz} orbitals being almost nonbonding.[900]

Complexes with the enantiomeric ligands cyclo-O,O′-(*R*,*R*)- or (*S*,*S*)-1,2-dimetylethylene dithiophosphate were synthesized and characterized via UV–visible and CD-spectroscopy and by an X-ray crystal structure, the results of which were correlated. The absence of an intrinsic configurational chirality on the metal results in CD-spectra due only to the less intense chirality induced on the Ni^{II} electronic *d–d* transitions by the ligands outer ring conformations and absolute configuration on the C$_2$ and C$_3$ atoms of the two chelating ligands.[864]

A huge number of Ni^{II} thiophosphate complexes and their adducts with nitrogen bases like pyridine, picoline, bipyridine, phenanthroline, or isochinoline have been prepared and characterized by spectroscopic methods.[894,901–903] For example, ^{14}N NMR was used to measure the pyridine exchange in a series of pyridine adducts.[904] The relationship between the intrinsic Lewis acidity of the Ni^{II} center in the parent complex, as measured by equilibrium constants for bis(pyridine) adduct formation, and the lability of pyridine in the adducts were explored. In another investigation, the interaction of NiL$_2$ with several pyridine-type adducts was studied via relative isotropic ^{1}H NMR spectroscopic shift studies.[905] The adduct formation has been examined thermodynamically by spectrophotometric methods, and formation constants and reaction enthalpies and entropies were measured.[906] For some N-adduct complexe structures deviating from the above mentioned ones were suggested from electronic and IR spectra.[876,907] Good agreement between electronic spectra of a number of complexes and calculated values using the ASED-MO method was observed.[908]

Adducts other than N bases are thiourea,[909] phosphine,[880] and N,O-donors (hydroxyquinoline derivatives).[910] In the last case {NiONS$_2$} complexes were formed. Generally, complexes of dithiophosphates are used as antiwear and antioxidant additives.

Few compounds with dithiophosphonate R(R′O)PS$_2$ or dithiophosphinate R$_2$PS$_2$ ligands have been reported. The resulting complexes (**347**) and (**348**)[911–913] also show a square planar coordination geometry.

Ni^{II} complexes of variously substituted dithiophosphonates have been investigated by vapor pressure osmometry and ^{31}P NMR spectroscopy.[914] Coordination polymers of the type [S$_2$P(R)-R′-(R)PS$_2$Ni]$_n$ (**350**) are formed when R′ = *p*-(C$_2$H$_4$)$_2$C$_6$H$_4$. However, when R′ = *o*-(C$_2$H$_4$)C$_6$H$_4$ and *o*-(C$_3$H$_6$)$_2$C$_6$H$_4$, an equilibrium in solution, consisting of *ansa*-type (**349**) and polymeric complexes (**350**) is found.[914]

Amine adducts of Ni^{II} diphenyldithiophosphinate with substituted ethylenediamins have been prepared and characterized. A dimeric pentacoordinate structure was proposed for [Ni$_2$(S$_2$PPh$_2$)$_4$(tmeda)].[915] One crystal structure of a square planar Ni^{II} complex (**351**) with an aminophosphonate ligand has been reported.[916]

Complex (**352**) has been synthesized, characterized by X-ray crystallography, and used as a catalyst in the oligomerization of ethylene to α-olefins, where it shows high activity.[917] Thiophosphate PS$_4^{3-}$ (**353**) can also be used as a ligand. With Ni^{II} discrete trinuclear complexes [Ni$_3$(PS$_4$)$_3$]$^{3-}$ can be crystallized from DMF by addition of Ph$_4$PBr. In the inorganic ring the thiophosphates serve as bridges between the nickel centers.[918]

6.3.4.7.5 Complexes with xanthates and related ligands

A great number of Ni^{II} complexes with xanthate ligands have recently been characterized by crystal structure. The binary complexes (**354**) show square planar coordination of the Ni^{II} center [Ni(S$_2$COR)$_2$] (R = Et,[919] Pr^i,[920] Pr^n,[920] Bu^n,[921] Cy-Hex,[922] PhCH$_2$,[923] CF$_3$CH$_2$, MeOCH$_2$CH$_2$,[924] etc.), the ligands coordinating in a bidentate manner. The crystal structure of an octahedral [Ni(S$_2$COR)$_3$]$^-$ complex (**355**) has also been reported.[925]

Furthermore, a series of ternary compounds have been crystallized. Most work has been done on adducts with N bases.

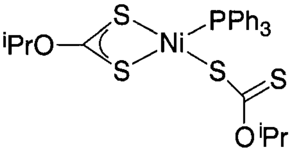
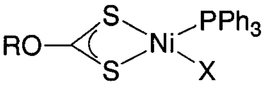
(359b) R' = Me, R = Cy



(360)



(361a) R = Amyl, X = Br
(361b) R = ^{i}Pr ,X = Cl

Analogous to the dithiophosphate complexes, *cis* octahedral complexes are formed with bidentate ligands like phenanthroline, 2,2′-bipyridine, or tmeda and *trans* octahedral complexes are formed with monodentate ligands like pyridine and its derivatives. Some examples are mentioned with linear bidentate ligands like 4,4′-bipyridine, which build up 1D chains by bridging the [NiL$_2$] molecules.[926–933]

With P-donors a variety of different structures are formed. Two complexes (**359a,b**) with a five-coordinate square pyramidal geometry and one S-donor in the apical position are reported.[934,935] In a related complex (**360**) the nickel center reveals a distorted square planar geometry, because one xanthate ligand switched to a monodentate coordination mode.[936] By reaction of [NiL$_2$] complexes with Ph$_2$P(CH$_2$)$_2$P(Ph)(CH$_2$)$_2$PPh$_2$, compound (**362**) is formed, which consists of a five-coordinate cation and a hexacoordinate anion.[937]

In (**362**), the cation is distorted trigonal pyramidal with the axial positions occupied by one S atom and the central P atom of the {P$_3$} ligand. In the anion the nickel center is bonded to six S-donors of three xanthate ligands. Upon reaction with dppe an approximately square planar {NiS$_2$P$_2$} complex results.[938] A similar coordination geometry is found for the two complexes (**361a,b**).[939,940]

The bis(xanthate) Ni^{II} complexes and their adduct complexes have been characterized by various physicochemical methods like NMR, IR, and UV.[941,942] Electrochemical investigations of [Ni(S$_2$COEt)$_2$] revealed two irreversible oxidation peaks at 0.35 V and 0.80 V (referenced to the Ag/Ag$^+$ electrode). The CV of [(EtOCS$_2$)$_3$Ni]$^-$ displays one reversible (−0.15 V) and two irreversible (0.35 V and 0.80 V) oxidation peaks.[943,944] The low-temperature EPR spectra of the oxidatively electrolyzed solution of [NiL$_3$]$^-$ indicates the presence of [Ni^{III}L$_3$], which disproportionates to [NiL$_2$] and the dimer of the oxidized ligand, EtOC(S)SS(S)COEt. The corresponding chemical oxidations were achieved with iodine. Xanthate Ni^{II} complexes are of interest as liquid crystals, and as additives in lubricating oils or in polymers as antioxidants.

6.3.4.7.6 Complexes with dithiocarbamate and related ligands

Quite a number of Ni^{II} complexes with dithiocarbamate ligands have been characterized structurally. These complexes have the general formula $[Ni(S_2CNRR')_2]$ with the carbamates being unsubstituted (R, R' = H), N-monosubstituted (R = alkyl, aryl; R' = H), or *N*,*N*-disubstituted (R, R' = alkyl, aryl).[945] As the carbamates coordinate bidentately through the S-donors, a square planar coordination geometry with four-membered chelate rings is found. The Ni—S bond lengths are in the range 2.19–2.22 Å.

The substituents R and R' may even bear further functional groups like in (**363a**)[946] and (**363b**)[947] or be part of a cyclic system like in (**363c**)[948] and (**363d**).[949] Similar complexes (**363e**) and (**363f**) have been made using tetrahydroquinoline dithiocarbamate and tetrahydroisoquinoline dithiocarbamate.[950] A convenient synthetic route to the preparation of carbodithioato derivatives of weak N nucleophiles has been reported: N–alkyldithiocarbamate ligands, when bidentately coordinated to Ni^{II}, were found to undergo facile electrophilic substitution reactions with a diversity of electrophiles, yielding novel carbodithioato derivatives of weak N bases, not available by other synthetic methods.[951,952] Furthermore, complexes with dithiocarbamate ligands containing electrophiles $[Ni(S_2CN(E)R]$ (E = electrophile, e.g., CONHPh, COOEt, $PhSO_2$; R = Me, *n*-butyl, Ph, $PhCH_2$) have been prepared and characterized by spectroscopic methods.[953]

Analytical techniques that have been applied to study the carbamate complexes are, *inter alia*, electronic,[954] IR, resonance Raman, NMR, UV, and XPS[955–958] spectroscopy. An interesting development is a correlation of the shifts in the infrared spectra with those observed for atomic core levels in the X-ray photoelectron spectra.[959] ^{59}Ni and ^{62}Ni isotopic labeling has been applied in an infrared study carried out on a variety of heterocyclic dithiocarbamate nickel complexes. Assignment of the Ni–ligand vibrational modes revealed that the Ni—S bond strength is practically independent of the substituent in the heterocycle.[960]

A comparative study of the electronic structures of *N*,*N*-diethyldithiocarbamate and pyrrole-*N*-carbodithioate has been undertaken.[961] The enthalpy of formation of $[Ni(S_2CNMe_2)_2]$ ($-146.1 \pm 10.9\,kJ\,mol^{-1}$) has been measured.[962] The square planar dithiocarbamate complexes can be oxidized to the corresponding five-coordinate Ni^{III} dithiocarbamate complexes $[Ni(S_2CNR_2)_2X]$ (X = I, Br, ClO_4) using Br_2, I_2, or $(NO)ClO_4$.[963,964]

A number of mixed ligand complexes have been reported. In many cases the square planar coordination geometry is conserved in complexes [NiLQ] (Q = xanthates, aldoximes, dimethylglyoxim,[954,965] Schiff bases derived from L,[966] or phosphines).[957,967–970] Comparison of a dithiocarbamate complex (**364**) with PPh_3 ligands and the corresponding complex (**365**) with the chelating phosphine dppe revealed that both complexes have planar $\{NiS_2P_2\}$ chromophores, but dppe forces the Ni—S distances to be symmetrical (2.200 Å and 2.204 Å), while PPh_3 induces asymmetry (2.227 Å and 2.198 Å).[971,972] On the contrary the phen adduct of $[Ni(S_2CNEt_2)_2]$ is the first example of the addition of a chelating diamine to form an octahedral complex $[Ni(dtc)_2(phen)]$ (**367**).[973]

The reactivity of (**367**) and (**368**) towards phosphine complexes of Ni^{II} has been investigated. Depending on the nature of the phosphine and the dithiocarbamate used, different complexes were obtained.[974] The stability constants for the Ni^{II} complexes of (**369**), (**370**), and (**371**) have been determined in aqueous solution. Both 1:1 and 1:2 complexes were observed.[975]

6.3.4.7.7 Complexes with thiooxalate and related ligands

Considering the four thiooxalates 1,1-dithiooxalate (i-dto), 1,2-dithiooxalate (dto), trithiooxalate (trto), and tetrathiooxalate (tto), dto is by far the most prominent in Ni^{II} coordination chemistry.[976]

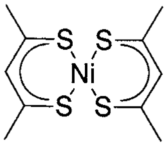
Dto coordinates to Ni^{II} in a bidentate manner via its sulfur donors, resulting in square planar dianion complexes $[Ni(dto)_2]^{2-}$. The nickel chelate with dto is much more stable than that with oxalate. However, the remaining dto oxygens tend to coordinate to further metal ions (e.g., the counterions) to yield definite multinuclear arrangements. In complexes with organic "onium" cations (e.g., anilinium,[977] pyridinium,[978–980] pyrazinium,[981] ethylenediammonium,[982] arsonium,[983] or phosphonium[984]) this interaction is lacking. Nevertheless the crystal structures of these compounds reveal that the ions are associated through H bonds, the motif depending on the nature of the cation. Supramolecular interactions lead to a 3D character.[985] The spectroscopic properties of the dto–nickel complexes are well examined and a comprehensive summary is given in a review.[978]

6.3.4.7.8 Complexes with dithioketones and related ligands

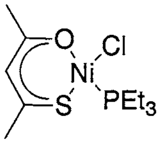
Dithioacetyacetone (sacsac) forms square planar complexes with Ni^{II}, the chelate rings being six membered. A comparative IR, ^1H NMR, and ^{13}C NMR study of nickel complexes with sacsac and the derivates acac, nacac, and sacac has been carried out.[986] An electrochemical study of [Ni(sacsac)$_2$] (**376**) revealed a one-electron quasi-reversible reduction at -1.54 V and an irreversible four-electron oxidation at $+0.64$ V. The product of the reduction reacts with H_2O, CO, CO_2, CH_3I, and $C_{12}H_{25}SH$.[987] Addition of N-donors L to [Ni(sacsac)$_2$] leads to five-coordinate complexes [Ni(sacsac)$_2$L] (L = variously substituted pyridines or anilines).[988,989]

Nickel ketoenolates are active catalysts in olefin polymerization. The reactions are promoted by phosphines as coligands. Complexes [Ni(sacsac)X(PR$_3$)] (R = Ph, Me, Et, cyclohexyl; X = Cl, Br),[990] [Ni(sacac)Cl(PR$_3$)] (**377**; R = Et, Bu^n) and [Ni(sacsac)Ph$_2$P(CH$_2$)$_n$PPh$_2$]BPh$_4$[991,992] (n = 1,2) have been reported, which disproportionate to some extent in solution. The crystal structure of [Ni(sacac)Cl(PEt$_3$)] (**377**) shows square planar geometry of the Ni^{II} ion with P *trans* to O and S *trans* to Cl. Changing the phosphine ligand affects the activity and selectivity of the oligomerization reaction, while changing sacac for sacsac increases catalyst activity.[993,994] Crystal structures of mixed ligand complexes (**378a**) and (**378b**) with derivatives of sacsac and diisopropyldithiocarbamate have been reported.[995,996]

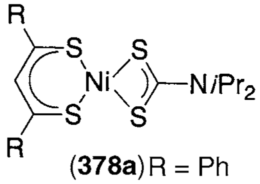
Also, the structure of the Ni^{II} complex (**379**) with the related ligand dimethyltetrathiomalonate has been determined.[997] The geometry at the nickel center is approximately square planar with an inversion center. (**379**) shows reversible redox properties.[998] Oxidation with I_2 affords1,3-bis (methylthio)-1,2-dithiolium triiodide.



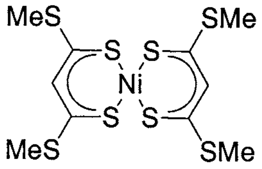
(**376**)



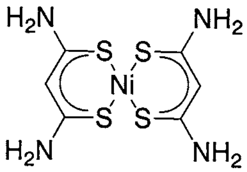
(**377**)



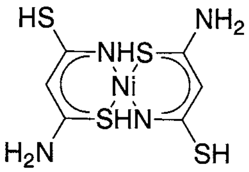
(**378a**) R = Ph
(**378b**) R = CF$_3$



(**379**)



(**380a**)

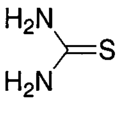


(**380b**)

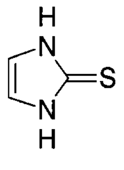
A related ligand is dithiomalonamid, which is able to form two different coordination isomers (**380a**) and (**380b**) with Ni^{II}.[999] One X-ray structure of the diphenyl derivative has been determined. In this case the ligand coordinates via the S-donors, so that a square planar {NiS$_4$} arrangement results. NMR spectra confirm that the structure is maintained in solution.[1000]

6.3.4.7.9 Complexes with thiourea and related ligands

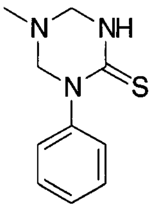
Thiourea and substituted thioureas coordinate as monodentate ligands to Ni^{II} to give either square planar [NiL$_4$] or octahedral complexes [NiL$_4$X$_2$] in most cases. Some of these complexes with parent thiourea (**381**), imidazolidene-2-thione (**382**),[1001] and 1-methylimidazoline-2-thione[1002] have been characterized by X-ray crystal structure. Solely for the complexes [NiL$_2$Cl$_2$] (L = (**383**))[1003] and [NiL$_2$X$_2$] (L = phenyl-thiourea; X = CN$^-$, SCN$^-$)[1004,1005] a high-spin tetrahedral coordination geometry is proposed.



(**381**)



(**382**)



(**383**)

Another exception is $[NiL_3(NCS)X]_2$ (L = thiourea, *o*-tolylthiourea; X = Cl^-, NO_3^-), which is a dinuclear complex with thiocyanato bridges.[1006] Numerous complexes with substituted thiourea have been synthesized[1007–1009] and characterized by spectroscopic or thermogravimetric methods. IR and Raman spectroscopy are excellent tools for proving coordination via the S-donor. For a series of $[NiL_4Cl_2]$ complexes the thermal degradation has been investigated, indicating two different decomposition mechanisms via intermediates $[NiLCl_2]$ or [NiLCl] to give NiS as the final product. The respective mechanism depends on the structure of the thiourea ligand.[1010]

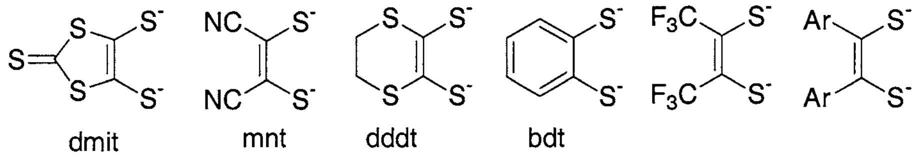
A theoretical study employing the discrete variational Xα implementation of Hartree–Fock–Slater theory has been carried out for $[Ni(thiourea)_4Cl_2]$. This accounts better for experimental data (optical spectra, magnetic properties, and charge density distribution) than crystal or ligand field theories and supports the existence of considerable covalency in the metal–ligand bonding.[1011] The dependence of the spin state of *trans*-$[NiL_4X_2]$ (L = diethyl-thiourea; X = Cl, Br, I) on pressure has been studied. High pressure shifts the singlet–triplet equilibrium observed for these complexes in favor for the triplet. This is consistent with pressure forcing the axial ligands closer to the nickel ion.[1012]

N,*N*′-diphenylthiourea (H_2L) has been reacted with Ni^{II} to give the neutral complex $[Ni(HL)_2]$, which has been characterized using spectroscopic and thermogravimetric analysis. In addition, the stability constants for $[Ni(HL)]^+$ and $[Ni(HL)_2]$ have been determined spectrophotometrically.[1013]

Various thiourea ligands have been used in the synthesis of mixed ligand complexes. A series of complexes $[NiQ_2L_2]$ (HQ = ethylacetoacetate, L = thiourea, allyl-, benzoyl-, methyl-, diphenylthiourea) have been prepared. The complexes are all paramagnetic ($\mu = 3.02$–$3.27\mu_B$) and have been assigned *trans*-octahedral structures.[1014]

6.3.4.7.10 Complexes with dithiolene ligands

Bis-1,2-dithiolene complexes have been widely studied due to their physical properties and their projected applications in the areas of conducting and magnetic materials, dyes, nonlinear optics, catalysis, and others. These applications arise from a combination of functional properties, specific geometries, and intermolecular interactions. A large number of new dithiolene ligands and resultant complexes have been prepared with the aim to vary and optimize the molecular properties and to prepare novel and improved materials. This interest, fired by the discovery of phenomena such as superconductivity and ferromagnetism in metal dithiolene salts, has resulted in the search for new analogues with better properties. A selection of frequently employed dithiolene ligands is given below.



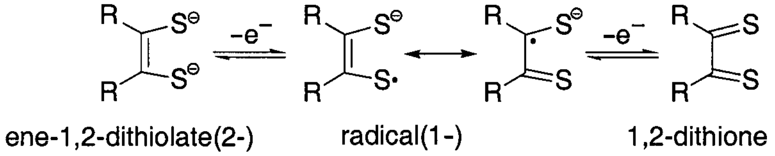
Several reviews presenting various aspects of dithiolene chemistry have appeared over the years,[1015–1026] so that this summary will only focus on some selected findings. Also, the photodissociations of Ni dithiolene complexes, which lead to long-lived Ni complex radicals, have been reviewed.[1027] Since many studies in the field of Ni–dithiolene chemistry deal with different oxidation states of the metal, this chapter will also cover much work related to Ni^{III} and Ni^{IV}.

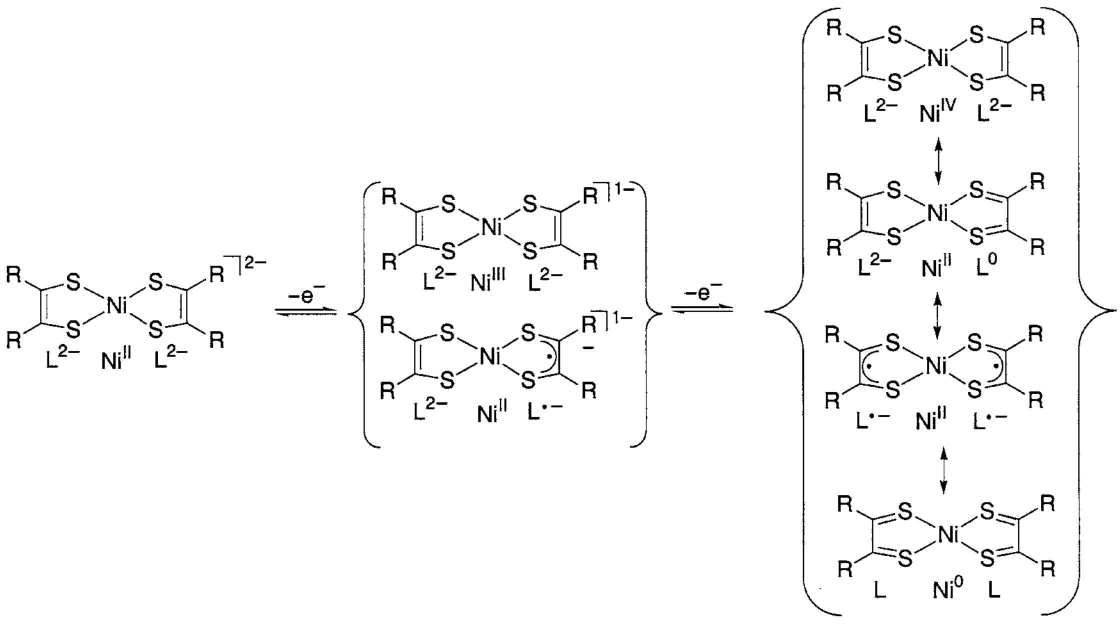
The most characteristic feature of nickel dithiolene complexes is the existence of an electron transfer series whose members are interrelated by reversible one-electron steps. Three members I–III of the series, I and III being diamagnetic and II having an $S = 1/2$ ground state, are preparatively accessible: $[Ni(S_2C_2R_2)_2]^{2-}$ (I) $\leftrightarrow$ $[Ni(S_2C_2R_2)_2]^{1-}$ (II) $\leftrightarrow$ $[Ni(S_2C_2R_2)_2]$ (III).

The well-known ambiguities in limiting descriptions of metal and ligand oxidation states are summarized below.

While the structural and electronic properties of the dianions are consistent with the indicated Ni^{II}–enedithiolate description, two and four formulations are conceivable for the monoanion and the neutral complex, respectively. For the latter, one is a ligand diradical whose spins are antiferromagnetically coupled, consistent with diamagnetism. Numerous members of the series have been isolated and/or generated in solution by chemical or electrochemical reactions. Because redox potentials are markedly dependent on the nature of the R substituent, certain members of a given series have not been isolated in substance.

$$\begin{array}{ccccc}[Ni(S_2C_2R_2)_2]^{2-} & \leftrightarrow & [Ni(S_2C_2R_2)_2]^{1-} & \leftrightarrow & [Ni(S_2C_2R_2)_2] \\ I & & II & & III\end{array}$$





There are few examples of complexes where all three oxidation states have been isolated. Two examples, $[Ni(S_2C_2(CF_3)_2)_2]^{0,1-,2-}$ and $[Ni(S_2C_2Ph_2)_2]^{0,1-,2-}$, had already been realized in the 1960s. For the two newer examples, $[Ni(S_2C_2Ph_2)_2]^{0,1-,2-}$ (**384**)[1028] and $[Ni(3,5\text{-}Bu^t{}_2bdt)_2]^{0,1-,2-}$ (**385**)[190], even X-ray structures of all three oxidation states are available. All members of the series show planar structures, the *d*(Ni—S) and *d*(C—S) bond lengths increase, the *d*(C—C) bond lengths decrease. For (**384**), DFT calculations reveal that the electroactive orbital is highly delocalized, and electron transfer reactions are largely ligand-based events. The isolation of the three species (**385**) confirms that ligands derived from 1,2-benzenedithiolate(2-) behave as normal 1,2-dithiolate ligands. Here the X-ray structures show a different trend: *d*(Ni—S) and *d*(C—S) decreasing and *d*(C—C) almost retaining its value. Together with XPS and EPR investigations this has led to the suggestion that the oxidation concerns electrons which reside in orbitals having $\{NiS_4\}$ character (compare also Section 6.3.3.6).

An enormous amount of research has gone into the synthesis and characterization of dmit ligand complexes and related selenium and oxygen isologues. Interest centers on the isolation of metallic or even superconducting materials, which owe these properties to extensive intermolecular S···S or Se···Se interactions.

The discovery of the first molecular superconductor containing a transition metal complex, TTF[Ni (dmit)$_2$]$_2$ (**386**), initiated a significant effort into the search for more of these fascinating materials.[1029]

Since then seven further superconducting (at low temperatures and/or under high pressures) dmit-based complexes with Ni or Pd as metal, synthesized via electrocrystallization, have become known. The donor–acceptor complex α-(EDT-TTF)[Ni(dmit)$_2$]$_2$ is the first ambient pressure superconductor with $T_c = 1.3$ K.[2578]

The electrocrystallization and characterization of a novel molecular metal which displays both electronic and ionic conduction has been reported. The complex Li$_{0.6}$(15-crown-5-ether)[Ni(dmit)$_2$]·H$_2$O is composed of stacks of [Ni(dmit)$_2$] units which provide pathways for electronic conduction. The stacks are separated by parallel stacks of 15-crown-5-ether moieties in a channel-like formation which facilitates ion conduction. The salt has a room temperature conductivity of 240 S cm^{-1}. Temperature-dependent magnetic susceptibility and NMR measurements were used to prove the existence of Li$^+$ movement within the crown ether channels.[1030]

Concerning molecule-based magnets, the first spin-ladder was synthesized: (*p*-EPYNN)[Ni (dmit)$_2$] (*p*-EPYNN = *p*-*N*-ethylpyridinium α-nitronyl nitroxide). Within the crystal lattice, the radical cation *p*-EPYNN units are arranged in 1D chains with ferromagnetic interactions. The chains of [Ni(dmit)$_2$] moieties in the ladder formation exhibit coexistent antiferromagnetic interactions.[1031,1032]

A much smaller amount of work has been done with nickel complexes of dmt ligands since they are more difficult to crystallize. Some complexes have been assembled combining [Ni(dmt)$_2$] with viologen-based cations for applications in electrical conductivity and dioxygen activation.[1033–1035]

Nickel complexes with the dmid ligand are also less recognized in research. A conductivity as high as 10^{-2} S cm^{-1} was reached with (Et$_4$N)$_{0.17}$[Ni(dmid)$_2$].[1036] (Bu$_4$N)$_x$[Ni(dmid)$_2$] complexes have been studied by XPS and for applications in electrical switching and memory devices.[1037,1038]

The aim of substituting the S by a Se substituent in dmise is to increase dimensionality in the crystal lattice in order to enhance the electrical properties.[1039,1040] In 1993, the first molecular conductors based on dmise, α- and β-(Me$_4$N)[Ni(dmise)$_2$]$_2$, were reported. The two structures show differences in molecular packing; both exhibit many short intermolecular S···S interactions, and the α structure also has some very short Se···Se distances. The β-phase showed the higher room temperature conductivity of 10 S cm^{-1}(bandgap: $E_g = 0.08$ eV (α), 0.05 eV (β)).[1041] For dsise, the first nickel complexes were reported in 1993 and (Me$_4$N)[Ni (dsise)$_2$]$_2$, a semiconductor, has the highest room temperature conductivity of 12 S cm^{-1}.[1042,1043]

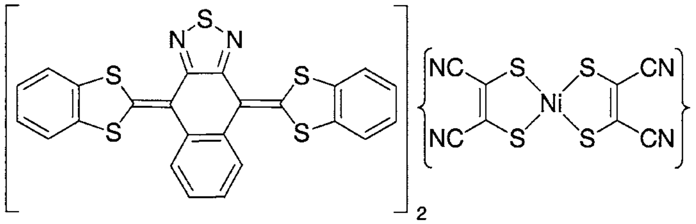
1,2-Dithiolene complexes with the maleonitriledithiolate (mnt) ligand form highly delocalized systems and are widespread in studies of conducting and magnetic materials. The electronic properties have been extensively studied with various computational methods including Hückel and extended Hückel approaches to identify the nature of the orbitals involved in intramolecular and intermolecular interactions. These structural properties allow the complexes to interact in the solid state via short stacking S···S and short interstack S···S contacts.[1044–1048]

In $(NH_4)[Ni(mnt)_2]\cdot H_2O$ ferromagnetic ordering was found below 4.5 K. This material consists of side-by-side stacks of planar $[Ni(mnt)_2]^-$ complexes forming 2D sheets that are separated by a network of ammonium cations and H_2O. The stacks show an equidistant arrangement of the anions, which prevents the dimerization to a singlet ground state, observed in other salts. The Curie temperature increases markedly with pressure until ferromagnetic order abruptly disappears at 6.8 kbar, indicating that the magnetic coupling is very sensitive to intermolecular separation.[1049,1050]

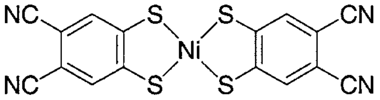
The charge transfer salt $(BDNT)_2[Ni(mnt)_2]$ (BDNT = 4,9-bis(1,3-benzodithiol-2-ylidene)-4,9-dihydronaphtho[2,3-c]1,2,5-thiadiazole) also shows ferromagnetic interaction with $J = 3.4$ K, which was concluded to arise from the $[Ni(mnt)_2]^-$ component on the basis of EPR evidence. In the absence of structural data, however, further understanding of this behavior could not be obtained. The anion was shown to be monoanionic, hence the valence of BDNT is +0.5.[1051]

4,5-Dicyanobenzene-1,2-dithiolate (dcbdt) forms the Ni^{II} complex (**387**) and the respective Ni^{III} and partially oxidized $Ni^{III/IV}$ salts. The paramagnetic Ni^{III} compound is dimerized and its magnetic susceptibility reveals very strong antiferromagnetic coupling.[1052]

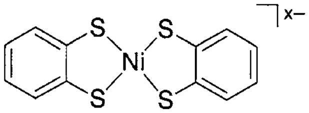
With reference to the exceptional properties of $Li_{0.6}$(15-crown-5-ether)$[Ni(dmit)_2]\cdot H_2O$ some mnt complexes with crown ether complexes of alkali metals as counterions have been reported.[1053–1055] $(NBu_4)_2[Ni(mnt)_2\text{-}Cu_4I_4]$ shows a very unusual structure. The $[Ni(mnt)_2]$ moiety supports a novel eight-membered Cu_4I_4 ring via two cyano groups, four of which coordinate to two copper ions in neighboring molecules, resulting in the formation of a unique doubly-bridged 1D chain structure.[1056] $(DT\text{-}TTF)_2[Ni(mnt)_2]$ shows high room temperature electrical conductivities (40 S cm^{-1}). Observation of a single line in the EPR spectra, which increases dramatically in width as the conductivity increases with temperature, is evidence for the presence of two magnetic subsystems which interact in the salt with paramagnetic $[Ni(mnt)_2]^-$ ions.[1057,1058]



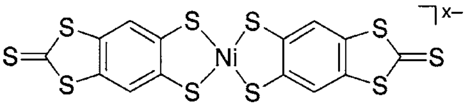
$(BDNT)_2[Ni(mnt)_2]$



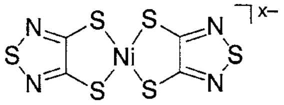
(**387**)



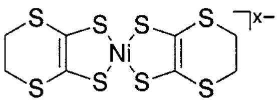
$[Ni(bdt]_2]^{x-}$(**388**)



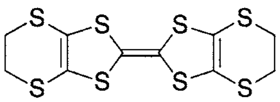
(**389**)



$[Ni(tdas)_2]^{x-}$(**390**)



$[Ni(dddt)_2]^{x-}$(**391**)



BEDT-TTF

Complexes with the bdt ligand are less recognized, but some type (**388**) complexes with ligands derived from bdt have shown interesting properties. $(NEt_4)_x[Ni(S_2C_6H_3CH_3)_2]$ ($x = 2$, 1) has been studied for its electrochemical and spectroscopic properties.[1059]

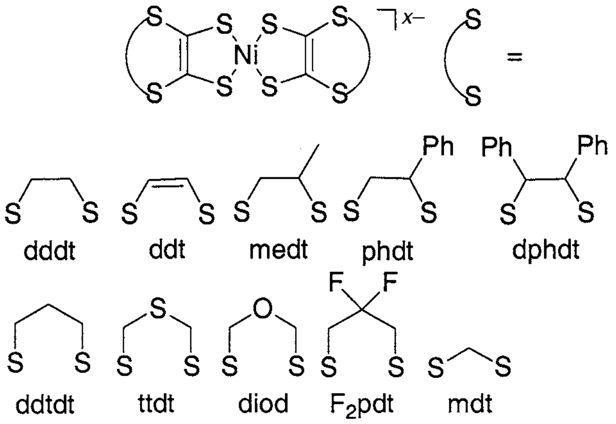
Complex (**389**) can be considered as a dmit analogue, in which the aromatic ring replaces the C=C bond. The complex was isolated as $(NBu_4)_x[NiL_2]$ ($x = 2$, 1, 0.29). The latter nonintegral salt, prepared by electrocrystallization, shows metallic conductivity down to 20 K. The magnetic properties of the 1:1 salt with radical metal complexes revealed Curie–Weiss behavior with a weak antiferromagnetic interaction.[1060,1061] In (**389**), the difference between the first and the second reduction potential is larger than for $[Ni(dmit)_2]^{x-}$.

The salt $(TTF)_2[Ni(tdas)_2]$ (**390**) was obtained by electrocrystallization with a room temperature conductivity of 0.1 $S\,cm^{-1}$. This indicates the potential of these complexes as components of conducting materials. Some tdas complexes have been characterized by X-ray crystal structure.[1062–1064]

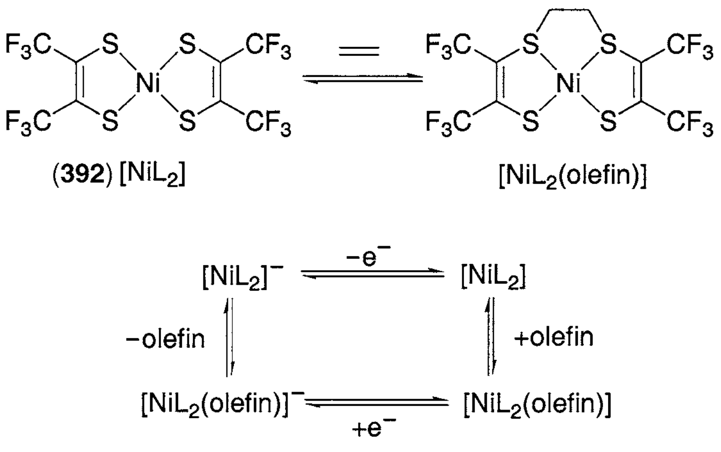
A range of multisulfur 1,2-dithiolene complexes of nickel has been prepared, in which the 1,2-dithiolene moiety has been extended by incorporation of heterorings, e.g., in dddt (**391**). The research motivation had its origin in the similarity to BEDT-TTF, the organic electron donor known to have the largest number of superconducting organic salts and those with the highest T_c. Nickel complexes with the dddt ligand have been synthesized with a range of counterions with the charge on the complex ranging between dianionic, monoanionic, and neutral. But the dddt complexes are exceptional as they can be electrochemically oxidized to mixed-valence cationic complexes. The redox chemistry of $(R_4N)[Ni(dddt)_2]$ has been studied using microelectrode techniques.[1065,1066] Besides a quasi-reversible one-electron reduction ($E \approx -0.7$ V) and oxidation ($E \approx 0.0$ V), a further irreversible oxidation ($E_{pa} \approx +0.9$ V) was observed, assigned to the formation of $[Ni(dddt)_2]_3(BF_4)_2$. The mechanism involves one-electron oxidation to $[NiL_2]^+$ followed by fast chemical processes leading either to the formation of the solid mixed valence complex, or to decomposition. $[Ni(dddt)_2]_3(HSO_4)_2$ and its isostructural analogue, $(BEDT\text{-}TTF)_3(HSO_4)_2$, are both metallic at room temperature and exhibit insulator transitions at 25 K and 130 K, respectively.[1067–1069] $[Ni(dddt)_2]_3[AuBr_2]_2$ also shows metallic behavior down to at least 1.3 K.[1070,1071] Despite nickel dddt complexes and the organic salts being structurally related, there are differences in material properties, caused by differences in the frontier orbitals. Thus, the influence of a much smaller HOMO/LUMO separation in the nickel complexes than in the organic analogues and the influence of these orbitals on the dimensionality of the salt play a key role in the conducting properties. $[Ni(dddt)_2]$ $[FeCl_4]$ shows 3D behavior of its magnetic susceptibility despite the isolated chain or sheet arrangement of the magnetic anions.[1072] This is regarded as a consequence of the coexistence of exchange paths involving the halides on the Fe and the π-electrons on the donor molecules. The complex shows an antiferromagnetic transition around liquid helium temperature if $[FeCl_4]^-$ is adopted as a counteranion, and the transition temperature is also affected by substitution of the central metal atom. $[Ni(dddt)_2]_x[Ni(dmit)_2]_y$ is an example for a salt where both anion and cation consists of a nickel dithiolene complex.[1073]

Some other ligands of the dddt family which are less recognized in research are depicted below. Examples in the literature have often been prepared for other applications such as optical materials. Especially on electrochemical and structural details much work has been done.[1074–1080]

The complex $Ni[(S_2C_2(CF_3)_2)]_2$ (**392**) is able to bind light olefins selectively and reversibly.[1081] According to Scheme 4, the reaction of olefins with (**392**) can be controlled electrochemically, where the oxidation state-dependent binding and release of olefins is fast on the electrochemical timescale. Olefin binding is supposed to occur via the ligand S-donors.



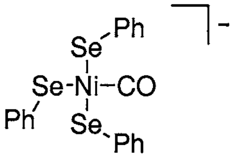
This sequence has been proposed as a novel approach to olefin separation and purification. However, there is disagreement about the reversibility of the reaction because it has been shown that irreversible reduction to the dianionic complex occurs through an ECE process.[1082] A convenient new route to 1,2-enedithiolate complexes of Ni has been reported, which starts from the bis(hydrosulfido) complex $[Ni(dppe)(SH)_2]$ and various α-bromoketoues(heterocycle-$C(O)CH_2Br$).[678]



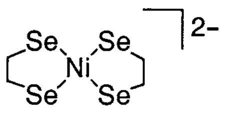
Scheme 4

6.3.4.7.11 Complexes with selenium- and tellurium-containing ligands

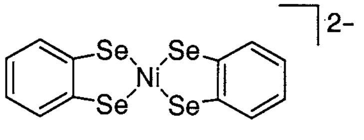
Nickel–selenium coordination compounds have received attention in recent years, because a unique Ni–selenocysteine interaction was revealed in the active site of [FeNiSe]-hydrogenases.[1083,1084] Of particular interest in this regard are mixed CO/selenolate complexes. Distorted square planar (**393**) was prepared from $[CpNi(CO)]_2$, PhSeSePh, and $[Fe(CO)_3(SePh)_3]^-$ and provides the first example of CO bound to a square planar Ni^{II} center in thiolate/selenolate environment.[1085,1086] Upon addition of RSSR, species of the series $[Ni(CO)(SR)_n(SePh)_{3-n}]^-$ are formed. ν(CO) ranges from 2,023 cm^{-1} to 2,043 cm^{-1} and is regarded as a spectroscopic reference for the CO binding site in [NiFeSe] hydrogenases.



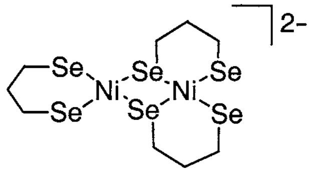
(**393**)



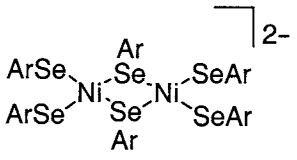
(**394**)



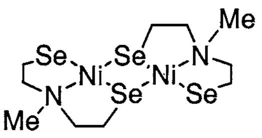
(**395**)



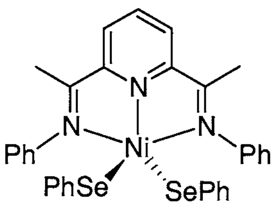
(**396**)



(**397**)



(**398**)

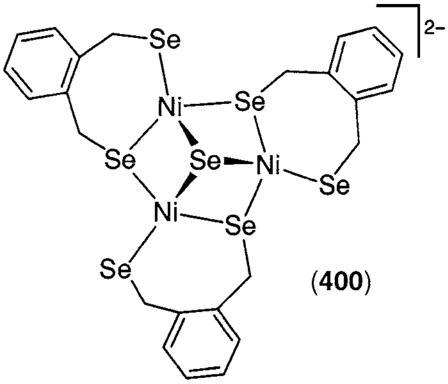


(**399**)

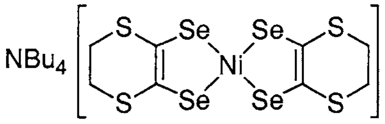
In (**393**), the average Ni—Se distance is 231.7(2) pm.[1085] Simple tetrahedral $[Ni(SePh)_4]^{2-}$ has been prepared by reaction of $NiCl_2 \cdot 4H_2O$ with LiSePh.[1087,1088] An excess of selenolate has to be used to prevent formation of $[Ni(SePh)_2]_8$. The PPh_4^+ salt is stable in air for several hours. Its average Ni—Se bond lengths (240.1(3) pm) are longer than in the homoleptic square planar systems.

Mono- and dinuclear Ni^{II} selenolates include four-coordinate (square planar) (**394**),[1089] (**395**),[1090] [Ni(dmp)(SeAr)$_2$] (Ar = 2,4,6-$Me_3C_6H_2Se$),[1091] (**396**),[1088] (**397**),[1088] and (**398**)[1092,1093], and five-coordinate (**399**),[86] [Ni(terpy) (SePh)$_2$]$_2$,[1091] [Ni(dmp)(SePh)$_2$]$_2$,[1091] and [Ni(terpy)(SeAr)$_2$] (Ar = 2,4,6-$Me_3C_6H_2Se$).[86] In general, most Ni^{II} alkaneselenolates are very sensitive to air. (**394**) is oxygen sensitive and decomposes in polar solvents. Its average Ni—Se bond lengths of 230.5(3) pm are interpreted in terms of a higher covalency of the Ni—Se bond compared to the Ni—S bond.[1089] The oxidized forms of (**395**) and (**398**) (one unpaired electron) have been investigated in detail by EPR spectroscopy.[1090,1093] One-electron oxidation of (**398**) gives a radical anion, which exhibits EPR spectra consistent with a $S = 1/2$ system. The g-values are similar to those of the analogous S-donor complex ($g_x = 2.23$, $g_y = 2.14$, $g_z = 2.05$), but the observation of ^{77}Se hyperfine coupling ($A_z = 129\,G$) indicates that the SOMO is largely Se in character.[1093] Tri- and tetranuclear homoleptic Ni^{II} selenolato complexes like (**400**) and $[Ni_4(SePr^i)_8]$ have been structurally characterized.[1094] They are isostructural with the corresponding thiolato complexes.

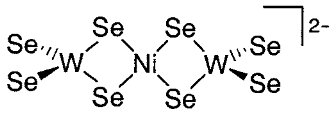
Selenium analogues of dithiolene complexes like (**401**) are attracting attention as components of conducting materials.[1095] The first and second redox potentials of (**401**) (converting between the dianion and the neutral state) are about 0.1 V higher than those of the sulfur derivative, suggesting that Se lowers the electron-donating ability. Further, (**401**) shows an irreversible oxidation wave leading to the radical cation.



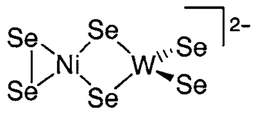
(**400**)



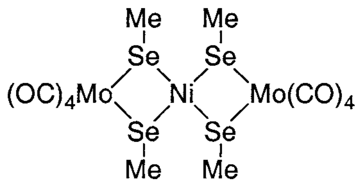
(**401**)



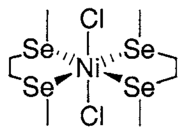
(**402**)



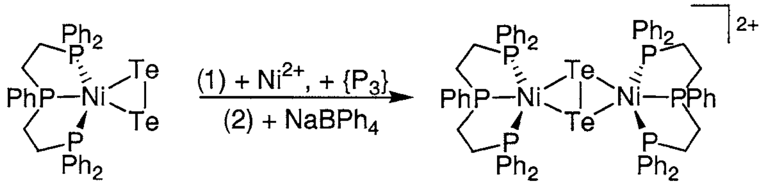
(**403**)



(**404**)



(**405**)



(**406a**) (**406b**)

Distorted square planar $\{NiSe_4\}$ cores are observed in mixed-metal selenides, e.g., (**402**). The $[Ni(WSe_4)_2]^{2-}$ anion is analogous to $[Ni(WS_4)_2]^{2-}$.[1096] Using slightly different reaction conditions, (**403**) was obtained, which contains a side-on Se_2 ligand.[1097] The Ni—Se bridge distances are much shorter in the latter compound, because there is no Se atom directly *trans* to these bridges. Trinuclear (**404**) was obtained from the reaction of Ni^{II} salts with the chelating metalloligand *cis*-$[Mn(CO)_4(SeMe)_2]^-$ and features Ni—Se distances of 233.1(1) pm.[1098]

Few thoroughly characterized Ni^{II} selenoether complexes have been reported, and most of them contain macrocyclic Se-containing ligands (see Section 6.3.4.10). Reaction of $MeSeCH_2CH_2$-SeMe with $NiCl_2$ gives (**405**) with two chelating diselenoethers and *trans*-chlorides.[1099] The related bromo and iodo complexes have also been prepared and analyzed by nickel K-edge EXAFS. The Ni—Se bond lengths are in the range 252–257 pm, which is 5–10 pm longer than Ni—S bonds in Ni^{II} thioethers.

Reaction of $[Ni^{II}\{P_3\}]$ scaffolds (where $\{P_3\}$ is a tridentate phosphine ligand) with a solution of polytelluride gives complexes (**406a**) with a side-on bound Te_2^{2-} moiety, which can be reacted with further $[Ni^{II}\{P_3\}]$ to give dinuclear (**406b**).[1100] Ni^{II} complexes with telluroethers and tellurolates are very scarce.[1101] Type (**407**) and (**408**) tellurolate complexes have been reported from the reaction of $[(dppe)NiCl_2]$ with NaTeAr and characterized spectroscopically.[1102] Te coordination has been invoked in Ni^{II} complexes of ligand (**409**),[1103] and simple telluroethers like Me_2Te and Et_2Te are assumed to bind to bi(chlorosulfato)nickel(II) to give compounds $[Ni(SO_3Cl)(R_2Te)_2]$.[1104,1105] Spectral data are more consistent with six-coordinate Ni^{II} in (**410**).[1106]

6.3.4.8 Halide Complexes

Ni^{II} forms weak complexes with fluoride ions in aqueous solution ($\log K_1 = 1.32$),[1107] while Ni^{II} complexes with the other halide ions are extremely weak ($\log K_1 < -0.8$).[1108,1109] The degree of complex formation in a concentrated aqueous solution of Ni^{II} chloride seems to increase with increasing temperature.[1110] In general, the complex formation of the Ni^{II} halide system is expected to be stronger in aprotic nonaqueous solvents than in water,[1111] mainly due to the weaker solvation of halide ions in such solvents.[1112] Significant complex formation between Ni^{II} and chloride is reported in methanol ($\log K_1 = 2.82$),[1113] in dimethyl sulfoxide ($\log K_1 = 1.51$–2.7, depending on ionic medium and strength),[1114–1116] and in *N*,*N*-dimethylformamide ($\log K_1 = 2.85$–3.14).[1117,1118] *N*,*N*-Dimethylacetamide is the only solvent where complex formation between Ni^{II} and bromide ions has been reported ($\log K_1 = 2.57$).[1119]

Tetrafluoronickelate(II) complexes were synthesized with various cations from aqueous media by treatment of $[Ni(acac)_2(H_2O)_2]$ with HF and MF.[1120] Experimental and theoretical studies were performed for the $K_2[NiF_4]$ complex.[1121] Core-level and valence-band X-ray angle-integrated photoemission data were analyzed by a CI impurity cluster model. Comparison of local d functional band calculations with angle-resolved photoemission data shows significant discrepancies, indicating that electron correlation effects are important. Two crystal modifications of $(NH_4)[NiF_3]$ were found.[1122] The low-temperature modification is cubic and crystallizes in the $CaTiO_3$ type of structure. The high-temperature structure is hexagonal and the compound crystallizes in the hexagonal $BaTiO_3$ type of structure.

Theoretical calculations based on the CNDO method were performed in order to understand the T_d/D_{4h} equilibrium of the tetrafluoro and tetrabromo complexes. The ability to form the square planar complexes decreases monotonically in the first row transition metal series: $Mn^{II} > Fe^{II} > Co^{II} > Ni^{II} > Cu^{II}$.[1123] The same ability decreases in the series: $F^- > Cl^- > Br^-$. A dipole moment covalency polarizability correlation ligand field model was used to analyze experimental optical and magnetic properties for a set of $[Ni^{II}X_6]^{4-}$ clusters.[1124] Using this model and a parametrization *d*-orbital theory, the theoretical absorption spectra of various $[NiX_6]^{4-}$ clusters were calculated without any fitting parameters. Good agreement was obtained for absorption spectra, EPR parameters, and magnetic susceptibility. MS-X_α calculations performed on various spin orbital configurations of $[NiCl_4]^{2-}$ were used to assign its ligand field spectrum and XPS spectrum.[1125] The calculated ligand field spectrum is in reasonably good agreement with observations. The calculated XPS spectrum suggested that part of the observed spectrum comes from satellite features and that multiplet splitting of ligand field states cannot represent the spectrum.

Complexation equilibria between Ni^{II} and Cl^- were studied in MeCN by spectrophotometry and calorimetry at 25 °C. Formation of $[Ni^{II}Cl_n]^{(2-n)+}$ ($n = 1$–4) species was suggested and the various formation constants, enthalpies, and entropies were determined.[1126] Individual electronic spectra of the complexes were obtained for both charge transfer (CT) bands (230–350 nm) and d–d transition bands (320–840 nm). Thermal analysis of pyridinium tetrachloronickelate(II) has shown that this complex is green and tetrahedral in the anhydrous state but yellow and octahedral when aquated.[1127] It undergoes dehydrohalogenation upon heating in the solid state to yield $[NiCl_2py_2]$. An attempt was made to track the changes in the Jahn–Teller active vibrational modes of some pseudotetrahedral $[MCl_4]^{2-}$ ions.[1128] The IR and Raman spectra of powdered $(Et_4N)_2[MCl_4]$ (M = Ni, Cu, Zn) and of Cu- and Ni-doped $(Et_4N)_2[ZnCl_4]$ were recorded both at room temperature and at 77 K, 100 K, and 170 K. Room temperature spectra show that for $[NiCl_4]^{2-}$ and $[CuCl_4]^{2-}$ the Jahn–Teller distortions are dynamically averaged, if present at all. The low-temperature spectra, however, show splittings that are indicative of a low-symmetry field, suggesting that at 77 K both complex anions are vibronically stabilized in a static C_{2v} field. Room temperature IR and Raman and low-temperature (100 K and 77 K) IR spectra of $R_2[MCl]_4$ have been recorded in the 4,000–50 cm^{-1} frequency range.[1129] The metal ions Zn^{II}, Ni^{II}, and Cu^{II} form a series of increasing ionic radius, while the counterions Bu_4N^+, Et_4N^+, Cs^+, and Rb^+ reflect the order of decreasing bulkiness. According to the IR and Raman spectra, the $[ML_4]^{2-}$ units are distorted tetrahedrons, the distortion increasing with the size of the counterion. Additional splittings due to the vibronic coupling (Jahn–Teller coupling) were observed for the Cu^{II} and Ni^{II} compounds.

While for larger halide ions (X = Cl, Br, I) tetrahedral $[NiX_4]^{2-}$ anions are usually found, (piperidinium)$_2$$[NiCl_4]$ adopts an unusual catena-poly[nickel-tri-μ-chloro(1-)] chloride structure (similar to a distorted $CsNiCl_3$ type), in which face-sharing $[NiCl_6]^{4-}$ octahedra, separated from one another by two crystallographically independent piperidinium cations and an isolated chloride anion, form a 1D chain.[1130] In (ET)$[NiCl_4]\cdot H_2O$ (ET = bis(ethylenedithio)tetrathiofulvalene), where the $[NiCl_4]^{2-}$ anions are sandwiched between lamellas of ET cations, the $[NiCl_4]^{2-}$ unit is not tetrahedral but distorted square planar.[1131] The solid-state synthesis of thermochromic $[(C_2H_5)_2NH_2]_2$ $[NiCl_4]$ was described as a useful procedure for a classroom demonstration to show the effect of ligand field splitting on color and the strength effect of hydrogen bonding in a solid crystal on the configuration of a complex.[1132]

The chloride ligands in $[NiCl_4]^{2-}$ ions in the interlayers of a Mg–Al hydrotalcite-like clay (NiCl-HT) are completely exchanged by bromide upon treatment with alkyl bromide in the liquid phase.[1133] The solvent exerts a very strong effect on the reactivity of interlamellar Cl^- anions in NiCl-HT towards butyl bromide. Thus, all the interstitial Cl^- anions of the interlayer $[NiCl_4]^{2-}$ ions appear as butyl chloride after 15 min in DMF, while in decane or toluene only 52% and 41% of interstitial Cl^-, respectively, were found in the organic phase after 15 min. The use of butanol as a solvent results in complete inhibition of the reaction. $[NiCl_4]^{2-}$ complex anions in NiCl-HT are isomorphically transformed into tetrahedral $[NiBr_4]^{2-}$ by halide exchange with BuBr in DMF.

Br, Cl, and P ligand K-edge absorption EXAFS was used to evaluate the bond angles in nickel halide and halo phosphine complexes.[1134] Particularly good results were obtained for $[NiBr_2(dppe)]$. Ligand K-edge X-ray absorption spectroscopy was used to investigate the metal–ligand bonding in the series of tetrahedral $[MCl_4]^{n-}$ complexes including the nickel one.[1135] The intensity of the pre-edge feature in these spectra reflects excited state multiplet effects, intermediate-strength ligand field excited state mixing, and ligand–metal covalency in the partially occupied d-orbital-derived MOs of each complex. A methodology which relates covalency to pre-edge intensity for d^{10-n} hole systems was developed. Application of this methodology to the experimental data provided quantitative information about the covalency of the ligand–metal bond. An analysis of the pre-edge and edge energies allowed the relative energy of the metal d-manifold as well as the charge on each chloride ligand to be quantified. The metal centers with the deepest d-manifold energies (closest to the ligand $3p$ orbital energy) are involved in the strongest ligand–metal bonding interactions and exhibit the largest metal d-derived orbital covalency.

$Li_2[NiBr_4]$ in THF regioselectively cleaves epoxides to give bromohydrins in high yield.[1136] The Br atom is predominantly found at the less-hindered carbon.

The layered double hydroxide (LDH) $Al_2Li(OH)_6[NiCl_4]_{1/2}$ was synthesized by anion exchange of $Al_2Li(OH)_6(NO_3)$, and the structure of $[NiCl_4]^{2-}$ in the interlayers was studied.[1137] The LDH has a hexagonal cell with an interlayer distance of 2.9 Å, which is too narrow for the usual tetrahedral $[NiCl_4]^{2-}$ structure. However, from EXAFS measurements it is concluded that the first neighbor Ni—Cl distances in the LDH are 2.10 Å, which is compatible with four-fold coordination.

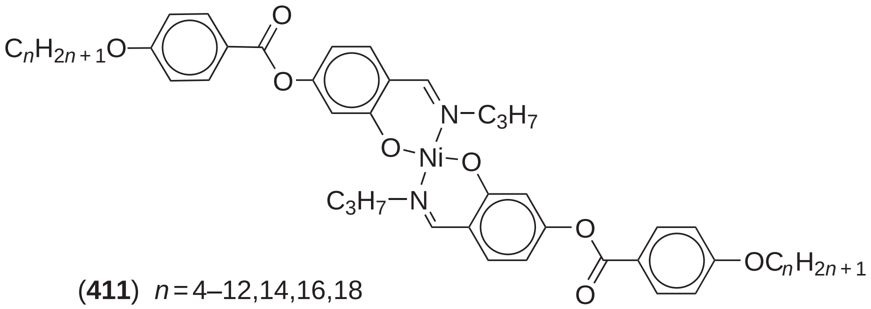
The electronic structure of *trans*-$[NiCl_2(H_2O)_4]\cdot 2H_2O$ has been investigated in detail, both by calculations and by absorption and luminescence spectroscopy.[1138]

6.3.4.9 Mononuclear Complexes with Open-chain Ligands Containing Mixed Donor Atoms

6.3.4.9.1 Complexes with mixed {N,O} ligands

(i) Complexes of Schiff base and related ligands

Schiff base complexes have been studied intensively. They are of interest as stereochemical and electrochemical models for biological sites and because of their catalytic activities. Earlier work has been exhaustively reviewed,[1139–1142] and the basic bidentate and tridentate coordination modes of Schiff base ligands have been well described. However, there are still new applications of bidentate Schiff bases evolving, since their syntheses are straightforward and peripheral groups can easily be altered. For example, transition metal–bischelates are widely used in thermotropic liquid crystals (metallomesogens). Ni^{II} complexes such as (**411**) form enantiotropic nematic phases over the temperature range 158–230 °C (melting points) and 160–253 °C (clearing points).[1143]



(**411**) $n = 4–12,14,16,18$

Earlier studies had shown that bidentate Schiff base ligands with bulky substituents and tetradentate ligands containing biphenyl or naphtyl moieties exhibit an endothermic spin equilibrium process. The preference of the low-spin state ($S = 0$) is strong for the four-coordinate chelates, but bulky substituents may shift it towards the paramagnetic state ($S = 1$). While such behavior is not observed for tetradentate ligands with aliphatic linkages, the incorporation of pyrazole in the $\{N_2O_2\}$ Schiff base may induce spin-equilibrium processes if the proper length of the linker is used.[1144] Complexes (**412**) with $n = 2$ or 3 form four-coordinate complexes in nondonor solvents. The complexes with $n = 2$ are fully diamagnetic, but a spin equilibrium process $S = 0 \leftrightarrow S = 1$ is observed for $n = 3$, and the complexes have a flattened tetrahedral geometry in the latter case. The four-coordinate Ni^{II} ions may increase their coordination number by coordinating solvent molecules like pyridine or DMSO in the axial positions, thereby enlarging the distances to equatorially bound donor atoms.

The use of imidazole or pyrazine containing asymmetric $\{N_3O\}$ Schiff bases (**413a**) and (**413c**) allows one to form monomeric complexes with square planar geometry around the Ni^{II} ions and a "rear-side" bridging system involving the unbound N atom of the heterocycle.[1145] These monomeric complexes may use their unbound heterocyclic N atom to form dinuclear species (**413b**) and (**413d**), respectively.

The coordination in [bis(4-isopropyliminomethyl)1,3-diphenylpyrazol-5-ylaminato)Ni^{II}] is pseudotetrahedral, the angle between the N—Ni—NH and NH′—Ni—N′ planes being 93.8° and the Ni—N(imine) bond lengths being 1.999 Å and 2.003 Å. This is significantly longer than the Ni—N(amine) bond lengths of 1.919 Å. Similar effects are observed in other pyrazole containing Ni^{II}–Schiff base complexes.[1146]

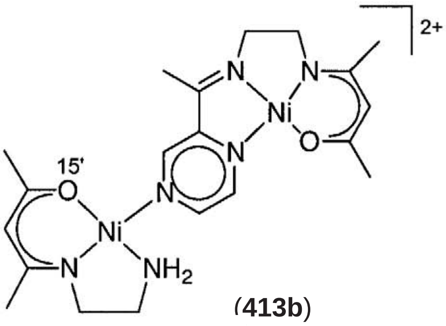
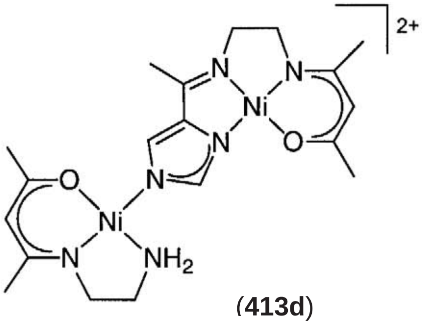
(**413c**)

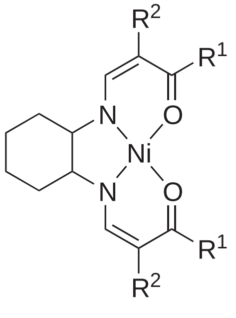


(**413b**)

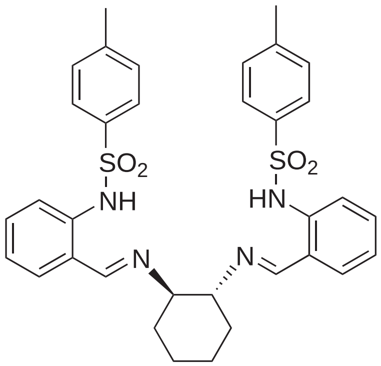


(**413d**)

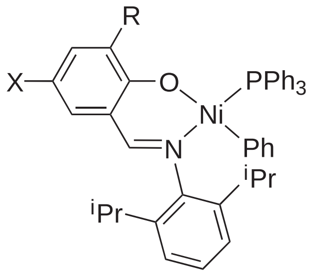
Chiral Schiff base complexes can act as catalysts of enantioselective reactions, e.g., for the oxidation of hydrocarbons.[1147,1148] Studies on chiral Ni^{II} complexes with {N$_2$O$_2$} Schiff bases derived from (1*R*,2*R*)- and (1*S*,2*S*)-1,2-diaminocyclohexane (**414**) have shown that substituents with high electron-withdrawing ability stabilize the lower oxidation state and promote the addition of axial ligands.[1149] The reduction potential of the planar complexes correlates with the ability to bind axial ligands (log β_2). Parent *N*,*N*′-(1*R*,2*R*)-(−)-1,2-cyclohexanebis(2-hydroxyacetophenonylideneiminato)nickel(II) ((**414**) with $R^1 = R^2 = H$) has an umbrella-type geometry with the dihedral angle between the planes defined by the two acetophenonylideneimine moieties of 43.5°. The Ni atom is in a distorted square planar environment.[1150] The distortion is more pronounced than in the salicylaldehyde analogue and it is caused by the interactions between the methyl group and methane, methylene, and phenyl hydrogens. The steric demands of the bulky groups are often the main cause of tetrahedral distortion in this type of complex.[1151,1152] {N$_4$} Schiff base complexes with very bulky tosyl groups (**415**) are square planar even in coordinating solvents, although the solid-state structure shows distinct tetrahedral distortion.[1153] Ni^{II} salicylaldiminato complexes[1154] with bulky substituents at the ketimine-N (type (**416**) complexes) are active catalyst for olefin polymerization[1155] and may even tolerate heteroatoms[1156] or perform polymerization in water.[1157] Functional groups such as 2-pyridyl or diphenylphosphino can be attached to Ni–salen type complexes (**417**).[1158,1159] For Ni^{II} Schiff base complexes involving P-donors see Section 6.3.4.6.3.



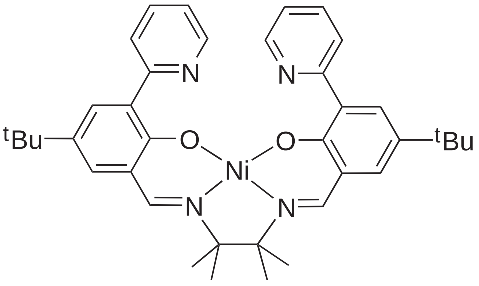
(414)



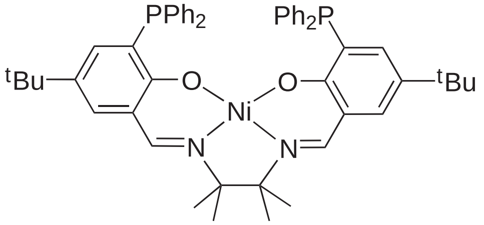
(415)



(416)



(417a)



(417b)

The solubility properties of Ni^{II} salen complexes can be varied by appropriate substituents. A choice of ligands containing *t*-butyl or methyl(triphenylphosphonium chloride) substituents at the aromatic rings (Figure 12) provides a series of Ni^{II} complexes with solubility adjustable for most commonly used solvents including water.[1160]

Ligand substitution in salicylaldiminate $[\text{NiA}_2]$ complexes has been studied in detail.[1161] Substitution in chiral $[\text{NiA}_2]$ species by chiral salen-type tetradentate H_2B ligands in acetone proceeds according to Equation (7):

$$\text{NiA}_2 + \text{H}_2\text{B} \leftrightarrow \text{NiB} + 2\text{HA} \tag{7}$$

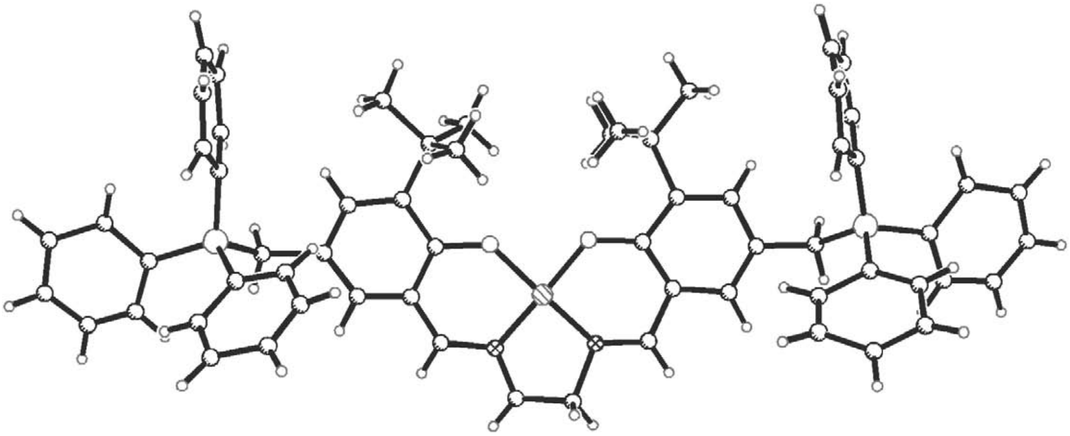


Figure 12 Crystal structure of *N*,*N*′-bis{3-*t*-butyl-5-[(triphenylphosphonium)methyl]salicylidene}-1,2-ethanediamine chloride with Ni^{II} ions.[1160]

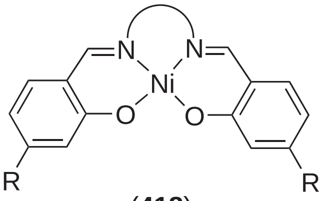
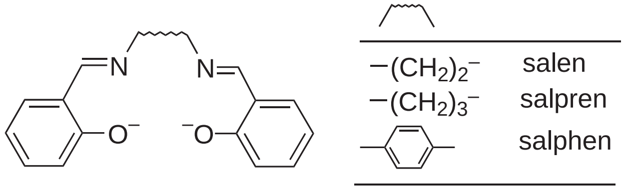
The substitution process is second order according to Equation (8). The substitution reaction (7) is an associatively controlled process consisting of three distinguishable steps: fast adduct formation $\{NiA_2,H_2B\}$ followed by rate-controlling loss of the first bidentate ligand HA and the loss of the second bidentate ligand with first order rate constant making the overall reaction a second-order process.[1162,1163] Ligand substitution is subject to chiral discrimination. The ratio of the second rate constants, k_{fast}/k_{slow}, with k_{fast} being the rate constant for the faster reacting pair of enantiomers, lies in the range 1.0–3.0, depending on the nature of the *N*-alkyl groups in NiA_2 and the organic groups attached to the ethylene bridge in H_2B ligands.[1164] The rate discrimination factor of 3.0 obtained for $NiA_2 =$ bis[N-dehydrodiethyl-salicylaldiminato]nickel(II) reacting with the *R*- and *S*-enantiomer of $H_2B = N,N'$-disalicylidene-1,2-diamino-4-methylpentane appears to be the highest stereoselectivity reported for any ligand substitution in Ni^{II} complexes.

$$\text{rate} = k \times [NiA_2] \times [H_2B] \tag{8}$$

Nickel(II) bis(salicylaldiminato) complexes are promising nonlinear optical systems.[1165] A series of ligands obtained by condensation of appropriate salicylaldehydes with diamines form complexes with Ni^{II} (e.g., (**418**)), and general structures have been determined.[1166] Thermal analysis, linear optical spectroscopy and second-order NLO response, sampled by the electric field-induced second-harmonic generation technique in combination with a quantum chemical analysis have shown a relationships between electronic structure and NLO properties of this class of inorganic NLO chromophores.[1167] Solution-phase hyperpolarizability values deduced from electric field-induced second-harmonic generation experiments are high. Similar behavior is found for the chiral 1,2-diaminocyclohexane derivatives.[1168]



(**418**)



(**419**)

The high structural and synthetic versatility of the Schiff base complexes provides a possibility to design host systems without functionalization procedure. Even relatively simple Ni^{II} $\{N_2O_2\}$ Schiff base complexes (**419**) are able to incorporate Ni^{II} both in the solid state and solution.[1169] In $[\{Ni(salen)\}_2Ba(ClO_4)_2(thf)]$ and $[\{Ni(salen)\}_2Ni(H_2O)_2](ClO_4)_2$, two [Ni(salen)] units act as bidentate O-donor ligands. In the Ni—Ni adduct, the central Ni^{II} ion is coordinated by two [Ni(salen)] units in a distorted octahedral geometry including two water molecules (Figure 13).

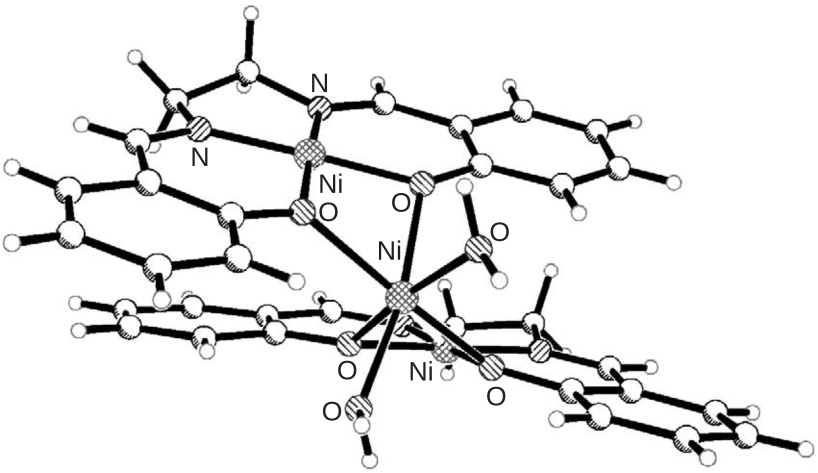


Figure 13 Molecular structure of the cation $[\{Ni(salen)\}_2Ni(H_2O_2]^{2+}$.

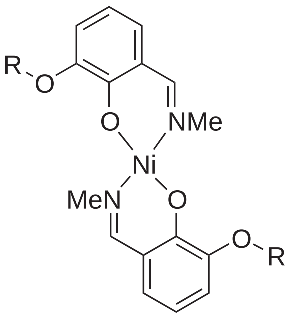
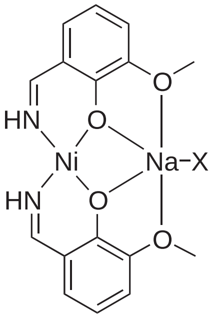
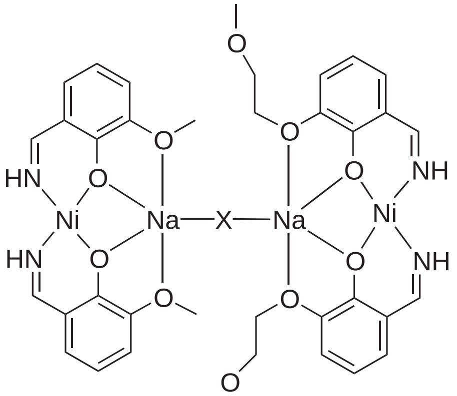
Schiff base ligands may be enriched by pendent arms bearing a potentially chelating site.[1170–1172] Insertion of a simple oxime function allows one to form oligonuclear structures with interesting magnetic properties.[1173] Polyether side arms are suitable to associate alkali metal cations with the Ni^{II} Schiff base unit. Addition of sodium picrate to $[NiL_2]$ (**420**; L = 3-methoxy-*N*-methylsalicylaldiminato) results in paramagnetic species $[NiL_2NaX]_2$ (X = picrate ion), which display cage structures with two side arms bound to Na^+.[1174,1175] Diamagnetic complexes are obtained from the reaction of Na^+ with 3-methoxysalicylaldiminato and 3-(2-methoxyethoxy)salicylaldiminato Ni^{II} complexes (**421a,b**).[1176,1177] The monometallic type (**420**) precursors react with Na^+ yielding mono- or bimetallic species with *cis*-$\{NiN_2O_2\}$ chromophores and the alkali cation accommodated in the ether-like outer cavity. In the presence of barium ions the precursor complexes change their configurations from *trans* to *cis* to offer a polyoxygen coordination site for the Ba^{2+} ion in $[(NiL_2)_2Ba\ (ClO_4)]^+$.[1178]



(**420**)
(R = Me, CH_2CH_2OMe)



(**421a**)



(**421b**)

Crown ethers may also be used to functionalize salicylideneimine complexes.[1179] The crown ether-functionalized tetra-*t*-butyl-salicylideneimines are useful in studies on the selective complexation and transport of cations (e.g., Na^+ and K^+). 4,5-Bis(3,5-di-*t*-butylsalicylideneimino) benzo-18-crown-6 coordinates Ni^{II} via the Schiff base $\{N_2O_2\}$ donor system and K^+ or Cs^+ at the crown site.[1180] These Ni–alkali metal complexes are able to transport amino acids from acidic aqueous solution to pure water.

The presence of N-donors in pendent arms makes Schiff base ligands very effective for the formation of bimetallic complexes with two Ni^{II} ions. Dinuclear complexes of compartmental Schiff base ligands are covered in Section 6.3.4.12.

{N,O} ligands with sp^3 N atoms are more flexible than those with sp^2 N-donors. Examples of mixed {N,O} ligands with sp^3 N-donor and terminal alcoholate include chiral bidentate {N,O},[1181] $\{N,O_2\}$ tridentate,[1182] and $\{N,O_3\}$ tetradentate ligands.[1183] The $\{N_2,O_2\}$ tetradentate ligand (**422**) coordinates Ni^{II} to yield blue $[Ni(\mathbf{422})(NCS)_2]\cdot H_2O\cdot 2EtOH$,[1184] where the neutral tetradentate ligand adopts a *cis*-α geometry with mutually *cis* N-bound thiocyanate moieties. The configuration around Ni^{II} is Λ with *R* configuration at the stereogenic N atoms. The absolute configuration of the complexes formed (Δ or Λ) depends on the metal ion involved.

Covalent modification of nucleic acids with metal complexes can be used for, *inter alia*, probing nucleic acid structure, understanding DNA reactivity, regulating gene expression, or chromosome modification triggering apoptosis. Ni^{II} complexes are well suited for covalent modification of DNA as the $Ni^{II/III}$ couple often lies close to the redox potential of the substrate ligand. Water-soluble Ni(salen)-type complexes (**432**) are able to form covalent bonds to nucleic acids, which occurs almost exclusively at guanine residues.[1185]

Ni(salen)–DNA adduct formation is closely related to that formed by the Ni(peptide) systems, although there are different mechanisms proposed for both types of complexes. In the case of Ni(salen), the addition of a phenol radical to the guanine heterocycle and formation of a covalent bond to guanine C8 (Equation (9)) is suggested.

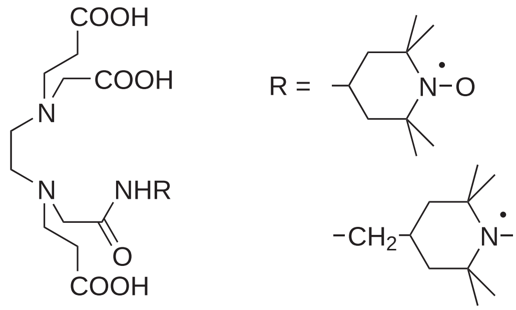
[Ni(salen)] complexes may interact with nucleic acids in different modes as well as with different chemical consequences.[1186,1187]

(ii) {N,O} edta-type and related polydentate chelating agents

The factors affecting stabilities of edta-type chelating agents have been comprehensively discussed.[1188] Spin-labeled edta ligands (**424a,b**) have been prepared, and the large difference in the EPR spectra of the free ligands and the Ni^{II} complexes indicates a substantial exchange contribution to the interaction in the case of (**424a**), which is attenuated for (**424b**).[1189]



(424a)

(424b)

Bonding angles exhibited by metal complexes with edta are distinctly strained, which is seen by the significant deviation from regular values.[1190] The Ni^{II} complex with edta forms a dinuclear $[Ni_2(edta)(H_2O)_4]\cdot 2H_2O$ species with two different subunits: the primary Ni^{II} center is hexacoordinated by the edta ligand (Figure 14). Constraints exerted by the ligand result in a highly distorted octahedron with deviation angles O—Ni—O up to 22.7°. The largest deviations are observed in the coordination plane of the ethylenediamine ring. The second Ni^{II} is in less distorted environment, since it is surrounded by four water molecules and two bridging carboxylates. These two subunits form alternating $Ni(edta)—Ni(H_2O)_4$ infinite zigzag chains hold together by H bonds and van der Waals interactions between O atoms of the remaining free carboxylates and water molecules. The magnetic properties can be described by a Heisenberg or Ising exchange model with a coupling of $J \sim -8.3\,K$.

Due to the steric constraints of the ligand, the partially protonated H_2cdta binds as a pentadentate ligand in $[Ni(H_2cdta)(H_2O)]$ where a water molecules completes the octahedral coordination sphere.[1191,1192]

Edta-type ligands with longer diamine or carboxylate chains are likely to function as hexadentate ligands towards larger metal ions by forming less strained structures.[1193] A symmetrical edta-type ligand, eddadp (ethylenediamine-*N*,*N*′-diacetate-*N*,*N*′-di-3-propionate) can form three geometrical isomers for hexadentate coordination: *trans*(O_5), *trans*(O_5O_6), and *trans*(O_6).[1194] Because of strain in the equatorial plane, the $Ba[Ni(eddadp)]\cdot 6H_2O$ complex adopts a *trans*(O_5) configuration. The strain analysis for the complexes with edta and its analogues for various metal ions indicates that expanding of the diamine ring or the equatorial glycine rings lowers the octahedral strain. The impact of the steric strain on the instability of the in-equatorial acetate coordination is also seen in the Ni^{II} complexes with eddadp.[1195] The hexadentate complex with propionate rings in equatorial

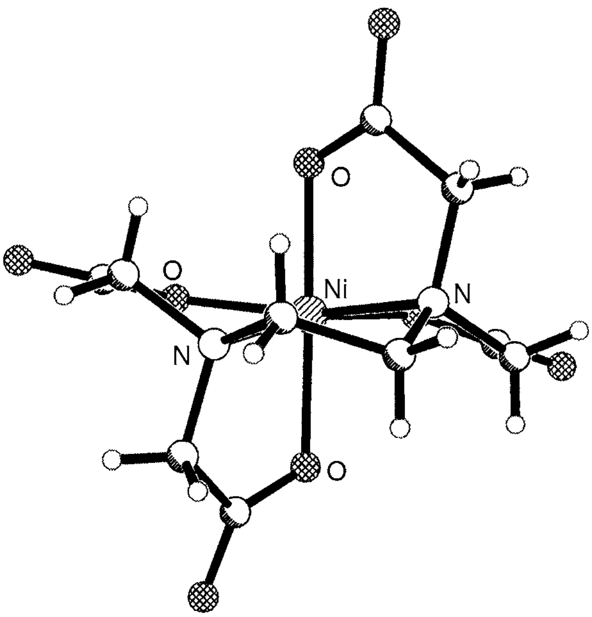


Figure 14 Molecular structure of the $[Ni(edta)]^{2-}$ subunit in $[Ni_2(edta)(H_2O)_4]\cdot 2H_2O$.

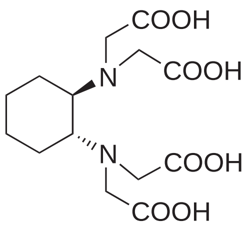
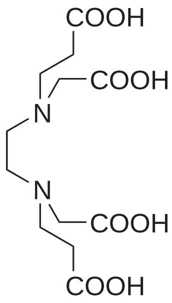
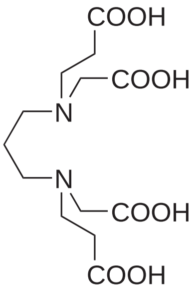
positions converts into a pentadentate species at high temperature. This conversion involves removal of one of the out-of-plane acetates, suggesting that acetate coordination is not stronger than that of propionate.



H_4cdta



$H_4eddadp$



$H_4pddadp$

In general, increasing the number of methylene groups in the diamine part (e.g., in $H_4pddadp$) decreases the stability constant of the [NiL] species, as does substitution of an acetic group by a 3-propionic group.[1196]

m-Phenylendiamine- and pyridine-2,6-diamine-*N*,*N*,*N*′,*N*′-tetraacetic acid form dinuclear complexes (**425a–c**), both in solution and in the stolid state.[1197,1198] The pyridine-N is not bonded to the metal.

Simple tetradentate ligands $HOOCCH_2NH(CH_2)_nNHCH_2COOH$ (**426**) in which two glycine building blocks are connected by a methylene chain have been employed in Ni^{II} coordination chemistry. 1,4-Diaminobutane-*N*,*N*′-diacetic acid forms a seven-membered chelate ring showing a negative chelate effect in octahedral Ni^{II} complexes [NiL] and $[NiL_2]^{2-}$.[1199] For the Ni^{II} complexes of 1,2-diaminoethane-*N*,*N*′-di-3-propionate (eddp) and 1,3-diaminopropane-*N*,*N*′-diacetate (1,3-pdda), only one (*uns-cis*) geometric isomer was found to dominate, confirming that six-membered chelate rings have a profound effect on the distribution of geometrical isomers. Two water molecules complete the octahedral environment in $[Ni(1,3\text{-pdda})(H_2O)_2]$.[1200] Ni^{II} complexes of the 1,4-diazacycloheptane-based ligands dachdR are octahedral $[Ni(dachdH)(H_2O)_2]$, square planar [Ni(dachdMe)], [Ni(dachdEt)], and [Ni(dachdPr)], or five-coordinate [Ni(dachdH)py], depending on the R substituent and the solvent.[1201,1202] The chiral (*all*-*R*)-1,2-bis(2-aza-3-carboxy-bicyclo[3.3.0]octan-2-yl)ethane (H_2baboc) has been prepared from a nonrecyclable industrial waste material.[1203,1204] It can be regarded as a new chiral analog of edda (ethylenedinitrilodiacetate) and forms the enantiomerically pure helical Ni^{II} complex [Ni(baboc)(H_2O)]·H_2O (**427**).[1205] This complex is pentacoordinated with a square pyramidal geometry. Comparison with the octahedral [Ni(edda)$(H_2O)_2$]·H_2O complex[1206] reveals that the steric influence of the chiral bicyclic system is responsible for the square pyramidal structure.

(**427**)

Nitrilotriacetate (nta^{3-}) is a powerful tetradentate chelating agent with log $\beta_{NiL} = 11.53$.[1207] The successive substitution of carboxylate by phosphonate group results in three ligands $N(CH_2CO_2H)_{3-r}(CH_2PO_3)_r$ with $r = 0$–3.[1208,1209] The high p*K* values for deprotonation of these ligands give rise to many protonated species. The stability of the NiL complex with the fully deprotonated ligand is highest for $r = 1$ and lowest for the pure phoshonate analogue ($r = 3$). α-Aminoalkylphosphinic acids differ from their carboxylate analogues quite remarkably. The phosphinate O atom is more difficult to protonate both in the free acid and in its metal complexes.[1210,1211] This causes certain azaphosphinate complexes to be resistant to proton mediated dissociation. The lower basicity of the O- and N-donors results in lower stability constants with respect to the carboxylate analogues. The insertion of alkyl or aryl substituents at P allows one to control the complex lipophilicity[1212] and makes phosphorus a stereogenic center when its O atom is bound to the metal ion.[1213] With acyclic tetradentate ligands incorporating two N-donors and two alkyl or aryl phosphinate donors (**428**), Ni^{II} forms equimolar complexes with significant phosphinate ligation.[1214] The stability sequence is reverse to the Irving–Williams series since the stability of the Ni^{II} complexes is distinctly higher than those of the Cu^{II} species.

(iii) Complexes with miscellaneous {N,O} ligands

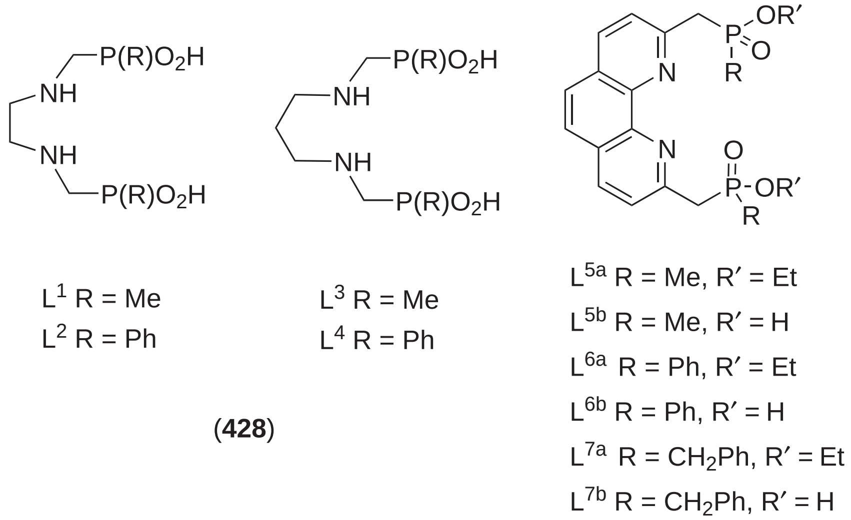
In contrast to many other *N,N*′-substituted oxamides which usually give diamagnetic square planar Ni^{II} species, paramagnetic Ni^{II} complexes such as [Ni_2(glyox)$(H_2O)_6$] can be obtained from the glycine-derived H_4glyox (**429**).[1215] Relatively strong antiferromagnetic coupling ($J = -12.5\,cm^{-1}$) is observed for [Ni_2(glyox)$(H_2O)_6$]. Square planar Ni^{II} complexes of oxamides such as (**430**) are useful for catalyzing the aerobic epoxidation of olefins.[1216]

Diamagnetic square planar (**431**) contains two *o*-semiquinonato-type radical ligands with a singlet ground state due to strong antiferromagnetic coupling. Its electronic structure is best described as a singlet diradical.[192,1217]

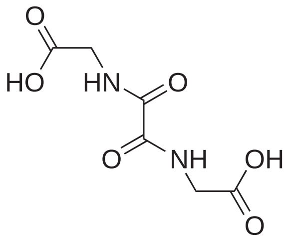
6.3.4.9.2 Complexes with mixed {N,S} ligands

(i) Thiosemicarbazide, thiosemicarbazones, and related ligands

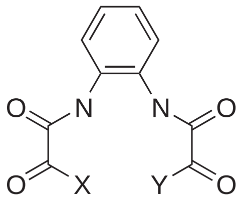
A great number of nickel complexes with thiosemicarbazide (**432**) and thiosemicarbazone (**433**) ligands and their substituted derivates have been examined. Thiosemicarbazone chemistry is



(**428**)



(**429**)
H_4glyox



(**430**)

(**431**)

partly inspired by the belief that coordination to metal ions may improve the anticancer, antiviral, fungicidal, and bactericidal potential of thiosemicarbazones.[1218,1219]

The interaction of thiosemicarbazide with Ni^{II} has been studied in solution and in the solid state, and the properties and stereochemistry of two isomeric forms, α and β, of [Ni(**432**)$_3$]I_2 have been reported. The crystal structure of the β-form reveals that Ni is octahedrally coordinated by three molecules of (**432**) through their S and hydrazine N atoms.[1220]

(**435**)

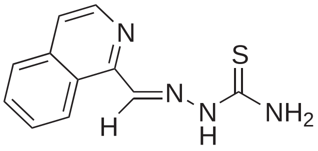
The basic thiosemicarbazone ligands coordinate in a {N,S} bidentate manner, generally via the azomethine N-donor and the thione or deprotonated amidothione group. Designating the ligands as HL, this usually results in square planar complexes [NiL_2],[1221–1227] [Ni(HL)$_2$]X_2,[1222,1228]

[Ni(HL)X_2],[1222] or [NiLX][1222,1229] as well as octahedral complexes [Ni(HL)$_2$$X_2$].[1222,1230–1232] The square planar [NiL_2] is the common and most widely encountered type, while tetrahedral complexes are very rare.[1233,1234]

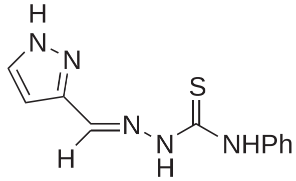
Ni^{II} complexes of thiosemicarbazones derived from *p*-fluorobenzaldehyde and differently substituted thiosemicarbazides (**434**, **435**) are square planar [NiL_2] species with the S and hydrizine-N atoms in *trans* position to each other and a slight tetrahedral distortion in some cases.[1235,1236]

5-Methyl-2-furfural thiosemicarbazone forms three types of Ni^{II} complexes. Two square planar species with *trans* configuration, [NiL_2] and [NiL_2]·2DMF, and a pseudo-octahedral [Ni$L_2$$X_2$] ($X = Cl^-$, Br^-).[1237] Likewise, the [NiL_2] complex of thiophene-2-carbaldehyde thiosemicarbazone is a square planar species with *trans* configuration.[1238] Simple theoretical calculations suggest a correlation between the biological activity of the metal complex and its LUMO energy level. The incorporation of the bulky vitamin K_3 into the thiosemicarbazone structure seems to favor the formation of an octahedral nickel complex in ethanol solution.[1239] Biological tests show that metal ion coordination indeed increases the antibacterial activities of the ligands.

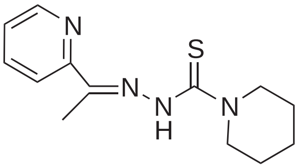
Tri- or tetradentate ligands can be obtained by attaching functional groups to the thiosemicarbazone scaffold. Tridentate ligands often possess an {N_2S} donor set, generating a broad range of coordination geometries, including square planar, octahedral, and trigonal bipyramidal complexes.[1240–1246] (**436**)–(**439**) are depicted as examples. In many cases, the lack of solubility of these complexes strongly reduces the possibility of *in vivo* testing.



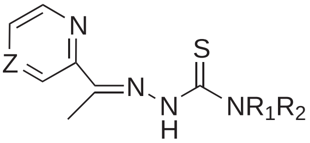
(**436**)



(**437**)



(**438**)



(**439**)

Complexes [NiL_2] with ligand (**439**) (HL) are less fungicidal than the free ligand,[1247] but it has been shown that with more sterically demanding groups R_1 and R_2 the fungitoxicity of the free ligands HL increases. With NiX_2 in hot EtOH, complexes [NiLX] (X = Cl, Br; Z = CH; R_1, $R_2 = (CH_2)_5$, $(CH_2)_6$) can be obtained, which have comparable fungitoxicity to the free ligands.[1248,1249] Attachment of an additional donor at the ligand (Z = CH; R_1 = H, Me; $R_2 = (CH_2)_n$(2-pyridyl), $n = 1$, 2) leads to complexes of the type [Ni(HL)X_2]. IR spectroscopic data suggest thione-S coordination, but the additional pyridine ring is apparently not involved in coordination.[1250]

Thiosemicarbazones attached to an amide moiety rather than an aldehyde or ketone moiety show better solubility. For example, the Ni^{II} complex with 2-pyridineformamide N(4)-methylthiosemicarbazone is square planar with {N,N,S} ligand coordination.[1251] The coordination sphere is completed by an O-bound acetate coligand.

Tridentate thiosemicarbazones with {N,S,O} donor set form [NiL_2] complexes with pseudo-octahedral geometry around the Ni^{II} ion.[1252,1253] Both acenaphthenequinone thiosemicarbazone (**440**) and isatin-β-thiosemicarbazone (**441**) coordinate as monodeprotonated ligands in a meridional fashion. The Ni—O bonds are unusually long and distinctly larger than the sum of covalent Pauling radii. The complex [Ni(**442**)$_2$] catalyzes H_2/D^+ exchange and is thus considered as a model complex for Ni-containing hydrogenases.[1254] The 1:1 complex [Ni(**442**)]$^+$ is formulated as an O-bridged dimer.[1255]

Bis(thiosemicarbazones) generally behave as dianionic, tetradentate {N_2S_2} ligands that form planar [NiL] complexes (with loss of two protons upon coordination) or planar [NiL]X (with loss of only one proton).[1256–1262,1269] (**443**) and (**444**) are depicted as examples. The same coordination mode is found for mixed bis(N(4)-substituted thiosemicarbazones) (**445**).[1263] The Ni—S bonds are significantly longer (~2.145 Å) than the Ni—N (~1.849 Å) bonds, and hence the coordination geometry around the $\mathrm{Ni^{II}}$ ion is trapezoidal.

Ligand (**446**) (resulting from the condensation of benzil and thiosemicarbazide) forms planar $\{\mathrm{NiN_4}\}$ complexes[1264,1265] even in strongly coordinating DMSO, but the solvent may partially substitute the bis(thiosemicarbazones) ligand. Template condensation of the appropriate mole ratios of $\mathrm{Ni^{II}}$, benzil, and thiosemicarbazide gives a neutral macrocyclic species formulated as octahedral (**447**).[1266]

(**447**)

Bis(semicarbazones) with $\{\mathrm{N_2O_2}\}$ donor set form six-coordinate complexes with distorted octahedral geometry. The well-studied (potentially pentadentate) 2,6-diacetylpyridine bis(semicarbazone) ($\mathrm{H_2daps}$, **448**) forms two type of crystals containing the same complex $[\mathrm{Ni(Hdaps)_2}]$.[1267] The ligands are coordinated through their pyridine and the imine N atoms and the O atom of one arm.

($\mathrm{H_2L_1}$**449**) is formally related to the tridentate thiosemicarbazone, but it coordinates either bidentate, (in $[\mathrm{Ni(HL)_2}]$) or tridentate (in $[\mathrm{NiL]_2}$).[1268] In contrast, (**450**) (R = Me, Ph; R′ = Me, Bz) coordinates tridentate, building square planar complexes [NiLX] with one, and octahedral complexes $[\mathrm{NiL_2}]$ with two equivalents of the ligand.[1270]

Thiocarbohydrazone ligands (**451**) bind bidentate through the hydrazine and thionic group.[1271] Bis[phenyl(2-pyridyl)methanone] thiocarbazone (**451a**) is a useful ligand in preparing compounds with specific magnetic properties.[1272] In the conformationally rigid tetrameric structure $[\mathrm{NiHL}]_4^{4+}$ (**452**) each metal center is octahedrally coordinated by the S atoms, the thiocarbazone N atoms and the pyridine N atoms from two different ligand molecules. These two ligands are bound to

Ni^{II} in a meridional fashion with pairs of S- and pyridine N atoms in *cis* positions, while the thiocarbazone N atoms are *trans* to each other as it is usually found in the related octahedral complexes with thiosemicarbazones.[1273,1274]

The neutral ligand $DtdtzH_2$ (**453**) can be deprotonated to yield hexadentate $Dtdtz^{2-}$ and forms pseudo-octahedral Ni^{II} complexes[1275] such as $[Ni(DtdtzH_2)](ClO_4)_2$ and [Ni(Dtdtz)]. The Ni ion has a $\{S_4N_2\}$ surrounding with a *cis*-S_2 (thioether), *cis*-S_2 (thione), and *trans*-N_2 arrangement. Deprotonation of $DtdtzH_2$ in [Ni(Dtdtz)] results in an increase of thiolate character, and the average C—S (thione) bond length increases by 0.04 Å while the average N—N bond length decreases by 0.03 Å. One consequence of this is the relative facility of oxidation of [Ni(Dtdtz)] to the Ni^{III} species at +0.24 V vs. SCE.

The reaction between S_4N_4 and Ni^{II} has been investigated in DMSO. Reaction was found to proceed very slowly, but after several days, the nickel complex $[Ni(S_2N_2H)_2]$ was formed and acidification of the solution was observed. ^1H and ^{15}N NMR studies revealed that the protonated form of the complex $[Ni(S_2N_2H_2)(S_2N_2H)]^+$ exists in solution. These studies also confirmed bidentate coordination of the ligand S=N—S—NH_2, where the additional proton is bound at the NH group.[1276]

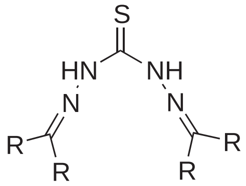
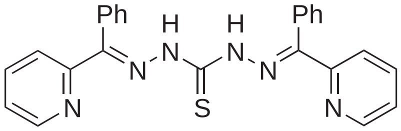
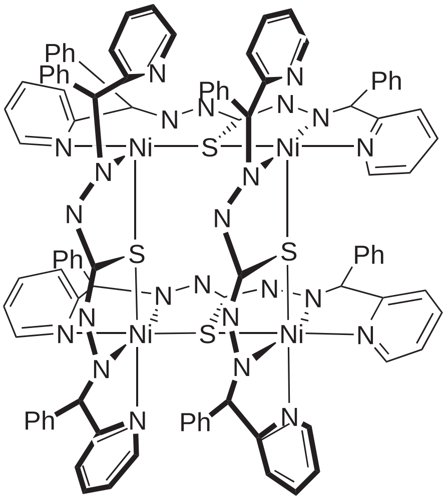
(**450**)



(**451**)



(**451a**)



(**452**)

(ii) Complexes with mixed amine/thiolate ligands

The crystal and molecular structure of the Ni^{II} complex of the simplest amino-thiolate ligand 2-mercaptoethylamine (aet) (**454**) has been determined and shows that the complex, contrary to earlier belief, has a *trans* configuration.[1277]

The reaction of (**454**) with metal salts results in multinuclear arrangements. For example the reaction of (**454**) with Pd^{2+} in water in the presence of Br^- gave the S-bridged hexanuclear $[Pd_2\{\mathbf{454}\}_4]Br_4$. The structure consists of four *cis*-(**454**) units bridging two square planar Pd^{II} moieties in a turnstile arrangement. Treatment of $[Pd(aet)_2]$ with Ni^{II} gave a mixture of products $[Pd_2\{(\mathbf{454})_2\}_{4-x}\{Pd(aet)_2\}_x]Br_4$ ($x = 0$–4), showing that the ligand transfer from Pd^{II} to Ni^{II} occurs under these conditions.[1278] With $[CoCl_2(en)_2]^+$, however, (**454**) reacts in water to give an S-bridged complex $[Ni\{Co(aet)_2(en)\}_2]^{4+}$, indicating that aet has transferred from Ni^{II} to

Co^{III}.[1279] In these reactions the Ni^{II} center normally retains its square planar geometry, but the reaction with [PtCl$_2$(bipy)] results in a pseudo-octahedral complex [{(H$_2$O)$_2$Ni(aet)$_2$}Pt(bipy)]$^{2+}$. Reaction with bipy gives [{(bipy)Ni(aet)$_2$}Pt(bipy)]$^{2+}$.[1280]

In coherence with the question how thiolate-sulfur modification influences the redox properties of sulfur-rich metalloenzymes such as [NiFe]hydrogenase and CO dehydrogenase, the examination of S-oxygenation of nickel thiolates is studied intensively. Prominent systems are *cis*-dithiolate[1,5-bis(2-mercaptoethyl)-1,5-diazacyclooctanato]nickel(II) (**455a**) and *cis*-dithiolate[1,5-bis(2-mercapto-2-methylpropyl)-1,5-diazacyclooctanato]nickel(II) (**455b**).[1281] A series of metal bound S-oxygenates of these systems could be prepared by reaction with ground state O$_2$, exited state $^1\Delta$ O$_2$, or H$_2$O$_2$. The compounds are fully characterized, including molecular structures from X-ray crystallography in most cases. All oxygenates are S-bound and maintain the square planar geometry of the parent dithiolates.

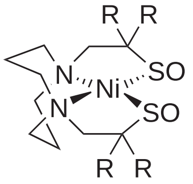
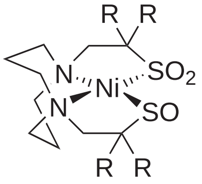
(**458b**) R = Me

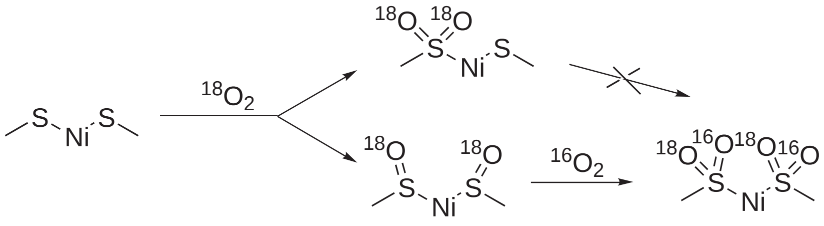


(**459**) R = Me



(**460a**) R = H
(**460b**) R = Me

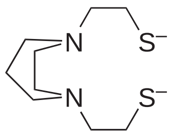
By reaction of (**455a**) with ground state O$_2$, a mixture of (**456a**) and (**457a**) is generated (Scheme 5), but surprisingly (**457a**) could not be reacted with further O$_2$ to yield (**456a**) (for this transformation H$_2$O$_2$ or singlet O$_2$ is needed).[1282] Using MALDI mass spectra and ^{16}O$_2$/^{18}O$_2$ mixtures, it could be shown that both O atoms of the resulting sulfones originate from different O$_2$ molecules, indicating a cross-site addition of molecular O$_2$ in the production of the bis(sulfinate) complex (**456a**).[1283,1284]



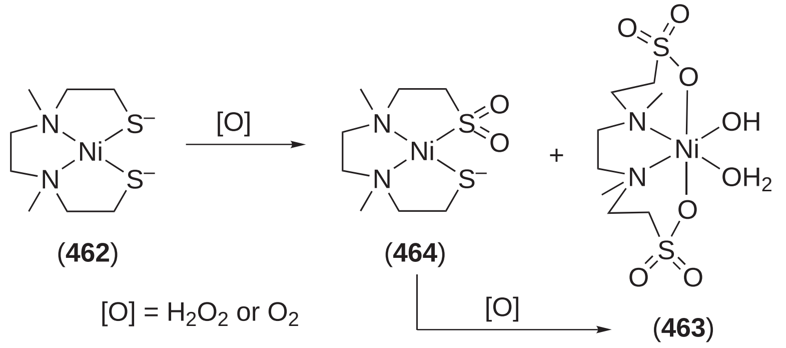
Scheme 5

This result suggests the intermediacy of a bis(sulfoxide) rather than mono(sulfone) in the production of (**456a**), consistent with the lack of reactivity of isolated (**457a**). With (**459**) a bis(sulfoxide) could be isolated. A series of further experiments, including reactions with singlet O_2, have been done to gain mechanistic information. Another question involved in this work is whether O_2 is bound by the nickel center or if the oxygenations are ligand based. In this context a ligand-based SO_2–adduct complex could be isolated.[1285] The S-based reactivity is consistent with *ab initio* calculations which show the HOMO for a square planar nickel dithiolate complex analogous to (**455a**) to lie on the thiolate sulfur. Calculated electrostatic potentials confirm that the thiolates are the most nucleophilic sites in the complex.[1286] However, some participation of the nickel centers in the oxygenation reactions could not be fully excluded. It was verified that the Ni^{I} oxidation state is stabilized upon conversion of the thiolates to thioethers, to RSO_x by oxygenation, and upon interaction with metal cations. In contrast, the Ni^{III} oxidation state is destabilized in the cationic thioether derivatives, but gains stability when those derivatives contain additional ligating sites leading to $N_2S_2O_2$ octahedral complexes.[1287,1288] A ligand (**461**) with a modified backbone framework, which is more easily accessible, has been reported.[1289]

Complex (**462**) reacts with a large excess of H_2O_2 to the fully oxygenated bis(sulfonato) complex (**463**).[1290,1291] With only little excess of H_2O_2 or O_2, a mixture of (**463**) and the mono (sulfone) complex (**464**) is formed. This complex is the only intermediate in the oxygenation reaction that could be isolated, and it is shown to be further reactive towards O_2 to yield the fully oxidized product (**463**) (Equation (10)).[1292]



(461)



(10)

For a better understanding of the reactivity observed for (**462**), DFT calculations have been undertaken, which show a possible reaction path toward the fully oxidized product (**463**). The difference in products between (**462**) and (**455a**) has been ascribed to an enlarged barrier of (**455a**) to form octahedral complexes, but from DFT results there is no obvious reason explaining the different reactivity. For the reaction path, the results are consistent with a switch in reactivity of O_2 with (**462**), following the first (electrophilic) addition of O_2 to the (nucleophilic) thiolate sulfur of (**464**). It is suggested that the resultant electrophilicity of the Ni—SO_2R bond site elicits the nucleophilic reactivity character of O_2, and provides a path for a four-centered peroxy intermediate or transition state. This results in subsequent and irreversible oxygenation steps. Such cooperativity or cascading dioxygen addition reactivity leads to the fully oxidized product (**463**).

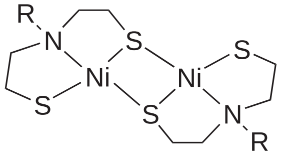
Ligands of the type $RN[(CH_2)_2SH]_2$ ($R =$ alkyl, aryl, $(CH_2)_2SH$, $(CH_2)_2SR$) form dimeric S-bridged complexes (**465**) with Ni^{II}. In the case of tripodal ligands the third arm rests uncoordinated.[1293–1296]

Treatment with additional ligands like CN^- leads to monomeric complexes. Reaction of dimeric bis{[μ-(2-mercaptoethyl)(2-mercaptoethyl)methylaminato]nickel(II)} with either O_2 or H_2O_2 leads to the formation of a dimeric product, bis{[μ-(2-sulfinatoethyl)(2-mercaptoethyl)methylaminato (2-)]nickel(II)}. The reaction is first order in [Ni] and proceeds at a very slow rate at 40 °C ($t_{1/2} = 7.8$ days; $k = 1.0 \times 10^{-6}\,s^{-1}$) under 1 atm of O_2.[1297] Also the monomeric species can be oxidized to the mono(sulfones).[1298–1302] These *trans*-dithiolates do not undergo successive O_2 addition to yield the bis(sulfone) like in (**455a**), which demonstrates the deactivation of the thiolate by the *trans*-sulfone.[1303]

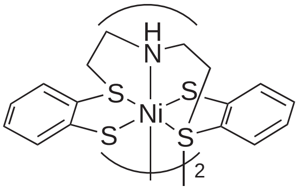
Ni^{II} complexes of various amine/thiophenolate ligands have been investigated (for Ni complexes of *ortho*-aminothiophenol see Section 6.3.4.9.2(iv)). Thiophenolate is expected to exhibit decreased bridging tendency compared to aliphatic thiolates, but complexes (**466**) and (**467**) still consist of two pseudo-octahedral NiL fragments bridged via thiolate donors. In contrast to the parent complex (**466**), the thiolate and thioether donors in (**467**) coordinate *cis* to the Ni center forming *meso* fragments. In contrast to (**466**), (**467**) readily dissociates in solution to give the mononuclear species. With PMe_3, the adduct [NiL(PMe_3)] is yielded, while reaction with I_2 gave the Ni^{III} complex [Ni(L)I].[1304]

Complex [Ni(**468**)] is formed with Ni^{II} salts and the amine-thiolate ligand, or by reduction of the corresponding Schiff base complex with $NaBH_4$·[Ni(**468**)] is easily deprotonated to form the dianionic complex, which is subsequently oxidized to the monoanion. On the other hand, the dianionic complex reacts with CH_3I to form the fourfold methylated octahedral complex (**469**).[1305] Since without preceding deprotonation only the S-donors are methylated, the complex with twofold amine methylation must be synthesized via protection and subsequent deprotection of the S-donors.[1306]

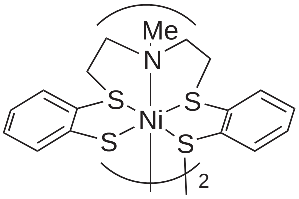
By reaction of [Ni(**468**)] with DMSO or formic acid, the nickel thiolate carbene complex (**470**) was formed in small amounts. In preparative amounts (**470**) could be obtained in a one-pot reaction of ligand H_2(**468**), $NiCl_2$, and $CH(OEt)_3$. First a dinuclear complex is formed which can be cleaved by reaction with nucleophiles like pyridine or PR_3. X-ray structures of these PR_3 adducts reveal that the metal centers are coordinated by two sulfur, one phosphorus, and one C(carbene) donor in a distorted plane.[1307,1308] Even $HNPPr_3$ and $HNSPPh_2$ ligands can be introduced, X-ray structures indicating an ylidic structure.[1309] Ligand (**471**) reacts with Ni^{II} to presumably give octahedral [Ni(**471**)$_2$].[1310]



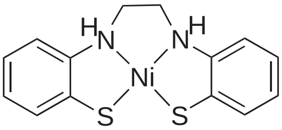
(465)



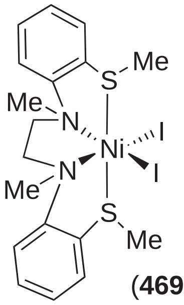
(466)



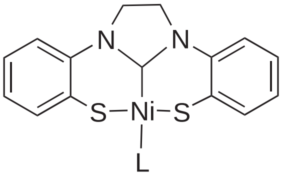
(467)



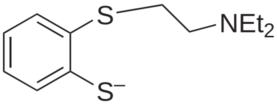
[Ni(**468**)]



(469)

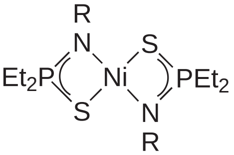


(470)



(471)

Complexes of type (**472**) are monomeric and square planar or tetrahedral, depending on the size of the R substituent (substituents other than Et at the ligand backbone have also been tested).[347,1311–1313] While (**472d**) is purely tetrahedral both in the solid state and in solution, (**472a**) and (**472b**) are almost entirely planar at room temperature. X-ray crystallography confirmed a planar structure for (**473a**) and a distorted tetrahedral structure for (**473b**).[1313] Many of these systems exhibit planar ⇌ tetrahedral equilibria in solution, the latter prevailing with larger R and increasing temperature. ^{31}P NMR spectroscopy has been a useful tool for investigating these equilibria. Both ΔH and ΔS values are positive, indicating that the tetrahedral form is entropically favored.



(472)

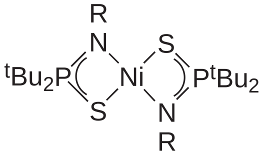
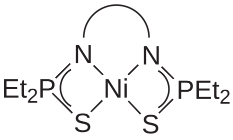
(**e**) R = *c*Hex
(**f**) R = Ph



(473)

(**a**) R = Et
(**b**) R = *c*Hex

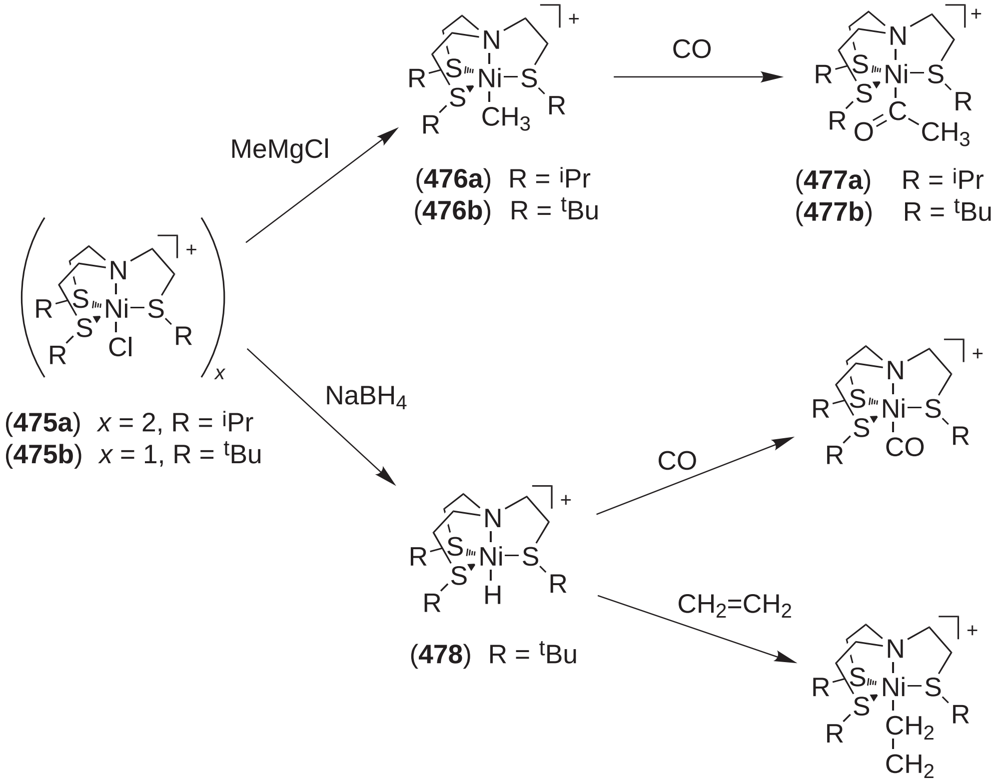


(474)

Similar equilibria planar ⇌ tetrahedral have been observed for Ni^{II} complexes (**474**) featuring tetradentate bis(thiophosphonic amidato) ligands with various spacers.[1314] (**472a**) inserts CS_2 to give a *P*,*P*-diethylthiophosphorylmethyldithiocarbamato complex with a $\{NiS_4\}$ chromophore.[1315]

(iii) Complexes with mixed amine/thioether ligands

Tripodal ligands $N[(CH_2)_2SR]_3$ form complexes (**475**) in which all three thioethers are coordinated (Scheme 6). For example with $R = Pr^i$ octahedral dimeric complexes $\{[NiLCl]_2\}(BPh_4)_2$, (**475a**), and with $R = Bu^t$ distorted trigonal bipyramidal complexes (**475b**) are formed. With MeMgCl both species react to give (**476**), which has been characterized crystallographically and by ^1H NMR spectroscopy. These complexes insert CO to give acyl complexes, although for $R = Bu^t$ the complex is only stable under a CO atmosphere. Upon reaction with $NaBH_4$, (**475**) affords a stable hydride (**478**) ($\delta_H = -37.8$ ppm) which in turn reacts reversibly with ethylene to give $[Ni\{NS_3\}CH_2CH_3]BPh_4$.[1316,1317] In addition, (**478**) leads to a $[Ni^I\{NS_3\}(CO)]$ complex that is covered in Section 6.3.5.4.



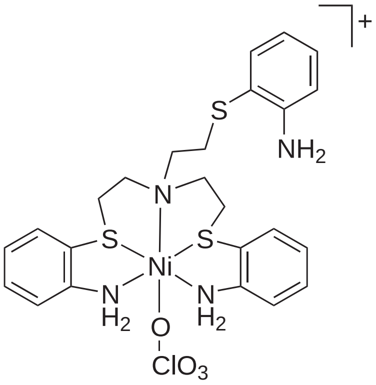
Scheme 6

The synthesis, X-ray crystal structures, and electronic spectra of $[NiL(ClO_4)]ClO_4$(**479**) (L = tris{[2-(2-aminophenyl)thio]ethyl}amine) and $[NiL'](ClO_4)_2$(**480**) (L′ = tris{[2-(2-aminoethyl)thio]ethyl}amine) have been reported.[1318] In (**479**) the Ni atom is bound equatorially to two S and two N atoms from two arms of the tripodal ligand while the two axial positions are occupied by the bridgehead nitrogen and an oxygen from a perchlorate. In (**480**), all three arms of the ligand are bound to the Ni providing a distorted-octahedral $\{S_3N_3\}$ donor set.

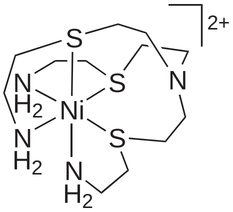
(**481**) coordinates to Ni^{II} in a bidentate fashion via the imidazole N atom and the thioether S atom. The thiourea S atom does not take part in coordination.[1319]

(**482**) and (**483**) function as tridentate $\{N_2S\}$ ligands forming complexes of the type $[NiL_2]X_2(H_2O)_n$ (X = Cl, NO_3, BF_4) and $[NiLCl_2(H_2O)]$.[1320] The $\{N_2S_2\}$ ligand (**484**) coordinates tetradentate to Ni^{II} and forms octahedral complexes of the type $[NiLX_2]$.[1321]

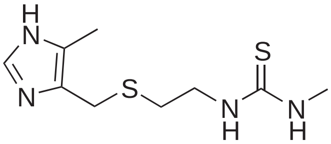
A number of further thioether-imidazole ligands with {NS}, $\{N_2S\}$, $\{N_2S_2\}$, and $\{N_4S_2\}$ donor set have been characterized by X-ray crystallography, and they show a comparable coordination behavior.[1322–1328]



(479)



(480)



(481)

A series of related pyridine-thioether ligands (**485**) have also been studied. All the ligands gave pseudo-octahedral monomeric complexes, with solvent molecules completing the coordination sphere where required.[1329–1331] Ligand (**486a**) is suggested to function as a tridentate ligand forming [Ni(**486a**)Cl_2]·H_2O,[1332] and tridentate binding has been confirmed for complexes [Ni(**486b**)X_2] and [Ni(**486c**)X_2] (X = halide).[1333] Formation of either monomeric pentacoordinate species [$NiLX_2$] or dimeric X-bridged hexacoordinate species $[NiLX_2]_2$ depends on the steric bulk of the ligand and the choice of halide ion. X-ray crystal structures reveal that (**487**) functions as a tridentate ($[NiL_2]^{2+}$) and (**488**) and (**489**) as pentadentate ligands ([NiLX]X).[1334,1335]

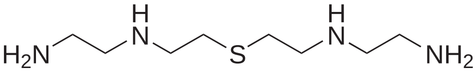
(487)



(489)

The cryptands (**490**) coordinate by three sulfur and three nitrogen donors only, forming distorted octahedral Ni^{II} complexes.[1336]

By a template reaction of 2-aminothiophenol, NaOEt, 1,2-$(BrCH_2)_2C_6H_4$, and $[Ni(ClO_4)_2]$·$6H_2O$, complex [Ni(**491**)Br_2] could be obtained. Interestingly, this complex could not be made from preformed (**491**) and Ni^{II} salts.[1337]

Optically active amine-thioether ligands (**492**) have been investigated in nickel-catalyzed asymmetric cross-coupling reactions of Grigard reagents.[1338]

(**493**) and (**494**) bear both thioether and thiolate donors besides potential N donors.[1339,1340] For the Ni^{II} complex of (**493**), spectroscopic data favor an octahedral geometry with four S- and two N-donors. In the case of (**494**), spectroscopic data are also consistent with a pseudo-octahedral geometry, but X-ray data showed two distinct environments, i.e., square planar and square pyramidal geometry.

(iv) Complexes with mixed imine/thiolate and imine/thioether ligands

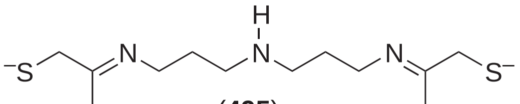
Schiff bases containing {N/S} donor groups are usually considered as interesting models for the Ni^{II} binding sites in enzymes. The biological significance of the nickel–cysteine sulfur interaction and the accessibility of several oxidation states of the metal ion in catalysis—either in bioinorganic systems or in metalloorganic chemistry—make S-donors very attractive also in Schiff base coordination chemistry.

A template synthesis employing $Ni(OAc)_2$, 2,5-dihydroxy-2,5-dimethyl-1,4-dithiane, and 3,3′-iminobis(propylamine) gave the water-soluble five-coordinate complex [Ni(**495**)], the crystal structure of which shows trigonal bipyramidal coordination of Ni^{II} with the central amine and terminal thiolates in plane and the two imino nitrogens in axial positions. Solvatochromism of the complex is interpreted in terms of S···H bonding, which may be of relevance to the catalytic cycle in hydrogenases.[1341]

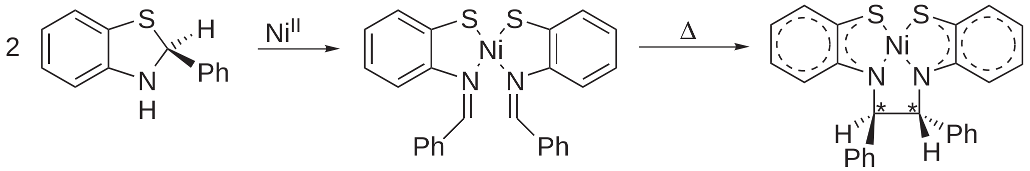
2-Phenylbenzothiazoline gives complex (**496a**) upon reaction with Ni^{II}. (**496a**) undergoes C—C bond formation even at room temperature and yields complex (**496b**), which contains a non-innocent ligand with two chiral centres. The crystal structures of both complexes reveal a square planar environment around the Ni^{II} ions.[1342,1343] The substitution of the phenyl group with two 3,5-di-*t*-butyl-4-hydroxyphenyl groups makes the carbon–carbon bond formation impossible even at high temperatures.[1344]

2,4-Di-*t*-butyl-6-aminothiophenol gives complex (**497**) under strictly anaerobic conditions. In the presence of air, deep blue-violet solutions are obtained from which mixtures of solid deep blue-black *cis*/*trans*-(**498**) can be isolated.[1345] For the square planar Ni complex, the *cis–trans* isomerization rate is fast. (**498**) is best described as a singlet diradical due to strong antiferromagnetic coupling of the benzosemiquinonate π-radicals.[192,1345]

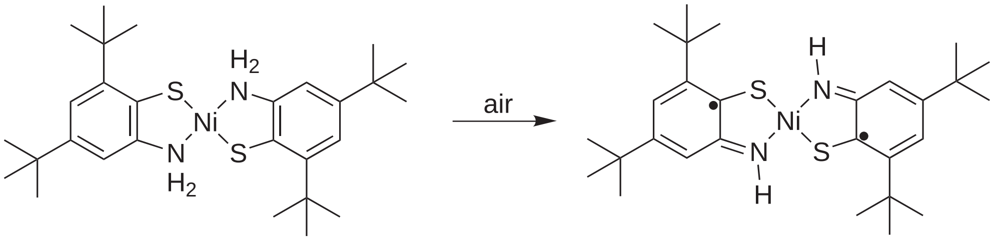
Methyl-2-amino-1-cyclopentenedithiocarboxylate coordinates to Ni^{II} in a bidentate manner through the thioketonate sulfur and the imine nitrogen atom, resulting in (**499**) with *trans* planar coordination geometry.[1346] Alkyl substituents (e.g., Me, Et, Pr^n, Pr^i, Bu^n) on the imine N atoms drive the coordination stereochemistry from planar to tetrahedral.[1347] Systematic distortion from square planar to tetrahedral was also observed as the number of methylene groups is increased in the tetradentate $\{N_2S_2\}$ ligands (**500**).[1348–1350] For $n = 3$, the complex is effectively tetrahedral in



(**495**)

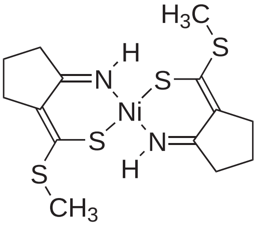


(**496a**) (**496b**)

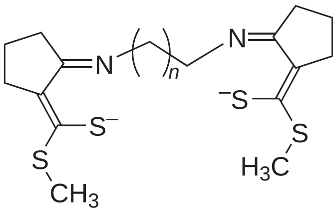


(**497**) (**498**)

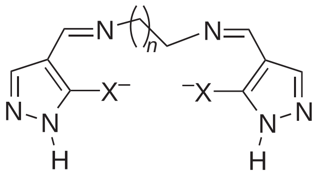
the solid ($\mu_{\mathrm{eff}} = 3.2\mu_B$), but in solution only 2–3% is in the high-spin form as assessed by ^{1}H NMR contact shift measurements. A similar study with similar conclusions has also carried out for Ni^{II} complexes of ligand (**501**)[1351–1353] and related systems with $\{N_2O_2\}$ and $\{N_2(NH)_2\}$ donor sets. A study on the whole series of tetradentate Schiff base Ni^{II} complexes (**502**) with $\{N_2(NH)_2\}$ and $\{N_2S_2\}$ Schiff base ligands revealed that the $\{N_2(NH)_2\}$ complexes are fully diamagnetic for



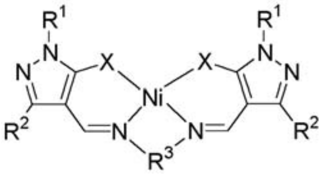
(**499**)



(**500**) $n = 1, 2, 3, 4$



(**501**) $n = 1, 3$; X = S, Se

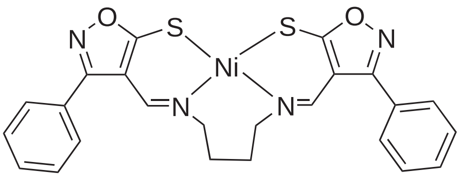


(**502**)

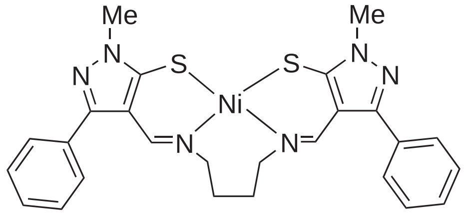
X = NH, S or O

R^1, R^2 = Ph or Me

R^3 = -$(CH_2)_3$-, -CHMeCH$_2$CHMe-, -$(CH_2)_2$- or -CHMeCH$_2$-



(**503**)



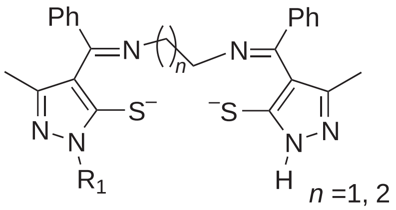
(**504**)

$n = 2$ and 3, while in the case of $\{N_2S_2\}$ donors the complexes are diamagnetic only for $n = 2$.[1352] The ligand field parameters derived from the electronic spectra as well as cyclic voltammetry have shown that the low-spin character ($S = 0$) is emphasized in both $\{N_2(NH)_2\}$ and $\{N_2S_2\}$ Ni^{II} complexes when compared with the corresponding $\{N_2O_2\}$ species.

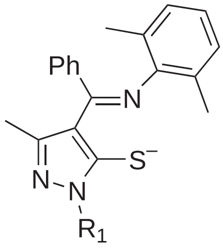
Incorporation of isoxazole instead of pyrazole has similar affects. Ni^{II} complexes with Schiff bases having pyrazole or isoxazole subunits and linkers with $n = 4$ (**503**, **504**) form a flattened tetrahedron with the dihedral angle (for the pyrazole derivative) between two N—Ni—S planes being 12.7°.[1354] In solution a spin equilibrium and racemization process $\Delta \rightleftharpoons \Lambda$ is observed.

Nickel(II) complexes of (**505**) exhibit spin equilibria in solution.[1355] With the bidentate analogues (**506**), complexes [Ni(**506**)$_2$] have been isolated.[1356] When $R_1 = Ph$, the complex is tetrahedral in solution. It has a temperature independent magnetic moment of $2.75\mu_B$. When $R_1 = Me$, the complex exhibits square planar–tetrahedral equilibrium in solution. Both are, however, diamagnetic in the solid state.

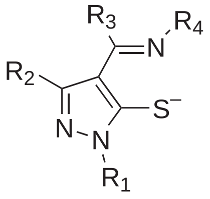
A detailed study involving racemization kinetics and spin states of a series of nine related complexes (**507**) has been undertaken.[1357] In an X-ray crystallographic study of a series of complexes ($R_1 = Pr^i$, $R_2 = Me$, $R_3 = H$, $R_4 = Me$, Ph, Bu^t) all complexes were found to possess pseudotetrahedral geometry.[1358]



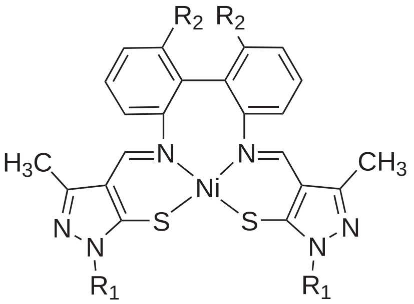
(**505**)



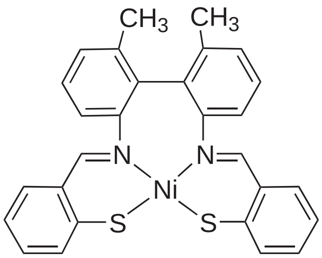
(**506**)



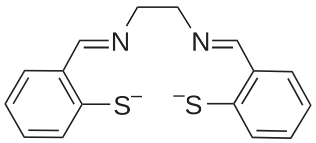
(**507**)



$R_1 = R_2 = CH_3$ (**508a**)
$R_1 = CH_3$, $R_2 = H$ (**508b**)
$R_1 = C_6H_5$, $R_2 = CH_3$ (**508c**)
$R_1 = C_6H_5$, $R_2 = H$ (**508d**)



(**509**)



(**510**)

Complexes (**508a**) and (**508b**) are paramagnetic with magnetic moments characteristic for distorted tetrahedral structures with relatively large zfs ($D = 36\,cm^{-1}$ and $53\,cm^{-1}$, respectively), whereas complexes (**508c**) and (**508d**) are diamagnetic.[1359] The solid-state structure of (**508a**) confirms the distorted tetrahedral geometry, while (**508d**) and the related complex (**509**) are much closer to square planar. The respective dihedral angles between the planes defined by the N—Ni—S and N′—Ni—S′ atoms are 77.4° and 35.7° for (**508a**) and (**508d**). In chloroform solution all complexes (**508**) show a $^1A_{1g} \leftrightarrow {}^3T_1$ spin equilibrium with equilibrium constants $K_{eq}(N_{HS}/N_{LS})$ in the range of 0.456–0.080. Surprisingly, the nature of the substituents on the pyrazolyl rings has a stronger influence on the spin state than the nature of the substituents on the biphenyl moiety.

In thiosalen-type complexes the Ni^{II} ion usually has a four-coordinate square planar geometry.[1360,1361] Complex [Ni(**510**)] shows a quasi-reversible reduction at −1.36 V and an irreversible oxidation at +1.00 V.[1362,1363] When the ethylene bridge is replaced by a phenylene bridge, again square planar complexes are isolated.[1360] Alkylation of the S atom results in distinct changes in the binding ability, since Ni^{II} complexes of such thioether ligands adopt an almost ideal octahedral geometry with two additional *trans* ligands (**511**; X = Cl, Br).[1364,1365] Both complexes (**511**) and (**512**) are paramagnetic. (**511a**) and (**511b**) are soluble and stable in noncoordinating solvents (CH_2Cl_2, $CHCl_3$), but dissociate in DMSO and other strongly coordinating solvents. In contrast, complexes (**512a**) and (**512b**) are stable in coordinating solvents, while (**512c**) is unstable and complex (**513**) crystallizes from a solution of (**512c**) in EtOH. In the case of longer dodecyl chains at the S atoms (**511b**), the S atoms have opposite relative configurations {*R*,*S*}, while with hexyl substituents the configuration at S is the same. The longer alkyl chains are fully extended in the all-*trans* conformation with resultant hydrophobic interactions and a bilayer packing in the crystals.

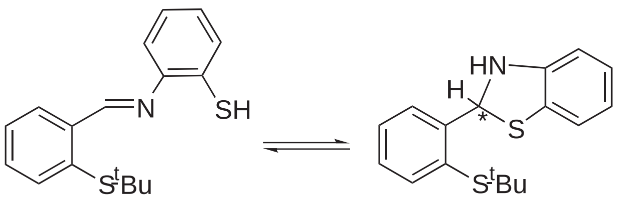
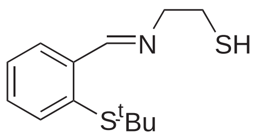
(**513**)



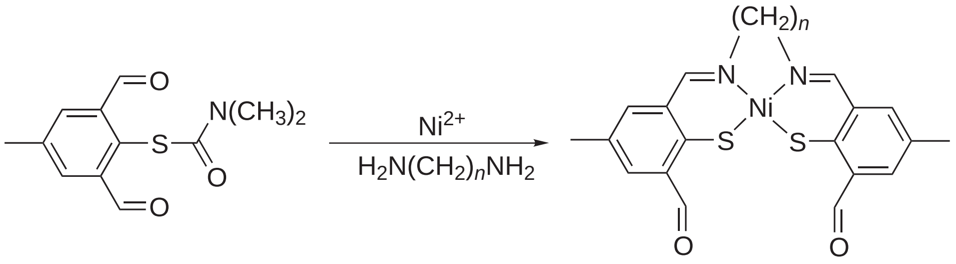
(**514**) H^tBuL^1



(**515**) H^tBuL^2

Potentially tridentate benzothiazolidine {NS_2} ligands (**514**) form mononuclear or dinuclear Ni^{II} complexes, depending on the anion used.[1366] Upon reaction with $Ni(OAc)_2$, HBu^tL^1 forms a monomeric complex $[Ni(Bu^tL^1)_2]$, which is a square planar species with slight distortion towards tetrahedral geometry. With other Ni^{II} salts it gives a dimeric, S-bridged complex $[Ni(L^1)]_2$ after loss of the *t*-butyl protecting group. The same coordination mode is found for (**515**) (Figure 15).

Complex (**516**) was prepared according to Equation (11). The dangling formyl groups can be used for further derivatization (e.g., (**517**) shown in Figure 16), and (**516**) serves as a valuable starting material for the synthesis of macrocyclic dinuclear species (compare Section 6.3.4.12).[1367]



(**516**)

(11)

The reaction of 2,2′-dithiodibenzaldehyde with Ni^{II} complexes containing coordinated primary amines results in Schiff base condensation and cleavage of the disulfide bond to form a chelating

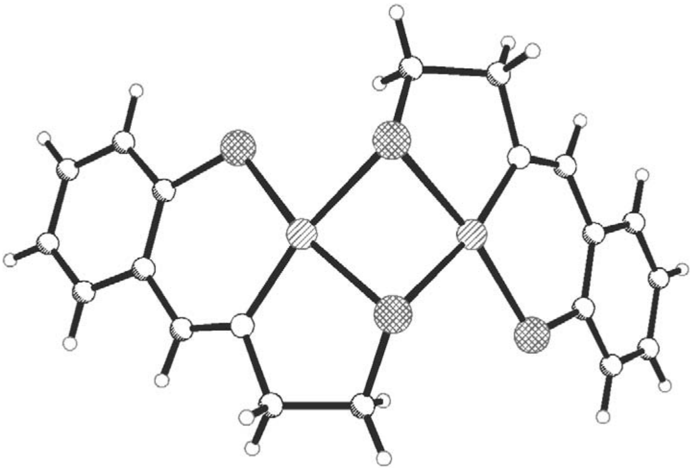


Figure 15 Molecular structure of $[Ni(L^2)]_2$ ($HBu^tL^2 = $ (**515**)).

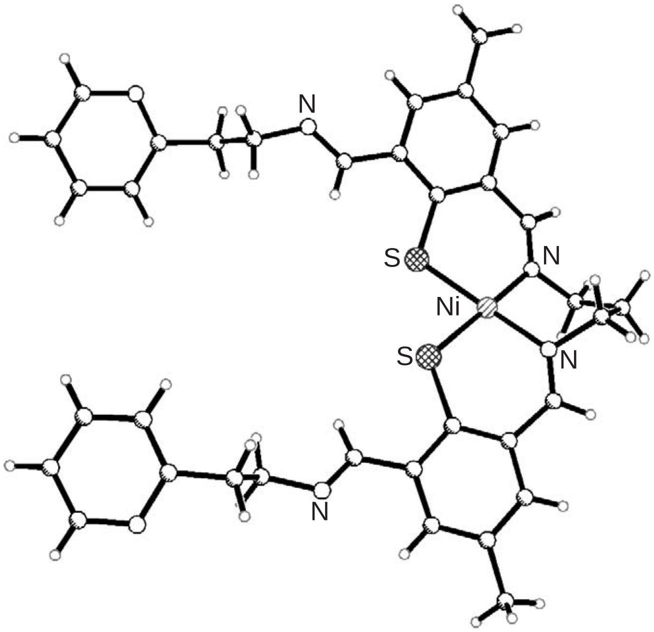

Figure 16 Molecular structure of (**517**).

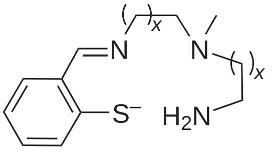
{N/S} ligand.[1363,1368] The method was used to synthesize Ni^{II} complexes with varying {N/S} donor sets, including complexes [Ni(**518a**)]BPh_4 and [Ni(**518b**)]BPh_4 with tetradentate {N_3S} Schiff base coordination. Although both complexes have similar planar structures, the complex with (**518b**) is significantly more distorted towards tetrahedral, because the six-membered chelate rings must deviate from planarity to assume boat or chair conformations. With (**519**), polymeric octahedral complexes are formed, the ligand coordinating via pyrrolyl, sulfide, and imine donors.[1369] Cimetidine (**520**), when reacted with NiX_2 ($X = BF_4$, NO_3), yielded complexes [Ni(**520**)$_2$]X_2. The complexes were assigned pseudo-octahedral stereochemistry with a {$NiN_2N_2{}^*S_2$} chromophore.[1370]

A number of differently substituted *N*-(thiocarbamoyl)benzamidines (**521**) (R = Et, Bu; NR_2 = morpholino) have been complexed with Ni^{II}. The ligands function in a bidentate manner, coordinating via the primary amine N and thione S atoms.[1371]

Quinazoline-2-thione-4-one (**522**) and its 3-phenyl derivative coordinate to Ni^{II} after deprotonation via the S and the N1 donor resulting in a square planar complex.[1372] The related 2-isopropylquinoline-8-thiolate (**523**) forms a distorted tetrahedral complex.[1373] For deprotonated 2-thiocarbamyl-thiazoline (HL = (**524**)) the octahedral complex $[NiL(H_2O)_4]^+$ is favored over the square planar $[NiL_2]$ complex.[1374]



(518)

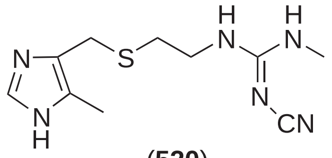
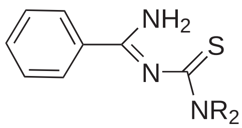
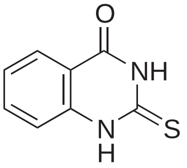
(519)



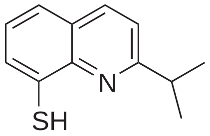
(520)



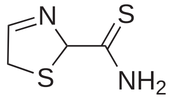
(521)



(522)

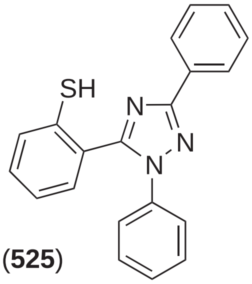


(523)

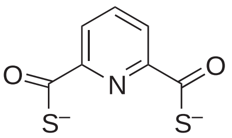


(524)

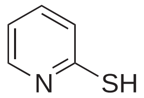
Ligand (**525**) forms with Ni^{II} a square planar complex with coordination through the S and the N4 atoms.[1375] In work aimed at the imitation of the low potentials observed for certain [FeNi]-hydrogenases, the complex $(Et_4N)_2[Ni(\textbf{526})_2]$ has been prepared. Its structure is tetragonally distorted octahedral with an essentially planar NiS_4 fragment and a *mer* configuration. The oxidation of this complex with I_2 in MeOH affords $[Ni^{III}(\textbf{526})_2]^-$, in which the geometry observed for Ni^{II} is preserved. Cyclic voltammetry of the Ni^{II} complex shows a reversible oxidation at −0.085 V (SCE) and the EPR spectrum of the ^{61}Ni-enriched Ni^{III} species has been obtained (compare Section 6.3.3.9.2).[1376]



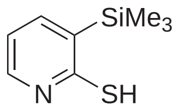
(525)



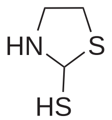
(526)



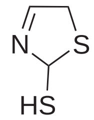
(527)



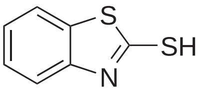
(528)



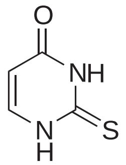
(529)



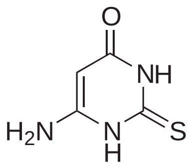
(530)



(531)



(532)

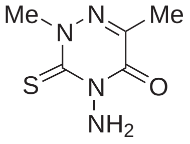


(533)

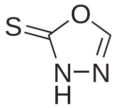
The electrochemical oxidation of a nickel electrode in a solution of pyridine-2-thione (HL = (**527**)) in MeCN gives polymeric, six-coordinate $[NiL_2]_n$. In the presence of py, bpy, or phen, the monomeric complexes $[NiL_2X_2]$ ($X_2 = py_2$, bpy, phen) are formed. The structure of $[NiL_2(bpy)]\cdot 0.5bpy$ reveals a distorted octahedral geometry, with the S-donors axial and the four N-donors roughly in a plane. Structural and spectroscopic data indicate that deprotonated (**527**) coordinates essentially as the $2\text{-}C_5H_5NS^-$ tautomer.[1377] With pyridine-2-thiol and pyrimidine-2-thiole $[NiL_3]^-$ anions have been characterized structurally.[1378] Ligand (**528**) functions as a bidentate {NS} donor resulting in planar Ni^{II} complexes.[1379] The sacrificial anode method has also been used to prepare this complex. With bpy or phen planar or octahedral complexes resulting in solution with (**528**) chelating in the thiolate form.[1380] For other mercapto-pyridine derivatives similar results have been found.[1381–1384]

$[NiL_2]$ complexes with ligands (**529**) and (**530**) have been synthesized using electrochemical methods. In the presence of further donors they form octahedral complexes.[1385] Ligand (**531**) forms $[NiL_2]$ complexes with Ni^{II}. With phen or bpy as coligands, magnetic and spectroscopic data of the resulting complexes again suggest planar or octahedral coordination of {NS} chelates.[1386,1387] Four-membered {NS} coordination is also present in the octahedral complexes $(Et_4N)[NiL_3]$ (HL = (**531**), (**532**), (**533**)).[1388]

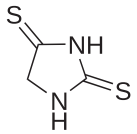
The neutral ligand (**534**) acts as a bidentate {NS} donor with all-*trans* coordination in [Ni(**534**)$_2$(H_2O)$_2$](ClO_4)$_2$. With NiX_2, polymeric octahedral [Ni(**534**)$_2$$X_2$] (X = Cl, Br) and [Ni(**534**)$_2$$X_2$($H_2O$)$_2$] (X = Br) have been characterized, with the ligand acting as a monodentate N-donor. A second isomer of [Ni(**534**)$_2$$Br_2$] can be isolated with bidentate {NS} coordination. Hence ligand (**534**) functions either as a monodentate N-donor or as a bidentate ligand depending on the nature of the counter ion and the conditions employed.[1389]



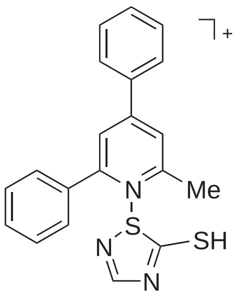
(**534**)



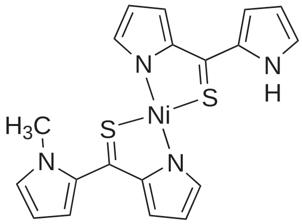
(**535**)



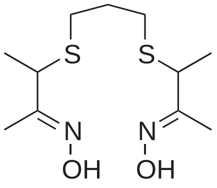
(**536**)



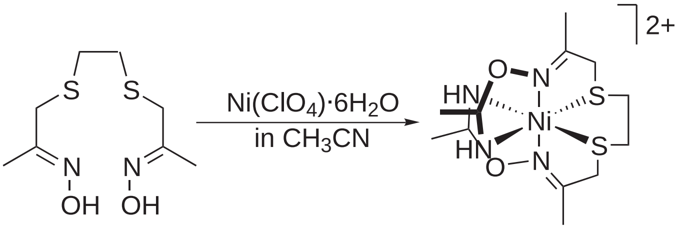
(**537**)



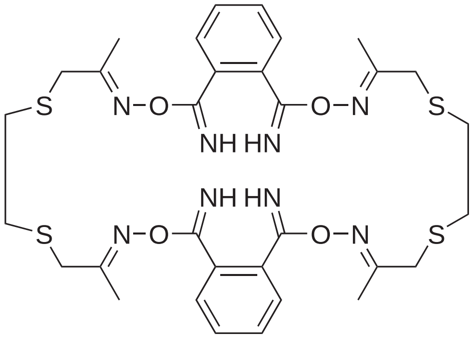
(**538**)



H$_2$[(**539**)]



H$_2$[(**540**)]
(**541**)



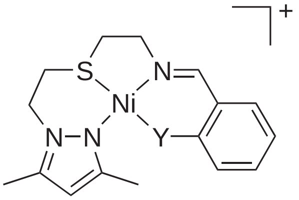
(**542**)

Complexation of (**535**) and (**536**) with Ni^{II} yielded complexes of the type $[NiL_2]$. The complexes were found to be diamagnetic, with the ligands binding in a monobasic {NS} bidentate fashion.[1390] [Ni(**537**H_{-1})$_2$(ClO_4)$_2$] has been prepared and characterized using chemical analysis, thermogravimetric, magnetic and a variety of spectroscopic techniques.[1391] A number of further thiadiazole ligands have been examined, confirming {NS} bonding.[1392] 2-Pyrrolylthiones form square planar $[NiL_2]$ complexes such as (**538**), similar to the related 2-thioacetylpyrrole and 2-thiobenzoylpyrrol.[1393]

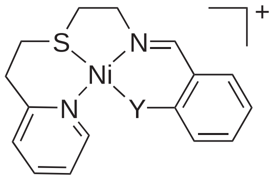
The mixed dithioether/dioxime ligand H$_2$[**539**] gives a planar Ni^{II} complex [Ni(H[**539**])]ClO_4.[1394] In contrast, upon reaction of $Ni(ClO_4)_2 \cdot 6H_2O$ with H$_2$[**540**] the octahedral complex (**541**) is formed by Ni-mediated coupling of the dioxime with two moles of MeCN.[1395] If H$_2$[**540**] is coupled with *o*-phtalonitrile in the presence of Ni^{II}, a dinuclear complex of (**542**) is obtained.[1396]

6.3.4.9.3 Complexes with mixed {N,O,S} ligands

Mixed {N,S,O} donor sets are useful to compare the coordination ability and the structural consequences of various donor sets and to induce a variety of structural properties. The solid-state structures of [Ni(pyzs)]BF_4, [Ni(pyrs)]BF_4 and [Ni(pyzo)]BF_4 containing dissymetric tetradentate ligands with {N_2S_2} (**543**) and {N_2SO} (**544**) donor sets are square planar.[1397] The phenolate-based complexes are essentially planar in nitromethane, but distorted octahedral in methanol, while thiophenolate-containing complexes remain square planar in both solvents.



(**543**)
Y = S:[Ni(pyzs)]$^+$
Y = O:[Ni(pyzo)]$^+$

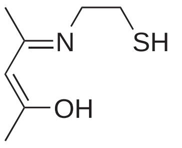


(**544**)
Y = O:[Ni(pyro)]$^+$
Y = S:[Ni(pyrs)]$^+$

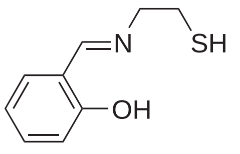
	R^1	R^2	$n = 2$	$n = 3$
(**545a**)	H	H	[Ni(cdsalen)]	[Ni(cdsalpd)]
(**545b**)	Me	H	[Ni(cdMesalen)]	[Ni(cdMesalpd)]
(**545c**)	H	3′-MeO	[Ni(cdMeOsalen)]	[Ni(cdOsalpd)]
(**545d**)	Me	5′-Me	[Ni(cdMe$_2$salen)]	[Ni(cdMe$_2$salpd)]
(**545e**)	H	4′,6′-(MeO)	[Ni{cd(MeO)$_2$salen}]	[Ni{cd(MeO)$_2$salpd}]
(**545f**)	Me	5′-MeO	[Ni(cdMeMeOsalen)]	[Ni(cdMeMeOsalpd)]
(**545g**)	H	3′,5′-Cl$_2$	[Ni(cdCl$_2$salen)]	[Ni(cdCl$_2$salpd)]

The Ni^{II} complexes (**545**) with tetradentate {N,N′,O,S} Schiff base ligands have a tetrahedrally distorted square planar geometry which is retained even in strongly coordinating solvents.[1398] Increasing the bulkiness of the ligand substituents does not induce significant changes in the complex structure. In most cases the reduction of Ni^{II} complexes to Ni^{I} does not change the coordination number, although in some cases six-coordinate species are formed.

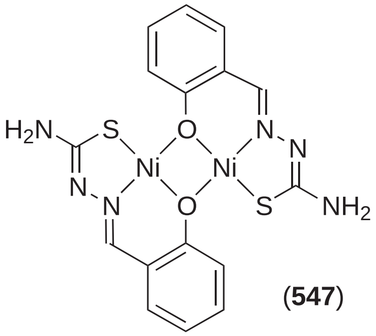
Tridentate {NOS} ligands (**546a**) and (**546b**) give thiolato-bridged dinuclear and trinuclear Ni^{II} complexes, respectively.[1399] In dinuclear (**547**) incorporating a salicylaldehyde thiosemicarbazone ligand, it is the phenolato-O that forms the bridges. The latter complex mediates silane alcoholysis and has been exploited as a model for the D_2/H^+ exchange reaction of hydrogenases.[1255] *N*,*N*′-disubstituted dithiooxamides form dinuclear species (**548**) with antiferromagnetic coupling very similar to the corresponding oxamides ($J = -13\,cm^{-1}$).[1400]



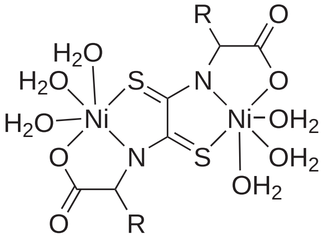
(546a)



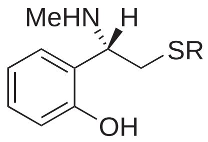
(546b)



(547)



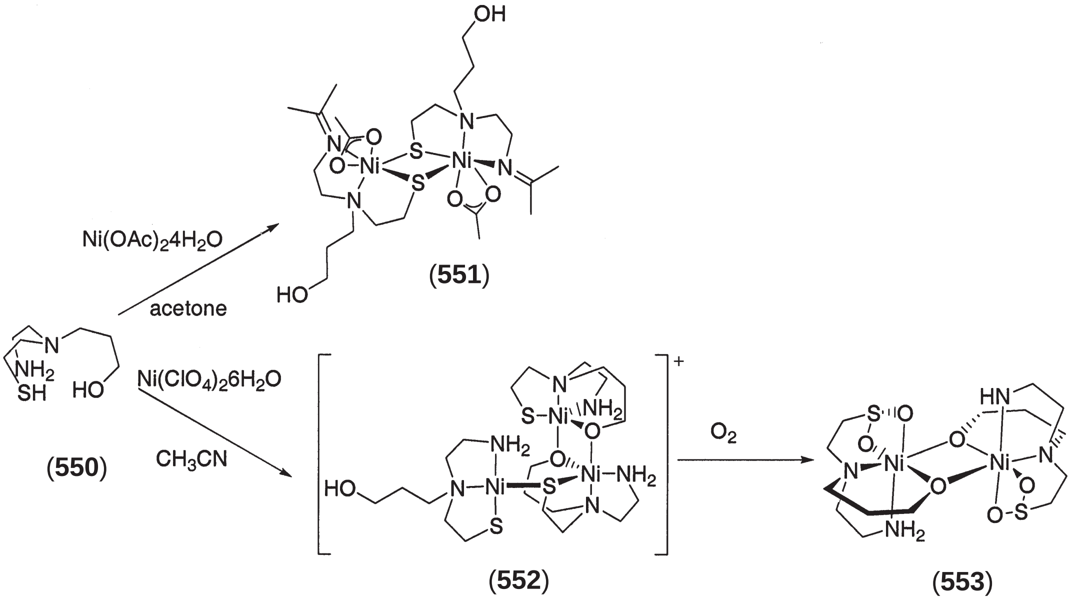
(548)



H [(**549**)]
R = H, CH_2Ph

Chiral (**549**) can act as a tripodal {NOS} ligand, and a hexacoordinate Ni^{II} species [Ni(**549**)$_2$] forms for R = CH_2Ph.[1401] However, the thioether ligand is labile, and square planar [Ni($\kappa N,O$-(**549**))$_2$] may also be present depending on the conditions. The protonated ligand gives octahedral [Ni($\kappa N,S$-H(**549**))$_2$Cl$_2$]. Using the related ligand with R = H, a trinuclear cluster [Ni_3S($\kappa N,S$-H(**549**))$_3$] consisting of three N,S-bound ligands and a central sulfide was isolated.[1402]

The tripodal ligand (**550**) with {N_2OS} donor set reacts with $Ni(OAc)_2 \cdot 4H_2O$ or $Ni(ClO_4)_2 \cdot 6H_2O$ to give multinuclear Ni^{II} complexes (Scheme 7).



Scheme 7

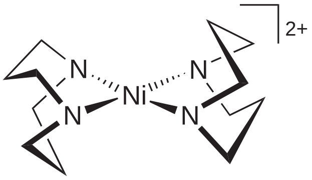
When $Ni(OAc)_2 \cdot 4H_2O$ is employed, a dimeric complex (**551**) with a coordinated Schiff base forms, because the amine donor reacts with the solvent acetone. With $Ni(ClO_4)_2 \cdot 6H_2O$, a trinuclear complex (**552**) is obtained which is readily oxidized upon exposure to air or by aqueous

H_2O_2 to yield the corresponding sulfinate complex (**553**). In the latter, the sulfinato group is O,O-bound—a very unusual coordination mode for Ni^{II} sulfinate complexes.[1403]

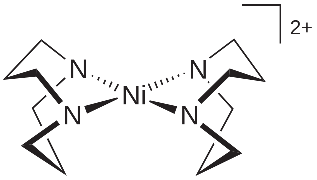
6.3.4.10 Complexes with Macrocyclic Ligands

Nickel complexes of macrocyclic ligands—in particular aza-type macrocycles—have received much attention, and an immense number of publications has appeared in the field. This is, among other aspects, due to the stabilization of uncommon oxidation states (high-valent nickel Ni^{III} and Ni^{IV}, and low-valent nickel Ni^{I}) by particular macrocycles and the use of such complexes in catalytic reactions, e.g., olefin epoxidation as well as electrochemical reduction of alkyl halides and carbon dioxide. Further impetus comes from the occurrence of a Ni-containing macrocyclic tetrapyrrol-derived cofactor (called F_{430}) in the active site of the enzyme S-methyl coenzyme M reductase, which catalyzes the final step in methane generation by several methanogenic organisms. This enzyme is assumed to contain Ni^{II} in its resting state and Ni^{I} in the active form. Several reviews on macrocyclic chemistry have appeared,[1404,1405] including an excellent review that specifically focuses on the macrocyclic chemistry of nickel.[91]

Square planar Ni^{II} complexes are most stable with 14-membered macrocyclic ligands, the prototype of which is [14]aneN_4 (cyclam). Hence, Ni^{II} complexes with cyclam-based ligands that form 6-5-6-5-membered chelate rings with the metal ion are particularly manifold. Also, Ni^{II} complexes of the small macrocycle [9]aneN_3 (tacn) and its heteroanalogues are being studied intensively. Since in this case the nickel ion cannot be accommodated within the cavity of the macrocyclic ligand, the chemistry of such complexes is somewhat distinct and will be covered in a separate section. The even smaller cyclic ligand 1,5-diazacyclooctane (daco), often referred to as a mesocycle, has been investigated in Ni^{II} coordination chemistry. The structures of $[Ni(daco)_2]Br_2$ (**554a**) and $[Ni(daco)_2]Br_2$ (**554b**) revealed boat/chair conformations with the ligands either related by a center of symmetry or by a mirror plane. Calculations confirmed that form (**554a**) has thermodynamic stability, while (**554b**) has chemical stability.[1406]



(554a)



(554b)

Daco-derived ligands, in particular derivatives alkylated with ethylene sulfide to provide pendent mercaptoethyl groups, have been used in model compounds for the active site of Ni^{II}-containing hydrogenases.[1407–1409]

6.3.4.10.1 Complexes with 1,4,7-triazacyclononane-type ligands

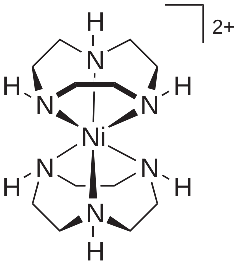
Largely due to the favorable ligating properties of the tridentate 1,4,7-triazacyclononane ligand ([9]aneN_3, tacn), numerous nickel complexes with tacn and derivatives thereof have been studied. Different to the larger macrocycles like [14]aneN_4, where the metal ion often resides within the macrocycle cavity, the small tacn ligand coordinates facially in octahedral complexes. Tacn-based complexes are particularly prominent in bioinorganic model chemistry (although this is less valid for nickel compared to other metal ions, e.g., iron or copper) and usually exhibit high stability constants.[1404] Of growing interest in tacn coordination chemistry is the appending of side arms bearing additional donor atoms, thereby increasing the number of coordination sites filled upon nickel binding to the macrocycle.

(i) Sandwich complexes with tacn ligands

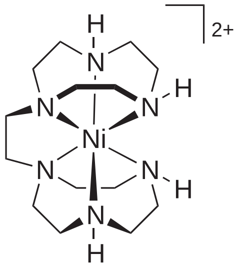
The sandwich complex $[Ni(tacn)_2]^{2+}$ (**555**) is known as a kinetically inert, thermodynamically stable system. Functionalized tacn ligands with "innocent" alkyl substituents like, for example, methyl or isopropyl, at all N atoms are not able to form sandwich complexes, which has been attributed to steric interaction between the bulky substituents.[1404] Asymmetrically functionalized Bztacn with only a single benzyl substituent, however, forms a sandwich complex with the benzyl amine donors occupying adjacent sites at the metal center (*syn* isomer), which—contrary to initial expectation—appears to be the sterically less hindered isomer.[1410]

A number of bis(tacn) ligands, composed of pairs of covalently linked tacn macrocycles, can form similar structures, provided the linker group between the sandwiching macrocycles is sufficiently flexible (e.g., (**556**)).[1411–1413] In particular, several Ni^{II} complexes of poly(tacn) derivatives with a central benzene have been studied, where the Ni is sandwiched between pairs of tacn macrocycles when these are attached to the *ortho* positions of the aromatic spacer group (e.g., (**557**)).[1412,1413]

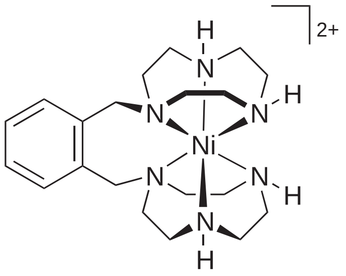
$[NiL_2]^{2+}$-type sandwich complexes of tacn ligands bearing one or three pendent alkyne arms (L = *N*,*N*′,*N*″-tris(3-prop-1-yne)-1,4,7-triazacyclononane or *N*-(4-but-2-yne)-1,4,7-triazacyclononane) have been synthesized.[1414] Contrary to expectation, the alkyne groups did not show any reactivity towards organometallic reagents like $Co_2(CO)_8$. The Ni^{II} complex of a chiral tacn-type ligand (**558**) with a cyclohexane ring fused to macrocycle framework (L = chtacn) has also been reported.[1415]



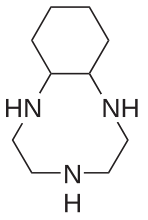
(555)



(556)



(557)



(558)

Electronic spectral data for selected tacn sandwich complexes of Ni^{II} are collected in Table 5. Three common maxima of octahedral Ni^{II} predominantly arise from spin-allowed transitions $^3A_{2g} \rightarrow {}^3T_{2g}$ (1,000–800 nm), $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ (550–500 nm), and $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ (300–400 nm). A detailed spectroscopic and ligand field analysis of the parent complex has been performed using the AOM.[1416] The band envelope of the low-energy transition, which is asymmetric or has a shoulder, has to be attributed to symmetry splitting and spin–orbit coupling within the $^3T_{2g}$ state, or a close approach of the $^1E_{2g}$ state such that the spin-forbidden $^3A_{2g} \rightarrow {}^1E_{2g}$ transition gains intensity through spin–orbit coupling with the $^3T_{2g}$ state. The contributions of these effects may differ in each individual case, where for parent $[Ni(tacn)_2]^{2+}$ the double-humped band shape is largely the result of two relatively narrow bands corresponding to transitions to spin–orbit levels which contain significant spin singlet character. The best fit ligand field parameters are $e_\sigma(N) = 4340$, $B = 840$, $C = 2830$, and $\zeta = 500\ \text{cm}^{-1}$.[1416]

The high ligand field splitting value of $[Ni(tacn)_2]^{2+}$ is due to this complex having the minimum possible cage size for Ni^{II}, and it has been assumed that the metal–ligand distances would be shorter were it not for the nonbonded repulsive interactions between pairs of methylene groups on

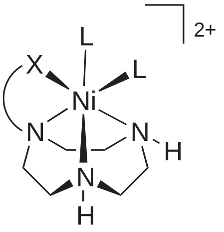
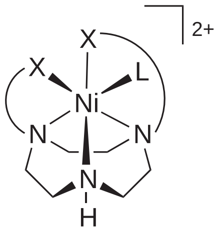
adjacent rings.[1417] The 10*Dq* value for the chiral derivative $[Ni(chtacn)_2]^{2+}$ is slightly lower than for the parent complex, presumably due to the donor strength difference between secondary and tertiary amines as well as steric reasons that originate from the bulk of the cyclohexane rings fused to the macrocycle.[1415] The latter effect is much more pronounced in the case of $[Ni(bztacn)_2]^{2+}$, where the benzyl substituents prevent the N-donors from approaching the optimum Ni—N distance of 2.08 Å (Ni—Nbz distances of 2.251 Å and 2.262 Å), resulting in a much weaker ligand field.[1415]

(ii) Complexes of tacn-based ligands with pendent donor side arms

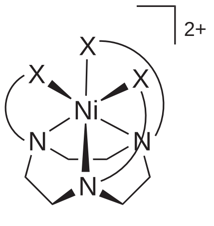
Nickel(II) complexes of tacn ligands with pendent donor arms have received considerable attention. One, two, or three N atoms of the macrocycle can be functionalized, leaving two, one, or no remaining coordination sites at the octahedrally coordinated metal ion (general types (**559**), (**560**), and (**561**)). For synthetic reasons, type (**561**) complexes are by far the most numerous. These systems comprise, *inter alia*, tacn ligands with three 3-aminopropyl (taptacn),[1418] imidazol-2-ylmethyl (timtacn),[1419,1420] 2-pyridylmethyl (tpmtacn),[97,1421] pyrazol-3-ylmethyl (tpz3mtacn),[1422] pyrazol-1-ylmethyl (tpz1mtacn),[1420] 2-hydroxy-3-methylbutyl (thmbtacn),[1423,1424] acetate (tacnta),[1425] or ethylacetate (tacntea)[1426] pendent arms. In the case of 1,4,7-triazacyclononane-*N*,*N*′,*N*″-tris(2-ethanesulfonate) (tacntes), the crystal structure reveals that one of the side arms remains uncoordinated with one water bound to the Ni ion.[1426]



(559)



(560)



(561)

The pseudo-octahedral $\{NiN_6\}$ core in type (**561**) complexes usually features a twist angle, e.g., 23.4° in $[Ni(tpmtacn)]^{2+}$.[97] Since the five-membered chelate rings of the coordinated tacn are not planar but adopt either the $\lambda\lambda\lambda$ or $\delta\delta\delta$ conformation for each set of chelate rings, the coordinated base fragment is chiral and the pendent arms may attach themselves in a clockwise or anticlockwise fashion for a given arrangement of the base fragment.

The kinetics and mechanism of complex formation has been studied in great detail for $[Ni(tacnta)]^-$: in the pH range 4.4–6.8, Ni^{2+} and the ligand species $Htacnta^{2-}$ equilibrate rapidly ($K = 13\,M^{-1}$) to form an intermediate [Ni(Htacnta)] which is subject to protonation ($pK_H = 5.77 \pm 0.04$). Spectral properties suggest that this is a monoacetato species with partial N coordination. In a second (first-order) rate-controlling step ($k_H = 154 \pm 15\,s^{-1}$) that is accompanied by proton release, the N_3O_3 coordination of the Ni is completed.[1427] When crystallized from nitric acid, $[Ni(tacnta)]^-$ forms as the hydronium salt, indicating extreme stability.[1425] This is in contrast to comparable complexes (such as EDTA complexes) where any acid protonates a carboxylate which is then left uncoordinated. The structure of $[Ni(tacnta)]^-$ displays very short Ni—N bond lenghts of 2.04 Å which are not the result of compression, but rather the very efficient packing of the tacnta ligand around small metal ions. Consequently, the 10*Dq* values for $[Ni(tacnta)]^-$ (Table 6) are higher than for other complexes of Ni^{II} with an N_3O_3 donor set, attributed to the donor strength of the tertiary N as well as to the highly favorable steric arrangement.[1425]

Multipole analysis with high-resolution X-ray data for $[Ni(thmbtacn)]^{2+}$ was carried out to determine the electron configuration in the C_3 symmetry-adapted orbitals of the Ni ion, confirming a higher occupancy of the crystal field-stabilized t_{2g} orbitals relative to the destabilized e_g orbitals. This is interpreted in terms of a predominantly ionic metal–ligand interaction.[1424]

For $[Ni(taptacn)]^{2+}$, electronic spectra confirm that the inner coordination sphere remains intact in CH_3CN or CH_3NO_2 solution. In aqueous acidic media, however, ready dissociation

[a] taphtacn = 1,4,7-tris(2-aminophenyl)-1,4,7-triazacyclononane. [b] tabtacn = 1,4,7-tris(2-aminobenzyl)-1,4,7-triazacyclononane.

and protonation of the primary amines is observed with successive pK_a values of 4.18 ± 0.05, 4.91 ± 0.01, and 5.64 ± 0.02 for the tri-, di-, and monoprotonated species.[1418] 10*Dq* values for tacn ligands with three pendent N-donor side arms are indicative of a quite strong ligand field (Table 6).

Ni^{II} complexes of tacn ligands with three 2-aminophenyl groups attached to the tacn scaffold either directly or via a methylene group have been reported.[1429,1430] In the former case the more rigid ligand enforces a stronger metal–ligand interaction according to the 10*Dq* values. Hexadentate tabtacn forms a stable complex with a distorted octahedral (C_3-symmetric) $\{NiN_6\}$ chromophore (Figure 17).[1430] The potentials for the $[LNi]^{3+/2+}$ couple are generally more negative for complexes containing the pure σ-donor tacn than those of a ligand containing three tertiary amine donors and pendent π-acceptor ligands that stabilize the +2 oxidation state, e.g., by ~400 mV for tpmtacn bearing three pyridine N atoms.[97]

Upon recrystallization, $[Ni(tpz1mtacn)]^{2+}$ affords $[Ni(L)(MeCN)]^{2+}$ (L = 1,4-bis(pyrazol-1-ylmethyl)-1,4,7-triazacyclononane) via a N-dealkylation reaction and loss of a pendent arm.[1420] More rational routes to Ni complexes of tacn ligands with only one or two pendent arms have been developed.[1431,1432] In $[Ni(L)(X)_n]^{x-}$ (e.g., L = 1-(3-aminopropyl)-1,4,7-triazacyclononane ($n = 2$) or 1-(1-methylimidazol-2-ylmethyl)-1,4,7-triazacyclononane ($n = 2$) or 1,4-bis(1-methylimidazol-2-ylmethyl)-1,4,7-triazacyclononane ($n = 1$), the coordination sphere is completed by additional ligands that bind either terminal ($X = Cl^-$, H_2O) or bridge two metal ions ($X = N_3^-$, OH^-, oxalate). The Ni^{II} complex of 1,4-bis(2-pyridylmethyl)-1,4,7-triazacyclononane has been shown to be extremely inert to ligand dissociation in aqueous solution.[1433] In (**562**), the tacn ligand provides a single bidentate arm.[1434]

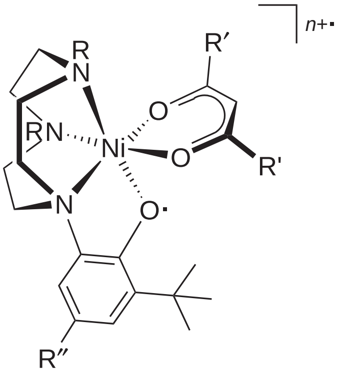
(562)



(563)

While permutation of the Irving–Williams order was found for the Cu^{2+} and Ni^{2+} complexes of parent tacn,[1435] L = 1,4,7-triazacyclononane-1-acetic acid follows the conventional stability order $Ni^{2+} < Cu^{2+}$ with $\log K_{NiL} = 17.85(3)$.[1436] The carboxylate group of the side chain prevents formation of the bis(ligand) species $[ML_2]$. The Ni^{II} complex of an asymmetric tacn ligand bearing two 1-methylimidazol-2-ylmethyl and one carboxymethyl pendent arm has been structurally characterized and reported to be remarkably stable in water even in the presence of a large excess of CN^- (changes in the electronic spectrum are only observed after 20 days).[1437]

A combination of hard and soft donor atoms is found in Ni^{II} complexes of the tetradendate tacn ligand with a diphenylphosphanylpropyl pendent arm.[1438] Side arm moieties may also be susceptible to oxidation, and nickel complexes of such ligands have been thoroughly investigated in order to distinguish metal-centered vs. ligand-centered redox processes. Ni complexes of phenolate–pendent arm ligands derived from tacn form very stable phenolato complexes in the presence of acac coligands (**563**). Upon electrochemical one-electron oxidation, spectral and magnetic features are characteristic of phenoxyl radical formation and ferromagnetic coupling to the high-spin Ni^{II} to give an $S = 3/2$ ground state.[1439]

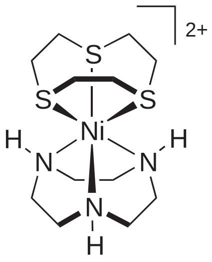
(iii) Complexes of heteroanalogous tacn-type ligands

Nickel(II) complexes of various heteroanalogues of the tridentate tacn ligand ($[9]aneN_3$) have been reported, where one, two, or all three N-donor atoms of the macrocycle are replaced by S, O, or combinations thereof. Such moieties have also been incorporated in bicyclic ligand systems that form complexes with Ni^{II}.[1440]

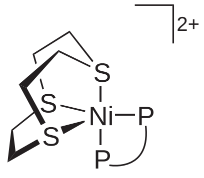
Most prominent are Ni complexes of the all-thia analogue of tacn, $[9]aneS_3$. A simple laboratory experiment for the synthesis of $[Ni([9]aneS_3)_2](BF_4)_2$ has been described.[1441] In this complex the metal atom is in a slightly distorted octahedral environment of S atoms provided by the facially coordinating $[9]aneS_3$.[1442,1443] The mixed-ligand complex $[Ni([9]aneN_3)([9]aneS_3)]^{2+}$ (**564**) allows for a direct comparison of the two cyclononane ligands. It has been prepared in a controlled fashion via the solvento complex $[Ni([9]aneN_3)(H_2O)_3]^{2+}$.[1444] While the Ni—N distances are comparable to those of $[Ni([9]aneN_3)_2]^{2+}$, the Ni—S bond lengths are slightly longer than those in $[Ni([9]aneS_3)_2]^{2+}$. The natural differences of the Ni—N and Ni—S distances impose a trigonal distortion, and unlike the homoleptic counterparts a trigonal twist of 3.5° is observed.

A Ni^{II} complex of a *C*-substituted 1,4,7-trithiacyclononane ligand has been mentioned.[1445] Also, a number of five-coordinate Ni^{II} complexes of $[9]aneS_3$ with diphosphane coligands have been structurally characterized (e.g., (**565**)).[1446,1447] A very particular case is the Ni^{II} complex of the highly rigid crown trithioether benzene trisulfide, bts (**566**), for which a sandwich structure has been proposed.[1448,1449] A $10Dq$ value of $13{,}020\,cm^{-1}$ has been determined, indicating a very strong ligand field. However, the complex decomposes within hours in the solid state and must be stored at low temperature under exclusion of light and air.[1449]

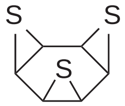
The molecular structure of the complex $[Ni([9]aneN_2S)_2]^{2+}$ reveals a center of symmetry, i.e., the sulfurs are placed *trans* to each other, which leads to a coordination geometry that is



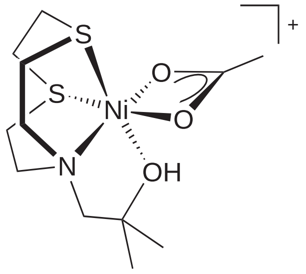
(564)



(565)



(566)



(567)

considerably distorted from octahedral.[1450,1451] A similar geometry was found for $[Ni([9]aneN_2O)_2]^{2+}$.[1452] If a single sulfoxide group is introduced into the macrocycle, coordination through the sulfoxide-O is observed, with the O atoms again occupying *trans* positions at the octahedral metal ion.[1453,1454] Ni—N distances are shorter for $[Ni([9]aneN_2SO)_2]^{2+}$ than for $[Ni([9]aneN_2S)_2]^{2+}$. The Ni^{II} sandwich complex $[Ni([9]aneNS_2)_2]^{2+}$ likewise features a center of inversion. Its Ni—N bond lengths are similar to those of $[Ni([9]aneN_2S)_2]^{2+}$ and $[Ni([9]aneN_3)_2]^{2+}$, but Ni—S distances are distinctly longer than in the symmetric $[Ni([9]aneS_3)_2]^{2+}$ system. The *trans* diastereomer is assumed to be present for $[Ni([9]aneS_2O)_2]^{2+}$ as well.[1455] A $[9]aneNS_2$ type ligand bearing a pendent alcohol substituent acts as a tetradentate ligand in (**567**),[1456] and the Ni^{II} complex of a pentadentate ligand bearing pyridyl side arms at the N atoms of $[9]aneN_2S$ has also been reported.[1457]

$[9]aneS_3$ exerts a stronger ligand field than does $[9]aneN_3$ (tacn). It has been argued that this is due to the fact that $[9]aneS_3$ can coordinate in a very low-strain manner. For mixed donor ligands such as $[9]aneN_2S$ the great differences in Ni—N and Ni—S bond lengths lead to a mismatch upon coordination to the metal ion, and the resulting steric strain lowers the ligand field strength.[1458] The 10*Dq* value for $[9]aneNS_2$ lies in-between those for $[9]aneN_2S$ and $[9]aneS_3$, while the value for $[9]aneOS_2$ is the lowest in the series (Table 7). The values for the Racah parameters *B* usually decrease upon gradual replacement of the harder secondary nitrogen donors with by the softer thioether donors, consistent with the more covalent nature of the Ni—S bond.[1459]

Since small metal ions like Ni^{2+} fit best into the $[9]aneX_3$ macrocycles, the macrocyclic effect is particularly large for Ni^{2+}.[1458] $E_{1/2}$ values for the Ni^{II}/Ni^{III} redox couple indicate that the relative stability of the trivalent complex decreases along the series $[9]aneN_3 > [9]aneN_2S > [9]aneNS_2 > [9]aneS_3 > [9]aneN_2O$, which is assumed to be controlled by the strength of the metal–ligand interactions.[101] Spectroscopic data confirm that these oxidations are metal-centered.[103]

6.3.4.10.2 Complexes with larger macrocyclic nitrogen ligands

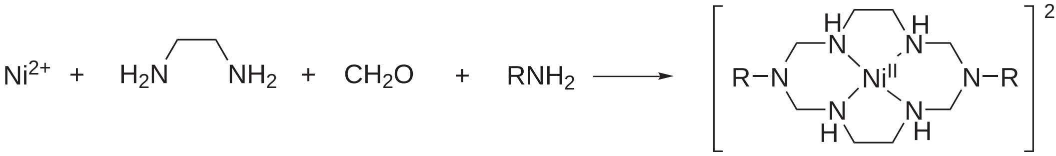
(i) Synthesis

Ni^{II} macrocyclic complexes can be prepared following two general procedures: either via complexation reactions between presynthesized macrocyclic ligands and the metal ion in solution, or by metal ion-directed template condensation reactions.[91] For Ni^{II}, the latter approach has been pursued more often than with other metal ions, since Ni^{II} does not impede ligand-forming reactions by redox processes or hydrolysis, and most Ni^{II} complexes are insensitive to moisture and oxygen. While complexation reactions offer the advantage that the macrocyclic ligand may be isolated and purified prior to the synthesis of the complex, the template synthesis often yields the desired product in one-pot reactions and generally provides selective routes to new ligand complexes in high yields.[91]

C-functionalization of azamacrocycles is in general more difficult to achieve than N-functionalization. The latter has been developed to an extent that macrocycles carrying side chains with various ligating groups are accessible, and Ni^{II} complexes can be prepared with high selectivity and predisposition for high thermodynamic and kinetic stability.

(a) Synthesis via template condensations. The synthesis of Ni^{II} macrocyclic complexes via the simple and convenient route of template condensation reactions is often carried out by heating amines and formaldehyde in the presence of the metal ion. In the cyclization reaction, formaldehyde links two *cis*-coordinated amine moieties to give methylenediamine (N—CH_2—N) linkages. While the nitrogen atoms of methylenediamine linkages of secondary nitrogens show a strong tendency to become tertiary upon cyclization,[1461–1467] the secondary nitrogens of methylenediamine linkages can be stabilized when coordinated to the metal ion. Hence, ligands containing methylenediamine linkages with secondary nitrogens are stable as long as they exist as part of metal complexes.

Hexaaza macrocyclic ligand complexes like (**568**) and (**569**) with various different alkyl groups at the uncoordinated bridgehead nitrogen atoms have been synthesized by template condensation of ethylenediamine, formaldehyde, and primary alkylamine in the presence of $NiCl_2$ in MeOH according to Equation (12). In the complexes, the Ni^{II} ions are found in square planar geometry with the tertiary bridgehead nitrogens noncoordinating.[1464,1468] Similarly, the Ni^{II} complexes of type (**570**) pentaaza macrocyclic ligands have been prepared by employing 3,7-diazanonane-1,9-diamine (2,3,2-tet), formaldehyde, and a primary amine as described in Equation (13).[1469] Nitroalkanes have also been utilized in place of the primary amine to give, for example, the square planar Ni^{II} complex of (**571**) from the reaction of $Ni(en)_3{}^{2+}$, formaldehyde, and nitroethane.[1470,1471] Subsequent reduction of the nitro functions gives Ni^{II} complexes of *trans*-6,13-diamino-6,13-dimethyl-1,24,8,11-tetraazacyclotetradecane:[1472]



(12)

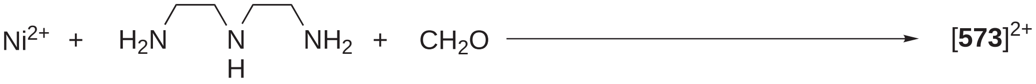
(572a) X = OH, *n* = 2 **(572b)** X = OH, *n* = 3
(572c) X = CN, *n* = 2 **(572d)** X = CN, *n* = 5

A wide variation of functional groups can be attached to the macrocyclic ligands by variations of the methods shown in Equations (12) and (13), e.g., by using carboxamide or sulfonamide instead of the primary amine. In the case of pendent pyridine units, these may react with $[Pt^{II}Cl_4]^{2-}$ and *cis*-$[Ru^{II}(bipy)_2Cl_2]$ in a 2:1 ratio to give supercomplexes *cis*-$[(Ni^{II}L)_2Pt^{II}Cl_2](PtCl_4)(ClO_4)_2$ and *cis*-$[(Ni^{II}L)_2Ru^{II}(bipy)_2](ClO_4)_6$, respectively.[1473,1474] Other complexes with functional groups linked to the azacyclam ligand have also been synthesized by a similar reaction giving, for example, pendent ferrocene,[1475] OH, and CN groups.[1476] These complexes are square planar in solutions, where the pendent hydroxyl groups in $[\mathbf{572a}]^{2+}$ and $[\mathbf{572b}]^{2+}$ do not coordinate to the Ni^{II} ion in water at pH $\leq$ 13.0 and ionic strength 1.0 M ($NaClO_4$). However, while many of these complexes remain square planar in the solid state with the functional side arms dangling, in $[\mathbf{572c}](BF_4)_2$, the complex containing a —CH_2CH_2—CN functional group, both CN coordinate intermolecularly to form a coordination polymer with an octahedral geometry around the metal. A 1D polymeric structure in the solid state has also been observed for derivatives of [15]aneN_4 with pendent primary amine or carboxylate arms.[1477]

Ni^{II} complexes of various polyaza polycyclic ligands, e.g., (**573**)–(**576**), have been synthesized by heating formaldehyde and appropriate amines at reflux in the presence of $NiCl_2$ in methanol solutions and then precipitating with $LiClO_4$ or CF_3SO_3Li as summarized in Equations (14)–(17).[1463,1465,1467,1478] The yields of these condensation reactions are generally high (50–90%), and all ligands contain methylenediamine linkages in which nitrogen atoms are either tertiary or coordinated secondary groups. The complexes contain football-shaped tetraazabicyclononane moieties or uncommon 1,3-diazacyclopentane and 1,3-diazacyclohexane subring moieties in the hexaaza macrocyclic framework. Even though such ligands contain more than four nitrogen atoms, only the central four N-donors act as a tetradentate scaffold in the square planar Ni^{II} complexes. These complexes are extremely stable and decompose only very slightly even in highly acidic media. Again, nitroethane can be used instead of the primary amine to give, for example, the Ni^{II} complex of the hexaaza macrotricyclic ligand (**577**):[1479]



(14)

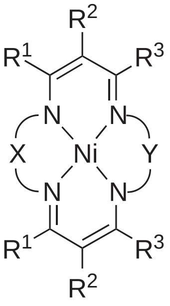
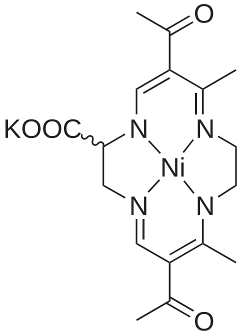
(580)



(581)



(582)

Octahedral coordination of Ni^{II} can be observed with macrobicyclic ligands. In (**578**), the hexaaza macrocyclic ligand serves as a pentadentate ligand, forming a six-coordinate species with an axial Cl^- ligand. The complex includes an uncommon four-membered chelate ring and the methoxy methyl pendent chain.[1466] A similar situation has been observed for the Ni^{II} complex of (**579**)—in this case the pendent amine arm fills the sixths coordination site.[1480]

The encapsulated Ni^{II} complex (**580**) was obtained from the reaction of $[Ni(en)_3]^{2+}$, formaldehyde, and ammonia, similarly to Equation (14). The yield was low (ca. 1%), probably because the Ni^{II} ion is a labile metal ion.[1461] The complex was extraordinarily stable against ligand substitution with donors such as NCS^-, Me_2SO, H_2O, or MeCN. The electronic spectrum of the complex is similar to that of $[Ni(en)_3]^{2+}$, but the ligand field strength of the complex was slightly stronger than that of $[Ni(en)_3]^{2+}$ because of the tris(methylene)amino caps.

Other template reactions involving Ni^{II} take advantage of Schiff base formation or related reactions. In continuation of extensive work following the initial publication by Jäger in 1964, numerous Ni^{II} complexes of tetraaza[14]annulenes and related [N_4] Jäger-type macrocycles (**581**) have been prepared by template condensation between diamines and 1,3-dicarbonyl compounds in the presence of the metal ion.[1481] A modified stepwise synthesis with final base-initiated formation of the ring-closing azomethine bond has been reported,[1482] and intermediates in the template synthesis if Ni^{II} dibenzotetraaza[14]annulenes have been isolated.[1483] Chiral groups have been introduced by means of enantiomerically pure building blocks, e.g., in the Ni^{II} complex of a 15-membered carboxylato-substituted macrocycle (**582**). This complex is acid sensitive and undergoes facile oxidative decarboxylation to generate the corresponding hydroxy-substituted species in a disproportionation reaction.[1484] A Ni^{II} complex of the sterically congested tetraaza[14]annulene derivative 5,7,12,14-tetraphenyldibenzo[b,i]-1,4,8,1-teraazacyclotetradecinate (TPTAA) has been prepared in a template synthesis via microwave heating, albeit in low yields.[1485]

The square planar Ni^{II} complex (**583**) was prepared from the template reaction of 3,3′-(ethylene bis(iminomethylidene)bis(2,4-pentanedionato)nickel(II) with 1,3-diamino-2-propanol (Equation (18)). The uncoordinated —OH group reacted smoothly with acylating agents, resulting in —COPh and —$COCH_3$ side arms.[1486]

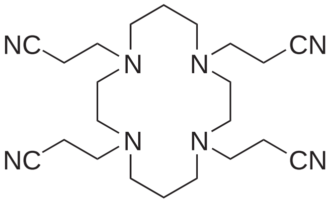
(584)

The Ni^{II} complex of a 16-membered macrocycle, 2,7-dimethyl-3,6-(1,1′-(2,2′-biimidazole)-1,3,6,8,11,14-hexaazacyclohexadeca-1,7-diene (**584**), was synthesized by condensation of a Ni^{II}–triethylenetetramine precursor complex and 1,1′-diacetyl-2,2′-bisimidazole.[1487] It forms a square planar geometry with iodide or perchlorate anions, but an octahedral structure in the presence of chloro or bromo coligands. Template syntheses have also been applied for the synthesis of Ni^{II} complexes of large ring tetraazamacrocycles having 18-, 20-, 22-, 24-, 26-, 28-, or 34-membered rings.[1488]

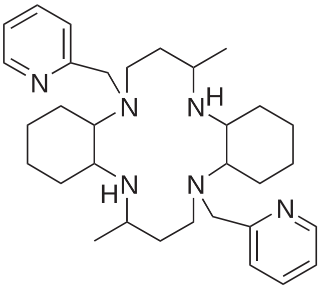
(b) Synthesis of Ni^{II} macrocyclic complexes from free ligands. This strategy allows one to design and presynthesize a wide variety of macrocyclic ligands and is often used for systems with pendent functional groups (in particular for cyclam derivatives) or ligands with other building blocks, e.g., pyridine, in the macrocyclic framework. After insertion of nickel, the functional groups may affect the properties of the macrocyclic complexes through coordination to the metal ion.

Strategies for selective partial alkylation of cyclam have been developed and Ni^{II} complexes of the variously substituted ligands prepared.[1489] In a series of tetra-*N*-alkylated cyclams, Ni^{II} incorporation was only observed for smaller substituents such as Me, Et, and Pr, while no complexes were formed with sterically demanding substituents like Pr^i, $PhCH_2$, or $2\text{-}MeC_6H_4CH_2$. Depending on the sterical hindrance of the *N*-substituents, the complexes are either square planar or pentacoordinate in solution, since an axial water molecule can bind in the case of the ligand with four small methyl substituents.[1490]

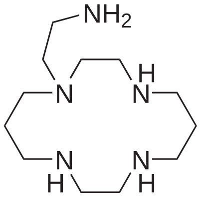
Side chains with functional groups such as amine, hydroxyl, amide, carboxylic, and nitrile moieties have been attached to the N-donor atoms of azamacrocycles.[1491–1497] Upon Ni^{II} complexation by these ligands, the side arms may or may not bind to the metal. For example, the cyclam derivative with four nitrile pendent chains (**585**) was prepared directly by heating cyclam in acrylonitrile.[1494] Its Ni^{II} complex has a square planar geometry without coordination of any of its nitrile groups to the metal ion. However, the corresponding ligand with four amide functions yielded an octahedral and a five-coordinate complex in which two and one of the pendent amide groups, respectively, are bonded to the Ni^{II} ion. Side arm coordination to the Ni^{II} was observed in cyclam derivatives with methylthioethyl groups, whereas no coordination was observed for a methoxyethyl substituent.[1498] The Ni^{II} complex of (**586**) is six-coordinate with the pendent arm donors in the apical positions.[1499] Also, both isomeric forms of bis(pyridylmethyl)cyclam (i.e., the 1,11- and 1,8-isomers) give six-coordinate complexes with the pyridyl groups bound to the metal.[1500]



(585)



(586)



(587)

N-(aminoethyl)cyclam (**587**) was prepared from the reaction between tritosylated cyclam and tosylaziridine. In the Ni^{II} complexes of the ligand, the amine group of the side chain displayed acidity-dependent coordination behavior. At $pH > 2.8$ the side arm apically bound to Ni^{II} ion to form a blue high-spin complex $[Ni(\mathbf{587})]^{2+}$, but at $pH < 2.8$ the amine of the side chain became protonated and formed $[Ni^{II}(\mathbf{587}H)]^{3+}$ as a mixture of a blue high-spin form and a yellow low-spin form.[1501]

In the Ni^{II} complex $[Ni(\mathbf{588})]I_2$ containing the small 12-membered tetraaza macrocycle (**588**) with four pendent pyrazole groups, the ligand wraps around the metal ion in an unusual fashion. It forms a distorted octahedral structure with two pendent arms of the ligand being coordinated, where the four amine nitrogens span two contiguous faces of the distorted octahedron about the nickel atom and the pyrazole nitrogens occupy the remaining pair of *cis* positions.[1502] A similar situation has been observed in the case of tetrakis(2-pyridylmethyl)cyclen, where two of the appended pyridine donors occupy *cis*-positions of the octahedral coordination environment.[1503]

Ni^{II} complexes of ligands containing pyridine in the macrocyclic framework with a single pyrrolidinyl pendent arm (**589a**) and (**589b**) have been prepared.[1504] In $[Ni(\mathbf{589b})(OClO_3)](ClO_4)$, octahedral coordination is set up by four nitrogens of the macrocycle, the pendent pyridine, and a ClO_4^- ion. The macrocyclic ligand occupies the corners of a square pyramid with the pendent group at the apical position.

The pendent-arm macrocycles (**590a**) and (**590b**) have been synthesized by the reaction of $[Ni(DMSO)_n](ClO_4)_2$ and the unsubstituted ligands with aqueous NaOH in EtOH, followed by the addition of 2-chloromethylpyridine or 1-(hydroxymethyl)pyrazole under nitrogen. The resulting Ni^{II} complexes are of six-coordinate with the macrocycle adopting a folded conformation and the two pendent 2-pyridylmethyl arms occupying *cis*-coordination sites.[1505]

The 12-membered macrocyclic triamine bearing a phenol pendent (**591**) was synthesized by one-pot annealation from coumarin and 1,7-diamino-4-azaheptane. Upon coordination to Ni^{II}, the pendent phenol readily dissociates its proton at acidic pH and becomes a strong fourth donor.[1506]

A cyclam derivative with an amine pendent donor attached at the bridgehead carbon atom was presynthesized from diethylaminomalonate and 1,9-diamino-3,7-diazanonane in refluxing MeOH, followed by BH_3–THF reduction.[1507] It acts as a pentadentate ligand at pH 8.5 and forms a six-coordinate complex (**592**) with a water molecule sitting at the remaining axial site.

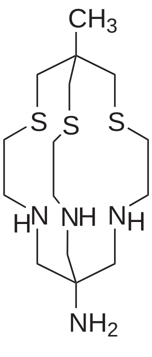
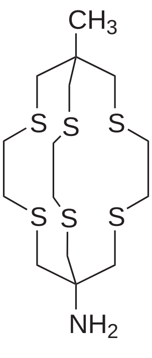
(**595d**)



(**595e**)



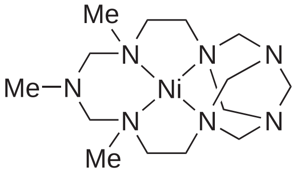
(**595f**)

Enantiomerically pure cyclam-type ligands derived from L-proline have been prepared via multistep procedures and shown to form complexes of Ni^{II}, e.g., (**593**).[1508] The Ni^{II} ion in (**594**) is encapsulated by a face-to-face bis(macrocyclic) ligand that forms upon treatment of $[Ni(tren)_2]^{2+}$ with formaldehyde.[1509]

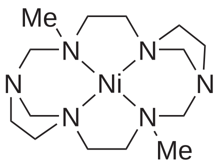
Sexadentate sarcophigine-type ligands (**595**) form particularly stable complexes with Ni^{II}. The Ni^{II} complexes of parent sarcophagine (sar, (**595a**)), $[Ni(sar)](ClO_4)_2$,[1510] as well as the 1,8-diammonio complexes [Ni(**595b**)][157,1511] have been studied in detail. $[Ni(sar)](ClO_4)_2$ has been proposed as a magnetic susceptibilty standard. It follows the Curie–Weiss law above 10 K to room temperature ($2.94\mu_B$), and the value of the axial anisotropy is $D = +1.400\,cm^{-1}$ with $g_{\perp} = 2.143(1)$ and $g_{\psi} = 2.125(1)$.[1510]

The encapsulating ligand with N_4S_2 donors (AMN_4S_2sar, (**595d**)) was prepared, and it coordinates to Ni^{II} to give an octahedral complex.[1512] It has been pointed out that the whole set of Ni^{II} complexes of (**595a–f**) provides a useful series to study the influence of spin-orbit mixing and differential nephelauxetic effects on the electronic spectra, since the N/S ratio can be systematically altered without significantly affecting the macrocyclic backbone structure.[1513] It has been found that the spin-forbidden $^3A_{2g} \rightarrow {}^1E_{1g}$ and $^3A_{2g} \rightarrow {}^1A_{1g}$ transitions undergo a dramatic shift to lower energy as the number of S-donors is increased.

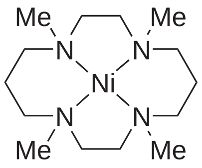
(c) Synthesis via modification of presynthesized Ni^{II} macrocyclic units. The most important modification of presynthesized Ni^{II} macrocyclic complexes is *N*-alkylation, which may also be used to link two or more macrocyclic units by a spacer group. *N*-methylated macrocyclic Ni^{II} complexes are often prepared by the deprotonation of secondary amines already bound to the metal ion with pulverized KOH in Me_2SO or MeCN media, followed by alkylation with CH_3I. For example, bis-*N*-alkylated complexes of (**596**) and (**597**), as well as the tetramethylated Ni^{II} cyclam derivatives (**598**) (Ni^{II}TMC), have been synthesized by this route.[1494,1514] While the bis-*N*-alkylated Ni^{II} complexes (**596**) and (**597**) were stable against ligand dissociation in acidic aqueous solution, other *N*-alkylated complexes may be dealkylated when heated in aqueous solutions.[1494,1514] Selective partial alkylation of cyclam–nickel complexes has also been reported.[1515]



(**596**)

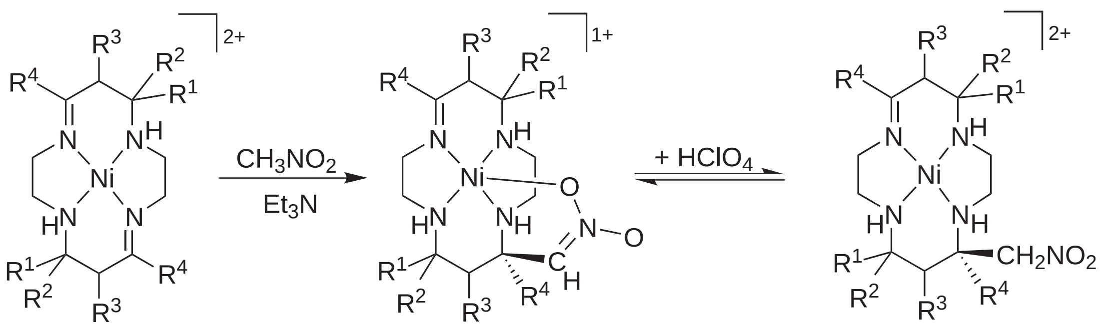


(**597**)



(**598**)

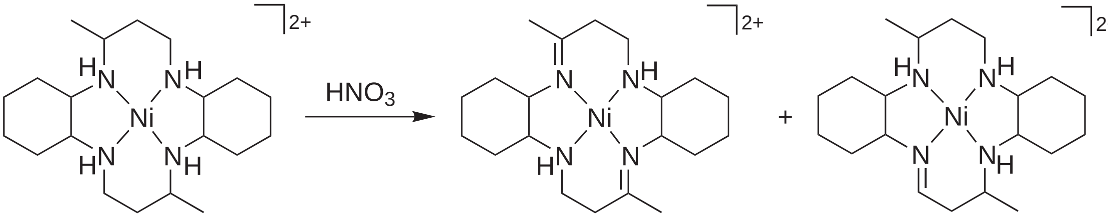
Nickel(II) complexes of type (**599**) unsaturated 14-membered tetrazamacrocycles react with the anion of nitromethane under basic conditions to give the 5-nitromethyl derivatives (**600**), and the square planar diperchlorates (**601**) upon treatment with $HClO_4$ (Equation (19)):[1516]



(**599**) (**600**) (**601**)

(19)

Some Ni^{II} complexes of polyaza macrocyclic ligands containing coordinated secondary amino groups can be chemically oxidized to give complexes with a higher degree of unsaturation in the ligand.[1517,1518] Oxidation of (**602**) with concentrated HNO_3 gives (**603**) or (**604**) selectively, depending on the reaction conditions (Equation (20)). The Ni^{III} species of the saturated ligand is a first intermediate in each case causing subsequent metal ion-assisted oxidative dehydrogenation of the ligand.



(602) **(603)** **(604)**

(20)

Nickel(II) complexes of tetraaza[14]annulenes, in particular of the much-studied 5,7,12,14-tetramethyldibenzo[b,i]-1,4,8,1-teraazacyclotetradecinate (TMTAA, (**605**)), have been modified in various ways. Lithiation of a methyl group followed by the addition of an electrophile gives extension of the methyl substituent,[1519] and selective alkylations in the periphery of 16-membered cyclidene complexes have been reported.[1520] Substitution at the γ,γ' positions has been extensively researched, because the *meso* positions of the ring are known to be highly reactive. Macrocycle modification at these positions usually involves reaction with acid chlorides[1521–1533] or benzylic bromides.[1534] For example, Ni^{II} dibenzotetraaza[14]annulene complexes have been equipped with chiral ester-type substituents bearing menthyl, bornyl, and quininyl groups.[1533]

Reaction of [Ni(TMTAA)] with acid in the presence of $AlCl_3$ gives complex (**606**) that features two isolated diimine units in the six-membered chelate rings (Equation (21)),[1535] while hydrogenation of [Ni(TMTAA)] leads to fully saturated cyclam macrocycles (**607**) (Equation (22)):[1536]

(607)

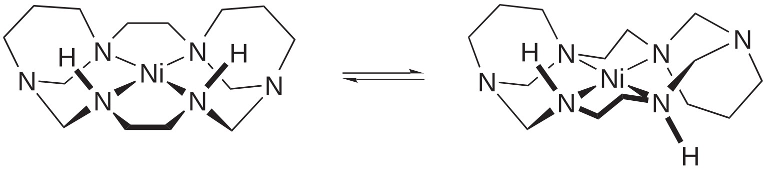
(22)

(ii) Structures and spectroscopic properties

The Ni—N bond distances, N—N bite distances, and N—M—N bite angles of Ni^{II} macrocyclic complexes depend on the coordination number of the metal ion and the type of macrocycle. These structural parameters also influence the electronic spectra and the electrochemical data.[91] In general, Ni—N bond distances of square planar complexes are shorter than those of the octahedral complexes due the absence of electrons in the $d_{x^2-y^2}$ orbital. Furthermore, as the Ni—N bond distance increases, the value of λ_{max} for the square planar Ni^{II} complex shifts to the longer wavelength. In addition, $Ni^{II} \rightarrow Ni^{I}$ electrochemical reduction of the complexes becomes easier and $Ni^{II} \rightarrow Ni^{III}$ electrochemical oxidation becomes more difficult as the Ni—N bond distances increase.

Square planar Ni^{II} complexes with saturated macrocyclic ligands usually have Ni—N bond distances ranging from 1.90 Å to 1.95 Å, depending on the type of ligand. The Ni—N bond distances increase when square planar Ni^{II} complexes bind axial ligands to form octahedral species.[91]

A 14-membered tetraaza macrocyclic complex may exist in one of five possible configurations I–V based on the stereochemistry of the donor nitrogens.[1537,1538] Most of the known square planar complexes of azamacrocyclic ligand have the *R*,*R*,*S*,*S* configuration, which is thermodynamically the most stable. In this form, the H atoms at the N atoms of each six-membered chelate rings are on the same side of the macrocycle plane, but on the opposite side with respect to the H atoms of the other six-membered ring. In the case of the *R*,*S*,*R*,*S* complex, the asymmetric *gauche* conformation in the five-membered chelate rings exerts significant strain on the ligand structure and leads to isomerization to the more stable *R*,*R*,*S*,*S* configuration. For example, in H_2O/MeCN media, (*R*,*S*,*R*,*S*)-[Ni(**576**)]$^{2+}$ isomerizes to (*R*,*R*,*S*,*S*)-[Ni(**576**)]$^{2+}$ via axial coordination of water followed by Ni—N(*t*) bond cleavage assisted by water acting as a general acid.[1570] The first-order rate constant is $k_{obs} = 4.16 \times 10^{-5}\,s^{-1}$ and is independent of pH and buffer concentration, but increases with increasing water contents. The activation parameters are $\Delta H^{\dagger} = 33 \pm 1\,kcal\,mol^{-1}$ and $\Delta S^{\dagger} = 24\,cal\,K^{-1}\,mol^{-1}$ at 25 °C. Reverse isomerization from the *R*,*R*,*S*,*S* to the *R*,*S*,*R*,*S* configuration is also possible. In this process, a strongly coordinating solvent[1539] or pendent donor group induces the configurational change of the macrocycle.[1507]



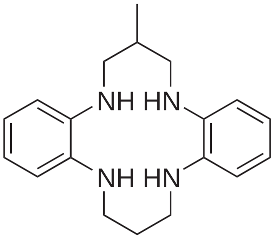
(*R*,*S*,*R*,*S*)-(**576**) (*R*,*R*,*S*,*S*)-(**576**)

A detailed structural analysis of all Ni complexes of 14-membered tetraazamacrocycles listed in the CSD was performed in 1998, and all compounds were grouped according to their macrocycle configuration by means of cluster analysis.[1540] Nickel(II) low-spin complexes have Ni—N distances of less than 2.02 Å, while high-spin complexes have distances of greater than 2.05 Å. The most stable configuration of the ligand is the *R*,*R*,*S*,*S*,-(*trans*-III) configuration, but the *trans*-I configuration becomes more stable relative to the *trans*-III configuration in going from octahedral to square planar Ni^{II} complexes.[1541] However, the addition and specific location of substituents on the macrocyclic backbone can change the identity of the lowest energy configuration. For example, for *C*-*rac* Ni^{II} complexes of 5,5,7,12,12,14-hexamethyl-cyclam all octahedral species were found in the *cis*-V configuration, while for the *C*-*meso* form the *trans*-III configuration was lower in energy.[1540] Unexpected *cis*-II and *cis*-V arrangements were found for the Ni^{II} complex of cyclam bearing two methyl substituents and one coordinating 2-ethane sulfonic acid group at the N atoms.[1542]

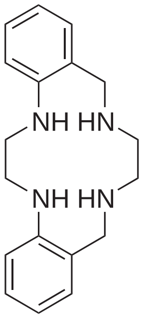
In the case of the smaller macrocycle [13]aneN_4, six configurational isomers exist for [Ni([13]aneN_4)]$^{2+}$ due to the orientation of the N—H protons above or below the plane of the macrocycle. X-ray crystallography and NMR spectroscopy, respectively, revealed that the *R*,*S*,*R*,*S*-[Ni([13]aneN_4)]$^{2+}$ form (*trans*-II) is the preferred one both in aqueous solution and in the solid state.[1543]

Fourteen-membered ring ligands of the cyclam type have "natural" hole sizes which lie between the ideal ones for low- and high-spin Ni^{II}. Hence these ligands can accommodate either type of Ni^{II} ion, depending on whether coordinating or noncoordinating anions are present. Benzoannelation may drastically alter the flexibility of the macrocyclic ligand scaffold, and comparative studies of the Ni^{II} complexation by, *inter alia*, (**608**)–(**610**), displaying different patterns of dibenzo substitution have been performed.[140,1544] The complex [Ni(**608**)](BF_4)$_2$ has a planar coordination geometry, while [Ni(**608**)(NCS)$_2$] has a *trans*-pseudo-octahedral geometry with the

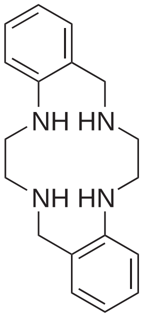
Ni^{II} in axial sites. For the six-coordinate high-spin complex there is a considerable expansion of the N_4 donor cavity to accommodate the larger metal ion.[140] The related (**610**) gives a folded ligand conformation in $[Ni(\mathbf{610})(H_2O)_2]^{2+}$ with the water ligands in *cis* positions.[1544] A folded macrocycle ligand for the parent $[Ni(cyclam)]^{2+}$ fragment is observed in, for example, *cis*-$[Ni(cyclam)(H_2O)_2]Cl_2$[1537] and $(\mu\text{-}C_2O_4)[Ni(cyclam)]_2(NO_3)_2$.[1545] The Ni^{II} complex of a cyclam derivative carrying eight methyl groups and a single hydroxyethyl side arm adopts an unusual distorted trigonal bipyramidal coordination geometry with the O atom of the donor arm in an equatorial position.[1546] Tetrakis(diphenylphosphinomethyl)cyclam forms a five-coordinate high-spin complex $[NiLCl]^{2+}$ with a Cl ligand in apical position and all phosphino side arms dangling.[1547] The Ni^{II} complexes of *cis*- and *trans*-6,13-dimethyl-1,4,8,11-tetraazacyclotetradecane-6,13-diamine (*cis*- and *trans*-diammac, (**611**) and (**612**)) as well as the Ni^{II} complex (**613**) of a-6,13-bis(2-pyridinyl)-1,4,8,11-tetraazacyclotetradecane (a-pypymac) feature hexacoordinate metal ions in with the macrocyclic ligands coordinating as a sexidentate.[1548–1550]



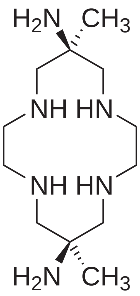
(**608**)



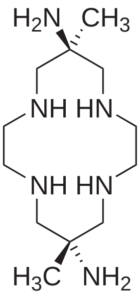
(**609**)



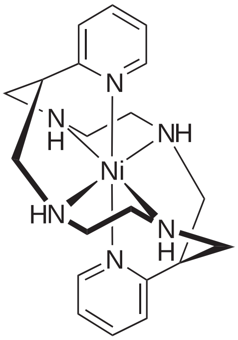
(**610**)



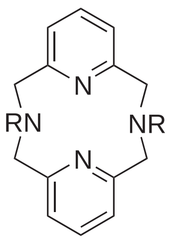
(**611**)



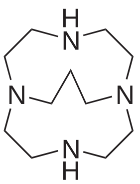
(**612**)



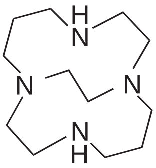
(**613**)



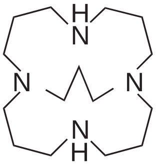
(**614**)



(**615**)



(**616**)

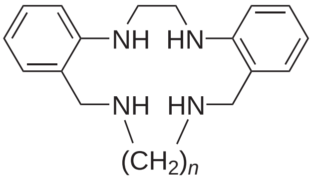


(**617**)

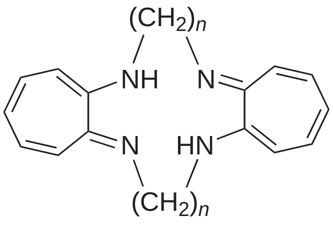
While *cis*-octahedral Ni^{II} complexes of cyclam are known to spontaneously isomerize in aqueous solution to the *trans*-octahedral isomer,[1551] such spontaneous isomerization does not occur for the Ni^{II} complex of $[12]aneN_4$ because the hole in the smaller 12-membered ring does not allow for four unconstrained Ni—N coplanar bonds. However, accommodation of square planar nickel ions may be enforced in the flexible [12]aneN_4 type scaffold.[1552] In contrast, increased rigidity is introduced by the pyridine rings in the related 2,11-diaza[3,3](2,6)pyridinophane ligands (**614**). These have a decisive tendency to form distorted *cis*-octahedral geometries in their Ni^{II} complexes, which is confirmed by the crystal structure of [Ni(**614**)(H_2O)Cl]Cl.[1553] The macrocyclic ligand adopts a *syn* boat–boat conformation in the latter complex. The same effect is obtained if two nonadjacent N atoms in the [12]aneN_4 macrocyclic skeleton are connected by an alkylene chain to give, for example, the structurally reinforced bowl tetraamines [2^43^1]adamanzane (**615**) or [2^33^2]adamanzane (**616**). In their Ni^{II} complexes, the ligand coordinates the metal in a cleft and two *cis* coordination sites of the distorted octahedral environment are available for coligand binding.[1554,1555] Ni^{II} complexes of the larger [3^5]adamanzane (**617**) are predominantly five-coordinate, with the half life for dissociation of $[Ni(\mathbf{617})Cl]^+$ amounting to 14–15 months in 5 M HCl solution.[1556]

The large 16-membered tetraazamacrocycle [16]aneN_4 adopts the lowest energy form in the complex $[Ni([16]aneN_4)]^{2+}$ with all four six-membered chelate rings in chair conformations and the N-bound H atoms alternating above and below the coordination plane.[1557] The analogous Ni^{II} complex of [15]aneN_4 exhibits a strong tendency to transform to an octahedral species with ClO_4^- anions bound to the axial sites. In this complex, the three six-membered chelate rings adopt chair/twist/chair conformations.[1557]

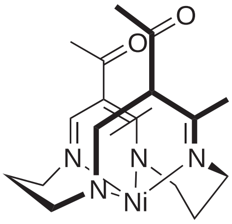
A comparative study of the effect of macrocyclic and chelate ring size on the structures of Ni^{II} complexes with dibenzo tetrazamacrocycles (**618**) incorporating 14- to 17-membered rings has been performed.[1558] All complexes [Ni(**618**)X_2] (X = Cl, NCS, NO_3) have *trans*-octahedral geometries with the macrocycle blocking the equatorial plane. While the planarity of the N_4 donor set is maintained, the distortion to a trapezoidal arrangement of the donors increases as the length of the methylene bridge between the benzyl N atoms is increased. In the case of Ni^{II} complexes of the tropocoronands (**619**) it has been reported that increasing the length of both alkyl linkages induces a gradual distortion of the coordination geometry from square planar to near tetrahedral.[1559]



(**618**)



(**619**)



(**620**)

The solid-state structures of the Jäger-type macrocycles vary widely with ring size.[1560] Ni^{II} complexes of the 14-membered rings are planar, the 15-membered rings adopt one of two possible geometries (either "saddle shaped" or Z-configuration), while the 16-membered rings are in general saddle shaped (e.g., (**620**), due to the conformations adopted by the two saturated six-membered chelate rings), with few exceptions.[1561] The low-energy absorption (~500–600 nm) of Ni^{II} dibenzotetraaza[14]annulene complexes, which has been assigned to a LMCT transition,[1562] depends on the degree of saddle-shaped distortion and exhibits a bathochromic shift upon substitution of the macrocycle.[1563] While the Ni–ligand interaction is dominated by σ-bonding, this shift has been assigned to Ni–ligand π-contributions.[1564,1565]

The UV–visible spectrophotometric properties of Ni^{II} macrocyclic complexes are affected by the substituents, the degree of unsaturation, the cavity size, and the chelate ring sequences of the macrocyclic ring (Table 8).[1473,1566] In addition, the presence of tertiary amine donors and the size of the subring moieties fused to the macrocyclic framework may alter such properties. In general, introduction of tertiary amine donors in the Ni^{II} macrocyclic complexes results in a decrease in the ligand field strength, thus causing the maximum absorption to shift to longer wavelengths. For the macrotricyclic complexes with fused subring moieties such as (**573**)–(**576**), the ligand field strength is shown to decrease as the size of the subring increases.[91]

Square planar Ni^{II} macrocyclic complexes are typically yellow, red, or brown in color and absorb around 400–500 nm, depending on the ligand structure. The octahedral Ni^{II} complexes absorb at 500–600 nm.

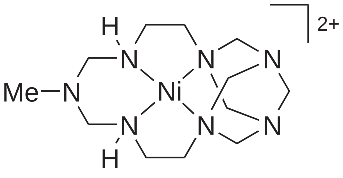
[Ni(Pr$_2$Me$_2$[14]aneN$_4$)]$^{2+}$	531(216)			1490

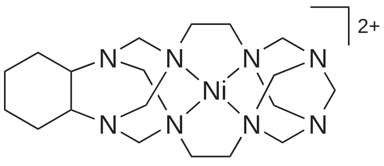
[a] Measured in acetonitrile solutions, 0.1 M (Bu^n)$_4$NClO$_4$, volts vs. SCE. [b] i = irreversible; qr = quasi-reversible. [c] Measured in MeNO$_2$. [d] Measured in H$_2$O. [e] Measured in MeCN. [f] Measured in Me$_2$SO. [g] Abbreviations: Me$_6$[14]aneN$_4$ = 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane; Me$_2$[13]aneN$_4$ = 8,10-dimethyl-1,4,7,11-tetraazacyclotridecane. [h] vs. Ag/AgCl. [i] vs. Ag/Ag$^+$. [j] Present in two forms, square planar (512 nm) and square pyramidal (394 nm and 650 nm).

The presence of two extra uncoordinated tertiary nitrogens at the bridgehead position of type (**568**)–(**570**) complexes does not affect the ligand field strength of the complexes, and variation of alkyl groups and the types of the pendent functional groups at the bridgehead nitrogen atoms only slightly affects the spectra of the complexes.[1464,1468,1473,1476]

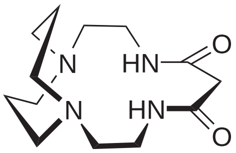
In contrast, subrings fused to the macrocyclic framework may have a significant influence on the spectral properties. For example, Ni^{II} complexes (**621**) and (**622**) absorb at significantly shorter wavelengths than the complexes of the usual 14-membered tetraaza macrocycles and exhibit unusually strong ligand field strength, which has been attributed to the short N—N bite distances of the six-membered chelate ring involving the tetraazabicyclononane ("football") moieties.[1464,1478] These N—N bite distances are similar to the values typical for five-membered chelate ring, and the macrocycles in (**621**) and (**622**) are thus rather similar to a [13]aneN_4 and a [12]aneN_4, respectively.



(**621**)



(**622**)



(**623**)

For the macrotricyclic complexes (**573**)–(**576**), which retain the same 14-membered macrocyclic framework, the size of the subring moieties slightly affects the spectroscopic properties of the complexes.[1465,1467] There is a qualitative relationship between Ni—N bond distances and λ_{max} values. As the Ni—N bond distance increases, the λ_{max} value increases.[91]

The constraints imposed by the additional trimethylene strap in the macrocyclic diamide complex of (**623**) causes the Ni^{II} ion to be pushed out of the N_4 plane and results in a lower ligand field strength than in the Ni^{II} complex of the corresponding monocyclic dioxocyclam ligand.[1571]

The introduction of *N*-alkyl substituents to the secondary N atoms of cyclam and its derivatives, e.g., to the secondary N atoms of (**573**) and (**621**), results in the shift of λ_{max} values to 10–20 nm longer wavelengths, indicating a decrease in the ligand field strength upon *N*-alkylation.[1514,1567,1573–1575] This is attributed to the steric effect of the *N*-alkyl groups and the longer Ni—N bond distances of the complexes. In the cases of partly *N*-alkylated tetraazamacrocycles, the effect is much less significant than in fully alkylated species. Effects of *C*-alkyl groups are comparatively weak or negligible, but properties of macrocyclic compounds containing both *N*- and *C*-alkyl groups may be effected significantly by the *C*-substituents.[1576–1578] For example, the wavelengths for the *d–d* transitions for complexes of (**625a,b**) are very longer than those of related di-*N*-alkylated 14-membered tetraazamacrocycles due to the very long Ni—N distances (1.992 Å).

The spectrum of the octahedral Ni^{II} complex (**580**) with a hexaaza macrobicyclic ligand is similar to that of $[Ni(en)_3]^{2+}$, but the ligand field strength of the complex is increased slightly by the capping of the $[Ni(en)_3]^{2+}$ moiety with two tris(methylene)amino groups.[1461]

The absorption maximum λ_{max} and the extinction coefficient of macrocyclic Ni^{II} complexes are affected by the configuration of the ligand.[1570,1579] For example, the maximum absorption band of (*R*,*S*,*R*,*S*)-[Ni(**567**)]$^{2+}$ appears at ~20 nm longer wavelengths than that of the *R*,*R*,*S*,*S* isomer. In addition, the value of the extinction coefficient in the visible region for the *R*,*S*,*R*,*S* complex is greater than that for the *R*,*R*,*S*,*S* isomer. Similar observations have also been made with other macrocyclic complexes[1579,1580] and have been attributed to steric strain in the case of the *R*,*S*,*R*,*S* complex, which is evident from the fact that the metal ion locates out of the coordination plane and the five-membered chelate rings display an asymmetric *gauche* conformation. The result is a poor overlap between the Ni^{II} ion and the nitrogen orbitals, and hence a weaker ligand field strength.

(iii) Electrochemical properties[91]

Electrochemical properties of the Ni^{II} macrocyclic complexes are related to the cavity size, the unsaturation, the degree of functionalization, and the subring moieties fused to the macrocycles.[1467,1514,1581,1582]

For Ni^{II} complexes of monocyclic ligands (e.g., (**568**)), oxidation to Ni^{III} usually occurs at +0.90 V to +0.93 V and reduction to Ni^{I} at −1.46 to −1.55 V vs. SCE. However, in the macropolycyclic ligand complexes (**573**)–(**576**) as well as (**621**) and (**622**), the oxidation and reduction processes are observed at +1.25 V to +1.60 V and at −0.94 V to −1.40 V vs. SCE, respectively. Electrochemical oxidation of the Ni^{II} species is obviously easier for the complexes of monocyclic ligands, whereas electrochemical reduction to Ni^{I} is easier for the macropolycyclic complexes. These anodic shifts in both oxidation and reduction potentials for Ni^{II} macropolycyclic complexes may in part be attributed to the tertiary nitrogen donors of the ligands.

The redox properties of complexes with hexaaza monocyclic ligands (e.g., (**568**)–(**570**)) are similar to those of the cyclam complex, indicating that the electrochemical properties of the complexes are only slightly affected by the presence of uncoordinated tertiary nitrogen atoms, length of the pendent chain, and the type of the functional group appended at the bridgehead nitrogen.[1476,1567] However, the redox potentials of the Ni^{II} complexes of type (**570**) derivatives containing carboxamide or sulfonamide functional groups are reported to be influenced by the nature of the functional group. In particular, the amide fragment controls the reduction potential for the Ni^{III}/Ni^{II} and Ni^{II}/Ni^{I} redox couples, which may be attributed to the π interaction between the nickel ion and the amido group.[1583]

Attachment of pendent noncoordinating donor groups at the cyclam N atoms may affect significantly the electronic spectra and redox properties of the Ni^{II} complexes. For example, the presence of the *N*-quinolinemethyl groups in (**624b**) makes the oxidation of Ni^{II} to Ni^{III} easier and reduction to Ni^{I} more difficult compared to (**624a**), which has been attributed to the steric crowding caused by the noncoordinationg substituents.[1572] In (**626**) and (**627**), crown ethers 15-crown-5 and 18-crown-6, respectively, have been attached to the type (**621**) Ni^{II} macrocyclic complex. The reduction potentials in the presence of alkali ions shift to the positive direction in the order $Li^+ > Na^+ > K^+$ and $K^+ > Na^+ > Li^+$, respectively,[1584] in accordance with the expected affinity of the alkali ions for the crown ether moieties. Ni^{II} complexation in a macrocycle host may also effect the redox properties of pendent groups: the Ni^{II} complex of the ferrocene-bridged cyclam derivative (**628**) features a rather short Fe—Ni distance (3.85 Å), and the redox potential of the Fe^{II}/Fe^{III} couple is shifted by +380 mV with respect to the Ni-devoid system.[1585]

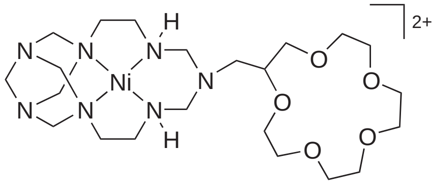
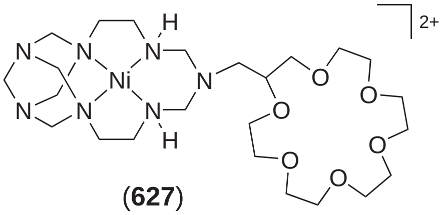
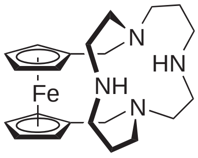
(625b) R = CH$_2$CH$_2$CH$_3$



(626)



(627)



(628)

In general, the introduction of *N*-alkyl substituents to the secondary amine donors of the macrocycle results in anodic shifts in both oxidation and reduction potentials of the complexes relative to the parent ligand systems, i.e., *N*-alkylation makes the attainment of the Ni^{I} state easier and the Ni^{III} state more difficult. The extent of anodic shifts depends on the number of alkyl groups introduced to the ligand.[1514,1567] Such stabilization of Ni^{I} species by *N*-alkylation is ascribed to solvation and stereochemical effects.[1575,1586] *N*-ethyl groups have greater inductive effects than *N*-methyl groups and yield less anodic shift in both oxidation and reduction potentials.[1514] This anodic shift of redox potentials may be attributed to weaker Ni—N interactions in the *N*-alkylated complexes, because the weaker Ni—N interaction for the tertiary amine results in the stabilization of antibonding σ-orbitals of the Ni^{II} complex, thus making it more favorable to add an electron, but less favorable to remove an electron.[91]

The configuration of the macrocyclic ligand also affects the electrochemical properties of Ni^{II} complexes.[1570,1574] For example, the oxidation and reduction potentials of (*R*,*S*,*R*,*S*)-[Ni(**576**)]$^{2+}$ are shifted by +0.14 V and +0.13 V, respectively, compared with those of the *R*,*R*,*S*,*S* isomer. Similar trends are also observed for a series of *R*,*S*,*R*,*S* and *R*,*R*,*S*,*S* isomers of *N*-methylated cyclam derivatives.[1587,1588] These anodic shifts of the redox potentials for the *R*,*S*,*R*,*S*-Ni^{II} complexes indicate that the complex is more difficult to oxidize to Ni^{III} but easier to reduce to Ni^{I}, compared with the *R*,*R*,*S*,*S* complex. The effect may be related to the reduced ligand field strength of the *R*,*S*,*R*,*S* complex, which stabilizes the antibonding σ-orbitals and thus makes addition of an electron more favorable while removal of an electron is less favorable.

The redox behavior of Ni^{II} tetraazaannulene complexes can be tuned by the appropriate choice of substituents bound to the ligand scaffold.[1589] It is interesting to note that in a series of Jäger-type Ni^{II} complexes, both the type (**629**) and type (**630**) systems give reversible oxidation, while (**631**) does not.[1590]

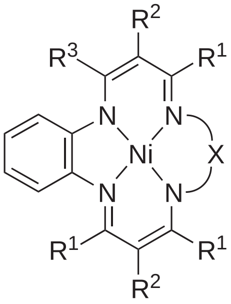
(630)



(631)

(iv) Equilibrium between square planar and octahedral species[91]

It is well established that some macrocyclic Ni^{II} complexes may exist as equilibrium mixtures of the yellow, diamagnetic, square planar $[Ni(L)]^{2+}$ and blue (or violet), paramagnetic, octahedral $[Ni(L)(S)_2]^{2+}$ species in coordinating solvents (S) such as water, acetonitrile, or Me_2SO.[1464,1467,1469,1473,1476,1583,1591,1592] Interconversion between these two forms depends on the ligand structure and reflects a balance between endothermic solvent coordination and exothermic Ni—N bond lengthening in octahedral species.[91] In water, the equilibrium constant K of Equation (23) is reduced when either the concentration of supporting electrolyte (e.g., $NaClO_4$) or the temperature is increased. Existence of the equilibrium is indicated by the absorption coefficients at λ_{max} measured in water for $[Ni(L)]^{2+}$, which are smaller than those measured in a noncoordinating solvent such as nitromethane or acetone.

$$[Ni(L)]^{2+} + 2H_2O \overset{K}{\rightleftharpoons} [Ni(L)(H_2O)_2]^{2+} \qquad (23)$$

The Ni^{II} cyclam complex, as well as Ni^{II} complexes such as (**568**) and (**570**) featuring hexaaza and pentaaza macrocyclic ligands display a low-spin square planar and high-spin octahedral complex interconversion in aqueous solution.[1464,1469,1473,1583] However, complexes (**568**) and (**569**) favor formation of the high-spin form upon addition of acid, which is in contrast to the cyclam complex. The protonation of tertiary nitrogen atoms at the bridgehead position facilitates the axial coordination of anion or water because of hydrogen bonding between them.[1469,1593]

$[Ni(cyclam)]^{2+}$ gives smaller coordination equilibrium constants than the open chain analogue, $[Ni(2,3,2\text{-tet})]^{2+}$. A comparative study of donor solvent coordination to Ni^{II} complexes of 2,3,2-tet, cyclam, the smaller $[12]aneN_4$, and $[14]aneS_4$ has been performed.[1594]

Thermodynamic data of Equation (23) for selected Ni^{II} macrocyclic complexes are summarized in Table 9. The exothermic nature of the processes reflects the increase in coordination number and the formation of two axial bonds, while the negative ΔS° reflects the increase in order due to the binding of two water molecules. The more flexible the macrocyclic ligands the larger the K values, since the octahedral species have longer Ni—N bond distances than the square planar species and thus require the ligand scaffold to adapt to this situation. For example, the formation constants of octahedral species for $[\mathbf{575}]^{2+}$ and $[\mathbf{576}]^{2+}$ are ca. 10 times greater than those for $[\mathbf{573}]^{2+}$ and $[\mathbf{574}]^{2+}$ at room temperature, and they are comparable to those of the complexes of the more flexible monocyclic ligands $Me_2[14]aneN_6$ and $Et_2[14]aneN_6$.[1467] The complexes (**575**) and (**576**), which have larger macrocyclic holes than (**573**) and (**574**), are obviously better suited to accommodate the larger octahedral Ni^{II} ions.

Both the $-\Delta H^\circ$ and $-\Delta S^\circ$ values are quite large for the Ni^{II} complex (**633**) bearing a pendent hydroxyethyl arm.[1595] If this complex is treated with a bidentate ligand that binds exclusively in a *cis* fashion, coordination forces the macrocycle to fold out of the plane to give a so-called *cis* folded product. Thermodynamic data for the binding of ethylenediamine to give (**635**)

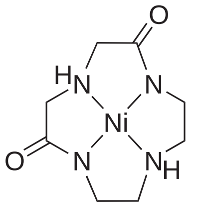
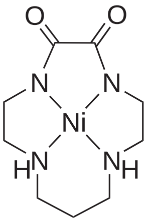
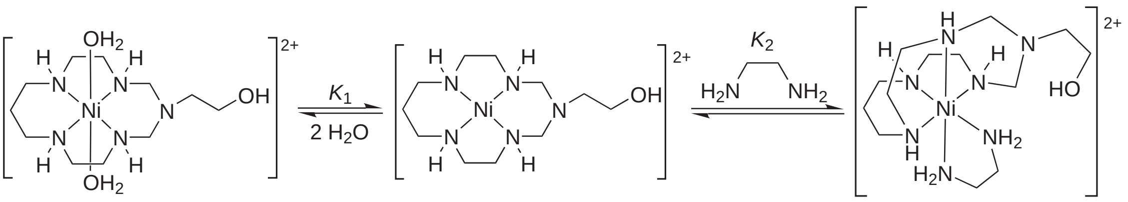
are: $K(25\,°C) = 4.17 \times 10^2\,l\,mol^{-1}$ ($\log K = 2.62$), $\Delta H^\circ = -38.5 \pm$ kJ mol^{-1}, and $\Delta S^\circ = -79 \pm 5$ J K^{-1} mol^{-1}. The presence of the pendent 2-hydroxyethyl arm apparently does not have a significant influence, since a similar value log $K = 2.56$ has been reported for the corresponding equilibrium involving the planar form of $[Ni(cyclam)]^{2+}$.[1598]



(632a)



(632b)



(633) **(634)** **(635)**

On the basis of spectral data it has been concluded that for macrocycles that do not coordinate Ni^{II} in a planar fashion, steric factors influence the ligand field strength more than the size of the macrocycle.[1599,1600] Ni^{II} complexes of the small $[12]aneN_4$ type ligands, which usually adopt *cis*-octahedral geometries when six-coordinate, show an equilibrium between the five-coordinate $[Ni(R_4[12]aneN_4)(H_2O)]^{2+}$ and the almost planar $[Ni(R_4[12]aneN_4)]^{2+}$ complex in solution (Equation 24; Table 10). The equilibrium is dominated by the solvation properties of the R groups, i.e., the larger (and less polar) the R groups, the larger the *K*, ΔS and ΔH values for the dissociation equilibrium.

Ni^{II} complexes of reinforced macrocyclic ligands such as (**636a**–**c**) are square planar and show no tendency to axially coordinate a solvent molecule (or a N_3^- ion), because the rigid ligand cannot adapt to the larger high-spin Ni^{II} ion.[1604]

trans II
(*R*,*R*,*S*,*S*)-[(**568**)]Cl]$^{2+}$

Azamacrocyclic complexes with pendent donor side arms may show an internal pH-dependent equilibrium between the uncoordinated and chelated forms of the substituent. When a pendent amine group is protonated, the diamagnetic, square planar Ni^{II} complexes are formed. At higher pH values, however, deprotonation and coordination of the amine group leads to paramagnetic, octahedral complexes. This change in Ni configuration is often accompanied by change of the macrocycle conformation. For example, in the octahedral cyclam diammine complex (**637**) the macrocycle adopts a folded conformation, while protonation of the amino groups gives a planar macrocycle in the square planar complex (**638**).[1605] Such protonation equilibria also give rise to a pH-dependent electrochemical behavior of the Ni^{II} complexes with pendent amino groups,[1606–1609] and the change in color associated with this process has been proposed as a probe in analytical applications. Even in cases where the pendent amine arms of tetraazamacrocycles are not involved in direct coordination, their deprotonation may increase the concentration of the octahedral species $[NiL(H_2O)_2]^{2+}$ in solution.[1610]

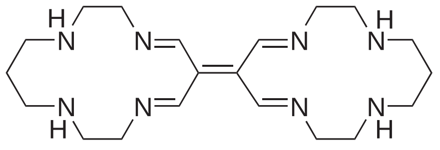
The high-spin/low-spin interconverison in a Ni^{II} complex of the cyclam derivative (**639**) bearing a luminescent naphthalene substituent has been used as a fluorescent molecular thermometer.[1611] The Ni^{II} tends to quench fluorescence of the proximate naphthalene subunit, but the two spin states exert a different influence on the emission properties. Emission is temperature dependent, since the high spin → low spin conversion is endothermic, i.e., a temperature increase favors formation of the low-spin form.

(v) Reactions and applications

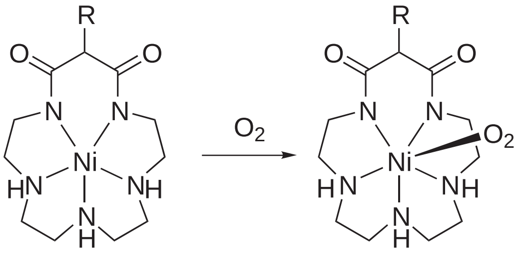
Nickel(II) complexes of common polyazamacrocyclic ligands are usually quite inert and rarely undergo metal exchange reactions. For the Ni^{II} complex (**568**), it was found that Au^{III} can substitute the Ni^{II}, while other metals cannot.[1612] The transmetallation rate is inhibited by acid and chloride: whereas four- and six-coordinate species $(\mathbf{568})^{2+}$ and $(\mathbf{568})Cl_2$ are able to react with $AuCl_4^-$, five-coordinate $(\mathbf{568})Cl^+$ does not react. This has been suggested to result from the presence of different configurations, i.e., the *R*,*R*,*S*,*S*-structure for $(\mathbf{568})^{2+}$ and the *R*,*S*,*R*,*S*-form for $(\mathbf{568})Cl^+$, where access of the $AuCl_4^-$ to the N atoms may be difficult in the latter case.[1612]

In the following, some selected classes of reactions and applications of Ni^{II} polyazamacrocyclic complexes are discussed. Other applications include, *inter alia*, the electrochemical reduction of allyl ethers[1613] and the epoxidation of alkenes.[1614]

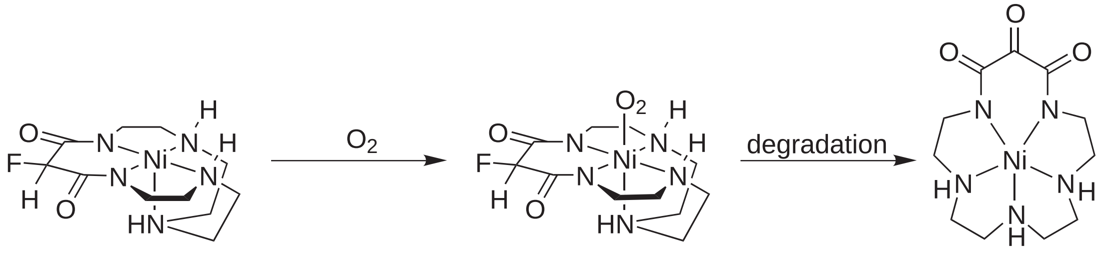
(a) Oxidation with H_2O_2 and O_2. Oxidation of $[Ni(cyclam)]^{2+}$ with hydrogen peroxide in acidic perchlorate media results in the formation of a dimeric bismacrocyclic complex $[Ni_2(\mathbf{640})][(ClO_4)_4$. This features two Ni^{II} ions in square planar geometry and full planarity across the carbon bridging framework.[1615]



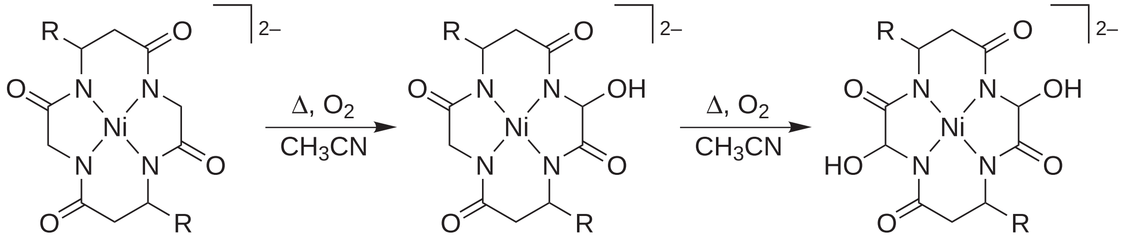
(**640**)



(**641**) (**641**)-O_2



(**642**)

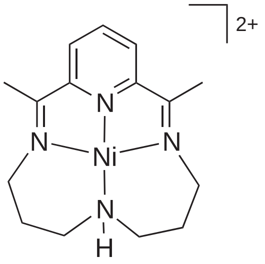


(**643**) (**644**) (**645**)

Although most of the square planar Ni^{II} macrocyclic complexes are not air sensitive, some Ni^{II} macrocyclic complexes, especially those with negatively charged ligands, are air sensitive and react with molecular oxygen. For example, the square pyramidal high-spin Ni^{II} complex (**641**) that contains a pentaaza macrocycle acting as a diamide ligand is air sensitive and shows a very low Ni^{II}/Ni^{III} oxidation potential of +0.24 V vs. SCE.[1616,1617] At room temperature in aqueous solution, it forms a 1:1 dioxygen adduct (**641**)–O_2, which is formulated as Ni^{III}–O_2^- based on the EPR spectral data. The magnetic moment of the O_2 adduct is $2.83\mu_B$, which is interpreted in terms of weak magnetic coupling of Ni^{III} with the superoxide. The O_2 uptake reaction is first order with respect to both $[O_2]$ and (**641**) in aqueous solutions, and a second-order rate constant of $1.7 \times 10^2\,M^{-1}\,s^{-1}$ at 35 °C has been determined. The O_2 complexation constant K is $1.9 \times 10^4\,M^{-1}$ at 35 °C.[1617] The dioxygen adducts react with added substrates such as benzene, toluene, and anisole to produce hydroxylated products of organic substrates, except with nitrobenzene, which suggests that the activated O_2 species has an electrophilic character.[1617] However, in the absence of substrates the O_2 complexes also undergo facile irreversible degradation in aqueous solutions and result in the hydroxylated derivatives of the corresponding ligands being formed in good yield.[1616,1618]

Some nickel complexes of type (**641**) are capable of mediating O_2-dependent DNA cleavage.[1619] In the case of R = F, reaction with O_2 leads to ligand oxidation to give (**642**).[155,1620] α-Hydroxylation of glycin in peptides is a biologically important reaction performed by the copper-containing enzyme peptidylglycin α-amidating monoxygenase (PAM). Selective α-hydroxylation was observed for the Ni^{II} complexes of cyclic tetrapeptides (**643**), giving (**644**) and (**645**) in a stepwise process.[1621] $^{18}O_2$ labeling confirms that the hydroxo O atom comes from aerial dioxygen. The reaction presumably proceeds via formation of a Ni^{III} superoxide, H atom abstraction and a glycyl radical intermediate.

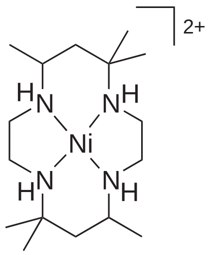
(b) DNA modification. Various Ni^{II} complexes promote oxidative modification of DNA in the presence of oxidants and effect strand scission subsequent to alkaline treatment. In particular, complexes with neutral tetraazamacrocyclic cyclam and cyclam-like ligands are known to enhance the reactivity of Ni^{II} in promoting DNA oxidation using $KHSO_5$.[1622–1624] Reaction occurs specifically at solvent-exposed guanines. These reactions depend strongly on the nature of the metal complex, and several features have been found to be essential for efficient DNA oxidation: (i) square planar rather than octahedral coordination, (ii) positively charged complexes with neutral rather than anionic ligands, and (iii) relatively high $E_{1/2}$ values for Ni^{II}/Ni^{III} oxidation. The 14-membered macrocycles with pyridine or imine N-donors are more efficient complexes for such a reaction. A high degree of unsaturation in the ring leads to conformational rigidity, which may be detrimental to the formation of key intermediates bound to DNA. Accordingly the complex (**646**) was found to be a very effective catalyst for the DNA oxidation. A mechanism in which the square planar Ni^{II} complex is oxidized to a square pyramidal or octahedral Ni^{III} complex possessing labile axial sites to bind to N7 of guanine has been proposed.[1625,1626] Evidence for such recognition has been obtained by a diagnostic ability of some Ni^{II} macrocyclic complexes to convert poly(dG-dC) from a B- to a Z-helix.[1627] Further, ^1H NMR monitoring of the interaction between the complexes and 5′-GMP is characteristic of coordination of guanine-N7 to the Ni ion, and ^1H and ^{31}P NMR spectra of DNA containing a single, isolated extrahelical guanine are consistent with selective binding of Ni to N7 of this unique base.[1628] Despite this mode of binding, however, the specificity of guanine oxidation reflects native DNA conformations that are independent of Ni.[1627] It should be noted that Ni^{II} macrocyclic complexes have also been reported to cleave RNA at specific uridine residues.[1629]



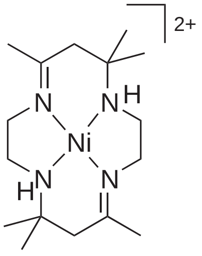
(**646**)

(c) Electrocatalytic reduction of CO_2. A number of Ni^{II} complexes show catalytic activity for the electrocatalytic reduction of CO_2 in water, which has been proposed to involve intermediate formation of Ni^I species. A pulse radiolysis study of the CO_2 reduction by $[Ni^I(cyclam)]^+$ in aqueous solution revealed that it proceeds via the reduction of $[Ni^I(cyclam)(CO_2)]^+$ or $[Ni^I(cyclam)H]^+$ adducts by $[Ni^I(cyclam)]^+$.[1630] CO and formate are usually produced by this way. The selectivity of the process is highly important in order to obtain a useful electrocatalyst in

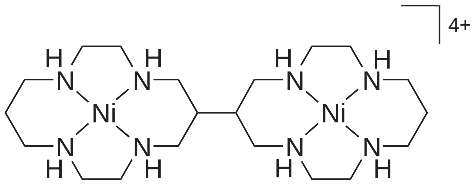
the electroreduction of CO_2: since many electrochemical systems available for reducing CO_2 require the presence of water, the reduction of molecular hydrogen is always a competing reaction that needs to be avoided. The Ni^{II} complexes of 14-membered tetraaza macrocyclic ligands, $[Ni(cyclam)]^{2+}$, (**647**)–(**649**) show catalytic activity in H_2O or aqueous MeCN. The total mole-for-mole yields of CO and H_2 are around 1 in most cases. The $[Ni(cyclam)]^{2+}$ complex is a very effective and selective catalyst for the electrochemical reduction of CO_2 to CO relative to the reduction of water to H_2 in aqueous solution when it is adsorbed onto mercury. The CO/H_2 product ratio is >100 for $[Ni(cyclam)]Cl_2$.[1631] It is suggested that the greater selectivity for the electroreduction of CO_2 compared with water is related to the size of the macrocyclic ligand and the presence of N—H groups in $[Ni(cyclam)]Cl_2$. The complexes $[Ni(cyclam)]^{2+}$ and $[Ni_2($**649**$)]^{4+}$ display analogous properties with respect to CO_2, leading to CO formation in water but $HCOO^-$ in addition to CO in low-water-content DMF.[1631–1636]



(**647**)



(**648**)



(**649**)

A Ni^{II} complex of a cyclam derivative with protonated amine pendant also catalyzes the electrochemical reduction of CO_2 to CO efficiently.[1507]

The Ni^{II} complex (**568**) has been reported to show a high activity for the electrocatalytic reduction of CO_2 to CO when a rotating copper disk electrode is used.[1637] In addition, water-soluble type (**570**) Ni^{II}–azacyclam complexes, where R = carboxamide or sulfonamide, either aliphatic or aromatic, are found to be active in the electrocatalytic reduction of CO_2 at a mercury cathode. The efficiency is comparable to that of $[Ni(cyclam)]^{2+}$.[1474] The complex of an azacyclam derivative with a 2-hydroxyethyl pendent arm ((**570**) with R = CH_2CH_2OH) showed less H_2 evolution than $[Ni(cyclam)]^{2+}$.[1638] In a series of dinuclear Ni^{II} complexes of pentaaza macrocycles with methylene bridges of varying lengths, the catalytic currents for the dinuclear species are comparable to those of mononuclear analogues. This is possibly the result of less effective absorption on the electrode due to ligand steric interactions.[1639]

Different isomeric forms of Ni^{II} macrocyclic complexes may behave differently in the CO_2 reduction, and subtile structural differences may be an important factor.[1640] The complexes C-*R*,*R*,*S*,*S*-(**650**)$(C1O_4)_2$ and C-*meso*-(**651**)$(C1O_4)_2$ have been shown to be better catalysts than $[Ni(cyclam)]^{2+}$ in terms of larger catalytic currents and more positive potentials in aqueous solution using a hanging mercury electrode. However, *R*,*S*,*S*,*R*-(**650**) does not show good catalytic activity. In the latter case, the axial methyl group may sterically hinder effective adsorption of the complex onto Hg, and may also hinder CO_2 binding to the complex.[1641]

Different to the charge-positive cyclam-type systems, neutral Ni^{II} complexes (**652**) with Jäger-type ligands are remarkably selective and persistent homogeneous catalysts for the electrochemical reduction of CO_2 to oxalate.[1642]

(d) Photoreduction of CO_2. Some Ni^{II} macrocyclic complexes mediate electron transfer and produce CO during the photochemical reduction of CO_2. Compared to the electrochemical reduction of CO_2 with $[Ni(cyclam)]^{2+}$, however, photochemical reduction of CO_2 using a photosensitizer, a sacrificial electron donor, and $[Ni(cyclam)]^{2+}$ as the catalyst has been only moderately successful. Enhanced catalytic activity has been observed for a bismacrocyclic dinulear Ni^{II} complex.[1643]

Ru^{II}/Ni^{II} heteronuclear complexes such as (**653**), in which a photosensitizer $[Ru(bpy)_3]^{2+}$ or $[Ru(phen)_3]^{2+}$ is covalently attached to the Ni^{II}–cyclam complex, have been synthesized in order to improve the efficiency of electron transfer from the photoexcited photosensitizer to the catalytic site.[1644–1646] However, these complexes did not perform particularly well, either due to unfavorable configuration of the Ni^{II}–cyclam subunit and the resulting steric hindrance or due to short lifetime of the excited states of the Ru photosensitizer moieties. A stable catalytic system has been prepared by immobilizing macrocyclic Ni^{II} complexes and $[Ru(bipy)_3]^{2+}$ in a nafion membrane.[1647]

(**656**)

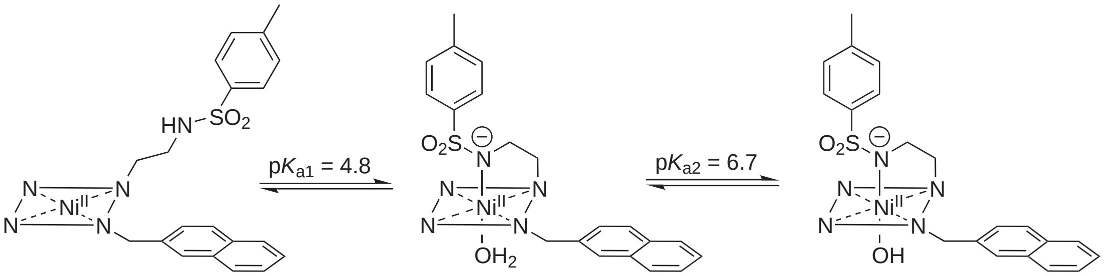
(e) Supramolecular assemblies. Ni^{II} macrocyclic complexes are frequently used as building blocks for the construction of 1D, 2D, and 3D supramolecular coordination networks. In general this involves reaction of the Ni^{II} complex with an oligofunctional linker, e.g., with the dianions of oxalic acid,[1648,1649] terephtalic acid,[1650] 1,4-benzenedicarboxylic acid,[1651] 2,5-pyridinedicarbocylic acid,[1651,1652] etc. or with the trianions of 1,3,5-benzenetricaboxylic acid[1651,1653,1654] and *cis*,*cis*-1,3,5-cyclohexanetricarboxylic acid.[1655] $[Ni(rac\text{-}Me_6[14]aneN_4)]^{2+}$ forms a dinuclear complex with the dianion of 2,5-pyridinedicarboxylic acid as a bridging ligand.[1652] One Ni atom is coordinated to the O atom of the 2-carboxylic group and to the pyridine-N atom (forming a five-membered chelate ring), while the second Ni is bound to both O atoms of the 5-carboxylic group (forming a four-membered chelate ring). Hydrogen bonding involving macrocyclic NH groups, both 2- and 5-carboxylic groups, perchlorate anions, and water molecules gives a supramolecular network in the solid state.[1652] Likewise, in cases where 1D polymeric chains or 2D layers result, these are often linked via H bonding interactions to give rise to 3D networks in the crystals. Inclusion studies have been carried out for host solids that are built from Ni^{II} complexes with tetra- and hexa-azamacrocyclic ligands and 1,3,5-benenetricarboxylate. In order to enforce H bonding patterns and π–π stacking interactions for the construction of more robust 3D open frameworks, the Ni^{II}

macrocyclic complex (**654**) bearing pyridyl pendent groups has been employed as a metal-based building block.[1655,1656]

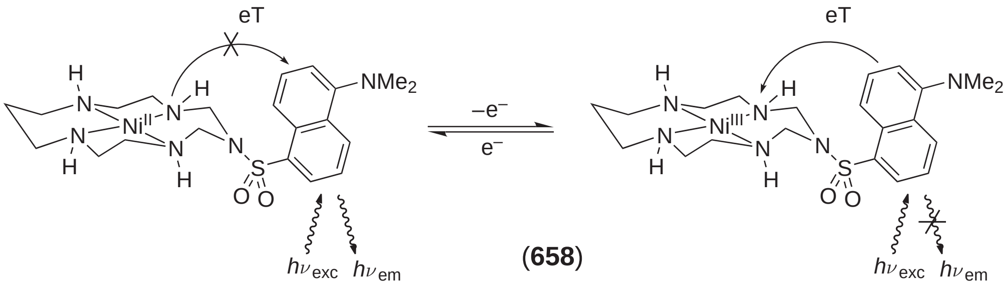
Nickel(II) complexes of saddle-shaped tetramethyldibenzotetraaza[14]annulene ligands (**655a,b**) are versatile receptors for a range of globular molecules. 1:1 complexes with the fullerenes C_{60} and C_{70} are known, in which the Ni^{II} complex acts as a divergent receptor in the solid state.[1657,1658] For smaller globular molecules such as 1,2-dicarba-*closo*-dodecaborane(12), P_4S_3, and cyclo-S_8, the [Ni(tmtaa)] complex associates through aromatic faces into dimers and these dimers then act as divergent homotopic receptors with a 1:2 ratio of guest:host species.[1659,1660] $[(H_2O)_2\cap([18]crown6)]$ has been confined in a disk-shaped cavity lined with six [Ni(tmtaa)] dimers,[1661] and ternary super-complexes of Ni^{II} dibenzotetraaza[14]annulene complexes with $[Co(C_2B_9H_{11})_2]^-$ and $[M\subset[2.2.2]$ cryptate$]^+$ (M = Na, K)[1662] as well as with C_{60} and CS_2 have been discovered.[1663]

Acceptor guest molecules such as quinone, TCNQ, or toluene can be accommodated in the flexible cavity of face-to-face bismacrocyclic Ni^{II} complexes (**656**). The host–guest interactions decrease the energy gap between the LUMO of the organic acceptors and the HOMO of the complex donors.[1664]

(f) Molecular switches of fluorescence. Manifold molecular systems have been developed in which a Ni macrocyclic complex (in most cases of the cyclam type) is connected to a fluorogenic fragment. Through intramolecular signal transduction, fluorescence is switched on and off by an external stimulus, e.g., by a pH change (**657**)[1665] or a change of redox potential (**658**).[1666] An alternative strategy uses the redox-driven intramolecular translocation of anionic ligands between two different transition metal centers in a two-component complex, one of which usually is a Ni–cyclam moiety.[1667] This application of Ni macrocyclic chemistry has been thoroughly reviewed.[1668–1671]



(657)



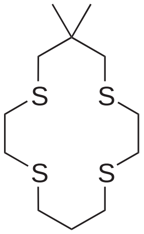
(658)

6.3.4.10.3 Complexes with larger macrocycles containing mixed donor atoms

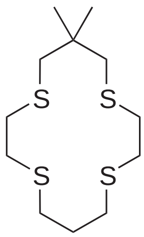
Various Ni^{II} macrocyclic complexes with donor atoms other than nitrogen have been reported, including macrocyclic ligands with mixed donor atoms. Reviews covering parts of the field have appeared.[1672–1674] In particular, macrocyclic Ni–thioether systems are the subject of intense interest, which is stimulated, *inter alia*, by the biological importance of redox-active Ni in sulfur-rich environments.[1675] In general, thioether coordination stabilizes lower spin and oxidation states. Ligand field splittings are roughly comparable with those of amine systems, but with a considerably greater nephelauxetic effect.

Ni^{II} complexes with tri-, tetra-, penta-, and hexa-thia crowns have been studied.[1675–1683] It has been shown that peripheral macrocycle modifications may lead to substantial improvements in Ni^{II} complexation: *gem*-dimethyl substituents at the [14]ansS_4 macrocycle (e.g., (**659**), (**660**)) enhance its Ni^{II} binding strength (by ΔG° of complexation of ca. $-1.1\,kcal\,mol^{-1}$ per *gem*-dimethyl pair),[1678,1679] as do both *cis*- and *trans*-fused cyclohexyl rings (**661**, **662**).[1676]

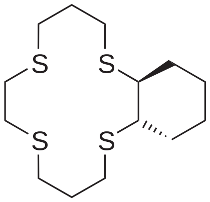
The formation and dissociation kinetics of Ni^{II} complexes of various [14]aneS_4 derivatives has been investigated. The rate-determining step is the chelate ring closure, i.e., the second bond formation (in contrast to acyclic thioether systems), and subsequent conformation reorganization is rapid. The latter behavior differs from that of the corresponding macrocyclic tetraamines, because any donor atom inversion associated with conformational changes is easily accomplished by thioether sulfurs, but requires deprotonation of coordinated amines.[1677]



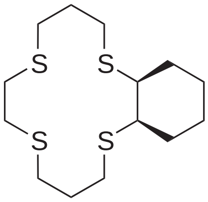
(**659**)



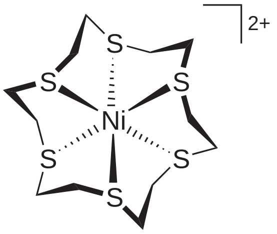
(**660**)



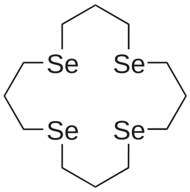
(**661**)



(**662**)



(**663**)



(**664**)

In contrast to [14]aneS_4, which can enforce fourfold thioether coordination to give a low-spin square planar Ni^{II} complex, each of the thiacrown complexes $[Ni([18]aneS_6)]^{2+}$, $[Ni([24]aneS_6)]^{2+}$, and $[Ni([12]aneS_3)_2]^{2+}$ comprise a near-octahedral NiS_6 coordination sphere with the crown thioethers wrapped around the high-spin Ni^{II} ion (e.g., (**663**)).[1680,1681] Since $[Ni([12]aneS_3)]^{2+}$ undergoes a substantial conformational change upon complexation (in contrast to $[Ni([9]aneS_3)]^{2+}$), $[Ni([12]aneS_3)_2]^{2+}$ decomposes immediately on contact with water (as does $[Ni([24]aneS_6)]^{2+}$). Ligand field splittings for $[Ni([18]aneS_6)]^{2+}$ and $[Ni([9]aneS_3)_2]^{2+}$ exceed those of $[Ni([24]aneS_6)]^{2+}$ and $[Ni([12]aneS_3)_2]^{2+}$ by ~10%.[1680] In the absence of coordinating anions the complexation of Ni^{II} by [12]aneS_4 and [16]aneS_4 leads to octahedral complexes $[NiL(solv)_2]^{2+}$ (solv = MeCN, H_2O).[1683] In the presence of anions such as chloride, however, dichloro-bridged dimeric cations exhibiting edge-sharing bioctahedral structures are formed, with the macrocyclic ligands coordinating in a *cis*-fashion around the metal ion. A similar structure is observed for $[Ni([14]aneS_4)Cl]_2{}^{+}$.[1682] Reaction of NiX_2 (X = Cl, Br, I) with the macrocyclic selenoether [16]aneSe_4 (**664**) afforded octahedral complexes *trans*-$[NiX_2([16]aneSe_4)]$, whose structures were deduced via Ni *K*-edge EXAFS. A ligand field analysis of the UV–visible spectra of analogous $[NiX_2([16]aneY_4)]$ complexes showed that the ligand fields decrease in the order $Y_4 = N_4 > S_4 > Se_4$.[1684]

Ni^{II} complexes of mixed P_2S_2,[1685] P_2O_2,[1686] P_2N_2,[1686] and PNS_2[1687] macrocyclic ligands have been investigated, as well as Ni^{II} complexes of pyridine-derived N_3O_2 systems.[1688] A comparative study of the 1:1 (metal/ligand) complex stabilities of 14- and 16-membered *cis*- and *trans*-dibenzo-substituted type (**665**) and (**666**) macrocycles incorporating *trans*-N_2O_2, -N_2S_2 and -N_4 donor sets towards, *inter alia*, Ni^{II} has been carried out,[1689] as well as a similar study for a series of dibenzo-substituted macrocyclic ligands incorporating N_2O_2, N_4O_2, N_2O_3, N_3O_3, and N_2O_4 mixed-donor sets.[1690] Ni^{II} complexes with pendent pyridylmethyl side arms at the N atoms of type (**665**) and (**666**) N_2S_2 ligands show distorted octahedral structures with *cis*-orientation of chemically identical donor atoms.[1691,1692] Ni^{II} complexes of the N_2S_3 crown (**667**) incorporating a 1,10-phenantroline unit are six-coordinate with five sites occupied by the macrocyclic ligand and one additional anionic or neutral coligand.[1693]

(669) **(670)**

The size of bonding cavities available to, *inter alia*, Ni^{II} has been specified for a series of type (**668**) macrocycles.[1694] The "bonding cavity" radii are found to increase by ~0.05 Å for each additional atom in the inner great ring, while changing the donor atom type has a relatively small influence. Along the N_2O_2 donor series, stabilities of the Ni^{II} complexes reach a maximum at the 16-membered ring complex with both the 15- and 16-membered compounds being considerably more stable than the 14-membered system.

cis-Dithiolate complexes of Ni^{II} diamine derivatives are known to template the synthesis of N/thioether macrocycles, and this has been extensively exploited for the sterically constrained (*N*,*N′*-bis(2-mercaptoethyl)-1,5-diazacyclooctane)nickel(II) (**669**) to give type (**670**) complexes,[1695–1698] and also for the 1,4-diazacycloheptane analogue.[1699] Upon template reaction with dihaloalkanes that are functionalized with heteroatom donors, Ni^{II} complexes of pentadentate N_2S_2X macrocyclic ligands are accessible. With X = NH, O, these form six-coordinate complexes in the solid state, e.g., $[NiLCl]^+$ (**671**). In solution, they undergo an equilibrium between (**671**) and four-coordinate (**672**), equally well for X = NH and O.[1698] The systematic enlargement and increasing flexibility of the macrocyclic N_2S_2 cavity ((**673**) → (**674**) → (**675**)) correlates with electrochemical properties. Due to the decrease in the energy of the $d_{x^2-y^2}$ orbital and decreasing field strength concomitant with increasing ring size, the Ni^{II}/Ni^{I} couple becomes more accessible along the series, while the Ni^{III} state is stabilized by the smaller cavities.[1700] Some data relating to Ni^{II} complexes of N_2S_2 macrocycles are summarized in Table 11.

6.3.4.11 Complexes with Bioligands

Nickel is now recognized as an essential element for bacteria, plants, animals, and humans. The biological role of nickel in enzymatic catalysis comprises various systems including urease, which has been known for almost 30 years. The basic role of nickel for CO dehydrogenase/acetyl-coenzyme A synthase, methyl-coenzyme M reductase, [NiFe] hydrogenases, and nickel superoxide dismutase are examples of biological involvement of nickel. Nickel is also a toxic element for living organisms and a well-established carcinogen. Selected biologically relevant complexes are discussed in the following.

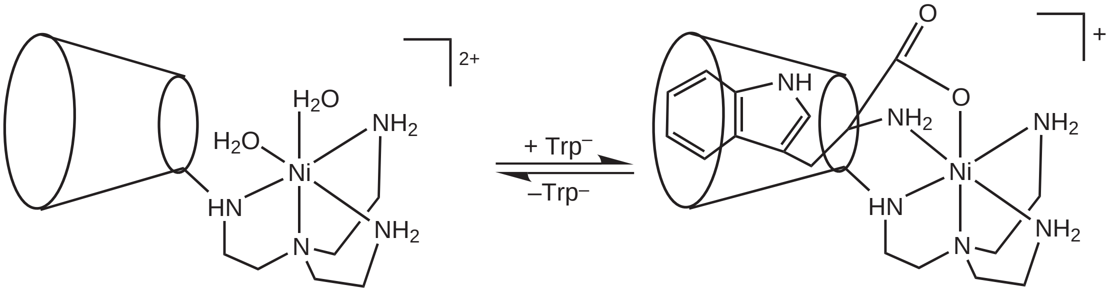
6.3.4.11.1 Complexes with amino acids and amino acid derivatives

(i) Complexes with α-amino acids

Natural α-amino acids provide a moderately effective {N,O} chelating donor set derived from carboxylate and amino groups, respectively. Several side-chain donor atoms may also be involved in metal ion coordination, especially those of Cys (thiol sulfur) and His (imidazole nitrogen(s)). (Abbreviations for amino acid residues are those recommended by IUPAC-IUB.[1702])

The major studies on Ni^{II} amino acids were performed in the 1980s and review articles[1703,1704] have covered most of the important results. α-Amino acids form with Ni^{II} two distinct complex species, [NiL] and [NiL_2]. The first (K_1) and the second (K_2) stability constant logarithms for complexes of simple {N,O} chelating amino acids are in the range 5–6 for log K_1 and 4–5 for log K_2. The side chains may be involved in the interaction with Ni^{II} leading to partly closed structures.[1703] However, only the β-carboxylate of Asp, the thiol-S of Cys, and the imidazole-N of His are involved so much that the stabilities of the respective complexes are distinctly higher. The log K_1 values of 7.15 for Asp, 8.66 for His, and 8.7 for Cys clearly indicate tridentate coordination of these amino acids. While the bis-His complex of Ni^{II} is pseudo-octahedral, the [NiL_2] complexes of Cys or its analogue *D*-penicillamine are square planar with very efficient {N,S} chelation.[1705,1706] Such {N,S} coordination is also likely in the five-coordinate Ni^{II}–cysteine complex with tridentate tris(3,5-disubstituted pyrazolyl)borate.[1707] Stability constants for ternary complexes [$NiABH_2$], [NiABH], and [NiAB] with L-cysteine and L-cysteic acid (A), and DL-2,3-diaminopropionic acid, DL-2,4-diaminobutyric acid, or DL-ornithine (B) have been determined by titration methods.[1708]

Ni^{II} coordination to simple amino acids in confined environments has attracted interest. The formation of a binary metallocyclodextrin is possible through binding of a metal ion by a functionalized cyclodextrin.[1709] Subsequent formation of a ternary metallocyclodextrin through the binding of a substrate, e.g., an amino acid, can take place. The metallocyclodextrin annulus partly encapsulates the amino acid, which also interacts with the adjacent metal ion, resembling a Michaelis complex. A study on the formation of metallo-6^A-((bis(2-aminoethyl)amino)ethyl) amino)-6^A-deoxy-β-cyclodextrins and their complexes with tryptophan has shown that Ni^{II} coordinated to such functionalized cyclodextrin is able to bind Trp orders of magnitude more efficiently than in simple binary systems (**677**).[1710]



(**677**)

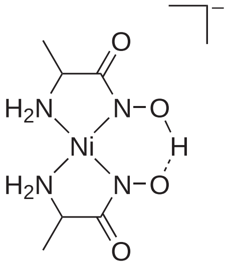
Interaction of Ni^{II} ions with amino acids is also important for asymmetric synthesis of amino acids. A convenient large-scale asymmetric synthesis of enantiometrically pure *trans*-cinnamylglycine and -α-alanine via reaction of cinnamyl halides with Ni^{II} complexes of a chiral Schiff base of glycine and alanine has been elaborated.[1711] Similar procedures have been applied to other amino acids as well.[1712]

(ii) Complexes with hydroxamic and oximic analogues of α-amino acids

Modification of a weakly coordinating amino acid carboxylate into a hydroxamic group changes dramatically the binding ability towards Ni^{II} ions.[1713] For Ni^{II}, the {N,N} chelation possible in the amino-hydroxamic ligands is more efficient than {N,O} coordination occurring in the simple amino acid complexes. While the {N,O} coordination results in octahedral or pseudo-octahedral complexes, {N,N} chelation may lead to planar complexes in which the {N,N} binding mode is especially favored. This conclusion has been widely confirmed, both in the solid state[1714–1716] as well as in solutions studies.[1717–1721] The {N,N} binding mode exhibited by aminohydroxamic acids is also much more effective than the {O,O} chelation offered by simple alkylhydroxamic systems.[1714] In the latter case the O-only chelation leads to formation of poorly soluble octahedral complexes.

In aqueous solution, depending on pH, α-aminohydroxamic acids having no competing donor system in a side chain (like glycinehydroxamic acid or alaninehydroxamic acid, H_2L) form different complex species with Ni^{II} ions. The major complexes are the {NiL}, and $[NiL(HL)]^-$

species with {N,N} donors involved. While the NiL complex is octahedral, the bis(ligand) complexes have square planar geometry. In the NiL_2 species ligands are in *trans* position to each other,[1716,1722] while in the $[NiL(HL)]^-$ complex they change to a *cis* geometry[1715] due to the strong interligand hydrogen bond (**678**).



[NiL(HL)]
(**678**)

Oxime derivatives of amino acids (and their amides) are more efficient ligands than the parent amino acids. Oximes of amino acid amides are particularly good ligands for Ni^{II} ions forming $\{N_4\}$ complexes with specific *cis* coordination of two amide ligands stabilized by a hydrogen bond between the two oximic O atoms (Figure 18).[1723]

Simultaneous modification of amino carboxylate groups into oximic and hydroxamic functions results in very powerful N-coordinating ligands for Ni^{II} ion. The stability of the NiL_2 complex is much higher than that of the respective amino acid or its oximic or hydroxamic analogue.[1724] Two hydrogen bonds stabilize very effectively the pseudomacrocyclic complex (Figure 19). Similar coordination behavior is observed for the dihydroxamic acid derived from oxalic acid (Figure 20).[1725]

6.3.4.11.2 Complexes with peptides

(i) Complexes with peptides bearing noncoordinating side chains

The coordination abilities of peptide ligands have been the subject of several reviews.[1726–1729] Peptides are very effective and specific ligands for Ni^{II} ions since they contain a variety of potential donor centers. The most important binding sites for Ni^{II} is usually the N-terminal nitrogen (**679A**), derived from a primary NH_2 group or secondary NH in the case of proline. The C-terminal carboxylate (**679B**) and carbonyl (**679C**) O atoms are also potential donors, although for Ni^{II} ion they are usually less effective than the nitrogen donors. Ni^{II} can promote ionization of the amide nitrogen of the peptide linkage (**679D**) to form a very stable Ni^{II}—amide bond. Thus,

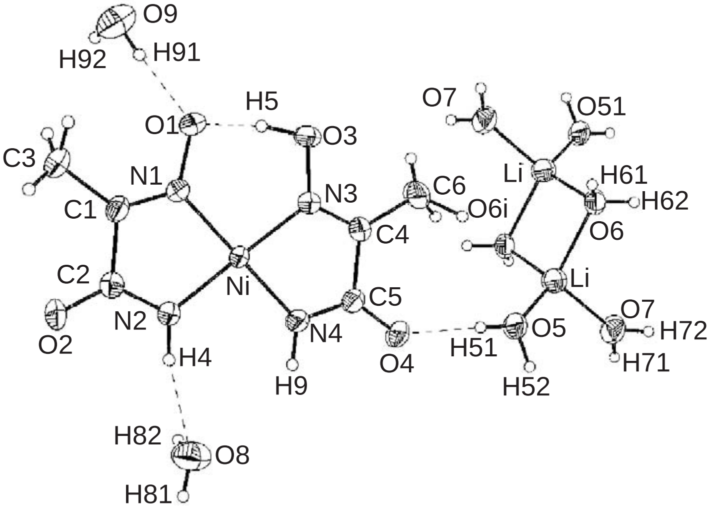


Figure 18 Crystal structure of Li[NiL(HL)] complex ($H_2L = $ 2-hydroxyiminopropanamide).

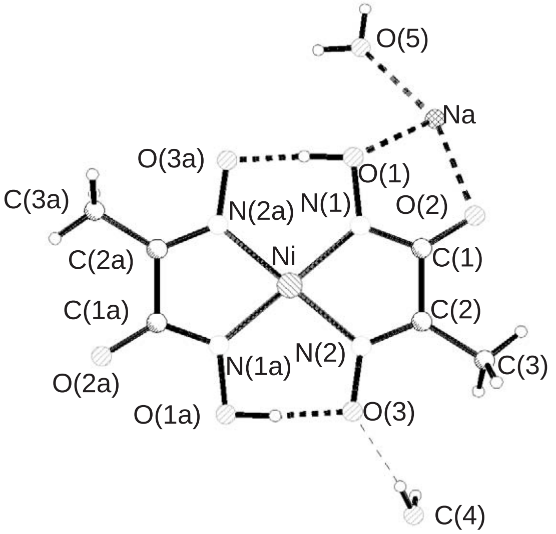

Figure 19 Crystal structure of $Na_2[NiL_2]\cdot4H_2O$ complex ($H_2L = $ 2-(hydroxyimino)propanohydroxamic acid).

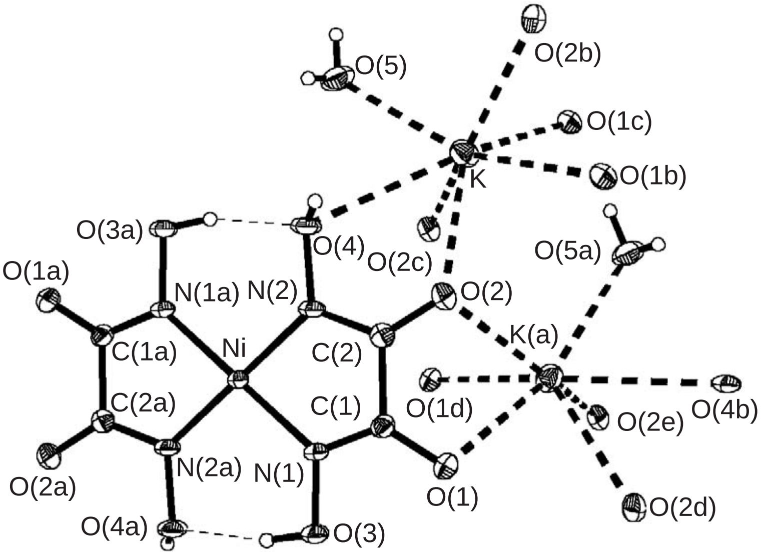

Figure 20 Crystal structure of $K_2[Ni(oxha)_2]\cdot2H_2O$.

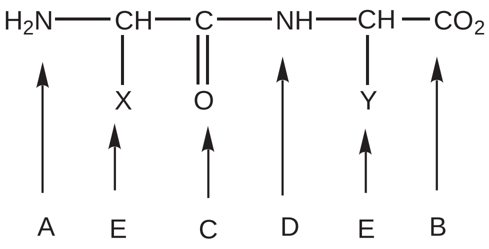
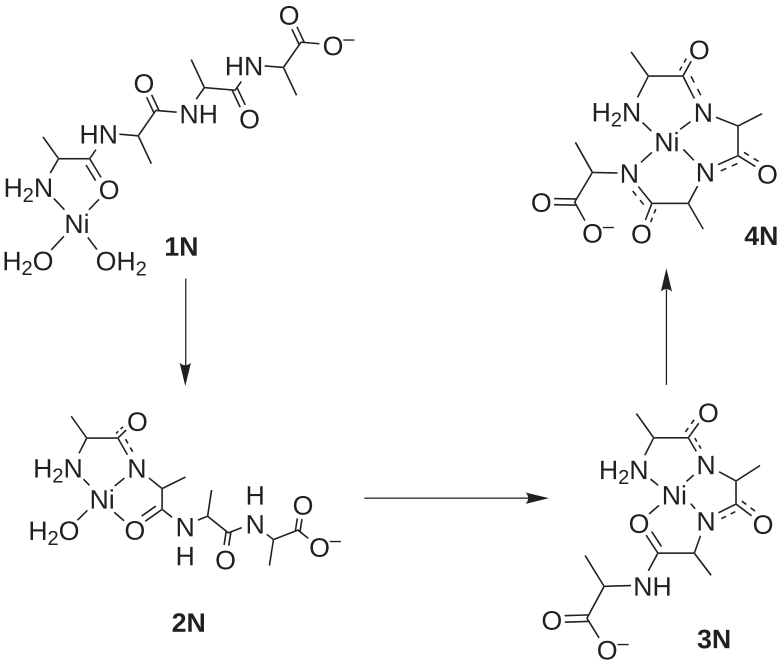
in the case of simple oligopeptides with noncoordinating side chains, complex formation with Ni^{II} starts at the N-terminal amino nitrogen and proceeds as shown in Scheme 8.[1726–1729] A characteristic feature of Ni^{II}–peptide systems is the cooperative deprotonation of the amide N atoms resulting in the transition from an octahedral (1 N) to a square planar (4 N) complex.[1726]



(679)



Scheme 8

(ii) Complexes with peptides containing side-chain donor systems

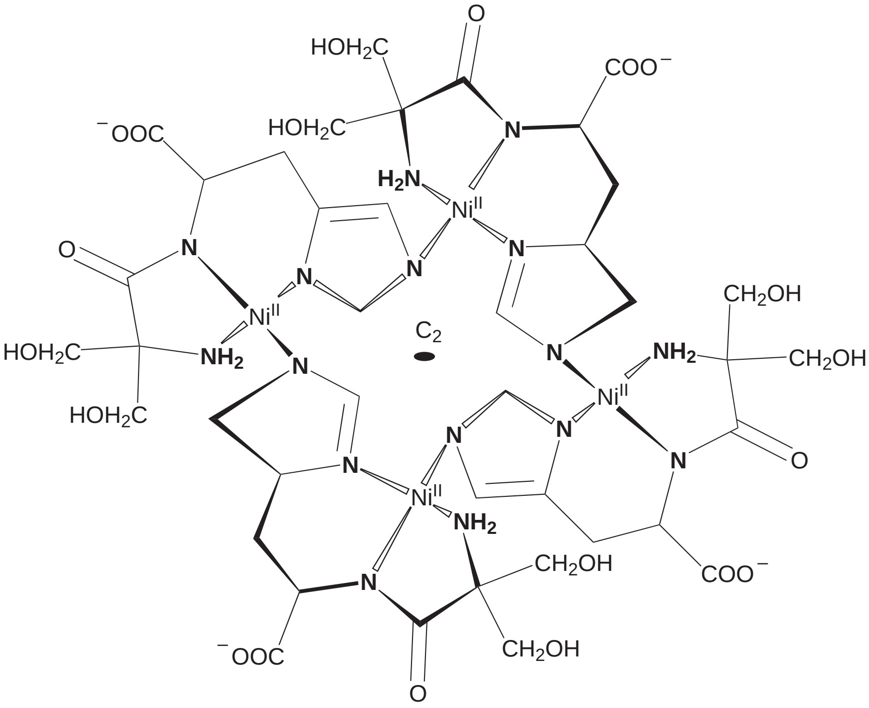
In addition to the backbone donor system the amino acid residues can contain a variety of donor centers (**679E**). The most important of these are the imidazole N atoms of His, the S atom of Cys, and to some extent the β-carboxylate O atom of Asp. Other side chain donors like the O atoms of Ser and phenolic O atoms of Tyr or amino N atoms of Lys are of minor importance for coordination of Ni^{II} ions. Also, thioether S-donors of Met play only a minor role in the interactions with Ni^{II} ions.[1730]

The β-carboxylate group of the Asp residue is not a favored donor for Ni^{II} ions. It may stabilize, however, the complexes formed between the metal ion and simple oligopeptides, particularly when present as the N-terminal residue.[1731] In the latter case, Ni^{II} coordinates to the N-terminal amino group (1 N species, Scheme 8) and the β-carboxylate closes the six-membered chelate ring. This binding mode stabilizes considerably the 1 N (NiL) species by a factor of up to 2 log units. The side chain of glutamic acid with its γ-carboxylate has a much smaller effect than Asp on the binding ability of peptides towards metal ions.

(iii) Complexes with peptides containing histidine

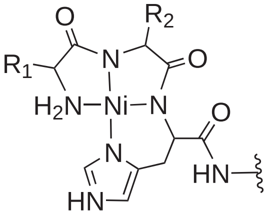
The Histidine residue with its imidazole side chain is one of the most effective ligation sites in metallopeptides. The His residue provides two N-donors and a six-membered chelate ring for coordination. Although the N-terminal amino-N usually initiates the Ni^{II} ion coordination to the peptide chain, an imidazole of His residue present in a peptide sequence may also act as a primary anchoring site for Ni^{II}. The competition between the terminal amino and the imidazole N donors to coordinate to Ni^{II} strongly depends on the position of His in the peptide chain.[1732,1733] Simple peptides with His in the N-terminal position bind Ni^{II} differently from ordinary peptides. The histamine-like $\{NH_2,N_{im}\}$ chelate of the His-1 residue is so efficient that it wins competition with the amide bonds and only pseudo-octahedral NiL and NiL_2 complexes are formed.[1734,1735]

The insertion of histidine in position two of the peptide chain results in the simultaneous binding of the N-terminal amine, the imidazole, and the intervening amide-N to the Ni^{II} ion. The major complex $[NiH_{-1}L]^+$ with $\{NH_2,N^-{}_{am},N_{im}\}$ binding mode is pseudo-octahedral and in aqueous solution it dominates in the pH range 6–10.[1734,1736,1737] The most characteristic feature of the short peptides having His-2 residues is the formation of the very stable diamagnetic tetrameric $Ni_4H_{-8}L_4$ complex with square-planar Ni^{II} ions bridged by imidazole rings (Scheme 9).[1736,1737]



Scheme 9 Tetramerie $Ni_4H_{-8}L_4$ complex with square-planar Ni^{II} ions.[1736,1737]

Coordination of the imidazole-N of His to Ni^{II} is most effective when His is located in the third position in the peptide chain. This position allows for the simultaneous formation of three fused chelate rings, involving a $\{NH_2,N^-_{am},N^-_{am},N_{im}\}$ donor set (**680**) and saturating all available coordination sites in the planar (4 N) Ni^{II} ion. The Xaa-Yaa-His- sequence corresponds to the N-terminal binding site for Ni^{II} in human serum albumin (Asp-Ala-His) and it is one of the most effective peptide chelating agents for Cu^{II} and Ni^{II} ions.[1738–1742] The albumin-like sequence has been studied extensively and numerous findings confirmed the coordination mode shown in (**680**), including the X-ray structure obtained for the Ni^{II} complex with glycylglycyl-α-hydroxy-D-L-histamine.[1743] Although the short peptides may not be reliable models of thermodynamic and kinetic properties of the N-terminal metal binding site in serum albumin, the available data allow to evaluate the impact of the Xaa-Yaa-dipeptide sequence on the stabilities of the Ni^{II} complexes with Xaa-Yaa-His.



(**680**)

The N-terminal peptide fragment of des-angiotensinogen Val-Ile-His-Asn contains two strongly hydrophobic amino acid residues on the N-terminal site of His-3. The potentiometric data have shown that the $NiH_{-2}L$ complex with this albumin-like sequence is more than two orders of magnitude more stable than the respective complex with Gly-Gly-His.[1744] The NMR-based molecular structure has shown that the side chains of Val-1 and Ile-2 form a well-ordered hydrophobic fence (Figure 21) shielding one side of the coordination plane from the bulk of

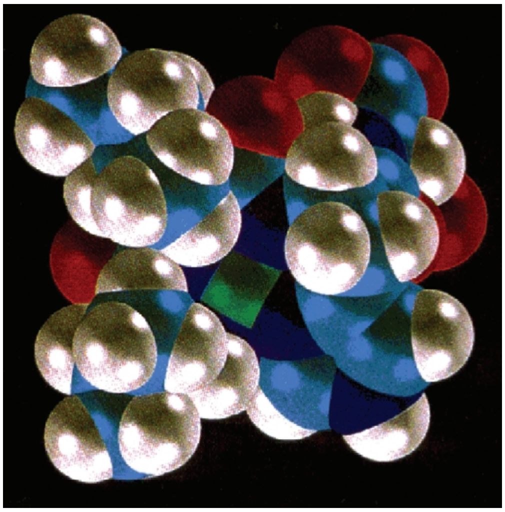


Figure 21 Space-filling model of the structure with the lowest overall energy showing the amino acid side chains hindering axial approach to Ni^{II}. Color code: C, light blue; H, white; N, dark blue; O, red; Ni^{II}, green.[1745]

the solution. The stability of the Ni^{II}–peptide complex depends on the rate of dissociation, and in the case of the Xaa-Yaa-His complex dissociation of nickel requires attack of water or H^+ on the bound amide-N. Thus, the protection of the metal–amide bonds by the hydrophobic fence increases the complex stability. The acidic properties of the N atoms of the residues involved in the Xaa-Yaa-His sequence may play a crucial role in the binding ability of the albumin-like peptides as well.[1745]

The unusual binding ability of the albumin-like peptides may be also critical for Ni^{II} ion binding by larger peptides. The human protamine HP2, which is a small basic protein providing compact DNA binding in vertebrate sperm, has the albumin-like N-terminal sequence Arg-Thr-His. This sequence binds to Ni^{II} much more effectively than simple albumin-like peptides,[1746] which indicates that HP2 is a likely target for toxic Ni^{II} ions. The Ni^{II} ion coordinated to the N-terminal tripeptide unit of HP2 induces very a specific secondary structure in the N-terminal pentadecacpetide of human protein.[1747] A striking double-loop conformation was found, exhibiting the interactions of the aromatic ring of Tyr-8 residue with the Ni^{II} coordination site at Arg-1, Thr-2, and His-3 (Figure 22). The resulting conformation could be critical for a possible physiological function of the N terminus of HP2 as a metal binding site.

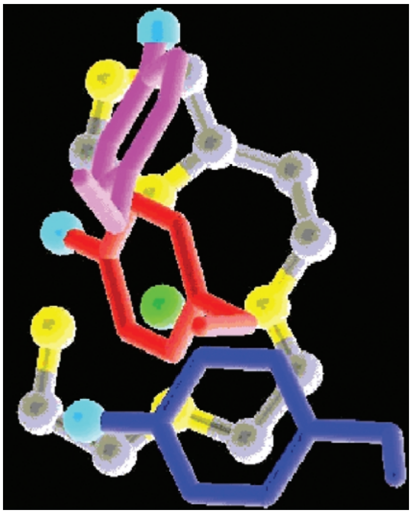

Figure 22 Positioning of the Tyr^8 phenol ring (colored stick structures) relative to the Ni^{II} (purple sphere) and its chelate ring (ball-and-stick structure). The lowest-energy representatives of conformational families 1–3 are shown in blue, green, and yellow, respectively. The phenol oxygen is a red sphere.[1747]

Ni^{II} complexes with Xaa-Yaa-His peptides are sensitive to oxygen species including dioxygen itself. The yellow solution containing Ni^{II} and Gly-Gly-His left for 48 h at ambient temperature gave rise to crystals which according to the X-ray structure contain the decarboxylation product Ni^{II}(Glycyl-Glycyl-α-hydroxy-D,L-histamine).[1743] The ability of Ni^{II} complexes to catalyze such oxidation reactions is often used to cleave specifically DNA.[1748,1749] Nickel peptide complexes with His-3 have also been used for very specific DNA cleavage by attachment to DNA recognition groups, e.g., a zinc-finger DNA binding domain[1750,1751] or a peptide nucleic acid (PNA) oligomer.[1752,1753] The strong equatorial ligand donors in the planar Ni^{II} complexes are essential for a mechanism that involves Ni^{III} as an intermediate.

When His is inserted in position 4 or further away from the N terminus, coordination equilibria become much more complicated and the binding ability is usually lower than that of albumin-like sequences. With respect to the molecular mechanisms of nickel carcinogenensis, much effort was undertaken to understand Ni^{II} binding to short and long fragments of many proteins associated with chromatin or proteins related to metal detoxification. Some histon proteins containing one or more His residues are potential binding sites for Ni^{II} ion. For the N-terminal tail of the histon H4 it was shown that H4 is a relatively good binding site for metal ions at the His residue and that coordinated Ni^{II} stabilizes a bent structure around the metal ion binding site.[1754] Lack of the N-terminal amino-N anchoring site makes His-18 the only primary ligation site and the formed complexes are relatively stable, thus making H4 a relevant metal ion binding site to be considered in the mechanism of nickel carcinogenicity.

Much more effective ligation for Ni^{II} ions was found in histone H3 containing the Cys-Ala-Ile-His sequence. The presence of two powerful donor systems (Cys and His) leads to formation of a planar Ni^{II} complex at physiological pH involving both side chain donors. Proposed structures are (**681a**) and (**681b**).[1755] Such complexes are formed with a short tetrapeptide fragment as well as with the whole histone (H3–H4) core tetramer *in vitro*.[1756] The binding constant obtained for the histone tetramer is relatively high (log K of 4.26–5.26, depending on the extent of protein aggregation). Complexes (**681**) facilitate the oxidation of 2′-deoxyguanosine in the presence of H_2O_2 and are a reasonable model for the oxidative concept of nickel-induced carcinogenicity.[1757] Ni^{II} also binds effectively the histone H2A at the -Thr-Glu-Ser-His-His-Lys- sequence forming an octahedral complex involving two imidazoles of the His residues.[1758,1759] The octahedral complex has similar stability to that found in the H3 histone, but it does not act as an oxidative catalyst. Nickel(II) ion binding to the H2A site, however, results in the hydrolysis of the Glu–Ser amide bond, with formation of the planar complex with the Ser-His-His-Lys- motif, which may then act as an oxidative catalyst.[1757] The coordination mode in the latter complex is characteristic for the albumin-like peptides. The presence of several His residues in the peptide sequence may influence the metal binding equilibria. However, the most effective position His-3 predominates (see the case of HP2 protein, *vide supra*). The same phenomenon is observed for the pNiXa-1 peptide: His-Arg-His-Arg-His-Glu-Gln-Gln-Gly-His-His-Asp-Ser-Ala-Lys-His-Gly-His.[1760]

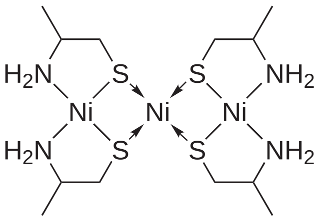
Proposed structure of different complexes formed by Ni^{II} with CH_3CO-Cys-Ala-Ile-His-NH_2[1755]

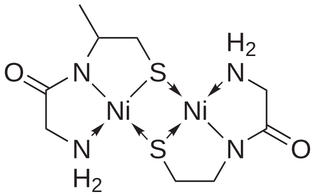
His residues in the peptide sequence are fundamental for Ni^{II} ion interactions with peptides. When the His residue is relatively distant from the N terminus, it may compete as a primary ligation site with the N-terminal amino nitrogen. However, even the higher number of His residues inserted inside the peptide sequence may be not able to compete with the albumin-like N terminus, unless the specific peptide structure is established.

(iv) Complexes with peptides containing cystein

Cysteinyl-S is the other powerful donor site for Ni^{II} ions. The binding abilities and the coordination eqilibria in Ni^{II}–peptide systems depend strongly on the position of Cys residues in the peptide sequence. The Ni^{II} binding to peptides containing Cys in the N-terminal position (Cys-Xaa-Yaa-) is similar to that observed for the Ni^{II}–Cys system.[1761,1762] Solely the Cys residue is involved in the direct metal ion binding via its $\{NH_2,S^-\}$ donor set. The stability constants are lower for the peptide systems due to steric effects and because the trimeric species (**682**) (which is characteristic for the Ni^{II}–Cys system) is only a minor species in the case of peptide ligands.



(682)



(683)

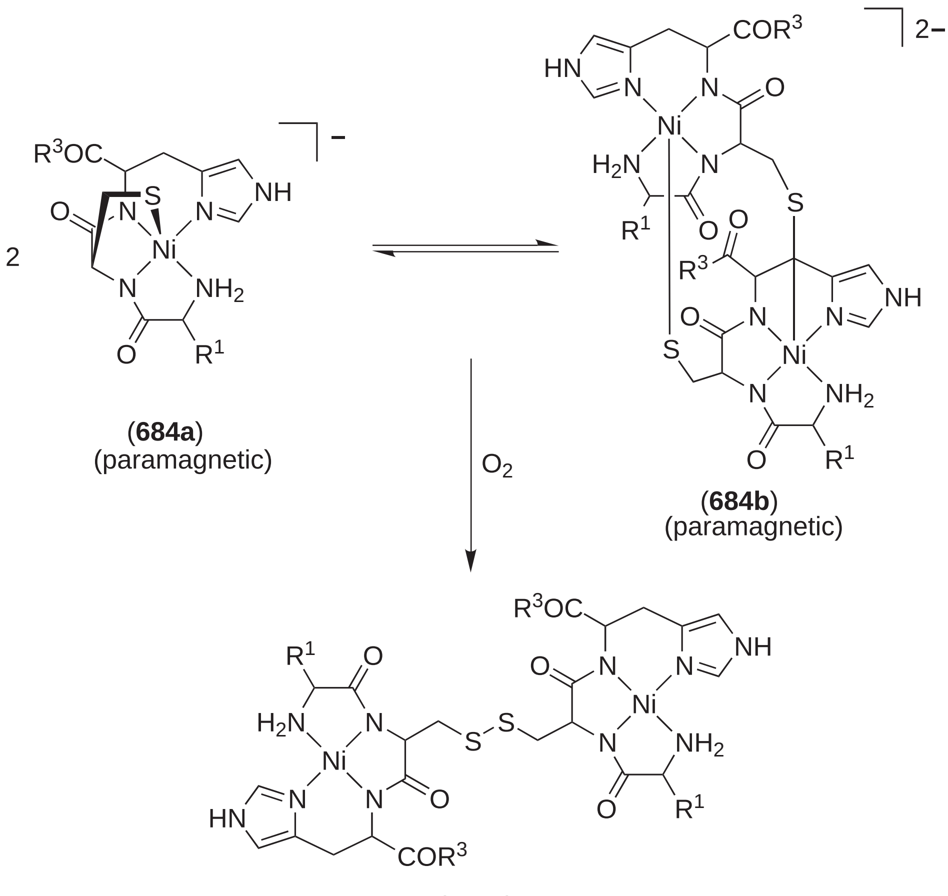
The Xaa-Cys sequence binds Ni^{II} ion via its $\{NH_2,N^-,S^-\}$ donor set forming square planar complexes. The dimeric species $[NiH_{-2}L]_2$ is a major complex above pH 6, it is very stable and sulfur acts as a bridging unit (**683**). When Cys was inserted into the albumin-like sequence Xaa-Cys-His,[1763] Ni^{II} binds to the $\{NH_2,2xN^-_{am},N_{im}\}$ donor set as in a typical Xaa-Yaa-His peptide. However, the complex obtained in the absence of air is a paramagnetic species, suggesting the involvement of a thiol donor in the apical coordination in an intramolecular fashion (**684a**) or via formation of a dimeric species (**684b**). In the presence of air the complex becomes diamagnetic due to oxidation to a disulfide-bridged dimer (**684c**).

Insertion of a thioamide (ψ[CSNH]) bond into a peptide backbone with noncoordinating side chains increases distinctly the coordination ability of the peptide toward Ni^{II}. The thioamide sulfur is a much more potent donor than the carbonyl-O and it is a basic donor for Ni^{II} ion coordination around physiological pH.[1764]

6.3.4.11.3 Complexes with porphyrins and related ligands

A handbook on inorganic and coordination chemistry of porphyrins has been published.[1765] Factor F_{430} is the nickel–hydrocorphinoid group of the enzyme methyl coenzyme M reductase.[47,48] The mystery of this particular metalloprotein is one of the major reasons for the development of Ni^{II}–porhyrin coordination chemistry, although not the only one.

Porphyrins are ideal ligands to form planar complexes with Ni^{II} ions. However, the small size of the low-spin Ni^{II} ion leads to short Ni—N bonds in the equatorial plane of the macrocycle. A number of structures determined for a variety of Ni^{II}–porhyrin complexes have shown that the problem of the short Ni—N bonds is solved by changes in the porphyrin core conformation.[1766] Three major core structures are usually observed for Ni^{II}–porphyrin complexes: a ruffled, a planar, and a saddled conformation. There is no simple relation between the core conformation and the Ni—N bond length. The structure of a simple unsubstituted (porphinato)Ni^{II} complex has a planar core both in solution and in the solid state.[1767] However, complexes with porhyrins with only slightly more bulky substituents like 2,3,7,8,12,13,17,18-octaethylporhyrin (OEP)[1768–1770] or protoporphyrin IX[1771] exist at least in two conformations in solution (planar and nonplanar). Ni(OEP) crystallizes in two planar forms and one ruffled tetragonal form. Besides the small size of the Ni^{II} ion, bulky substituents also result in nonplanar conformations that relieve steric



(**684a**)
(paramagnetic)

(**684b**)
(paramagnetic)

(**684c**)
(diamagnetic)

crowding at the periphery of the macrocycle.[1772] Crystallographic studies have shown that in the series of substituted tetraphenylporphyrins[1773] the macrocycle distortion increases gradually in the order TPP < DETPP < tTETPP < cTETPP < HETPP < OETPP. Metal-free porphyrins with more bulky substituents usually assume a nonplanar saddle-shaped conformation, while a ruffled conformation can be induced by small metal ions. Coordination of the these porphyrins with Ni^{II} only in one case, Ni^{II}tTETPP, resulted in a highly nonplanar ruffled conformation, while Ni^{II}DETPP, Ni^{II}cTETPP, and Ni^{II}HETPP exhibit a saddle-distorted conformation of the macrocycle[1773] (Figure 23). The complex of another highly substituted porphyrin, 5,10,15,20-tetrabutyl-2,3,7,8,12,13,17,18,-octaethylporhyrin, has a significantly distorted ruffled-shaped core conformation (Figure 24) with very short average Ni—N bond distances in the crystal (1.873 Å) and in solution (1.87 Å according to EXAFS data).[1774]

A detailed analysis of Ni^{II} complexes with *meso*-substituted porphyrins bearing zero, one, two, or four *t*-butyl groups revealed that both the out-of-plane and in-plane distortion depend on the perturbation symmetry of the peripheral substituents (number and position of substitutents), and their orientation.[1775] These results have implications for understanding the role of nonplanar distortions in the function of metalloproteins containing nonplanar porphyrins.[1776]

Meso-tetracyclohexylporhyrin contains four nonplanar electron donating bulky *meso* substituents, causing distinct steric crowding at the porhyrin periphery.[1777] Its Ni^{II} complex has a ruffled conformation of the core with the shortest Ni—N distances being 1.881–1.897 Å. The electron donating effect of the cyclohexyl groups is seen in the redox properties of the porhyrin in the complex. It is easier to oxidize and harder to reduce than in the case of its tetraphenylporhyrins congeners.

Polar substituents have been attached to the porphyrin core in order to achieve water-solubility. (**685**) has been synthesized by reaction of the Ni^{II} complex of tetrakis(pentafluorophenyl)-porphyrin with dimethylammonium hydrochloride in DMF, followed by methylation with methyl trifluoromethanesulfonate (triflate) in trimethyl phosphate.[1778] The triflate and chloride salts are

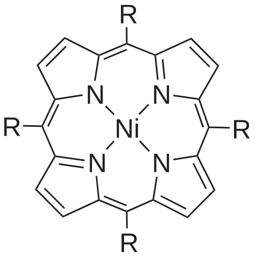
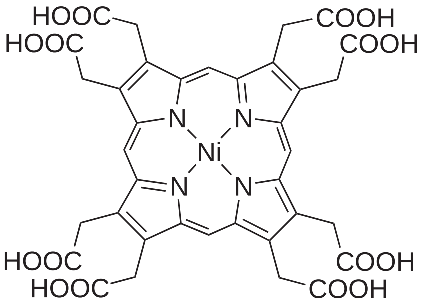
water soluble. The fluorine substituents reduce the tendency to aggregation and adsorption to electrode surfaces often found for water-soluble porphyrins. (**686**) also is water soluble, and several esters of (**686**) have been studied.[1779] These latter complexes are highly nonplanar as indicated by resonance Raman and NMR spectroscopic experiments. Consistent with this, EXAFS measurements show short Ni—N bond lengths in the range 1.92(2)–1.89(2) Å. Unlike [Ni(uroporphyrin)], which undergoes aggregation in low pH (<3) or high ionic strength media, complexes (**686**) remain unassociated, probably because of the degree of distortion from planarity.



(**685**)
R = $C_6F_4NMe_3^+$–4



(**686**)

Crystallographic work on a Ni^{II} complex of the *N*-oxide dianion of OEP has revealed direct coordination of the O-donor (Figure 25).[1780]

In general, the combined effect of the small Ni^{II} ion and substituents larger than H atoms is required to shift the conformational equilibrium toward a nonplanar structure. Binding a ligand in the axial position raises the coordination number and the effective size of the metal ion, which becomes paramagnetic. Only nitrogenous bases are observed to form six-coordinate species.[1781] However, the occurrence of six-coordinate, pseudo-octahedral Ni^{II} inserted in a tetrapyrrole ring is rare. Work on Ni^{II} complexes with tetraphenyl-porphyrins bearing β-pyrrole electron-withdrawing substituents[1782] has shown that expansion of the porhyrin core takes place when the saddle-shaped and slightly ruffled low-spin [Ni^{II}(TPP(Br)$_4$(CN)$_4$)] (2,3,12,13-tetrabromo-7,8,17,18-tetracyano-5,10,15,20-tetraphenylporhyrin) complex binds two pyridines. (Ni—N)$_{av}$ bond distances increase from 1.929 Å [Ni—N(Br)] and 1.911 Å [Ni—N(CN)] to 2.073 Å and 2.040 Å, respectively. This expansion is accompanied by a significant decrease of the saddle distortion and a clear increase of

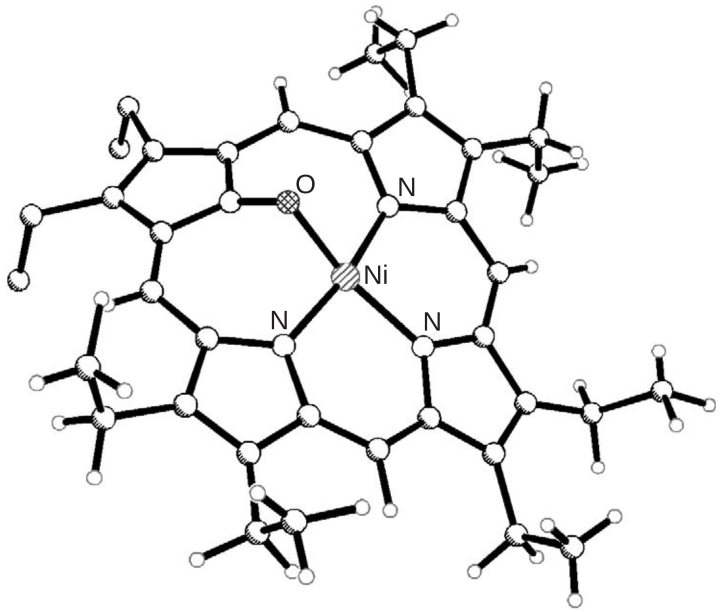


Figure 25 Predominant form of the Ni^{II} complex of octaethylporphyrin *N*-oxide.[1780]

the ruffling of the porphyrin present in $[Ni(TPP(Br)_4(CN)_4)(py)_2]$. The macrocycle present in $[Ni(TPP(CN)_4)(1\text{-}MeIm)_2]$ displays a waved conformation and it is only slightly nonplanar.

Cleavage of one peripheral β,β'-double bond in [NiTPP] gives the secochlorinato complex (**687a**), a metallochlorin-like pigment.[1783] Stepwise decarbonylation yields (**687b**) and the *meso*-tetraphenylchlorophinato complex (**687c**).[1784] Both (**687a**) and (**687c**) exist in severely ruffled conformations. While more rigid ligands such as homoporphyrins are unable to increase their cavity size for accommodating the larger Ni^I ion (and hence favor ligand-centered reduction), one-electron reduction of the more flexible secochlorin and chlorophin complexes gives Ni^I species.[1785]

The complex with the reduced porphyrin derivative 5,10,15,20-tetramethylisobacteriochlorin, [Ni(TMiBC)] (**688**), has an S_4-ruffled conformation and a bond length pattern indicative of a reduction of aromaticity, both of which are more pronounced than those found for the corresponding porphyrin and chlorin complexes.[1786]

(691)

Oxidaton of heme goes through the biliverdin species. Octaethylbiliverdin can exist in coordinated form as the fully reduced trianion $(OEB)^{3-}$, as the two-electron-oxidized monoanion $(OEB_{ox})^{-}$, or as the one-electron-oxidized radical $(OEB\cdot)^{2-}$. Nickel forms complexes with all three moieties, $[Ni^{II}(OEB)]^n$ with $n = +1$, 0, and -1 (**689**).[1787] The most highly oxidized species $[Ni(OEB_{ox})]I_3$ could be crystallized. The structure shows a helical coordination of the linear tetrapyrrole ligand around nickel with Ni—N distances of 1.867 Å and 1.879 Å.

Complexes (**690**) undergo two one-electron reversible reductions and two oxidations, all of which appeared ligand centered. Thus, these ligands behave electrochemically much like bacteriochlorins; smaller potential differences between the first oxidation and reduction waves are found than for porphyrins.[1788] A type (**690**) complex with $R_1 = R_2 = R_3 = Me$ on electrooxidation gave a partially oxidized material $[\mathbf{690}]_{2.5}(BF_4)_2 \cdot C_{10}H_7Cl$, characterized crystallographically.[1789] It has a columnar arrangement of stacked metallomacrocycles. The intermolecular spacing (<3.4 Å) suggested π-overlap, and ESR spectroscopic measurements showed the oxidation to be ligand centered. The material has an intermolecular charge transfer band at ca. 3,000 cm^{-1}. Similarly, chemical oxidation of (**690**) ($R_1 = R_2 = H$, $R_3 = Pr$) with iodine afforded $[(\mathbf{690})I_{1.67}]$.[1790] This complex consisted of $[\mathbf{690}]^{0.33+}$ cations packed in a slipped stack along the *b*-axis, and surrounded by disordered chains of iodine, identified as I_5^- by Raman spectroscopy. Again, the oxidation was identified as ligand based.

The Ni-complex of corrole (octaalkyl derivative (**691**)) is a $S = 1/2$ low-spin Ni^{II} species with a ligand-centered π-cation radical.[291,292]

6.3.4.11.4 Complexes with core-modified heteroanalogues of porphyrins

Metalloporphyrin reactivity and catalytic properties can also be controlled by modifications of the porphyrin core. Ni coordination chemistry of core-modified porphyrins has been reviewed.[1791,1792] Several X-ray structures of four-, five-, and six-coordinate Ni^{II} complexes with oxa-, thia-, and dioxatetraarylporphyrins are known.

The Ni^{II} complex with 5,20-di-(*p*-tolyl)-10,15-bisphenyl-21-oxaporhyrin, [Ni(ODTDPP)Cl], exhibits a saddle-shaped conformation of the oxaporhyrin macrocycle.[1793] The Ni—N bond distances are close to those of the related thiaporphyrin complex. The furan ring is planar and binds to Ni^{II} ion in the η^1 fashion (Figure 26). Similarly, in the structure of $[Ni^I(ODTDPP)]$ the metal is located in the furan plane, which binds Ni^I in the η^1 fashion through its oxygen donor, and the core conformation is saddle shaped.

In the related Ni^{II} complex with tetraphenyl-21-thiaporphyrin, [Ni(STPP)Cl], the metal ion is found in approximately square pyramidal geometry with an apical Cl, and the thiophene ring is bent from the STPP ligand core and coordinates through a pyramidal S.[1794,1795] The reduction product $[Ni^I(STPP)]$ binds various nitrogenous bases and SO_2 to give paramagnetic five-coordinate species,[1796] and the structure of the diphenyldi-*p*-tolyl-21-thiaporphyrinato derivative, $[Ni^I(SDPDTP)]$, was determined. Again, the thiophene ring is topped 52.3° out of the N3 plane with pyramidal coordination of the thiophene-S.[1797] $[Ni^{II}(SDPDTP)Cl]$ reacts with the Grignard reagent PhMgX to give a paramagnetic (*s*-phenyl)nickel(II) derivative with a Ni-bound phenyl group.[1798] Spectroscopic properties of the Ni^{II} complex of 5,20-di-(*p*-tolyl)-10,15-bisphenyl-21-selenaporhyrin, $[Ni^{II}(SeDPDTP)Cl]$, are very similar to those of the S-analogon, and hence a similar structure with side-on bound Se is proposed.[1799]

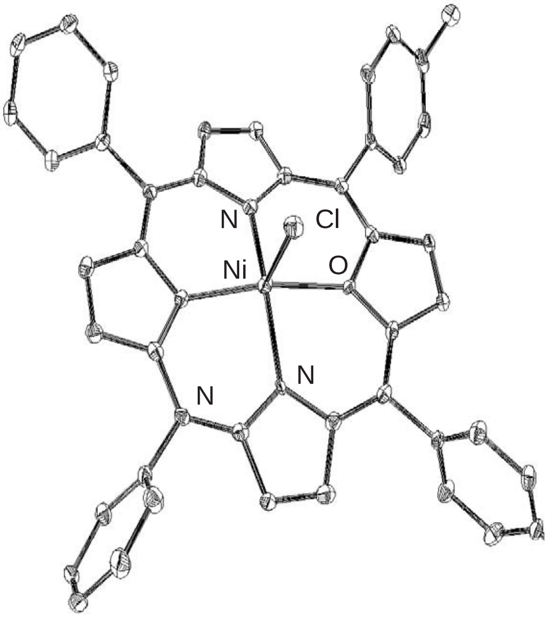

Figure 26 Molecular structure of $[(ODTDPP)Ni^{II}Cl]$.[1793]

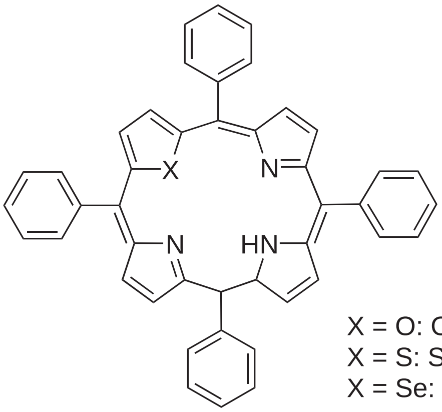
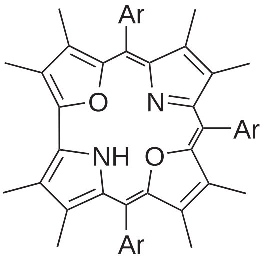
The Ni^{II} complex of 5,10,15-triaryl-21,23-dioxacorrole (**692**), [Ni(21,23-O_2Cor)Cl], is a high-spin Ni^{II} species,[1800] in contrast to diamagnetic Ni^{II} oxacorrole.[1801]



X = O: OTPP
X = S: STPP
X = Se: SeTPP



(**692**)

Replacement of a pyrrol-N by a methine-C, e.g., in the inverted porphyrins, imposes formation of a Ni—C bond, which was demonstrated for [Ni^{II}(CTTP)] (Figure 27, CTTP = 2-aza-5,10,15,20-tetra(*p*-tolyl)-21-carbaporhyrin) and [Ni^{II}(2-NCH_3CTPP)] (2-NCH_3CTPP = 2-aza-2-methyl-5,10,15,20-tetraphenyl-21-carbaporphyrin) complexes.[1802,1803] The coordination core geometry is essentially planar, although some ruffling is observed for tetraphenyl-carbaporphyrin complexes.[1791]

In the complex of calix[4]phyrin (**693**) with an inward-pointing carbon atom, the Ni^{II} ion is located in the middle of the core and the molecule shows a ruffled structure.[1804] The higher structural flexibility of the complex formed with this type of ligands could be attractive for studies of their organometallic and redox chemistry. Nickel(II) azuliporphyrin (**694**) retains a cross-conjugated borderline aromatic structure, as judged by UV–visible and NMR spectroscopy as well as X-ray crystallography.[1805]

Meso substitution of porphyrines to give tetraazaporphyrines, so-called porphyrazines, modulates the electronic character of the macrocycle. While porphyrazines have received considerably less attention than porphyrines over many years, this has changed due to the development of efficient syntheses of soluble derivatives.[1806–1809] Also, various porphyrazines (and phtalocyanines) with peripheral groups for metal ion coordination have been prepared and used for the construction of multimetallic complexes.[1806] Ni porphyrazines (**695**) typically show absorptions spectra with a strong Q band at around 615 nm.

(696)

(697)

The Ni complex of *cis*-dihydroxylated porphyrazine (**696**) gives (**697**) upon reaction with air.[1810] The decaptation reaction is assumed to result from Ni-mediated air oxidation of the *cis*-diol unit and subsequent loss of CO_2.

6.3.4.11.5 Complexes with carbohydrates

The chemistry of Ni^{II} complexes with carbohydrates is of potential importance in inorganic and bioinorganic chemistry, although the details, e.g., about the stereochemistry, of the complexes are largely unexplored due to the difficulties in isolating particular complexes.[1811–1815] Aminocarbohydrates are much more efficient ligands for metal ions due to an anchoring role of the amino-N. Simple aminocarbohydrates coordinate to Ni^{II} ion via an {N,O} donor set and the complexes formed are moderately stable.[1816,1817] The use of good chelating agents like ethane-1,2-diamine (en) as an anchor to 1-deoxy-D-galactitol[1818] leads to more stable complexes, although the involvement of the deprotonated sugar hydroxyl-O in Ni^{II} coordination takes place above pH 10. The complexes of Ni^{II} with ligands derived from *N*-glycoside derivatives have been reviewed.[1819]

Reactions of $[Ni(tren)(H_2O)_2]X_2$ (tren = tris(2-aminoethyl)amine; X = Cl, Br, SO_4) with mannose-type aldoses, having a 2,3-*cis* configuration resulted in {bis(N-aldosyl-2-aminoethyl)(2-aminoethyl)-amine}Ni^{II} complexes, [Ni(*N*,*N*′-(aldosyl)$_2$-tren)]X_2 (aldosyl = D-mannosyl or L-rhamnosyl).[1820,1821] The ligand binds hexadentate with $\{N_4,O_2\}$ coordination, where the tren unit acts as a tetradentate chelate and the two O atoms are in *cis*- arrangement (Figure 28). The octahedron around Ni is considerably distorted with *trans* and *cis* angles of 153.9° and 76.6°, respectively. Both sugar moieties adopt the stable β-$^4C_1$-pyranose form and bind to the nickel through the glycosidic N and the O atom of the C-2 hydroxyl group. D-Mannosyl and L-rhamnosyl derivatives form complexes which are almost exact enantiomeric forms compared to each other. The reaction with D-glucose, D-glucosamine, and D-galactosamine having 2,3,-*trans* configuration results in the formation of monosugar complexes [Ni(N-(aldosyl)-tren)$(H_2O)_2$]Cl_2, while the reaction of tris (*N*-aldosyl-2-aminoethyl)amine with Ni^{II} gives the tris(sugar) complexes, [Ni(*N*,*N*′,*N*″-(aldosyl)$_3$-tren]X_2 (aldosyl = D-mannosyl, L-rhamnosyl, D-glucosyl, maltosyl, and melibiosyl). In tris(L-Rha), Ni^{II} is only bound to four N-donors of tren while two additional binding sites are occupied by a bidentate sulfate anion. The sugar moieties are anchored to the metal only via their glycosidic N atom, but all hydroxyl groups are noncoordinating.

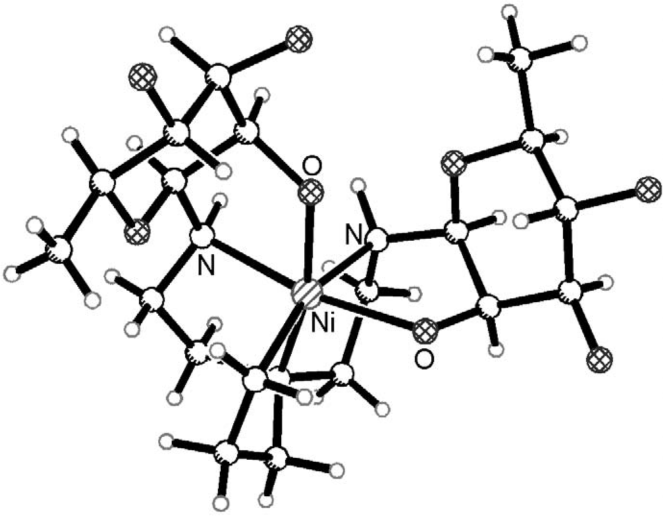

Figure 28 X-ray structure of $[Ni(N,N'\text{-}(L\text{-}Rha)_2tren)]^{2+}$.

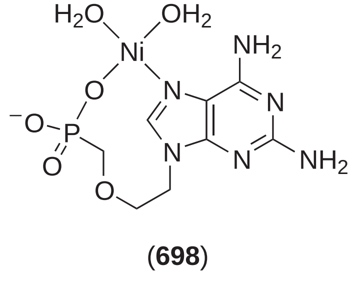
Reaction of $[Ni(tn)_3]X_2$ (tn = 1,3-diaminopropane) with aldopentoses gives mononuclear Ni^{II} complexes $[Ni(aldose\text{-}tn)_2]X_2$ [aldose-tn = 1-(*N*-aldosyl)-amino-3-aminopropane, aldose = D-xylose, D-lyxose, D-ribose, and D-arabinose].[1822] $[Ni(D\text{-}Ara\text{-}tn)_2]Br_2{\cdot}2H_2O$ contains a Ni^{II} ion ligated by two tridentate ligands, 1-amino-3-(*N*-D-arabinosyl)propane. These are coordinated to Ni through their primary amino and *N*-glycosidic N atoms and the C-2 hydroxy group of the sugar moiety in a meridional mode, resulting in a Λ-C_2-helical configuration around the metal center. The sugar rings adopt an unusual α-C_4 chair conformation and the sugar chelate ring conformation is δ.

The differentiation of diastereomeric Ni^{II} *N*-glycoside complexes is possible with the use of tandem mass spectrometry.[1823,1824]

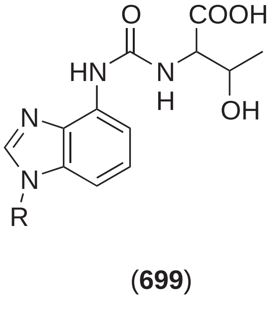
6.3.4.11.6 Complexes with nucleosides, nucleotides, and related ligands

Earlier reviews[1825,1826] have discussed interactions of Ni^{II} ions with subunits of nucleic acids. Ni^{II} is not very effective in its interactions with nucleosides and nucleotides. Ni^{II} coordinates to N-donors of the nucleic bases and it may form macrochelates bridging phosphate and a nucleic base. The most effective binding donor is N_7 of purines, found in Ni^{II} complexes with guanosine and inosine 5′-monophosphates. Several structures have shown a monodentate metal binding to purine nucleotides via N_7 (Figure 29).[1827,1828] However, potentiometric, NMR, and calorimetric studies on the interactions of Ni^{II} strongly suggest the formation of a macrocyclic chelate between N_7 and the phosphate moiety.[1829–1831] The stacking interactions between the purine base rings can also influence the stability of the complexes formed. Ni^{II} ions have some effect on the phosphate hydrolysis in nucleotides, thus corroborating coordination to the phosphate group.[1832]

The antiviral nucleotide analogue 9-[2-(phosphonomethoxy)ethyl]-2,6-diaminopurine also uses its N_7 as a major binding site and forms a N_7-phosphonate macrochelate (**698**).[1833] Another antiviral analogue of 2′-deoxyguanosine, acyclovir (9-[(2-hydroxyethoxy)-methyl]guanine) forms with Ni^{II} a bis-complex with two N_7 coordinated in *trans* position to each other.[1834]



(698)



(699)

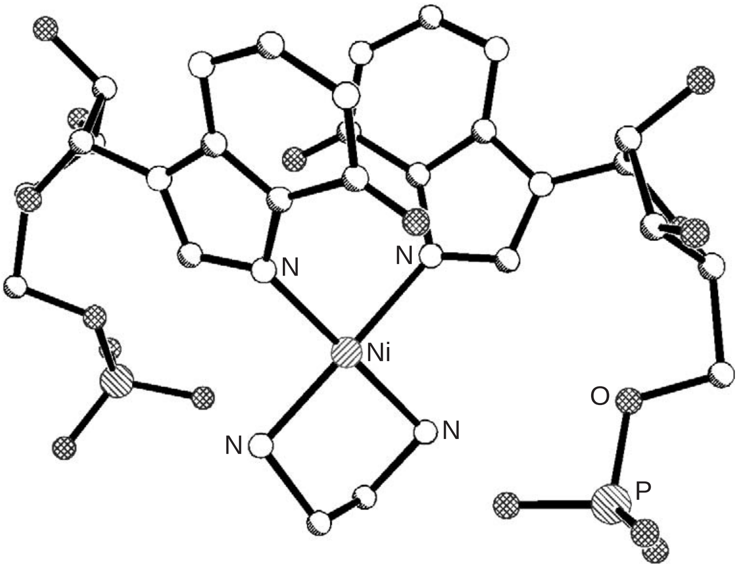


Figure 29 Molecular structure of the complex $[Ni(5'GMPH)_2(en)(H_2O_2)_2]$.

Regular pyrimidines are less effective ligands for Ni^{II} ions. They may use, *inter alia*, their C=O donor to yield monodentate coordination.[1835] Insertion of a sulfur atom into a pyrimidine moiety increases considerably its binding ability.[1836] Thiolation of uridine at C(2) or C(4) results in formation of a quite effective $\{S,N_3\}$ four-membered chelate in the complexes with Ni^{II}. Thiolation of purine at C(6) increases the stability constant by 3.5 orders of magnitude.

Hypermodified nucleosides that contain an attached amino acid at C(6) are important in the biochemistry of RNAs. The Ni^{II} complex with N-[(9-β-D-ribofuranozylpurin-6-yl)-carbamoyl]-threonine (**699**) forms a very stable complex involving N(1) of the purine ring, the amide-N and the carboxylate of the attached threonine as donors.[1837]

Chiral peptide nucleic acids (cPNAs) are synthetic analogues of DNA in which the natural phosphate-deoxyribose backbone is replaced by a peptide chain (**700**). Although both the peptide backbone chain and the nucleobases resting in the side chains are able to coordinate to Ni^{II} ions, the oligopeptide donor system dominates metal ion coordination (Figure 30).[1838,1839] Nucleobases which do not interact directly with the metal ion can stabilize very effectively the complexes formed by means of hydrogen bonds and the stacking interactions present within the complex molecule.

6.3.4.11.7 Ligands for biomimetic and related nickel complexes

For the known nickel sites in biological systems, four-coordinate square planar, five-coordinate, and six-coordinate octahedral geometries are found.[1840–1846] In general, the flexible coordination geometry of nickel causes its coordination properties in metallo-biomolecules to be critically influenced by the protein structure.

Biomimetic chemistry of nickel was extensively reviewed.[1847,1848] Elaborate complexes have been developed in order to model structural and spectroscopic properties as well as the catalytic function of the biological sites. Biomimetic systems for urease are described in Section 6.3.4.12.7, and model systems for [Ni,Fe]-hydrogenases are collected in Section 6.3.4.12.5.

Each catalytic center of methyl coenzyme M reductase, (MCR), contains a yellow chromophore factor F_{430}.[48] The structure of Ni–F_{430} determined by the crystallographic analysis and the proposed mechanism of MCR is shown in Scheme 10.[47]

This cofactor is a rare, highly saturated Ni-containing porphinoid system called "corphin," meaning a hybrid of corrinoid and porphinoid tetrapyrrolic macrocycle. It is a most reduced

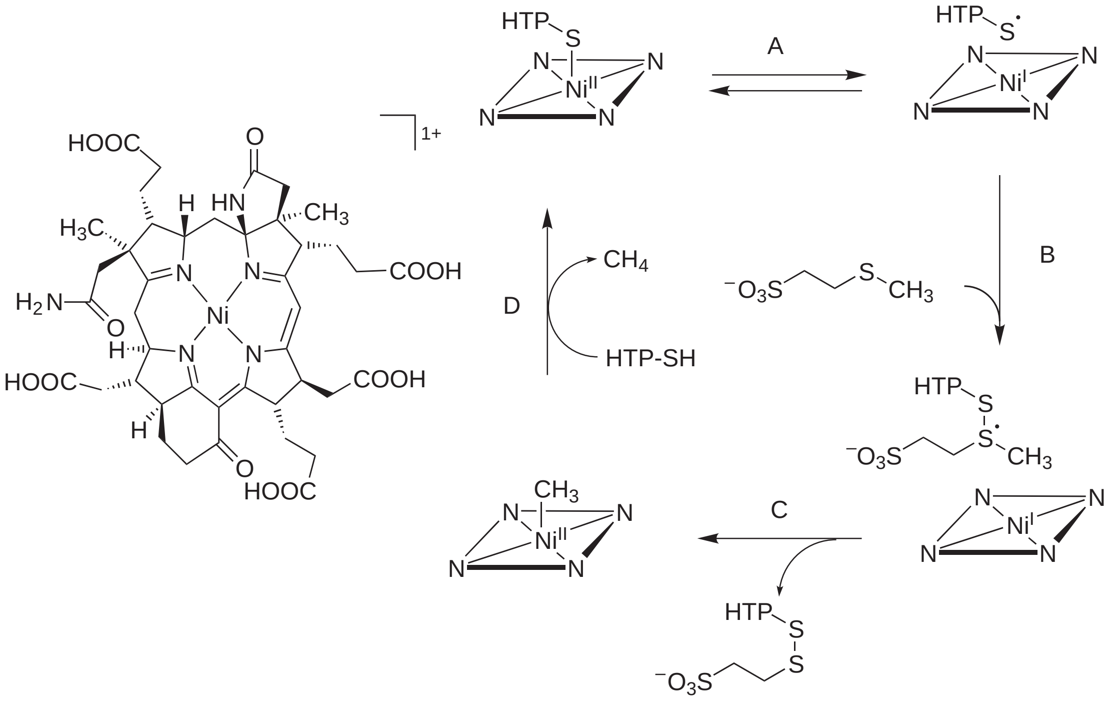
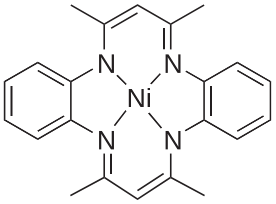
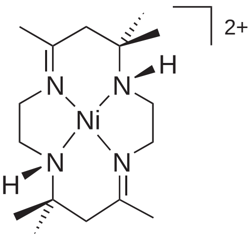
tetrapyrrole found in biological systems, having only five double bonds within the cycle. Macrocyclic ligands including porphyrins have been used to model the site in methyl-coenzyme-M reductase, and porphyrins seem to be natural models for the nickel–F_{430} site in methyl coenzyme-M reductase (MCR). However, the involvement of Ni^{I} in MCR has lead to considerable interest in the chemistry of Ni^{I} with F_{430} and isobacteriochlorins, the only tetra-pyrrolic ligands that afford isolable Ni^{I} species when reduced.[1849,1850] The reduction of Ni^{II} porphyrin systems very often results in the formation of a ligand-based radical rather than in metal-based reduction. Some useful models, both electrochemically as well as functionally, are the Ni complexes with cyclam-derived macrocyclic tetraaza ligands (**701**)–(**703**); compare Section 6.3.4.10).[1851,1852] The complexes were found to be homogeneous catalysts for the dehalogenation of cyclohexyl bromide by sodium borohydride with the effectiveness depending on the solvent and the structure of the complex. None of these complexes, however, cleaves methyl CoM to methane.



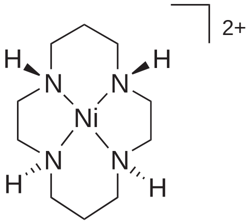
Scheme 10



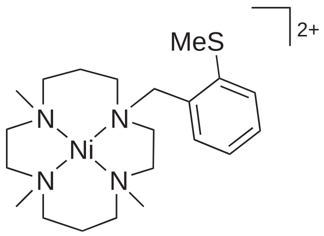
(**701**)



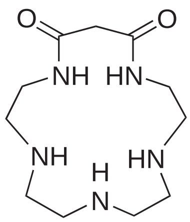
(**702**)



(**703**)



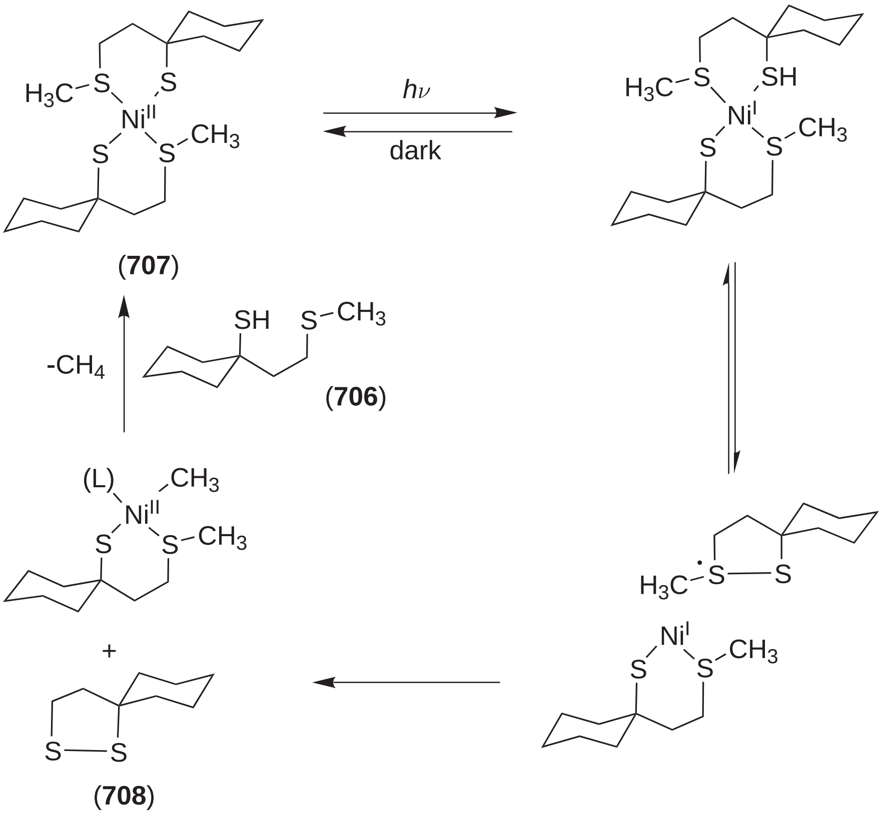
(**704**)



(**705**)

The cyclam-based complex (**704**) bearing a methylthio pendent arm has been proposed as a model for F_{430}.[1853] While participation of the thioether group in Ni coordination is observed neither in solution nor in the solid state, the Ni^{II} species is reversibly reduced to Ni^{I} around −0.7 V vs. SCE, followed by thioether bond cleavage and formation of a thiol group at more negative potentials. Reduction of (**704**) with Na/Hg in DMF produces small amounts of methane. In contrast to some initial reports,[1854,1855] the Ni^{II} complex of (**705**) is not capable to effect C—S bond cleavage of Me-CoM.[1856]

It has been demonstrated that the MCR enzyme is active only if the metal center of coenzyme F_{430} is in the Ni^{I} form.[1857] The natural substrate Me-CoM or simple methyl thioethers, however, do not react with Ni^{I} F_{430}, which has lead to the proposal of a catalytic mechanism in which the addition of a thiyl radical to the S atom of the thioether giving a sulfuranyl radical intermediate is the central step (Scheme 10).[266,1858] Such reactivity has been reproduced with the model substrate (**706**), which forms a square planar Ni^{II} complex (**707**). Upon irradiation (i.e., generation of a Ni^{I}/thiyl radical pair by excitation of the LMCT band), formation of the spirodisulfide (**708**) and methane is observed (Scheme 11).[1859] In order to model individual species involved in the catalytic cycle depicted in Scheme 10, pentacoordinate thiophenolate complexes of $[Ni^{II}(tmc)]^{2+}$ (tmc = tetramethylcyclam)[1967] and paramagnetic Ni^{II}–methyl derivatives of $[Ni^{II}(tmc)]^{2+}$ have been prepared and characterized.[1860–1862]



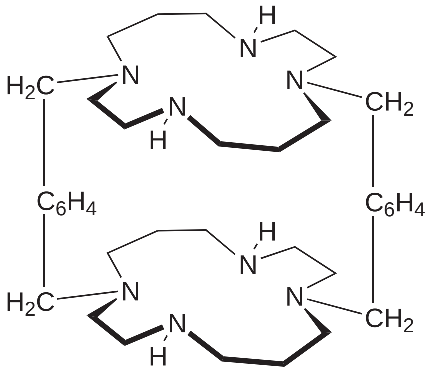
Scheme 11

6.3.4.12 Di- and Oligonuclear Ni^{II} Complexes with Compartmental Dinucleating Ligands

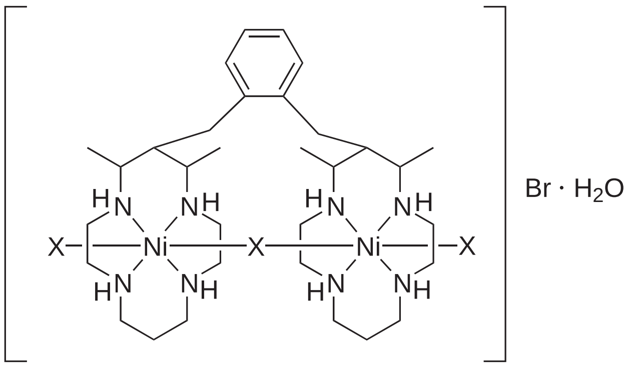
Due to the interest in electronic and magnetic metal–metal interactions as well as due to the occurrence of multimetallic sites in the active centers of various enzymes, di- and oligonuclear complexes of compartmental ligands are receiving increasing attention. Various types of multifunctional ligands have been designed and employed in order to preorganize the metal ions.

6.3.4.12.1 Complexes with bis(macrocyclic) ligands

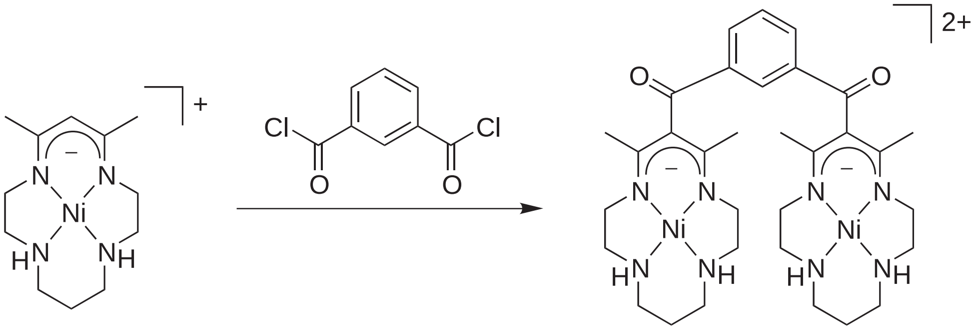
The covalent linkage of multiple macrocyclic moieties has proven to be an effective method for arranging two or more Ni ions in close proximity and in specific spatial arrangement. Preorganization can be tuned by the characteristics of the spacer fragment between the macrocycles, e.g., by its rigidity and size and by the orientation it imposes on the coordination subunits. In [Ni$_2$(**709**)](ClO$_4$)$_4$ the two Ni^{II} ions are each located in one cyclam subunit at a distance of 6.829 Å.[1863] The cylindical macrotricyclic topology enforces a face-to-face conformation of the two cyclam rings, and inclusion of substrate molecules in the cavity is expected. Likewise, in the dinuclear bismacrocyclic complex (**710**) the two cyclam rings are arranged in a face-to-face manner, and ligands such as X = Cl$^-$, Br$^-$, or CO$_3$$^{2-}$ adopt a bridging position. The chloro-bridged dinickel(II) complex features a pseudo-1D Ni—Cl alternate linear chain structure in the solid state and exhibits antiferromagnetic exchange coupling between the two Ni^{II} ions.[1864] By the reaction of the Ni^{II} complex (**711**) with isophthaloyl dichloride the dinuclear Ni^{II} complex (**712**) is obtained in which the two coordination planes are almost coplanar with the metal ions being 12.8 Å apart (Equation (26)).[1865]



(709)



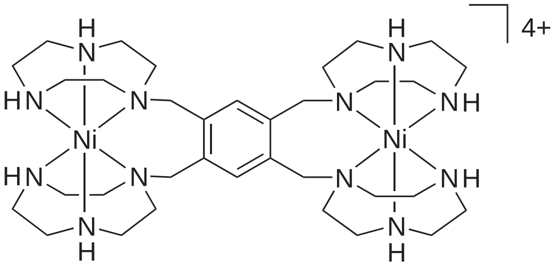
(710)



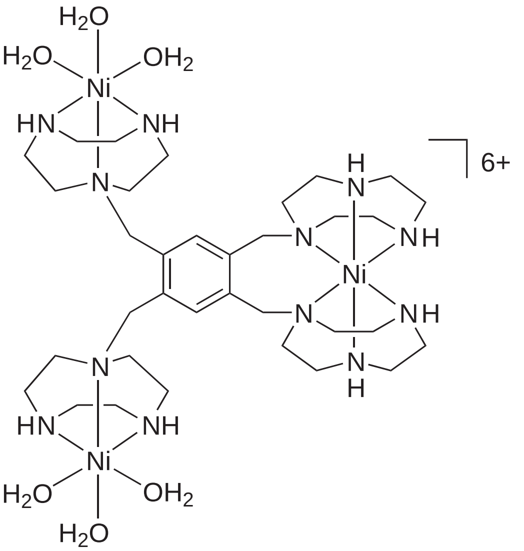
(26)

(711) **(712)**

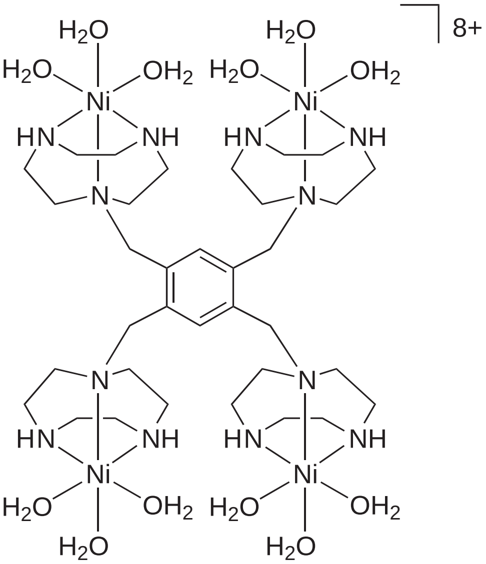
With a tetramacrocyclic ligand derived from four 1,4,7-triazacyclononane units that are attached to a central benzene ring, each two of the TACN subunits may sandwich one metal ion. Dinuclear, trinuclear, and tetranuclear Ni^{II} complexes (**713**)–(**715**) have been shown to form, depending on the stoichiometry and reaction conditions.[1866]



(713)



(714)



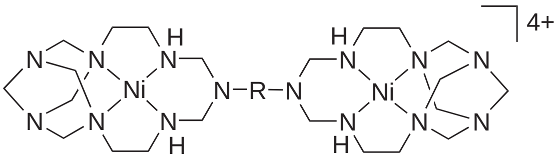
(715)

Template condensation reactions of the nickel(II) complex of 3,7-bis(2-aminoethyl)-1,3,5,7-tetraazabicyclo[3.3.1]nonane with formaldehyde and the appropriate primary diamines such as ethylenediamine, 1,4-butanediamine, and *p*-xylenediamine yield dinickel(II) complexes of bis-heptaazamacrocyclic ligands (**716**)–(**718**). Similarly, the dinuclear Ni^{II} complexes (**719**) and (**720**) were prepared by using $[Ni(2,3,2\text{-tet})](ClO_4)_2$, formaldehyde, and $NH_2—(CH_2)_n—NH_2$ ($n = 2$, 3, 4, 5, 6, 10) or melamine, respectively.

The electrochemical data indicate that each Ni^{II} ion is independent in all these cases, without interaction between the adjacent Ni^{II} centers.[1867–1871] Despite the absence of any electronic coupling, such dinuclear complexes with two Ni^{II} macrocyclic subunits in close proximity may show cooperative effects, e.g., in the binding of anionic guest molecules. In the case of (**720**), much higher association constants with sulfate have been observed, as compared to the related mononuclear melamine-substituted azacyclam complex. Stabilization of the sulfate adduct has been ascribed to H bonding between the sulfate coordinated to one Ni^{II} and a water molecule axially coordinated to the adjacent Ni^{II}. In the presence of sulfate, two single-electron Ni^{II}/Ni^{III} redox steps are observed.[1870]

In (**721**) and (**722**), the two Ni^{II} macrocyclic fragments are directly bridged by a short C—C linkage. The dimethylcyclam coordination subunits in (**721**) may adopt different conformations, with steric repulsion between the 1,3-diaxial methyl substituents being of major importance.[1872,1873] (**722**) has a folded structure with a torsion angle $Ni—C_{bridgehead}—C_{bridgehead}—Ni$ of 55° in the solid state, which corresponds to the lowest energy conformation according to molecular mechanics calculations.[1874]

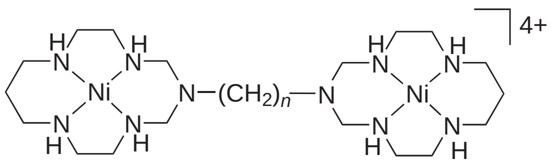
The denticity of the ligand compartments in bis(macrocyclic) Ni^{II} complexes can be increased by adding donor substituents to the macrocycles. For example, type (**723**) dinickel(II) complexes



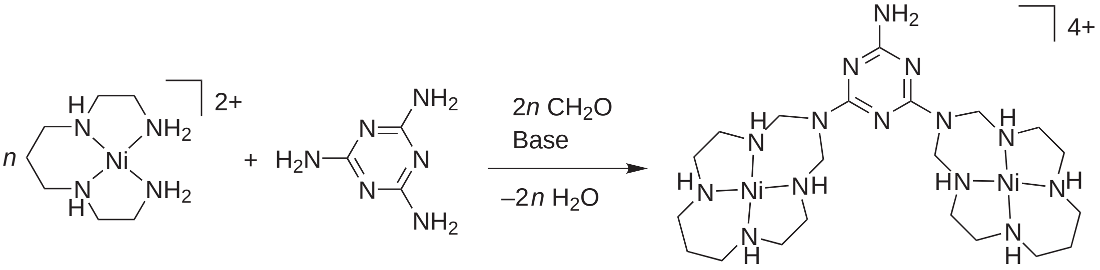
(716) R = $-(CH_2)_2-$

(717) R = $-(CH_2)_4-$

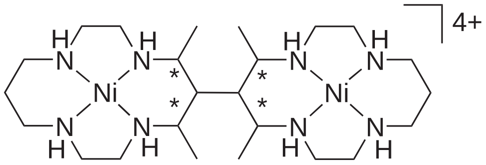
(718) R = $-p\text{-}CH_2\text{-}C_6H_4\text{-}CH_2-$



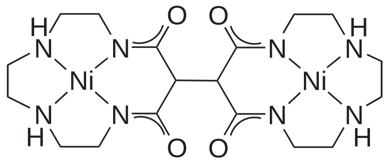
(719) n = 2, 3, 4, 5, 6, 10



(720)



(721)



(722)

of bis(pentadentate) TACN-derived ligands with various spacers have been investigated. Electrochemical potentials for the Ni^{II}/Ni^{III} couple decrease with the length of alkyl group linking the two coordination compartments, indicating that an increase in Ni· · ·Ni separation leads to a decrease in electrostatic repulsion in the oxidized state. Splitting of the oxidation waves due to separate one-electron oxidation steps has only been observed in the case of (**723a**) and (**723e**).[1875]

Pyrazolato-bridged bis(tacn) ligands and their dinickel complexes are mentioned in Sections 6.3.4.12.6 and 6.3.4.12.7.

6.3.4.12.2 Di- and oligonuclear complexes with open-chain alkoxo- or phenolato-based dinucleating ligands

Alkoxide or phenolate moieties are the most prominent bridging groups and are frequently incorporated in dinucleating ligand systems employed in nickel coordination chemistry. Compartmental ligands may be of the side-off (**724a**) or the end-off type (**724b**), or of the macrocyclic type (**724c**).[1876] Nickel complexes of the latter are described separately in the subsequent section.

Generic type (**724d**) dinickel(II) complexes built around an aliphatic μ-alkoxo fragment have been prepared with various combinations of X and Y donor groups and exogeneous coligands Z. *N*,*N*′-bridging diazine and diazole coligands Z (e.g., pyrazolate or phtalazine) have proven particularly suited. Some representative examples of ligands for the construction of type (**724d**) dinickel(II) complexes are discussed below.[1877–1880]

In most cases the Ni^{II} ions are low spin and in square planar coordination environment. Dinickel(II) complexes $[Ni_2L(pyrazolate)]$ of dinucleating ligands like (**725**) and dinickel complexes such as (**726**) feature two nearly reversible electrode processes at very negative potential,

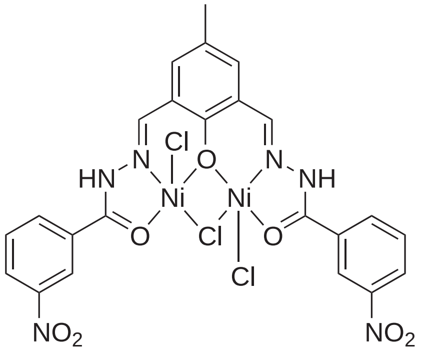
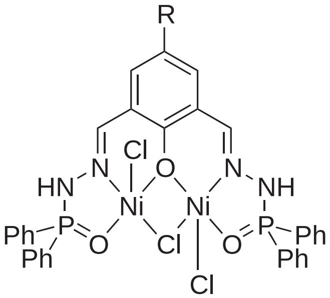
corresponding to the formation of Ni^INi^{II} and Ni^INi^I species.[1881] The reaction of pentadentate (**727**) with $NiCl_2$, however, gives trinuclear [Ni_3(**727**)(EtOH)Cl_5] with three distorted octahedral chromophores as well as dinuclear [Ni_2(**727**)Cl_3] with two distorted trigonal bipyramidal chromophores.[1880] The trinuclear species can be regarded as being formed out of the dinuclear compound onto which an additional $NiCl_2$ unit is stuck, concomitant with some conformational changes of the ligand. $NiBr_2$ only forms the dinuclear species, presumably because of steric effects. If the alkoxide bridging group is omitted, e.g., in (**728**), complexes of the type [Ni_2L_2] form, which for L = (**728**) have a double-stranded helix structure with the Ni^{II} ions in square planar environment, both in solution and in the solid state.[1882]

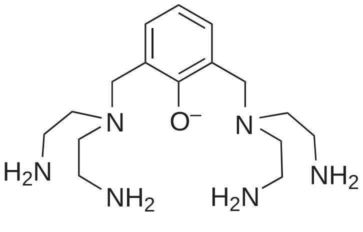
Various dinickel(II) complexes related to (**724d**) but with a phenolate bridging moiety, type (**724e**), have been investigated. To illustrate the great variety, (**729**) and (**730**) are depicted as examples.[1883,1884]



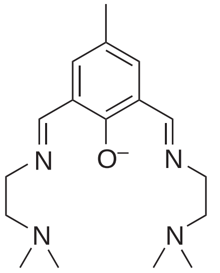
(**729**)



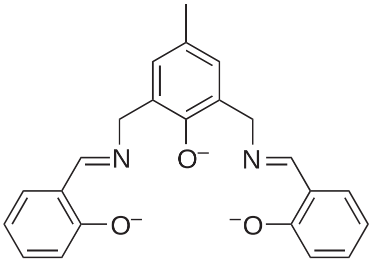
(**730**)



(**731**)



(**732**)

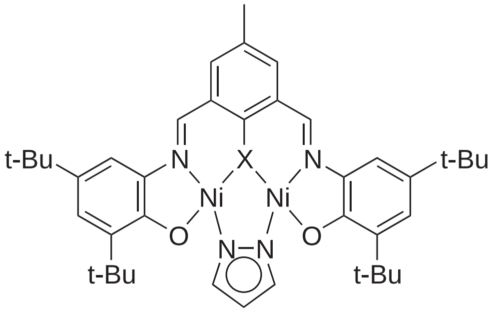


(**733**)

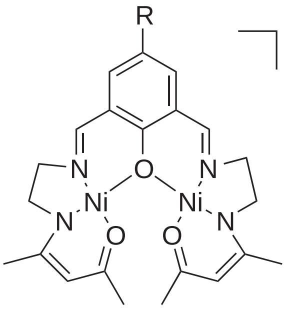
The flexible ligand (**731**) forms stable dinickel(II) complexes both in solution and in the solid state. The crystal structure of [Ni_2(**731**)Cl_3] reveals the bridging phenolato-O, a secondary Cl bridge, and two terminal Cl ligands, i.e., six-coordinate metal ions.[1885]

The reaction of (**732**) with $NiCl_2$ gives [Ni_2(**732**)(μ-Cl)Cl_2(H_2O)$_2$] with two high-spin six-coordinate metal ions, which are coupled ferromagnetically.[1886] In contrast, [Ni_2(**733**)(pz)(Hpz)(MeOH)] with a *N*,*N'*-bridging exogeneous pyrazolate is a mixed-spin species, since one Ni ion features a square planar coordination environment and the adjacent Ni is six-coordinate due to the binding of a MeOH and an additional pyrazole in the axial positions.[1887] A second complex, [Ni_4(**733**)$_2$(pz)$_2$(MeOH)], has been isolated with the same ligand. In the solid state, it adopts a zigzag tetranuclear structure, in which two mixed-spin building blocks are associated with two phenoxo bridges and one methanol bridge.

In (**734**), replacement of the phenolate group by a thiophenolate, i.e., replacement of the endogenous O by its homologue S, leads to significant differences in the solution and redox properties. The bulky *t*-butyl substituents induce good solubility and allow for physical studies in a range of solvents, including nonpolar ones.[1888] Both systems are reduced in two steps separated by several hundreds millivolts, indicating strong electronic interaction and stabilization of the mixed-valent form. However, while reduction is almost solvent-independent for (**734a**), (**734b**) exists as a mixture of solvated species in coordinating solvents, which strongly influences the redox properties. Overall, the sulfur dinuclear complex is harder to oxidize than the oxygen analogue.[1888]



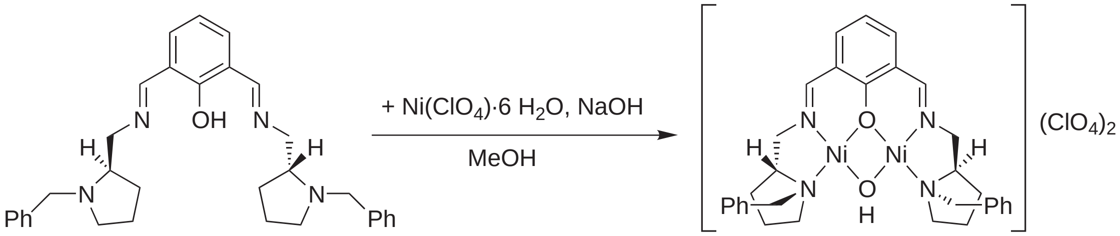
(734a) X = S
(734b) X = O



(735)

A twisted bifurcated shape is observed for the dinickel(II) complex of a bis(tetradentate) compartmental type (**724e**) ligand, (**735**).[1889] (**735**) is diamagnetic with both Ni^{II} being four-coordinate. NMR studies indicate C_2 symmetry of the bimetallic arrangement, which is confirmed by the crystal structure. Due to steric congestion, the two subunits of the complex (i.e., the two ketoenamine portions) cannot be coplanar, resulting in a twist of the two coordination planes against each other and a bifurcated overall shape. Racemization appears prohibited without breaking of metal–ligand bonds.

Attempts have been made to exploit the intrinsic C_2 symmetry of the phenolate-based dinickel core in enantioselective catalytic reactions. Therefore, enantiomerically pure C_2-symmetric ligands such as (**736a**) and the corresponding dinickel systems (**736b**) have been prepared (Equation (27)),[1890] and (**736b**) was tested in the epoxidation of unfunctionalized alkenes with sodium hypochlorite as the oxidant. The catalytic reaction was found to be highly pH dependent with an optimum at a pH of 9. While the complex is catalytically active, significant enantioselectivity was not achieved.



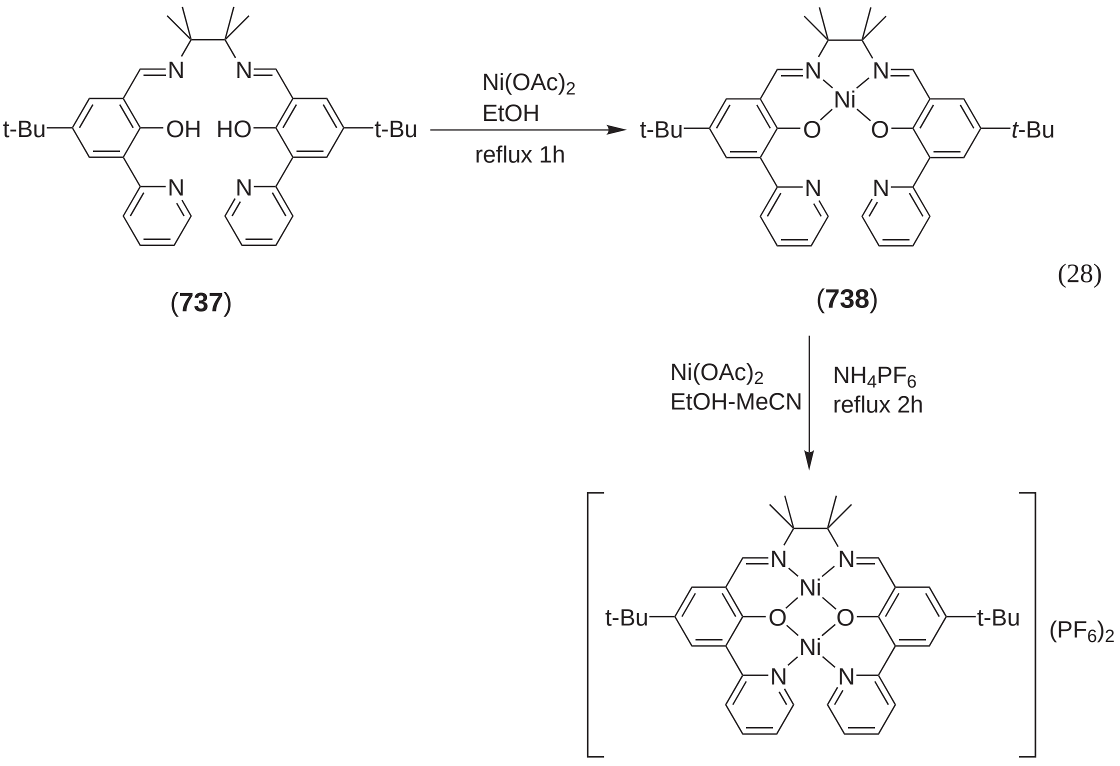
(736a) **(736b)**

(27)

Acyclic side-off dinucleating systems with nonequivalent binding sites are relatively scarce in nickel coordination chemistry. Stepwise metallation of (**737**) first gives mononuclear (**738**) and then dinuclear (**739**), where the first Ni^{II} occupies the salen-type N_2O_2 inner binding site and the second Ni^{II} binds to the pyridyl groups in the outer site.[1891] As revealed by an X-ray crystal structure, the former exhibits a square planar coordination geometry while the latter is ligated by two additional ethanol solvent molecules in axial positions. Because of the stepwise synthetic procedure (Equation (28)), heterobimetallic Ni^{II}/Cu^{II} complexes can also be obtained.

Unsymmetric compartmental ligands that allow for the controlled synthesis of unsymmetric Ni_2 or heterobimetallic NiM complexes have received particular attention.[1876,1892] A wide range of such ligands derived particularly from 2-hydroxy-3-hydroxymethyl-5-methylbenzaldehyde and 2-hydroxy-3-hydroxymethyl-bromo-benzaldehyde has now been prepared and used for Ni complexation. These ligands have monopodal iminic pendent arms and either mono- or dipodal aminic pendent arms and the terminal donors of the pendent arms can be provided by pyridine, imidazole, and tertiary amino groups.[1893–1897] Complexes are usually prepared by reaction of the requisite Ni^{II} salts with the preformed ligand.

The reaction of Ni^{II} perchlorate with (**740a**) gave the complex (**741**), in which the imine bond of the proligand had undergone hydrolysis. In the resulting dimeric Ni_2 structure with a Ni$\cdot\cdot\cdot$Ni distance of 3.088 Å, both metal ions are in octahedral coordination environment. When (**740b**) was used,



(**737**)

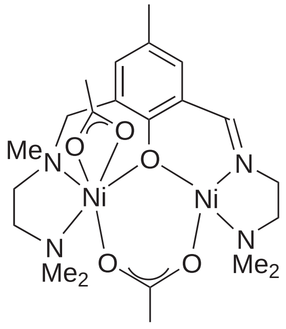
(**744**)

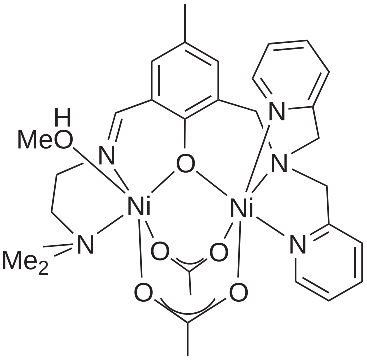


(**745**)

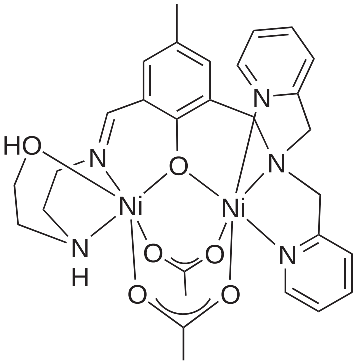
surprisingly complex (**742**) was obtained, i.e., both hydrolytic cleavage of the pendent imine function and loss of a C_2H_4 moiety from the terminal NEt_2 group had occurred. While loss of C_2H_4 has been suggested to proceed via a Hofmann elimination reaction, the ethylene which would be produced by this reaction has not been detected. For cleavage of the iminic pendent arm, the presence of both weakly coordinating anions (ClO_4^-, BF_4^-) and Ni^{II} cations appears to be required.[1898]

Strategies to control the binding mode of acetate to Ni_2 complexes of unsymmetrical compartmental proligands have been developed. The formation of a *syn–syn* bidentate acetate bridge is assumed to be a key feature, and complexes such as (**743**)[1894,1895,1897] (with a *syn–syn* bidentate acetate bridge augmented by a bridging N-bonded thiocyanate anion), (**744**)[1897] (which has the *syn–syn* bidentate acetate bridge augmented by a μ^2-η^1,η^2 acetate anion), and (**745**) (in which one acetate is chelated to the Ni atom in the aminic compartment with bridging between the two Ni atoms being provided by the cresolato-O atom of and a *syn–syn* bidentate acetate)[1895] have been obtained by subtle variations of the ligand scaffold and careful addition of the thiocyanate coligand. The synthetic procedure uses the same reaction conditions for all of the above products and it has been concluded that the presence of five-membered chelating rings derived from the iminic pendent arms gives rise to *syn–syn* bidentate acetate bridging whereas the introduction of a six-membered chelating ring at the iminic binding generates a monodentate bridging acetate.[1897]

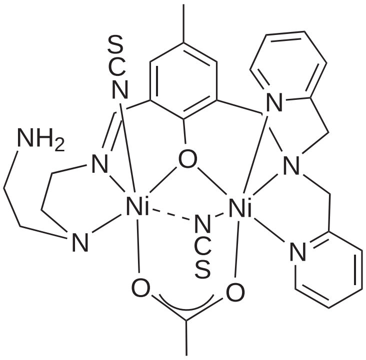
An unsymmetrical ligand capable of providing adjacent N_2O and N_3O donor compartments gives complex (**746**) that features a donor asymmetric Ni_2 core with two six-coordinate metal ions due to the binding of an additional methanol solvent molecule.[1894] Incorporation of the solvating atom into the pendent arms, i.e., increasing the donor capacity of the arm by an additional O atom afforded (**747**), in which the thermal alcohol is coordinated. In the presence of added thiocyanate ion, however, neither an additional terminal amine nor the terminal alcohol are coordinated, e.g., in (**748**), reflecting the comparative bond strengths of the putative donor groups.[1899] The two isothiocyanate anions in (**748**) are *trans* to each other and the isothiocyanato bridge is unsymmetric with Ni—N distances of 2.73 Å and 2.04 Å.



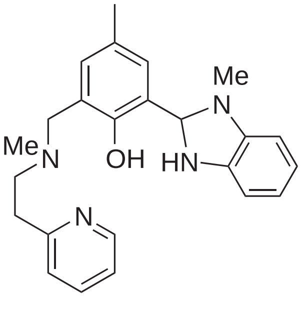
(**746**)



(**747**)



(**748**)



(**749**)

The unsymmetric phenolato-derived ligand (**749**) bearing a tridentate N_2O donor set and a bidentate NO donor set has produced a trinuclear Ni^{II} complex that incorporates two unusual tridentate acetate bridges in a μ^3-η^2,η^1 bridging mode, and the dihydrobenzoimidazole ring system present in (**749**) has been oxidized to a benzimidazole ring system.[1900]

6.3.4.12.3 Di- and oligonuclear complexes with compartmental macrocycles incorporating O bridges

Macrocyclic Schiff base compartmental ligands (**750**) (Robson-type ligands) derived from the [2 + 2] condensation of a 2,6-diformyl- or 2,6-diketo-substituted phenol and a diamine are very prominent in dinuclear Ni coordination chemistry.[1901–1903] Particular interest lies in magnetic exchange interactions between the adjacent metal ions as well as in bioinorganic chemistry, where such dinuclear complexes have been proposed as synthetic analogues for bimetallosites.

	R^1	R^2	*n*	*m*
(**750a**)	Me	H	3	3
(**750b**)	t-Bu	H	3	3
(**750c**)	Me	Me	2	2
(**750d**)	Me	H	2	2
(**750e**)	Me	H	2	3
(**750f**)	Me	H	2	4

The stereochemistry and the spin state of the Ni ion in the resulting complexes can be controlled by the ring size of the macrocycle. A larger cavity size (C_3 linkers) results in a weaker ligand field and Ni^{II} will adopt an octahedral geometry. For example, in [Ni$_2$(**750a**)(NCMe)$_4$]$^{2+}$ both metal ions bind MeCN ligands in the axial positions.[1903] Six-coordination can also be achieved by the assembly of two dinuclear units to give tetranuclear complexes with a central Ni_4O_4 cubane-type core.[1904] In contrast, [Ni$_2$(**750c**)]$^{2+}$ and [Ni$_2$(**750d**)]$^{2+}$ where the ligand incorporates C_2 linkers show square planar Ni^{II} centers and are diamagnetic.[1902,1905] Ligands (**750c**) and (**750d**) with reduced cavity size can accommodate only the small Cu^{II} and Ni^{II} ions because the "salen" (*N*,*N*′-ethylenedisalicyclaldiminate)-like entity embedded in the macrocyclic framework has little flexibility compared with salen itself. Disymmetric ligands with two different lateral spacers ((**750e,f**)) give mixed-spin ($S_1 = 0$, $S_2 = 1$) dinickel(II) complexes, while in strongly coordinating solvents the high-spin state ($S_1 = S_2 = 1$) is found for these systems, and even for [Ni$_2$(**750d**)]$^{2+}$.[1905] Symmetric (**750a**) can form heterodinuclear complexes like [PdNi(**750a**)(MeCN)]$^{2+}$, which was prepared in a stepwise fashion by reaction Pd^{II} acetate with the mononuclear Ni^{II} complex of the macrocycle. The Ni ion is six-coordinate with MeCN ligands in the axial position.[1906]

Similar observations have been made for type (**751**) ligands with saturation of the azomethine linkages, but the saturation has significant effects on various physicochemical properties of the dinuclear complexes.[1907] In [Ni$_2$(**751c**)(MeOH)$_2$(ClO$_4$)$_2$], each metal ion bears one methanol and one perchlorate ligand in the axial positions,[1908] and four axial water molecules are found in [Ni$_2$(**751c**)(H$_2$O)$_4$]$^{2+}$.[1909] In the presence of pyridine, the latter transforms into the square pyramidal complex [Ni$_2$(**751c**)(py)$_2$]$^{2+}$. Likewise, various N-donor ligands such as NH_3, imidazole, pyridine, pyrazine, etc., can be attached, and equilibrium constants for the replacement of axially bound methanol solvent molecules by these bases have been determined.[1910] Pyrazolate appears to act as an additional bridging ligand.[1910] Stepwise two-electron reduction and two-electron oxidation is observed electrochemically for [Ni$_2$(**751c**) (MeOH)$_2$ (ClO$_4$)$_2$].[1908] In general, reduction to the Ni^{I}Ni^{II} and Ni^{I}Ni^{I} species occurs at significantly higher potentials for complexes of type (**750**) ligands compared to type (**751**) ligands.[1905] Apparently, the reduced state is stabilized by the C=N groups. In the presence of acetate, complexes [Ni$_2$(L)(OAc)$_2$] (L = (**751a**), (**751c**), (**751d**), (**751e**)) have been isolated.[1907] The structure of [Ni$_2$(**751a**)(OAc)$_2$] shows that the macrocycle adopts a folded conformation and the acetate binds as a chelating bidentate ligand.[1907] However, in $[Ni_2(\mathbf{751c})(\mu\text{-}OAc)(H_2O)_2]^+$ the acetate bridges the two Ni ions, as do amino acids like glycine in $[Ni_2(\mathbf{751c})(\mu\text{-}O_2CCH_2NH_3)(H_2O)_2]^{2+}$ (and similarly for β-alanine and glycylglycine).[1911] The disymmetric ligand (**751b**) with different hole sizes forms a mixed-spin ($S_1 = 0$, $S_2 = 1$) complex $[Ni_2(\mathbf{751b})(H_2O)_2]^{2+}$, where two axial water molecules are bound to the high-spin ion nested in the larger cavity.[1909]

	n	m

(751c)	3	3
(751d)	4	2
(751e)	5	2

Additional coordinating side arms can be attached to the aminic N atoms of type (**751**) ligands. Picolyl pendent arms at one compartment give one hexadentate site and one tetradentate site (**752**). Two Ni ions can be inserted in a stepwise process to first give [Ni(**752**)] with a six-coordinate metal ion (which can be protonated at the azomethine N atoms to give $[Ni(\mathbf{752})H_2]^{2+}$) and the dinuclear $[Ni_2(\mathbf{752})]^{2+}$ with one six-coordinate and one four-coordinate Ni^{II}.[1912] (**752**) and related systems are also capable of forming heterdinuclear NiM complexes (M = Zn, Co. etc.). The Ni ion usually resides in the open site, either square planar or five-coordinate with an additional Cl ligand.[1913] A different strategy to increase denticity of the ligand is the use of spacers with additional donor atoms, e.g., (**753**).[1914,1915] Both dinickel complexes $[Ni_2(\mathbf{753})]^{2+}$ and $[Ni_2(\mathbf{753})(H_2O)_2]^{2+}$ have been structurally characterized. In the former, the Ni ions are in square pyramidal N_3O_2 environment and the macrocycle adopts a twisted configuration, while in the latter the Ni are six-coordinate due to two additional water ligands. Attachment of additional N-donors in (**754**) gives rise to two hexadentate coordination sites, and a dinickel(II) complex with six-coordinate metal ions and the pendent arms approaching from opposite sides of the macrocycle is proposed.[1916]

If the spacer contains potentially bridging alcohol groups, the nuclearity of the complexes depends on the spacer length. $H_4(\mathbf{755a})$ may accommodate four metal ions in its tetraanionic form. For example, the heterotetranuclear macrocyclic unit $[Cu_2Ni_2(\mathbf{755a})O(OAc)]^+$ is prepared from the dicopper precursor without scrambling of the metal ions. It contains a central O atom, an acetate spanning the two Ni ions, and the Ni and Cu ions, respectively, in an alkoxide-bridged side-by-side geometry.[1917,1918] The analogous thiophenolate-based ligand (**755b**) gives a tetranickel complex with five different bridging groups (thiophenolato-S, alkoxo-O, μ-1,1 acetato, μ-1,3 acetato, and a central μ_4-OH).[1919] In the case of shorter spacers, the alcohol groups remain noncoordinating, e.g., in type (**756**) complexes.[1920] In the latter, the two Ni^{II} ions are six-coordinate with anions and/or water molecules in the axial positions.

Considerable work has concentrated on the controlled synthesis of heterobimetallic NiM complexes of disymmetric Robson-type macrocycles.[1903,1921] (**757**) forms both $Cu^{II}Ni^{II}$ and $Mn^{II}Ni^{II}$ complexes. In $[CuNi(\mathbf{757})(H_2O)(DMF)]^{2+}$,[1922] the Cu^{II} resides in the N_2O_2 site with the ethylene lateral chain and assumes a planar geometry. The Ni^{II}, in the N_2O_2 site bonded by the tetramethylene chain, acquires a pseudo-octahedral geometry by further interaction with DMF and water oxygen atoms at the axial sites. A very strong antiferromagnetic interaction operates between the metal ions ($J = -90\,cm^{-1}$ based on $-2JS_{Cu}S_{Ni}$). The electronic structure of the spin-doublet ground state was studied by means of EPR spectroscopy, and the recognition of a four-line hyperfine structure due to Cu ($I_{cu} = 3/2$) and the relationships $g_\perp > g_\psi$ and $A_\psi = -(1/3)$ A_{cu} (A_{cu} is the hyperfine coupling constant for the analogous CuZn complex)[1923,1924] demonstrated that one unpaired electron of the spin-coupled complex exists in the molecular orbital of d_{z^2} character comprising d_{z^2}(Cu) and d_{z^2}(Ni) and is delocalized over the CuNi dinuclear core. The dinuclear $Ni^{II}Mn^{II}$ complex $[NiMn(\mathbf{757})(DMF)_2]^{2+}$ has the Ni^{II} in the N_2O_2 site with the ethylene

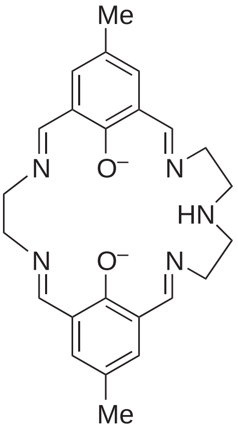
(**757**)

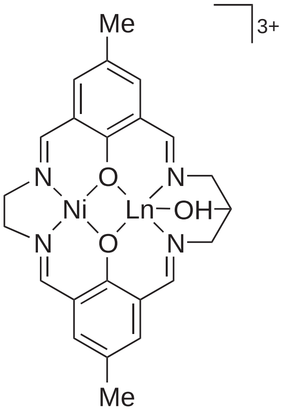
lateral chain and the Mn^{II} in the N_2O_2 site derived from the tetramethylene lateral chain.[1925] The Ni^{II} has a planar geometry and is diamagmetic. Cyclic voltammetry indicates that the NiMn complex is reversibly reduced to a $Ni^{I}Mn^{II}$ species (near −0.1 V vs. SCE) and oxidized to $Ni^{II}Mn^{III}$ species (near +1.5 V). The deeply green-colored $Ni^{I}Mn^{II}$ complex was generated *in situ* by controlled potential reduction and shows three visible bands of significant intensity at 570 nm, 640 nm, and 800 nm. These bands are attributable to *d–d* transitions of planar Ni^{I}.[1926]

Further distinction of the metal binding sites is achieved by an additional amine N atom within one lateral chain to provide a four-coordinate and a potential five-coordinate site. A series of $Ni^{II}M^{II}$ (M = Mn, Fe, Co, Ni, Cu, Zn) complexes of (**758**) have been obtained which contain planar Ni^{II}.[1927] A macrocyclic ligand with an additional alkoxo group is able to coordinate simultaneously Ni^{II} and various Ln^{III} ions (Ln = La, Ce, Pr, Nd, Sm, Eu). Both in solution and in the solid state, three Cl coligands are bound to the lanthanide ions in [(**759**)Cl_3].[1928] Ni complexes of unsymmetrical compartmental macrocycles having $N(amine)_2O_2$ and $N(imine)_2O_2$ metal binding sites are still limited. [Cu(**760**)] reacts with $NiCl_2$ to form dinuclear [$CuNiCl_2$(**760**)].[1929]

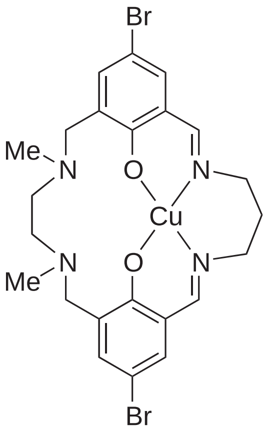
(**751b**) reacts with $VO(acac)_2$ to give a mixture of oxovanadium(IV) and -(V) complexes.[1930] This mixture reacts with Ni^{II} perchlorate to afford three complexes $[(V^{IV}O)($**751b**$)Ni(H_2O)_2]^{2+}$, $[Ni($**751b**$)(V^{IV}O)]^{2+}$, and $[\{(V^{IV}O)($**751b**$)Ni(H_2O)\}\{V^{V}O_2\}(H$**751b**$)\}]^{2+}$. Related oxovanadium(IV)–nickel(II) complexes of symmetrical macrocyclic ligands have also been prepared.[1931]



(**758**)



(**759**)



[Cu(**760**)]

Instead of the aliphatic spacers of the Robson-type ligands, other groups have been used to link the two bis(imino)phenolato subunits and such ligands have been employed in Ni coordination chemistry. Tetraanionic (**761**) forms neutral complexes [Ni_2(**761**)] with diamagnetic square planar metal ions, which are resistant to hexacoordination even in strongly coordinating γ-picoline.[1932] Pseudomacrocyclic structures are observed in dicationic (**762**), where the two dioxime ligands are connected via strong hydrogen bonds. Type (**762**) complexes can be doubly deprotonated at the dioxime units to give neutral dinickel complexes with hexacoordinate metal ions due to coligands in the axial positions (the complex with pyridine has been structurally characterized).[1932,1933]

(**763c**)

Pyridine-*N*-oxide-derived ligands (**763**) are neutral analogues of the Robson-type systems and may also form dinuclear Ni complexes. Attempts to prepare $[Ni_2(\mathbf{763a})]^{4+}$ by treating (**763a**) with nickel nitrate, however, yielded $[Ni_2(\mathbf{763c})(H_2O)_4](NO_3)_4$ due to partial solvolysis of two Schiff base groups. It shows a nonplanar stepped structure where *cis* coordination sites of the hexacoordinate metal ions are occupied by water.[1934] The Ni^{II} ions are coupled antiferromagnetically ($J = -15.5\,cm^{-1}$).

The expanded pyridine-modified macrocycle (**764**) is able to accommodate four Ni^{II} ions in a dimer-of-dimer arrangement.[1935] Molecular-sized chiral cavities are present in dinickel calixsalen complexes (**765**). These have been proposed as hosts for guests molecules, and inclusion of MeCN has been found in the solid state.[1936] Multidentate macrocycles incorporating only a single phenolate bridging unit are also capable of forming dinickel complexes, given the macrocycle size is large enough as in (**766**).[1937] They strongly prefer coligands that form a secondary bridge between the metal ions (Cl in (**766**)).

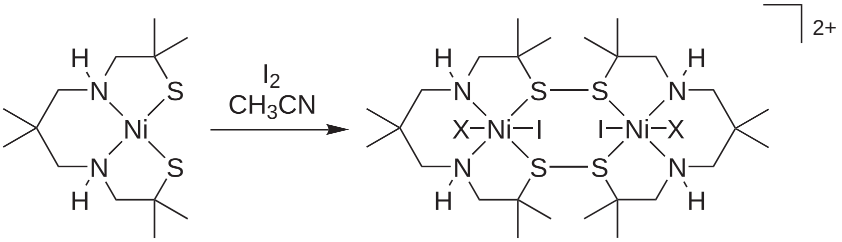
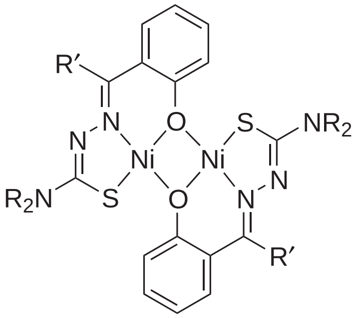
(**767**) (**768**)

6.3.4.12.4 *Di- and oligonuclear complexes with thiolate-based dinucleating ligands*

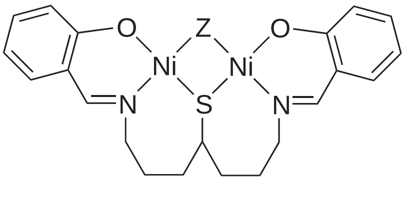
Thiolates exhibit a strong tendency to bridge Ni^{II} ions (as well as other metal ions), but often the reaction between the metal ion and a thiolate ligand is difficult to control and the formation of higher aggregates and polymers is observed. Control of the product nuclearity can be achieved, *inter alia*, by appropriate fine-tuning of the ligand scaffold, e.g., by steric bulk or by incorporating the thiolate donor within a macrocyclic framework.[1938] Another difficulty is the propensity of Ni-bound thiolates to undergo oxidation, e.g., to sulphenates or sulphinates.[1952] The noninnocence of Ni-bound thiolate adds to the interest in such systems. Besides their redox activity, Ni-bound thiolates may also become protonated, which is of relevance to the reactivity of the Ni/Fe hydrogenase active site. For example, the dinuclear Ni^{II} thiolate complex (**767**)[199] is reversibly protonated at a single terminal thiolate-S by upon addition of $[H(OEt_2)_2]\{B[3,5\text{-}(CF_3)C_6H_3]_4\}$ to give (**768**).[200] An analogous complex that features a benzylated thiolate ligand has been structurally characterized. Upon reaction with iodine, mononuclear Ni^{II} complexes of linear tetradentate $\{N_2S_2\}$ diaminodithiolate ligands are oxidatively coupled to give dinuclear complexes of macrocyclic bis(disulfide)tetramines (**769**),[1939] which are easily demetallated.



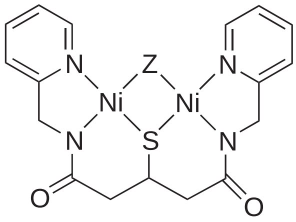
(**769**) X = CH_3CN



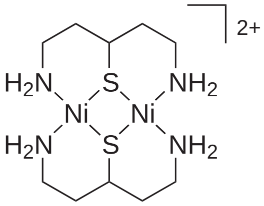
(**770**)



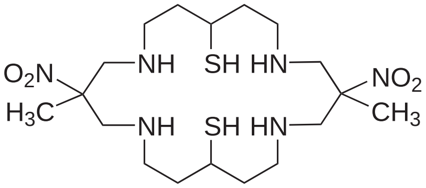
(**771**)



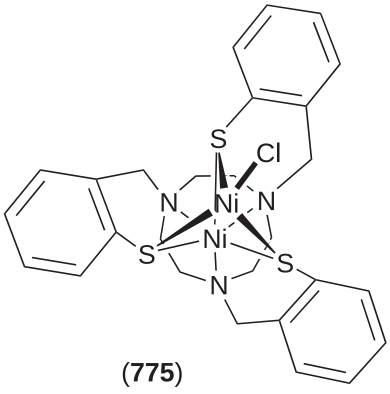
(**772**)



(**773**)



(**774**)



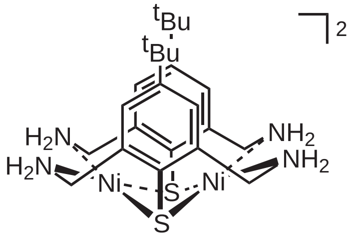
(**775**)

Deprotonated thioamides, which bind in the imino thiolate form ($RN=CR\text{-}S^-$), exhibit a very low bridging tendency due to their lower S-basicity. If incorporated in a chelate scaffold with phenolate-O, it is the latter which forms the bridge, e.g., in (**770**).[1940,1941]

Ni^{II} complexes of dinucleating ligands containing an endogenous aliphatic thiolate bridging group and iminic or aminic side arms, e.g., (**771**) and (**772**), can accommodate three-atom bridges (e.g., carboxylates), two-atom bridges (e.g., pyrazolate), or one-atom bridges (provided they are large enough, e.g., iodide) at the Z site.[1942,1943] Complex (**773**) which contains two Ni^{II} ions in a square planar N_2S_2 coordination environment (even in aqueous solution)[1944] can serve as a starting material for the preparation of macrocyclic bis(thiolato) bridged dinickel complexes via template reactions. Reaction of (**773**) with formaldehyde and nitroethane in basic methanol gives a diamagnetic dinickel(II) complex of (**774**) with two essentially planar *cis*-$\{NiN_2S_2\}$ chromophores. One O atom of each nitro groups interacts axially with the respective Ni ion at quite long distances (2.89 Å).[1945]

Even better control of the nuclearity is achieved with aromatic thiolate donors such as thiophenolates, because these are less electron rich.[1938] A hexadentate, triazacyclononane-derived ligand with 4-*t*-butyl-2-mercaptobenzyl pendent arms forms homo- and heterodinuclear Ni complexes.[1946] In the Ni_2 complex (**775**) one metal ion is six-coordinate with a *fac*-N_3S_3 donor set and the other is four-coordinate in a S_3Cl environment, both Ni^{II} being high spin and strongly antiferromagnetically coupled ($J = -135\,cm^{-1}$) due to the face-sharing octahedral/tetrahedral arrangement.

Tridentate 4-*t*-butyl-2,6-di(aminomethyl)thiophenolate forms dinickel(II) complex (**776**) in a controlled fashion, and the $\{N_2Ni(\mu\text{-}SR)_2NiN_2\}$ core structure is also retained in solution.[1947] (**776**) readily adds another equivalent of the ligand to afford (**777**) containing two face-sharing octahedral $\{NiN_3S_3\}$ subunits.[1948] (**777**) shows a rich electrochemistry and can be chemically oxidized by iodine to a robust $Ni^{II}Ni^{III}$ species, which has been structurally characterized. The mixed-valent $Ni^{II}Ni^{III}$ compound is valence-trapped and has a $S = 3/2$ ground state below ~80 K. Upon going from (**776**) to (**777**), the Ni^{III} state becomes more easily accessible.[1948] Similar chemistry has been observed for the corresponding amine-selenophenolate complexes.[1947,1948] Linking two of the terminal amine groups in (**776**) leads to (**778**), in which the hexadentate chelating ligand allows for the axial binding of coligands to the central $\{N_2Ni(\mu\text{-}SR)_2NiN_2\}$ core because of its weaker ligand field.[1950] Binding of anions (e.g., thiocyanate) to (**778**) occurs selectively at the axial trans positions of the Ni^{II} ion in the closed compartment, i.e., where the secondary N atoms exert a slightly weaker ligand field. The resulting complex (**779**) features adjacent octahedral *cis*-$\{NiN_4S_2\}$ and planar *cis*-$\{NiN_2S_2\}$ sites. Binding of thiocyanate is accompanied by an unexpected inversion of configuration at both secondary N-donor atoms. Both (**778**) and (**779**) undergo two successive reductions, assigned to formation of the $Ni^{II}Ni^{I}$ and $Ni^{I}Ni^{I}$ species.[1950] An axial coordination site can be occupied intramolecularly by an additional NH donor of a slightly modified septadentate ligand.[1951] In (**780**), the remaining position trans to this NH is the reactive site where solvent molecules and anionic coligands L such as thiocyanate and chloride can bind.



(**776**)

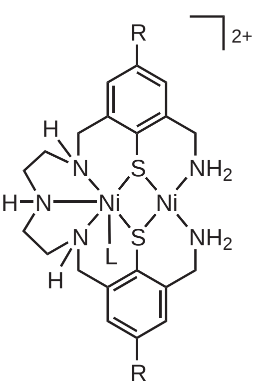
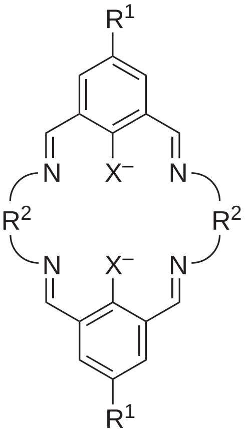
(**778**)

(**779**) L = NCS^-

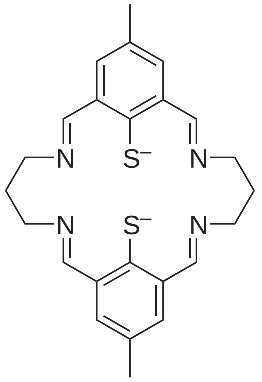


(**780**)

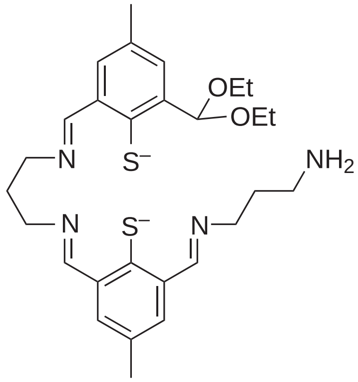
Dinickel(II) complexes of general type (**781**) macrocycles have been studied in detail since the early 1990s.[1952–1955] (**782**) is the most prominent scaffold employed, and the structures of its dinickel(II) complexes show the anticipated differences from the analogous phenolate complexes.[1946,1954,1956,1957] In particular, the thiophenolate complex $[Ni_2(\mathbf{782})]^{2+}$ is bowed in dramatic contrast to the flat structures of the phenolate analogues, i.e., the S atoms adopt a pyramidal geometry whereas the oxygen atoms are trigonal. Furthermore, the nickel atoms in the phenolate complexes are in octahedral environment (and hence high spin) whereas in the thiophenolate complex the nickel atoms are in a square planar environment (and hence low spin). $[Ni_2(\mathbf{782})]^{2+}$ features a rich redox chemistry with four one-electron processes observed, and the two reversible reduction processes (−1.46 V, −1.01 V vs. 0.01 M $AgNO_3$|Ag in MeCN solution) as well as the two oxidation processes (+0.63 V, +1.07 V; the first process is reversible, while the second is quasi-reversible) occur more readily than in the analogous phenolate complex (−1.40 V, +1.05 V, +1.26 V).[1954] The oxidation waves are sensitive to axial coordination by solvent molecules, as is expected for the formation of Ni^{III}. The mixed valent $Ni^{II}Ni^{III}$ thiophenolate complex has been isolated but is unstable even in the solid state.[1953] An unusual trinickel(II) complex, $[Ni_3(\mathbf{783})_2]^{2+}$ was obtained from incomplete template cyclisation and acetal formation in ethanolic solvents. It incorporates one central high-spin Ni^{II} ion and two square-planar low-spin Ni^{II} ions within each acyclic ligand.



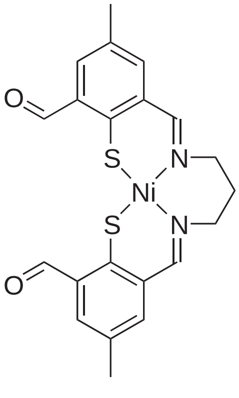
(**781**)
(X = O, S)



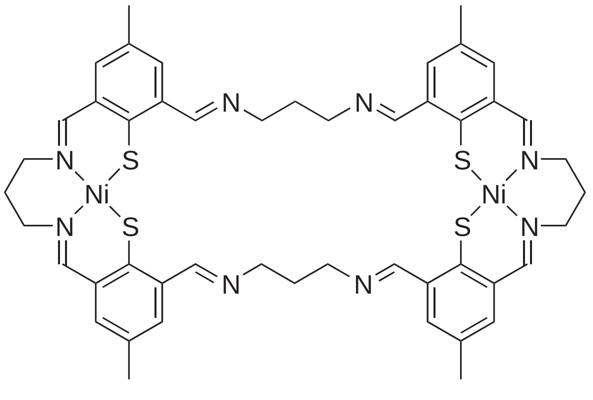
(**782**)



(**783**)



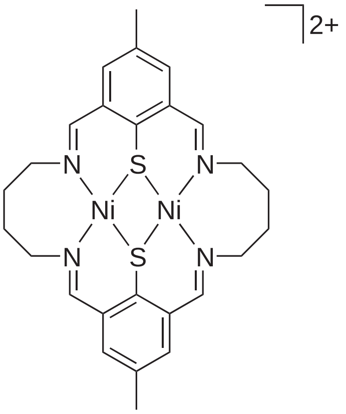
(**784**)



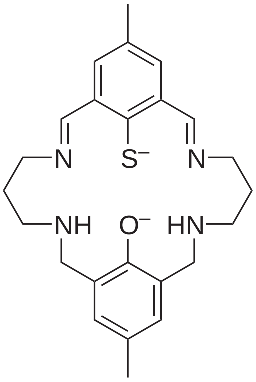
(**785**)

By judicious choice of reaction conditions an acyclic Ni^{II} complex (**784**) could be isolated, which serves as a valuable starting material for the preparation of unsymmetrical and mixed metal complexes by subsequent reaction with various amines. Also, a symmetrical Schiff base macrocycle of larger size has been obtained as a minor byproduct upon condensation of (**784**) with 1,3-diaminopropane. The resulting Ni^{II} complex (**785**) is again bimetallic, although room to bind four metal ions is in principle available.[1367]

Enlargement of the metal binding cavity was expected to favor high-spin nickel centers in thiophenolate macrocycles.[1953] Complex (**786**) incorporating 1,4-diaminobutane linkages is still diamagnetic in the solid state but exhibits a greater tetrahedral distortion away from square planar than is the case for the analogous $[Ni_2(\mathbf{782})]^{2+}$. Consistent with this, (**786**) exhibits an increased tendency to coordinate solvent molecules in the axial sites. When reacted with NaSCN, both systems form complexes with two thiocyanate ions on just one of the two nickel ions, even if four equivalents of NaSCN are used. It is assumed that the charge-neutral nature of the product complex is important for the course of this reaction, since it leads to reduced solubility and consequent crystallization from the reaction mixture.[1958–1960] [(**786**)(NCS)$_2$] thus contains juxtaposed high and low-spin Ni^{II} ions despite the provision of potentially equivalent macrocycle binding sites. Metal–ligand bonds for the high-spin Ni ions are typically about 0.15–0.20 Å longer than those for the low-spin nickel ions.[1961–1963]



(786)



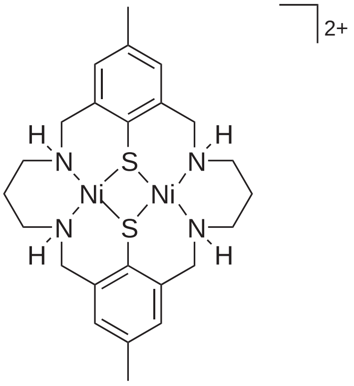
(787)

Several examples of dinickel(II) complexes of Schiff base macrocycles with mixed phenolate/thiophenolate bridging units have been reported.[1960,1964,1965] Again, [Ni$_2$(**787**)(MeCN)$_2$]$^{2+}$ has Ni^{II} ions in differing spin states,[1965] despite the provision of two potentially equivalent macrocycle binding sites. One nickel ion is in a square planar environment whilst the other is octahedrally coordinated due to axial binding of two acetonitrile solvent molecules. The replacement of one thiophenolate diimine moiety of (**782**) by a phenolate diamine moiety in (**787**) leads to a significant reduction of the ligand field strength of the resulting macrocycle, since in the absence of coordinating counterions the dinickel(II) complexes of (**782**) are diamagnetic. In the presence of NaSCN, the dinickel(II) complex of (**787**) produces an example in which both Ni^{II} centers are six-coordinate and high spin. Similar to the complexes of (**782**) just two thiocyanate ions are incorporated (even when four equivalents are used), forming a neutral complex which precipitates from solution. In this case, however, rather than both anions binding to the same nickel ion,[1953] one thiocyanate binds to each of the two Ni ions, as is also seen for the phenolate amine analogue.[1959] One of the two metal ions coordinates an additional DMF solvent molecule to give [Ni$_2$(**787**)(NCS)$_2$(DMF)]. Both Ni^{II} ions are established to be high-spin by examination of the structural information,[1966] and this was confirmed by a magnetic moment determination.[1960,1964] This is a rare example of a high-spin square pyramidal thiolate-coordinated Ni^{II} ion.[1967] In the case of the pure amine phenolate macrocycle, the axial binding ability of dinickel(II) complexes gives a delicate balance between high-spin square pyramidal and high-spin octahedral geometries, which depends on the choice of axial ligand.[1962,1968–1970] The phenolate ligand has insufficient ligand field strength to induce spin pairing, but reducing the ring size of the phenolate macrocycle (e.g., by replacing one propylene lateral unit by an ethylene lateral unit) does result in the observation of square planar (diamagnetic) nickel ions in the smaller compartment.[1962] The redox potentials for [Ni$_2$(**787**)(MeCN)$_2$] in MeCN at -1.50(irrev.) V, -1.23(quasir.) V, $+0.65$(irrev.) V, and $+1.00$(rev.) V vs. 0.01 M AgNO$_3$|Ag do not simply fall in between those obtained for the dinickel(II) complexes of the corresponding bis(thiophenolato) and bis(phenolato) bridged species, and in particular the reductions, which are expected to be more sensitive to changes to the macrocyclic donors, are quite different.[1964]

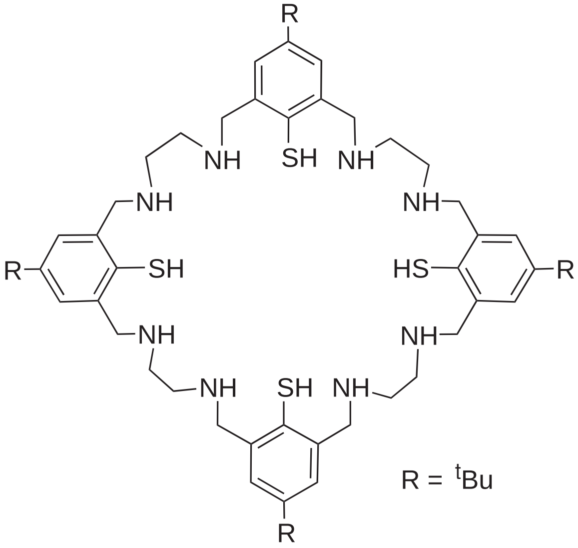
The Ni^{II} templated $(2+2)$ condensation of 2,6-diformly-4-methyl-thiophenol with 1,5-diaminopentan-3-ol gives a tetranuclear complex with a combination of thiophenolate and alkoxide bridging.[1971] The large Schiff base macrocycle provides two bridging thiophenolate and alkoxy moieties, and encircles four Ni^{II} ions with a central μ_4-OH$^-$ group. There are five different bridging groups, and all four Ni^{II} ions have different coordination environments, largely due to the mixture of acetate ions and acetic acid molecules which differentiate the two faces of the planar Ni_4 array. The Ni^{II} ions in this complex are six-coordinate and high spin, as was observed in the tetraphenolate analogues.[1960,1964,1972–1974]

Whereas most of the complexes described above can be electrochemically reduced or oxidized, no structurally characterized examples of metal-centered redox products are known and reported examples of isolated redox products are few. These include the one-electron oxidation product of $[Ni_2^{II}(\mathbf{782})]^{2+}$, the black complex $[Ni_2(\mathbf{782})Ce(NO_3)_6]$, in which the oxidation is believed to be primarily metal centered, and the macrocyclic ligand oxidation product obtained in low yields from the oxidation of $[Ni_2^{II}(\mathbf{786})]^{2+}$ with iodine.[1953,1955,1964]

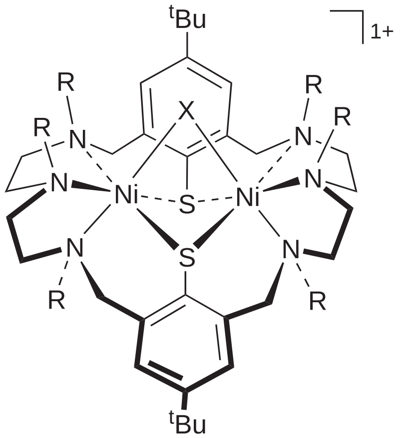
In general, the amine analogues of Schiff base macrocycles are more robust than the parent Schiff bases. The dinickel(II) complex (**788**) of a tetraamine thiophenolate Schiff base macrocycle was prepared by sodium borohydride reduction of the appropriate Schiff base macrocyclic complex.[1975] Despite the acid workup, the Ni^{II} ions remain bound and in the +2 oxidation state, possibly due to the experiment being carried out in air. As for $[Ni_2(\mathbf{782})]^{2+}$ the macrocycle is bowed and the Ni^{II} ions are in square planar coordination environments. However, in this case the greater flexibility of the amine bonds allows formation of a bowl structure with the "walls" provided by the phenyl rings and the alkyl lateral chains, thus distinguishing the two faces of the macrocyclic complex. Electrochemical experiments show that (**788**) is harder to reduce than the Schiff base counterpart (−1.86(quasirev.) V and −1.18(rev.) V vs. 0.01 M $AgNO_3|Ag$, in MeCN).[1953,1975] Contrary to what is expected from comparison with related mononuclear Ni^{II} thiophenolate species,[1976–1978] potentials for the two oxidation processes occur at the same values as those observed for the imine analogue (+0.69(rev.) V and +1.10(quasirev.) V).[1953,1975]



(**788**)



(**789**)

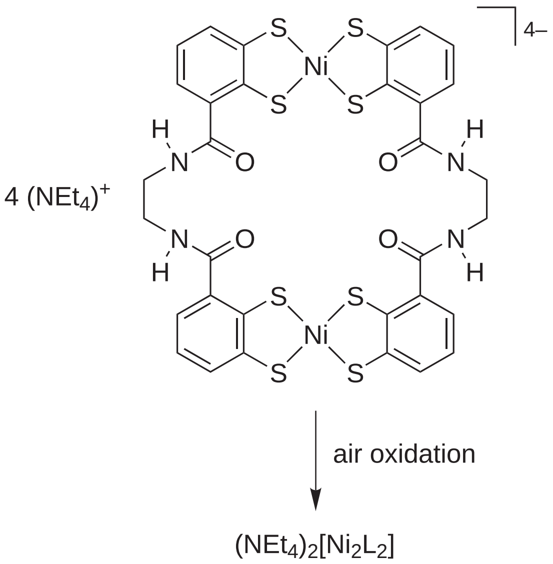


(**790a**) R = H, X = Cl
(**790b**) R = Me, X = Cl
(**790c**) R = Me, X = OH

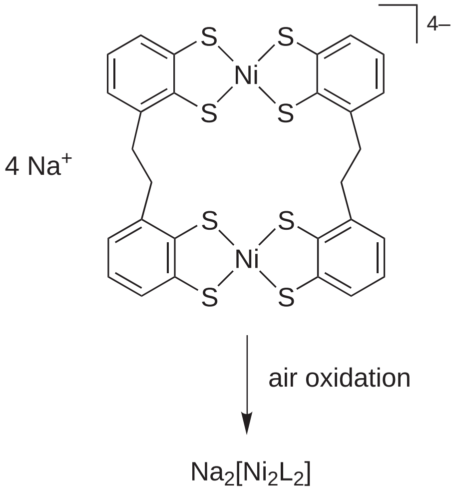
Three Ni^{II} complexes have been produced from the large, metal-free amine macrocycle (**789**)·8HCl by neutralizing *in situ* with NEt_3 and adding an appropriate amount of a suitable Ni^{II} salt. A purple, diamagnetic, neutral dinickel(II) complex and a tetranickel(II) perchlorate complex were prepared.[1979] The latter complex was converted to the neutral thiocyanate salt and structurally characterized.[1979] It features a mixture of square planar (low-spin) and octahedral (high-spin) Ni^{II} ions and seems to link together two independent dinickel complexes, because pairs of thiophenolate-S form doubly bridged pairs of Ni centers rather than connecting all of the nickel centers together. The two octahedral centers have bound two thiocyanate ions in *cis* positions.[1979] A related tetranickel(II) complex of a 40-membered macrocyclic octaamine-thiophenolate ligand has also been reported.[1980]

Face-sharing bioctahedral dinickel complexes (**790**) with a central $[N_3Ni(\mu\text{-SR})_2(\mu\text{-X})NiN_3]$ core featuring coordinatively unsaturated Ni ions are formed from a macrocyclic amine thiophenolate ligand.[1981] Permethylation drastically facilitates substitution at the X position, possibly due to the more hydrophobic microenvironment. While (**790b**) readily reacts with NBu_4OH to give (**790c**), complex (**790a**) was found to be unreactive. All three complexes undergo two successive electrochemical one-electron oxidations assigned to formation of the $Ni^{II}Ni^{III}$ and $Ni^{III}Ni^{III}$ species, but the latter is not stable on the timescale of the cyclovoltammetric experiment, in contrast to related coordinatively saturated Ni amine-thiolate complexes. Differences of the redox potentials for (**790a–c**) follow the trend expected from the ligand field strength.[1981] (**790c**) reacts with CO_2 in MeOH to give the methylcarbonato bridged complex, presumably via an intermediate hydrogencarbonato species.[1982] While primary alcohols show this CO_2 fixation reaction, secondary or tertiary alcohols do not, which is ascribed to the restricted space within the hydrohopbic binding pocket.

Bis(benzenedithiolate) ligands with an appropriate spacer between the benzenedithiolate donors form dinuclear Ni^{II} complexes (**791**) and (**792**), in which the square planar NiS_4 subunits are linked in a double-stranded fashion by the carbon backbone and they adopt a coplanar arrangement in a stair-like manner.[193] In both cases, Ni^{II}_2 and Ni^{III}_2 have been isolated. Electrochemical redox transformation shows a single two-electron wave, indicating that no strong intramolecular interaction of the metal ions exists. Reduction is more difficult and less reversible for (**792**) with the shorter spacer unit, because the electron-donating alkyl bridge creates a more electron-rich environment.



(**791**)

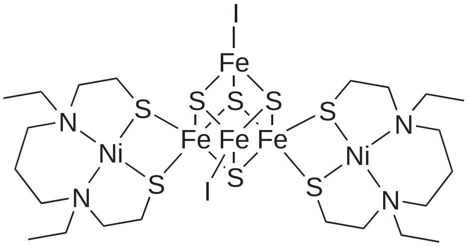


(**792**)

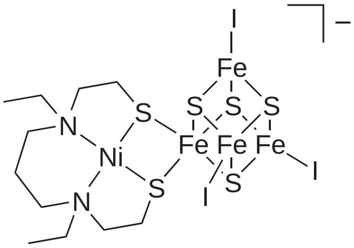
6.3.4.12.5 Heterobimetallic Ni/Fe complexes as model systems for the Ni/Fe hydrogenase and CO-dehydrogenase/acetyl CoA synthase active sites

Thiolate-bridged dinickel complexes and, in particular, heterobimetallic Ni/Fe complexes have attracted much interest as model systems for the hydrogenase enzymes. A review covering this field of biomimetic Ni coordination chemistry has appeared.[1983] An important synthetic route to thiolate-bridged heterobimetallic complexes is the addition of a solution of a metal complex with labile ligands to a mononuclear metal thiolate complex, although the high tendency of metal thiolate complexes to aggregate and to form homometallic clusters is an often encountered obstacle to this strategy. In order to control the cluster-forming process, the thiolates of the mononuclear thiolate precursor are often incorporated within a polychelate ligand that wraps around the metal center. The chelate effect then prevents dissociation of the thiolate-containing ligand and directs subsequent reactions with metal salt and complex reagents towards the terminal thiolate donors. Mixed NiFe complexes have most commonly been obtained via reaction of a Ni^{II} thiolate complex with a labile Fe species, giving a range of synthetic models for the NiFe hydrogenase active site.

Reaction of the Ni^{II} thiolate species [Ni(L)] (L = *N*,*N*′-diethyl-*N*,*N*′-bis(2-mercaptoethyl)-1,3-propanediamine) with the tetraiodo cluster anion $[Fe_4S_4I_4]^{2-}$ yields $[Ni(L)(Fe_4S_4I_2)(L)Ni]$ (**793**).[1984] It incorporates a dithiolate bridge between Ni and Fe centers with a Ni—Fe distance of 2.827(1) Å and exhibits a quasi-reversible oxidation wave at $E_{1/2} = +0.15$ V (vs. SCE). The corresponding monosubstituted cluster anion $[Ni(L)Fe_4S_4I_3]^-$ (**794**) was also reported.[1985]

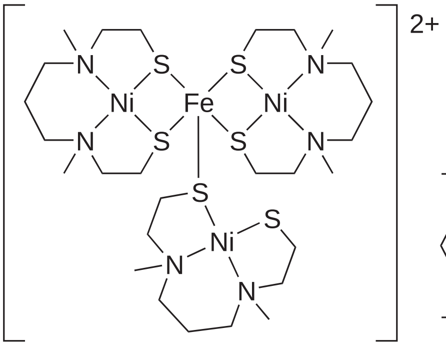


(**793**)

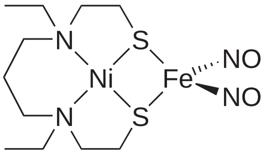


(**794**)

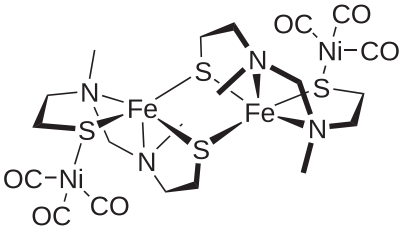
The same Ni^{II} thiolato building block and the respective methyl derivative have also been utilized in various other reactions with Fe^{II} complexes. Treatment with $[Fe(H_2O)_6](ClO_4)_2$ gave $[\{Ni(L)\}_3Fe](ClO_4)_2$ (**795**), the single-crystal X-ray structure of which confirms the formation of a Ni_3Fe cluster with mono- and dithiolato bridges.[1986,1987] It contains a central high-spin Fe^{II} surrounded by five thiolate donors, which form bridges to three square planar Ni^{II} centers. The remaining sixth thiolate is at a nonbonding distance of 3.197(8) Å, while the Ni^{II} centers have retained their square planar arrangements. The Ni—Fe distances in (**795**) are 2.976(4) Å, 3.123(3) Å, and 3.269(4) Å. A further Ni–Fe complex derived from [Ni(L)] was obtained from the reaction with $[Fe(CO)_2(NO)_2]$ to give $[Ni(L)Fe(NO)_2]$ (**796**).[1988] It shows the Ni^{II} ion in a square planar N_2S_2 environment with the Fe center in a distorted tetrahedral coordination environment ligated by two bridging thiolates and two terminal NO ligands. As the NO groups are bound in a linear fashion, they may be regarded as formally $3e^-$ donors. The oxidation state at Fe can therefore be assigned as −2 with the complex having an overall 18-electron configuration. The Ni—Fe distance is relatively short at 2.797(1) Å with the Ni—S—Fe ang1es somewhat acute at 76.11(4)°, similar to the angles of 74° observed in the NiFe hydrogenase active site.[1989] (**796**) exhibits a quasi-reversible oxidation at $E_{1/2} = -0.12$ V (vs. SCE) assigned to the Fe(−2/−1) couple on the basis that oxidation of [Ni(L)] does not occur below +0.86 V (vs. SCE).



(**795**)



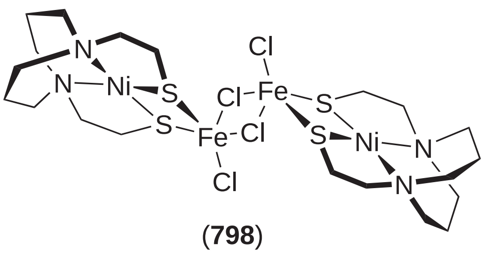
(**796**)



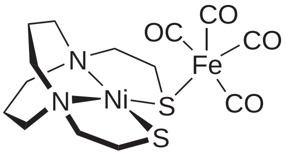
(**797**)

In a related approach, reaction of [Ni(dsdm)] (H_2dsdm = *N*,*N*′-dimethyl-*N*,*N*′-bis(2-sulfanylethyl)ethylenediamine)) with K[HFe(CO)$_4$] gave [Fe(dsdm)Ni(CO)$_3$]$_2$ (**797**).[1990] In this case, however, reshuffling of the ligands and of the metal oxidation states occurred, since the product consists of a Ni(0)–Fe^{II}–Fe^{II}–Ni(0) core, with one thiolate from each dsdm ligand bridging the two Fe^{II} centers and the remaining thiolates bridging the Fe^{II} and Ni(CO)$_3$ moieties. The Ni—Fe distance in (**797**) is relatively long at 3.899(1) Å.

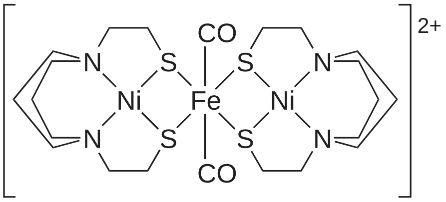
A number of thiolate-bridged NiFe systems have been reported to result from (H_2L′)-(L′ = *N*,*N*′-bis(2-mercaptoethyl)-1,5-diazacyclooctane), which reacts with Ni^{II} to first yield [Ni(L′)] as a suitable precursor complex. This has subsequently been treated with a variety of Fe^{II} compounds.[1991–1993] For example, reaction with anhydrous FeCl$_2$ gives [Ni(L′)FeCl-(μ-Cl$_2$)ClFe(L′)Ni] (**798**),[1993] in which the Ni^{II} and Fe^{II} ions have square planar and pseudo-square pyramidal geometries, respectively, and lie 3.100(1) Å apart. The thiolate donors and the bridging Cl ligands provide the basal plane to the square pyramid at Fe^{II}, with the terminal Cl occupying the axial site to give a planar Fe$_2$(μ-Cl)$_2$ core. (**798**) shows a reversible reduction at $E_{1/2} = -0.64$ V assigned to a Ni^{II}/Ni^{I} couple, and an irreversible reduction at $E_{pc} = -1.53$ V (vs. NHE). The reaction of [Ni(L′)] with [Fe$_2$(CO)$_9$] leads to [Ni(L′)Fe(CO)$_4$] (**799**).[1992] In this case the Ni and Fe centers remain in their original oxidation states of +2 and 0, respectively, and the Fe(CO)$_4$ fragment is simply bound to [Ni(L′)] via a single thiolate bridge at a large Ni—Fe distance of 3.76(1) Å. (**799**) was one of the early examples that confirmed the ability of Ni-coordinated thiolates to bind to Fe–carbonyl fragments with some control over stoichiometry. Upon oxidation, (**799**) forms [Ni(L′)Fe(CO)$_2$(L′)Ni](BF$_4$)$_2$ (**800**) in which Fe^0 has been oxidized to Fe^{II}.[1992] The Fe^{II} ion in (**800**) links two Ni(L′) units each through two thiolate bridges. The Ni ions remain in the Ni^{II} formal oxidation state in a square planar N$_2$S$_2$ donor set, and the Ni—S distances do not change significantly while the Ni—Fe distance decreases from 3.76(1) Å in (**799**) to 3.088 Å in (**800**), which is accompanied by a decrease in the Ni—S—Fe angle from 89.3(4)° to 76.99(7)°.



(**798**)



(**799**)



(**800**)

Reaction of pentadentate (H_2L″) (L″ = *N*,*N*′-dimethyl-*N*,*N*′-bis(2-mercaptoethyl)-bis(aminoethyl)sulphide) with Ni^{II} forms [Ni(L″)]. When treated with [FeCp(CO)$_2$I], this Ni^{II} thiolate complex gives rise to [Ni(L″)FeCp]I (**801**), which is related to the reduced from of the NiFe hydrogenase enzyme.[1994] In (**801**), the thioether donor occupies the apical position of a square pyramidal coordination geometry, and the Ni—S(thioether) bond (2.283(6) Å) is shorter than the Ni—S(thiolate bridge) distances (2.308(6) Å and 2.315(6) Å). The Ni(μ-S)$_2$Fe core exhibits a very acute Ni—S—Fe bridging angle of 58–59° (compared with 74° in [NiFe] hydrogenase from *D. gigas*),[1989,1995] which brings the two metal ions within close proximity (2.54 Å, i.e., similar to the value of 2.5–2.6 Å observed for the Ni—Fe distance in the Ni—SI form of the enzyme.[1996–1998]

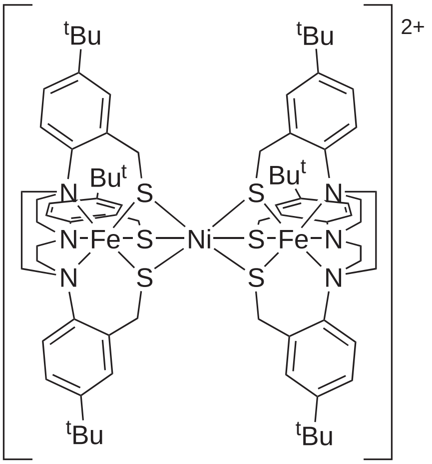
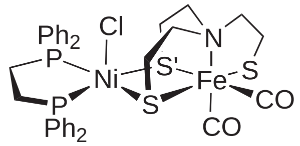
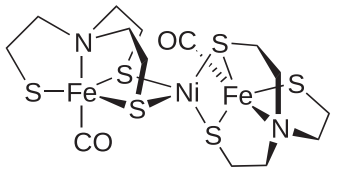
(**802**)



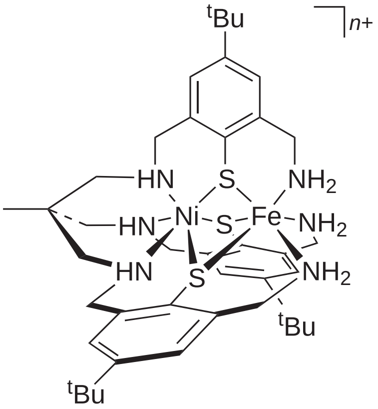
(**803**)



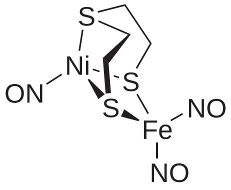
(**804**)



(**805**)



(**806**)

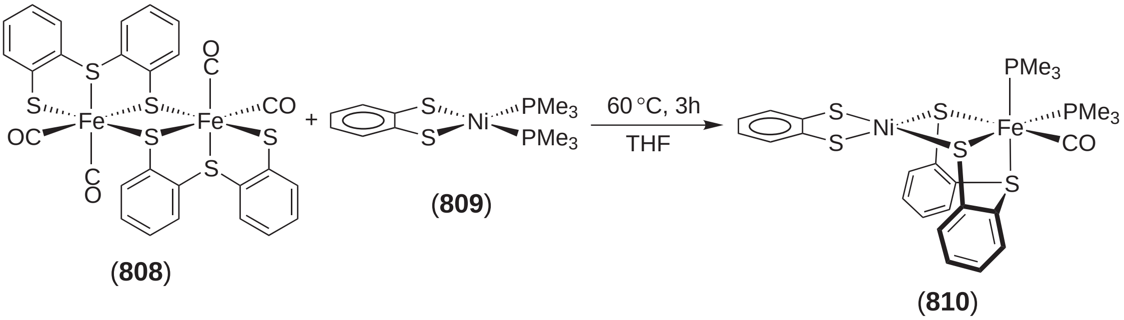


(**807**)

Instead of terminal N-donor ligands at the Ni center, soft phosphines have frequently been employed since these are better models for the soft cysteine sulfurs of the enzyme. For example, addition of [$Fe_3(CO)_{12}$] to [(dppe)Ni(pdt)] (dppe = ethane-l,2-diphenylphosphine, pdt = 1,3-propanedithiolate)[1999] gives the neutral heterobimetallic complex [(dppe)Ni(pdt)$Fe(CO)_3$] (**802**).[1994] It should be noted that a bridging derivative of 1,3-propanedithiolate is relevant in the active site of [Fe]-only hydrogenase.[2000,2001] In (**802**), the Ni coordination sphere has a distorted tetrahedral arrangement and the angle between the Ni–S1–S2 and Fe–S1–S2 planes of 80.3° compares with an angle of 81° in the enzyme.[1989,1995,2002]

In a reverse methodology, construction of thiolate-bridged Ni—Fe cores starts from a chelating thiolate ligand already bound to Fe and subsequent reaction of with a source of Ni^{II}. A set of four redox-related complexes [Fe(L)Ni(L)Fe]$^{+/2+/3+/4+}$ (L^{3-} = 1,4,7-tris(4-*t*-butyl-2-mercaptobenzyl)-1,4,7-triazacyclononane) was prepared using this approach.[2003–2005] Reaction of the mononuclear species [Fe(L)][2005] with $NiCl_2 \cdot 6H_2O$ and subsequent metathesis yields [Fe(L)Ni(L)Fe] $(PF_6)_2$ (**803**), the crystal structure of which confirms the three face-sharing thiolate bridged octahedra with two terminal Fe^{III} ions and a central Ni^{II} ion. (**803**) exhibits three reversible redox processes, two reversible oxidations and a reversible reduction at $E_{1/2} = +0.69\,V$, $-0.02\,V$, and $-0.90\,V$ (vs. Fc/Fc^+). It was concluded, however, that any assignment of the formal metal oxidation states to individual centers via a localized charge model was inappropriate, because the one-electron oxidations and reductions affected all the three metal ions simultaneously.[2005] It was confirmed that the Fe ions remained equivalent in all four compounds, consistent with some computational studies of the active site of [NiFe] hydrogenase from *D. gigas*.[2006,2007] According to these studies, redox chemistry of the active site involves the cluster as a whole, but the Fe remains in the same redox state throughout.

Several bis(thiolato) bridged NiFe complexes have been prepared by the reaction of $[Fe(L)(CO)]^{-}(L^{3-}=N(CH_2CH_2S)_3{}^{3-})$ and appropriate Ni^{II} species. For example, treatment with $[dppeNiCl_2]$ under CO gave $[\{Fe(L)(CO)_2\text{-}S,S'\}NiCl(dppe)]$ (**804**) where the Ni^{II} is found in a distorted square pyramidal geometry with two bridging thiolate moieties occupying two *cis* positions in the basal plane.[2008,2009] The remainder of the coordination sphere comprises a dppe molecule in the basal plane and a Cl^{-} ion at the axial position. (**804**) was the first literature example of a model complex featuring a bis-thiolate bridged heterodinuclear Ni—Fe center with CO at the Fe^{II}. When the reaction was performed under nitrogen, the monocarbonyl rather than the dicarbonyl complex was formed. The CO ligands may also be replaced by a single NO.[2010] Reaction of $[Fe(L)(CO)]^{-}$ with the DMSO solvate of $NiCl_2$ gave a trinuclear FeNiFe complex (**805**) in which the central Ni^{II} ion resides in an almost regular tetrahedral thiolate environment.[2009] Complex (**810**) resulted from the reaction of dinuclear (**808**) with labile (**809**).[2011] Its bridging Ni—S distances (2.230–2.241 Å) are distinctly longer than the terminal Ni—S distances (2.14–2.25 Å), but the latter are typical for diamagnetic four-coordinate Ni^{II} thiolate species. The $[Ni(SR)_2]$ fragment withdraws electron density from the Fe center of the $[Fe(CO)L_2(SR)_2]$ core, thus causing a blue-shift of the $\nu(CO)$ frequency.



(**808**) (**809**) (**810**)

A particularly elaborate strategy for obtaining NiFe heterobimetallic complexes uses preorganized dinucleating ligand scaffolds, e.g., for the synthesis of complex (**806**) which is based on a compartmental mixed amine thiophenolate ligand that enforces triple thiolate bridging.[2012,2013] (**806**) was prepared by sequential addition of $NiCl_2$ and $FeCl_2$ to a solution of the ligand. The synthesis does not formally involve the formation of the Ni^{II} complex as a direct precursor, but presumably this occurs *in situ*. (**806**), like the related compounds (**803**),[2003–2005] has interesting electrochemical properties. It shows a reversible oxidation at $E_{1/2}=+0.45\,V$ and a reversible reduction at $E_{1/2}=-0.43$ vs. SCE, and these redox states were characterized as: $[Ni^{III}(L)Fe^{III}]^{3+} \Leftrightarrow [Ni^{II}(L)Fe^{III}]^{2+} \Leftrightarrow [Ni^{II}(L)Fe^{II}]^{+}$.

Dinuclear Ni^{II} complexes can also serve as precursors for the synthesis of heterobimetallic NiFe systems. Thus, treatment of $[Ni(\mu\text{-}SCH_2CH_2SCH_2CH_2S)]_2$ with $[Fe(NO)_2(SePh)_2]^{-}$ in the presence of $NaNO_2$ yields (**807**),[2014] illustrating that a monometallic fragment with terminal thiolates is not a prerequisite for forming NiFe complexes (mononuclear fragments may well be generated from the dinickel starting material in solution, however). In (**807**) the Ni is presumably reduced to Ni^{0} and is found in a distorted tetrahedral arrangement with S(thioether)—Ni—S(thiolate) angles of ca. 90°. The very acute Fe—S—Ni angle gives rise to a Ni—Fe distance of 2.8 Å, which is similar to the characteristics of the oxidized form of the NiFe active site of *D. gigas* hydrogenase.

In view of the X-ray crystallographic findings for the Ni/Fe active site of carbon monoxide dehydrogenase (CODH),[41,42] which showed the Ni to be part of an [Ni–Fe–S] cluster, the single example of a synthetic $NiFe_3S_4$ cubane-type cluster (**812**) is of particular interest.[2015] Examples for larger mixed Ni/Fe/S clusters include $[Fe_3Ni_5S_6I_8]^{4-}$.[2016] Previous to the X-ray crystal structure of CODH, it was believed that the Ni is not part of the Fe/S cluster but is attached to it via a bridging thiolate (from cysteine). Hence, attempts have been made to prepare CODH model systems with the $Ni(\mu\text{-}SR)[Fe_4S_4]$ motif. Prominent examples are compounds (**793**), (**811**), and (**813**), in which two Ni^{II} are covalently bound to an Fe_4S_4 core via bridging thiolates. The Ni coordination geometry remains nearly unchanged with respect to the mononuclear Ni precursor complexes.[1984,2017]

Mononuclear Ni complexes have been investigated as functional models for individual steps of the reactions mediated by the CODH/acetyl coenzyme A synthase.[2018–2020] These are mentioned in the respective sections on mononuclear Ni complexes. The dinuclear type (**770**) complexes are active catalysts for CO oxidation in aqueous medium with electron transfer to methylviologen and production of CO_2.[2021] The proposed mechanism involves CO interaction with the Ni^{II} and subsequent nucleophilic attack by water, followed by decarboxylation of the $Ni–COO^-$ intermediate by the methylviologen.

6.3.4.12.6 Di- and oligonuclear complexes with dinucleating ligands incorporating diazine, diazole, and triazenido bridging units

The N—N groups of diazoles and related compounds (e.g., pyrazolate, triazolate) as well as the N—N group of diazines (like pyridazine, phtalazine) are very useful bridging units in Ni^{II} coordination chemistry. Such dinuclear complexes have been studied, *inter alia*, with respect to magnetic and electronic exchange interactions as well as cooperative substrate activations. Somewhat related dinucleating ligands are those based on a naphtyridine unit. The intrinsic C_2 symmetry of the naphtyridine-based dinickel core (e.g., (**814b**)) has been exploited in enantioselective catalytic reactions.[2022]

While attempts to prepare binary Ni^{II} pyrazolates by reacting pure metal with molten pyrazoles were largely unsuccessful, air-stable polymeric compounds of composition $[Ni(4\text{-}Xpz)_2]_x$ (X = H, Cl) as well as the corresponding 3,5-dimethylpyrazole derivatives $[Ni(4\text{-}Xdmpz)_2]_x$ were obtained by the reaction of nickellocene with the appropriate pyrazole.[2023] Extended-chain double pyrazolate-bridged structures are assumed in all cases, but spectroscopic and magnetic data indicate a planar $\{NiN_4\}$ chromophore in 4-Xpz ligands vs. a tetrahedral $\{NiN_4\}$ chromophore in the case of the more bulky 4-Xdmpz compounds. Pyrazolate-bridged dinickel systems may also be obtained from mononuclear precursors by thermal transformation. For example, bis(3,5-dimethylpyrazole-1-carbodithioato)nickel(II) (**815**) undergoes a facile irreversible decomposition to give the dimeric complex (**816**).[2024]

Dinickel complexes (**817**), which contain both bridging and terminal pyrazolate ligands, have allowed the detection of different types of dynamic processes, namely *N*,*N*′ metal shift, rotation of the terminal ligand, and bridging-terminal intermolecular pyrazolate exchange.[2025] Spin saturation transfer experiments reveal a slow motion of the terminal pyrazolate ligand that consists of a combination of *N*,*N*′-metallotropic shift and rotation around the Ni—N bond, but exchange of the bridging and terminal pyrazolate ligands was only detected as a very slow process in cross experiments with different pyrazolate ligands. In contrast, (**817**)·HBr displays dynamic NMR spectra due to rapidly interconverting isomers in solution.

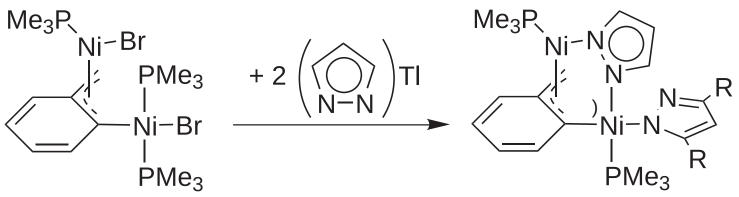
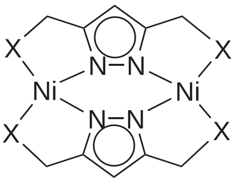
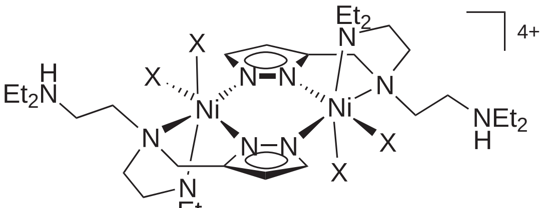
(**815**) (**816**)



(**817**)



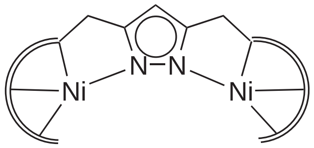
(**818**)



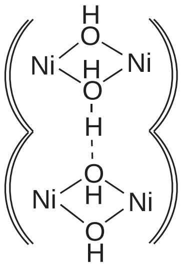
(**819**) X = EtCN, MeOH

Chelating side arms have been attached to the 3- and 5-positions of the dinucleating pyrazole, in order to control the nuclearity and the characteristics of pyrazole-bridged dinickel species. Bis(pyrazolato)-bridged dinickel(II) complexes of general type (**818**) are formed with 3,5-bis(2′-pyridyl)pyrazole[2026] and pyrazole-3,5-dicarboxylic acid.[2027] In the former case, a complex with two octahedral Ni^{II} ions due to coordination of methanol solvent molecules in the axial positions has been structurally characterized.[2026] Bis(pyrazolato)-bridged dinickel systems may also form with ligands carrying a single chelate side arm. In this case, open coordination sides remain for solvent (or other coligand) binding, e.g., in (**819**).[2028]

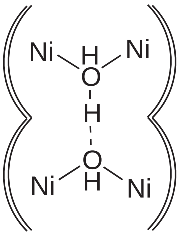
Type (**820**) dinickel complexes offer the opportunity of substrate binding within the bimetallic pocket, and highly preorganized complexes of this type have also been employed as model systems for the urease metalloenzyme (see Section 6.3.4.12.7). The Ni—Ni separation in type (**820**) complexes can be controlled by changing the lengths of the chelating side arms in the 3- and 5-positions of the heterocycle. For example, in (**821**) with longer side arms (i.e., six-membered outer chelate rings) the Ni···Ni distance is around 3.6 Å and an OH bridge is found within the bimetallic pocket. In contrast, the shorter side arms (i.e., five-membered outer chelate rings) in (**822**) pull the two Ni^{II} back and apart, thus enforcing a larger Ni···Ni distance of around 4.4 Å which prevents the small OH group from spanning the metal ions. Instead, an additional water molecule is incorporated to give an intramolecular $(H_3O_2)^-$ unit with a short O—H—O hydrogen bridge.[422,2028] A $(H_3O_2)^-$ group can also span four Ni^{II} ions, as has been shown in tetranickel complexes with phtalazine- or phenolate-derived dinucleating ligands (type (**823**) and (**824**), respectively).[2029,2079]



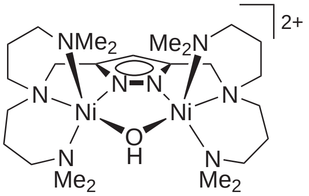
(**820**)



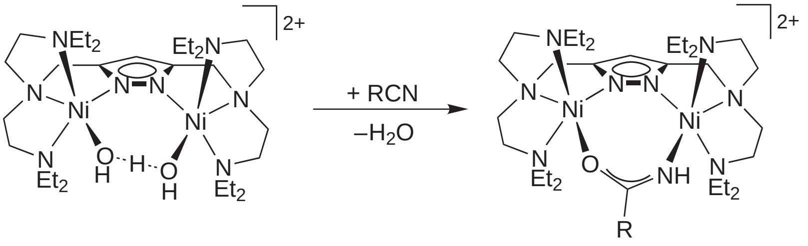
(**823**)



(**824**)

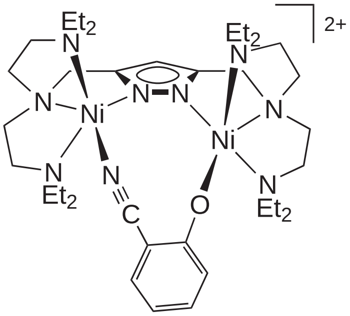


(**821**)

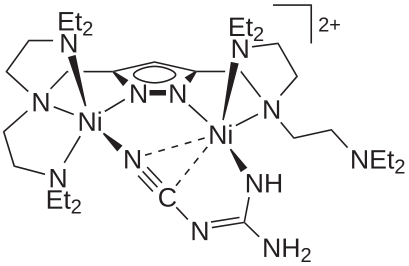


(**822**)

(**825**)
(R = Me, C_2H_3, Ph)



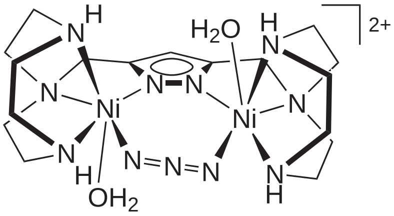
(**826**)



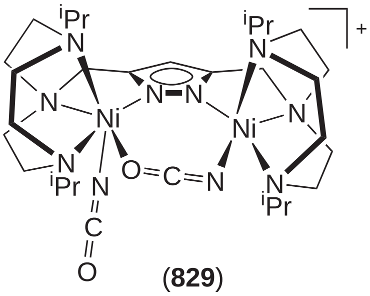
(**827**)

The H_3O_2 function in (**822**) is hydrolytically active and is capable of, *inter alia*, nitrile hydration to give complexes (**825**) with N,O-bridging amidato groups.[422] Replacement of the additional water by the end-on bound nitrile is assumed as a first step in this reaction, which is corroborated by the structural characterization of (**826**).[2030] The particular geometric constraints in (**822**) can also give rise to unusual binding modes within the bimetallic pocket, e.g., a unique cyanoguanidine coordination with enforced side-on π-interaction of the $C{\equiv}N$ group with a high-spin Ni^{II} site (**827**).[2030]

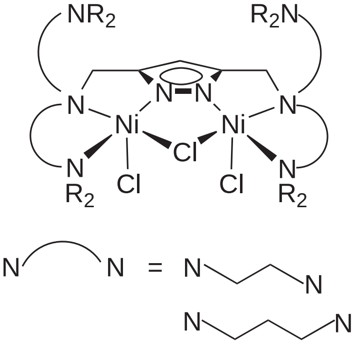
In the case of macrocyclic tacn side arms, stability constants of type (**820**) dinickel complexes are considerably higher and six-coordination can be achieved due to the binding of additional coligands, either at both Ni^{II} (in (**828**))[2031] or at only one of them (in (**829**)).[2082]



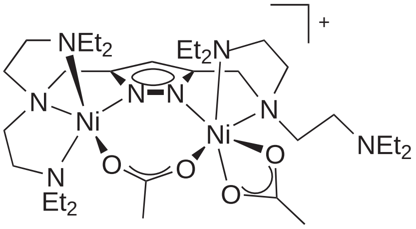
(**828**)



(**829**)



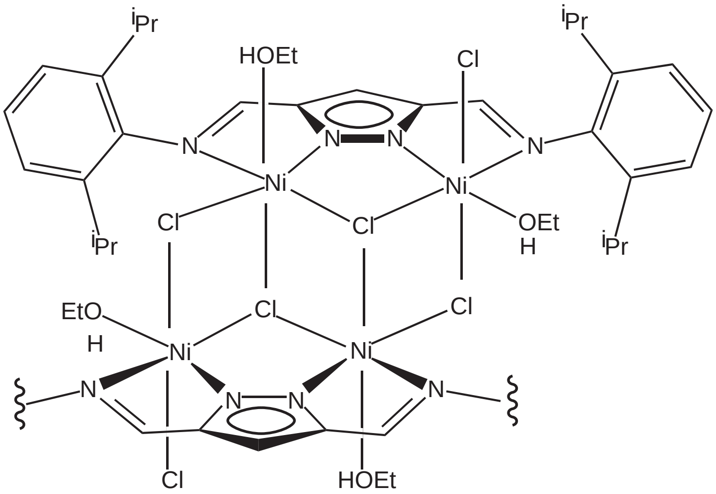
(**830**)



(**831**)

With open-chain chelate arms at the heterocycle, however, coordination of additional coligands may be accompanied by detachment of some ligand side arms, e.g., in (**830**) or (**831**).[422,2032,2072]

A pyrazole ligand bearing Schiff base chelate arms with bulky substituents forms a hexanuclear Ni^{II} cage complex (**832**) that incorporates an interstitial μ_6-Cl atom (Figure 31). The cage structure is opened up in the presence of coordinating solvents to give, *inter alia*, (**833**) (from ethanol).[2033]



(**833**)

Unsymmetrical compartmental pyrazole ligands with different chelating side arms in the 3- and 5-positions have been developed for the controlled synthesis of unsymmetric dinickel(II)

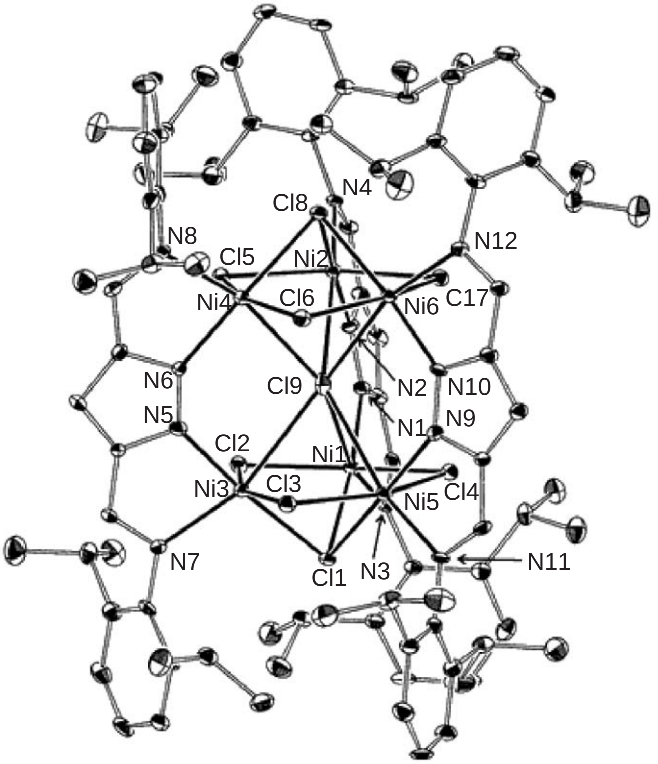


Figure 31 Hexanuclear Ni^{II} cage complex (**832**) with an interstitical μ_6-Cl atom[2033] (reproduced by permission of the Royal Society of Chemistry).

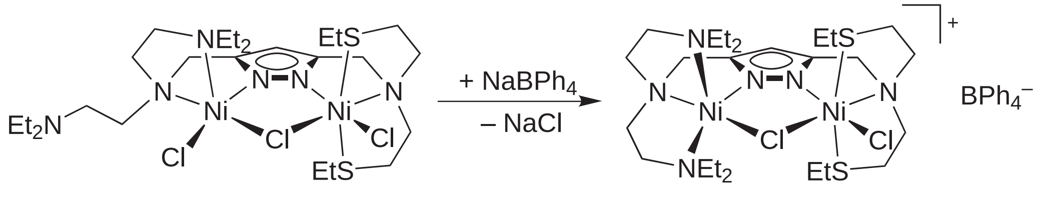
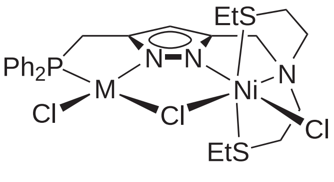
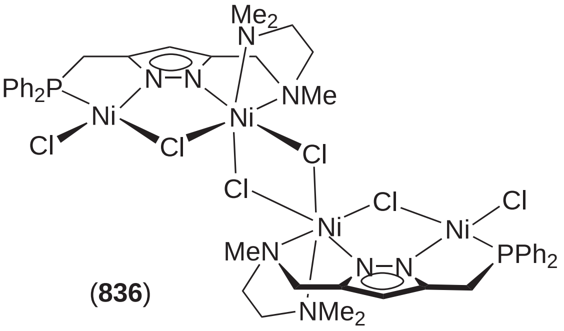
complexes or heterobimetallic NiPd compounds, e.g., (**834**)–(**836**).[2034,2035] (**835a**) and (**836**) are mixed-spin systems with one tetracoordinate low-spin and one hexacoordinate high-spin Ni^{II} per pyrazolate-based bimetallic unit. Structural, spectroscopic, and electrochemical characteristics of these systems reveal that the coordination subunits are only moderately coupled with regard to conformational and electronic aspects.[2035]



(**834a**) (**834b**)



(**835a**) M = Ni
(**835b**) M = Pd



(**836**)

Dinickel(II) complexes of dinucleating 1,2,4-triazole- and pyridazine-based ligands have mainly been studied with respect to magnetic exchange interactions. With 1,2,4-triazole, Ni^{II} forms oligomeric and polymeric coordination compounds. Using 3,5-dialkyl substituted triazoles and thiocyanate as a coligand, trimeric species could be isolated and characterized crystallographically.[2036] Subsequently, a series of di- and trinuclear triazole-based Ni^{II} complexes have been characterized and their magnetic properties investigated,[2037–2041] and related complexes have also been obtained with 2,5-diamino-1,3,4-thiadiazole.[2042] Triply triazolato-bridged systems show antiferromagnetic coupling with J ranging from $-10\,cm^{-1}$ to $-20\,cm^{-1}$ (Table 12). In the case of two triazole or thiadiazole bridges and an exogenous coligand, the exchange was found to be ferromagnetic with NCS^- but antiferromagnetic with OH^-.

3-(Pyridin-2-yl)-1,2,4-triazole and 4-amino-3,5-bis(pyridin-2-yl)-1,2,4-triazole give compounds (**837**) and (**838**), respectively, with solvent or chloride coligands filling the remaining sites of the distorted octahedral environment.[2043,2044] A similar constitution is indicated by FAB mass spectrometry for Ni^{II} complexes of (**839**).[2045] Weak to moderate antiferromagnetic coupling is observed in these cases. 4-Amino-3,5-bis(hydroxymethyl)-1,2,4-triazole (**840**), however, forms a tetranuclear complex with a Ni_4O_4 cubane cluster where three ligands are singly deprotonated and one ligand is doubly deprotonated. The latter bridges two Ni_4O_4 entities to give dumbbell-like pairs of clusters. Hexacoordination of each Ni^{II} ion is completed by a thiocyanate anion.[2046] The nature of the magnetic exchange is overall antiferromagnetic.

Table 12 Magnetic exchange parameter in triply triazolato-bridged Ni^{II} comlexes.

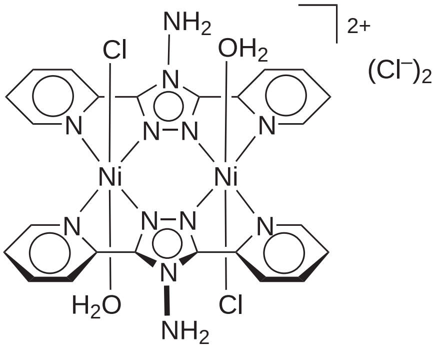
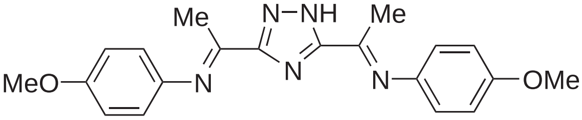
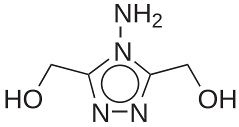
(837)



(838)



(839)



(840)

The Ni^{II} complex of bis(pyridazine)carboxamide can act as a bidentate ligands towards other metal ions, e.g., in (**841**).[2047–2049] 3,6-Bis(2-pyridyl)pyridazine (dppn, (**842**)) forms a tetranickel complex $[Ni_4(\mu\text{-}OH)_2(\mu\text{-dppn})_4(\mu\text{-}H_2O)_2]^{6+}$ with two central H_3O_2 units spanning the four metal ions. Each Ni atom is six-coordinate with distorted octahedral $\{N_4O_2\}$ geometry.[2050] 3,6-Dicarboxylatopyridazine (**843**) and 3,6-bis(1′-pyrazolyl)pyridazine (**844**) give the typical doubly bridged $[Ni_2L_2(H_2O)_4]$ complexes with water in the axial positions. The magnetic coupling constant J (for the Hamiltonian $H = -2JS_1S_2$) is around $-15\,cm^{-1}$.[2051,2052] If longer and oligodentate chelate arms are attached to the pyridazine or phtalazine heterocycle, preorganized bimetallic systems such as (**845**) can be obtained.[2053–2055] Dinickel(II) complexes of phtalazine-derived compartmental ligands have been investigated as model systems for the urease metalloenzyme (see below).[2079–2081]

3,6-Bis(2-pyridyl)-1,2,4,5-tetrazine (bptz, (**846**)) can act as a dinucleating ligand towards Ni^{II}.[2056] From the reaction of $[Ni(MeCN)_6]^{2+}$ with bptz, tetranuclear squares $[Ni_4(bptz)_4(MeCN)_8]^{8+}$ or metallapentagons $[Ni_5(bptz)_5(MeCN)_{10}]^{10+}$ have been isolated, depending on the choice of the templating counteranion (ClO_4^- or BF_4^- vs. SbF_6^-).[2057,2058]

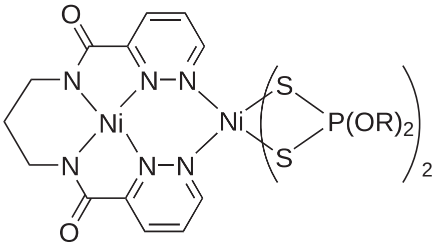
In contrast to diazine heterocycles, ligands based on a N—N single bond derived from hydrazine have rarely been used as bridging scaffolds in Ni chemistry. Ligands (**847a–c**) contain a flexible diazine unit and terminal pyridine and pyrazine residues, respectively. (**847a**) forms a spiral-like dinickel(II) complex, in which three ligands wrap themselves around the six-coordinate metal ions. The diazine N atoms act as bridging groups, and the pyridine-N ligate to the remaining coordination sites.[2059] The magnetic moment is close to the value expected for uncoupled Ni^{II} centers. (**847b**) and (**847c**) form tetranuclear compounds $[Ni_4(L)_4(H_2O)_4]^{4+}$, where the Ni ions are linked solely by alkoxo O atoms to form a square $[Ni_4(\mu_2\text{-}O)_4]$ array and are coupled antiferromagnetically.[2060]

The single N atom of pyridine can also bridge two Ni^{II} ions. Pentadentate ligands (**848a**) and (**848b**) in their twofold deprotonated form give helical dinickel complexes, in which the metal ions are bridged by the two pyridine-N and are ligated by two donor atoms of one chelate arm of each ligand, featuring overall six-coordination.[2061,2062]

Triazenido ligands can exhibit various coordination modes, and they can also act as a bridge spanning two Ni^{II} ions. A representative example is complex (**849**), where three 1,2-bis(phenyltriazenido)benzene ligands encapsulate a $Ni(\mu\text{-}OH)_2Ni$ core.[2063]

6.3.4.12.7 *Model complexes for the urease active site*

Urease is an exceptional metallohydrolase that contains two proximite Ni^{II} ions within its active site.[24,25] It efficiently catalyzes the hydrolysis of urea to finally give carbon dioxide and two moles



(**841**)

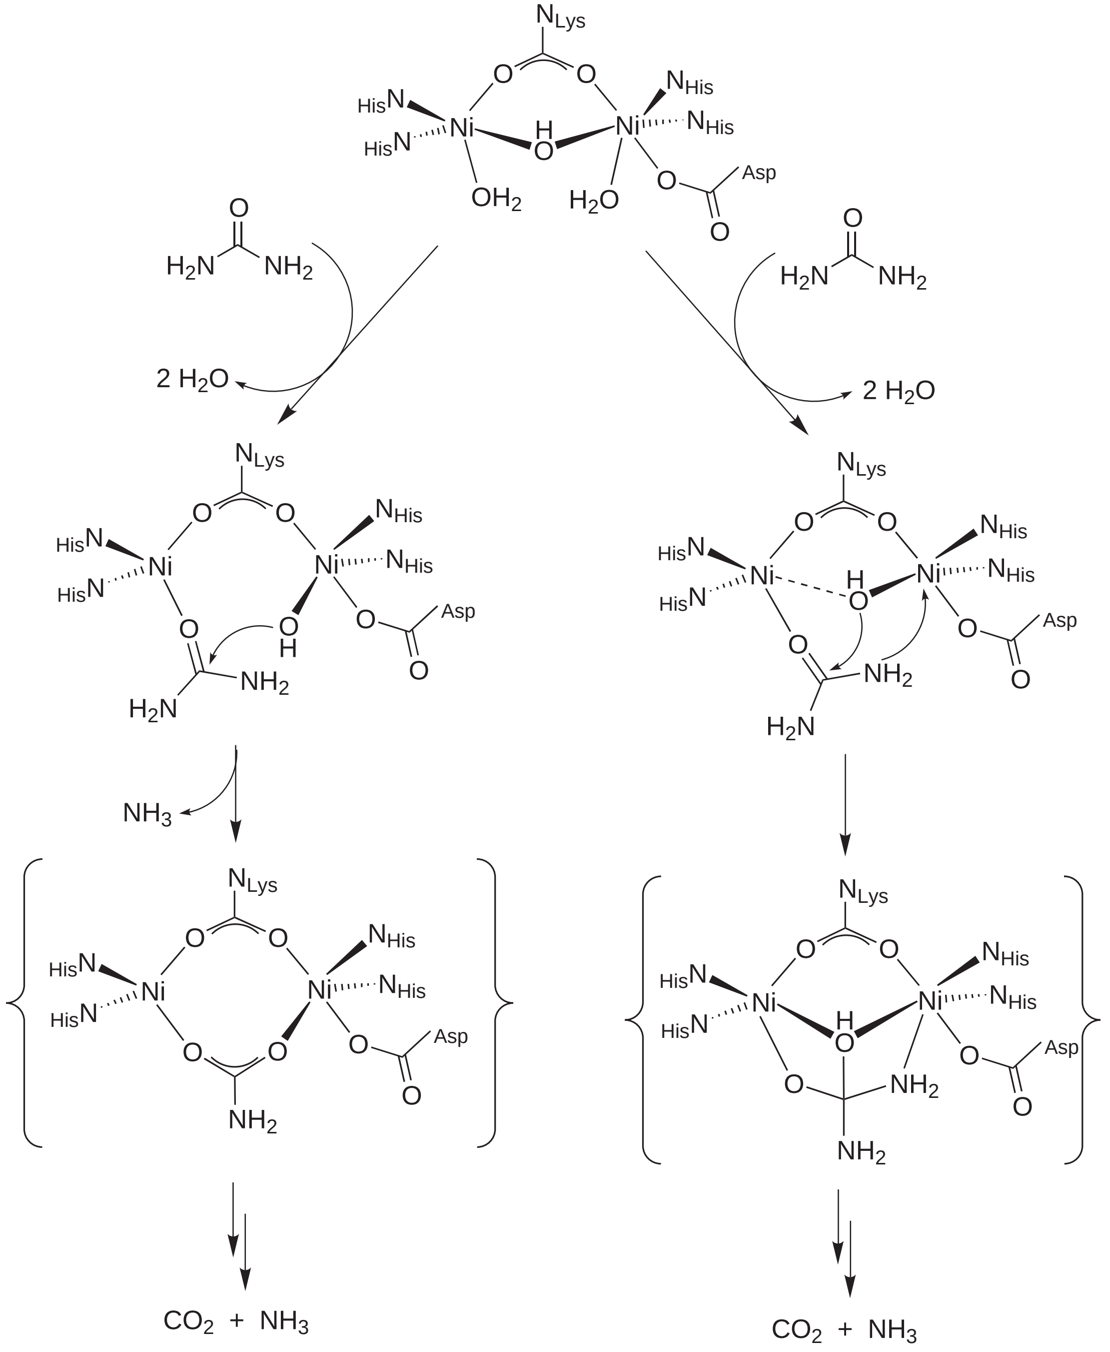
of ammonia. Due to the exceptional stability of urea and the importance of urea degradation for environmental, agricultural and medical sciences, the urease enzyme and its mode of action has received much attention. Since the first X-ray crystal structure of microbial urease was published in 1995,[23] accumulating crystallographic evidence has meanwhile provided a detailed picture of the enzyme active site and a solid background for an understanding of its mechanism of catalysis.[26,27] The initially proposed mechanism of urease activity assumes that urea is activated by coordination to one Ni^{II} ion in conjunction with extensive hydrogen bonding within the active site pocket of the protein and is subsequently attacked by a nucleophilic hydroxide terminally bound to the opposite Ni^{II}.[2064] The resulting carbamate then decomposes further to produce carbonic acid and another molecule of ammonia (Scheme 12, left-hand sequence). Based on the crystal structures of urease inhibited by either phosphate or diamidophosphate, as well as on the basis of model calculations, an alternative mechanism has been proposed and the sequence of events outlined in the right-hand part of Scheme 12 now seems most probable.[28,29] It implies that urea first coordinates to one nickel ion through its carbonyl oxygen atom, followed by a transition towards a bridging binding mode and concomitant nucleophilic attack by the bridging hydroxide. However, details of this process are still under debate, and cyanate has also been proposed as a possible intermediate in the urease mechanism.[2065]

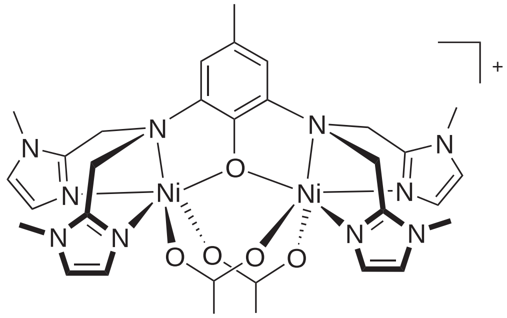


Scheme 12

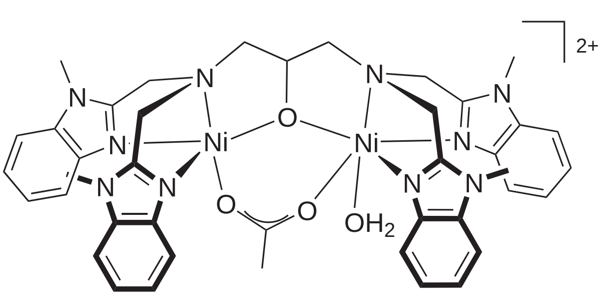
As a consequence, the design and investigation of dinuclear Ni^{II} model complexes that mimic characteristics of the urease active site and that are capable of binding and degrading urea continues to be of particular interest. Among the specific active site structural features of urease are the nonsymmetric N/O-rich coordination environment with a Ni—Ni distance of around 3.5 Å, the bridging carbamate (often modeled by a bridging carboxylate), and the presence of a hydrolytically active Ni-bound hydroxide or water. The ability to bind urea is a prerequisite for urease-like activity, and different urea binding modes have been observed in synthetic model compounds.

In order to provide a dinucleating scaffold for proper orientation of two proximite Ni^{II} ions, compartmental ligands based on bridging alkoxide, phenolate, pyrazolate, or phtalazine units have been employed.[422,2066–2082] Selected examples are discussed below.

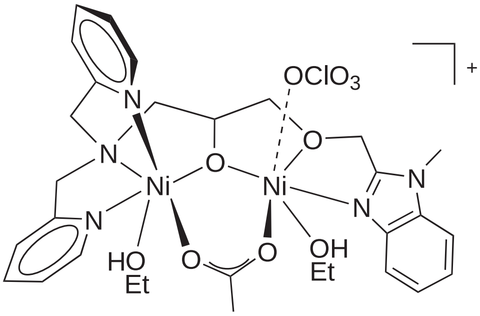
In (**850**)[2066], (**851**),[2069] and (**852**)[2076] the two nickel ions are additionally spanned by carboxylate bridges, whereas (**853**)[2072], (**854**)[2083], (**855**)[422], (**856**),[422] and (**858**)[2079] feature bridging hydroxide,



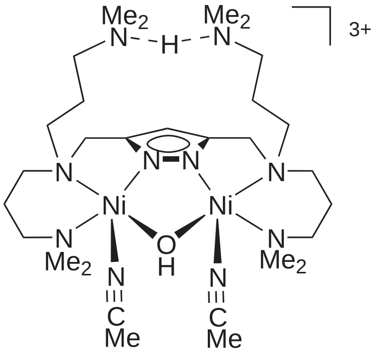
(**850**)



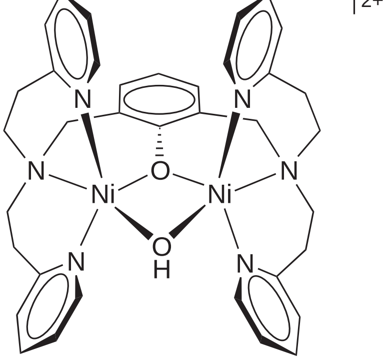
(**851**)



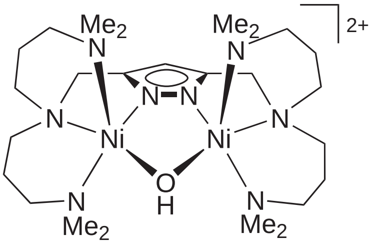
(**852**)



(**853**)



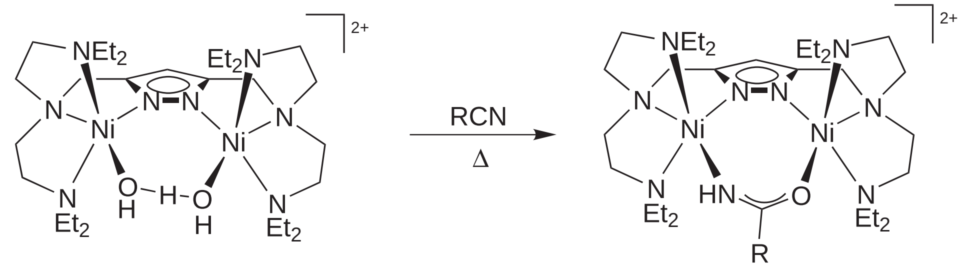
(**854**)



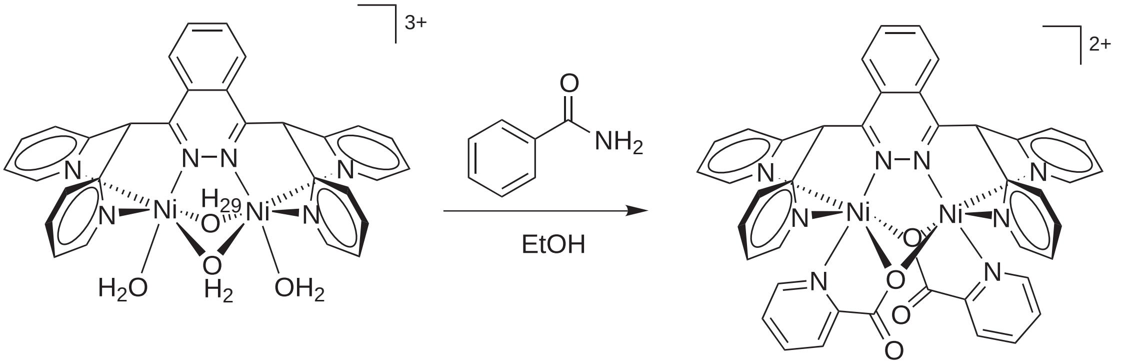
(**855**)

water, or H_3O_2 moieties. In some cases (e.g., (**852**))[2076], the bimetallic scaffolds are nonsymmetric due to the different coordination compartments of the dinucleating ligand. (**853**)[2072] provides additional N functional groups in proximity to the bimetallic core—during complex formation, these basic amine functions pick up a proton to give the Ni-bound hydroxide, which resembles essential characteristics of the protein surrounding in the urease active site. Several compounds have readily accessible coordination sites available for substrate binding: e.g., the acetonitrile ligands in (**853**) are easily replaced by DMF or N-bound thiocyanate.[2072] A dinickel(II) complex of a tetrakis(benzimidazolyl) substituted 2-hydroxy-1,3-diaminopropane ligand (similar to the ligand in (**851**)) was found to readily absorb CO_2 in methanol solution to give a monomethyl carbonato bridged species.[2084]

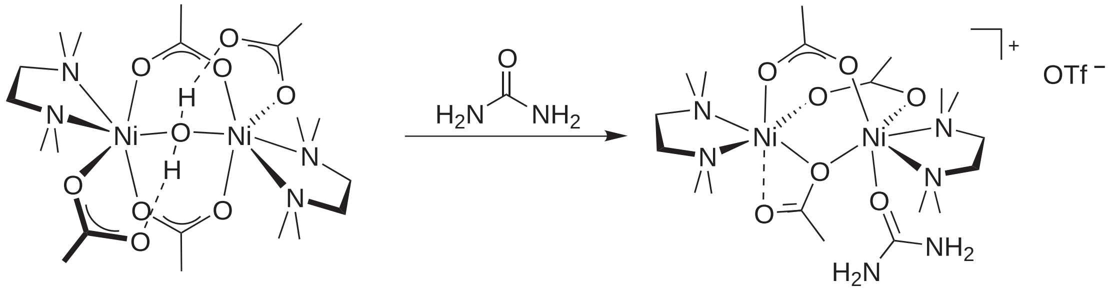
Complex (**854**) has been tested in the catalysis of bis(p-nitrophenyl)phosphate hydrolysis. A plot of the rate constant vs. pH showed a sigmoid curve with an inflection point at a pH close to the pK_a of the Ni-coordinated water (~8.5), which is consistent with the metal-bound hydroxide acting as the nucleophile.[2083] (**856**) is capable of nitrile hydration to give complexes with N,O-bridging amidato groups (**857**),[422] and complex (**858**) effects the hydrolytic cleavage of picolinamide in ethanol to give (**859**).[2079] The latter is proposed to occur by the bridging hydroxide, which is suitably arranged for nucleophilic attack.



(**856**) (**857**)



(**858**) (**859**)



(**860**) (**861**)

Complex (**860**)[2085] containing a (μ-aqua)bis(μ-carboxylato) core reacts with urea to provide the first example of urea coordination to a dinickel(II) site.[2067] In the resulting (**861**), the urea molecule binds through its carbonyl-O to one of the $\mathrm{Ni^{II}}$ ions, which is the most commonly observed coordination mode.

Urea bound with η^1-O has also been found in the (μ-alkoxide)(μ-carboxylato) complex (**862**),[2070] in the phenolate-bridged species (**863**),[2071] in several pyrazolate-based dinickel(II) compounds with additional carboxylate bridges and either symmetric (**864**, **865**) or nonsymmetric (**866**) cores,[2072] and in the phtalazine-derived complex (**867**).[2080] In the latter two cases, species with *N*-substituted urea have also been structurally characterized,[2072,2081] as well as a phtalazine-based dinickel complex with S-bound thiourea.[2081] Whereas (**865**) provides additional terminal sites for solvent coordination,[2072] (**867**) incorporates both a μ-aqua and a μ-hydroxide group.[2081] In (**864**), (**865**), and (**866**), the urea is additionally tied up with the bimetallic core by H bonding between the urea NH and the O atoms of the bridging acetate,[2072] while type (**867**) complexes feature urea H bonding interactions with the bridging

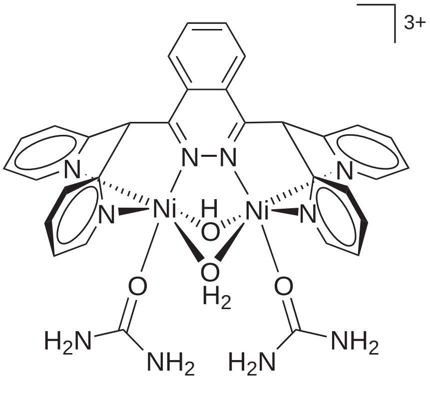
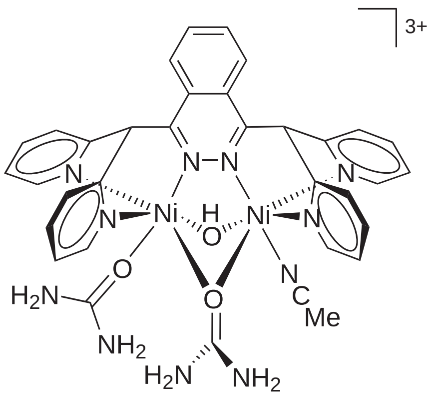
(**866**)



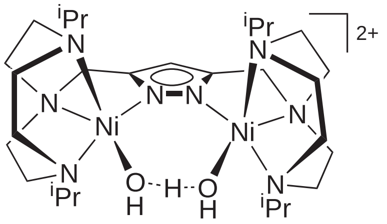
(**867**)

hydroxide.[2080,2081] All Ni^{II} ions with η^1-O-bound urea are usually six-coordinate. The urea C—O bond lengths generally do not change appreciably upon coordination, indicating very little polarization of the substrate.

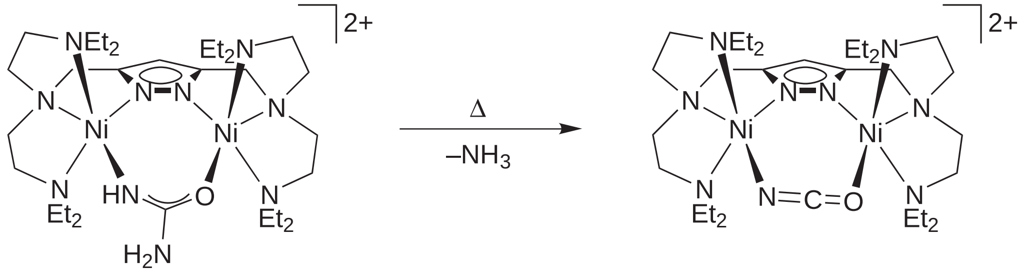
Complex (**868**) is a unique example where urea forms a single-atom bridge between the proximate metal ions through its carbonyl-O atom.[2080] An N,O-bridging coordination of (deprotonated) urea occurs in (**869**),[2074] which forms in an equilibrium reaction between the active H_3O_2-bridged species (**856**) and the substrate ($K_1 = 4.3 \pm 0.4$ M in acteone, 2.7 ± 0.5 M in MeCN).[2086] Kinetic studies by stopped-flow methods provided insight into the process of urea bridge incorporation: it was shown to follow a rate nonlinear in urea concentration, indicating that two urea molecules are involved. A detailed kinetic scheme has been derived.[2086] Starting from the related H_3O_2-bridged dinickel complex (**870**) with tacn side arms attached to the pyrazolate, not only parent urea but also *N*-substituted urea derivatives could be incorporated in the N,O-bridging position.[2082]



(**868**)



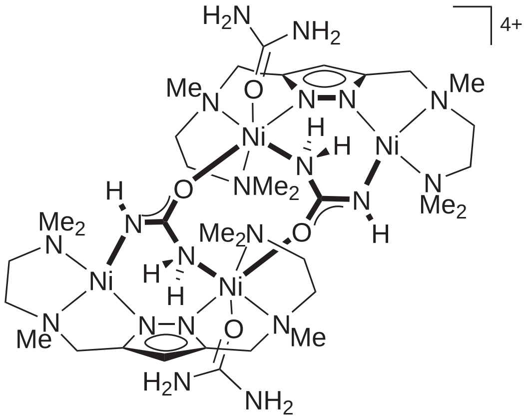
(**870**)



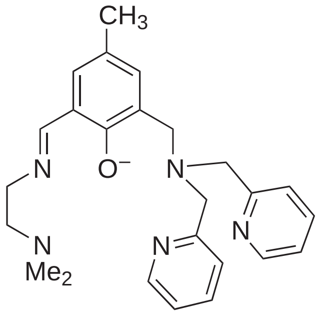
(**869**) (**871**)

An unprecedented μ_3-κN:κN′:κO triply bridging coordination mode of deprotonated urea has been observed in the tetranuclear Ni^{II} complex (**872**), which assembles from two pyrazolate-based bimetallic entities.[2077] In (**872**), the presence of two terminal four-coordinate low-spin Ni^{II} and two central six-coordinate high-spin Ni^{II} leads to a mixed-spin situation, while results from UV–visible spectroscopy and magnetic measurements in solution suggest the coordination of additional solvent ligands to the outer metal ions at low temperature.[2077]

While dinickel(II) complexes with bound urea in various coordination modes are known, very few systems mediate the hydrolytic degradation of the substrate. Ethanolysis of urea in a slow catalytic reaction (4 equivalents of ethyl carbamate after 12 h at 80 °C) has been reported for (**862**).[2070] Compound (**865**) produces 2.2 equivalents of ethyl carbamate after 6 days at 80 °C.[2078] Several complexes that promote the elimination of ammonia from coordinated urea to yield metal-bound cyanate are known. A series of dinuclear Ni^{II} complexes of the nonsymmetric ligand (**873**) react with urea in refluxing ethanol solution to give dinickel products with N-bridging cyanate.[2075] Heating of (**869**) gives rise to ammonia extrusion from the N,O-bridging ureate and formation of the cyanate-bridged complex (**871**).[422]



(**872**)



(**873**)

Both complexes (**867**) and (**868**) promote the hydrolysis of urea in a two-step process.[2080] Heating of (**867**) or (**868**) in acetonitrile solution produced ammonia with kinetic first-order dependence on complex concentration and an observed rate constant of $(7.7 \pm 0.5) \times 10^{-4}$ h^{-1} to yield a cyanate complex as the reaction product. When the reaction was carried out in 50% aqueous acetonitrile solution, ammonia was produced at the same rate but without buildup of the cyanate-containing product, suggesting that the latter is hydrolyzed in the presence of water. The hydrolysis rate was also first order in water, indicating that it occurred by attack of an external water on the coordinated cyanate.[2080]

In an analogous reaction, urea substrates having alkyl substituents at only one of the N atoms undergo alkylamine elimination to form a dinickel cyanate complex.[2081] In contrast, no reaction was observed for *N,N′*-dialkylated substrates.

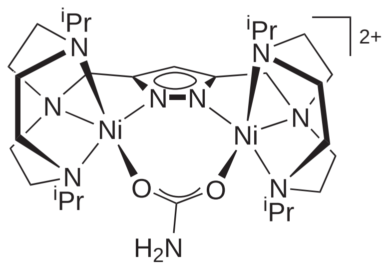
The results of most model studies for Ni-mediated urea degradation reported to date are consistent with a cyanate intermediate. While this differs from the most likely mechanism of urease activity as deduced from protein crystallography, there is still no definitive evidence ruling out a transient Ni-bound cyanate intermediate for the enzyme.

Crystal structures of dinickel complexes with O,O-bridging and O,N-bridging (O-methylated) carbamate have been reported.[2074,2082] (**874**) produces one equivalent of ammonia upon heating in methanol/water solution.[2082]

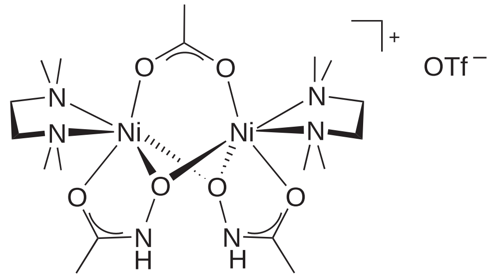
Acetohydroxamic acid (AHA) is known as a potent inhibitor of urease, and the crystal structure of the AHA-inhibited enzyme has been reported[2087,2088] (as well as structural details with other inhibitors such as β-mercaptoethanol[2089] and phenylphosphorodiamidate).[28] The structure of the AHA-inhibited active site reveals the binding mode of the AHA inhibitor with its hydroxamate-O symmetrically bridging both metal ions and the carbonyl-O chelating to one of the Ni^{II}. Such AHA coordination has been closely modeled in (**875**) and (**876**), which are readily prepared from the reaction of (**860**) and (**861**) with AHA.[2090] A similar situation is observed in the complex with salicylhydroxamic acid (**877**).[2091] Compound (**878**) containing a deprotonated bridging *N*-hydroxyglutarimide was obtained in an unusual hydroxylamine elimination and cyclization reaction upon reaction of (**860**) with glutarodihydroxamic acid.[2092] Finally, it should be noted that four distinct hydroxamate binding modes have been observed in a heptanuclear Ni^{II} complex with 2-(dimethyl amino)phenylhydroxamic acid (2-dmAphaH), $[Ni_7(2\text{-dmAphaH-1})_2(2\text{-dmApha})_8(H_2O)_2]SO_4\cdot 15H_2O$.[2093]

6.3.4.12.8 *Chain complexes with oligo(pyridylamido) ligands*

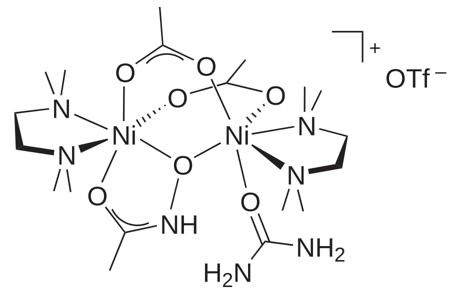
Linear multinuclear metal complexes are attracting attention in the context of molecular electronics due to their projected use as molecular wires. Oligo(pyridyl)amido ligands are efficient scaffolds for lining up several Ni^{II} ions like a string. The first structurally characterized trinickel complex of this type, $[Ni_3(dpa)_4Cl_2]$ (dpa = bis(2-pyridyl)amide), showed a nearly linear Ni_3 unit with Ni—Ni distances of around 244 pm.[2094] Penta-, hepta-, and nonanuclear systems have meanwhile been described, where the oligo(pyridyl)amido ligand coordinates in an all-*syn* form.[2095–2099] An example is the heptanickel(II) complex (**879**) (Figure 32).[2099]



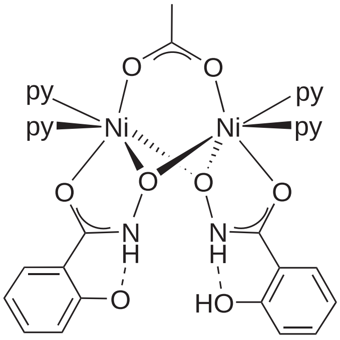
(**874**)



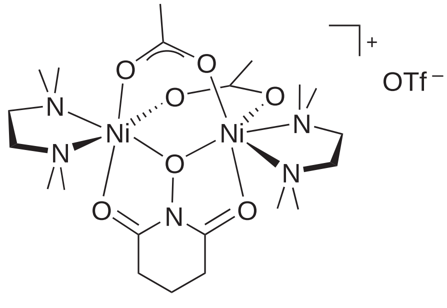
(**875**)



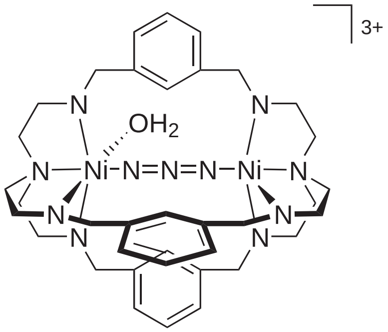
(**876**)



(**877**)



(**878**)



(**879**)

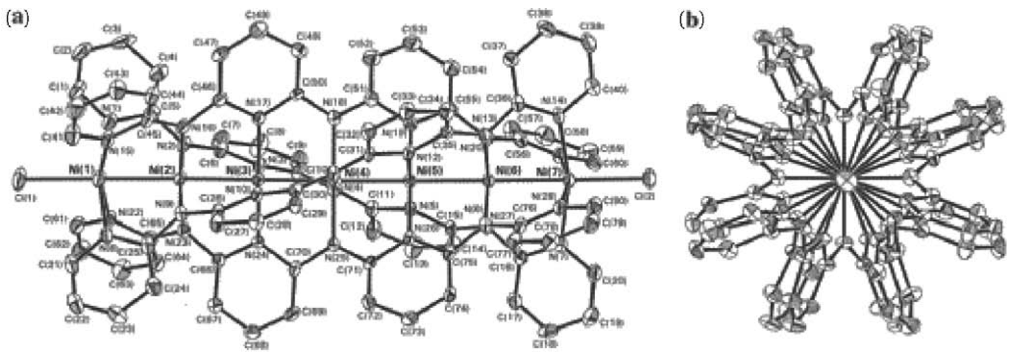


Figure 32 Molecular structure of the heptanickel complex (**879**). (reprinted with permission from ref. 2099; © 1999, American Chemical Society).

In these multinuclear Ni^{II} complexes, all the internal nickel ions are in a low-spin state, whereas the two external nickel ions are in a high-spin state. The antiferromagnetic coupling constants decrease in the order $-99\,cm^{-1}$, $-8.3\,cm^{-1}$, $-3.8\,cm^{-1}$, and $-1.7\,cm^{-1}$ for the tri-, penta, hepta-, and nonanickel dichloride complexes. In their neutral forms there are no metal–metal bonds. Upon abstraction of the terminal chlorides and one-electron oxidation, however, the Ni—Ni distances shorten significantly, indicating formation of partial Ni—Ni bonds. Magnetic data for $[Ni_3(dpa)_4(PF_6)_3]$ are consistent with one unpaired electron and delocalized Ni—Ni bonding.[2100] Coupling constants in the one-electron oxidized unsymmetrical pentanickel complexes $[Ni_5(tpda)_4(H_2O)(BF_4)](BF_4)_2$ and $[Ni_5(tpda)_4(SO_3CF_3)_2](SO_3CF_3)$ are estimated to be $-555\,cm^{-1}$ and $-318\,cm^{-1}$, respectively, i.e., much higher than in the neutral form.[2101]

6.3.4.13 Magnetic Properties of Polynuclear Complexes

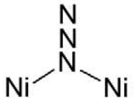
High-spin Ni^{II} has received increasing attention in the field of molecular magnetism. Since the energy barrier to reorientation of magnetization for a metal cluster is related to the spin (S) of the ground state and the zfs (D) of that spin, high-spin systems with large magnetic anisotropy are required. Nickel(II) has been proposed as a promising candidate in this respect, due to the possibility of achieving ferromagnetic exchange and the large single-ion zfs. Consequently, the first single-molecule magnets based on Ni^{II} centers have been discovered, a Ni_{12} cluster based on 6-chloro-2-pyridonate and acetate ligands and a Ni_{21} cluster with citrate and hydroxide.[60,61,2102] The former ($S=12$ ground state) is the highest spin molecule to show quantum tunneling of magnetization.

6.3.4.13.1 Complexes with bridging azido ligands

In the field of molecular magnetism the flexidentate azido ligand plays a prominent role, since it mediates different kinds of magnetic coupling depending on its various modes of coordination. For Ni^{II}, many polynuclear complexes with azido bridging ligands have been discovered, which feature a great variety of different architectures. An excellent review has appeared.[2103] Related pseudohalides like thiocyanate, selenocyanate, etc., have also been used, although the structural variety is much less diverse in those cases. Coordination chemistry of the latter systems is covered in Section 6.3.4.3.2.

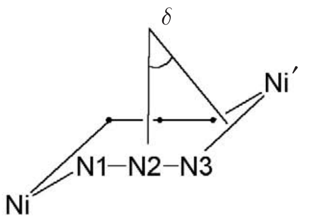
The Ni^{II}–azido compounds are best divided according to their dimensionality: discrete molecules and 1D, 2D, and 3D systems. When acting as a bridging ligand, the N_3^- anion usually adopts the μ-1,3 (end-to-end, EE) or the μ-1,1 (end-on, EO) binding mode,[2103–2105] although few examples of triply (μ_3-1,1,3 and μ_3-1,1,1) and quadruply (μ_4-1,1,1,1 and μ_4-1,1,3,3) bridging azide have been reported. Magnetostructural correlations for the two major binding modes of the azido ligand have emerged: systems with μ-1,3 azido bridges usually exhibit antiferromagnetic coupling while μ-1,3 coordination entails ferromagnetic coupling. For very large $Ni(\mu\text{-}1,3\text{-}N_3)Ni$ bond angles, however, the magnetic coupling may be reversed. In addition to the angle β measuring the linearity of the Ni–NNN–Ni skeleton, two dihedral angles are often discussed for magnetostructural correlations: δ (the dihedral angle between the plane defined for the six N azido atoms and the N1–M–N3′ plane) is commonly considered for complexes with double EE azido bridges and τ (the dihedral angle between the mean planes M–N1–N2–N3 and N1–N2–N3–M) for complexes with single EE azido bridges.[2103]

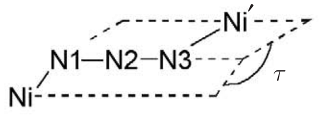
For magnetostructural correlation, intimate knowledge of the molecular structure is a prerequisite, and hence the following discussion is mainly restricted to compounds characterized by X-ray crystallography. J-values are given with respect to the $H=-J_{ij}S_iS_j$ Hamiltonian (reported values have been adapted for cases where the $H=-2J_{ij}S_iS_j$ Hamiltonian has been used in the literature).



μ-1,1 (EO)

μ-1,3 (EE)



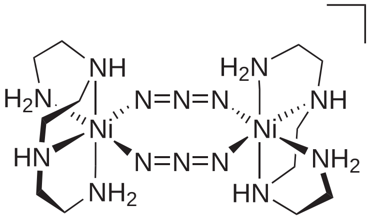


(i) Dinuclear complexes

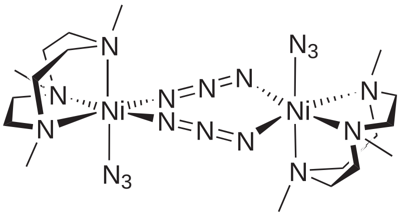
(a) With μ-1,3-azido ligands. Compounds with only one azido bridge, with two azido bridges, or with three azido bridges have been structurally characterized. Systems with only one μ-1,3 azido bridging ligand comprise (i) $[Ni_2(N_3)_2(Me_4cyclam)_2(\mu\text{-}N_3)]I$ (Me_4cyclam = 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane) reported earlier[2106,2107] with octahedral coordination of the Ni^{II} ions and two terminal azido ligands in *trans* position with regard to the bridge, (ii) $[Ni_2(trenpy)_2(\mu\text{-}N_3)](ClO_4)_3$[2108] with a pentadentate capping ligand (trenpy = *N*,*N*-bis(2-aminoethyl)-*N*′-2-(pyridylmethyl)ethane-1,2-diamine), (iii) $[Ni_2(L)(\mu\text{-}N_3)](N_3)(ClO_4)_2$, and (iv) $[Ni_2(L)(H_2O)(\mu\text{-}N_3)](CF_3SO_3)_3$ (**879**) where L is a cryptate host.[2109,2110] While the Ni–(μ-1,3-N_3)–Ni central unit is nonlinear in the first two complexes (as is also the case in the 1D systems with only one azido bridging ligand in μ-1,3 coordination mode), the geometrical constraints imposed by the rigid dimetallic cryptate induce a rather unusual quasi-linearity (Ni—N—N angles close to 165°) in the latter two complexes.

Table 13 collects the main structural data and the exchange coupling parameter *J*. $[Ni_2(L)(H_2O)(\mu\text{-}N_3)](CF_3SO_3)_2$ is a rare example with ferromagnetic coupling mediated by the EE azido bridges.[2109,2110] This has been ascribed to both the linearity of the azide bridge and the pentacoordination of one of the Ni^{II} ions. DFT calculations predict weak antiferromagnetic coupling for compounds only slightly distorted from linearity (β up to 30°), and a dramatic enhancement of the antiferromagnetism at larger β-values. A single case with only one end-to-end azido bridging ligand and also a pyrazole bridge has been reported, though no magnetic data are given.[2112]

Numerous dinuclear complexes with two μ-1,3 azido bridging ligands have been reported. Bi-, tri-, or tetradentate amine ligands are commonly used as capping ligands, while in some cases additional terminal azido ligands are present. In general, the counteranion is a nonligating anion such as ClO_4^-, PF_6^-, or $B(C_6H_5)_4^-$. In most cases, the two azido ligands of the $[Ni_2(\mu\text{-}N_3)_2]^{2+}$ core are coplanar like in (**880**). $[Ni_2(L')_2(N_3)_2(\mu\text{-}N_3)_2]$ ((**881**); L′ = 1,4,7-trimethyl-1,4,7-triazacyclononane)[2113] and $[Ni_2(bispicen)_2(\mu\text{-}N_3)_2](ClO_4)_2$ (bispicen = *N*,*N*′-bis(2-pyridylmethyl)ethylenediamine)[2114] are exceptions, with the two azido bridging ligands crossing each other. The main structural data and the exchange coupling parameter, *J*, are listed in Table 14.



(**880**)



(**881**)

Both extended Hückel and DFT calculation have been carried out in order to rationalize the observed trends. According to the magnetochemical theories,[2120,2121] the antiferromagnetic contribution to the exchange coupling J_{AF} is proportional to the squared energy difference ($\varepsilon_1 - \varepsilon_2$), where ($\varepsilon_1 - \varepsilon_2$) represents each of the gaps created between the symmetric and antisymmetric

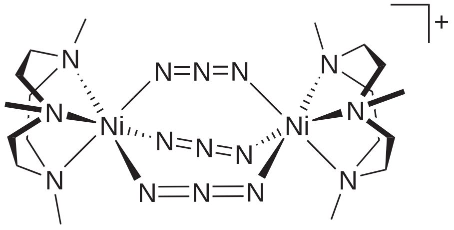
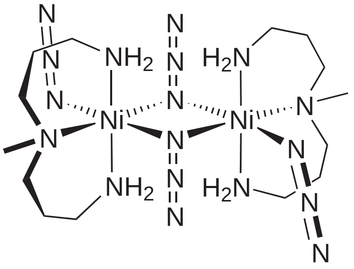
[a] L = 1,5,9-triazacyclododecane; L′ = 1,4,7-trimethyl-1,4,7-triazacyclononane; tren = 2,2′, 2″-triaminotriethylamine; 222-tet = triethylenetetriethylenetetramine; aep = aminoethylpyridine; hmcyclam = 5,5,7,12,12,14-hexamethylcyclotetradecane; bispicen = *N*,*N*′-bis(2-pyridylmethyl)ethylenediamine. [b] In this case the azide bridges of the [Ni_2(μ-N_3)$_2$]$^{2+}$ moiety (N_3)$_2$ are not coplanar.

combinations of the Ni^{II} magnetic orbitals ($z^2 \pm z^2$ and $x^2-y^2 \pm x^2-y^2$). The main factor determining the J-value is the [Ni–(μ-N_3)$_2$–Ni] dihedral angle δ, i.e., the more planar the structure (dihedral angle δ close to 0°), the more antiferromagnetic is the coupling.[2115]

A single dinuclear complex has been reported with three EE azido bridges, i.e., with a [Ni(μ-1,3-N_3)$_3$Ni] central core: [Ni_2(L′)$_2$(μ-1,3-N_3)$_3$](ClO_4)(**882**).[2113,2116] The Ni—N—N angles lie between 115.6° and 119.2° (average value = 118.1°), and the J-value is −67.9 cm^{-1}.



(882)



(883)

(b) With µ-*1,1-azido ligands*. Complexes with μ-1,1-azido ligands show ferromagnetic coupling, as indicated above. While most compounds have two azido bridges with a [Ni(μ-1,1-N_3)$_2$Ni]$^{2+}$ core structure, few examples with three azido bridges have also been reported. Most of the former compounds show a planar [Ni–(N_3)$_2$–Ni] unit with an inversion center. The coordination of the Ni^{II} ions is generally completed by di-, tri-, or tetradentate amine capping ligands. Weakly coordinating counteranions such as ClO_4^- or PF_6^- are usually employed, and azido terminal ligands may be present in some cases. Complexes (**883**) and (**884**) are depicted as representative examples. The main structural data and the exchange coupling parameter, J, are collected in Table 15.

[$Ni_2(Medpt)_2(N_3)_2(\mu$-$N_3)_2]$ (**883**)	2.207, 2.197	104.0	Yes	+46.7	2128,2129
[$Ni_2(232$-tet$)_2(\mu$-$N_3)_2](PF_6)_2$	2.177, 2.183	104.6	Yes	+34.3	2130

[a] Pepci = *N*′-(2-pyridin-2-ylethyl)pyridine-2-carbaldimide; $Me_3[12]N_3$ = 2,4,4-trimethyl-1,5,9-triazacyclododec-1-ene; 232-tet = *N*,*N*′-bis(2-aminoethyl)-1,3-propanediamine; Medpt = methyl-bis(3-aminopropyl)amine.

All Ni_2 dinuclear complexes have Ni—N—Ni angles in the narrow range 101–105° and exhibit ferromagnetic coupling with *J*-values between $+27\,cm^{-1}$ and $+73\,cm^{-1}$. It should be noted though, that due to the zfs effects manifest at low temperatures the magnitude of J should be treated with care in the ferromagnetic case.

A hysteresis cycle in the molar susceptibility measurements has been observed for [$Ni_2(Medpt)_2(N_3)_2(\mu$-$N_3)_2$] (**883**). This has been ascribed to a phase transition caused by an asymmetrization process of the rhombus-like centrosymmetric [Ni–$(N_3)_2$–Ni] core that occurs with falling temperature. The asymmetrization transition can be explained in terms of a second-order Jahn–Teller distortion, taking into account the local symmetry of the dinuclear [Ni–$(N_3)_2$–Ni] entity (D_{2h}, rhombic symmetry) before the arrangement.[2128]

Only two complexes with three azido bridging ligands have been reported: [$Ni_2L'_2(\mu$-$N_3)_3]ClO_4$ (L′ = 1,4,7-trimethyl-1,4,7-triazacyclononane)[2113] (**884**) and [$Ni_2(L)_2(\mu$-$N_3)_3]ClO_4$ (L = (*N*,*N*′-dimethyl-1,4,7-triazacyclononane)calix[4]arene).[2131] While the geometry of the triple bridge is similar in both complexes, the average Ni—N—Ni angles of 85.9° and 86.2° are much smaller than in the doubly bridged systems and the Ni···Ni distances are considerably shorter (2.896 Å and 2.852 Å, respectively). Both complexes show ferromagnetic coupling ($J = +30.7\,cm^{-1}$ and $+17.2\,cm^{-1}$, respectively).

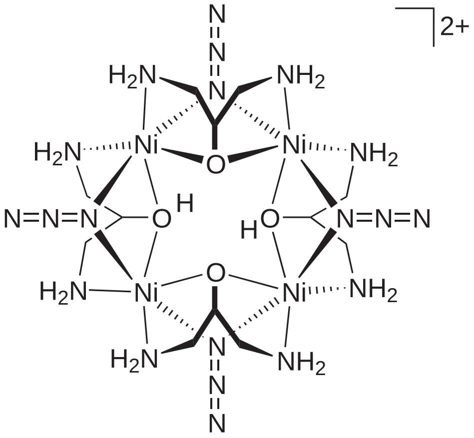
DFT calculations have been carried out in order to explain the exchange interactions in EO azido-bridged Ni^{II} complexes.[2132] There is a clear correlation between the calculated exchange coupling constant and the Ni—N—Ni bridging angle θ (analogous to that of the hydroxo-bridged species), but the interaction is predicted to be ferromagnetic for all the range of θ angles explored. A maximum is expected at $\theta \approx 104°$ for the Ni(μ-1,1-N_3)$_2$Ni core and at $\theta \approx 95°$ for the Ni(μ-1,1-N_3)$_3$Ni core. Also, the Ni—N bond distance is seen to have a strong influence on the value of the coupling constant, while the out-of-plane displacement τ of the azido bridge only has a negligible influence. Positive spin density has been calculated at the bridging N atom, indicating a predominant spin delocalization mechanism.

Ab initio DDCI2 (difference-dedicated configuration interaction) calculations seem to provide accurate estimations of the magnetic exchange coupling constants, as demonstrated for the doubly azido-bridged nickel(II) dimer [$Ni_2(terpy)_2(\mu$-1,1-$N_3)_2]^{2+}$.[2133]

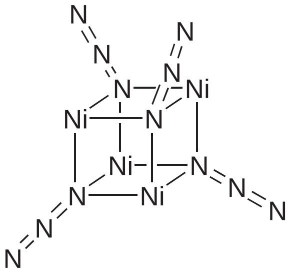
(ii) Trinuclear, tetranuclear, and high nuclearity complexes

[$Ni_3(2,2,2$-tet$)_3(\mu$-$N_3)_3](PF_6)_3$ and its perchlorate analogue have been suggested as trinuclear complexes with an irregular triangle structure.[2117] While a crystal structure is lacking, EXAFS and XANES spectra support the occurrence of azido-bridged trinuclear nickel(II) compounds with Ni···Ni separations of 5.16 Å and 5.12 Å, respectively. Two J parameters had to be introduced in order to fit the magnetic data. The values $J_{1,2} = -72\,\text{cm}^{-1}$ and $-60.3\,\text{cm}^{-1}$ and $J_3 = -36\,\text{cm}^{-1}$ and $-29\,\text{cm}^{-1}$, respectively, are in agreement with the assumed EE coordination mode for the azido bridging ligand.

Tetranuclear Ni^{II} complexes with EO azido bridging ligand have been reported both with open frame and cubane-like structures. In $[\text{Ni}_4$(2-oxo-1,3-diaminopropane)$_2$(2-hydroxo-1,3-diaminopropane)$_2$ (μ-1,1-$\text{N}_3)_4](\text{ClO}_4)_2$[2134] (**885**) the four Ni^{II} atoms are in a distorted octahedral environment and are related by an S_4 symmetry axis forming a quasi-perfect square. The Ni^{II} ions are bridged by an oxygen atom of the amine ligand (OHpn and Opn) and an EO azide bridge, yielding ferromagnetic coupling with $J = +21.3\,\text{cm}^{-1}$. Magnetization measurements are indicative of an $S = 4$ spin ground state.



(885)



(886)

Few Ni_4 complexes with a cubane-like structure and four triply bridging μ_3-1,1,1-N_3 ligands symmetrically bound to three Ni^{II} ions have been discovered (**886**),[2135,2136] but magnetic data are only reported in the case of $[\text{Ni}_4(\text{dmb})_4(\text{EtOH})_4(\mu_3\text{-1,1,1-N}_3)_4]$ (dbm = dibenzoylmethane).[2135,2136] Its magnetic behavior was well reproduced by a model with a single $J = +11.9\,\text{cm}^{-1}$.

Centrosymmetric tetranuclear units have been obtained with tridentate ligands resulting from the solvolysis of dpk (dpk = di-2-piridylketone).[2137,2138] The Ni^{II} ions are bridged by both μ-oxo and μ_3-oxo from the dpk derivative and μ-1,1 azido ligands, to give a face-share dicubane-like coordination core with two missing vertices. The magnetic properties of the two species $[\text{Ni}_4(\text{dpkOH})_2(\text{dpkOMe})_2(\mu\text{-N}_3)_2(\text{H}_2\text{O})_2](\text{ClO}_4)_2{\cdot}2\text{H}_2\text{O}$[2137] and $[\text{Ni}_4(\text{dpkOH})_4\ (\mu\text{-N}_3)_2(\text{N}_3)_2]{\cdot}2\text{H}_2\text{O}$[2138] are characteristic of intramolecular ferromagnetic coupling and have been modeled with $J_1 = +18.0\,\text{cm}^{-1}$, $J_2 = +16.3\,\text{cm}^{-1}$, $J_3 = +27.1\,\text{cm}^{-1}$, $J_4 = -1.6\,\text{cm}^{-1}$ and $J_1 = +18.8\,\text{cm}^{-1}$, $J_2 = +6.9\,\text{cm}^{-1}$, $J_3 = +1.3\,\text{cm}^{-1}$, $J_4 = +0.2\,\text{cm}^{-1}$, respectively.

A very unusual nonanuclear cage compound $[\text{Ni}_9(\mu_4\text{-1,1,1,1-N}_3)_2(\text{O}_2\text{CMe})_8(\text{dpkO})_4]$ has been obtained from the reaction of NaN_3 with the similar complex containing OH^- instead of N_3^-.[2139] It features two azide ligands in the extremely rare μ_4-1,1,1,1 binding mode. Magnetic measurements reveal moderate ferromagnetic coupling and an $S = 9$ ground state.

Preorganized bimetallic building blocks have been used for the assembly of tetranuclear Ni^{II} complexes. In (**888**), the metal ions of each Ni_2 subunit are spanned by two thiophenolate-S and by a μ-pyridazine.[2140] Magnetic data for the related dinuclear complex (**887b**) show intramolecular ferromagnetic exchange with $J = +23.0\,\text{cm}^{-1}$. Crosslinking of two such Ni_2 units (**887a**) by EE azido bridges in (**888**) gives an $S = 4$ ground state, i.e., coupling between the Ni_2 constituents is also ferromagnetic, which is rationalized on the basis of the dihedral Ni—N_3—Ni torsion angle of 76.4°. Analysis of the magnetic susceptibilty data for X gives $J_1 = +12.9\,\text{cm}^{-1}$ and $J_2 = +7.2\,\text{cm}^{-1}$, where J_1 represents the exchange interaction in the dinuclear subunit and J_2 describes the interaction via the azido linkages.

Tetranuclear Ni^{II} complexes (**889**), (**890a**), and (**890b**) with unusual μ_3-1,1,3 and μ_4-1,1,3,3 azide binding modes have been obtained from discrete pyrazolate-based dinuclear building blocks.[2141] (**890a**) and (**890b**) represent the only known examples of such EE/EO μ_4 coordination of azide in molecular compounds.

Finally is should be noted that a great variety of complexes may arise from the combination of different metals and different bridges. The trinuclear complex $Mn(N_3)_4[Ni(en)_2(NO_2)]_2$ is given as an example here: the metal ions in the linear Ni—M—Ni sequence are linked by both EO azide and μ-NO_2^- to give an $S = 9/2$ triad state.[2142]

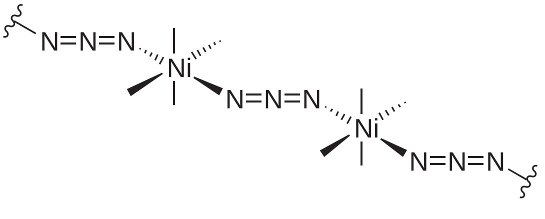
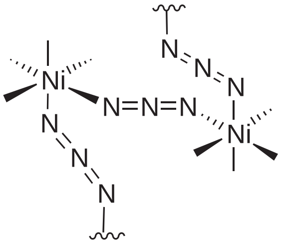
(iii) One-dimensional uniform systems

For these types of 1D systems only Ni^{II} compounds with a single 1,3-azido bridging ligand have been reported. Depending on the position of the two adjacent azido bridging ligands at each Ni^{II} ion, two different types of 1D system—*trans*-(**891a**) or *cis*-(**891b**)—can be distinguished. The hexacoordination of each Ni^{II} ion is usually completed by chelating nitrogen ligands. The main structural data and the exchange coupling parameter J are given in Table 16 for *trans*-complexes and in Table 17 for *cis*-complexes.



(891a)



(891b)

In a 1D chain where the Ni^{II} ions are bridged by one μ-1,3 azido ligand, two different azido bridges may be present in the chain with the Ni^{II} ions related by an inversion center located at the

central N of each azido bridge. Such compounds have a structurally and magnetically alternating chain and are discussed in the following section. Two different Ni^{II} ions may be present, located at an inversion center. In this case, all azido bridges are equivalent and the chain is structurally alternating but magnetically uniform, e.g., in *trans*-$[Ni(N\text{-Eten})_2(\mu\text{-}N_3)]_n(PF_6)_n$, which is included here.

Extended Hückel calculations were performed on dimeric fragments in order to derive magneto-structural correlations for both kinds of complexes, *trans* and *cis*.[2155,2156] Since bond distances are similar in all the complexes reported, the wide range of bond angles (Ni—N—N angles and dihedral Ni—N_3—Ni torsion) must play a significant role in the superexchange interaction between the nickel atoms. According to the MO calculations, for a *trans* chain (where the d_{z^2} orbitals are oriented in the chain direction and are operative in the exchange pathway) the maximum coupling is expected for Ni—N—N angles of 108° while for larger values the antiferromagnetic interaction must decrease. At around 164° an accidentally orthogonal valley is found. It is assumed that the main interactions occur through the π pathway using the nonbonding MO of the azido ligand, while the σ pathway is poorly operative. For all Ni—N—N angles the maximum coupling can be expected for a torsion value of 180°, decreasing gradually thereafter as the torsion angles decrease. However, the magnitude of this effect is lower than the effect of the bond angle.

In the *cis* complexes, the torsion angle is usually smaller than that in *trans* complexes (Tables 16 and 17), leading to decreased antiferromagnetic coupling. In this case, the chains are helical and the compactness of this helix is a further factor that needs to be considered: the more compact the helicoidal structure, the greater the antiferromagnetic coupling.

While most 1D chain compounds with EE azido bridges show global antiferromagnetic coupling, there are a few exceptions. In *trans*-$[\{Ni(5\text{-Mepz})_4(\mu\text{-}N_3)\}_n](ClO_4)_n\cdot nH_2O$,[2150] the torsion angle of the azido bridge (75.5°) is in the range where the antiferromagnetic contribution is minimized to favor ferromagnetic coupling. This compound shows spin canting caused by perturbation of ferromagnetism and zfs. Dehydration enhances the magnetic interactions to afford a soft magnet with $T_c = 2.3\,K$ and a coercive field of 20 G.[2151] *cis*-$[Ni(L)(\mu\text{-}N_3)(N_3)]_n$ (L = tridentate Schiff base from pyridine-2-aldehyde and *N*,*N*,2,2-tetramethylpropane-1,3-diamine) was reported to exhibit metamagnetic behavior,[2154] which was ascribed to the combination of the large Ni—N—N angles deviating from 108°, the small torsion angle, and the axial–equatorial binding mode of the azide.

Uniform 1D systems obtained from $S = 1$ ions like Ni^{II} are of particular interest with respect to the experimental investigation of the so-called Haldane's gap, i.e., a quantic gap created between the ground state ($S = 0$) and the first excited state of a chain where the local S-value is an integer.[2157–2162]

(iv) One-dimensional alternating systems

(l) With only μ-1,1-azido ligands. Some complexes of this type with general formula $[Ni(L)(\mu\text{-}N_3)_2]_n$ have been reported for Ni^{II},[2149,2163] where L is a bidentate nitrogen ligand like ethylenediamine, 1,3-diaminopropane, and *N*-ethylethylendiamine. Although all neighboring Ni^{II} ions are linked by two EO azide bridges, the chains are structurally and magnetically alternating. For example, in $[Ni(N\text{-Eten})(\mu\text{-}N_3)_2]_n$ the Ni^{II} ions are alternatively related by an inversion center or by a twofold axis. One of the Ni–N–Ni–N rings is planar, the other is not.

As can be expected from the EO coordination mode of the azido ligand, all these complexes show ferromagnetic coupling. The field dependence of the magnetization in the low temperature region has been interpreted as indicative of metamagnetic behavior.

While the first two complexes in Table 18 were analyzed with a single J parameter employing a model derived for a uniform ferromagnetic 1D system, a general formula for an isotropic ferro-ferromagnetic $S = 1$ Heisenberg chain has been developed and gives $J_1 = +57.3\,cm^{-1}$ and $J_2 = +29.0\,cm^{-1}$ for $[Ni(N\text{-Eten})(\mu\text{-}N_3)_2]_n$.[2149]

(m) With only μ-1,3-azido ligands. For these compounds, alternation in the chain may be achieved either by different geometries in adjacent EE azido bridges (type A) or by consecutive single and double μ-1,3 azido linkages (type B). Examples for both types have been reported (Table 19). An equation for the analysis of magnetic susceptibility data of the antiferromagnetic alternating Heisenberg chain with local $S = 1$ has been developed by Borrás-Almenar *et al.*[2164] by following the Bonner–Fisher procedure.

[Ni_2(dpt)$_2$(μ-N_3)(μ-N_3)$_2$]$_n$ (ClO_4)$_n$ (**892**)	128.2/124.4, 119.2	B	57.4, 180	−41.4, −84.6	2167,2168
[Ni_2L(μ-N_3)(μ-N_3)$_2$]$_n$	122.5−131.3, 114.9/116.4	B	76.8/42.4, 47.7		2169

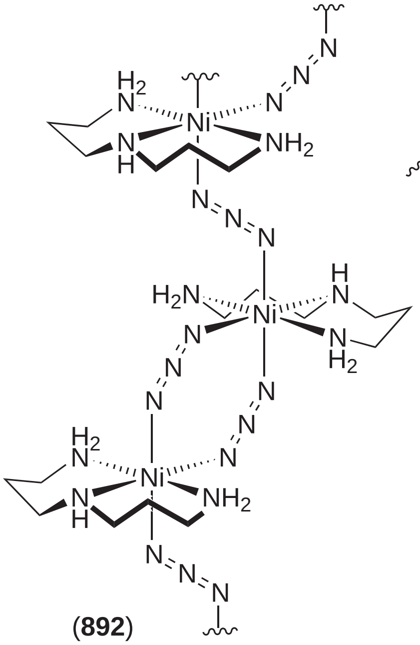
[a] 333-tet = *N*,*N′*-bis(3-aminopropyl)-1,3-propanediamine; *N*-Eten = *N*-ethylethylendiamine; dpt = bis(3-aminopropyl)amine; L = 3,5-bis{[*N*-2-dimethylamino)ethyl-*N*-methyl]aminomethyl}pyrazolate.

Type A: This has been found in [Ni(333-tet)(μ-N_3)]$_n$$ClO_4$ (333-tet = *N*,*N′*-bis(3-aminopropyl)-1,3-propanediamine)[2156] and [Ni(*N*-Eten)$_2$(μ-N_3)]$_n$(ClO_4)$_n$ (*N*-Eten = *N*-ethylethylendiamine).[2149] In both cases, the Ni^{II} ions are related by an inversion center located at the central nitrogen of each azido bridge, which produces a structurally and magnetically alternating antiferromagnetic chain. Using the Borrás-Almenar expression, the values $J = -80.7\,cm^{-1}$, $J' = -37.4\,cm^{-1}$ (alternation parameter $J'/J = \alpha = 0.46$) were derived for [Ni(333-tet)(μ-N_3)]ClO_4, and $J = -68.4\,cm^{-1}$, $J' = -37.8\,cm^{-1}$ ($\alpha = 0.55$) for [Ni(*N*-Eten)$_2$(μ-N_3)]$_n$(ClO_4)$_n$. As expected from the individual Ni—N—N angles of the alternating chain (123.6°/142.4° and 134.8°/143.7°, respectively), two very different values of *J* were obtained in both cases. The greater experimental *J*-value has been assigned to the bridge of 123.6°/134.8° (closer to 108–110° for which the maximum susceptibility is expected) and the smaller value to the greater angle (142.4°/143.7°). The alternance parameter α is close to the theoretical ratio between the gaps calculated by extended Hückel methods. [Ni(333-tet)(μ-N_3)]ClO_4 has been extensively studied as a model of the gapless point of the Affleck–Haldane conjecture.[2165,2166]

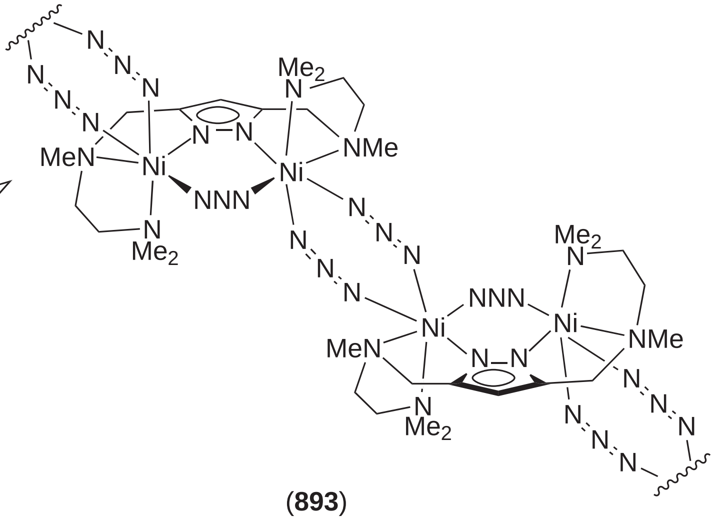
Type B: Both double and unsupported single azide bridges have been observed in [(Ni_2(dpt)$_2$ (μ-N_3)(μ-N_3)$_2$)]$_n$(ClO_4)$_n$ ((**892**); dpt = bis(3-aminopropyl)amine).[2167,2168] In the Ni–(N_3)$_2$–Ni fragment, the azido ligands are not coplanar but cross each other. By using the Borrás-Almenar equation,[2164] the following values were determined: $J = -84.6\,cm^{-1}$, $J' = -41.4\,cm^{-1}$ ($\alpha = 0.49$). Considering its very small Ni—N—N angle of 119.2°, the greater value can be assigned to the single bridge.

An alternative strategy to obtain 1D alternating chains in a more rational manner is the linkage of distinct and well-defined bimetallic building blocks, giving a 1D coordination polymer with inherent alternation in the chain structure. This approach has been followed in the case of [Ni_2L(μ-N_3)(μ-N_3)$_2$]$_n$ ((**893**); L = bis(tridentate) pyrazolate ligand) as well as the related [Ni_2L (μ-Cl)(μ-Cl)$_2$]$_n$:[2169,2579]in its dinuclear constituents the Ni^{II} ions are spanned by the pyrazolate and an EE azido bridge (the EE mode being induced by the chelating side arms that enforce a rather large metal–metal separation), and these bimetallic units are linked by double EE bridges.[2169]

Magnetic susceptibilty data indicate overall antiferromagentic coupling, but an unusual feature at low temperature awaits a more detailed study.



(892)



(893)

(n) With μ-1,3- and μ-1,1-azido bridges. Within this series of complexes, not only the alternating ferromagnetic-antiferromagnetic sequence (F–AF) resulting from an EO–EE azide bridge alternation has been observed, but also more complicated alternations like, for example, F–F–F–AF. Usually, the magnetic data have been interpreted and fitted by numerical extrapolations of $S = 1$ rings of finite length, assuming an isotropic Heisenberg system with quantic spin $S = 1$.[2170–2172] Some structural and magnetic parameters for these alternating chain compounds are collected in Table 20.

Antiferromagnetic coupling along Ni(μ-1,3-N_3)$_2$Ni linkages follows the common trend, i.e., the higher the δ angle the lower the J-value. A distinct topology with alternating double EO and single EE bridges has been reported for [Ni_2(Medien)(μ-1,1-N_3)$_2$(μ-1,3-N_3)]$_n$.[2173] A sequence with one end-to-end and three end-on bridges in alternation has been reported for [Ni_2(tmeda)$_2$(μ-1,1-N_3)$_3$(μ-1,3-N_3)]$_n$ (**894**),[2174] which exhibits very small Ni—N—Ni angles for the azido ligands in EO mode (average value 84.2°). Different fitting procedures have been tested: either with the Borrás-Almenar formula[2164] for an antiferromagnetic alternating $S = 1$ chain or with the standard formula for a dinuclear Ni^{II} unit, assuming that J_{EO} is zero in the latter case. The parameters $J_1 = -31.8\,cm^{-1}$, $J_2 = -6.9\,cm^{-1}$ are obtained for the alternating chain, while the second approach gives $J = -29.3\,cm^{-1}$. Either way, antiferromagnetic coupling is present in both parts of the chain.

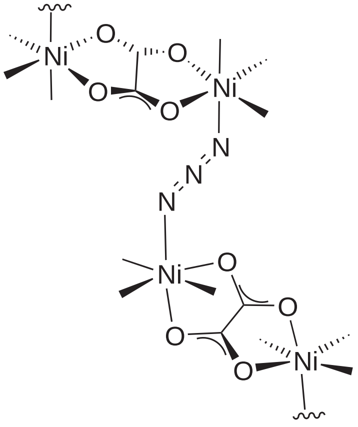
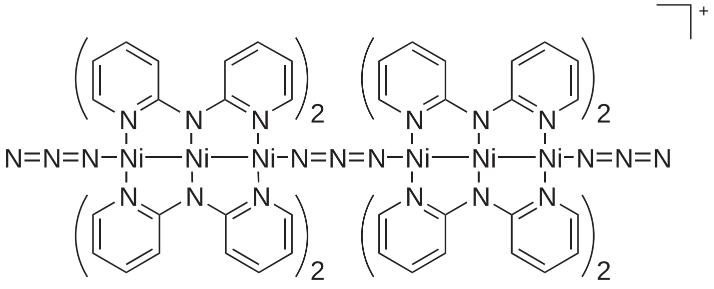
[a] Ni—N—N angles and δ and τ angles for the Ni-(μ-1,3-N_3)-Ni linkages, Ni—N—Ni angles for the Ni-(μ-1,1-N_3)-Ni subunit (°), *J* in cm^{-1}. *N*,*N*-dmen = *N*,*N*-dimethylethylenediamine; aep = 2-aminoethylpyridine; Medien = Methyldiethylenetriamine; *N*,*N*,*N′*-Me_3en = *N*,*N*,*N′*-trimethylethylendiamine; *N*,*N′*-dmen = *N*,*N′*-dimethylethylenediamine; tmeda = *N*,*N*,*N′*,*N′*-tetramethylethylenediamine. [b] Using a different model, see text.

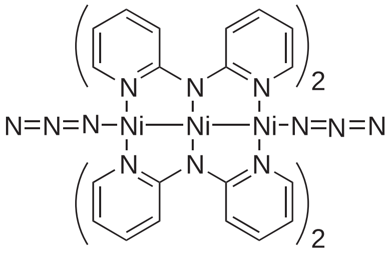
(o) Combination of μ-1,1-azido bridges with other linkages in alternating chains. A straightforward strategy to obtain alternating chains is the use of different types of bridging ligands. This approach has been followed for the synthesis of $[Ni_2(dpt)_2(\mu\text{-ox})(\mu\text{-}N_3))_n](PF_6)_n$ (and its Medpt derivative) in which oxalato and azido bridges alternate (**895**).[2180,2181] The oxalato group is coordinated in the common bis-bidentate mode, and the azido ligand is coordinated in an asymmetric EE mode with Ni—N—N = 120.1° and 119.41° and a very large torsion angle along the Ni–N_3–Ni group (102.1°). $J_1 = -27.4\,\text{cm}^{-1}$, $J_2 = -2.7\,\text{cm}^{-1}$ ($\alpha = 0.1$) have been obtained by means of the Borrás-Almenar equation.[2164] Since the J parameter is found in the range $-30\,\text{cm}^{-1}$ to $-39\,\text{cm}^{-1}$ for all Ni–oxalato systems reported, assignment of the two J-values is evident. The low value for J_2 is presumably due to the very high torsion angle of the Ni–N_3–Ni entity.



(895)



(896)



(897)

An unusual 1D alternating chain compound (**896**) consists of trinickel(II) units $[Ni_3(dba)_4]^{2+}$ (dba = di(α-pyridyl)amide) that are linked by EE azido bridges.[2182] Within the N_3 entity, the two terminal Ni^{II} are high spin ($S = 1$) while the central Ni^{II} is low spin ($S = 0$) Thus, the $S = 1$ ions in the 1D structure are alternately bridged by the $S = 0$ anions and by μ-1,3-azide. Magnetic data reveal overall antiferromagnetic behavior and are fitted by a dimer model to give results similar to those for the related dinuclear complex (**897**).[2182]

(v) Two-dimensional systems

The anionic substructure of the salt $Cs_2[Ni(N_3)_4]\cdot H_2O$[2183] consists of a 2D structure formed by $Ni(N_3)_6$ octahedra connected via four EE azido groups placed in a distorted plane, but no magnetic data have been reported.

The compound $[Ni(2,2\text{-mettn})(\mu\text{-}N_3)]_n$ (2,2-mettn = 2,2-dimethyl-propanediamine) forms a 2D layer system with ferro-antiferromagnetic alternation, in which each azido ligand coordinates three Ni^{II} ions in a μ_3-1,1,3 mode.[2184,2185] The sheets are linked by hydrogen and van der Waals forces. This system shows a spin canting phenomenon at unexpectedly high temperatures (close to 50 K). A metamagnetic 2D compound $[Ni(N,N\text{-}Et_2\text{-}N'\text{-Meen})(\mu\text{-}N_3)_2]_n$ (N,N-Et_2-N'-Meen = N,N-diethyl-N'-methylethylenediamine) has been reported, where dinuclear nickel units with double EO azido bridges are further linked to four equivalent entities by means of single EE azido bridges.[2186] Magnetic data reveal intralayer ferromagnetic interactions and interlayer antiferromagnetic interactions.

The structure of $[Ni(bpa)(N_3)_2]_n$ (bpa = 1,2-bis(4-pyridyl)ethane) is deduced from the X-ray analysis of the isomorphous Mn compound. Its 2D sheet arrangement is composed of chains of octahedrally coordinated metal ions bridged by double μ-1,3 azido linkages that are connected through bpa ligands.[2187] Magnetic data for the Ni^{II} system are characteristic of strong overall antiferromagnetic exchange, and treatment as a uniform linear $S=1$ chain (assuming that coupling through the bpa ligands is negligible) gives $J=-80\,cm^{-1}$. Quite similar, the structure of $[Ni(4,4'\text{-bipy})(N_3)_2]_n$ is proposed to consist of chains of Ni^{II} ions that are alternately bridged by double EO/mixed EO–EE/mixed EO–EE azido linkages, where the chains are connected by 4,4′-bipyridine to give a 2D sheet structure.[2188]

6.3.4.13.2 Cyanide-based oligo- and polynuclear complexes

Stimulated by the favorable and tunable magnetic properties of 3D bimetallic assemblies of the Prussian blue type derived from $[M(CN)_6]^{3-}$ ($M=Cr^{III}$, Fe^{III}), oligonuclear and polymeric compounds of cyanometallate building blocks are receiving great attention. Ni^{II} can be involved either as the diamagnetic $[Ni(CN)_4]^{2-}$ anion acting as a bridge between paramagnetic metal ions, or as coordinatively unsaturated paramagnetic (high-spin) $[NiL_x]^{m+}$ entities that are bound to the N atoms of (dia- or paramagnetic) cyanide complexes, e.g., of hexacyanometallate building blocks $[M(CN)_6]^{3-}$ ($M=Fe$, Cr, Mn). Examples for the type $[NiL]_3[M(CN)_6]_2$ where L is a tetraza macrocycle with *trans* oriented accessible coordination sites are particularly manifold.[2189–2195] Honeycomb-like structures are formed if the [NiL] groups connect with three cyanide groups in a *fac* arrangement at the M ion, whereas a brick-wall structure results if the [NiL] groups bind in a *mer* arrangement.[2194,2195] Assembly reactions between $[(Me_3tacn)Mo(CN)_3]$ and $[(cyclam)Ni(H_2O)_2]^{2+}$ affords linear trinuclear $[(Me_3tacn)_2(cyclam)NiMo_2(CN)_6]^{2+}$ with ferromagnetic coupling ($J=+17.0\,cm^{-1}$ to $+17.6\,cm^{-1}$ depending on the counterion) and an $S=4$ ground state.[2195] Depending on the stoichiometry of the reaction, $[(Me_3tacn)_2(cyclam)_3(H_2O)_2Ni_3Mo_2(CN)_6]^{6+}$ with a zigzag structure and 1D $[(Me_3tacn)(cyclam)NiMo(CN)_3]^{2+}$ has also been obtained. Again, the magnetic behavior indicates ferromagnetic coupling.[2196] Reaction of $[(Me_3tacn)Mo(CN)_3]$ with $[Ni(H_2O)_6]^{2+}$, however, produces face-centered cubic $[(Me_3tacn)_8Mo_8Ni_6(CN)_{24}]^{12+}$ involving cyanide linkage isomerization and formation of low-spin $[Ni(CN)_4]^{2-}$ constituents. The related giant 24-metal cluster $[(Me_3tacn)_{12}Cr_{12}Ni_{12}(CN)_{48}]^{12+}$ with 12 *trans*-coordinated $[Ni(CN)_4]^{2-}$ units has been reported to result from the reaction of $[(Me_3tacn)Cr(CN)_3]$, NiI_2, and KCN.[2197] While antiferromagnetic coupling is often operative via diamagnetic $[Ni(CN)_4]^{2-}$,[2198] some 1D complexes $[NiL][Ni(CN)_4]$ (where L is a tetraaza macrocycle) show ferromagnetic interactions.[2199] Other paramagnetic ions partially coordinated with amine ligands can also be bridged by $[Ni(CN)_4]^{2-}$ to give molecular, 1D, 2D, and 3D structures, e.g., 1D polymeric $[Cu(L)Ni(CN)_4]$ with weak antiferromagnetic interactions, where L is a di- or tridentate amine ligand.[2200] The 2D coordination polymer $[Fe(py)_2Ni(CN)_4]$ consists of 2D extended cyanide sheets constructed by the alternate linkage between square planar Ni^{II} (C-bound) and octahedral Fe^{II} (N-bound) through cyano bridges, with the py ligands in *trans* positions at the Fe atoms.[2201] It undergoes a cooperative spin crossover transition between 210 K and 170 K. Using pyrazine (pz) instead of pyridine, the related 3D coordination spin crossover polymer $[Fe(pz)Ni(CN)_4]$ showing a significantly wider hysteresis loop was obtained.[2202]

6.3.4.13.3 Oligonuclear and polymeric complexes with other bridging ligands

Architectures of known oligo- and polynuclear Ni^{II} complexes are manifold, and only selected classes of compounds and selected examples can be mentioned.

The oxalate dianion is a very powerful magnetic exchange mediator. Various complexes of general type (**898**) with oxalate acting as a bis(bidentate) bridging ligand have been reported, in most cases with di-, tri-, or tetradentate amine capping ligands (e.g., (**899**), (**900**)) and, *inter alia*, $\{N_4O_2\}$,[2203–2212] $\{N_3O_3\}$,[2206,2213–2216] $\{N_2O_4\}$,[2205,2217] or $\{O_6\}$ coordination environment of the distorted octahedral Ni^{II} ions. Antiferromagnetic exchange is usually found, with coupling constants J in the range $-10\,cm^{-1}$ to $-20\,cm^{-1}$ (based on the Hamiltonian $H=-2JS_1S_2$). In general, replacement of O by N atoms in the capping ligands is accompanied by an increase of the antiferromagnetic coupling. For example, $J=-11\,cm^{-1}$ has been reported for (**901**),[2217] whereas type (**900**) systems exhibit values of $J=-17\,cm^{-1}$ to $-20\,cm^{-1}$.[2215,2217] In the mixed oxalate/tetracyanonickelate bridged complex (**902**), the magnetic exchange ($J=-15.6\,cm^{-1}$) probably takes mainly place through the oxalate.[2218] With bis(macrocyclic) pentaazaligands, polymeric Ni^{II} oxalate-bridged supramolecular structures form.[2219]

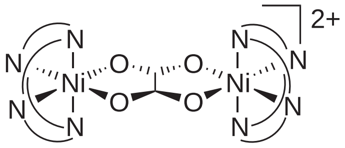
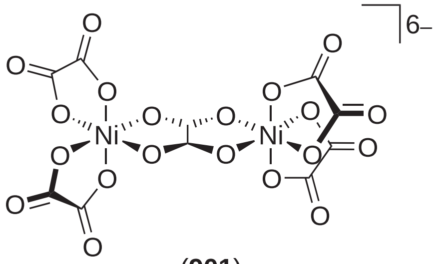
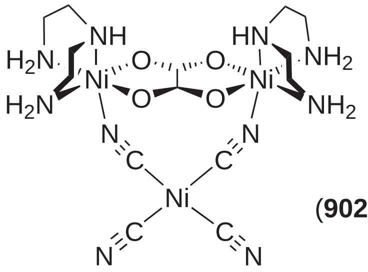
(899)



(900)



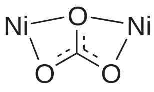
(901)



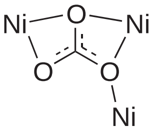
(902)

One-dimensional compounds *catena*-[(μ-MO_4-O,O′)Ni(L)] (M = Cr, Mo, W) have been structurally characterized, where L is a tetraazamacrocycle and the tetraoxometallates are in *trans* positions on each octahedral Ni^{II} ion. For M = Cr, weak intrachain ferromagnetic interactions were observed, which is explained by means of accidental degeneracy of the σ-type frontier orbitals.[2220,2221] For M = Mo and W, the Ni^{II} ions couple antiferromagnetically.[2222,2223] Tri-, tetra-, and nonanickel(II) compounds $[Ni_3(H_2O)_3(PW_{10}O_{39})H_2O]^{7-}$, $[Ni_4(H_2O)_2(PW_{10}O_{34})_2]^{10-}$, and $[Ni_9(OH)_3(H_2O)_6(HPO_4)(PW_{10}O_{34})_3]^{16-}$ contain the tungstophosphate ligand $[PW_9O_{34}]^{9-}$. Ferromagnetic interactions are present in the Ni_3 and Ni_4 species, while Ni_9 presents an antiferromagnetic triangle formed by three ferromagnetic triangular clusters.[2224,2225]

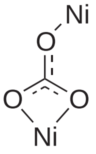
Different coordination modes have been described for the carbonate ion when it acts as a bridge in oligonuclear Ni^{II} complexes. The most common situation (**903a**)[2226–2230] as well as bridging mode (**903b**)[2231] are characterized by strong antiferromagnetic coupling due to the large Ni—O—Ni bond angles, whereas for (**903c**)[2232] only weak antiferromagnetic coupling was found. The tetranuclear butterfly-like complex $[Ni_4(\mu\text{-}CO_3)_2(aetpy)_8]^{4+}$ (aetpy = 2-(aminoethyl)pyridine, type (**903d**)) shows spin frustration with a quasi-degenerate set of spin levels $S = 0$, $S = 1$, $S = 2$.[2233]



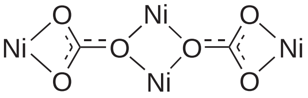
(903a)



(903b)



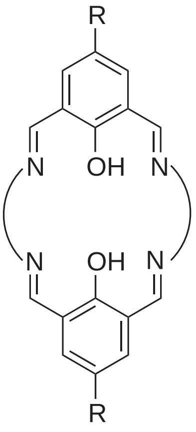
(903c)



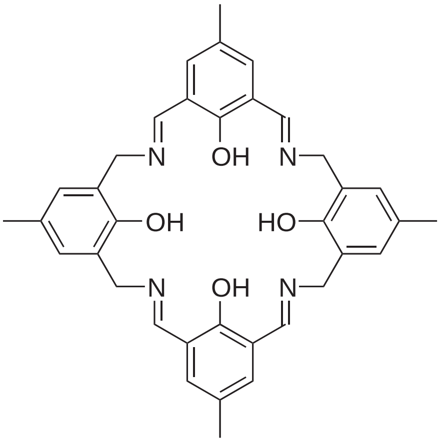
(903d)

High-nuclearity Ni_7 and Ni_{21} clusters have been prepared with citrate as a ligand.[59,2234] The Ni_7 complex has an $S = 7$ ground state,[2234] and single molecule magnet behavior at low temperature has been observed for a Ni_{21} compound with $S = 3$ ground state and magnetic anisotropy.[59]

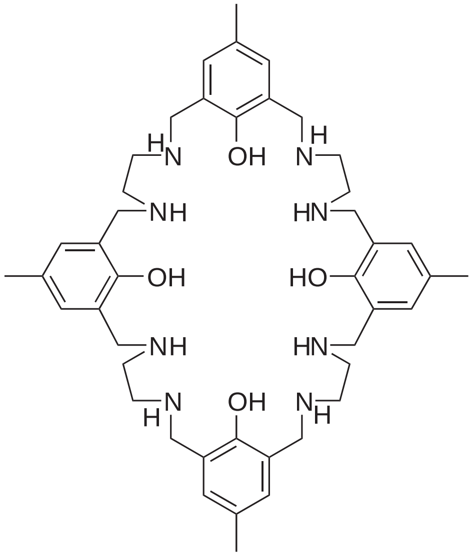
Ni^{II}–Ni^{II} magnetic exchange interactions have been thoroughly studied in various dinuclear complexes of Robson-type Schiff base macrocyclic ligands ((**904**); compare also Section 6.3.4.12.3). Although a large number of structural parameters seem to affect the superexchange mechanism, a magnetostructural correlation showing linear dependence of antiferromagnetic exchange coupling constants on the Ni—O—Ni bridge angle as well as on the intramolecular Ni· · ·Ni distance was deduced for such phenoxo-bridged complexes.[2235] In addition, an increase in tetragonal distortion around the metal ions increases the magnitude of the antiferromagnetic coupling, as does the transition from distorted octahedral to square pyramidal coordination.[2236] Similar correlations also hold for other types of phenoxo-, alkoxo-, or hydroxo-bridged dinickel(II) systems: the magnetic coupling becomes less antiferromagnetic as the Ni—O—Ni angles diminish.[2237,2238]



(904)



(905)

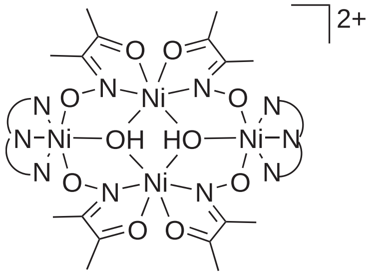


(906)

Large macrocycles like (**905**) and (**906**) form square- or rectangle-like tetranuclear Ni^{II}_4 complexes which may encircle a μ_4-OH (**905**)[2239] or μ_3-OH group (**906**).[2240,2241] The former system behaves as an essentially noninteracting pair of Ni_2 units within which there is antiferromagnetic coupling. The coupled pairs are probably those involving the dialdehyde-derived phenoxo bridges, because these subunits are almost planar.[2239] Imidazolate-bridged and 8-hydroxyquinoline-based cyclic Ni_4 complexes as well as a [2 × 2]-grid structure have been reported and magnetically analyzed.[2242–2244] Other topologies of magnetically coupled Ni_4 species include a tetrameric Ni^{II} chair (**907**)[2245] as well as a Ni_4 complex with planar triangular shape (**908**) (Figure 33).[2246] (**907**) shows antiferromagnetic internal coupling but ferromagnetic spin alignment, because the large Ni—O(H)—Ni angles between the inner and outer Ni ions are the determining feature, which by setting the larger $-2J$ value drive the two central spins parallel. Global magnetic coupling in (**908**) is ferromagnetic.

Several examples of tetranuclear Ni^{II} complexes with a Ni_4O_4 cubane core and μ_3-OR^- or μ_3-OH^- at the four corners have been described (**909**).[2247–2256] In most cases, the Ni_4O_4 skeleton is not a regular cube, but has different sets of faces. The dominant parameter in the magnetostructural correlation is the averaged Ni—O—Ni angle of each cubane face. Ferromagnetic coupling is observed when this angle is close to orthogonality, while Ni—O—Ni angles in the vicinity of and larger than 99° lead to antiferromagnetic interaction.[2257] Depending on the symmetry of the individual cubane, different J models have been used to analyze the magnetic data of such systems.

Reaction of $[Ni(acac)_2(H_2O)_2]$ with benzotriazolate (bta; or a derivative thereof) gives a pentanuclear compound $[Ni_5(OH)(bta)_5(acac)_4(H_2O)_4]$.[2258,2259] Its structure is composed of a tetrahedral arrangement of four six-coordinate Ni^{II} ions centered on the fifth, and the complex exhibits antiferromagnetic coupling with an intermediate spin [$S = 0$, $S = 1$] ground state.[2259] The ground



(907)

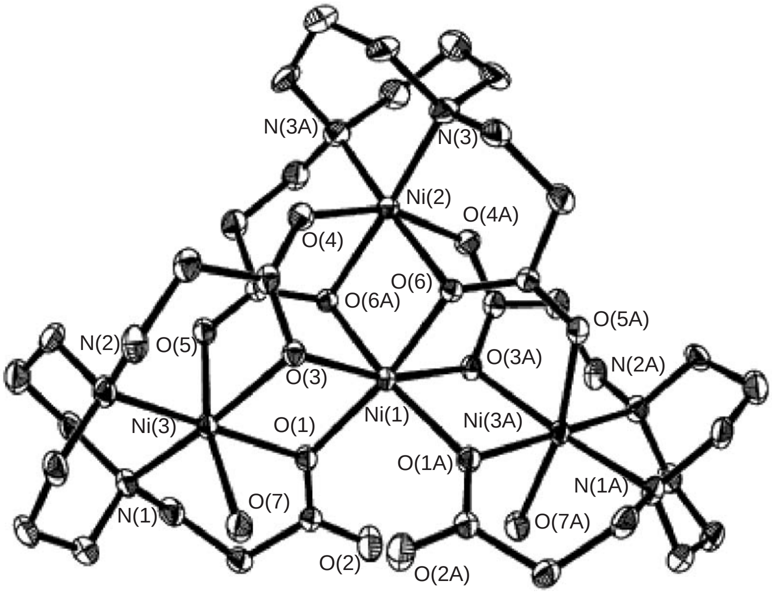

Figure 33 Structure of the $[Ni_4L_3(H_2O)_2]^{2+}$ cation (**908**) (H_2L=bis(3-propionyloxy)-4,5-diazacyclootane).[2246] Reproduced by permission of The Royal Society of Chemistry.

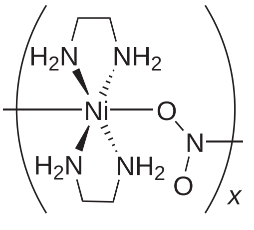
state increases with the cluster symmetry, since a totally symmetric related Ni_5 species has a $[S=1, S=2]$ ground state.[2260] Further, a nonanuclear Ni_9 complex could be obtained with the same type of ligands, where two regular tetrahedra (like in the Ni_5 complexes) share a common vertex. This compound features an intermediate spin $[S=2, S=3]$ ground state.[2260]

Type (**910**) Ni_3 complexes (as well as analogous heterotrinuclear species involving Ni^{II}) form with 1,4,7-tris(4-*t*-butyl-2-mercaptobenzyl)-1,4,7-triazacyclononane ($X=S$) and 1,4,7-tris(3,5-dimethyl-2-hydroxybenzyl)-1,4,7-triazacyclononane ($X=O$).[2261] The central Ni^{II} is connected to the outer ones via six thiolate or phenolate bridging pendent arms, respectively. Magnetic data indicate that the thiolate complex has an $S=1$ ground state whereas in the phenolate complex it is $S=3$. This is a consequence of the smaller Ni—S—Ni angle which cancels the orthogonality of the magnetic orbitals and provides an antiferromagnetic coupling pathway through overlap between filled 3*s* sulfur orbitals and the half-filled e_g set of Ni^{II}.[2261] In some different Ni_3 complexes incorporating both phenolato and acetate bridges, the Ni—O—Ni angle is much larger than 90° (as required for orthogonality) and antiferromagnetic coupling is observed.[2262,2263] A variety of linear heterotrinuclear and heterotetranuclear complexes incorporating Ni^{II} have been developed by proper design of the ligand scaffold and their magnetic properties investigated.[2264–2266]

One-dimensional Ni^{II} chains are attracting interest in connection with the Haldane conjecture.[2267,2268] Theoretical models for the exchange alternation and single-ion anisotropy in the antiferromagnetic Heisenberg $S=1$ chain have been developed.[2271] Prominent examples of such compounds is the alternating chain system $\{[Ni_2(edta)(H_2O)_4]\cdot 2H_2O\}_x$,[2269–2271] and in particular the thoroughly studied $[Ni(en)_2(NO_2)](ClO_4)$ ((**911**), often abbreviated as NENP).[2272–2274] For the latter system, magnetic measurements allowed an estimate of $13\,cm^{-1}$ for the Haldane gap.[2274] Using different anions, a dimerized Ni^{II} chain with nitro-nitrito bridges could be obtained, which also has an energy gap between the singlet ground state and low-lying excited states.[2275] Several kinds of 1D Ni^{II}–nitrito systems of the type $[\{NiL(\mu\text{-}NO_2)\}_n](ClO_4)_n$ have been



(**911**)

characterized in this connection, where L is a noncyclic tetraamine ligand,[2276] and another type of carboxylate-bridged Ni^{II} chain is known with diethylentriamine-N′-acetic acid.[2277]

The complex $[Ni_3(fum)_2(\mu_3\text{-}OH)_2(H_2O)_4]_n{\cdot}(2H_2O)_n$ (fum = fumarate) has a 3D structure formed by chains of fused Ni^{II} octahedral units and behaves as a 3D ferrimagnet.[2278]

6.3.4.13.4 Complexes with nitronyl nitroxide and verdazyl radical ligands

Complexes with radical ligands, e.g., nitronyl nitroxides (NITs, (**912**)) and imino nitroxides (IMs, (**913**)), have been actively pursued for the design of molecular based ferromagnets, since direct magnetic exchange is possible.[2279] NITs are poor O-donors towards transition metals, and hence electron-withdrawing coligands such as hexafluoroacetylacetonato (hfac) have to be used in Ni^{II} complexes of simple NITs. Magnetic properties of [Ni(hfac)$_2$(**912**)$_2$] indicate weak to strong antiferromagnetic coupling between the Ni^{II} and the radicals.[2280–2282] Auxiliary donor substituents at the NIT moiety enhance the coordination ability, and various NIT chelate ligands (in particular with pyridyl groups) have been employed in Ni chemistry. (**914**) binds via the pyridyl-N without involvement of the NIT O atom.[2283,2284] Magnetic data of [Ni(hfac)$_2$(**914**)$_2$] and [Ni(**914**)$_4$Cl$_2$] show antiferromagnetic coupling of about $-10\,cm^{-1}$.[2283] NITs and IMs with 2-pyridyl groups have been used most often, since (**915**) can act as a N,O-bidentate chelate ligand.[2285–2291] The Ni^{II} complex of a related NIT-triazole ligand (**916**) has also been reported.[2292] NITmepy (**915b**) and IMmepy (**917**) form Ni^{II} complexes with ferromagnetic interactions.[2293] The introduction of a methyl group at the *o*-position of the pyridyl ring (**915b**) can result in a coordination number lower than OC-6. For example, IMmepy forms [NiCl$_2$(**917**)], which is a dimer with pentacoordinate Ni^{II} ions bridged by two chlorides with a large Ni—Ni distance (3.5808 Å). Upon use of the slim thiocyanate, however, a six-coordinate complex *cis*(NCS)-*trans*(py)-[Ni(NCS)$_2$(IMmepy)$_2$] is formed. This complex shows distinctly longer Ni—N$_{py}$ bonds and nonplanarity between the pyridine and the imino nitroxide planes due to the steric requirements of the hexacoordination.[2293] Pyridyl-based NIT diradicals that have been studies in their Ni^{II} complexes are, *inter alia*, (**918**)[2294] and the tetradentate bipyridine derivative in (**919**). Complex (**919**) exhibits an unusually large Ni^{II}–nitroxide ferromagnetic interaction ($+39.6\,cm^{-1}$)[2295,2296] which arises from the near-coplanarity between the π-conjugated radical plane and the equatorial plane of the *trans*-diaqua-$\{Ni\{(N_2O_2)\}(H_2O)_2\}$ octahedron. Deviation from this geometry results in an antiferromagnetic component.

The carboxyphenyl-substituted ligand (**920**) forms a ladder-type polymeric structure where the nickel is coordinated simultaneously by carboxylate-O, NIT-O, and water.[2297] Binding to the NIT substituent can be enhanced by appropriate chelate sites, e.g., in (**921**).[2298] Complex (**921**) shows weak ferromagnetic coupling via the diamagnetic Ni^{II}. The spin-labeled dioxime 2,2,5,5-tetramethyl-1-oxylpyrrolidine-3,4-dione dioxime (H$_2$L) forms with Ni^{II} a planar complex [Ni(HL)$_2$] (**922**) with an intramolecular hydrogen bond between the oximic oxygens.[2299] In the solid state the square planar environment of the metal is completed to distorted octahedral by the O atom of the N—O groups of a neighboring molecule. This leads to formation of a parquet-like layered polymer structure in the solid. The Ni—O distance is, however, long (2.953 Å) and the Ni^{II} ion remains low spin. The layered polymer structure is responsible for the formation of exchange clusters >N—O• • •Ni• • •O—N< with effective interactions between the magnetic orbitals of the nitroxyl groups via the diamagnetic metal ions.

The presence of β-hydrogen in the nitroxide radical may lead to disproportionation reactions. In spin-trapping experiments, N-*t*-butyl-α-phenyl nitrone yields rather unstable spin adducts. This type of radical can be stabilized by coordination to Ni^{II}. The Ni^{II} complex with N-oxy-*N*-*t*-butyl-(2-pyridyl)phenylmethanamine (**923**) reveals a distorted octahedral geometry with antiferromagnetic interactions between the unpaired electrons of the metal ion and the radical spins.[2300]

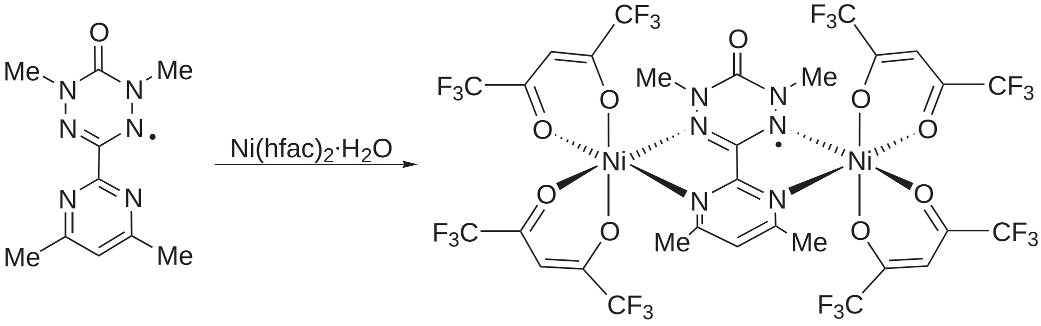
Verdazyl radicals have been proposed as attractive alternatives to NITs, because they offer several potential donor atoms. The first verdazyl radical complexes of open-shell ions were reported in 2000. Electron-withdrawing hfac ancillary ligands and chelate assistance by a pyridyl substituent have been used to prepare (**925**) from (**924**). The verdazyl–Ni^{II} coupling is strong and ferromagnetic ($J = +120\,cm^{-1}$ as a lower limit), which is explained by orthogonality of the magnetic orbitals.[2301] The dinuclear complex (**927**) is accessible from the pyrimidine–verdazyl ligand (**926**). It has an $S = 5/2$ ground state due to strong Ni^{II}–verdazyl ferromagnetic coupling ($J = +110\,cm^{-1}$).[2302] Other verdazyl ligands employed in Ni^{II} coordination chemistry are tridentate (**928**) (which gives $[Ni(\mathbf{928})_2]^{2+}$) and water-soluble (**929**) (which gives $[Ni(\mathbf{929})_2H_2O)_2]$).[2304]

6.3.4.14 Miscellaneous Complexes of Nickel(II)

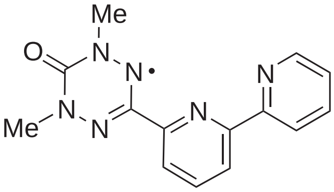
6.3.4.14.1 Complexes with silyl and silylene ligands

Quite a number of silylnickel and silylenenickel compounds have been reported, and only a few can be cited here.[2305–2309] Bis(silyl)nickel complexes have been implicated as important intermediates in Ni-catalyzed double silylation of various organic substrates. Using an *o*-bis(dimethylsilyl)carborane ligand, complex (**930**) could be isolated and structurally characterized.[2310] Its unusual thermal stability is attributed to the advantageous steric and electronic properties of the carboranyl unit. (**930**) undergoes subsequent double silylation reactions with unsaturated organic substrates. (**931**) is another example of a bis(silyl)nickel(II) complex.[315]

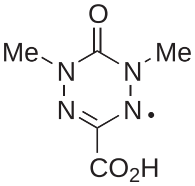
Reaction of the 1-silacyclopropene (**932**) with $[Ni(PEt_3)_4]$ gives nickelasilabutene (**933**).[2311]



(**926**) (**927**)



(**928**)



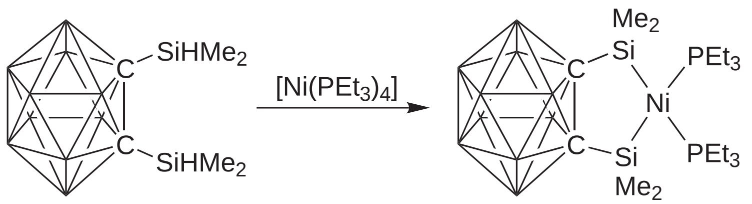
(**929**)

6.3.4.14.2 *Hydride complexes*

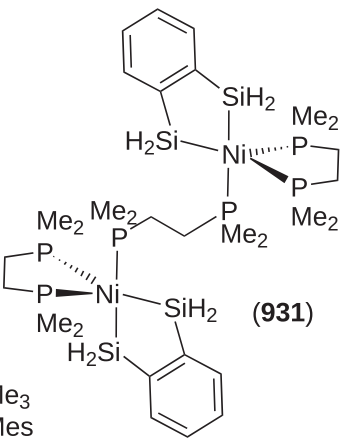
Ni hydrides have been implicated as reactive species in various organometallic transformations and catalytic processes, e.g., ethene oligomerization by (**934**).[2312] Giving the importance of Ni hydrides in industrial and possibly enzymatic processes, only few examples will be mentioned here in order to indicate the scope: *inter alia*, stereoselective cyclization of a 1,3-diene and the carbonyl group in a chain is mediated by a Ni^{II} hydride complex generated from $[Ni(acac)_2]$ and DIBAL-H in the presence of PPh_3,[2313] and silane alcoholysis is catalyzed by a Ni^{II} complex with {N,O,S} coordination.[1255] Ethylene dimerization by [Ni(acac)H][2314] and oxidative addition of H_2 to Ni^{II} complexes such as $[NiCl_2(PH_3)_2]$ to give the formal Ni^{IV} complex $[NiH_2Cl_2(PH_3)_2]$ have been studied by DFT and *ab initio* methods, respectively.[2315]

Square planar Ni^{II} hydride complexes *trans*-$[NiH(X)(PCy_3)_2]$ (**935**) are conveniently accessible by addition of HX to the dinitrogen complex $[(PCy_3)_2Ni\text{-}NN\text{-}Ni(PCy_3)_2]$, and subsequent substitution of X gives rise to manifold derivatives such as *trans*-$[NiH(CH_3)(PCy_3)_2]$ and *trans*-$[NiH(Ph)(PCy_3)_2]$.[2316] The *trans* influence of the X ligand on the Ni—H bond has been investigated, using the IR-derived ν(Ni—H) stretching frequencies and the ^1H NMR chemical shifts.[2317] CO_2 and MeI were used as chemical probes: derivatives with a stronger Ni—H bond (S- and O-donors) show no reactivity while the C-bond derivatives exhibit CO_2 insertion at the hydride. While *trans*-$[NiH(CH_3)(PCy_3)_2]$ gives the hydridonickel formate complex *trans*-$[NiH(HCO_2)(PCy_3)_2]$, *trans*-$[NiH(Ph)(PCy_3)_2]$ simply gives *trans*-$[Ni(HCO_2)(Ph)(PCy_3)_2]$.[2318] In the C-donor derivatives, the Ni—H bond is reactive towards MeI via H-atom abstraction by methyl radicals. With CCl_4 and $CHBr_3$, *trans*-$[NiH(Cl)(PCy_3)_2]$ reacts to give $[NiCl_3(PCy_3)]^-$ and $[NiBr_3(PCy_3)]^-$, respectively.[2319]

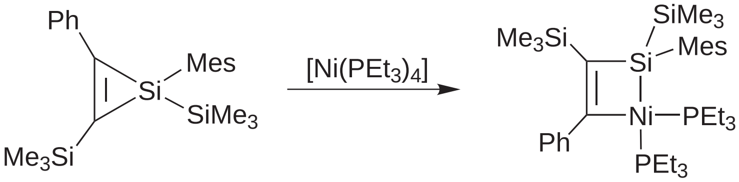
Complexes $[Ni(H)(diphosphine)_2]^+$ can be prepared by two ways, either by reaction of $[Ni^{II}(diphosphine)_2]^{2+}$ with H_2 in the presence of base, or by reaction of $[Ni^0(diphosphine)_2]$ with $NH_4{}^+$. A linear free energy relationship exists between the half-wave potentials of the Ni^I/Ni^{II} couples of different $[Ni(diphosphine)_2]$ complexes and the hydride donor ability of the corresponding $[Ni(H)(diphosphine)_2]^+$.[2320] Several methods have been used to determine those hydride



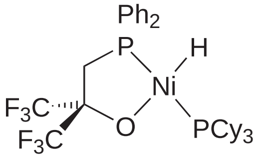
(**930**)



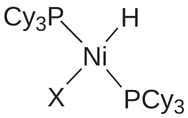
(**931**)



(**932**) (**933**)



(**934**)



(**935**)

donor abilities, which is useful for understanding the differences in the reactivity of $[Ni(diphosphine)_2]^{2+}$ towards H_2.[2321]

6.3.5 COMPLEXES OF NICKEL(I)

6.3.5.1 Introduction

Similar to the high-valent Ni story, significant impetus for the interest in low-valent Ni chemistry stems from the involvement of Ni^{I} species in bioinorganic processes, predominantly from the unique Ni^{I} state of the active form of coenzyme F_{430} of methylcoenzyme M reductase (MCR) and the possible relevance of Ni^{I} in [Ni,Fe] hydrogenase. This also contributes to the particular prominence of nitrogen- and sulfur-based ligand systems in studies on Ni^{I} complexes. However, not every ligand environment can support Ni^{I}, and in many cases Ni^{0} is produced directly upon reduction of Ni^{II} compounds. Hence, most Ni^{I} species with simple N and O ligands are thermodynamically and kinetically unstable with respect to disproportionation into Ni^{0} and Ni^{II}. Stabilization of Ni^{I} is more easily achieved by soft donor ligation (C, P, As, S donor atoms) or by a macrocyclic environment. The redox chemistry of nickel has been reviewed.[63]

6.3.5.2 Complexes with Nitrogen Donor Ligands

6.3.5.2.1 Complexes with macrocyclic nitrogen donor ligands

Similar to porphyrin systems, Ni^{I} complexes with macrocyclic $\{N_4\}$ ligands (in particular of the cyclam type) have been considered particularly instructive with respect to the chemistry of the active site of methyl coenzyme M reductase. In most cases, Ni^{I} species are produced by reduction of the corresponding Ni^{II} complexes. Electrochemical properties of the Ni^{II} macrocyclic complexes are related to the cavity size, the unsaturation, the degree of functionalization, and the subring moieties fused to the macrocycles. These aspects are also covered in the sections dealing with Ni^{II}, and the reader should refer to Section 6.3.4.10.2(iii) for additional information.

Electrochemical reduction has been used to great extent in the synthesis of Ni^{I} macrocyclic complexes. For example, the divalent nickel complexes of cyclam (**936**), tetramethylcyclam (tmc, (**937**)), *meso*-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane (**938**), and decamethylcyclam (**939**) were reduced to their corresponding Ni^{I} complexes in aqueous solution.[2322] Redox potentials for the Ni^{II}/Ni^{I} couple are −1.58 V, −1.15 V, −1.42 V, and −0.98 V (vs. SCE), respectively, indicating that the major effect is the strength of the Ni—L interaction, in agreement with the clear correlation between the redox potentials and $10\Delta q$ values determined spectrophotochemically. The effects of *N*-methylation on the Ni^{II}/Ni^{I} couples and on the properties of the Ni^{I} complex in solution have been studied for a large series of tetraazamacrocyclic cyclam analogues.[2323] The positive shift in redox potential observed on methylation is largely a consequence of the decrease in solvation energy of the Ni^{II} complex. However, the lifetime of the Ni^{I} complex is not linearly related to the redox potential. Methyl substituents bound to the N atoms of cyclam slow down the ligand loss reaction in water.[2322] Disulfides react with [Ni(**937**)]$^+$ by oxidative addition to give [Ni(**937**)(SR)]$^+$.[1967]

R,*S*,*R*,*S*-[Ni(**937**)]$^+$ reacts with a series of alkyl halides in aqueous alkaline solution to form alkylnickel(II) complexes of the type [RNi(**937**)]$^+$. Kinetic data indicate that the reaction occurs in two steps, the first being a one-electron transfer from [Ni(**937**)]$^+$ to RX (X = halide), yielding an alkyl radical R. The second step involves rapid capture of the alkyl radical by [Ni(**937**)]$^+$.[2324] [Ni(**937**)]$^+$ has also been reacted with a number of variously disubstituted alkanes, including 1,4-dihaloalkanes,[2325] 1,5-dihaloalkanes,[2326] 1,2-disubstituted alkanes, 1,3-disubstituted alkanes, 1,4-disubstituted alkanes, 1,5-disubstituted alkanes, and 1,6-disubstituted alkanes.[2327] Reaction products ranged from ethylene to cyclopentane depending on the disubstituted alkane employed. Further, Ni^{I} macrocycle complexes have been used as electron transfer catalysts in the radical cyclization of halogeno ethers. When the Ni^{I} macrocycle complexes were generated electrochemically from their corresponding Ni^{II} complexes, enhanced catalytic activity relative to those generated by reduction with Zn or Mn metal was observed.[2328]

The effect of steric crowding on the rates of reaction of the Ni^{I} tetraaza macrocycle complex [Ni(dmc)]$^+$ with organic halides and hydroperoxides has also been examined. Reaction with this complex was found to be about 104 times slower than with the corresponding [Ni(tmc)]$^+$ complex.[2329]

meso-(**941**)

The Ni^{I} complexes may exist in different isomeric forms, and the form obtained may depend upon whether pulse radiolysis of electroreduction are employed to synthesize them.[2323] Usually, isomeric integrity of tmc nickel complexes is not maintained upon going from Ni^{II} to Ni^{I}:

chemical reduction (Na/Hg) of either Ni^{II} isomer (*R,R,S,S* or *R,S,R,S*) resulted in production of both Ni^{I} isomers.[1967,2324] *R,R,S,S*-[Ni(**937**)](OTf)·NaOTf has been structurally characterized.[1967] The {N4} environment is rigorously planar, but two sets of distinct Ni—N distances are observed (2.120(5) Å and 2.095(5) Å), which is a common phenomenon in square planar Ni^{I} (and Ni^{II}) complexes. Upon reduction, the average Ni—N distance has increased by 0.12 Å to accommodate the larger Ni^{I} ion. Comparison of $[Ni^{II}(R,S,S,R\text{-}(\mathbf{940}))]^{2+}$ with $[Ni^{I}(R,S,S,R\text{-}(\mathbf{940}))]^{+}$ shows a lengthening of the Ni—N bonds from 1.948–1.969 Å in the Ni^{II} complex to 2.053–2.083 Å in the Ni^{I} analogue because of the placing of an extra electron in the $d_{x^2-y^2}$ orbital and reduction of ligand field strength, but distortion of the macrocycle core is not observed.[2330]

The X-ray crystal structure of *meso*-$[Ni^{I}(\mathbf{942a})]^{+}$ reveals a distorted square planar environment with Ni—N bonds that are 0.128 Å ($Ni—N_{amine}$) and 0.077 Å ($Ni—N_{imine}$) longer than for the *meso*-$[Ni^{II}(\mathbf{942a})]^{2+}$ complex due to the extra electron in the $d_{x^2-y^2}$ orbital. Similar values have been deduced from EXAFS data both for $[Ni^{I}(\mathbf{942a})]^{+}$ and $[Ni^{I}(\mathbf{942b})]^{+}$, while for $[Ni^{II}(\mathbf{943a})]^{+}$ the reduction is ligand centered to give a π anion radical.[2331] EXAFS data on the CO adducts of $[Ni^{I}(\mathbf{942a})]^{+}$ and $[Ni^{I}(\mathbf{942b})]^{+}$ clearly showed pentacoordination with the presence of a short Ni—C bond (1.78–1.80 Å), which is accompanied by a dramatic increase of the Ni—N distances and further distortion of the macrocycle. Coordination of CO to the π anion radical $[Ni^{II}(\mathbf{943a})]^{+}$ likewise gives $[Ni^{I}(\mathbf{943a})(CO)]^{+}$, which involves substantial displacement of the metal ion out of the $\{N_4\}$ plane. The latter reaction provides an alternative route toward Ni^{I} formation.[2331]

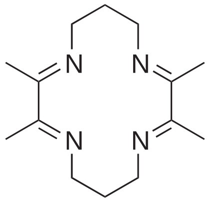
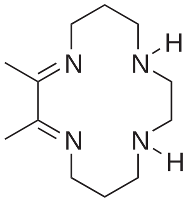
(942b)



(943a)



(943b)

Binding constants and ν(CO) for various Ni^{I}–CO complexes were determined; representative examples are collected in Table 21. Generally, the CO binding ability is related to the electron donating ability of the ligand and to steric effects. CO stretching frequencies decrease and CO binding constants increase as $[NiL]^{+}$ becomes a more powerful reductant. $[Ni(\mathbf{937})]^{+}$ is an exception, and its stronger binding of CO has been attributed to the macrocycle conformation that protects the bound CO in the cavity of the four methyl groups.[2331]

Ni^{I} complexes (**944**)–(**950**) with various different saturated polyaza macrotricyclic ligands having noncoordinated nitrogen atoms in the ligand framework have been prepared by reduction of the Ni^{II} complexes with Na/Hg in acetonitrile. The crystal and molecular structures of (**948**), (**946**), and (**945**) were determined.[1582,2333] Both complexes were found to have essentially square

Table 21 Carbon monoxide binding constants[a] and carbonyl vibrational frequencies in CH_3CN at 25 °C.

planar coordination geometry, although some square pyramidal (**948**) or tetrahedral (**945**, **946**) distortion was discernible. Usually, there are two sets of Ni—N bond distances, e.g., three at 1.978(3) (av.) Å and one at 1.878(4) Å in the case of (**946**), without any noticeable expansion of the macrocyclic hole.[2333]

A square pyramidal Ni^I complex, *R*,*S*,*R*,*S*-[Ni(**945**)(NHC(OH)CH_3)]$^+$ has been obtained by the reduction of *R*,*R*,*S*,*S*-[Ni(**945**)]$^{2+}$ with Na/Hg in MeCN under a N_2 atmosphere.[2334] In the formation of the complex, the solvent MeCN was hydrated to acetamide and coordinated to the Ni^I ion in the iminol form. All Ni—N bonds are significantly longer than those of the square planar Ni^I complex *R*,*R*,*S*,*S*-[Ni(**945**)]$^+$.

EPR spectra of the dinickel(I) complexes (**951**)–(**953**) with bis(macrocyclic) ligands show that the two metals behave independently.[1867]

Irradiation of solutions of $[Ni(L)]^{2+}$ and 0.01 M HCO_2Na (L = (**939**), (**947**)) with γ-rays or 3 MeV electrons afforded $[Ni(L)]^+$.[2335] Injection of methyl coenzyme M ($MeSCH_2CH_2SO_3^-$) gave methane, blank experiments without the Ni complexes did not.

Reaction of $[CH_3Co(dmgBF_2)_2L]$ ($dmgBF_2$ = (difluoroboryl)dimethylglyoximato, L = py, PEt_3) with two equivalents of [Ni(**937**)]$^+$ gave $[Co(dmgBF_2)_2L]^-$, [Ni(**937**)]$^{2+}$, and [Ni(**937**)CH_3]$^+$ in 80% yield.[1862] The overall transformation provides a model for the transfer of a CH_3 group from methylcobalamin to the Ni-containing enzyme CO dehydrogenase during acetyl CoA synthesis. *R*,*R*,*S*,*S*-[Ni(**937**)CH_3](BAr'_4) (BAr'_4 = $B(3,5\text{-}(CF_3)_2C_6H_3)_4^-$) was characterized by X-ray diffraction. The products and stoichiometry of the reaction are consistent with a three-step mechanism initiated by electron transfer from $[Ni(tmc)]^+$ to $[CH_3Co(dmgBF_2)_2L]^-$. The second step is rapid CH_3—Co bond homolysis yielding $[Co(dmgBF_2)_2L]^-$ and CH_3, and then the CH_3 radical is captured by the second equivalent of [Ni(**937**)]$^+$, yielding [Ni(**937**)CH_3]$^+$.

The fact that Ni^{II} tetraamine macrocycle complexes catalyze CO_2 electroreduction, even in aqueous solution (compare Section 6.3.4.10.2(v)), encouraged detailed studies of the interaction of

CO_2 with the reduced Ni^I species. *Inter alia*, cyclic voltammetry has been used to measure the binding constant for complexation of CO_2 by various electrogenerated Ni^I tetraazamacrocycle complexes.[2336] Complexes $[Ni(L)]^+$ (L = conjugated diimine or tetraimine macrocycle, or sterically hindered tetraamine macrocycle) do not bind CO_2 strongly. Interestingly, the complex which binds CO_2 most strongly is that with parent cyclam (**936**); $[Ni(cyclam)]^{2+}$ is the most effective catalyst for CO_2 electroreduction. The mechanism of the latter reaction has been studied in aqueous solution at mercury electrodes, using electrochemical techniques,[1635] and the thermodynamics and kinetics of CO_2 and H^+ binding to $[Ni(cyclam)]^+$ in aqueous solution have been explored.[2337] Reduction of $[Ni(cyclam)]^{2+}$ by hydrogen atoms proceeds by an inner-sphere mechanism ($k = 5 \pm 2 \times 10^9\,M^{-1}\,s^{-1}$) to give $[Ni(H)(cyclam)]^{2+}$, which decomposes to $[Ni(cyclam)]^+$ and H^+ ($k = 6.3 \pm 0.7 \times 10^5\,s^{-1}$). Reduction by $CO_2{}^-$ is also inner-sphere ($k = 6.7 \pm 0.2 \times 10^9\,M^{-1}\,s^{-1}$); the intermediate $[Ni(CO_2)(cyclam)]^+$ decomposes to $[Ni(cyclam)]^+$ and CO_2 ($k = 2.0 \pm 0.2 \times 10^6\,s^{-1}$). The equilibrium constant for CO_2 dissociation is 0.062 M; this compares with a pK_a of 1.8 for the hydride complex, and suggests why $[Ni(cyclam)]^{2+}$ is selective as a catalyst for CO_2 electroreduction even in aqueous solution at pH 4.

6.3.5.2.2 Complexes with nonmacrocyclic nitrogen donor ligands

Since most Ni^I species with simple N-donor ligands are prone to disproportionation into Ni^0 and Ni^{II}, relatively few Ni^I complexes with nonmacrocyclic N-donor ligands have been reported. Formation of Ni^I species is in most cases proposed on the basis of electrochemical data, although ligand-centered redox processes have to be considered. The ligands usually contain imine donor atoms or aromatic N-heterocycles, which because of their π-acceptor ability favor stabilization of lower oxidation states.

Ni^{II} complexes with aminopyridine ligands (**954**)–(**956**) can be reversibly reduced to relatively stable EPR-active Ni^I complexes in solution.[2338] The EPR spectrum of the more flexible [Ni(**954**)]$^{2+}$ is rhombic with $g_\perp > g_\parallel$ ($g_x = 2.239$ and $g_y = 2.199$, $g_\parallel = 2.025$) indicative of a $(d_{z^2})^1$ ground state in trigonal bipyramidal coordination geometry, while the EPR spectrum of the methylated [Ni(**955**)]$^{2+}$ is characteristic of a $(d_{x^2-y^2})^1$ ground state with $g_\parallel > g_\perp$ ($g_\parallel = 2.324$, $g_\perp = 2.079$), suggesting a square planar environment. Dissociation of one of the ethylpyridine arms in the latter case is corroborated by the identical spectra of [Ni(**955**)]$^{2+}$ and [Ni(**956**)]$^{2+}$. The half-wave Ni^{II}/Ni^I potentials increase in the series [Ni(**954**)]$^{2+}$ (−1.01 V) < [Ni(**955**)]$^{2+}$ (−0.91 V) < [Ni(**956**)]$^{2+}$ (−0.83 V; all vs. SCE), showing that *N*-methylation stabilizes the lower oxidation state.[1575,2338]

The Ni^I complex with the ligand 1,2-bis(pyridine-2-carboxamido)benzene (H_2bphen), generated by reduction with Na amalgam of the homologous Ni^{II} complex, was studied by EPR and electronic spectroscopy.[2339] Analysis of the spectroscopic data revealed that the complex exhibits low covalency in the σ in-plane bonding and high covalency in the out-of-plane π bonds, which has enabled the assignment of the electronic bands at 13,500 cm^{-1} and 19,600 cm^{-1} of $[Ni^I(bphen)]^-$ (**957**). This may have implications for the spectral characterization of cofactor F_{430}.

Catenane ligands such as (**958**) strongly stabilize Ni^I with respect to Ni^{II} because of the overwhelming preference of this ligand for tetrahedral coordination.[2340,2341] The Ni^I complex could be generated by constant potential electrolysis of [Ni(**958**)]$^{2+}$ at −0.45 V in CH_3CN and, furthermore, a second reversible one-electron transfer (assigned to Ni^I/Ni^0) was found at −1.325 V. Crystal structures of both the Ni^{II} and Ni^I complexes have been obtained.[2341] The orange Ni^{II} complex is very distorted four-coordinate, with the Ni^{II} ion lying almost in a plane surrounded by three of the four N atoms (mean Ni—N distance = 2.01(4) Å), which may in part be due to the maximizing of π–π interactions in the ligands. However, the Ni^I ion is at the center of a tetrahedral coordination sphere (mean Ni—N distance = 1.98(2) Å) and π–π stacking interactions are no longer significant.

Nickel complexes of bpy and related ligands are active electrocatalysts for CO_2 reduction. $[Ni(terpy)_2]^{2+}$ undergoes two successive one-electron reductions at −1.20 V and −1.38 V in DMF.[2342] In the presence of CO_2, the cathodic peak current for the first process is enhanced greatly. Electrodes modified with films of poly-$[Ni(4'\text{-vinylterpy})_2](PF_6)_2$ (grown by repetitive cyclic voltammetry between 0.00 V and −1.70 V of a solution of the complex in CH_3CN) were also active for CO_2 electroreduction in DMF, and, unlike the complex in solution, for O_2 reduction in water. Interestingly, both two-electron O_2 reduction (giving H_2O_2) and four-electron reduction to H_2O occurred.

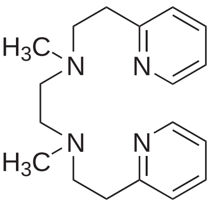
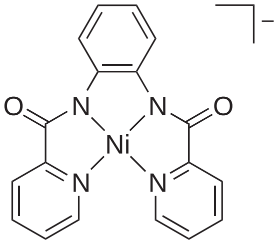
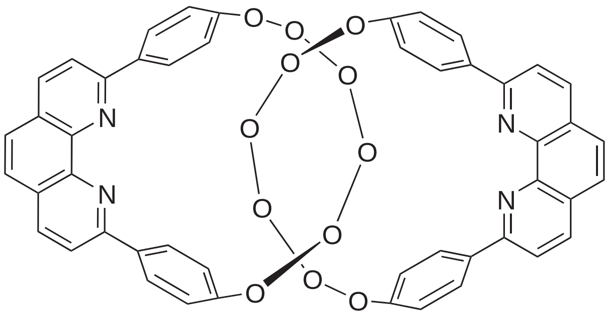
(955)



(956)



(957)



(958)

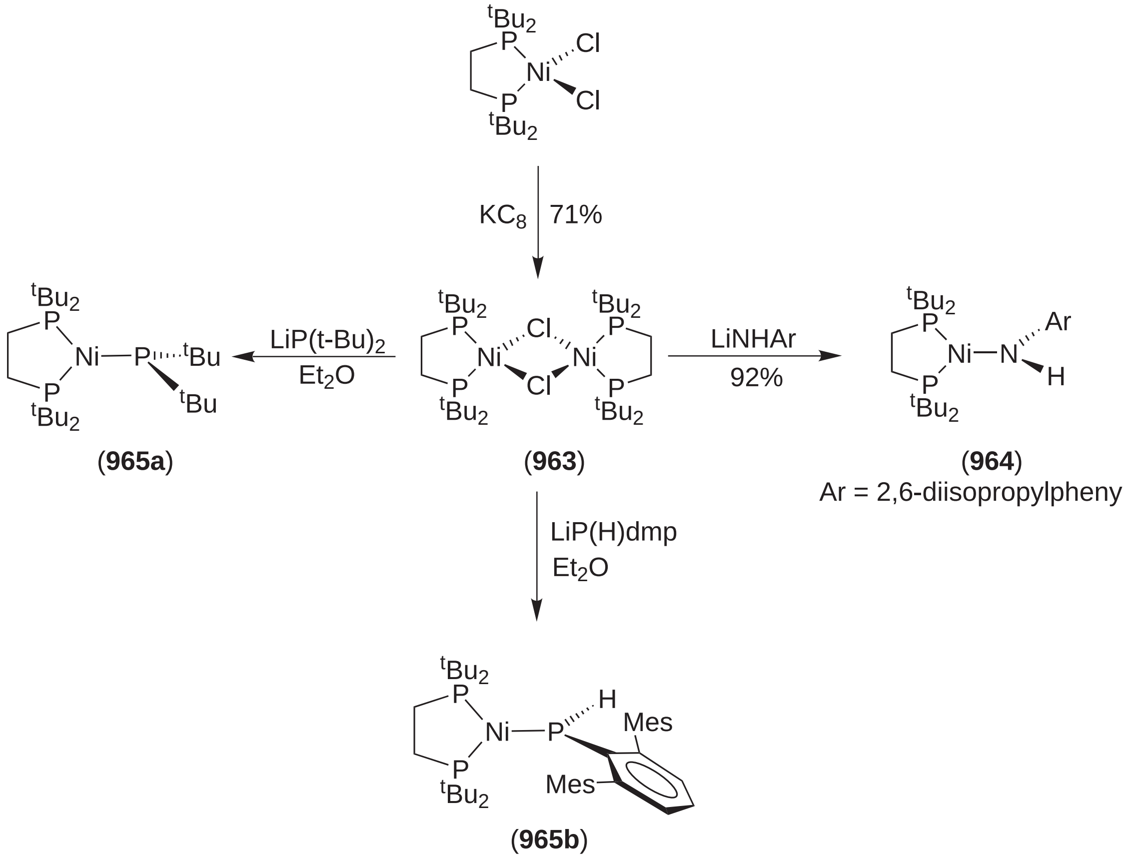
Like several other systems, Ni complexes of (**954**) and (**955**) show high catalytic activity in the electroreduction of 1,2-*trans*-dibromocyclohexane into cyclohexene.[2338]

For a terminal amido complex of Ni^I, see Section 6.3.5.4 ((**964**) in Scheme 13).

6.3.5.2.3 *Complexes with porphyrins and related ligands*

The redox properties of Ni^{II} porphyrins have been extensively studied and a detailed review of their electrochemistry in nonaqueous media has appeared.[2343] Nickel porphyrins are typically reduced in two one-electron transfer steps, although some Ni^{II} porphyrins with highly electron-withdrawing groups can be reduced by a total of three electrons.[2344] In most cases, the initial oxidations and reductions involve the porphyrin π-system, but examples where the first electron is added to the central metal ion to give a Ni^I species[2345–2347] are well documented. The study of Ni^I with porphyrin-type $\{N_4\}$ ligands (and their reduced analogues) receives major impetus from the interest in the active site of methyl coenzyme M reductase (compare Section 6.3.4.11.7). The pentamethyl ester of coenzyme F_{430} has been reversibly reduced from the Ni^{II} form to the Ni^I form, and UV–visible spectra (characteristic absorption maxima at 380 nm and 750 nm) as well as quasi-axial EPR spectra indicate that the Ni^I complex is approximately square planar with the unpaired electron in an orbital of $d_{x^2-y^2}$ character.[2348]

Major factors that determine the Ni^{II}/Ni^I redox properties are the core size, the flexibility of the macrocycle, and the electronic properties of substituents.[2349] Molecular mechanics has been used to examine the effect of macrocyclic reduction on the core–hole size of porphyrins and applied to the nickel–tetrapyrrole F_{430} cofactor.[2350] Macrocycle reduction at the two methin protons provides the F_{430} macrocycle with the flexibility necessary to accommodate both high-spin (six-coordinate) and low-spin (square planar four-coordinate) Ni^{II}. However, the relative inability to ruffle due to the steric effect of peripheral substituents implies that the $\{N_4\}$ core of F_{430} cannot contract sufficiently to coordinate optimally a low-spin Ni^{II} ion, which appears to be a key factor for stabilization of the larger Ni^I and high-spin Ni^{II}.[2351]

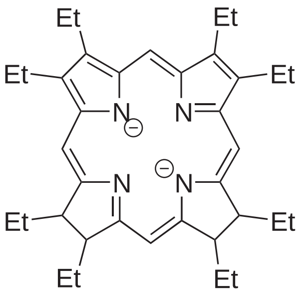


Scheme 13

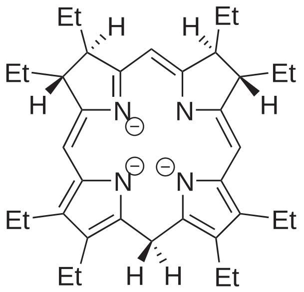
The relationship between half-wave potential, the site of electron transfer, and the catalytic activity of a given $[(\text{porphyrin})\text{Ni}]^-$ complex towards CH_3I reduction has been investigated for various Ni^{II} porphyrin compounds. For example, five out of seven electrogenerated complexes, $[(\text{porphyrin})\text{Ni}]^-$, reacted catalytically with CH_3I under an applied potential, suggesting the presence of Ni^I in the singly reduced species.[2346]

Complexes of isobacteriochlorins are frequently used as F_{430} mimics because they, too, can be reduced to isolable Ni^I complexes;[2352,2353] reduction leads to nickel hexahydroporphyrin complexes. $[Ni^I(\text{oeibc})]$ has been studied as a model for the active site of F_{430} using EPR and ENDOR spectroscopy; bond lengths and spectroscopic data were correlated.[2354] The stability of $[Ni^I(\text{oeibc})]$ is greatest in polar solvents. With weak acids such as water, alcohols, and thiols it affords H_2 with an apparent stoichiometry of 2:1 Ni^I:H_2.[2355] The reactions of $[Ni^I(\mathbf{959})]^-$ with alkyl and aryl halides have been studied, and the organic products resulted from reduction or dehydrohalogenation;[2356] alkene formation was favored by polar solvents, and isomerization of alkenes occurred during reaction. This implies the intermediacy of Ni—H and Ni—R species in the reactions. Detailed vibrational studies have been reported.[2357] Although the Ni^I complex of (**959**) is very resistant to further reduction, in the presence of proton donors reduction of the macrocycle ring occurs,[2353] affording initially the Ni^I complex of (**960**), the first complex of this precorrin to be identified.

Reduction of both nickel porphyrins and thiaporphyrins to Ni^I species has been studied by EPR and ^2H NMR spectroscopy.[1796,2358] The Ni^I complex of 5,10,15,20-tetraphenyl-21-thiaporphyrin has been isolated and characterized. Reaction of this complex with sulfur dioxide produced a paramagnetic five-coordinated Ni^I–SO_2 adduct, while reaction with nitrogenous base ligands (amines, pyridines, imidazoles) yielded five- and six-coordinate complexes. In addition, the crystal structure of Ni^I diphenyldi-*p*-tolyl-21-thiaporphyrin has been determined. The coordination geometry about the nickel center is essentially square planar with extremely short Ni—N and Ni—S bonds (Ni—N = 2.015(2) Å, 2.014(12) Å, and 1.910(14) Å and Ni—S = 2.143(6) Å).[2359]



(959)



(960)

6.3.6.3 Complexes with Phosphines and Arsines

Complexes with phosphines (and arsines) are particularly prominent in Ni^I chemistry. For $[NiCl(PPh_3)_2]$ (**961**) previous studies have reported that the formally 15-electron species oligomerizes in the solid state. However, crystallographic analyses have revealed no short intermolecular interactions, but a distorted trigonal planar geometry with a contracted P—Ni—P angle of 111.52(2)° (thf solvated)[2360] and 114.94(2)° (unsolvated).[2361] The angular distortion most probably arise from a first-order Jahn–Teller effect which, for a d^9 complex, is expected to destabilize the ML_3 structure from D_{3h} to C_{2v}. Both tricoordinate heteroleptic complexes $[Ni(PR_3)_2L]^+$-($R = Ph$, Pr^i, Cy; $L = OEt_2$, CO) and tetracoordinate complexes $[Ni(PR_3)_{4-n}L_n]^+$ ($L = P(OR')_3$, CO) have been investigated in detail by EPR spectroscopy, which allowed the determination of the consequences of the Jahn–Teller distortion of the d^9 species and vibronic effects.[2362,2363] $[NiCl(PPh_3)_3]$ (**962**) has a distorted tetrahedral geometry.[2364]

Nickel complexes of the type $[Ni(L)_2]^{2+}$ ($L = $ dppm, dppe, dppv, dppb, dppp), $[Ni(L)(L')]^{2+}$-($L = $ dppe, dppp, dppb; $L' = $ dppm, dppp), and $[Ni(dppm)_2(CH_3CN)]^{2+}$ have been prepared and characterized. The half-wave potentials for the Ni^{II}/Ni^I couple were found to become more positive as the bite size of the diphosphine was increased. X-ray crystal structural studies of $[Ni(dppm)_2](BF_4)_2$ and $[Ni(dppb)_2](BF_4)_2$ revealed that increasing the bite size results in larger tetrahedral distortion. The most stable Ni^I complex, $[Ni(dppp)_2](PF_6)$, could be isolated and characterized.[2365] The relative stability and interchangeability of the various oxidation states for nickel complexed to 1,2-bis(dialkylphosphino)benzene (alkyl = Me, Et, Pr^i, Pr^n) depends on the ligand: the reduction potentials and electrochemical reversibilities are highly sensitive to the substituents at P, with potentials for electrooxidation being shifted to more positive potentials as the bulk of the alkyl substituent is increased.[2366] The complexes $[Ni(L)_2]^{2+}$ and $[Ni(L)_2X]^+$ ($L = $ dppv, dppb, *o*-$C_6H_4(PPh_2)(PMePh)$, *o*-$C_6H_4(PPh_2)(PBuPh)$; $X = Cl$, Br) have been prepared and characterized.[2367] For $[Ni(L)_2]^{2+}$, two successive one-electron metal-based reductions are observed. $[Ni(L)_2X]^{2+}$ loses halide upon reduction to give the stable $[Ni(L)_2]^+$. The Ni^I/Ni^{II} potentials vary according to the nature of the chelate bridge (no link < ethene < ethane < *o*-phenylene), and additional effects are observed due to changes of the substituents at P.

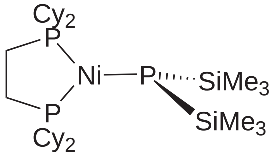
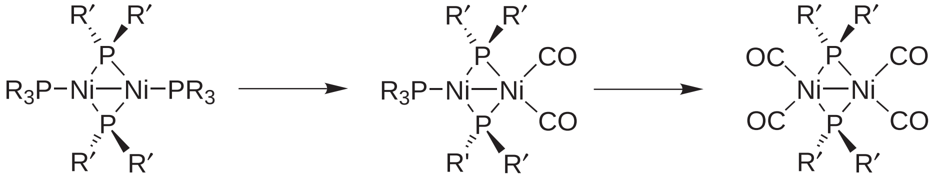
Reduction of Ni^{II} chloride complexes $[NiCl_2(L)]$ (L = various diphosphinomethanes, -ethanes, and -propanes) with, for example, potassium naphthalenide in THF gives the corresponding Ni^I chlorides $[NiCl(L)]$.[2368] By treatment of (**963**) with LiNHAr, a terminal amido complex of Ni^I (**964**) was prepared (Scheme 13).[2369] It contains planar three-coordinate nickel and a planar amido ligand with d(Ni—N) = 1.881(2) Å. The {P,Ni,P} and {C,N,H} planes are orthogonal with a 91° dihedral angle.

Nickel(I) phosphido complexes (**965a**) and (**965b**) have been obtained from (**963**) according to Scheme 13. The Ni atom in paramagnetic (**965a**) is planar (like in the respective Ni^{II} complex, compare Section 6.3.4.5.2), and the phosphido-P is substantially pyramidalized with d(Ni—P) = 2.2077(12) Å (the Ni—P(diphosphane) bond lengths are 2.2169(12) Å and 2.2351(12) Å).[2370] In the related phosphido complex $[(Cy_2PCH_2CH_2PCy_2)NiP(SiMe_3)_2]$ (**966**) the Ni—P distances for the diphosphine ligand are slightly shorter (2.192(2) Å, 2.202(2) Å) than the Ni—P bond for the phosphido ligand (2.225(2) Å).[2371]

Various type (**967**) dinuclear complexes with phosphido bridges have been prepared, usually by reduction of $[(R_3P)_2NiX_2]$ with, for example, sodium.[2372–2375] The terminal phosphines can be exchanged by other phosphines or by CO, yielding (**968**) and (**969**) in the latter case.[2373,2374] Diphenylphosphide Ni^I complexes have also been prepared electrochemically.[2376]



(**966**)



(**967**) (**968**) (**969**)

A typical synthetic scheme is shown in Scheme 14.[2377] [(Dcpm)NiCl$_2$] (dcpm = bis(dicyclohexbis(dicyclohexylphosphino)methane) is reduced with Bu_3SnH in toluene at room temperature to form the air sensitive "A-frame" (**971**). The Ni—Ni bond distance for (**971**) is 2.904(3) Å, which indicates a lack of any Ni—Ni metal bonding. (**972**) is formed by the reaction of (**970**) and excess LiH, and (**971**) is an intermediate in the synthesis of the bridging phosphido Ni^I complex. The Ni—Ni bond distance in (**972**) is 2.3910(8) Å, corresponding to a single Ni—Ni metal bond. Ni—Ni distances in "A-frame" complexes with bridging hydrides ((**971**) and type (**973**)) as well as bridging phosphido ligands are collected in Table 22.

An "A-fame" structure has also been found for $[Ni_2Cl_2(\mu\text{-SO})(\mu\text{-dppm})_2]$, which forms upon oxidative addition of $SOCl_2$ to a Ni^0 complex.[2384] Type (**974a**) complexes with nonequivalent metal centers have been formulated as mixed oxidation state systems with a coordinative Ni—Ni bond involving donation of an electron pair from a tetrahedral Ni^0 to a T-shaped Ni^{II} center. However, these complexes are fluxional and easy interconversion between (**974a**) and (**974b**) is observed. (**974a**) is prepared by reaction of the Ni^0 complex $[Ni_2(CO)_2(\mu\text{-dppm})_2]$ with the Ni^{II} complex $[NiCl_2(dppm)_2]$.[2385]

Tripod-like tetradentate polytertiary phosphines or closely related ligands such as tris(2-diphenylphosphinoethyl)amine (NP_3), tris(2-diphenylphosphinoethyl)phosphine (PP_3), and tris(2-diphenylarsenoethyl)amine (NAs_3) have been shown to be suitable for the stabilization of Ni^I.[2386,2387] The Ni^I complex is usually obtained by oxidation of a suitable Ni^0 precursor. The crystal structure of (**975**) reveals a trigonal bipyramidal configuration with the As atoms occupying the equatorial positions. Compound (**976**) (similar to the related NP_3 compound) exhibits an unusual trigonal pyramidal geometry in which the nickel atom is solely coordinated to the four P atoms of the ligand.[2386,2388] In solution, however, electrochemical measurements indicate that a trigonal bipyramidal structure with an elongated Ni—I bond can also have a finite lifetime.[2387] Electrons are accepted successively in the Ni—I σ^* MO upon exceeding the d^8 configuration, and structural trends in the complete series of complexes $[(NP_3)Ni^{II}I]^+$, $[(NP_3)Ni^{I}]^+$, and $[(NP_3)Ni^0]$ have been investigated in detail.[2387] (**976**) reacts readily with chlorinated solvents and disproportionates in acetonitrile to give $[(PP_3)Ni(NCMe)]^{2+}$ and $[Ni_2(PP_3)_2]$.[2389]

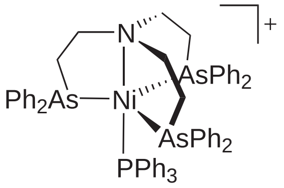
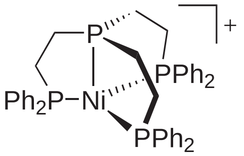
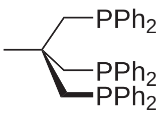
(**974a**) (**974b**)



(**975**)



(**976**)



(**977**)

It is well-known that the tridentate triphos (**977**) (P_3) readily stabilizes Ni^I, and P_3 has become one of the most preferred ligands in low-valent nickel chemistry. Structural reorganizations concomitant with $Ni^{II} \rightarrow Ni^I$ reduction in $[(P_3)NiI]^{+/0}$ have been revealed by X-ray crystallography: there is a 0.13 Å elongation of the Ni—I bond upon reduction (2.414(4) Å vs. 2.546(2) Å), while the Ni—P bond lengths become slightly shorter in the uncharged species.[2390] The additional electron occupies a metal d_π orbital that is involved in antibonding interactions with the iodine p_π orbitals.

Only a few further examples of Ni^I complexes with the P_3 ligand scaffold will be mentioned here. Reduction of the dithiocarbamate complex $[(triphos)Ni(S_2CNEt_2)]BPh_4$ with $Na[BH_4]$ yields [(triphos)Ni(SH)] which has a distorted tetrahedral structure and a room temperature magnetic moment of 2.11 μ_B corresponding to a doublet ground state.[2391] In addition, the related compound $[(triphos)Ni(\mu\text{-}S_2)\text{–}Ni(triphos)]ClO_4$ is a novel nickel dimer bridged by two sulfur atoms. The Ni_2S_2 bridging framework is planar, with a Ni—Ni distance of 3.865(1) Å, while a formal oxidation of +1/+2 has been assigned.[2392]

Five-coordinate Ni^{II} arsine complexes of the ligands (**978**)–(**980**) of formulas $[Ni(L_3)(L_2)]^{2+}$-(L_3 = tridentate (**980**), L_2 = bidentate (**978**), (**979**)) and $[Ni(L_3)_2]^{2+}$ (the latter are also five-coordinate

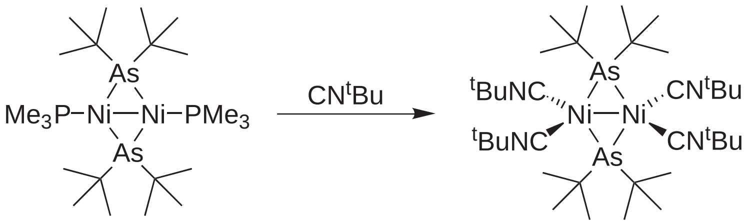
(**980**)
(R = Me, Ph)



(**981**) (**982**)

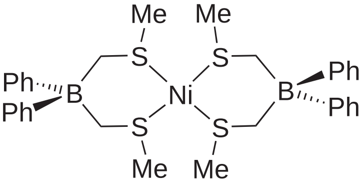
with a single "dangling" $AsMe_2$ group) have been studied electrochemically, and extensive Ni-centered redox chemistry was observed.[2393,2394] The arsine donor sets stabilize (on the voltammetric timescale) all Ni oxidations states from 0 to +4: all complexes showed two oxidations and two reductions in CV experiments in CH_3CN. The reductions are assigned to Ni^I/Ni^{II} and Ni^0/Ni^I couples. Thus the relative stability of the five-coordinate Ni^I complexes with these ligands makes an interesting contrast with $[Ni(diars)]^{2+}$ which is reduced to Ni^0 in a single two-electron process.

The arsenido-bridged complex (**981**) (which is similar to the phosphido-bridged species (**967**), $R' = Bu^t$) can be obtained from the reaction of $[(Me_3P)_2NiCl_2]$ with $LiAsMe_2$.[2395] It reacts with $CNBu^t$ to give (**982**). Both contain a planar centrosymmetric Ni_2As_2 core with Ni—Ni bond lengths of 2.429(1) Å and 2.693(2) Å, respectively.

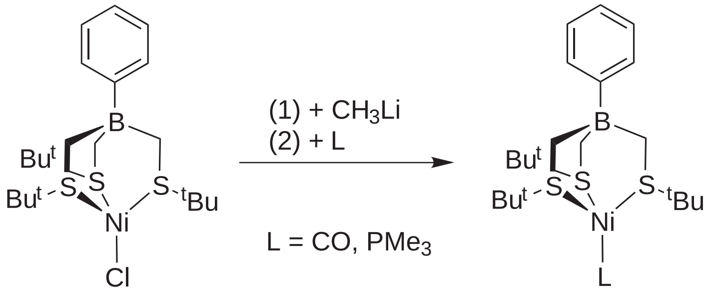
6.3.5.4 Complexes with Sulfur- and Selenium-containing Ligands

The interest in low-valent Ni complexes in S-rich environments has been stimulated by the presence of Ni in [Ni,Fe] hydrogenase and CODH. While thiolate ligation usually favors higher oxidation states, thioethers stabilize Ni^I and Ni^0. In most cases, however, Ni^I ions of an $\{NiS_4\}$ chromophore are unstable with respect to disproportionation. The cyclic voltammogram of square planar (**983**) with homoleptic thioether coordination exhibits a quasi-reversible wave at −0.42 V (vs. NHE), which on the basis of the rhombic EPR spectrum ($g_1 = 2.27$, $g_2 = 2.11$, and $g_3 = 2.03$) of the chemically reduced species (Na/Hg) is assigned to metal-centered reduction.[838]

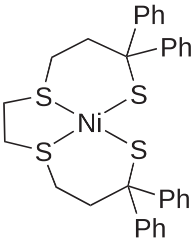
Reaction of (**984**) with MeLi in the presence of donor ligands such as CO or PMe_3 traps the Ni^I species (**985**), which could be characterized by X-ray crystallography.[839] Oxygenation of a related Ni^I complex $\{S_3\}Ni(CO)$ leads to O_2 activation and O—O bond rupture with formation of a bis(μ-oxo)nickel(III) complex.[184,185]



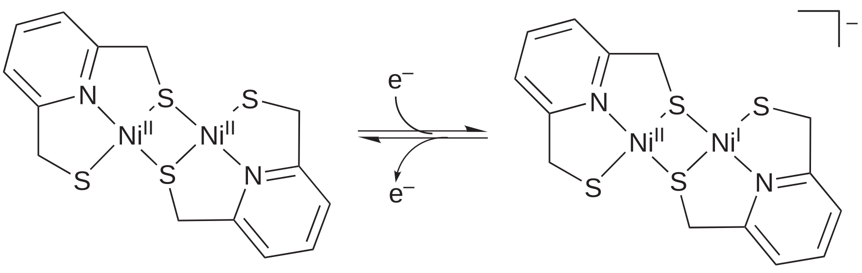
(**983**)



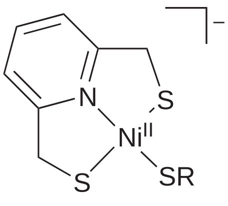
(**984**) (**985**)



(**986**)



(**987**) (**988**)



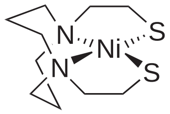
(**989**)

(**986**) gives a reversible Ni^{II}/Ni^{I} redox wave, but reversibility is lost under a CO atmosphere. Upon chemical reduction, CO increases the stability of the reduced species and a Ni^{I}–CO compound was observed by IR spectroscopy.[843]

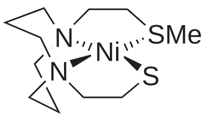
The "reduced" cluster $Ni_8S(SBu^t)_9^-$ has six Ni atoms in a trigonal prism, with the other two capping trigonal faces.[797]

The dinickel(II) complex (**987**) has been electrochemically reduced at $E_{1/2} = -1.21$ V (vs. SCE) to form the mixed-valence $Ni^{I}Ni^{II}$ complex (**988**), which could then be cleaved with RSSR to afford (**989**).[2396]

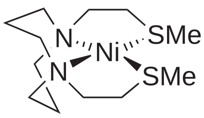
Square planar $\{N_2S_2\}Ni^{II}$ complexes (**990a–f**) show reversible Ni^{II}/Ni^{I} couples, and the Ni^{I} species prepared chemically have been characterized by EPR spectroscopy (axial signal with $g_{\parallel} > g_{\perp}$, indicative of a $(d_{x^2-y^2})^1$ ground state).[2397] In CH_3CN, each substitution of a thioether for a thiolate donor gives a 700 mV positive shift in the Ni^{II}/Ni^{I} potential, and each substitution of a sulfinate for a thiolate gives a 300 mV positive shift. Thus, the Ni^{I} complex is most readily accessed (-0.482 V vs. NHE) for (**990c**) and least for (**990a**), and the ability to stabilize Ni^{I} increases in the order $SR^- < SO_2R^- < SR_2$.



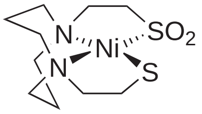
(**990a**)



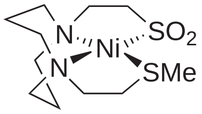
(**990b**)



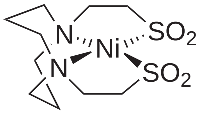
(**990c**)



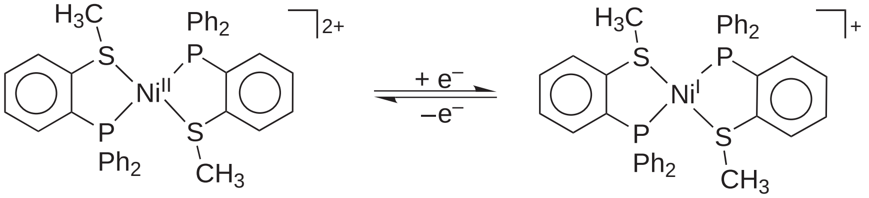
(**990d**)



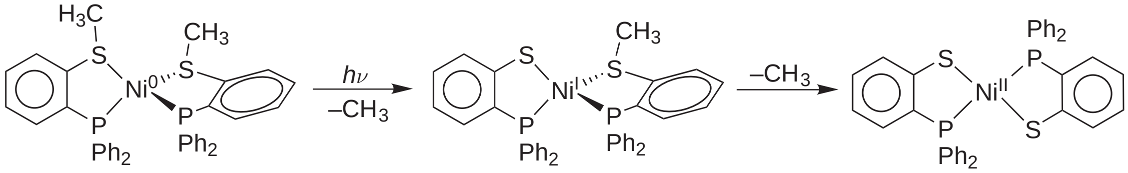
(**990e**)



(**990f**)



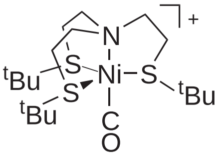
(**991**) (**992**)



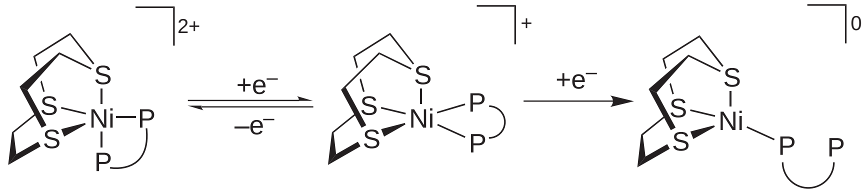
(**994**) (**993**) (**995**)

The cyclic voltammogram of (**991**) in MeCN shows two redox events assigned to $Ni^{II/I}$ and $Ni^{I/0}$, and chemical reduction of (**991**) with Cp_2Co provided a Ni^{I} species (**992**) characterized at 100 K by an axial EPR signal with $g_x = g_y = 2.10$ and $g_z = 1.96$. Hyperfine spectral features resulting from coupling to two ^{31}P nuclei suggest a retention of substantially square planar geometry. In contrast, the isotropic character of the EPR signal of (**993**) presumed to be the first product of the photochemical demethylation of (**994**) ultimately yielding the doubly demethylated complex (**995**) suggests the intervening thioether/thiolate Ni^{I} species to be pseudotetrahedral.[2398] It is concluded that delocalization of the odd electron is favored for the dithioether ligand environment, whereas electron/thiolate ligand repulsion encourages tetrahedral character.

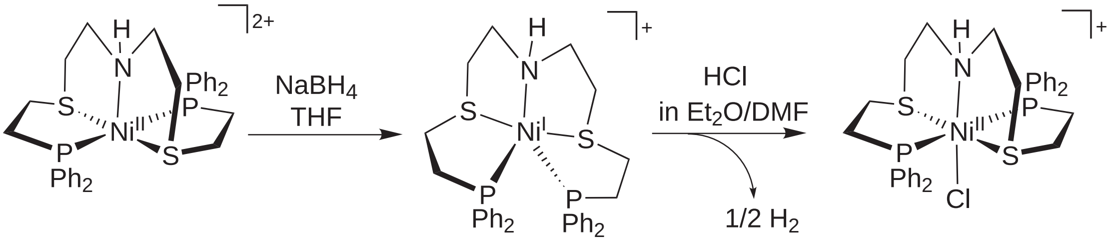
The Ni^{I} complex (**996**) has been structurally characterized. It displays an axial EPR spectrum and an intense ν(CO) band at 2,026 cm^{-1}.[1316,1317]



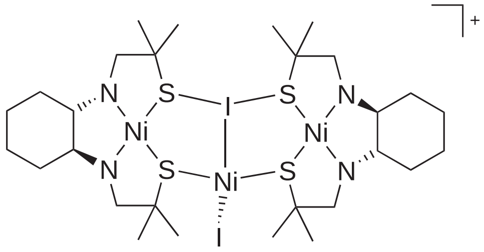
(**996**)



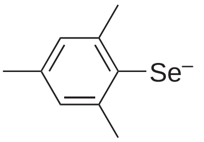
(**565**)



(**997**) (**998**) (**999**)



(**1000**)



(**1001**)

Upon reduction of (**565**), the stereochemistry is proposed to change from trigonal bipyramidal (Ni^{II}) to square pyramidal (Ni^{I}) and tetrahedral (Ni^{0}).[1446]

(**997**) can be reduced to the Ni^{I} species (**998**) with $NaBH_4$. Both complexes have been structurally characterized by X-ray diffraction, and (**998**) was demonstrated to be an authentic Ni^{I} complex.[2399] Upon reduction, the P—Ni—N angles expand, while the P—Ni—P angle contracts, and overall structural changes are in the direction of trigonal bipyramidal coordination with the S atoms positioned axially. While the Ni—N and Ni—P distances are nearly constant, the Ni—S bond lengths increase significantly (by 0.24–0.25 Å) due to the $(d_{z^2})^1$ ground state. Upon protonation of the Ni^{I} complex, Ni-mediated formation of H_2 has been observed according to the stoichiometry $Ni^{I} + H^{+} \rightarrow Ni^{II} + 1/2\ H_2$, and the kinetics of this process has been investigated. The overall reaction (**998**) + HCl → (**999**) + 1/2 H_2 proceeds by two parallel pathways dependent on chloride concentration, but the common initial step is protonation of Ni^{I}.

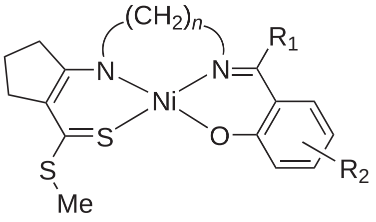
Based on charge balance requirements, a mixed-valent $Ni^{II}{}_2Ni^{I}$ formulation with a central NiI^{2+} group has been proposed for the trinuclear complex (**1000**).[2400]

[Ni(terpy)(**1001**)$_2$] is reduced by aqueous dithionate to a Ni^{I} complex, which displays reversible CO binding, and also reacts with H^{-}.[2401]

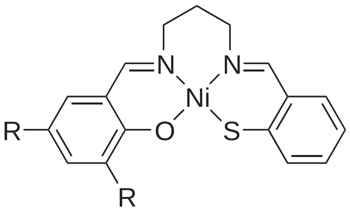
Various Ni/chalcogenide/phosphane clusters are known, which are formally mixed-valent Ni^{II}/Ni^{I} species. Examples include [$Ni_8S_6(PPh_3)_6Cl_2$] and [$Ni_8S_5(PPh_3)_7$],[2402] [$Ni_{23}Se_{12}(PEt_3)_{13}$],[2403] [$Ni_{34}Se_{22}(PPh_3)_{10}$],[2404] [$Ni_{20}Se_{12}(SeMe)_{10}$]$^{2-}$,[2405] [$Ni_9Te_6(PEt_3)_8$], and [$Ni_{20}Te_{18}(PEt_3)_{12}$].[2406]

6.3.5.5 Miscellaneous Complexes of Nickel(I)

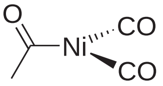
A set of Ni^I complexes (**1002**) of tetradentate Schiff base ligands with NN′OS donor environment were prepared from the corresponding Ni^{II} complexes and studied by spectroscopic and electrochemical techniques.[2407] By comparison with related complexes with salen-type ligands, it was found that values of $E_{1/2}$ for the Ni^{II}/Ni^I couple increase by ~0.07 V in the order $Ni\{N_2O_2\} < Ni\{NN'OS\} < Ni\{N_2S_2\}$, and tetrahedral distortion is an important factor in the relative stabilization of the Ni^I species. EPR data show that the Ni^I complexes (**1002**) are typically four-coordinate, although in the case of a trimethylene bridge formation of six-coordinate Ni^I complexes is observed. Ni^I complexes (**1003**) are obtained either electrochemically or chemically from the corresponding Ni^{II} species, and reduction potentials were found to be strongly dependent on the degree of tetrahedral distortion of the latter. EPR data show that the *g*-values are very sensitive both to the coordination sphere and to the extent of tetrahedral distortion.[2408]



(1002)



(1003)



(1004)

$\{N_3\}Ni(TCSQ)(TCQ)$ (TCQ = tetrachloroquinone, TCSQ = terachlorosemiquinone) exhibits strong ferromagnetic Ni^I semiquinone coupling and the effective magnetic moment is $2.97\mu_B$. However, a Ni^{II} description cannot be completely ruled out.[772]

Sequential bond dissociation energies have been determined for $[Ni(CO)_x]^+$ ($x = 1–4$), $[Ni(N_2)_x]^+$ ($x = 1-4$), and $[Ni(NO)_x]^+$ ($x = 1–3$) by collision-induced dissociation in a guided ion beam tandem mass spectrometer.[2409] The trend in bond energies for loss of a ligand is sketched in Figure 33, which can be understood in terms of σ-donor and π-acceptor capabilities of the ligands and the number of electrons donated by each ligand.

Guided ion beam tandem mass spectrometry has also been employed to study the reaction of Ni^+ with CS_2 and COS.[2410] The ground state ion Ni^+ undergoes endothermic reaction to form NiS^+ in both cases, as well as $NiCS^+$ and $NiCO^+$, respectively. Threshold values for the reactions and bond dissociation energies for the products have been determined.

The d^9 species $(OC)_2NiCHO$ has been prepared by the reaction of H atoms with $Ni(CO)_4$ in a krypton matrix at 77 K. The complex is not thermally interconvertible with its isomer, $HNi(CO)_3$, and EPR spectroscopy reveals that components in the *xy* plane of the principal *g*-values $g_{zz} = 2.0024(2)$ and $g_{xx} = g_{yy} = 2.0207(2)$ split at 4 K. Hence, structure (**1004**) was proposed.[2411] The oxides $KNa_2[NiO_2]$ and $K_3[NiO_2]$ contain Ni^I with virtually linear coordination.[2412]

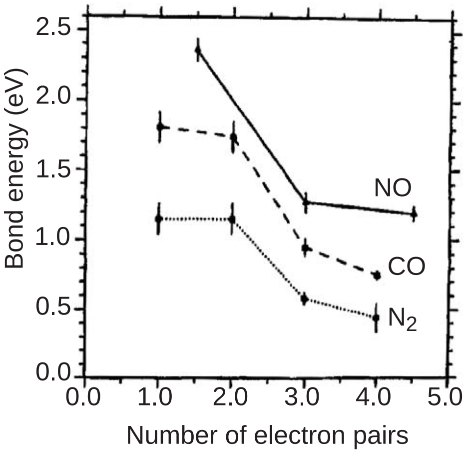


Figure 34 Trend in bond energies for loss of a ligand from $[Ni(CO)_x]^+$ ($x = 1–4$), $[Ni(N_2)_x]^+$ ($x = 1–4$), and $[Ni(NO)_x]^+$ ($x = 1–3$) (reprinted with permission from ref. 2409; © 1995, American Chemical Society).

6.3.6 COMPLEXES OF NICKEL(0)

Detailed procedures for the synthesis of various often used [Ni^0L_4] complexes (L = phosphines, arsines, stibines, alkyl isocyanides) and [$Ni^0L'_2$] complexes (L′ = bipyridine, phenantroline, diphosphines, diarsines) have been compiled.[2413]

6.3.6.1 Carbonyl and Nitrosyl Complexes

6.3.6.1.1 Carbonyl complexes

An accurate solid-state structure is reported for $Ni(CO)_4$, which is tetrahedral with d(Ni—C) = 1.817 Å.[2414] The luminescence spectrum of $Ni(CO)_4$ following photolysis with an XeCl laser is strong enough to be visually detected. A three-step mechanism is advanced: luminescence is primarily from the $Ni(CO)_3$ fragment with its smaller HOMO–LUMO gap resulting in visible emission.[2415] Calculation of the sequential Ni—CO binding energies for the series $Ni(CO)_x$ (x = 1–4) yields 125.4 kJ mol^{-1}, 121.2 kJ mol^{-1}, 150.4 kJ mol^{-1}, and 100.32 kJ mol^{-1}, which is in good agreement with experimental results.[2416] Di-*t*-butoxytin(II) and bis(trimethylsiloxy)tin(II) react with $Ni(CO)_4$, yielding the disubstituted complexes $[Ni(CO)_3Sn(OCMe_3)_2]_2$ and $[Ni(CO)_3Sn(OSiMe_3)_2]_2$, respectively.[2417]

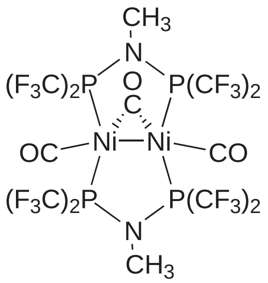
Although $Ni(CO)_4$ was discovered many years ago, no neutral $Ni_2(CO)_x$ compound has ever been synthesized in macroscopic amounts. However, several communications report ionic species such as $[Ni_2(CO)_8]^+$, $[Ni_2(CO)_7]^-$, and $[Ni_2(CO)_6]^+$, where structures with one or two bridging carbonyls are proposed.[2418] Plausible structures for neutral $Ni_2(CO)_x$ (x = 5, 6, 7) have been investigated by theoretical methods, and decomposition temperatures well below room temperature have been predicted.[2419,2420] Tetra-, penta-, and hexanuclear nickel carbonyl clusters have been investigated by means of molecular orbital theory. It is found that the neutral forms are more stable than the corresponding anionic forms but the anionic forms gain in stability as the nuclearity rises.[2421] Nickel carbonyl cluster anions are manifold, and structural systematics have been reviewed.[2422,2423] An example includes the anion $[Ni_9(CO)_{16}]^{2-}$ with a close-packed two-layer metal core.[2424]

Neutral dinuclear nickel carbonyl units can be stabilized by the replacement of four carbonyl groups in $Ni_2(CO)_7$ with small-bite bidentate ditertiary phosphine ligands to give (diphos)$_2$-$Ni_2(CO)_2$-(μ-CO) derivatives. Some binuclear nickel carbonyls of this type which have been isolated and structurally characterized[2425–2427] are (**1005**) and (**1006**). The complexes $[Ni(CO)_2(\eta^1\text{-dppm})_2]$, $[Ni_2(\mu\text{-dppm})_2(\mu\text{-CO})(CO)_2]$, and $[Ni_2(\mu\text{-dppm})_2(CO)_4]$ have all been isolated by minor modifications of the same synthetic procedure, i.e., BH_4^- reduction of a solution of $NiCl_2$ and dppm in MeOH under CO.[2428] The different species are interconvertible in solution, and reaction of CO with $[Ni(CO)_2(\eta^1\text{-dppm})_2]$ gives $[Ni(CO)_3(\eta^1\text{-dppm})]$. In general, the Ni—Ni bond distances in the structurally characterized (diphos)$_2Ni_2(CO)_2(\mu$-CO) derivatives fall in a rather wide range, 2.53–2.69 Å, which in general is lower than the 2.73 Å Ni—Ni bond distance calculated for the parent μ-carbonylhexacarbonyldinickel. The stabilization of $Ni_2(CO)_7$ by such phosphine substitution of carbonyl ligands is typical in metal carbonyl chemistry and arises from an increase in the electron density on the nickel atoms by replacement of CO groups with the weaker acceptor phosphine ligands.

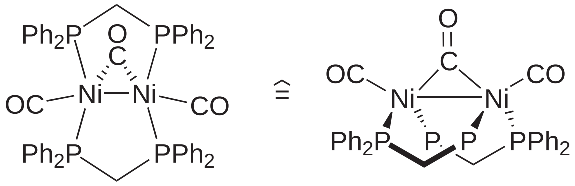
A convenient synthetic route to the Ni^0 cradle complex $[Ni_2(\mu\text{-CO})(CO)_2(PPh_2CH_2PPh_2)_2]$ (**1006**) has been reported, which involves the simultaneous reaction of $Ni(COD)_2$ with CO and dppm.[2429] Also, $[Ni(CO)_2\{HC(PPh_2)_3\}]$ has been used to prepare the Ni^0 dimer (**1006**). The crystal structure of (**1006**) has been determined, showing approximate tetrahedral geometry about each of the Ni atoms, with an unusual *cis* arrangement of the two bridging dppm ligands, one bridging CO ligand and two terminal CO ligands.[2425]

6.3.6.1.2 Nitrosyl complexes

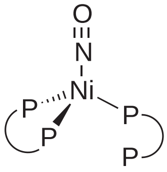
The oxidation state of the metal in $\{Ni(NO)\}^x$ species often is not obvious at first sight, since the nitrosyl group may be considered as a cationic NO^+, a neutral paramagnetic NO, or an anionic NO^- ligand. A common criterion to distinguish between the limiting descriptions is the geometry of the complex and of the triatomic Ni—N—O moiety: in tetracoordinate $\{Ni(NO)\}^{10}$ complexes, square planar geometry with a strongly bent N—N—O group (120°) indicates a NO^- formulation,



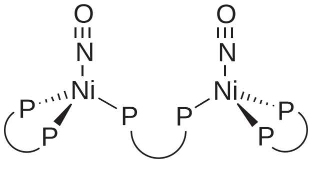
(1005)



(1006)



(1007)



(1008)

while a tetrahedral geometry with a linear Ni—N—O is assumed characteristic for NO^+. In many cases, however, an intermediate situation is observed. For example, $[Ni(NO)(PMe_3)_3]^+$ is tetrahedral and belongs to the NO^+ type with an Ni—N—O angle of 175.4(5)°,[2430] while the metal ion in $[Ni(NO)(NO_2)(dppe)]_2$ is found in a distorted tetrahedral environment with an Ni—N—O angle of 153.4(8)°.[2431] No simple correlation can be drawn between the ν(NO) stretch and the NO coordination mode. Most Ni^0 nitrosyl complexes have phosphine coligands, and some examples with diphosphines involve mononuclear (**1007**) and dinuclear (**1008**).[2432] In the case of $[NiX(NO)\{1,2\text{-}C_6H_4(PMePh)_2\}]$, configurational stability of the complexes has been investigated.[2433]

Parent NiNO and $Ni(NO)_2$ have been prepared by cocondensation of Ni and NO in solid argon and investigated by IR spectroscopy in combination with DFT calculations.[2434–2437] Two different isomeric forms have been evidenced for the dinitrosyl, $Ni(\eta^1\text{-}NO)_2$ and $Ni(\eta^2\text{-}NO)_2$, differing by their coordination modes and electronic structure.[2436]

6.3.6.2 Complexes with CO_2, CS_2, and related ligands—Electroreduction of CO_2

In neat low-temperature CO_2 matrices, CO_2 is side-on coordinated to Ni atoms and the binding energy is weak (18 kcal mol^{-1}).[2438,2439] The calculated OCO angle is 145°, which is quite a large value compared to those of other CO_2 complexes. In dinitrogen matrices, the binding of CO_2 is enhanced due to formation of $[Ni(N_2)_n(CO_2)]$ ($n = 1, 2$).[2437]

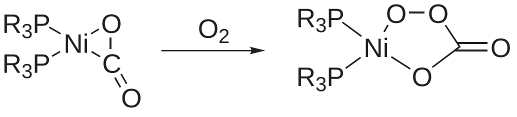
The key role played by diverse nickel complexes in the development of CO_2 coordination chemistry and CO_2 electroreduction catalysts has been highlighted,[2440] and several reviews discussing CO_2 electroreduction and photoreduction are available.[2441–2445]

The Aresta complex $[Ni(CO_2)(PCy_3)_2]$ has been investigated further. ^{31}P and ^{13}C NMR in the solid state and in solution have been used to determine a direct correlation of the modes of bonding of CO_2 in $[Ni(CO_2)(PCy_3)_2]$. It was found that, in solution at 173 K, CO_2 is η^2-CO bonded to nickel, and that the ^{31}P and ^{13}C chemical shifts were almost identical to the values found in the solid state. In solution, however, a dynamic process averages the two P atoms at room temperature via an intramolecular motion.[2446] In addition, vibrational studies and CASSCF calculations on $[Ni(CO_2)(PCy_3)_2]$ have been reported.[2447] FTIR and Raman spectra could be assigned with the aid of $^{13}CO_2$ and $C^{18}O_2$ labeling, normal coordinate analysis, and NMR data. It is suggested that the fluxional behavior, and the fact that two C—O stretches (1,150 cm^{-1}, 1093 cm^{-1}) are seen, can best be explained by the existence of an unstable end-on $Ni(\eta^1\text{-}CO_2)$ isomer in both the solid state and solution.

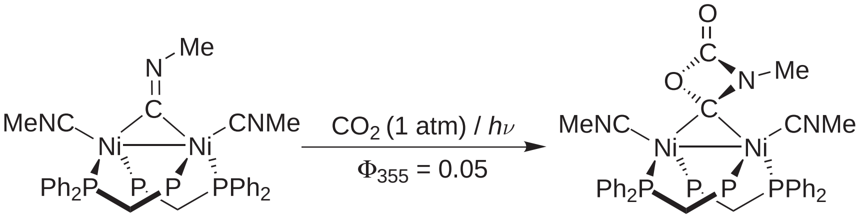
The stability of Ni–CO_2 complexes is related to the basicity of ancillary phosphines and to the P—Ni—P bond angle. For example, it was calculated that the total energy for the complex

$[Ni(PH_3)_2(CO_2)]$ is a function of the P—Ni—P angle, being the most favorable when this angle is 120°.[2448] Ni(dppe) does not interact with CO_2, which is ascribed to the insufficient basicity of the diphosphine. In contrast, the more basic chelating diphosphines $Cy_2P\text{-}(CH_2)_n\text{-}PCy_2$ do react with CO_2 and afford CO_2/Ni^0 adducts for $n = 2, 3, 4$. They show the characteristic strong IR absorption at around $1740\,cm^{-1}$ for bound CO_2 and a doublet at 162–165 ppm in the ^{13}C NMR. The complex in which the P—Ni—P angle is about 90° ($n = 2$) is unstable and cannot be isolated owing to rapid disproportionation.[2449]

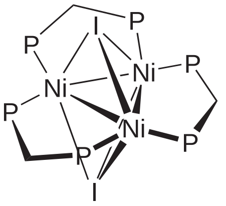
Upon reaction of complexes $[Ni(PR_3)_2(CO_2)]$ with O_2, Ni^{II} peroxocarbonate species (**1009**) are formed.[2448,2450] In the case of $[Ni(PCy_3)_2(CO_2)]$, a detailed study using labeled $^{13}CO_2$, $C^{18}O_2$, and $^{18}O_2$ has revealed details of the mechanism of this reaction.[2449] It implies initial CO_2 decoordination, followed by O_2 coordination and subsequent CO_2 insertion into the O—O bond of the intermediate $[Ni(PCy_3)_2(O_2)]$.



(**1009**)



(**1010**) (**1011**)



(**1012**)

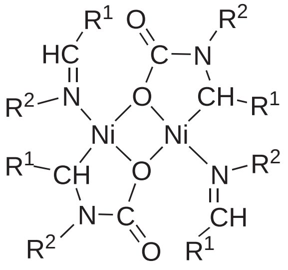
Photochemical activation of CO_2 has been achieved using the long-lived ligand-centered charge-transfer excited state of the binuclear Ni^0 complex $[Ni_2(\mu\text{-}CNMe)(CNMe)_2(PPh_2CH_2PPh_2)_2]$ (**1010**). Through bimolecular association of CO_2 to the excited state (**1010**), complex (**1011**) is formed.[2451,2452] The association of CO_2 with (**1010**) results in its activation towards O-atom transfer reactions. Prolonged exposure to CO_2 results in the formation of $[Ni_2(\mu\text{-}CO)(CO)_2(PPh_2CH_2PPh_2)_2]$ (**1006**).[2453,2454]

Upon reaction of (**1010**) with NiI_2, trinuclear $[Ni_3(\mu_3\text{-}I)_2(dppm)_3]$ (**1012**) is formed. The latter can also be obtained directly from $[Ni(cod)_2]$, NiI_2 and dppm. (**1012**) photoreduces carbon dioxide to its radical anion, which can be trapped by cyclohexene.[2455]

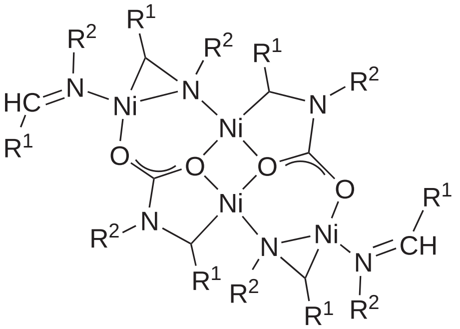
The reaction between $[Ni(cod)_2]$, CO_2, and benzaldehyde-*N*-furfurylideneimine (L) in 1,4-dioxane or THF gave a 24-membered organometallic macrocycle $[(L)Ni(\text{—}CH(R_1)\text{—}N(R_2)\text{—}COO\text{—})]_6(solv)_n$ ($R_1 = Ph$, R_2 = furfurylidene, solv = 1,4-dioxane or THF).[2456,2457] According to the X-ray analyses, six monomeric nickelacyclic units are connected through six $Ni\text{–}\mu_2\text{-}OCO\text{–}Ni$ bridges in these macrocycles, with cavity diameters of around 9.3 Å. The complexes isomerize in benzene to form dimeric $[(L)Ni(\text{—}CH(R_1)\text{—}N(R_2)\text{—}COO\text{—})]_2(solv)_n$ (**1013**), and they react with PPh_3 to give tetranuclear species. The macrocycle partially eliminates CO_2 above 20°, followed by elimination of half of the monodentately coordinated Schiff base ligands to form a planar tetrameric complex (**1014**). This is a reversible process.

The reaction of $Ni(CNAr)_4$ ((**1015**); $Ar = 2,6\text{-}Me_2C_6H_3$) with carbon dioxide in the presence of Li^+ leads to the formation of $Ni(CO)_2(CNAr)_2$ (**1016**) and the arylisocyanate ArNCO (Equation (29)).[2458,2459] Complex $[Ni(CNMe)_4]$ reacts similarly with carbon dioxide in the presence of Li^+ to produce $[Ni(CO)_2(CNMe)_2]$. ^{13}C-labeling studies indicate that the carbonyl ligands of $Ni(CO)_2(CNR)_2$ are produced by multiple bond metatheses between CO_2 and CNR ($R = 2,6\text{-}Me_2C_6H_3$, Me), not by deoxygenation of CO_2. Hence, the reaction of (**1015**) with $^{13}CO_2$ gave $Ni(CO)_2(CNAr)_2$ and $ArN{=}^{13}C{=}O$. The reaction of $Ni(^{13}CNMe)_4$ with CO_2 gave $Ni(^{13}CO)_2(CNMe)_2$. The reactions are catalytic and first order in $[Li^+]$ over the range $[Li^+]/[\mathbf{1015}]$:

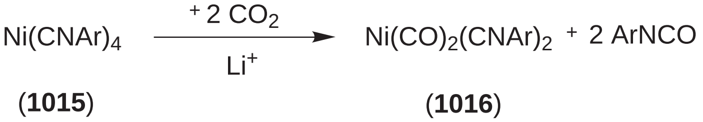
0.01–40. Kinetic studies indicate that the rate of reaction of (**1015**) with CO_2 is first order in $[CO_2]$. The reaction order in (**1015**) is complex. At high $[Li^+]$ and high $[CO_2]$, the reaction rate is second order in [**1015**] but the rate saturates and becomes nearly independent of [**1015**] at low $[Li^+]$ and low $[CO_2]$.



(**1013**)



(**1014**)



$$\underset{(\mathbf{1015})}{Ni(CNAr)_4} \xrightarrow[Li^+]{+2\,CO_2} \underset{(\mathbf{1016})}{Ni(CO)_2(CNAr)_2} + 2\,ArNCO \qquad (29)$$

The reactions of carbon dichalcogenides other than CO_2 with Ni^0 have also been studied quite intensively.[2460,2461] *Inter alia*, Ni polymeric complexes with metallic properties have been prepared using CS_2 as the starting material.[2462] Some further impetus was given by the observation that CS_2 can mimic the binding of CO to the CODH enzyme active site, although CS_2 itself does not undergo oxidation/reduction and does not appear to bind to center C (the site of CO oxidation and CO_2 reduction).[2463]

Several classes of discrete Ni/CS_2 compounds have been prepared, usually by reaction of CS_2 with Ni^0 phosphine complexes. Reactions of CS_2, CO_2, and COS with Ni^0 complexes have been reviewed.[2440] Compounds of varying stoichiometry have been obtained, depending on the phosphine used:

$$2[Ni(cod)_2] + 2PR_3 + 2CS_2 \rightarrow [Ni(PR_3)_2(CS_2)_2]_2 \ (R = Ph, p-\text{toluene, cyclohexyl})$$

$$[Ni(cod)_2] + 2PR_3 + 2CS_2 \rightarrow [Ni(PR_3)_2(CS_2)_2] \ (R = Me, Et)$$

A single-crystal X-ray analysis of the triphenylphosphine complex $[Ni(PPh_3)(CS_2)]_2$ has revealed that the complex has the binuclear structure (**1017**).[2460] The complex $[Ni(PMe_3)_2(CS_2)_2]$ displays NiPSCS coordination (**1018**) and is severely distorted from square planar. Of interest is the fact that the $SC(S)SC(PMe_3)S$ linkage can be formally described as a condensation product of two molecules of CS_2 with one molecule of PMe_3.[2464]

The decisive factor for reaction to occur has been shown to be the HOMO energy of the complex, relative to the LUMO energy of the potential ligand. For example, [Ni(bipy)(cod)] reacts with SeCS, CS_2, and SCO, whereas $[Ni(PPh_3)_2(C_2H_4)]$ only reacts with CS_2, and not SCO. Generally the carbon dichalcogenides are bonded side-on (η^2), and it is always the most electronegative heteroatom of the asymmetric ligands SeCS and SCO which does not interact with the central metal atom.[2465] Reactions of the CS_2 complex (**1019**) are described in Section 6.3.4.5.1.[648–650]

When laser-ablated Ni atoms were reacted with CS_2 during cocondensation in excess argon, the C-bonded $Ni(\eta^1\text{-}CS_2)$ and side-on bonded $Ni(\eta^2\text{-}CS)S$ complexes were formed on annealing, whereas the inserted SNiCS was formed on photolysis. All species were characterized by IR spectroscopy and DFT calculations.[2466] The reaction of low-valent $[Ni(CO)_x]^-$ ($x = 2, 3$) with CS_2 has been studied by FT-ICR spectroscopy.[2467]

6.3.6.3 Complexes with Nitrogen-containing Ligands

Aliphatic amines, which are hard bases, are unfavorable for coordination to soft Ni^0. If the principles of ligand preorganization and donor prepositioning are applied, however, (diamine)Ni^0 complexes are accessible, which has been demonstrated for complex (**1020**) with a rigid *N*,*N*′-dimethyl-3,7-diazabicyclo[3.3.1]nonane ligand.[2468]

Bis(bipyridyl)nickel(0) has been prepared by metal-vapor methods and electrochemical data were obtained for it. In these low-valence states, a significant proportion of the electron density lies on the bipy ligand.[2469] Also, the crystal and molecular structure of 4,6-dimethyl-2,2′-dipyridyldicarbonylnickel(0) (**1021**) has been determined. The coordination geometry about Ni is tetrahedral.[2470]

In a series of studies of the spectroscopy and photochemistry of nickel(0)–α-diimine complexes, the structural differences among the complexes NiL_2 and $Ni(CO)_2L$ ($L = \alpha$-diimine) have been examined by means of molecular orbital calculations and electronic absorption Raman resonance studies.[2471,2472] Summing up earlier work, the noninnocence of α-diimine ligands with a flat —N═C—C═N— skeleton in low-valent Ni chemistry and the course of substitution reactions of Ni^0 complexes with 1,4-diaza-1,3-dienes or α,α'-bipyridine have been reviewed.[2473]

6.3.6.4 Complexes with Dinitrogen and Dioxygen

The new dinitrogen complex $[Ni(CO)_3N_2]$ can be generated in a pressure cell by UV photolysis of tetracarbonylnickel in liquid krypton, doped with N_2 at 114 K. The decomposition of this complex was followed over the temperature range 122–127 K and a value of the Ni—N_2 bond dissociation energy estimated at 10 kcal mol^{-1}.[2474]

Various theoretical studies on the coordination of N_2 (and related molecules) to Ni^0 compounds have been carried out. These include *ab initio* calculations on $Ni(N_2)$ and $Ni(N_2)_4$ (in comparison with $[Ni(CO)_4]$),[2475] on $[Ni(PH_3)(N_2)]$,[2476] on $[Ni(PH_3)_2(N_2)]$,[2477,2478] on the series of complexes $[Ni(PH_3)_2(N_2)]$, $[Ni(PH_3)_2(NCH_2)]$, and $[Ni(PH_3)_2(N_2H_3)]$,[2479] as well as *ab initio* calculations (MP2 and CCSD(T) level) on $[Ni(CO)_2(N_2)]$.[2480] Also, the bonding between $[Ni(PH_3)_2]$ and O_2 has been analyzed by quasi-relativistic DFT calculations.[2481]

$[Ni(PCy_3)_2(O_2)]$ is proposed as a reactive intermediate in the reaction of $[Ni(PCy_3)_2(CO_2)]$ with dioxygen to give the peroxocarbonate complex $[Ni(PCy_3)_2(CO_4)]$ (see Section 6.3.6.2).[2449]

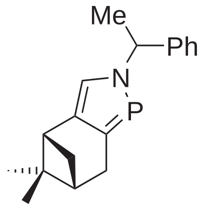
6.3.6.5 Complexes with Phosphines, Arsines, and Stibines

Phosphorus is the most common donor atom in Ni^0 chemistry. Likewise, As- and Sb-based ligands are well suited for stabilizing low-valent Ni^0. Ni^0 phosphine chemistry is extensive, and the general synthetic approaches have been summarized previously.

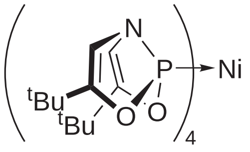
6.3.6.5.1 Complexes with mono- and oligodentate phosphines and phosphido ligands

Tetrakisphosphine complexes of Ni^0 are usually prepared either from labile Ni^0 precursors (such as $[Ni(cod)_2]$ or $[Ni(CO)_2(cod)]$) or by reduction of an appropriate Ni^{II} complex in the presence of phosphine. Despite the large number of homoleptic Ni–phosphine complexes NiL_4, however, relatively few X-ray crystal structures are known. Some examples are collected in Table 23. Typical Ni^0—P distances are in the range 2.14–2.21 Å. $[Ni(PMePh_2)_4]$ was obtained serendipitously upon treatment of $[NiBr(NPMe_3)]_4$ with LiCCPh.

Crystals of the first homoleptic Ni^0–trialkylphosphine complex to be analyzed by X-ray crystallography, $[Ni(PEt_3)_4]$, were obtained serendipitously on recrystallizing the product of reaction between $[NiCl_2(PEt_3)_2]$ and lithium 2-bis(trimethylsilyl)methylpyridine.[2482] In all cases, for NiL_4 phosphine complexes there are distortions from overall tetrahedral geometry caused by the steric requirements of the ligands.



(1022)



(1023)

Several complexes $[Ni(PPh_3)_3(\eta^1\text{-NCR})]$ (R = $PhCH_2$, 2-MeC_6H_4, Me_3Si) have been synthesized, and the crystal structure of one example (R = Me_3Si) obtained.[2487] Again, the overall geometry is distorted tetrahedral. The reaction of $[Ni(PPh_3)_4]$ with CH_2Br_2 in the presence of Zn followed by carbonylation gives the η^2-(C,C) ketene complex $[Ni(CH_2{=}C{=}O)(PPh_3)_2]$ (**1024a**). This complex can be considered as a model for homogeneous CO reduction.[2488] From qualitative MO arguments and EH model calculations, however, η^2-(C,O) bonding of a ketene ligand in bis(phosphane)nickel(0) complexes is suggested to be preferred over η^2-(C,C) coordin-

Table 23 X-ray crystallographic results for homoleptic Ni^0L_4 phosphine complexes.

Complex	*Geometry*	*d(Ni—P)*(Å)	*References*
$[Ni(PEt_3)_4]$	Distorted tetrahedral (C_{2v}); P—Ni—P angles ranging from 102.4(2)° to 111.6(1)°	2.210(1), 2.151(1)	2482
$[Ni(PH_2Mes)_4]$	Distorted tetrahedral; P—Ni—P angles ranging from 106.9(3)° to 111.3(2)°	2.140(8)–2.158(7)	2483
$[Ni(PMePh_2)_4]$	Distorted tetrahedral; P—Ni—P angles ranging from 103.35(4)° to 122.40(4)°	2.193(1)–2.206(1)	
$[Ni(PPh_2NHPh)_4]$	Compressed tetrahedron; P—Ni—P angles ranging from 104.89(4)° to 117.21(4)°	2.175(1)–2.183(1)	2484
[Ni(**1022**)$_4$]	Distorted tetrahedron; P—Ni—P angles ranging from 103.1(1)° to 117.4(1)°	2.143(1), 2.146(1)	2485

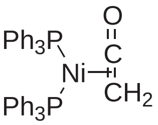
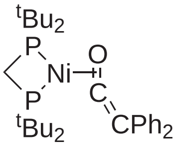
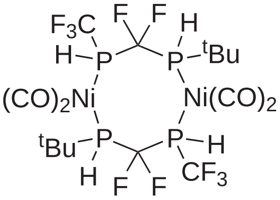
ation, and increasing relative stability of η^2-(C,O) bonding is predicted with decreasing P—Ni—P angle.[2489] Hence, complex (**1024b**) with a small diphosphine bite angle shows the latter coordination mode.[2489]



(1024a)

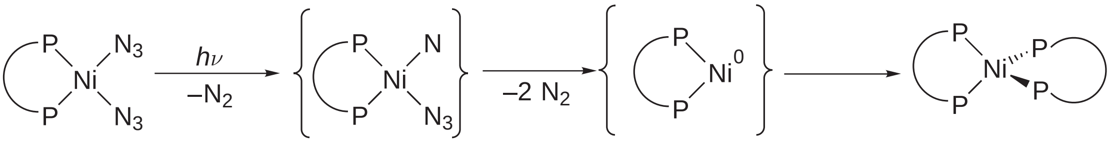


(1024b)



(1025)

Examples of new Ni^0 complexes with bulky diphosphine ligands prepared by reduction of $[Ni(L\text{-}L)X_2]$ (X = Cl, Br) include [Ni(L-L)] and [Ni(L-L)(toluene)] (L-L = 1,2-bis(dicyclohexylphosphino)ethane (dcpe); 1,3-bis(dicyclohexylphosphino)propane (dcpp); 1,4-bis(dicyclohexylphosphino) butane (dcpb)), as well as $Ni_2(dcpe)_3$, $Ni_2(dcpb)_3$, $Ni(dcpe)_2$, and $Ni(depe)_2$ (depe = 1,2-bis-(diethylphosphino)ethane). The electronic spectra of these complexes have been investigated.[2490] The reaction of $[NiCl_2(L\text{-}L)]$ (L-L = dppe, dppp) with NaOR gives $[Ni(L\text{-}L)_2]$, $Ni(OR)_2$, and aldehyde or acetone in a 1:1:1 ratio (R = Me, Et, Pr^i), as well as NaCl.[2491] When L-L = dcpe, the product is $[Ni_2(dcpe)_3]$ or (with additional diphosphine present) $[Ni(dcpe)_2]$. Under CO, the corresponding complexes $[Ni(CO)_2(L\text{-}L)]$ are formed in high yield. An unusual route to $[Ni^0L_4]$ and $[Ni^0(L\text{-}L)_2]$ phosphine complexes is the CT excitation of Ni^{II} azido compounds $[Ni(N_3)_2L_2]$ and $[Ni(N_3)_2(L\text{-}L)]$, respectively, according to Equation (30).[2492] Formation of the Ni^0 products (**1026**) goes via reactive nitren intermediates, which has been corroborated by trapping experiments. The trifluoromethyl-1,3-diphosphane $Bu^t(H)PCF_2P(H)CF_3$ reacts with $Ni(CO)_4$ to give dinuclear (**1025**):[2493]



(1026)

(30)

X-ray crystallographic data for homoleptic $[Ni^0(L\text{-}L)_2]$ diphosphine complexes with a $\{NiP_4\}$ core are collected in Table 24.

The organometallic diphosphine ligand (**1031**) forms Ni^0 complexes [Ni(**1031**)$_2$] and [Ni(**1031**)(CO)$_2$].[2498] [Ni(**1031**)$_2$] shows a reversible two-electron oxidation at −0.70 V (Cr-centered according to EPR), followed by a reversible process at −0.52 V and a quasi-reversible process at −0.16 V. The latter are assumed to be Ni based.

Upon reaction with various Ni^0 precursors, the rigid *cis*-1,2-bis(diphenylphosphino)ethen gives mononuclear (**1032a**) or polymeric (**1032b**), depending on the stoichiometry.[2499] NiL_2

Table 24 X-ray crystallographic data for homoleptic $Ni^0(L\text{-}L)_2$ diphosphine complexes.

fragments can be inserted into the P—P bond of 1,2,3,4-tetraphenyl-1,2-dihydro-1,2-diphosphete, and two limiting descriptions are possible for the resulting product: either a nickeldiphospholene (**1033a**) with square planar metal ion and a formal +2 oxidation state of Ni, or a 1,4-phosphadiene (**1033b**) complex with tetrahedral Ni^0.[2500] Both forms exist depending on the coligands, and isomerization has been observed in some cases. The X-ray crystal structure of the species with a dppe coligand reveals a situation intermediate between square planar and tetrahedral (LNiL/PNiP interplane angle 38°). A single-crystal X-ray determination of the reaction product of $Ni(CO)_4$ with the small-bite didentate ligand 1,2-bis(dimethylphosphino)-methane has revealed a dimeric structure, $[\mu\text{-}(CH_3)_2PCH_2P(CH_3)_2]_2Ni_2(CO)_4$, for what was previously assumed to be the monomeric complex $[(CH_3)_2PCH_2P(CH_3)_2]Ni(CO)_2$. The coordination geometry about the two Ni atoms is essentially tetrahedral with a nonbonded Ni—Ni distance of 4.39 Å.[2501]

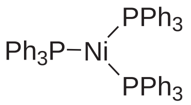
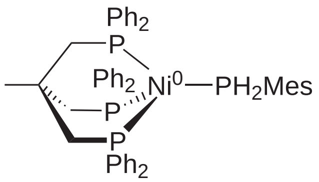
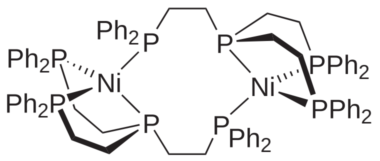
The coordinatively unsaturated $[Ni(PPh_3)_3]$ (**1034**) has trigonal planar Ni,[2502] the structure showing some close approach of three *o*-phenyl H atoms to the central Ni (2.74–3.09 Å) with implications for *ortho*-metallation.



(**1034**)



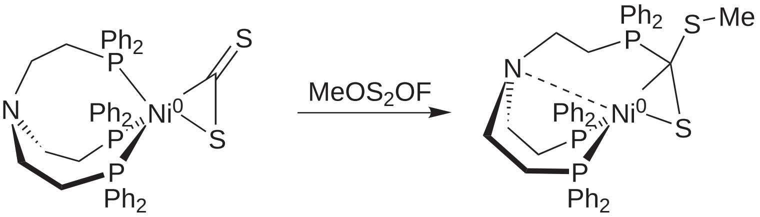
(**1035**)



(**1036**)

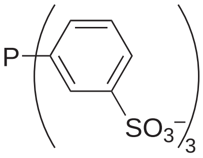
The particular ability of the tris(2-diphenylphosphinomethyl)ethane (P_3) and related tripod-like tetradentate tris(2-diphenylphosphinoethyl)phosphine (PP_3), tris(2-diphenylphosphinoethyl)amine (NP_3) and tris(2-diphenylarsenoethyl)amine (NAs_3) to stabilize low-valent Ni species has already been outlined in previous sections (e.g., Section 6.3.6.3). Some further examples in Ni^0 chemistry are given here. Complex (**1035**) is obtained from the reaction of $[Ni(PH_2Mes)_4]$ with P_3, and its structure has been established by X-ray crystallography.[2482] It is concluded that the coordination properties of P_3 are dominated by its relatively small cone angle and that the basicity of P_3 is comparable to that of the monodentate tertiary phosphines. The electrochemistry of $[Ni(PP_3)X]^+$ (X = Cl, Br, I, MeCN) has been studied in CH_3CN and CH_2Cl_2,[171,2388] revealing that the cations undergo reduction to the Ni^0 complexes $[Ni(PP_3)X]^-$. For X = Br and I, this is followed by loss of X^- and formation of a PP_3-bridged Ni^0 dimer (**1036**). In CH_3CN, $[Ni(PP_3)I]^-$ also undergoes iodide displacement by solvent.

[Ni(NP_3)] reacts with CS_2 to initially give (**1037**), which forms (**1038**) upon subsequent methylation by $MeOSO_2F$ (Equation (31)):[2503]

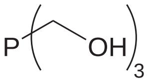


(**1037**) (**1038**) (31)

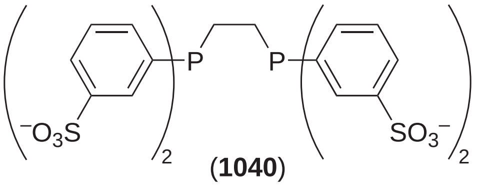
Nickel(0) complexes with water-soluble phosphines have attracted interest in the context of homogeneous catalysis. A comprehensive study of the coordination chemistry of tris(sodium-*m*-sulfonatophenyl)phosphine (**1039**) has appeared.[2504] The complexes [$Ni(CO)_2$(**1039**)$_2$]·$6H_2O$ have been made by reaction of (**1039**) with $Ni(CO)_4$ under phase-transfer conditions, and the homoleptic [Ni(**1039**)$_3$]·$9H_2O$ has been made from Ni^0 precursors and (**1039**) under phase-transfer conditions, or from $NiCl_2$, (**1039**), and BH_4^- in water. A related complex [$Ni(CO)_2$(**1040**)$_2$] with the bidentate ligand (**1040**) has also been studied.[2505]



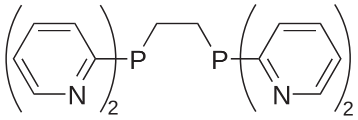
(**1039**)



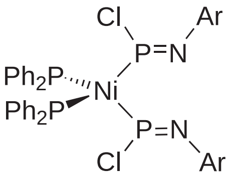
(**1041**)



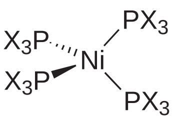
(**1040**)



(**1042**)



(**1043**)



(**1044**)
(X = F, Cl, Br, Me)

[$Ni^0\{P(CH_2OH)_3\}_4$] has been prepared by the reaction of $P(CH_2OH)_3$ (**1041**) with [$Ni(cod)_2$] in toluene and is assumed to be tetrahedral. It is similar to its PMe_3 and PEt_3 analogues in many respects, with the main differences being enhanced water solubility, increased stability of the low oxidation state, and high coordination number.[2506] With the same intention to increase water solubility, complexes [$Ni(CO)_2L_2$] and [NiL_4] with 2-pyridylphosphine ligands ($L = PPh_{3-n}py_n$) as well as with the chelating ligand (**1042**) have been prepared.[2507]

Chloro(2,4,6-tri-*t*-butylphenylimino)phosphine, Cl—P=NAr ($Ar = 2,4,6\text{-}Bu^t{}_3C_6H_2$), has been reacted with a variety of Ni^0 complexes, yielding σ-complexes of P-functionalized iminophosphines.[2508] The structure of [$Ni(PEt_3)_2(Cl\text{—}P\text{=}NAr)_2$] ($Ar = 2,4,6\text{-}Bu^t{}_3C_6H_2$; (**1043**)) has been obtained; the complex is almost perfectly tetrahedral with the chloroiminophosphine η^1-bonded as a consequence of its carbene-like frontier orbitals.[2509]

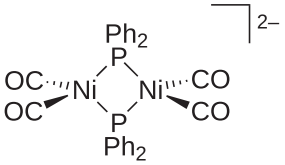
Bis(η^3-allyl)nickel(0) and bis(η^5-pentadienyl)iron(II) have been used as starting materials in the preparation of $[Ni(PF_3)_4]$ and $[Ni(PF_2H)_4]$.[2510] The electronic structure of the fluorophosphine complex $[Ni(PF_3)_4]$ has been investigated by various spectroscopic and theoretical methods.[2511–2515] *Inter alia*, a theoretical treatment by the multiple scattering X_α method showed that π back donation is of the same magnitude as in $[Ni(CO)_4]$.[2516] Photoelectron spectra of $[Ni(PF_3)_4]$ have been measured using synchrotron radiation. Unexpectedly, this formally d^{10} complex shows $p-d$ resonance between 70 eV and 100 eV,[2517] which is attributed to covalent mixing of d character into unoccupied molecular orbitals. Force constant calculations have been carried out for $[Ni(PBr_3)_4]$ using simple valence force field with interaction constants. The force constant values were compared for the coordinated and free ligand, and also with k(Ni—P) stretching in the series of molecules $[Ni(PX_3)_4]$ (X = F, Cl, Me). It was found that the k(Ni—P) stretching force constant was lowest for $[Ni(PBr_3)_4]$ in the series (**1044**).[2518]

Protonation of a number of Ni^0 phosphine complexes has been carried out using $H_2C(SO_2CF_3)_2$. The resultant complex cations $[L_3NiH]^+$ (L = Ph_3P, Ph_2PMe, Et_3P) were isolated as their $HC(SO_2CF_3)_2^-$ salts. However, protonation of $[Ni\{P(OEt)_3\}_4]$ was found to yield $[(EtO)_3P\}_4NiH][HC(SO_2CF_3)_2]$. In addition, the compounds $[(Et_3P)_3NiH][HC(SO_2CF_3)_2]$ and $[(Ph_3P)_3NiH][HC(SO_2CF_3)_2]$ were found to be stereochemically nonrigid in CH_2Cl_2 solution.[2519]

It has been shown that some phosphine or phosphite Ni^0 complexes have long-lived emissive excited states at room temperature and possess photochemical reactivity towards organic substrates.[2520]

An improved method for the preparation of $[Ni(CO)_2(PR_3)_2]$ has been reported. The preparation involves reaction of the dithiocarbamate, $[Ni(S_2COEt)_2]$, with the relevant phosphine PR_3. Yields of up to 50% have been recorded.[2521] Infrared carbonyl stretching frequencies of the newly characterized difluorophosphine-coupled $[Ni(CO)_3(PF_2H)]$ and $[Ni(CO)_2(PF_2H)_2]$ indicate that the bonding capabilities of this particular phosphine are intermediate between PH_3 and PF_3.[2522] New bis(dialkylamino)phosphine Ni^0 complexes of the type $[Ni(CO)_3L]$ (L = Me_2NPF_2, $(Me_2N)_2PF$, $CH_3NCH_2CH_2N(CH_3)PF$, $(Me_2N)_2PH$, $CH_3NCH_2CH_2N(CH_3)PH$) have been prepared in good yield and characterized spectroscopically.[2523]

A selection of the extensive bimetallic Ni carbonyl phosphido chemistry is given in the following. Toluene solutions of $[Ni(CO)_2(PPh_3)_2]$ react with excess K metal to give the $[Ni_2(CO)_4(\mu\text{-}PPh_2)_2]^{2-}$ ion (**1045**) which contains two tetrahedral Ni centers fused along a common edge.[2524] Each Ni achieves an 18-electron configuration without the formation of a Ni—Ni bond (d(Ni—Ni) = 3.397(1) Å) in contrast to the two-electron oxidation product $Ni_2(CO)_4(\mu\text{-}PPh_2)_2$ (d(Ni—Ni) = 2.510(2) Å).

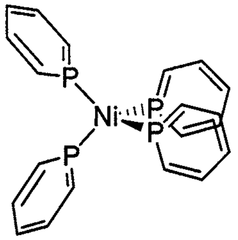


(**1045**)

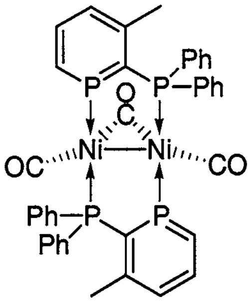
6.3.6.5.2 *Complexes with diphosphenes, phosphabenzene, biphosphinine, and other unsaturated phosphorus donor ligands*

The orange, air-stable, homoleptic tetrakis(η^1-phosphabenzene)nickel (**1046**) is tetrahedral (point symmetry S_4) and can be obtained from phosphabenzene and $[Ni(cod)_2]$.[2525] It features a short Ni—P bond length of 2.1274(5) Å with considerable Ni → P π-backbonding and a ν(Ni—P) stretch at 168 cm^{-1}. In solution, partial dissociation of one phosphabenzene ligand is observed. 2-Diphenylphosphino-3-methylphosphinine forms with $[Ni(cod)_2]$ in the presence of the CO the dinuclear complex (**1047**) with a W-frame structure.[2526]

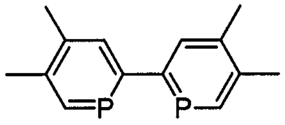
2,2′-Biphosphinines, the P analogues of bipyridine, are particularly suited as ligands for reduced metal species (reduction of biphosphinines is much easier than of bipyridine). Complexes [Ni(**1048**)$_2$] and [Ni(**1048**)L$_2$] (L = PPh_3, etc.) have been prepared by several procedures (from 2,2′-biphosphinine and $[NiCl_2(dppe)]$ or from $[NiCl_2(PPh_3)_2]$ in the presence of excess Zn powder to afford [Ni(**1048**)L$_2$], or with $NiBr_2$ under the same conditions to afford [Ni(**1048**)$_2$], or from the biphosphinine dianion and the respective $Ni^{II}X_2$ precursor) and are stable to air (in contrast to $[Ni(bipy)_2]$).[2527,2528] [Ni(**1048**)$_2$] has a distorted tetrahedral structure with Ni—P bond lengths (2.141–2.149(1) Å) that are significantly longer than those for (**1046**).[2526] Electrochemistry shows



(1046)



(1047)



(1048)

two reversible monoelectronic reduction waves at −1.68 V and −1.92 V (vs. SCE), corresponding to successive reduction of the coordinated biphosphinines. By accepting the first electron to give [Ni(**1048**)$_2$]$^-$, the complex distorts towards a more planar geometry.[2529]

Phosphaalkenes can coordinate to Ni^0 either in a η^1 or in a η^2 fashion, since the P lone pair σ-orbital and the π-orbital of the P=C bond are the highest occupied molecular orbitals of nearly equal energy. The Ni^0 complex (**1049**) was the first η^2 complex of a phosphaalkene to be identified and was prepared from a Ni^{II} compound by the redox reaction outlined in Equation (32).[2530,2531] P-halogenophosphaalkenes display different reactivity towards [Ni(cod)(PBu$_3$)$_2$], undergoing either coordination to give η^2 phosphaalkene complexes (**1050**) or oxidative addition of the P—X bond (**1051**), depending on X (Equation (33)).[2532] A high P—X bond energy (X = F) favors the former product, whereas weaker P—X bonds (P—I) lead to oxidative addition. X = Cl is an intermediate situation:

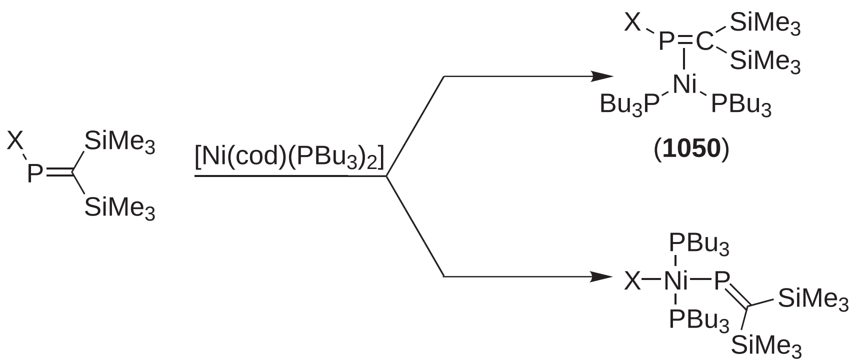
(1049)



(1050)

(33)

(1051)

Selected further examples of Ni^0 phosphaalkene complexes include (**1052**),[2533] (**1053**),[2534] and (**1054**)[2535] as well as various others.[2536–2538] A methylenediylphosphenium ion may be stabilized in a metallaphosphaallene form (**1055**) according to Equation (34).[2539]

Reaction of (diisopropylamino)phosphaethyne P≡CN(Pr^i)$_2$ with [Ni(CO)$_3$(P{C$_6$H$_{11}$}$_3$)] affords the planar 16-electron Ni^0 complex (**1056**) with η^2-bound phosphaethyne.[2540] Upon coordination, the P≡C triple bond distance increases to 1.665(2) Å, which is typical for phosphaalkenes. Upon reaction with $[Ni(cod)_2]$, the same phosphaethyne gives (**1057a**) with a 1,3-diphosphacyclobutadiene and a side-on π ligand,[2541] and with $Ni(CO)_4$ it gives (**1057b**).[2575]

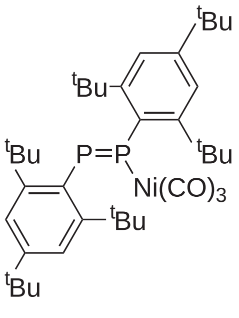
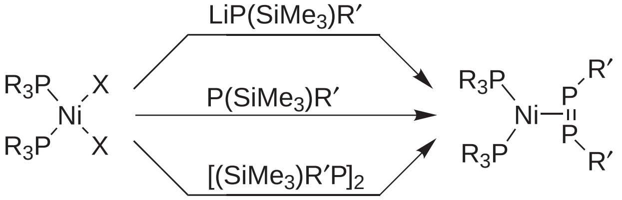
The diphosphene $(2,4,6\text{-Bu}^t{}_3C_6H_2)_2P_2$ reacts with $Ni(CO)_4$ to give (**1058**), the first Ni^0 complex with a η^1-diphosphene.[2542] Only one $Ni(CO)_3$ moiety attaches, even if the diphosphene is treated with an excess of $Ni(CO)_4$. $[Ni(PEt_3)_2(\eta^2\text{-}Me_3SiPPSiMe_3)]$, the crystal structure of which has been determined,[2543] shows the diphosphene ligand coordinated in the more common η^2 mode. $(CF_3P)_4$ and $(CF_3P)_5$ have been reacted with a number of zerovalent tertiary phosphine nickel complexes. Generally η^2-CF_3PPCF_3 complexes of the formula $[L_2Ni(CF_3PPCF_3)]$ were obtained, which were characterized by NMR spectroscopy and single-crystal X-ray methods.[2544] Various synthetic routes are meanwhile available for the synthesis of Ni^0 diphosphene complexes.[2370,2545,2546] Some approaches are collected in Equation (35).



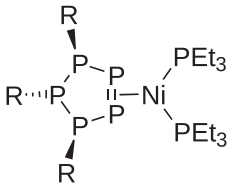
(**1058**)



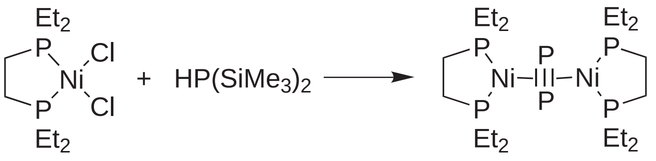
(35)

An unusual diphosphene complex of Ni^0 is (**1059**), which forms upon reaction of $[NiCl_2(PEt_3)_2]$ with two equivalents of $Na[\textit{cyclo}\text{-}(P_5tBu_4)]$.[2547] The P=P bond in (**1059**) (2.1183(11) Å) is clearly shorter than all other P—P bonds in the P_5 ring, and the Ni atom is surrounded by four P atoms in an almost square planar fashion.

By slight modification of the synthetic procedure outlined in Equation (35), a P_2 unit side-on bound to two Ni^0 complex fragments can be obtained according to Equation (36) (**1060**). X-ray crystallography shows a butterfly structure with $d(P{\equiv}P) = 2.121(6)$ Å:[2548]



(**1059**) R = ^tBu

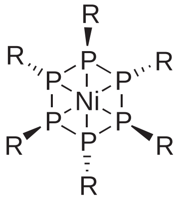


(36)

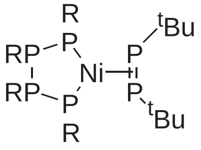
(**1060**)

6.3.6.6.3 *Complexes with miscellaneous phosphorus donor ligands*

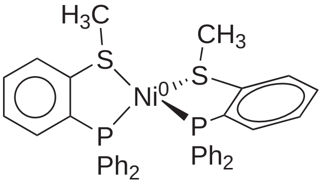
Diamagnetic $[Ni(PBu^t)_6]$ (**1061**) has been prepared simply by reaction of $NiCl_2$ with $P(SiMe_3)_3$ and $(PBu^t)_3$, while the reaction of $(PBu^t)_3$ with $[Ni(CO)_4]$ affords $[Ni_5(PBu^t)_6(CO)_6]$. The crystal and molecular structures of both complexes have been determined, and (**1061**) features a Ni at the center of a near-planar hexagon of PBu^t moieties.[2549] It can be regarded as an isomer of (**228**) (see Section 6.3.4.5.2). The electronic structure of this unique complex (**1061**) has been discussed and investigated theoretically.[2550,2551] The system could be regarded as essentially a 16-electron Ni^0 species, with three of the six P—P σ-bonds interacting with the central Ni atom.



(**1061**) R = ^tBu

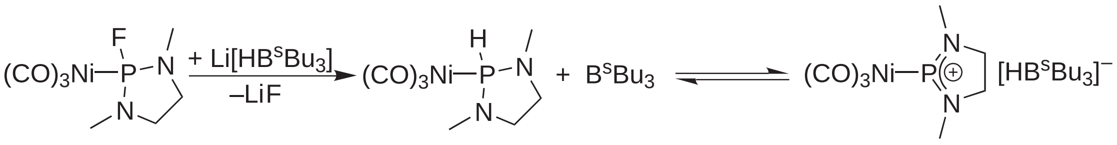


(**228**) R = ^tBu



(**994**)

Reactions of the tetrahedral Ni^0 complex (**994**) have already been discussed in Section 6.3.5.4.[2397] A nickel carbonyl cation (**1062**) containing a cyclophosphenium ligand has been assembled through a hydride abstraction reaction according to Equation (37).[2552]



(**1062**)

(37)

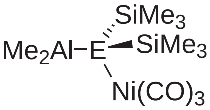
6.3.6.5.4 *Complexes with arsenic and antimony donor ligands*

In most studies of Ni complexes with As or Sb donor ligands, the complete range of redox states is covered. Therefore, the reader should also refer to the examples given in the respective sections for Ni^{II} and Ni^I.

Reactions of tetracarbonylnickel with $SbCl_3$ proceed to the monosubstituted stage only. A complete vibrational assignment has been made for $[Ni(CO)_3(SbCl_3)]$ under C_{3v} symmetry.[2553]

The reaction of $[Ni_6(CO)_{12}]^{2-}$ with $SbCl_3$ affords the large clusters $[Ni_{13}Sb_2(CO)_{24}]^{n-}$ ($n = 2, 3, 4$).[2554] They can formally be regarded as exotic bidentate stibine ligands, $[Ni_{11}Sb_2(CO)_{18}]^{n-}$ (nickel-centered icosahedra, one antimony atom capping each Ni_5 plane) bridging two $[Ni(CO)_3]$ fragments.

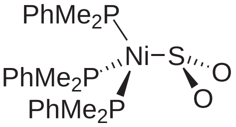
Complexes (**1063**) have been obtained by the reaction of $Ni(CO)_4$ with monomeric Lewis base-stabilized aluminum pnictines [dmap-$AlMe_2$-$E(SiMe_3)_2$] (E = P, As, Sb).[2555]



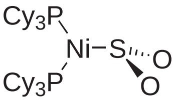
(**1063**)
(E = P, As, Sb)

6.3.6.6 Miscellaneous Complexes of Nickel(0)

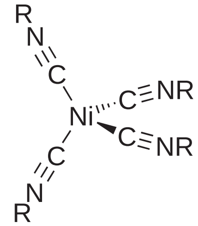
A general strategy for the synthesis of complexes $[NiL_3(SO_2)]$ (L = monodentate phosphane), $[NiL_2(SO_2)_2]$ (L_2 = two monodentate phosphanes or a bidentate N-donor ligand), and $[NiL_2(SO_2)]$ (L = bidentate phosphane) has been worked out.[2556–2558] Upon oxidation with dioxygen, sulfato complexes are formed.[2557] The SO_2 ligand may coordinate in η^1-pyramidal, η^1-planar, or η^2-S,O side-on mode, which depends on the coligands.[2559] Various theoretical studies have been carried out to see if the bonding options differed significantly in energy, and various different and partially counteracting influences have been identified.[2559–2562] In complexes of the type $[NiL_3(SO_2)]$, coligands L with higher basicity favor the η^1-pyramidal coordination mode of SO_2, while steric repulsion acts against the bent structure.[2561] Selected Ni^0 complexes with SO_2 that have been structurally characterized include four-coordinate (**1064**) and three-coordinate (**1065**), both with η^1-pyramidal SO_2 ligand.[2563,2564]



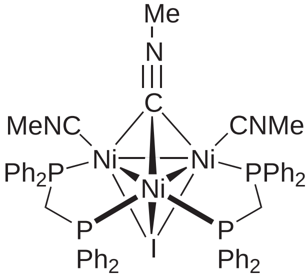
(**1064**)



(**1065**)



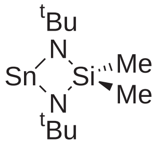
(**1066**)
R = C_6F_5 (**a**)
CF_3 (**b**)
$SiMe_3$ (**c**)



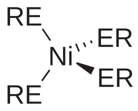
(**1067**)

Some new homoleptic isocyanide complexes (**1066**) are collected here, which include fluorinated [2565,2566] and silylated ones.[2567] For the reaction of $[Ni(CNR)_4]$ with CO_2 see Section 6.3.6.2. A triangulo Ni_3 cluster featuring a μ^3-η^1-isocyanide ligand has been reported (**1067**).[2568] The ν(CN) band of the μ^3-η^1-isocyanide ligand appears at $1943\,cm^{-1}$, which is relatively high. When the precursor to this complex, $[Ni_2(\mu\text{-}CNMe)(CNMe)_2(dppe)_2]$, is treated with $HgCl_2$, a spirocyclic Ni_4Hg cluster is formed, in which a central Hg^{2+} ion is surrounded by four Ni atoms.[2569]

A remarkably stable, deep red Ni^0 stannylene complex, [Ni(**1068**)$_4$], has been prepared by the reaction of [Ni(1,5-cyclooctadiene)$_2$] with (**1068**) in toluene at $-78\,^{\circ}\text{C}$.[2570] In spite of the bulkiness of (**1068**) and the known tendency of analogous Ni^0 phosphine complexes to dissociate in solution, [Ni(**1068**)$_4$] remains intact in solution and, moreover, melts at 178–180 °C without decomposition. X-ray crystallography shows tetrahedral geometry about the nickel atom, with Ni—Sn bond lengths of 2.3898(2)–2.399(2) Å.



(**1068**)



(**1069**)
(E = In, Ga; R = C(SiMe)$_3$

Tetrahedral Ni/In and Ni/Ga complexes (**1069**) are analogues of [Ni(CO)$_4$]. They have been obtained by the reaction of tetrahedral [EC(SiMe$_3$)$_3$]$_4$ (E = Ga, In) with [Ni(cod)$_2$].[2571,2572] Both complexes show surprisingly high thermal stability, decomposing only above 285 °C (E = In) or not below 320 °C (E = Ga). Calculations reveal that the Ni—E bond dissociation energies are rather high and have significant contribution from the $\text{Ni} \rightarrow \text{E}\ \pi$ back-donation. More detailed studies of the bonding situation have been published.[2573,2574]

ACKNOWLEDGMENTS

This compilation would not have been possible without the great help of many people. In particular we would like to thank Mrs. Petra Unger (Universität Göttingen) for terrific typing work and Dr. Silke Buchler (Universität Heidelberg) for her valuable contributions to the sections dealing with Ni^{II} complexes of sulfur ligands. Jens Ackermann, Bernhard Bauer-Siebenlist, and Gilles Noel (Universität Göttingen) as well as A. Dobosz, H. Szyszuk, E. Gumienna-Kontecka, and M. Luczkowski (Wroclaw University) are sincerely thanked for preparing many of the drawings and figures. Finally, several colleagues provided references to their work, which we gratefully acknowledge.
