An **algebraic multigrid** preconditioner is a preconditioner that uses principles similar to those used for PDE problems on grids, when the “grid” for the problem is unknown or nonexistent and only the matrix is available.

### Facts:

1. If  $A$  is an M-matrix, then for every subset  $S$  of off-diagonal indices there exists a lower triangular matrix  $L = [l_{ij}]$  with unit diagonal and an upper triangular matrix  $U = [u_{ij}]$  such that  $A = LU - R$ , where

$$l_{ij} = 0 \text{ if } (i, j) \in S, \quad u_{ij} = 0 \text{ if } (i, j) \in S, \quad \text{and } r_{ij} = 0 \text{ if } (i, j) \notin S.$$

The factors  $L$  and  $U$  are unique and the splitting  $A = LU - R$  is a regular splitting [Var60, MV77]. The idea of generating such approximate factorizations was considered by a number of people, one of the first of whom was Varga [Var60]. The idea became popular when it was used by Meijerink and van der Vorst to generate preconditioners for the conjugate gradient method and related iterations [MV77]. It has proved a successful technique in a range of applications and is now widely used with many variations. For example, instead of specifying the sparsity pattern of  $L$ , one might begin to compute the entries of the exact  $L$ -factor and set entries to 0 if they fall below some threshold (see, e.g., [Mun80]).

2. For a real symmetric positive definite matrix  $A$  arising from a standard finite difference or finite element approximation for a second order self-adjoint elliptic partial differential equation on a grid

with spacing  $h$ , the condition number of  $A$  is  $O(h^{-2})$ . When  $A$  is preconditioned using the incomplete Cholesky decomposition  $LL^T$ , where  $L$  has the same sparsity pattern as the lower triangle of  $A$ , the condition number of the preconditioned matrix  $L^{-1}AL^{-T}$  is still  $O(h^{-2})$ , but the constant multiplying  $h^{-2}$  is smaller. When  $A$  is preconditioned using the modified incomplete Cholesky decomposition, the condition number of the preconditioned matrix is  $O(h^{-1})$  [DKR68, Gus78].

3. For a general matrix  $A$ , the incomplete  $LU$  decomposition can be used as a preconditioner in a non-Hermitian matrix iteration such as GMRES, QMR, or BiCGSTAB. At each step of the preconditioned algorithm one must solve a linear system  $M\mathbf{z} = \mathbf{r}$ . This is accomplished by first solving the lower triangular system  $L\mathbf{y} = \mathbf{r}$  and then solving the upper triangular system  $U\mathbf{z} = \mathbf{y}$ .
4. One difficulty with incomplete Cholesky and incomplete  $LU$  decompositions is that the solution of the triangular systems may not parallelize well. In order to make better use of parallelism, sparse approximate inverses have been proposed as preconditioners. Here, a sparse matrix  $M^{-1}$  is constructed directly to approximate  $A^{-1}$ , and each step of the iteration method requires computation of a matrix-vector product  $\mathbf{z} = M^{-1}\mathbf{r}$ . For an excellent recent survey of all of these preconditioning methods see [Ben02].
5. Multigrid methods have the very desirable property that for many problems arising from elliptic PDEs the number of cycles required to reduce the error to a desired fixed level is independent of the grid size. This is in contrast to methods such as ICCG and MICCG (incomplete and modified incomplete Cholesky decomposition used as preconditioners in the CG algorithm). Early developers of multigrid methods include Fedorenko [Fed61] and later Brandt [Bra77]. A very readable and up-to-date introduction to the subject can be found in [BHM00].
6. Algebraic multigrid methods represent an attempt to use principles similar to those used for PDE problems on grids, when the origin of the problem is not necessarily known and only the matrix is available. An example is the AMG code by Ruge and Stüben [RS87]. The AMG method attempts to achieve mesh-independent convergence rates, just like standard multigrid methods, without making use of the underlying grid. A related class of preconditioners are *domain decomposition* methods. (See [QV99] and [SBG96] for recent surveys.)

## 41.5 Preconditioned Algorithms

### Facts:

1. It is easy to modify the algorithms of the previous sections to use left preconditioning: Simply replace  $A$  by  $M^{-1}A$  and  $\mathbf{b}$  by  $M^{-1}\mathbf{b}$  wherever they appear. Since one need not actually compute  $M^{-1}$ , this is equivalent to solving linear systems with coefficient matrix  $M$  for the preconditioned quantities. For example, letting  $\mathbf{z}_k$  denote the preconditioned residual  $M^{-1}(\mathbf{b} - A\mathbf{x}_k)$ , the left-preconditioned BiCGSTAB algorithm is as follows:

#### Left-Preconditioned BiCGSTAB.

Given  $\mathbf{x}_0$ , compute  $\mathbf{r}_0 = \mathbf{b} - A\mathbf{x}_0$ , solve  $M\mathbf{z}_0 = \mathbf{r}_0$ , and set  $\mathbf{p}_0 = \mathbf{z}_0$ .

Choose  $\hat{\mathbf{z}}_0$  such that  $\langle \mathbf{z}_0, \hat{\mathbf{z}}_0 \rangle \neq 0$ . For  $k = 1, 2, \dots$ ,

Compute  $A\mathbf{p}_{k-1}$  and solve  $M\mathbf{q}_{k-1} = A\mathbf{p}_{k-1}$ .

Set  $\mathbf{x}_{k-1/2} = \mathbf{x}_{k-1} + a_{k-1}\mathbf{p}_{k-1}$ , where  $a_{k-1} = \frac{\langle \mathbf{z}_{k-1}, \hat{\mathbf{z}}_0 \rangle}{\langle \mathbf{q}_{k-1}, \hat{\mathbf{z}}_0 \rangle}$ .

Compute  $\mathbf{r}_{k-1/2} = \mathbf{r}_{k-1} - a_{k-1}A\mathbf{p}_{k-1}$  and  $\mathbf{z}_{k-1/2} = \mathbf{z}_{k-1} - a_{k-1}\mathbf{q}_{k-1}$ .

Compute  $A\mathbf{z}_{k-1/2}$  and solve  $M\mathbf{s}_{k-1/2} = A\mathbf{z}_{k-1/2}$ .

Set  $\mathbf{x}_k = \mathbf{x}_{k-1/2} + \omega_k\mathbf{z}_{k-1/2}$ , where  $\omega_k = \frac{\langle \mathbf{z}_{k-1/2}, \mathbf{s}_{k-1/2} \rangle}{\langle \mathbf{s}_{k-1/2}, \mathbf{s}_{k-1/2} \rangle}$ .

Compute  $\mathbf{r}_k = \mathbf{r}_{k-1/2} - \omega_k A\mathbf{z}_{k-1/2}$  and  $\mathbf{z}_k = \mathbf{z}_{k-1/2} - \omega_k\mathbf{s}_{k-1/2}$ .

Compute  $\mathbf{p}_k = \mathbf{z}_k + b_k(\mathbf{p}_{k-1} - \omega_k\mathbf{q}_{k-1})$ , where  $b_k = \frac{a_{k-1}}{\omega_k} \frac{\langle \mathbf{z}_k, \hat{\mathbf{z}}_0 \rangle}{\langle \mathbf{z}_{k-1}, \hat{\mathbf{z}}_0 \rangle}$ .

- Right or Hermitian preconditioning requires a little more thought since we want to generate approximations  $\mathbf{x}_k$  to the solution of the original linear system, not the modified one  $AM^{-1}\mathbf{y} = \mathbf{b}$  or  $L^{-1}AL^{-*}\mathbf{y} = L^{-1}\mathbf{b}$ .

If the CG algorithm is applied directly to the problem  $L^{-1}AL^{-*}\mathbf{y} = L^{-1}\mathbf{b}$ , then the iterates satisfy

$$\begin{aligned} \mathbf{y}_k &= \mathbf{y}_{k-1} + a_{k-1}\hat{\mathbf{p}}_{k-1}, & a_{k-1} &= \frac{\langle \hat{\mathbf{r}}_{k-1}, \hat{\mathbf{r}}_{k-1} \rangle}{\langle \hat{\mathbf{p}}_{k-1}, L^{-1}AL^{-*}\hat{\mathbf{p}}_{k-1} \rangle}, \\ \hat{\mathbf{r}}_k &= \hat{\mathbf{r}}_{k-1} - a_{k-1}L^{-1}AL^{-*}\hat{\mathbf{p}}_{k-1}, \\ \hat{\mathbf{p}}_k &= \hat{\mathbf{r}}_k + b_{k-1}\hat{\mathbf{p}}_{k-1}, & b_{k-1} &= \frac{\langle \hat{\mathbf{r}}_k, \hat{\mathbf{r}}_k \rangle}{\langle \hat{\mathbf{r}}_{k-1}, \hat{\mathbf{r}}_{k-1} \rangle}. \end{aligned}$$

Defining

$$\mathbf{x}_k \equiv L^{-*}\mathbf{y}_k, \quad \mathbf{r}_k \equiv L\hat{\mathbf{r}}_k, \quad \mathbf{p}_k \equiv L^{-*}\hat{\mathbf{p}}_k,$$

we obtain the following preconditioned CG algorithm for  $A\mathbf{x} = \mathbf{b}$ :

**Preconditioned Conjugate Gradient Method (PCG).**  
 (For Hermitian Positive Definite Problems, with Hermitian Positive Definite Preconditioners)  
 Given an initial guess  $\mathbf{x}_0$ , compute  $\mathbf{r}_0 = \mathbf{b} - A\mathbf{x}_0$  and solve  
 $M\mathbf{z}_0 = \mathbf{r}_0$ . Set  $\mathbf{p}_0 = \mathbf{z}_0$ . For  $k = 1, 2, \dots$ ,  
 Compute  $A\mathbf{p}_{k-1}$ .  
 Set  $\mathbf{x}_k = \mathbf{x}_{k-1} + a_{k-1}\mathbf{p}_{k-1}$ , where  $a_{k-1} = \frac{\langle \mathbf{r}_{k-1}, \mathbf{z}_{k-1} \rangle}{\langle \mathbf{p}_{k-1}, A\mathbf{p}_{k-1} \rangle}$ .  
 Compute  $\mathbf{r}_k = \mathbf{r}_{k-1} - a_{k-1}A\mathbf{p}_{k-1}$ .  
 Solve  $M\mathbf{z}_k = \mathbf{r}_k$ .  
 Set  $\mathbf{p}_k = \mathbf{z}_k + b_{k-1}\mathbf{p}_{k-1}$ , where  $b_{k-1} = \frac{\langle \mathbf{r}_k, \mathbf{z}_k \rangle}{\langle \mathbf{r}_{k-1}, \mathbf{z}_{k-1} \rangle}$ .

**Applications:**

- Figure 41.4 shows the convergence (in terms of the 2-norm of the residual) of the ICCG algorithm (CG with incomplete Cholesky decomposition as a preconditioner, where the sparsity pattern of

**FIGURE 41.4** Convergence of ICCG (dashed) and multigrid (solid) for the problem given in the introduction with  $a(x, y, z) = 1 + x + 3yz$ ,  $h = 1/50$  (for ICCG), and  $h = 1/64$  (for multigrid).

$L$  was taken to match that of the lower triangle of  $A$ ) and a multigrid method (using standard restriction and prolongation operators and the Gauss-Seidel algorithm for relaxation) for the same problem used in sections 2 and 3. The horizontal axis represents iterations for ICCG or cycles for the multigrid method. Each multigrid V-cycle costs about twice as much as an ICCG iteration, since it performs two triangular solves and two matrix vector multiplications on each coarse grid, while doing one of each on the fine grid. There is also a cost for the restriction and prolongation operations. The grid size was taken to be  $64^3$  for the multigrid method since this enabled easy formation of coarser grids by doubling  $h$ . The coarsest grid, on which the problem was solved directly, was taken to be of size  $4 \times 4 \times 4$ . It should be noted that the number of multigrid cycles can be reduced by using the multigrid procedure as a preconditioner for the CG algorithm (although this would require a different relaxation method in order to maintain symmetry). The only added expense is the cost of inner products in the CG algorithm.

## 41.6 Convergence Rates of CG and MINRES

In this section, we again let  $A$  and  $\mathbf{b}$  denote the already preconditioned matrix and right-hand side vector, and we assume that  $A$  is Hermitian (and also positive definite for CG).

### Facts:

1. The CG error vector and the MINRES residual vector at step  $k$  can be written in the form

$$\mathbf{e}_k = P_k^C(A)\mathbf{e}_0, \quad \mathbf{r}_k = P_k^M(A)\mathbf{r}_0,$$

where  $P_k^C$  and  $P_k^M$  are the  $k$ th degree polynomials with value 1 at the origin that minimize the  $A$ -norm of the error in the CG algorithm and the 2-norm of the residual in the MINRES algorithm, respectively. In other words, the error  $\mathbf{e}_k$  in the CG approximation satisfies

$$\|\mathbf{e}_k\|_A = \min_{p_k} \|p_k(A)\mathbf{e}_0\|_A$$

and the residual  $\mathbf{r}_k$  in the MINRES algorithm satisfies

$$\|\mathbf{r}_k\| = \min_{p_k} \|p_k(A)\mathbf{r}_0\|,$$

where the minimum is taken over all polynomials  $p_k$  of degree  $k$  or less with  $p_k(0) = 1$ .

2. Let an eigendecomposition of  $A$  be written as  $A = U\Lambda U^*$ , where  $U$  is a unitary matrix and  $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_n)$  is a diagonal matrix of eigenvalues. If  $A$  is positive definite, define  $A^{1/2}$  to be  $U\Lambda^{1/2}U^*$ . Then the  $A$ -norm of a vector  $\mathbf{v}$  is just the 2-norm of the vector  $A^{1/2}\mathbf{v}$ . The equalities in Fact 1 imply

$$\begin{aligned} \|\mathbf{e}_k\|_A &= \min_{p_k} \|A^{1/2} p_k(A)\mathbf{e}_0\| = \min_{p_k} \|p_k(A)A^{1/2}\mathbf{e}_0\| \\ &= \min_{p_k} \|U p_k(\Lambda)U^* A^{1/2}\mathbf{e}_0\| \leq \min_{p_k} \|p_k(\Lambda)\| \|\mathbf{e}_0\|_A, \end{aligned}$$

$$\|\mathbf{r}_k\| = \min_{p_k} \|U p_k(\Lambda)U^* \mathbf{r}_0\| \leq \min_{p_k} \|p_k(\Lambda)\| \|\mathbf{r}_0\|.$$

These bounds are *sharp*; that is, for each step  $k$  there is an initial vector for which equality holds [Gre79, GG94, Jou96], but the initial vector that gives equality at step  $k$  may be different from the one that results in equality at some other step  $j$ .

The problem of describing the convergence of these algorithms therefore reduces to one in approximation theory — How well can one approximate zero on the set of eigenvalues of  $A$  using a  $k$ th degree polynomial with value 1 at the origin? While there is no simple expression for the maximum value of the minimax polynomial on a discrete set of points, this minimax polynomial can be calculated if the eigenvalues of  $A$  are known and, more importantly, this sharp upper bound provides intuition as to what constitute “good” and “bad” eigenvalue distributions. Eigenvalues tightly clustered around a single point (away from the origin) are good, for instance, because the polynomial  $(1 - z/c)^k$  is small in absolute value at all points near  $c$ . Widely spread eigenvalues, especially if they lie on both sides of the origin, are bad, because a low degree polynomial with value 1 at the origin cannot be small at a large number of such points.

3. Since one usually has only limited information about the eigenvalues of  $A$ , it is useful to have error bounds that involve only a few properties of the eigenvalues. For example, in the CG algorithm for Hermitian positive definite problems, knowing only the largest and smallest eigenvalues of  $A$ , one can obtain an error bound by considering the minimax polynomial on the *interval* from  $\lambda_{min}$  to  $\lambda_{max}$ ; i.e., the Chebyshev polynomial shifted to the interval and scaled to have value 1 at the origin. The result is

$$\frac{\|\mathbf{e}_k\|_A}{\|\mathbf{e}_0\|_A} \leq 2 \left[ \left( \frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1} \right)^k + \left( \frac{\sqrt{\kappa} + 1}{\sqrt{\kappa} - 1} \right)^k \right]^{-1} \leq 2 \left( \frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1} \right)^k,$$

where  $\kappa = \lambda_{max}/\lambda_{min}$  is the ratio of largest to smallest eigenvalue of  $A$ .

If additional information is available about the interior eigenvalues of  $A$ , one often can improve on this estimate while maintaining a simpler expression than the sharp bound in Fact 2. Suppose, for example, that  $A$  has just a few eigenvalues that are much larger than the others, say,  $\lambda_1 \leq \dots \leq \lambda_{n-\ell} \ll \lambda_{n-\ell+1} \leq \dots \leq \lambda_n$ . Consider a polynomial  $p_k$  that is the product of a factor of degree  $\ell$  that is zero at  $\lambda_{n-\ell+1}, \dots, \lambda_n$  and the  $(k - \ell)$ th degree scaled and shifted Chebyshev polynomial on the interval  $[\lambda_1, \lambda_{n-\ell}]$ :

$$p_k(x) = \left[ T_{k-\ell} \left( \frac{2x - \lambda_{n-\ell} - \lambda_1}{\lambda_{n-\ell} - \lambda_1} \right) / T_{k-\ell} \left( \frac{-\lambda_{n-\ell} - \lambda_1}{\lambda_{n-\ell} - \lambda_1} \right) \right] \cdot \left( \prod_{i=n-\ell+1}^n \frac{\lambda_i - x}{\lambda_i} \right).$$

Since the second factor is zero at  $\lambda_{n-\ell+1}, \dots, \lambda_n$  and less than one in absolute value at each of the other eigenvalues, the maximum absolute value of this polynomial on  $\{\lambda_1, \dots, \lambda_n\}$  is less than the maximum absolute value of the first factor on  $\{\lambda_1, \dots, \lambda_{n-\ell}\}$ . It follows that

$$\frac{\|\mathbf{e}_k\|_A}{\|\mathbf{e}_0\|_A} \leq 2 \left( \frac{\sqrt{\kappa_{n-\ell}} - 1}{\sqrt{\kappa_{n-\ell}} + 1} \right)^{k-\ell}, \quad \kappa_{n-\ell} \equiv \frac{\lambda_{n-\ell}}{\lambda_1}.$$

Analogous results hold for the 2-norm of the residual in the MINRES algorithm applied to a Hermitian positive definite linear system. For estimates of the convergence rate of the MINRES algorithm applied to indefinite linear systems see, for example, [Fis96].

## 41.7 Convergence Rate of GMRES

### Facts:

1. Like MINRES for Hermitian problems, the GMRES algorithm for general linear systems produces a residual at step  $k$  whose 2-norm satisfies  $\|\mathbf{r}_k\| = \min_{p_k} \|p_k(A)\mathbf{r}_0\|$ , where the minimum is over all  $k$ th degree polynomials  $p_k$  with  $p_k(0) = 1$ . To derive a bound on this expression that is

independent of the direction of  $\mathbf{r}_0$ , we could proceed as in the previous section by employing an eigendecomposition of  $A$ . To this end, assume that  $A$  is diagonalizable and let  $A = V\Lambda V^{-1}$  be an eigendecomposition, where  $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_n)$  is a diagonal matrix of eigenvalues and the columns of  $V$  are right eigenvectors of  $A$ . Then it follows that

$$\|\mathbf{r}_k\| = \min_{p_k} \|V p_k(\Lambda) V^{-1} \mathbf{r}_0\| \leq \kappa(V) \min_{p_k} \|p_k(\Lambda)\| \cdot \|\mathbf{r}_0\|,$$

where  $\kappa(V) = \|V\| \cdot \|V^{-1}\|$  is the condition number of the eigenvector matrix  $V$ . We can assume that the columns of  $V$  have been scaled to make this condition number as small as possible. As in the Hermitian case, the polynomial that minimizes  $\|V p_k(\Lambda) V^{-1} \mathbf{r}_0\|$  is not necessarily the one that minimizes  $\|p_k(\Lambda)\|$ , and it is not clear whether this bound is sharp. It turns out that if  $A$  is a normal matrix, then  $\kappa(V) = 1$  and the bound is sharp [GG94, Jou96]. In this case, as in the Hermitian case, the problem of describing the convergence of GMRES reduces to a problem in approximation theory — How well can one approximate zero on the set of *complex* eigenvalues using a  $k$ th degree polynomial with value 1 at the origin?

If the matrix  $A$  is nonnormal but has a fairly well-conditioned eigenvector matrix  $V$ , then the above bound, while not necessarily sharp, gives a reasonable estimate of the actual size of the residual. In this case again, it is  $A$ 's eigenvalue distribution that essentially determines the behavior of GMRES.

2. In general, however, the behavior of GMRES cannot be determined from eigenvalues alone. In fact, it is shown in [GS94b] and [GPS96] that *any* nonincreasing sequence of residual norms can be obtained with the GMRES method applied to a problem whose coefficient matrix has any desired eigenvalues. Thus, for example, eigenvalues tightly clustered around 1 are not necessarily good for nonnormal matrices; one can construct a nonnormal matrix whose eigenvalues are equal to 1 or as tightly clustered around 1 as one might like, for which the GMRES algorithm makes no progress until step  $n$  (when it must find the exact solution).

The convergence behavior of the GMRES algorithm for nonnormal matrices is a topic of current research. The analysis must involve quantities other than the eigenvalues. Some partial results have been obtained in terms of the *field of values* [EES83, Eie93, BGT05], in terms of the  $\epsilon$ -*pseudospectrum* [TE05], and in terms of the *polynomial numerical hull of degree  $k$*  [Gre02, Gre04].

## 41.8 Inexact Preconditioners and Finite Precision Arithmetic, Error Estimation and Stopping Criteria, Text and Reference Books

There are a number of topics of current or recent research that will not be covered in this article. Here we list a few of these with sample references.

### Facts:

1. The effects of finite precision arithmetic on both the convergence rate and the ultimately attainable accuracy of iterative methods have been studied. Example papers include [DGR95, Gre89, Gre97b, GRS97, GS92, GS00, Pai76, Vor90], and [Woz80].
2. A related topic is inexact preconditioners. Suppose the preconditioning system  $M\mathbf{z} = \mathbf{r}$  is solved inexactly, perhaps by using an iterative method inside the outer iteration for  $A\mathbf{x} = \mathbf{b}$ . How accurately should the preconditioning system be solved in order to obtain the best overall performance of the process? The answer is surprising. See [BF05, ES04], and [SS03] for recent discussions of this question.
3. Another related idea is the use of different preconditioners at different steps of the iteration, sometimes called *flexible* iterative methods. See, for example, [Saa93].

4. Finally, there is the important question of when an iterative method should be stopped. Sometimes one wishes to stop when the 2-norm of the error or the  $A$ -norm of the error in the CG method reaches a certain threshold. But one cannot compute these quantities directly. For discussions of estimating the  $A$ -norm of the error in the CG algorithm, as well as its connections to Gauss quadrature, see, for instance, [GM97, GS94, HS52], and [ST02]
5. A number of text and reference books on iterative methods are available. These include [Axe95, Gre97, Hac94, Saa03], and [Vor03]

*University of Split, Croatia*

The eigenvalue decomposition (EVD) is an infinite iterative procedure — finding eigenvalues is equivalent to finding zeros of the characteristic polynomial, and, by the results of Abel and Galois, there is no algebraic formula for roots of the polynomial of degree greater than four. However, the number of arithmetic operations required to compute EVD to some prescribed accuracy is also finite — EVD of a general symmetric matrix requires  $O(n^3)$  operations, while for matrices with special structure this number can be smaller. For example, the EVD of a tridiagonal matrix can be computed in  $O(n^2)$  operations (see Sections 42.5 and 42.6).

Basic methods for the symmetric eigenvalue computations are the power method, the inverse iteration method, and the QR iteration method (see Section 42.1). Since direct application of those methods to a general symmetric matrix requires  $O(n^4)$  operations, the most commonly used algorithms consist of two steps: the given matrix is first reduced to tridiagonal form, followed by the computation of the EVD of the tridiagonal matrix by QR iteration, the divide and conquer method, bisection and inverse iteration, or the method of multiple relatively robust representations. Two other methods are the Jacobi method, which does not require tridiagonalization, and the Lanczos method, which computes only a part of the tridiagonal matrix.

Design of an efficient algorithm must take into account the target computer, the desired speed and accuracy, the specific goal (whether all or some eigenvalues and eigenvectors are desired), and the matrix size and structure (small or large, dense or sparse, tridiagonal, etc.). For example, if only some eigenvalues and eigenvectors are required, one can use the methods of Sections 42.5, 42.6, and 42.8. If high relative accuracy is desired and the matrix is positive definite, the Jacobi method is the method of choice. If the matrix is sparse, the Lanczos method should be used. We shall cover the most commonly used algorithms, like those which are implemented in LAPACK (see Chapter 75) and MATLAB<sup>®</sup>(see Chapter 71). The algorithms

provided in this chapter are intended to assist the reader in understanding the methods. Since the actual software is very complex, the reader is advised to use professional software in practice.

Efficient algorithms should be designed to use BLAS, and especially BLAS 3, as much as possible (see Chapter 74). The reasons are twofold: First, calling predefined standardized routines makes programs shorter and more easily readable, and second, processor vendors can optimize sets of standardized routines for their processor beyond the level given by compiler optimization. Examples of such optimized libraries are the *Intel Math Kernel Library* and *AMD Core Math Library*. Both libraries contain processor optimized BLAS, LAPACK, and FFT routines.

This chapter deals only with the computation of EVD of real symmetric matrices. The need to compute EVD of a complex Hermitian matrix (see Chapter 8) does not arise often in applications, and it is theoretically and numerically similar to the real symmetric case addressed here. All algorithms described in this chapter have their Hermitian counterparts (see e.g., [ABB99], [LSY98], and Chapters 71, 75, and 76).

The chapter is organized as follows: In Section 42.1, we describe basic methods for EVD computations. These methods are necessary to understand algorithms of Sections 42.3 to 42.6. In Section 42.2, we describe tridiagonalization by Householder reflections and Givens rotations. In Sections 42.3 to 42.6, we describe methods for computing the EVD of a tridiagonal matrix—QR iteration, the divide and conquer method, bisection and inverse iteration, and the method of multiple relatively robust representations, respectively. The Jacobi method is described in Section 42.7 and the Lanczos method is described in Section 42.8. For each method, we also describe the existing LAPACK or Matlab implementations. The respective timings of the methods are given in Section 42.9.

## 42.1 Basic Methods

---

### Definitions:

The **eigenvalue decomposition** (EVD) of a real symmetric matrix  $A = [a_{ij}]$  is given by  $A = U\Lambda U^T$ , where  $U$  is a  $n \times n$  real orthonormal matrix,  $U^T U = U U^T = I_n$ , and  $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_n)$  is a real diagonal matrix.

The numbers  $\lambda_i$  are the **eigenvalues** of  $A$ , the columns  $\mathbf{u}_i$ ,  $i = 1, \dots, n$ , of  $U$  are the **eigenvectors** of  $A$ , and  $A\mathbf{u}_i = \lambda_i \mathbf{u}_i$ ,  $i = 1, \dots, n$ .

If  $|\lambda_1| > |\lambda_2| \geq \dots \geq |\lambda_n|$ , we say that  $\lambda_1$  is the **dominant eigenvalue**.

**Deflation** is a process of reducing the size of the matrix whose EVD is to be determined, given that one eigenvector is known (see Fact 4 below for details).

The **shifted matrix** of the matrix  $A$  is the matrix  $A - \mu I$ , where  $\mu$  is the **shift**.

The simplest method for computing the EVD (also in the unsymmetric case) is the **power method**: given starting vector  $\mathbf{x}_0$ , the method computes the sequences

$$\mathbf{v}_k = \mathbf{x}_k^T A \mathbf{x}_k, \quad \mathbf{x}_{k+1} = A \mathbf{x}_k / \|A \mathbf{x}_k\|, \quad k = 0, 1, 2, \dots, \quad (42.1)$$

until convergence. Normalization of  $\mathbf{x}_k$  can be performed in any norm and serves the numerical stability of the algorithm (avoiding overflow or underflow).

**Inverse iteration** is the power method applied to the inverse of a shifted matrix, starting from  $\mathbf{x}_0$ :

$$\mathbf{v}_k = \mathbf{x}_k^T A \mathbf{x}_k, \quad \mathbf{v}_{k+1} = (A - \mu I)^{-1} \mathbf{x}_k, \quad \mathbf{x}_{k+1} = \mathbf{v}_{k+1} / \|\mathbf{v}_{k+1}\|, \quad k = 0, 1, 2, \dots \quad (42.2)$$

Given starting  $n \times p$  matrix  $X_0$  with orthonormal columns, the **orthogonal iteration** (also **subspace iteration**) forms the sequence of matrices

$$Y_{k+1} = A X_k, \quad X_{k+1} R_{k+1} = Y_{k+1} \quad (\text{QR factorization}), \quad k = 0, 1, 2, \dots, \quad (42.3)$$

where  $X_{k+1} R_{k+1}$  is the reduced QR factorization of  $Y_{k+1}$  ( $X_{k+1}$  is an  $n \times p$  matrix with orthonormal columns and  $R_{k+1}$  is a upper triangular  $p \times p$  matrix).

Starting from the matrix  $A_0 = A$ , the **QR iteration** forms the sequence of matrices

$$A_k = Q_k R_k \quad (\text{QR factorization}), \quad A_{k+1} = R_k Q_k, \quad k = 0, 1, 2, \dots \quad (42.4)$$

Given the shift  $\mu$ , the **shifted QR iteration** forms the sequence of matrices

$$A_k - \mu I = Q_k R_k \quad (\text{QR factorization}), \quad A_{k+1} = R_k Q_k + \mu I, \quad k = 0, 1, 2, \dots \quad (42.5)$$

### Facts:

The Facts 1 to 14 can be found in [GV96, §8.2], [Par80, §4, 5], [Ste01, §2.1, 2.2.1, 2.2.2], and [Dem97, §4].

1. If  $\lambda_1$  is the dominant eigenvalue and if  $\mathbf{x}_0$  is not orthogonal to  $\mathbf{u}_1$ , then in Equation 42.1  $v_k \rightarrow \lambda_1$  and  $\mathbf{x}_k \rightarrow \mathbf{u}_1$ . In other words, the power method converges to the dominant eigenvalue and its eigenvector.
2. The convergence of the power method is linear in the sense that

$$|\lambda_1 - v_k| = O\left(\left|\frac{\lambda_2}{\lambda_1}\right|^k\right), \quad \|\mathbf{u}_1 - \mathbf{x}_k\|_2 = O\left(\left|\frac{\lambda_2}{\lambda_1}\right|^k\right).$$

More precisely,

$$|\lambda_1 - v_k| \approx \left|\frac{c_2}{c_1}\right| \left|\frac{\lambda_2}{\lambda_1}\right|^k,$$

where  $c_i$  is the coefficient of the  $i$ -th eigenvector in the linear combination expressing the starting vector  $\mathbf{x}_0$ .

3. Since  $\lambda_1$  is not readily available, the convergence is in practice determined using residuals. If  $\|A\mathbf{x}_k - v_k\mathbf{x}_k\|_2 \leq \text{tol}$ , where  $\text{tol}$  is a user prescribed stopping criterion, then  $|\lambda_1 - v_k| \leq \text{tol}$ .
4. After computing the dominant eigenpair, we can perform deflation to reduce the given EVD to the one of size  $n - 1$ . Let  $Y = [\mathbf{u}_1 \ X]$  be an orthogonal matrix. Then

$$\begin{bmatrix} \mathbf{u}_1 & X \end{bmatrix}^T A \begin{bmatrix} \mathbf{u}_1 & X \end{bmatrix} = \begin{bmatrix} \lambda_1 & 0 \\ 0 & A_1 \end{bmatrix},$$

where  $A_1 = X^T A X$ .

5. The EVD of the shifted matrix  $A - \mu I$  is given by  $U(\Lambda - \mu I)U^T$ . Sometimes we can choose shift  $\mu$  such that the shifted matrix  $A - \mu I$  has better ratio between the dominant eigenvalue and the absolutely closest one, than the original matrix. In this case, applying the power method to the shifted matrix will speed up the convergence.
6. Inverse iteration requires solving the system of linear equations  $(A - \mu I)\mathbf{v}_{k+1} = \mathbf{x}_k$  for  $\mathbf{v}_{k+1}$  in each step. At the beginning, we must compute the LU factorization of  $A - \mu I$ , which requires  $2n^3/3$  operations and in each subsequent step we must solve two triangular systems, which requires  $2n^2$  operations.
7. If  $\mu$  is very close to some eigenvalue of  $A$ , then the eigenvalues of the shifted matrix satisfy  $|\lambda_1| \gg |\lambda_2| \geq \dots \geq |\lambda_n|$ , so the convergence of the inverse iteration method is very fast.
8. If  $\mu$  is very close to some eigenvalue of  $A$ , then the matrix  $A - \mu I$  is nearly singular, so the solutions of linear systems may have large errors. However, these errors are almost entirely in the direction of the dominant eigenvector so the inverse iteration method is both fast and accurate.
9. We can further increase the speed of convergence of inverse iterations by substituting the shift  $\mu$  with the Rayleigh quotient  $v_k$  in each step, at the cost of computing new LU factorization each time. See Chapter 8.2 for more information about the Rayleigh quotient.
10. If

$$|\lambda_1| \geq \dots \geq |\lambda_p| > |\lambda_{p+1}| \geq \dots \geq |\lambda_n|,$$

then the subspace iteration given in Equation 42.3 converges such that

$$X_k \rightarrow [\mathbf{u}_1, \dots, \mathbf{u}_p], \quad X_k^T A X_k \rightarrow \text{diag}(\lambda_1, \dots, \lambda_p),$$

at a speed which is proportional to  $|\lambda_{p+1}/\lambda_p|^k$ .

11. If  $|\lambda_1| > |\lambda_2| > \dots > |\lambda_n|$ , then the sequence of matrices  $A_k$  generated by the QR iteration given in Equation 42.4 converges to diagonal matrix  $\Lambda$ . However, this result is not of practical use, since the convergence may be very slow and each iteration requires  $O(n^3)$  operations. Careful implementation, like the one described in section 42.3, is needed to construct a useful algorithm.
12. The QR iteration is equivalent to orthogonal iteration starting with the matrix  $X_0 = I$ . More precisely, the matrices  $X_k$  from Equation 42.3 and  $A_k$  from Equation 42.4 satisfy  $X_k^T A X_k = A_k$ .
13. Matrices  $A_k$  and  $A_{k+1}$  from Equations 42.4 and Equation 42.5 are orthogonally similar. In both cases

$$A_{k+1} = Q_k^T A_k Q_k.$$

14. The QR iteration method is essentially equivalent to the power method and the shifted QR iteration method is essentially equivalent to the inverse power method on the shifted matrix.
15. [Wil65, §3, 5, 6, 7] [TB97, §V] Let  $U \Lambda U^T$  and  $\tilde{U} \tilde{\Lambda} \tilde{U}^T$  be the exact and the computed EVDs of  $A$ , respectively, such that the diagonals of  $\Lambda$  and  $\tilde{\Lambda}$  are in the same order. Numerical methods generally compute the EVD with the errors bounded by

$$|\lambda_i - \tilde{\lambda}_i| \leq \phi \epsilon \|A\|_2, \quad \|\mathbf{u}_i - \tilde{\mathbf{u}}_i\|_2 \leq \psi \epsilon \frac{\|A\|_2}{\min_{j \neq i} |\lambda_i - \tilde{\lambda}_j|},$$

where  $\epsilon$  is machine precision and  $\phi$  and  $\psi$  are slowly growing polynomial functions of  $n$  which depend upon the algorithm used (typically  $O(n)$  or  $O(n^2)$ ).

### Examples:

1. The eigenvalue decomposition of the matrix

$$A = \begin{bmatrix} 4.5013 & 0.6122 & 2.1412 & 2.0390 \\ 0.6122 & 2.6210 & -0.4941 & -1.2164 \\ 2.1412 & -0.4941 & 1.1543 & -0.1590 \\ 2.0390 & -1.2164 & -0.1590 & -0.9429 \end{bmatrix}$$

computed by the MATLAB command  $[U, \text{Lambda}] = \text{eig}(A)$  is  $A = U \Lambda U^T$  with (properly rounded to four decimal places)

$$U = \begin{bmatrix} -0.3697 & 0.2496 & 0.1003 & -0.8894 \\ 0.2810 & -0.0238 & 0.9593 & -0.0153 \\ 0.3059 & -0.8638 & -0.1172 & -0.3828 \\ 0.8311 & 0.4370 & -0.2366 & -0.2495 \end{bmatrix}, \quad \Lambda = \begin{bmatrix} -2.3197 & 0 & 0 & 0 \\ 0 & 0.6024 & 0 & 0 \\ 0 & 0 & 3.0454 & 0 \\ 0 & 0 & 0 & 6.0056 \end{bmatrix}.$$

2. Let  $A$ ,  $U$ , and  $\Lambda$  be as in the Example 1, and set  $\mathbf{x}_0 = [1 \ 1 \ 1 \ 1]^T$ . The power method in Equation 42.1 gives  $\mathbf{x}_6 = [0.8893 \ 0.0234 \ 0.3826 \ 0.2496]^T$ . By setting  $\mathbf{u}_1 = -U_{:,4}$  we have  $\|\mathbf{u}_1 - \mathbf{x}_6\|_2 = 0.0081$ . Here (Fact 2),  $c_2 = 0.7058$ ,  $c_1 = -1.5370$ , and

$$\left| \frac{c_2}{c_1} \right| \left| \frac{\lambda_2}{\lambda_1} \right|^6 = 0.0078.$$

Similarly,  $\|\mathbf{u}_1 - \mathbf{x}_{50}\|_2 = 1.3857 \cdot 10^{-15}$ . However, for a different (bad) choice of the starting vector,  $\mathbf{x}_0 = [0 \ 1 \ 0 \ 0]^T$ , where  $c_2 = 0.9593$  and  $c_1 = -0.0153$ , we have  $\|\mathbf{u}_1 - \mathbf{x}_6\|_2 = 0.7956$ .

3. The deflation matrix  $Y$  and the deflated matrix  $A_1$  (Fact 4) for the above example are equal to (correctly rounded):

$$Y = \begin{bmatrix} -0.8894 & -0.0153 & -0.3828 & -0.2495 \\ -0.0153 & 0.9999 & -0.0031 & -0.0020 \\ -0.3828 & -0.0031 & 0.9224 & -0.0506 \\ -0.2495 & -0.0020 & -0.0506 & 0.9670 \end{bmatrix},$$

$$A_1 = \begin{bmatrix} 6.0056 & 0 & 0 & 0 \\ 0 & 2.6110 & -0.6379 & -1.3154 \\ 0 & -0.6379 & 0.2249 & -0.8952 \\ 0 & -1.3154 & -0.8952 & -1.5078 \end{bmatrix}.$$

4. Let  $A$  and  $\mathbf{x}_0$  be as in Example 2. For the shift  $\mu = 6$ , the inverse iteration method in Equation 42.2 gives  $\|\mathbf{u}_1 - \mathbf{x}_6\|_2 = 6.5187 \cdot 10^{-16}$ , so the convergence is much faster than in Example 2 (Fact 7).  
 5. Let  $A$  be as in Example 1. Applying six steps of the QR iteration in Equation 42.4 gives

$$A_6 = \begin{bmatrix} 6.0055 & -0.0050 & -0.0118 & -0.0000 \\ -0.0050 & 3.0270 & 0.3134 & 0.0002 \\ -0.0118 & 0.3134 & -2.3013 & -0.0017 \\ -0.0000 & 0.0002 & -0.0017 & 0.6024 \end{bmatrix}.$$

and applying six steps of the shifted QR iteration in Equation 42.5 with  $\mu = 6$  gives

$$A_6 = \begin{bmatrix} -2.3123 & 0.1452 & -0.0215 & -0.0000 \\ 0.1452 & 0.6623 & 0.4005 & 0.0000 \\ -0.0215 & 0.4005 & 2.9781 & -0.0000 \\ 0.0000 & 0.0000 & 0.0000 & 6.0056 \end{bmatrix}.$$

In this case both methods converge. The convergence towards the matrix where the eigenvalue nearest to the shift can be deflated is faster for the shifted iterations.

## 42.2 Tridiagonalization

The QR iteration in Equation 42.4 in Section 42.1 and the shifted QR iteration in Equation 42.5 in Section 42.1 require  $O(n^3)$  operations (one QR factorization) for each step, which makes these algorithms highly unpractical. However, if the starting matrix is tridiagonal, one step of these iterations requires only  $O(n)$  operations. As a consequence, the practical algorithm consists of three steps:

1. Reduce  $A$  to tridiagonal form  $T$  by orthogonal similarities,  $X^T A X = T$ .
2. Compute the EVD of  $T$ ,  $T = Q \Lambda Q^T$ .
3. Multiply  $U = X Q$ .

The EVD of  $A$  is then  $A = U \Lambda U^T$ . Reduction to tridiagonal form can be performed by using Householder reflectors or Givens rotations and it is a finite process requiring  $O(n^3)$  operations. Reduction to tridiagonal form is a considerable compression of data since an EVD of  $T$  can be computed very quickly. The EVD of  $T$  can be efficiently computed by various methods such as QR iteration, the divide and conquer method (DC), bisection and inverse iteration, or the method of multiple relatively robust representations (MRRR). These methods are described in subsequent sections.

**Facts:**

All the following facts, except Fact 6, can be found in [Par80, §7], [TB97, pp. 196–201], [GV96, §8.3.1], [Ste01, pp. 158–162], and [Wil65, pp. 345–367].

1. Tridiagonal form is not unique (see Examples 1 and 2).
2. The reduction of  $A$  to tridiagonal matrix by Householder reflections is performed as follows. Let us partition  $A$  as

$$A = \left[ \begin{array}{c|c} a_{11} & \mathbf{a}^T \\ \hline \mathbf{a} & B \end{array} \right].$$

Let  $H$  be the appropriate Householder reflection (see Chapter 38.4), that is,

$$\mathbf{v} = \mathbf{a} + \text{sign}(a_{21})\|\mathbf{a}\|_2\mathbf{e}_1, \quad H = I - 2\frac{\mathbf{v}\mathbf{v}^T}{\mathbf{v}^T\mathbf{v}},$$

and let

$$H_1 = \left[ \begin{array}{c|c} 1 & \mathbf{0}^T \\ \hline \mathbf{0} & H \end{array} \right].$$

Then

$$H_1 A H_1 = \left[ \begin{array}{c|c} a_{11} & \mathbf{a}^T H \\ \hline H\mathbf{a} & H B H \end{array} \right] = \left[ \begin{array}{c|c} a_{11} & v_1 \mathbf{e}_1^T \\ \hline v_1 \mathbf{e}_1 & A_1 \end{array} \right], \quad v_1 = -\text{sign}(a_{21})\|\mathbf{a}\|_2.$$

This step annihilates all elements in the first column below the first subdiagonal and all elements in the first row to the right of the first subdiagonal. Applying this procedure recursively yields the triangular matrix  $T = X^T A X$ ,  $X = H_1 H_2 \cdots H_{n-2}$ .

3.  $H$  does not depend on the normalization of  $\mathbf{v}$ . The normalization  $v_1 = 1$  is useful since  $\mathbf{a}_{2:n}$  can be overwritten by  $\mathbf{v}_{2:n}$  and  $v_1$  does not need to be stored.
4. Forming  $H$  explicitly and then computing  $A_1 = H B H$  requires  $O(n^3)$  operations, which would ultimately yield an  $O(n^4)$  algorithm. However, we do not need to form the matrix  $H$  explicitly — given  $\mathbf{v}$ , we can overwrite  $B$  with  $H B H$  in just  $O(n^2)$  operations by using one matrix-vector multiplication and two rank-one updates.
5. The entire tridiagonalization algorithm is as follows:

**Algorithm 1:** Tridiagonalization by Householder reflections

Input: real symmetric  $n \times n$  matrix  $A$

Output: the main diagonal and sub- and superdiagonal of  $A$  are overwritten by  $T$ ,  
the Householder vectors are stored in the lower triangular part of  $A$   
below the first subdiagonal

**for**  $j = 1 : n - 2$

$$\mu = \text{sign}(a_{j+1,j})\|A_{j+1:n,j}\|_2$$

**if**  $\mu \neq 0$ , **then**

$$\beta = a_{j+1,j} + \mu$$

$$\mathbf{v}_{j+2:n} = A_{j+2:n,j}/\beta$$

**endif**

$$a_{j+1,j} = -\mu$$

$$a_{j,j+1} = -\mu$$

$$v_{j+1} = 1$$

$$\gamma = -2/\mathbf{v}_{j+1:n}^T \mathbf{v}_{j+1:n}$$

$$\mathbf{w} = \gamma A_{j+1:n,j+1:n} \mathbf{v}_{j+1:n}$$

$$\mathbf{q} = \mathbf{w} + \frac{1}{2}\gamma \mathbf{v}_{j+1:n} (\mathbf{v}_{j+1:n}^T \mathbf{w})$$

$$A_{j+1:n,j+1:n} = A_{j+1:n,j+1:n} + \mathbf{v}_{j+1:n} \mathbf{q}^T + \mathbf{q} \mathbf{v}_{j+1:n}^T$$

$$A_{j+2:n,j} = \mathbf{v}_{j+2:n}$$

**endfor**

6. [DHS89] When symmetry is exploited in performing rank-2 update, Algorithm 1 requires  $4n^3/3$  operations. Another important enhancement is the derivation of the block-version of the algorithm. Instead of performing rank-2 update on  $B$ , thus obtaining  $A_1$ , we can accumulate  $p$  transformations and perform rank- $2p$  update. In the first  $p$  steps, the algorithm is modified to update only columns and rows  $1, \dots, p$ , which are needed to compute the first  $p$  Householder vectors. Then the matrix  $A$  is updated by  $A - UV^T - VU^T$ , where  $U$  and  $V$  are  $n \times p$  matrices. This algorithm is rich in matrix-matrix multiplications (roughly one half of the operations is performed using BLAS 3 routines), but it requires extra workspace for  $U$  and  $V$ .
7. If the matrix  $X$  is needed explicitly, it can be computed from the stored Householder vectors by Algorithm 2. In order to minimize the operation count, the computation starts from the smallest matrix and the size is gradually increased, that is, the algorithm computes the sequence of matrices

$$H_{n-2}, \quad H_{n-3}H_{n-2}, \dots, \quad X = H_1 \cdots H_{n-2}.$$

A column-oriented version is possible as well, and the operation count in both cases is  $4n^3/3$ . If the Householder matrices  $H_i$  are accumulated in the order in which they are generated, the operation count is  $2n^3$ .

**Algorithm 2:** Computation of the tridiagonalizing matrix  $X$

Input: output from Algorithm 1

Output: matrix  $X$  such that  $X^TAX = T$ , where  $A$  is the input of Algorithm 1 and  $T$  is tridiagonal.

$$X = I_n$$

**for**  $j = n - 2 : -1 : 1$

$$v_{j+1} = 1$$

$$\mathbf{v}_{j+2:n} = A_{j+2:n,j}$$

$$\gamma = -2/\mathbf{v}_{j+1:n}^T \mathbf{v}_{j+1:n}$$

$$\mathbf{w} = \gamma X_{j+1:n,j+1:n}^T \mathbf{v}_{j+1:n}$$

$$X_{j+1:n,j+1:n} = X_{j+1:n,j+1:n} + \mathbf{v}_{j+1:n} \mathbf{w}^T$$

**endfor**

8. The error bounds for Algorithms 1 and 2 are as follows: The matrix  $\tilde{T}$  computed by Algorithm 1 is equal to the matrix, which would be obtained by exact tridiagonalization of some perturbed matrix  $A + E$  (backward error), where  $\|E\|_2 \leq \psi \epsilon \|A\|_2$  and  $\psi$  is a slowly increasing function of  $n$ . The matrix  $\tilde{X}$  computed by Algorithm 2 satisfies  $\tilde{X} = X + F$ , where  $\|F\|_2 \leq \phi \epsilon$  and  $\phi$  is a slowly increasing function of  $n$ .
9. Givens rotation parameters  $c$  and  $s$  are computed as in Fact 5 of Section 38.4. Tridiagonalization by Givens rotations is performed as follows:

**Algorithm 3:** Tridiagonalization by Givens rotations

Input: real symmetric  $n \times n$  matrix  $A$

Output: the matrix  $X$  such that  $X^TAX = T$  is tridiagonal, main diagonal and sub- and superdiagonal of  $A$  are overwritten by  $T$

$$X = I_n$$

**for**  $j = 1 : n - 2$

**for**  $i = j + 2 : n$

set  $x = a_{j+1,j}$  and  $y = a_{i,j}$

compute  $G = \begin{bmatrix} c & s \\ -s & c \end{bmatrix}$  via Fact 5 of Section 38.4

**Algorithm 3:** Tridiagonalization by Givens rotations (Continued)

$$\begin{aligned} \begin{bmatrix} A_{j+1,j:n} \\ A_{i,j:n} \end{bmatrix} &= G \begin{bmatrix} A_{j+1,j:n} \\ A_{i,j:n} \end{bmatrix} \\ \begin{bmatrix} A_{j:n,j+1} & A_{j:n,i} \end{bmatrix} &= \begin{bmatrix} A_{j:n,j+1} & A_{j:n,i} \end{bmatrix} G^T \\ \begin{bmatrix} X_{1:n,j+1} & X_{1:n,i} \end{bmatrix} &= \begin{bmatrix} X_{1:n,j+1} & X_{1:n,i} \end{bmatrix} G^T \\ \text{endfor} & \\ \text{endfor} & \end{aligned}$$

10. Algorithm 3 requires  $(n-1)(n-2)/2$  plane rotations, which amounts to  $4n^3$  operations if symmetry is properly exploited. The operation count is reduced to  $8n^3/3$  if fast rotations are used. Fast rotations are obtained by factoring out absolutely larger of  $c$  and  $s$  from  $G$ .
11. The Givens rotations in Algorithm 3 can be performed in different orderings. For example, the elements in the first column and row can be annihilated by rotations in the planes  $(n-1, n)$ ,  $(n-2, n-1), \dots (2, 3)$ . Since Givens rotations act more selectively than Householder reflectors, they can be useful if  $A$  has some special structure. For example, Givens rotations are used to efficiently tridiagonalize symmetric band matrices (see Example 4).
12. Error bounds for Algorithm 3 are the same as the ones for Algorithms 1 and 2 (Fact 8), but with slightly different functions  $\psi$  and  $\phi$ .

**Examples:**

1. Algorithms 1 and 2 applied to the matrix  $A$  from Example 1 in Section 42.1 give

$$T = \begin{bmatrix} 4.5013 & -3.0194 & 0 & 0 \\ -3.0194 & -0.3692 & 1.2804 & 0 \\ 0 & 1.2804 & 0.5243 & -0.9303 \\ 0 & 0 & -0.9303 & 2.6774 \end{bmatrix},$$

$$X = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & -0.2028 & 0.4417 & -0.8740 \\ 0 & -0.7091 & -0.6817 & -0.1800 \\ 0 & -0.6753 & 0.5833 & 0.4514 \end{bmatrix}.$$

2. Tridiagonalization is implemented in the MATLAB function  $T = \text{hess}(A)$  ( $[X, T] = \text{hess}(A)$  if  $X$  is to be computed, as well). In fact, the function `hess` is more general and it computes the Hessenberg form of a general square matrix. For the same matrix  $A$  as above, the matrices  $T$  and  $X$  computed by `hess` are:

$$T = \begin{bmatrix} 2.6562 & 1.3287 & 0 & 0 \\ 1.3287 & 2.4407 & 2.4716 & 0 \\ 0 & 2.4716 & 3.1798 & 2.3796 \\ 0 & 0 & 2.3796 & -0.9429 \end{bmatrix}, X = \begin{bmatrix} 0.4369 & 0.2737 & 0.8569 & 0 \\ 0.7889 & 0.3412 & -0.5112 & 0 \\ -0.4322 & 0.8993 & -0.0668 & 0 \\ 0 & 0 & 0 & 1.0000 \end{bmatrix}.$$

3. The block version of tridiagonal reduction is implemented in the LAPACK subroutine `DSYTRD` (file `dsytrd.f`). The computation of  $X$  is implemented in the subroutine `DORGTR`. The size of the required extra workspace (in elements) is  $lwork = nb * n$ , where  $nb$  is the optimal block size (here,  $nb = 64$ ), and it is determined automatically by the subroutines. The timings are given in Section 42.9.

4. Computation of Givens rotation in Algorithm 3 is implemented in the MATLAB functions `planerot` and `givens`, BLAS 1 subroutine `DROTG`, and LAPACK subroutine `DLARTG`. These implementations avoid unnecessary overflow or underflow by appropriately scaling  $x$  and  $y$ . Plane rotations (multiplications with  $G$ ) are implemented in the BLAS 1 subroutine `DROT`. LAPACK subroutines `DLAR2V`, `DLARGV`, and `DLARTV` generate and apply multiple plane rotations. LAPACK subroutine `DSBTRD` tridiagonalizes a symmetric band matrix by using Givens rotations.

## 42.3 Implicitly Shifted QR Method

This method is named after the fact that, for a tridiagonal matrix, each step of the shifted QR iterations given by Equation 42.5 in Section 42.1 can be elegantly implemented without explicitly computing the shifted matrix  $A_k - \mu I$ .

### Definitions:

**Wilkinson's shift**  $\mu$  is the eigenvalue of the bottom right  $2 \times 2$  submatrix of  $T$ , which is closer to  $t_{n,n}$ .

### Facts:

The following facts can be found in [GV96, pp. 417–422], [Ste01, pp. 163–171], [TB97, pp. 211–224], [Par80, §8], [Dem97, §5.3.1], and [Wil65, §8.50, 8.54].

$T = [t_{ij}]$  is a real symmetric tridiagonal matrix of order  $n$  and  $T = QAQ^T$  is its EVD.

1. The stable formula for the Wilkinson's shift is

$$\mu = t_{n,n} - \frac{t_{n,n-1}^2}{\tau + \text{sign}(\tau)\sqrt{\tau^2 + t_{n,n-1}^2}}, \quad \tau = \frac{t_{n-1,n-1} - t_{n,n}}{2}.$$

2. The following recursive function implements the implicitly shifted QR method given by Equation 42.5:

#### Algorithm 4: Implicitly shifted QR method for tridiagonal matrices

Input: real symmetric tridiagonal  $n \times n$  matrix  $T$

Output: the diagonal of  $T$  is overwritten by its eigenvalues

**function**  $T = \text{QR\_iteration}(T)$

**repeat**      % one sweep

    compute a suitable shift  $\mu$

    set  $x = t_{11} - \mu$  and  $y = t_{21}$

    compute  $G = \begin{bmatrix} c & s \\ -s & c \end{bmatrix}$  via Fact 5 of Chapter 38.4

$$\begin{bmatrix} T_{1,1,3} \\ T_{2,1,3} \end{bmatrix} = G \begin{bmatrix} T_{1,1,3} \\ T_{2,1,3} \end{bmatrix}$$

$$\begin{bmatrix} T_{1,3,1} & T_{1,3,2} \end{bmatrix} = \begin{bmatrix} T_{1,3,1} & T_{1,3,2} \end{bmatrix} G^T$$

**for**  $i = 2 : n - 1$

    set  $x = t_{i,i-1}$  and  $y = t_{i+1,i-1}$

    compute  $G = \begin{bmatrix} c & s \\ -s & c \end{bmatrix}$  via Fact 5 of Section 38.4

**Algorithm 4:** Implicitly shifted QR method for tridiagonal matrices (Continued)

$$\begin{bmatrix} T_{i,j-1:i+2} \\ T_{i+1,j-1:i+2} \end{bmatrix} = G \begin{bmatrix} T_{i,j-1:i+2} \\ T_{i+1,j-1:i+2} \end{bmatrix}$$

$$\begin{bmatrix} T_{i-1:i+2,i} & T_{i-1:i+2,i+1} \end{bmatrix} = \begin{bmatrix} T_{i-1:i+2,i} & T_{i-1:i+2,i+1} \end{bmatrix} G^T$$

**endfor**

**until**  $|t_{i,j+1}| \leq \epsilon \sqrt{|t_{i,i} \cdot t_{i+1,i+1}|}$  for some  $i$  % deflation

set  $t_{i+1,i} = 0$  and  $t_{i,i+1} = 0$

$T_{1:i,1:i} = QR\_iteration(T_{1:i,1:i})$

$T_{i+1:n,i+1:n} = QR\_iteration(T_{i+1:n,i+1:n})$

3. Wilkinson's shift (Fact 1) is the most commonly used shift. With Wilkinson's shift, the algorithm always converges in the sense that  $t_{n-1,n} \rightarrow 0$ . The convergence is quadratic, that is,  $||[T_{k+1}]_{n-1,n}| \leq c|[T_k]_{n-1,n}|^2$  for some constant  $c$ , where  $T_k$  is the matrix after  $k$ -th sweep. Even more, the convergence is usually cubic. However, it can also happen that some  $t_{i,j+i}$ ,  $i \neq n - 1$ , becomes sufficiently small before  $t_{n-1,n}$ , so the practical program has to check for deflation at each step.
4. The plane rotation parameters at the start of the sweep are computed as if the shifted matrix  $T - \mu I$  has been formed. Since the rotation is applied to the original  $T$  and not to  $T - \mu I$ , this creates new nonzero elements at the positions (3,1) and (1,3), the so-called **bulge**. The subsequent rotations simply chase the bulge out of the lower right corner of the matrix. The rotation in the (2,3) plane sets the elements (3,1) and (1,3) back to zero, but it generates two new nonzero elements at positions (4,2) and (2,4); the rotation in the (3,4) plane sets the elements (4,2) and (2,4) back to zero, but it generates two new nonzero elements at positions (5,3) and (3,5), etc. The procedure is illustrated in Figure 42.1: "x" denotes the elements that are transformed by the current plane rotation, "\*" denotes the newly generated nonzero elements (the bulge), and 0 denotes the zeros that are reintroduced by the current plane rotation.

The effect of this procedure is the following. At the end of the first sweep, the resulting matrix  $T_1$  is equal to the the matrix that would have been obtained by factorizing  $T - \mu I = QR$  and computing  $T_1 = RQ + \mu I$  as in Equation 42.5.

5. Since the convergence of Algorithm 4 is quadratic (or even cubic), an eigenvalue is isolated after just a few steps, which requires  $O(n)$  operations. This means that  $O(n^2)$  operations are needed to compute all eigenvalues.
6. If the eigenvector matrix  $Q$  is desired, the plane rotations need to be accumulated similarly to the accumulation of  $X$  in Algorithm 3. This accumulation requires  $O(n^3)$  operations (see Example 2 below and Fact 5 in Section 42.9). Another, usually faster, algorithm to compute  $Q$  is given in Fact 9 in Section 42.9.

FIGURE 42.1 Chasing the bulge in one sweep of the implicit QR iteration for  $n = 6$ .

7. The computed eigenvalue decomposition  $T = Q\Lambda Q^T$  satisfies the error bounds from Fact 15 in section 42.1 with  $A$  replaced by  $T$  and  $U$  replaced by  $Q$ . The deflation criterion implies  $|t_{i,i+1}| \leq \epsilon \|T\|_F$ , which is within these bounds.
8. Combining Algorithms 1, 2, and 4 we get the the following algorithm:

**Algorithm 5:** Real symmetric eigenvalue decomposition  
 Input: real symmetric  $n \times n$  matrix  $A$   
 Output: eigenvalue matrix  $\Lambda$  and, optionally, eigenvector matrix  $U$  of  $A$   
**if** only eigenvalues are required, **then**  
   Compute  $T$  by Algorithm 1  
    $T = QR\_iteration(T)$    % Algorithm 4  
    $\Lambda = \text{diag}(T)$   
**else**  
   Compute  $T$  by Algorithm 1  
   Compute  $X$  by Algorithm 2  
    $T = QR\_iteration(T)$    % with rotations accumulated in  $Q$   
    $\Lambda = \text{diag}(T)$   
    $U = XQ$   
**endif**

9. The EVD computed by Algorithm 5 satisfies the error bounds given in Fact 15 in section 42.1. However, the algorithm tends to perform better on matrices, which are graded downwards, that is, on matrices that exhibit systematic decrease in the size of the matrix elements as we move along the diagonal. For such matrices the tiny eigenvalues can usually be computed with higher relative accuracy (although counterexamples can be easily constructed). If the tiny eigenvalues are of interest, it should be checked whether there exists a symmetric permutation that moves larger elements to the upper left corner, thus converting the given matrix to the one that is graded downwards.

### Examples:

1. For the matrix  $T$  from Example 1 in section 42.2, after one sweep of Algorithm 4, we have

$$T = \begin{bmatrix} 2.9561 & 3.9469 & 0 & 0 \\ 3.9469 & 0.8069 & -0.7032 & 0 \\ 0 & -0.7032 & 0.5253 & 0.0091 \\ 0 & 0 & 0.0091 & 3.0454 \end{bmatrix}.$$

2. Algorithm 4 is implemented in the LAPACK subroutine DSTEQR. This routine can compute just the eigenvalues, or both eigenvalues and eigenvectors. To avoid double indices, the diagonal and subdiagonal entries of  $T$  are stored in one dimensional vectors,  $d_i = T_{ii}$  and  $e_i = T_{i+1,i}$ , respectively. The timings are given in Section 42.9.
3. Algorithm 5 is implemented in the Matlab routine `eig`. The command `Lambda = eig(A)` returns only the eigenvalues, `[U, Lambda] = eig(A)` returns the eigenvalues and the eigenvectors (see Example 1 in Section 42.1).
4. The LAPACK implementation of Algorithm 5 is given in the subroutine DSYEV. To compute only eigenvalues, DSYEV calls DSYTRD and DSTEQR without eigenvector option. To compute both eigenvalues and eigenvectors, DSYEV calls DSYTRD, DORGTR, and DSTEQR with the eigenvector option. The timings are given in Section 42.9.

## 42.4 Divide and Conquer Method

This is currently the fastest method for computing the EVD of a real symmetric tridiagonal matrix  $T$ . It is based on splitting the given tridiagonal matrix into two matrices, then computing the EVDs of the smaller matrices and computing the final EVD from the two EVDs. The method was first introduced in [Cup81], but numerically stable and efficient implementation was first derived in [GE95].

### Facts:

The following facts can be found in [Dem97, pp. 216–228], [Ste01, pp. 171–185], and [GE95].

$T = [t_{ij}]$  is a real symmetric tridiagonal matrix of order  $n$  and  $T = U\Lambda U^T$  is its EVD.

1. Let  $T$  be partitioned as

$$T = \left[ \begin{array}{ccc|ccc} d_1 & e_1 & & & & \\ e_1 & d_2 & e_2 & & & \\ & & \ddots & \ddots & \ddots & \\ & & & e_{k-1} & d_k & \\ \hline & & & e_k & & \\ & & & & d_{k+1} & e_{k+1} \\ & & & & \ddots & \ddots & \ddots \\ & & & & & e_{n-2} & d_{n-1} & e_{n-1} \\ & & & & & & e_{n-1} & d_n \end{array} \right] \equiv \begin{bmatrix} T_1 & e_k \mathbf{e}_k \mathbf{e}_1^T \\ e_k \mathbf{e}_1 \mathbf{e}_k^T & T_2 \end{bmatrix}.$$

We assume that  $T$  is unreduced, that is,  $e_i \neq 0$  for all  $i$ . Further, we assume that  $e_i > 0$  for all  $i$ , which can be easily be attained by diagonal similarity with a diagonal matrix of signs (see Example 1 below). Let

$$\hat{T}_1 = T_1 - e_k \mathbf{e}_k \mathbf{e}_k^T, \quad \hat{T}_2 = T_2 - e_k \mathbf{e}_1 \mathbf{e}_1^T. \quad (42.6)$$

In other words,  $\hat{T}_1$  is equal to  $T_1$  except that  $d_k$  is replaced by  $d_k - e_k$ , and  $\hat{T}_2$  is equal to  $T_2$  except that  $d_{k+1}$  is replaced by  $d_{k+1} - e_k$ .

Let  $\hat{T}_i = \hat{U}_i \hat{\Lambda}_i \hat{U}_i^T$ ,  $i = 1, 2$ , be the respective EVDs and let  $\mathbf{v} = \begin{bmatrix} \hat{U}_1^T \mathbf{e}_k \\ \hat{U}_2^T \mathbf{e}_1 \end{bmatrix}$  ( $\mathbf{v}$  consists of the last column of  $\hat{U}_1^T$  and the first column of  $\hat{U}_2^T$ ). Set  $\hat{U} = \hat{U}_1 \oplus \hat{U}_2$  and  $\hat{\Lambda} = \hat{\Lambda}_1 \oplus \hat{\Lambda}_2$ . Then

$$T = \begin{bmatrix} \hat{U}_1 & \\ & \hat{U}_2 \end{bmatrix} \left[ \begin{bmatrix} \hat{\Lambda}_1 & \\ & \hat{\Lambda}_2 \end{bmatrix} + e_k \mathbf{v} \mathbf{v}^T \right] \begin{bmatrix} \hat{U}_1^T \\ & \hat{U}_2^T \end{bmatrix} = \hat{U} (\hat{\Lambda} + e_k \mathbf{v} \mathbf{v}^T) \hat{U}^T. \quad (42.7)$$

If

$$\hat{\Lambda} + e_k \mathbf{v} \mathbf{v}^T = X \Lambda X^T$$

is the EVD of the rank-one modification of the diagonal matrix  $\hat{\Lambda}$ , then  $T = U\Lambda U^T$ , where  $U = \hat{U}X$  is the EVD of  $T$ . Thus, the original tridiagonal eigenvalue problem is reduced to two smaller tridiagonal eigenvalue problems and one eigenvalue problem for the rank-one update of a diagonal matrix.

2. If the matrix  $\hat{\Lambda} + e_k \mathbf{v} \mathbf{v}^T$  is permuted such that  $\hat{\lambda}_1 \geq \dots \geq \hat{\lambda}_n$ , then  $\lambda_i$  and  $\hat{\lambda}_i$  are interlaced, that is,

$$\lambda_1 \geq \hat{\lambda}_1 \geq \lambda_2 \geq \hat{\lambda}_2 \geq \dots \geq \lambda_{n-1} \geq \hat{\lambda}_{n-1} \geq \lambda_n \geq \hat{\lambda}_n.$$

Moreover, if  $\hat{\lambda}_{i-1} = \hat{\lambda}_i$  for some  $i$ , then one eigenvalue is obviously known exactly, that is,  $\lambda_i = \hat{\lambda}_i$ . In this case,  $\lambda_i$  can be deflated by applying to  $\hat{\Lambda} + e_k \mathbf{v} \mathbf{v}^T$  a plane rotation in the  $(i-1, i)$  plane, where the Givens rotation parameters  $c$  and  $s$  are computed from  $v_{i-1}$  and  $v_i$  as in Fact 5 of Section 38.4.

3. If all  $\hat{\lambda}_i$  are different, then the eigenvalues  $\lambda_i$  of  $\hat{\Lambda} + e_k \mathbf{v}\mathbf{v}^T$  are solutions of the so-called secular equation,

$$1 + e_k \sum_{i=1}^n \frac{v_i^2}{\hat{\lambda}_i - \lambda} = 0.$$

The eigenvalues can be computed by bisection, or by some faster zero finder of the Newton type, and they need to be computed as accurately as possible.

4. Once the eigenvalues  $\lambda_i$  of  $\hat{\Lambda} + e_k \mathbf{v}\mathbf{v}^T$  are known, the corresponding eigenvectors are

$$\mathbf{x}_i = (\hat{\Lambda} - \lambda_i I)^{-1} \mathbf{v}.$$

5. Each  $\lambda_i$  and  $\mathbf{x}_i$  in Facts 3 and 4 is computed in  $O(n)$  operations, respectively, so the overall computational cost for computing the EVD of  $\hat{\Lambda} + e_k \mathbf{v}\mathbf{v}^T$  is  $O(n^2)$ .
6. The accuracy of the computed EVD is given by Fact 15 in section 42.1. However, if some eigenvalues are too close, they may not be computed with sufficient relative accuracy. As a consequence, the eigenvectors computed by using Fact 4 may not be sufficiently orthogonal. One remedy to this problem is to solve the secular equation from Fact 3 in double of the working precision. A better remedy is based on the solution of the following inverse eigenvalue problem. If  $\hat{\lambda}_1 > \dots > \hat{\lambda}_n$  and  $\lambda_1 > \hat{\lambda}_1 > \lambda_2 > \hat{\lambda}_2 > \dots > \lambda_{n-1} > \hat{\lambda}_{n-1} > \lambda_n > \hat{\lambda}_n$ , then  $\lambda_i$  are the exact eigenvalues of the matrix  $\hat{\Lambda} + e_k \hat{\mathbf{v}}\hat{\mathbf{v}}^T$ , where

$$\hat{v}_i = \text{sign } v_i \sqrt{\frac{\prod_{j=1}^n (\lambda_j - \hat{\lambda}_i)}{\prod_{j=1, j \neq i}^n (\hat{\lambda}_j - \hat{\lambda}_i)}}.$$

Instead of computing  $\mathbf{x}_i$  according to Fact 4, we compute  $\hat{\mathbf{x}}_i = (\hat{\Lambda} - \lambda_i I)^{-1} \hat{\mathbf{v}}$ . The eigenvector matrix of  $T$  is now computed as  $U = \hat{U} \hat{X}$ , where  $\hat{X} = [\hat{\mathbf{x}}_1 \dots \hat{\mathbf{x}}_n]$ , instead of  $U = \hat{U} X$  as in Fact 1. See also Fact 8.

7. The algorithm for the divide and conquer method is the following:

**Algorithm 6:** Divide and conquer method

Input: real symmetric tridiagonal  $n \times n$  matrix  $T$  with  $t_{i-1,i} > 0$  for all  $i$

Output: eigenvalue matrix  $\Lambda$  and eigenvector matrix  $U$  of  $T$

**function**  $(\Lambda, U) = \text{Divide\_and\_Conquer}(T)$

**if**  $n = 1$ , **then**

$U = 1$

$\Lambda = T$

**else**

$k = \text{floor}(n/2)$

form  $\hat{T}_1$  and  $\hat{T}_2 =$  as in Equation 42.6 in Fact 1

$(\hat{\Lambda}_1, \hat{U}_1) = \text{Divide\_and\_Conquer}(\hat{T}_1)$

$(\hat{\Lambda}_2, \hat{U}_2) = \text{Divide\_and\_Conquer}(\hat{T}_2)$

form  $\hat{\Lambda} + e_k \mathbf{v}\mathbf{v}^T$  as in Equation 42.7 in Fact 1

compute the eigenvalues  $\lambda_i$  via Fact 3

compute  $\hat{\mathbf{v}}$  via Fact 6

$\hat{\mathbf{x}}_i = (\hat{\Lambda} - \lambda_i I)^{-1} \hat{\mathbf{v}}$

$U = \begin{bmatrix} \hat{U}_1 & \\ & \hat{U}_2 \end{bmatrix} \hat{X}$

**endif**

8. The rationale for the approach of Fact 6 and Algorithm 6 is the following: The computations of  $\hat{\mathbf{v}}$  and  $\hat{\mathbf{x}}_i$  involve only subtractions of exact quantities, so there is no cancellation. Thus, all entries of each  $\hat{\mathbf{x}}_i$  are computed with high relative accuracy so  $\hat{\mathbf{x}}_i$  are mutually orthonormal to working

precision. Also, the transition from the matrix  $\hat{\Lambda} + e_k \mathbf{v}\mathbf{v}^T$  to the matrix  $\hat{\Lambda} + e_k \hat{\mathbf{v}}\hat{\mathbf{v}}^T$  induces only perturbations that are bounded by  $\epsilon \|T\|$ . Thus, the EVD computed by Algorithm 6 satisfies the error bounds given in Fact 15 in section 42.1, producing at the same time numerically orthogonal eigenvectors. For details see [Dem97, pp. 224–226] and [GE95].

9. Although Algorithm 6 requires  $O(n^3)$  operations (this is due to the computation of  $U$  in the last line), it is in practice usually faster than Algorithm 4 from Fact 2 in section 42.3. This is due to deflations which are performed when solving the secular equation from Fact 3, resulting in matrix  $\hat{X}$  having many zeros.
10. The operation count of Algorithm 6 can be reduced to  $O(n^2 \log n)$  if the Fast Multipole Method, originally used in particle simulation, is used for solving secular equation from Fact 3 and for multiplying  $\hat{U}\hat{X}$  in the last line of Algorithm 6. For details see [Dem97, pp. 227–228] and [GE95].

### Examples:

1. Let  $T$  be the matrix from Example 1 in section 42.2 pre- and postmultiplied by the matrix  $D = \text{diag}(1, -1, -1, 1)$ :

$$T = \begin{bmatrix} 4.5013 & 3.0194 & 0 & 0 \\ 3.0194 & -0.3692 & 1.2804 & 0 \\ 0 & 1.2804 & 0.5243 & 0.9303 \\ 0 & 0 & 0.9303 & 2.6774 \end{bmatrix}.$$

The EVDs of the matrices  $\hat{T}_1$  and  $\hat{T}_2$  from Equation 42.6 in Fact 1 are

$$\hat{T}_1 = \begin{bmatrix} 4.5013 & 3.0194 \\ 3.0194 & -1.6496 \end{bmatrix}, \quad \hat{U}_1 = \begin{bmatrix} 0.3784 & -0.9256 \\ -0.9256 & -0.3784 \end{bmatrix}, \quad \hat{\Lambda}_1 = \begin{bmatrix} -2.8841 & 0 \\ 0 & 5.7358 \end{bmatrix},$$

$$\hat{T}_2 = \begin{bmatrix} -0.7561 & 0.9303 \\ 0.9303 & 2.6774 \end{bmatrix}, \quad \hat{U}_2 = \begin{bmatrix} -0.9693 & -0.2458 \\ 0.2458 & -0.9693 \end{bmatrix}, \quad \hat{\Lambda}_2 = \begin{bmatrix} -0.9920 & 0 \\ 0 & 2.9132 \end{bmatrix},$$

so, in Equation 42.7 in Fact 1, we have

$$\hat{\Lambda} = \text{diag}(-2.8841, 5.7358, -0.9920, 2.9132),$$

$$\mathbf{v} = [-0.9256 \quad -0.3784 \quad -0.9693 \quad -0.2458]^T.$$

2. Algorithm 6 is implemented in the LAPACK subroutine DSTEDC. This routine can compute just the eigenvalues or both, eigenvalues and eigenvectors. The routine requires workspace of approximately  $n^2$  elements. The timings are given in Section 42.9.

## 42.5 Bisection and Inverse Iteration

The bisection method is convenient if only part of the spectrum is needed. If the eigenvectors are needed, as well, they can be efficiently computed by the inverse iteration method (see Facts 7 and 8 in Section 42.1).

### Facts:

The following facts can be found in [Dem97, pp. 228–213] and [Par80, pp. 65–75].

$A$  is a real symmetric  $n \times n$  matrix and  $T$  is a real symmetric tridiagonal  $n \times n$  matrix.

1. (Sylvester's theorem) For a real nonsingular matrix  $X$ , the matrices  $A$  and  $X^T A X$  have the same inertia. (See also Section 8.3.)

2. Let  $\alpha, \beta \in \mathbb{R}$  with  $\alpha < \beta$ . The number of eigenvalues of  $A$  in the interval  $[\alpha, \beta)$  is equal to  $\nu(A - \beta I) - \nu(A - \alpha I)$ . By systematically choosing the intervals  $[\alpha, \beta)$ , the bisection method pinpoints each eigenvalue of  $A$  to any desired accuracy.
3. In the factorization  $T - \mu I = LDL^T$ , where  $D = \text{diag}(d_1, \dots, d_n)$  and  $L$  is the unit lower bidiagonal matrix, the elements of  $D$  are computed by the recursion

$$d_1 = t_{11} - \mu, \quad d_i = (t_{ii} - \mu) - t_{i,i-1}^2/d_{i-1}, \quad i = 2, \dots, n,$$

and the subdiagonal elements of  $L$  are given by  $l_{i+1,i} = t_{i+1,i}/d_i$ . By Fact 1 the matrices  $T$  and  $D$  have the same inertia, thus the above recursion enables an efficient implementation of the bisection method for  $T$ .

4. The factorization from Fact 3 is essentially Gaussian elimination without pivoting. Nevertheless, if  $d_i \neq 0$  for all  $i$ , the above recursion is very stable (see [Dem97, Lemma 5.4] for details).
5. Even when  $d_{i-1} = 0$  for some  $i$ , if the IEEE arithmetic is used, the computation will continue and the inertia will be computed correctly. Namely, in that case, we would have  $d_i = -\infty$ ,  $l_{i+1,i} = 0$ , and  $d_{i+1} = t_{i+1,i+1} - \mu$ . For details see [Dem97, pp. 230–231] and the references therein.
6. Computing one eigenvalue of  $T$  by using the recursion from Fact 3 and bisection requires  $O(n)$  operations. For a computed eigenvalue the corresponding eigenvector is computed by inverse iteration given by Equation 42.2. The convergence is very fast (Fact 7 in Section 42.1), so the cost of computing each eigenvector is also  $O(n)$  operations. Therefore, the overall cost for computing all eigenvalues and eigenvectors is  $O(n^2)$  operations.
7. Both, bisection and inverse iteration are highly parallel since each eigenvalue and eigenvector can be computed independently.
8. If some of the eigenvalues are too close, the corresponding eigenvectors computed by inverse iteration may not be sufficiently orthogonal. In this case, it is necessary to orthogonalize these eigenvectors (for example, by the modified Gram–Schmidt procedure). If the number of close eigenvalues is too large, the overall operation count can increase to  $O(n^3)$ .
9. The EVD computed by bisection and inverse iteration satisfies the error bounds from Fact 15 in Section 42.1.

### Examples:

1. The bisection method for tridiagonal matrices is implemented in the LAPACK subroutine DSTEBZ. This routine can compute all eigenvalues in a given interval or the eigenvalues from  $\lambda_l$  to  $\lambda_k$ , where  $l < k$ , and the eigenvalues are ordered from smallest to largest. Inverse iteration (with reorthogonalization) is implemented in the LAPACK subroutine DSTEIN. The timings for computing half of the largest eigenvalues and the corresponding eigenvectors are given in Section 42.9.

## 42.6 Multiple Relatively Robust Representations

---

The computation of the tridiagonal EVD which satisfies the error bounds of Fact 15 in section 42.1 such that the eigenvectors are orthogonal to working precision, all in  $O(n^2)$  operations, has been the “holy grail” of numerical linear algebra for a long time. The method of Multiple Relatively Robust Representations (MRRR) does the job, except in some exceptional cases. The key idea is to implement inverse iteration more carefully. The practical algorithm is quite elaborate and only main ideas are described here.

### Facts:

The following facts can be found in [Dhi97], [DP04], and [DPV04].

$T = [t_{ij}]$  denotes a real symmetric tridiagonal matrix of order  $n$ .  $D$ ,  $D_+$ , and  $D_-$  are diagonal matrices with the  $i$ -th diagonal entry denoted by  $d_i$ ,  $D_+(i)$ , and  $D_-(i)$ , respectively.  $L$  and  $L_+$  are unit lower bidiagonal matrices and  $U_-$  is a unit upper bidiagonal matrix, where we denote  $(L)_{i+1,i}$  by  $l_i$ ,  $(L_+)_{i+1,i}$  by  $L_+(i)$ , and  $(U_-)_{i,i+1}$  by  $U_-(i)$ .

1. Instead of working with the given  $T$ , the MRRR method works with the factorization  $T = LDL^T$  (computed, for example, as in Fact 3 in Section 42.5 with  $\mu = 0$ ). If  $T$  is positive definite, then all eigenvalues of  $LDL^T$  are determined to high relative accuracy in the sense that small relative changes in the elements of  $L$  and  $D$  cause only small relative changes in the eigenvalues. If  $T$  is indefinite, then the tiny eigenvalues of  $LDL^T$  are determined to high relative accuracy in the same sense. The bisection method based on Algorithms 7a and 7b computes the well determined eigenvalues of  $LDL^T$  to high relative accuracy, that is, the computed eigenvalue  $\hat{\lambda}$  satisfies  $|\lambda - \hat{\lambda}| = O(n\epsilon|\hat{\lambda}|)$ .
2. The MRRR method is based on the following three algorithms:

**Algorithm 7a:** Differential stationary qd transform

Input: factors  $L$  and  $D$  of  $T$  and the computed eigenvalue  $\hat{\lambda}$

Output: matrices  $D_+$  and  $L_+$  such that  $LDL^T - \hat{\lambda}I = L_+D_+L_+^T$  and vector  $\mathbf{s}$

$$s_1 = -\hat{\lambda}$$

**for**  $i = 1 : n - 1$

$$D_+(i) = s_i + d_i$$

$$L_+(i) = (d_i l_i) / D_+(i)$$

$$s_{i+1} = L_+(i) l_i s_i - \hat{\lambda}$$

**endfor**

$$D_+(n) = s_n + d_n$$

**Algorithm 7b:** Differential progressive qd transform

Input: factors  $L$  and  $D$  of  $T$  and the computed eigenvalue  $\hat{\lambda}$

Output: matrices  $D_-$  and  $U_-$  such that  $LDL^T - \hat{\lambda}I = U_-D_-U_-^T$  and vector  $\mathbf{p}$

$$p_n = d_n - \hat{\lambda}$$

**for**  $i = n - 1 : -1 : 1$

$$D_-(i + 1) = d_i l_i^2 + p_{i+1}$$

$$t = d_i / D_-(i + 1)$$

$$U_-(i) = l_i t$$

$$p_i = p_{i+1} t - \hat{\lambda}$$

**endfor**

$$D_-(1) = p_1$$

**Algorithm 7c:** Eigenvector computation

Input: output of Algorithms 7a and 7b and the computed eigenvalue  $\hat{\lambda}$

Output: index  $r$  and the eigenvector  $\mathbf{u}$  such that  $LDL^T \mathbf{u} = \hat{\lambda} \mathbf{u}$ .

**for**  $i = 1 : n - 1$

$$\gamma_i = s_i + \frac{d_i}{D_-(i+1)} p_{i+1}$$

**endfor**

$$\gamma_n = s_n + p_n + \hat{\lambda}$$

find  $r$  such that  $|\gamma_r| = \min_i |\gamma_i|$

$$u_r = 1$$

**for**  $i = r - 1 : -1 : 1$

$$u_i = -L_+(i) u_{i+1}$$

**endfor**

**for**  $i = r : n - 1$

$$u_{i+1} = -U_-(i) u_i$$

**endfor**

$$\mathbf{u} = \mathbf{u} / \|\mathbf{u}\|_2$$

3. Algorithm 7a is accurate in the sense that small relative perturbations (of the order of few  $\epsilon$ ) in the elements  $l_i, d_i$ , and the computed elements  $L_+(i)$  and  $D_+(i)$  make  $LDL^T - \hat{\lambda}I = L_+D_+L_+^T$  an exact equality. Similarly, Algorithm 7b is accurate in the sense that small relative perturbations in the elements  $l_i, d_i$ , and the computed elements  $U_-(i)$  and  $D_-(i)$  make  $LDL^T - \hat{\lambda}I = U_-D_-U_-^T$  an exact equality.
4. The idea behind the Algorithm 7c is the following: Index  $r$  is the index of the column of the matrix  $(LDL^T - \hat{\lambda}I)^{-1}$  with the largest norm. Since the matrix  $LDL^T - \hat{\lambda}I$  is nearly singular, the eigenvector is computed in just one step of inverse iteration given by Equation 42.2 starting from the vector  $\gamma_r \mathbf{e}_r$ . Further,  $LDL^T - \hat{\lambda}I = N\Delta N^T$ , where  $N\Delta N^T$  is the so-called twisted factorization obtained from  $L_+, D_+, U_-$ , and  $D_-$ :

$$\Delta = \text{diag}(D_+(1), \dots, D_+(r-1), \gamma_r, D_-(r+1), \dots, D_-(n)),$$

$$N_{ii} = 1, \quad N_{i+1,i} = L_+(i), \quad i = 1, \dots, r-1, \quad N_{i,i+1} = U_-(i), \quad i = r, \dots, n-1.$$

Since  $\Delta \mathbf{e}_r = \gamma_r \mathbf{e}_r$  and  $N \mathbf{e}_r = \mathbf{e}_r$ , solving  $N\Delta N^T \mathbf{u} = \gamma_r \mathbf{e}_r$  is equivalent to solving  $N^T \mathbf{u} = \mathbf{e}_r$ , which is exactly what is done by Algorithm 7c.

5. If an eigenvalue  $\lambda$  is well separated from other eigenvalues in the relative sense (the quantity  $\min_{\mu \in \sigma(A), \mu \neq \lambda} |\lambda - \mu|/|\lambda|$  is large, say greater than  $10^{-3}$ ), then the computed vector  $\hat{\mathbf{u}}$  satisfies  $\|\sin \Theta(\mathbf{u}, \hat{\mathbf{u}})\|_2 = O(n\epsilon)$ . If all eigenvalues are well separated from each other, then the computed EVD satisfies error bounds of Fact 15 in Section 42.1 and the computed eigenvectors are numerically orthogonal, that is,  $|\hat{\mathbf{u}}_i^T \hat{\mathbf{u}}_j| = O(n\epsilon)$  for  $i \neq j$ .
6. If there is a cluster of poorly separated eigenvalues which is itself well separated from the rest of  $\sigma(A)$ , the MRRR method chooses a shift  $\mu$  which is near one end of the cluster and computes a new factorization  $LDL^T - \mu I = L_+D_+L_+^T$ . The eigenvalues within the cluster are then recomputed by bisection as in Fact 1 and their corresponding eigenvectors are computed by Algorithms 7a, 7b, and 7c. When properly implemented, this procedure results in the computed EVD, which satisfies the error bounds of Fact 15 in Section 42.1 and the computed eigenvectors are numerically orthogonal.

### Examples:

1. The MRRR method is implemented in the LAPACK subroutine DSTEGR. This routine can compute just the eigenvalues, or both eigenvalues and eigenvectors. The timings are given in Section 42.9.

## 42.7 Jacobi Method

The Jacobi method is the oldest method for EVD computations [Jac846]. The method does not require tridiagonalization. Instead, the method computes a sequence of orthogonally similar matrices which converge to  $\Lambda$ . In each step a simple plane rotation which sets one off-diagonal element to zero is performed.

### Definitions:

$A$  is a real symmetric matrix of order  $x$  and  $A = U\Lambda U^T$  is its EVD.

The **Jacobi method** forms a sequence of matrices,

$$A_0 = A, \quad A_{k+1} = G(i_k, j_k, c, s)A_k G(i_k, j_k, c, s)^T, \quad k = 1, 2, \dots,$$

where  $G(i_k, j_k, c, s)$  is the plane rotation matrix defined in Chapter 38.4. The parameters  $c$  and  $s$  are chosen such that  $[A_{k+1}]_{i_k j_k} = [A_{k+1}]_{j_k i_k} = 0$  and are computed as described in Fact 1.

The plane rotation with  $c$  and  $s$  as above is also called the **Jacobi rotation**.

The **off-norm** of  $A$  is defined as  $\text{off}(A) = (\sum_i \sum_{j \neq i} a_{ij}^2)^{1/2}$ , that is, off-norm is the Frobenius norm of the matrix consisting of all off-diagonal elements of  $A$ .

The choice of **pivot elements**  $[A_k]_{i_k j_k}$  is called the **pivoting strategy**.

The **optimal pivoting** strategy, originally used by Jacobi, chooses pivoting elements such that  $|[A_k]_{i_k j_k}| = \max_{i < j} |[A_k]_{ij}|$ .

The **row cyclic** pivoting strategy chooses pivot elements in the systematic row-wise order,

$$(1, 2), (1, 3), \dots, (1, n), (2, 3), (2, 4), \dots, (2, n), (3, 4), \dots, (n-1, n).$$

Similarly, the column-cyclic strategy chooses pivot elements column-wise.

One pass through all matrix elements is called **cycle** or **sweep**.

### Facts:

The Facts 1 to 8 can be found in [Wil65, pp. 265–282], [Par80, §9], [GV96, §8.4], and [Dem97, §5.3.5].

1. The Jacobi rotations parameters  $c$  and  $s$  are computed as follows: If  $[A_k]_{i_k j_k} = 0$ , then  $c = 1$  and  $s = 0$ , otherwise

$$\tau = \frac{[A_k]_{i_k i_k} - [A_k]_{j_k j_k}}{2[A_k]_{i_k j_k}}, \quad t = \frac{\text{sign}(\tau)}{|\tau| + \sqrt{1 + \tau^2}}, \quad c = \frac{1}{\sqrt{1 + t^2}}, \quad s = c \cdot t.$$

2. After each rotation, the off-norm decreases, that is,

$$\text{off}^2(A_{k+1}) = \text{off}^2(A_k) - 2[A_k]_{i_k j_k}^2.$$

With the appropriate pivoting strategy, the method converges in the sense that

$$\text{off}(A_k) \rightarrow 0, \quad A_k \rightarrow \Lambda, \quad \prod_{k=1}^{\infty} R_{(i_k, j_k)}^T \rightarrow U.$$

3. For the optimal pivoting strategy the square of the pivot element is greater than the average squared element,  $[A_k]_{i_k j_k}^2 \geq \text{off}^2(A) \frac{1}{n(n-1)}$ . Thus,

$$\text{off}^2(A_{k+1}) \leq \left(1 - \frac{2}{n(n-1)}\right) \text{off}^2(A_k)$$

and the method converges.

4. For the row cyclic and the column cyclic pivoting strategies, the method converges. The convergence is ultimately quadratic in the sense that  $\text{off}(A_{k+n(n-1)/2}) \leq \gamma \text{off}^2(A_k)$  for some constant  $\gamma$ , provided  $\text{off}(A_k)$  is sufficiently small.
5. We have the following algorithm:

**Algorithm 8:** Jacobi method with row-cyclic pivoting strategy

Input: real symmetric  $n \times n$  matrix  $A$

Output: the eigenvalue matrix  $\Lambda$  and the eigenvector matrix  $U$

$U = I_n$

**repeat**      % one cycle

**for**  $i = 1 : n - 1$

**for**  $j = i + 1 : n$

      compute  $c$  and  $s$  according to Fact 1

$$\begin{bmatrix} A_{i,1:n} \\ A_{j,1:n} \end{bmatrix} = G(i, j, c, s) \begin{bmatrix} A_{i,1:n} \\ A_{j,1:n} \end{bmatrix}$$

$$\begin{bmatrix} A_{1:n,i} & A_{1:n,j} \end{bmatrix} = \begin{bmatrix} A_{1:n,i} & A_{1:n,j} \end{bmatrix} G(i, j, c, s)^T$$

$$\begin{bmatrix} U_{1:n,i} & U_{1:n,j} \end{bmatrix} = \begin{bmatrix} U_{1:n,i} & U_{1:n,j} \end{bmatrix} G(i, j, c, s)^T$$

**endfor**

**endfor**

**until**  $\text{off}(A) \leq \text{tol}$  for some user defined stopping criterion  $\text{tol}$

$\Lambda = \text{diag}(A)$

6. Detailed implementation of the Jacobi method can be found in [Rut66] and [WR71].
7. The EVD computed by the Jacobi method satisfies the error bounds from Fact 15 in Section 42.1.
8. The Jacobi method is suitable for parallel computation. There exist convergent parallel strategies which enable simultaneous execution of several rotations.
9. [GV96, p. 429] The Jacobi method is simple, but it is slower than the methods based on tridiagonalization. It is conjectured that standard implementations require  $O(n^3 \log n)$  operations. More precisely, each cycle clearly requires  $O(n^3)$  operations and it is conjectured that  $\log n$  cycles are needed until convergence.
10. [DV92], [DV05] If  $A$  is positive definite, the method can be modified such that it reaches the speed of the methods based on tridiagonalization and at the same time computes the eigenvalues with high relative accuracy. (See Chapter 46 for details.)

### Examples:

1. Let  $A$  be the matrix from Example 1 in section 42.1. After executing two cycles of Algorithm 8, we have

$$A = \begin{bmatrix} 6.0054 & -0.0192 & 0.0031 & 0.0003 \\ -0.0192 & 3.0455 & -0.0005 & -0.0000 \\ 0.0031 & -0.0005 & 0.6024 & -0.0000 \\ 0.0003 & -0.0000 & 0.0000 & -2.3197 \end{bmatrix}.$$

## 42.8 Lanczos Method

---

If the matrix  $A$  is large and sparse and if only some eigenvalues and their eigenvectors are desired, sparse matrix methods are the methods of choice. For example, the power method can be useful to compute the eigenvalue with the largest modulus. The basic operation in the power method is matrix-vector multiplication, and this can be performed very fast if  $A$  is sparse. Moreover,  $A$  need not be stored in the computer — the input for the algorithm can be just a program which, given some vector  $\mathbf{x}$ , computes the product  $A\mathbf{x}$ . An “improved” version of the power method, which efficiently computes several eigenvalues (either largest in modulus or near some target value  $\mu$ ) and the corresponding eigenvectors, is the Lanczos method.

### Definitions:

$A$  is a real symmetric matrix of order  $n$ .

Given a nonzero vector  $\mathbf{x}$  and an index  $k < n$ , the **Krylov matrix** is defined as

$$K_k = [\mathbf{x} \quad A\mathbf{x} \quad A^2\mathbf{x} \quad \cdots \quad A^{k-1}\mathbf{x}].$$

### Facts:

The following facts can be found in [Par80, §13], [GV96, §9], [Dem97, §7], and [Ste01, §5.3].

1. The Lanczos method is based on the following observation. If  $K_k = XR$  is the QR factorization of the matrix  $K_k$  (see Sections 5.5 and 38.4), then the  $k \times k$  matrix  $T = X^TAX$  is tridiagonal. The matrices  $X$  and  $T$  can be computed by using only matrix-vector products in just  $O(kn)$  operations. Let  $T = Q\Lambda Q^T$  be the EVD of  $T$  (computed by any of the methods from Sections 42.3 to 42.6). Then  $\lambda_i$  approximate well some of the largest and smallest eigenvalues of  $A$ . The columns of the matrix  $U = XQ$  approximate the corresponding eigenvectors of  $A$ . We have the following algorithm:

**Algorithm 9:** Lanczos methodInput: real symmetric  $n \times n$  matrix  $A$ , unit vector  $\mathbf{x}$  and index  $k < n$ Output: matrices  $\Lambda$  and  $U$  $X_{:,1} = \mathbf{x}$ **for**  $i = 1 : k$      $\mathbf{z} = A X_{:,i}$      $t_{ii} = X_{:,i}^T \mathbf{z}$     **if**  $i = 1$ , **then**         $\mathbf{z} = \mathbf{z} - t_{ii} X_{:,i}$     **else**         $\mathbf{z} = \mathbf{z} - t_{ii} X_{:,i} - t_{i,i-1} X_{:,i-1}$     **endif**     $\mu = \|\mathbf{z}\|_2$     **if**  $\mu = 0$ , **then**

stop

2. As  $j$  increases, the largest (smallest) eigenvalues of the matrix  $T_{1:j,1:j}$  converge towards some of the largest (smallest) eigenvalues of  $A$  (due to the Cauchy interlace property). The algorithm can be redesigned to compute only largest or smallest eigenvalues. Also, by using shift and invert strategy, the method can be used to compute eigenvalues near some specified value. In order to obtain better approximations,  $k$  should be greater than the number of required eigenvalues. On the other side, in order to obtain better accuracy and efficacy,  $k$  should be as small as possible (see Facts 3 and 4 below).
3. The eigenvalues of  $A$  are approximated from the matrix  $T_{1:k,1:k}$ , thus, the last element  $v = t_{k+1,k}$  is not needed. However, this element provides key information about accuracy at no extra computational cost. The exact values of residuals are as follows:  $\|AU - UA\|_2 = v$  and, in particular,  $\|AU_{:,i} - \lambda_i U_{:,i}\|_2 = v|q_{ki}|$ ,  $i = 1, \dots, k$ . Further, there are  $k$  eigenvalues  $\tilde{\lambda}_1, \dots, \tilde{\lambda}_k$  of  $A$  such that  $|\lambda_i - \tilde{\lambda}_i| \leq v$ . For the corresponding eigenvectors, we have  $\sin 2\Theta(\mathbf{u}_i, \tilde{\mathbf{u}}_i) \leq 2v / \min_{j \neq i} |\lambda_i - \tilde{\lambda}_j|$ . In practical implementations of Algorithm 9,  $v$  is usually used to determine the index  $k$ .
4. Although theoretically very elegant, the Lanczos method has inherent numerical instability in the floating point arithmetic, and so it must be implemented carefully (see, e.g., [LSY98]). Since the Krylov vectors are, in fact, generated by the power method, they converge towards an eigenvector of  $A$ . Thus, as  $k$  increases, the Krylov vectors become more and more parallel. As a consequence, the recursion in Algorithm 9, which computes the orthogonal bases  $X$  for the subspace range  $K_k$ , becomes numerically unstable and the computed columns of  $X$  cease to be sufficiently orthogonal. This affects both the convergence and the accuracy of the algorithm. For example, it can happen that  $T$  has several eigenvalues which converge towards some simple eigenvalue of  $A$  (these are the so called ghost eigenvalues).

The loss of orthogonality is dealt with by using the full reorthogonalization procedure. In each step, the new  $\mathbf{z}$  is orthogonalized against all previous columns of  $X$ . In Algorithm 9, the formula  $\mathbf{z} = \mathbf{z} - t_{ii} X_{:,i} - t_{i,i-1} X_{:,i-1}$  is replaced by  $\mathbf{z} = \mathbf{z} - \sum_{j=1}^{i-1} (\mathbf{z}^T X(:, j)) X(:, j)$ . To obtain better orthogonality, the latter formula is usually executed twice.

The full reorthogonalization raises the operation count to  $O(k^2n)$ . The selective reorthogonalization is the procedure in which the current  $z$  is orthogonalized against some selected columns of  $X$ . This is the way to attain sufficient numerical stability and not increase the operation count too much. The details of selective reorthogonalization procedures are very subtle and can be found in the references. (See also Chapter 44.)

5. The Lanczos method is usually used for sparse matrices. Sparse matrix  $A$  is stored in the sparse format in which only values and indices of nonzero elements are stored. The number of operations required to multiply some vector by  $A$  is also proportional to the number of nonzero elements. (See also Chapter 43.)

### Examples:

1. Let  $A$  be the matrix from Example 1 in section 42.1 and let  $x = [1/2 \ 1/2 \ 1/2 \ 1/2]^T$ . For  $k = 2$ , the output of Algorithm 9 is

$$\Lambda = \begin{bmatrix} -2.0062 & & & \\ & & & \\ & & & \\ & & & 5.7626 \end{bmatrix}, \quad U = \begin{bmatrix} -0.4032 & -0.8804 \\ 0.4842 & -0.2749 \\ 0.3563 & -0.3622 \\ 0.6899 & -0.1345 \end{bmatrix},$$

with  $v = 1.4965$  (c.f. Fact 3). For  $k = 3$ , the output is

$$\Lambda = \begin{bmatrix} -2.3107 & 0 & 0 \\ 0 & 2.8641 & 0 \\ 0 & 0 & 5.9988 \end{bmatrix}, \quad U = \begin{bmatrix} 0.3829 & -0.0244 & 0.8982 \\ -0.2739 & -0.9274 & 0.0312 \\ -0.3535 & -0.1176 & 0.3524 \\ -0.8084 & 0.3541 & 0.2607 \end{bmatrix},$$

with  $v = 0.6878$ .

2. The Lanczos method is implemented in the ARPACK routine `DSDRV*`, where `*` denotes the computation mode [LSY98, App. A]. The routines from ARPACK are implemented in the MATLAB command `eigs`. Generation of a sparse symmetric  $10,000 \times 10,000$  matrix with 10% nonzero elements with the MATLAB command `A=sprandsym(10000,0.1)` takes 15 seconds on a processor described in Fact 1 in section 42.9. The computation of 100 largest eigenvalues and the corresponding eigenvectors with `[U,Lambda]=eigs(A,100,'LM',opts)` takes 140 seconds. Here, index  $k = 200$  is automatically chosen by the algorithm. (See also Chapter 76.)

## 42.9 Comparison of Methods

In this section, we give timings for the LAPACK implementations of the methods described in Sections 42.2 to 42.6. The timing for the Lanczos method is given in Example 2 in Section 42.8.

### Definitions:

A measure of processor's **efficacy** or **speed** is the number of floating-point operations per second (flops).

### Facts:

$A$  is an  $n \times n$  real symmetric matrix and  $A = U\Lambda U^T$  is its EVD.  $T$  is a tridiagonal  $n \times n$  real symmetric matrix and  $T = Q\Lambda Q^T$  is its EVD.  $T = X^T A X$  is the reduction of  $A$  to a tridiagonal from Section 42.2.

1. Our tests were performed on the Intel Xeon processor running at 2.8 MHz with 2 Mbytes of cache memory. This processor performs up to 5 Gflops (5 billion operations per second). The peak performance is attained for the matrix multiplication with the BLAS 3 subroutine DGEMM.

TABLE 42.1 Execution times(s) for LAPACK routines for various matrix dimensions  $n$ .

Routine	Input	Output	Example	$n = 500$	$n = 1000$	$n = 2000$
DSYTRD	$A$	$T$	2.3	0.10	0.78	5.5
DSYTRD/DORGTR		$T, X$		0.17	1.09	8.6
DSTEQR	$T$	$\Lambda$	3.2	0.03	0.11	0.44
		$\Lambda, Q$		0.32	2.23	15.41
DSYEV	$A$	$\Lambda$	3.4	0.12	0.85	5.63
		$\Lambda, U$		0.46	3.13	22.30
DSTEDC	$T$	$\Lambda$	4.2	0.02	0.08	0.28
		$\Lambda, Q$		0.05	0.12	0.36
DSTEBZ	$T$	$\Lambda$	5.1	0.21	0.81	3.15
DSTEIN		$Q$		0.04	0.17	0.72
DSTEGR	$T$	$\Lambda$	6.1	0.07	0.25	0.87
		$\Lambda, Q$		0.09	0.35	1.29

- Our test programs were compiled with the Intel `ifort` FORTRAN compiler (version 9.0) and linked with the Intel Math Kernel Library (version 8.0.2).
- Timings for the methods are given in Table 42.1. The execution times for DSTEBZ (bisection) and DSTEIN (inverse iteration) are for computing one half of the eigenvalues (the largest ones) and the corresponding eigenvectors, respectively.
- The performance attained for practical algorithms is lower than the peak performance from Fact 1. For example, by combining Facts 6 and 7 in Section 42.2 with Table 42.1, we see that the tridiagonalization routines DSYTRD and DORGTR attain the speed of 2 Gflops.
- The computation times for the implicitly shifted QR routine, DSTEQR, grow with  $n^2$  when only eigenvalues are computed, and with  $n^3$  when eigenvalues and eigenvectors are computed, as predicted in Facts 5 and 6 in Section 42.3.
- The execution times for DSYEV are approximately equal to the sums of the timings for DSYTRD (tridiagonalization), DORGTR (computing  $X$ ), and DSTEQR with the eigenvector option (computing the EVD of  $T$ ).
- The divide and conquer method, implemented in DSTEDC, is the fastest method for computing the EVD of a tridiagonal matrix.
- DSTEBZ and DSTEIN (bisection and inverse iteration) are faster, especially for larger dimensions, than DSTEQR (tridiagonal QR iteration), but slower than DSTEDC (divide and conquer) and DSTEGR (multiple relatively robust representations).
- Another algorithm to compute the EVD of  $T$  is to use DSTEQR to compute only the eigenvalues and then use DSTEIN (inverse iteration) to compute the eigenvectors. This is usually considerably faster than computing both, eigenvalues and eigenvectors, by DSTEQR.
- The executions times for DSTEGR are truly proportional to  $O(n^2)$ .
- The new LAPACK release, in which some of the above mentioned routines are improved with respect to speed and/or accuracy, is announced for the second half of 2006.

43.1	The Generalized Eigenvalue Problem .....	43-1
43.2	Dense Matrix Techniques .....	43-3
43.3	Sparse Matrix Techniques .....	43-9
	References .....	43-11

The definitions and basic properties of eigenvalues and eigenvectors are given in Section 4.3. A natural generalization is presented here in Section 43.1. Algorithms for computation of eigenvalues, eigenvectors, and their generalizations will be discussed in Sections 43.2 and 43.3. Although the characteristic equation is important in theory, it plays no role in practical eigenvalue computations.

If a large fraction of a matrix's entries are zeros, the matrix is called **sparse**. A matrix that is not sparse is called **dense**. Dense matrix techniques are methods that store the matrix in the conventional way, as an array, and operate on the array elements. Any matrix that is not too big to fit into a computer's main memory can be handled by dense matrix techniques, regardless of whether the matrix is dense or not. However, since the time to compute the eigenvalues of an  $n \times n$  matrix by dense matrix techniques is proportional to  $n^3$ , the user may have to wait awhile for the results if  $n$  is very large. Dense matrix techniques do not exploit the zeros in a matrix and tend to destroy them. With modern computers, dense matrix techniques can be applied to matrices of dimension up to 1000 or more. If a matrix is very large and sparse, and only a portion of the spectrum is needed, sparse matrix techniques (Section 43.3) are preferred.

The usual approach is to preprocess the matrix into Hessenberg form and then to effect a similarity transformation to triangular form:  $T = S^{-1}AS$  by an iterative method. This yields the eigenvalues of  $A$  as the main-diagonal entries of  $T$ . For  $k = 1, \dots, n - 1$ , the first  $k$  columns of  $S$  span an invariant subspace. The eigenvectors of an upper-triangular matrix are easily computed by back substitution, and the eigenvectors of  $A$  can be deduced from the eigenvectors of  $T$  [GV96, § 7.6], [Wat02, § 5.8]. If a matrix  $A$  is very large and sparse, only a partial similarity transformation is possible because a complete similarity transformation would require too much memory and take too long to compute.

### 43.1 The Generalized Eigenvalue Problem

---

Many matrix eigenvalue problems are most naturally viewed as generalized eigenvalue problems.

#### Definitions:

Given  $A \in \mathbb{C}^{n \times n}$  and  $B \in \mathbb{C}^{n \times n}$ , the nonzero vector  $\mathbf{v} \in \mathbb{C}^n$  is called an **eigenvector** of the pair  $(A, B)$  if there are scalars  $\mu, \nu \in \mathbb{C}$ , not both zero, such that

$$\nu A\mathbf{v} = \mu B\mathbf{v}.$$

Then, the scalar  $\lambda = \mu/\nu$  is called the **eigenvalue** of  $(A, B)$  associated with the eigenvector  $\mathbf{v}$ . If  $\nu = 0$ , then the eigenvalue is  $\infty$  by convention.

The expression  $A - xB$ , with indeterminate  $x$ , is called a **matrix pencil**. Whether we refer to the pencil  $A - xB$  or the pair  $(A, B)$ , we are speaking of the same object. The pencil (or the pair  $(A, B)$ ) is called **singular** if  $A - \lambda B$  is singular for all  $\lambda \in \mathbb{C}$ . The pencil is **regular** if there exists a  $\lambda \in \mathbb{C}$  such that  $A - \lambda B$  is nonsingular. We will restrict our attention to regular pencils.

The **characteristic polynomial** of the pencil  $A - xB$  is  $\det(xB - A)$ , and the **characteristic equation** is  $\det(xB - A) = 0$ .

Two pairs  $(A, B)$  and  $(C, D)$  are **strictly equivalent** if there exist nonsingular matrices  $S_1$  and  $S_2$  such that  $C - \lambda D = S_1(A - \lambda B)S_2$  for all  $\lambda \in \mathbb{C}$ . If  $S_1$  and  $S_2$  can be taken to be unitary, then the pairs are **strictly unitarily equivalent**.

A pair  $(A, B)$  is called **upper triangular** if both  $A$  and  $B$  are upper triangular.

### Facts:

The following facts are discussed in [GV96, § 7.7] and [Wat02, § 6.7].

1. When  $B = I$ , the generalized eigenvalue problem for the pair  $(A, B)$  reduces to the standard eigenvalue problem for the matrix  $A$ .
2.  $\lambda$  is an eigenvalue of  $(A, B)$  if and only if  $A - \lambda B$  is singular.
3.  $\lambda$  is an eigenvalue of  $(A, B)$  if and only if  $\ker(\lambda B - A) \neq \{0\}$ .
4. The eigenvalues of  $(A, B)$  are exactly the solutions of the characteristic equation  $\det(xB - A) = 0$ .
5. The characteristic polynomial  $\det(xB - A)$  is a polynomial in  $x$  of degree  $\leq n$ .
6. The pair  $(A, B)$  (or the pencil  $A - xB$ ) is singular if and only if  $\det(\lambda B - A) = 0$  for all  $\lambda$ , if and only if the characteristic polynomial  $\det(xB - A)$  is equal to zero.
7. If the pair  $(A, B)$  is regular, then  $\det(xB - A)$  is a nonzero polynomial of degree  $k \leq n$ .  $(A, B)$  has  $k$  finite eigenvalues.
8. The degree of  $\det(xB - A)$  is exactly  $n$  if and only if  $B$  is nonsingular.
9. If  $B$  is nonsingular, then the eigenvalues of  $(A, B)$  are exactly the eigenvalues of the matrices  $AB^{-1}$  and  $B^{-1}A$ .
10. If  $\lambda \neq 0$ , then  $\lambda$  is an eigenvalue of  $(A, B)$  if and only if  $\lambda^{-1}$  is an eigenvalue of  $(B, A)$ .
11. Zero is an eigenvalue of  $(A, B)$  if and only if  $A$  is a singular matrix.
12. Infinity is an eigenvalue of  $(A, B)$  if and only if  $B$  is a singular matrix.
13. Two pairs that are strictly equivalent have the same eigenvalues.
14. If  $C - \lambda D = S_1(A - \lambda B)S_2$ , then  $\mathbf{v}$  is an eigenvector of  $(A, B)$  if and only if  $S_2^{-1}\mathbf{v}$  is an eigenvector of  $(C, D)$ .
15. (Schur's Theorem) Every  $A \in \mathbb{C}^{n \times n}$  is unitarily similar to an upper triangular matrix  $S$ .
16. (Generalized Schur Theorem) Every pair  $(A, B)$  is strictly unitarily equivalent to an upper triangular pair  $(S, T)$ .
17. The characteristic polynomial of an upper triangular pair  $(S, T)$  is  $\prod_{k=1}^n (\lambda t_{kk} - s_{kk})$ . The eigenvalues of  $(S, T)$  are  $\lambda_k = s_{kk}/t_{kk}$ ,  $k = 1, \dots, n$ . If  $t_{kk} = 0$  and  $s_{kk} \neq 0$ , then  $\lambda_k = \infty$ . If  $t_{kk} = 0$  and  $s_{kk} = 0$  for some  $k$ , the pair  $(S, T)$  is singular.

### Examples:

1. Let  $A = \begin{bmatrix} 1 & 2 \\ 3 & 4 \end{bmatrix}$  and  $B = \begin{bmatrix} 1 & 2 \\ 0 & 1 \end{bmatrix}$ . Then the characteristic polynomial of the pair  $(A, B)$  is  $x^2 + x - 2 = 0$ , and the eigenvalues are 1 and  $-2$ .

2. Since the pencil

$$\begin{bmatrix} 2 & 5 \\ 0 & 7 \end{bmatrix} - x \begin{bmatrix} 5 & 1 \\ 0 & 3 \end{bmatrix}$$

is upper triangular, its characteristic polynomial is  $(5x - 2)(3x - 7)$ , and its eigenvalues are  $2/5$  and  $7/3$ .

3. The pencil

$$\begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix} - x \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}$$

has characteristic equation  $x = 0$ . It is a regular pencil with eigenvalues 0 and  $\infty$ .

## 43.2 Dense Matrix Techniques

---

The steps that are usually followed for solving the unsymmetric eigenvalue problem are preprocessing, eigenvalue computation with the *QR* Algorithm, and eigenvector computation.

The most widely used public domain software for this problem is from LAPACK [ABB99], and Chapter 75. Versions in FORTRAN and C are available. The most popular proprietary software is MATLAB, which uses computational routines from LAPACK. Several of LAPACK's computational routines will be mentioned in this section. LAPACK also has a number of driver routines that call the computational routines to perform the most common tasks, thereby making the user's job easier. A very easy way to use LAPACK routines is to use MATLAB.

This section presents algorithms for the reader's edification. However, the reader is strongly advised to use well-tested software written by experts whenever possible, rather than writing his or her own code. The actual software is very complex and addresses details that cannot be discussed here.

### Definitions:

A matrix  $A \in \mathbb{C}^{n \times n}$  is called **upper Hessenberg** if  $a_{ij} = 0$  whenever  $i > j + 1$ . This means that every entry below the first subdiagonal of  $A$  is zero. An upper Hessenberg matrix is called **unreduced upper Hessenberg** if  $a_{j+1,j} \neq 0$  for  $j = 1, \dots, n - 1$ .

### Facts:

The following facts are proved in [Dem97], [GV96], [Kre05], or [Wat02].

1. Preprocessing is a two step process involving balancing the matrix and transforming by unitary similarity to upper Hessenberg form.
2. The first step, which is optional, is to balance the matrix. The balancing operation begins by performing a permutation similarity transformation that exposes any obvious eigenvalues. The remaining submatrix is irreducible. It then performs a diagonal similarity transformation  $D^{-1}AD$  that attempts to make the norms of the  $i$ th row and  $i$ th column as nearly equal as possible,  $i = 1, \dots, n$ . This has the effect of reducing the overall norm of the matrix and in diminishing the effects of roundoff errors [Osb60]. The scaling factors in  $D$  are taken to be powers of the base of floating point arithmetic (usually 2). No roundoff errors are caused by this transformation.
3. All modern balancing routines, including the code GEBAL in LAPACK, are derived from the code in Parlett and Reinsch [PR69]. See also [Kre05].

**Algorithm 1: Balancing an Irreducible Matrix.** An irreducible matrix  $A \in \mathbb{C}^{n \times n}$  is input. On output,  $A$  has been overwritten by  $D^{-1}AD$ , where  $D$  is diagonal.

$b \leftarrow$  base of floating point arithmetic (usually 2)

$D \leftarrow I_n$

done  $\leftarrow$  0

while done = 0

    done  $\leftarrow$  1

    for  $j = 1 : n$

$c \leftarrow \sum_{i \neq j} |a_{ij}|, \quad r \leftarrow \sum_{k \neq j} |a_{jk}|$

$s \leftarrow c + r, \quad f \leftarrow 1$

        while  $bc < r$

$c \leftarrow bc, \quad r \leftarrow r/b, \quad f \leftarrow bf$

        while  $br < c$

$c \leftarrow c/b, \quad r \leftarrow br, \quad f \leftarrow f/b$

        if  $c + r < 0.95s$

            done  $\leftarrow$  0,  $d_{jj} \leftarrow f d_{jj}$

$A_{1:n,j} \leftarrow f A_{1:n,j}, \quad A_{j,1:n} \leftarrow (1/f) A_{j,1:n}$

    end

4. In most cases balancing will have little effect on the outcome of the computation, but sometimes it results in greatly improved accuracy [BDD00, § 7.2].
5. The second preprocessing step is to transform the matrix to upper Hessenberg form. This is accomplished by a sequence of  $n - 2$  steps. On the  $j$ th step, zeros are introduced into the  $j$ th column.
6. For every  $\mathbf{x} \in \mathbb{C}^n$  there is a unitary matrix  $U$  such that  $U\mathbf{x} = \alpha\mathbf{e}_1$ , for some scalar  $\alpha \in \mathbb{C}$ , where  $\mathbf{e}_1$  is the vector having a 1 in the first position and zeros elsewhere.  $U$  can be chosen to be a rank-one modification of the identity matrix:  $U = I + \mathbf{u}\mathbf{v}^*$ . (See Section 38.4 for a discussion of Householder and Givens matrices.)
- 7.

**Algorithm 2. Unitary Similarity Transformation to Upper Hessenberg Form.** A general matrix  $A \in \mathbb{C}^{n \times n}$  is input. On output,  $A$  has been overwritten by an upper Hessenberg matrix  $Q^*AQ$ . The unitary transforming matrix  $Q$  has also been generated.

$Q \leftarrow I_n$

for  $j = 1 : n - 2$

    Let  $\mathbf{x} = A_{j+1:n,j} \in \mathbb{C}^{n-j}$ .

    Build unitary  $U \in \mathbb{C}^{(n-j) \times (n-j)}$  such that  $U^*\mathbf{x} = \gamma\mathbf{e}_1$ .

$A_{j+1:n,j:n} \leftarrow U^* A_{j+1:n,j:n}$

$A_{1:n,j+1:n} \leftarrow A_{1:n,j+1:n}U$

$Q_{1:n,j+1:n} \leftarrow Q_{1:n,j+1:n}U$

end

8. The cost of the reduction to Hessenberg form is proportional to  $n^3$  for large  $n$ ; that is, it is  $O(n^3)$ .
9. For large matrices, efficient cache use can be achieved by processing several columns at a time. This allows the processor(s) to run at much closer to maximum speed. See [GV96, p. 225], [Wat02, p. 210], and the LAPACK code GEHRD [ABB99].

10. Once the matrix is in upper Hessenberg form, if any of the subdiagonal entries  $a_{j+1,j}$  is zero, the matrix is block upper triangular with a  $j \times j$  block and an  $n - j \times n - j$  block, and the eigenvalue problem decouples to two independent problems of smaller size. Thus, we always work with unreduced upper Hessenberg matrices.
11. In practice we set an entry  $a_{j+1,j}$  to zero whenever

$$|a_{j+1,j}| < \epsilon(|a_{jj}| + |a_{j+1,j+1}|),$$

where  $\epsilon$  is the computer's unit roundoff.

12. If  $T \in \mathbb{C}^{n \times n}$  is upper triangular and nonsingular, then  $T^{-1}$  is upper triangular. If  $H \in \mathbb{C}^{n \times n}$  is upper Hessenberg, then  $TH$ ,  $HT$ , and  $THT^{-1}$  are upper Hessenberg.
13. The standard method for computing the eigenvalues of a Hessenberg matrix is the QR algorithm, an iterative method that produces a sequence of unitarily similar matrices that converges to upper triangular form.
14. The most basic version of the QR algorithm starts with  $A_0 = A$ , an unreduced upper Hessenberg matrix, and generates a sequence  $(A_m)$  as follows: Given  $A_{m-1}$ , a decomposition  $A_{m-1} = Q_m R_m$ , where  $Q_m$  is unitary and  $R_m$  is upper triangular, is computed. Then the factors are multiplied back together in reverse order to yield  $A_m = R_m Q_m$ . Equivalently  $A_m = Q_m^* A_{m-1} Q_m$ .
15. Upper Hessenberg form is preserved by iterations of the QR algorithm.
16. The QR algorithm can also be applied to non-Hessenberg matrices, but the operations are much more economical in the Hessenberg case.
17. The basic QR algorithm converges slowly, so shifts of origin are used to accelerate convergence:

$$A_{m-1} - \mu_m I = Q_m R_m, \quad R_m Q_m + \mu_m I = Q_m^* A_{m-1} Q_m = A_m,$$

where  $\mu_m \in \mathbb{C}$  is a shift chosen to approximate an eigenvalue.

18. Often it is convenient to take several steps at once:

**Algorithm 3. Explicit QR iteration of degree  $k$ .**

Choose  $k$  shifts  $\mu_1, \dots, \mu_k$ .

Let  $p(A) = (A - \mu_1 I)(A - \mu_2 I) \cdots (A - \mu_k I)$ .

Compute a QR decomposition  $p(A) = QR$ .

$A \leftarrow Q^* A Q$

19. A QR iteration of degree  $k$  is equivalent to  $k$  iterations of degree 1 with shifts  $\mu_1, \dots, \mu_k$  applied in succession in any order [Wat02]. Upper Hessenberg form is preserved. In practice  $k$  is never taken very big; typical values are 1, 2, 4, and 6.
20. One important application of multiple steps is to complex shifts applied to real matrices. Complex arithmetic is avoided by taking  $k = 2$  and shifts related by  $\mu_2 = \overline{\mu_1}$ .
21. The usual choice of  $k$  shifts is the set of eigenvalues of the lower right-hand  $k \times k$  submatrix of the current iterate. With this choice of shifts at each iteration, the entry  $a_{n-k+1,n-k}$  typically converges to zero quadratically [WE91], isolating a  $k \times k$  submatrix after only a few iterations. However, convergence is not guaranteed, and failures do occasionally occur. No shifting strategy that guarantees convergence in all cases is known. For discussions of shifting strategies and convergence see [Wat02] or [WE91].
22. After each iteration, all of the subdiagonal entries should be checked to see if any of them can be set to zero. The objective is to break the big problem into many small problems in as few iterations as possible. Once a submatrix of size  $1 \times 1$  has been isolated, an eigenvalue has been found. The eigenvalues of a  $2 \times 2$  submatrix can be found by careful use of the quadratic formula. Complex conjugate eigenvalues of real matrices are extracted in pairs.

23. The explicit  $QR$  iteration shown above is expensive and never used in practice. Instead the iteration is performed implicitly.

**Algorithm 4: Implicit  $QR$  iteration of degree  $k$  (chasing the bulge).**

```

Choose  $k$  shifts  $\mu_1, \dots, \mu_k$ .
 $\mathbf{x} \leftarrow \mathbf{e}_1$  % first column of identity matrix
for  $j = 1 : k$ 
     $\mathbf{x} \leftarrow (A - \mu_j I)\mathbf{x}$ 
end %  $\mathbf{x}$  is the first column of  $p(A)$ .
 $\hat{\mathbf{x}} \leftarrow \mathbf{x}_{1:k+1}$  %  $\mathbf{x}_{k+2:n} = 0$ 
Let  $U \in \mathbb{C}^{k+1 \times k+1}$  be unitary with  $U^* \hat{\mathbf{x}} = \alpha \mathbf{e}_1$ 
 $A_{1:k+1,1:n} \leftarrow U^* A_{1:k+1,1:n}$ 
 $A_{1:n,1:k+1} \leftarrow A_{1:n,1:k+1} U$ 
Return  $A$  to upper Hessenberg form as in Algorithm 2 (Fact 7).

```

24. The initial transformation in the implicit  $QR$  iteration disturbs the upper Hessenberg form of  $A$ , making a bulge in the upper left-hand corner. The size of the bulge is equal to  $k$ . In the case  $k = 2$ , the pattern of nonzeros is

$$\begin{bmatrix} * & * & * & * & * & * \\ * & * & * & * & * & * \\ * & * & * & * & * & * \\ * & * & * & * & * & * \\ & & & & * & * & * \\ & & & & & * & * \end{bmatrix}.$$

The subsequent reduction to Hessenberg form chases the bulge down through the matrix and off the bottom. The equivalence of the explicit and implicit  $QR$  iterations is demonstrated in [GV96, § 7.5] and [Wat02, § 5.7]. For this result it is crucial that the matrix is unreduced upper Hessenberg.

25. For a fixed small value of  $k$ , the implicit  $QR$  iteration requires only  $O(n^2)$  work. Typically only a small number of iterations, independent of  $n$ , are needed per eigenvalue found; the total number of iterations is  $O(n)$ . Thus, the implicit  $QR$  algorithm is considered to be an  $O(n^3)$  process.
26. The main unsymmetric  $QR$  routine in LAPACK [ABB99] is HSEQR, a multishift implicit  $QR$  algorithm with  $k = 6$ . For processing small submatrices ( $50 \times 50$  and under), HSEQR calls LAHQR, a multishift  $QR$  code with  $k = 2$ . Future versions of LAPACK will include improved  $QR$  routines that save work by doing aggressive early deflation [BBM02b] and make better use of cache by chasing bulges in bunches and aggregating the transforming matrices [BBM02a].
27. If eigenvectors are wanted, the aggregate similarity transformation matrix  $S$ , the product of all transformations from start to finish, must be accumulated.  $T = S^{-1}AS$ , where  $A$  is the original matrix and  $T$  is the final upper triangular matrix. In the real case,  $T$  will not quite be upper triangular. It is **quasi-triangular** with a  $2 \times 2$  block along the main diagonal for each complex conjugate pair of eigenvalues. This causes complications in the descriptions of the algorithms, but does not cause any practical problems.
28. The eigenvectors of  $T$  are computed by back substitution [Wat02, § 5.8]. For each eigenvector  $\mathbf{x}$  of  $T$ ,  $S\mathbf{x}$  is an eigenvector of  $A$ . The total additional cost of the eigenvector computation is  $O(n^3)$ . In LAPACK these tasks are performed by the routines HSEQR and TREVC.
29. Invariant subspaces can also be computed. The eigenvalues of  $A$  are  $\lambda_1 = t_{11}, \dots, \lambda_n = t_{nn}$ . If  $\lambda_1, \dots, \lambda_k$  are disjoint from  $\lambda_{k+1}, \dots, \lambda_n$ , then, because  $T$  is upper triangular, the first  $k$  columns of  $S$  span the invariant subspace associated with  $\{\lambda_1, \dots, \lambda_k\}$ .

30. If an invariant subspace associated with  $k$  eigenvalues that are not at the top of  $T$  is wanted, then those  $k$  eigenvalues must be moved to the top by a sequence of swapping operations. Each operation is a unitary similarity transformation that reverses the positions of two adjacent main-diagonal entries of  $T$ . The transformations are applied to  $S$  as well. Once the desired eigenvalues have been moved to the top, the first  $k$  columns of the transformed  $S$  span the desired invariant subspace. For details see [BD93] and [GV96, § 7.6]. In LAPACK these tasks are performed by the routines TREXC and TRSEN.
31. An important difference between the symmetric and unsymmetric eigenvalue problems is that in the unsymmetric case, the eigenvalues can be ill conditioned. That is, a small perturbation in the entries of  $A$  can cause a large change in the eigenvalues. Suppose  $\lambda$  is an eigenvalue of  $A$  of algebraic multiplicity 1, and let  $E$  be a perturbation that is small in the sense that  $\|E\|_2 \ll \|A\|_2$ . Then  $A + E$  has an eigenvalue  $\lambda + \delta$  near  $\lambda$ . A condition number for  $\lambda$  is the smallest number  $\kappa$  such that

$$|\delta| \leq \kappa \|E\|_2$$

for all small perturbations  $E$ . If  $\mathbf{x}$  and  $\mathbf{y}$  are eigenvectors of  $A$  and  $A^T$ , respectively, associated with  $\lambda$ , then [Wat02, § 6.5]

$$\kappa \approx \frac{\|\mathbf{x}\|_2 \|\mathbf{y}\|_2}{|\mathbf{y}^T \mathbf{x}|}.$$

If  $\kappa \gg 1$ ,  $\lambda$  is ill conditioned. If  $\kappa$  is not much bigger than 1,  $\lambda$  is well conditioned.

32. Condition numbers can also be defined for eigenvectors and invariant subspaces [GV96, § 7.2], [Wat02, § 6.5]. Eigenvectors associated with a tight cluster of eigenvalues are always ill conditioned. A more meaningful object is the invariant subspace associated with all of the eigenvalues in the cluster. This space will usually be well conditioned, even though the eigenvectors are ill conditioned. The LAPACK routines TRSNA and TRSEN compute condition numbers for eigenvalues, eigenvectors, and invariant subspaces.
33. The invariant subspace associated with  $\{\lambda_1, \dots, \lambda_k\}$  will certainly be ill conditioned if any of the eigenvalues  $\lambda_{k+1}, \dots, \lambda_n$  are close to any of  $\lambda_1, \dots, \lambda_k$ . A necessary (but not sufficient) condition for well conditioning is that  $\lambda_1, \dots, \lambda_k$  be well separated from  $\lambda_{k+1}, \dots, \lambda_n$ . A related practical fact is that if two eigenvalues are very close together, it may not be possible to swap them stably by LAPACK's TREXC.
34. (Performance) A 3.0 GHz Pentium 4 machine with 1 GB main memory and 1 MB cache computed the complete eigensystem of a random  $1000 \times 1000$  real matrix using MATLAB in 56 seconds. This included balancing, reduction to upper Hessenberg form, triangularization by the QR algorithm, and back solving for the eigenvectors. All computed eigenpairs  $(\lambda, \mathbf{v})$  satisfied  $\|A\mathbf{v} - \lambda\mathbf{v}\|_1 < 10^{-15} \|A\|_1 \|\mathbf{v}\|_1$ .
35. (Generalized eigenvalue problem) The steps for solving the dense, unsymmetric, generalized eigenvalue problem  $A\mathbf{v} = \lambda B\mathbf{v}$  are analogous to those for solving the standard problem. First (optionally) the pair  $(A, B)$  is balanced (by routine GGBAL in LAPACK). Then it is transformed by a strictly unitary equivalence to a condensed form in which  $A$  is upper Hessenberg and  $B$  is upper triangular. Then the QZ algorithm completes the reduction to triangular form. Details are given in [GV96, § 7.7] and [Wat02, § 6.7]. In LAPACK, the codes GGHRD and HGEQZ reduce the pair to Hessenberg-triangular form and perform the QZ iterations, respectively.
36. Once  $A$  has been reduced to triangular form, the eigenvalues are  $\lambda_j = a_{jj}/b_{jj}$ ,  $j = 1, \dots, n$ . The eigenvectors can be obtained by routines analogous to those used for the standard problem (LAPACK codes TGEVC and GGBAK), and condition numbers can be computed (LAPACK codes TGSNA and TGSEN).

**Examples:**

1. The matrix

$$A = \begin{bmatrix} -5.5849 \times 10^{-01} & -2.4075 \times 10^{+07} & -6.1644 \times 10^{+14} & 6.6275 \times 10^{+00} \\ -7.1724 \times 10^{-09} & -2.1248 \times 10^{+00} & -3.6183 \times 10^{+06} & 2.6435 \times 10^{-06} \\ -4.1508 \times 10^{-16} & -2.1647 \times 10^{-07} & 1.6229 \times 10^{-01} & -7.6315 \times 10^{-14} \\ 4.3648 \times 10^{-03} & 1.2614 \times 10^{+06} & -1.1986 \times 10^{+13} & -6.2002 \times 10^{-01} \end{bmatrix}$$

was balanced by Algorithm 1 (Fact 3) to produce

$$B = \begin{bmatrix} -0.5585 & -0.3587 & -1.0950 & 0.1036 \\ -0.4813 & -2.1248 & -0.4313 & 2.7719 \\ -0.2337 & -1.8158 & 0.1623 & -0.6713 \\ 0.2793 & 1.2029 & -1.3627 & -0.6200 \end{bmatrix}.$$

2. The matrix
- $B$
- of Example 1 was reduced to upper Hessenberg form by Algorithm 2 (Fact 7) to yield

$$H = \begin{bmatrix} -0.5585 & 0.7579 & 0.0908 & -0.8694 \\ 0.6036 & -3.2560 & -0.0825 & -1.8020 \\ 0 & 0.9777 & 1.2826 & -0.8298 \\ 0 & 0 & -1.5266 & -0.6091 \end{bmatrix}.$$

3. Algorithm 4 (Fact 23) was applied to the matrix
- $H$
- of Example 2, with
- $k = 1$
- and shift
- $\mu_1 = h_{44} = -0.6091$
- , to produce

$$\begin{bmatrix} -3.1238 & -0.5257 & 1.0335 & 1.6798 \\ -1.3769 & 0.3051 & -1.5283 & 0.1296 \\ 0 & -1.4041 & 0.3261 & -1.0462 \\ 0 & 0 & -0.0473 & -0.6484 \end{bmatrix}.$$

The process was repeated twice again (with  $\mu_1 = h_{44}$ ) to yield

$$\begin{bmatrix} -3.1219 & 0.7193 & 1.2718 & -1.4630 \\ 0.8637 & 1.8018 & 0.0868 & -0.3916 \\ 0 & 0.6770 & -1.2385 & 1.1642 \\ 0 & 0 & -0.0036 & -0.5824 \end{bmatrix}$$

and

$$\begin{bmatrix} -3.0939 & -0.6040 & 1.3771 & 1.2656 \\ -0.8305 & 1.8532 & -0.3517 & 0.5050 \\ 0 & 0.2000 & -1.3114 & -1.3478 \\ 0 & 0 & 0.00003 & -0.5888 \end{bmatrix}.$$

The (4,4) entry is an eigenvalue of  $A$  correct to four decimal places.

This matrix happens to have a real eigenvalue. If it had not, Algorithm 4 could have been used with  $k = 2$  to extract the complex eigenvalues in pairs.

4. For an example of an ill-conditioned eigenvalue (Fact 31) consider a matrix

$$A = \begin{bmatrix} 1 & t \\ 0 & 1 + \epsilon \end{bmatrix},$$

where  $t$  is large or  $\epsilon$  is small or both. Since  $A$  is upper triangular, its eigenvalues are 1 and  $1 + \epsilon$ .

Eigenvectors of  $A$  and  $A^T$  associated with the eigenvalue 1 are

$$\mathbf{x} = \begin{bmatrix} 1 \\ 0 \end{bmatrix} \quad \text{and} \quad \mathbf{y} = \begin{bmatrix} 1 \\ -t/\epsilon \end{bmatrix},$$

respectively. Since  $\|\mathbf{x}\|_2 = 1$ ,  $\|\mathbf{y}\|_2 = \sqrt{1 + t^2/\epsilon^2}$ , and  $|\mathbf{y}^T \mathbf{x}| = 1$ , the condition number of eigenvalue  $\lambda = 1$  is  $\kappa = \sqrt{1 + t^2/\epsilon^2} \approx t/\epsilon$ . Thus if, for example,  $t = 10^7$  and  $\epsilon = 10^{-7}$ , we have  $\kappa \approx 10^{14}$ .

5. This example illustrates Fact 32 on the ill conditioning of eigenvectors associated with a tight cluster of eigenvalues. Given a positive number  $\epsilon$  that is as small as you please, the matrices

$$A_1 = \begin{bmatrix} 2 + \epsilon & 0 & 0 \\ 0 & 2 - \epsilon & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

and

$$A_2 = \begin{bmatrix} 2 & \epsilon & 0 \\ \epsilon & 2 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

both have eigenvalues 1,  $2 + \epsilon$ , and  $2 - \epsilon$ , and they are very close together:  $\|A_1 - A_2\|_2 = \sqrt{2}\epsilon$ . However, unit eigenvectors associated with clustered eigenvalues  $2 + \epsilon$  and  $2 - \epsilon$  for  $A_1$  are

$$\mathbf{e}_1 = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \quad \text{and} \quad \mathbf{e}_2 = \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix},$$

while unit eigenvectors for  $A_2$  are

$$\frac{1}{\sqrt{2}} \begin{bmatrix} 1 \\ 1 \\ 0 \end{bmatrix} \quad \text{and} \quad \frac{1}{\sqrt{2}} \begin{bmatrix} 1 \\ -1 \\ 0 \end{bmatrix}.$$

Thus, the tiny perturbation of order  $\epsilon$  from  $A_1$  to  $A_2$  changes the eigenvectors completely; the eigenvectors are ill conditioned. In contrast the two-dimensional invariant subspace associated with the cluster  $2 + \epsilon, 2 - \epsilon$  is  $\text{Span}(\mathbf{e}_1, \mathbf{e}_2)$  for both  $A_1$  and  $A_2$ , and it is well conditioned.

### 43.3 Sparse Matrix Techniques

---

If the matrix  $A$  is large and sparse and just a few eigenvalues are needed, sparse matrix techniques are appropriate. Some examples of common tasks are: (1) find the few eigenvalues of largest modulus, (2) find the few eigenvalues with largest real part, and (3) find the few eigenvalues nearest some target value  $\tau$ . The corresponding eigenvectors might also be wanted. These tasks are normally accomplished by computing the low-dimensional invariant subspace associated with the desired eigenvalues. Then the information about the eigenvalues and eigenvectors is extracted from the invariant subspace.

The most widely used method for the sparse unsymmetric eigenvalue problem is the implicitly restarted Arnoldi method, as implemented in ARPACK [LSY98], which is discussed in Chapter 76. A promising variant is the Krylov–Schur algorithm of Stewart [Ste01]. MATLAB’s sparse eigenvalue command “eigs” calls ARPACK.

**Definitions:**

Given a subspace  $\mathcal{S}$  of  $\mathbb{C}^n$ , a vector  $\mathbf{v} \in \mathcal{S}$  is called a **Ritz vector** of  $A$  from  $\mathcal{S}$  if there is a  $\theta \in \mathbb{C}$  such that  $A\mathbf{v} - \theta\mathbf{v} \perp \mathcal{S}$ . The scalar  $\theta$  is the **Ritz value** associated with  $\mathcal{S}$ . The pair  $(\theta, \mathbf{v})$  is a **Ritz pair**.

**Facts:**

- [Wat02, § 6.1] Let  $\mathbf{v}_1, \dots, \mathbf{v}_m$  be a basis for a subspace  $\mathcal{S}$  of  $\mathbb{C}^n$ , and let  $V = [\mathbf{v}_1 \cdots \mathbf{v}_m]$ . Then  $\mathcal{S}$  is invariant under  $A$  if and only if there is a  $B \in \mathbb{C}^{m \times m}$  such that  $AV = VB$ .
- [Wat02, § 6.1] If  $AV = VB$ , then the eigenvalues of  $B$  are eigenvalues of  $A$ . If  $\mathbf{x}$  is an eigenvector of  $B$  associated with eigenvalue  $\mu$ , then  $V\mathbf{x}$  is an eigenvector of  $A$  associated with  $\mu$ .
- [Wat02, § 6.4] Let  $\mathbf{v}_1, \dots, \mathbf{v}_m$  be an orthonormal basis of  $\mathcal{S}$ ,  $V = [\mathbf{v}_1 \cdots \mathbf{v}_m]$ , and  $B = V^*AV$ . Then the Ritz values of  $A$  associated with  $\mathcal{S}$  are exactly the eigenvalues of  $B$ . If  $(\theta, \mathbf{x})$  is an eigenpair of  $B$ , then  $(\theta, V\mathbf{x})$  is a Ritz pair of  $A$ , and conversely.
- If  $A$  is very large and sparse, it is essential to store  $A$  in a sparse data structure, in which only the nonzero entries of  $A$  are stored. One simple structure stores two integers  $n$  and  $nnz$ , which represent the dimension of the matrix and the number of nonzeros in the matrix, respectively. The matrix entries are stored in an array  $ent$  of length  $nnz$ , and the row and column indices are stored in two integer arrays of length  $nnz$  called  $row$  and  $col$ , respectively. For example, if the nonzero entry  $a_{ij}$  is stored in  $ent(m)$ , then this is indicated by setting  $row(m) = i$  and  $col(m) = j$ . The space needed to store a matrix in this data structure is proportional to  $nnz$ .
- Many operations that are routinely applied to dense matrices are impossible if the matrix is stored sparsely. Similarity transformations are out of the question because they quickly turn the zeros to nonzeros, transforming the sparse matrix to a full matrix.
- One operation that is always possible is to multiply the matrix by a vector. This requires one pass through the data structure, and the work is proportional to  $nnz$ .

**Algorithm 5. Sparse Matrix-Vector Multiply.** Multiply  $A$  by  $\mathbf{x}$  and store the result in  $\mathbf{y}$ .

```

 $\mathbf{y} \leftarrow \mathbf{0}$ 
for  $m = 1 : nnz$ 
    [ $\mathbf{y}(row(m)) \leftarrow \mathbf{y}(row(m)) + ent(m) * \mathbf{x}(col(m))$ ]
end

```

- Because the matrix-vector multiply is so easy, many sparse matrix methods access the matrix  $A$  in only this way. At each step,  $A$  is multiplied by one or several vectors, and this is the only way  $A$  is used.
- The following standard methodology is widely used. A starting vector  $\mathbf{v}_1$  is chosen, and the algorithm adds one vector per step, so that after  $j - 1$  steps it has produced  $j$  orthonormal vectors  $\mathbf{v}_1, \dots, \mathbf{v}_j$ . Let  $V_j = [\mathbf{v}_1, \dots, \mathbf{v}_j] \in \mathbb{C}^{n \times j}$  and let  $\mathcal{S}_j = \text{Span}(V_j) = \text{Span}(\mathbf{v}_1, \dots, \mathbf{v}_j)$ . The  $j$ th step uses information from  $\mathcal{S}_j$  to produce  $\mathbf{v}_{j+1}$ . The Ritz values of  $A$  associated with  $\mathcal{S}_j$  are the eigenvalues of the  $j \times j$  matrix  $B_j = V_j^*AV_j$ . The Ritz pair  $(\theta, \mathbf{w})$  for which  $\theta$  has the largest modulus is an estimate of the largest eigenvalue of  $A$ , and  $\mathbf{x} = V_j\mathbf{w}$  is an estimate of the associated eigenvector. The residual  $\mathbf{r}_j = A\mathbf{x} - \mathbf{x}\theta$  gives an indication of the quality of the approximate eigenpair.
- Several methods use the residual  $\mathbf{r}_j$  to help decide on the next basis vector  $\mathbf{v}_{j+1}$ . These methods typically use  $\mathbf{r}_j$  to determine another vector  $\mathbf{s}_j$ , which is then orthonormalized against  $\mathbf{v}_1, \dots, \mathbf{v}_j$  to produce  $\mathbf{v}_{j+1}$ . The choice  $\mathbf{s}_j = \mathbf{r}_j$  leads to a method that is equivalent to the Arnoldi process. However, Arnoldi's process should not be implemented this way in practice. (See Chapter 44.) The choice  $\mathbf{s}_j = (D - \theta I)^{-1}\mathbf{r}_j$ , where  $D$  is the diagonal part of  $A$ , gives Davidson's method. The Jacobi–Davidson methods have more elaborate ways of choosing  $\mathbf{s}_j$ . (See [BDD00, § 7.12] for details.)
- Periodic purging is employed to keep the dimension of the active subspace from becoming too large. Given  $m$  vectors, the purging process keeps the most promising  $k$ -dimensional subspace of

$\mathcal{S}_m = \text{Span}(V_m)$  and discards the rest. Again, let  $B_m = V_m^* A V_m$ , and let  $B_m = U_m T_m U_m^*$  be a unitary similarity transformation to upper triangular form. The Ritz values lie on the main diagonal of  $T_m$  and can be placed in any order. Place the  $k$  most promising Ritz values at the top. Let  $\tilde{V}_m = V_m U_m$ , and let  $\tilde{V}_k$  denote the  $n \times k$  submatrix of  $\tilde{V}_m$  consisting of the first  $k$  columns. The columns of  $\tilde{V}_k$  are the vectors that are kept.

11. After each purge, the algorithm can be continued from step  $k$ . Once the basis has been expanded back to  $m$  vectors, another purge can be carried out. After a number of cycles of expansion and purging, the invariant subspace associated with the desired eigenvalues will have been found.
12. When purging is carried out in connection with the Arnoldi process, it is called an implicit restart, and there are some extra details. (See Chapter 44 and [Ste01]).
13. The implicitly restarted Arnoldi process is well suited for computing the eigenvalues on the periphery of the spectrum of  $A$ . Thus, it is good for computing the eigenvalues of maximum modulus or those of maximum or minimum real part.
14. For computing interior eigenvalues, the shift-and-invert strategy is often helpful. Suppose the eigenvalues nearest some target value  $\tau$  are sought. The matrix  $(A - \tau I)^{-1}$  has the same eigenvectors as  $A$ , but the eigenvalues are different. If  $\lambda_1, \dots, \lambda_n$  are the eigenvalues of  $A$ , then  $(\lambda_1 - \tau)^{-1}, \dots, (\lambda_n - \tau)^{-1}$  are the eigenvalues of  $(A - \tau I)^{-1}$ . The eigenvalues of  $(A - \tau I)^{-1}$  of largest modulus correspond to the eigenvalues of  $A$  closest to  $\tau$ . These can be computed by applying the implicitly restarted Arnoldi process to  $(A - \tau I)^{-1}$ . This is feasible whenever operations of the type  $\mathbf{w} \leftarrow (A - \tau I)^{-1} \mathbf{x}$  can be performed efficiently. If a sparse decomposition  $A - \tau I = PLU$  can be computed, as described in Chapter 41, then that decomposition can be used to perform the operation  $\mathbf{w} \leftarrow (A - \tau I)^{-1} \mathbf{x}$  by back solves. If the  $LU$  factors take up too much space to fit into memory, this method cannot be used.
15. Another option for solving  $(A - \tau I)\mathbf{w} = \mathbf{x}$  is to use an iterative method, as described in Chapter 41. However, this is very computationally intensive, as the systems must be solved to high accuracy if the eigenvalues are to be computed accurately.
16. The shift-and-invert strategy can also be applied to the generalized eigenvalue problem  $A\mathbf{v} = \lambda B\mathbf{v}$ . The implicitly restarted Arnoldi process is applied to the operator  $(A - \tau B)^{-1}B$  to find eigenvalues near  $\tau$ .
17. If the matrix is too large for the shift-and-invert strategy, Jacobi–Davidson methods can be considered. These also require the iterative solution of linear systems. In this family of methods, inaccurate solution of the linear systems may slow convergence of the algorithm, but it will not cause the eigenvalues to be computed inaccurately.
18. Arnoldi-based and Jacobi–Davidson algorithms are described in [BDD00]. A brief overview is given in [Wat02, § 6.4]. Balancing of sparse matrices is discussed in [BDD00, § 7.2].

The implicitly restarted Arnoldi method (IRAM) [Sor92] is a variant of Arnoldi's method for computing a selected subset of eigenvalues and corresponding eigenvectors for large matrices. Implicit restarting is a synthesis of the implicitly shifted QR iteration and the Arnoldi process that effectively limits the dimension of the Krylov subspace required to obtain good approximations to desired eigenvalues. The space is repeatedly expanded and contracted with each new Krylov subspace generated by an updated starting vector obtained by implicit application of a matrix polynomial to the old starting vector. This process is designed to filter out undesirable components in the starting vector in a way that enables convergence to the desired invariant subspace. This method has been implemented and is freely available as ARPACK. The MATLAB<sup>®</sup> function `eigs` is based upon ARPACK. Use of this software is described in Chapter 76.

In this article, all matrices, vectors, and scalars are complex and the algorithms are phrased in terms of complex arithmetic. However, when the matrix (or matrix pair) happens to be real then the computations may be organized so that only real arithmetic is required. Multiplication of a vector  $\mathbf{x}$  by a scalar  $\lambda$  is denoted by  $\mathbf{x}\lambda$  so that the eigenvector–eigenvalue relation is  $A\mathbf{x} = \mathbf{x}\lambda$ . This convention provides for direct generalizations to the more general invariant subspace relations  $AX = XH$ , where  $X$  is an  $n \times k$  matrix and  $H$  is a  $k \times k$  matrix with  $k < n$ . More detailed discussion of all facts and definitions may be found in the overview article [Sor02].

## 44.1 Krylov Subspace Projection

---

The classic power method is the simplest way to compute the dominant eigenvalue and corresponding eigenvector of a large matrix. Krylov subspace projection provides a way to extract additional eigen-information from the power method iteration by considering all possible linear combinations of the sequence of vectors produced by the power method.

**Definitions:**

The best approximate eigenvectors and corresponding eigenvalues are extracted from the **Krylov subspace**

$$\mathcal{K}_k(A, \mathbf{v}) := \text{span}\{\mathbf{v}, A\mathbf{v}, A^2\mathbf{v}, \dots, A^{k-1}\mathbf{v}\}.$$

The approximate eigenpairs are constructed through a Galerkin condition. An approximate eigenvector  $\mathbf{x} \in \mathcal{S}$  is called a **Ritz vector** with corresponding **Ritz value**  $\theta$  if the **Galerkin condition**

$$\mathbf{w}^*(A\mathbf{x} - \mathbf{x}\theta) = 0, \text{ for all } \mathbf{w} \in \mathcal{K}_k(A, \mathbf{v})$$

is satisfied.

**Facts:** [Sor92], [Sor02]

1. Every  $\mathbf{w} \in \mathcal{K}_k$  is of the form  $\mathbf{w} = \phi(A)\mathbf{v}_1$  for some polynomial  $\phi$  of degree less than  $k$  and  $\mathcal{K}_{j-1} \subset \mathcal{K}_j$  for  $j = 2, 3, \dots, k$ .
2. If a sequence of orthogonal bases  $V_k = [\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k]$  has been constructed with  $\mathcal{K}_k = \text{range}(V_k)$  and  $V_k^* V_k = I_k$ , then a new basis vector  $\mathbf{v}_{k+1}$  is obtained by the **projection formulas**

$$\begin{aligned} \mathbf{h}_k &= V_k^* A \mathbf{v}_k, \\ \mathbf{f}_k &= A \mathbf{v}_k - V_k \mathbf{h}_k, \\ \mathbf{v}_{k+1} &= \mathbf{f}_k / \|\mathbf{f}_k\|_2. \end{aligned}$$

The vector  $\mathbf{h}_k$  is constructed to achieve  $V_k^* \mathbf{f}_k = 0$  so that  $\mathbf{v}_{k+1}$  is a vector of unit length that is orthogonal to the columns of  $V_k$ .

3. The columns of  $V_{k+1} = [V_k, \mathbf{v}_{k+1}]$  provide an orthonormal basis for  $\mathcal{K}_{k+1}(A, \mathbf{v}_1)$ .
4. The basis vectors are of the form  $\mathbf{v}_j = \phi_{j-1}(A)\mathbf{v}_1$ , where  $\phi_{j-1}$  is a polynomial of degree  $j - 1$  for each  $j = 1, 2, \dots, k + 1$ .
5. This construction fails when  $\mathbf{f}_k = 0$ , but then

$$AV_k = V_k H_k,$$

where  $H_k = V_k^* A V_k = [\mathbf{h}_1, \mathbf{h}_2, \dots, \mathbf{h}_k]$  (with a slight abuse of notation). This “good breakdown” happens precisely when  $\mathcal{K}_k$  is an invariant subspace of  $A$ . Hence,  $\sigma(H_k) \subset \sigma(A)$ .

## 44.2 The Arnoldi Factorization

---

The projection formulas given above result in the fundamental Arnoldi method for constructing an orthonormal basis for  $\mathcal{K}_k$ .

**Definitions:**

The relations between the matrix  $A$ , the basis matrix  $V_k$  and the residual vector  $\mathbf{f}_k$  may be concisely expressed as

$$AV_k = V_k H_k + \mathbf{f}_k \mathbf{e}_k^*,$$

where  $V_k \in \mathbb{C}^{n \times k}$  has orthonormal columns,  $V_k^* \mathbf{f}_k = 0$ , and  $H_k = V_k^* A V_k$  is a  $k \times k$  upper Hessenberg matrix with nonnegative subdiagonal elements.

The above expression shall be called a **k-step Arnoldi factorization** of  $A$ . When  $A$  is Hermitian,  $H_k$  will be real, symmetric, and tridiagonal and then the relation is called a **k-step Lanczos factorization** of  $A$ . The columns of  $V_k$  are referred to as **Arnoldi vectors** or **Lanczos vectors**, respectively. The Hessenberg matrix  $H_k$  is called **unreduced** if all subdiagonal elements are nonzero.

**Facts:** [Sor92], [Sor02]

1. The explicit steps needed to form a  $k$ -step Arnoldi factorization are shown in Algorithm 1.

**Algorithm 1:  $k$ -step Arnoldi factorization.** A square matrix  $A$ , a nonzero vector  $\mathbf{v}$  and a positive integer  $k \leq n$  are input.  
 Output is an  $n \times k$  ortho-normal matrix  $V_k$ , an upper Hessenberg matrix  $H_k$  and a vector  $\mathbf{f}_k$  such that  $AV_k = V_k H_k + \mathbf{f}_k \mathbf{e}_k^T$ .

```

 $\mathbf{v}_1 = \mathbf{v} / \|\mathbf{v}\|_2;$ 
 $\mathbf{w} = A\mathbf{v}_1; \alpha_1 = \mathbf{v}_1^* \mathbf{w};$ 
 $\mathbf{f}_1 \leftarrow \mathbf{w} - \mathbf{v}_1 \alpha_1;$ 
 $V_1 \leftarrow [\mathbf{v}_1]; H_1 \leftarrow [\alpha_1];$ 
for  $j = 1, 2, 3, \dots, k - 1,$ 
     $\beta_j = \|\mathbf{f}_j\|_2; \mathbf{v}_{j+1} \leftarrow \mathbf{f}_j / \beta_j;$ 
     $V_{j+1} \leftarrow [V_j, \mathbf{v}_{j+1}];$ 

     $\hat{H}_j \leftarrow \begin{bmatrix} H_j \\ \beta_j \mathbf{e}_j^* \end{bmatrix};$ 

     $\mathbf{w} \leftarrow A\mathbf{v}_{j+1};$ 
     $\mathbf{h} \leftarrow V_{j+1}^* \mathbf{w};$ 
     $\mathbf{f}_{j+1} \leftarrow \mathbf{w} - V_{j+1} \mathbf{h};$ 
     $H_{j+1} \leftarrow [\hat{H}_j, \mathbf{h}];$ 
end
    
```

2. Ritz pairs satisfying the Galerkin condition (see Section 44.1) are derived from the eigenpairs of the small projected matrix  $H_k$ . If  $H_k \mathbf{y} = \mathbf{y} \theta$  with  $\|\mathbf{y}\|_2 = 1$ , then the vector  $\mathbf{x} = V_k \mathbf{y}$  is a vector of unit norm that satisfies

$$\|A\mathbf{x} - \mathbf{x}\theta\|_2 = \|(AV_k - V_k H_k)\mathbf{y}\|_2 = |\beta_k \mathbf{e}_k^* \mathbf{y}|,$$

where  $\beta_k = \|\mathbf{f}_k\|_2$ .

3. If  $(\mathbf{x}, \theta)$  is a Ritz pair constructed as shown in Fact 2, then

$$\theta = \mathbf{y}^* H_k \mathbf{y} = (V_k \mathbf{y})^* A (V_k \mathbf{y}) = \mathbf{x}^* A \mathbf{x}$$

is always a Rayleigh quotient (assuming  $\|\mathbf{y}\|_2 = 1$ ).

4. The Rayleigh quotient residual  $\mathbf{r}(\mathbf{x}) := A\mathbf{x} - \mathbf{x}\theta$  satisfies  $\|\mathbf{r}(\mathbf{x})\|_2 = |\beta_k \mathbf{e}_k^* \mathbf{y}|$ . When  $A$  is Hermitian, this relation provides computable rigorous bounds on the accuracy of the approximate eigenvalues [Par80]. When  $A$  is non-Hermitian, one needs additional sensitivity information. Nonnormality effects may corrupt the accuracy. In exact arithmetic, these Ritz pairs are eigenpairs of  $A$  whenever  $\mathbf{f}_k = 0$ . However, even with a very small residual these may be far from actual eigenvalues when  $A$  is highly nonnormal.
5. The orthogonalization process is based upon the *classical Gram–Schmidt* (CGS) scheme. This process is notoriously unstable and will fail miserably in this application without modification.

FIGURE 44.1 DGKS Correction.

The iterative refinement technique proposed by Daniel, Gragg, Kaufman, and Stewart (DGKS) [DGK76] provides an excellent way to construct a vector  $\mathbf{f}_{j+1}$  that is numerically orthogonal to  $V_{j+1}$ . It amounts to computing a correction

$$\mathbf{c} = V_{j+1}^* \mathbf{f}_{j+1}; \quad \mathbf{f}_{j+1} \leftarrow \mathbf{f}_{j+1} - V_{j+1} \mathbf{c}; \quad \mathbf{h} \leftarrow \mathbf{h} + \mathbf{c};$$

just after computing  $\mathbf{f}_{j+1}$  if necessary, i.e., when  $\mathbf{f}_{j+1}$  is not sufficiently orthogonal to the columns of  $V_{j+1}$ . This formulation is crucial to both accuracy and performance. It provides numerically orthogonal basis vectors and it may be implemented using the Level 2 BLAS operation `_GEMV` [DDH88]. This provides a significant performance advantage on virtually every platform from workstation to supercomputer.

6. The *modified Gram-Schmidt* (MGS) process will generally fail to produce orthogonal vectors and cannot be implemented with Level 2 BLAS in this setting. ARPACK relies on a restarting scheme wherein the goal is to reach a state of dependence in order to obtain  $\mathbf{f}_k = 0$ . MGS is completely inappropriate for this situation, but the CGS with DGKS correction performs beautifully.
7. Failure to maintain orthogonality leads to numerical difficulties in the Lanczos/Arnoldi process. Loss of orthogonality typically results in the presence of spurious copies of the approximate eigenvalue.

### Examples:

1. Figure 44.1 illustrates how the DGKS mechanism works. When the vector  $\mathbf{w} = A\mathbf{v}$  is nearly in the  $\text{range}(V)$  then the projection  $V\mathbf{h}$  is possibly inaccurate, but vector  $\mathbf{f} = \mathbf{w} - V\mathbf{h}$  is not close to  $\text{range}(V)$  and can be safely orthogonalized to compute the correction  $\mathbf{c}$  accurately. The corrected vector  $\mathbf{f} \leftarrow \mathbf{f} - V\mathbf{c}$  will be numerically orthogonal to the columns of  $V$  in almost all cases. Additional corrections might be necessary in very unusual cases.

## 44.3 Restarting the Arnoldi Process

The number of Arnoldi steps required to calculate eigenvalues of interest to a specified accuracy cannot be pre-determined. Usually, eigen-information of interest does not appear until  $k$  gets very large. In Figure 44.2 the distribution in the complex plane of the Ritz values (shown in grey dots) is compared with the spectrum (shown as  $+s$ ). The original matrix is a normally distributed random matrix of order 200 and the Ritz values are from a ( $k = 50$ )-step Arnoldi factorization. Eigenvalues at the extremes of the spectrum of  $A$  are clearly better approximated than the interior eigenvalues.

For large problems, it is intractable to compute and store a numerically orthogonal basis set  $V_k$  for large  $k$ . Storage requirements are  $\mathcal{O}(n \cdot k)$  and arithmetic costs are  $\mathcal{O}(n \cdot k^2)$  flops to compute the basis vectors

FIGURE 44.2 Typical distribution of Ritz values.

plus  $\mathcal{O}(k^3)$  flops to compute the eigensystem of  $H_k$ . Thus, restarting schemes have been developed that iteratively replace the starting vector  $\mathbf{v}_1$  with an “improved” starting vector  $\mathbf{v}_1^+$  and then compute a new Arnoldi factorization of fixed length  $k$  to limit the costs. Beyond this, there is an interest in forcing  $\mathbf{f}_k = 0$  and, thus, producing an invariant subspace. However, this is useful only if the spectrum  $\sigma(H_k)$  has the desired properties.

The structure of  $\mathbf{f}_k$  suggests the restarting strategy. The goal will be to iteratively force  $\mathbf{v}_1$  to be a linear combination of eigenvectors of interest.

**Facts:** [Sor92], [Sor02]

1. If  $\mathbf{v} = \sum_{j=1}^k \mathbf{q}_j \gamma_j$  where  $A\mathbf{q}_j = \mathbf{q}_j \lambda_j$  and

$$A\mathbf{v} = H\mathbf{v} + \mathbf{f}_k^T$$

is a  $k$ -step Arnoldi factorization with unreduced  $H$ , then  $\mathbf{f} = 0$  and  $\sigma(H) = \{\lambda_1, \lambda_2, \dots, \lambda_k\}$ .

2. Since  $\mathbf{v}_1$  determines the subspace  $\mathcal{K}_k$ , this vector must be constructed to select the eigenvalues of interest. The starting vector must be forced to become a linear combination of eigenvectors that span the desired invariant subspace. There is a necessary and sufficient condition for  $\mathbf{f}$  to vanish that involves Schur vectors and does not require diagonalizability.

## 44.4 Polynomial Restarting

Polynomial restarting strategies replace  $\mathbf{v}_1$  by

$$\mathbf{v}_1 \leftarrow \psi(A)\mathbf{v}_1,$$

where  $\psi$  is a polynomial constructed to damp unwanted components from the starting vector. If  $\mathbf{v}_1 = \sum_{j=1}^n \mathbf{q}_j \gamma_j$  where  $A\mathbf{q}_j = \mathbf{q}_j \lambda_j$ , then

$$\mathbf{v}_1^+ = \psi(A)\mathbf{v}_1 = \sum_{j=1}^n \mathbf{q}_j \gamma_j \psi(\lambda_j),$$

where the polynomial  $\psi$  has also been normalized to give  $\|\mathbf{v}_1\|_2 = 1$ . Motivated by the structure of  $\mathbf{f}_k$ , the idea is to force the starting vector to be closer and closer to an invariant subspace by constructing  $\psi$  so that  $|\psi(\lambda)|$  is as small as possible on a region containing the unwanted eigenvalues.

An iteration is defined by repeatedly restarting until the updated Arnoldi factorization eventually contains the desired eigenspace. An explicit scheme for restarting was proposed by Saad in [Saa92]. One of the more successful choices is to use Chebyshev polynomials in order to damp unwanted eigenvector components.

### Definitions:

The polynomial  $\psi$  is sometimes called a **filter polynomial**, which may also be specified by its roots. The roots of the filter polynomial may also be referred to as **shifts**. This terminology refers to their usage in an implicitly shifted QR-iteration. One straightforward choice of shifts is to find the eigenvalues  $\theta_j$  of the projected matrix  $H$  and sort these into two sets according to a given criterion: the wanted set  $\mathcal{W} = \{\theta_j : j = 1, 2, \dots, k\}$  and the unwanted set  $\mathcal{U} = \{\theta_j : j = k + 1, k + 2, \dots, k + p\}$ . Then one specifies the polynomial  $\psi$  as the polynomial with these unwanted Ritz values as its roots. This choice of roots, called **exact shifts**, was suggested in [Sor92].

**Facts:** [Sor92], [Sor02]

1. Morgan [Mor96] found a remarkable property of this strategy. If exact shifts are used to define  $\psi(\tau) = \prod_{j=k+1}^{k+p} (\tau - \theta_j)$  and if  $\hat{\mathbf{q}}_j$  denotes a Ritz vector of unit length corresponding to  $\theta_j$ , then the Krylov space generated by  $\mathbf{v}_1^+ = \psi(A)\mathbf{v}_1$  satisfies

$$\mathcal{K}_m(A, \mathbf{v}_1^+) = \text{Span}\{\hat{\mathbf{q}}_1, \hat{\mathbf{q}}_2, \dots, \hat{\mathbf{q}}_k, A\hat{\mathbf{q}}_j, A^2\hat{\mathbf{q}}_j, \dots, A^p\hat{\mathbf{q}}_j\},$$

for any  $j = 1, 2, \dots, k$ . Thus, polynomial restarting with exact shifts will generate a new subspace that contains all of the possible choices of updated starting vector consisting of linear combinations of the wanted Ritz vectors.

2. Exact shifts tend to perform remarkably well in practice and have been adopted as the shift selection of choice in ARPACK when no other information is available. However, there are many other possibilities such as the use of Leja points for certain containment regions or intervals [BCR96].

## 44.5 Implicit Restarting

There are a number of schemes used to implement polynomial restarting. We shall focus on an implicit restarting scheme.

### Definitions:

A straightforward way to implement polynomial restarting is to explicitly construct the starting vector  $\mathbf{v}_1^+ = \psi(A)\mathbf{v}_1$  by applying  $\psi(A)$  through a sequence of matrix-vector products. This is called **explicit restarting**. A more efficient and numerically stable alternative is **implicit restarting**. This technique applies a sequence of implicitly shifted QR steps to an  $m$ -step Arnoldi or Lanczos factorization to obtain a truncated form of the implicitly shifted QR-iteration.

On convergence, the IRAM iteration (see Algorithm 2) gives an orthonormal matrix  $V_k$  and an upper Hessenberg matrix  $H_k$  such that  $AV_k \approx V_k H_k$ . If  $H_k Q_k = Q_k R_k$  is a Schur decomposition of  $H_k$ , then we call  $\hat{V}_k \equiv V_k Q_k$  a **Schur basis** for the Krylov subspace  $\mathcal{K}_k(A, \mathbf{v}_1)$ . Note that if  $AV_k = V_k H_k$  exactly, then  $\hat{V}_k$  would form the leading  $k$  columns of a unitary matrix  $\hat{V}$  and  $R_k$  would form the leading  $k \times k$  block of an upper triangular matrix  $R$ , where  $A\hat{V} = \hat{V}R$  is a complete Schur decomposition. We refer to this as a **partial Schur decomposition** of  $A$ .

**Algorithm 2: IRAM iteration**

Input is an  $n \times k$  ortho-normal matrix  $V_k$ , an upper Hessenberg matrix  $H_k$  and a vector  $\mathbf{f}_k$  such that  $AV_k = V_k H_k + \mathbf{f}_k \mathbf{e}_k^T$ .

Output is an  $n \times k$  ortho-normal matrix  $V_k$ , an upper triangular matrix  $H_k$  such that  $AV_k = V_k H_k$ .

**repeat until** convergence,

Beginning with the  $k$ -step factorization,  
apply  $p$  additional steps of the Arnoldi process  
to compute an  $m = k + p$  step Arnoldi factorization

$$AV_m = V_m H_m + \mathbf{f}_m \mathbf{e}_m^* .$$

Compute  $\sigma(H_m)$  and select  $p$  shifts  $\mu_1, \mu_2, \dots, \mu_p$ ;

$$Q = I_m;$$

**for**  $j = 1, 2, \dots, p$ ,

$$\text{Factor } [Q_j, R_j] = \text{qr}(H_m - \mu_j I);$$

$$H_m \leftarrow Q_j^* H_m Q_j;$$

$$Q \leftarrow Q Q_j;$$

**end**

$$\hat{\beta}_k = H_m(k+1, k); \sigma_k = Q(m, k);$$

$$\mathbf{f}_k \leftarrow \mathbf{v}_{k+1} \hat{\beta}_k + \mathbf{f}_m \sigma_k;$$

$$V_k \leftarrow V_m Q(:, 1:k); H_k \leftarrow H_m(1:k, 1:k);$$

**end**

**Facts:** [Sor92], [Sor02]

1. Implicit restarting avoids numerical difficulties and storage problems normally associated with Arnoldi and Lanczos processes. The algorithm is capable of computing a few ( $k$ ) eigenvalues with user specified features such as largest real part or largest magnitude using  $2nk + \mathcal{O}(k^2)$  storage. The computed Schur basis vectors for the desired  $k$ -dimensional eigenspace are numerically orthogonal to working precision.
2. Desired eigen-information from a high-dimensional Krylov space is continually compressed into a fixed size  $k$ -dimensional subspace through an implicitly shifted QR mechanism. An Arnoldi factorization of length  $m = k + p$ ,

$$AV_m = V_m H_m + \mathbf{f}_m \mathbf{e}_m^*,$$

is compressed to a factorization of length  $k$  that retains the eigen-information of interest. Then the factorization is expanded once more to  $m$ -steps and the compression process is repeated.

3. QR steps are used to apply  $p$  linear polynomial factors  $A - \mu_j I$  implicitly to the starting vector  $\mathbf{v}_1$ . The first stage of this shift process results in

$$AV_m^+ = V_m^+ H_m^+ + \mathbf{f}_m \mathbf{e}_m^* Q,$$

where  $V_m^+ = V_m Q$ ,  $H_m^+ = Q^* H_m Q$ , and  $Q = Q_1 Q_2 \cdots Q_p$ . Each  $Q_j$  is the orthogonal matrix associated with implicit application of the shift  $\mu_j = \theta_{k+j}$ . Since each of the matrices  $Q_j$  is Hessenberg, it turns out that the first  $k-1$  entries of the vector  $\mathbf{e}_m^* Q$  are zero (i.e.,  $\mathbf{e}_m^* Q = [\sigma \mathbf{e}_k^T, \hat{\mathbf{q}}^*]$ ). Hence, the leading  $k$  columns remain in an Arnoldi relation and provide an updated  $k$ -step Arnoldi factorization

$$AV_k^+ = V_k^+ H_k^+ + \mathbf{f}_k^+ \mathbf{e}_k^*,$$

with an updated residual of the form  $\mathbf{f}_k^+ = V_m^+ \mathbf{e}_{k+1} \hat{\beta}_k + \mathbf{f}_m \sigma$ . Using this as a starting point, it is possible to apply  $p$  additional steps of the Arnoldi process to return to the original  $m$ -step form.

4. Virtually any explicit polynomial restarting scheme can be applied with implicit restarting, but considerable success has been obtained with exact shifts. Exact shifts result in  $H_k^+$  having the  $k$  wanted Ritz values as its spectrum. As convergence takes place, the subdiagonals of  $H_k$  tend to zero and the most desired eigenvalue approximations appear as eigenvalues of the leading  $k \times k$  block of  $R$  as a partial Schur decomposition of  $A$ . The basis vectors  $V_k$  tend to numerically orthogonal Schur vectors.
5. The basic IRAM iteration is shown in Algorithm 2.

**Examples:**

1. The expansion and contraction process of the IRAM iteration is visualized in Figure 44.3.

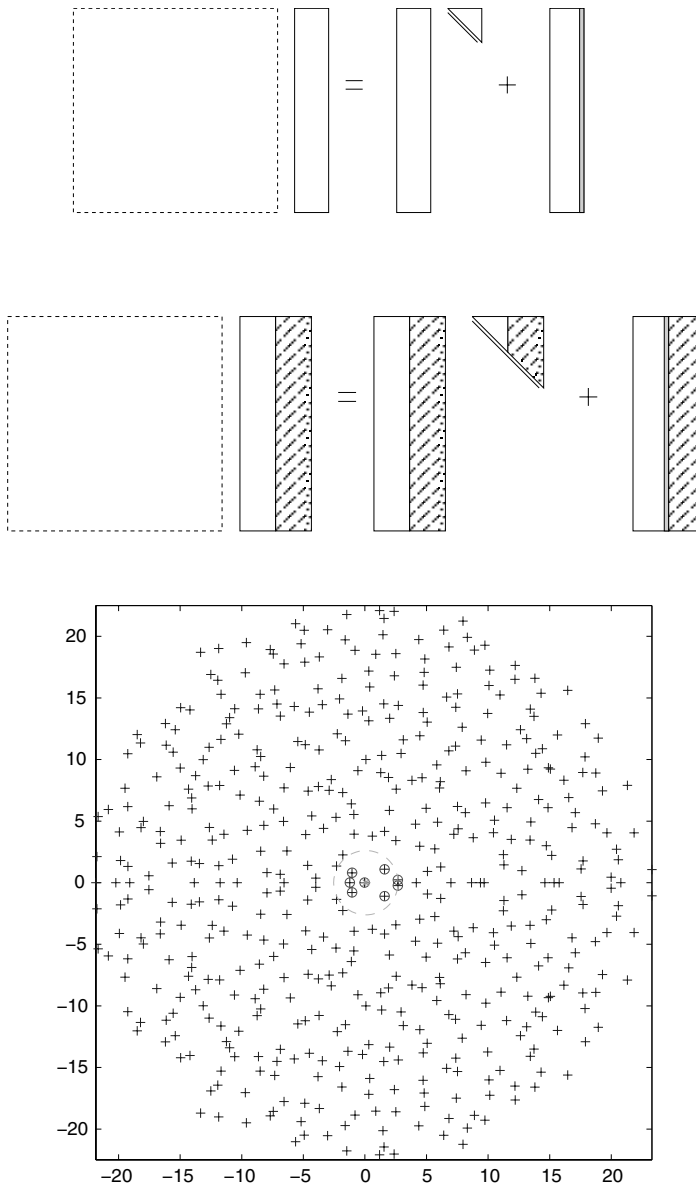

FIGURE 44.3 Visualization of IRAM.

## 44.6 Convergence of IRAM

IRAM converges linearly. An intuitive explanation follows. If  $\mathbf{v}_1$  is expressed as a linear combination of eigenvectors  $\{\mathbf{q}_j\}$  of  $A$ , then

$$\mathbf{v}_1 = \sum_{j=1}^n \mathbf{q}_j \gamma_j \Rightarrow \psi(A)\mathbf{v}_1 = \sum_{j=1}^n \mathbf{q}_j \psi(\lambda_j) \gamma_j.$$

Applying the same polynomial (i.e., using the same shifts) repeatedly for  $\ell$  iterations will result in the  $j$ -th original expansion coefficient being attenuated by a factor

$$\left( \frac{\psi(\lambda_j)}{\psi(\lambda_1)} \right)^\ell,$$

where the eigenvalues have been ordered according to decreasing values of  $|\psi(\lambda_j)|$ . The leading  $k$  eigenvalues become dominant in this expansion and the remaining eigenvalues become less and less significant as the iteration proceeds. Hence, the starting vector  $\mathbf{v}_1$  is forced into an invariant subspace as desired. The adaptive choice of  $\psi$  provided with the exact shift mechanism further enhances the isolation of the wanted components in this expansion. Hence, the wanted eigenvalues are approximated ever better as the iteration proceeds. Making this heuristic argument precise has turned out to be quite difficult. Some fairly sophisticated analysis is required to understand convergence of these methods.

## 44.7 Convergence in Gap: Distance to a Subspace

To fully discuss convergence we need some notion of nearness of subspaces. When nonnormality is present or when eigenvalues are clustered, the distance between the computed subspace and the desired subspace is a better measure of success than distance between eigenvalues. The subspaces carry uniquely defined Ritz values with them, but these can be very sensitive to perturbations in the nonnormal setting.

### Definitions:

A notion of distance that is useful in our setting is the **containment gap** between the subspaces  $\mathcal{W}$  and  $\mathcal{V}$  :

$$\delta(\mathcal{W}, \mathcal{V}) := \max_{\mathbf{w} \in \mathcal{W}} \min_{\mathbf{v} \in \mathcal{V}} \frac{\|\mathbf{w} - \mathbf{v}\|_2}{\|\mathbf{w}\|_2}.$$

*Note:*  $\delta(\mathcal{W}, \mathcal{V})$  is the sine of the largest canonical angle between  $\mathcal{W}$  and the closest subspace of  $\mathcal{V}$  with the same dimension as  $\mathcal{W}$ .

In keeping with the terminology developed in [BER04] and [BES05],  $\mathcal{X}_g$  shall be the invariant subspace of  $A$  associated with the so called “good” eigenvalues (the desired eigenvalues) and  $\mathcal{X}_b$  is the complementary subspace.  $\mathbf{P}_g$  and  $\mathbf{P}_b$  are the spectral projectors with respect to these spaces.

It is desirable to have **convergence in Gap** for the Krylov method, meaning

$$\delta(\mathcal{K}_m(A, \mathbf{v}_1^{(\ell)}), \mathcal{X}_g) \rightarrow 0.$$

Fundamental quantities required to study convergence.

### 1. Minimal Polynomial for $\mathcal{X}_g$ :

$$a_g := \text{minimal polynomial of } A \text{ with respect to } \mathbf{P}_g \mathbf{v}_1,$$

which is the monic polynomial of least degree s.t.  $a_g(A)\mathbf{P}_g \mathbf{v}_1 = \mathbf{0}$ .

2. **Nonnormality constant  $\kappa(\Omega)$** : The smallest positive number s.t.

$$\|f(A) \Pi_{\mathcal{U}}\|_2 \leq \kappa(\Omega) \max_{z \in \Omega} |f(z)|$$

uniformly for all functions  $f$  analytic on  $\Omega$ . This constant and its historical origins are discussed in detail in [BER04].

3.  **$\varepsilon$ -pseudospectrum of  $A$** :

$$\Lambda_\varepsilon(A) := \{z \in \mathbf{C} : \|(zI - A)^{-1}\|_2 \geq \varepsilon^{-1}\}.$$

**Facts:** [BER04], [BES05]

1. Two fundamental convergence questions:

- What is the gap  $\delta(\mathcal{U}_g, \mathcal{K}_k(A, \mathbf{v}_1))$  as  $k$  increases?
- How does  $\delta(\mathcal{U}_g, \mathcal{K}_m(A, \widehat{\mathbf{v}}_1))$  depend on  $\widehat{\mathbf{v}}_1 = \Phi(A)\mathbf{v}_1$ , and how can we optimize the asymptotic behavior?

Key ingredients to convergence behavior are the nonnormality of  $A$  and the distribution of  $\mathbf{v}_1$  w. r. t.  $\mathcal{U}_g$ . The goal of restarting is to attain the unrestarted iteration performance, but within **restricted subspace dimensions**.

2. **Convergence with no restarts:** In [BES05], it is shown that

$$\delta(\mathcal{U}_g, \mathcal{K}_\ell(A, \mathbf{v}_1)) \leq C_o C_b \min_{p \in \mathcal{P}_{\ell-2m}} \max_{z \in \Omega_b} |1 - a_g(z)p(z)|,$$

where the compact set  $\Omega_g \subseteq \mathbf{C} \setminus \Omega_b$  contains all the good eigenvalues.

$$C_o := \max_{\psi \in \mathcal{P}_{m-1}} \frac{\|\psi(A)\mathbf{P}_b\mathbf{v}_1\|_2}{\|\psi(A)\mathbf{P}_g\mathbf{v}_1\|_2}, \quad C_b := \kappa(\Omega_b).$$

3. Rate of convergence estimates are obtained from complex approximation theory. Construct conformal map  $\mathcal{G}$  taking the exterior of  $\Omega_b$  to the exterior of the unit disk with  $\mathcal{G}(\infty) = \infty$  and  $\mathcal{G}'(\infty) > 0$ . Define  $\rho := (\min_{j=1,\dots,L} |\mathcal{G}(\lambda_j)|)^{-1}$ . Then (Gaier, Walsh)

$$\limsup_{k \rightarrow \infty} \min_{p \in \mathcal{P}_k} \max_{z \in \Omega_b} \left| \frac{1}{a_g(z)} - p(z) \right|^{1/k} = \rho.$$

The image of  $\{|z| = \rho^{-1}\}$  is a curve  $\mathcal{C} := \mathcal{G}^{-1}(\{|z| = \rho^{-1}\})$  around  $\Omega_b$ . This critical curve passes through a good eigenvalue “closest to”  $\Omega_b$ . The curve contains at least one good eigenvalue, with all bad and no good eigenvalues in its interior.

4. Convergence with the exact shift strategy has not yet been fully analyzed. However, convergence rates have been established for restarts with asymptotically optimal points. These are the Fejér, Fekete, or Leja points for  $\Omega_b$ . In [BES05], computational experiments are shown that indicate that exact shifts behave very much like optimal points for certain regions bounded by pseudo-spectral level curves or lemniscates.
5. Let  $\Psi_M$  interpolate  $1/a_g(z)$  at the  $M$  restart shifts:

$$\delta(\mathcal{U}_g, \mathcal{K}_\ell(A, \widehat{\mathbf{v}}_1)) \leq C_o C_g \max_{z \in \Omega_b} |1 - \Psi_M(z)a_g(z)| \leq C_o C_g C_r r^M$$

for any  $r > \rho$  (see [Gai87], [FR89]). Here,  $\widehat{\mathbf{v}}_1 = \Phi(A)\mathbf{v}_1$ , where  $\Phi$  is the aggregate restart polynomial (its roots are all the implicit restart shifts that have been applied). The subspace dimension is  $\ell = 2m$ , the restart degree is  $m$ , and the aggregate degree is  $M = \nu m$ .

## 44.8 The Generalized Eigenproblem

---

In many applications, the generalized eigenproblem  $A\mathbf{x} = M\mathbf{x}\lambda$  arises naturally. A typical setting is a finite element discretization of a continuous problem where the matrix  $M$  arises from inner products of basis functions. In this case,  $M$  is symmetric and positive (semi) definite, and for some algorithms this property is a necessary condition. Generally, algorithms are based upon transforming the generalized problem to a standard problem.

## 44.9 Krylov Methods with Spectral Transformations

---

### Definitions:

A very successful scheme for converting the generalized problem to a standard problem that is amenable to a Krylov or a subspace iteration method is to use the **spectral transformation** suggested by Ericsson and Ruhe [ER80],

$$(A - \sigma M)^{-1}M\mathbf{x} = \mathbf{x}\nu.$$

**Facts:** [Sor92], [Sor02]

1. An eigenvector  $\mathbf{x}$  of the spectral transformation is also an eigenvector of the original problem  $A\mathbf{x} = M\mathbf{x}\lambda$ , with the corresponding eigenvalue given by  $\lambda = \sigma + \frac{1}{\nu}$ .
2. There is generally rapid convergence to eigenvalues near the shift  $\sigma$  because they are transformed to extremal well-separated eigenvalues. Perhaps an even more influential aspect of this transformation is that eigenvalues far from  $\sigma$  are damped (mapped near zero).
3. One strategy is to choose  $\sigma$  to be a point in the complex plane that is near eigenvalues of interest and then compute the eigenvalues  $\nu$  of largest magnitude of the spectral transformation matrix. It is not necessary to have  $\sigma$  extremely close to an eigenvalue. This transformation together with the implicit restarting technique is usually adequate for computing a significant number of eigenvalues near  $\sigma$ .
4. Even when  $M = I$ , one generally must use the shift-invert spectral transformation to find interior eigenvalues. The extreme eigenvalues of the transformed operator  $A_\sigma$  are generally large and well separated from the rest of the spectrum. The eigenvalues  $\nu$  of largest magnitude will transform back to eigenvalues  $\lambda$  of the original  $A$  that are in a disk about the point  $\sigma$ . This is illustrated in Figure 44.4, where the  $+$  symbols are the eigenvalues of  $A$  and the circled ones are the computed eigenvalues in the disk (dashed circle) centered at the point  $\sigma$ .
5. With shift-invert, the Arnoldi process is applied to the matrix  $A_\sigma := (A - \sigma M)^{-1}M$ . Whenever a matrix-vector product  $\mathbf{w} \leftarrow A_\sigma \mathbf{v}$  is required, the following steps are performed:
  - $\mathbf{z} = M\mathbf{v}$ ,
  - Solve  $(A - \sigma M)\mathbf{w} = \mathbf{z}$  for  $\mathbf{w}$ .

The matrix  $A - \sigma M$  is factored initially with a sparse direct LU-decomposition or in a symmetric indefinite factorization and this single factorization is used repeatedly to apply the matrix operator  $A_\sigma$  as required.

6. The scheme is modified to preserve symmetry when  $A$  and  $M$  are both symmetric and  $M$  is positive (semi)definite. One can utilize a weighted  $M$  (semi) inner product in the Lanczos/Arnoldi process [ER80], [GLS94], [MS97]. This amounts to replacing the computation of  $\mathbf{h} \leftarrow V_{j+1}^* \mathbf{w}$  and  $\beta_j = \|\mathbf{f}_j\|_2$  with  $\mathbf{h} \leftarrow V_{j+1}^* M\mathbf{w}$  and  $\beta_j = \sqrt{\mathbf{f}_j^* M \mathbf{f}_j}$ , respectively, in the Arnoldi process described in Algorithm 1.
7. The matrix operator  $A_\sigma$  is self-adjoint with respect to this (semi)inner product, i.e.,  $\langle A_\sigma \mathbf{x}, \mathbf{y} \rangle = \langle \mathbf{x}, A_\sigma \mathbf{y} \rangle$  for all vectors  $\mathbf{x}, \mathbf{y}$ , where  $\langle \mathbf{w}, \mathbf{v} \rangle := \sqrt{\mathbf{w}^* M \mathbf{v}}$ . This implies that the projected Hessenberg

FIGURE 44.4 Eigenvalues from shift-invert.

matrix  $H$  is actually symmetric and tridiagonal and the standard three-term Lanczos recurrence is recovered with this inner product.

8. There is a subtle aspect to this approach when  $M$  is singular. The most pathological case, when  $\text{null}(A) \cap \text{null}(M) \neq \{0\}$ , is not treated here. However, when  $M$  is singular there may be infinite eigenvalues of the pair  $(A, M)$  and the presence of these can introduce large perturbations to the computed Ritz values and vectors. To avoid these difficulties, a purging operation has been suggested by Ericsson and Ruhe [ER80]. If  $\mathbf{x} = V\mathbf{y}$  with  $H\mathbf{y} = \mathbf{y}\theta$ , then

$$A_\sigma \mathbf{x} = V H \mathbf{y} + \mathbf{f} \mathbf{e}_k^T \mathbf{y} = \mathbf{x} \theta + \mathbf{f} \mathbf{e}_k^T \mathbf{y}.$$

Replacing the  $\mathbf{x}$  with the improved eigenvector approximation  $\mathbf{x} \leftarrow (\mathbf{x} + \frac{1}{\theta} \mathbf{f} \mathbf{e}_k^T \mathbf{y})$  and renormalizing has the effect of purging undesirable components without requiring any additional matrix vector products with  $A_\sigma$ .

9. The residual error of the purged vector  $\mathbf{x}$  with respect to the original problem is

$$\|A\mathbf{x} - M\mathbf{x}\lambda\|_2 = \|M\mathbf{f}\|_2 \frac{|\mathbf{e}_k^T \mathbf{y}|}{|\theta|^2},$$

where  $\lambda = \sigma + 1/\theta$ . Since  $|\theta|$  is usually quite large under the spectral transformation, this new residual is generally considerably smaller than the original.

### 45.1 Singular Value Decomposition

---

#### Definitions:

Given a complex matrix  $A$  having  $m$  rows and  $n$  columns, if  $\sigma$  is a nonnegative scalar and  $\mathbf{u}$  and  $\mathbf{v}$  are nonzero  $m$ - and  $n$ -vectors, respectively, such that

$$A\mathbf{v} = \sigma\mathbf{u} \quad \text{and} \quad A^*\mathbf{u} = \sigma\mathbf{v},$$

then  $\sigma$  is a **singular value** of  $A$  and  $\mathbf{u}$  and  $\mathbf{v}$  are corresponding **left** and **right singular vectors**, respectively. (For generality it is assumed that the matrices here are complex, although given these results, the analogs for real matrices are obvious.)

If, for a given positive singular value, there are exactly  $t$  linearly independent corresponding right singular vectors and  $t$  linearly independent corresponding left singular vectors, the singular value has **multiplicity**  $t$  and the space spanned by the right (left) singular vectors is the corresponding **right (left) singular space**.

Given a complex matrix  $A$  having  $m$  rows and  $n$  columns, the matrix product  $U\Sigma V^*$  is a **singular value decomposition** for a given matrix  $A$  if

- $U$  and  $V$ , respectively, have orthonormal columns.
- $\Sigma$  has nonnegative elements on its principal diagonal and zeros elsewhere.
- $A = U\Sigma V^*$ .

Let  $p$  and  $q$  be the number of rows and columns of  $\Sigma$ .  $U$  is  $m \times p$ ,  $p \leq m$ , and  $V$  is  $n \times q$  with  $q \leq n$ . There are three **standard forms** of the SVD. All have the  $i$ th diagonal value of  $\Sigma$  denoted  $\sigma_i$  and ordered as follows:  $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_k$ , and  $r$  is the index such that  $\sigma_r > 0$  and either  $k = r$  or  $\sigma_{r+1} = 0$ .

1.  $p = m$  and  $q = n$ . The matrix  $\Sigma$  is  $m \times n$  and has the same dimensions as  $A$  (see Figures 45.1 and 45.2).
2.  $p = q = \min\{m, n\}$ . The matrix  $\Sigma$  is square (see Figures 45.3 and 45.4).
3. If  $p = q = r$ , the matrix  $\Sigma$  is square. This form is called a **reduced SVD** and denoted is by  $\hat{U}\hat{\Sigma}\hat{V}^*$  (see Figures 45.5 and 45.6).

$$\boxed{A} = \boxed{U} \boxed{\Sigma} \boxed{V^*}$$

FIGURE 45.1 The first form of the singular value decomposition where  $m \geq n$ .

$$\boxed{A} = \boxed{U} \boxed{\Sigma} \boxed{V^*}$$

FIGURE 45.2 The first form of the singular value decomposition where  $m < n$ .

**Facts:**

The results can be found in [GV96, pp. 70–79]. Additionally, see Chapter 5.6 for introductory material and examples of SVDs, Chapter 17 for additional information on singular value decomposition, Chapter 15 for information on perturbations of singular values and vectors, and Section 39.9 for information about numerical rank.

1. If  $U\Sigma V^*$  is a singular value decomposition for a given matrix  $A$ , then the diagonal elements  $\{\sigma_i\}$  of  $\Sigma$  are singular values of  $A$ . The columns  $\{\mathbf{u}_i\}_{i=1}^p$  of  $U$  and  $\{\mathbf{v}_i\}_{i=1}^q$  of  $V$  are left and right singular vectors of  $A$ , respectively.
2. If  $m \geq n$ , the first standard form of the SVD can be found as follows:
  - (a) Let  $A^*A = V\Lambda V^*$  be an eigenvalue decomposition for the Hermitian, positive semidefinite  $n \times n$  matrix  $A^*A$  such that  $\Lambda$  is diagonal (with the diagonal entries in nonincreasing order) and  $V$  is unitary.
  - (b) Let the  $m \times n$  matrix  $\Sigma$  have zero off-diagonal elements and for  $i = 1, \dots, n$  let  $\sigma_i$ , the  $i$ th diagonal element of  $\Sigma$ , equal  $\sqrt{\lambda_i}$ , the positive square root of the  $i$ th diagonal element of  $\Lambda$ .
  - (c) For  $i = 1, \dots, n$ , let the  $m \times m$  matrix  $U$  have  $i$ th column,  $\mathbf{u}_i$ , equal to  $1/\sigma_i A\mathbf{v}_i$  if  $\sigma_i \neq 0$ . If  $\sigma_i = 0$ , let  $\mathbf{u}_i$  be of unit length and orthogonal to all  $\mathbf{u}_j$  for  $j \neq i$ , then  $U\Sigma V^*$  is a singular decomposition of  $A$ .
3. If  $m < n$  the matrix  $A^*$  has a singular value decomposition  $U\Sigma V^*$  and  $V\Sigma^T U^*$  is a singular value decomposition for  $A$ . The diagonal elements of  $\Sigma$  are the square roots of the eigenvalues of  $AA^*$ . The eigenvalues of  $A^*A$  are those of  $AA^*$  plus  $n - m$  zeros. The notation  $\Sigma^T$  rather than  $\Sigma^*$  is used because in this case the two are identical and the transpose is more suggestive. All elements of  $\Sigma$  are real so that taking complex conjugates has no effect.
4. The value of  $r$ , the number of nonzero singular values, is the rank of  $A$ .
5. If  $A$  is real, then  $U$  and  $V$  (in addition to  $\Sigma$ ) can be chosen real in any of the forms of the SVD.
6. The range of  $A$  is exactly the subspace of  $\mathbb{C}^m$  spanned by the  $r$  columns of  $U$  that correspond to the positive singular values.
7. In the first form, the null space of  $A$  is that subspace of  $\mathbb{C}^n$  spanned by the  $n - r$  columns of  $V$  that correspond to zero singular values.
8. In reducing from the first form to the third (reduced) form, a basis for the null space of  $A$  has been discarded if columns of  $V$  have been deleted. A basis for the space orthogonal to the range of  $A$  (i.e., the null space of  $A^*$ ) has been discarded if columns of  $U$  have been deleted.
9. In the first standard form of the SVD,  $U$  and  $V$  are unitary.
10. The second form can be obtained from the first form simply by deleting columns  $n + 1, \dots, m$  of  $U$  and the corresponding rows of  $S$ , if  $m > n$ , or by deleting columns  $m + 1, \dots, n$  of  $V$  and the corresponding columns of  $S$ , if  $m < n$ . If  $m \neq n$ , then only one of  $U$  and  $V$  is square and either  $UU^* = I_m$  or  $VV^* = I_n$  fails to hold. Both  $U^*U = I_p$  and  $V^*V = I_p$ .
11. The reduced (third) form can be obtained from the second form by taking only the  $r \times r$  principle submatrix of  $\Sigma$ , and only the first  $r$  columns of  $U$  and  $V$ . If  $A$  is rank deficient (i.e.,  $r < \min\{m, n\}$ ), then neither  $U$  nor  $V$  is square and neither  $U^*U$  nor  $V^*V$  is an identity matrix.
12. If  $p < m$ , let  $\tilde{U}$  be an  $m \times (m - p)$  matrix of columns that are mutually orthonormal to one another as well as to the columns of  $U$  and define the  $m \times m$  unitary matrix

$$\widehat{U} = [U \quad \tilde{U}].$$

If  $q < n$ , let  $\tilde{V}$  be an  $n \times (n - q)$  matrix of columns that are mutually orthonormal to one another as well as to the columns of  $V$  and define the  $n \times n$  unitary matrix

$$\widehat{V} = [V \quad \tilde{V}].$$

Let  $\widehat{\Sigma}$  be the  $m \times n$  matrix

$$\widehat{\Sigma} = \begin{bmatrix} \Sigma & 0 \\ 0 & 0 \end{bmatrix}.$$

Then

$$A = \widehat{U} \widehat{\Sigma} \widehat{V}^*, \quad A\widehat{V} = \widehat{U} \widehat{\Sigma}^*, \quad A^* = \widehat{V} \widehat{\Sigma}^T \widehat{U}^*, \quad \text{and} \quad A^* \widehat{U} = \widehat{V} \widehat{\Sigma}^T.$$

13. Let  $U\Sigma V^*$  be a singular value decomposition for  $A$ , an  $m \times n$  matrix of rank  $r$ . Then:
  - (a) There are exactly  $r$  positive elements of  $\Sigma$  and they are the square roots of the  $r$  positive eigenvalues of  $A^*A$  (and also  $AA^*$ ) with the corresponding multiplicities.
  - (b) The columns of  $V$  are eigenvectors of  $A^*A$ ; more precisely,  $\mathbf{v}_j$  is a normalized eigenvector of  $A^*A$  corresponding to the eigenvalue  $\sigma_j^2$ , and  $\mathbf{u}_j$  satisfies  $\sigma_j \mathbf{u}_j = A\mathbf{v}_j$ .
  - (c) Alternatively, the columns of  $U$  are eigenvectors of  $AA^*$ ; more precisely,  $\mathbf{u}_j$  is a normalized eigenvector of  $AA^*$  corresponding to the eigenvalue  $\sigma_j^2$ , and  $\mathbf{v}_j$  satisfies  $\sigma_j \mathbf{v}_j = A^* \mathbf{u}_j$ .
14. The singular value decomposition  $U\Sigma V^*$  is not unique. If  $U\Sigma V^*$  is a singular value decomposition, so is  $(-U)\Sigma(-V^*)$ . The singular values may be arranged in any order if the columns of singular vectors in  $U$  and  $V$  are reordered correspondingly.
15. If the singular values are in nonincreasing order then the only option for the construction of  $\Sigma$  is the choice for its dimensions  $p$  and  $q$  and these must satisfy  $r \leq p \leq m$  and  $r \leq q \leq n$ .
16. If  $A$  is square and if the singular values are ordered in a nonincreasing fashion, the matrix  $\Sigma$  is unique.
17. Corresponding to a simple (i.e., nonrepeated) singular value  $\sigma_j$ , the left and right singular vectors,  $\mathbf{u}_j$  and  $\mathbf{v}_j$ , are unique up to scalar multiples of modulus one. That is, if  $\mathbf{u}_j$  and  $\mathbf{v}_j$  are singular vectors, then for any real value of  $\theta$  so are  $e^{i\theta} \mathbf{u}_j$  and  $e^{i\theta} \mathbf{v}_j$ , but no other vectors are singular vectors corresponding to  $\sigma_j$ .
18. Corresponding to a repeated singular value, the associated left singular vectors  $\mathbf{u}_j$  and right singular vectors  $\mathbf{v}_j$  may be selected in any fashion such that they span the proper subspace. Thus, if  $\mathbf{u}_{j_1}, \dots, \mathbf{u}_{j_r}$  and  $\mathbf{v}_{j_1}, \dots, \mathbf{v}_{j_r}$  are the left and right singular vectors corresponding to a singular value  $\sigma_j$  of multiplicity  $s$ , then so are  $\mathbf{u}'_{j_1}, \dots, \mathbf{u}'_{j_r}$  and  $\mathbf{v}'_{j_1}, \dots, \mathbf{v}'_{j_r}$  if and only if there exists an  $s \times s$  unitary matrix  $Q$  such that  $[\mathbf{u}'_{j_1}, \dots, \mathbf{u}'_{j_r}] = [\mathbf{u}_{j_1}, \dots, \mathbf{u}_{j_r}] Q$  and  $[\mathbf{v}'_{j_1}, \dots, \mathbf{v}'_{j_r}] = [\mathbf{v}_{j_1}, \dots, \mathbf{v}_{j_r}] Q$ .

### Examples:

For examples illustrating SVD see Section 5.6.

## 45.2 Algorithms for the Singular Value Decomposition

Generally, algorithms for computing singular values are analogs of algorithms for computing eigenvalues of symmetric matrices. See Chapter 42 and Chapter 46 for additional information. The idea is always to find square roots of eigenvalues of  $A^T A$  without actually computing  $A^T A$ . As before, we assume the matrix  $A$  whose singular values or singular vectors we seek is  $m \times n$ . All algorithms assume  $m \geq n$ ; if  $m < n$ , the algorithms may be applied to  $A^T$ . To avoid undue complication, all algorithms will be presented as if the matrix is real. Nevertheless, each algorithm has an extension for complex matrices. Algorithm 1 is presented in three parts. It is analogous to the QR algorithm for symmetric matrices. The developments for it can be found in [GK65], [GK68], [BG69], and [GR70]. Algorithm 1a is a Householder reduction of a matrix to bidiagonal form. Algorithm 1c is a step to be used iteratively in Algorithm 1b. Algorithm 2 computes the singular values and singular vectors of a bidiagonal matrix to high relative accuracy [DK90], [Dem97].

Algorithm 3 gives a “Squareroot-free” method to compute the singular values of a bidiagonal matrix to high relative accuracy — it is the method of choice when only singular values are desired [Rut54], [Rut90], [FP94], [PM00]. Algorithm 4 computes the singular values of an  $n \times n$  bidiagonal matrix by the bisection method, which allows  $k$  singular values to be computed in  $O(kn)$  time. By specifying the input tolerance  $tol$  appropriately, Algorithm 4 can also compute the singular values to high relative accuracy. Algorithm 5 computes the SVD of a bidiagonal by the divide and conquer method [GE95]. The most recent method, based on the method of multiple relatively robust representations (not presented here), is the fastest and allows computation of  $k$  singular values as well as the corresponding singular vectors of a bidiagonal matrix in  $O(kn)$  time [DP04a], [DP04b], [GL03], [WLV05]. All of the above mentioned methods first reduce the matrix to bidiagonal form. The following algorithms iterate directly on the input matrix. Algorithms 6 and 7 are analogous to the Jacobi method for symmetric matrices. Algorithm 6 — also known as the “one-sided Jacobi method for SVD” — can be found in [Hes58] and Algorithm 7 can be found in [Kog55] and [FH60]. Algorithm 7 begins with an orthogonal reduction of the  $m \times n$  input matrix so that all the nonzeros lie in the upper  $n \times n$  portion. (Although this algorithm was named biorthogonalization in [FH60], it is not the biorthogonalization found in certain iterative methods for solving linear equations.) Many of the algorithms require a tolerance  $\varepsilon$  to control termination. It is suggested that  $\varepsilon$  be set to a small multiple of the unit round off precision  $\varepsilon_o$ .

**Algorithm 1a:** Householder reduction to bidiagonal form:

Input:  $m, n, A$  where  $A$  is  $m \times n$ .

Output:  $B, U, V$  so that  $B$  is upper bidiagonal,  $U$  and  $V$  are products of Householder matrices, and  $A = UB V^T$ .

1.  $B \leftarrow A$ . (This step can be omitted if  $A$  is to be overwritten with  $B$ .)
2.  $U = I_{m \times n}$ .
3.  $V = I_{n \times n}$ .
4. For  $k = 1, \dots, n$ 
  - a. Determine Householder matrix  $Q_k$  with the property that:
    - Left multiplication by  $Q_k$  leaves components  $1, \dots, k - 1$  unaltered, and

$$\bullet Q_k \begin{bmatrix} 0 \\ \vdots \\ 0 \\ b_{k-1,k} \\ b_{k,k} \\ b_{k+1,k} \\ \vdots \\ b_{m,k} \end{bmatrix} = \begin{bmatrix} 0 \\ \vdots \\ 0 \\ b_{k-1,k} \\ s \\ 0 \\ \vdots \\ 0 \end{bmatrix}, \text{ where } s = \pm \sqrt{\sum_{i=k}^m b_{i,k}^2}.$$

- b.  $B \leftarrow Q_k B$ .
- c.  $U \leftarrow U Q_k$ .
- d. If  $k \leq n - 2$ , determine Householder matrix  $P_{k+1}$  with the property that:
  - Right multiplication by  $P_{k+1}$  leaves components  $1, \dots, k$  unaltered, and
  - $[0 \cdots 0 \ b_{k,k} \ b_{k,k+1} \ b_{k,k+2} \ \cdots \ b_{k,n}] P_{k+1} = [0 \cdots 0 \ b_{k,k} \ s \ 0 \cdots 0]$ , where  $s = \pm \sqrt{\sum_{j=k+1}^n b_{k,j}^2}$ .
- e.  $B \leftarrow B P_{k+1}$ .
- f.  $V \leftarrow P_{k+1} V$ .

**Algorithm 1b:** Golub–Reinsch SVD:Input:  $m, n, A$  where  $A$  is  $m \times n$ .Output:  $\Sigma, U, V$  so that  $\Sigma$  is diagonal,  $U$  and  $V$  have orthonormal columns,  $U$  is  $m \times n$ ,  $V$  is  $n \times n$ , and  $A = U\Sigma V^T$ .

1. Apply Algorithm 1a to obtain  $B, U, V$  so that  $B$  is upper bidiagonal,  $U$  and  $V$  are products of Householder matrices, and  $A = UVV^T$ .
2. Repeat:
  - a. If for any  $i = 1, \dots, n-1$ ,  $|b_{i,i+1}| \leq \varepsilon (|b_{i,i}| + |b_{i+1,i+1}|)$ , set  $b_{i,i+1} = 0$ .
  - b. Determine the smallest  $p$  and the largest  $q$  so that  $B$  can be blocked as

$$B = \begin{bmatrix} B_{1,1} & 0 & 0 \\ 0 & B_{2,2} & 0 \\ 0 & 0 & B_{3,3} \end{bmatrix} \begin{array}{l} p \\ n-p-q \\ q \end{array}$$

where  $B_{3,3}$  is diagonal and  $B_{2,2}$  has no zero superdiagonal entry.

- c. If  $q = n$ , set  $\Sigma =$  the diagonal portion of  $B$  **STOP**.
- d. If for  $i = p+1, \dots, n-q-1$ ,  $b_{i,i} = 0$ , then
  - Apply Givens rotations so that  $b_{i,i+1} = 0$  and  $B_{2,2}$  is still upper bidiagonal. (For details, see [GL96, p. 454].)
  - else
    - Apply Algorithm 1c to  $n, B, U, V, p, q$ .

**Algorithm 1c:** Golub–Kahan SVD step:Input:  $n, B, Q, P, p, q$  where  $B$  is  $n \times n$  and upper bidiagonal,  $Q$  and  $P$  have orthogonal columns, and  $A = QBP^T$ .Output:  $B, Q, P$  so that  $B$  is upper bidiagonal,  $A = QBP^T$ ,  $Q$  and  $P$  have orthogonal columns, and the output  $B$  has smaller off-diagonal elements than the input  $B$ . In storage,  $B, Q$ , and  $P$  are overwritten.

1. Let  $B_{2,2}$  be the diagonal block of  $B$  with row and column indices  $p+1, \dots, n-q$ .
2. Set  $C =$  lower, right  $2 \times 2$  submatrix of  $B_{2,2}^T B_{2,2}$ .
3. Obtain eigenvalues  $\lambda_1, \lambda_2$  of  $C$ . Set  $\mu =$  whichever of  $\lambda_1, \lambda_2$  that is closer to  $c_{2,2}$ .
4.  $k = p+1, \alpha = b_{k,k}^2 - \mu, \beta = b_{k,k} b_{k,k+1}$ .
5. For  $k = p+1, \dots, n-q-1$ 
  - a. Determine  $c = \cos(\theta)$  and  $s = \sin(\theta)$  with the property that:

$$[\alpha \quad \beta] \begin{bmatrix} c & s \\ -s & c \end{bmatrix} = \begin{bmatrix} \sqrt{\alpha^2 + \beta^2} & 0 \end{bmatrix}.$$

- b.  $B \leftarrow B R_{k,k+1}(c, s)$  where  $R_{k,k+1}(c, s)$  is the Givens rotation matrix that acts on columns  $k$  and  $k+1$  during right multiplication.
- c.  $P \leftarrow P R_{k,k+1}(c, s)$ .
- d.  $\alpha = b_{k,k}, \beta = b_{k+1,k}$ .
- e. Determine  $c = \cos(\theta)$  and  $s = \sin(\theta)$  with the property that:

$$\begin{bmatrix} c & -s \\ s & c \end{bmatrix} \begin{bmatrix} \alpha \\ \beta \end{bmatrix} = \begin{bmatrix} \sqrt{\alpha^2 + \beta^2} \\ 0 \end{bmatrix}.$$

- f.  $B \leftarrow R_{k,k+1}(c, -s)B$ , where  $R_{k,k+1}(c, -s)$  is the Givens rotation matrix that acts on rows  $k$  and  $k+1$  during left multiplication.
- g.  $Q \leftarrow Q R_{k,k+1}(c, s)$ .
- h. if  $k \leq n-q-1$   $\alpha = b_{k,k+1}, \beta = b_{k,k+2}$ .

**Algorithm 2a:** High Relative Accuracy Bidiagonal SVD:

Input:  $n, B$  where  $B$  is an  $n \times n$  upper bidiagonal matrix.

Output:  $\Sigma$  is an  $n \times n$  diagonal matrix,  $U$  and  $V$  are orthogonal  $n \times n$  matrices, and  $B = U\Sigma V^T$ .

1. Compute  $\underline{\sigma}$  to be a reliable underestimate of  $\sigma_{\min}(B)$  (for details, see [DK90]).
2. Compute  $\bar{\sigma} = \max_i(b_{i,i}, b_{i,i+1})$ .
3. Repeat:
  - a. For all  $i = 1, \dots, n - 1$ , set  $b_{i,i+1} = 0$  if a relative convergence criterion is met (see [DK90] for details).
  - b. Determine the smallest  $p$  and largest  $q$  so that  $B$  can be blocked as

$$B = \begin{bmatrix} B_{1,1} & 0 & 0 \\ 0 & B_{2,2} & 0 \\ 0 & 0 & B_{3,3} \end{bmatrix} \begin{matrix} p \\ n - p - q \\ q \end{matrix}$$

where  $B_{3,3}$  is diagonal and  $B_{2,2}$  has no zero superdiagonal entry.

- c. If  $q = n$ , set  $\Sigma =$  the diagonal portion of  $B$ . **STOP**.
- d. If for  $i = p + 1, \dots, n - q - 1$ ,  $b_{i,i} = 0$ , then
  - Apply Givens rotations so that  $b_{i,i+1} = 0$  and  $B_{2,2}$  is still upper bidiagonal. (For details, see [GV96, p. 454].)
  - else
    - Apply Algorithm 2b with  $n, B, U, V, p, q, \bar{\sigma}, \underline{\sigma}$  as inputs.

**Algorithm 2b:** Demmel–Kahan SVD step:

Input:  $n, B, Q, P, p, q, \bar{\sigma}, \underline{\sigma}$  where  $B$  is  $n \times n$  and upper bidiagonal,  $Q$  and  $P$  have orthogonal columns such that  $A = QB P^T$ ,  $\bar{\sigma} \approx \|B\|$  and  $\underline{\sigma}$  is an underestimate of  $\sigma_{\min}(B)$ .

Output:  $B, Q, P$  so that  $B$  is upper bidiagonal,  $A = QB P^T$ ,  $Q$  and  $P$  have orthogonal columns, and the output  $B$  has smaller off-diagonal elements than the input  $B$ . In storage,  $B, Q$ , and  $P$  are overwritten.

1. Let  $B_{2,2}$  be the diagonal block of  $B$  with row and column indices  $p + 1, \dots, n - q$ .
2. If  $\text{tol}^* \underline{\sigma} \leq \varepsilon_0 \bar{\sigma}$ , then
  - a.  $c' = c = 1$ .
  - b. For  $k = p + 1, n - q - 1$ 
    - $\alpha = cb_{k,k}; \beta = b_{k,k+1}$ .
    - Determine  $c$  and  $s$  with the property that:

$$[\alpha \quad \beta] \begin{bmatrix} c & s \\ -s & c \end{bmatrix} = [r \quad 0], \text{ where } r = \sqrt{\alpha^2 + \beta^2}.$$

- If  $k \neq p + 1, b_{k-1,k} = s'r$ .
- $P \leftarrow P R_{k,k+1}(c, s)$ , where  $R_{k,k+1}(c, s)$  is the Givens rotation matrix that acts on columns  $k$  and  $k + 1$  during right multiplication.
- $\alpha = c'r, \beta = sb_{k+1,k+1}$ .

(continued)

**Algorithm 2b:** Demmel–Kahan SVD step: (Continued)

- Determine  $c'$  and  $s'$  with the property that:

$$\begin{bmatrix} c' & -s' \\ s' & c' \end{bmatrix} \begin{bmatrix} \alpha \\ \beta \end{bmatrix} = \begin{bmatrix} \sqrt{\alpha^2 + \beta^2} \\ 0 \end{bmatrix}.$$

- $Q \leftarrow QR_{k,k+1}(c, -s)$ , where  $R_{k,k+1}(c, -s)$  is the Givens rotation matrix that acts on rows  $k$  and  $k + 1$  during left multiplication.
  - $b_{k,k} = \sqrt{\alpha^2 + \beta^2}$ .
- c.  $b_{n-q-1,n-q} = (b_{n-q,n-q}c)s'$ ;  $b_{n-q,n-q} = (b_{n-q,n-q}c)c'$ .  
Else
- d. Apply Algorithm 1c to  $n, B, Q, P, p, q$ .

**Algorithm 3a:** High Relative Accuracy Bidiagonal Singular Values:

Input:  $n, B$  where  $B$  is an  $n \times n$  upper bidiagonal matrix.

Output:  $\Sigma$  is an  $n \times n$  diagonal matrix containing the singular values of  $B$ .

1. Square the diagonal and off-diagonal elements of  $B$  to form the arrays  $\mathbf{s}$  and  $\mathbf{e}$ , respectively, i.e., for  $i = 1, \dots, n-1, s_i = b_{i,i}^2, e_i = b_{i,i+1}^2$ , end for  $s_n = b_{n,n}^2$ .
2. Repeat:
  - a. For all  $i = 1, \dots, n-1$ , set  $e_i = 0$  if a relative convergence criterion is met (see [PM00] for details).
  - b. Determine the smallest  $p$  and largest  $q$  so that  $B$  can be blocked as

$$B = \begin{bmatrix} B_{1,1} & 0 & 0 \\ 0 & B_{2,2} & 0 \\ 0 & 0 & B_{3,3} \end{bmatrix} \begin{matrix} p \\ n-p-q \\ q \end{matrix}$$

where  $B_{3,3}$  is diagonal and  $B_{2,2}$  has no zero superdiagonal entry.

- c. If  $q = n$ , set  $\Sigma = \sqrt{\text{diag}(\mathbf{s})}$ . **STOP**.
- d. If for  $i = p+1, \dots, n-q-1, s_i = 0$  then  
Apply Givens rotations so that  $e_i = 0$  and  $B_{2,2}$  is still upper bidiagonal. (For details, see [GV96, p. 454].)  
else  
Apply Algorithm 3b with inputs  $n, \mathbf{s}, \mathbf{e}$ .

**Algorithm 3b:** Differential quotient-difference (dqds) step:

Input:  $n, \mathbf{s}, \mathbf{e}$  where  $\mathbf{s}$  and  $\mathbf{e}$  are the squares of the diagonal and superdiagonal entries, respectively, of an  $n \times n$  upper bidiagonal matrix.

Output:  $\mathbf{s}$  and  $\mathbf{e}$  are overwritten on output.

1. Choose  $\mu$  by using a suitable shift strategy. The shift  $\mu$  should be smaller than  $\sigma_{\min}(B)^2$ . See [FP94, PM00] for details.
2.  $d = s_1 - \mu$ .

**Algorithm 3b:** Differential quotient-difference (dqds) step: (Continued)

1. For  $k = 1, \dots, n - 1$ 
  - a.  $s_k = d + e_k$ .
  - b.  $t = s_{k+1}/s_k$ .
  - c.  $e_k = e_k t$ .
  - d.  $d = dt - \mu$ .
  - e. If  $d < 0$ , go to step 1.
2.  $s_n = d$ .

**Algorithm 4a:** Bidiagonal Singular Values by Bisection:

Input:  $n, B, \alpha, \beta, tol$  where  $n \times n$  is a bidiagonal matrix,  $[\alpha, \beta]$  is the input interval, and  $tol$  is the tolerance for the desired accuracy of the singular values.

Output:  $w$  is the output array containing the singular values of  $B$  that lie in  $[\alpha, \beta]$ .

1.  $n_\alpha = \text{Negcount}(n, B, \alpha)$ .
2.  $n_\beta = \text{Negcount}(n, B, \beta)$ .
3. If  $n_\alpha = n_\beta$ , there are no singular values in  $[\alpha, \beta]$ . **STOP.**
4. Put  $[\alpha, n_\alpha, \beta, n_\beta]$  onto *Worklist*.
5. While *Worklist* is not empty do
  - a. Remove  $[low, n_{low}, up, n_{up}]$  from *Worklist*.
  - b.  $mid = (low + up)/2$ .
  - c. If  $(up - low < tol)$ , then
    - For  $i = n_{low} + 1, n_{up}, w(i - n_a) = mid$ ;
 Else
    - $n_{mid} = \text{Negcount}(n, B, mid)$ .
    - If  $n_{mid} > n_{low}$  then  
Put  $[low, n_{low}, mid, n_{mid}]$  onto *Worklist*.
    - If  $n_{up} > n_{mid}$  then  
Put  $[mid, n_{mid}, up, n_{up}]$  onto *Worklist*.

**Algorithm 4b:**  $\text{Negcount}(n, B, \mu)$ :

Input: The  $n \times n$  bidiagonal matrix  $B$  and a number  $\mu$ .

Output:  $\text{Negcount}$ , i.e., the number of singular values smaller than  $\mu$  is returned.

1.  $t = -\mu$ .
2. For  $k = 1, \dots, n - 1$ 
  - $d = b_{k,k}^2 + t$ .
  - If  $(d < 0)$  then  $\text{Negcount} = \text{Negcount} + 1$
  - $t = t * (b_{k,k+1}^2/d) - \mu$ .
- End for
3.  $d = b_{n,n}^2 + t$ .
4. If  $(d < 0)$ , then  $\text{Negcount} = \text{Negcount} + 1$ .

**Algorithm 5:** DC\_SVD( $n, B, \Sigma, U, V$ ): Divide and Conquer Bidiagonal SVD:

Input:  $n, B$  where  $B$  is an  $(n+1) \times n$  lower bidiagonal matrix.

Output:  $\Sigma$  is an  $n \times n$  diagonal matrix,  $U$  is an  $(n+1) \times (n+1)$  orthogonal matrix,  $V$  is an orthogonal  $n \times n$  matrix, so that  $B = U\Sigma V^T$ .

1. If  $n < n_0$ , then apply Algorithm 1b with inputs  $n+1, n, B$  to get outputs  $\Sigma, U, V$ .  
Else

$$\text{Let } B = \begin{pmatrix} B_1 & \alpha_k \mathbf{e}_k & 0 \\ 0 & \beta_k \mathbf{e}_1 & B_2 \end{pmatrix}, \text{ where } k = n/2.$$

- a. Call DC\_SVD( $k-1, B_1, \Sigma_1, U_1, W_1$ ).
- b. Call DC\_SVD( $n-k, B_2, \Sigma_2, U_2, W_2$ ).
- c. Partition  $U_i = (Q_i \quad \mathbf{q}_i)$ , for  $i = 1, 2$ , where  $\mathbf{q}_i$  is a column vector.
- d. Extract  $l_1 = Q_1^T \mathbf{e}_k, \lambda_1 = \mathbf{q}_1^T \mathbf{e}_k, l_2 = Q_2^T \mathbf{e}_1, \lambda_2 = \mathbf{q}_2^T \mathbf{e}_1$ .
- e. Partition  $B$  as

$$B = \begin{pmatrix} c_0 \mathbf{q}_1 & Q_1 & 0 & -s_0 \mathbf{q}_1 \\ s_0 \mathbf{q}_2 & 0 & Q_2 & c_0 \mathbf{q}_2 \end{pmatrix} \begin{pmatrix} r_0 & 0 & 0 \\ \alpha_k l_1 & \Sigma_1 & 0 \\ \beta_k l_2 & 0 & \Sigma_2 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} 0 & W_1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & W_2 \end{pmatrix}^T = (Q \quad q) \begin{pmatrix} M \\ 0 \end{pmatrix} W^T$$

where  $r_0 = \sqrt{(\alpha_k \lambda_1)^2 + (\beta_k \lambda_2)^2}, c_0 = \alpha_k \lambda_1 / r_0, s_0 = \beta_k \lambda_2 / r_0$ .

- f. Compute the singular values of  $M$  by solving the secular equation

$$f(w) = 1 + \sum_{k=1}^n \frac{z_k^2}{d_k^2 - w^2} = 0,$$

and denote the computed singular values by  $\hat{w}_1, \hat{w}_2, \dots, \hat{w}_n$ .

- g. For  $i = 1, \dots, n$ , compute

$$\hat{z}_i = \sqrt{(\hat{w}_n^2 - d_i^2) \prod_{k=1}^{i-1} \frac{(\hat{w}_k^2 - d_i^2)}{(d_k^2 - d_i^2)} \prod_{k=1}^{n-1} \frac{(\hat{w}_k^2 - d_i^2)}{(d_{k+1}^2 - d_i^2)}}.$$

- h. For  $i = 1, \dots, n$ , compute the singular vectors

$$\mathbf{u}_i = \left( \frac{\hat{z}_1}{d_1^2 - \hat{w}_i^2}, \dots, \frac{\hat{z}_n}{d_n^2 - \hat{w}_i^2} \right) / \sqrt{\sum_{k=1}^n \frac{\hat{z}_k^2}{(d_k^2 - \hat{w}_i^2)^2}},$$

$$\mathbf{v}_i = \left( -1, \frac{d_2 \hat{z}_2}{d_2^2 - \hat{w}_i^2}, \dots, \frac{d_n \hat{z}_n}{d_n^2 - \hat{w}_i^2} \right) / \sqrt{1 + \sum_{k=2}^n \frac{(d_k \hat{z}_k)^2}{(d_k^2 - \hat{w}_i^2)^2}}$$

and let  $U = [\mathbf{u}_1, \dots, \mathbf{u}_n], V = [\mathbf{v}_1, \dots, \mathbf{v}_n]$ .

- i. Return  $\Sigma = \begin{pmatrix} \text{diag}(\hat{w}_1, \hat{w}_2, \dots, \hat{w}_n) \\ 0 \end{pmatrix}, U \leftarrow (QU \quad q), V \leftarrow WV$ .

**Algorithm 6:** Biorthogonalization SVD:Input:  $m, n, A$  where  $A$  is  $m \times n$ .Output:  $\Sigma, U, V$  so that  $\Sigma$  is diagonal,  $U$  and  $V$  have orthonormal columns,  $U$  is  $m \times n$ ,  $V$  is  $n \times n$ , and  $A = U\Sigma V^T$ .

1.  $U \leftarrow A$ . (This step can be omitted if  $A$  is to be overwritten with  $U$ .)
2.  $V = I_{n \times n}$ .

3. Set  $N^2 = \left( \sum_{i=1}^n \sum_{j=1}^n u_{i,j}^2 \right)$ ,  $s = 0$ , and  $first = \mathbf{true}$ .

4. Repeat until  $s^{1/2} \leq \varepsilon^2 N^2$  and  $first = \mathbf{false}$ .

- a. Set  $s = 0$  and  $first = \mathbf{false}$ .

- b. For  $i = 1, \dots, n - 1$ .

- i. For  $j = i + 1, \dots, n$

- $s \leftarrow s + \left( \sum_{k=1}^m u_{k,i} u_{k,j} \right)^2$ .

- Determine  $d_1, d_2, c = \cos(\theta)$ , and  $s = \sin(\varphi)$  such that:

$$\begin{bmatrix} c & -s \\ s & c \end{bmatrix} \begin{bmatrix} \sum_{k=1}^m u_{k,i}^2 & \sum_{k=1}^m u_{k,i} u_{k,j} \\ \sum_{k=1}^m u_{k,i} u_{k,j} & \sum_{k=1}^m u_{k,j}^2 \end{bmatrix} \begin{bmatrix} c & s \\ -s & c \end{bmatrix} = \begin{bmatrix} d_1 & 0 \\ 0 & d_2 \end{bmatrix}.$$

- $U \leftarrow U R_{i,j}(c, s)$  where  $R_{i,j}(c, s)$  is the Givens rotation matrix that acts on columns  $i$  and  $j$  during right multiplication.
- $V \leftarrow V R_{i,j}(c, s)$ .

5. For  $i = 1, \dots, n$ :

- a.  $\sigma_i = \sqrt{\sum_{k=1}^m u_{k,i}^2}$ .

- b.  $U \leftarrow U \Sigma^{-1}$ .

**Algorithm 7:** Jacobi Rotation SVD:Input:  $m, n, A$  where  $A$  is  $m \times n$ .Output:  $\Sigma, U, V$  so that  $\Sigma$  is diagonal,  $U$  and  $V$  have orthonormal columns,  $U$  is  $m \times n$ ,  $V$  is  $n \times n$ , and  $A = U\Sigma V^T$ .

1.  $B \leftarrow A$ . (This step can be omitted if  $A$  is to be overwritten with  $B$ .)

2.  $U = I_{m \times n}$ .

3.  $V = I_{n \times n}$ .

4. If  $m > n$ , compute the QR factorization of  $B$  using Householder matrices so that  $B \leftarrow QA$ , where  $B$  is upper triangular, and let  $U \leftarrow UQ$ . (See A6 for details.)

5. Set  $N^2 = \sum_{i=1}^n \sum_{j=1}^n b_{i,j}^2$ ,  $s = 0$ , and  $first = \mathbf{true}$ .

6. Repeat until  $s \leq \varepsilon^2 N^2$  and  $first = \mathbf{false}$ .

- a. Set  $s = 0$  and  $first = \mathbf{false}$ .

- b. For  $i = 1, \dots, n - 1$

(continued)

**Algorithm 7:** Jacobi Rotation SVD: (Continued)

i. For  $j = i + 1, \dots, n$ :

- $s = s + b_{i,j}^2 + b_{j,i}^2$ .
- Determine  $d_1, d_2, c = \cos(\theta)$  and  $s = \sin(\varphi)$  with the property that  $d_1$  and  $d_2$  are positive and

$$\begin{bmatrix} c & -s \\ s & c \end{bmatrix} \begin{bmatrix} b_{i,i} & b_{i,j} \\ b_{j,i} & b_{j,j} \end{bmatrix} \begin{bmatrix} \hat{c} & \hat{s} \\ -\hat{s} & \hat{c} \end{bmatrix} = \begin{bmatrix} d_1 & 0 \\ 0 & d_2 \end{bmatrix}.$$

- $B \leftarrow R_{i,j}(c, s) B R_{i,j}(\hat{c}, -\hat{s})$  where  $R_{i,j}(c, s)$  is the Givens rotation matrix that acts on rows  $i$  and  $j$  during left multiplication and  $R_{i,j}(\hat{c}, -\hat{s})$  is the Givens rotation matrix that acts on columns  $i$  and  $j$  during right multiplication.
- $U \leftarrow U R_{i,j}(c, s)$ .
- $V \leftarrow V R_{i,j}(\hat{c}, \hat{s})$ .

7. Set  $\Sigma$  to the diagonal portion of  $B$ .

Zlatko Drmač  
*University of Zagreb*

To compute the eigenvalues and singular values to high relative accuracy means to have a guaranteed number of accurate digits in all computed approximate values. If  $\tilde{\lambda}_i$  is the computed approximation of  $\lambda_i$ , then the desirable high relative accuracy means that  $|\lambda_i - \tilde{\lambda}_i| \leq \varepsilon |\lambda_i|$ , where  $0 \leq \varepsilon \ll 1$  independent of the ratio  $|\lambda_i| / \max_j |\lambda_j|$ . This is not always possible. The proper course of action is to first determine classes of matrices and classes of perturbations under which the eigenvalues (singular values) undergo only small relative changes. This means that the development of highly accurate algorithms is determined by the framework established by the perturbation theory.

Input to the perturbation theory is a perturbation matrix whose size is usually measured in a matrix norm. This may not be always adequate in numerical solutions of real world problems. If numerical information stored in the matrix represents a physical system, then choosing different physical units can give differently scaled rows and columns of the matrix, but representing the same physical system. Different scalings may be present because matrix entries represent quantities of different physical nature. It is possible that the smallest matrix entries are determined as accurately as the biggest ones. Choosing the most appropriate scaling from the application's point of view can be difficult task. It is then desirable that simple change of reference units do not cause instabilities in numerical algorithms because changing the description (scaling the data matrix) does not change the underlying physical system. This issue is often overlooked or ignored in numerical computations and it can be the cause of incorrectly computed and misinterpreted results with serious consequences.

This chapter describes algorithms for computation of the singular values and the eigenvalues of symmetric matrices to high relative accuracy. Accurate computation of eigenvectors and singular vectors is not considered. Singular values are discussed in sections 46.1 to 46.3; algorithms for computation of singular values are also given in Chapter 45.2.

Algorithms for computing the eigenvalues of symmetric matrices are given in Chapter 42. Sections 45.4 to 45.5 discuss numerical issues concerning the accuracy of the computed approximate eigenvalues, divided into the cases positive definite and symmetric indefinite (a negative definite matrix  $A$  is handled by applying methods for positive definite matrices to  $-A$ ).

For symmetric  $H$  (which may contain initial uncertainty), perturbation theory determines whether or not it is numerically feasible to compute even the smallest eigenvalues with high relative accuracy. State of the art perturbation theory, which is a necessary prerequisite for algorithmic development, is given in Chapter 15. The insights from the perturbation theory are then capitalized in the development of numerical algorithms capable of achieving optimal theoretical accuracy. Unlike in the case of standard accuracy, positive definite and indefinite matrices are analyzed separately.

All matrices are assumed to be over the real field  $\mathbb{R}$ . Additional relevant preparatory results can be found in Chapter 8 and Chapter 17.

## 46.1 Accurate SVD and One-Sided Jacobi SVD Algorithm

Numerical computation of the SVD inevitably means computation with errors. How many digits in the computed singular values are provably accurate is answered by perturbation theory adapted to a particular algorithm. For dense matrices with no additional structure, the Jacobi SVD algorithm is proven to be more accurate than any other method that first bidiagonalizes the matrix. The simplest form is the one-sided Jacobi SVD introduced by Hestenes [Hes58]. It represents an implicit form of the classical Jacobi algorithm [Jac46] for symmetric matrices, with properly adjusted stopping criterion. Basic properties of classical Jacobi algorithm are listed in Section 42.7. Detailed analysis and implementation details can be found in [DV92], [Drm94], [Mat96], and [Drm97].

### Definitions:

Two vectors  $\mathbf{x}, \mathbf{y} \in \mathbb{R}^m$  are **numerically orthogonal** if  $|\mathbf{x}^T \mathbf{y}| \leq \varepsilon \|\mathbf{x}\|_2 \|\mathbf{y}\|_2$ , where  $\varepsilon \geq 0$  is at most round-off unit  $\epsilon$  times a moderate function of  $m$ .

The square matrix  $\tilde{U}$  is a **numerically orthogonal matrix** if each pair of its columns is numerically orthogonal.

A numerical algorithm that computes approximations  $\tilde{U} \approx U$ ,  $\tilde{V} \approx V$  and  $\tilde{\Sigma} \approx \Sigma$  of the SVD  $A = U\Sigma V^T$  of  $A$  is **backward stable** if  $\tilde{U}, \tilde{V}$  are numerically orthogonal and  $\tilde{U}\tilde{\Sigma}\tilde{V}^T = A + \delta A$ , with **backward error**  $\delta A$  small compared to  $A$ .

### Facts:

1. There is no loss of generality in considering real tall matrices, i.e.,  $m \geq n$ . In case  $m < n$ , consider  $A^T$  with the SVD  $A^T = V\Sigma^T U^T$ .
2. Let  $\tilde{U} \approx U$ ,  $\tilde{V} \approx V$ ,  $\tilde{\Sigma} \approx \Sigma$  be the approximations of the SVD of  $A = U\Sigma V^T$ , computed by a backward stable algorithm as  $A + \delta A = \tilde{U}\tilde{\Sigma}\tilde{V}^T$ . Since the orthogonality of  $\tilde{U}$  and  $\tilde{V}$  cannot be guaranteed, the product  $\tilde{U}\tilde{\Sigma}\tilde{V}^T$  in general does not represent an SVD. However, there exist orthogonal  $\hat{U}$  close to  $\tilde{U}$  and an orthogonal  $\hat{V}$ , close to  $\tilde{V}$ , such that  $(I + E_1)(A + \delta A)(I + E_2) = \hat{U}\hat{\Sigma}\hat{V}^T$ , where  $E_1, E_2$ , which represent departure from orthogonality of  $\tilde{U}, \tilde{V}$ , are small in norm.
3. Different algorithms produce differently structured  $\delta A$ . Consider the singular values  $\sigma_1 \geq \dots \geq \sigma_n$  and  $\tilde{\sigma}_1 \geq \dots \geq \tilde{\sigma}_n$  of  $A$  and  $A + \delta A$ , respectively.
  - If  $\|\delta A\|_2 \leq \varepsilon \|A\|_2$  and without any additional structure of  $\delta A$  ( $\delta A$  small in norm), then the best error bound in the singular values is  $\max_{1 \leq i \leq n} |\sigma_i - \tilde{\sigma}_i| \leq \|\delta A\|_2$ , i.e.,  $\max_{1 \leq i \leq n} \frac{|\sigma_i - \tilde{\sigma}_i|}{\sigma_i} \leq \kappa_2(A) \varepsilon$ .

- [DV92] Let, for all  $i$ , the  $i$ th column  $\delta \mathbf{a}_i$  of  $\delta A$  satisfy  $\|\delta \mathbf{a}_i\|_2 \leq \varepsilon \|\mathbf{a}_i\|_2$ , where  $\mathbf{a}_i$  is the  $i$ th column of  $A$ . ( $\delta A$  is column-wise small perturbation.) Then  $A + \delta A = (B + \delta B)D$ , where  $A = BD$ ,  $D = \text{diag}(\|\mathbf{a}_1\|_2, \dots, \|\mathbf{a}_n\|_2)$ , and  $\|\delta B\|_F \leq \sqrt{n}\varepsilon$ . Let  $A$  have full column rank and let  $p$  be the rank of  $\delta A$ . Then  $\max_{1 \leq i \leq n} \frac{|\sigma_i - \bar{\sigma}_i|}{\sigma_i} \leq \|\delta B B^\dagger\|_2 \leq \sqrt{p}\varepsilon \|B^\dagger\|_2$ .
  - [vdS69]  $\|B^\dagger\|_2 \leq \kappa_2(B) \leq \sqrt{n} \min_{S=\text{diag}} \kappa_2(AS) \leq \sqrt{n}\kappa_2(A)$ . This implies that a numerical algorithm with column-wise small backward error  $\delta A$  computes more accurate singular values than an algorithm with backward error that is only small in norm.
4. In the process of computation of the SVD of  $A$ , an algorithm can produce intermediate matrix with singular values highly sensitive even to smallest entry-wise rounding errors.
  5. The matrix  $A$  may have initial uncertainty on input and, in fact,  $A = A_0 + \delta A_0$ , where  $A_0$  is the true unknown data matrix and  $\delta A_0$  the initial error already present in  $A$ . If  $\delta A$  generated by the algorithm is comparable with  $\delta A_0$ , the computed SVD is as accurate as warranted by the data.
  6. [Hes58] If  $H = A^T A$ , then the classical Jacobi algorithm can be applied to  $H$  implicitly. The one-sided (or implicit) Jacobi SVD method starts with general  $m \times n$  matrix  $A^{(0)} = A$  and it generates the sequence  $A^{(k+1)} = A^{(k)} V^{(k)}$ , where the matrix  $V^{(k)}$  is the plane rotation as in the classical symmetric Jacobi method for the matrix  $H^{(k)} = (A^{(k)})^T A^{(k)}$ . Only  $H^{(k)}[\{i_k, j_k\}]$  is needed to determine  $V^{(k)}$ , where  $(i_k, j_k)$  is the pivot pair determined by pivot strategy.
  7. In the one-sided Jacobi SVD algorithm applied to  $A \in \mathbb{R}^{m \times n}$ ,  $m \geq n$ ,  $A^{(k)}$  tends to  $U\Sigma$ , with diagonal  $\Sigma = \text{diag}(\sigma_1, \dots, \sigma_n)$  carrying the singular values. If  $A$  has full column rank, then the columns of  $U$  are the  $n$  corresponding left singular vectors. If  $\text{rank}(A) < n$ , then for each  $\sigma_i = 0$  the  $i$ th column of  $U$  is zero. The  $m$ -rank( $A$ ) left singular vectors from the orthogonal complement of  $\text{range}(A)$  cannot be computed using one-sided Jacobi SVD. The accumulated product  $V^{(0)} V^{(1)} \dots$  converges to orthogonal matrix  $V$  of right singular vectors.
  8. Simple implementation of Jacobi rotation in the one-sided Jacobi SVD algorithm (one-sided Jacobi rotation) is given in Algorithm 1. At any moment in the algorithm,  $d_1, \dots, d_n$  contain the squared Euclidean norms of the columns of current  $A^{(k)}$ , and  $\xi$  stores the Euclidean inner product of the pivot columns in the  $k$ th step.

**Algorithm 1:** One-sided Jacobi rotation

ROTATE ( $A_{1:m,i}, A_{1:m,j}, d_i, d_j, \xi, [V_{1:m,i}, V_{1:m,j}]$ )

- 1:  $\vartheta = \frac{d_j - d_i}{2 \cdot \xi}; t = \frac{\text{sign}(\vartheta)}{|\vartheta| + \sqrt{1 + \vartheta^2}}; c = \frac{1}{\sqrt{1 + t^2}}; s = t \cdot c;$
- 2:  $[A_{1:m,i} \ A_{1:m,j}] = [A_{1:m,i} \ A_{1:m,j}] \begin{bmatrix} c & s \\ -s & c \end{bmatrix};$
- 3:  $d_i = d_i - t \cdot \xi; d_j = d_j + t \cdot \xi;$
- 4: **if**  $V$  is wanted, **then**
- 5:  $[V_{1:m,i} \ V_{1:m,j}] = [V_{1:m,i} \ V_{1:m,j}] \begin{bmatrix} c & s \\ -s & c \end{bmatrix}$
- 6: **end if**

In case of cancellation in computation of the smaller of  $d_i, d_j$ , the value is refreshed by explicit computation of the squared norm of the corresponding column.

9. [dR89], [DV92] Numerical convergence of the one-sided Jacobi SVD algorithm (Algorithm 2) is declared at step  $k$  if  $\max_{i \neq j} \frac{|(A_{1:m,i}^{(k)})^T A_{1:m,j}^{(k)}|}{\|A_{1:m,i}^{(k)}\|_2 \|A_{1:m,j}^{(k)}\|_2} \leq \zeta \approx m\varepsilon$ . This stopping criterion guarantees that computed approximation  $\bar{A}^{(k)}$  of  $A^{(k)}$  can be written as  $\tilde{U}\tilde{\Sigma}$ , where the columns of  $\tilde{U}$  are numerically orthogonal, and  $\tilde{\Sigma}$  is diagonal.

**Algorithm 2:** One-sided Jacobi SVD (de Rijk's row-cyclic pivoting)

$(U, \Sigma, [V]) = \text{SVD0}(A)$

$\zeta = m\epsilon$ ;  $\hat{p} = n(n-1)/2$ ;  $s = 0$ ; *convergence* = **false**;

**if**  $V$  is wanted, **then initialize**  $V = I_n$  **end if**

**for**  $i = 1$  **to**  $n$  **do**  $d_i = A_{1:m,i}^T A_{1:m,i}$  **end for**;

**repeat**

$s = s + 1$ ;  $p = 0$ ;

**for**  $i = 1$  **to**  $n - 1$  **do**

find index  $i_0$  such that  $d_{i_0} = \max_{i \leq \ell \leq n} d_\ell$ ; **swap**( $d_i, d_{i_0}$ );

**swap**( $A_{1:m,i}, A_{1:m,i_0}$ ); **swap**( $V_{1:m,i}, V_{1:m,i_0}$ );

**for**  $j = i + 1$  **to**  $n$  **do**

$\xi = A_{1:m,i}^T A_{1:m,j}$ ;

**if**  $|\xi| > \zeta \sqrt{d_i d_j}$  **then** % apply Jacobi rotation

**call** ROTATE( $A_{1:m,i}, A_{1:m,j}, d_i, d_j, \xi, [V_{1:m,i}, V_{1:m,j}]$ );

**else**  $p = p + 1$  **end if**

**end for**

**end for**

**if**  $p = \hat{p}$ , **then** *convergence* = **true**; **go to** ► **end if**

**until**  $s > 30$

► **if** *convergence*, **then** % numerical orthogonality reached

**for**  $i = 1$  **to**  $n$  **do**  $\Sigma_{ii} = \sqrt{d_i}$ ;  $U_{1:m,i} = A_{1:m,i} \Sigma_{ii}^{-1}$  **end for**

**else**

**Error:** Numerical convergence did not occur after 30 sweeps.

**end if**

10. [DV92], [Mat96], [Drm97] Let  $\tilde{A}^{(k)}$ ,  $k = 0, 1, 2, \dots$  be the matrices computed by Algorithm 2 in floating point arithmetic. Write each  $\tilde{A}^{(k)}$  as  $\tilde{A}^{(k)} = B^{(k)} D^{(k)}$ , with diagonals  $D^{(k)}$  and  $B^{(k)}$  with columns of unit Euclidean norms. Then

- $\tilde{A}^{(k+1)} = (\tilde{A}^{(k)} + \delta \tilde{A}^{(k)}) \check{V}^{(k)}$ , where  $\check{V}^{(k)}$  is the exact plane rotation transforming pivot columns, and  $\delta \tilde{A}^{(k)}$  is zero except in the  $i_k$ th and the  $j_k$ th columns.
- $\tilde{A}^{(k)} + \delta \tilde{A}^{(k)} = (B^{(k)} + \delta B^{(k)}) D^{(k)}$ , with  $\|\delta B^{(k)}\|_F < c_k \epsilon$ , where  $c_k$  is a small factor (e.g.,  $c_k < 20$ ) that depends on the implementation of the rotation.
- The above holds as long as the Euclidean norms of the  $i_k$ th and the  $j_k$ th columns of  $\tilde{A}^{(k)}$  do not underflow or overflow. It holds even if the computed angle is so small that the computed value of  $\tan \phi_k$  underflows (gradually or flushed to zero). This, however, requires special implementation of the Jacobi rotation.
- If all matrices  $\tilde{A}^{(j)}$ ,  $j = 0, \dots, k-1$  are nonsingular, then for all  $i = 1, \dots, n$ ,

$$\max \left\{ 0, \prod_{j=0}^{k-1} (1 - \eta_j) \right\} \leq \frac{\sigma_i(\tilde{A}^{(k)})}{\sigma_i(A)} \leq \prod_{j=0}^{k-1} (1 + \eta_j),$$

where  $\eta_j = \|\delta \tilde{A}^{(j)} (\tilde{A}^{(j)})^\uparrow\|_2 \leq c_j \epsilon \| (B^{(j)})^\uparrow \|_2$ , and  $\sigma_i(\cdot)$  stands for the  $i$ th largest singular value of a matrix. The accuracy of Algorithm 2 is determined by  $\beta \equiv \max_{k \geq 0} \| (B^{(k)})^\uparrow \|_2$ . It is observed in practice that  $\beta$  never exceeds  $\|B^\uparrow\|_2$  too much.

- If  $A$  initially contains column-wise small uncertainty and if  $\beta / \|B^\uparrow\|_2$  is moderate, then Algorithm 2 computes as accurate approximations of the singular values as warranted by the data.

### Examples:

1. Using orthogonal factorizations in finite precision arithmetic does not guarantee high relative accuracy in SVD computation. Bidiagonalization, as a preprocessing step in state-of-the-art SVD

algorithms, is an example. We use MATLAB with roundoff  $\epsilon = \text{eps} \approx 2.22 \cdot 10^{-16}$ . Let  $\xi = 10/\epsilon$ . Then floating point bidiagonalization of

$$A = \begin{pmatrix} 1 & 1 & \boxed{1} \\ 0 & 1 & \xi \\ 0 & -1 & \xi \end{pmatrix} \text{ yields } \tilde{A}^{(1)} = \begin{pmatrix} 1 & \alpha & 0 \\ 0 & \beta & \beta \\ 0 & \boxed{\beta} & \beta \end{pmatrix}, \quad \tilde{A}^{(2)} = \begin{pmatrix} 1 & \alpha & 0 \\ 0 & \gamma & \gamma \\ 0 & 0 & 0 \end{pmatrix},$$

$\alpha \approx 1.4142135\text{e}+0$ ,  $\beta \approx 3.1845258\text{e}+16$ ,  $\gamma \approx 4.5035996\text{e}+16$ . The matrices  $\tilde{A}^{(1)}$  and  $\tilde{A}^{(2)}$  are computed using Givens plane rotations at the positions indicated by  $\boxed{\cdot}$ . The computed matrix  $\tilde{A}^{(1)}$  entry-wise approximates with high relative accuracy the matrix  $A^{(1)}$  from the exact computation (elimination of  $A_{13}$ ). However,  $A$  and  $A^{(1)}$  are nonsingular and  $\tilde{A}^{(1)}$  is singular. The smallest singular value of  $A$  is lost —  $\tilde{A}^{(1)}$  carries no information about  $\sigma_3$ . Transformation from  $\tilde{A}^{(1)}$  to  $\tilde{A}^{(2)}$  is again perfectly entry-wise accurate. But, even exact SVD of the bidiagonal  $\tilde{A}^{(2)}$  cannot restore the information lost in the process of bidiagonalization. (See Fact 4 above.)

On the other hand, let  $\hat{A}^{(1)}$  denote the matrix obtained from  $A$  by perturbing  $A_{13}$  to zero. This changes the third column  $\mathbf{a}_3$  of  $A$  by  $\|\delta \mathbf{a}_3\|_2 \leq (\epsilon/14)\|\mathbf{a}_3\|_2$  and causes, at most,  $\epsilon/5$  relative perturbation in the singular values. (See Fact 3 above. Here,  $A = BD$  with  $\kappa(B) < 2$ .) If we apply Givens rotation from the left to annihilate the  $(3, 2)$  entry in  $\hat{A}^{(1)}$ , the introduced perturbation is column-wise small. Also, the largest singular value decouples; the computed matrix is  $\hat{A}^{(2)} = \begin{bmatrix} 1 & 1 \\ 0 & \alpha \end{bmatrix} \oplus \sigma_1$ .

## 46.2 Preconditioned Jacobi SVD Algorithm

The accuracy properties and the run-time efficiency of the one-sided Jacobi SVD algorithm can be enhanced using appropriate preprocessing and preconditioning. More details can be found in [Drm94], [Drm99], [DV05a], and [DV05b].

### Definitions:

**QR factorization with column pivoting** of  $A \in \mathbb{R}^{m \times n}$  is the factorization  $A\Pi = Q \begin{bmatrix} R \\ 0 \end{bmatrix}$ , where  $\Pi$  is a permutation matrix,  $Q$  is orthogonal, and  $R$  is  $n \times n$  upper triangular.

The QR factorization with **Businger–Golub pivoting** chooses  $\Pi$  to guarantee that  $r_{kk}^2 \geq \sum_{i=k}^j r_{ij}^2$  for all  $j = k, \dots, n$  and  $k = 1, \dots, n$ .

The QR factorization with **Powell–Reid’s complete (row and column) pivoting** computes the QR factorization using row and column permutations,  $\Pi_r A \Pi_c = Q \begin{bmatrix} R \\ 0 \end{bmatrix}$ , where  $\Pi_c$  is as in Businger–Golub pivoting and  $\Pi_r$  enhances numerical stability in case of  $A$  with differently scaled rows.

QR factorization with pivoting of  $A$  is **rank revealing** if small singular values of  $A$  are revealed by correspondingly small diagonal entries of  $R$ .

### Facts:

- [Drm94], [Hig96]. Let the QR factorization  $A = Q \begin{bmatrix} R \\ 0 \end{bmatrix}$  of  $A \in \mathbb{R}^{m \times n}$ ,  $m \geq n$ , be computed using the Givens or the Householder algorithm in the IEEE floating point arithmetic with rounding relative error  $\epsilon < 10^{-7}$ . Let the computed approximations of  $Q$  and  $R$  be  $\tilde{Q}$  and  $\tilde{R}$ , respectively. Then there exist an orthogonal matrix  $\hat{Q}$  and a backward perturbation  $\delta A$  such that

$$A + \delta A = \hat{Q} \begin{bmatrix} \tilde{R} \\ 0 \end{bmatrix}, \quad \|\tilde{Q}_{1:m,i} - \hat{Q}_{1:m,i}\|_2 \leq \epsilon_{qr}, \quad \|\delta A_{1:m,i}\|_2 \leq \epsilon_{qr} \|A_{1:m,i}\|_2$$

holds for all  $i = 1, \dots, n$ , with  $\varepsilon_{qr} \leq O(mn)\epsilon$ . This remains true if the factorization is computed with pivoting. It suffices to assume that the matrix  $A$  is already prepermuted on input, and that the factorization itself is performed without pivoting.

2. [Drm94], [Mat96], [Drm99] Let  $A = BD$ , where  $D$  is diagonal and  $B$  has unit columns in Euclidean norm.
  - If  $\|B^\dagger\|_2$  is moderate, then the computed  $\tilde{R}$  allows approximation of the singular values of  $A$  to high relative accuracy. If  $\tilde{R}$  is computed with Businger–Golub pivoting, then Algorithm 2 applied to  $\tilde{R}^T$  converges swiftly and computes the singular values of  $A$  with relative accuracy determined by  $\|B^\dagger\|_2$ .
  - Let  $A$  have full column rank and let its QR factorization be computed by Businger–Golub column pivoting. Write  $R = ST$ , where  $S$  is the diagonal matrix and  $T$  has unit rows in Euclidean norm. Then  $\|T^{-1}\|_2 \leq n\|B^\dagger\|_2$ .
3. [DV05a] The following algorithm carefully combines the properties of the one–sided Jacobi SVD and the properties of the QR factorization (Facts 1 and 2):

**Algorithm 3:** Preconditioned Jacobi SVD

$(U, \Sigma, [V]) = \text{SVD1}(A)$

Input:  $A \in \mathbb{R}^{m \times n}$ ,  $m \geq n$ .

- 1:  $(P_r A)P_c = Q_1 \begin{bmatrix} R_1 \\ 0 \end{bmatrix}$ ; %  $R_1 \in \mathbb{R}^{\rho \times n}$ , rank revealing QRF.
- 2:  $R_1^T = Q_2 \begin{bmatrix} R_2 \\ 0 \end{bmatrix}$ ; %  $R_2 \in \mathbb{R}^{\rho \times \rho}$ .
- 3:  $(U_2, \Sigma_2, V_2) = \text{SVD0}(R_2^T)$ ; % one-sided Jacobi SVD on  $R_2^T$ .

Output:  $U = P_r^T Q_1 \begin{bmatrix} U_2 & 0 \\ 0 & I_{m-\rho} \end{bmatrix}$ ;  $\Sigma = \begin{bmatrix} \Sigma_2 & 0 \\ 0 & 0 \end{bmatrix}$ ;  $V = P_c Q_2 \begin{bmatrix} V_2 & 0 \\ 0 & I_{n-\rho} \end{bmatrix}$ .

4. [Drm99], [DV05a], [DV05b]
  - Let  $A$  and the computed matrix  $\tilde{R}_1 \approx R_1$  in Algorithm 3 be of full column rank. Let  $\tilde{R}_2$  be computed approximation of  $R_2$  in Step 2. Then, there exist perturbations  $\delta A$ ,  $\delta \tilde{R}_1$ , and there exist orthogonal matrices  $\hat{Q}_1$ ,  $\hat{Q}_2$  such that

$$(I + \delta A A^\dagger)A(I + \tilde{R}_1^{-1} \delta \tilde{R}_1) = \hat{Q}_1 \begin{bmatrix} \tilde{R}_2^T \\ 0 \end{bmatrix} \hat{Q}_2^T.$$

Thus, the first two steps of Algorithm 3 preserve the singular values if  $\|B^\dagger\|_2$  is moderate.

- Let the one-sided Jacobi SVD algorithm with row cyclic pivot strategy be applied to  $\tilde{R}_2^T$ . Let the stopping criterion be satisfied at the matrix  $(\tilde{R}_2^T)^{(k)}$  during the  $s$ th sweep. Write  $(\tilde{R}_2^T)^{(k)} = \tilde{U}_2 \tilde{\Sigma}$ , where  $\tilde{\Sigma}$  is diagonal and  $\tilde{U}_2$  is numerically orthogonal. Then there exist an orthogonal matrix  $\hat{V}_2$  and a backward error  $\delta \tilde{R}_2$  such that  $\tilde{U}_2 \tilde{\Sigma} = (\tilde{R}_2 + \delta \tilde{R}_2)^T \hat{V}_2$ ,  $\|\delta(\tilde{R}_2)_{1:\rho,i}\|_2 \leq \varepsilon_J \|(\tilde{R}_2)_{1:\rho,i}\|_2$ ,  $i = 1, \dots, \rho$ , with  $\varepsilon_J \leq (1 + 6\epsilon)^{s(2n-3)} - 1$ . If  $\hat{U}_2$  is the closest orthogonal matrix to  $\tilde{U}_2$ , then  $\tilde{R}_2^T = \hat{V}_2 \tilde{\Sigma} \hat{U}_2^T (I + E)$ , where the dominant part of  $\|E\|_2$  is  $\|\delta \tilde{R}_2 \tilde{R}_2^{-1}\|_2$ . Similar holds for any serial or parallel convergent pivot strategy.
- Assembling the above yields

$$(I + \delta A A^\dagger)A(I + \tilde{R}_1^{-1} \delta \tilde{R}_1) = \hat{Q}_1 \begin{bmatrix} \hat{V}_2 & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} \tilde{\Sigma} \\ 0 \end{bmatrix} \hat{U}_2^T \hat{Q}_2^T (I + \hat{Q}_2 E \hat{Q}_2^T).$$

The upper bound on the maximal relative error  $\|\Sigma^{-1}(\Sigma - \tilde{\Sigma})\|_2$  is dominated by  $\|\delta AA^\dagger\|_2 + \|\tilde{R}_1^{-1}\delta\tilde{R}_1\|_2 + \|\delta\tilde{R}_2\tilde{R}_2^{-1}\|_2$ .

- Let  $A$  have the structure  $A = BD$ , where full-column rank  $B$  has equilibrated columns and  $D$  is arbitrary diagonal scaling. The only relevant condition number for relative accuracy of Algorithm 3 is  $\|B^\dagger\|_2$ .
5. [DV05a], [DV05b] Algorithm 3 outperforms Algorithm 2 both in speed and accuracy.
  6. [Drm99], [Drm00b], [Hig00], [DV05a] It is possible that  $\kappa_2(B)$  is large, but  $A$  is structured as  $A = D_1CD_2$  with diagonal scalings  $D_1, D_2$  (diagonal entries in nonincreasing order) and well conditioned  $C$ . In that case, desirable backward error for the first QR factorization (Step 1) is  $P_rD_1(C + \delta C)D_2P_c$  with satisfactory bound on  $\|\delta C\|_2$ . This is nearly achieved if the QR factorization is computed with Powell–Reid’s complete pivoting or its simplification, which replaces row pivoting with initial sorting. Although theoretical understanding of this fact is not complete, initial row sorting (descending in  $\|\cdot\|_\infty$  norm) is highly recommended.

**Examples:**

1. The key step of the preconditioning is in transposing the computed triangular factors. If  $A$  is a  $100 \times 100$  Hilbert matrix, written as  $A = BD$  (cf. Fact 2), then  $\kappa_2(B) > 10^{19}$ . If in Step 2 of Algorithm 3, we write  $R_1^T$  as  $R_1^T = B_1D_1$ , where  $D_1$  is diagonal and  $B_1$  has unit columns in Euclidean norm, then  $\kappa_2(B_1) < 50$ .
2. Take  $\gamma = 10^{-20}, \delta = 10^{-40}$  and consider the matrix

$$A = \begin{bmatrix} 1 & \gamma & \gamma \\ -\gamma & \gamma & \gamma^2 \\ 0 & \delta & 0 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \gamma & 0 \\ 0 & 0 & \delta \end{bmatrix} \begin{bmatrix} 1 & \gamma & 1 \\ -1 & 1 & 1 \\ 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & \gamma \end{bmatrix},$$

with singular values nearly  $\sigma_1 \approx 1, \sigma_2 \approx \gamma, \sigma_3 \approx 2\gamma\delta$ , cf. [DGE99].  $A$  cannot be written as  $A = BD$  with diagonal  $D$  and well-conditioned  $B$ . Algorithm 2 computes no accurate digit of  $\sigma_3$ , while Algorithm 3 approximates all singular values to nearly full accuracy. (See Fact 5.) The computed  $\tilde{R}_1^T$  in Step 2 is

$$\tilde{R}_1^T = \begin{bmatrix} -1.0000000000000000e + 0 & 0 & 0 \\ -1.0000000000000000e - 20 & -1.0000000000000000e - 20 & 0 \\ -1.0000000000000000e - 20 & -1.0000000000000000e - 40 & -2.0000000000000000e - 60 \end{bmatrix}.$$

Note that the neither the columns of  $A$  nor the columns of  $\tilde{R}_1$  reveal the singular value of order  $10^{-60}$ . On the other hand, the Euclidean norms of the column of  $\tilde{R}_1^T$  nicely approximate the singular values of  $A$ . (See Facts 2, 3.) If the order of the rows of  $A$  is changed,  $\tilde{R}_1$  is computed with zero third row.

### 46.3 Accurate SVD from a Rank Revealing Decomposition: Structured Matrices

In some cases, the matrix  $A$  is given implicitly as the product of two or three matrices or it can be factored into such a product using more general nonorthogonal transformations. For instance, some specially structured matrices allow Gaussian eliminations with complete pivoting  $P_1AP_2 = LDU$  to compute entry-wise accurate  $\tilde{L} \approx L, \tilde{D} \approx D, \tilde{U} \approx U$ . Moreover, it is possible that the triple  $\tilde{L}, \tilde{D}, \tilde{U}$  implicitly defines the SVD of  $A$  to high relative accuracy, and that direct application of any SVD algorithm directly to  $A$  does not return accurate SVD. For more information on matrices and bipartite graphs, see Chapter 30. For more information on sign pattern matrices, see Chapter 33. For more information on totally nonnegative (TN) matrices, see Chapter 21.

**Definitions:**

The singular values of  $A$  are said to be **perfectly well determined to high relative accuracy** if the following holds: No matter what the entries of the matrix are, changing an arbitrary nonzero entry  $a_{k\ell}$  to  $\theta a_{k\ell}$ , with arbitrary  $\theta \neq 0$ , will cause perturbation  $\sigma_i \rightsquigarrow \tilde{\sigma}_i \in [\theta_l \sigma_i, \theta_u \sigma_i]$ ,  $\theta_l = \min\{|\theta|, 1/|\theta|\}$ ,  $\theta_u = \max\{|\theta|, 1/|\theta|\}$ ,  $i = 1, \dots, n$ .

The **sparsity pattern**  $\text{Struct}(A)$  of  $A$  is defined as the set of indices  $(k, \ell)$  of the entries of  $A$  permitted to be nonzero.

The **bipartite graph**  $\mathcal{G}(S)$  of the sparsity pattern  $S$  is the graph with vertices partitioned into row vertices  $r_1, \dots, r_m$  and column vertices  $c_1, \dots, c_n$ , where  $r_k$  and  $r_l$  are connected if and only if  $(k, l) \in S$ .

If  $\mathcal{G}(S)$  is acyclic, matrices with sparsity pattern  $S$  are **biacyclic**.

The **sign** pattern  $\text{sgn}(A)$  prescribes locations and signs of nonzero entries of  $A$ .

A sign pattern  $S$  is **total signed compound** (TSC) if every square submatrix of every matrix  $A$  such that  $\text{sgn}(A) = S$  is either **sign nonsingular** (nonsingular and determinant expansion is the sum of monomials of like sign) or **sign singular** (determinant expansion degenerates to sum of monomials, which are all zero); cf. Chapter 33.2.

$A \in \mathbb{R}^{m \times n}$  is **diagonally scaled totally unimodular** (DSTU) if there exist diagonal  $D_1, D_2$  and **totally unimodular**  $Z$  (all minors of  $Z$  are from  $\{-1, 0, 1\}$ ) such that  $A = D_1 Z D_2$ .

A decomposition  $A = X D Y^T$  with diagonal matrix  $D$  is called an **RRD** if  $X$  and  $Y$  are full-column rank, well-conditioned matrices. (RRD is an abbreviation for “rank revealing decomposition,” but that term is defined slightly differently in Chapter 39.9, where  $X, Y$  are required to be orthogonal and  $D$  is replaced by an upper triangular matrix.)

**Facts:**

1. [DG93] The singular values of  $A$  are perfectly well determined to high relative accuracy if and only if the bipartite graph  $\mathcal{G}(S)$  is acyclic (forest of trees). Sparsity pattern  $S$  with acyclic  $\mathcal{G}(S)$  allows at most  $m + n - 1$  nonzero entries. A bisection algorithm computes all singular values of biacyclic matrices to high relative accuracy.
2. [DK90], [FP94] Bidiagonal matrices are a special case of acyclic sparsity pattern. Let  $n \times n$  bidiagonal matrix  $B$  be perturbed by  $b_{ii} \rightsquigarrow b_{ii} \varepsilon_{2i-1}$ ,  $b_{i,i+1} \rightsquigarrow b_{i,i+1} \varepsilon_{2i}$  for all admissible  $i$ s, and let  $\varepsilon = \prod_{i=1}^{2n-1} \max\{|\varepsilon_i|, 1/|\varepsilon_i|\}$ , where all  $\varepsilon_i \neq 0$ . If  $\tilde{\sigma}_1 \geq \dots \geq \tilde{\sigma}_n$  are the singular values of the perturbed matrix, then for all  $i$ ,  $\sigma_i / \varepsilon \leq \tilde{\sigma}_i \leq \varepsilon \sigma_i$ . The singular values of bidiagonal matrices are efficiently computed to high relative accuracy by the zero shift QR algorithm and the differential qd algorithm.
3. [DGE99] Let  $\mathcal{S}_\pm$  be a sparsity-and-sign pattern. Let each matrix  $A$  with pattern  $\mathcal{S}_\pm$  have the property that small relative changes of its (nonzero) entries cause only small relative perturbations of its singular values. This is equivalent with  $\mathcal{S}_\pm$  being total signed compound (TSC).
4. [Drm98a], [DGE99] Let  $A$  be given by an RRD  $A = X D Y^T$ . Without loss of generality assume that  $X$  and  $Y$  have equilibrated (e.g., unit in Euclidean norm) columns. Algorithm 4 computes the SVD of  $A$  to high relative accuracy.

**Algorithm 4:** RRD Jacobi SVD

$(U, \Sigma, V) = \text{SVD2}(X, D, Y)$

Input:  $X \in \mathbb{R}^{m \times p}$ ,  $Y \in \mathbb{R}^{n \times p}$  full column rank,  $D \in \mathbb{R}^{p \times p}$  diagonal.

1:  $\Upsilon = Y D$ ;  $\Upsilon P = Q \begin{bmatrix} R \\ 0 \end{bmatrix}$  % rank revealing QR factorization.

2:  $Z = (X P) R^T$ ; % explicit standard matrix multiplication.

3:  $(U_z, \Sigma_z, V_z) = \text{SVD1}(Z)$  % one-sided Jacobi SVD on  $Z$ .

Output:  $U = U_z$ ;  $\Sigma = \begin{bmatrix} \Sigma_z & 0 \\ 0 & 0 \end{bmatrix}$ ;  $V = Q \begin{bmatrix} V_z & 0 \\ 0 & I_{n-p} \end{bmatrix}$ .  $X D Y^T = U \Sigma V^T$ .

## 5. [Drm98a], [DGE99], [DM04]

- In Step 2 of Algorithm 4, the matrix  $R^T$  has the structure  $R^T = LS$ , where  $S$  is diagonal scaling,  $L$  has unit columns, and  $\|L^{-1}\|_2$  is bounded by a function of  $p$  independent of input data. The upper bound on  $\kappa_2(L)$  depends on pivoting  $P$  in Step 1 and can be  $O(n^{1+(1/4)\log_2 n})$ . For the Businger–Golub, pivoting the upper bound is  $O(2^n)$ , but in practice one can expect an  $O(n)$  bound.
- The product  $Z = (XP)R^T$  must not be computed by fast (e.g., Strassen) algorithm if all singular values are wanted to high relative accuracy. The reason is that fast matrix multiplication algorithms can produce larger component-wise perturbations than the standard  $O(n^3)$  algorithm.
- The computed  $\tilde{U}$ ,  $\tilde{\Sigma}$ ,  $\tilde{V}$  satisfy: There exist orthogonal  $\hat{U} \approx \tilde{U}$ , orthogonal  $\hat{V} \approx \tilde{V}$ , and  $E_1, E_2$  such that  $\hat{U} \tilde{\Sigma} \hat{V}^T = (I + E_1)A(I + E_2)$ ,  $\|E_1\|_2 \leq O(\epsilon)\kappa_2(X)$ ,  $\|E_2\|_2 \leq O(\epsilon)\kappa_2(L)\kappa_2(Y)$ . The relative errors in the computed singular values are bounded by  $O(\epsilon)\kappa_2(L) \max\{\kappa_2(X), \kappa_2(Y)\}$ . Here,  $O(\epsilon)$  denotes machine precision  $\epsilon$  multiplied by a moderate polynomial in  $m, n, p$ .

## 6. [DGE99] Classes of matrices with accurate LDU factorization and, thus, accurate SVD computation by Algorithm 4, or other algorithms tailored for special classes of matrices (e.g., QR and qd algorithms for bidiagonal matrices), include:

- *Acyclic matrices*: Accurate LDU factorization with pivoting uses the correspondence between the monomials in determinant expansion and perfect matchings in  $\mathcal{G}(S)$ .
- *Total signed compound (TSC) matrices*: LDU factorization with complete pivoting  $P_r A P_c = LDU$  of an TSC matrix  $A$  can be computed in a forward stable way. Cancellations in Gaussian eliminations can be avoided by computing some elements as quotients of minors. All entries of  $L, D, U$  are computed to high relative accuracy. The behavior of  $\kappa(L)$  and  $\kappa(U)$  is not fully analyzed, but they behave well in practice.
- *Diagonally scaled totally unimodular (DSTU) matrices*: This class includes acyclic and certain finite element (e.g., mass-spring systems) matrices. Gaussian elimination with complete pivoting is modified by replacing dangerous cancellations by exactly predicted exact zeros. All entries of  $L, D, U$  are computed to high relative accuracy, and  $\kappa(L), \kappa(U)$  are at most  $O(mn)$  and  $O(n^2)$ , respectively.

7. [Dem99] In some cases, new classes of matrices and accurate SVD computation are derived from relations with previously solved problems or by suitable matrix representations. The following cases are analyzed and solved with  $O(n^3)$  complexity:

- *Cauchy matrices*:  $C = C(x, y)$ ,  $c_{ij} = 1/(x_i + y_j)$ , and the parameters  $x_i$ 's,  $y_i$ 's are the initial data. The algorithm extends to Cauchy-like matrices  $C' = D_1 C D_2$ , where  $C$  is a Cauchy matrix and  $D_1, D_2$  are diagonal scalings. The required LDU factorization is computed with  $\frac{4}{3}n^3$  operations and given as input to Algorithm 4. It should be noted that this does not imply that Cauchy matrices determine their singular values perfectly well. The statement is: For a Cauchy matrix  $C$ , given by set of parameters  $x_i$ 's,  $y_i$ 's stored as floating point numbers in computer memory, all singular values of  $C$  can be computed in a forward stable way. Thus, for example, singular values of a notoriously ill-conditioned Hilbert matrix can be computed to high relative accuracy.
- *Vandermonde matrices*:  $V = [v_{ij}]$ ,  $v_{ij} = x_i^{j-1}$ . An accurate algorithm exploits the fact that postmultiplication of  $V$  by the discrete Fourier transform matrix gives a Cauchy-like matrix. The finite precision arithmetic requires a guard digit and extra precision to tabulate certain constants.
- *Unit displacement rank matrix  $X$* : Solution of matrix equation  $AX + XB = d_1 d_2^T$ , where  $A, B$  are diagonal, or normal matrices with known accurate spectral decompositions. The class of unit displacement rank matrices generalizes the Cauchy-like matrices ( $A$  and  $B$  diagonal) and Vandermonde matrices ( $A$  diagonal and  $B$  circular shift).

8. [DK04] Weakly diagonally dominant M-matrices given with  $a_{ij} \leq 0$  for  $i \neq j$  and with the row-sums  $s_i = \sum_{j=1}^n a_{ij} \geq 0$ ,  $i = 1, \dots, n$  known with small relative errors, allow accurate LDU factorization with complete pivoting.
9. [Koe05] Totally nonnegative (TN) matrix  $A$  can be expressed as the product of nonnegative bidiagonal matrices. If  $A$  is given implicitly by this bidiagonal representation, then all its singular values (and eigenvalues, too) can be computed from the bidiagonals to high relative accuracy. Accurate bidiagonal representation for given TN matrix  $A$  is possible for totally positive cases (all minors positive), provided certain pivotal minors can be computed accurately.
10. [DK05a] The singular values of the matrix  $V$  with entries  $v_{ij} = P_i(x_j)$ , where the  $P_i$ s are orthonormal polynomials and the  $x_j$ s are the nodes, can be computed to high relative accuracy.
11. [Drm00a] Accurate SVD of the RRD  $XDY^T$  extends to the triple product  $XS Y^T$ , where  $S$  is not necessarily diagonal, but it can be accurately factored by Gaussian eliminations with pivoting.

### Examples:

1. An illustration of the power of the algorithms described in this section is the example of a  $100 \times 100$  Hilbert matrix described in [Dem99]. Its singular values range over 150 orders of magnitude and are computed using the package Mathematica with 200-decimal digit software floating point arithmetic. The computed singular values are rounded to 16 digits and used as reference values. The singular values computed in IEEE double precision floating point ( $\epsilon \approx 10^{-16}$ ) by the algorithms described in this section agree with the reference values with relative error less than  $34 \cdot \epsilon$ .
2. [DGE99] Examples of sign patterns of TSC matrices:

$$\begin{bmatrix} + & + & 0 & 0 & 0 \\ + & - & + & 0 & 0 \\ 0 & + & + & + & 0 \\ 0 & 0 & + & - & + \\ 0 & 0 & 0 & + & + \end{bmatrix}, \quad \begin{bmatrix} + & + & + & + & + \\ + & - & 0 & 0 & 0 \\ + & 0 & - & 0 & 0 \\ + & 0 & 0 & - & 0 \\ + & 0 & 0 & 0 & - \end{bmatrix}.$$

TSC matrices must be sparse because an  $m \times n$  TSC matrix can have at most  $\frac{3}{2}(m+n) - 2$  nonzero entries.

## 46.4 Positive Definite Matrices

### Definitions:

The **Cholesky factorization with pivoting** of symmetric positive definite  $n \times n$  matrix  $H$  computes the Cholesky factorization  $P^T H P = L L^T$ , where the permutation matrix  $P$  is such that  $\ell_{ii}^2 \geq \sum_{k=i}^j \ell_{kj}^2$ ,  $1 \leq i \leq j \leq n$ .

The **component-wise relative distance** between  $H$  and its component-wise relative perturbation  $\tilde{H}$  is  $\text{reldist}(H, \tilde{H}) = \max_{i,j} \frac{|h_{ij} - \tilde{h}_{ij}|}{|h_{ij}|}$ , where  $0/0 = 0$ .

A **diagonally scaled representation** of symmetric matrix  $H$  with positive diagonal entries is a factored representation  $H = D A D$  with  $D = \text{diag}(\sqrt{h_{11}}, \dots, \sqrt{h_{nn}})$ ,  $a_{ij} = \frac{h_{ij}}{\sqrt{h_{ii} h_{jj}}}$ .

### Facts:

1. [Dem89], [Dem92] Let  $H = D A D$  be a diagonally scaled representation of positive definite  $H$ , and let  $\lambda_{\min}(A)$  denote the minimal eigenvalue of  $A$ .
  - If  $\delta H$  is a symmetric perturbation such that  $H + \delta H$  is not positive definite, then

$$\max_{1 \leq i, j \leq n} \frac{|\delta h_{ij}|}{\sqrt{h_{ii} h_{jj}}} \geq \frac{\lambda_{\min}(A)}{n} = \frac{1}{n \|A^{-1}\|_2}.$$

- If  $\delta H = -\lambda_{\min}(A)D^2$ , then  $\max_{i,j} \frac{|\delta h_{ij}|}{\sqrt{h_{ii}h_{jj}}} = \lambda_{\min}(A)$ ,  $\text{reldist}(H, H + \delta H) = \lambda_{\min}(A)$ , and  $H + \delta H$  is singular.
2. [Dem89] Let  $H = DAD$  be an  $n \times n$  symmetric matrix with positive diagonal entries, stored in the machine memory. Let  $H$  be the input matrix in the Cholesky factorization algorithm. Then the following holds:
    - If the Cholesky algorithm successfully completes all operations and computes lower triangular matrix  $\tilde{L}$ , then there exists symmetric backward perturbation  $\delta H$  such that  $\tilde{L}\tilde{L}^T = H + \delta H$  and  $|\delta h_{ij}| \leq \eta_C \sqrt{h_{ii}h_{jj}}$ ,  $\eta_C \leq O(n\epsilon)$ .
    - If  $\lambda_{\min}(A) > n\eta_C$ , then the Cholesky algorithm will succeed and compute  $\tilde{L}$ .
    - If  $\lambda_{\min}(A) < \epsilon$ , then there exists simulation of rounding errors in which the Cholesky algorithm fails to complete all operations.
    - If  $\lambda_{\min}(A) \leq -n\eta_C$ , then it is certain that the Cholesky algorithm will fail.
  3. [DV92] If  $H = DAD \in \text{PD}_n$  is perturbed to a positive definite  $\tilde{H} = H + \delta H$ , then
    - $\max_{1 \leq i \leq n} \frac{|\lambda_i - \tilde{\lambda}_i|}{\lambda_i} \leq \|L^{-1}\delta H L^{-T}\|_2 \leq \frac{\|D^{-1}\delta H D^{-1}\|_2}{\lambda_{\min}(A)} = \|A^{-1}\|_2 \|D^{-1}\delta H D^{-1}\|_2$ .
    - Let  $\delta H = \eta D^2$ , with any  $\eta \in (0, \lambda_{\min}(A))$ . Then for some index  $i$  it holds that  $\frac{|\lambda_i - \tilde{\lambda}_i|}{\lambda_i} \geq \sqrt[n]{1 + \frac{\eta}{\lambda_{\min}(A)}}$ .
  4. [DV92], [VS93] Let  $H = DAD$  be positive definite and  $c > 0$  constant such that for all  $\epsilon \in (0, 1/c)$  and for all symmetric component-wise relative perturbations  $\delta H$  with  $|\delta h_{ij}| \leq \epsilon |h_{ij}|$ ,  $1 \leq i, j \leq n$ , the ordered eigenvalues  $\lambda_i$  and  $\tilde{\lambda}_i$  of  $H$  and  $H + \delta H$  satisfy  $\max_{1 \leq i \leq n} \frac{|\lambda_i - \tilde{\lambda}_i|}{\lambda_i} \leq c\epsilon$ . Then  $\|A^{-1}\|_2 < (1+c)/2$ . The same holds for more general perturbations, e.g.,  $\delta H$  with  $|\delta h_{ij}| \leq \epsilon \sqrt{h_{ii}h_{jj}}$ .
  5. [vdS69] It holds that  $\|A^{-1}\|_2 \leq \kappa_2(A) \leq n \min_{D=\text{diag}} \kappa_2(DHD) \leq n\kappa_2(H)$ .
  6. For a general dense positive definite  $H = DAD$  stored in the machine memory, eigenvalue computation with high relative accuracy is numerically feasible if and only if  $\lambda_{\min}(A)$  is not smaller than the machine round-off unit. It is possible that matrix  $H$  is theoretically positive definite and that errors in computing its entries as functions of some parameters cause the stored matrix to be indefinite. Failure of the Cholesky algorithm is a warning that the matrix is entry-wise close to a symmetric matrix that is not positive definite.
  7. [VH89] If  $P^T H P = L L^T$  is the Cholesky factorization with pivoting of positive definite  $H$ , then the SVD  $L = U \Sigma V^T$  of  $L$  is computed very efficiently by the one-sided Jacobi SVD algorithm, and  $H$  is diagonalized as  $H = (P U) \Sigma^2 (P U)^T$ .

**Algorithm 5:** Positive definite Jacobi EVD

 $(\lambda, U) = \text{EIG}_+(H)$ 

 Input:  $H \in \text{PD}_n$ ;

- 1:  $P^T H P = L L^T$ ; % Cholesky factorization with pivoting.
- 2: **if**  $L$  computed successfully, **then**
- 3:  $(U, \Sigma) = \text{SVD0}(L)$  % One-sided Jacobi SVD on  $L$ .  $V$  is not computed.
- 4:  $\lambda_i = \Sigma_{ii}^2$ ,  $U_{1:n,i} = P U_{1:n,i}$ ,  $i = 1, \dots, n$ ;
- 5: Output:  $\lambda = (\lambda_1, \dots, \lambda_n)$ ;  $U$
- 6: **else**
- 7: **Error:**  $H$  is not numerically positive definite
- 8: **end if**

8. [DV92], [Mat96], [Drm98b]. Let  $\tilde{\lambda}_1 \geq \dots \geq \tilde{\lambda}_n$  be the approximations of the eigenvalues  $\lambda_1 \geq \dots \geq \lambda_n$  of  $H = DAD$ , computed by Algorithm 5. Then
- The computed approximate eigenvalues of  $H$  are the exact eigenvalues of a nearby symmetric positive definite matrix  $H + \delta H$ , where  $\max_{1 \leq i, j \leq n} \frac{|\delta h_{ij}|}{\sqrt{h_{ii}h_{jj}}} \leq \varepsilon$ , and  $\varepsilon$  is bounded by  $O(n)$  times the round-off unit  $\epsilon$ .
  - $\max_{1 \leq i \leq n} \frac{|\lambda_i - \tilde{\lambda}_i|}{\lambda_i} \leq n\varepsilon \|A^{-1}\|_2$ . The dominant part in the forward relative error is committed during the Cholesky factorization. The one-sided Jacobi SVD contributes to this error with, at most,  $O(n)\epsilon\sqrt{\|A^{-1}\|_2} + O(n^2)\epsilon$ .
9. Numerical properties of Algorithm 5, given in Fact 8, are better appreciated if compared with algorithms that first reduce  $H$  to tridiagonal matrix  $T$  and then diagonalize  $T$ . For such tridiagonalization based procedures the following hold:
- The computed approximate eigenvalues of  $H$  are the exact eigenvalues of a nearby symmetric matrix  $H + \delta H$ , where  $\|\delta H\|_2 \leq \varepsilon \|H\|_2$  and  $\varepsilon$  is bounded by a low degree polynomial in  $n$  times the round-off unit  $\epsilon$ .
  - The computed eigenvalue approximations  $\tilde{\lambda}_i \approx \lambda_i$  satisfy the *absolute error* bound  $|\lambda_i - \tilde{\lambda}_i| \leq \varepsilon \|H\|_2$ , that is,  $\max_{1 \leq i \leq n} \frac{|\lambda_i - \tilde{\lambda}_i|}{\lambda_i} \leq \varepsilon \kappa_2(H)$ .
10. In some applications it might be possible to work with a positive definite matrix implicitly as  $H = C^T C$ , where only a full column rank  $C$  is explicitly formed. Then the spectral computation with  $H$  is replaced with the SVD of  $C$ . The Cholesky factor  $L$  of  $H$  is computed implicitly from the QR factorization of  $C$ . This implicit formulation has many numerical advantages and it should be the preferred way of computation with positive definite matrices. An example is natural factor formulation of stiffness matrices in finite element computations.
11. [Drm98a], [Drm98b] Generalized eigenvalues of  $HM - \lambda I$  and  $H - \lambda M$  can be computed to high relative accuracy if  $H = D_H A_H D_H$ ,  $M = D_M A_M D_M$  with diagonal  $D_H$ ,  $D_M$  and moderate  $\|A_H^{-1}\|_2$ ,  $\|A_M^{-1}\|_2$ .

### Examples:

1. In this numerical experiment we use MATLAB 6.5, Release 13 (on a Pentium 4 machine under MS Windows<sup>R</sup> 2000), and the function `eig(.)` for eigenvalue computation. Let

$$H = \begin{bmatrix} 10^{40} & 10^{29} & 10^{19} \\ 10^{29} & 10^{20} & 10^9 \\ 10^{19} & 10^9 & 1 \end{bmatrix}.$$

The sensitivity of the eigenvalues of  $H$  and the accuracy of numerical algorithms can be illustrated by applications of the algorithms to various functions and perturbations of  $H$ . Let  $P^T H P$  be obtained from  $H$  by permutation similarity with permutation matrix  $P$ . Let  $H + \Delta H$  be obtained from  $H$  by changing  $H_{22}$  into  $-H_{22} = -10^{20}$ , and let  $H + \delta H$  be obtained from  $H$  by multiplying  $H_{13}$  and  $H_{31}$  by  $1 + \epsilon$ , where  $\epsilon \approx 2.22 \cdot 10^{-16}$  is the round-off unit in MATLAB. For the sake of experiment, the eigenvalues of numerically computed  $(H^{-1})^{-1}$  are also examined. The values returned by `eig(.)` are shown in Table 46.1. All six approximations of the spectrum of  $H$  are with small absolute error,  $\max_{1 \leq i \leq 3} \frac{|\lambda_i - \tilde{\lambda}_i|}{\|H\|_2} \leq O(\epsilon)$ . Some results might be different if a different version of MATLAB or operating system is used.

2. Let  $H$  be the matrix from Example 1.  $H$  is positive definite,  $\kappa_2(H) > 10^{40}$ , and its  $H = DAD$  representation with  $D = \text{diag}(10^{20}, 10^{10}, 1)$  gives  $\kappa_2(A) < 1.4$ ,  $\|A^{-1}\|_2 < 1.2$ . The Cholesky factor

TABLE 46.1

$\tilde{\lambda}_1$	1.000000000000000e + 040	1.000000000000000e + 040	1.000000000000000e + 040
$\tilde{\lambda}_2$	-8.100009764062724e + 019	9.900000000000000e + 019	9.900000000000000e + 019
$\tilde{\lambda}_3$	-3.966787845610502e + 023	9.818181818181818e - 001	9.818181818181817e - 001
	$\text{eig}(H + \Delta H)$	$\text{eig}(P^T H P), P \simeq (3, 2, 1)$	$\text{eig}(H + \delta H)$
$\tilde{\lambda}_1$	1.000000000000000e + 040	1.000000000000000e + 040	1.000000000000000e + 040
$\tilde{\lambda}_2$	-8.100009764062724e + 019	9.900000000000000e + 019	1.208844819952007e + 024
$\tilde{\lambda}_3$	-3.966787845610502e + 023	9.818181818181819e - 001	9.899993299416013e - 001

$L$  of  $H$  is successfully computed in MATLAB by the `chol(·)` function. The matrix  $L^T L$ , which is implicitly diagonalized in Algorithm 5, reads

$$\hat{H} = L^T L = \begin{bmatrix} 1.000000000e + 40 & 9.949874371e + 18 & 9.908673886e - 02 \\ 9.949874371e + 18 & 9.900000000e + 19 & 8.962732759e - 02 \\ 9.908673886e - 02 & 8.962732759e - 02 & 9.818181818e - 01 \end{bmatrix}.$$

The diagonal of  $\hat{H}$  approximates the eigenvalues of  $H$  with all shown digits correct. To see that, write  $\hat{H}$  as  $\hat{H} = \hat{D} \hat{A} \hat{D}$ , where  $\hat{D} = \text{diag}(\sqrt{\hat{H}_{11}}, \sqrt{\hat{H}_{22}}, \sqrt{\hat{H}_{33}})$  and

$$\hat{A} = \begin{bmatrix} 1.000000000e + 00 & 1.000000000e - 11 & 1.000000000e - 21 \\ 1.000000000e - 11 & 1.000000000e + 00 & 9.090909091e - 12 \\ 1.000000000e - 21 & 9.090909091e - 12 & 1.000000000e + 00 \end{bmatrix}$$

with  $\|\hat{A} - I_3\| < 1.4 \cdot 10^{-11}$ ,  $\|\hat{A}^{-1}\|_2 \approx 1$ . Algorithm 5 computes the eigenvalues of  $H$ , as  $\lambda_1 \approx 1.0e + 40, \lambda_2 \approx 9.900000000000002e + 19, \lambda_3 \approx 9.818181818181817e - 01$ .

- Smallest eigenvalues can be irreparably damaged simply by computing and storing matrix entries. This rather convincing example is discussed in [DGE99]. The stiffness matrix of a mass spring system with 3 masses,

$$K = \begin{bmatrix} k_1 + k_2 & -k_2 & 0 \\ -k_2 & k_2 + k_3 & -k_3 \\ 0 & -k_3 & k_3 \end{bmatrix}, \quad k_1, k_2, k_3 \text{ spring constants,}$$

is computed with  $k_1 = k_3 = 1$  and  $k_2 = \epsilon/2$ , where  $\epsilon$  is the round-off unit. Then the true and the computed assembled matrix are, respectively,

$$K = \begin{bmatrix} 1 + \epsilon/2 & -\epsilon/2 & 0 \\ -\epsilon/2 & 1 + \epsilon/2 & -1 \\ 0 & -1 & 1 \end{bmatrix}, \quad \tilde{K} = \begin{bmatrix} 1 & -\epsilon/2 & 0 \\ -\epsilon/2 & 1 & -1 \\ 0 & -1 & 1 \end{bmatrix}.$$

$\tilde{K}$  is the component-wise relative perturbation of  $K$  with  $\text{reldist}(K, \tilde{K}) = \epsilon/(2 + \epsilon) < \epsilon/2$ .  $K$  is positive definite with minimal eigenvalue near  $\epsilon/4$ ,  $\tilde{K}$  is indefinite with minimal eigenvalue near  $-\epsilon^2/8$ . MATLAB's function `chol(·)` fails to compute the Cholesky factorization of  $\tilde{K}$  and reports that the matrix is not positive definite.

On the other hand, writing  $K = A^T A$  with

$$A = \begin{bmatrix} \sqrt{k_1} & 0 & 0 \\ -\sqrt{k_2} & \sqrt{k_2} & 0 \\ 0 & -\sqrt{k_3} & \sqrt{k_3} \end{bmatrix} = \begin{bmatrix} \sqrt{k_1} & 0 & 0 \\ 0 & \sqrt{k_2} & 0 \\ 0 & 0 & \sqrt{k_3} \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ -1 & 1 & 0 \\ 0 & -1 & 1 \end{bmatrix}$$

clearly separates physical parameters and the geometry of the connections. Since  $A$  is bidiagonal, for any choice of  $k_1, k_2, k_3$ , the eigenvalues of  $K$  can be computed as squared singular values of  $A$  to nearly the same number of accurate digits to which the spring constants are given.

## 46.5 Accurate Eigenvalues of Symmetric Indefinite Matrices

Relevant relative perturbation theory for floating point computation with symmetric indefinite matrices is presented in [BD90], [DV92], [VS93], [DMM00], and [Ves00]. Full review of perturbation theory is given in Chapter 15.

### Definitions:

**Bunch–Parlett factorization** of symmetric  $H$  is the factorization  $P^T H P = L B L^T$ , where  $P$  is a permutation matrix,  $B$  is a block-diagonal matrix with diagonal blocks of size  $1 \times 1$  or  $2 \times 2$ , and  $L$  is a full column rank unit lower triangular matrix, where the diagonal blocks in  $L$  that correspond to  $2 \times 2$  blocks in  $B$  are  $2 \times 2$  identity matrices.

A **symmetric rank revealing decomposition (SRRD)** of  $H$  is a decomposition  $H = X D X^T$ , where  $D$  is diagonal and  $X$  is a full column rank well-conditioned matrix.

Let  $\mathcal{J}$  denote a nonsingular symmetric matrix. Matrix  $B$  is  **$\mathcal{J}$ -orthogonal** if  $F^T \mathcal{J} F = \mathcal{J}$ . (Warning: this is a nonstandard usage of  $F$ , since in this book  $F$  usually denotes a field.)

The **hyperbolic SVD** decomposition of the matrix pair  $(G, \mathcal{J})$  is a decomposition of  $G$ ,  $G = W \Sigma F^{-1}$ , where  $W$  is orthogonal,  $\Sigma$  is diagonal, and  $F$  is  $\mathcal{J}$ -orthogonal.

### Facts:

1. If  $H = U \Sigma V^T$  is the SVD of an  $n \times n$  symmetric  $H$ , where  $\Sigma = \bigoplus_{i=1}^m \sigma_i I_{n_i}$ , then the matrix  $V^T U$  is block-diagonal with  $m$  symmetric and orthogonal blocks of sizes  $n_i \times n_i$ ,  $i = 1, \dots, m$  along its diagonal. The  $n_i$  eigenvalues of the  $i$ th block are from  $\{-1, 1\}$  and they give the signs of  $n_i$  eigenvalues of  $H$  with absolute value  $\sigma_i$ .
2. If  $H = G \mathcal{J} G^T$  is a factorization with full column rank  $G \in \mathbb{R}^{n \times r}$  and  $\mathcal{J} = \text{diag}(\pm 1)$ , then the eigenvalue problems  $Hx = \lambda x$  and  $(G^T G)y = \lambda \mathcal{J} y$  are equivalent. If  $F$  is the  $\mathcal{J}$ -orthogonal eigenvector matrix of the pencil  $G^T G - \lambda \mathcal{J}$  ( $F^T \mathcal{J} F = \mathcal{J}$ ,  $F^T (G^T G) F = \Sigma^2 = \text{diag}(\sigma_1^2, \dots, \sigma_r^2)$ ), then the matrix  $\Sigma^2 \mathcal{J} = \text{diag}(\lambda_1, \dots, \lambda_r)$  contains the nonzero eigenvalues of  $H$  with the columns of  $(GF)\Sigma^{-1}$  as corresponding eigenvectors.
3. [Ves00] Let  $H$  have factorization  $H = G \mathcal{J} G^T$  as in Fact 2. Suppose that  $H$  is perturbed implicitly by changing  $G \rightsquigarrow G + \delta G$ , thus  $\tilde{H} = (G + \delta G) \mathcal{J} (G + \delta G)^T$ . Write  $G = B D$ , where  $D$  is diagonal and  $B$  has unit columns in the Euclidean norm, and let  $\delta B = \delta G D^{-1}$ . Let  $\theta \equiv \|\delta B B^\dagger\|_2 < 1$ . Then  $\tilde{H}$  has the same number of zero eigenvalues as  $H$  and  $\max_{\lambda_i \neq 0} \frac{|\delta \lambda_i|}{|\lambda_i|} \leq 2\theta + \theta^2$ .
4. [Sla98], [Sla02] The factorization  $H = G \mathcal{J} G^T$  in Fact 2 is computed by a modification of Bunch–Parlett factorization. Let  $\tilde{G}$  be the computed factor and let  $\tilde{\mathcal{J}} = \text{diag}(\pm 1)$  be the computed signature matrix. Then
  - A backward stability relation  $H + \delta H = \tilde{G} \tilde{\mathcal{J}} \tilde{G}^T$  holds with the entry-wise bound  $|\delta H| \leq O(n) \epsilon (|H| + |\tilde{G}| |\tilde{G}|^T)$ .
  - Let  $\tilde{G}$  have rank  $n$ . If  $\tilde{\mathcal{J}} = \mathcal{J}$  and if  $\hat{\lambda}_1 \geq \dots \geq \hat{\lambda}_n$  are the exact eigenvalues of the pencil  $\tilde{G}^T \tilde{G} - \lambda \mathcal{J}$ , then, for all  $i$ ,  $|\lambda_i - \hat{\lambda}_i| \leq \frac{O(n^2) \epsilon}{\sigma_{\min}^2(D^{-1} \tilde{G} \tilde{F})} |\lambda_i|$ , where  $D$  denotes a diagonal matrix such that  $D^{-1} \tilde{G}$  has unit rows in Euclidean norm,  $\tilde{F}$  is the eigenvector matrix of  $\tilde{G}^T \tilde{G} - \lambda \mathcal{J}$ , and  $\sigma_{\min}(\cdot)$  denotes the minimal singular value of a matrix.

5. [Ves93] The one-sided (implicit)  $\mathcal{J}$ -symmetric Jacobi algorithm essentially computes the hyperbolic SVD of  $(G, \mathcal{J})$ ,  $(W, \Sigma, F) = \text{HSVD}(G, \mathcal{J})$ . It follows the structure of the one-sided Jacobi SVD (Algorithm 2) with the following modifications:

- On input,  $A$  is replaced with the pair  $(G, \mathcal{J})$ .
- In step  $k$ ,  $G^{(k+1)} = G^{(k)} V^{(k)}$  is computed from  $G^{(k)}$  using Jacobi plane rotations exactly as in Algorithm 2 if  $\mathcal{J}_{ii}$  and  $\mathcal{J}_{jj}$  are of the same sign. (Here,  $i = i_k, j = j_k$  are the pivot indices in  $G^{(k)}$ .)
- If  $\mathcal{J}_{ii}$  and  $\mathcal{J}_{jj}$  have opposite signs, then the Jacobi rotation is replaced with hyperbolic rotation

$$\begin{bmatrix} \cosh \zeta_k & \sinh \zeta_k \\ \sinh \zeta_k & \cosh \zeta_k \end{bmatrix}, \quad \tanh 2\zeta_k = -\frac{2\xi}{d_i + d_j},$$

$$\xi = (G^{(k)})_{1:n,i}^T (G^{(k)})_{1:n,j}, \quad d_\ell = (G^{(k)})_{1:n,\ell}^T (G^{(k)})_{1:n,\ell}, \quad \ell = i, j. \quad \text{The tangent is determined as}$$

$$\tanh \zeta_k = \frac{\text{sign}(\tanh 2\zeta_k)}{|\tanh 2\zeta_k| + \sqrt{\tanh^2 2\zeta_k - 1}}.$$

- The limit of  $G^{(k)}$  is  $W\Sigma$ , and the accumulated product  $V^{(0)} V^{(1)} \dots V^{(k)} \dots$  converges to  $\mathcal{J}$ -orthogonal  $F$ , and  $G = W\Sigma F^{-1}$  is the hyperbolic SVD of  $G$ .
  - The iterations are stopped at index  $k$  if  $\max_{i \neq j} \frac{|(G^{(k)})_{1:n,i}^T (G^{(k)})_{1:n,j}|}{\|(G^{(k)})_{1:n,i}\|_2 \|(G^{(k)})_{1:n,j}\|_2} \leq \tau$ . The tolerance  $\tau$  is usually set to  $n\epsilon$ .
6. [Ves93] The eigenvalue problem of a symmetric indefinite matrix can be implicitly solved as a hyperbolic SVD problem. Algorithm 6 uses the factorization  $H = G\mathcal{J}G^T$  (Fact 2) and hyperbolic SVD  $\text{HSVD}(G, \mathcal{J})$  (Fact 5) to compute the eigenvalues and eigenvectors of  $H$ .

**Algorithm 6:** Hyperbolic Jacobi

$(\lambda, U) = \text{EIG0}(H)$

Input:  $H \in \mathcal{S}_n$

- 1:  $H = G\mathcal{J}G^T, \mathcal{J} = I_p \oplus (I_{n-p});$  % Bunch–Parlett factorization (modified).
- 2:  $(W, \Sigma, F) = \text{HSVD}(G, \mathcal{J})$  % One-sided  $\mathcal{J}$ -symmetric Jacobi algorithm.
- 3:  $\lambda_i = \mathcal{J}_{ii} \cdot \Sigma_{ii}^2; U_{1:n,i} = W_{1:n,i}, i = 1, \dots, n;$

Output:  $\lambda = (\lambda_1, \dots, \lambda_n); U$

7. [Sla02] Let  $\tilde{G}^{(0)} = \tilde{G}, \tilde{G}^{(k)}, k = 1, 2, \dots$  be the sequence of matrices computed by the one-sided  $\mathcal{J}$ -symmetric Jacobi algorithm in floating point arithmetic. Write each  $\tilde{G}^{(k)}$  as  $\tilde{G}^{(k)} = B^{(k)} D^{(k)}$ , where  $D^{(k)}$  is the diagonal matrix with Euclidean column norms of  $\tilde{G}^{(k)}$  along its diagonal.
- $\tilde{G}^{(k+1)}$  is the result of an exactly  $\mathcal{J}$ -orthogonal plane transformation of  $\tilde{G}^{(k)} + \delta \tilde{G}^{(k)} = (B^{(k)} + \delta B^{(k)}) D^{(k)}$ , where  $\|\delta B^{(k)}\|_F \leq c_k \epsilon$  with moderate factor  $c_k$ .
  - Let  $\tilde{\lambda}_1 \geq \dots \geq \tilde{\lambda}_n$  be computed as  $\mathcal{J}_{ii} (\tilde{G}^{(k)})_{1:n,i}^T (\tilde{G}^{(k)})_{1:n,i}, i = 1, \dots, n$ , where  $\tilde{G}^{(k)}$  is the first matrix which satisfies stopping criterion. If  $k'$  is the index of last applied rotation, then  $\max_{1 \leq i \leq n} \frac{|\hat{\lambda}_i - \tilde{\lambda}_i|}{|\hat{\lambda}_i|} \leq 2\eta + \eta^2$ , with  $\hat{\lambda}_i$  as in Fact 4, and  $\eta = O(\epsilon) \sum_{j=0}^{k'} \|(B^{(j)})^\dagger\|_2 + O(n^2)\epsilon + O(\epsilon^2)$ .
8. [DMM03] Accurate diagonalization of indefinite matrices can be derived from their accurate SVD decomposition. (See Fact 1.)

**Algorithm 7:** Signed SVD
 $(\lambda, Q) = \text{EIG1}(H)$ 
Input:  $H \in \mathcal{S}_n$ 

- 1:  $H = XDY^T$ ; % rank revealing decomposition.
- 2:  $(U, \Sigma, V) = \text{SVD2}(X, D, Y)$ ; % accurate SVD.
- 3: Recover the signs of the eigenvalues,  $\lambda_i = \pm\sigma_i$ , using the structure of  $V^T U$ ;
- 4: Recover the eigenvector matrix  $Q$  using the structure of  $V^T U$ .

Output:  $\lambda = (\lambda_1, \dots, \lambda_n)$ ;  $Q$ 

Let  $H \approx \tilde{U} \tilde{\Sigma} \tilde{V}^T$ ,  $\tilde{\Sigma} = \text{diag}(\tilde{\sigma}_1, \dots, \tilde{\sigma}_n)$ , be the SVD computed by Algorithm 7.

- If all computed singular values  $\tilde{\sigma}_i$ ,  $i = 1, \dots, n$ , are well separated, Algorithm 7 chooses  $\tilde{\lambda}_i = \tilde{\sigma}_i \text{sign}(\tilde{V}_{1:n,i}^T \tilde{U}_{1:n,i})$ , with the eigenvector  $\tilde{Q}_{1:n,i} = \tilde{V}_{1:n,i}$ .
  - If singular values are clustered, then clusters are determined by perturbation theory and the signs are determined inside each individual cluster.
9. [DMM03] If the rank revealing factorization in Step 1 of Algorithm 7 is computed as  $H \approx \tilde{X} \tilde{D} \tilde{Y}^T$  with  $\|\tilde{X} - X\| \leq \xi$ ,  $\|\tilde{Y} - Y\| \leq \xi$ ,  $\max_{i=1:n} |d_{ii} - \tilde{d}_{ii}|/|d_{ii}| \leq \xi$ , then the computed eigenvalues  $\tilde{\lambda}_i$  satisfy  $|\lambda_i - \tilde{\lambda}_i| \leq \xi' \kappa(L) \max\{\kappa(X), \kappa(Y)\} |\lambda_i|$ ,  $i = 1, \dots, n$ . Here,  $\xi$  and  $\xi'$  are bounded by the round-off  $\epsilon$  times moderate functions of the dimensions, and it is assumed that the traces of the diagonal blocks of  $V^T U$  (Cf. Fact 1) are computed correctly.
  10. [DK05b] An accurate symmetric rank revealing decomposition  $H = XDX^T$  can be given as input to Algorithm 7 or it can replace Step 1 in Algorithm 6 by defining  $G = X\sqrt{|D|}$ ,  $\mathcal{J} = \text{diag}(\text{sign}(d_{11}), \dots, \text{sign}(d_{mm}))$ . Once an accurate SRRD is available, the eigenvalues are computed to high relative accuracy. For the following structured matrices, specially tailored algorithms compute accurate SRRDs:
    - Symmetric scaled Cauchy matrices,  $H = DCD$ ,  $D$  diagonal,  $C$  Cauchy matrix.
    - Symmetric Vandermonde matrices,  $V = (v^{(i-1)(j-1)})_{i,j=1}^n$ , where  $v \in \mathbb{R}$ .
    - Symmetric totally nonnegative matrices.

**Examples:**

1. [Ves96] Initial factorization or rank revealing decomposition is the key for success or failure of the algorithms presented in this section. Let  $\epsilon = 10^{-7}$  and

$$H = \begin{bmatrix} 1 & 1 & 1 \\ 1 & 0 & 0 \\ 1 & 0 & \epsilon \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 1 & \sqrt{\epsilon} \end{bmatrix} \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 0 & \sqrt{\epsilon} \end{bmatrix}.$$

This factorization implies that all eigenvalues of  $H$  are determined to high relative accuracy. Whether or not they will be determined to that accuracy by Algorithm 6 (or any other algorithm depending on initial factorization) depends on the factorization. In Algorithm 6, the factorization in Step 1 chooses to start with  $1 \times 1$  pivot, which after the first step gives

$$\begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 1 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & -1 & -1 \\ 0 & -1 & -1 + \epsilon \end{bmatrix} \begin{bmatrix} 1 & 1 & 1 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

The  $2 \times 2$  Schur complement is ill-conditioned (entry-wise  $\epsilon$  close to singularity, the condition number behaving as  $1/\epsilon$ ) and the smallest eigenvalue is lost.

Multiplying matrices is an important problem from both the theoretical and the practical point of view. Determining the arithmetic complexity of this problem, that is, the minimum number of arithmetic operations sufficient for computing an  $n \times n$  matrix product, is still an open issue. Other important computational problems like computing the inverse of a nonsingular matrix, solving a linear system, computing the determinant, or more generally the coefficients of the characteristic polynomial of a matrix have a complexity related to that of matrix multiplication. Certain combinatorial problems, like the all pair shortest distance problem of a digraph, are strictly related to matrix multiplication. This chapter deals with fast algorithms for multiplication of unstructured matrices. Fast algorithms for structured matrix computations are presented in Chapter 48.

### 47.1 Basic Concepts

---

Let  $A = [a_{i,j}]$ ,  $B = [b_{i,j}]$ , and  $C = [c_{i,j}]$  be  $n \times n$  matrices over the field  $F$  such that  $C = AB$ , that is,  $C$  is the matrix product of  $A$  and  $B$ .

#### Facts:

1. The elements of the matrices  $A$ ,  $B$ , and  $C$  are related by the following equations:

$$c_{i,j} = \sum_{k=1}^n a_{i,k} b_{k,j}, \quad i, j = 1, \dots, n.$$

2. Each element  $c_{i,j}$  is the scalar product of the  $i$ th row of  $A$  and the  $j$ th column of  $B$  and can be computed by means of  $n$  multiplications and  $n - 1$  additions. This computation is described in Algorithm 1.
3. The overall cost of computing the  $n^2$  elements of  $C$  is  $n^3$  multiplications and  $n^3 - n^2$  additions, that is  $2n^3 - n^2$  arithmetic operations.

**Algorithm 1.** Conventional matrix multiplicationInput: the elements  $a_{i,j}$  and  $b_{i,j}$  of two  $n \times n$  matrices  $A$  and  $B$ ;Output: the elements  $c_{i,j}$  of the matrix product  $C = AB$ ;**for**  $i = 1$  **to**  $n$  **do**    **for**  $j = 1$  **to**  $n$  **do**         $c_{i,j} = 0$         **for**  $k = 1$  **to**  $n$  **do**             $c_{i,j} = c_{i,j} + a_{i,k}b_{k,j}$ 

4. [Hig02, p. 71] The computation of  $c_{i,j}$  by means of Algorithm 1 is element-wise forward numerically stable. More precisely, if  $\tilde{C}$  denotes the matrix actually computed by performing Algorithm 1 in floating point arithmetic with machine precision  $\epsilon$ , then  $|C - \tilde{C}| \leq n\epsilon|A||B| + O(\epsilon^2)$ , where  $|A|$  denotes the matrix with elements  $|a_{i,j}|$  and the inequality holds element-wise.

**Examples:**

- For  $2 \times 2$  matrices Algorithm 1 requires 8 multiplications and 4 additions. For  $5 \times 5$  matrices Algorithm 1 requires 125 multiplications and 100 additions.

## 47.2 Fast Algorithms

**Definitions:**

Define  $\omega \in \mathbb{R}$  as the infimum of the real numbers  $w$  such that there exists an algorithm for multiplying  $n \times n$  matrices with  $O(n^w)$  arithmetic operations.  $\omega$  is called the **exponent of matrix multiplication complexity**.

Algorithms that do not use commutativity of multiplication, are called **noncommutative algorithms**.

Algorithms for multiplying the  $p \times p$  matrices  $A$  and  $B$  of the form

$$m_k = \left( \sum_{i,j=1}^p \alpha_{i,j,k} a_{i,j} \right) \left( \sum_{i,j=1}^p \beta_{i,j,k} b_{i,j} \right), \quad k = 1, \dots, t,$$

$$c_{i,j} = \sum_{k=1}^t \gamma_{i,j,k} m_k,$$

where  $\alpha_{i,j,k}, \beta_{i,j,k}, \gamma_{i,j,k}$  are given scalar constants, are called **bilinear noncommutative algorithms** with **nonscalar multiplications**.

**Facts:**

- [Win69] *Winograd's commutative algorithm*. For moderately large values of  $n$ , it is possible to compute the product of  $n \times n$  matrices with less than  $2n^3 - n^2$  arithmetic operations by means of the following simple identities where  $n = 2m$  is even:

$$u_i = \sum_{k=1}^m a_{i,2k-1} a_{i,2k}, \quad v_i = \sum_{k=1}^m b_{2k-1,j} b_{2k,j}, \quad i = 1, n,$$

$$w_{i,j} = \sum_{k=1}^m (a_{i,2k-1} + b_{2k,j})(a_{i,2k} + b_{2k-1,j}), \quad i, j = 1, n,$$

$$c_{i,j} = w_{i,j} - u_i - v_j, \quad i, j = 1, n.$$

- The number of arithmetic operations required is  $n^3 + 4n^2 - 2n$ , which is less than  $2n^3 - n^2$  already for  $n \geq 8$ . This formula, which for large values of  $n$  is faster by a factor of about 2 with respect to the

conventional algorithm, relies on the commutative property of multiplication. It can be extended to the case where  $n$  is odd.

3. [Str69] *Strassen's formula*. It is possible to multiply  $2 \times 2$  matrices with only 7 multiplications instead of 8, but with a higher number of additions by means of the following identities:

$$\begin{aligned} m_1 &= (a_{1,2} - a_{2,2})(b_{2,1} + b_{2,2}), & m_5 &= a_{1,1}(b_{1,2} - b_{2,2}), \\ m_2 &= (a_{1,1} + a_{2,2})(b_{1,1} + b_{2,2}), & m_6 &= a_{2,2}(b_{2,1} - b_{1,1}), \\ m_3 &= (a_{1,1} - a_{2,1})(b_{1,1} + b_{1,2}), & m_7 &= (a_{2,1} + a_{2,2})b_{1,1}, \\ m_4 &= (a_{1,1} + a_{1,2})b_{2,2}, \\ c_{1,1} &= m_1 + m_2 - m_4 + m_6, & c_{1,2} &= m_4 + m_5, \\ c_{2,1} &= m_6 + m_7, & c_{2,2} &= m_2 - m_3 + m_5 - m_7. \end{aligned}$$

4. The overall number of arithmetic operations required by the Strassen formula is higher than the number of arithmetic operations required by the conventional matrix multiplication described in Algorithm 1 of section 47.1. However, the decrease from 8 to 7 of the number of multiplications provides important consequences.
5. The identities of Fact 3 do not exploit the commutative property of multiplication like the identities of Fact 1, therefore they are still valid if the scalar factors are replaced by matrices.
6. Strassen's formula provides a bilinear noncommutative algorithm where the constants  $\alpha_{i,j,k}$ ,  $\beta_{i,j,k}$ ,  $\gamma_{i,j,k}$  are in the set  $\{0, 1, -1\}$ .
7. If  $n$  is even, say  $n = 2m$ , then  $A$ ,  $B$ , and  $C$  can be partitioned into four  $m \times m$  blocks, that is,

$$A = \begin{bmatrix} A_{1,1} & A_{1,2} \\ A_{2,1} & A_{2,2} \end{bmatrix}, \quad B = \begin{bmatrix} B_{1,1} & B_{1,2} \\ B_{2,1} & B_{2,2} \end{bmatrix}, \quad C = \begin{bmatrix} C_{1,1} & C_{1,2} \\ C_{2,1} & C_{2,2} \end{bmatrix},$$

where  $A_{i,j}, B_{i,j}, C_{i,j} \in F^{m \times m}$ ,  $i, j = 1, 2$ , so that an  $n \times n$  matrix product can be viewed as a  $2 \times 2$  block matrix product. More specifically it holds that

$$\begin{aligned} C_{1,1} &= A_{1,1}B_{1,1} + A_{1,2}B_{2,1}, & C_{1,2} &= A_{1,1}B_{1,2} + A_{1,2}B_{2,2}, \\ C_{2,1} &= A_{2,1}B_{1,1} + A_{2,2}B_{2,1}, & C_{2,2} &= A_{2,1}B_{1,2} + A_{2,2}B_{2,2}. \end{aligned}$$

8. If  $n = 2m$ , the four blocks  $C_{i,j}$  of Fact 7 can be computed by means of Strassen's formula with  $7m \times m$  matrix multiplications and  $18m \times m$  matrix additions, i.e., with  $7(2m^3 - m^2) + 18m^2$  arithmetic operations. The arithmetic cost of matrix multiplication is reduced roughly by a factor of  $7/8$ .
9. [Str69] *Strassen's algorithm*. Furthermore, if  $m$  is even then the seven  $m \times m$  matrix products of Fact 8 can be computed once again by means of Strassen's formula. If  $n = 2^k$ ,  $k$  a positive integer, Strassen's formula can be repeated recursively until the size of the blocks is 1. Algorithm 2 synthesizes this computation.
10. The number  $M(k)$  of arithmetic operations required by Algorithm 2 to multiply  $2^k \times 2^k$  matrices is such that

$$\begin{aligned} M(k) &= 7M(k-1) + 18(2^{k-1})^2, \\ M(0) &= 1, \end{aligned}$$

which provides  $M(k) = 7 \cdot 7^k - 6 \cdot 4^k = 7n^{\log_2 7} - 6n^2$ , where  $n = 2^k$  and  $\log_2 7 = 2.8073 \dots < 3$ . This yields the bound  $\omega \leq \log_2 7$  on the exponent  $\omega$  of matrix multiplication complexity.

11. In practice it is not convenient to carry out Strassen's algorithm up to matrices of size 1. In fact, for  $2 \times 2$  matrices Strassen's formula requires much more operations than the conventional multiplication formula (see Example 1). Therefore, in the actual implementation the recursive iteration of Strassen's algorithm is stopped at size  $p = 2^r$ , where  $p$  is the largest value such that the conventional method applied to  $p \times p$  matrices is faster than Strassen's method.

12. Strassen's algorithm can be carried out even though  $n$  is not an integer power of 2. Assume that  $2^{k-1} < n < 2^k$ , set  $p = 2^k - n$ , and embed the matrices  $A, B, C$  into matrices  $\widehat{A}, \widehat{B}, \widehat{C}$  of size  $2^k$  in the following way:

$$\widehat{A} = \begin{bmatrix} A & \mathbf{0}_{np} \\ \mathbf{0}_{pn} & \mathbf{0}_{pp} \end{bmatrix}, \widehat{B} = \begin{bmatrix} B & \mathbf{0}_{np} \\ \mathbf{0}_{pn} & \mathbf{0}_{pp} \end{bmatrix}, \widehat{C} = \begin{bmatrix} C & \mathbf{0}_{np} \\ \mathbf{0}_{pn} & \mathbf{0}_{pp} \end{bmatrix}.$$

Then one has  $\widehat{C} = \widehat{A}\widehat{B}$  so that Strassen's algorithm can be applied to  $\widehat{A}$  and  $\widehat{B}$  in order to compute  $C$ . Even in this case the cost of Strassen's algorithm is still  $O(n^{\log_2 7})$ .

**Algorithm 2.** Strassen's algorithm

**Procedure** Strassen( $k, A, B$ )

Input: the elements  $a_{i,j}$  and  $b_{i,j}$  of the  $2^k \times 2^k$  matrices  $A$  and  $B$ ;

Output: the elements  $c_{i,j}$  of the  $2^k \times 2^k$  matrix  $C = AB$ ;

**If**  $k = 0$  **then**

output  $c_{1,1} = a_{1,1}b_{1,1}$ ;

**else**

partition  $A, B,$  and  $C$  into  $2^{k-1} \times 2^{k-1}$  blocks  $A_{i,j}, B_{i,j}, C_{i,j}$ , respectively,  
where  $i, j = 1, 2$ ;

compute

$$\begin{aligned} P_1 &= A_{1,2} - A_{2,2}, & Q_1 &= B_{2,1} + B_{2,2}, & P_5 &= A_{1,1}, & Q_5 &= B_{1,2} - B_{2,2}, \\ P_2 &= A_{1,1} + A_{2,2}, & Q_2 &= B_{1,1} + B_{2,2}, & P_6 &= A_{2,2}, & Q_6 &= B_{2,1} - B_{1,1}, \\ P_3 &= A_{1,1} - A_{2,1}, & Q_3 &= B_{1,1} + B_{1,2}, & P_7 &= A_{2,1} + A_{2,2}, & Q_7 &= B_{1,1}, \\ P_4 &= A_{1,1} + A_{1,2}, & Q_4 &= B_{2,2}, \end{aligned}$$

**for**  $i = 1$  **to**  $7$  **do**

$M_i = \text{Strassen}(k-1, P_i, Q_i)$ ;

compute

$$\begin{aligned} C_{1,1} &= M_1 + M_2 - M_4 + M_6, & C_{1,2} &= M_4 + M_5, \\ C_{2,1} &= M_6 + M_7, & C_{2,2} &= M_2 - M_3 + M_5 - M_7. \end{aligned}$$

13. [Hig02, p. 440] *Numerical stability of Strassen's algorithm.* Let  $\widetilde{C}$  be the  $n \times n$  matrix obtained by performing Strassen's algorithm in floating point arithmetic with machine precision  $\epsilon$  where  $n = 2^k$ . Then the following bound holds:  $\max_{i,j} |\widetilde{c}_{i,j} - c_{i,j}| \leq \gamma_n \epsilon \max_{i,j} |a_{i,j}| \max_{i,j} |b_{i,j}| + O(\epsilon^2)$ , where  $\gamma_n = 6n^{\log_2 12}$  and  $\log_2 12 \approx 3.585$ . Thus, Strassen's algorithm has slightly less favorable stability properties than the conventional algorithm: the error bound does not hold component-wise but only norm-wise, and the multiplicative factor  $6n^{\log_2 12}$  is larger than the factor  $n^2$  of the bound given in Fact 4 of section 47.1.

**Examples:**

1. For  $n = 16$ , applying the basic Strassen algorithm to the  $2 \times 2$  block matrices with blocks of size 8 and computing the seven products with the conventional algorithm requires  $7 * (2 * 8^3 - 8^2) + 18 * 8^2 = 7872$  arithmetic operations. Using the conventional algorithm requires  $2 * 16^3 - 16^2 = 7936$  arithmetic operations. Thus, it is convenient to stop the recursion of Algorithm 2 when  $n = 16$ . A similar analysis can be performed if the Winograd commutative formula of Fact 1 is used.

## 47.3 Other Algorithms

---

### Facts:

- [Win71] *Winograd's formula*. The following identities enable one to compute the product of  $2 \times 2$  matrices with 7 multiplications and with 15 additions; this is the minimum number of additions among bilinear noncommutative algorithms for multiplying  $2 \times 2$  matrices with 7 multiplications:

$$\begin{aligned} s_1 &= a_{2,1} + a_{2,2}, & s_2 &= s_1 - a_{1,1}, & s_3 &= a_{1,1} - a_{2,1}, & s_4 &= a_{1,2} - s_2, \\ t_1 &= b_{1,2} - b_{1,1}, & t_2 &= b_{2,2} - t_1, & t_3 &= b_{2,2} - b_{1,2}, & t_4 &= t_2 - b_{2,1}, \\ m_1 &= a_{1,1}b_{1,1}, & m_2 &= a_{1,2}b_{2,1}, & m_3 &= s_4b_{2,2}, & m_4 &= a_{2,2}t_4, \\ m_5 &= s_1t_1, & m_6 &= s_2t_2, & m_7 &= s_3t_3, \\ u_1 &= m_1 + m_6, & u_2 &= u_1 + m_7, & u_3 &= u_1 + m_5, \\ c_{1,1} &= m_1 + m_2, & c_{1,2} &= u_3 + m_3, \\ c_{2,1} &= u_2 - m_4, & c_{2,2} &= u_2 + m_5. \end{aligned}$$

The numerical stability of the recursive version of Winograd's formula is slightly inferior since the error bound of Fact 13 of Section 47.2 holds with  $\gamma_n = 12n^{\log_2 18}$ ,  $\log_2 18 \approx 4.17$ .

- [Win71], [BD78], [AS81] No algorithm exists for multiplying  $2 \times 2$  matrices with less than 7 multiplications. The number of nonscalar multiplications needed for multiplying  $n \times n$  matrices is at least  $2n^2 - 1$ .
- If  $n = 3^k$ , the matrices  $A$ ,  $B$ , and  $C$  can be partitioned into 9 blocks of size  $n/3$  so that  $n \times n$  matrix multiplication is reduced to computing the product of  $3 \times 3$  block matrices. Formulas for  $3 \times 3$  matrix multiplication that do not use the commutative property can be recursively used for general  $n \times n$  matrix multiplication.
- In general, if there exists a bilinear noncommutative formula for computing the product of  $q \times q$  matrices with  $t$  nonscalar multiplications, then matrices of size  $n = q^k$  can be multiplied with the cost of  $O(q^t) = O(n^{\log_q t})$  arithmetic operations.
- There exist algorithms for multiplying  $3 \times 3$  matrices that require 25 multiplications [Gas71], 24 multiplications [Fid72], 23 multiplications [Lad76]. None of these algorithms beats Strassen's algorithm since  $\log_3 21 < \log_2 7 < \log_3 22$ . No algorithm is known for multiplying  $3 \times 3$  matrices with less than 23 nonscalar multiplications.
- [HM73] *Rectangular matrix multiplication and the duality property*. If there exists a bilinear noncommutative algorithm for multiplying two (rectangular) matrices of size  $n_1 \times n_2$  and  $n_2 \times n_3$ , respectively, with  $t$  nonscalar multiplications, then there exist bilinear noncommutative algorithms for multiplying matrices of size  $n_{\sigma_1} \times n_{\sigma_2}$  and  $n_{\sigma_2} \times n_{\sigma_3}$  with  $t$  nonscalar multiplications for any permutation  $\sigma = (\sigma_1, \sigma_2, \sigma_3)$ .
- If there exists a bilinear noncommutative algorithm for multiplying  $n_1 \times n_2$  and  $n_2 \times n_3$  matrices with  $t$  nonscalar multiplications, then square matrices of size  $q = n_1 n_2 n_3$  can be multiplied with  $t^3$  multiplications.
- From Fact 7 and Fact 4 it follows that if there exists a bilinear noncommutative algorithm for multiplying  $n_1 \times n_2$  and  $n_2 \times n_3$  matrices with  $t$  nonscalar multiplications, then  $n \times n$  matrices can be multiplied with  $O(n^w)$  arithmetic operations, where  $w = \log_{n_1 n_2 n_3} t^3$ .
- [HK71] There exist bilinear noncommutative algorithms for multiplying matrices of size  $2 \times 2$  and  $2 \times 3$  with 11 multiplications; there exist algorithms for multiplying matrices of size  $2 \times 3$  and  $3 \times 3$  with 15 multiplications.
- There are several implementations of fast algorithms for matrix multiplication based on Strassen's formula and on Winograd's formula. In 1970, R. Brent implemented Strassen's algorithm on an IBM 360/67 (see [Hig02, p. 436]). This implementation was faster than the conventional algorithm already for  $n \geq 110$ . In 1988, D. Bailey provided a Fortran implementation for the Cray-2. Fortran codes, based on the Winograd variant have been provided since the late 1980s. For detailed comments and for more bibliography in this regard, we refer the reader to [Hig02, Sect. 23.3].

## 47.4 Approximation Algorithms

Matrices can be multiplied faster if we allow that the matrix product can be affected by some arbitrarily small nonzero error. Throughout this section, the underlying field  $F$  is  $\mathbb{R}$  or  $\mathbb{C}$  and we introduce a parameter  $\lambda \in F$  that represents a nonzero number with small modulus. Multiplication by  $\lambda$  and  $\lambda^{-1}$  is negligible in the complexity estimate for two reasons: firstly, by choosing  $\lambda$  equal to a power of 2, multiplication by  $\lambda$  can be accomplished by shifting the exponent in the base-two representation of floating point numbers. This operation has a cost lower than the cost of multiplication. Secondly, in the block application of matrix multiplication algorithms, multiplication by  $\lambda$  corresponds to multiplying an  $m \times m$  matrix by the scalar  $\lambda$ . This operation costs only  $m^2$  arithmetic operations like matrix addition.

### Definitions:

Algorithms for multiplying the  $p \times p$  matrices  $A$  and  $B$  of the form

$$m_k = \left( \sum_{i,j=1}^p \alpha_{i,j,k} a_{i,j} \right) \left( \sum_{i,j=1}^p \beta_{i,j,k} a_{i,j} \right), \quad k = 1, \dots, t,$$

$$c_{i,j} = \sum_{k=1}^t \gamma_{i,j,k} m_k + \lambda p_{i,j}(\lambda),$$

where  $\alpha_{i,j,k}, \beta_{i,j,k}, \gamma_{i,j,k}$  are given rational functions of  $\lambda$  and  $p_{i,j}(\lambda)$  are polynomials, are called **Arbitrary Precision Approximating (APA) algorithms** with  $t$  **nonscalar multiplications** [Bin80], [BCL79].

### Facts:

1. [BLR80] The matrix-vector product

$$\begin{bmatrix} f_1 \\ f_2 \end{bmatrix} = \begin{bmatrix} a & b \\ 0 & a \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} ax + by \\ ay \end{bmatrix}$$

cannot be computed with less than three multiplications. However, the following APA algorithm approximates  $f_1$  and  $f_2$  with two nonscalar multiplications:

$$\begin{aligned} m_1 &= (a + \lambda b)(x + \lambda^{-1}y), & m_2 &= ay, \\ f_1 &\approx f_1 + \lambda bx = m_1 - \lambda^{-1}m_2, \\ f_2 &= m_2. \end{aligned}$$

The algorithm is not defined for  $\lambda = 0$ , but for  $\lambda \rightarrow 0$  the output of the algorithm converges to the exact solution if performed in exact arithmetic.

2. [BCL79] Consider the  $2 \times 2$  matrix product  $C = AB$  where  $a_{1,2} = 0$ , i.e.,

$$\begin{bmatrix} c_{1,1} & c_{1,2} \\ c_{2,1} & c_{2,2} \end{bmatrix} = \begin{bmatrix} a_{1,1} & 0 \\ a_{2,1} & a_{2,2} \end{bmatrix} \begin{bmatrix} b_{1,1} & b_{1,2} \\ b_{2,1} & b_{2,2} \end{bmatrix}.$$

The elements  $c_{i,j}$  can be approximated with 5 nonscalar multiplications by means of the following identities:

$$\begin{aligned} m_1 &= (a_{1,1} + a_{2,2})(b_{1,2} + \lambda b_{2,1}), & m_2 &= a_{1,1}(b_{1,1} + \lambda b_{2,1}), & m_3 &= a_{2,2}(b_{1,2} + \lambda b_{2,2}), \\ m_4 &= (a_{1,1} + \lambda a_{2,1})(b_{1,1} - b_{1,2}), & m_5 &= (\lambda a_{2,1} - a_{2,2})b_{1,2}, \\ c_{1,1} &= m_2 - \lambda a_{1,1}b_{2,1}, & c_{1,2} &= m_1 - m_3 - \lambda(a_{1,1}b_{2,1} + a_{2,2}b_{2,1} - a_{2,2}b_{2,2}), \\ c_{2,1} &= \lambda^{-1}(m_1 - m_2 + m_4 + m_5), & c_{2,2} &= \lambda^{-1}(m_3 + m_5). \end{aligned}$$

3. Formulas of Fact 2 can be suitably adjusted to the case where only the element  $a_{2,1}$  of the matrix  $A$  is zero.

4. The product of a  $3 \times 2$  matrix and a  $2 \times 2$  matrix can be approximated with 10 nonscalar multiplications by simply combining the formulas of Fact 2 and of Fact 3 in the following way:

$$\begin{bmatrix} \cdot & \cdot \\ \cdot & \cdot \\ \cdot & \cdot \end{bmatrix} = \left( \begin{bmatrix} \# & \# \\ 0 & \# \\ 0 & 0 \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ \star & 0 \\ \star & \star \end{bmatrix} \right) \begin{bmatrix} \cdot & \cdot \\ \cdot & \cdot \end{bmatrix}.$$

5. Facts 4, 7, and 8 of section 47.3 are still valid for APA algorithms. By Fact 7 of Section 47.3 it follows that 1000 nonscalar multiplications are sufficient to approximate the product of  $12 \times 12$  matrices.
6. By Fact 8 of Section 47.3 it follows that  $O(n^{\log_{12} 1000})$  arithmetic operations are sufficient to approximate the product of  $n \times n$  matrices, where  $\log_{12} 1000 = 2.7798 \dots < \log_2 7$ .
7. [BLR80] A rounding error analysis of an APA algorithm shows that the relative error in the output is bounded by  $\alpha\lambda^h + \epsilon\beta\lambda^{-k}$ , where  $\alpha$  and  $\beta$  are positive constant depending on the input values,  $h$  and  $k$  are positive constants depending on the algorithm and  $\epsilon$  is the machine precision. This bound grows to infinity as  $\lambda$  converges to zero. Asymptotically, in  $\epsilon$  the minimum bound is  $\gamma\epsilon^{\frac{h}{h+k}}$ , for a constant  $\gamma$ .
8. [Bin80] *From approximate to exact computations*. Given an APA algorithm for approximating a  $k \times k$  matrix product with  $t$  nonscalar multiplications, there exists an algorithm for  $n \times n$  exact matrix multiplication requiring  $O(n^w \log n)$  arithmetic operations where  $w = \log_k t$ . In particular, by Fact 5 an  $O(n^w \log n)$  algorithm exists for exact matrix multiplication with  $w = \log_{12} 1000$ . This provides the bound  $\omega \leq \log_{12} 1000$  for the exponent  $\omega$  of matrix multiplication defined in Section 47.2.
9. The exact algorithm is obtained from the approximate algorithm by applying the approximate algorithm with  $O(\log n)$  different values (not necessarily small) of  $\lambda$  and then taking a suitable linear combination of the  $O(\log n)$  different values obtained in this way in order to get the exact product. More details on this approach, which is valid for any APA algorithm that does not use the commutative property of multiplication, can be found in [Bin80].

### Examples:

1. The algorithm of Fact 1 computes  $f_1(\lambda) = f_1 + \lambda bx$  that is close to  $f_1$  for a small lambda. On the other hand, one has  $f_1 = (f_1(1) + f_1(-1))/2$ ; i.e., a linear combination of the values computed by the APA algorithm with  $\lambda = 1$  and with  $\lambda = -1$  provides exactly  $f_1$ .

## 47.5 Advanced Techniques

---

More advanced techniques have been introduced for designing fast algorithms for  $n \times n$  matrix multiplication. The asymptotically fastest algorithm currently known requires  $O(n^{2.38})$  arithmetic operations, but it is faster than the conventional algorithm only for huge values of  $n$ . Finding the infimum  $\omega$  of the numbers  $w$  for which there exist  $O(n^w)$  complexity algorithms is still an open problem. In this section, we provide a list of the main techniques used for designing asymptotically fast algorithms for  $n \times n$  matrix multiplication.

### Facts:

1. [Pan78] *Trilinear aggregating technique*. Different schemes for (approximate) matrix multiplication are based on the technique of trilinear aggregating by V. Pan. This technique is very versatile: Different algorithms based on this technique have been designed for fast matrix multiplication of several sizes [Pan84]; in particular, an algorithm for multiplying  $70 \times 70$  matrices with 143,640 multiplications which leads to the bound  $\omega < 2.795$ .

2. [Sch81] *Partial matrix multiplication*. In the expression

$$c_{i,j} = \sum_{r=1}^m a_{i,r} b_{r,j}, \quad i, j = 1, \dots, m,$$

there are  $m^3$  terms which are summed up. A partial matrix multiplication is encountered if some  $a_{i,j}$  or some  $b_{i,j}$  are zero, or if not all the elements  $c_{i,j}$  are computed so that in the above expression there are less than  $m^3$  terms, say,  $k < m^3$ . A. Schönhage [Sch81] has proved that if there exists a noncommutative bilinear (APA) algorithm for computing (approximating) partial  $m \times m$  matrix multiplication with  $k$  terms that uses  $t$  nonscalar multiplications, then  $\omega \leq 3 \log_k t$ . This result applied to the formula of Fact 2 of Section 47.4 provides the bound  $\omega \leq 3 \log_6 5 < 2.695$ .

3. [Sch81] *Disjoint matrix multiplication*. A. Schönhage has proven that it is possible to approximate two disjoint matrix products with less multiplications than the number of multiplications needed for computing separately these products. In particular, he has provided an APA algorithm for simultaneously multiplying a  $4 \times 1$  matrix by a  $1 \times 4$  and a  $1 \times 9$  matrix by a  $9 \times 1$  with only 17 nonscalar multiplications. Observe that 16 multiplications are *needed* for the former product and 9 multiplications are *needed* for the latter.
4. [Sch81] *The  $\tau$ -theorem*. A. Schönhage has proven the  $\tau$ -theorem. Namely, if the set of disjoint matrix products of size  $m_i \times n_i$  times  $n_i \times p_i$ , for  $i = 1, \dots, k$  can be approximated with  $t$  nonscalar multiplications by a bilinear noncommutative APA algorithm, then  $\omega \leq 3\tau$ , where  $\tau$  solves the equation  $\sum_{i=1}^k (m_i n_i p_i)^\tau = t$ . From the disjoint matrix multiplication of Fact 3 it follows the equation  $16^\tau + 9^\tau = 17$ , which yields  $\omega \leq 3\tau = 2.5479\dots$
5. [Str87], [Str88] *Asymptotic spectrum: the laser method*. In 1988, V. Strassen introduced a powerful and sophisticated method, which, by taking tensor powers of set of bilinear forms that apparently are not completely related to matrix multiplication, provides some scheme for fast matrix multiplication. The name *laser method* was motivated from the fact that by tensor powering a set of “incoherent” bilinear forms it is possible to obtain a “coherent” set of bilinear forms.
6. *Lower bounds*. At least  $2n^2 - 1$  multiplications are needed for multiplying  $n \times n$  matrices by means of noncommutative algorithms [BD78]. If  $n \geq 3$ , then  $2n^2 + n - 2$  multiplications are needed [Bla03]. The lower bound  $\frac{5}{2}n^2 - 3n$  has been proved in [Bla01]. The nonlinear asymptotic lower bound  $n^2 \log n$  has been proved in [Raz03]. At least  $n^2 + 2n - 2$  multiplications are needed for approximating the product of  $n \times n$  matrices by means of a noncommutative APA algorithm [Bin84]. The lower bound turns to  $n^2 + \frac{3}{2}n - 2$  multiplications if commutativity is allowed. The product of  $2 \times 2$  matrices can be approximated with 6 multiplications by means of a commutative algorithm [Bin84], 5 multiplications are needed. Seven multiplications are needed for approximating  $2 \times 2$  matrix product by means of noncommutative algorithms [Lan05].
7. *History of matrix multiplication complexity*. After the 1969 paper by V. Strassen [Str69], where it was shown that  $O(n^{\log_2 7})$  operations were sufficient for  $n \times n$  matrix multiplication and inversion, the exponent  $\omega$  of matrix multiplication complexity remained stuck at 2.807... for almost 10 years until when V. Pan, relying on the technique of trilinear aggregating, provided a bilinear noncommutative algorithm for  $70 \times 70$  matrix multiplication using 143,640 products. This led to the upper bound  $\omega \leq \log_{70} 143640 \approx 2.795$ . A few months later, Bini, Capovani, Lotti, and Romani [BCL79] introduced the concept of APA algorithms, and presented a scheme for approximating a  $12 \times 12$  matrix product with 1000 products. In [Bin80] Bini showed that from any APA algorithm for matrix multiplication it is possible to obtain an exact algorithm with almost the same asymptotic complexity. This led to the bound  $\omega \leq \log_{12} 1000 \approx 2.7798$ . The technique of partial matrix multiplication was introduced by Schönhage [Sch81] in 1981 together with the  $\tau$ -theorem, yielding the bound  $\omega \leq 2.55$ , a great improvement with respect to the previous estimates. This bound relies on the tools of trilinear aggregating and of approximate algorithms. Based on the techniques so far developed, V. Pan obtained the bound  $\omega < 2.53$  in [Pan80] and one year later, F. Romani obtained the bound  $\omega < 2.52$  in [Rom82]. The landmark bound  $\omega < 2.5$  was obtained

**TABLE 47.1** Main steps in the history of fast matrix multiplication

$\omega <$			
2.81	1969	[Str69]	Bilinear algorithms
2.79	1979	[Pan78]	Trilinear aggregating
2.78	1979	[BCL79],[Bin80]	Approximate algorithms
2.55	1981	[Sch81]	$\tau$ -theorem
2.53	1981	[Pan80]	
2.52	1982	[Rom82]	
2.50	1982	[CW72]	Refinement of the $\tau$ -theorem
2.48	1987,1988	[Str87],[Str88]	Laser method
2.38	1990	[CW82]	

by Coppersmith and Winograd [CW72] in 1982 by means of a refinement of the  $\tau$ -theorem. In [Str87] Strassen introduced the powerful *laser method* and proved the bound  $\omega < 2.48$ . The laser method has been perfected by Coppersmith and Winograd [CW82], who proved the best estimate known so far, i.e.,  $\omega < 2.38$ . Table 47.1 synthesizes this picture together with the main concepts used.

## 47.6 Applications

Some of the main applications of matrix multiplication are outlined in this section. For more details the reader is referred to [Pan84].

### Definitions:

A square matrix  $A$  is **strongly nonsingular** if all its principal submatrices are nonsingular.

### Facts:

1. *Classic matrix inversion.* Given a nonsingular  $n \times n$  matrix  $A$ , the elements of  $A^{-1}$  can be computed by means of Gaussian elimination in  $O(n^3)$  arithmetic operations.
2. *Inversion formula.* Let  $n = 2m$  and partition the  $n \times n$  nonsingular matrix  $A$  into four square blocks of size  $m$  as

$$A = \begin{bmatrix} A_{1,1} & A_{1,2} \\ A_{2,1} & A_{2,2} \end{bmatrix}.$$

Assume that  $A_{1,1}$  is nonsingular. Denote  $S = A_{2,2} - A_{2,1}A_{1,1}^{-1}A_{1,2}$  the Schur complement of  $A_{1,1}$  in  $A$  and  $R = A_{1,1}^{-1}$ . Then  $S$  is nonsingular and the inverse of  $A$  can be written as

$$A^{-1} = \begin{bmatrix} R + RA_{1,2}S^{-1}A_{2,1}R & -RA_{1,2}S^{-1} \\ -S^{-1}A_{2,1}R & S^{-1} \end{bmatrix}.$$

Moreover,  $\det A = \det S \det A_{1,1}$ .

3. *Fast matrix inversion.* Let  $n = 2^k$ , with  $k$  positive integer and assume that  $A$  is strongly nonsingular. Then also  $A_{1,1}$  and the Schur complement  $S$  are strongly nonsingular and the inversion formula of Fact 2 can be applied again to  $S$  by partitioning  $S$  into four square blocks of size  $n/4$ , recursively repeating this procedure until the size of the blocks is 1. The algorithm obtained in this way is described in Algorithm 3. Denoting by  $\mathcal{I}(n)$  the complexity of this algorithm for inverting a strongly nonsingular  $n \times n$  matrix and denoting by  $\mathcal{M}(n)$  the complexity of the algorithm used

for  $n \times n$  matrix multiplication, we obtain the expression

$$\begin{aligned} \mathcal{I}(n) &= 2\mathcal{I}(n/2) + 6\mathcal{M}(n/2) + n^2/2, \\ \mathcal{I}(1) &= 1. \end{aligned}$$

If  $\mathcal{M}(n) = O(n^w)$  with  $w \geq 2$ , then one deduces that  $\mathcal{I}(n) = O(n^w)$ . That is, the complexity of matrix inversion is not asymptotically larger than the complexity of matrix multiplication.

4. The complexity of matrix multiplication is not asymptotically greater than the complexity of matrix inversion. This property follows from the simple identity

$$\begin{bmatrix} I & A & 0 \\ 0 & I & B \\ 0 & 0 & I \end{bmatrix}^{-1} = \begin{bmatrix} I & -A & AB \\ 0 & I & -B \\ 0 & 0 & I \end{bmatrix}.$$

5. Combining Facts 3 and 4, we deduce that matrix multiplication and matrix inversion have the same asymptotical complexity.

**Algorithm 3:** Fast matrix inversion

**Procedure** Fast\_Inversion( $k, A$ )

Input: the elements  $a_{i,j}$  of the  $2^k \times 2^k$  strongly nonsingular matrix  $A$ ;

Output: the elements  $b_{i,j}$  of  $B = A^{-1}$ .

**If**  $k = 0$ , **then**

output  $b_{1,1} = a_{1,1}^{-1}$ ;

**else**

partition  $A$ , into  $2^{k-1} \times 2^{k-1}$  blocks  $A_{i,j}$ ,  $i, j = 1, 2$ ;

set  $R = \text{Fast\_Inversion}(k-1, A_{1,1})$ ;

compute  $S = A_{2,2} - A_{2,1}RA_{1,2}$  and  $V = \text{Fast\_Inversion}(k-1, S)$

output

$$\begin{bmatrix} R + RA_{1,2}VA_{2,1}R & -RA_{1,2}V \\ -VA_{2,1}R & V \end{bmatrix}$$

6. The property of strong singularity for  $A$  is not a great restriction if  $F = \mathbb{R}$  or  $F = \mathbb{C}$ . In fact, if  $A$  is nonsingular then  $A^{-1} = (A^*A)^{-1}A^*$  and the matrix  $A^*A$  is strongly nonsingular.
7. *Computing the determinant.* Let  $A$  be strongly nonsingular. From Fact 2,  $\det A = \det S \det A_{1,1}$ . Therefore, an algorithm for computing  $\det A$  can be recursively designed by computing  $S$  and then by applying recursively this algorithm to  $S$  and to  $A_{1,1}$  until the size of the blocks is 1. Denoting by  $\mathcal{D}(n)$  the complexity of this algorithm one has

$$\mathcal{D}(n) = 2\mathcal{D}(n/2) + \mathcal{I}(n/2) + 2\mathcal{M}(n/2) + n^2/4,$$

hence, if  $\mathcal{M}(n) = O(n^w)$  with  $w \geq 2$ , then  $\mathcal{D}(n) = O(n^w)$ . In [BS83] it is shown that  $\mathcal{M}(n) = O(\mathcal{D}(n))$

8. *Computing the characteristic polynomial.* The coefficients of the characteristic polynomial  $p(x) = \det(A - xI)$  of the matrix  $A$  can be computed with the same asymptotic complexity of matrix multiplication.
9. *Combinatorial problems.* The complexity of some combinatorial problems is related to matrix multiplication, in particular, the complexity of the *all pair shortest distance problem* of finding the shortest distances  $d(i, k)$  from  $i$  to  $k$  for all pairs  $(i, k)$  of vertices of a given digraph. We refer the reader to section 18 of [Pan84] for more details. The problem of Boolean matrix multiplication can be reduced to that of general matrix multiplication.

### 48.1 Structured Matrices

---

In various application fields, the matrices encountered have special structures that can be exploited to facilitate the solution process. Sparsity is one of these features. However, the matrices we consider in this chapter are mostly dense matrices with a special structure. Structured matrices have been around for a long time and are encountered in various fields of application. (See [GS84, KS98, BTY01].) Some interesting families are listed below. For simplicity, we give the definitions for real square matrices of size  $n$ .

#### Definitions:

**Toeplitz matrices:** Matrices with constant diagonals, i.e.,  $[T]_{i,j} = t_{i-j}$  for all  $1 \leq i, j \leq n$ :

$$T = \begin{bmatrix} t_0 & t_{-1} & \cdots & t_{2-n} & t_{1-n} \\ t_1 & t_0 & t_{-1} & & t_{2-n} \\ \vdots & t_1 & t_0 & \ddots & \vdots \\ t_{n-2} & & \ddots & \ddots & t_{-1} \\ t_{n-1} & t_{n-2} & \cdots & t_1 & t_0 \end{bmatrix}.$$

(See Chapter 16.2 for additional information on families of Toeplitz matrices.)

**Lower shift matrix:** The matrix with ones on the first subdiagonal and zeros elsewhere:

$$Z_n = \begin{bmatrix} 0 & 0 & \cdots & 0 & 0 \\ 1 & 0 & 0 & & 0 \\ \vdots & 1 & 0 & \ddots & \vdots \\ 0 & & \ddots & \ddots & 0 \\ 0 & 0 & \cdots & 1 & 0 \end{bmatrix}.$$

**Circulant matrices:** Toeplitz matrices where each column is a circular shift of its preceding column:

$$C = \begin{bmatrix} c_0 & c_{n-1} & \cdots & c_2 & c_1 \\ c_1 & c_0 & c_{n-1} & & c_2 \\ c_2 & c_1 & c_0 & & \vdots \\ \vdots & \ddots & \ddots & \ddots & \ddots \\ c_{n-2} & & & \ddots & \ddots & c_{n-1} \\ c_{n-1} & c_{n-2} & \cdots & c_2 & c_1 & c_0 \end{bmatrix}.$$

**$n$ -Cycle matrix:** The  $n \times n$  matrix with ones along the subdiagonal and in the 1,  $n$ -entry, and zeros elsewhere, i.e.,

$$C_n = \begin{bmatrix} 0 & 0 & \cdots & 0 & 1 \\ 1 & 0 & 0 & & 0 \\ \vdots & 1 & 0 & \ddots & \vdots \\ 0 & & \ddots & \ddots & 0 \\ 0 & 0 & \cdots & 1 & 0 \end{bmatrix}.$$

**Hankel matrices:** Matrices with constant elements along their antidiagonals, i.e.,

$$H = \begin{bmatrix} h_0 & h_1 & \cdots & h_{n-2} & h_{n-1} \\ h_1 & h_2 & \ddots & \ddots & h_n \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ h_{n-2} & \ddots & \ddots & \ddots & h_{2n-2} \\ h_{n-1} & h_n & \cdots & h_{2n-2} & h_{2n-1} \end{bmatrix}.$$

**Anti-identity matrix:** The matrix with ones along the antidiagonal and zeros elsewhere, i.e.,

$$P_n = \begin{bmatrix} 0 & 0 & \cdots & 0 & 1 \\ 0 & 0 & \ddots & 1 & 0 \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & 1 & \ddots & \ddots & 0 \\ 1 & 0 & \cdots & 0 & 0 \end{bmatrix}.$$

**Cauchy matrices:** Given vectors  $\mathbf{x} = [x_1, \dots, x_n]^T$  and  $\mathbf{y} = [y_1, \dots, y_n]^T$ , the Cauchy matrix  $C(\mathbf{x}, \mathbf{y})$  has  $i, j$ -entry equal to  $\frac{1}{x_i + y_j}$ .

**Vandermonde matrices:** A matrix having each row equal to successive powers of a number, i.e.,

$$V = \begin{bmatrix} 1 & v_1^1 & \cdots & v_1^{n-2} & v_1^{n-1} \\ 1 & v_2^1 & \cdots & v_2^{n-2} & v_2^{n-1} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 1 & v_n^1 & \cdots & v_n^{n-2} & v_n^{n-1} \end{bmatrix}.$$

**Block matrices:** An  $m \times m$  block matrix with  $n \times n$  blocks is a matrix of the form

$$\begin{bmatrix} A^{(1,1)} & A^{(1,2)} & \dots & A^{(1,m)} \\ A^{(2,1)} & A^{(2,2)} & \dots & A^{(2,m)} \\ \vdots & \vdots & \ddots & \vdots \\ A^{(m-1,1)} & A^{(m-1,2)} & \dots & A^{(m-1,m)} \\ A^{(m,1)} & A^{(m,2)} & \dots & A^{(m,m)} \end{bmatrix},$$

where each block  $A^{(i,j)}$  is an  $n \times n$  matrix.

**Toeplitz-block matrices:**  $mn \times mn$  block matrices where each block  $\{A^{(i,j)}\}_{i,j=1}^m$  is an  $n \times n$  Toeplitz matrix.

**Block-Toeplitz matrices:**  $mn \times mn$  block matrices of the form

$$T = \begin{bmatrix} A^{(0)} & A^{(-1)} & \dots & A^{(1-m)} \\ A^{(1)} & A^{(0)} & \dots & A^{(2-m)} \\ \vdots & \vdots & \ddots & \vdots \\ A^{(m-1)} & A^{(m-2)} & \dots & A^{(0)} \end{bmatrix},$$

where  $\{A^{(i)}\}_{i=1-m}^{m-1}$  are arbitrary  $n \times n$  matrices.

**Block-Toeplitz-Toeplitz-block (BTTB) matrices:** The blocks  $A^{(i)}$  are themselves Toeplitz matrices.

Block matrices for other structured matrices such as the block-circulant matrices or the circulant-block matrices can be defined similarly.

**Facts:**

1. The transpose of a Toeplitz matrix is a Toeplitz matrix.
2. Any linear combination of Toeplitz matrices is a Toeplitz matrix.
3. The lower shift matrices  $Z_n$  are Toeplitz matrices. The  $n \times n$  Toeplitz matrix  $T = [t_{ij}]$  with  $t_{ij} = t_{i-j}$  satisfies  $T = t_0 I_n + \sum_{k=1}^{n-1} t_k Z_n^k + \sum_{k=1}^{n-1} t_{-k} (Z_n^T)^k$ .
4. Every circulant matrix is a Toeplitz matrix, but not conversely.
5. The transpose of a circulant matrix is a circulant matrix.
6. Any linear combination of circulant matrices is a circulant matrix.
7. The  $n$ -cycle matrix  $C_n$  is a circulant matrix. The  $n \times n$  circulant matrix  $C = [c_{ij}]$  with  $c_{i1} = c_{i-1}$  satisfies  $C = \sum_{k=0}^{n-1} c_k C_n^k$ .
8. An important property of circulant matrices is that they can be diagonalized by discrete Fourier transform matrices (see Section 47.3 and Chapter 58.3). Thus circulant matrices are normal.
9. A Hankel matrix is symmetric.
10. Any linear combination of Hankel matrices is a Hankel matrix.
11. Multiplication of a Toeplitz matrix and the anti-identity matrix  $P_n$  is a Hankel matrix, and multiplication of a Hankel matrix and  $P_n$  is a Toeplitz matrix. For  $H$  as in the definition,

$$P_n H = \begin{bmatrix} h_{n-1} & h_n & \dots & h_{2n-2} & h_{2n-1} \\ h_{n-2} & h_{n-1} & h_n & & h_{2n-2} \\ \vdots & h_{n-2} & h_{n-1} & \ddots & \vdots \\ h_1 & & \ddots & \ddots & h_n \\ h_0 & h_1 & \dots & h_{n-2} & h_{n-1} \end{bmatrix},$$

$$HP_n = \begin{bmatrix} h_{n-1} & h_{n-2} & \cdots & h_1 & h_0 \\ h_n & h_{n-1} & h_{n-2} & & h_1 \\ \vdots & h_n & h_{n-1} & \ddots & \vdots \\ h_{2n-2} & & \ddots & \ddots & h_{-1} \\ h_{2n-1} & h_{2n-2} & \cdots & h_n & h_{n-1} \end{bmatrix}.$$

12. The Kronecker product  $A \otimes T$  of any matrix  $A$  and a Toeplitz matrix  $T$  is a Toeplitz-block matrix and Kronecker product  $T \otimes A$  is a block-Toeplitz matrix.
13. Most of the applications, such as partial differential equations and image processing, are concerned [Jin02], [Ng04] with two-dimensional problems where the matrices will have block structures.

### Examples:

1.  $\begin{bmatrix} 1 & 2 & 1 & 1 \\ 3 & 1 & 1 & 1 \\ -5 & 2 & 1 & 2 \\ 0 & -5 & 3 & 1 \end{bmatrix}$  is a BTTB matrix with  $A^{(0)} = \begin{bmatrix} 1 & 2 \\ 3 & 1 \end{bmatrix}$ ,  $A^{(-1)} = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}$ ,  $A^{(1)} = \begin{bmatrix} -5 & 2 \\ 0 & 5 \end{bmatrix}$ .
2. For  $\mathbf{x} = \begin{bmatrix} 1 \\ 1 \\ 5 \end{bmatrix}$  and  $\mathbf{y} = \begin{bmatrix} 1 \\ 2 \\ 3 \end{bmatrix}$ ,  $C(\mathbf{x}, \mathbf{y}) = \begin{bmatrix} \frac{1}{2} & \frac{1}{3} & \frac{1}{4} \\ \frac{1}{2} & \frac{1}{3} & \frac{1}{4} \\ \frac{1}{6} & \frac{1}{7} & \frac{1}{8} \end{bmatrix}$ .

## 48.2 Direct Toeplitz Solvers

Most of the early work on Toeplitz solvers was focused on direct methods. These systems arise in a variety of applications in mathematics and engineering. In fact, Toeplitz structure was one of the first structures analyzed in signal processing.

### Definitions:

**Toeplitz systems:** A system of linear equations with a Toeplitz coefficient matrix.

### Facts:

1. Given an  $n \times n$  Toeplitz system  $T\mathbf{x} = \mathbf{b}$ , a straightforward application of the Gaussian elimination method will result in an algorithm of  $O(n^3)$  complexity.
2. However, since the matrix is determined by only  $(2n - 1)$  entries rather than  $n^2$  entries, it is to be expected that a solution can be obtained in less than  $O(n^3)$  operations. There are a number of fast Toeplitz solvers that can reduce the complexity to  $O(n^2)$  operations. The original references for these algorithms are Schur [Sch17], Levinson [Lev46], Durbin [Dur60], and Trench [Tre64].
3. In the 1980s, superfast algorithms of complexity  $(n \log^2 n)$  operations for Toeplitz systems were proposed by a different group of researchers: Bitmead and Anderson [BA80], Brent et al. [BGY80], Morf [Mor80], de Hoog [Hoo87], and Ammar and Gragg [AG88]. The key to these direct methods is to solve the system recursively. In this section, we will give a brief summary of the development of these methods. We refer the reader to the works cited for more details.
4. If the Toeplitz matrix  $T$  has a singular or ill-conditioned principal submatrix, then a breakdown or near-breakdown can occur in the direct Toeplitz solvers. Such breakdowns will cause numerical instability in subsequent steps of the algorithms and result in inaccurately computed solutions. The question of how to avoid breakdowns or near-breakdowns by skipping over singular submatrices

or ill-conditioned submatrices has been studied extensively, and various such algorithms have been proposed. (See Chan and Hansen [CH92].)

5. The fast direct Toeplitz solvers are in general numerically unstable for indefinite systems. Look-ahead methods are numerically stable and, although it may retain the  $O(n^2)$  complexity, it requires  $O(n^3)$  operations in the worst case.
6. The stability properties of direct methods for symmetric positive definite Toeplitz systems were discussed in Sweet [Swe84], Bunch [Bun85], Cybenko [Cyb87], and Bojanczyk et al. [BBH95].
7. Gohberg et al. [GKO95] have shown how to perform Gaussian elimination in a fast way for matrices having special displacement structures. Such matrices include Toeplitz, Vandermonde, Hankel, and Cauchy matrices. They have shown how to incorporate partial pivoting into Cauchy solvers. They pointed out that although pivoting cannot be incorporated directly for Toeplitz matrices, Toeplitz problems can be transformed by simple orthogonal operations to Cauchy problems. The solutions to the original problems can be recovered from those of the transformed systems by the reverse orthogonal operations. Thus, fast Gaussian elimination with partial pivoting can be carried out for Toeplitz systems.

Brent and Sweet [BS95] gave a rounding error analysis on the Cauchy and Toeplitz variants of the recent method of Gohberg et al. [GK095]. It has been shown that the error growth depends on the growth in certain auxiliary vectors, the generators, which are computed by the Gohberg algorithm. In certain circumstances, growth in the generators can be large, so the error growth is much larger than would be encountered when using normal Gaussian elimination with partial pivoting.

### 48.3 Iterative Toeplitz Solvers

---

A circulant matrix is a special form of Toeplitz matrix where each row of the matrix is a circular shift of its preceding row. Because of the periodicity, circulant systems can be solved quickly via a deconvolution by discrete Fast Fourier Transforms (FFTs) [Ng04]. Circulant approximations to Toeplitz matrices have been used for some time in signal and image processing [Ng04]. However, in these applications, the circulant approximation so obtained is used to replace the given Toeplitz matrix in subsequent computations. In effect, the matrix equation is changed and, hence, so is the solution.

Development of solely circulant-based iterative methods for Toeplitz systems started in the 1970s. Rino [Rin70] developed a method for generating a series expansion solution to Toeplitz systems by writing a Toeplitz matrix as the sum of a circulant matrix and another Toeplitz matrix and presented a method for choosing the circulant matrix. Silverman and Pearson [SP73] applied similar methods to deconvolution.

In 1986, Strang [Str86] and Olkin [Olk86] independently proposed to precondition Toeplitz matrices by circulant matrices in conjugate gradient iterations. Their motivation was to exploit the fast inversion of circulant matrices. Numerical results in [SE87] and [Olk86] show that the method converges very fast for a wide range of Toeplitz matrices. This has later been proved theoretically in [CS89] and in other papers for other circulant preconditioners [Ng04]. Circulant approximations are used here only as preconditioners for Toeplitz systems and the solutions to the Toeplitz systems are unchanged.

One of the main important results of this methodology is that the complexity of solving a large class of  $n \times n$  Toeplitz systems can be reduced to  $O(n \log n)$  operations, provided that a suitable preconditioner is used. Besides the reduction of the arithmetic complexity, there are important types of Toeplitz matrix where the fast direct Toeplitz solvers are notoriously unstable, e.g., indefinite and certain non-Hermitian Toeplitz matrices. Therefore, iterative methods provide alternatives for solving these Toeplitz systems.

### 48.4 Linear Systems with Matrix Structure

---

This section provides some examples of the latest developments on iterative methods for the iterative solution of linear systems of equations with structured coefficient matrices such as Toeplitz-like, Toeplitz-plus-Hankel, and Toeplitz-plus-band matrices. We would like to make use of their structure to construct some good preconditioners for such matrices.

**Facts:**

1. Toeplitz-like systems: Let  $A$  be an  $n \times n$  structured matrix with respect to  $Z_n$  (the lower shift matrix):

$$\nabla A_n = A_n - Z_n A_n Z_n^* = G S G^*$$

for some  $n \times r$  generator matrix  $G$  and  $r \times r$  signature matrix  $S = (I_p \oplus -I_q)$ . If we partition the columns of  $G$  into two sets  $\{x_i\}_{i=0}^{p-1}$  and  $\{y_i\}_{i=0}^{q-1}$ ,

$$G = [x_0 \ x_1 \ \dots \ x_{p-1} \ y_0 \ y_1 \ \dots \ y_{q-1}] \quad \text{with } p + q = r,$$

then we know from the representation that we can express  $A$  as a linear combination of lower triangular Toeplitz matrices,

$$A = \sum_{i=0}^{p-1} L(x_i) L^*(x_i) - \sum_{i=0}^{q-1} L(y_i) L^*(y_i).$$

For example, if  $T_{m,n}$  is an  $m \times n$  Toeplitz matrix with  $m \geq n$ , then  $T_{m,n}^* T_{m,n}$  is in general not a Toeplitz matrix. However,  $T_{m,n}^* T_{m,n}$  does have a small displacement rank,  $r \leq 4$ , and the displacement representation of  $T_{m,n}^* T_{m,n}$  is

$$T_{m,n}^* T_{m,n} = L_n(x_0) L_n(x_0)^* - L_n(y_0) L_n(y_0)^* + L_n(x_1) L_n(x_1)^* - L_n(y_1) L_n(y_1)^*,$$

where

$$x_0 = T_{m,n}^* T_{m,n} e_1 / \|T_{m,n} e_1\|, \quad y_0 = Z_n Z_n^* x_0,$$

$$x_1 = [0, t_{-1}, t_{-2}, \dots, t_{1-n}]^*, \quad \text{and} \quad y_1 = [0, t_{m-1}, t_{m-2}, \dots, t_{m-n+1}]^*.$$

2. For structured matrices with displacement representations, it was suggested in [CNP94] to define the displacement preconditioner to be the circulant approximation of the factors in the displacement representation of  $A$ , i.e., the circulant approximation  $C$  of  $A$  is

$$\sum_{i=0}^{p-1} C(L(x_i)) C^*(L_n(x_i)) - \sum_{i=0}^{q-1} C(L_n(y_i)) C^*(L_n(y_i)).$$

Here,  $C(X)$  denotes some circulant approximations to  $X$ .

3. The displacement preconditioner approach is applied to Toeplitz least squares and Toeplitz-plus-Hankel least squares problems [Ng04].
4. The systems of linear equations with Toeplitz-plus-Hankel coefficient matrices arise in many signal processing applications. For example, the inverse scattering problem can be formulated as Toeplitz-plus-Hankel systems of equations (see [Ng04].)

The product of  $P_n$  and  $H$  and the product of  $H$  and  $P_n$  both give Toeplitz matrices.

Premultiplying  $P_n$  to a vector  $v$  corresponds to reversing the order of the elements in  $v$ . Since

$$Hv = H P_n P_n v$$

and  $H P_n$  is a Toeplitz matrix, the Hankel matrix-vector products  $Hv$  can be done efficiently using FFTs. A Toeplitz-plus-Hankel matrix can be expressed as  $T + H = T + P_n P_n H$ .

5. Given circulant preconditioners  $C^{(1)}$  and  $C^{(2)}$  for Toeplitz matrices  $T$  and  $P_n H$ , respectively, it was proposed in [KK93] to use

$$M = C^{(1)} + P_n C^{(2)}$$

as a preconditioner for the Toeplitz-plus-Hankel matrix  $T + H$ . With the equality  $P_n^2 = I$ , we have

$$Mz = C^{(1)}z + P_n C^{(2)} P_n P_n z = v,$$

which is equivalent to

$$P_n Mz = P_n C^{(1)} P_n P_n z + C^{(2)}z = P_n v.$$

By using these two equations, the solution of  $z = M^{-1}v$  can be determined.

6. We consider the solution of systems of the form  $(T + B)x = b$ , where  $T$  is a Toeplitz matrix and  $B$  is a banded matrix with bandwidth  $2b + 1$  independent of the size of the matrix. These systems appear in solving Fredholm integro-differential equations of the form

$$L\{x(\theta)\} + \int_{\alpha}^{\beta} K(\phi - \theta)x(\phi)d\phi = b(\theta).$$

Here,  $x(\theta)$  is the unknown function to be found,  $K(\theta)$  is a convolution kernel,  $L$  is a differential operator and  $b(\theta)$  is a given function. After discretization,  $K$  will lead to a Toeplitz matrix,  $L$  to a banded matrix, and  $b(\theta)$  to the right-hand side vector [Ng04]. Toeplitz-plus-band matrices also appear in signal processing literature and have been referred to as peripheral innovation matrices.

Unlike Toeplitz systems, there exist no fast direct solvers for solving Toeplitz-plus-band systems. It is mainly because the displacement rank of the matrix  $T + B$  can take any value between 0 and  $n$ . Hence, fast Toeplitz solvers that are based on small displacement rank of the matrices cannot be applied. Conjugate gradient methods with circulant preconditioners do not work for Toeplitz-plus-band systems either. The main reason is that when the eigenvalues of  $B$  are not clustered, the matrix  $C(T) + B$  cannot be inverted easily.

In [CN93], it was proposed to use the matrix  $E + B$  to precondition  $T + B$ , where  $E$  is the band-Toeplitz preconditioner such that  $E$  is spectrally equivalent to  $T$ . Note that  $E$  is a banded matrix, and the banded system  $(E + B)y = z$  can be solved by using any band matrix solver.

7. Banded preconditioners are successfully applied to precondition Sinc-Galerkin systems (Toeplitz-plus-band systems) arising from the Sinc-Galerkin method to partial differential equations (see [Ng04].)
8. In most of applications we simply use the circulant or other transform-based preconditioners [Ng04]. We can extend the results for point circulant or point transform-based preconditioners to block circulant preconditioners or block transform-based preconditioners [Jin02] for block-Toeplitz, Toeplitz-block, and Toeplitz-block-block-Toeplitz matrices.
9. Consider the system  $(A \otimes B)x = b$ , where  $A$  is an  $m$ -by- $m$  Hermitian positive definite matrix and  $B$  is an  $n$ -by- $n$  Hermitian positive definite Toeplitz matrix. By using a circulant approximation  $C(B)$  to  $B$ , the preconditioned system becomes

$$(A \otimes C(B))^{-1}(A \otimes B)x = (A \otimes C(B))^{-1}b,$$

or

$$(I \otimes C(B)^{-1}B)x = (A^{-1} \otimes C(B)^{-1})b.$$

When  $B$  is a Hermitian positive definite Toeplitz matrix,  $C(B)$  can be obtained in  $O(n)$  operation [Jin02], [Ng04]. The initialization cost is about  $O(m^3 + m^2n + mn \log n)$  operations. Moreover, since the cost of multiplying  $B$  by becomes  $O(n \log n)$ , we see that the cost per iteration is equal to  $O(mn \log n)$  when iterative methods are employed.

10. When Toeplitz matrices have full rank, Toeplitz least squares problems

$$\min \|Tx - b\|_2^2$$

are equivalent to solving the normal equation matrices

$$T^*Tx = T^*b.$$

Circulant preconditioners can be applied effectively and efficiently to solving Toeplitz least squares problems if Toeplitz matrices have full rank. When Toeplitz matrices do not have full rank, it is still an open research problem to find efficient algorithms for solving rank-deficient Toeplitz least squares problem. One possibility is to consider the generalized inverses of Toeplitz matrices. In the literature, computing the inverses and the generalized inverses of structured matrices are important practical computational problems. (See, for instance, Pan and Rami [PR01] and Bini et al. [BCV03].)

11. Instead of Toeplitz least squares problems  $\min \|Tx - b\|_2^2$ , we are interested in the 1-norm problem, i.e.,  $\min \|Tx - b\|_1$ . The advantage of using the 1-norm is that the solution is more robust than using the 2-norm in statistical estimation problems. In particular, a small number of outliers have less influence on the solution. It is interesting to develop efficient algorithms for solving 1-norm Toeplitz least squares problems. Fu et al. [FNN06] have considered the least absolute deviation (LAD) solution of image restoration problems.
12. It is interesting to find good preconditioners for Toeplitz-related systems with large displacement rank. Good examples are Toeplitz-plus-band systems studied. Direct Toeplitz-like solvers cannot be employed because of the large displacement rank. However, iterative methods are attractive since coefficient matrix-vector products can be computed efficiently at each iteration. For instance, for the Toeplitz-plus-band matrix, its matrix-vector product can be computed in  $O(n \log n)$  operations. The main concern is how to design good preconditioners for such Toeplitz-related systems with large displacement rank. Recently, Lin et al. [LNC05] proposed and developed factorized banded inverse preconditioners for matrices with Toeplitz structure. Also, Lin et al. [LCN04] studied incomplete factorization-based preconditioners for Toeplitz-like systems with large displacement ranks in image processing.

## 48.5 Total Least Squares Problems

---

1. The least squares problem  $Tf \approx g$  is

$$\min_f \|Tf - g\|_2.$$

If the matrix  $T$  is known exactly, but the vector  $g$  is corrupted by random errors that are uncorrelated with zero mean and equal variance, then the least squares solution provides the best unbiased estimate of  $f$ . However, if  $T$  is also corrupted by errors, then the total least squares (TLS) method may be more appropriate. The TLS problem minimizes

$$\min_{\hat{T}, \hat{g}} \|[T \ g] - [\hat{T} \ \hat{g}]\|_F^2$$

with the constraint  $\hat{T}\hat{f} = \hat{g}$ . If the smallest singular value of  $T$  is larger than the smallest singular value  $\sigma^2$  of  $[T \ g]$ , then there exists a unique TLS solution  $f_{TLS}$ , which can be represented as the solution to the normal equations:

$$(T^T T - \sigma^2 I) f = T^T g,$$

or as the solution to the eigenvalue problem:

$$\begin{bmatrix} T^T T & T^T g \\ g^T T & g^T g \end{bmatrix} \begin{bmatrix} f \\ -1 \end{bmatrix} = \sigma^2 \begin{bmatrix} f \\ -1 \end{bmatrix}.$$

Kamm and Nagy [KN98] proposed using Newton and Rayleigh quotient iterations for large TLS Toeplitz problems. Their method is a modification of a method suggested by Cybenko and Van Loan [CV86] for computing the minimum eigenvalue of a symmetric positive definite Toeplitz matrix. Specifically, first note that the TLS solution  $f_{TLS}$  solves the eigenvalue problem. Moreover, this eigenvalue problem is equivalent to

$$T^T T f - T^T g = \sigma^2 f$$

and

$$g^T T f - g^T g = -\sigma^2,$$

which can be combined to obtain the following secular equation for  $\sigma^2$ :

$$g^T g - g^T T (T^T T - \sigma^2 I)^{-1} T^T g - \sigma^2 = 0.$$

Therefore,  $\sigma^2$  is the smallest root of the rational equation

$$h(\sigma^2) = g^T g - g^T T (T^T T - \sigma^2 I)^{-1} T^T g - \sigma^2$$

and can be found using Newton's method. Note that if  $\sigma^2$  is less than the smallest singular value  $\hat{\sigma}^2$  of  $T$ , then the matrix  $T^T T - \sigma^2 I$  is positive definite. Assume for now that the initial estimate is within the interval  $[\sigma^2, \hat{\sigma}^2)$ . An analysis given in [CV86] shows that subsequent Newton iterates will remain within this interval and will converge from the right to  $\sigma^2$ .

2. In the above computation,  $\hat{T}$  is not necessary to have Toeplitz structure. In another development, Ng [NPP00] presented an iterative, regularized, and constrained total least squares algorithm by requiring  $\hat{T}$  to be Toeplitz. Preliminary numerical tests are reported on some simulated optical imaging problems. The numerical results showed that the regularized constrained TLS method is better than the regularized least squares method.
3. Other interesting areas are to design efficient algorithms based on preconditioning techniques for finding eigenvalues and singular values of Toeplitz-like matrices. Ng [Ng00] has employed preconditioned Lanczos methods for the minimum eigenvalue of a symmetric positive definite Toeplitz matrix.

Computational problems, especially in science and engineering, often involve large matrices. Examples of such problems include large sparse systems of linear equations [FGN92],[Saa03],[vdV03], e.g., arising from discretizations of partial differential equations, eigenvalue problems for large matrices [BDD00],[LM05], linear time-invariant dynamical systems with large state-space dimensions [FF94],[FF95],[Fre03], and large-scale linear and nonlinear optimization problems [KR91],[Wri97],[NW99],[GMS05]. The large matrices in these problems exhibit special structures, such as sparsity, that can be exploited in computational procedures for their solution. Roughly speaking, computational problems involving matrices are called “large-scale” if they can be solved only by methods that exploit these special matrix structures.

In this section, as in Chapter 44, multiplication of a vector  $\mathbf{v}$  by a scalar  $\lambda$  is denoted by  $\mathbf{v}\lambda$  rather than  $\lambda\mathbf{v}$ .

### 49.1 Basic Concepts

---

Many of the most efficient algorithms for large-scale matrix computations are based on approximations of the given large matrix by small matrices obtained via Petrov–Galerkin projections onto suitably chosen small-dimensional subspaces. In this section, we present some basic concepts of such projections.

#### Definitions:

Let  $C \in \mathbb{C}^{n \times n}$  and let  $V_j = [\mathbf{v}_1 \ \mathbf{v}_2 \ \cdots \ \mathbf{v}_j] \in \mathbb{C}^{n \times j}$  be a matrix with orthonormal columns, i.e.,

$$\mathbf{v}_i^* \mathbf{v}_k = \begin{cases} 0 & \text{if } i \neq k, \\ 1 & \text{if } i = k, \end{cases} \quad \text{for all } i, k = 1, 2, \dots, j.$$

The matrix

$$C_j := V_j^* C V_j \in \mathbb{C}^{j \times j}$$

is called the **orthogonal Petrov–Galerkin projection** of  $C$  onto the subspace

$$S = \text{span}\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_j\}$$

of  $\mathbb{C}^n$  spanned by the columns of  $V_j$ .

Let  $C \in \mathbb{C}^{n \times n}$ , and let  $V_j = [\mathbf{v}_1 \ \mathbf{v}_2 \ \dots \ \mathbf{v}_j] \in \mathbb{C}^{n \times j}$  and  $W_j = [\mathbf{w}_1 \ \mathbf{w}_2 \ \dots \ \mathbf{w}_j] \in \mathbb{C}^{n \times j}$  be two matrices such that  $W_j^T V_j$  is nonsingular. The matrix

$$C_j := (W_j^T V_j)^{-1} W_j^T C V_j \in \mathbb{C}^{j \times j}$$

is called the **oblique Petrov–Galerkin projection** of  $C$  onto the subspace

$$S = \text{span}\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_j\}$$

of  $\mathbb{C}^n$  spanned by the columns of  $V_j$  and orthogonally to the subspace

$$T = \text{span}\{\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_j\}$$

of  $\mathbb{C}^n$  spanned by the columns of  $W_j$ .

A **flop** is the work associated with carrying out any one of the elementary operations  $a + b$ ,  $a - b$ ,  $ab$ , or  $a/b$ , where  $a, b \in \mathbb{C}$ , in floating-point arithmetic.

Let  $A = [a_{ik}] \in \mathbb{C}^{m \times n}$  be a given matrix. Matrix-vector multiplications with  $A$  are said to be **fast** if for any  $\mathbf{x} \in \mathbb{C}^n$ , the computation of  $\mathbf{y} = A\mathbf{x}$  requires significantly fewer than  $2mn$  flops.

A matrix  $A = [a_{ik}] \in \mathbb{C}^{m \times n}$  is said to be **sparse** if only a small fraction of its entries  $a_{ik}$  are nonzero.

For a sparse matrix  $A = [a_{ik}] \in \mathbb{C}^{m \times n}$ ,  $\text{nnz}(A)$  denotes the number of nonzero entries of  $A$ .

A matrix  $A = [a_{ik}] \in \mathbb{C}^{m \times n}$  is said to be **dense** if most of its entries  $a_{ik}$  are nonzero.

### Facts:

The following facts on sparse matrices can be found in [Saa03, Chap. 3] and the facts on computing Petrov–Galerkin projections of matrices in [Saa03, Chap. 6].

1. For a sparse matrix  $A = [a_{ik}] \in \mathbb{C}^{m \times n}$ , only its nonzero or potentially nonzero entries  $a_{ik}$ , together with their row and column indices  $i$  and  $k$ , need to be stored.
2. Matrix-vector multiplications with a sparse matrix  $A = [a_{ik}] \in \mathbb{C}^{m \times n}$  are fast. More precisely, for any  $\mathbf{x} \in \mathbb{C}^n$ ,  $\mathbf{y} = A\mathbf{x}$  can be computed with at most  $2\text{nnz}(A)$  flops.
3. If  $C \in \mathbb{C}^{n \times n}$  and  $j \ll n$ , the computational cost for computing the orthogonal Petrov–Galerkin projection of  $C$  onto the  $j$ -dimensional subspace  $S = \text{span}\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_j\}$  of  $\mathbb{C}^n$  is dominated by the  $j$  matrix-vector products  $\mathbf{y}_i = C\mathbf{v}_i$ ,  $i = 1, 2, \dots, j$ .
4. If  $C \in \mathbb{C}^{n \times n}$  and  $j \ll n$ , the computational cost for computing the oblique Petrov–Galerkin projection of  $C$  onto the  $j$ -dimensional subspace  $S = \text{span}\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_j\}$  of  $\mathbb{C}^n$  and orthogonally to the  $j$ -dimensional subspace  $T = \text{span}\{\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_j\}$  of  $\mathbb{C}^n$  is dominated by the  $j$  matrix-vector products  $\mathbf{y}_i = C\mathbf{v}_i$ ,  $i = 1, 2, \dots, j$ .
5. If matrix-vector products with a large matrix  $C \in \mathbb{C}^{n \times n}$  are fast, then orthogonal and oblique Petrov–Galerkin projections  $C_j$  of  $C$  can be generated with low computational cost.

## 49.2 Sparse Matrix Factorizations

---

In this section, we present some basic concepts of sparse matrix factorizations. A more detailed description can be found in [DER89].

### Definitions:

Let  $A \in \mathbb{C}^{n \times n}$  be a sparse nonsingular matrix. A **sparse LU factorization** of  $A$  is a factorization of the form

$$A = PLUQ,$$

where  $P, Q \in \mathbb{R}^{n \times n}$  are permutation matrices,  $L \in \mathbb{C}^{n \times n}$  is a sparse unit lower triangular matrix, and  $U \in \mathbb{C}^{n \times n}$  is a sparse nonsingular upper triangular matrix.

**Fill-in** of a sparse LU factorization  $A = PLUQ$  is the set of nonzero entries of  $L$  and  $U$  that appear in positions  $(i, k)$  where  $a_{ik} = 0$ .

Let  $A = A^* \in \mathbb{C}^{n \times n}$ ,  $A \succ 0$ , be a sparse Hermitian positive definite matrix. A **sparse Cholesky factorization** of  $A$  is a factorization of the form

$$A = PLL^*P^T,$$

where  $P \in \mathbb{R}^{n \times n}$  is a permutation matrix and  $L \in \mathbb{C}^{n \times n}$  is a sparse lower triangular matrix.

**Fill-in** of a sparse Cholesky factorization  $A = PLL^*P^T$  is the set of nonzero entries of  $L$  that appear in positions  $(i, k)$  where  $a_{ik} = 0$ .

Let  $T \in \mathbb{C}^{n \times n}$  be a sparse nonsingular (upper or lower) triangular matrix, and let  $\mathbf{b} \in \mathbb{C}^n$ . A **sparse triangular solve** is the solution of a linear system

$$T\mathbf{x} = \mathbf{b}$$

with a sparse triangular coefficient matrix  $T$ .

### Facts:

The following facts can be found in [DER89].

1. The permutation matrices  $P$  and  $Q$  in a sparse LU factorization of  $A$  allow for reorderings of the rows and columns of  $A$ . These reorderings serve two purposes. First, they allow for pivoting for numerical stability in order to avoid division by the number 0 or by numbers close to 0, which would result in breakdowns or numerical instabilities in the procedure used for the computation of the factorization. Second, the reorderings allow for pivoting for sparsity, the goal of which is to minimize the amount of fill-in.
2. For Cholesky factorizations of matrices  $A = A^* \succ 0$ , the positive definiteness of  $A$  implies that pivoting for numerical stability is not needed. Therefore, the permutation matrix  $P$  in a sparse Cholesky factorization serves the single purpose of pivoting for sparsity.
3. For both sparse LU and sparse Cholesky factorizations, the problem of “optimal” pivoting for sparsity, i.e., finding reorderings that minimize the amount of fill-in, is NP-complete. This means that for practical purposes, minimizing the amount of fill-in of factorizations of large sparse matrices is impossible in general. However, there are a large number of pivoting strategies that — while not minimizing fill-in — efficiently limit the amount of fill-in for many important classes of large sparse matrices. (See, e.g., [DER89].)
4. A sparse triangular solve with the matrix  $T$  requires at most  $2nnz(T)$  flops.
5. Not every large sparse matrix  $A$  has a sparse LU factorization with limited amounts of fill-in. For example, LU or Cholesky factorizations of sparse matrices  $A$  arising from discretization of partial differential equations for three-dimensional problems are often prohibitive due to the large amount of fill-in.

**Examples:**

1. Given a sparse  $LU$  factorization  $A = PLUQ$  of a sparse nonsingular matrix  $A \in \mathbb{C}^{n \times n}$ , the solution  $\mathbf{x}$  of the linear system  $A\mathbf{x} = \mathbf{b}$  with any right-hand side  $\mathbf{b} \in \mathbb{C}^n$  can be computed as follows:

$$\begin{aligned} \text{Set } \mathbf{c} &= P^T \mathbf{b}, \\ \text{Solve } L\mathbf{z} &= \mathbf{c} \text{ for } \mathbf{z}, \\ \text{Solve } U\mathbf{y} &= \mathbf{z} \text{ for } \mathbf{y}, \\ \text{Set } \mathbf{x} &= Q^T \mathbf{y}. \end{aligned}$$

Since  $P$  and  $Q$  are permutation matrices, the first and the last steps are just reorderings of the entries of the vectors  $\mathbf{b}$  and  $\mathbf{y}$ , respectively. Therefore, the main computational cost is the two triangular solves with  $L$  and  $U$ , which requires at most  $2(\text{nnz}(L) + \text{nnz}(U))$  flops.

2. Given a sparse Cholesky factorization  $A = PLL^*P^T$  of a sparse Hermitian positive definite matrix  $A \in \mathbb{C}^{n \times n}$ , the solution  $\mathbf{x}$  of the linear system  $A\mathbf{x} = \mathbf{b}$  with any right-hand side  $\mathbf{b} \in \mathbb{C}^n$  can be computed as follows:

$$\begin{aligned} \text{Set } \mathbf{c} &= P^T \mathbf{b}, \\ \text{Solve } L\mathbf{z} &= \mathbf{c} \text{ for } \mathbf{z}, \\ \text{Solve } L^* \mathbf{y} &= \mathbf{z} \text{ for } \mathbf{y}, \\ \text{Set } \mathbf{x} &= P^T \mathbf{y}. \end{aligned}$$

Since  $P$  is a permutation matrix, the first and the last steps are just reorderings of the entries of the vectors  $\mathbf{b}$  and  $\mathbf{y}$ , respectively. Therefore, the main computational cost is the two triangular solves with  $L$  and  $L^*$ , which requires at most  $4\text{nnz}(L)$  flops.

3. In large-scale matrix computations, sparse factorizations are often not applied to a given sparse matrix  $A \in \mathbb{C}^{n \times n}$ , but to a suitable “approximation”  $A_0 \in \mathbb{C}^{n \times n}$  of  $A$ . For example, if sparse factorizations of  $A$  itself are prohibitive due to excessive fill-in, such approximations  $A_0$  can often be obtained by computing an “incomplete” factorization of  $A$  that simply discards unwanted fill-in entries. Given a sparse  $LU$  factorization

$$A_0 = PLUQ$$

of a sparse nonsingular matrix  $A_0 \in \mathbb{C}^{n \times n}$ , which in some sense approximates the original matrix  $A \in \mathbb{C}^{n \times n}$ , one then uses iterative procedures that only involve matrix-vector products with the matrix

$$C := A_0^{-1} A = Q^T U^{-1} L^{-1} P^T A,$$

or possibly its transpose  $C^T$ . In the context of solving linear systems  $A\mathbf{x} = \mathbf{b}$ , the matrix  $A_0$  is called a **preconditioner**, and the matrix  $C$  is called the **preconditioned** coefficient matrix.

In general, the matrix  $C = A_0^{-1} A$  is full. However, if  $C$  is only used in the form of matrix-vector products, then there is no need to explicitly form  $C$ . Instead, for any  $\mathbf{v} \in \mathbb{C}^n$ , the result of the matrix-vector product  $\mathbf{y} = C\mathbf{v}$  can be computed as follows:

$$\begin{aligned} \text{Set } \mathbf{c} &= A\mathbf{v}, \\ \text{Set } \mathbf{d} &= P^T \mathbf{c}, \\ \text{Solve } L\mathbf{f} &= \mathbf{d} \text{ for } \mathbf{f}, \\ \text{Solve } U\mathbf{z} &= \mathbf{f} \text{ for } \mathbf{z}, \\ \text{Set } \mathbf{y} &= Q^T \mathbf{z}. \end{aligned}$$

Since  $P$  and  $Q$  are permutation matrices, the second and the last steps are just reorderings of the entries of the vectors  $\mathbf{c}$  and  $\mathbf{z}$ , respectively. Therefore, the main computational cost is the matrix-vector product with the sparse matrix  $A$  in the first step, the triangular solve with  $L$  in the

third step, and the triangular solve with  $U$  in the fourth step, which requires a total of at most  $2(\text{nnz}(A) + \text{nnz}(L) + \text{nnz}(U))$  flops. Similarly, each matrix product with  $C^T$  can be computed with at most  $2(\text{nnz}(A) + \text{nnz}(L) + \text{nnz}(U))$  flops. In particular, matrix-vector products with both  $C$  and  $C^T$  are fast.

4. For sparse Hermitian matrices  $A = A^* \in \mathbb{C}^{n \times n}$ , preconditioning is often applied in a symmetric manner. Suppose

$$A_0 = PLL^*P^T$$

is a sparse Cholesky factorization of a sparse matrix  $A_0 = A_0^* \in \mathbb{C}^{n \times n}$ ,  $A_0 > 0$ , which in some sense approximates the original matrix  $A$ . Then the symmetrically preconditioned matrix  $C$  is defined as

$$C := (PL)^{-1}A(L^*P^T)^{-1} = L^{-1}P^TAP(L^*)^{-1}.$$

Note that  $C = C^*$  is a Hermitian matrix. For any  $\mathbf{v} \in \mathbb{C}^n$ , the result of the matrix-vector product  $\mathbf{y} = C\mathbf{v}$  can be computed as follows:

$$\begin{aligned} &\text{Solve } L^*\mathbf{c} = \mathbf{v} \text{ for } \mathbf{c}, \\ &\text{Set } \mathbf{d} = P\mathbf{c}, \\ &\text{Set } \mathbf{f} = A\mathbf{d}, \\ &\text{Set } \mathbf{z} = P^T\mathbf{f}, \\ &\text{Solve } L\mathbf{y} = \mathbf{z} \text{ for } \mathbf{y}. \end{aligned}$$

The main computational cost is the triangular solve with  $L^*$  in the first step, the matrix-vector product with the sparse matrix  $A$  in the third step, and the triangular solve with  $L$  in the last step, which requires a total of at most  $2(\text{nnz}(A) + 2\text{nnz}(L))$  flops. In particular, matrix-vector products with  $C$  are fast.

### 49.3 Krylov Subspaces

Petrov–Galerkin projections are often used in conjunction with Krylov subspaces. In this section, we present the basic concepts of Krylov subspaces. In the following, it is assumed that  $C \in \mathbb{C}^{n \times n}$  and  $\mathbf{r} \in \mathbb{C}^n$ ,  $\mathbf{r} \neq \mathbf{0}$ .

**Definitions:**

The sequence

$$\mathbf{r}, C\mathbf{r}, C^2\mathbf{r}, \dots, C^{j-1}\mathbf{r}, \dots$$

is called the **Krylov sequence** induced by  $C$  and  $\mathbf{r}$ .

Let  $j \geq 1$ . The subspace

$$K_j(C, \mathbf{r}) := \text{span}\{\mathbf{r}, C\mathbf{r}, C^2\mathbf{r}, \dots, C^{j-1}\mathbf{r}\}$$

of  $\mathbb{C}^n$  spanned by the first  $j$  vectors of the Krylov sequence is called the  **$j$ th Krylov subspace** induced by  $C$  and  $\mathbf{r}$ .

A sequence of linearly independent vectors

$$\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_j \in \mathbb{C}^n$$

is said to be a **nested basis** for the  $j$ th Krylov subspace  $K_j(C, \mathbf{r})$  if

$$\text{span}\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_i\} = K_i(C, \mathbf{r}) \quad \text{for all } i = 1, 2, \dots, j.$$

Let  $p(\lambda) = c_0 + c_1\lambda + c_2\lambda^2 + \cdots + c_{d-1}\lambda^{d-1} + \lambda^d$  be a monic polynomial of degree  $d$  with coefficients in  $\mathbb{C}$ . The **minimal polynomial of  $C$  with respect to  $\mathbf{r}$**  is the unique monic polynomial of smallest possible degree for which  $p(C)\mathbf{r} = \mathbf{0}$ .

The **grade of  $C$  with respect to  $\mathbf{r}$** ,  $d(C, \mathbf{r})$ , is the degree of the minimal polynomial of  $C$  and  $\mathbf{r}$ .

### Facts:

The following facts can be found in [Hou75, Sect. 1.5], [SB02, Sect. 6.3], or [Saa03, Sect. 6.2].

1. The vectors

$$\mathbf{r}, C\mathbf{r}, C^2\mathbf{r}, \dots, C^{j-1}\mathbf{r}$$

are linearly independent if and only if  $j \leq d(C, \mathbf{r})$ .

2. Let  $d = d(C, \mathbf{r})$ . The vectors

$$\mathbf{r}, C\mathbf{r}, C^2\mathbf{r}, \dots, C^{d-2}\mathbf{r}, C^{d-1}\mathbf{r}, C^j\mathbf{r}$$

are linearly dependent for all  $j > d$ .

3. The dimension of the  $j$ th Krylov subspace  $K_j(C, \mathbf{r})$  is given by

$$\dim K_j(C, \mathbf{r}) = \begin{cases} j & \text{if } j \leq d(C, \mathbf{r}), \\ d(C, \mathbf{r}) & \text{if } j > d(C, \mathbf{r}). \end{cases}$$

4.  $d(C, \mathbf{r}) = \text{rank} [\mathbf{r} \quad C\mathbf{r} \quad C^2\mathbf{r} \quad \cdots \quad C^{n-1}\mathbf{r}]$ .

## 49.4 The Symmetric Lanczos Process

In this section, we assume that  $C = C^* \in \mathbb{C}^{n \times n}$  is a Hermitian matrix and that  $\mathbf{r} \in \mathbb{C}^n$ ,  $\mathbf{r} \neq \mathbf{0}$  is a nonzero starting vector. We discuss the **symmetric Lanczos process** [Lan50] for constructing a nested basis for the Krylov subspace  $K_j(C, \mathbf{r})$  induced by  $C$  and  $\mathbf{r}$ .

### Algorithm (Symmetric Lanczos process)

Compute  $\beta_1 = \|\mathbf{r}\|_2$ , and set  $\mathbf{v}_1 = \mathbf{r}/\beta_1$ , and  $\mathbf{v}_0 = \mathbf{0}$ .

For  $j = 1, 2, \dots$ , do:

- 1) Compute  $\mathbf{v} = C\mathbf{v}_j$ , and set  $\mathbf{v} = \mathbf{v} - \mathbf{v}_{j-1}\beta_j$ .
- 2) Compute  $\alpha_j = \mathbf{v}_j^*\mathbf{v}$ , and set  $\mathbf{v} = \mathbf{v} - \mathbf{v}_j\alpha_j$ .
- 3) Compute  $\beta_{j+1} = \|\mathbf{v}\|_2$ .  
If  $\beta_{j+1} = 0$ , stop.  
Otherwise, set  $\mathbf{v}_{j+1} = \mathbf{v}/\beta_{j+1}$ .

end for

### Facts:

The following facts can be found in [CW85], [SB02, Sect. 6.5.3], or [Saa03, Sect. 6.6].

1. In exact arithmetic, the algorithm stops after a finite number of iterations. More precisely, it stops when  $j = d(C, \mathbf{r})$  is reached.

2. The **Lanczos vectors**

$$\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_j$$

generated during the first  $j$  iterations of the algorithm form a nested basis for the  $j$ th Krylov subspace  $K_j(C, \mathbf{r})$ .

3. The Lanczos vectors satisfy the three-term recurrence relations

$$\mathbf{v}_{i+1}\beta_{i+1} = C\mathbf{v}_i - \mathbf{v}_i\alpha_i - \mathbf{v}_{i-1}\beta_i, \quad i = 1, 2, \dots, j.$$

4. These three-term recurrence relations can be written in compact matrix form as follows:

$$CV_j = V_j T_j + \beta_{j+1}\mathbf{v}_{j+1}\mathbf{e}_j^T = V_{j+1}T_j^{(e)}.$$

Here, we set

$$V_j = [\mathbf{v}_1 \quad \mathbf{v}_2 \quad \dots \quad \mathbf{v}_j], \quad \mathbf{e}_j^T = [0 \quad 0 \quad \dots \quad 0 \quad 1] \in \mathbb{R}^{1 \times j},$$

$$T_j = \begin{bmatrix} \alpha_1 & \beta_2 & 0 & \dots & 0 \\ \beta_2 & \alpha_2 & \beta_3 & \ddots & \vdots \\ 0 & \beta_3 & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & \beta_j \\ 0 & \dots & 0 & \beta_j & \alpha_j \end{bmatrix}, \quad T_j^{(e)} = \begin{bmatrix} T_j \\ \beta_{j+1}\mathbf{e}_j^T \end{bmatrix}, \quad \text{and} \quad V_{j+1} = [V_j \quad \mathbf{v}_{j+1}].$$

Note that  $T_j \in \mathbb{C}^{j \times j}$  and  $T_j^{(e)} \in \mathbb{C}^{(j+1) \times j}$  are tridiagonal matrices.

5. In exact arithmetic, the Lanczos vectors are orthonormal. Since the Lanczos vectors are the columns of  $V_j$ , this orthonormality can be stated compactly as follows:

$$V_j^* V_j = I_j \quad \text{and} \quad V_j^* \mathbf{v}_{j+1} = \mathbf{0}.$$

6. These orthogonality relations, together with the above compact form of the three-term recurrence relations, imply that

$$T_j = V_j^* C V_j.$$

Thus, the  $j$ th **Lanczos matrix**  $T_j$  is the orthogonal Petrov–Galerkin projection of  $C$  onto the  $j$ th Krylov subspace  $K_j(C, \mathbf{r})$ .

7. The computational cost of each  $j$ th iteration of the symmetric Lanczos process is fixed, and it is dominated by the matrix-vector product  $\mathbf{v} = C\mathbf{v}_j$ . In particular, the computational cost for generating the orthogonal Petrov–Galerkin projection  $T_j$  of  $C$  is dominated by the  $j$  matrix-vector products with  $C$ .
8. If  $C$  is a sparse matrix or a preconditioned matrix with a sparse preconditioner, then the matrix-vector products with  $C$  are fast. In this case, the symmetric Lanczos process is a very efficient procedure for computing orthogonal Petrov–Galerkin projections  $T_j$  of  $C$  onto Krylov subspaces  $K_j(C, \mathbf{r})$ .
9. The three-term recurrence relations used to generate the Lanczos vectors explicitly enforce orthogonality only among each set of three consecutive vectors,  $\mathbf{v}_{j-1}$ ,  $\mathbf{v}_j$ , and  $\mathbf{v}_{j+1}$ . As a consequence, in finite-precision arithmetic, round-off error will usually cause loss of orthogonality among all Lanczos vectors  $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_{j+1}$ .
10. For applications of the Lanczos process in large-scale matrix computations, this loss of orthogonality is often benign, and only delays convergence. More precisely, in such applications, the Lanczos matrix  $T_j \in \mathbb{C}^{j \times j}$  for some  $j \ll n$  is used to obtain an approximate solution of a matrix problem involving the large matrix  $C \in \mathbb{C}^{n \times n}$ . Due to round-off error and the resulting loss of orthogonality, the number  $j$  of iterations that is needed to obtain a satisfactory approximate solution is larger than the number of iterations that would be needed in exact arithmetic.

## 49.5 The Nonsymmetric Lanczos Process

In this section, we assume that  $C \in \mathbb{C}^{n \times n}$  is a general square matrix, and that  $\mathbf{r} \in \mathbb{C}^n$ ,  $\mathbf{r} \neq \mathbf{0}$ , and  $\mathbf{l} \in \mathbb{C}^n$ ,  $\mathbf{l} \neq \mathbf{0}$ , is a pair of right and left nonzero starting vectors. The **nonsymmetric Lanczos process** [Lan50] is an extension of the symmetric Lanczos process that simultaneously constructs a nested basis for the Krylov subspace  $K_j(C, \mathbf{r})$  induced by  $C$  and  $\mathbf{r}$ , and a nested basis for the Krylov subspace  $K_j(C^T, \mathbf{l})$  induced by  $C^T$  and  $\mathbf{l}$ . In the context of the nonsymmetric Lanczos process,  $K_j(C, \mathbf{r})$  is called the  $j$ th **right** Krylov subspace, and  $K_j(C^T, \mathbf{l})$  is called the  $j$ th **left** Krylov subspace.

**Algorithm** (Nonsymmetric Lanczos process)

Compute  $\rho_1 = \|\mathbf{r}\|_2$ ,  $\eta_1 = \|\mathbf{l}\|_2$ , and set  $\mathbf{v}_1 = \mathbf{r}/\rho_1$ ,  $\mathbf{w}_1 = \mathbf{l}/\eta_1$ ,  $\mathbf{v}_0 = \mathbf{w}_0 = \mathbf{0}$ , and  $\delta_0 = 1$ .

For  $j = 1, 2, \dots$ , do:

- 1) Compute  $\delta_j = \mathbf{w}_j^T \mathbf{v}_j$ .  
If  $\delta_j = 0$ , stop.
- 2) Compute  $\mathbf{v} = C\mathbf{v}_j$ , and set  $\beta_j = \eta_j \delta_j / \delta_{j-1}$  and  $\mathbf{v} = \mathbf{v} - \mathbf{v}_{j-1} \beta_j$ .
- 3) Compute  $\alpha_j = \mathbf{w}_j^T \mathbf{v}$ , and set  $\mathbf{v} = \mathbf{v} - \mathbf{v}_j \alpha_j$ .
- 4) Compute  $\mathbf{w} = C^T \mathbf{w}_j$ , and set  $\gamma_j = \rho_j \delta_j / \delta_{j-1}$  and  $\mathbf{w} = \mathbf{w} - \mathbf{w}_j \alpha_j - \mathbf{w}_{j-1} \gamma_j$ .
- 5) Compute  $\rho_{j+1} = \|\mathbf{v}\|_2$  and  $\eta_{j+1} = \|\mathbf{w}\|_2$ .  
If  $\rho_{j+1} = 0$  or  $\eta_{j+1} = 0$ , stop.  
Otherwise, set  $\mathbf{v}_{j+1} = \mathbf{v}/\rho_{j+1}$  and  $\mathbf{w}_{j+1} = \mathbf{w}/\eta_{j+1}$ .

end for

### Facts:

The following facts can be found in [SB02, Sect. 8.7.3] or [Saa03, Sect. 7.1].

1. The occurrence of  $\delta_j = 0$  in Step 1 of the nonsymmetric Lanczos process is called an **exact breakdown**. In finite-precision arithmetic, one also needs to check for  $\delta_j \approx 0$ , which is called a **near-breakdown**. It is possible to continue the nonsymmetric Lanczos process even if an exact breakdown or a near-breakdown has occurred, by using so-called “look-ahead” techniques. (See, e.g., [FGN93] and the references given there.) However, in practice, exact breakdowns and even near-breakdowns are fairly rare and, therefore, here we consider only the basic form of the nonsymmetric Lanczos process without look-ahead.
2. In exact arithmetic and if no exact breakdowns occur, the algorithm stops after a finite number of iterations. More precisely, it stops when  $j = \min\{d(C, \mathbf{r}), d(C^T, \mathbf{l})\}$  is reached.
3. The **right Lanczos vectors** and the **left Lanczos vectors**

$$\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_j \quad \text{and} \quad \mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_j$$

generated during the first  $j$  iterations of the algorithm form a nested basis for the  $j$ th right Krylov subspace  $K_j(C, \mathbf{r})$  and the  $j$ th left Krylov subspace  $K_j(C^T, \mathbf{l})$ , respectively.

4. The right and left Lanczos vectors satisfy the three-term recurrence relations

$$\mathbf{v}_{i+1} \rho_{i+1} = C\mathbf{v}_i - \mathbf{v}_i \alpha_i - \mathbf{v}_{i-1} \beta_i, \quad i = 1, 2, \dots, j,$$

and

$$\mathbf{w}_{i+1} \eta_{i+1} = C^T \mathbf{w}_i - \mathbf{w}_i \alpha_i - \mathbf{w}_{i-1} \gamma_i, \quad i = 1, 2, \dots, j,$$

respectively.

5. These three-term recurrence relations can be written in compact matrix form as follows:

$$CV_j = V_j T_j + \rho_{j+1} \mathbf{v}_{j+1} \mathbf{e}_j^T = V_{j+1} T_j^{(e)},$$

$$C^T W_j = W_j \tilde{T}_j + \eta_{j+1} \mathbf{w}_{j+1} \mathbf{e}_j^T.$$

Here, we set

$$V_j = [\mathbf{v}_1 \quad \mathbf{v}_2 \quad \cdots \quad \mathbf{v}_j], \quad W_j = [\mathbf{w}_1 \quad \mathbf{w}_2 \quad \cdots \quad \mathbf{w}_j],$$

$$T_j = \begin{bmatrix} \alpha_1 & \beta_2 & 0 & \cdots & 0 \\ \rho_2 & \alpha_2 & \beta_3 & \ddots & \vdots \\ 0 & \rho_3 & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & \beta_j \\ 0 & \cdots & 0 & \rho_j & \alpha_j \end{bmatrix}, \quad \tilde{T}_j = \begin{bmatrix} \alpha_1 & \gamma_2 & 0 & \cdots & 0 \\ \eta_2 & \alpha_2 & \gamma_3 & \ddots & \vdots \\ 0 & \eta_3 & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & \gamma_j \\ 0 & \cdots & 0 & \eta_j & \alpha_j \end{bmatrix},$$

$$\mathbf{e}_j^T = [0 \quad 0 \quad \cdots \quad 0 \quad 1] \in \mathbb{R}^{1 \times j}, \quad \text{and} \quad T_j^{(e)} = \begin{bmatrix} T_j \\ \rho_{j+1} \mathbf{e}_j^T \end{bmatrix}.$$

Note that  $T_j, \tilde{T}_j \in \mathbb{C}^{j \times j}$ , and  $T_j^{(e)} \in \mathbb{C}^{(j+1) \times j}$  are tridiagonal matrices.

6. The matrix  $T_j^{(e)}$  has full rank, i.e.,  $\text{rank } T_j^{(e)} = j$ .  
 7. In exact arithmetic, the right and left Lanczos vectors are **biorthogonal** to each other, i.e.,

$$\mathbf{w}_i^T \mathbf{v}_k = \begin{cases} 0 & \text{if } i \neq k, \\ \delta_i & \text{if } i = k, \end{cases} \quad \text{for all } i, k = 1, 2, \dots, j.$$

Since the right and left Lanczos vectors are the columns of  $V_j$  and  $W_j$ , respectively, the biorthogonality can be stated compactly as follows:

$$W_j^T V_j = D_j, \quad W_j^T \mathbf{v}_{j+1} = \mathbf{0}, \quad \text{and} \quad V_j^T \mathbf{w}_{j+1} = \mathbf{0}.$$

Here,  $D_j$  is the diagonal matrix

$$D_j = \text{diag}(\delta_1, \delta_2, \dots, \delta_j).$$

Note that  $D_j$  is nonsingular, as long as no exact breakdowns occur.

8. These biorthogonality relations, together with the above compact form of the three-term recurrence relations, imply that

$$T_j = D_j^{-1} V_j^* C V_j = (W_j^T V_j)^{-1} W_j^T C V_j.$$

Thus, the  $j$ th **Lanczos matrix**  $T_j$  is the oblique Petrov–Galerkin projection of  $C$  onto the  $j$ th right Krylov subspace  $K_j(C, \mathbf{r})$ , and orthogonally to the  $j$ th left Krylov subspace  $K_j(C^T, \mathbf{l})$ .

9. The matrices  $T_j$  and  $\tilde{T}_j^T$  are diagonally similar:

$$\tilde{T}_j^T = D_j T_j D_j^{-1}.$$

10. The computational cost of each  $j$ th iteration of the nonsymmetric Lanczos process is fixed, and it is dominated by the matrix-vector product  $\mathbf{v} = C \mathbf{v}_j$  with  $C$  and by the matrix-vector product  $\mathbf{w} = C^T \mathbf{w}_j$  with  $C^T$ . In particular, the computational cost for generating the oblique Petrov–Galerkin projection  $T_j$  of  $C$  is dominated by the  $j$  matrix-vector products with  $C$  and the  $j$  matrix-vector products with  $C^T$ .

11. If  $C$  is a sparse matrix or a preconditioned matrix with a sparse preconditioner, then the matrix-vector products with  $C$  and  $C^T$  are fast. In this case, the nonsymmetric Lanczos process is a very efficient procedure for computing oblique Petrov–Galerkin projections  $T_j$  of  $C$  onto right Krylov subspaces  $K_j(C, \mathbf{r})$ , and orthogonally to left Krylov subspaces  $K_j(C^T, \mathbf{l})$ .
12. The three-term recurrence relations, which are used to generate the right and left Lanczos vectors, explicitly enforce biorthogonality only between three consecutive right vectors,  $\mathbf{v}_{j-1}$ ,  $\mathbf{v}_j$ ,  $\mathbf{v}_{j+1}$ , and three consecutive left vectors,  $\mathbf{w}_{j-1}$ ,  $\mathbf{w}_j$ ,  $\mathbf{w}_{j+1}$ . As a consequence, in finite-precision arithmetic, round-off error will usually cause loss of biorthogonality between all right vectors  $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_{j+1}$  and all left vectors  $\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_{j+1}$ .
13. For applications of the Lanczos process in large-scale matrix computations, this loss of orthogonality is often benign, and only delays convergence. More precisely, in such applications, the Lanczos matrix  $T_j \in \mathbb{C}^{j \times j}$  for some  $j \ll n$  is used to obtain an approximate solution of a matrix problem involving the large matrix  $C \in \mathbb{C}^{n \times n}$ . Due to round-off error and the resulting loss of biorthogonality, the number  $j$  of iterations that is needed to obtain a satisfactory approximate solution is larger than the number of iterations that would be needed in exact arithmetic. (See, e.g., [CW86].)
14. If  $C = C^*$  is a Hermitian matrix and  $\mathbf{l} = \bar{\mathbf{r}}$ , i.e., the left starting vector  $\mathbf{l}$  is the complex conjugate of the right starting vector  $\mathbf{r}$ , then the right and left Lanczos vectors satisfy

$$\mathbf{w}_i = \bar{\mathbf{v}}_i \quad \text{for all } i = 1, 2, \dots, j + 1,$$

and the nonsymmetric Lanczos process reduces to the symmetric Lanczos process.

## 49.6 The Arnoldi Process

The **Arnoldi process** [Arn51] is another extension of the symmetric Lanczos process for Hermitian matrices to general square matrices. Unlike the nonsymmetric Lanczos process, which produces bases for both right and left Krylov subspaces, the Arnoldi process generates basis vectors only for the right Krylov subspaces. However, these basis vectors are constructed to be orthonormal, resulting in a numerical procedure that is much more robust than the nonsymmetric Lanczos process.

In this section, we assume that  $C \in \mathbb{C}^{n \times n}$  is a general square matrix, and that  $\mathbf{r} \in \mathbb{C}^n$ ,  $\mathbf{r} \neq \mathbf{0}$ , is a nonzero starting vector.

### Algorithm (Arnoldi process)

Compute  $\rho_1 = \|\mathbf{r}\|_2$ , and set  $\mathbf{v}_1 = \mathbf{r}/\rho_1$ .

For  $j = 1, 2, \dots$ , do:

- 1) Compute  $\mathbf{v} = C\mathbf{v}_j$ .
- 2) For  $i = 1, 2, \dots, j$ , do:
  - Compute  $h_{ij} = \mathbf{v}^* \mathbf{v}_i$ , and set  $\mathbf{v} = \mathbf{v} - \mathbf{v}_i h_{ij}$ .
 end for
- 3) Compute  $h_{j+1,j} = \|\mathbf{v}\|_2$ .  
 If  $h_{j+1,j} = 0$ , stop.  
 Otherwise, set  $\mathbf{v}_{j+1} = \mathbf{v}/h_{j+1,j}$ .

end for

### Facts:

The following facts can be found in [Saa03, Sect. 6.3].

1. In exact arithmetic, the algorithm stops after a finite number of iterations. More precisely, it stops when  $j = d(C, \mathbf{r})$  is reached.

2. The **Arnoldi vectors**

$$\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_j$$

generated during the first  $j$  iterations of the algorithm form a nested basis for the  $j$ th Krylov subspace  $K_j(C, \mathbf{r})$ .

3. The Arnoldi vectors satisfy the  $(i + 1)$ -term recurrence relations

$$\mathbf{v}_{i+1}h_{i+1,i} = C\mathbf{v}_i - \mathbf{v}_i h_{ii} - \mathbf{v}_{i-1}h_{i-1,i} - \dots - \mathbf{v}_2h_{2i} - \mathbf{v}_1h_{1i}, \quad i = 1, 2, \dots, j.$$

These  $(i + 1)$ -term recurrence relations can be written in compact matrix form as follows:

$$CV_j = V_j H_j + h_{j+1,j} \mathbf{v}_{j+1} \mathbf{e}_j^T = V_{j+1} H_j^{(e)}.$$

Here, we set

$$V_j = [\mathbf{v}_1 \quad \mathbf{v}_2 \quad \dots \quad \mathbf{v}_j], \quad \mathbf{e}_j^T = [0 \quad 0 \quad \dots \quad 0 \quad 1] \in \mathbb{R}^{1 \times j},$$

$$H_j = \begin{bmatrix} h_{11} & h_{12} & h_{13} & \dots & h_{1j} \\ h_{21} & h_{22} & h_{23} & \ddots & \vdots \\ 0 & h_{32} & \ddots & \ddots & h_{j-2,j} \\ \vdots & \ddots & \ddots & \ddots & h_{j-1,j} \\ 0 & \dots & 0 & h_{j,j-1} & h_{jj} \end{bmatrix},$$

$$H_j^{(e)} = \begin{bmatrix} H_j \\ h_{j+1,j} \mathbf{e}_j^T \end{bmatrix}, \quad \text{and} \quad V_{j+1} = [V_j \quad \mathbf{v}_{j+1}].$$

Note that  $H_j \in \mathbb{C}^{j \times j}$  and  $H_j^{(e)} \in \mathbb{C}^{(j+1) \times j}$  are upper Hessenberg matrices.

4. The matrix  $H_j^{(e)}$  has full rank, i.e.,  $\text{rank } H_j^{(e)} = j$ .
5. Since the Arnoldi vectors are the columns of  $V_j$ , this orthonormality can be stated compactly as follows:

$$V_j^* V_j = I_j \quad \text{and} \quad V_j^* \mathbf{v}_{j+1} = \mathbf{0}.$$

6. These orthogonality relations, together with the above compact form of the recurrence relations, imply that

$$H_j = V_j^* C V_j.$$

Thus, the  $j$ th **Arnoldi matrix**  $H_j$  is the orthogonal Petrov–Galerkin projection of  $C$  onto the  $j$ th Krylov subspace  $K_j(C, \mathbf{r})$ .

7. As in the case of the symmetric Lanczos process, each  $j$ th iteration of the Arnoldi process requires only a single matrix-vector product  $\mathbf{v} = C\mathbf{v}_j$ . If  $C$  is a sparse matrix or a preconditioned matrix with a sparse preconditioner, then the matrix-vector products with  $C$  are fast.
8. However, unlike the Lanczos process, the additional computations in each  $j$ th iteration do increase with  $j$ . In particular, each  $j$ th iteration requires the computation of  $j$  inner products of vectors of length  $n$ , and the computation of  $j$  SAXPY-type updates of the form  $\mathbf{v} = \mathbf{v} - \mathbf{v}_j h_{ij}$  with vectors of length  $n$ .
9. For most large-scale matrix computations, the increasing work per iteration limits the number of iterations that the Arnoldi process can be run. Therefore, in practice, the Arnoldi process is usually combined with restarting; i.e., after a number of iterations (with the matrix  $C$  and starting vector  $\mathbf{r}$ ), the algorithm is started again with the same matrix  $C$ , but a different starting vector, say  $\mathbf{r}_1$ .
10. On the other hand, the  $(i + 1)$ -term recurrence relations used to generate the Arnoldi vectors explicitly enforce orthogonality among the first  $i + 1$  vectors,  $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_{i+1}$ . As a result, the Arnoldi process is much less susceptible to round-off error in finite-precision arithmetic than the Lanczos process.

## 49.7 Eigenvalue Computations

In this section, we consider the problem of computing a few eigenvalues, and possibly eigenvectors, of a large matrix  $C \in \mathbb{C}^{n \times n}$ . We assume that matrix-vector products with  $C$  are fast. In this case, orthogonal and, in the non-Hermitian case, oblique Petrov–Galerkin projections of  $C$  onto Krylov subspaces  $K_j(C, \mathbf{r})$  can be computed efficiently, as long as  $j \ll n$ .

### Facts:

The following facts can be found in [CW85], [CW86], and [BDD00].

1. Assume that  $C = C^* \in \mathbb{C}^{n \times n}$  is a Hermitian matrix. We choose any nonzero starting vector  $\mathbf{r} \in \mathbb{C}^n$ ,  $\mathbf{r} \neq \mathbf{0}$ , e.g., a vector with random entries, and run the symmetric Lanczos process. After  $j$  iterations of the algorithm, we have computed the  $j$ th Lanczos matrix  $T_j$ , which — in exact arithmetic — is the orthogonal Petrov–Galerkin projection of  $C$  onto the  $j$ th Krylov subspace  $K_j(C, \mathbf{r})$ . Neglecting the last term in the compact form of the three-term recurrence relations used in the first  $j$  iterations of the symmetric Lanczos process, we obtain the approximation

$$CV_j \approx V_j T_j.$$

This approximation suggests to use the  $j$  eigenvalues  $\lambda_i^{(j)}$ ,  $i = 1, 2, \dots, j$ , of the  $j$ th Lanczos matrix  $T_j \in \mathbb{C}^{j \times j}$  as approximate eigenvalues of the original matrix  $C$ . Furthermore, if one is also interested in approximate eigenvectors, then the above approximation suggests to use

$$\mathbf{x}_i^{(j)} = V_j \mathbf{z}_i^{(j)} \in \mathbb{C}^n, \quad \text{where} \quad T_j \mathbf{z}_i^{(j)} = \mathbf{z}_i^{(j)} \lambda_i^{(j)}, \quad \mathbf{z}_i^{(j)} \neq \mathbf{0},$$

as an approximate eigenvector of  $C$  corresponding to the approximate eigenvalue  $\lambda_i^{(j)}$  of  $C$ .

2. Assume that  $C \in \mathbb{C}^{n \times n}$  is a general square matrix. Here one can use either the nonsymmetric Lanczos process or the Arnoldi process to obtain approximate eigenvalues.
3. In the case of the nonsymmetric Lanczos process, one chooses any nonzero starting vectors  $\mathbf{r} \in \mathbb{C}^n$ ,  $\mathbf{r} \neq \mathbf{0}$ , and  $\mathbf{l} \in \mathbb{C}^n$ ,  $\mathbf{l} \neq \mathbf{0}$ ,  $\mathbf{r} \in \mathbb{C}^n$ ,  $\mathbf{r} \neq \mathbf{0}$ . In analogy to the symmetric case, the eigenvalues of Lanczos matrix  $T_j \in \mathbb{C}^{j \times j}$  computed by  $j$  iterations of the nonsymmetric Lanczos process are used as approximate eigenvalues of the original matrix  $C$ . Corresponding approximate right eigenvectors are given by the same formula as above. Furthermore, one can also obtain approximate left eigenvectors from the left eigenvectors of  $T_j$  and the first  $j$  left Lanczos vectors. A discussion of many practical aspects of using the nonsymmetric Lanczos process for eigenvalue computations can be found in [CW86].
4. In the case of the Arnoldi process, one only needs to choose a single nonzero starting vector  $\mathbf{r} \in \mathbb{C}^n$ ,  $\mathbf{r} \neq \mathbf{0}$ . Here, one has the approximation

$$CV_j \approx V_j H_j,$$

where  $V_j$  is the matrix containing the first  $j$  Arnoldi vectors as columns and  $H_j$  is the  $j$ th Arnoldi matrix. The eigenvalues  $\lambda_i^{(j)}$ ,  $i = 1, 2, \dots, j$ , of  $H_j \in \mathbb{C}^{j \times j}$  are used as approximate eigenvalues of  $C$ . Furthermore, for each  $i$ ,

$$\mathbf{x}_i^{(j)} = V_j \mathbf{z}_i^{(j)} \in \mathbb{C}^n, \quad \text{where} \quad H_j \mathbf{z}_i^{(j)} = \mathbf{z}_i^{(j)} \lambda_i^{(j)}, \quad \mathbf{z}_i^{(j)} \neq \mathbf{0},$$

is an approximate eigenvector of  $C$  corresponding to the approximate eigenvalue  $\lambda_i^{(j)}$  of  $C$ .

## 49.8 Linear Systems of Equations

In this section, we consider the problem of solving large systems of linear equations,

$$C\mathbf{x} = \mathbf{b},$$

where  $C \in \mathbb{C}^{n \times n}$  is a nonsingular matrix and  $\mathbf{b} \in \mathbb{C}^n$ . We assume that any possible preconditioning was already applied and so, in general,  $C$  is a preconditioned version of the original coefficient matrix.

In particular, the matrix  $C$  may actually be dense. However, we assume that matrix-vector products with  $C$  and possibly  $C^T$  are fast. This is the case when  $C$  is a preconditioned version of a sparse matrix  $A$  and a preconditioner  $A_0$  that allows a sparse  $LU$  or Cholesky factorization.

**Facts:**

The following facts can be found in [FGN92] or [Saa03].

1. Let  $\mathbf{x}_0 \in \mathbb{C}^n$  be an arbitrary initial guess for the solution of the linear system, and denote by

$$\mathbf{r}_0 = \mathbf{b} - C\mathbf{x}_0$$

the corresponding residual vector. A Krylov subspace-based iterative method for the solution of the above linear system constructs a sequence of approximate solutions of the form

$$\mathbf{x}_j \in \mathbf{x}_0 + K_j(C, \mathbf{r}_0), \quad j = 1, 2, \dots,$$

i.e., the  $j$ th iterate is an additive correction of the initial guess, where the correction is chosen from the  $j$ th Krylov subspace  $K_j(C, \mathbf{r}_0)$  induced by the coefficient matrix  $C$  and the initial residual  $\mathbf{r}_0$ . Now let  $V_j \in \mathbb{C}^{n \times j}$  be a matrix the columns of which form a nested basis for  $K_j(C, \mathbf{r}_0)$ . Then, any possible  $j$ th iterate can be parametrized in the form

$$\mathbf{x}_j = \mathbf{x}_0 + V_j \mathbf{z}_j, \quad \text{where } \mathbf{z}_j \in \mathbb{C}^j.$$

Moreover, the corresponding residual vector is given by

$$\mathbf{r}_j = \mathbf{b} - C\mathbf{x}_j = \mathbf{r}_0 - CV_j \mathbf{z}_j.$$

Different Krylov subspace-based iterative methods are then obtained by specifying the choice of the basis matrix  $V_j$  and the choice of the parameter vector  $\mathbf{z}_j$ .

2. The **biconjugate gradient algorithm** (BCG) [Lan52] employs the nonsymmetric Lanczos process to generate nested bases for the right Krylov subspaces  $K_j(C, \mathbf{r}_0)$  and the left Krylov subspaces  $K_j(C^T, \mathbf{l})$ . Here,  $\mathbf{l} \in \mathbb{C}^n$ ,  $\mathbf{l} \neq \mathbf{0}$ , is an arbitrary nonzero starting vector. The biorthogonality of the right and left Lanczos vectors is exploited to construct the  $j$ th iterate  $\mathbf{x}_j$  such that the corresponding residual vector  $\mathbf{r}_j$  is orthogonal to the left Lanczos vectors, i.e.,  $W_j^T \mathbf{r}_j = \mathbf{0}$ . Using the recurrence relations of the Lanczos process and the above relation for  $\mathbf{r}_j$ , one can show that the defining condition  $W_j^T \mathbf{r}_j = \mathbf{0}$  is equivalent to  $\mathbf{z}_j$  being the solution of the linear system

$$T_j \mathbf{z}_j = \mathbf{e}_1^{(j)} \rho_1,$$

where  $\mathbf{e}_1^{(j)}$  denotes the first unit vector of length  $j$ . Moreover, the corresponding iterates  $\mathbf{x}_j$  can be obtained via a simple update from the previous iterate  $\mathbf{x}_{j-1}$ , resulting in an elegant overall computational procedure. Unfortunately, in general, it cannot be guaranteed that all Lanczos matrices  $T_j$  are nonsingular. As a result, BCG iterates  $\mathbf{x}_j$  may not exist for every  $j$ . More precisely, BCG breaks down if  $T_j$  is singular, and it exhibits erratic convergence behavior when  $T_j$  is nearly singular.

3. The possible breakdowns and the erratic convergence behavior can be avoided by replacing the  $j \times j$  linear system  $T_j \mathbf{z}_j = \mathbf{e}_1^{(j)} \rho_1$  by the  $(j+1) \times j$  least-squares problem

$$\min_{\mathbf{z} \in \mathbb{C}^j} \left\| \mathbf{e}_1^{(j+1)} \rho_1 - T_j^{(e)} \mathbf{z} \right\|_2.$$

Since  $T_j^{(e)} \in \mathbb{C}^{(j+1) \times j}$  always has full rank  $j$ , the above least-squares problem has a unique solution  $\mathbf{z}_j$ . The resulting iterative procedure is the **quasi-minimal residual method** (QMR) [FN91].

4. The **generalized minimal residual algorithm** (GMRES) [SS86] uses the Arnoldi process to generate orthonormal basis vectors for the Krylov subspaces  $K_j(C, \mathbf{r}_0)$ . The orthonormality of the columns of the Arnoldi basis matrix  $V_j$  allows one to choose  $\mathbf{z}_j$  such that the residual vector  $\mathbf{r}_j$  has the smallest possible norm, i.e.,

$$\|\mathbf{r}_j\|_2 = \|\mathbf{r}_0 - CV_j \mathbf{z}_j\|_2 = \min_{\mathbf{z} \in \mathbb{C}^j} \|\mathbf{r}_0 - CV_j \mathbf{z}\|_2.$$

Using the compact form of the recurrence relations used to generate the Arnoldi vectors, one readily verifies that the above minimal residual property is equivalent to  $\mathbf{z}_j$  being the solution of the least-squares problem

$$\min_{\mathbf{z} \in \mathbb{C}^j} \left\| \mathbf{e}_1^{(j+1)} \rho_1 - H_j^{(e)} \mathbf{z} \right\|_2,$$

where  $H_j^{(e)} \in \mathbb{C}^{(j+1) \times j}$  is an upper Hessenberg matrix.

5. The idea of quasi-minimization of the residual vector can also be applied to Lanczos-type iterations that, in each  $j$ th step, perform two matrix–vector products with  $C$ , instead of one product with  $C$  and one product with  $C^T$ . The resulting algorithm is called the **transpose-free quasi-minimal residual method** (TFQMR) [Fre93]. We stress that QMR and TFQMR produce different sequences of iterates and, thus, QMR and TFQMR are not mathematically equivalent algorithms.

## 49.9 Dimension Reduction of Linear Dynamical Systems

In this section, we discuss the application of the nonsymmetric Lanczos process to a large-scale matrix problem that arises in dimension reduction of time-invariant linear dynamical systems. A more detailed description can be found in [Fre03].

### Definitions:

Let  $A, E \in \mathbb{C}^{n \times n}$ . The matrix pencil  $A - sE$ ,  $s \in \mathbb{C}$ , is said to be **regular** if the matrix  $A - sE$  is singular only for finitely many values  $s \in \mathbb{C}$ .

A **single-input, single-output, time-invariant linear dynamical system** is a system of differential-algebraic equations (DAEs) of the form

$$\begin{aligned} E \frac{d}{dt} \mathbf{x} &= A\mathbf{x} + \mathbf{b}u(t), \\ y(t) &= \mathbf{l}^T \mathbf{x}(t), \end{aligned}$$

together with suitable initial conditions. Here,  $A, E \in \mathbb{C}^{n \times n}$  are given matrices such that  $A - sE$  is a regular matrix pencil,  $\mathbf{b} \in \mathbb{C}^n$ ,  $\mathbf{b} \neq \mathbf{0}$ , and  $\mathbf{l} \in \mathbb{C}^n$ ,  $\mathbf{l} \neq \mathbf{0}$ , are given nonzero vectors,  $\mathbf{x}(t) \in \mathbb{C}^n$  is the vector of **state variables**,  $u(t) \in \mathbb{C}$  is the given input function,  $y(t) \in \mathbb{C}$  is the output function, and  $n$  is the **state-space dimension**.

The rational function

$$H : \mathbb{C} \mapsto \mathbb{C} \cup \infty, \quad H(s) := \mathbf{l}^T (sE - A)^{-1} \mathbf{b},$$

is called the **transfer function** of the above time-invariant linear dynamical system.

A **reduced-order model** of state-space dimension  $j$  ( $< n$ ) of the above system is a single-input, single-output, time-invariant linear dynamical system of the form

$$\begin{aligned} E_j \frac{d}{dt} \mathbf{z} &= A_j \mathbf{z} + \mathbf{b}_j u(t), \\ y(t) &= \mathbf{l}_j^T \mathbf{z}(t), \end{aligned}$$

where  $A_j, E_j \in \mathbb{C}^{j \times j}$  and  $\mathbf{b}_j, \mathbf{l}_j \in \mathbb{C}^j$ , together with suitable initial conditions.

Let  $s_0 \in \mathbb{C}$  be such that the matrix  $A - s_0 E$  is nonsingular. A reduced-order model of state-space dimension  $j$  of the above system is said to be a **Padé model** about the expansion point  $s_0$  if the matrices  $A_j, E_j$  and the vectors  $\mathbf{b}_j, \mathbf{l}_j$  are chosen such that the Taylor expansions about  $s_0$  of the transfer function  $H$  of the original system and of the reduced-order transfer function

$$H_j : \mathbb{C} \mapsto \mathbb{C} \cup \infty, \quad H_j(s) := \mathbf{l}_j^T (sE_j - A_j)^{-1} \mathbf{b}_j,$$

agree in as many leading Taylor coefficients as possible, i.e.,

$$H_j(s) = H(s) + \mathcal{O}((s - s_0)^{q(j)}),$$

where  $q(j)$  is as large as possible.

### Facts:

The following facts can be found in [FF94], [FF95], or [Fre03].

1. In the “generic” case,  $q(j) = 2j$ .
2. In the general case,  $q(j) \geq 2j$ ; the case  $q(j) > 2j$  occurs only in certain degenerate situations.
3. The transfer function  $H$  can be rewritten in terms of a single square matrix  $C \in \mathbb{C}^{n \times n}$  as follows:

$$H(s) = \mathbf{1}^T (I_n + (s - s_0)C)^{-1} \mathbf{r}, \quad \text{where } C := (s_0 E - A)^{-1} E, \quad \mathbf{r} := (s_0 E - A)^{-1} \mathbf{b}.$$

Note that the matrix  $C$  can be viewed as a preconditioned version of the matrix  $E$  using the “shift-and-invert” preconditioner  $s_0 E - A$ .

4. In many cases, the state-space dimension  $n$  of the original time-invariant linear dynamical system is very large, but the large square matrices  $A, E \in \mathbb{C}^{n \times n}$  are sparse. Furthermore, these matrices are usually such that sparse  $LU$  factorizations of the shift-and-invert preconditioner  $s_0 E - A$  can be computed with limited amounts of fill-in. In this case, matrix-vector products with the preconditioned matrix  $C$  and its transpose  $C^T$  are fast.
5. The above definition of Padé models suggests the computation of these reduced-order models by first explicitly generating the leading  $q(j)$  Taylor coefficients of  $H$  about the expansion point  $s_0$ , and then constructing the Padé model from these. However, this process is extremely ill-conditioned and numerically unstable. (See the discussion in [FF94] or [FF95].)
6. A much more stable way to compute Padé models without explicitly generating the Taylor coefficients is based on the nonsymmetric Lanczos process. The procedure is simply as follows: One uses the vectors  $\mathbf{r}$  and  $\mathbf{1}$  from the above representation of the transfer function  $H$  as right and left starting vectors, and applies the nonsymmetric Lanczos process to the preconditioned matrix  $C$ . After  $j$  iterations, the algorithm has produced the  $j \times j$  tridiagonal Lanczos matrix  $T_j$ . The reduced-order model defined by

$$A_j := s_0 T_j - I_j, \quad E_j := T_j, \quad \mathbf{b}_j := (\mathbf{1}^T \mathbf{r}) \mathbf{e}_1^{(j)}, \quad \mathbf{l}_j := \mathbf{e}_1^{(j)}$$

is a Padé model of state-space dimension  $j$  about the expansion point  $s_0$ . Here,  $\mathbf{e}_1^{(j)}$  denotes the first unit vector of length  $j$ .

7. In the large-scale case, Padé models of state-space dimension  $j \ll n$  often provide very accurate approximations of the original system of state-space dimension  $n$ . In particular, this is the case for applications in VLSI circuit simulation. (See [FF95],[Fre03], and the references given there.)
8. Multiple-input multiple-output time-invariant linear dynamical systems are extensions of the above single-input single-output case with the vectors  $\mathbf{b}$  and  $\mathbf{1}$  replaced by matrices  $B \in \mathbb{C}^{n \times m}$  and  $L \in \mathbb{C}^{n \times p}$ , respectively, where  $m$  is the number of inputs and  $p$  is the number of outputs. The approach outlined in this section can be extended to the general multiple-input multiple-output case. A suitable extension of the nonsymmetric Lanczos process that can handle multiple right and left starting vectors is needed in this case. For a discussion of such a Lanczos-type algorithm and its application in dimension reduction of general multiple-input multiple-output time-invariant linear dynamical systems, we refer the reader to [Fre03] and the references given there.

### 50.1 What Is Linear Programming?

---

#### Definitions:

**Optimization** is maximization or minimization of a real-valued function, called the **objective function**, on a set, called the **feasible region** or the set of **feasible solutions**.

The values of function on the set are called **feasible values**.

An **optimal solution** (optimizer) is a feasible solution where the objective function reaches an **optimal value** (optimum), i.e., maximal or minimal value, respectively.

An optimization problem is **infeasible** if there are no feasible solutions, i.e., the feasible region is empty.

It is **unbounded** if the feasible values are arbitrary large, in the case of a maximization problem, or arbitrary small, in the case of a minimization problem.

A **mathematical program** is an optimization problem where the feasible region is a subset of  $\mathbb{R}^n$ , a finite dimensional real space; i.e., the objective function is a function of one or several real variables.

A **linear form** in variables  $x_1, \dots, x_n$  is  $c_1x_1 + \dots + c_nx_n$ , where  $c_i$  are given numbers.

An **affine function** is a linear form plus a given number.

The term *linear function*, which is not used here, means a linear form in some textbooks and an affine function in others.

A **linear constraint** is one of the following three constraints:  $f \leq g$ ,  $f = g$ ,  $f \geq g$ , where  $f$  and  $g$  are affine functions. In standard form,  $f$  is a linear form and  $g$  is a given number.

A **linear program** is a mathematical program where the objective function is an affine function and the feasible region is given by a finite system of linear constraints, all of them to be satisfied.

### Facts:

For background reading on the material in this subsection see [Vas03].

1. Linear constraints with equality signs are known as linear equations. The main tool of simplex method, pivot steps, allows us to solve any system of linear equations.
2. In some textbooks, the objective function in a linear program is required to be a linear form. Dropping a constant in the objective function does not change optimal solutions, but the optimal value changes in the obvious way.
3. Solving an optimization problem usually means finding the optimal value and an optimal solution or showing that they do not exist. By comparison, solving a system of linear equations usually means finding all solutions. In both cases, in real life we only find approximate solutions.
4. Linear programs with one and two variables can be solved graphically. In the case of one variable  $x$ , the feasible region has one of the following forms: Empty, a point  $x = a$ , a finite interval  $a \leq x \leq b$ , with  $a < b$ , a ray  $x \geq a$  or  $x \leq a$ , the whole line. The objective function  $f = cx + d$  is represented by a straight line. Depending on the sign of  $c$  and whether we want maximize or minimize  $f$ , we move in the feasible region to the right or to the left as far as we can in search for an optimal solution.

In the case of two variables, the feasible region is a closed convex set with finitely many vertices (corners). Together with the feasible region, we can draw in plane levels of the objective function. Unless the objective function is constant, every level (where the function takes a certain value) is a straight line. This picture allows us to see whether the program is feasible and bounded. If it is, the picture allows us to find a vertex which is optimal.

5. Linear programming is about formulating, collecting data, and solving linear programs, and also about analyzing and implementing solutions in real life.
6. Linear programming is an important part of mathematical programming. In its turn, mathematical programming is a part of *operations research*. *Systems engineering* and *management science* are engineering and business versions of operations research.
7. Every linear program is either infeasible, or unbounded, or has an optimal solution.

### Examples:

1. Here are 3 linear forms in  $x, y, z$ :  $2x - 3y + 5z, x + z, y$ .
2. Here are 3 affine functions of  $x, y, z$ :  $2x - 3y + 5z - 1, x + z + 3, y$ .
3. Here are 3 functions of  $x, y, z$  that are not affine:  $xy, x^2 + z^3, \sin z$ .
4. The constraint  $|x| \leq 1$  is not linear, but it is equivalent to a system of two linear constraints,  $x \leq 1, x \geq -1$ .
5. (An infeasible linear program) Here is a linear program:  
Maximize  $x + y$  subject to  $x \leq -1, x \geq 0$ .  
It has two variables and two linear constraints. The objective function is a linear form. The program is infeasible.
6. (An unbounded linear program) Here is a linear program:  
Maximize  $x + y$ .  
This program has two variables and no constraints. The objective function is a linear form. The program is unbounded.
7. Here is a linear program:  
Minimize  $x + y$  subject to  $x \geq 1, y \geq 2$ .  
This program has two variables and two linear constraints. The objective function is a linear form. The optimal value (the maximum) is 3. An optimal solution is  $x = 1, y = 2$ . It is unique.

## 50.2 Setting Up (Formulating) Linear Programs

**Examples:**

1. Finding the maximum of  $n$  given numbers  $c_1, \dots, c_n$  does not look like a linear program. However, it is equivalent to the following linear program with  $n$  variables  $x_i$  and  $n + 1$  linear constraints:  
 $c_1x_1 + \dots + c_nx_n \rightarrow \max$ , all  $x_i \geq 0$ ,  $x_1 + \dots + x_n = 1$ .

An equivalent linear program with one variable  $y$  and  $n$  linear constraints is  $y \rightarrow \min$ ,  $y \geq c_i$  for all  $i$ .

2. (Diet problem [Vas03, Ex. 2.1]). The general idea is to select a mix of different foods in such a way that basic nutritional requirements are satisfied at minimum cost. Our example is drastically simplified.

According to the recommendations of a nutritionist, a person’s daily requirements for protein, vitamin A, and calcium are as follows: 50 grams of protein, 4000 IUs (international units) of vitamin A, 1000 milligrams of calcium. For illustrative purposes, let us consider a diet consisting only of apples (raw, with skin), bananas (raw), carrots (raw), dates (domestic, natural, pitted, chopped), and eggs (whole, raw, fresh) and let us, if we can, determine the amount of each food to be consumed in order to meet the recommended dietary allowances (RDA) at minimal cost.

Food	Unit	Protein (g)	Vit. A (IU)	Calcium (mg)
Apple	1 medium (138 g)	0.3	73	9.6
Banana	1 medium (118 g)	1.2	96	7
Carrot	1 medium (72 g)	0.7	20253	19
Dates	1 cup (178 g)	3.5	890	57
Egg	1 medium (44 g)	5.5	279	22

Since our goal is to meet the RDA with minimal cost, we also need to compile the costs of these foods:

Food	Cost (in cents)
1 apple	10
1 banana	15
1 carrot	5
1 cup dates	60
1 egg	8

Using these data, we can now set up a linear program. Let  $a, b, c, d, e$  be variables representing the quantities of the five foods we are going to use in the diet. The objective function to be minimized is the total cost function (in cents),

$$C = 10a + 15b + 5c + 60d + 8e,$$

where the coefficients represent cost per unit of the five items under consideration.

What are the constraints? Obviously,

$$a, b, c, d, e \geq 0. \tag{i}$$

These constraints are called *nonnegativity constraints*.

Then, to ensure that the minimum daily requirements of protein, vitamin A, and calcium are satisfied, it is necessary that

$$\begin{cases} 0.3a + 1.2b + 0.7c + 3.5d + 5.5e \geq 50 \\ 73a + 96b + 20253c + 890d + 279e \geq 4000 \\ 9.6a + 7b + 19c + 57d + 22e \geq 1000, \end{cases} \tag{ii}$$

where, for example, in the first constraint, the term  $0.3a$  expresses the number of grams of protein in each apple multiplied by the quantity of apples needed in the diet, the second term  $1.2b$  expresses the number of grams of protein in each banana multiplied by the quantity of bananas needed in the diet, and so forth.

Thus, we have a linear program with 5 variables and 8 linear constraints.

3. (Blending problem [Vas03, Ex. 2.2]). Many coins in different countries are made from cupronickel (75% copper, 25% nickel). Suppose that the four available alloys (scrap metals)  $A$ ,  $B$ ,  $C$ ,  $D$  to be utilized to produce the coin contain the percentages of copper and nickel shown in the following table:

Alloy	$A$	$B$	$C$	$D$
% copper	90	80	70	60
% nickel	10	20	30	40
\$/lb	1.2	1.4	1.7	1.9

The cost in dollars per pound of each alloy is given as the last row in the same table.

Notice that none of the four alloys contains the desired percentages of copper and nickel. Our goal is to combine these alloys into a new blend containing the desired percentages of copper and nickel for cupronickel while minimizing the cost. This lends itself to a linear program.

Let  $a$ ,  $b$ ,  $c$ ,  $d$  be the amounts of alloys  $A$ ,  $B$ ,  $C$ ,  $D$  in pounds to make a pound of the new blend. Thus,

$$a, b, c, d \geq 0. \quad (i)$$

Since the new blend will be composed exclusively from the four alloys, we have

$$a + b + c + d = 1. \quad (ii)$$

The conditions on the composition of the new blend give

$$\begin{cases} .9a + .8b + .7c + .6d = .75 \\ .1a + .2b + .3c + .4d = .25. \end{cases} \quad (iii)$$

For example, the first equality states that 90% of the amount of alloy  $A$ , plus 80% of the amount of alloy  $B$ , plus 70% of the amount of alloy  $C$ , plus 60% of the amount of alloy  $D$  will give the desired 75% of copper in a pound of the new blend. Likewise, the second equality gives the desired amount of nickel in the new blend.

Taking the preceding constraints into account, we minimize the cost function

$$C = 1.2a + 1.4b + 1.7c + 1.9d.$$

In this problem, all the constraints, except (i), are *equalities*. In fact, there are three linear equations and four unknowns. However, the three equations are not independent. For example, the sum of the equations in (iii) gives (ii). Thus, (ii) is redundant.

In general, a constraint is said to be *redundant* if it follows from the other constraints of our system. Since it contributes no new information regarding the solutions of the linear program, it can be dropped from consideration without changing the feasible set.

4. (Manufacturing problem [Vas03, Ex. 2.3]). We are now going to state a program in which the objective function, a profit function, is to be maximized. A factory produces three products: P1, P2, and P3. The unit of measure for each product is the standard-sized boxes into which the product is placed. The profit per box of P1, P2, and P3 is \$2, \$3, and \$7, respectively. Denote by  $x_1$ ,  $x_2$ ,  $x_3$  the number of boxes of P1, P2, and P3, respectively. So the profit function we want to maximize is

$$P = 2x_1 + 3x_2 + 7x_3.$$

The five resources used are raw materials R1 and R2, labor, working area, and time on a machine. There are 1200 lbs of R1 available, 300 lbs of R2, 40 employee-hours of labor, 8000 m<sup>2</sup> of working area, and 8 machine-hours on the machine.

The amount of each resource needed for a box of each of the products is given in the following table (which also includes the aforementioned data):

Resource	Unit	P1	P2	P3	Available
R1	lb	40	20	60	1200
R2	lb	4	1	6	300
Labor	hour	.2	.7	2	40
Area	m <sup>2</sup>	100	100	800	8000
Machine	hour	.1	.3	.6	8
Profit	\$	2	3	7	→ max

As we see from this table, to produce a box of P1 we need 40 pounds of R1, 4 pounds of R2, 0.2 hours of labor, 100 m<sup>2</sup> of working area, and 0.1 hours on the machine. Also, the amount of resources needed to produce a box of P2 and P3 can be deduced from the table. The constraints are

$$x_1, x_2, x_3 \geq 0, \tag{i}$$

and

$$\begin{cases} 40x_1 + 20x_2 + 60x_3 \leq 1200 & \text{(pounds of R1)} \\ 4x_1 + x_2 + 6x_3 \leq 300 & \text{(pounds of R2)} \\ .2x_1 + .7x_2 + 2x_3 \leq 40 & \text{(hours of labor)} \\ 100x_1 + 100x_2 + 800x_3 \leq 8000 & \text{(area in m}^2\text{)} \\ .1x_1 + .3x_2 + .8x_3 \leq 8 & \text{(machine).} \end{cases} \tag{ii}$$

5. (Transportation problem [Vas03, Ex. 2.4]). Another concern that manufacturers face daily is *transportation costs* for their products. Let us look at the following hypothetical situation and try to set it up as a linear program. A manufacturer of widgets has warehouses in Atlanta, Baltimore, and Chicago. The warehouse in Atlanta has 50 widgets in stock, the warehouse in Baltimore has 30 widgets in stock, and the warehouse in Chicago has 50 widgets in stock. There are retail stores in Detroit, Eugene, Fairview, Grove City, and Houston. The retail stores in Detroit, Eugene, Fairview, Grove City, and Houston need at least 25, 10, 20, 30, 15 widgets, respectively. Obviously, the manufacturer needs to ship widgets to all five stores from the three warehouses and he wants to do this in the cheapest possible way. This presents a perfect backdrop for a linear program to minimize shipping cost. To start, we need to know the cost of shipping one widget from each warehouse to each retail store. This is given by a shipping cost table.

	1.D	2.E	3.F	4.G	5.H
<b>1. Atlanta</b>	55	30	40	50	40
<b>2. Baltimore</b>	35	30	100	45	60
<b>3. Chicago</b>	40	60	95	35	30

Thus, it costs \$30 to ship one unit of the product from Baltimore to Eugene (E), \$95 from Chicago to Fairview (F), and so on.

In order to set this up as a linear program, we introduce variables that represent the number of units of product shipped from each warehouse to each store. We have numbered the warehouses according to their alphabetical order and we have enumerated the stores similarly. Let  $x_{ij}$ , for all  $1 \leq i \leq 3$ ,  $1 \leq j \leq 5$ , represent the number of widgets shipped from warehouse # $i$

to store # $j$ . This gives us 15 unknowns. The objective function (the quantity to be minimized) is the shipping cost given by

$$\begin{aligned} C = & 55x_{11} + 30x_{12} + 40x_{13} + 50x_{14} + 40x_{15} \\ & + 35x_{21} + 30x_{22} + 100x_{23} + 45x_{24} + 60x_{25} \\ & + 40x_{31} + 60x_{32} + 95x_{33} + 35x_{34} + 30x_{35}, \end{aligned}$$

where  $55x_{11}$  represents the cost of shipping one widget from the warehouse in Atlanta to the retail store in Detroit (D) multiplied by the number of widgets that will be shipped, and so forth.

What are the constraints? First, our 15 variables satisfy the condition that

$$x_{ij} \geq 0, \quad \text{for all } 1 \leq i \leq 3, 1 \leq j \leq 5, \quad (i)$$

since shipping a negative amount of widgets makes no sense. Second, since the warehouse # $i$  cannot ship more widgets than it has in stock, we get

$$\begin{cases} x_{11} + x_{12} + x_{13} + x_{14} + x_{15} \leq 50 \\ x_{21} + x_{22} + x_{23} + x_{24} + x_{25} \leq 30 \\ x_{31} + x_{32} + x_{33} + x_{34} + x_{35} \leq 50. \end{cases} \quad (ii)$$

Next, working with the amount of widgets that each retail store needs, we obtain the following five constraints:

$$\begin{cases} x_{11} + x_{21} + x_{31} \geq 25 \\ x_{12} + x_{22} + x_{32} \geq 10 \\ x_{13} + x_{23} + x_{33} \geq 20 \\ x_{14} + x_{24} + x_{34} \geq 30 \\ x_{15} + x_{25} + x_{35} \geq 15. \end{cases} \quad (iii)$$

The problem is now set up. It is a linear program with 15 variables and 23 linear constraints.

6. (Job assignment problem [Vas03, Ex. 2.5]). Suppose that a production manager must assign  $n$  workers to do  $n$  jobs. If every worker could perform each job at the same level of skill and efficiency, the job assignments could be issued arbitrarily. However, as we know, this is seldom the case. Thus, each of the  $n$  workers is evaluated according to the time he or she takes to perform each job. The time, given in hours, is expressed as a number greater than or equal to zero. Obviously, the goal is to assign workers to jobs in such a way that the total time is as small as possible. In order to set up the notation, we let  $c_{ij}$  be the time it takes for worker # $i$  to perform job # $j$ . Then the times could naturally be written in a table. For example, take  $n = 3$  and let the times be given as in the following table:

	a	b	c
A	10	70	40
B	20	60	10
C	10	20	90

We can examine all six assignments and find that the minimum value of the total time is 40. So, we conclude that the production manager would be wise to assign worker **A** to job **a**, worker **B** to job **c**, and worker **C** to job **b**.

In general, this method of selection is not good. The total number of possible ways of assigning jobs is  $n! = n \times (n-1) \times (n-2) \times \cdots \times 2 \times 1$ . This is an enormous number even for moderate  $n$ . For  $n = 70$ ,

$$\begin{aligned} n! = & 119785716699698917960727837216890987364589381425 \\ & 464258575553628646280095827898453196800000000000000. \end{aligned}$$

It has been estimated that if a Sun Workstation computer had started solving this problem at the time of the Big Bang, by looking at all possible job assignments, then by now it would not yet have finished its task.

Although it is not obvious, the job assignment problem (with any number  $n$  of workers and jobs) can be expressed as a linear program. Namely, we set

$$x_{ij} = 0 \quad \text{or} \quad 1 \quad (i)$$

depending on whether the worker  $i$  is assigned to do the job  $j$ . The total time is then

$$\sum_i \sum_j c_{ij} x_{ij} \text{ (to be minimized).} \quad (ii)$$

The condition that every worker  $i$  is assigned to exactly one job is

$$\sum_j x_{ij} = 1 \quad \text{for all } i. \quad (iii)$$

The condition that exactly one worker is assigned to every job  $j$  is

$$\sum_i x_{ij} = 1 \quad \text{for all } j. \quad (iv)$$

The constraints (i) are not linear. If we replace them by linear constraints  $x_{i,j} \geq 0$ , then we obtain a linear program with  $n^2$  variables and  $n^2 + 2n$  linear constraints. Mathematically, it is a transportation problem with every demand and supply equal 1. As such, it can be solved by the simplex method (see below). (When  $n = 70$  it takes seconds.)

The simplex method for transportation problem does not involve any divisions. Therefore, an optimal solution it gives integral values for all components  $x_{i,j}$ . Thus, the conditions (i) hold, and the simplex method solves the job assignment problem. (Another way to express this is that all vertices of the feasible region (iii) to (iv) satisfy (i).)

## 50.3 Standard and Canonical Forms for Linear Programs

---

### Definitions:

LP in **canonical form** [Vas03] is  $\mathbf{c}^T \mathbf{x} + d \rightarrow \min, \mathbf{x} \geq 0, A\mathbf{x} \leq \mathbf{b}$ , where  $\mathbf{x}$  is a column of distinct (decision) variables,  $\mathbf{c}^T$  is a given row,  $d$  is a given number,  $A$  is a given matrix, and  $\mathbf{b}$  is a given column.

LP in **standard form** [Vas03] is  $\mathbf{c}^T \mathbf{x} + d \rightarrow \min, \mathbf{x} \geq 0, A\mathbf{x} = \mathbf{b}$ , where  $\mathbf{x}, \mathbf{c}, d, A$ , and  $\mathbf{b}$  are as in the previous paragraph.

The **slack variable** for a constraint  $f \leq c$  is  $s = c - f \geq 0$ . The **surplus variable** for a constraint  $f \geq c$  is  $s = f - c \geq 0$ .

### Facts:

For background reading on the material in this section, see [Vas03].

1. Every LP can be written in normal as well as standard form using the following five little tricks (*normal* is a term used by some texts):
  - (a) Maximization and minimization problems can be converted to each other. Namely, the problems  $f(\mathbf{x}) \rightarrow \min, \mathbf{x} \in S$  and  $-f(\mathbf{x}) \rightarrow \max, \mathbf{x} \in S$  are equivalent in the sense that they have the same optimal solutions and  $\max = -\min$ .
  - (b) The equation  $f = g$  is equivalent to the system of two inequalities,  $f \geq g, g \leq f$ .
  - (c) The inequality  $f \leq g$  is equivalent to the inequality  $-f \geq -g$ .

- (d) The inequality  $f \leq g$  is equivalent to  $f + x = g, x \geq 0$ , where  $x = g - f$  is a new variable called a *slack variable*.
- (e) A variable  $x$  unconstrained in sign can be replaced in our program by two new nonnegative variables,  $x = x' - x''$ , where  $x', x'' \geq 0$ .
2. The same tricks are sufficient for rewriting any linear program in different standard, canonical, and normal forms used in different textbooks and software packages. In most cases, all decision variables in these forms are assumed to be nonnegative.

**Examples:**

1. The canonical form  $\mathbf{c}^T \mathbf{x} + d \rightarrow \min, \mathbf{x} \geq 0, A\mathbf{x} \leq \mathbf{b}$  can be rewritten in the following standard form:

$$\mathbf{c}^T \mathbf{x} + d \rightarrow \min, \mathbf{x} \geq 0, \mathbf{y} \geq 0, A\mathbf{x} + \mathbf{y} = \mathbf{b}.$$

2. The standard form  $\mathbf{c}^T \mathbf{x} + d \rightarrow \min, \mathbf{x} \geq 0, A\mathbf{x} = \mathbf{b}$  can be rewritten in the following canonical form:

$$\mathbf{c}^T \mathbf{x} + d \rightarrow \min, \mathbf{x} \geq 0, A\mathbf{x} \leq \mathbf{b}, -A\mathbf{x} \leq -\mathbf{b}.$$

3. The diet problem (Example 2 in Section 50.2) can be put in canonical form by replacing (ii) with

$$\begin{cases} -0.3a - 1.2b - 0.7c - 3.5d - 5.5e \geq -50 \\ -73a - 96b - 20253c - 890d - 279e \geq -4000 \\ -9.6a + 7b - 19c - 57d - 22e \geq -1000. \end{cases} \quad (ii)$$

4. The blending problem (Example 3 in Section 50.2) is in standard form.

## 50.4 Standard Row Tableaux

---

**Definitions:**

A **standard row tableau** (of [Vas03]) is

$$\begin{array}{c} \mathbf{x}^T \quad 1 \\ \left[ \begin{array}{cc} A & \mathbf{b} \\ \mathbf{c}^T & d \end{array} \right] = \mathbf{u} \\ \rightarrow \min, \mathbf{x} \geq 0, \mathbf{u} \geq 0 \end{array} \quad (\text{SRT})$$

with given matrix  $A$ , columns  $\mathbf{b}$  and  $\mathbf{c}$ , and number  $d$ , where all decision variables in  $\mathbf{x}, \mathbf{u}$  are distinct.

This tableau means the following linear program:

$$A\mathbf{x} + \mathbf{b} = \mathbf{u} \geq 0, \mathbf{x} \geq 0, \mathbf{c}^T \mathbf{x} + d \rightarrow \min.$$

The **basic solution** for the standard tableau (SRT) is  $\mathbf{x} = 0, \mathbf{u} = \mathbf{b}$ . The corresponding value for the objective function is  $d$ .

A standard tableau (SRT) is **row feasible** if  $\mathbf{b} \geq 0$ , i.e., the basic solution is feasible. Graphically, a feasible tableau looks like

$$\begin{array}{c} \oplus \quad 1 \\ \left[ \begin{array}{cc} * & \oplus \\ * & * \end{array} \right] = \oplus \\ \rightarrow \min, \end{array}$$

where  $\oplus$  stands for nonnegative entries or variables.

A standard tableau (SRT) is **optimal** if  $\mathbf{b} \geq \mathbf{0}$  and  $\mathbf{c} \geq \mathbf{0}$ . Graphically, an optimal tableau looks like

$$\begin{array}{c} \oplus \quad 1 \\ \left[ \begin{array}{cc} * & \oplus \\ \oplus & * \end{array} \right] = \oplus \\ \rightarrow \min. \end{array}$$

A **bad row** in a standard tableau is a row of the form  $[\ominus -] = \oplus$ , where  $\ominus$  stands for nonpositive entries,  $-$  stands for a negative number, and  $\oplus$  stands for a nonnegative variable.

A **bad column** in a standard tableau is a column of the form  $\begin{bmatrix} \oplus \\ \ominus \end{bmatrix}$ , where  $\oplus$  stands for a nonnegative variable and nonnegative numbers and  $\ominus$  stands for a negative number.

**Facts:**

For background reading on the material in this section see [Vas03].

1. Standard row tableaux are used in simplex method; see Section 50.6 below.
2. The canonical form above can be written in a standard tableau as follows:

$$\begin{array}{c} \mathbf{x}^T \quad 1 \\ \left[ \begin{array}{cc} -A & \mathbf{b} \\ \mathbf{c}^T & d \end{array} \right] = \mathbf{u} \\ \rightarrow \min, \mathbf{x} \geq 0, \mathbf{u} \geq 0 \end{array}$$

where  $\mathbf{u} = \mathbf{b} - A\mathbf{x} \geq 0$ .

3. The standard form above can be transformed into canonical form  $\mathbf{c}^T \mathbf{x} + d \rightarrow \min, \mathbf{x} \geq 0, -A\mathbf{x} \leq -\mathbf{b}, A\mathbf{x} \leq \mathbf{b}$ , which gives the following standard tableau:

$$\begin{array}{c} \mathbf{x}^T \quad 1 \\ \left[ \begin{array}{cc} -A & \mathbf{b} \\ A & -\mathbf{b} \\ \mathbf{c}^T & d \end{array} \right] = \mathbf{u} \\ \rightarrow \min, \mathbf{x} \geq 0; \mathbf{u}, \mathbf{v} \geq 0. \end{array}$$

To get a smaller standard tableau, we can solve the system of linear equations  $A\mathbf{x} = \mathbf{b}$ . If there are no solutions, the linear program is infeasible. Otherwise, we can write the answer in the form  $\mathbf{y} = B\mathbf{z} + \mathbf{b}'$ , where the column  $\mathbf{y}$  contains some variables in  $\mathbf{x}$  and the column  $\mathbf{z}$  consists of the rest of variables. This gives the standard tableau

$$\begin{array}{c} \mathbf{z}^T \quad 1 \\ \left[ \begin{array}{cc} B & \mathbf{b}' \\ \mathbf{c}'^T & d' \end{array} \right] = \mathbf{y} \\ \rightarrow \min, \mathbf{y} \geq 0, \mathbf{z} \geq 0, \end{array}$$

where  $\mathbf{c}'^T \mathbf{z} + d'$  is the objective function  $\mathbf{c}^T \mathbf{x} + \mathbf{b}$  expressed in the terms of  $\mathbf{z}$ .

4. The basic solution of an optimal tableau is optimal.
5. An optimal tableau allows us to describe all optimal solutions as follows. The variables on top with nonzero last entries in the corresponding columns must be zeros. Crossing out these columns and the last row, we obtain a system of linear constraints on the remaining variables describing the set of all optimal solutions. In particular, the basic solution is the only optimal solution if all entries in the c-part are positive.
6. A bad row shows that the linear program is infeasible.
7. A bad column in a feasible tableau shows that the linear program is unbounded.

**Examples:**

1. The linear programs in Example 1 of Section 50.2 and written in an SRT and in an SCT in Example 1 of Section 50.8 below.
2. Consider the blending problem, Example 3 in Section 50.2. We solve the system of linear equations for  $a, b$  and the objective function  $f$  and, hence, obtain the standard tableau

$$\begin{array}{ccc} c & d & 1 \\ \left[ \begin{array}{ccc} 1 & 2 & -0.5 \\ -2 & -3 & 1.5 \\ 0.1 & 0.1 & 1.5 \end{array} \right] & = & \begin{array}{l} a \\ b \\ f \rightarrow \min. \end{array} \end{array}$$

The tableau is not optimal and has no bad rows or columns. The associated LP can be solved graphically, working in the  $(c, d)$ -plane. In Example 1 of Section 50.6, we will solve this LP by the simplex method.

## 50.5 Pivoting

---

**Definitions:**

Given a system of linear equations  $\mathbf{y} = A\mathbf{z} + \mathbf{b}$  solved for  $m$  variables, a **pivot step** solves it for a subset of  $m$  variables which differs from  $\mathbf{y}$  in one variable.

Variables in  $\mathbf{y}$  are called **basic variables**. The variables in  $\mathbf{z}$  are called **nonbasic variables**.

**Facts:**

For background reading on the material in this section see [Vas03].

1. Thus, a pivot step switches a basic and a nonbasic variable. In other words, one variable leaves the basis and another variable enters the basis.
2. Here is the pivot rule:

$$\begin{array}{cc} x & y \\ \left[ \begin{array}{cc} \alpha^* & \beta \\ \gamma & \delta \end{array} \right] = \begin{array}{l} u \\ v \end{array} & \mapsto & \begin{array}{cc} u & y \\ \left[ \begin{array}{cc} 1/\alpha & -\beta/\alpha \\ \gamma/\alpha & \delta - \beta\gamma/\alpha \end{array} \right] = \begin{array}{l} x \\ v. \end{array} \end{array}$$

We switch the two variables  $x$  and  $u$ . The pivot entry  $\alpha$  marked by  $*$  must be nonzero,  $\beta$  represents any entry in the pivot row that is not the pivot entry,  $\gamma$  represents any entry in the pivot column that is not the pivot entry, and  $\delta$  represents any entry outside the pivot row and column.

3. A way to solve any of linear equations  $A\mathbf{x} = \mathbf{b}$  is to write it in the row tableau

$$\begin{array}{c} \mathbf{x}^T \\ [A] = \mathbf{b} \end{array}$$

and move as many constants from the right margin to the top margin by pivot steps. After this we drop the rows that read  $c = c$  with a constant  $c$ . If one of the rows reads  $c_1 = c_2$  with distinct constants  $c_1, c_2$ , the system is infeasible. The terminal tableau has no constants remaining at the right margin. If no rows are left, the answer is  $0 = 0$  (every  $\mathbf{x}$  is a solution). If no variables are left at the right margin, we obtain the unique solution  $\mathbf{x} = \mathbf{b}'$ . Otherwise, we obtain the answer in the form  $\mathbf{y} = B\mathbf{z} + \mathbf{b}'$  with nonempty disjoint sets of variables  $\mathbf{y}, \mathbf{z}$ .

This method requires somewhat more computations than the Gauss elimination, but it solves the system with parametric  $\mathbf{b}$ .

**Examples:**

1. Here is a way to solve the system  $\begin{cases} x + 2y = 3 \\ 4x + 7y = 5 \end{cases}$

by two pivot steps:

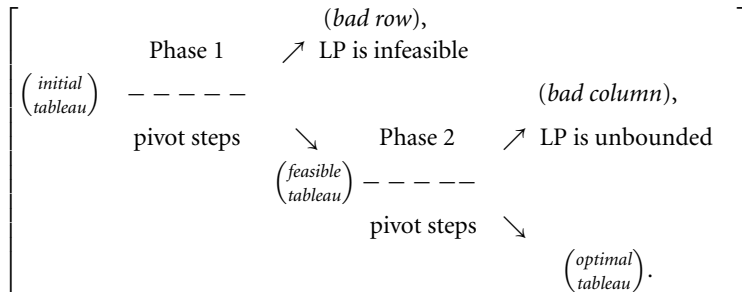

$$\begin{bmatrix} x & y \\ 1^* & 2 \\ 4 & 7 \end{bmatrix} = \begin{matrix} 3 \\ 5 \end{matrix} \mapsto \begin{bmatrix} 3 & y \\ 1 & -2 \\ 4 & -1^* \end{bmatrix} = \begin{matrix} x \\ 5 \end{matrix} \mapsto \begin{bmatrix} 3 & 5 \\ -7 & 2 \\ 4 & -1 \end{bmatrix} = \begin{matrix} x \\ y' \end{matrix}$$

i.e.,  $x = -11, y = 7$ .

## 50.6 Simplex Method

The simplex method is the most common method for solving linear programs. It was suggested by Fourier for linear programs arising from linear approximation (see below). Important early contributions to linear programming were made by L. Walras and L. Kantorovich. The fortuitous synchronization of the advent of the computer and George B. Dantzig’s reinvention of the simplex method in 1947 contributed to the explosive development of linear programming with applications to economics, business, industrial engineering, actuarial sciences, operations research, and game theory. For their work in linear programming, P. Samuelson (b. 1915) was awarded the Nobel Prize in Economics in 1970, and L. Kantorovich (1912–1986) and T. C. Koopmans (1910–1985) received the Nobel Prize in Economics in 1975.

Now we give the simplex method in terms of standard tableaux. The method consists of finitely many pivot steps, separated in two phases (stages). In Phase 1, we obtain either a feasible tableau or a bad row. In Phase 2, we work with feasible tableaux. We obtain either a bad column or an optimal tableau. Following is the scheme of the simplex method, where LP stands for the linear program:

Both phases are similar and can be reduced to each other. We start Definitions with Phase 2 and Phase 1 in detail, dividing a programming loop (including a pivot step) for each phase into four substeps.

**Definitions:**

**Phase 2 of simplex method.** We start with a feasible tableau (SRT).

1. Is the tableau optimal? If yes, we write the answer:  $\min = d$  at  $\mathbf{x} = 0, \mathbf{u} = \mathbf{b}$ .
2. Are there any bad columns? If yes, the linear program is unbounded.
3. (Choosing a pivot entry) We choose a negative entry in the  $c$ -part, say,  $c_j$  in column  $j$ . Then we consider all negative entries  $a_{i,j}$  above to choose our pivot entry. For every  $a_{i,j} < 0$  we compute  $b_i/a_{i,j}$  where  $b_i$  is the last entry in the row  $i$ . Then we maximize  $b_i/a_{i,j}$  to obtain our pivot entry  $a_{i,j}$ .
4. Pivot and go to Substep 1.

**Phase 1 of simplex method.** We start with a standard tableau (SRT).

1. Is the tableau feasible? If yes, go to Phase 2.
2. Are there bad rows? If yes, the LP is infeasible.
3. (Choosing a pivot entry) Let the first negative number in the **b**-part be in the row  $i$ . Consider the subtableau consisting of the first  $i$  rows with the  $i$ th row multiplied by  $-1$ , and choose the pivot entry as in Substep 3 of Phase 2.
4. Pivot and go to Substep 1.

A pivot step (in Phase 1 or 2) is **degenerate** if the last entry in the pivot row is 0, i.e., the (basic) feasible solution stays the same.

A **cycle** in the simplex method (Phase 1 or 2) is a finite sequence of pivot steps which starts and ends with the same tableau.

### Facts:

For background reading on the material in this section see [Vas03].

1. In Phase 2, the current value of the objective function (the last entry in the last row) either improves (decreases) or stays the same (if and only if the pivot step is degenerate).
2. In Phase 1, the first negative entry in the last column increases or stays the same (if and only if the pivot step is degenerate).
3. Following this method, we either terminate in finitely many pivot steps or, after a while, all our steps are degenerate, i.e., the basic solution does not change and we have a cycle.
4. The basic solutions in a cycle are all the same.
5. To prevent cycling, we can make a perturbation (small change in the **b**-part) such that none of the entries in this part of the tableau is ever 0 (see [Vas03] for details).
6. Another approach was suggested by Bland. We can make an ordered list of our variables, and then whenever there is a choice we choose the variable highest on the list (see [Vas03] for a reference and the proof that this rule prevents cycling). Bland's rule also turns the simplex method into a deterministic algorithm, i.e., it eliminates freedom of choices allowed by simplex method. Given an initial tableau and an ordered list of variables, Bland's rule dictates a unique finite sequence of pivot steps resulting in a terminal tableau.
7. With Bland's rule, the simplex method (both phases) terminates in at most  $\binom{m+n}{n} - 1$  pivot steps where  $m$  is the number of basis variables and  $n$  is the number of nonbasic variables (so the tableau has  $m+1$  rows and  $n+1$  columns). The number  $\binom{m+n}{n}$  here is an upper bound for the number of all standard tableaus that can be obtained from the initial tableau by pivot steps, up to permutation of the variables on the top (between themselves) and permutation of the variables at the right margin (between themselves).
8. If all data for an LP are rational numbers, then all entries of all standard tableaus are rational numbers. In particular, all basic solutions are rational. If the LP is feasible and bounded, then there is an optimal solution in rational numbers. However, like for a system of linear equations, the numerators and denominators could be so large that finding them could be impractical.

### Examples:

1. Consider the blending problem, Example 3 in Section 50.2.

We start with the standard tableau in Example 2 of Section 50.3. The simplex method allows two choices for the first pivot entry, namely, 1 or 2 in the first row. We pick 1 as the pivot entry:

$$\begin{array}{ccc|l} c & d & 1 & \\ \hline 1^* & 2 & -0.5 & = a \\ -2 & -3 & 1.5 & = b \\ 0.1 & 0.1 & 1.5 & = f \rightarrow \min \end{array} \quad \mapsto \quad \begin{array}{ccc|l} a & d & 1 & \\ \hline 1 & -2 & 0.5 & = c \\ -2 & 1 & 0.5 & = b \\ 0.1 & -0.1 & 1.55 & = f \rightarrow \min . \end{array}$$

Now the tableau is feasible, and we can proceed with Phase 2:

$$\begin{array}{ccc|l} a & d & 1 & \\ \hline 1 & -2^* & 0.5 & = c \\ -2 & 1 & 0.5 & = b \\ 0.1 & -0.1 & 1.55 & = f \rightarrow \min \end{array} \quad \mapsto \quad \begin{array}{ccc|l} a & c & 1 & \\ \hline 0.5 & -0.5 & 0.25 & = d \\ -1.5 & -0.5 & 0.75 & = b \\ 0.15 & 0.05 & 1.525 & = f \rightarrow \min \end{array} .$$

The tableau is optimal, so  $\min = 1.525$  at  $a = 0, b = 0.75, c = 0$ , and  $d = 0.25$ .

## 50.7 Geometric Interpretation of Phase 2

---

### Definitions:

A subset  $S$  of  $\mathbf{R}^N$  is **closed** if  $S$  contains the limit of any convergent sequence in  $S$ .

A **convex linear combination** or **mixture** of two points  $\mathbf{x}, \mathbf{y}$ , is  $\alpha \mathbf{x} + (1 - \alpha)\mathbf{y}$ , where  $0 \leq \alpha \leq 1$ . A particular case of a mixture is the **halfsum**  $\mathbf{x}/2 + \mathbf{y}/2$ .

The **line segment** connecting distinct points  $\mathbf{x}, \mathbf{y}$  consists of all mixtures of  $\mathbf{x}, \mathbf{y}$ .

A set  $S$  is **convex** if it contains all mixtures of its points.

An **extreme point** in a convex set is a point that is not the halfsum of any two distinct points in the set, i.e., the set stays convex after removing the point.

In the case of a closed convex set with finitely many extreme points, the extreme points are called **vertices**.

Two extreme points in a convex set are **adjacent** if the set stays convex after deleting the line segment connecting the points.

### Facts:

For background reading on the material in this section see [Vas03].

1. The feasible region for any linear program is a closed convex set with finitely many extreme points (vertices).
2. Consider a linear program and the associated feasible tableaux. The vertices of the feasible region are the basic solutions of the feasible tableaux. Permutation of rows or columns does not change the basic solution.
3. A degenerate pivot step does not change the basic solution. Any nondegenerate pivot step takes us from a vertex to an adjacent vertex with a better value for the objective function.
4. The set of optimal solutions for any linear program is a closed convex set with finitely many extreme points.
5. The number of pivot steps in Phase 2 without cycles (say, with Bland's rule) is less than the number of vertices in the feasible region.
6. For (SRT) with  $m + 1$  rows and  $n + 1$  columns, the number of vertices in the feasible region is at most  $\binom{m+n}{m}$ . When  $n = 1$ , this upper bound can be improved to 2. When  $n = 2$ , this upper bound can be improved to  $m + 2$ . It is unknown (in 2005) whether, for arbitrary  $m, n$ , a bound exists that is a polynomial in  $m + n$ .
7. The total number of pivot steps in both phases (with Bland's rule) is less than  $\binom{m+n}{m}$ .

## 50.8 Duality

---

### Definitions:

A **standard column tableau** has the form

$$\begin{array}{c} -y \\ 1 \end{array} \left[ \begin{array}{cc} A & b \\ \mathbf{c}^T & d \end{array} \right] \quad y \geq 0, \mathbf{v} \geq 0 \tag{SCT}$$

$$\begin{array}{c} \parallel \\ \mathbf{v}^T \end{array} \quad \begin{array}{c} \downarrow \\ \max. \end{array}$$

The **associated LP** is  $-\mathbf{y}^T \mathbf{b} + d \rightarrow \max, -\mathbf{y}^T A + \mathbf{c}^T = \mathbf{v}^T \geq 0, \mathbf{y} \geq 0$ .

The **basic solution** associated with (SCT) is  $\mathbf{y} = 0, \mathbf{v} = \mathbf{c}$ .

The tableau (SCT) is **column feasible** if  $\mathbf{c} \geq 0$ , i.e., the basic solution is feasible. (So, a tableau is optimal if and only if it is both row and column feasible.)

The linear program in (SCT) is **dual** to that in (SRT). We can write both as the row and the column problem with the same matrix:

$$\begin{array}{r}
 \mathbf{x}^T \quad 1 \\
 -\mathbf{y} \left[ \begin{array}{cc} A & \mathbf{b} \\ \mathbf{c}^T & d \end{array} \right] = \mathbf{u} \quad \mathbf{x} \geq 0, \mathbf{u} \geq 0 \\
 \phantom{-\mathbf{y}} \phantom{\left[ \right]} = z \rightarrow \min \quad \mathbf{y} \geq 0, \mathbf{v} \geq 0 \\
 = \mathbf{v}^T = w \rightarrow \max.
 \end{array} \tag{ST}$$

**Facts:**

For background reading on the material in this section, see [Vas03].

1. The linear program in the standard row tableau (SRT) can be written in the following standard column tableau:

$$\begin{array}{r}
 -\mathbf{x} \quad \left[ \begin{array}{cc} -A^T & \mathbf{c} \\ \mathbf{b}^T & -d \end{array} \right] \quad \mathbf{x} \geq 0, \mathbf{u} \geq 0 \\
 1 \\
 \phantom{1} \quad \quad \quad \parallel \quad \downarrow \\
 \phantom{1} \quad \quad \quad \mathbf{u}^T \quad \max.
 \end{array}$$

Then the dual problem becomes the row problem with the same matrix. This shows that the dual of the dual is the primal program.

2. The pivot rule for column and row tableaux is the same inside tableaux:

$$\begin{array}{r}
 -x \quad \left[ \begin{array}{cc} \alpha^* & \beta \\ \gamma & \delta \end{array} \right] \rightarrow -u \quad \left[ \begin{array}{cc} 1/\alpha & -\beta/\alpha \\ \gamma/\alpha & \delta - \beta\gamma/\alpha \end{array} \right] \\
 -u \\
 \phantom{-u} \quad \quad \parallel \quad \parallel \quad \quad \parallel \quad \parallel \\
 \phantom{-u} \quad \quad u \quad v \quad \quad \quad x \quad v
 \end{array}$$

3. If a linear program has an optimal solution, then the simplex method produces an optimal tableau. This tableau is also optimal for the dual program, hence both programs have the same optimal values (the duality theorem).
4. The duality theorem is a deep fact with several interpretations and applications. Geometrically, the duality theorem means that certain convex sets can be separated from points outside them by hyperplanes. We will see another interpretation of the duality theorem in the theory of matrix games (see below). For problems in economics, the dual problems and the duality theorem also have important economic interpretations (see examples below).
5. If a linear program is unbounded, then (after writing it in a standard row tableau) the simplex method produces a row feasible tableau with a bad column. The bad column shows that the dual problem is infeasible.
6. There is a standard tableau that has both a bad row and a bad column, hence there is an infeasible linear program such that the dual program is also infeasible.
7. Here is another way to express the duality theorem: Given a feasible solution for a linear program and a feasible solution for the dual problem, they are both optimal if and only if the feasible values are the same.
8. Given a feasible solution for a linear program and a feasible solution for the dual problem, they are both optimal if and only if for every pair of dual variables at least one value is 0, i.e., the *complementary slackness* condition  $\mathbf{v}^T \mathbf{x} + \mathbf{y}^T \mathbf{u} = 0$  in terms of (ST) holds.
9. More precisely, given a feasible solution  $(\mathbf{x}, \mathbf{u})$  for the row program in (ST) and a feasible solution  $(\mathbf{y}, \mathbf{v})$  for the column program, the difference  $(\mathbf{c}^T \mathbf{x} + d) - (-\mathbf{y}^T \mathbf{u} + d)$  between the corresponding feasible values is  $\mathbf{v}^T \mathbf{x} + \mathbf{y}^T \mathbf{u}$ .

10. All pairs  $(\mathbf{x}, \mathbf{u}), (\mathbf{y}, \mathbf{v})$  of optimal solutions for the row and column programs in (ST) are described by the following system of linear constraints:  $A\mathbf{x} + \mathbf{b} = \mathbf{u} \geq 0, \mathbf{x} \geq 0, -\mathbf{y}^T A + \mathbf{c} = \mathbf{v} \geq 0, \mathbf{y} \geq 0, \mathbf{v}^T \mathbf{x} + \mathbf{y}^T \mathbf{u} = 0$ . This is a way to show that solving a linear program can be reduced to finding a feasible solution for a finite system of linear constraints.

**Examples:**

(Generalizations of Examples 1 to 4 in section 50.2 above and their duals):

1. The linear programs  $c_1x_1 + \dots + c_nx_n \rightarrow \max, \text{ all } x_i \geq 0, x_1 + \dots + x_n = 1, \text{ and } y \rightarrow \min, y \geq c_i$  for all  $i$  in Example 1 are dual to each other. To see this, we use the standard tricks:  $y = y' - y''$  with  $y', y'' \geq 0; x_1 + \dots + x_n = 1$  is equivalent to  $x_1 + \dots + x_n \leq 1, -x_1 - \dots - x_n \leq -1$ .

We obtain the following standard tableau:

$$\begin{array}{rcc}
 & y' & y'' & 1 \\
 -\mathbf{x} & \left[ \begin{array}{ccc} \mathbf{J} & -\mathbf{J} & -\mathbf{c} \end{array} \right] & = \oplus \\
 1 & \left[ \begin{array}{ccc} 1 & -1 & 0 \end{array} \right] & = y \rightarrow \min \\
 & = \oplus & = \oplus & \rightarrow \max,
 \end{array}$$

where  $\mathbf{J}$  is the column of  $n$  ones,  $\mathbf{c} = [c_1, \dots, c_n]^T$ , and  $\mathbf{x} = [x_1, \dots, x_n]^T$ .

2. Consider the general diet problem (a generalization of Example 2):

$$A\mathbf{x} \geq \mathbf{b}, \mathbf{x} \geq 0, C = \mathbf{c}^T \mathbf{x} \rightarrow \min,$$

where  $m$  variables in  $\mathbf{x}$  represent different foods and  $n$  constraints in the system  $A\mathbf{x} \geq \mathbf{b}$  represent ingredients. We want to satisfy given requirements  $\mathbf{b}$  in ingredients using given foods at minimal cost  $C$ .

On the other hand, we consider a warehouse that sells the ingredients at prices  $y_1, \dots, y_n \geq 0$ . Its objective is to maximize the profit  $P = \mathbf{y}^T \mathbf{b}$ , matching the price for each food:  $\mathbf{y}^T A \leq \mathbf{c}^T$ .

We can write both problems in a standard tableau using slack variables  $\mathbf{u} = A\mathbf{x} - \mathbf{b} \geq 0$  and  $\mathbf{v}^T = \mathbf{c}^T - \mathbf{y}^T A \geq 0$ :

$$\begin{array}{rcc}
 & \mathbf{x}^T & 1 \\
 -\mathbf{y} & \left[ \begin{array}{cc} A & -\mathbf{b} \end{array} \right] & = \mathbf{u} & \mathbf{x} \geq 0, \mathbf{u} \geq 0 \\
 1 & \left[ \begin{array}{cc} \mathbf{c}^T & 0 \end{array} \right] & = C \rightarrow \min & \mathbf{y} \geq 0, \mathbf{v} \geq 0 \\
 & = \mathbf{v}^T & = P & \rightarrow \max.
 \end{array}$$

So, these two problems are dual to each other. In particular, the simplex method solves both problems and if both problems are feasible, then  $\min(C) = \max(P)$ .

The optimal prices for the ingredients in the dual problem are also called *dual* or *shadow* prices. These prices tell us how the optimal value reacts to small changes in  $\mathbf{b}$ ; see Section 50.9 below.

3. Consider the general mixing problem (a generalization of Example 3):

$$A\mathbf{x} = \mathbf{b}, \mathbf{x} \geq 0, C = \mathbf{c}^T \mathbf{x} \rightarrow \min,$$

where  $m$  variables in  $\mathbf{x}$  represent different alloys and  $n$  constraints in  $A\mathbf{x} = \mathbf{b}$  represent elements. We want to satisfy given requirements  $b$  in elements using given alloys at minimal cost  $C$ .

On the other hand, consider a dealer who buys and sells the elements at prices  $y_1, \dots, y_n$ . A positive price means that the dealer sells, and negative price means that the dealer buys. Dealer's objective is to maximize the profit  $P = \mathbf{y}^T \mathbf{b}$  matching the price for each alloy:  $\mathbf{y}^T A \leq \mathbf{c}$ .

To write the problems in standard tableaux, we use the standard tricks and artificial variables:

$$\begin{array}{l}
 \mathbf{u}' = A\mathbf{x} - \mathbf{b} \geq 0, \mathbf{u}'' = -A\mathbf{x} + \mathbf{b} \geq 0; \\
 \mathbf{v}^T = \mathbf{c}^T - \mathbf{y}^T A \geq 0; \mathbf{y} = \mathbf{y}' - \mathbf{y}'', \mathbf{y}' \geq 0, \mathbf{y}'' \geq 0.
 \end{array}$$

Now we manage to write both problems in the same standard tableau:

$$\begin{array}{r} \mathbf{x}^T \quad 1 \\ -\mathbf{y}' \left[ \begin{array}{cc} A & -\mathbf{b} \end{array} \right] = \mathbf{u}' \\ -\mathbf{y}'' \left[ \begin{array}{cc} -A & \mathbf{b} \end{array} \right] = \mathbf{u}'' \\ 1 \left[ \begin{array}{cc} \mathbf{c}^T & 0 \end{array} \right] = C \rightarrow \min \\ = \mathbf{v}^T = P \rightarrow \max. \end{array} \quad \begin{array}{l} \mathbf{x} \geq 0; \mathbf{u}', \mathbf{u}'' \geq 0 \\ \mathbf{y}', \mathbf{y}'' \geq 0; \mathbf{v} \geq 0 \end{array}$$

4. Consider a generalization of the manufacturing problem in Example 4:

$$P = \mathbf{c}^T \mathbf{x} \rightarrow \max, \quad A\mathbf{x} \leq \mathbf{b}, \quad \mathbf{x} \geq 0,$$

where the variables in  $\mathbf{x}$  are the amounts of products,  $P$  is the profit (or revenue) you want to maximize, constraints  $A\mathbf{x} \leq \mathbf{b}$  correspond to resources (e.g., labor of different types, clean water you use, pollutants you emit, scarce raw materials), and the given column  $\mathbf{b}$  consists of amounts of resources you have. Then the dual problem

$$\mathbf{y}^T \mathbf{b} \rightarrow \min, \quad \mathbf{y}^T A \geq \mathbf{c}^T, \quad \mathbf{y} \geq 0$$

admits the following interpretation. Your competitor, Bob, offers to buy you out at the following terms: You go out of business and he buys all resources you have at price  $\mathbf{y}^T \geq 0$ , matching your profit for every product you may want to produce, and he wants to minimize his cost.

Again Bob's optimal prices are your resource shadow prices by the duality theorem. The shadow price for a resource shows the increase in your profit per unit increase in the quantity  $b_0$  of the resource available or decrease in the profit when the limit  $b_0$  decreases by one unit. While changing  $b_0$ , we do not change the limits for the other resources and any other data for our program. There are only finitely many values of  $b_0$  for which the downward and upward shadow prices are different. One of these values could be the borderline between the values of  $b_0$  for which the corresponding constraint is binding or nonbinding (in the sense that dropping of this constraint does not change the optimal value).

The shadow price of a resource cannot increase when supply  $b_0$  of this resource increases (the law of diminishing returns, see the next section).

5. (General transportation problem and its dual). We have  $m$  warehouses and  $n$  retail stores. The warehouse # $i$  has  $a_i$  widgets available and the store # $j$  needs  $b_j$  widgets.

It is assumed that the following *balance condition* holds:

$$\sum_{i=1}^m a_i = \sum_{j=1}^n b_j.$$

If total supply is greater than total demand, the problem can be reduced to the one with the balance condition by introducing a fictitious store where the surplus can be moved at zero cost. If total supply is less than total demand, the program is infeasible.

The cost of shipping a widget from warehouse # $i$  to store # $j$  is denoted by  $c_{ij}$  and the number of widgets shipped from warehouse # $i$  to store # $j$  is denoted by  $x_{ij}$ . The linear program can be stated as follows:

$$\left\{ \begin{array}{l} \text{minimize} \quad C(x_{11}, \dots, x_{mm}) = \sum_{i=1}^m \sum_{j=1}^n c_{ij} x_{ij} \\ \text{subject to} \quad \sum_{i=1}^m x_{ij} \geq b_j, \quad j = 1, \dots, n \\ \sum_{j=1}^n x_{ij} \leq a_i, \quad i = 1, \dots, m \\ x_{ij} \geq 0, \quad i = 1, \dots, m, \quad j = 1, \dots, n. \end{array} \right.$$

The dual program is

$$-\sum_{i=1}^m a_i u_i + \sum_{j=1}^n b_j v_j \rightarrow \max, w_{ij} = c_{ij} + u_i - v_j \geq 0 \quad \text{for all } i, j; u \geq 0, v \geq 0.$$

So, what is a possible meaning of the dual problem? The control variables  $u_i, v_j$  of the dual problem are called *potentials* or “zones.” While the potentials correspond to the constraints on each retail store and each warehouse (or to the corresponding slack variables), there are other variables  $w_{ij}$  in the dual problem that correspond to the decision variable  $x_{ij}$  of the primal problem.

Imagine that you want to be a mover and suggest a simplified system of tariffs. Instead of  $mn$  numbers  $c_{i,j}$ , we use  $m + n$  “zones.” Namely, you assign a “zone”  $u_i \geq 0 \ i = 1, 2$  to each of the warehouses and a “zone”  $v_j \geq 0 \ j = 1, 2$  to each of the retail stores. The price you charge is  $v_j - u_i$  instead of  $c_{i,j}$ . To beat competition, you want  $v_j - u_i \leq c_{i,j}$  for all  $i, j$ . Your profit is  $-\sum a_i u_i + \sum b_j v_j$  and you want to maximize it.

The simplex method for any transportation problem can be implemented using  $m$  by  $n$  tables rather than  $mn + 1$  by  $m + n + 1$  tableaux. Since all pivot entries are  $\pm 1$ , no division is used. In particular, if all  $a_i, b_j$  are integers, we obtain an optimal solution with integral  $x_{i,j}$ .

Phase 1 is especially simple. If  $m, n \geq 2$ , we choose any position and write down the maximal possible number (namely, the minimum of supply and demand). Then we cross out the row or column and adjust the demand or supply respectively. If  $m = 1 < n$ , we cross out the column. Thus, we find a feasible solution in  $m + n - 1$  steps, which correspond to pivot steps, and the  $m + n - 1$  selected positions correspond to the basic variables.

Every transportation problem with the balance condition has an optimal solution. (See [Vas03] for details.)

## 50.9 Sensitivity Analysis and Parametric Programming

Sensitivity analysis is concerned with how small changes in data affect the optimal value and optimal solutions, while large changes are studied in parametric programming.

Consider the linear program given by (SRT) with the last column being an affine function of a parameter  $t$ , i.e., we replace  $b, d$  by affine functions  $b + b_1 t, d + d_1 t$  of a parameter  $t$ . Then the optimal value becomes a function  $f(t)$  of  $t$ .

### Facts:

For background reading on the material in this section, see [Vas03].

1. The function  $f(t)$  is defined on a closed convex set  $S$  on the line, i.e.,  $S$  is one of the following “intervals”: empty set, a point, an interval  $a \leq t \leq b$  with  $a < b$ , a ray  $t \geq a$ , a ray  $t \leq a$ , the whole line.
2. The function  $f(t)$  is piece-wise linear, i.e., the interval  $S$  is a finite union of subintervals  $S_k$  with  $f(t)$  being an affine function on each subinterval.
3. The function  $f(t)$  is *convex* in the sense that the set of points in the plane below the plot is a convex set. In particular, the function  $f(t)$  is continuous.
4. In parametric programming, there are methods for computing  $f(t)$ . The set  $S$  is covered by a finite set of tableaux optimal for various values of  $t$ . The number of these tableaux is at most  $\binom{m+n}{m}$ .
5. Suppose that the LP with  $t = 0$  (i.e., the LP given by (SRT)) has an optimal tableau  $T_0$ . Let  $\mathbf{x} = \mathbf{x}^{(0)}, \mathbf{u} = \mathbf{u}^{(0)}$  be the corresponding optimal solution (the basic solution), and let  $\mathbf{y} = \mathbf{y}^{(0)}, \mathbf{v} = \mathbf{v}^{(0)}$  be the corresponding optimal solution for the dual problem (see (ST) for notation). Assume that the  $\mathbf{b}$ -part of  $T_0$  has no zero entries. Then the function  $f(t)$  is affine in an interval containing 0. Its slope, i.e., derivative  $f'(0)$  at  $t = 0$ , is  $f'(0) = d_1 + \mathbf{b}_1^T \mathbf{v}^{(0)}$ . Thus, we can easily compute  $f'(0)$

from  $T_0$ . In other words, the optimal tableaux give the partial derivatives of the optimal value with respect to the components of given  $\mathbf{b}$  and  $d$ .

6. If we pivot the tableau with a parameter, the last column stays an affine function of the parameter and the rest of the tableau stays independent of parameter.
7. Similar facts are true if we introduce a parameter into the last row rather than into the last column.
8. If both the last row and the last column are affine functions of parameter  $t$ , then after pivot steps, the  $A$ -part stays independent of  $t$ , the  $\mathbf{b}$ -part and  $\mathbf{c}$ -part stay affine functions of  $t$ , but the  $d$ -part becomes a quadratic polynomial in  $t$ . So the optimal value is a piece-wise quadratic function of  $t$ .
9. If we want to maximize, say, profit (rather than minimize, say, cost), then the optimal value is concave (convex upward), i.e., the set of points below the graph is convex. The fact that the slope is nonincreasing is referred to as the *law of diminishing returns*.

## 50.10 Matrix Games

---

Matrix games are very closely related with linear programming.

### Definitions:

A matrix game is given by a matrix  $A$ , the **payoff matrix**, of real numbers.

There are two players. The players could be humans, teams, computers, or animals. We call them *He* and *She*. He chooses a row, and She chooses a column. The corresponding entry in the matrix represents what she pays to him (the payoff of the row player). Games like chess, football, and blackjack can be thought of as (very large) matrix games. Every row represents a strategy, i.e., his decision what to do in every possible situation. Similarly, every column corresponds to a strategy for her. The rows are his (**pure**) **strategies** and columns are her (pure) strategies.

A **mixed strategy** is a mixture of pure strategies. In other words, a mixed strategy for him is a probability distribution on the rows and a mixed strategy for her is a probability distribution on the columns.

We write his mixed strategy as columns  $\mathbf{p} = (p_i)$  with  $\mathbf{p} \geq 0, \sum p_i = 1$ . We write her mixed strategy as rows  $\mathbf{q}^T = (q_j)$  with  $\mathbf{q} \geq 0, \sum q_j = 1$ .

The corresponding payoff is  $\mathbf{p}^T A \mathbf{q}$ , the mathematical expectation.

A pair of strategies (his strategy, her strategy) is an **equilibrium** or a **saddle point** if neither player can gain by changing his or her strategy. In other words, no player can do better by a unilateral change. (The last sentence can be used to define the term “equilibrium” in any game, while “saddle point” is used only for zero-sum two-player games; sometimes it is restricted to the pure joint strategies.)

In other words, at an equilibrium, the payoff  $\mathbf{p}^T A \mathbf{q}$  has maximum as function of  $\mathbf{p}$  and minimum as function of  $\mathbf{q}$ .

His mixed strategy  $\mathbf{p}$  is **optimal** if his worst case payoff  $\min(\mathbf{p}^T A)$  is maximal. The maximum is the **value of the game** (for him). Her mixed strategy  $\mathbf{q}^T$  is **optimal** if her worst case payoff  $\min(-A \mathbf{q})$  is maximal. The maximum is the value of the game for her.

If the payoff matrix is skew-symmetric, the matrix game is called **symmetric**.

### Facts:

For background reading on the material in this section, see [Vas03].

1. A pair  $(i, j)$  of pure strategies is a saddle point if and only if the entry  $a_{i,j}$  of the payoff matrix  $A = a_{i,j}$  is both largest in its column and the smallest in its row.
2. Every matrix game has an equilibrium.
3. A pair (his strategy, her strategy) is an equilibrium if and only if both strategies are optimal.
4. His payoff  $\mathbf{p}^T A \mathbf{q}$  at any equilibrium  $(\mathbf{p}, \mathbf{q})$  equals his value of the game and equals the negative of her value of the game (the *minimax theorem*).
5. To solve a matrix game means to find an equilibrium and the value of the game.

6. Solving a matrix game can be reduced to solving the following dual pair of linear programs written in a standard tableau:

$$\begin{array}{r}
 \mathbf{q}^T \quad \mu' \quad \mu'' \quad 1 \\
 -\mathbf{p} \left[ \begin{array}{cccc} -A & \mathbf{1}_m & -\mathbf{1}_m & 0 \end{array} \right] = * \geq 0 \\
 -\lambda' \left[ \begin{array}{cccc} \mathbf{1}_n^T & 0 & 0 & -1 \end{array} \right] = * \geq 0 \\
 -\lambda'' \left[ \begin{array}{cccc} -\mathbf{1}_n^T & 0 & 0 & 1 \end{array} \right] = * \geq 0 \\
 1 \left[ \begin{array}{cccc} 0 & 1 & -1 & 0 \end{array} \right] = \mu \rightarrow \min \\
 \parallel \quad \parallel \quad \parallel \quad \parallel \\
 * \quad * \quad * \quad \lambda \rightarrow \max.
 \end{array}$$

Here,  $A$  is the  $m$  by  $n$  payoff matrix,  $\mathbf{1}_n^T$  is the row of  $n$  ones,  $\mathbf{1}_m$  is the column of  $m$  ones,  $\mathbf{p}$  is his mixed strategy,  $\mathbf{q}^T$  is her mixed strategy. Note that her problem is the row problem and his problem is the column problem. Their problems are dual to each other. Since both problems have feasible solutions (take, for example,  $\mathbf{p} = \mathbf{1}_m/m$ ,  $\mathbf{q} = \mathbf{1}_n/n$ ), the duality theorem says that  $\min(f) = \max(g)$ . That is,

his value of the game =  $\max(\lambda) = \min(\mu) = -$ her value of the game.

Thus, the minimax theorem follows from the duality theorem.

7. We can save two rows and two columns and get a row feasible tableau as follows:

$$\begin{array}{r}
 \mathbf{q}/(\mu + c) \quad 1 \\
 -\mathbf{p}/(\lambda + c) \left[ \begin{array}{cc} -A - c\mathbf{1}_m\mathbf{1}_n^T & \mathbf{1}_m \\ -\mathbf{1}_n^T & 0 \end{array} \right] = * \geq 0 \\
 1 \left[ \begin{array}{cc} & \end{array} \right] = -1/(\mu + c) \rightarrow \min \\
 \parallel \quad \parallel \\
 * \quad -1/(\lambda + c) \rightarrow \max.
 \end{array}$$

Here we made sure that the value of game is positive by adding a number  $c$  to all entries of  $A$ , i.e., replacing  $A$  by  $A + c\mathbf{1}_m\mathbf{1}_n^T$ . E.g.,  $c = 1 - \min(A)$ . Again his and her problems are dual to each other, since they share the same standard tableau. Since the tableau is feasible, we bypass Phase 1.

8. An arbitrary dual pair (ST) of linear programs can be reduced to a symmetric matrix game, with the following payoff matrix

$$M = \begin{bmatrix} 0 & -A & -\mathbf{b} \\ A^T & 0 & -\mathbf{c} \\ \mathbf{b}^T & \mathbf{c}^T & 0 \end{bmatrix}.$$

Its size is  $(m + n + 1) \times (m + n + 1)$ , where  $m \times n$  is the size of the matrix  $A$ .

9. The definition of equilibria makes sense for any game (not only for two-player zero-sum games). However, finding equilibria is not the same as solving the game when there are equilibria with different payoffs or when cooperation between players is possible and makes sense.
10. For any symmetric game, the value is 0, and the optimal strategies for the row and column players are the transposes of each other.

**Examples:**

1. [Vas03, Ex. 19.3] Solve the matrix game

$$A = \begin{bmatrix} 5 & 0 & 6 & 1 & -2 \\ 2 & 1 & 2 & 1 & 2 \\ -9 & 0 & 5 & 2 & -9 \\ -9 & -8 & 0 & 4 & 2 \end{bmatrix}.$$

We mark the maximal entries in every column by \*. Then we mark the minimal entries in each row by '. The positions marked by both \* and ' are exactly the saddle points:

$$A = \begin{bmatrix} 5^* & 0 & 6^* & 1 & -2' \\ 2 & 1^{*'} & 2 & 1' & 2^* \\ -9' & 0 & 5 & 2 & -9' \\ -9' & -8 & 0 & 4^* & 2^* \end{bmatrix}.$$

In this example, the position  $(i, j) = (2, 2)$  is the only saddle point. The corresponding payoff (the value of the game) is 1.

- This small matrix game is known as Heads and Tails or Matching Pennies. We will call the players *He* and *She*. He chooses: heads (*H*) or tails (*T*). Independently, she chooses: *H* or *T*. If they choose the same, he pays her a penny. Otherwise, she pays him a penny. Here is his payoff in cents:

$$\begin{array}{cc} & \textit{She} \\ & \textit{H} \quad \textit{T} \\ \textit{He} \begin{array}{l} \textit{H} \\ \textit{T} \end{array} & \begin{bmatrix} -1 & 1 \\ 1 & -1 \end{bmatrix} \end{array}.$$

There is no equilibrium in pure strategies. The only equilibrium in mixed strategies is  $([1/2, 1/2]^T, [1/2, 1/2])$ . The value of game is 0. The game is not symmetric in the usual sense. However the game is symmetric in the following sense: if we switch the players and also switch *H* and *T* for a player, then we get the same game.

- Another game is Rock, Scissors, Paper. In this game two players simultaneously choose *Rock*, *Scissors*, or *Paper*, usually by a show of hand signals on the count of three, and the payoff function is defined by the rules *Rock breaks Scissors*, *Scissors cuts Paper*, *Paper covers Rock*, and every strategy ties against itself. Valuing a win at 1, a tie at 0, and a loss at  $-1$ , we can represent the game with the following matrix, where, for both players, strategy 1 is *Rock*, strategy 2 is *Scissors*, and strategy 3 is *Paper*:

$$A = \begin{bmatrix} 0 & 1 & -1 \\ -1 & 0 & 1 \\ 1 & -1 & 0 \end{bmatrix}.$$

The only optimal strategy for the column player is  $\mathbf{q}^T = [1/3, 1/3, 1/3]$ . Since the game is symmetric, the value is 0, and  $\mathbf{q}$  is the only optimal strategy for the row player.

## 50.11 Linear Approximation

---

### Definitions:

An  $l^p$ -**best linear approximation** (fit) of a given column  $\mathbf{w}$  with  $n$  entries by the columns of a given  $m$  by  $n$  matrix  $A$  is  $A\mathbf{x}$ , where  $\mathbf{x}$  is an optimal solution for  $\|\mathbf{w} - A\mathbf{x}\|_p \rightarrow \min$ . (See Chapter 37 for information about  $\|\cdot\|_p$ .)

In other words, we want the vector  $\mathbf{w} - A\mathbf{x}$  of **residuals** (offsets, errors) to be smallest in a certain sense.

### Facts:

For background reading on the material in this section, see [Vas03].

- Most common values for  $p$  are 2, 1,  $\infty$ . In statistics, usually  $p = 2$  and the first column of the matrix  $A$  is the column of ones. In simple regression analysis,  $n = 2$ . In multiple regression,  $n \geq 3$ .

In time series analysis, the second column of  $A$  is an arithmetic progression representing time; typically, this column is  $[1, 2, \dots, m]^T$ . (See Chapter 52 for more information.)

2. If  $n = 1$  and the matrix  $A$  is a column of ones, we want to approximate given numbers  $w_i$  by one number  $Y$ . When  $p = 2$ , the best fit is the arithmetic mean  $(\sum w_i)/m$ . When  $p = 1$ , the best fits are the medians. When  $p = \infty$ , the best fit is the midrange  $(\min(w_i) + \max(w_i))/2$ .
3. When  $p = 2$ , the  $l^2$ -norm is the usual Euclidean norm, the most common way to measure the size of a vector, and this norm is used in Euclidean geometry. The best fit is known as the least squares fit. To find it, we drop a perpendicular from  $w$  onto the column space of  $A$ . In other words, we want the vector  $w - Ax$  to be orthogonal to all columns of  $A$ ; that is,  $A^T(w - Ax) = 0$ . This gives a system of  $n$  linear equations  $A^T Ax = A^T w$  for  $n$  unknowns in the column  $x$ . The system always has a solution. Moreover, the best fit  $Ax$  is the same for all solutions  $x$ . In the case when  $w$  belongs to the column space, the best fit is  $w$  (this is true for all  $p$ ). Otherwise,  $x$  is unique. (See Section 5.8 or Chapter 39 for more information about least squares methods.)
4. The best  $l^\infty$ -fit is also known as the least-absolute-deviation fit and the Chebyshev approximation.
5. When  $p = 1$ , finding the best fit can be reduced to a linear program. Namely, we reduce the optimization problem with the objective function  $\|e\|_1 \rightarrow \min$ , where  $e = (e_i) = w - Ax$ , to a linear program using  $m$  additional variables  $u_i$  such that  $|e_i| \leq u_i$  for all  $i$ . We obtain the following linear program with  $m + n$  variables  $a_j, u_i$  and  $2m$  linear constraints:

$$\sum u_i \rightarrow \min, \quad -u_i \leq w_i - A_i x \leq u_i \quad \text{for } i = 1, \dots, m,$$

where  $A_i$  is the  $i$ th row of the given matrix  $A$ .

6. When  $p = \infty$ , finding the best fit can also be reduced to a linear program. Namely reduce the optimization problem with the objective function  $\|e\|_\infty \rightarrow \min$ , where  $e = (e_i) = w - Ax$ , to a linear program using an additional variable  $u$  such that  $|e_i| \leq u$  for all  $i$ . A similar trick was used when we reduced solving matrix games to linear programming. We obtain the following linear program with  $n + 1$  variables  $a_j, u$  and  $2m$  linear constraints:

$$t \rightarrow \min, \quad -u \leq w_i - A_i x \leq u \quad \text{for } i = 1, \dots, m,$$

where  $A_i$  is the  $i$ th row of the given matrix  $A$ .

7. Any linear program can be reduced to finding a best  $l^\infty$ -fit.

**Examples:**

1. [Vas03, Prob. 22.7] Find the best  $l^p$ -fit  $w = ch^2$  for  $p = 1, 2, \infty$  given the following data:

i	1	2	3
Height $h$ in m	1.6	1.5	1.7
Weight $w$ in kg	65	60	70

Compare the optimal values for  $c$  with those for the best fits of the form  $w/h^2 = c$  with the same  $p$  (the number  $w/h^2$  in  $\text{kg}/\text{m}^2$  is known as BMI, the body mass index). Compare the minimums with those for the best fits of the form  $w = b$  with the same  $p$ .

*Solution*

Case  $p = 1$ . We could convert this problem to a linear program with four variables and then solve it by the simplex method (see Fact 6 above). But we can just solve graphically the nonlinear program with the objective function

$$f(c) = |65 - 1.6^2c| + |60 - 1.5^2c| + |70 - 1.7^2c|$$

to be minimized and no constraints. The function  $f(c)$  is piece-wise affine and convex. The optimal solution is  $c = x_1 = 65/1.6^2 \approx 25.39$ . This  $c$  equals the median of the three observed BMIs  $65/1.6^2, 60/1.5^2$  and  $70/1.7^2$ . The optimal value is

$$\min = |65 - c_1 1.6^2| + |60 - c_1 1.5^2| + |70 - c_1 1.7^2| = 6.25.$$

To compare this with the best  $l^1$ -fit for the model  $w = b$ , we compute the median  $b = x_1 = 65$  and the corresponding optimal values:

$$\min = |65 - x_1| + |60 - x_1| + |70 - x_1| = 10.$$

So the model  $w = ch^2$  is better than  $w = b$  for our data with the  $l^1$ -approach.

*Case  $p = 2$ .* Our optimization problem can be reduced to solving a linear equation for  $c$  (see Fact 3 above). Also we can solve the problem using calculus, taking advantage of the fact that our objective function

$$f(c) = (65 - 1.6^2c)^2 + (60 - 1.5^2c)^2 + (70 - 1.7^2c)^2$$

is differentiable. The optimal solution is  $c = x_2 = 2518500/99841 \approx 25.225$ . This  $x_2$  is not the mean of the observed BMIs, which is about 25.426. The optimal value is  $\min \approx 18$ .

The mean of  $w_i$  is 65, and the corresponding minimal value is  $5^2 + 0^2 + 5^2 = 50$ . So, again the model  $w = ch^2$  is better than  $w = b$ .

*Case  $p = \infty$ .* We could reduce this problem to a linear program with two variables and then solve it by graphical method or simplex method (see Fact 7 above). But we can do a graphical method with one variable. The objective function to minimize now is

$$f(c) = \max(|65 - 1.6^2c|, |60 - 1.5^2c|, |70 - 1.7^2c|).$$

This objective function  $f(c)$  is piecewise affine and convex. The optimal solution is

$$c_\infty = 6500/257 \approx 25.29.$$

It differs from the midrange of the BMIs, which is about 25.44. The optimal value is  $\approx 3$ .

On the other hand, the midrange of the weights  $w_i$  is 65, which gives  $\min = 5$  for the model  $w = b$  with the best  $l^\infty$ -fit. So, again the model  $w = ch^2$  is better than  $w = b$ .

2. [Vas03, Ex. 2, p. 255] A student is interested in the number  $w$  of integer points  $[x, y]$  in the disc  $x^2 + y^2 \leq r^2$  of radius  $r$ . He computed  $w$  for some  $r$ :

$r$		1	2	3	4	5	6	7	8	9
$w$		5	13	29	45	81	113	149	197	253

The student wants to approximate  $w$  by a simple formula  $w = ar + b$  with constants  $a, b$ . But you feel that the area of the disc,  $\pi r^2$  would be a better approximation and, hence, the best  $l^2$ -fit of the form  $w = ar^2$  should work even better for the numbers above.

Compute the best  $l^2$ -fit (the least squares fit) for both models,  $w = ar + b$  and  $w = ar^2$ , and find which is better. Also compare both optimal values with

$$\sum_{i=1}^9 (w_i - \pi i^2)^2.$$

*Solution*

For our data, the equation  $w = ar + b$  is the system of linear equations  $A\mathbf{x} = \mathbf{w}$ , where

$$\mathbf{w} = [5, 13, 29, 45, 81, 113, 149, 197, 253]^T,$$

$$A = \begin{bmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{bmatrix}^T, \text{ and } \mathbf{x} = \begin{bmatrix} a \\ b \end{bmatrix}.$$

The least-squares solution is the solution to  $A^T A \mathbf{x} = A^T w$ , i.e.,

$$\begin{bmatrix} 285 & 45 \\ 45 & 9 \end{bmatrix} \begin{bmatrix} a \\ b \end{bmatrix} = \begin{bmatrix} 6277 \\ 885 \end{bmatrix}.$$

So,  $a = 463/15, b = -56$ . The error

$$\sum_{i=1}^9 (w_i - 463i/15 + 56)^2 = 48284/15 \approx 3218.93.$$

For  $w = ar^2$ , the system is  $Ba = w$ , where  $w$  is as above and  $B = [1^2, 3^2, 3^2, 4^2, 5^2, 6^2, 7^2, 8^2, 9^2]^T$ . The equation  $B^T Ba = B^T w$  is  $415398a = 47598$ , hence  $a = 23799/7699 \approx 3.09118$ . The error

$$\sum_{i=1}^9 (w_i - 23799i^2/7699)^2 = 2117089/7699 \approx 274.982.$$

So, the model  $w = ar^2$  gives a much better least-squares fit than the model  $w = ar + b$  although it has one parameter instead of two.

The model  $w = \pi r^2$  without parameters gives the error

$$\sum_{i=1}^9 (w_i - \pi i)^2 = 147409 - 95196\pi + 15398\pi^2 \approx 314.114.$$

It is known that  $w_i/h_i^2 \rightarrow \pi$  as  $i \rightarrow \infty$ . Moreover,  $|w_i - \pi r_i^2|/r_i$  is bounded as  $i \rightarrow \infty$ . It follows that  $a \rightarrow \pi$  for the the best  $L_p$ -fit  $w = ar^2$  for any  $p \geq 1$  as we use data for  $r = 1, 2, \dots, n$  with  $n \rightarrow \infty$ .

## 50.12 Interior Point Methods

---

### Definitions:

A point  $\mathbf{x}$  in a convex subset  $X \subset \mathbf{R}^n$  is **interior** if

$$\{\mathbf{x} + (\mathbf{x} - \mathbf{y})\delta/\|\mathbf{y} - \mathbf{x}\|_2 : \mathbf{y} \in X, \mathbf{y} \neq \mathbf{x}\} \subset X$$

for some  $\delta > 0$ .

The **boundary** of  $X$  is the points in  $X$ , which are not interior.

An **interior solution** for a linear program is an interior point of the feasible region.

An **interior point method** for solving bounded linear programs starts with given interior solutions and produces a sequence of interior solutions which converges to an optimal solution.

An **exterior point method** for linear programs starts with a point outside the feasible region and produces a sequence of points which converges to feasible solution (in the case when the LP is feasible).

### Facts:

For background reading on the material in this section see [Vas03].

1. In linear programming, the problem of finding a feasible solution (i.e., Phase 1) and the problem of finding an optimal solution starting from a feasible solution (i.e., Phase 2) can be reduced to each other. So, the difference between interior point methods and exterior point methods is not so sharp.
2. The simplex method, Phase 1, can be considered as an exterior point method which (theoretically) converges in finitely many steps. The ellipsoid method [Ha79] is truly an exterior point method. Haćijan proved an exponential convergence for the method.

3. In the simplex method, Phase 2, we travel from a vertex to an adjacent vertex and reach an optimal vertex (if the LP is bounded) in finitely many steps. The vertices are not interior solutions unless the feasible region consists of single point. If an optimal solution for a linear program is interior, then all feasible solutions are optimal.
4. The first interior point method was given by Brown in the context of matrix games. The convergence was proved by J. Robinson. J. von Neumann suggested a similar method with better convergence.
5. Karmarkar suggested an interior point method with exponential convergence. After him, many similar methods were suggested. They can be interpreted as follows. We modify our objective function by adding a penalty for approaching the boundary. Then we use Newton's method. The recent progress is related to understanding of properties of convex functions which make minimization by Newton's method efficient. Recent interior methods beat simplex methods for very large problems.
6. [Vas03, Sec. A8] On the other hand, it is known that for LPs with small numbers of variables (or, by duality, with a small number of constraints), there are faster methods than the simplex method.

For example, consider an (SRT) with only two variables on top and  $m$  variables at the right margin (basis variables). The feasible region  $S$  has at most  $m + 2$  vertices. Phase 2, starting with any vertex, terminates in at most  $m + 1$  pivot steps.

At each pivot step, it takes at most two comparisons to check whether the tableau is optimal or to find a pivot column. Then in  $m$  sign checks, at most  $m$  divisions, and at most  $m - 1$  comparisons we find a pivot entry or a bad column.

Next, we pivot to compute the new  $3m + 3$  entries of the tableau. In one division, we find the new entry in the pivot row that is not the last entry (the last entry was computed before) and in  $2m$  multiplications and  $2m$  additions, we find the new entries outside the pivot row and column. Finally, we find the new entries in the pivot column in  $m + 1$  divisions. So a pivot step, including finding a pivot entry and pivoting, can be done in  $8m + 3$  operations — arithmetic operations and comparisons.

Thus, Phase 2 can be done in  $(m + 1)(8m + 3)$  operations. While small savings in this number are possible (e.g., at the  $(m + 1)$ -th pivot step we need to compute only the last column of the tableau), it is unlikely that any substantial reduction of this number for any modification of the simplex method can be achieved (in the worst case). Concerning the number of pivot steps, for any  $m \geq 1$  it is clearly possible for  $S$  to be a bounded convex  $(m + 2)$ -gon, in which case for any vertex there is a linear objective function such that the simplex method requires exactly  $\lfloor 1 + n/2 \rfloor$  pivot steps with only one choice of pivot entry at each step. It is also possible to construct an  $(m + 2)$ -gon, an objective point, and an initial vertex such that  $m$  pivot steps, with unique choice of pivot entry at each step, are required. There is an example with two choices at the first step such that the first choice leads to the optimal solution while the second choice leads to  $m$  additional pivot steps with unique choice.

Using a fast median search instead of the simplex method, it is possible to have Phase 2 done in  $\leq 100m + 100$  operations.

### 51.1 Introduction

---

Semidefinite programming, SDP, refers to optimization problems where variables  $X$  in the objective function and/or constraints can be symmetric matrices restricted to the cone of positive semidefinite matrices. (We restrict ourselves to real symmetric matrices,  $\mathcal{S}_n$ , since the vast majority of applications are for the real case. The complex case requires using the complex inner-product space.) An example of a *simple linear SDP* is

$$\begin{aligned} p^* = & \min && \text{tr } CX \\ \text{(SDP)} & && \text{subject to } TX = \mathbf{b} \\ & && X \geq 0, \end{aligned}$$

where  $T : \mathcal{S}_n \rightarrow \mathbb{R}^m$ . The details are given in the definitions in section 51.2; the SDP relaxation of the Max-Cut problem is given in Example 1 in this section. The linear SDP is a generalization of the standard *linear programming problem* (see Chapter 50), (LP)  $\min \mathbf{c}^T \mathbf{x}$ , s.t.  $A\mathbf{x} = \mathbf{b}$ ,  $\mathbf{x} \geq \mathbf{0}$ , where  $A \in \mathbb{R}^{m \times n}$ , and the element-wise nonnegativity constraint  $\mathbf{x} \geq \mathbf{0}$  is replaced by the positive semidefinite constraint,  $X \geq 0$ . These cone constraints are the *hard constraints* for these linear problems, i.e., they introduce a combinatorial element into the problem. In the LP case, this refers to finding the *active constraints*, i.e., finding the *active set* at the optimum  $\{j : x_j^* = 0\}$ . For SDP, this translates to finding the set of zero eigenvalues of the optimum  $X^*$ . However, for SDP this is further complicated by the unknown eigenvectors.

But there are surprisingly many parallels between semidefinite and linear programming as well as interesting differences. The parallels include: elegant and strong duality theory, many important applications, and the successful interior-point approaches for handling the hard constraints. The differences include possible existence of duality gaps, as well as possible failure of strict complementarity. Since LP is such a well-known area, we emphasize the similarities and differences between LP and SDP as we progress through this chapter.

The study of SDP, or linear matrix inequalities (LMI), dates back to the work of Lyapunov on the stability of trajectories from differential equations in 1890, [Lya47]. More recently, applications in control theory appear in the work of [Yak62]. More details are given in [BEF94].

*Cone Programming* also called *generalized linear programming*, is a generalization of SDP [BF63]. Other books dealing with problems over cones that date back to the 1960s are [Lue69], [Hol75], and [Jah86]. More recently, SDP falls into the class of *symmetric or homogeneous cone programming* [Fay97], [SA01], which includes optimization over combinations of: the nonnegative orthant; the cone of positive semidefinite matrices, and the Lorentz (or second-order) cone.

Positive definite and Euclidean matrix completion problems are feasibility questions in SDP. Research dates back to the early 1980s [DG81], [GJM84]. This continues to be an active area of research [Lau98], [Joh90]. (More recently, positive definite completion theory is being used to solve large scale instances of SDP [BMZ02], [FKM01].)

Combinatorial optimization applications fueled the popularity of SDP in the 1980s, [Lov79] and the strong approximation results in [GW95] and Example 1 in this section. A related survey paper is [Ren99]. SDP continues to attract new applications in, e.g., molecular conformation [AKW99], sensor localization [Jin05], [SY06], and optimization over polynomials [HL03].

The fact that SDP is a convex program that can be solved to any desired accuracy in polynomial time follows from the seminal work in [NN94].

**Examples:**

1. Suppose that we are given the weighted undirected graph  $G = (V, E)$  with vertex set  $V = \{1, \dots, n\}$  and nonnegative edge weights  $w_{ij}$ ,  $ij \in E$  (with  $w_{ij} = 0$ ,  $ij \notin E$ ). The Max-Cut problem finds the partition of the vertices into two parts so as to maximize the sum of the weights on the edges that are cut (vertices in different parts). This problem arises in, e.g., physics and VLSI design. We can model this problem as a  $\pm 1$  program with quadratic functions.

$$(MC) \quad \begin{aligned} \mu^* = \quad & \max && \frac{1}{4} \sum_{ij=1}^n w_{ij} (1 - x_i x_j) = \frac{1}{4} \mathbf{x}^T L \mathbf{x} \\ & \text{subject to} && x_j^2 = 1, \quad j = 1, \dots, n, \end{aligned}$$

where  $L$  is the Laplacian matrix of the graph,  $L_{ij} = \begin{cases} \sum_{k \neq i} w_{ik} & \text{if } i = j; \\ -w_{ij} & \text{if } i \neq j. \end{cases}$  We consider the simple example with vertex set  $V = \{1, 2, 3\}$  and nonnegative edge weights  $w_{12} = 1, w_{13} = 2, w_{23} = 2$ .

Here, the Laplacian matrix  $L = \begin{bmatrix} 3 & -1 & -2 \\ -1 & 3 & -2 \\ -2 & -2 & 4 \end{bmatrix}$ . The optimal solution places vertices 1 and 2

in one part and vertex 3 in the other; thus it cuts the edges 13 and 23. An optimal solution is  $\mathbf{x}^* = \begin{bmatrix} 1 \\ 1 \\ -1 \end{bmatrix}$ . with optimal value  $\mu^* = 4$ .

The well known semidefinite relaxation for the Max-Cut problem is obtained using the commutativity of the trace  $\mathbf{x}^T L \mathbf{x} = \text{tr } L \mathbf{x} \mathbf{x}^T = \text{tr } L X$  and discarding the (hard) rank one constraint on  $X$ .

$$(MCSDP) \quad \begin{aligned} \mu^* \leq \nu^* = \quad & \max && \frac{1}{4} \text{tr } L X \\ & \text{subject to} && \text{diag}(X) = \mathbf{e} \\ & && X \geq 0, \end{aligned}$$

where the linear transformation  $\text{diag}(X) : \mathcal{S}_n \rightarrow \mathbb{R}^n$  denotes the diagonal of  $X$ , and  $\mathbf{e}$  is the vector of ones. The optimal solution to MCSDP is  $X^* = \begin{bmatrix} 1 & 1 & -1 \\ 1 & 1 & -1 \\ -1 & -1 & 1 \end{bmatrix}$ . (This is verified using duality; see Example 3 in section 51.4 below.) In fact, here  $X^*$  is rank one, and column one of  $X^*$  provides the optimal solution  $\mathbf{x}^*$  of MC and the optimal value  $\mu^* = \nu^* = 4$ .

For this simple example,  $X^*$  was rank one and the SDP relaxation obtained the exact solution of the NP-hard MC problem. This is not true in general. However, the MCSDP relaxation is a surprisingly strong relaxation for MC. A randomized approximation algorithm based on MCSDP provides a  $\pm 1$  vector  $\mathbf{x}$  with objective value at least .87856 times the optimal value  $\mu^*$  [GW94]. Empirical tests obtain even stronger results.

## 51.2 Specific Notation and Preliminary Results

Note that in this section all matrices are real.

### Definitions:

For general  $m \times n$  matrices  $M, N \in \mathbb{R}^{m \times n}$ , we use the matrix inner product  $\langle M, N \rangle = \text{tr } N^T M$ . The corresponding norm is  $\|M\|_F = \sqrt{\text{tr } M^T M}$ , the **Frobenius norm**.

$\mathcal{S}_n$  denotes the space of **symmetric  $n \times n$  matrices**.

The set of **positive semidefinite (respectively definite) matrices** is denoted by PSD (respectively, PD);  $X \succeq 0$  means  $X \in \text{PSD}$ .

The **linear SDP** is

$$\begin{aligned} \text{(SDP)} \quad p^* = \quad & \min \quad \text{tr } CX \\ & \text{subject to} \quad TX = \mathbf{b} \\ & \quad \quad \quad X \succeq 0, \end{aligned}$$

where the variable  $X \in \mathcal{S}_n$ , the linear transformation  $T : \mathcal{S}_n \rightarrow \mathbb{R}^m$ , the vector  $\mathbf{b} \in \mathbb{R}^m$ , and the matrix  $C \in \mathcal{S}_n$  are (given) problem parameters. The constraint  $TX = \mathbf{b}$  can be written concretely as  $\text{tr } A_k X = b_k$ , for some given  $A_k \in \mathcal{S}_n$ ,  $k = 1, \dots, m$ . Thus, SDP can be expressed explicitly as

$$\begin{aligned} \text{(SDP)} \quad p^* = \quad & \min \quad \sum_{ij} C_{ij} X_{ij} \\ & \text{subject to} \quad \sum_{ij} A_{ijk} X_{ij} = b_k, \quad k = 1, \dots, m \\ & \quad \quad \quad X \succeq 0, \end{aligned}$$

where  $A_{ijk}$  denotes the  $ij$  element of the symmetric matrix  $A_k$ .

For  $M \in \mathbb{R}^{m \times n}$ ,  $\text{vec}(M) \in \mathbb{R}^{mn}$  is the vector formed from the columns of  $M$ .

For  $S \in \mathcal{S}_n$ ,  $\text{svec}(S) \in \mathbb{R}^{\frac{n(n+1)}{2}}$  is the vector formed from the upper triangular part of  $S$ , taken column-wise, with the strict upper triangular part multiplied by  $\sqrt{2}$ . The inverse of  $\text{svec}$  is denoted  $\text{sMat}$ .

For  $U \in \mathcal{S}_n$ , the **symmetric Kronecker product** is defined by

$$(M \otimes N) \text{svec}(U) = \text{svec} \left( \frac{1}{2} (\text{NUM}^T + \text{MUN}^T) \right).$$

For a linear transformation between two vector spaces  $T : V \rightarrow W$ , the **adjoint linear transformation** is denoted  $T^{\text{adj}} : W \rightarrow V$ , i.e., it is the unique linear transformation that satisfies the adjoint equation for the inner products in the respective vector spaces

$$\langle T\mathbf{v}, \mathbf{w} \rangle_W = \langle \mathbf{v}, T^{\text{adj}} \mathbf{w} \rangle_V, \quad \forall \mathbf{v} \in V, \mathbf{w} \in W.$$

If  $V = W$ , then this reduces to the definition of the **adjoint of a linear operator** given in Chapter 5.3.

We follow the standard notation used in SDP: for  $\mathbf{y} \in \mathbb{R}^n$ ,  $\text{Diag}(\mathbf{y})$  denotes the diagonal matrix formed using the vector  $\mathbf{y}$ , while the adjoint linear transformation is  $\text{diag}(X) = \text{Diag}^{\text{adj}}(X) \in \mathbb{R}^n$ .

For an inner product space  $V$ , the **polar cone** of  $S \subseteq V$  is

$$S^+ = \{\phi : \langle \phi, \mathbf{s} \rangle \geq 0, \forall \mathbf{s} \in S\}.$$

Given a set  $K \subseteq \mathbb{R}^n$ , we let  $\text{cone}(K)$  denote the convex cone generated by  $K$ . (See Chapter 9.1 for more information on cones.) A set  $K$  is a convex cone if it is closed under nonnegative scalar multiplication and

addition, i.e.,

$$\alpha K \subseteq K, \forall \alpha \geq 0, \quad K + K \subseteq K.$$

For a convex cone  $K$ , the convex cone  $\mathcal{F} \subseteq K$  is a **face** of  $K$  (denoted  $\mathcal{F} \triangleleft K$ ) if

$$\mathbf{x}, \mathbf{y} \in K, \mathbf{z} = \alpha \mathbf{x} + (1 - \alpha)\mathbf{y} \in \mathcal{F}, 0 < \alpha < 1 \quad \text{implies} \quad \mathbf{x}, \mathbf{y} \in \mathcal{F}.$$

**Facts:**

1. In the space of real, symmetric matrices,  $\mathcal{S}_n$ , the matrix inner product reduces to  $\langle X, Y \rangle = \text{tr} XY$ .
2. For general compatible matrices  $M, N$ , the trace is commutative, i.e.,  $\text{tr} MN^T = \text{tr} N^T M = \sum_{i=1}^n \sum_{j=1}^n M_{ij} N_{ij}$ .
3.  $\text{svec}$  (and  $\text{sMat}$ ) is an isometry between  $\mathcal{S}_n$  (equipped with the Frobenius norm) and  $\mathbb{R}^{\frac{n(n+1)}{2}}$  (equipped with the Euclidean norm). The  $\text{svec}$  transformation is used in algorithms when solving symmetric matrix equations. Using the isometry (rather than the ordinary  $\text{vec}$ ) provides additional robustness.
4. PSD is a closed convex cone and the interior of PSD consists of the positive definite matrices. The following are equivalent: (a)  $A \succeq 0$  ( $A \succ 0$ ), (b) the vector of eigenvalues  $\lambda(A) \geq 0$  ( $\lambda(A) > 0$ ), (c) all principal minors  $\geq 0$  (all leading principal minors  $> 0$ ).
5. The Kronecker product  $K \otimes L$  is easily formed using the blocks  $K_{ij} L$ . It is useful in changing matrix equations into vector equations (see [HJ94]), (here  $K$  is the unknown matrix)  $\text{vec}(NKM^T) = (M \otimes N)\text{vec}(K)$ . Similarly, the symmetric Kronecker product  $M \overset{\circ}{\otimes} N$  changes matrix equations with symmetric matrix variables  $U \in \mathcal{S}_n$  to vector equations. (See the definition in section 51.2.) By extending the definition from  $\mathcal{S}_n$  to  $\mathbb{R}^{n \times n}$ , the symmetric Kronecker product can be expressed explicitly using the standard Kronecker product see ([TW05]),

$$8M \overset{\circ}{\otimes} N = (I + A)(N \otimes M^T + M \otimes N^T) + (N \otimes M^T + M \otimes N^T)(I + A),$$

where  $A$  is the matrix representation of the transpose transformation. Matrix equations with symmetric matrix variables arise when finding the search direction in interior-point methods for SDP; see section 51.6. Surprisingly (see [TW05]), for  $A, B \in \mathcal{S}_n$ ,

$$A \overset{\circ}{\otimes} B \succeq 0 \iff A \otimes B \succeq 0;$$

$$A \overset{\circ}{\otimes} B \succ 0 \iff A \otimes B \succ 0.$$

6. If  $A \in \mathbb{R}^{m \times n}$  and the linear transformation  $T\mathbf{v} = A\mathbf{v}$ , then  $T^{\text{adj}} \cong A^T$ .
7. The polar cone is a closed convex cone and the second polar  $(K^+)^+ = K$  if and only if  $K$  is a closed convex cone.

**Examples:**

- 1.

$$A = \begin{bmatrix} 1 & 2 & 3 \\ 2 & 4 & 5 \\ 3 & 5 & 6 \end{bmatrix}, \mathbf{v} = \begin{bmatrix} 1 \\ 2\sqrt{2} \\ 4 \\ 3\sqrt{2} \\ 5\sqrt{2} \\ 6 \end{bmatrix}, \quad \text{svec}(A) = \mathbf{v} \\ \|A\|_F = \|\mathbf{v}\|_2 = \sqrt{129}.$$

2. The polars: (a)  $(\mathbb{R}^n)^+ = \{\mathbf{0}\}$ ;  $\{\mathbf{0}\}^+ = \mathbb{R}^n$ , (b) for the unit vector  $\mathbf{e}_i \in \mathbb{R}^n$ ,  $\{\mathbf{e}_i\}^+ = \{\mathbf{v} \in \mathbb{R}^n : v_i \geq 0\}$ , (c)  $(\text{cone}\{(1 \ 1)^T, (1 \ 0)^T\})^+ = \text{cone}\{[0 \ 1]^T, [1 \ -1]^T\}$ ; (d) let  $\mathcal{I} = \{\mathbf{v} \in \mathbb{R}^3 : v_3^2 \leq v_1 v_2, v_1 \geq 0, v_2 \geq 0\}$  be the so-called ice-cream cone [Ber73], i.e., the cone of vectors that makes an angle at most 45 degrees with the vector  $(1 \ 1 \ 1)^T$ . Then  $\mathcal{I} = \mathcal{I}^+$ .

## 51.3 Geometry

Extending LP to SDP can be thought of as replacing a polyhedral cone (the nonnegative orthant  $(\mathbb{R}^+)^n$ ) by the nonpolyhedral cone PSD. We now see that many of the geometric properties follow through from  $K = (\mathbb{R}^+)^n$  to  $K = \text{PSD}$ .

### Definitions:

A cone  $K$  is called **self-polar** if it equals its polar  $K = K^+$

A face  $\mathcal{F} \triangleleft K$  is called **facially exposed** if  $\mathcal{F} = K \cap \phi^\perp$ , for some  $\phi \in K^+$ .

A face  $\mathcal{F} \triangleleft K$  is called **projectionally exposed** if  $\mathcal{F}$  is the image of  $K$  under an orthogonal projection,  $\mathcal{F} = P(K)$ .

### Facts:

- Both  $(\mathbb{R}^+)^n$  and PSD are closed convex cones with nonempty interior. And both are self-polar cones, i.e.,  $((\mathbb{R}^+)^n)^+ = (\mathbb{R}^+)^n$ ,  $(\text{PSD})^+ = \text{PSD}$ . (See [Ber73].)
- Suppose that  $\hat{X} \in \text{relint } \mathcal{F} \subseteq \text{PSD}$  and  $\text{rank } \hat{X} = r$ . Then  $\hat{X} = PD_r P^T$ , where  $P$  is the  $n \times r$  matrix with orthonormal columns of eigenvectors corresponding to nonzero (positive) eigenvalues. We get that  $\mathcal{F} \triangleleft \text{PSD}$  if and only if  $\mathcal{F} = P S_+^r P^T$ . Equivalently, faces  $\mathcal{F} \triangleleft \text{PSD}$  are characterized by  $\{Y \in \text{PSD} : \mathcal{R}(Y) \subseteq \mathcal{R}(\hat{X})\}$ , where  $\hat{X}$  is any matrix in the relative interior of  $\mathcal{F}$  and  $\mathcal{R}$  denotes the range. Equivalently, we could use  $\mathcal{N}(Y) \supset \mathcal{N}(\hat{X})$ , where  $\mathcal{N}$  denotes nullspace. (See [Boh48], [BC75].)
- Both  $(\mathbb{R}^+)^n$  and PSD are facially and projectionally exposed, i.e., all faces are both facially and projectionally exposed [BW81], [BLP87], [ST90].
- The following relates to closure conditions that are needed for strong duality results. Suppose that  $\mathcal{F} \triangleleft \text{PSD}$ . Then (see [RTW97]),

PSD +  $\mathcal{F}^\perp$  is closed; PSD + Span  $\mathcal{F}$  is not closed.

### Examples:

- Consider the face  $\mathcal{F} = \{X \in \text{PSD} : X\mathbf{e} = 0\}$ , i.e., the face of PSD of centered matrices, positive semidefinite matrices with row and column sums equal to 0. Let  $P = (\mathbf{e} \ V)$  be an orthogonal matrix, i.e.,  $V^T \mathbf{e} = 0$ ,  $V^T V = I$ . Then we get  $\mathcal{F} = V\{X \in \mathcal{S}_{n-1} : X \geq 0\}V^T$ , i.e., a one-to-one mapping between the face  $\mathcal{F}$  and the semidefinite cone in  $\mathcal{S}_{n-1}$ . This relationship is used in [AKW99] to map Euclidean distance matrices to positive semidefinite matrices of full rank.

## 51.4 Duality and Optimality Conditions

Duality lies behind efficient algorithms in optimization. Unlike LP, strong duality can fail for SDP if a *constraint qualification* does not hold. We consider duality the linear *primal* SDP introduced above a game-theoretic approach.

### Definitions:

The corresponding **Lagrangian function** (or payoff function from primal player  $X$ , who plays matrix  $X$ , to dual player  $Y$ , who plays vector  $\mathbf{y}$ ) is  $L(X, \mathbf{y}) = \text{tr } CX + \mathbf{y}^T (\mathbf{b} - TX)$ .

The dual problem is

$$\begin{aligned}
 d^* = \quad & \text{maximize} && \mathbf{b}^T \mathbf{y} \\
 \text{DSDP} \quad & \text{subject to} && T^{\text{adj}} \mathbf{y} \preceq C \\
 & \text{(equivalently)} && T^{\text{adj}} \mathbf{y} + Z = C, \quad Z \succeq 0.
 \end{aligned}$$

**Weak duality**  $p^* \geq d^*$  holds. If  $p^* = d^*$  and  $d^*$  is attained, then **Strong duality** holds.

**Complementary slackness** holds if  $\text{tr} ZX = 0$ ; **strict complementarity** holds if, in addition,  $Z + X \succ 0$ .

**Facts:**

1. The optimal strategy of player  $X$  over all possible strategies by the dual player  $Y$  has optimal value greater or equal to that of the optimal strategy for player  $Y$  over all strategies for player  $X$ , i.e.,

$$p^* = \min_{X \succeq 0} \max_{\mathbf{y}} L(X, \mathbf{y}) \geq d^* = \max_{\mathbf{y}} \min_{X \succeq 0} b^T \mathbf{y} + \text{tr} X(C - T^{\text{adj}} \mathbf{y}).$$

The first equality in the min–max problem can be seen from the *hidden constraint* for the inner maximization problem. The inequality follows from interchanging min and max. The hidden constraint in the inner minimization of the max–min problem yields our dual problem and weak duality. However, *strong duality* can fail. (See [RTW97].)

2. For  $X, Z \succeq 0$ , complementary slackness  $\text{tr} ZX = 0$  is equivalent to  $ZX = 0$ .
3. *Characterization of Optimality Theorem*

The primal-dual pair  $X, (\mathbf{y}, Z)$ , with  $X \succeq 0, Z \succeq 0$ , is primal-dual optimal for SDP and DSDP if and only if

$$\begin{aligned}
 & T^{\text{adj}} \mathbf{y} + Z - C = 0 && \text{(dual feasibility)} \\
 \text{(OPT)} \quad & TX - \mathbf{b} = 0 && \text{(primal feasibility)} \\
 & ZX = 0 && \text{(complementary slackness)}.
 \end{aligned}$$

4. The theorem in the previous fact is used to derive efficient primal-dual interior-point methods.
5. Again we note the similarity between the above optimality conditions and those for LP, where  $Z, X$  are diagonal matrices. However, in contrast to LP, the Goldman–Tucker theorem [GT56] can fail, i.e., a strict complementary solution may not exist. This means that there may be no optimal solution with  $X + Z \succ 0$  positive definite; see [Sha00], [WW05]. This can result in loss of superlinear convergence for numerical algorithms for SDP. Moreover, in LP,  $Z, X$  are diagonal matrices and so is  $ZX$ . This means that the optimality conditions OPT are a square system. However, for SDP, the product of two symmetric matrices  $ZX$  is not necessarily symmetric. Therefore, the optimality conditions are an overdetermined nonlinear system of equations. This gives rise to many subtle algorithmic difficulties.

**Examples:**

1. The lack of closure noted in Fact 4 in section 51.3 is illustrated by the sequence

$$\begin{bmatrix} \frac{1}{i} & 1 \\ 1 & i \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & -i \end{bmatrix} \rightarrow \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \notin \text{PSD} + \text{Span} \left\{ \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix} \right\}.$$

This gives rise to an SDP with a duality gap. Let  $C = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$  and  $A_1 = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}$ . Then a primal SDP is  $0 = \min \text{tr} CX$  s.t.  $\text{tr} A_1 X = 0, X \succeq 0$ . But the dual program has optimal value  $-\infty = \max 0\mathbf{y}$  s.t.  $\mathbf{y}A_1 \preceq C$ , i.e., it is infeasible.

2. For fixed  $\alpha > 0$ , we use parameters  $\mathbf{b} = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$  and  $C = \begin{bmatrix} \alpha & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}$ ,  $A_1 = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix}$ ,  $A_2 =$

$$\begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}.$$

Then we get the primal and dual SDP pair with a finite duality gap:  $\alpha = \min \alpha U_{11}$  s.t.

$$U_{22} = 0, U_{11} + 2U_{23} = 1, U \succeq 0; 0 = \max y_2 \text{ s.t. } \begin{bmatrix} y_2 & 0 & 0 \\ 0 & y_1 & y_2 \\ 0 & y_2 & 0 \end{bmatrix} \preceq \begin{bmatrix} \alpha & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}.$$

3. We now verify that  $X^* = \begin{bmatrix} 1 & 1 & -1 \\ 1 & 1 & -1 \\ -1 & -1 & 1 \end{bmatrix}$  is optimal for MCSDP in Example 1 in Section 51.1.

The dual of MCSDP is  $\min e^T \mathbf{y}$  s.t.  $\text{Diag}(\mathbf{y}) \succeq \frac{1}{4}L$ . Since  $\mathbf{y} = [1 \ 1 \ 2]^T$  is feasible for this dual, optimality follows from checking strong duality  $\text{tr} LX^* = e^T \mathbf{y} = 4$ . Equivalently, one can check complementary slackness  $(\text{Diag}(\mathbf{y}) - L)X^* = 0$ .

## 51.5 Strong Duality without a Constraint Qualification

### Definitions:

A **constraint qualification**, CQ, is a condition on the constraints that guarantees that strong duality holds at an optimum point.

**Slater's Constraint Qualification** (strict feasibility) is defined as:  $\exists X \succ 0, TX = \mathbf{b}$ .

### Facts:

1. Suppose that Slater's CQ holds. Then strong duality holds for SDP and DSDP, i.e.,  $p^* = d^*$  and  $d^*$  is attained.
2. [BW81] *Duality Theorem*: Suppose that  $p^*$  is finite. Let  $\mathcal{F}_\epsilon$  denote the minimal face of PSD that contains the feasible set of SDP. Consider the extended dual program

$$\begin{aligned} \text{DSDP}_\epsilon \quad d_\epsilon^* = & \text{maximize} && \mathbf{b}^T \mathbf{y} \\ & \text{subject to} && T^{\text{adj}} \mathbf{y} + Z = C \\ & && Z \in \mathcal{F}_\epsilon^+. \end{aligned}$$

Then  $p^* = d_\epsilon^*$  and  $d_\epsilon^*$  is attained, i.e., strong duality holds between SDP and  $\text{DSDP}_\epsilon$ .

3. An algorithm for finding the minimal face  $\mathcal{F}_\epsilon$  defined above is given in [BW81].

### Examples:

We can apply the strong duality results to the two examples given in Section 51.4.

1. For the first example, replace PSD in the primal with the minimal face  $\mathcal{F} = \text{PSD} \cap \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix}^\perp = \text{cone}\{A_1\}$ ; so  $\mathcal{F}^+ = \{A_1\}^+$  and the dual is now feasible.

2. For the second example, replace PSD in the primal with the minimal face  $\mathcal{F} = \text{PSD} \cap \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}^\perp$ ;

so  $U_{23}$  is no longer restricted to be 0 in the dual.

3. The strong duality results are needed in many SDP applications to combinatorial problems where Slater's constraint qualification (strict feasibility) fails, e.g., [WZ99], [ZKR98].

## 51.6 A Primal-Dual Interior-Point Algorithm

As mentioned above, it was the development of efficient polynomial-time algorithms for SDP at the end of the 1980s that spurred the increased interest in the field. We look at the specific method derived in [HRV96]. (See also [KSH97], [Mon97].)

We assume that Slater's constraint qualification (strict feasibility) holds for both primal and dual problems.

### Definitions:

For each  $\mu > 0$ , the log-barrier approach applied to DSDP requires the solution of the **log-barrier problem**

$$\text{DSDP } \mu \quad d_\mu^* = \begin{array}{ll} \text{maximize} & \mathbf{b}^T \mathbf{y} + \mu \log \det Z \\ \text{subject to} & T^{\text{adj}} \mathbf{y} + Z = C, \quad Z \succ 0. \end{array}$$

The **Lagrangian** is  $L(X, \mathbf{y}, Z) = \mathbf{b}^T \mathbf{y} + \mu \log \det Z + \text{tr} X(C - T^{\text{adj}} \mathbf{y} - Z)$ , where we use  $X$  for the Lagrange multiplier vector.

### Facts:

1. The derivative, with respect to  $(X, \mathbf{y}, Z)$  of the Lagrangian, yields the optimality conditions for the barrier problem:

$$\text{OPT } \mu \quad \begin{array}{ll} T^{\text{adj}} \mathbf{y} + Z - C = 0 & \text{(dual feasibility)} \\ TX - b = 0 & \text{(primal feasibility)} \\ \mu Z^{-1} - X = 0 & \text{(perturbed complementary slackness).} \end{array}$$

We let  $X_\mu, \mathbf{y}_\mu, Z_\mu$  denote the unique solution of  $\text{OPT}_\mu$ , i.e., the unique optimum of the log-barrier problem. The set  $\{X_\mu, \mathbf{y}_\mu, Z_\mu : \mu \downarrow 0\}$  is called the **central path**. Successful primal-dual interior-point methods are actually path-following methods, i.e., they follow the central path to the optimum at  $\mu = 0$ .

2. The last equation in the optimality conditions  $\text{OPT}_\mu$  is very nonlinear and leads to ill-conditioning as  $\mu$  gets close to zero. Therefore, it is replaced by the more familiar

$$\text{OPT } \mu \quad ZX - \mu I = 0 \quad \text{(perturbed complementary slackness).}$$

We denote the resulting optimality conditions using

$$F_\mu(X, \mathbf{y}, Z) = 0.$$

This system has the same appearance as the one used in LP. However, it is an overdetermined nonlinear system, i.e.,  $F_\mu : \mathcal{S}_n \times \mathbb{R}^m \times \mathcal{S}_n \rightarrow \mathcal{S}_n \times \mathbb{R}^m \times \mathbb{R}^{n \times n}$ , since the product  $ZX$  is not necessarily symmetric. Therefore, the successful application of Newton's method done in LP must be modified. A Gauss-Newton method is used in [KMR01]. Another approach is to symmetrize the last equation of  $\text{OPT}_\mu$ . A general symmetrization scheme is presented in [MZ98].

3. We derive and present (arguably) the most popular algorithm for SDP, the **HKM method** [HRV96], [KSH97], [Mon97].

We consider a current estimate  $X, \mathbf{y}, Z$  of the optimum of the log-barrier problem  $\text{DSDP } \mu$ , where both  $X \succ 0, Z \succ 0$ . Since we want  $ZX = \mu I$ , we set  $\mu = \frac{1}{n} \text{tr} ZX$ . We use a centering parameter  $0 < \sigma$  that is adaptive in that it decreases (respectively increases) according to the decrease (respectively increase) in the duality gap estimate at each iteration. Small  $\sigma$  signifies an aggressive step in decreasing  $\mu$  to 0. We replace  $\mu \leftarrow \sigma \mu$  in the optimality conditions. We denote

the optimality conditions using  $F_\mu = F_\mu(X, \mathbf{y}, Z) = \begin{bmatrix} R_d \\ \mathbf{r}_p \\ R_c \end{bmatrix}$ , i.e., using three residuals. To derive

the HKM method, we solve for the Newton direction  $d_N = \begin{bmatrix} \Delta X \\ \Delta \mathbf{y} \\ \Delta Z \end{bmatrix}$  in the Newton equation

$$F'_\mu(X, \mathbf{y}, Z) = \begin{bmatrix} 0 & T^{\text{adj.}} & I \\ T & 0 & 0 \\ Z & 0 & \cdot X \end{bmatrix} d_N = - \begin{bmatrix} R_d \\ \mathbf{r}_p \\ R_c \end{bmatrix} = -F_\mu.$$

To solve the above linearized system efficiently, we use block elimination. We use the first equation to solve for

$$\Delta Z = -R_d - T^{\text{adj.}} \Delta \mathbf{y}.$$

We then substitute into the third equation and solve for

$$\Delta X = Z^{-1} \left( (R_d + T^{\text{adj.}} \Delta \mathbf{y}) X - R_c \right).$$

We then substitute this into the second equation and obtain the so-called *Schur complement* system, which is similar to the normal equation in LP:

$$\begin{aligned} TZ^{-1} T^{\text{adj.}} \Delta \mathbf{y} X &= -TZ^{-1} (R_d X - R_c) - \mathbf{r}_p \\ &= -TZ^{-1} (R_d X - ZX + \mu I) - TX + \mathbf{b} \\ &= \mathbf{b} - TZ^{-1} (R_d X + \mu I). \end{aligned}$$

This is a positive definite linear system. Once  $\Delta \mathbf{y}$  is found, we can backsolve for  $\Delta X, \Delta Z$ .

We now observe another major difference with LP and a major difficulty for SDP. Though  $\Delta Z$  is now symmetric, this is not true, in general, for  $\Delta X$ , since the product of symmetric matrices is not necessarily symmetric. Therefore, we symmetrize  $\Delta X \leftarrow \frac{1}{2}(\Delta X + \Delta X^T)$ . We have now obtained the search direction  $(\Delta X, \Delta \mathbf{y}, \Delta Z)$ .

Next, a line search is performed that maintains  $X, Z$  positive definite, i.e., we find the next iterate  $(X, \mathbf{y}, Z)$  using the primal and dual steplengths  $X \leftarrow X + \alpha_p \Delta X \succ 0, Z \leftarrow Z + \alpha_d \Delta Z \succ 0$  and set  $\mathbf{y} \leftarrow \mathbf{y} + \alpha_d \Delta \mathbf{y}$ . We then update  $\sigma, \mu$  and repeat the iteration, i.e., we go back to Fact 3 above.

4. See [HRV96] for more details on the HKM algorithm, including a predictor-corrector approach. Details on different symmetrization schemes that lead to various search directions and convergence proofs can be found in [MT00]. Algorithms based on bundle methods that handle large-scale SDP can be found in [HO00].

## 51.7 Applications of SDP

There are a surprising number of important applications for SDP, several of which have already been mentioned. Early applications in engineering involved solutions of linear matrix inequalities, LMIs, e.g., Lyapunov and Riccati equations; see [BEF94]. Semidefinite programming plays an important role in combinatorial optimization where it is used to solve nonlinear convex relaxations of NP-hard problems [Ali95], [WZ99], [ZKR98]. This includes strong theoretical results that characterize the quality of the bounds; see [GR00]. Matrix completion problems have been mentioned above. This includes Euclidean Distance Matrix completion problems with applications to, e.g., molecular conformation; see [AKW99]. Further applications to control theory, finance, nonlinear programming, etc. can be found in [BEF94] and [WSV00].

**Facts:**

1. SDP arises naturally when finding relaxations for hard combinatorial problems. We saw one simple case, the Max-Cut problem, MC, in the introduction in Example 1, i.e., MC was modeled as a quadratic maximization problem and the binary  $\pm 1$  variables were modeled using the quadratic constraints  $x_j^2 = 1$ .
2. In addition to  $\pm 1$  binary variables in Fact 1, we can model 0,1 variables using the quadratic constraints  $x_j^2 - x_j = 0$ . Linear constraints  $A\mathbf{x} - \mathbf{b} = 0$  can be modeled using the quadratic constraint  $\|A\mathbf{x} - \mathbf{b}\|^2 = 0$ . Thus, in general, many hard combinatorial optimization problems are equivalent to a quadratically constrained quadratic program, QQP. Denote the quadratic function  $q_i(\mathbf{y}) = \frac{1}{2}\mathbf{y}^T Q_i \mathbf{y} + \mathbf{y}^T b_i + c_i$ ,  $\mathbf{y} \in \mathbb{R}^n$ ,  $i = 0, 1, \dots, m$ . Then we have

$$\text{(QQP)} \quad q^* = \min_{\mathbf{y}} q_0(\mathbf{y}) \\ \text{subject to } q_i(\mathbf{y}) = 0, \quad i = 1, \dots, m.$$

(For simplicity, we restrict to equality constraints.)

3. SDP arises naturally from the Lagrangian relaxation of QQP in Fact 2 above. We write the Lagrangian  $L(\mathbf{y}, \mathbf{x})$ , with Lagrange multiplier vector  $\mathbf{x}$ .

$$L(\mathbf{y}, \mathbf{x}) = \begin{array}{lll} \text{quadratic in } \mathbf{y} & \text{linear in } \mathbf{y} & \text{constant in } \mathbf{y} \\ \frac{1}{2}\mathbf{y}^T(Q_0 - \sum_{i=1}^m x_i Q_i)\mathbf{y} & + \mathbf{y}^T(b_0 - \sum_{i=1}^m x_i b_i) & + (c_0 - \sum_{i=1}^m x_i c_i). \end{array}$$

Weak duality follows from the primal-dual pair relationship

$$q^* = \min_{\mathbf{y}} \max_{\mathbf{x}} L(\mathbf{y}, \mathbf{x}) \geq d^* = \max_{\mathbf{x}} \min_{\mathbf{y}} L(\mathbf{y}, \mathbf{x}).$$

We now homogenize the Lagrangian by adding  $y_0$  to the linear term:  $y_0 \mathbf{y}^T (b_0 - \sum_{i=1}^m x_i b_i)$ ,  $y_0^2 = 1$ . Then, after moving the constraint on  $y_0$  into the Lagrangian, the dual program becomes

$$\begin{aligned} d^* &= \max_{\mathbf{x}} \min_{\mathbf{y}} L(\mathbf{y}, \mathbf{x}) \\ &= \max_{\mathbf{x}, t} \min_{\mathbf{y}} \frac{1}{2}\mathbf{y}^T(Q_0 - \sum_{i=1}^m x_i Q_i)\mathbf{y} (+t y_0^2) \\ &\quad + y_0 \mathbf{y}^T (b_0 - \sum_{i=1}^m x_i b_i) \\ &\quad + (c_0 - \sum_{i=1}^m x_i c_i)(-t). \end{aligned}$$

We now exploit the *hidden constraint* from the inner minimization of a homogeneous quadratic function, i.e., the Hessian of the Lagrangian must be positive semidefinite. This gives rise to the SDP

$$\text{(D)} \quad \begin{array}{ll} d^* = \sup & -t - \sum_{i=1}^m x_i c_i \\ \text{s.t.} & T \begin{bmatrix} t \\ \mathbf{x} \end{bmatrix} \leq B \\ & \mathbf{x} \in \mathbb{R}^m, \quad t \in \mathbb{R}, \end{array}$$

where the linear transformation  $T : \mathbb{R}^{m+1} \rightarrow \mathcal{S}_{n+1}$  and the matrix  $B$  are defined by

$$B = \begin{bmatrix} 0 & b_0^T \\ b_0 & Q_0 \end{bmatrix}, \quad T \begin{bmatrix} t \\ \mathbf{x} \end{bmatrix} = \begin{bmatrix} -t & \sum_{i=1}^m x_i b_i^T \\ \sum_{i=1}^m x_i b_i & \sum_{i=1}^m x_i Q_i \end{bmatrix}.$$

The dual, DD, of the program D gives rise to the SDP relaxation of QQP.

$$\begin{aligned}
 p^* = \inf \quad & \text{tr } BU \\
 \text{(DD)} \quad & \text{s.t. } T^{\text{adj}} U = \begin{bmatrix} -1 \\ -c \end{bmatrix} \\
 & U \succeq 0.
 \end{aligned}$$

### 52.1 Introduction and Mise-En-Scène

---

Linear algebra is used extensively in statistical science, in particular in linear statistical models, see, e.g., Graybill [Gra01], Ravishanker and Dey [RD02], Rencher [Ren00], Searle [Sea97], Seber and Lee [SL03], Sengupta and Jammalamadaka [SJ03], and Stapleton [Sta95]; as well as in applied economics, see, e.g., Searle and Willett [SW01]; econometrics, see, e.g., Davidson and MacKinnon [DM04], Magnus and Neudecker [MN99], and Rao and Rao [RR98]; Markov chain theory, see, e.g., Chapter 54 or Kemeny and Snell [KS83]; multivariate statistical analysis, see, e.g., Anderson [And03], Kollo and von Rosen [KvR05], and Seber [Seb04]; psychometrics, see, e.g., Takane [Tak04] and Takeuchi, Yanai, and Mukherjee [TYM82]; and random matrix theory, see, e.g., Bleher and Its [BI01] and Mehta [Meh04]. Moreover, there are several books on linear algebra and matrix theory written by (and mainly for) statisticians, see, e.g., Bapat [Bap00], Graybill [Gra83], Hadi [Had96], Harville [Har97], [Har01], Healy [Hea00], Rao and Rao [RR98], Schott [Sch05], Searle [Sea82], and Seber [Seb06].

As Miller and Miller [MM04, p. 1] and Wackerly, Mendenhall, and Scheaffer [WMS02, p. 2] point out: “Statistics is a theory of information, with inference making as its objective” and may be viewed as encompassing “the science of basing inferences on observed data and the entire problem of making decisions in the face of uncertainty.”

In this chapter we present an introduction (Section 52.2) to the use of linear algebra in studying properties of random vectors (Section 52.3) and in linear statistical models (Section 52.4); for further uses, see, e.g., [PSS05] and [PS05], and for an introduction to the use of linear algebra in multivariate statistical analysis see Chapter 53 or [PSS05].

We begin (in Section 52.2) with a brief introduction to the basic concepts of statistics and random variables [MM04], [WMS02], [WS00], with special emphasis (in Section 52.3) on random vectors — vectors where each entry is a random variable.

All matrices (with at least two rows and two columns) considered in this chapter are nonrandom.

## 52.2 Introduction to Statistics and Random Variables

### Notation:

In this chapter most uppercase, light-face italic letters, in particular  $X$ ,  $Y$ , and  $Z$ , denote scalar random variables, but the notation  $P(A)$  is reserved for the probability of the set  $A$ . Throughout this chapter, the uppercase, light-face roman letter  $E$  denotes expectation.

### Definitions:

The focus in statistics is on making inferences concerning a large body of data called a **population** based on a subset collected from it called a **sample**. An **experiment** associated with this sample is repeatable and its outcome is not predetermined. A **simple event** is one associated with an experiment, which cannot be decomposed, and a simple event corresponds to one and only one **sample point**. The **sample space** associated with an experiment is the set of all possible sample points.

Suppose that  $S$  is a sample space associated with an experiment. To every subset  $A$  of  $S$  we assign a real number  $P(A)$ , called the **probability** of  $A$ , so that the following axioms hold: (1)  $P(A) \geq 0$ , (2)  $P(S) = 1$ , (3) If  $A_1, A_2, A_3, \dots$  form a sequence of pairwise mutually exclusive subsets in  $S$ , i.e.,  $A_i \cap A_j = \emptyset$  if  $i \neq j$ , then  $P(A_1 \cup A_2 \cup A_3 \cup \dots) = \sum_{i=1}^{\infty} P(A_i)$ .

A **random variable** is a real-valued function for which the domain is a sample space.

A random variable which can assume a finite or countably infinite number of values is **discrete**.

The **probability**  $P(Y = y)$  that the random variable  $Y$  takes on the value  $y$  is defined as the sum of the probabilities of all sample points in  $S$  that have the value  $y$ , and the **probability function** of  $Y$  is the set of all the probabilities  $P(Y = y)$ .

If the random variable  $Y$  has the probability function  $P(Y = 0) = p$  and  $P(Y = 1) = 1 - p$  for some real number  $p$  in the interval  $[0, 1]$ , then  $Y$  is a **Bernoulli random variable**.

The **cumulative distribution function** (cdf) is  $F(y) = P(Y \leq y)$  of the random variable  $Y$  for  $-\infty < y < \infty$ . A random variable  $Y$  is **continuous** when its cdf  $F(y)$  is continuous for  $-\infty < y < \infty$ , and then its **probability density function** (pdf)  $f(y) = dF(y)/dy$ .

Suppose that the continuous random variable  $Y$  has pdf  $f(y) = 1$  for  $0 \leq y \leq 1$  and  $f(y) = 0$  otherwise. Then  $Y$  follows a **uniform distribution** on the interval  $[0, 1]$ .

The **expectation** (or **expected value** or **mean** or **mean value**)  $E(Y)$  of the random variable  $Y$  is  $E(Y) = \sum_y yP(Y = y)$  when  $Y$  is discrete with probability function  $P(Y = y)$  and is  $E(Y) = \int_{-\infty}^{+\infty} yf(y)dy$  when  $Y$  is continuous with pdf  $f(y)$ .

The **variance**  $\sigma^2$  of the random variable  $Y$  is

$$\sigma^2 = \text{var}(Y) = E((Y - \mu)^2),$$

where  $\mu = E(Y)$  and the **standard deviation**  $\sigma = \sqrt{\sigma^2}$ .

### Facts:

1. The variance  $\sigma^2 = \text{var}(Y) = E(Y^2) - E^2(Y)$ .
2. For any random variable  $Y$ , the expectation of its square  $E(Y^2) \geq E^2(Y)$  with equality if and only if the random variable  $Y = E(Y)$  with probability 1.
3. If  $Y$  is a Bernoulli random variable with probability function  $P(Y = 0) = p$  and  $P(Y = 1) = 1 - p$ , then the expectation  $E(Y) = 1 - p$  and the variance  $\text{var}(Y) = p(1 - p)$ .
4. If the random variable  $Z$  follows a uniform distribution on the interval  $[0, 1]$ , then the expectation  $E(Z) = 1/2$  and the variance  $\text{var}(Z) = 1/12$ .

**Examples:**

1. Every person’s blood type is A, B, AB, or O. In addition, each individual either has the Rhesus (Rh) factor (+) or does not (-). A medical technician records a person’s blood type and Rh factor. The sample space for this experiment is  $\{A+, B+, AB+, O+, A-, B-, AB-, O-\}$  with eight sample points.
2. Consider the experiment of tossing a single fair coin and define the random variable  $Y = 0$  if the outcome is “heads,” and  $Y = 1$  if the outcome is “tails.” Then  $Y$  is a Bernoulli random variable, and  $P(Y = 0) = \frac{1}{2} = P(Y = 1)$ ,  $E(Y) = \frac{1}{2}$ ,  $\text{var}(Y) = \frac{1}{4}$ .
3. Suppose that a bus always arrives at a particular stop in the interval between 12 noon and 1 p.m. and that the probability that the bus will arrive in any given subinterval of time is proportional only to the length of the subinterval. Let  $Y$  denote the length of time that a person arriving at the stop at 12 noon must wait for the bus to arrive, and let us code 12 noon as 0 and measure the time in hours. Then the random variable  $Y$  follows a uniform distribution on the interval  $[0, 1]$ .

### 52.3 Random Vectors: Basic Definitions and Facts

---

Linear algebra is extensively used in the study of random vectors, where we consider the simultaneous behavior of two or more random variables assembled as a vector. In this section all vectors and matrices are real.

**Notation:**

In this section uppercase, light-face italic letters, such as  $X, Y,$  and  $Z,$  denote scalar random variables and lowercase bold roman letters, such as  $\mathbf{x}, \mathbf{y},$  and  $\mathbf{z},$  denote random vectors. Uppercase, light-face italic letters such as  $A$  and  $B$  denote nonrandom matrices.

**Definitions:**

Let  $A \in \mathbb{R}^{n \times k}$  and  $B \in \mathbb{R}^{n \times q}$ . Then the **partitioned matrix**  $[A \mid B]$  is the  $n \times (k + q)$  matrix formed by placing  $A$  next to  $B$ .

A  $k \times 1$  **random vector**  $\mathbf{y}$  is a vector  $\mathbf{y} = [Y_1, \dots, Y_k]^T$  of  $k$  random variables  $Y_1, \dots, Y_k$ . The **expectation** (or **expected value** or **mean vector**) of  $\mathbf{y}$  is the  $k \times 1$  vector  $E(\mathbf{y}) = [E(Y_1), \dots, E(Y_k)]^T$ . Sometimes, for clarity, a vector of constants (belonging to  $\mathbb{R}^n$ ) is called a **nonrandom vector** and a matrix of constants a **nonrandom matrix**. (Random matrices are not considered in this chapter.)

The **covariance**  $\text{cov}(Y, Z)$  between the two random variables  $Y$  and  $Z$  is  $\text{cov}(Y, Z) = E((Y - \mu)(Z - \nu))$ , where  $\mu = E(Y)$  and  $\nu = E(Z)$ .

The **correlation** (or **correlation coefficient** or **product-moment correlation**)  $\text{cor}(Y, Z)$  between the two random variables  $Y$  and  $Z$  is  $\text{cor}(Y, Z) = \text{cov}(Y, Z) / \sqrt{\text{var}(Y)\text{var}(Z)}$ .

The **covariance matrix** (or **variance-covariance matrix** or **dispersion matrix**) of the  $k \times 1$  random vector  $\mathbf{y} = [Y_1, \dots, Y_k]^T$  is the  $k \times k$  matrix  $\text{var}(\mathbf{y}) = \Sigma$  of variances and covariances of all the entries of  $\mathbf{y}$ :

$$\begin{aligned} \text{var}(\mathbf{y}) = \Sigma &= [\sigma_{ij}] = [\text{cov}(Y_i, Y_j)] = [E(Y_i - \mu_i)(Y_j - \mu_j)] \\ &= E((\mathbf{y} - \boldsymbol{\mu})(\mathbf{y} - \boldsymbol{\mu})^T), \end{aligned}$$

where  $\boldsymbol{\mu} = E(\mathbf{y})$ . The determinant  $\det \Sigma$  is the **generalized variance** of the random vector  $\mathbf{y}$ . The variances  $\sigma_{ii}$  are often denoted as  $\sigma_i^2$  and, in this, chapter, we will assume that they are all positive. If  $\sigma_i = 0$ , then the random variable  $Y_i = E(Y_i)$  with probability 1, and then we interpret  $Y_i$  as a constant. In statistics it is quite common to denote **standard deviations** as  $\sigma_i$ . (The reader should note that in all the other chapters of this book except in the two statistics chapters,  $\sigma_i$  denotes the  $i$ th largest singular value.)

The **cross-covariance matrix**  $\text{cov}(\mathbf{y}, \mathbf{z})$  between the  $k \times 1$  random vector  $\mathbf{y} = [Y_1, \dots, Y_k]^T$  and the  $q \times 1$  random vector  $\mathbf{z} = [Z_1, \dots, Z_q]^T$  is the  $k \times q$  matrix of all the covariances  $\text{cov}(Y_i, Z_j); i = 1, \dots, k$  and  $j = 1, \dots, q$ :

$$\text{cov}(\mathbf{y}, \mathbf{z}) = [\text{cov}(Y_i, Z_j)] = [E(Y_i - \mu_i)(Z_j - \nu_j)] = E((\mathbf{y} - \boldsymbol{\mu})(\mathbf{z} - \boldsymbol{\nu})^T),$$

where  $\boldsymbol{\mu} = [\mu_i] = E(\mathbf{y})$  and  $\boldsymbol{\nu} = [\nu_j] = E(\mathbf{z})$ . The random vectors  $\mathbf{y}$  and  $\mathbf{z}$  are **uncorrelated** whenever the cross-covariance matrix  $\text{cov}(\mathbf{y}, \mathbf{z}) = \mathbf{0}$ .

The **correlation matrix**  $\text{cor}(\mathbf{y}) = R$ , say, of the  $k \times 1$  random vector  $\mathbf{y} = [Y_1, \dots, Y_k]^T$ , is the  $k \times k$  matrix of correlations of all the entries in  $\mathbf{y}$ :  $\text{cor}(\mathbf{y}) = R = [\rho_{ij}] = [\text{cor}(Y_i, Y_j)] = [\frac{\sigma_{ij}}{\sigma_i \sigma_j}]$ , where  $\sigma_i = \sqrt{\sigma_{ii}}$  = standard deviation of  $Y_i$ ;  $\sigma_i, \sigma_j > 0$ .

Let  $\mathbf{1}_k$  denote the  $k \times 1$  column vector with every entry equal to 1. Then  $J_k = \mathbf{1}_k \mathbf{1}_k^T$  is the  $k \times k$  **all-ones matrix** (with all  $k^2$  entries equal to 1) and  $C_k = I_k - \frac{1}{k} J_k$  is the  $k \times k$  **centering matrix**.

Suppose that the real positive numbers  $p_1, p_2, \dots, p_k$  are such that  $\sum_{i=1}^k p_i = 1$ . Then the  $k \times 1$  random vector  $\mathbf{y} = [Y_1, \dots, Y_k]^T$  follows a **multinomial distribution** with parameters  $n$  and  $p_1, p_2, \dots, p_k$  if the joint probability function of  $Y_1, Y_2, \dots, Y_k$  is given by

$$P(Y_1 = y_1, Y_2 = y_2, \dots, Y_k = y_k) = \frac{n!}{y_1! y_2! \dots y_k!} p_1^{y_1} p_2^{y_2} \dots p_k^{y_k},$$

where for each  $i$ ,  $y_i = 0, 1, 2, \dots, n$  and  $\sum_{i=1}^k y_i = n$ . When  $k = 2$  the distribution is **binomial**, and when  $k = 3$  the distribution is **trinomial**.

Let the symmetric matrices  $A \in \mathbb{R}^{k \times k}$  and  $B \in \mathbb{R}^{k \times k}$ . Then  $A \succeq B$  means  $A - B$  is positive semidefinite and  $A \succ B$  means  $A - B$  is positive definite. The partial ordering induced by  $\succeq$  is called the **partial semidefinite ordering** (or **Loewner partial ordering** or **Löwner partial ordering**). (See Section 8.5 for more information.)

Let the  $(k + q) \times 1$  random vector  $\mathbf{x}$  have covariance matrix  $\Sigma$ . Consider the following partitioning:

$$\mathbf{x} = \begin{bmatrix} \mathbf{y} \\ \mathbf{z} \end{bmatrix}, \quad E(\mathbf{x}) = \begin{bmatrix} \boldsymbol{\mu} \\ \boldsymbol{\nu} \end{bmatrix}, \quad \text{var}(\mathbf{x}) = \Sigma = \begin{bmatrix} \Sigma_{yy} & \Sigma_{yz} \\ \Sigma_{zy} & \Sigma_{zz} \end{bmatrix},$$

where  $\mathbf{y}$  and  $\mathbf{z}$  have  $k$  and  $q$  elements, respectively. Then the **partial covariance matrix**  $\Sigma_{zz \cdot y}$  of the  $q \times 1$  random vector  $\mathbf{z}$  after **adjusting for** (or **controlling for** or **removing the effect of** or **allowing for**) the  $k \times 1$  random vector  $\mathbf{y}$  is the (uniquely defined) **generalized Schur complement**

$$\Sigma / \Sigma_{yy} = [\sigma_{ij \cdot y}] = \Sigma_{zz} - \Sigma_{zy} \Sigma_{yy}^- \Sigma_{yz}$$

of  $\Sigma_{yy}$  in  $\Sigma$ ; any **generalized inverse**  $\Sigma_{yy}^-$  satisfying  $\Sigma_{yy} = \Sigma_{yy} \Sigma_{yy}^- \Sigma_{yy}$  may be chosen.

When  $\Sigma_{yy}$  is positive definite, we use the inverse  $\Sigma_{yy}^{-1}$  instead of a generalized inverse  $\Sigma_{yy}^-$  and refer to  $\Sigma / \Sigma_{yy} = \Sigma_{zz} - \Sigma_{zy} \Sigma_{yy}^{-1} \Sigma_{yz}$  as the **Schur complement** of  $\Sigma_{yy}$  in  $\Sigma$ .

The  $q \times 1$  random vector  $\mathbf{e}_{z \cdot y} = \mathbf{z} - \boldsymbol{\nu} - \Sigma_{zy} \Sigma_{yy}^- (\mathbf{y} - \boldsymbol{\mu})$  is the (uniquely defined) vector of **residuals** of the  $q \times 1$  random vector  $\mathbf{z}$  from its **regression** on the  $k \times 1$  random vector  $\mathbf{y}$ .

The  $ij$ th entry of the **partial correlation matrix** of  $q \times 1$  random vector  $\mathbf{z} = [Z_1, \dots, Z_q]^T$  after adjusting for the  $k \times 1$  random vector  $\mathbf{y}$  is the **partial correlation coefficient** between  $z_i$  and  $z_j$  after adjusting for  $\mathbf{y}$ :

$$\rho_{ij \cdot y} = \frac{\sigma_{ij \cdot y}}{\sqrt{\sigma_{ii \cdot y} \sigma_{jj \cdot y}}}; \quad i, j = 1, \dots, q,$$

which is well defined provided the diagonal entries of the associated partial covariance matrix are all positive.

**Facts:**

- [WMS02, Th. 5.13, p. 265] Let the  $k \times 1$  random vector  $\mathbf{y} = [Y_1, \dots, Y_k]^T$  follow a multinomial distribution with parameters  $n$  and  $p_1, \dots, p_k$  and let the  $k \times 1$  vector  $\mathbf{p} = [p_1, \dots, p_k]^T$ . Then:
  - The random variable  $Y_i$  can be represented as the sum of  $n$  independently and identically distributed Bernoulli random variables with parameter  $p_i$ ;  $i = 1, \dots, k$ .
  - The expectation  $E(\mathbf{y}) = n\mathbf{p}$  and the covariance matrix

$$\text{var}(\mathbf{y}) = n(\text{diag}(\mathbf{p}) - \mathbf{p}\mathbf{p}^T) = \Psi_k,$$

say, where  $\text{diag}(\mathbf{p})$  is the  $k \times k$  diagonal matrix formed from the  $k \times 1$  nonrandom vector  $\mathbf{p}$ .

- The covariance matrix  $\Psi_k$  is singular since all its row (and column) totals are 0, and the  $\text{rank}(\Psi_k) = k - 1$ .
- When the  $k \times 1$  multinomial probability vector  $\mathbf{p} = \mathbf{1}_k/k$ , then the multinomial covariance matrix  $\Psi_k = \frac{n}{k}C_k$ , where  $C_k$  is the  $k \times k$  centering matrix.
  - The  $k \times k$  covariance matrix  $\text{var}(\mathbf{y}) = \Sigma = E(\mathbf{y}\mathbf{y}^T) - \boldsymbol{\mu}\boldsymbol{\mu}^T$ , where  $\boldsymbol{\mu} = E(\mathbf{y})$ .
  - The  $k \times k$  correlation matrix  $\text{cor}(\mathbf{y}) = [\text{diag}(\Sigma)]^{-1/2}\Sigma[\text{diag}(\Sigma)]^{-1/2}$ , where  $\Sigma = \text{var}(\mathbf{y})$ .
  - The  $k \times q$  cross-covariance matrix

$$\text{cov}(\mathbf{y}, \mathbf{z}) = \Sigma_{yz} = \Sigma_{zy}^T = (\text{cov}(\mathbf{z}, \mathbf{y}))^T = E(\mathbf{y}\mathbf{z}^T) - \boldsymbol{\mu}\boldsymbol{\nu}^T,$$

where  $\boldsymbol{\mu} = E(\mathbf{y})$  and  $\boldsymbol{\nu} = E(\mathbf{z})$ .

- [RM71, Lemma 2.2.4, p. 21]: The product  $AB^{-1}C$  (for  $A \neq \mathbf{0}$ ,  $C \neq \mathbf{0}$ ) is invariant with respect to the choice of  $B^{-1} \iff \text{range}(C) \subseteq \text{range}(B)$  and  $\text{range}(A^T) \subseteq \text{range}(B^T)$ .
- Consider the  $(k + q) \times (k + q)$  covariance matrix

$$\Sigma = \begin{bmatrix} \Sigma_{yy} & \Sigma_{yz} \\ \Sigma_{zy} & \Sigma_{zz} \end{bmatrix}.$$

Then the range (or column space)  $\text{range}(\Sigma_{yz}) \subseteq \text{range}(\Sigma_{yy})$  and  $\text{range}(\Sigma_{zy}) \subseteq \text{range}(\Sigma_{zz})$ , and, hence, the matrix  $\Sigma_{zy}\Sigma_{yy}^{-}\Sigma_{yz}$  and the generalized Schur complement  $\Sigma/\Sigma_{yy} = \Sigma_{zz} - \Sigma_{zy}\Sigma_{yy}^{-}\Sigma_{yz}$  are invariant (unique) with respect to the choice of generalized inverse  $\Sigma_{yy}^{-}$ .

- Let the  $k \times 1$  random vector  $\mathbf{x} = [X_1, \dots, X_k]^T$ . Then the  $k \times 1$  centered vector  $C_k\mathbf{x} = [X_1 - \bar{X}, \dots, X_k - \bar{X}]^T$ , where  $C_k$  is the  $k \times k$  centering matrix and the arithmetic mean (or average)  $\bar{X} = \sum_{i=1}^k X_i/k$ .
- A nonsingular positive semidefinite matrix is positive definite.
- A covariance matrix is always symmetric and positive semidefinite.
- A cross-covariance matrix is usually rectangular.
- A correlation matrix is always symmetric and positive semidefinite.
- The diagonal entries of a correlation matrix are all equal to 1 and the off-diagonal entries are all at most equal to 1 in absolute value.
- [PS05, p. 168] The (generalized) Schur complement of the leading principal submatrix of a positive semidefinite matrix is positive semidefinite.
- Let  $\mathbf{y}$  be a  $k \times 1$  random vector with covariance matrix  $\Sigma$ . Then the variance  $\text{var}(\mathbf{a}^T\mathbf{y}) = \mathbf{a}^T\Sigma\mathbf{a}$  for all nonrandom  $\mathbf{a} \in \mathbb{R}^k$ . (Since variance must be nonnegative this fact shows that a covariance matrix must be positive semidefinite.)
- Let  $\mathbf{y}$  be a  $k \times 1$  random vector with expectation  $\boldsymbol{\mu} = E(\mathbf{y})$ , covariance matrix  $\Sigma = \text{var}(\mathbf{y})$ , and let the matrix  $A \in \mathbb{R}^{n \times k}$  and the nonrandom vector  $\mathbf{b} \in \mathbb{R}^n$ . Then the expectation  $E(A\mathbf{y} + \mathbf{b}) = AE(\mathbf{y}) + \mathbf{b} = A\boldsymbol{\mu} + \mathbf{b}$  and the covariance matrix  $\text{var}(A\mathbf{y} + \mathbf{b}) = A\text{var}(\mathbf{y})A^T = A\Sigma A^T$ .
- Let  $\mathbf{y}$  be a  $k \times 1$  random vector with expectation  $\boldsymbol{\mu} = E(\mathbf{y})$ , covariance matrix  $\Sigma = \text{var}(\mathbf{y})$ , and let the matrix  $A \in \mathbb{R}^{k \times k}$ , not necessarily symmetric. Then  $E(\mathbf{y}^T A\mathbf{y}) = \boldsymbol{\mu}^T A\boldsymbol{\mu} + \text{tr}(A\Sigma)$ .

18. [Rao73a, p. 522] Let  $\mathbf{y}$  be a  $k \times 1$  random vector with expectation  $\boldsymbol{\mu} = E(\mathbf{y})$  and covariance matrix  $\Sigma = \text{var}(\mathbf{y})$ , and let  $[\boldsymbol{\mu} \mid \Sigma]$  denote the  $k \times (k+1)$  partitioned matrix with  $\boldsymbol{\mu}$  as its first column. Then  $\mathbf{y} - \boldsymbol{\mu} \in \text{range}(\Sigma)$  and  $\mathbf{y} \in \text{range}([\boldsymbol{\mu} \mid \Sigma])$ , both with probability 1.
19. Let the  $(k+q) \times 1$  random vector  $\mathbf{x}$  have covariance matrix  $\Sigma$ . Consider the following partitioning:

$$\mathbf{x} = \begin{bmatrix} \mathbf{y} \\ \mathbf{z} \end{bmatrix}, \quad E(\mathbf{x}) = \begin{bmatrix} \boldsymbol{\mu} \\ \boldsymbol{\nu} \end{bmatrix}, \quad \Sigma = \begin{bmatrix} \Sigma_{yy} & \Sigma_{yz} \\ \Sigma_{zy} & \Sigma_{zz} \end{bmatrix},$$

where  $\mathbf{y}$  and  $\mathbf{z}$  have  $k$  and  $q$  components, respectively. Then

- The variance  $\text{var}(\mathbf{a}^T \mathbf{y} + \mathbf{b}^T \mathbf{z}) = \mathbf{a}^T \Sigma_{yy} \mathbf{a} + 2\mathbf{a}^T \Sigma_{yz} \mathbf{b} + \mathbf{b}^T \Sigma_{zz} \mathbf{b}$  for all nonrandom  $\mathbf{a} \in \mathbb{R}^k$  and for all nonrandom  $\mathbf{b} \in \mathbb{R}^q$ .
- The covariance matrix  $\text{var}(A\mathbf{y} + B\mathbf{z}) = A\Sigma_{yy}A^T + A\Sigma_{yz}B^T + B\Sigma_{zy}A^T + B\Sigma_{zz}B^T$  for all  $A \in \mathbb{R}^{n \times k}$  and all  $B \in \mathbb{R}^{n \times q}$ .
- [PS05b, pp. 187–188] For any  $A \in \mathbb{R}^{q \times k}$  the covariance matrix

$$\text{var}(\mathbf{z} - A\mathbf{y}) \succeq \text{var}(\mathbf{z} - \Sigma_{zy} \Sigma_{yy}^- \mathbf{y})$$

with respect to the partial semidefinite ordering, and the partial covariance matrix

$$\text{var}(\mathbf{z} - \Sigma_{zy} \Sigma_{yy}^- \mathbf{y}) = \Sigma_{zz} - \Sigma_{zy} \Sigma_{yy}^- \Sigma_{yz} = \Sigma_{zz \cdot y} = \Sigma / \Sigma_{yy},$$

the generalized Schur complement of  $\Sigma_{yy}$  in  $\Sigma$ .

- Let  $q = k$ . Then the covariance matrix  $\text{var}(\mathbf{y} + \mathbf{z}) = \text{var}(\mathbf{y}) + \text{var}(\mathbf{z})$  if and only if  $\text{cov}(\mathbf{y}, \mathbf{z}) = -\text{cov}(\mathbf{z}, \mathbf{y})$ , i.e., the cross-covariance matrix  $\text{cov}(\mathbf{y}, \mathbf{z})$  is skew-symmetric; the condition that  $\text{cov}(\mathbf{y}, \mathbf{z}) = \mathbf{0}$  is sufficient, but not necessary (unless  $k = 1$ ).
- The vector  $\Sigma_{zy} \Sigma_{yy}^- \mathbf{y}$  is not necessarily invariant with respect to the choice of generalized inverse  $\Sigma_{yy}^-$ , but its covariance matrix  $\text{var}(\Sigma_{zy} \Sigma_{yy}^- \mathbf{y}) = \Sigma_{zy} \Sigma_{yy}^- \Sigma_{yz}$  is invariant (and, hence, unique).

### Examples:

1. Let the  $4 \times 1$  random vector  $\mathbf{x}$  have covariance matrix  $\Sigma$ . Consider the following partitioning:

$$\mathbf{x} = \begin{bmatrix} \mathbf{y} \\ \mathbf{z} \end{bmatrix}, \quad \Sigma = \begin{bmatrix} 1 & 0 & a & b \\ 0 & 1 & c & d \\ a & c & 1 & 0 \\ b & d & 0 & 1 \end{bmatrix},$$

where  $\mathbf{y}$  and  $\mathbf{z}$  each have 2 components. Then  $\text{var}(\mathbf{y} + \mathbf{z}) = \text{var}(\mathbf{y}) + \text{var}(\mathbf{z})$  if and only if  $a = d = 0$  and  $c = -b$ , with  $b^2 \leq 1$ .

2. Let the  $k \times 1$  random vector  $\mathbf{y} = [Y_1, \dots, Y_k]^T$  follow a multinomial distribution with parameters  $n$  and  $\mathbf{p} = [p_1, \dots, p_k]^T$ , with  $p_1 + \dots + p_k = 1$  and  $p_1 > 0, \dots, p_k > 0$ , and let the  $k \times k$  matrix  $A = [a_{ij}]$ . Then the expectation  $E(\mathbf{y}^T A \mathbf{y}) = n(n-1) \mathbf{p}^T A \mathbf{p} + n \sum_{i=1}^k a_{ii} p_i$ .
3. Let the  $3 \times 1$  random vector  $\mathbf{y} = [Y_1, Y_2, Y_3]^T$  follow a trinomial distribution with parameters  $n$  and  $p_1, p_2, p_3$ , with  $p_1 + p_2 + p_3 = 1$  and  $p_1 > 0, p_2 > 0, p_3 > 0$ , and let the  $3 \times 1$  vector  $\mathbf{p} = [p_1, p_2, p_3]^T$ . Then:
- The expectation  $E(\mathbf{y}) = n[p_1, p_2, p_3]^T$  and the covariance matrix

$$\Psi_3 = \text{var}(\mathbf{y}) = n \begin{bmatrix} p_1(1-p_1) & -p_1 p_2 & -p_1 p_3 \\ -p_1 p_2 & p_2(1-p_2) & -p_2 p_3 \\ -p_1 p_3 & -p_2 p_3 & p_3(1-p_3) \end{bmatrix},$$

which has rank equal to 2 since  $\Psi_3$  is singular and the determinant of the top left-hand corner of  $\Psi_3$  equals  $n^2 p_1 p_2 p_3 > 0$ .

- The partial covariance matrix of  $Y_1$  and  $Y_2$  adjusting for  $Y_3$  is the Schur complement  $\Psi_3 / (p_3(1 - p_3)) = nS$ , say, where

$$S = \begin{bmatrix} p_1(1 - p_1) & -p_1 p_2 \\ -p_1 p_2 & p_2(1 - p_2) \end{bmatrix} - \begin{bmatrix} -p_1 p_3 \\ -p_2 p_3 \end{bmatrix} \frac{1}{p_3(1 - p_3)} \begin{bmatrix} -p_1 p_3 & -p_2 p_3 \end{bmatrix} = \frac{p_1 p_2}{p_1 + p_2} \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix},$$

which has rank equal to 1, and so  $\text{rank}(\Psi_3) = 2$ .

- When  $p_1 = p_2 = p_3 = 1/3$ , then the covariance matrix  $\Psi_3 = (n/3)C_3$  and the partial covariance matrix of  $Y_1$  and  $Y_2$  adjusting for  $Y_3$  is  $(n/3)C_2$ ; here,  $C_h$  is the  $h \times h$  centering matrix,  $h = 2, 3$ .
4. [PS05, p. 183] If the  $3 \times 3$  symmetric matrix

$$R_3 = \begin{bmatrix} 1 & r_{12} & r_{13} \\ r_{12} & 1 & r_{23} \\ r_{13} & r_{23} & 1 \end{bmatrix} = \begin{bmatrix} R_2 & \mathbf{r}_2 \\ \mathbf{r}_2^T & 1 \end{bmatrix}$$

is a correlation matrix, then  $r_{ij}^2 \leq 1$  for all  $1 \leq i < j \leq 3$ . But not all symmetric matrices with diagonal elements all equal to 1 and all off-diagonal elements  $r_{ij}$  such that  $r_{ij}^2 \leq 1$  are correlation matrices. For example, consider  $R_3$  with  $r_{13}^2 \leq 1$  and  $r_{23}^2 \leq 1$ . Then  $R_3$  is a correlation matrix if and only if

$$r_{13}r_{23} - \sqrt{(1 - r_{13}^2)(1 - r_{23}^2)} \leq r_{12} \leq r_{13}r_{23} + \sqrt{(1 - r_{13}^2)(1 - r_{23}^2)}.$$

When  $r_{13} = 0$  and  $r_{12} = r_{23} = r$ , say, then this condition becomes  $r^2 \leq 1/2$  and so the matrix

$$\begin{bmatrix} 1 & 0.8 & 0 \\ 0.8 & 1 & 0.8 \\ 0 & 0.8 & 1 \end{bmatrix}$$

is not a correlation matrix.

When  $r_{12}^2 \leq 1$ , then the matrix  $R_3$  is a correlation matrix if and only if any one of the following conditions holds:

- $\det(R_3) = 1 - r_{12}^2 - r_{13}^2 - r_{23}^2 + 2r_{12}r_{13}r_{23} \geq 0$ .
- (i)  $\mathbf{r}_2 \in \text{range}(R_2)$  and (ii)  $1 \geq \mathbf{r}_2^T R_2^- \mathbf{r}_2$  for some and, hence, for every generalized inverse  $R_2^-$ .

5. Let the random vector  $\mathbf{x}$  be  $2 \times 1$  and write

$$\mathbf{x} = \begin{bmatrix} Y \\ Z \end{bmatrix}, \quad E(\mathbf{x}) = \begin{bmatrix} \mu \\ \nu \end{bmatrix}, \quad \text{var}(\mathbf{x}) = \Sigma = \begin{bmatrix} \sigma_y^2 & \sigma_{yz} \\ \sigma_{yz} & \sigma_z^2 \end{bmatrix},$$

with  $\sigma_y^2 > 0$ . Then the residual vector  $\mathbf{e}_{z \cdot y} = \mathbf{z} - \boldsymbol{\nu} - \Sigma_{zy} \Sigma_{yy}^- (\mathbf{y} - \boldsymbol{\mu})$  of the random vector  $\mathbf{z}$  from its regression on  $\mathbf{y}$  becomes the scalar residual

$$e_{z \cdot y} = Z - \nu - \frac{\sigma_{yz}}{\sigma_y^2} (Y - \mu)$$

of the random variable  $Z$  from its regression on  $Y$ . The matrix of partial covariances of the random vector  $\mathbf{z}$  after adjusting for  $\mathbf{y}$  becomes the single partial variance

$$\sigma_{z \cdot y}^2 = \sigma_z^2 - \frac{\sigma_{yz}^2}{\sigma_y^2} = \sigma_z^2(1 - \rho_{yz}^2)$$

of the random variable  $Z$  after adjusting for the random variable  $Y$ ; here, the correlation coefficient  $\rho_{yz} = \sigma_{yz}/(\sigma_y\sigma_z)$ .

## 52.4 Linear Statistical Models: Basic Definitions and Facts

### Notation:

In this section, the uppercase, light-face italic letter  $X$  is reserved for the nonrandom  $n \times p$  model matrix and  $V$  is reserved for an  $n \times n$  covariance matrix. The uppercase, light-face italic letter  $H$  is reserved for the (symmetric idempotent)  $n \times n$  hat matrix  $X(X^T X)^{-1} X^T$  and  $M = I - H$  is reserved for the (symmetric idempotent)  $n \times n$  residual matrix. The lowercase, bold-face roman letter  $\mathbf{y}$  is reserved for an observable  $n \times 1$  random vector and  $\mathbf{x}$  is reserved for a column of the  $n \times p$  model matrix  $X$ .

### Definitions:

The **general linear model** (or **Gauss–Markov model** or **Gauß–Markov model**) is the model

$$\mathcal{M} = \{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$$

defined by the equation  $\mathbf{y} = X\boldsymbol{\beta} + \boldsymbol{\varepsilon}$ , where  $E(\mathbf{y}) = X\boldsymbol{\beta}$ ,  $E(\boldsymbol{\varepsilon}) = \mathbf{0}$ ,  $\text{var}(\mathbf{y}) = \text{var}(\boldsymbol{\varepsilon}) = \sigma^2 V$ . The vector  $\mathbf{y}$  is an  $n \times 1$  observable random vector,  $\boldsymbol{\varepsilon}$  is an  $n \times 1$  unobservable random error vector,  $X$  is a known  $n \times p$  **model matrix** (or **design matrix**, particularly when its entries are  $-1, 0$ , or  $+1$ ),  $\boldsymbol{\beta}$  is a  $p \times 1$  vector of unknown parameters,  $V$  is a known  $n \times n$  positive semidefinite matrix, and  $\sigma^2$  is an unknown positive constant. The realization of the  $n \times 1$  observable random vector  $\mathbf{y}$  will also be denoted by  $\mathbf{y}$ .

The classical theory of linear statistical models covers the **full-rank model**, where  $X$  has full column rank and  $V$  is positive definite. In the full-rank model, the **ordinary least squares estimator**

$$\text{OLSE}(\boldsymbol{\beta}) = \hat{\boldsymbol{\beta}} = (X^T X)^{-1} X^T \mathbf{y} = X^\dagger \mathbf{y}$$

and the **generalized least squares estimator** (or **Aitken estimator**)

$$\text{GLSE}(\boldsymbol{\beta}) = \tilde{\boldsymbol{\beta}} = (X^T V^{-1} X)^{-1} X^T V^{-1} \mathbf{y},$$

where  $X^\dagger$  denotes the Moore–Penrose inverse of  $X$ .

When either  $X$  or  $V$  is (or both  $X$  and  $V$  are) rank deficient, then it is usually assumed that  $\text{rank}(X) < \text{rank}(V)$ . The model  $\mathcal{M} = \{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$  is called a **weakly singular model** (or **Zyskind–Martin model**) whenever  $\text{range}(X) \subseteq \text{range}(V)$ , and then  $\text{rank}(X) < \text{rank}(V)$ , and is **consistent** if the realization  $\mathbf{y}$  satisfies  $\mathbf{y} \in \text{range}([X \mid V])$ .

Let  $\hat{\boldsymbol{\beta}}$  be any vector minimizing  $\|\mathbf{y} - X\boldsymbol{\beta}\|^2 = (\mathbf{y} - X\boldsymbol{\beta})^T (\mathbf{y} - X\boldsymbol{\beta})$ . Then  $\hat{\mathbf{y}} = X\hat{\boldsymbol{\beta}} = \text{OLSE}(X\boldsymbol{\beta})$  is the **ordinary least squares estimator** (OLSE) of  $X\boldsymbol{\beta}$ . When  $\text{rank}(X) < p$ , then  $\hat{\boldsymbol{\beta}}$  is an **ordinary least squares solution** to  $\min_{\boldsymbol{\beta}} (\mathbf{y} - X\boldsymbol{\beta})^T (\mathbf{y} - X\boldsymbol{\beta})$ . Moreover,  $\hat{\boldsymbol{\beta}}$  is any solution to the **normal equations**  $X^T X\hat{\boldsymbol{\beta}} = X^T \mathbf{y}$ . The vector of OLS **residuals** is  $\mathbf{e} = \mathbf{y} - \hat{\mathbf{y}} = \mathbf{y} - X\hat{\boldsymbol{\beta}}$  and the **residual sum of squares**  $\text{SSE} = \mathbf{e}^T \mathbf{e} = (\mathbf{y} - \hat{\mathbf{y}})^T (\mathbf{y} - \hat{\mathbf{y}})$ .

The **coefficient of determination** (or **coefficient of multiple determination** or **squared multiple correlation**)  $R^2 = 1 - (\text{SSE}/\mathbf{y}^T C_n \mathbf{y})$  identifies the proportion of variance explained in a **multiple linear regression** where the model matrix  $X = [\mathbf{1}_n \mid \mathbf{x}_{[1]} \mid \cdots \mid \mathbf{x}_{[p-1]}]$  with  $p - 1$  **regressor vectors** (or **regressors**)  $\mathbf{x}_{[1]}, \dots, \mathbf{x}_{[p-1]}$  each  $n \times 1$ . In **simple linear regression**  $p = 2$  and the model matrix  $X = [\mathbf{1}_n \mid \mathbf{x}]$

with the single regressor vector  $\mathbf{x}$ . The **sample correlation coefficient**  $r = \mathbf{x}^T C_n \mathbf{y} / \sqrt{\mathbf{x}^T C_n \mathbf{x} \cdot \mathbf{y}^T C_n \mathbf{y}}$ , where it is usually assumed that  $\mathbf{x}$  is an  $n \times 1$  nonrandom vector (such as a regressor vector) and  $\mathbf{y}$  is a realization of the  $n \times 1$  random vector  $\mathbf{y}$ .

Let the matrix  $A \in \mathbb{R}^{k \times n}$  and let the matrix  $K \in \mathbb{R}^{k \times p}$ . Then the linear estimator  $A\mathbf{y}$  is a **linear unbiased estimator** (LUE) of  $K\boldsymbol{\beta}$  if  $E(A\mathbf{y}) = K\boldsymbol{\beta}$  for all  $\boldsymbol{\beta} \in \mathbb{R}^p$ . Let the matrix  $B \in \mathbb{R}^{k \times n}$ . Then the LUE  $B\mathbf{y}$  of  $K\boldsymbol{\beta}$  is the **best linear unbiased estimator** (BLUE) of  $K\boldsymbol{\beta}$  if it has the smallest covariance matrix (in the positive semidefinite ordering) in that  $\text{var}(A\mathbf{y}) \succeq \text{var}(B\mathbf{y})$  for all LUEs  $A\mathbf{y}$  of  $K\boldsymbol{\beta}$ .

The **hat matrix**  $H = X(X^T X)^{-1} X^T$  associated with the model matrix  $X$  is so named since  $\hat{\mathbf{y}} = H\mathbf{y}$ . The **residual matrix**  $M = I - H$  and vector of OLS residuals is  $\mathbf{e} = \mathbf{y} - \hat{\mathbf{y}} = \mathbf{y} - H\mathbf{y} = M\mathbf{y}$ . Let the nonrandom vector  $\mathbf{a} \in \mathbb{R}^n$ . Then the linear estimator  $\mathbf{a}^T \mathbf{y}$ , which is unbiased for 0, i.e.,  $E(\mathbf{a}^T \mathbf{y}) = 0$ , is a **linear zero function**.

The **Watson efficiency**  $\phi$  under the full-rank model  $\mathcal{M} = \{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$ , with the  $n \times p$  model matrix  $X$  having full column rank equal to  $p < n$  and with the  $n \times n$  covariance matrix  $V$  positive definite, measures the relative efficiency of the OLSE( $\boldsymbol{\beta}$ ) =  $\hat{\boldsymbol{\beta}}$  vs. the BLUE( $\boldsymbol{\beta}$ ) =  $\tilde{\boldsymbol{\beta}}$  and is defined by the ratio of the corresponding generalized variances:

$$\phi = \frac{\det[\text{var}(\tilde{\boldsymbol{\beta}})]}{\det[\text{var}(\hat{\boldsymbol{\beta}})]} = \frac{\det^2(X^T X)}{\det(X^T V X) \cdot \det(X^T V^{-1} X)}.$$

The **Bloomfield–Watson efficiency**  $\psi$  under the general linear model  $\mathcal{M} = \{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$  with no rank assumptions measures the relative efficiency of the OLSE( $X\boldsymbol{\beta}$ ) =  $X\hat{\boldsymbol{\beta}}$  vs. the BLUE( $\boldsymbol{\beta}$ ) =  $\tilde{\boldsymbol{\beta}}$  and is defined by:  $\psi = \frac{1}{2} \|HV - VH\|^2 = \|HVM\|^2$ , where the norm  $\|A\| = \text{tr}^{1/2}(A^T A)$  is defined for any  $k \times q$  matrix  $A$ .

The  $n \times n$  covariance matrix  $(1 - \rho)I_n + \rho \mathbf{1}_n \mathbf{1}_n^T = (1 - \rho)I_n + \rho J_n$  has **intraclass correlation structure** (or **equicorrelation structure**) and is the **intraclass correlation matrix** (or the **equicorrelation matrix**). The parameter  $\rho$  is the **intraclass correlation** (or **intraclass correlation coefficient**).

**Facts:**

The following facts, except for those with a specific reference, can be found in [Gro04], [PS89], or [SJ03, §4.1–4.3]. Throughout this set of facts,  $X$  denotes the  $n \times p$  nonrandom model matrix.

1. The hat matrix  $H = X(X^T X)^{-1} X^T$  associated with the model matrix  $X$  is invariant (unique) with respect to choice of generalized inverse  $(X^T X)^-$  and is a symmetric idempotent matrix:  $H = H^T = H^2$ , and  $\text{rank}(H) = \text{tr}(H) = \text{rank}(X)$ . Moreover, the hat matrix  $H$  is the orthogonal projector onto  $\text{range}(X)$ .
2. If the  $p \times p$  matrix  $Q$  is nonsingular, then the hat matrix associated with the model matrix  $XQ$  equals the hat matrix associated with the model matrix  $X$ .
3. The residual sum of squares  $SSE = \mathbf{y}^T M\mathbf{y} = (\mathbf{y} - \hat{\mathbf{y}})^T (\mathbf{y} - \hat{\mathbf{y}}) = \mathbf{y}^T \mathbf{y} - \mathbf{y}^T X\hat{\boldsymbol{\beta}}$ , where  $M$  is the residual matrix and  $\hat{\boldsymbol{\beta}} = \text{OLSE}(\boldsymbol{\beta})$ .
4. In simple linear regression the coefficient of determination  $R^2 = r^2$ , the square of the sample correlation coefficient. In multiple linear regression with model matrix  $X = [\mathbf{1}_n | X_0] = [\mathbf{1}_n | \mathbf{x}_{[1]} | \cdots | \mathbf{x}_{[p-1]}]$  and  $(p - 1) \times 1$  nonrandom vector  $\mathbf{a} \in \mathbb{R}^p$ ,

$$R^2 = \max_{\mathbf{a}} r_{\mathbf{a}}^2 = \max_{\mathbf{a}} \frac{(\mathbf{a}^T X_0^T C_n \mathbf{y})^2}{\mathbf{a}^T X_0^T C_n X_0 \mathbf{a} \cdot \mathbf{y}^T C_n \mathbf{y}},$$

the square of the sample correlation coefficient  $r_{\mathbf{a}}$  between the variables whose observed values are in vectors  $\mathbf{y}$  and  $X_0 \mathbf{a}$ .

5. The vector  $X\hat{\boldsymbol{\beta}}$  is invariant (unique) with respect to the choice of least squares solution  $\hat{\boldsymbol{\beta}}$ , but  $\hat{\boldsymbol{\beta}}$  is unique if and only if  $X$  has full column rank equal to  $p \leq n$ , and then  $\hat{\boldsymbol{\beta}} = \text{OLSE}(\boldsymbol{\beta}) = (X^T X)^{-1} X^T \mathbf{y} = X^\dagger \mathbf{y}$ , where  $X^\dagger$  is the Moore–Penrose inverse of  $X$ . The covariance matrix  $\text{var}(\hat{\boldsymbol{\beta}}) = \sigma^2 (X^T X)^{-1} X^T V X (X^T X)^{-1}$ .

6. The Watson efficiency  $\phi$  is always positive, and  $\phi \leq 1$  with equality if and only if  $\text{OLSE}(\beta) = \text{BLUE}(\beta)$ .
7. [DLL02, p. 477], [Gus97, p. 67] *Bloomfield–Watson–Knott Inequality*. The Watson efficiency

$$\phi = \frac{\det^2(X^T X)}{\det(X^T V X) \cdot \det(X^T V^{-1} X)} \geq \prod_{i=1}^m \frac{4\lambda_i \lambda_{n-i+1}}{(\lambda_i + \lambda_{n-i+1})^2},$$

for all  $n \times p$  model matrices  $X$  with full column rank  $p$ . Here  $m = \min(p, n - p)$  and  $\lambda_1 \geq \dots \geq \lambda_n$  denote the necessarily positive eigenvalues of the  $n \times n$  positive definite covariance matrix  $V$ . The ratios  $4\lambda_i \lambda_{n-i+1}/(\lambda_i + \lambda_{n-i+1})^2$  in the lower bound for the Watson efficiency are the squared *antieigenvalues* of the covariance matrix  $V$ .

8. [DLL02, p. 454] Let  $p = 1$  and set the  $n \times 1$  model matrix  $X = \mathbf{x}$ . Then the Bloomfield–Watson–Knott Inequality is the *Kantorovich Inequality* (or *Frucht–Kantorovich Inequality*):

$$\frac{(\mathbf{x}^T \mathbf{x})^2}{\mathbf{x}^T V \mathbf{x} \cdot \mathbf{x}^T V^{-1} \mathbf{x}} \geq \frac{4\lambda_1 \lambda_n}{(\lambda_1 + \lambda_n)^2},$$

where  $\lambda_1$  and  $\lambda_n$  are, respectively, the largest and smallest eigenvalues of the  $n \times n$  positive definite covariance matrix  $V$ .

9. The Bloomfield–Watson efficiency

$$\begin{aligned} \psi &= \frac{1}{2} \|HV - VH\|^2 = \|HVM\|^2 = \text{tr}(HVMVH) = \text{tr}(HVMV) \\ &= \text{tr}(HV^2 - HVHV) = \text{tr}(HV^2) - \text{tr}((HV)^2) \geq 0, \end{aligned}$$

with equality if and only if  $\text{OLSE}(\beta) = \text{BLUE}(\beta)$  if and only if the Watson efficiency  $\phi = 1$ .

10. [DLL02, p. 473] *The Bloomfield–Watson Trace Inequality*. Let  $A$  be a nonrandom symmetric  $n \times n$  matrix, not necessarily positive semidefinite. Then for all the nonrandom matrices  $U \in \mathbb{R}^{n \times p}$  that satisfy  $U^T U = I_p$ :

$$\text{tr}(U^T A^2 U) - \text{tr}((U^T A U)^2) \leq \frac{1}{4} \sum_{i=1}^{\min(p, n-p)} (\alpha_i - \alpha_{n-i+1})^2,$$

where  $\alpha_1 \geq \dots \geq \alpha_n$  denote the eigenvalues of the  $n \times n$  matrix  $A$ .

11. The Bloomfield–Watson efficiency

$$\psi = \text{tr}(HV^2) - \text{tr}((HV)^2) \leq \frac{1}{4} \sum_{i=1}^{\min(p, n-p)} (\lambda_i - \lambda_{n-i+1})^2,$$

for all  $n \times n$  hat matrices  $H$  with rank  $p$  (and so for all  $n \times p$  model matrices  $X$  with full column rank  $p$ ). Here,  $\lambda_1 \geq \dots \geq \lambda_n$  denote the necessarily positive eigenvalues of the  $n \times n$  positive definite covariance matrix  $V$ .

12. The  $n \times n$  intraclass correlation matrix  $R_{\text{ic}} = (1 - \rho)I_n - \rho \mathbf{1}_n \mathbf{1}_n^T$  has eigenvalues  $1 - \rho$  with multiplicity  $n - 1$  and  $1 + \rho(n - 1)$  with multiplicity 1, and so  $R_{\text{ic}}$  is singular if and only if  $\rho = -1/(n - 1)$  or  $\rho = 1$ .
13. The intraclass correlation coefficient  $\rho$  is such that  $-1/(n - 1) \leq \rho \leq 1$  and the  $n \times n$  intraclass correlation matrix is positive definite if and only if  $-1/(n - 1) < \rho < 1$ .
14. The inverse of the  $n \times n$  positive definite intraclass correlation matrix

$$((1 - \rho)I_n - \rho \mathbf{1}_n \mathbf{1}_n^T)^{-1} = \frac{1}{1 - \rho} \left( I_n - \frac{\rho}{1 + \rho(n - 1)} \mathbf{1}_n \mathbf{1}_n^T \right).$$

15. *Gauss–Markov Theorem* (or *Gauß–Markov Theorem*). In the full-rank model  $\{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$ , the generalized least squares estimator  $\tilde{\boldsymbol{\beta}} = \text{GLSE}(\boldsymbol{\beta}) = (X^T V^{-1} X)^{-1} X^T V^{-1} \mathbf{y} = \text{BLUE}(\boldsymbol{\beta})$ . In the full-rank model  $\{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 I\}$ , the ordinary least-squares estimator  $\text{OLSE}(\boldsymbol{\beta}) = \hat{\boldsymbol{\beta}} = (X^T X)^{-1} X^T \mathbf{y} = X^+ \mathbf{y} = \text{BLUE}(\boldsymbol{\beta})$ .
16. In the model  $\{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$ , where  $V$  is positive definite, but with  $X$  possibly with less than full column rank, the

$$\text{BLUE}(X\boldsymbol{\beta}) = X(X^T V^{-1} X)^{-} X^T V^{-1} \mathbf{y}.$$

17. [Sea97, §5.4] Let the matrix  $K \in \mathbb{R}^{k \times p}$ . Then  $K\boldsymbol{\beta}$  is estimable  $\iff \exists$  matrix  $A \in \mathbb{R}^{n \times k}$ :  $K^T = X^T A \iff \text{range}(K^T) \subseteq \text{range}(X^T) \iff K\tilde{\boldsymbol{\beta}}$  is invariant for any choice of  $\tilde{\boldsymbol{\beta}} = (X^T X)^{-} X^T \mathbf{y}$ .
18. [Rao73b, p. 282] Consider the general linear model  $\{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$ , where  $X$  and  $V$  need not be of full rank. Let the matrix  $G \in \mathbb{R}^{n \times n}$ . Then  $G\mathbf{y} = \text{BLUE}(X\boldsymbol{\beta}) \iff G[X | VM] = [X | \mathbf{0}]$ , where the residual matrix  $M = I - H$ . Let the matrix  $A \in \mathbb{R}^{k \times n}$  and the matrix  $K \in \mathbb{R}^{k \times p}$ . Then the corresponding condition for  $A\mathbf{y}$  to be the BLUE of an estimable parametric function  $K\boldsymbol{\beta}$  is  $A[X | VM] = [K | \mathbf{0}]$ .
19. Let  $G_1$  and  $G_2$  both be  $n \times n$ . If  $G_1 \mathbf{y}$  and  $G_2 \mathbf{y}$  are two BLUEs of  $X\boldsymbol{\beta}$  under the model  $\{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$ , then  $G_1 \mathbf{y} = G_2 \mathbf{y}$  for all  $\mathbf{y} \in \text{range}([X | V])$ . The matrix  $G$  yielding the BLUE is unique if and only if  $\text{range}([X | V]) = \mathbb{R}^n$ .
20. Every linear zero function can be written as  $\mathbf{b}^T M\mathbf{y}$  for some nonrandom  $\mathbf{b} \in \mathbb{R}^n$ . Let the matrix  $G \in \mathbb{R}^{n \times n}$ . Then an unbiased estimator  $G\mathbf{y} = \text{BLUE}(X\boldsymbol{\beta})$  if and only if  $G\mathbf{y}$  is uncorrelated with every linear zero function.
21. [Rao71] Let the matrix  $A \in \mathbb{R}^{n \times n}$ . Then the linear estimator  $A\mathbf{y} = \text{BLUE}(X\boldsymbol{\beta})$  under the model  $\{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$  if and only if there exists a matrix  $\Lambda$  so that  $A$  is a solution to *Pandora's box*

$$\begin{bmatrix} V & X \\ X^T & \mathbf{0} \end{bmatrix} \begin{bmatrix} A^T \\ \Lambda \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ X^T \end{bmatrix}.$$

22. [Rao71] Let the  $(n + p) \times (n + p)$  matrix  $B$  be defined as any generalized inverse:

$$B = \begin{bmatrix} V & X \\ X^T & \mathbf{0} \end{bmatrix}^- = \begin{bmatrix} B_1 & B_2 \\ B_3 & -B_4 \end{bmatrix}.$$

Let  $\mathbf{k}^T \boldsymbol{\beta}$  be estimable; then the  $\text{BLUE}(\mathbf{k}^T \boldsymbol{\beta}) = \mathbf{k}^T \tilde{\boldsymbol{\beta}} = \mathbf{k}^T B_2^T \mathbf{y} = \mathbf{k}^T B_3 \mathbf{y}$ , the variance  $\text{var}(\mathbf{k}^T \tilde{\boldsymbol{\beta}}) = \sigma^2 \mathbf{k}^T B_4 \mathbf{k}$ , and the quadratic form  $\mathbf{y}^T B_1 \mathbf{y} / f$  is an unbiased estimator of  $\sigma^2$  with  $f = \text{rank}([V | X]) - \text{rank}(X)$ .

23. [PS89] In the model  $\{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$  with no rank assumptions, the  $\text{OLSE}(X\boldsymbol{\beta}) = \text{BLUE}(X\boldsymbol{\beta})$  if and only if any one of the following equivalent conditions holds:
- $HV = VH$ .
  - $HV = HVH$ .
  - $HVM = \mathbf{0}$ .
  - $X^T VL = \mathbf{0}$ , where the  $n \times l$  matrix  $L$  has  $\text{range}(L) = \text{range}(M)$ .
  - $\text{range}(VX) \subseteq \text{range}(X)$ .
  - $\text{range}(VX) = \text{range}(X) \cap \text{range}(V)$ .
  - $HVH \leq V$ , i.e.,  $V - HVH$  is positive semidefinite.
  - $\text{rank}(V - HVH) = \text{rank}(V) - \text{rank}(HVH)$ .
  - $\text{rank}(V - HVH) = \text{rank}(V) - \text{rank}(VX)$ .
  - $\text{range}(X)$  has a basis consisting of  $r$  eigenvectors of  $V$ , where  $r = \text{rank}(X)$ .
  - $V$  can be expressed as  $V = \alpha I + XAX^T + LBL^T$ , where  $\alpha \in \mathbb{R}$ ,  $\text{range}(L) = \text{range}(M)$ , and the  $p \times p$  matrices  $A$  and  $B$  are symmetric, and such that  $V$  is positive semidefinite.

More conditions can be obtained by replacing  $V$  with its Moore–Penrose inverse  $V^\dagger$  and the hat matrix  $H$  with the residual matrix  $M = I - H$ .

24. Suppose that the positive definite covariance matrix  $V$  has  $h$  distinct eigenvalues:  $\lambda_{\{1\}} > \lambda_{\{2\}} > \cdots > \lambda_{\{h\}} > 0$  with multiplicities  $m_1, \dots, m_h$ ,  $\sum_{i=1}^h m_i = n$ , and with associated orthonormalized sets of eigenvectors  $U_{\{1\}}, \dots, U_{\{h\}}$ , respectively,  $n \times m_1, \dots, n \times m_h$ . Then  $\text{OLSE}(X\beta) = \text{BLUE}(X\beta)$  if and only if any one of the following equivalent conditions holds:
- $\text{rank}(U_{\{1\}}^T X) + \cdots + \text{rank}(U_{\{h\}}^T X) = \text{rank}(X)$ .
  - $U_{\{i\}}^T H U_{\{i\}} = (U_{\{i\}}^T H U_{\{i\}})^2$  for all  $i = 1, \dots, h$ .
  - $U_{\{i\}}^T H U_{\{j\}} = \mathbf{0}$  for all  $i \neq j$ ;  $i, j = 1, \dots, h$ .
25. [Rao73b] Let the  $p \times p$  matrix  $U$  be such that the  $n \times n$  matrix  $W = V + XU X^T$  has  $\text{range}(W) = \text{range}([X \mid V])$ . Then the  $\text{BLUE}(X\beta) = X(X^T W^- X)^- X^T W^- \mathbf{y}$ .
26. When  $V$  is nonsingular, the  $n \times n$  matrix  $G$  such that  $G\mathbf{y}$  is the BLUE of  $X\beta$  is unique, but when  $V$  is singular this may not be so. However, the numerical value of  $\text{BLUE}(X\beta)$  is unique with probability 1.
27. [SJ03, §7.4] The residual vector associated with the  $\text{BLUE}(X\beta)$  is

$$\tilde{\mathbf{e}} = \mathbf{y} - X\tilde{\beta} = VM(MVM)^- M\mathbf{y} = M\mathbf{y} + HVM(MVM)^- M\mathbf{y},$$

which is invariant (unique) with respect to choice of generalized inverse  $(MVM)^-$ . The weighted sum of squares of BLUE residuals, which is needed when estimating  $\sigma^2$ , can be written as  $(\mathbf{y} - X\tilde{\beta})^T V^-(\mathbf{y} - X\tilde{\beta}) = \tilde{\mathbf{e}}^T V^- \tilde{\mathbf{e}} = \mathbf{y}^T M(MVM)^- M\mathbf{y}$ .

### Examples:

1. Let  $n = 3$  and  $p = 2$  with the model matrix  $X = \begin{bmatrix} 1 & 1 \\ 1 & 0 \\ 1 & -1 \end{bmatrix}$ . Then  $X$  has full column rank equal to 2, the matrix  $X^T X$  is nonsingular, and the hat matrix is

$$H = X(X^T X)^- X^T = X(X^T X)^{-1} X^T = \frac{1}{6} \begin{bmatrix} 5 & 2 & -1 \\ 2 & 2 & 2 \\ -1 & 2 & 5 \end{bmatrix}$$

with  $\text{rank}(H) = \text{tr}(H) = 2$ . The  $\text{OLSE}(\beta)$  is

$$\hat{\beta} = (X^T X)^{-1} X^T \mathbf{y} = \begin{bmatrix} \frac{1}{3}(y_1 + y_2 + y_3) \\ \frac{1}{2}(y_1 - y_3) \end{bmatrix},$$

where  $\mathbf{y} = [y_1, y_2, y_3]^T$ . The vector of OLS residuals is

$$M\mathbf{y} = \frac{1}{6} \begin{bmatrix} 1 & -2 & 1 \\ -2 & 4 & -2 \\ 1 & -2 & 1 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \end{bmatrix} = \frac{1}{6}(y_1 - 2y_2 + y_3) \begin{bmatrix} 1 \\ -2 \\ 1 \end{bmatrix}$$

with residual sum of squares  $SSE = (y_1 - 2y_2 + y_3)^2/6$ .

Now let the variance  $\sigma^2 = 1$  and let the covariance matrix

$$V = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \delta & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

with  $\delta > 0$ . Then  $V$  is positive definite and

$$\text{BLUE}(\boldsymbol{\beta}) = \text{GLSE}(\boldsymbol{\beta}) = \tilde{\boldsymbol{\beta}} = \begin{bmatrix} \frac{1}{2\delta+1}(\delta y_1 + y_2 + \delta y_3) \\ \frac{1}{2}(y_1 - y_3) \end{bmatrix},$$

while the covariance matrices are

$$\text{var}(\tilde{\boldsymbol{\beta}}) = \begin{bmatrix} \frac{\delta}{2\delta+1} & 0 \\ 0 & \frac{1}{2} \end{bmatrix}, \quad \text{var}(\hat{\boldsymbol{\beta}}) = \begin{bmatrix} \frac{\delta+2}{9} & 0 \\ 0 & \frac{1}{2} \end{bmatrix}.$$

Hence, the Watson efficiency

$$\phi = \frac{9\delta}{(2\delta+1)(\delta+2)} \leq 1$$

with equality if and only if  $\delta = 1$ . As  $\delta \rightarrow 0$  or  $\delta \rightarrow \infty$ , the Watson efficiency  $\phi \rightarrow 0$ .

Since the eigenvalues of  $V$  here are 1 (multiplicity 2) and  $\delta$  (multiplicity 1), we find that the lower bound for  $\phi$  in the Bloomfield–Watson–Knott Inequality [here,  $m = \min(p, n - p) = \min(2, 1) = 1$ ] is equal to  $4\delta/(1+\delta)^2$ , and it is easy to show that this is less than  $9\delta/((2\delta+1)(\delta+2))$  (unless  $\delta = 1$ , and then both these ratios are equal to 1).

The Bloomfield–Watson efficiency

$$\psi = \frac{2}{9}(1 - \delta)^2 \geq 0$$

with equality if and only if  $\delta = 1$ . As  $\delta \rightarrow 0$  the Bloomfield–Watson efficiency  $\psi \rightarrow 2/9$ , and as  $\delta \rightarrow \infty$  the Bloomfield–Watson efficiency  $\psi \rightarrow \infty$ . We note that when  $\delta = 0$ , then  $\Sigma$  is singular, but  $\psi$  is well-defined and equal to  $2/9$ . We find that the upper bound for  $\psi$  in the Bloomfield–Watson Trace Inequality is  $(1 - \delta)^2/4$  and certainly  $(1 - \delta)^2/4 \geq 2(1 - \delta)^2/9$  with equality if and only if  $\delta = 1$ .

2. Let  $n = 3$  and  $p = 1$  with the model matrix  $X = \mathbf{x} = \begin{bmatrix} 1 \\ 2 \\ 3 \end{bmatrix}$  and with  $\boldsymbol{\beta} = \beta$ , a scalar. The hat matrix

$$H = X(X^T X)^{-1} X^T = \frac{1}{\mathbf{x}^T \mathbf{x}} \mathbf{x} \mathbf{x}^T = \frac{1}{14} \begin{bmatrix} 1 & 2 & 3 \\ 2 & 4 & 6 \\ 3 & 6 & 9 \end{bmatrix}$$

and so

$$\hat{\boldsymbol{\beta}} = \text{OLSE}(\boldsymbol{\beta}) = \frac{\mathbf{x}^T \mathbf{y}}{\mathbf{x}^T \mathbf{x}} = \frac{y_1 + 2y_2 + 3y_3}{14},$$

where the realization  $\mathbf{y} = [y_1, y_2, y_3]^T$ .

Let the covariance matrix have intraclass correlation structure:

$$V = \begin{bmatrix} 1 & \rho & \rho \\ \rho & 1 & \rho \\ \rho & \rho & 1 \end{bmatrix}$$

with  $-1/2 < \rho < 1$ . Then  $V$  is positive definite and its inverse

$$V^{-1} = \frac{1}{(1 - \rho)(1 + 2\rho)} \begin{bmatrix} 1 + \rho & -\rho & -\rho \\ -\rho & 1 + \rho & -\rho \\ -\rho & -\rho & 1 + \rho \end{bmatrix}.$$

And so

$$\tilde{\beta} = \text{BLUE}(\beta) = \text{GLSE}(\beta) = \frac{\mathbf{x}^T V^{-1} \mathbf{y}}{\mathbf{x}^T V^{-1} \mathbf{x}} = \frac{(1 - 4\rho)y_1 + 2(1 - \rho)y_2 + 3y_3}{6(1 - \rho)}.$$

The variances are (with  $\sigma^2 = 1$ ):

$$\text{var}(\tilde{\beta}) = \frac{1}{\mathbf{x}^T V^{-1} \mathbf{x}} = \frac{(1 - \rho)(1 + 2\rho)}{2(7 - 4\rho)}; \quad \text{var}(\hat{\beta}) = \frac{\mathbf{x}^T V \mathbf{x}}{(\mathbf{x}^T \mathbf{x})^2} = \frac{7 + 11\rho}{98},$$

and so the Watson efficiency

$$\phi = \frac{\text{var}(\tilde{\beta})}{\text{var}(\hat{\beta})} = \frac{49(1 - \rho)(1 + 2\rho)}{(7 - 4\rho)(7 + 11\rho)} \rightarrow 0$$

as  $\rho \rightarrow -1/2$  or as  $\rho \rightarrow 1$ . As  $\rho \rightarrow 0$  the Watson efficiency  $\phi \rightarrow 1$ .

Since the eigenvalues of  $V$  here are  $1 - \rho$  (multiplicity 2) and  $1 + 2\rho$  (multiplicity 1), we find that the lower bound for  $\phi$  in the Bloomfield–Watson–Knott Inequality (which is now the Kantorovich Inequality) is  $4(1 - \rho)(1 + 2\rho)/(2 + \rho)^2$  and it is easy to show that this is less than  $\phi = 49(1 - \rho)(1 + 2\rho)/((7 - 4\rho)(7 + 11\rho))$  (unless  $\rho = 0$  and then both these ratios are equal to 1).

The Bloomfield–Watson efficiency  $\psi = 54\rho^2/49$ , which is well defined for all  $\rho$ ; when  $\rho = -1/2$ , then  $\psi = 27/98$  and when  $\rho = 1$ , then  $\psi = 54/49$ . We find that the upper bound for  $\psi$  in the Bloomfield–Watson Trace Inequality is  $9\rho^2/4$  and certainly  $9\rho^2/4 \geq \psi = 54\rho^2/49$ , with equality if and only if  $\rho = 0$ .

3. [DLL02, p. 475] Let  $A$  be a nonrandom symmetric  $n \times n$  matrix, not necessarily positive semidefinite, and let the nonrandom vector  $\mathbf{u} = [u_1, \dots, u_n]^T$  be such that  $\mathbf{u}^T \mathbf{u} = 1$ . Then from the Bloomfield–Watson Trace Inequality with  $U = \mathbf{u}$ , we obtain the special case

$$\mathbf{u}^T A^2 \mathbf{u} - (\mathbf{u}^T A \mathbf{u})^2 \leq \frac{1}{4}(\alpha_1 - \alpha_n)^2,$$

where  $\alpha_1$  and  $\alpha_n$  are, respectively, the largest and smallest eigenvalues of  $A$ . Now let  $a_1, \dots, a_n$  denote  $n$  nonrandom scalars, not necessarily all positive, and let  $\bar{a} = \sum_{i=1}^n a_i/n$ . Then the Popoviciu–Nair Inequality

$$\frac{1}{n} \sum_{i=1}^n (a_i - \bar{a})^2 \leq \frac{1}{4}(a_{\max} - a_{\min})^2$$

follows directly from the special case above of the Bloomfield–Watson Trace Inequality with  $\mathbf{u} = \mathbf{1}/\sqrt{n}$  and  $A = \text{diag}\{a_i\}$ .

4. When the covariance matrix  $V$  has intraclass correlation structure, then the  $\text{OLSE}(X\beta) = \text{BLUE}(X\beta)$  if and only if  $X^T \mathbf{1}_n = \mathbf{0}$  or  $X\mathbf{f} = \mathbf{1}_n$  for some nonrandom  $p \times 1$  vector  $\mathbf{f}$ , and so  $\text{OLSE}(X\beta) = \text{BLUE}(X\beta)$  when the columns of  $X$  are centered or when  $\mathbf{1}_n \in \text{range}(X)$  as in Example 1

above, where  $X = \begin{bmatrix} 1 & 1 \\ 1 & 0 \\ 1 & -1 \end{bmatrix}$  with first column equal to  $\mathbf{1}_3$ .

5. Let the  $n \times p$  model matrix  $X = [\mathbf{1} \mid X_0]$ , where  $\mathbf{1}$  is the  $n \times 1$  column vector with every entry equal to 1 and  $X_0$  is  $n \times (p - 1)$ . Then the hat matrix associated with  $X$ ,

$$H = \frac{1}{n} \mathbf{1}_n \mathbf{1}_n^T + C_n X_0 (X_0^T C_n X_0)^- X_0^T C_n$$

coincides with the hat matrix associated with  $X_c = [\mathbf{1}_n \mid C_n X_0]$ , since  $X_c = XQ$ , with the  $p \times p$  matrix  $Q = \begin{bmatrix} 1 & -\mathbf{q}^T \\ \mathbf{0} & I_{p-1} \end{bmatrix}$  for some  $\mathbf{q}$ .

When  $p = 2$ , we may write  $X_0 = \mathbf{x}$ , an  $n \times 1$  vector, and if  $X$  now has rank equal to 2, then  $\mathbf{x}^T C_n \mathbf{x} > 0$  and the hat matrix

$$H = \frac{1}{n} \mathbf{1}_n \mathbf{1}_n^T + \frac{1}{\mathbf{x}^T C_n \mathbf{x}} C_n \mathbf{x} \mathbf{x}^T C_n = \frac{1}{n} J_n + \frac{1}{\mathbf{x}^T C_n \mathbf{x}} C_n \mathbf{x} \mathbf{x}^T C_n.$$

And so the quadratic forms

$$\mathbf{y}^T H \mathbf{y} = n \bar{y}^2 + \frac{(\mathbf{x}^T C_n \mathbf{y})^2}{\mathbf{x}^T C_n \mathbf{x}}, \quad \mathbf{y}^T M \mathbf{y} = \mathbf{y}^T C_n \mathbf{y} + \frac{(\mathbf{x}^T C_n \mathbf{y})^2}{\mathbf{x}^T C_n \mathbf{x}},$$

where  $\bar{y} = \sum_{i=1}^n y_i / n = \mathbf{1}_n^T \mathbf{y} / n$ .

Vectors and matrices arise naturally in the analysis of statistical data and we have seen this in Chapter 52. For example, suppose we take a random sample of  $n$  females and measure their heights  $x_i$  ( $i = 1, 2, \dots, n$ ), giving us the vector  $\mathbf{x} = [x_1, x_2, \dots, x_n]^T$ . We can treat  $\mathbf{x}$  as simply a random vector, which can give rise to different values depending on the sample chosen, or as a vector of observed values (the data) taken on by the random vector from which we calculate a statistic like a sample mean (average). We use the former approach when we want to make inferences about the female population. In this case, we find that the value of a given  $x_i$  will depend on how it varies across the population, and this is described by its statistical “distribution,” which is defined by a univariate function of one variable called a probability density function (pdf). For example,  $x_i$  may follow the well-known normal distribution, which seems to apply to many naturally occurring measurements. This distribution has a probability density function totally characterized by two (unknown) parameters, the population mean  $\mu$  and the population variance  $\sigma^2$ , where  $\sigma$  is the standard deviation; we write  $x_i \sim N_1(\mu, \sigma^2)$ , where “ $\sim$ ” means “distributed as.” (Throughout this chapter  $\sigma$  will always refer to a standard deviation and not to a singular value.) When the sample is random, the choice of any female does not affect the choice of any other, so that technically we say that the  $x_i$  are statistically independent and they all have the same distribution.

Three important aspects of statistical inference are: (1) estimating  $\mu$  from the data and deriving the distributional properties of the estimate from the assumed underlying pdf; (2) finding a so-called confidence interval for  $\mu$ , which is an interval containing the true value of  $\mu$  with a given probability, e.g., 0.95 or, when typically expressed as a percentage, 95%; and (3) testing a hypothesis (called the null hypothesis  $H_0$ ) about whether  $\mu$  is equal to some predetermined value  $\mu_0$ , say. Symbolically, we write  $H_0 : \mu = \mu_0$ . To test  $H_0$ , we need to have a test statistic and be able to derive its distribution when  $H_0$  is true and when

it is false, called the noncentral distribution in the latter case. Noncentral distributions are usually quite complex, but they have a role in determining how good a test is in detecting departures from the null hypothesis.

In multivariate analysis we are interested in measuring not just a single characteristic or variable on each female, but we may also want to record weight, income, blood pressure, and so on, so that each  $x_i$  gets replaced by a  $d$ -dimensional vector  $\mathbf{x}_i$  of  $d$  variables. Then  $\mathbf{x}$  from the sample of recorded heights gets replaced by a matrix  $X$  with rows  $\mathbf{x}_i^T$ . In this case the probability density function for  $\mathbf{x}_i$  is said to be multivariate and the population mean is now a vector  $\boldsymbol{\mu}$ , say. We can look at  $X$  as either a matrix of numbers, or a random matrix, which we use for carrying out statistical inferences. In doing this, the univariate normal distribution extends naturally to the multivariate normal distribution, which has a pdf totally characterized by its mean  $\boldsymbol{\mu}$  and its covariance matrix  $\text{var}(\mathbf{x}) = \Sigma$ . One can then derive other distributions based on various functions of  $X$ , which can then be used for inference.

The vectors  $\mathbf{x}_i$  can be regarded as a cluster of points in  $\mathbb{R}^d$ . Such a set of points can also come from sampling a mixed population of men and women so that there would be two overlapping clusters. Alternatively, the population of females could be a mixture of races, each with its own characteristics, leading to several overlapping clusters. In order to study such clusters, we need techniques to somehow reduce the dimension of the data (hopefully, to two dimensions) in some optimal fashion, but still retain as much of the original variation as possible. We will introduce just three dimension-reducing techniques below. The first method, called principal component analysis, is used for a single cluster. The second method, called discriminant coordinates, is used for several clusters and the reduction in dimension is carried out to maximize group separation. The third method, called canonical variates, is also used for a single cluster, but utilizes the internal variation within the vectors. Looking at how one variable within a vector depends on the other variables lends itself to a range of other techniques, such as multivariate linear regression where we might compare the internal relationships in one cluster with those in others. For example, comparing how blood pressure depends on other variables for both males and females.

We finally introduce just one other topic called metric multidimensional scaling. Instead of having observations on  $n$  people or objects, we simply have measures of similarity or dissimilarity between each pair of objects. The challenge then is to try and represent these objects as a cluster in a low-dimensional space so that the inter-point Euclidean distances will closely reproduce the dissimilarity measures. Once we have the cluster we can then examine it to try and uncover any underlying structure or clustering of the objects.

It is hoped that these few applications will demonstrate the richness of the subject and its interplay between statistics and matrices. In this chapter we assume some of the basic statistical ideas defined in Chapter 52. However, there has to be a change in notation as we now need to continually distinguish between random and nonrandom vectors and matrices.

## 53.1 Data Matrix

---

### Notation:

The latter part of the alphabet from  $u$  to  $z$ , upper or lower case, together with  $Q$  we reserve for random quantities, and the remainder of the alphabet for nonrandom quantities. All quantities in this section are real, though in practice some of the theory can be extended to complex quantities, as, for example, in the theory of time series.

### Definitions:

If  $\mathbf{w} = [\mathbf{y}^T, \mathbf{z}^T]^T$  is a random vector, then  $\mathbf{y}$  and  $\mathbf{z}$  are said to be **uncorrelated** if and only if their cross-covariance  $\text{cov}(\mathbf{y}, \mathbf{z}) = \mathbf{0}$ . We say that  $\mathbf{y}$  and  $\mathbf{z}$  are **statistically independent** if and only if the probability density function (pdf) of  $\mathbf{w}$  is the product of the pdfs of  $\mathbf{y}$  and  $\mathbf{z}$ .

Let  $X = [x_{ij}] = \begin{bmatrix} \mathbf{x}_1^T \\ \mathbf{x}_2^T \\ \dots \\ \mathbf{x}_n^T \end{bmatrix} = [\mathbf{x}^{(1)}, \mathbf{x}^{(2)}, \dots, \mathbf{x}^{(d)}]$  be an  $n \times d$  matrix of random variables with rows  $\mathbf{x}_i^T$  such

that all  $\mathbf{x}_i$  have the same covariance matrix  $\Sigma$  and are uncorrelated, i.e.,  $\text{cov}(\mathbf{x}_r, \mathbf{x}_s) = \delta_{rs} \Sigma$ , where  $\delta_{rs} = 1$  for  $r = s$  and  $\delta_{rs} = 0$  for  $r \neq s$ . We call a matrix with the above properties a **data matrix**. As mentioned in the introduction, the  $\mathbf{x}_i$  often constitute a random sample, which we now formally define. A **random sample** of vectors  $\mathbf{x}_i$  ( $i = 1, 2, \dots, n$ ) of size  $n$  consists of  $n$  random vectors that are **independently and identically distributed (i.i.d.)**, that is, they are statistically independent of each other and have the same pdf. When this is the case, we see from the data matrix above that the  $n$  elements of  $\mathbf{x}^{(j)}$  form a random sample from the  $j$ th characteristic or variable, being just the  $j$ th elements in each  $\mathbf{x}_i$ . However,  $\mathbf{x}^{(j)}$  and  $\mathbf{x}^{(k)}$  ( $j \neq k$ ) can be correlated.

The **moment generating function** or m.g.f. of any random vector  $\mathbf{x}$  is defined to be  $M_{\mathbf{x}}(\mathbf{t}) = E(e^{\mathbf{t}^T \mathbf{x}})$ . It can be used for finding such things as the mean and covariance matrix, or the distribution of related random variables.

**Facts:**

1. For a random variable  $x$ ,  $M_x(t) = E(e^{xt}) = \sum_{r=0}^{\infty} E(x^r) \frac{t^r}{r!}$ . The coefficient of  $\frac{t^r}{r!}$  in the power series expansion of  $M_x(t)$  gives us  $E(x^r)$  from which we can get  $\mu = E(x)$  and  $\text{var}(x) = E(x^2) - \mu^2$ .
2. Statistical independence implies zero covariance but not generally vice versa except for one notable exception, the multivariate normal distribution (see next section).

## 53.2 Multivariate Normal Distribution

---

**Definitions:**

Let  $\mathbf{x} = [x_i] = [x_1, x_2, \dots, x_d]^T$  be a  $d \times 1$  random vector with mean  $\boldsymbol{\mu}$  and positive definite covariance matrix  $\Sigma$ . Then  $\mathbf{x}$  is said to follow a **(nonsingular) multivariate normal distribution** when its pdf is

$$f(\mathbf{x} : \boldsymbol{\mu}, \Sigma) = (2\pi)^{-d/2} (\det \Sigma)^{-1/2} \exp\{-\frac{1}{2}(\mathbf{x} - \boldsymbol{\mu})^T \Sigma^{-1/2}(\mathbf{x} - \boldsymbol{\mu})\},$$

where  $-\infty < x_j < \infty$ ,  $j = 1, 2, \dots, d$ . We write  $\mathbf{x} \sim N_d(\boldsymbol{\mu}, \Sigma)$ . When  $d = 1$  we have the univariate normal distribution. When  $\Sigma$  is singular, the pdf of  $\mathbf{x}$  does not exist but it can be defined via a transformation  $\mathbf{x} = A\mathbf{y}$  where  $\mathbf{y}$  does have a nonsingular distribution. This is mentioned further below.

The **noncentral  $\chi^2$ -distribution** with  $p$  degrees of freedom and noncentrality parameter  $\delta$ , denoted by  $\chi_{p,\delta}^2$ , is the distribution of  $\mathbf{x}^T \mathbf{x}$  when  $\mathbf{x} \sim N_p(\boldsymbol{\mu}, I_p)$  and  $\delta = \boldsymbol{\mu}^T \boldsymbol{\mu}$ . The distribution is said to be **central** whenever  $\delta = 0$ , and we denote it by  $\chi_p^2$ .

The **noncentral F-distribution** with  $m, n$  degrees of freedom and noncentrality parameter  $\delta$ , denoted by  $F(m, n; \delta)$ , is the distribution of the so-called **F-ratio**  $F = \frac{u/m}{v/n}$ , where  $u \sim \chi_{m,\delta}^2$ ,  $v \sim \chi_n^2$ , and  $u$  and  $v$  are independent. The distribution is **central** whenever  $\delta = 0$  and we then write  $F \sim F(m, n)$ .

**Facts:**

All the following facts except those with a specific reference can be found in [And03, Ch. 2], [Rao73, Sec. 8a], or [SL03, Ch. 1].

We can extend our definition to include the singular multivariate normal distribution using one of the first two facts below as a definition, each of which includes both the nonsingular and singular cases. When we write  $\mathbf{x} \sim N_d(\boldsymbol{\mu}, \Sigma)$ , we include both possibilities unless otherwise stated.

1. Assuming for the trivial case that  $y \sim N_1(b, 0)$  means  $y = b$  with probability 1, then the random  $d \times 1$  vector  $\mathbf{x}$  follows a multivariate normal distribution if and only if  $y = \mathbf{a}^T \mathbf{x}$  is univariate normal for all  $d \times 1$  vectors  $\mathbf{a}$ .
2. A random  $d \times 1$  vector  $\mathbf{x}$  with mean  $\boldsymbol{\mu}$  and covariance matrix  $\Sigma$  follows a multivariate normal distribution of rank  $m \leq d$  when it has the same distribution as  $A\mathbf{z} + \boldsymbol{\mu}$ , where  $A$  is any  $d \times m$  matrix satisfying  $\Sigma = AA^T$  and  $\mathbf{z} \sim N_m(\mathbf{0}, I_m)$ .
3. Given  $\mathbf{x} \sim N_d(\boldsymbol{\mu}, \Sigma)$ , then the m.g.f. of  $\mathbf{x}$  is  $M_{\mathbf{x}}(\mathbf{t}) = e^{\mathbf{t}^T \boldsymbol{\mu} + \frac{1}{2} \mathbf{t}^T \Sigma \mathbf{t}}$ . When  $\Sigma$  is positive definite, this m.g.f. uniquely determines the nonsingular multivariate normal distribution.
4. Given  $\mathbf{x} \sim N_d(\boldsymbol{\mu}, \Sigma)$  and  $A$   $m \times d$ , then  $A\mathbf{x} \sim N_m(A\boldsymbol{\mu}, A\Sigma A^T)$ . The distribution is nonsingular if and only if  $A\Sigma$  has full row rank  $m$  ( $m \leq d$ ), which is assured when  $\Sigma$  is positive definite and  $A$  has rank  $m$ .
5. Any subset of the components of a multivariate normal random variable is multivariate normal.
6. If the cross-covariance matrix of any two vectors which contain disjoint subsets of  $\mathbf{x}$  is zero, then the two vectors are statistically independent.
7. If the cross-covariance matrix  $\text{cov}(A\mathbf{x}, B\mathbf{x}) = \mathbf{0}$ , then  $A\mathbf{x}$  and  $B\mathbf{x}$  are statistically independent.
8. If  $\Sigma$  is positive definite, then  $(\mathbf{x} - \boldsymbol{\mu})^T \Sigma^{-1} (\mathbf{x} - \boldsymbol{\mu}) \sim \chi_d^2$ , the central  $\chi^2$ -distribution with  $d$  degrees of freedom.
9. Let  $\mathbf{x}$  be an  $n \times 1$  random vector with  $E(\mathbf{x}) = \boldsymbol{\mu}$  and  $\text{var}(\mathbf{x}) = \Sigma$ , and having any distribution. If  $A$  is any symmetric  $n \times n$  matrix, then  $E[(\mathbf{x} - \mathbf{a})^T A (\mathbf{x} - \mathbf{a})] = \text{tr}(A\Sigma) + (\boldsymbol{\mu} - \mathbf{a})^T A (\boldsymbol{\mu} - \mathbf{a})$ .
10. Let  $\mathbf{x} = [x_i]$  be an  $n \times 1$  random vector with  $E(x_i) = \theta_i$  and  $\mu_r = E(x_i - \theta_i)^r$ ;  $r = 2, 3, 4$ . If  $A$  is any  $n \times n$  symmetric matrix and  $\mathbf{a}$  is the column vector of the diagonal elements of  $A$ , then

$$\text{var}(\mathbf{x}^T A \mathbf{x}) = (\mu_4 - 3\mu_2^2) \mathbf{a}^T \mathbf{a} + 2\mu_2^2 \text{tr} A^2 + 4\mu_2 \boldsymbol{\theta}^T A^2 \boldsymbol{\theta} + 4\mu_3 \boldsymbol{\theta}^T A \mathbf{a}.$$

### Examples:

1. If  $x \sim N_1(0, \sigma^2)$ , then  $M_x(t) = e^{\frac{1}{2} \sigma^2 t^2}$  from Fact 3 above. Since  $\mu = 0$ ,  $\mu_r = E(x^r)$  can be found by expanding  $M_x(t)$  and finding the coefficient of  $t^r/r!$ . For example,  $\mu_2 = \sigma^2$ ,  $\mu_3 = 0$ , and  $\mu_4 = 3\mu_2^2$ .
2. If the  $x_i$  ( $i = 1, 2, \dots, n$ ) are i.i.d. as  $N_1(0, \sigma^2)$ , then by either multiplying pdfs together for independent random variables or using m.g.f.s we find that  $\mathbf{x} \sim N_n(\mathbf{0}, \sigma^2 I_n)$ . Substituting the results from the previous example into Fact 10 we get  $\text{var}(\mathbf{x}^T A \mathbf{x}) = 2\sigma^4 \text{tr} A^2$ .

## 53.3 Inference for the Multivariate Normal

---

### Definitions:

Given a random sample  $\{\mathbf{x}_i\}$  that are i.i.d., from the nonsingular multivariate normal distribution, the **likelihood function** is defined to be the joint pdf of the sample expressed as a function of the unknown parameters, namely,

$$L(\mathbf{u}, \Sigma) = \prod_{i=1}^n f(\mathbf{x}_i; \boldsymbol{\mu}, \Sigma).$$

The parameter estimates that maximize this function are called the **maximum likelihood estimates**. The **sample mean** of the sample is defined to be  $\bar{\mathbf{x}} = \sum_{i=1}^n \mathbf{x}_i/n$ , and is not to be confused with the complex conjugate.

**Facts:**

1. The maximum likelihood estimates of  $\boldsymbol{\mu}$  and  $\Sigma$  are, respectively,  $\hat{\boldsymbol{\mu}} = \bar{\mathbf{x}}$  and  $\hat{\Sigma} = Q/n = \sum_{i=1}^n (\mathbf{x}_i - \bar{\mathbf{x}})(\mathbf{x}_i - \bar{\mathbf{x}})^T/n$ . Here, “ $\hat{\phantom{x}}$ ” denotes “estimate of” in statistics.
2.  $Q = X^T C X$ , where  $X$  is the data matrix previously defined and the centering matrix  $C = I_n - \frac{1}{n} \mathbf{1}\mathbf{1}^T$  is symmetric and idempotent. Also,  $CX = [\mathbf{x}_1 - \bar{\mathbf{x}}, \dots, \mathbf{x}_n - \bar{\mathbf{x}}]^T = \tilde{X}$ , say, and  $Q = \tilde{X}^T \tilde{X}$ .

## 53.4 Principal Component Analysis

---

**Definitions:**

Let  $\mathbf{x}$  be a random  $d$ -dimensional vector with mean  $\boldsymbol{\mu}$  and positive definite covariance matrix  $\Sigma$ . Let  $T = [\mathbf{t}_1, \mathbf{t}_2, \dots, \mathbf{t}_d]$  be an orthogonal matrix such that  $T^T \Sigma T = \Lambda = \text{diag}(\lambda_1, \lambda_2, \dots, \lambda_d)$ , where  $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_d > 0$  are the ordered eigenvalues of  $\Sigma$ . The sum  $\text{tr}\Sigma$  is sometimes called the **total variance**. If  $\mathbf{y} = [y_j] = T^T(\mathbf{x} - \boldsymbol{\mu})$ , then  $y_j = \mathbf{t}_j^T(\mathbf{x} - \boldsymbol{\mu})$  ( $j = 1, 2, \dots, d$ ) is called the  $j$ th **population principal component** of  $\mathbf{x}$ , and  $z_j = \lambda_j^{-1/2} y_j$  is called the  $j$ th **standardized population principal component**.

In practice,  $\boldsymbol{\mu}$  and  $\Sigma$  are unknown and have to be estimated from a sample  $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$ . Assuming that the underlying distribution is multivariate normal we can use the estimates of the previous section,  $\bar{\mathbf{x}}$  and  $\hat{\Sigma} = \tilde{X}^T \tilde{X}/n$ . Carrying out a similar factorization on  $\hat{\Sigma}$  as we did for  $\Sigma$ , we obtain the eigenvalues  $\hat{\lambda}_1 \geq \hat{\lambda}_2 \geq \dots \geq \hat{\lambda}_d > 0$  and an orthogonal matrix  $\hat{T} = [\hat{\mathbf{t}}_1, \hat{\mathbf{t}}_2, \dots, \hat{\mathbf{t}}_d]$  of corresponding eigenvectors. For each observation  $\mathbf{x}_i$ , we can define a vector  $\hat{\mathbf{y}}_i = \hat{T}^T(\mathbf{x}_i - \bar{\mathbf{x}})$  of **sample principal components** or **estimated principal components** yielding  $\hat{Y}^T = [\hat{\mathbf{y}}_1, \hat{\mathbf{y}}_2, \dots, \hat{\mathbf{y}}_n] = \hat{T}^T \tilde{X}^T$ .

Although the above method is mainly used descriptively, asymptotic inference for large  $n$  can be carried out on the assumption that the underlying distribution is normal.

**Facts:**

The following facts can be found in [Chr01, Sec. 3.1–3.3], [Rao73, Sec. 8g2], or in [Seb04, Sec. 5.2].

1. As  $\text{var}(\mathbf{y}) = \Lambda$ , which is diagonal, the  $y_j$  are uncorrelated and  $\text{var}(y_j) = \lambda_j$ .
2.  $\sum_{j=1}^d \text{var}(y_j) = \sum_{j=1}^d \text{var}(x_j) = \text{tr}\Sigma$ . We can use  $\lambda_j/\text{tr}\Sigma$  to measure the relative magnitude of  $\lambda_j$ . If the  $\lambda_i$  ( $i = k + 1, \dots, d$ ) are relatively small so that the corresponding  $y_i$  are “small” (with zero means and small variances), then  $\mathbf{y}_{(k)} = [y_1, y_2, \dots, y_k]^T$  can be regarded as a  $k$ -dimensional approximation for  $\mathbf{y}$ . Thus,  $\mathbf{y}_{(k)}$  can be used as a “proxy” for  $\mathbf{x}$  in terms of explaining a major part of the total variance.
3. Let  $T_{(k)} = [\mathbf{t}_1, \dots, \mathbf{t}_k]$ . Then:
  - $\max_{\mathbf{a}^T \mathbf{a} = 1} \text{var}(\mathbf{a}^T \mathbf{x}) = \text{var}(\mathbf{t}_1^T \mathbf{x}) = \text{var}(\mathbf{t}_1^T(\mathbf{x} - \boldsymbol{\mu})) = \text{var}(y_1) = \lambda_1$ , so that  $y_1$  is the normalized linear combination of the elements of  $\mathbf{x} - \boldsymbol{\mu}$  with maximum variance  $\lambda_1$ .
  - $\max_{\mathbf{a}^T \mathbf{a} = 1, T_{(k-1)}^T \mathbf{a} = \mathbf{0}} \text{var}(\mathbf{a}^T \mathbf{x}) = \text{var}(\mathbf{t}_k^T \mathbf{x}) = \text{var}(y_k) = \lambda_k$ , so that  $\mathbf{t}_k^T(\mathbf{x} - \boldsymbol{\mu})$  is the normalized linear combination of the elements  $\mathbf{x} - \boldsymbol{\mu}$  uncorrelated with  $y_1, y_2, \dots, y_{k-1}$ , with maximum variance  $\lambda_k$ .
4.  $\hat{y}_{ij} = \hat{\mathbf{t}}_j^T(\mathbf{x}_i - \bar{\mathbf{x}})$ , the score of the  $i$ th individual on the  $j$ th sample principal component, is related to the orthogonal projection of  $\mathbf{x}_i - \bar{\mathbf{x}}$  onto  $\text{range}(\hat{\mathbf{t}}_j)$ , namely  $P_{\hat{\mathbf{t}}_j}(\mathbf{x}_i - \bar{\mathbf{x}}) = \hat{\mathbf{t}}_j \hat{y}_{ij} = \hat{y}_{ij} \hat{\mathbf{t}}_j$ .

**Examples:**

1. Suppose we assume that each  $\mathbf{x}_i$  is just an observed vector, i.e., a constant. Let  $\mathbf{v}$  be a discrete random vector taking the values  $\mathbf{x}_i$  ( $i = 1, 2, \dots, n$ ) with probability  $\frac{1}{n}$ . Then  $E(\mathbf{v}) = \sum_{i=1}^n \mathbf{x}_i P(\mathbf{v} = \mathbf{x}_i) =$

$\sum_{i=1}^n \mathbf{x}_i / n = \bar{\mathbf{x}}$  and, similarly,  $\text{var}(\mathbf{v}) = \widehat{\Sigma}$ . This means that the sample principal components for  $\mathbf{x}$  are the population components for  $\mathbf{v}$  so that all the optimal properties of population principal components hold correspondingly for the sample principal components.

- Entomologists are interested in the number of distinct taxa present in a population of winged aphids as they are difficult to identify. Forty aphids were trapped and 19 variables on each aphid were measured. A principal component analysis was carried out and the first two components accounted for 85% of the estimate of the total variance giving an effective reduction from 19 to 2 dimensions. The 2-dimensional  $\widehat{\mathbf{y}}_i$  were plotted showing the presence of four groups. Also, the  $\widehat{\mathbf{t}}_r$  ( $r = 1, 2$ ) suggested which two linear combinations of the 19 measurements gave the best discrimination. As the aphids came from slightly different populations, the original assumption that the sample is from a homogeneous population is not quite true, but it does provide a starting place for further study, e.g., use discriminant coordinates described in the next section with four groups.

## 53.5 Discriminant Coordinates

### Definitions:

Suppose we have  $n$   $d$ -dimensional observations of which  $n_i$  belong to group  $i$  from the  $i$ th underlying population ( $i = 1, 2, \dots, g$ ;  $n = \sum_{i=1}^g n_i$ ). Let  $\mathbf{x}_{ij}$  be the  $j$ th observation in group  $i$ , and define

$$\bar{\mathbf{x}}_i = \frac{1}{n_i} \sum_{j=1}^{n_i} \mathbf{x}_{ij} \quad \text{and} \quad \bar{\mathbf{x}} = \frac{1}{n} \sum_{i=1}^g \sum_{j=1}^{n_i} \mathbf{x}_{ij}.$$

Let  $W_g = \sum_{i=1}^g \sum_{j=1}^{n_i} (\mathbf{x}_{ij} - \bar{\mathbf{x}}_i)(\mathbf{x}_{ij} - \bar{\mathbf{x}}_i)^T$ , the **within-groups matrix**, and let  $W_b = \sum_{i=1}^g n_i (\bar{\mathbf{x}}_i - \bar{\mathbf{x}})(\bar{\mathbf{x}}_i - \bar{\mathbf{x}})^T$ , the **between-groups matrix**. Since  $W_g$  and  $W_b$  are positive definite with probability 1, the eigenvalues of  $W_g^{-1} W_b$ , which are the same as those of  $W_g^{-1/2} W_b W_g^{-1/2}$ , are positive and distinct with probability 1, say  $\lambda_1 > \lambda_2 > \dots > \lambda_d > 0$ .

Let  $W_g^{-1} W_b \mathbf{c}_r = \lambda_r \mathbf{c}_r$  be suitably scaled eigenvectors and define  $C^T = [\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_k]$  ( $k \leq d$ ). If we define  $\mathbf{y}_{ij} = C \mathbf{x}_{ij}$ , then the  $k$  elements of  $\mathbf{z}_{ij}$  are called the first  $k$  **discriminant coordinates** (or **canonical variates**). These coordinates are determined so as to emphasize group separation, but with decreasing effectiveness so that  $k$  has to be determined. The coordinates can be computed using an appropriate transformation combined with a principal component analysis. Typically the  $\mathbf{c}_i$  are scaled so that  $C S C^T = I_r$ , where  $S = W_g / (n - g)$ .

### Examples:

- Trivariate measurements  $\mathbf{x}_{ij}$  were taken on the skulls of six collections (four subspecies with three collections apparently from the same species) of anteaters. Using six groups of data from six underlying populations in the above theory, we found that  $[\lambda_1, \lambda_2, \lambda_3] = [2.400, 0.905, 0.052]$ . Since  $\lambda_3$  was small, we chose  $k = 2$ . We could, therefore, transform the 3-dimensional observations  $\mathbf{x}_{ij}$  into the 2-dimensional  $\mathbf{y}_{ij} = C \mathbf{x}_{ij}$  and still account for most of the variation in the data. The 2-dimensional reductions were then plotted to help us look for any patterns. As an aid to our search, it was possible to draw a circle with center the reduced mean of each group so that the circle contained any reduced random observation from its population with probability 0.95. The center of the circle locates the center of gravity of the group and the boundary of the circle shows where the bulk of the observations are expected to lie. The closeness of these circles indicated how "close" the groups and subspecies were. We found that three of the circles almost overlapped completely, confirming a common underlying species, and the remaining circles had little overlap, suggesting the presence of four species.

## 53.6 Canonical Correlations and Variates

### Definitions:

Let  $\mathbf{z} = \begin{bmatrix} \mathbf{x} \\ \mathbf{y} \end{bmatrix}$  denote a  $d$ -dimensional random vector with mean  $\boldsymbol{\mu}$  and positive definite covariance matrix  $\Sigma$ . Let  $\mathbf{x}$  and  $\mathbf{y}$  have dimensions  $d_1$  and  $d_2 = d - d_1$ , respectively, and consider the partition

$$\Sigma = \begin{bmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{bmatrix},$$

where  $\Sigma_{ii}$  is  $d_i \times d_i$  and  $\Sigma_{21} = \Sigma_{12}^T$  has rank  $r$ . Let  $\rho_1^2$  be the maximum value of the squared correlation between arbitrary linear combinations  $\boldsymbol{\alpha}^T \mathbf{x}$  and  $\boldsymbol{\beta}^T \mathbf{y}$ , and let  $\boldsymbol{\alpha} = \mathbf{a}_1$  and  $\boldsymbol{\beta} = \mathbf{b}_1$  be the corresponding maximizing values of  $\boldsymbol{\alpha}$  and  $\boldsymbol{\beta}$ . Then the positive square root  $\sqrt{\rho_1^2}$  is called the **first (population) canonical correlation** between  $\mathbf{x}$  and  $\mathbf{y}$ , and  $u_1 = \mathbf{a}_1^T \mathbf{x}$  and  $v_1 = \mathbf{b}_1^T \mathbf{y}$  are called the **first (population) canonical variables**.

Let  $\rho_2^2$  be the maximum value of the squared correlation between  $\boldsymbol{\alpha}^T \mathbf{x}$  and  $\boldsymbol{\beta}^T \mathbf{y}$ , where  $\boldsymbol{\alpha}^T \mathbf{x}$  is uncorrelated with  $\mathbf{a}_1^T \mathbf{x}$  and  $\boldsymbol{\beta}^T \mathbf{y}$  is uncorrelated with  $\mathbf{b}_1^T \mathbf{y}$ , and let  $u_2 = \mathbf{a}_2^T \mathbf{x}$  and  $v_2 = \mathbf{b}_2^T \mathbf{y}$  be the maximizing values. Then the positive square root  $\sqrt{\rho_2^2}$  is called the **second canonical correlation**, and  $u_2$  and  $v_2$  are called the **second canonical variables**. Continuing in this manner, we obtain  $r$  pairs of canonical variables  $\mathbf{u} = [u_1, u_2, \dots, u_r]^T$  and  $\mathbf{v} = [v_1, v_2, \dots, v_r]^T$ . We can then regard  $\mathbf{u}$  and  $\mathbf{v}$  as lower-dimensional "representations" of  $\mathbf{x}$  and  $\mathbf{y}$ .

### Facts:

- [Seb04, Sec. 5.7] If  $m = \text{rank} \Sigma_{12} \geq 1$  and  $\Sigma$  is positive definite, then  $\Sigma_{11}^{-1} \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21}$  has  $m$  positive eigenvalues  $\rho_1^2 \geq \rho_2^2 \geq \dots \geq \rho_m^2$ , say, and  $\rho_1^2 < 1$ . Moreover,  $\Sigma_{11}^{-1} \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21}$  and  $\Sigma_{22}^{-1} \Sigma_{21} \Sigma_{11}^{-1} \Sigma_{12}$  have the same (nonzero) eigenvalues. Let  $\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_m$  and  $\mathbf{b}_1, \mathbf{b}_2, \dots, \mathbf{b}_m$  be the corresponding eigenvectors of  $\Sigma_{11}^{-1} \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21}$  and  $\Sigma_{22}^{-1} \Sigma_{21} \Sigma_{11}^{-1} \Sigma_{12}$ , respectively. Suppose that  $\boldsymbol{\alpha}$  and  $\boldsymbol{\beta}$  are arbitrary vectors such that for  $r \leq m$ ,  $\boldsymbol{\alpha}^T \mathbf{x}$  is uncorrelated with each  $\mathbf{a}_j^T \mathbf{x}$  ( $j = 1, 2, \dots, r - 1$ ), and  $\boldsymbol{\beta}^T \mathbf{y}$  is uncorrelated with each  $\mathbf{b}_j^T \mathbf{y}$  ( $j = 1, 2, \dots, r - 1$ ). Let  $u_j = \mathbf{a}_j^T \mathbf{x}$  and  $v_j = \mathbf{b}_j^T \mathbf{y}$ , for  $j = 1, 2, \dots, r$ . Then:
  - The maximum squared correlation between  $\boldsymbol{\alpha}^T \mathbf{x}$  and  $\boldsymbol{\beta}^T \mathbf{y}$  is given by  $\rho_r^2$  and it occurs when  $\boldsymbol{\alpha} = \mathbf{a}_r$  and  $\boldsymbol{\beta} = \mathbf{b}_r$ .
  - $\text{cov}(u_j, u_k) = 0$  for  $j \neq k$ , and  $\text{cov}(v_j, v_k) = 0$  for  $j \neq k$ .
  - The squared correlation between  $u_j$  and  $v_j$  is  $\rho_j^2$ .
  - Since  $\rho_j^2$  is independent of scale, we can scale  $\mathbf{a}_j$  and  $\mathbf{b}_j$  such that  $\mathbf{a}_j^T \Sigma_{11} \mathbf{a}_j = 1$  and  $\mathbf{b}_j^T \Sigma_{22} \mathbf{b}_j = 1$ . The  $u_j$  and  $v_j$  then have unit variances.
  - If the  $d_1 \times d_2$  matrix  $\Sigma_{12}$  has row full rank, and  $d_1 < d_2$ , then  $m = d_1$ . All the eigenvalues of  $\Sigma_{11}^{-1} \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21}$  are then positive, while  $\Sigma_{22}^{-1} \Sigma_{21} \Sigma_{11}^{-1} \Sigma_{12}$  has  $d_1$  positive eigenvalues and  $d_2 - d_1$  zero eigenvalues. The rank of  $\Sigma_{12}$  can vary as there may be constraints on  $\Sigma_{12}$ , such as  $\Sigma_{12} = \mathbf{0}$  (rank 0) or  $\Sigma_{12} = \mathbf{a} \mathbf{1}_{d_1} \mathbf{1}_{d_1}^T$  (rank 1).
- [Bri01, p. 370]. Suppose  $\mathbf{x}$  and  $\mathbf{y}$  have means  $\boldsymbol{\mu}_x$  and  $\boldsymbol{\mu}_y$ , respectively. Let  $\mathbf{u} = A(\mathbf{x} - \boldsymbol{\mu}_x)$  and  $\mathbf{v} = B(\mathbf{y} - \boldsymbol{\mu}_y)$ , where  $A$  and  $B$  are any matrices, each with  $r$  rows that are linearly independent, satisfying  $A \Sigma_{11} A^T = I_r$  and  $B \Sigma_{22} B^T = I_r$ . Then  $E[(\mathbf{u} - \mathbf{v})^T (\mathbf{u} - \mathbf{v})]$  is minimized when  $\mathbf{u}$  and  $\mathbf{v}$  are vectors of the canonical variables.
- [BS93], [SS80] When  $\Sigma$  is singular, then the (population) canonical correlations are the positive square roots of the eigenvalues of  $\Sigma_{11}^{-} \Sigma_{12} \Sigma_{22}^{-} \Sigma_{21}$ ; any generalized inverses  $\Sigma_{11}^{-}$  and  $\Sigma_{22}^{-}$  may be chosen. There will be  $u$  canonical correlations equal to 1, where  $u = \text{rank}(\Sigma_{11}) + \text{rank}(\Sigma_{22}) - \text{rank}(\Sigma)$ .

## 53.7 Estimation of Correlations and Variates

### Definitions:

Let  $\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_n$  be a random sample and let  $\bar{\mathbf{z}} = \frac{1}{n} \sum_{i=1}^n \mathbf{z}_i = \begin{bmatrix} \bar{x} \\ \bar{y} \end{bmatrix}$  be the sample mean and  $\widehat{\Sigma} = \frac{1}{n} \sum_{i=1}^n (\mathbf{z}_i - \bar{\mathbf{z}})(\mathbf{z}_i - \bar{\mathbf{z}})^T$ , where  $\widehat{\Sigma}$  is partitioned in the same way as  $\Sigma$ , namely

$$n\widehat{\Sigma} = \begin{bmatrix} \tilde{X}^T \tilde{X} & \tilde{X}^T \tilde{Y} \\ \tilde{Y}^T \tilde{X} & \tilde{Y}^T \tilde{Y} \end{bmatrix} = \begin{bmatrix} Q_{11} & Q_{12} \\ Q_{21} & Q_{22} \end{bmatrix},$$

say. Assuming that  $d_1 \leq d_2$ , let  $r_1^2 > r_2^2 > \dots > r_{d_1}^2 > 0$  be the eigenvalues of  $Q_{11}^{-1} Q_{12} Q_{22}^{-1} Q_{21}$ , with corresponding eigenvectors  $\hat{\mathbf{a}}_1, \hat{\mathbf{a}}_2, \dots, \hat{\mathbf{a}}_{d_1}$ . We define  $u_{ij} = \hat{\mathbf{a}}_j^T (\mathbf{x}_i - \bar{\mathbf{x}})$ , the  $i$ th element of  $\mathbf{u}_j = \tilde{X} \hat{\mathbf{a}}_j$ , where  $\hat{\mathbf{a}}_j$  is scaled so that  $1 = n^{-1} \hat{\mathbf{a}}_j^T \tilde{X}^T \tilde{X} \hat{\mathbf{a}}_j = \sum_{i=1}^n u_{ij}^2 / n = \mathbf{u}_j^T \mathbf{u}_j / n$ . Then  $\sqrt{r_j^2}$  is the  $j$ th **sample canonical correlation**. Moreover,  $u_{ij}$  is the  $j$ th **sample canonical variable** of  $\mathbf{x}_i$ . In a similar fashion, we define  $v_{ij} = \hat{\mathbf{b}}_j^T (\mathbf{y}_i - \bar{\mathbf{y}})$ , the  $i$ th element of  $\mathbf{v}_j = \tilde{Y} \hat{\mathbf{b}}_j$ , to be the  $j$ th sample canonical variable of  $\mathbf{y}_i$ . Here,  $\hat{\mathbf{b}}_1, \hat{\mathbf{b}}_2, \dots, \hat{\mathbf{b}}_{d_1}$  are the corresponding eigenvectors of  $Q_{22}^{-1} Q_{21} Q_{11}^{-1} Q_{12}$ , scaled so that  $\mathbf{v}_j^T \mathbf{v}_j / n = 1$ . The  $u_{ij}$  and  $v_{ij}$  are the **scores** of the  $i$ th observation on the  $j$ th canonical variables.

### Facts:

1. When  $\Sigma$  is positive definite and  $n - 1 \geq d$ , then, with probability 1,  $n\widehat{\Sigma}$  is positive definite and  $\text{rank } Q_{12} = d_1$ .
2. The Canonical correlations  $\sqrt{r_j^2}$  are all distinct with probability 1.
3.  $r_j^2$  is the square of the sample correlation between the canonical variables whose values are in the vectors  $\mathbf{u}_j$  and  $\mathbf{v}_j$ .

### Examples:

1. Length and breadth head measurements were carried out on the first and second sons of 25 families to see what relationships existed. Here,  $\mathbf{x}$  refers to the two measurements on the first son and  $\mathbf{y}$  to the second. It was found that  $r_1 = 0.7885$  and  $r_2 = 0.0537$ , indicating that just one pair of sample canonical variables  $(u_1, v_1)$  would give a reasonable reduction in dimension from 2 to 1. Plotting  $u_1$  against  $v_1$  using the 25 pairs  $(u_{i1}, v_{i1})$  gave a reasonably linear plot. The first linear combinations  $(u_1, v_1)$  of the two measurements suggested that they could be interpreted as a measure of "girth" while the second  $(u_2, v_2)$  could be interpreted as "shape" measurements. We can conclude that there is a strong correlation between the head sizes of first and second brothers, but not between the head shapes.

## 53.8 Matrix Quadratic Forms

To carry out inference for multivariate normal distributions we now require further theory.

### Definitions:

If  $X$  is an  $n \times d$  data matrix and  $A = [a_{ij}]$  is a symmetric  $n \times n$  matrix, then the expression  $X^T A X = \sum_{i=1}^n \sum_{j=1}^n a_{ij} \mathbf{x}_i \mathbf{x}_j^T$  is said to be a **matrix quadratic form**. We have already had one example, namely,  $Q = X^T C X$  in section 53.3. When the  $\{\mathbf{x}_i\}$  are a random sample from a distribution with mean  $\boldsymbol{\mu}$  and covariance matrix  $\Sigma$  we define  $S = Q/(n-1)$  to be the **sample covariance matrix**. (Some authors define it as  $\widehat{\Sigma}$  in Section 53.3)

If the  $\mathbf{x}_i$  are i.i.d. as  $N_d(\mathbf{0}, \Sigma)$ , with  $d \leq n$  and  $\Sigma = [\sigma_{ij}]$  positive semidefinite, then  $W = X^T X$  is said to have a **Wishart distribution** with  $n$  degrees of freedom and scale matrix  $\Sigma$ , and we write  $W \sim W_d(n, \Sigma)$ . If  $\Sigma$  is positive definite then the distribution is said to be **nonsingular**.

Suppose  $\mathbf{y} \sim N_d(\mathbf{0}, \Sigma)$  independently of  $W \sim W_d(m, \Sigma)$  and that both distributions are nonsingular. Then **Hotelling's  $T^2$  distribution** is defined to be the distribution of  $T^2 = m\mathbf{y}^T W^{-1} \mathbf{y}$  and we denote this distribution by  $T^2 \sim T_{d,m}^2$ .

Finally, in inference we are usually interested in **contrasts**  $\mathbf{a}^T \boldsymbol{\mu}$ , in the  $\mu_i$ , where  $\mathbf{a}$  is a vector whose entries sum to 0, i.e.,  $\mathbf{a}^T \mathbf{1}_d = 0$ . Examples are  $\mu_1 - \mu_2 = [1, -1, 0, \dots, 0] \boldsymbol{\mu}$  and  $\mu_1 - \frac{1}{2}(\mu_2 + \mu_3)$ .

**Facts:**

All facts, unless otherwise indicated, appear in [Seb04, Secs. 2.3–2.4, 3.3–3.4, 3.6.2].

1.  $E(S) = \Sigma$ , irrespective of the distribution of the  $\mathbf{x}_i$ .
2. [HS79] Let  $X$  be an  $n \times d$  data matrix and let  $A$  and  $B$  be matrices of appropriate sizes. If  $\text{vec}$  is the usual “stacking” operator, then:
  - $\text{cov}[\text{vec}(AXB), \text{vec}(CXD)] = (B^T \Sigma D) \otimes (AC^T)$ .
  - If  $U = AXB$  and  $V = CXD$ , then  $U$  and  $V$  are pairwise uncorrelated, that is,  $\text{cov}(u_{ij}, v_{rs}) = 0$  for all  $i, j, r$ , and  $s$ , if  $AC^T = 0$  and/or  $B^T \Sigma D = \mathbf{0}$ .
3. Suppose  $W = [w_{ij}]$  has a Wishart distribution  $W_d(m, \Sigma)$ , with  $\Sigma$  possibly singular. Then the following hold:
  - $E(W) = m\Sigma$ .
  - Let  $A$  be a  $q \times d$  matrix with  $\text{rank } q \leq d$ . Then  $AWA^T \sim W_q(m, A\Sigma A^T)$ . When  $\Sigma$  is positive definite, then this distribution is nonsingular.
  - When  $\sigma_{jj} > 0$ , then  $w_{jj}/\sigma_{jj} \sim \chi_m^2$ , ( $j = 1, 2, \dots, d$ ). However, the  $w_{jj}$  ( $j = 1, \dots, d$ ) are not statistically independent.
  - When  $\Sigma$  is positive definite, then  $\det \Sigma > 0$  and  $\det W / \det \Sigma$  is distributed as the product of  $d$  independent chi-square variables with respective degrees of freedom  $m, m - 1, \dots, m - d + 1$ .
4. (See [SK79, p. 97], [Sty89].) Let  $W \sim W_d(m, \Sigma)$  with  $\Sigma$  possibly singular, and let  $A$  be an  $n \times n$  symmetric matrix. Then:
  - $E(WAW) = m[\Sigma A^T \Sigma + \text{tr}(A\Sigma)\Sigma] + m^2 \Sigma A \Sigma$ .
  - If  $m > d + 1$  and  $\Sigma$  is nonsingular, then

$$E(WAW^{-1}) = \frac{1}{m - d - 1} [m\Sigma A \Sigma^{-1} - A^T - (\text{tr} A)I],$$

$$E(W^{-1}AW) = \frac{1}{m - d - 1} [m\Sigma^{-1}A\Sigma - A^T - (\text{tr} A)I].$$

- If  $m > d + 3$  and  $\Sigma$  is nonsingular, then

$$E(W^{-1}AW^{-1}) = \frac{(m - d - 2)\Sigma^{-1}A\Sigma^{-1} + \Sigma^{-1}A^T\Sigma^{-1} - (\text{tr} A \Sigma^{-1})\Sigma^{-1}}{(m - d)(m - d - 1)(m - d - 3)}.$$

5. Suppose that the rows  $\mathbf{x}_i^T$  of  $X$  are uncorrelated with  $\text{var}(\mathbf{x}_i) = \Sigma_i$  for  $i = 1, 2, \dots, n$ , and  $A$  is an  $n \times n$  symmetric matrix. Then:
  - $E(X^T AX) = \sum_{i=1}^n a_{ii} \Sigma_i + E(X^T)AE(X)$ .
  - If  $\Sigma_i = \Sigma$  for all  $i$ , then  $E(X^T AX) = (\text{tr} A)\Sigma + E(X^T)AE(X)$ .
6. [Das71, Th. 5], [EP73, Th. 2.3] Suppose that the rows of  $X$  are independent and  $A$  is an  $n \times n$  positive semidefinite matrix of rank  $r \geq d$ . If for each  $\mathbf{x}_i$  and all  $\mathbf{b}$  and  $c$  with  $\mathbf{b} \neq \mathbf{0}$  the probability  $\Pr(\mathbf{b}^T \mathbf{x}_i = c) = 0$ , then  $X^T AX$  is positive definite with probability 1.

7. Suppose that rows of  $X$  are i.i.d. as  $N_d(\mathbf{0}, \Sigma)$ , with  $\Sigma$  possibly singular, and let  $A$  and  $B$  be  $n \times n$  symmetric matrices.
- If  $A$  has rank  $r \leq d$ , then  $X^T A X \sim W_d(r, \Sigma)$  if and only if  $A = A^2$ .
  - Suppose  $X^T A X$  and  $X^T B X$  have Wishart distributions. They are statistically independent if and only if  $AB = \mathbf{0}$ .
8. Referring to the definition of Hotelling's  $T^2$ ,  $\frac{m-d+1}{md} T_{d,m}^2 \sim F(d, m-d+1)$ , the F-distribution with  $d$  and  $m-d+1$  degrees of freedom. When  $\mathbf{y} \sim N_d(\boldsymbol{\theta}, \Sigma)$ , then  $F \sim F(d, m-d+1; \delta)$ , the corresponding noncentral F-distribution with noncentrality parameter  $\delta = \boldsymbol{\theta}^T \Sigma \boldsymbol{\theta}$ .
9. Suppose that the rows of  $X$  are i.i.d. as nonsingular  $N_d(\boldsymbol{\mu}, \Sigma)$ . Then:
- $\bar{\mathbf{x}} \sim N_d(\boldsymbol{\mu}, \Sigma/n)$ .
  - $Q = (n-1)S \sim W_d(n-1, \Sigma)$ .
  - $\bar{\mathbf{x}}$  and  $S$  are statistically independent.
  - $T^2 = n(\bar{\mathbf{x}} - \boldsymbol{\mu})^T S^{-1}(\bar{\mathbf{x}} - \boldsymbol{\mu}) \sim T_{d,n-1}^2$ . This statistic can be used for testing the null hypothesis  $H_0: \boldsymbol{\mu} = \boldsymbol{\mu}_0$ .
10. Given  $H_0: \boldsymbol{\mu} \in \mathcal{V}$ , where  $\mathcal{V}$  is a  $p$ -dimensional vector subspace of  $\mathbb{R}^d$ , then:
- $T_{\min}^2 = \min_{\boldsymbol{\mu} \in \mathcal{V}} T^2 \sim T_{d-p,n-1}^2$ .
  - If  $H_0: \boldsymbol{\mu} = K\boldsymbol{\beta}$ , where  $K$  is a known  $d \times p$  matrix of rank  $p$  and  $\boldsymbol{\beta}$  is a vector of  $p$  unknown parameters, then  $\mathcal{V} = \text{range}(K)$ , and  $T_{\min}^2 = n(\bar{\mathbf{x}}^T S^{-1} \bar{\mathbf{x}} - \bar{\mathbf{x}}^T S^{-1} K \boldsymbol{\beta}^*)$ , where  $\boldsymbol{\beta}^* = (K^T S^{-1} K)^{-1} K^T S^{-1} \bar{\mathbf{x}}$ .
11. If  $H_0: A\boldsymbol{\mu} = \mathbf{0}$ , where  $A$  is  $(d-p) \times d$  of rank  $d-p$ , then  $\mathcal{V} = \ker(A)$  (also called the null space) and  $T_{\min}^2 = n(A\bar{\mathbf{x}})^T (ASA^T)^{-1} A\bar{\mathbf{x}}$ .
- Let  $A$  be a  $q \times d$  matrix of rank  $q \leq d$ . Then the quadratic  $n(A\bar{\mathbf{x}} - A\boldsymbol{\mu})^T (ASA^T)^{-1} (A\bar{\mathbf{x}} - A\boldsymbol{\mu}) \sim T_{q,n-1}^2$ . This can be used for testing  $H_0: A\boldsymbol{\mu} = \mathbf{c}$ .
  - If  $A$  is a matrix with rows which are contrasts so that  $A\mathbf{1}_d = \mathbf{0}$ , then

$$n\bar{\mathbf{x}}^T A^T (ASA^T)^{-1} A\bar{\mathbf{x}} = n\bar{\mathbf{x}}^T S^{-1} \bar{\mathbf{x}} - \frac{n(\bar{\mathbf{x}}^T S^{-1} \mathbf{1}_d)^2}{\mathbf{1}_d^T S^{-1} \mathbf{1}_d}.$$

12. Let  $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_{n_1}$  be a random sample from  $N_d(\boldsymbol{\mu}_1, \Sigma)$  and let  $\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_{n_2}$  be an independent random sample from  $N_d(\boldsymbol{\mu}_2, \Sigma)$ , both distributions being nonsingular. Let  $Q_1 = \sum_{i=1}^{n_1} (\mathbf{v}_i - \bar{\mathbf{v}})(\mathbf{v}_i - \bar{\mathbf{v}})^T$  and  $Q_2 = \sum_{i=1}^{n_2} (\mathbf{w}_i - \bar{\mathbf{w}})(\mathbf{w}_i - \bar{\mathbf{w}})^T$ . If  $\boldsymbol{\theta} = \boldsymbol{\mu}_1 - \boldsymbol{\mu}_2$  and  $A$  is a  $q \times d$  matrix of rank  $q \leq d$ , then:
- $\bar{\mathbf{z}} = \bar{\mathbf{v}} - \bar{\mathbf{w}} \sim N_d(\boldsymbol{\theta}, (\frac{1}{n_1} + \frac{1}{n_2})\Sigma)$ .
  - $Q = Q_1 + Q_2 \sim W_d(n_1 + n_2 - 2, \Sigma)$ .
  - The statistic

$$\frac{n_1 n_2}{n_1 + n_2} (A\bar{\mathbf{z}} - A\boldsymbol{\theta})^T (AS_p A^T)^{-1} (A\bar{\mathbf{z}} - A\boldsymbol{\theta}) \sim T_{q, n_1 + n_2 - 2}^2,$$

where  $S_p = Q/(n_1 + n_2 - 2)$ . This can be used to test  $H_0: A\boldsymbol{\theta} = \mathbf{0}$ . When  $A$  is a certain  $(d-1) \times d$  contrast matrix, then the methodology relating to  $H_0$  is called *profile analysis*.

### Examples:

1. Suppose the rows of  $X$  are i.i.d. nonsingular  $N_d(\mathbf{0}, \Sigma)$ . Then  $\bar{\mathbf{x}} = X^T \mathbf{1}_n / n$  and  $W_1 = n\bar{\mathbf{x}}\bar{\mathbf{x}}^T = X^T A X$ , where  $A = \mathbf{1}_n \mathbf{1}_n^T / n$  is symmetric and idempotent of rank 1. Also, from Section 53.3,  $W_2 = (\mathbf{x}_i - \bar{\mathbf{x}})(\mathbf{x}_i - \bar{\mathbf{x}})^T = X^T C X$ , where  $C = I_n - A$  is symmetric and idempotent of rank  $n-1$ . Since  $AC = \mathbf{0}$ , we have from Fact 7 above that  $W_1 \sim W_d(1, \Sigma)$ ,  $W_2 \sim W_d(n-1, \Sigma)$ , and  $W_1$  and  $W_2$  are statistically independent.

2. (cf. Fact 10) Suppose we have a group of 30 animals all subject to the same conditions, and the length of each animal is observed at  $d$  points in time  $t_1, t_2, \dots, t_d$ . The  $d$  lengths for the  $i$ th animal will give us a  $d$ -dimensional vector,  $\mathbf{x}_i$  say, and we assume that the  $\mathbf{x}_i$  are all i.i.d., as nonsingular  $N_d(\boldsymbol{\mu}, \Sigma)$ . We are interested in testing the hypothesis  $H_0$  that the “growth curve” is a third degree polynomial so that  $H_0 : \mu_j = \beta_0 + \beta_1 t_j + \beta_2 t_j^2 + \beta_3 t_j^3$  ( $j = 1, 2, \dots, d$ ) or  $H_0 : \boldsymbol{\mu} = K\boldsymbol{\beta}$ , where the  $j$ th row of  $K$  is  $[1, t_j, t_j^2, t_j^3]$  and  $\boldsymbol{\beta} = [\beta_0, \beta_1, \beta_2, \beta_3]^T$  is a vector of unknown parameters. We then test  $H_0$  by calculating  $T_{\min}^2$  given in Fact 10, and this statistic, which has a Hotellings  $T^2$  distribution when  $H$  is true, can then be converted to an  $F$ -statistic using Fact 8. If this  $F$ -value is significantly large we reject  $H_0$ .
3. (cf. Fact 11) The lengths of the femur and humerus on the left- and right-hand sides are measured for  $n = 100$  males aged over 40 years to see if men are symmetrical with respect to the lengths of these bones. For the  $i$ th male, we therefore have a four-dimensional observation vector  $\mathbf{x}_i$ . Assuming that the population of measurements is multivariate normal with mean  $\boldsymbol{\mu} = [\mu_1, \mu_2, \mu_3, \mu_4]^T$ , where  $\mu_1$  and  $\mu_2$  refer to the left side, then we are interested in testing the contrasts  $\mu_1 - \mu_3 = 0$  and  $\mu_2 - \mu_4 = 0$ . Thus,  $A$  has rows  $[1, 0, -1, 0]$  and  $[0, 1, 0, -1]$ , giving us  $H_0 : A\mathbf{1}_4 = \mathbf{0}$ . We can then test  $H_0$  using  $T_{\min}^2$  defined in Fact 11, and this  $T^2$  statistic is then converted to an  $F$ -statistic, as in the previous example.

## 53.9 Multivariate Linear Model: Least Squares Estimation

### Definitions:

Let  $Y$  be an  $n \times d$  data matrix which comes from an experimental design giving rise to  $n$  observations, the rows of  $Y$ . Then we can use observations on the  $j$ th characteristic (variable)  $\mathbf{y}^{(j)}$ , the  $j$ th column of  $Y$ , to construct a linear regression model  $\mathbf{y}^{(j)} = \boldsymbol{\theta}^{(j)} + \mathbf{u}^{(j)} = K\boldsymbol{\beta}^{(j)} + \mathbf{u}^{(j)}$  as in Section 52.2 (with  $K$  replaced by  $X$  there). Because the design is the same for each variable, the design matrix  $K$  will be independent of  $j$  ( $j = 1, 2, \dots, d$ ), though the models will not be independent as the  $\mathbf{y}^{(j)}$  are not independent. Putting all  $d$  regression models together, we get  $Y = \Theta + \mathbf{U}$ , where  $\Theta = KB$ ,  $B$  is  $p \times d$  matrix of unknown parameters,  $K$  is  $n \times p$  of rank  $r$  ( $r \leq p$ ), and  $U = [\mathbf{u}^{(1)}, \dots, \mathbf{u}^{(d)}] = [\mathbf{u}_1, \dots, \mathbf{u}_n]^T$ . We shall assume that the  $\mathbf{u}_i$  are a random sample from a distribution with mean  $\mathbf{0}$  and covariance matrix  $\Sigma = [\sigma_{ij}]$ . Then  $Y = KB + U$  is called a **multivariate linear model**. When  $d = 1$ , this reduces to the **univariate linear model** or **Gauss–Markov model**; see Chapter 52 and [Seb04, ch. 8].

Now, for the  $j$ th model,  $\hat{\boldsymbol{\theta}}^{(j)} = P\mathbf{y}^{(j)}$  is the (ordinary) least squares estimate of  $\boldsymbol{\theta}^{(j)}$ , where  $P = K(K^T K)^{-1}K^T$ , and  $\hat{\Theta} = PY$  is defined to be the **least squares estimate of  $\Theta$** . When  $r = p$ , then setting  $\hat{\Theta} = K\hat{B}$  we have  $\hat{B} = (K^T K)^{-1}K^T \hat{\Theta} = (K^T K)^{-1}K^T Y$ , called the **the least squares estimate of  $B$** . If  $r < p$ , then  $\hat{B}$  is not unique and is given by  $\hat{B} = (K^T K)^{-}K^T Y$ , where  $(K^T K)^{-}$  is any generalized inverse of  $K^T K$ .

If  $K$  has less than full rank, then each of the  $d$  associated univariate models also has less than full rank. Moreover,  $\mathbf{a}_i^T \boldsymbol{\beta}^{(j)}$  is estimable for each  $i = 1, 2, \dots, q$  and each model  $j = 1, 2, \dots, d$  if  $\mathbf{a}_i \in \text{range}(K^T)$ . Let  $A = [\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_q]^T$ . Combining these linear combinations we say that  $AB$  is **estimable** when  $A = LK$  for some  $q \times n$  matrix  $L$ .

### Facts:

All the following facts can be found in [Seb04, Ch. 8].

1. If  $K^T = [\mathbf{k}_1, \dots, \mathbf{k}_n]$  then, transposing the model,  $\mathbf{y}_i = B^T \mathbf{k}_i + \mathbf{u}_i$ .
2. The cross-covariance  $\text{cov}(\mathbf{y}_r, \mathbf{y}_s) = \text{cov}(\mathbf{u}_r, \mathbf{u}_s) = \delta_{rs} \Sigma$ , where  $\delta_{rs} = 1$  when  $r = s$  and 0, otherwise.
3. The cross-covariance  $\text{cov}(\mathbf{y}^{(j)}, \mathbf{y}^{(k)}) = \text{cov}(\mathbf{u}^{(j)}, \mathbf{u}^{(k)}) = \sigma_{jk} I_d$  for all  $j, k = 1, \dots, d$ .
4. If  $K$  has full rank  $p$ , then  $\hat{\boldsymbol{\beta}}^{(j)} = (K^T K)^{-1}K^T \mathbf{y}^{(j)}$  and  $\text{cov}(\hat{\boldsymbol{\beta}}^{(j)}, \hat{\boldsymbol{\beta}}^{(k)}) = \sigma_{jk}(K^T K)^{-1}$  (all  $j, k = 1, \dots, d$ ).

5. Let  $F(\Theta) = (Y - \Theta)^T(Y - \Theta)$ . Then:
  - $F(\widehat{\Theta}) = Y^T(I_n - P)Y = U^T(I_n - P)U$ .
  - $E[U^T(I_n - P)U] = (n - r)\Sigma$ .
6.  $F(\Theta) - F(\widehat{\Theta})$  is positive semidefinite for all  $\Theta = XB$ , and equal to 0 if and only if  $\Theta = \widehat{\Theta}$ . We say that  $\widehat{\Theta}$  is the minimum of  $F(\Theta)$ . Then:
  - $\text{tr}F(\Theta) \geq \text{tr}F(\widehat{\Theta})$ .
  - $\det F(\Theta) \geq \det F(\widehat{\Theta})$ .
  - $\|F(\Theta)\| \geq \|F(\widehat{\Theta})\|$ , where  $\|A\| = \{\text{tr}(AA^T)\}^{1/2}$ .
 Any of these three results could be used as a definition of  $\widehat{\Theta}$ .
7. *Multivariate Gauss–Markov Theorem.* If  $\phi = \sum_{j=1}^d \mathbf{h}_j^T \theta^{(j)}$ , a linear combination of all the elements of  $\Theta$ , then  $\hat{\phi} = \sum_{j=1}^d \mathbf{h}_j^T \hat{\theta}^{(j)}$  is the linear unbiased estimate with minimum variance or BLUE (best linear unbiased estimate) of  $\phi$ . (See also Chapter 52.)

### Examples:

1. [Seb04, Sec. 8.6.4] By setting  $V^T = [\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_{n_1}]$ ,  $W^T = [\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_{n_2}]$ , and  $Y = \begin{bmatrix} V \\ W \end{bmatrix}$ , we see that the *two-sample problem* mentioned in Fact 12 of Section 53.8 is a special case of the multivariate model with

$$XB = \begin{bmatrix} \mathbf{1}_{n_1} & \mathbf{0} \\ \mathbf{0} & \mathbf{1}_{n_2} \end{bmatrix} \begin{bmatrix} \boldsymbol{\mu}_1^T \\ \boldsymbol{\mu}_2^T \end{bmatrix}.$$

## 53.10 Multivariate Linear Model: Statistical Inference

---

### Definitions:

Let  $Y = \Theta + U$ , where  $\Theta = KB$ , be a multivariate linear model. We now assume that the underlying distribution (of the  $\mathbf{u}_i$ ) is a nonsingular multivariate normal distribution  $N_d(\mathbf{0}, \Sigma)$ .

### Facts:

The following facts appear in [Seb04, Sec. 8.6].

1. The likelihood function for  $Y$ , i.e., the pdf of  $\text{vec } Y$ , can be expressed in the form

$$(2\pi)^{-nd/2} (\det \Sigma)^{-n/2} \exp\{\text{tr}[-\frac{1}{2}(Y - \Theta)^T \Sigma^{-1}(Y - \Theta)]\}.$$

2. The maximum likelihood estimates of  $\Sigma$  and  $\Theta$  that maximize the likelihood function are  $\widehat{\Theta}$  (the least squares estimate) and  $\widehat{\Sigma} = E/n$ , where  $E = (Y - \widehat{\Theta})^T(Y - \widehat{\Theta})$ ;  $E$  is usually called the residual matrix or error matrix. If the  $n \times p$  matrix  $K$  has full rank (i.e., rank  $p$ ), then the maximum likelihood estimate of  $B$  is  $\widehat{B}$ .
3. Let  $E$  be the residual matrix and assume  $n - r \geq d$ . Then
  - $E$  is positive definite with probability 1.
  - $E \sim W_d(n - r, \Sigma)$ .
  - $E$  is statistically independent of  $\widehat{\Theta}$ , and of  $\widehat{B}$  if  $K$  has full rank.
  - The maximum value of the likelihood function is  $(2\pi)^{-nd/2} (\det \widehat{\Sigma})^{-n/2} e^{-nd/2}$ .
  - If  $K$  has full rank, then  $\widehat{\beta}^{(j)} \sim N_n(\beta^{(j)}, \sigma_{jj}(K^T K)^{-1})$ .

4. Suppose that  $K$  has rank  $r < p$ . Let  $A$  be a known  $q \times p$  matrix of rank  $q$  and let  $AB$  be estimable. We are interested in testing  $H_0 : AB = C$ , where  $C$  is known.

- The minimum,  $E_H$  say, of  $(Y - KB)^T(Y - KB)$  subject to  $AB = C$  occurs when  $B$  equals

$$\widehat{B}_H = \widehat{B} - (K^T K)^{-1} A^T [A(K^T K)^{-1} A^T]^{-1} (A\widehat{B} - C).$$

Although  $\widehat{B}_H$  is not unique,  $\widehat{\Theta}_H = K\widehat{B}_H$  is unique. Moreover,  $E_H = (Y - \widehat{\Theta}_H)^T(Y - \widehat{\Theta}_H)$  is positive definite with probability 1.

- $H = E_H - E = (A\widehat{B} - C)^T [A(K^T K)^{-1} A^T]^{-1} (A\widehat{B} - C)$  is positive definite with probability 1, and  $H$  and  $E$  are statistically independent (both irrespective of whether  $H_0$  is true or not).
  - $E(H) = q\Sigma + (AB - C)^T [A(X^T X)^{-1} A^T]^{-1} (AB - C) = q\Sigma + D$ , where  $D$  is positive definite;  $D$  is zero when  $H_0$  is true. This means that  $E(H)$ , and, therefore,  $H$  itself, tends to be “inflated” when  $H_0$  is false so that a test statistic for  $H_0$  can be based on a suitable function of  $H$ .
  - When  $H_0$  is true,  $H \sim W_d(q, \Sigma)$ .
  - Let  $E_H^{1/2}$  be the positive definite square root of  $E_H$ . Then when  $H_0$  is true,  $V = E_H^{-1/2} H E_H^{-1/2}$ , a scaled function of  $H$ , has a  $d$ -dimensional multivariate Beta distribution with parameters  $q$  and  $n - r$ .
5. [Seb04, Sec. 8.6.2] Four different criteria are usually computed for testing  $H_0$ , and these are essentially based on the eigenvalues of  $V$  given above, which measure the scaled magnitude of  $H$  in some sense. They detect different kinds of departures from  $H_0$  and are all significantly large when  $H_0$  is false.
- *Roy’s maximum root statistic*  $\phi_{max}$ , the maximum eigenvalue of  $HE^{-1}$ .
  - *Wilks’ Lambda or likelihood ratio statistic*  $\Lambda = (\det E / \det E_H)^{n/2}$ .
  - *Lawley–Hotelling trace statistic*  $(n - r)\text{tr}(HE^{-1})$ .
  - *Pillai’s trace statistic*  $\text{tr}(HE_H^{-1})$ .

**Example:**

1. [Seb04, Sec. 8.7.2] To test the general linear hypothesis  $H_0 : ABD = \mathbf{0}$ , where  $A$  is  $q \times p$  of rank  $q \leq p$  and  $D$  is  $d \times v$  of rank  $v \leq d$ , we let  $Y_D = YD$  so that the linear model  $Y = KB + U$  is transformed to

$$Y_D = KBD + UD = K\Lambda + U_0,$$

say, where the rows of  $U_0$  are i.i.d.  $N_v(\mathbf{0}, D^T \Sigma D)$ . Then  $H_0$  becomes  $A\Lambda = \mathbf{0}$  and

- $H$  becomes  $H_D = D^T H D = (A\widehat{B}D)^T [A(K^T K)^{-1} A^T]^{-1} A\widehat{B}D$  and  $E$  becomes  $E_D = D^T E D \sim W_v(n - r, D^T \Sigma D)$ .
- When  $ABD = \mathbf{0}$  is true, then  $H_D \sim W_v(q, D^T \Sigma D)$ .

We can now use Facts 4 and 5 above to test  $H_0$  using  $H_D$  and  $E_D$  instead of  $H$  and  $E$ . This hypothesis arises in carrying out a so-called profile analysis of more than two populations.

## 53.11 Metric Multidimensional Scaling

**Definitions:**

Given a set of  $n$  objects, a **proximity measure**  $d_{rs}$  is a measure of the “closeness” of objects  $r$  and  $s$ ; here, “closeness” does not necessarily refer to physical distance. We shall consider only one such measure as there are several. A proximity  $d_{rs}$  is called a **(symmetric) dissimilarity** if  $d_{rr} = 0$ ,  $d_{rs} \geq 0$ , and  $d_{rs} = d_{sr}$ ,

for all  $r, s = 1, 2, \dots, n$ ; the matrix  $D = [d_{rs}]$  is called a **dissimilarity matrix**. We say that  $D$  is **Euclidean** if there exists a  $p$ -dimensional configuration of points  $\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_n$  for some  $p$  such that all interpoint Euclidean distances satisfy  $\|\mathbf{y}_r - \mathbf{y}_s\| = d_{rs}$ .

### Facts:

1. Let  $A = [a_{ij}]$  be a symmetric  $n \times n$  matrix, where  $a_{rs} = -\frac{1}{2}d_{rs}^2$ . Define  $b_{rs} = a_{rs} - \bar{a}_r - \bar{a}_s + \bar{a}$ , where  $\bar{a}_r$  is the average of the elements of  $A$  in the  $r$ th row,  $\bar{a}_s$  is the average for the  $s$ th column, and  $\bar{a}$  is the average of all the elements. Hence,  $B = [b_{rs}] = CAC$ , where  $C = I - \frac{1}{n}\mathbf{1}\mathbf{1}^T$  is the usual centering matrix. Then  $D = [d_{rs}]$  is Euclidean if and only if  $B$  is positive semidefinite; see [Seb04, p. 236].
2. If  $D$  is not Euclidean, then some eigenvalues of  $B$  will be negative. However, if the first  $k$  eigenvalues are comparatively large and positive, and the remaining positive or negative eigenvalues are near zero, then the rows of  $Y_k = [\mathbf{y}^{(1)}, \mathbf{y}^{(2)}, \dots, \mathbf{y}^{(k)}]$  will give a reasonable configuration. If the original objects are  $d$ -dimensional points  $\mathbf{x}_i$  ( $i = 1, 2, \dots, n$ ) to begin with so that  $\|\mathbf{x}_r - \mathbf{x}_s\|^2 = d_{rs}^2$ , then  $D$  is Euclidean and the  $n$  rows of  $Y_k$  will give a  $k$ -dimensional reduction of a  $d$ -dimensional system of points.

### Example:

1. The migration pattern that occurred with the colonization of islands in the Pacific Ocean can be investigated linguistically and values of  $d_{rs}$  can be constructed based on linguistic information. For example, the proportion  $p_{rs}$  of the words for, say, 50 items that islands  $r$  and  $s$  have in common can be used as a measure of similarity (with  $p_{rr} = 1$ ), which we can convert into a dissimilarity  $d_{rs} = (2 - 2p_{rs})^{1/2}$ . Then  $a_{rs} = -\frac{1}{2}d_{rs}^2 = p_{rs} - 1$  and, when computing  $b_{rs}$ , the  $-1$  drops out so that we can leave it out and set  $a_{rs} = p_{rs}$ . If  $A$  is positive semidefinite then so is  $B$ , which implies that  $D$  is Euclidean. Using  $B$ , we can then find a  $Y_k$  from which we can construct a lower dimensional map to see which islands are closest together linguistically. The same method can also be applied to blood groups using a different  $d_{rs}$ .

Markov chains are encountered in several applications arising in different contexts, and model many real problems which evolve in time. Throughout, we denote by  $P[X = j]$  the probability that the random variable  $X$  takes the value  $j$ , and by  $P[X = j|Y = i]$  the conditional probability that  $X$  takes the value  $j$ , given that the random variable  $Y$  takes the value  $i$ . Moreover, we denote by  $E[X]$  the expected value of the random variable  $X$  and by  $E[X|A]$  the conditional expectation of  $X$ , given the event  $A$ .

### 54.1 Basic Concepts

---

#### Definitions:

Given a denumerable set  $E$ , a **discrete stochastic process** on  $E$  is a family  $\{X_t : t \in T\}$  of random variables  $X_t$  indexed by some denumerable set  $T$  and with values in  $E$ , i.e.,  $X_t \in E$  for all  $t \in T$ . Here,  $E$  is the **state space**, and  $T$  is the **time space**.

The discrete stochastic process  $\{X_n : n \in \mathbb{N}\}$  is a **Markov chain** if

$$P[X_{n+1} = j_{n+1}|X_0 = j_0, X_1 = j_1, \dots, X_n = j_n] = P[X_{n+1} = j_{n+1}|X_n = j_n], \quad (54.1)$$

for any  $(n + 2)$ -tuple of states  $\{j_0, \dots, j_{n+1}\} \in E$ , and for all time  $n \in \mathbb{N}$ .

A Markov chain  $\{X_n : n \in \mathbb{N}\}$  is **homogeneous** if

$$P[X_{n+1} = j|X_n = i] = P[X_1 = j|X_0 = i], \quad (54.2)$$

for all states  $i, j \in E$  and for all time  $n \in \mathbb{N}$ .

Given a homogeneous Markov chain  $\{X_n : n \in \mathbb{N}\}$  we define the **transition matrix** of the Markov chain to be the matrix  $P = [p_{i,j}]_{i,j \in E}$  such that

$$p_{i,j} = P[X_1 = j|X_0 = i], \quad \text{for all } i, j \text{ in } E.$$

Throughout, unless differently specified, for the sake of notational simplicity we will indicate with the term **Markov chain** a homogeneous Markov chain.

A **finite Markov chain** is a Markov chain with finite space state  $E$ ; an **infinite Markov chain** is a Markov chain with infinite space state  $E$ .

A row vector  $\boldsymbol{\pi} = (\pi_i)_{i \in E}$  such that

$$\boldsymbol{\pi}P = \boldsymbol{\pi} \quad (54.3)$$

is an **invariant vector**.

If the invariant vector  $\boldsymbol{\pi}$  is such that

$$\pi_i \geq 0 \text{ for all } i, \quad \text{and} \quad \sum_{i \in E} \pi_i = 1, \quad (54.4)$$

then  $\boldsymbol{\pi}$  is an **invariant probability vector**, or **stationary distribution**. The definition of stationary distribution extends the definition given in Section 9.4 to the case of an infinite matrix  $P$ .

### Facts:

1. The Markov property in Equation (54.1) means that the state  $X_n$  of the system at time  $n$  is sufficient to determine which state might be occupied at time  $n + 1$ , and the past history  $X_0, X_1, \dots, X_{n-1}$  does not influence the future state at time  $n + 1$ .
2. In a homogeneous Markov chain, the property in Equation (54.2) means that the laws which govern the evolution of the system are independent of the time  $n$ ; therefore, the evolution of the Markov chain is ruled by the transition matrix  $P$ , whose  $(i, j)$ th entry represents the probability to change from state  $i$  to state  $j$  in one time unit.
3. The number of rows and columns of the transition matrix  $P$  is equal to the cardinality of  $E$ . In particular, if the set  $E$  is finite,  $P$  is a finite matrix (see Examples 1 and 5); if the set  $E$  is infinite,  $P$  is an infinite matrix, i.e., a matrix with an infinite number of rows and columns (see Examples 2–4).
4. The matrix  $P$  is row stochastic, i.e., it is a matrix with nonnegative entries such that  $\sum_{j \in E} P_{i,j} = 1$  for any  $i \in E$ , i.e., the sum of the entries on each row is equal to 1.
5. If  $|E| < \infty$ , the matrix  $P$  has spectral radius 1. Moreover, the vector  $\mathbf{1}_{|E|}$  is a right eigenvector of  $P$  corresponding to the eigenvalue 1; any nonzero invariant vector is a left eigenvector of  $P$  corresponding to the eigenvalue 1; the invariant probability vector  $\boldsymbol{\pi}$  is a nonnegative left eigenvector of  $P$  corresponding to the eigenvalue 1, normalized so that  $\boldsymbol{\pi} \mathbf{1}_{|E|} = 1$ .
6. In the analysis of Markov chains, we may encounter matrix products  $A = BC$ , where  $B = [b_{i,j}]_{i,j \in E}$  and  $C = [c_{i,j}]_{i,j \in E}$  are nonnegative matrices such that  $\sum_{j \in E} b_{i,j} \leq 1$  and  $\sum_{j \in E} c_{i,j} \leq 1$  for any  $i \in E$  (see, for instance, Fact 7 below). The  $(i, j)$ th entry of  $A$ , given by  $a_{i,j} = \sum_{h \in E} b_{i,h} c_{h,j}$ , is well defined also if the set  $E$  is infinite, since  $0 \leq \sum_{h \in E} b_{i,h} c_{h,j} \leq \sum_{h \in E} b_{i,h} \leq 1$ . Moreover,  $A$  is a nonnegative matrix such that  $\sum_{j \in E} a_{i,j} \leq 1$  for any  $i \in E$ . Indeed,  $\sum_{j \in E} a_{i,j} = \sum_{j \in E} \sum_{h \in E} b_{i,h} c_{h,j} = \sum_{h \in E} b_{i,h} \sum_{j \in E} c_{h,j} \leq \sum_{h \in E} b_{i,h} \leq 1$ . Similarly, the product  $\boldsymbol{v} = \boldsymbol{u}B$ , where  $\boldsymbol{u} = (u_i)_{i \in E}$  is a nonnegative row vector such that  $\sum_{i \in E} u_i \leq 1$ , is well defined also in the case where  $E$  is infinite; moreover,  $\boldsymbol{v} = (v_i)_{i \in E}$  is a nonnegative vector such that  $\sum_{i \in E} v_i \leq 1$ .
7. [Nor99, Theorem 1.1.3] The dynamic behavior of a homogeneous Markov chain is completely characterized by the transition matrix  $P$ :

$$P[X_{n+k} = j | X_n = i] = (P^k)_{i,j},$$

for all times  $n \geq 0$ , all intervals of time  $k \geq 0$ , and all pairs of states  $i$  and  $j$  in  $E$ .

8. In addition to the system dynamics, one must choose the starting point  $X_0$ . Let  $\boldsymbol{\pi}^{(0)} = (\pi_i^{(0)})_{i \in E}$  be a probability distribution on  $E$ , i.e., a nonnegative row vector such that the sum of its components is equal to one. Assume that  $\pi_i^{(0)} = P[X_0 = i]$ , and define the row vector  $\boldsymbol{\pi}^{(n)} = (\pi_i^{(n)})_{i \in E}$  to be the probability vector of the Markov chain at time  $n \geq 1$ , that is,  $\pi_i^{(n)} = P[X_n = i | X_0]$ .

Then

$$\boldsymbol{\pi}^{(n+1)} = \boldsymbol{\pi}^{(n)} P, \quad n \geq 0, \tag{54.5}$$

$$\boldsymbol{\pi}^{(n)} = \boldsymbol{\pi}^{(0)} P^n, \quad n \geq 0. \tag{54.6}$$

9. If the initial distribution  $\boldsymbol{\pi}^{(0)}$  coincides with the invariant probability vector  $\boldsymbol{\pi}$ , then  $\boldsymbol{\pi}^{(n)} = \boldsymbol{\pi}$  for any  $n \geq 0$ .
10. In certain applications (see for instance, Example 5) we are interested in the asymptotic behavior of the Markov chain. In particular, we would like to compute, if it exists, the vector  $\lim_{n \rightarrow \infty} \boldsymbol{\pi}^{(n)}$ . From Equation (54.5) of Fact 8 one deduces that, if such limit exists, it coincides with the invariant probability vector, i.e.,  $\lim_{n \rightarrow \infty} \boldsymbol{\pi}^{(n)} = \boldsymbol{\pi}$ .

**Examples:**

1. *Random walk on  $\{0, 1, \dots, k\}$ :* Consider a particle which moves on the interval  $[0, k]$  in unit steps at integer instants of time; let  $X_n \in \{0, 1, \dots, k\}$ ,  $n \geq 0$ , be the position of the particle at time  $n$  and let  $0 < p < 1$ . Assume that, if the particle is in the open interval  $(0, k)$ , at the next unit time it will move to the right with probability  $p$  and to the left with probability  $q = 1 - p$ ; if the particle is in position 0, it will move to the right with probability 1; if the particle is in position  $k$ , it will move to the left with probability 1. Clearly, the discrete stochastic process  $\{X_n : n \in \mathbb{N}\}$  is a homogeneous Markov chain with space state the set  $E = \{0, 1, \dots, k\}$ . The transition matrix is the  $(k + 1) \times (k + 1)$  matrix  $P = [p_{i,j}]_{i,j=0,\dots,k}$ , given by

$$P = \begin{bmatrix} 0 & 1 & 0 & \dots & 0 \\ q & 0 & p & \ddots & \vdots \\ 0 & \ddots & \ddots & \ddots & 0 \\ \vdots & \ddots & q & 0 & p \\ 0 & \dots & 0 & 1 & 0 \end{bmatrix}.$$

From Equation (54.6) of Fact 8 one has that, if the particle is in position 0 at time 0, the probability vector at time  $n = 10$  is the vector

$$[\pi_0^{(10)}, \pi_1^{(10)}, \dots, \pi_k^{(10)}] = [1, 0, \dots, 0] P^{10}.$$

2. *Random walk on  $\mathbb{N}$ :* If we allow the particle to move on  $\mathbb{N}$ , we have a homogeneous Markov chain with state space the set  $E = \mathbb{N}$ . The transition matrix is semi-infinite and is given by

$$P = \begin{bmatrix} 0 & 1 & 0 & 0 & \dots \\ q & 0 & p & 0 & \ddots \\ 0 & q & 0 & p & \ddots \\ 0 & 0 & q & 0 & \ddots \\ \vdots & \ddots & \ddots & \ddots & \ddots \end{bmatrix}.$$

3. *Random walk on  $\mathbb{Z}$* : If we allow the particle to move on  $\mathbb{Z}$ , we still have a homogeneous Markov chain, with state space the set  $E = \mathbb{Z}$ . The transition matrix is bi-infinite and is given by

$$P = \begin{bmatrix} \ddots & \ddots & \ddots & \ddots & \ddots \\ \ddots & 0 & p & 0 & \ddots \\ \ddots & q & 0 & p & \ddots \\ \ddots & 0 & q & 0 & \ddots \\ \ddots & \ddots & \ddots & \ddots & \ddots \end{bmatrix}.$$

4. *A simple queueing system* [BLM05, Example 1.3]: Simple queues consist of one server which attends to one customer at a time, in order of their arrivals. We assume that time is discretized into intervals of length one, that a random number of customers join the system during each interval, that customers do not leave the queue, and that the server removes one customer from the queue at the end of each interval, if there is any. Defining  $\alpha_n$  as the number of new arrivals during the interval  $[n-1, n)$  and  $X_n$  as the number of customers in the system at time  $n$ , we have

$$X_{n+1} = \begin{cases} X_n + \alpha_{n+1} - 1 & \text{if } X_n + \alpha_{n+1} \geq 1 \\ 0 & \text{if } X_n + \alpha_{n+1} = 0. \end{cases}$$

If  $\{\alpha_n\}$  is a collection of independent random variables, then  $X_{n+1}$  is conditionally independent of  $X_0, \dots, X_{n-1}$  if  $X_n$  is known. If, in addition, the  $\alpha_n$ 's are identically distributed, then  $\{X_n\}$  is homogeneous. The state space is  $\mathbb{N}$  and the transition matrix is

$$P = \begin{bmatrix} q_0 + q_1 & q_2 & q_3 & q_4 & \cdots \\ q_0 & q_1 & q_2 & q_3 & \ddots \\ & q_0 & q_1 & q_2 & \ddots \\ 0 & & \ddots & \ddots & \ddots \end{bmatrix},$$

where  $q_i$  is the probability  $P[\alpha = i]$  that  $i$  new customers join the queue during a unit time interval,  $\alpha$  denoting any of the identically distributed random variables  $\alpha_n$ . Markov chains having transition matrix of the form

$$P = \begin{bmatrix} B_1 & B_2 & B_3 & B_4 & \cdots \\ A_0 & A_1 & A_2 & A_3 & \ddots \\ & A_0 & A_1 & A_2 & \ddots \\ 0 & & \ddots & \ddots & \ddots \end{bmatrix},$$

where  $A_i, B_{i+1}, i \geq 0$ , are nonnegative  $k \times k$  matrices, are called M/G/1-type Markov chains, and model a large variety of queuing problems. (See [Neu89], [LR99], and [BLM05].)

5. *Search engines* (see Section 63.5, [PBM99], [ANT02] and [Mol04, Section 2.11]): PageRank is used by Google to sort, in order of relevance, the pages on the Web that match the query of the user. From the Web page *Google Technology* at <http://www.google.com/technology/>: "The heart of our software is PageRank<sup>TM</sup>, a system for ranking Web pages developed by our founders Larry Page and Sergey Brin at Stanford University. And while we have dozens of engineers working to improve every aspect of Google on a daily basis, PageRank continues to provide the basis for all

of our Web search tools.” Surfing on the Web is seen as a random walk, where either one starts from a Web page and goes from one page to the next page by randomly following a link (if any), or one simply chooses a random page from the Web. Let  $E$  be the set of Web pages that can be reached by following a sequence of hyperlinks starting from a given Web page. If  $k$  is the number of Web pages, i.e.,  $k = |E|$ , the connectivity matrix is defined as the  $k \times k$  matrix  $G = [g_{i,j}]$  such that  $g_{i,j} = 1$  if there is a hyperlink from page  $i$  to page  $j$ , and zero otherwise. Let  $r_i = \sum_j g_{i,j}$  and  $c_i = \sum_j g_{j,i}$  be the row and column sums of  $G$ ; the quantities  $r_i$  and  $c_i$  are called the out-degree and the in-degree, respectively, of the page  $i$ . Let  $0 < q < 1$  and let  $P = [p_{i,j}]$  be the  $k \times k$  stochastic matrix such that  $p_{i,j} = qg_{i,j}/r_i + (1 - q)/k$ ,  $i, j = 1, \dots, k$ . The value  $q$  is the probability that the random walk on  $E$  follows a link and, therefore,  $1 - q$  is the probability that an arbitrary page is chosen. The matrix  $P$  is the transition matrix of the Markov chain that models the random walk on  $E$ . The importance of a Web page is related to the probability to reach such page during this random walk as the time tends to infinity. Therefore, Google’s PageRank is determined by the invariant probability vector  $\pi$  of  $P$ : The larger the value of an entry  $\pi_i$  of  $\pi$ , the higher the relevance of the  $i$ th Web page in the set  $E$ .

## 54.2 Irreducible Classes

---

Some of the Definitions and Facts given in this section extend the corresponding Definitions and Facts of Chapter 9 and Chapter 29. Indeed, in these chapters, it is assumed that the matrices have a finite size, while in the framework of Markov chains we may encounter infinite matrices.

### Definitions:

The **transition graph** of a Markov chain with transition matrix  $P$  is the digraph of  $P$ ,  $\Gamma(P)$ . That is, the digraph defined as follows: To each state in  $E$  there corresponds a vertex of the digraph and one defines a directed arc from vertex  $i$  to vertex  $j$  for each pair of states such that  $p_{i,j} > 0$ . More information about digraphs can be found in Chapter 9 and Chapter 29.

A **closed walk** in a digraph is a walk in which the first vertex equals the last vertex.

State  $i$  **leads to**  $j$  (or  $i$  **has access to**  $j$ ) if there is a walk from  $i$  to  $j$  in the transition graph. States  $i$  and  $j$  **communicate** if  $i$  leads to  $j$  and  $j$  leads to  $i$ .

A Markov chain is called **irreducible** if the transition graph is strongly connected, i.e., if all the states communicate. A Markov chain is called **reducible** if it is not irreducible.

The strongly connected components of the transition graph are the **communicating classes of states**, or of the Markov chain. Communicating classes are also called **access equivalence classes** or **irreducible classes**.

A communicating class  $C$  is a **final class** if for every state  $i$  in  $C$ , there is no state  $j$  outside of  $C$  such that  $i$  leads to  $j$ . If, on the contrary, there is a state in  $C$  that leads to some state outside of  $C$ , the class is a **passage class**. A single state that forms a final class by itself is **absorbing**. In Section 9.4, passage classes are called transient classes, and final classes are called ergodic classes; in fact, transient and ergodic states of Markov chains will be introduced in Section 54.3, and for finite Markov chains the states in a passage class are transient, and the states in a final class are ergodic, cf. Section 54.4.

A state  $i$  is **periodic** with period  $\delta \geq 2$  if all closed walks through  $i$  in the transition graph have a length that is a multiple of  $\delta$ . A state  $i$  is **aperiodic** if it is not periodic.

A Markov chain is **periodic** with period  $\delta$  if all states are periodic and have the same period  $\delta$ .

### Facts:

1. A Markov chain is irreducible if and only if the transition matrix  $P$  is irreducible, i.e., if  $P$  is not permutation similar to a block triangular matrix, cf. Section 9.2, Section 27.1.
2. If we adopt the convention that each state communicates with itself, then the relation *communicates* is an equivalence relation and the communicating classes are the equivalence classes of this relation, cf. Section 9.1.

3. A Markov chain is irreducible if and only if the states form one single communicating class, cf. Section 9.1, Section 9.2.
4. If a Markov chain with transition matrix  $P$  has  $K \geq 2$  communicating classes, denoted by  $C_1, C_2, \dots, C_K$ , then the states may be permuted so that the transition matrix  $P' = \Pi P \Pi^T$  associated with the permuted states is block triangular:

$$P' = \begin{bmatrix} P_{1,1} & P_{1,2} & \dots & P_{1,K} \\ & P_{2,2} & \ddots & \vdots \\ & & \ddots & P_{K-1,K} \\ 0 & & & P_{K,K} \end{bmatrix}$$

where  $P_{i,j}$  is the submatrix of transition probabilities from the states of  $C_i$  to  $C_j$ , the diagonal blocks are irreducible square matrices, and  $\Pi$  is the permutation matrix associated with the rearrangement, cf. Section 9.2.

5. [Çin75, Theorem (3.16), Chap. 5] Periodicity is a class property and all states in a communicating class have the same period. Thus, for irreducible Markov chains, either all states are aperiodic, or all have the same period  $\delta$ , which we may call the period of the Markov chain itself.

**Examples:**

1. Figure 54.1 is the transition graph associated with the Markov chain on  $E = \{1, 2, 3\}$  with transition matrix

$$P = \begin{bmatrix} 1 & 0 & 0 \\ \frac{1}{3} & \frac{1}{3} & \frac{1}{3} \\ \frac{1}{4} & \frac{1}{2} & \frac{1}{4} \end{bmatrix}.$$

The two sets  $C_1 = \{1\}$  and  $C_2 = \{2, 3\}$  are two communicating classes.  $C_2$  is a passage class, while  $C_1$  is a final class, therefore state 1 is absorbing.

2. Figure 54.2 is the transition graph associated with the Markov chain on  $E = \{k \in \mathbb{N} : k \geq 1\}$  with transition matrix having following structure:

$$P = \begin{bmatrix} 0 & * & & & & & & 0 \\ 0 & 0 & * & & & & & \\ * & 0 & 0 & * & & & & \\ 0 & 0 & 0 & 0 & * & & & \\ 0 & 0 & * & 0 & 0 & * & & \\ 0 & 0 & 0 & 0 & 0 & 0 & \ddots & \\ 0 & 0 & 0 & 0 & * & 0 & \ddots & \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots & \ddots & \ddots \end{bmatrix},$$

FIGURE 54.1 Transition graph of the Markov chain of Example 1.

FIGURE 54.2 Graph of an infinite irreducible periodic Markov chain of period 3.

where “\*” denotes a nonzero element. This is an example of a periodic irreducible Markov chain of period 3.

### 54.3 Classification of the States

**Definitions:**

Let  $T_j$  be the time of the first visit to  $j$ , without taking into account the state at time 0, i.e.,

$$T_j = \min\{n \geq 1 : X_n = j\}.$$

Define

$$f_j = P[T_j < \infty | X_0 = j],$$

that is,  $f_j$  is the probability that, starting from  $j$ , the Markov chain returns to  $j$  in a finite time.

A state  $j \in E$  is **transient** if  $f_j < 1$ .

A state  $j \in E$  is **recurrent** if  $f_j = 1$ . A recurrent state  $j \in E$  is **positive recurrent** if the expected return time  $E[T_j | X_0 = j]$  is finite; it is **null recurrent** if the expected return time  $E[T_j | X_0 = j]$  is infinite. Positive recurrent states are also called **ergodic**.

A Markov chain is **positive/null recurrent** or **transient** if all its states are positive/null recurrent or transient, respectively.

A **regular Markov chain** is a positive recurrent Markov chain that is aperiodic.

The matrix  $R = \sum_{n=0}^{\infty} P^n$  is the **potential matrix** of the Markov chain.

**Facts:**

1. Transient states may be visited only a finite number of times by the Markov chain. On the contrary, once the Markov chain has visited one recurrent state, it will return to it over and over again; if  $j$  is null recurrent the expected time between two successive visits to  $j$  is infinite.
2. [Çin75, Cor. (2.13), Chap. 5] For the potential matrix  $R = [r_{i,j}]$  one has  $r_{j,j} = 1/(1 - f_j)$ , where we set  $1/0 = \infty$ .
3. [Çin75, Sec. 3, Chap. 5] The  $(j, j)$ th entry of  $R$  is the expected number of returns of the Markov chain to state  $j$ . A state  $j$  is recurrent if and only if  $r_{j,j} = \infty$ . A state  $j$  is transient if and only if  $r_{j,j} < \infty$ .
4. [Nor99, Theorems 1.5.4, 1.5.5, 1.7.7] The nature of a state is a class property. More specifically, the states in a passage class are transient; in a final class the states are either all positive recurrent, or all null recurrent, or all transient.
5. [Nor99, Theorem 1.5.6] If a final class contains a finite number of states only, then all its states are positive recurrent.
6. From Facts 4 and 5 one has that, for a communicating class with a finite number of states, either all the states are transient or all the states are positive recurrent.
7. From Fact 4 above, if a Markov chain is irreducible, the states are either all positive recurrent, or all null recurrent, or all transient. Therefore, an irreducible Markov chain is either positive recurrent or null recurrent or transient.

8. [Nor99, Secs. 1.7 and 1.8] Assume that the Markov chain is irreducible. The Markov chain is positive recurrent if and only if there exists a strictly positive invariant probability vector, that is, a row vector  $\pi = (\pi_i)_{i \in E}$  such that  $\pi_i > 0$  that satisfies Equations (54.3), (54.4) of Section 54.1. The invariant vector  $\pi$  is unique among nonnegative vectors, up to a multiplicative constant.
9. [Nor99, Secs. 1.7 and 1.8], [BLM05, Sec. 1.5] If the Markov chain is irreducible and null recurrent, there exists a strictly positive invariant vector, unique up to a multiplicative constant, such that the sum of its elements is not finite. Thus, there always exists an invariant vector for the transition matrix of a recurrent Markov chain. Some transient Markov chains also have an invariant vector (with infinite sum of the entries, like in the null recurrent case) but some do not.
10. [Çin75, Theorem (3.2), Chap. 5], [Nor99, Secs. 1.7 and 1.8] If  $j$  is a transient or null recurrent state, then for any  $i \in E$ ,  $\lim_{n \rightarrow \infty} (P^n)_{i,j} = 0$ . If  $j$  is a positive recurrent and aperiodic state, then  $\lim_{n \rightarrow \infty} (P^n)_{j,j} > 0$ . If  $j$  is periodic with period  $\delta$ , then  $\lim_{n \rightarrow \infty} (P^{n\delta})_{j,j} > 0$ .
11. [Nor99, Secs. 1.7 and 1.8] Assume that the Markov chain is irreducible, aperiodic, and positive recurrent. Then  $\lim_{n \rightarrow \infty} (P^n)_{i,j} = \pi_j > 0$  for all  $j$ , independently of  $i$ , where  $\pi = (\pi_i)_{i \in E}$  is the stationary distribution.
12. Facts 3, 4, 6, and 10 provide a criterium to classify the states. First identify the communicating classes. If a communicating class contains a finite number of states, the states are all positive recurrent if the communicating class is final; the states are all transient if the communicating class is a passage class. If a communicating class has infinitely many states, we apply Fact 3 to determine if they are recurrent or transient; for recurrent states we use Fact 10 to determine if they are null or positive recurrent.

### Examples:

1. Let  $P$  be the transition matrix of Example 1 of Section 54.2. Observe that with positive probability the Markov chain moves from state 2 or 3 to state 1, and when the Markov chain will be in state 1, it will remain there forever. Indeed, according to Facts 4 and 5, states 2 and 3 are transient since they belong to a passage class, and state 1 is positive recurrent since it is absorbing. Moreover, if we partition the matrix  $P$  into the  $2 \times 2$  block matrix

$$P = \begin{bmatrix} 1 & 0 \\ A & B \end{bmatrix},$$

where

$$A = \begin{bmatrix} \frac{1}{3} \\ \frac{1}{4} \end{bmatrix}, \quad B = \begin{bmatrix} \frac{1}{3} & \frac{1}{3} \\ \frac{1}{2} & \frac{1}{4} \end{bmatrix},$$

we may easily observe that

$$P^n = \begin{bmatrix} 1 & 0 \\ \sum_{i=0}^{n-1} B^i A & B^n \end{bmatrix}.$$

Since  $\|B\|_1 = \frac{5}{6}$ , then  $\rho(B) < 1$ , and therefore  $\lim_{n \rightarrow \infty} B^n = 0$  and  $\sum_{n=0}^{\infty} B^n = (I - B)^{-1}$ . A simple computation leads to

$$\lim_{n \rightarrow \infty} P^n = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 0 & 0 \\ 1 & 0 & 0 \end{bmatrix}, \quad R = \sum_{n=0}^{\infty} P^n = \begin{bmatrix} \infty & 0 & 0 \\ \infty & \frac{9}{4} & 1 \\ \infty & \frac{3}{2} & 2 \end{bmatrix},$$

in accordance with Facts 3 and 10.

2. [BLM05, Ex. 1.19] The transition matrix

$$P = \begin{bmatrix} 0 & 1 & & & 0 \\ \frac{1}{2} & 0 & & & \\ & \frac{1}{2} & 0 & & \\ & & \ddots & \ddots & \ddots \\ 0 & & & \ddots & \ddots \end{bmatrix}$$

is irreducible, and  $\pi = [\frac{1}{2}, 1, 1, \dots]$  is an invariant vector. The vector  $\pi$  has “infinite” mass, that is, the sum of its components is infinite. In fact, the Markov chain is actually null recurrent (see [BLM05, Sec. 1.5]).

3. [BLM05, Ex. 1.20] For the transition matrix

$$P = \begin{bmatrix} 0 & 1 & & & 0 \\ \frac{1}{4} & 0 & & & \\ & \frac{1}{4} & 0 & & \\ & & \ddots & \ddots & \ddots \\ 0 & & & \ddots & \ddots \end{bmatrix}$$

one has  $\pi P = \pi$  with  $\pi = [1, 4, 12, 36, 108, \dots]$ . The vector  $\pi$  has unbounded elements. In this case the Markov chain is transient.

4. [BLM05, Ex. 1.21] For the transition matrix

$$P = \begin{bmatrix} 0 & 1 & & & 0 \\ \frac{3}{4} & 0 & & & \\ & \frac{3}{4} & 0 & & \\ & & \ddots & \ddots & \ddots \\ 0 & & & \ddots & \ddots \end{bmatrix}$$

one has  $\pi P = \pi$  with  $\pi = \frac{4}{3}[\frac{1}{4}, \frac{1}{3}, \frac{1}{9}, \frac{1}{27}, \dots]$  and  $\sum_i \pi_i = 1$ . In this case the Markov chain is positive recurrent by Fact 8.

## 54.4 Finite Markov Chains

---

The transition matrix of a finite Markov chain is a finite dimensional stochastic matrix; the reader is advised to consult Section 9.4 for properties of finite stochastic matrices.

### Definitions:

A  $k \times k$  matrix  $A$  is **weakly cyclic of index  $\delta$**  if there exists a permutation matrix  $\Pi$  such that  $A' = \Pi A \Pi^T$  has the block form

$$A' = \begin{bmatrix} 0 & 0 & \dots & 0 & A_{1,\delta} \\ A_{2,1} & 0 & \ddots & & 0 \\ 0 & A_{3,2} & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 & 0 \\ 0 & \dots & 0 & A_{\delta,\delta-1} & 0 \end{bmatrix},$$

where the zero diagonal blocks are square.

**Facts:**

1. If  $P$  is the transition matrix of a finite Markov chain, there exists an invariant probability vector  $\pi$ . If  $P$  is irreducible, the vector  $\pi$  is strictly positive and unique, cf. Section 9.4.
2. For a finite Markov chain no state is null recurrent, and not all states are transient. The states belonging to a final class are positive recurrent, and the states belonging to a passage class are transient, cf. Section 9.4.
3. [BP94, Theorem (3.9), Chap. 8] Let  $P$  be the transition matrix of a finite Markov chain. The Markov chain is
  - (a) Positive recurrent if and only if  $P$  is irreducible.
  - (b) Regular if and only if  $P$  is primitive.
  - (c) Periodic if and only if  $P$  is irreducible and periodic.
4. [BP94, Theorem (3.16), Chap. 8] Let  $P$  be the transition matrix of a finite irreducible Markov chain. Then the Markov chain is periodic if and only if  $P$  is a weakly cyclic matrix.
5. If  $P$  is the transition matrix of a regular Markov chain, then there exists  $\lim_{n \rightarrow \infty} P^n = \mathbf{1}\pi$ , where  $\pi$  is the probability invariant vector. If the Markov chain is periodic, the sequence  $\{P^n\}_{n \geq 0}$  is bounded, but not convergent.
6. [Mey89] Assume that  $E = \{1, 2, \dots, k\}$  and that  $P$  is irreducible. Let  $1 \leq m \leq k - 1$  and  $\alpha = \{1, \dots, m\}$ ,  $\beta = \{m + 1, \dots, k\}$ . Then
  - (a) The matrix  $I - P[\alpha]$  is an  $M$ -matrix.
  - (b) The matrix  $P' = P[\alpha] + P[\alpha, \beta](I - P[\beta])^{-1}P[\beta, \alpha]$ , such that  $I - P'$  is the Schur complement of  $I - P[\beta]$  in the matrix

$$\begin{bmatrix} I - P[\alpha] & -P[\alpha, \beta] \\ -P[\beta, \alpha] & I - P[\beta] \end{bmatrix},$$

is a stochastic irreducible matrix.

- (c) If we partition the invariant probability vector  $\pi$  as  $\pi = [\pi_\alpha, \pi_\beta]$ , with  $\pi_\alpha = (\pi_i)_{i \in \alpha}$  and  $\pi_\beta = (\pi_i)_{i \in \beta}$ , we have  $\pi_\alpha P' = \pi_\alpha$ ,  $\pi_\beta = \pi_\alpha P[\alpha, \beta](I - P[\beta])^{-1}$ .

**Examples:**

1. The matrix

$$P = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$$

is the transition matrix of a periodic Markov chain of period 2. In fact,  $P$  is an irreducible matrix of period 2.

2. The Markov chain with transition matrix

$$P = \begin{bmatrix} \frac{1}{5} & \frac{1}{5} \\ 1 & 0 \end{bmatrix}$$

is regular. In fact,  $P^2 > 0$ , i.e.,  $P$  is primitive.

3. Let

$$P = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} & 0 & 0 \\ \frac{1}{4} & \frac{1}{2} & \frac{1}{4} & 0 \\ \frac{1}{3} & 0 & \frac{1}{3} & \frac{1}{3} \\ 0 & 0 & \frac{1}{2} & \frac{1}{2} \end{bmatrix}$$

be the transition matrix of a Markov chain. The matrix  $P$  is irreducible and aperiodic, therefore the Markov chain is regular. The vector  $\pi = \frac{1}{13}[4, 4, 3, 2]$  is the stationary distribution. According to Fact 5, one has

$$\lim_{n \rightarrow \infty} P^n = \frac{1}{13} \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix} [4 \ 4 \ 3 \ 2].$$

## 54.5 Censoring

---

### Definitions:

Partition the state space  $E$  into two disjoint subsets,  $\alpha$  and  $\beta$ , and denote by  $\{t_0, t_1, t_2, \dots\}$  the time when the Markov chain visits the set  $\alpha$ :

$$t_0 = \min\{n \geq 0 : X_n \in \alpha\}, \quad t_{k+1} = \min\{n \geq t_k + 1 : X_n \in \alpha\},$$

for  $k \geq 0$ . The **censored process** restricted to the subset  $\alpha$  is the sequence  $\{Y_n\}_{n \geq 0}$ , where  $Y_n = X_{t_n}$ , of successive states visited by the Markov chain in  $\alpha$ .

### Facts:

1. [BLM05, Sec. 1.6] The censored process  $\{Y_n\}$  is a Markov chain.
2. [BLM05, Sec. 1.6] Arrange the states so that the transition matrix can be partitioned as

$$P = \begin{bmatrix} P[\alpha] & P[\alpha, \beta] \\ P[\beta, \alpha] & P[\beta] \end{bmatrix}.$$

Then the transition matrix of  $\{Y_n\}$  is

$$P' = P[\alpha] + \sum_{n=0}^{+\infty} (P[\alpha, \beta] P[\beta]^n P[\beta, \alpha])$$

provided that  $\sum_{n=0}^{+\infty} (P[\alpha, \beta] P[\beta]^n P[\beta, \alpha])$  is convergent. If the series  $S' = \sum_{n=0}^{+\infty} P[\beta]^n$  is convergent, then we may rewrite  $P'$  as  $P' = P[\alpha] + P[\alpha, \beta] S' P[\beta, \alpha]$ .

3. [BLM05, Theorem 1.23] Assume that the Markov chain is irreducible and positive recurrent. Partition the stationary distribution  $\pi$  as  $\pi = [\pi_\alpha, \pi_\beta]$ , with  $\pi_\alpha = (\pi_i)_{i \in \alpha}$  and  $\pi_\beta = (\pi_i)_{i \in \beta}$ . Then one has  $\pi_\alpha P' = \pi_\alpha$ ,  $\pi_\beta = \pi_\alpha P[\alpha, \beta] S'$ , where  $P'$  and  $S'$  are defined in Fact 2.
4. [BLM05, Secs. 1.6, 3.5, 4.5] In the case of finite Markov chains, censoring is equivalent to Schur complementation (see Fact 6 of Section 54.4). Censoring is at the basis of several numerical methods for computing the invariant probability vector  $\pi$ ; indeed, from Fact 3, if the invariant probability vector  $\pi_\alpha$  associated with the censored process is available, the vector  $\pi_\beta$  can be easily computed from  $\pi_\alpha$ . A smart choice of the sets  $\alpha$  and  $\beta$  can lead to an efficient computation of the stationary distribution. As an example of this fact, Ramaswami's recursive formula for computing the vector  $\pi$  associated with an M/G/1-type Markov chain is based on successive censorings, where the set  $A$  is finite, and  $\beta = \mathbb{N} - \alpha$ .

## 54.6 Numerical Methods

---

### Definitions:

Let  $A$  be a  $k \times k$  matrix. A splitting  $A = M - N$ , where  $\det M \neq 0$ , is a **regular splitting** if  $M^{-1} \geq 0$  and  $N \geq 0$ . A regular splitting is said to be **semiconvergent** if the matrix  $M^{-1}N$  is semiconvergent.

### Facts:

1. The main computational problem in Markov chains is the computation of the invariant probability vector  $\pi$ . If the space state  $E$  is finite and the Markov chain is irreducible, classical techniques for solving linear systems can be adapted and specialized to this purpose. We refer the reader to the book [Ste94] for a comprehensive treatment on these numerical methods; in facts below we analyze the methods based on LU factorization and on regular splittings of  $M_0$ -matrices. If the space state  $E$  is infinite, general numerical methods for computing  $\pi$  can be hardly designed. Usually, when the state space is infinite, the matrix  $P$  has some structures which are specific of the real problem modeled by the Markov chain, and numerical methods for computing  $\pi$  which exploit the structure of  $P$  can be designed. Quite common structures arising in queueing problems are the (block) tridiagonal structure, the (block) Hessenberg structure, and the (block) Toeplitz structure (see, for instance, Example 4 Section 54.1). We refer the reader to the book [BLM05] for a treatment on the numerical solution of Markov chains, where the matrix  $P$  is infinite and structured.
2. [BP94, Cor. (4.17), Chap. 6], [Ste94, Sec. 2.3] If  $P$  is a  $k \times k$  irreducible stochastic matrix, then the matrix  $I - P$  has a unique LU factorization  $I - P = LU$ , where  $L$  is a lower triangular matrix with unit diagonal entries and  $U$  is upper triangular. Moreover,  $L$  and  $U$  are  $M_0$ -matrices,  $U$  is singular,  $U\mathbf{1}_k = 0$ , and  $(U)_{k,k} = 0$ .
3. [Ste94, Sec. 2.5] The computation of the LU factorization of an  $M_0$ -matrix by means of Gaussian elimination involves additions of nonnegative numbers in the computation of the off-diagonal entries of  $L$  and  $U$ , and subtractions of nonnegative numbers in the computation of the diagonal entries of  $U$ . Therefore, numerical cancellation cannot occur in the computation of the off-diagonal entries of  $L$  and  $U$ . In order to avoid possible cancellation errors in computing the diagonal entries of  $U$ , Grassmann, Taksar, and Heyman have introduced in [GTH85] a simple trick, which fully exploits the property that  $U$  is an  $M_0$ -matrix such that  $U\mathbf{1}_k = 0$ . At the general step of the elimination procedure, the diagonal entries are not updated by means of the classical elimination formulas, but are computed as minus the sum of the off-diagonal entries. Details are given in Algorithm 1.
4. If  $I - P = LU$  is the LU factorization of  $I - P$ , the invariant probability vector  $\pi$  is computed by solving the two triangular systems  $\mathbf{y}L = \mathbf{x}$  and  $\mathbf{x}U = 0$ , where  $\mathbf{x}$  and  $\mathbf{y}$  are row vectors, and then by normalizing the solution  $\mathbf{y}$ . From Fact 2, the nontrivial solution of the latter system is  $\mathbf{x} = \alpha \mathbf{e}_k^T$ , for any  $\alpha \neq 0$ . Therefore, if we choose  $\alpha = 1$ , the vector  $\pi$  can be simply computed by solving the system  $\mathbf{y}L = \mathbf{e}_k^T$  by means of back substitution, and then by setting  $\pi = (1/\mathbf{y}\mathbf{1})\mathbf{y}$ , as described in Algorithm 2.
5. [BP94, Cor. (4.17), Chap. 6] If  $P$  is a  $k \times k$  irreducible stochastic matrix, the matrix  $I - P^T$  has a unique LU factorization  $I - P^T = LU$ , where  $L$  is a lower triangular matrix with unit diagonal entries, and  $U$  is upper triangular. Moreover, both  $L$  and  $U$  are  $M_0$ -matrices,  $U$  is singular, and  $(U)_{k,k} = 0$ . Since  $L$  is nonsingular, the invariant probability vector can be computed by calculating a nonnegative solution of the system  $U\mathbf{y} = 0$  by means of back substitution, and by setting  $\pi = (1/\|\mathbf{y}\|_1)\mathbf{y}^T$ .
6. If  $P$  is a  $k \times k$  irreducible stochastic matrix, and if  $\hat{P}$  is the  $(k-1) \times (k-1)$  matrix obtained by removing the  $i$ th row and the  $i$ th column of  $P$ , where  $i \in \{1, \dots, k\}$ , then the matrices  $I - \hat{P}^T$  and  $I - \hat{P}$  have a unique LU factorization, where both the factors  $L$  and  $U$  are  $M$ -matrices. Therefore, if  $i = k$  and if the matrix  $I - P^T$  is partitioned as

$$I - P^T = \begin{bmatrix} I - \hat{P}^T & \mathbf{a} \\ \mathbf{b}^T & c \end{bmatrix},$$

- one finds that the vector  $\hat{\pi} = [\pi_1, \dots, \pi_{k-1}]^T$  solves the nonsingular system  $(I - \hat{P}^T)\hat{\pi} = -\pi_k \mathbf{a}$ . Therefore, the vector  $\pi$  can be computed by solving the system  $(I - \hat{P}^T)\mathbf{y} = -\mathbf{a}$ , say by means of LU factorization, and then by setting  $\pi = [\mathbf{y}^T, 1]/(1 + \|\mathbf{y}\|_1)$ .
7. [Ste94, Sec. 3.6] Let  $P$  be a finite irreducible stochastic matrix, and let  $I - P^T = M - N$  be a regular splitting of  $I - P^T$ . Then the matrix  $H = M^{-1}N$  has spectral radius 1 and 1 is a simple eigenvalue of  $H$ .
  8. [Ste94, Theorem 3.3], [BP94], [Var00] Fact 7 above is not sufficient to guarantee that any regular splitting of  $I - P^T$ , where  $P$  is a finite stochastic irreducible matrix, is semiconvergent (see the Example below). In order to be semiconvergent, the matrix  $H$  must not have eigenvalues of modulus 1 different from 1, and the Jordan blocks associated with 1 must have dimension 1.
  9. An iterative method for computing  $\pi$  based on a regular splitting  $I - P^T = M - N$  consists in generating the sequence  $\mathbf{x}_{n+1} = M^{-1}N\mathbf{x}_n$ , for  $n \geq 0$ , starting from an initial column vector  $\mathbf{x}_0$ . If the regular splitting is semiconvergent, by choosing  $\mathbf{x}_0 \geq 0$  such that  $\|\mathbf{x}_0\|_1 = 1$ , the sequence  $\{\mathbf{x}_n\}_n$  converges to  $\pi^T$ . The convergence is linear and the asymptotic rate of convergence is the second largest modulus eigenvalue  $\theta$  of  $M^{-1}N$ .
  10. [Ste94, Theorem 3.6] If  $P$  is a finite stochastic matrix, the methods of Gauss–Seidel, Jacobi, and SOR, for  $0 < \omega \leq 1$ , applied to  $I - P^T$ , are based on regular splittings.
  11. If  $E$  is finite, the invariant probability vector is, up to a multiplicative constant, the nonnegative left eigenvector associated with the dominating eigenvalue of  $P$ . The power method applied to the matrix  $P^T$  is the iterative method defined by the trivial regular splitting  $I - P^T = M - N$ , where  $M = I$ ,  $N = P^T$ . If  $P$  is primitive, the power method is convergent.
  12. [Ste94, Theorems 3.6, 3.7] If  $P$  is a  $k \times k$  irreducible stochastic matrix, and if  $\hat{P}$  is the  $(k-1) \times (k-1)$  matrix obtained by removing the  $i$ th row and the  $i$ th column of  $P$ , where  $i \in \{1, \dots, k\}$ , then any regular splitting of the matrix  $I - \hat{P}^T = M - N$  is convergent. In particular, the methods of Gauss–Seidel, Jacobi, and SOR, for  $0 < \omega \leq 1$ , applied to  $I - \hat{P}^T$ , being based on regular splittings, are convergent.
  13. [Ste94, Theorem 3.17] Let  $P$  be a  $k \times k$  irreducible stochastic matrix and let  $\epsilon > 0$ . Then the splitting  $I - P^T = M_\epsilon - N_\epsilon$ , where  $M_\epsilon = D - L + \epsilon I$  and  $N_\epsilon = U + \epsilon I$ , is a semiconvergent regular splitting for every  $\epsilon > 0$ .
  14. [Ste94, Theorem 3.18] Let  $P$  be a  $k \times k$  irreducible stochastic matrix, let  $I - P^T = M - N$  be a regular splitting of  $I - P^T$ , and let  $H = M^{-1}N$ . Then the matrix  $H_\alpha = (1 - \alpha)I + \alpha H$  is semiconvergent for any  $0 < \alpha < 1$ .

### Algorithms:

1. The following algorithm computes the LU factorization of  $I - P$  by using the Grassmann, Taksar, Heyman (GTH) trick of Fact 3:

#### Computation of the LU factorization of $I - P$ with GTH trick

Input: the  $k \times k$  irreducible stochastic matrix  $P$ .

Output: the matrix  $A = [a_{i,j}]$  such that  $a_{i,j} = l_{i,j}$  for  $i > j$ , and  $a_{i,j} = u_{i,j}$  for  $i \leq j$ , where  $L = [l_{i,j}]$ ,  $U = [u_{i,j}]$  are the factors of the LU factorization of  $I - P$ .

Computation:

1– set  $A = I - P$ ;

2– for  $m = 1, \dots, k - 1$ :

(a) for  $i = m + 1, \dots, k$ , set  $a_{i,m} = a_{i,m}/a_{m,m}$ ;

(b) for  $i, j = m + 1, \dots, k$ , set  $a_{i,j} = a_{i,j} - a_{i,m}a_{m,j}$  if  $i \neq j$ ;

(c) for  $i = m + 1, \dots, k$  set  $a_{i,i} = -\sum_{l=m+1, l \neq i}^k a_{i,l}$ .

2. The algorithm derived by Fact 4 above is the following:

**Computation of  $\pi$  through LU factorization**

Input: the factor  $L = [l_{i,j}]$  of the LU factorization of the matrix  $I - P$ , where  $P$  is a  $k \times k$  irreducible stochastic matrix.

Output: the invariant probability vector  $\pi = (\pi_i)_{i=1,k}$ .

Computation:

1- set  $\pi_k = 1$ ;

2- for  $j = k - 1, \dots, 1$  set  $\pi_j = -\sum_{i=j+1}^k \pi_i l_{i,j}$ ;

3- set  $\pi = (\sum_{i=1}^k \pi_i)^{-1} \pi$ .

**Examples:**

The matrix

$$P = \begin{bmatrix} 0.5 & 0 & 0 & 0.5 \\ 0.2 & 0.8 & 0 & 0 \\ 0 & 0.6 & 0.4 & 0 \\ 0 & 0 & 0.1 & 0.9 \end{bmatrix}$$

is the transition matrix of an irreducible and aperiodic Markov chain. The splitting  $I - P^T = M - N$  associated with the Jacobi method is a regular splitting. One may easily verify that the iteration matrix is

$$M^{-1}N = D \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \end{bmatrix} D^{-1},$$

where  $D = \text{diag}(1, \frac{5}{2}, \frac{5}{6}, 5)$ . Therefore, the regular splitting is not semiconvergent since the iteration matrix has period 4 (see Fact 8 above).

Differential equations and differential-algebraic equations arise in numerous branches of science and engineering that include biology, chemistry, medicine, structural mechanics, and electrical engineering. This chapter is concerned with linear differential(-algebraic) equations with constant coefficients that can be analyzed completely via techniques from linear algebra. We discuss the existence and uniqueness of solutions of such equations as well as the stability theory.

### 55.1 Linear Differential Equations with Constant Coefficients: Basic Concepts

---

#### Definitions:

A **linear differential equation** in an unknown function  $x : \mathbb{R} \rightarrow \mathbb{C}$ ,  $t \mapsto x(t)$ , has the form

$$\dot{x} = ax + f,$$

where  $a \in \mathbb{C}$  and the inhomogeneity  $f : \mathbb{R} \rightarrow \mathbb{C}$  is a given function. Here  $\dot{x}$  denotes the derivative of  $x(t)$  with respect to  $t$ .

A **linear differential equation of order  $k$**  for an unknown function  $x : \mathbb{R} \rightarrow \mathbb{C}$  has the form

$$a_k x^{(k)} + \dots + a_0 x = f,$$

where  $a_0, \dots, a_k \in \mathbb{C}$ ,  $a_k \neq 0$  and  $f : \mathbb{R} \rightarrow \mathbb{C}$ . Here  $x^{(k)}$  denotes the  $k$ -th derivative of  $x(t)$  with respect to  $t$ .

A **system of linear differential(-algebraic) equations with constant coefficients** has the form

$$E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f},$$

where  $E, A \in \mathbb{C}^{m \times n}$  are **coefficient matrices**,  $\mathbf{x} : \mathbb{R} \rightarrow \mathbb{C}^n$  is a vector-valued function of unknowns, and the inhomogeneity  $\mathbf{f} : \mathbb{R} \rightarrow \mathbb{C}^m$  is a given vector-valued function.

If  $E = I_n$  and  $A \in \mathbb{C}^{n \times n}$ , then  $E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$  is a system of **ordinary differential equations**; otherwise it is a system of **differential-algebraic equations**.

2. Consider a one-dimensional heat equation

$$\frac{\partial}{\partial t} T(t, \xi) = c \frac{\partial^2}{\partial \xi^2} T(t, \xi), \quad (t, \xi) \in (0, t_e) \times (0, l),$$

together with an initial condition  $T(0, \xi) = g(\xi)$  and Cauchy boundary conditions

$$\alpha_1 T(t, 0) + \alpha_2 \frac{\partial}{\partial n} T(t, 0) = u(t),$$

$$\beta_1 T(t, l) + \beta_2 \frac{\partial}{\partial n} T(t, l) = v(t).$$

Here  $T(t, \xi)$  is the temperature field in a thin beam of length  $l$ ,  $c > 0$  is the heat conductivity of the material,  $g(\xi)$ ,  $u(t)$ , and  $v(t)$  are given functions, and  $\frac{\partial}{\partial n}$  denotes the derivative in the direction of the outward normal. A spatial discretization by a finite difference method with  $n + 1$  equidistant grid points leads to the initial value problem  $\dot{\mathbf{x}} = A_{a,b} \mathbf{x} + \mathbf{f}$ ,  $\mathbf{x}(0) = \mathbf{x}_0$ , where

$$\mathbf{x}(t) = [ T(t, h), T(t, 2h), \dots, T(t, nh) ]^T, \quad \mathbf{x}_0 = [ g(h), g(2h), \dots, g(nh) ]^T,$$

$$\mathbf{f}(t) = [ cu(t)/(h^2\alpha_1 - h\alpha_2), 0, \dots, 0, cv(t)/(h^2\beta_1 + h\beta_2) ]^T,$$

and

$$A_{a,b} = \frac{c}{h^2} \begin{bmatrix} -a & 1 & & & \\ & 1 & -2 & 1 & \\ & & \ddots & \ddots & \ddots \\ & & & 1 & -2 & 1 \\ & & & & 1 & -b \end{bmatrix} \in \mathbb{R}^{n \times n}$$

with  $h = l/(n + 1)$ ,  $a = (2h\alpha_1 - \alpha_2)/(h\alpha_1 - \alpha_2)$ , and  $b = (2h\beta_1 + \beta_2)/(h\beta_1 + \beta_2)$ .

3. A simple pendulum as shown in Figure 55.2 describes the movement of a mass point with mass  $m$  and Cartesian coordinates  $(x, y)$  under the influence of gravity in a distance  $l$  around the origin.

FIGURE 55.2 A simple pendulum.

The equations of motion have the form

$$\begin{aligned} m\ddot{x} + 2x\lambda &= 0, \\ m\ddot{y} + 2y\lambda + mg &= 0, \\ x^2 + y^2 - l^2 &= 0, \end{aligned}$$

where  $\lambda$  is a Lagrange multiplier. Transformation of this system into the first-order form by introducing new variables  $v = \dot{x}$  and  $w = \dot{y}$  and linearization at the equilibrium  $x_e = 0$ ,  $y_e = -l$ ,  $v_e = 0$ ,  $w_e = 0$ , and  $\lambda_e = mg/(2l)$  yields the homogeneous first-order linear differential-algebraic system

$$\begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & m & 0 & 0 \\ 0 & 0 & 0 & m & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \tilde{x} \\ \tilde{y} \\ \tilde{v} \\ \tilde{w} \\ \tilde{\lambda} \end{bmatrix} = \begin{bmatrix} 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ -2\lambda_e & 0 & 0 & 0 & 0 \\ 0 & -2\lambda_e & 0 & 0 & 2l \\ 0 & -2l & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \tilde{x} \\ \tilde{y} \\ \tilde{v} \\ \tilde{w} \\ \tilde{\lambda} \end{bmatrix},$$

where  $\tilde{x} = x - x_e$ ,  $\tilde{y} = y - y_e$ ,  $\tilde{v} = v - v_e$ ,  $\tilde{w} = w - w_e$ , and  $\tilde{\lambda} = \lambda - \lambda_e$ .

The motion of the pendulum can also be described by the ordinary differential equation

$$\ddot{\varphi} = -\omega^2 \sin(\varphi),$$

where  $\varphi$  is an angle between the vertical axis and the pendulum and  $\omega = \sqrt{g/l}$  is an angular frequency of the motion. By introducing a new variable  $\psi = \dot{\varphi}$  and linearization at the equilibrium  $\varphi_e = 0$  and  $\psi_e = 0$ , we obtain the first-order homogeneous system

$$\begin{bmatrix} \tilde{\varphi} \\ \tilde{\psi} \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -\omega^2 & 0 \end{bmatrix} \begin{bmatrix} \tilde{\varphi} \\ \tilde{\psi} \end{bmatrix}.$$

4. Consider a simple RLC electrical circuit as shown in Figure 55.3. Using Kirchoff's and Ohm's laws, the circuit can be described by the system  $E\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{f}$  with

$$E = \begin{bmatrix} L & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}, \quad A = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 1/C & 0 & 0 & 0 \\ -R & 0 & 0 & 1 \\ 0 & 1 & 1 & 1 \end{bmatrix}, \quad \mathbf{x} = \begin{bmatrix} i \\ v_L \\ v_C \\ v_R \end{bmatrix}, \quad \mathbf{f} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ -v \end{bmatrix}.$$

Here  $R$ ,  $L$ , and  $C$  are the resistance, inductance, and capacitance, respectively;  $v_R$ ,  $v_L$ , and  $v_C$  are the corresponding voltage drops,  $i$  is the current, and  $v$  is the voltage source. From the last two equations

FIGURE 55.3 A simple RLC circuit.

in the system, we find  $v_R = Ri$  and  $v_L = v - v_C - Ri$ . Substituting  $v_L$  in the first equation and introducing a new variable  $w_C = i/C$ , we obtain the system of ordinary differential equations

$$\begin{bmatrix} \dot{v}_C \\ \dot{w}_C \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -1/(LC) & -R/L \end{bmatrix} \begin{bmatrix} v_C \\ w_C \end{bmatrix} + \begin{bmatrix} 0 \\ v/(LC) \end{bmatrix}.$$

This shows the relationship to the mass–spring–damper model as in Application 1.

## 55.2 Linear Ordinary Differential Equations

---

### Facts:

The following facts can be found in [Gan59a, pp. 116–124, 153–154].

1. Let  $J_A = T^{-1}AT$  be in Jordan canonical form. Then  $e^{At} = Te^{J_A t}T^{-1}$ . (See Chapter 6 and Chapter 11 for more information on the Jordan canonical form and the matrix exponential.)
2. Every solution of the homogeneous system  $\dot{\mathbf{x}} = A\mathbf{x}$  has the form  $\mathbf{x}(t) = e^{At}\mathbf{v}$  with  $\mathbf{v} \in \mathbb{C}^n$ .
3. The initial value problem  $\dot{\mathbf{x}} = A\mathbf{x}$ ,  $\mathbf{x}(t_0) = \mathbf{x}_0$  has the unique solution  $\mathbf{x}(t) = e^{A(t-t_0)}\mathbf{x}_0$ .
4. The initial value problem  $\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$ ,  $\mathbf{x}(t_0) = \mathbf{x}_0$  has a unique solution for every initial vector  $\mathbf{x}_0$  and every continuous inhomogeneity  $\mathbf{f}$ . This solution is given by

$$\mathbf{x}(t) = e^{A(t-t_0)}\mathbf{x}_0 + \int_{t_0}^t e^{A(t-\tau)}\mathbf{f}(\tau) d\tau.$$

### Examples:

1. Let

$$A = \begin{bmatrix} 3 & 3 & 1 \\ 0 & 0 & 0 \\ -1 & -1 & 1 \end{bmatrix}, \quad \mathbf{x}_0 = \begin{bmatrix} 1 \\ 2 \\ 3 \end{bmatrix}, \quad \mathbf{f}(t) = \begin{bmatrix} -3t^2 - 3t \\ 2t \\ t^2 + t - 1 \end{bmatrix}.$$

For

$$T = \begin{bmatrix} 1 & 0 & -1 \\ 0 & 0 & 1 \\ -1 & 1 & 0 \end{bmatrix} \quad \text{and} \quad T^{-1} = \begin{bmatrix} 1 & 1 & 0 \\ 1 & 1 & 1 \\ 0 & 1 & 0 \end{bmatrix},$$

we have

$$J_A = T^{-1}AT = \left[ \begin{array}{cc|c} 2 & 1 & 0 \\ 0 & 2 & 0 \\ \hline 0 & 0 & 0 \end{array} \right].$$

Then

$$\begin{aligned} e^{At} &= \begin{bmatrix} 1 & 0 & -1 \\ 0 & 0 & 1 \\ -1 & 1 & 0 \end{bmatrix} \left[ \begin{array}{cc|c} e^{2t} & te^{2t} & 0 \\ 0 & e^{2t} & 0 \\ \hline 0 & 0 & 1 \end{array} \right] \begin{bmatrix} 1 & 1 & 0 \\ 1 & 1 & 1 \\ 0 & 1 & 0 \end{bmatrix} \\ &= \begin{bmatrix} (1+t)e^{2t} & (1+t)e^{2t} - 1 & te^{2t} \\ 0 & 1 & 0 \\ -te^{2t} & -te^{2t} & (1-t)e^{2t} \end{bmatrix}. \end{aligned}$$

Every solution of the homogeneous system  $\dot{\mathbf{x}} = A\mathbf{x}$  has the form

$$\mathbf{x}(t) = e^{At}\mathbf{v} = \begin{bmatrix} ((1+t)v_1 + (1+t)v_2 + tv_3)e^{2t} - v_2 \\ v_2 \\ (-tv_1 - tv_2 + (1-t)v_3)e^{2t} \end{bmatrix}$$

with  $\mathbf{v} = [v_1, v_2, v_3]^T$ . The solution of the initial value problem  $\dot{\mathbf{x}} = A\mathbf{x}$ ,  $\mathbf{x}(0) = \mathbf{x}_0$  has the form

$$\mathbf{x}(t) = e^{At}\mathbf{x}_0 = \begin{bmatrix} (3+6t)e^{2t} - 2 \\ 2 \\ (3-6t)e^{2t} \end{bmatrix}.$$

The initial value problem  $\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$ ,  $\mathbf{x}(0) = \mathbf{x}_0$  has the solution

$$\mathbf{x}(t) = \begin{bmatrix} (3+6t)e^{2t} + t - 2 \\ t^2 + 2 \\ (3-6t)e^{2t} + 1 \end{bmatrix}.$$

### Applications:

1. Consider the matrix  $A$  from the mass–spring–damper example

$$A = \begin{bmatrix} 0 & 1 \\ -k/m & -d/m \end{bmatrix}.$$

The Jordan canonical form of  $A$  is given by  $J_A = T^{-1}AT = \text{diag}(\lambda_1, \lambda_2)$ , where

$$T = \begin{bmatrix} 1 & 1 \\ \lambda_1 & \lambda_2 \end{bmatrix}, \quad T^{-1} = \frac{1}{\lambda_2 - \lambda_1} \begin{bmatrix} \lambda_2 & -1 \\ -\lambda_1 & 1 \end{bmatrix}$$

and

$$\lambda_1 = \frac{-d - \sqrt{d^2 - 4km}}{2m}, \quad \lambda_2 = \frac{-d + \sqrt{d^2 - 4km}}{2m}$$

are the eigenvalues of  $A$ . We have

$$e^{At} = T \text{diag}(e^{\lambda_1 t}, e^{\lambda_2 t}) T^{-1} = \frac{1}{\lambda_2 - \lambda_1} \begin{bmatrix} \lambda_2 e^{\lambda_1 t} - \lambda_1 e^{\lambda_2 t} & e^{\lambda_2 t} - e^{\lambda_1 t} \\ \lambda_1 \lambda_2 (e^{\lambda_1 t} - e^{\lambda_2 t}) & \lambda_2 e^{\lambda_2 t} - \lambda_1 e^{\lambda_1 t} \end{bmatrix}.$$

The solution of the mass–spring–damper model with the initial conditions  $x(0) = x_0$  and  $v(0) = 0$  is given by

$$x(t) = \frac{x_0}{\lambda_2 - \lambda_1} (\lambda_2 e^{\lambda_1 t} - \lambda_1 e^{\lambda_2 t}), \quad v(t) = \frac{\lambda_1 \lambda_2 x_0}{\lambda_2 - \lambda_1} (e^{\lambda_1 t} - e^{\lambda_2 t}).$$

2. Since the matrix  $A_{a,b}$  in the semidiscretized heat equation is symmetric, there exists an orthogonal matrix  $U$  such that  $U^T A_{a,b} U = \text{diag}(\lambda_1, \dots, \lambda_n)$ , where  $\lambda_1, \dots, \lambda_n \in \mathbb{R}$  are the eigenvalues of  $A_{a,b}$ . (See Chapter 7.2 and Chapter 45.) In this case  $e^{A_{a,b} t} = U \text{diag}(e^{\lambda_1 t}, \dots, e^{\lambda_n t}) U^T$ .

### 55.3 Linear Differential-Algebraic Equations

**Definitions:**

A **Drazin inverse**  $A^D$  of a matrix  $A \in \mathbb{C}^{n \times n}$  is defined as the unique solution of the system of matrix equations

$$A^D A A^D = A^D, \quad A A^D = A^D A, \quad A^{k+1} A^D = A^k,$$

where  $k$  is a smallest nonnegative integer such that  $\text{rank}(A^{k+1}) = \text{rank}(A^k)$ .

Let  $E, A \in \mathbb{C}^{m \times n}$ . A pencil of the form

$$\lambda E - A = \text{diag}(\mathcal{L}_{n_1}, \dots, \mathcal{L}_{n_p}, \mathcal{M}_{m_1}, \dots, \mathcal{M}_{m_q}, \mathcal{J}_k, \mathcal{N}_s)$$

is called pencil in **Kronecker canonical form** if the block entries have the following properties: every entry  $\mathcal{L}_{n_j} = \lambda L_{n_j} - R_{n_j}$  is a bidiagonal block of size  $n_j \times (n_j + 1)$ ,  $n_j \in \mathbb{N}$ , where

$$L_{n_j} = \begin{bmatrix} 1 & 0 & & \\ & \ddots & \ddots & \\ & & 1 & 0 \end{bmatrix}, \quad R_{n_j} = \begin{bmatrix} 0 & 1 & & \\ & \ddots & \ddots & \\ & & 0 & 1 \end{bmatrix};$$

every entry  $\mathcal{M}_{m_j} = \lambda L_{m_j}^T - R_{m_j}^T$  is a bidiagonal block of size  $(m_j + 1) \times m_j$ ,  $m_j \in \mathbb{N}$ ; the entry  $\mathcal{J}_k = \lambda I_k - A_k$  is a block of size  $k \times k$ ,  $k \in \mathbb{N}$ , where  $A_k$  is in Jordan canonical form; the entry  $\mathcal{N}_s = \lambda N_s - I_s$  is a block of size  $s \times s$ ,  $s \in \mathbb{N}$ , where  $N_s = \text{diag}(N_{s_1}, \dots, N_{s_r})$ ; and

$$N_{s_j} = \begin{bmatrix} 0 & 1 & & \\ & \ddots & \ddots & \\ & & \ddots & 1 \\ & & & 0 \end{bmatrix}$$

is a nilpotent Jordan block with index of nilpotency  $s_j$ .

The numbers  $n_1, \dots, n_p$  are called the **right Kronecker indices** of the pencil  $\lambda E - A$ .

The numbers  $m_1, \dots, m_q$  are called the **left Kronecker indices** of the pencil  $\lambda E - A$ .

The number  $\nu = \max_{1 \leq j \leq r} s_j$  is called the **index** of the pencil  $\lambda E - A$ .

A matrix pencil  $\lambda E - A$  with  $E, A \in \mathbb{C}^{m \times n}$  is called **regular**, if  $m = n$  and  $\det(\lambda E - A) \neq 0$  for some  $\lambda \in \mathbb{C}$ . Otherwise, the pencil is called **singular**.

Let  $E, A \in \mathbb{C}^{m \times n}$ . Subspaces  $W_l \subset \mathbb{C}^m$  and  $W_r \subset \mathbb{C}^n$  are called **left** and **right reducing subspaces** of the pencil  $\lambda E - A$  if  $W_l = E W_r + A W_r$  and  $\dim(W_l) = \dim(W_r) - p$ , where  $p$  is the number of  $\mathcal{L}_{n_j}$  blocks in the Kronecker canonical form.

Let  $\lambda E - A$  be a regular pencil. Subspaces  $W_l, W_r \subset \mathbb{C}^n$  are called **left** and **right deflating subspaces** of  $\lambda E - A$  if  $W_l = E W_r + A W_r$  and  $\dim(W_l) = \dim(W_r)$ .

Let  $W_1, W_2 \subset \mathbb{C}^n$  be subspaces such that  $W_1 \cap W_2 = \{0\}$  and  $W_1 + W_2 = \mathbb{C}^n$ . A matrix  $P \in \mathbb{C}^{n \times n}$  is called a **projection** onto  $W_1$  along  $W_2$  if  $P^2 = P$ ,  $\text{range}(P) = W_1$ , and  $\text{ker}(P) = W_2$ .

Let  $\lambda E - A$  be a regular pencil. If  $T_l, T_r \in \mathbb{C}^{n \times n}$  are nonsingular matrices such that  $T_l^{-1}(\lambda E - A)T_r$  is in Kronecker canonical form, then

$$P_l = T_l \begin{bmatrix} I_k & 0 \\ 0 & 0 \end{bmatrix} T_l^{-1}, \quad P_r = T_r \begin{bmatrix} I_k & 0 \\ 0 & 0 \end{bmatrix} T_r^{-1}$$

are the **spectral projections** onto the left and right deflating subspaces of  $\lambda E - A$  corresponding to the finite eigenvalues along the left and right deflating subspaces corresponding to the eigenvalue at infinity.

**Facts:**

1. [Cam80, p. 8] If  $A \in \mathbb{C}^{n \times n}$  is nonsingular, then  $A^D = A^{-1}$ .
2. [Cam80, p. 8] Let

$$J_A = T^{-1}AT = \begin{bmatrix} A_1 & \mathbf{0} \\ \mathbf{0} & A_0 \end{bmatrix}$$

be in Jordan canonical form, where  $A_1$  contains all the Jordan blocks associated with the nonzero eigenvalues, and  $A_0$  contains all the Jordan blocks associated with the eigenvalue 0. Then

$$A^D = T \begin{bmatrix} A_1^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} T^{-1}.$$

3. [Gan59b, pp. 29–37] For every matrix pencil  $\lambda E - A$  with  $E, A \in \mathbb{C}^{m \times n}$  there exist nonsingular matrices  $T_l \in \mathbb{C}^{m \times m}$  and  $T_r \in \mathbb{C}^{n \times n}$  such that  $T_l^{-1}(\lambda E - A)T_r$  is in Kronecker canonical form. The Kronecker canonical form is unique up to permutation of the diagonal blocks, i.e., the kind, size, and number of the blocks are characteristic for the pencil  $\lambda E - A$ . (For more information on matrix pencils, see Section 43.1.)
4. [Gan59b, p. 47] If  $\mathbf{f}(t) = [f_1(t), \dots, f_{n_j}(t)]^T$  is an  $n_j$ -times continuously differentiable vector-valued function and  $g(t)$  is an arbitrary  $(n_j + 1)$ -times continuously differentiable function, then the system  $L_{n_j}\dot{\mathbf{x}} = R_{n_j}\mathbf{x} + \mathbf{f}$  has a continuously differentiable solution of the form

$$\mathbf{x}(t) = \begin{bmatrix} x_1(t) \\ x_2(t) \\ \vdots \\ x_{n_j+1}(t) \end{bmatrix} = \begin{bmatrix} g(t) \\ g^{(1)}(t) - f_1(t) \\ \vdots \\ g^{(n_j)}(t) - \sum_{i=1}^{n_j} f_i^{(n_j-i)}(t) \end{bmatrix}.$$

A consistent initial condition has to satisfy this defining equation at  $t_0$ .

5. [Gan59b, p. 47] A system of differential-algebraic equations  $L_{m_j}^T \dot{\mathbf{x}} = R_{m_j}^T \mathbf{x} + \mathbf{f}$  with a vector-valued function  $\mathbf{f}(t) = [f_1(t), \dots, f_{m_j+1}(t)]^T$  has a unique solution if and only if  $\mathbf{f}$  is  $m_j$ -times continuously differentiable and  $\sum_{i=1}^{m_j+1} f_i^{(i-1)}(t) \equiv 0$ . If this holds, then the solution is given by

$$\mathbf{x}(t) = \begin{bmatrix} x_1(t) \\ \vdots \\ x_{m_j}(t) \end{bmatrix} = \begin{bmatrix} -\sum_{i=1}^{m_j} f_{i+1}^{(i-1)}(t) \\ \vdots \\ -f_{m_j+1}(t) \end{bmatrix}.$$

A consistent initial condition has to satisfy this defining equation at  $t_0$ .

6. [Gan59b, p. 48] A system  $N_{s_j}\dot{\mathbf{x}} = \mathbf{x} + \mathbf{f}$  has a unique continuously differentiable solution  $\mathbf{x}$  if  $\mathbf{f}$  is  $s_j$ -times continuously differentiable. This solution is given by

$$\mathbf{x}(t) = -\sum_{i=0}^{s_j-1} N_{s_j}^i \mathbf{f}^{(i)}(t).$$

A consistent initial condition has to satisfy this defining equation at  $t_0$ .

7. [Cam80, pp. 37–39] If the pencil  $\lambda E - A$  is regular of index  $\nu$ , then for every  $\nu$ -times differentiable inhomogeneity  $\mathbf{f}$  there exists a solution of the differential-algebraic system  $E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$ . Every solution of this system has the form

$$\mathbf{x}(t) = e^{\hat{E}^D \hat{A}(t-t_0)} \hat{E}^D \hat{E} \mathbf{v} + \int_{t_0}^t e^{\hat{E}^D \hat{A}(t-\tau)} \hat{E}^D \hat{\mathbf{f}}(\tau) d\tau - (I - \hat{E}^D \hat{E}) \sum_{j=0}^{\nu-1} (\hat{E} \hat{A}^D)^j \hat{A}^D \hat{\mathbf{f}}^{(j)}(t),$$

where  $\mathbf{v} \in \mathbb{C}^n$ ,  $\hat{E} = (\lambda_0 E - A)^{-1} E$ ,  $\hat{A} = (\lambda_0 E - A)^{-1} A$ , and  $\hat{\mathbf{f}} = (\lambda_0 E - A)^{-1} \mathbf{f}$  for some  $\lambda_0 \in \mathbb{C}$  such that  $\lambda_0 E - A$  is nonsingular.

8. [Cam80, pp. 37–39] If the pencil  $\lambda E - A$  is regular of index  $\nu$  and if  $\mathbf{f}$  is  $\nu$ -times differentiable, then the initial value problem  $E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$ ,  $\mathbf{x}(t_0) = \mathbf{x}_0$  possesses a solution if and only if there exists  $\mathbf{v} \in \mathbb{C}^n$  that satisfies

$$\mathbf{x}_0 = \hat{E}^D \hat{E} \mathbf{v} - (I - \hat{E}^D \hat{E}) \sum_{j=0}^{\nu-1} (\hat{E} \hat{A}^D)^j \hat{A}^D \hat{\mathbf{f}}^{(j)}(t_0).$$

If such a  $\mathbf{v}$  exists, then the solution is unique.

9. [KM06, p. 21] The existence of a unique solution of  $E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$ ,  $\mathbf{x}(t_0) = \mathbf{x}_0$  does not imply that the pencil  $\lambda E - A$  is regular.
10. [Cam80, pp. 41–44] If the pencil  $\lambda E - A$  is singular, then the initial value problem  $E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$ ,  $\mathbf{x}(t_0) = \mathbf{x}_0$  may have no solutions or the solution, if it exists, may not be unique.
11. [Sty02, pp. 23–26] Let the pencil  $\lambda E - A$  be regular of index  $\nu$ . If

$$T_l^{-1}(\lambda E - A)T_r = \begin{bmatrix} \lambda I - A_k & \mathbf{0} \\ \mathbf{0} & \lambda N_s - I \end{bmatrix}$$

is in Kronecker canonical form, then the solution of the initial value problem  $E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$ ,  $\mathbf{x}(t_0) = \mathbf{x}_0$  can be represented as

$$\mathbf{x}(t) = \mathcal{F}(t - t_0)E\mathbf{x}_0 + \int_{t_0}^t \mathcal{F}(t - \tau)\mathbf{f}(\tau) d\tau + \sum_{j=0}^{\nu-1} F_{-j-1}\mathbf{f}^{(j)}(t),$$

where

$$\mathcal{F}(t) = T_r \begin{bmatrix} e^{A_k t} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} T_l^{-1}, \quad F_{-j} = T_r \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & -N_s^{j-1} \end{bmatrix} T_l^{-1}.$$

**Examples:**

1. The system

$$\begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \dot{\mathbf{x}} = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \mathbf{x} + \begin{bmatrix} 0 \\ g(t) \end{bmatrix}, \quad \mathbf{x}(0) = \begin{bmatrix} 1 \\ 0 \end{bmatrix}$$

has no solution if  $g(t) \neq 0$ . For  $g(t) \equiv 0$ , this system has the solution  $\mathbf{x}(t) = [e^t, \phi(t)]^T$ , where  $\phi(t)$  is a differentiable function such that  $\phi(0) = 0$ .

2. The system

$$\begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{bmatrix} \dot{\mathbf{x}} = \begin{bmatrix} 0 & 0 \\ 1 & 0 \\ 0 & 1 \end{bmatrix} \mathbf{x} + \begin{bmatrix} -\sin(t) \\ -\cos(t) \\ 0 \end{bmatrix}, \quad \mathbf{x}(0) = \begin{bmatrix} 1 \\ 1 \\ 0 \end{bmatrix}$$

has a unique solution  $\mathbf{x}(t) = [\cos(t), 0]^T$ , but the pencil  $\lambda E - A$  is singular.

**Applications:**

1. The pencil in the linearized pendulum example has the Kronecker canonical form

$$\text{diag}(\mathcal{J}_2, \mathcal{N}_3) = \lambda \left[ \begin{array}{cc|ccc} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 \end{array} \right] - \left[ \begin{array}{cc|ccc} -i\sqrt{g/l} & 0 & 0 & 0 & 0 \\ 0 & i\sqrt{g/l} & 0 & 0 & 0 \\ \hline 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{array} \right].$$

This pencil is regular of index 3. Since the linearized pendulum system is homogeneous, it has a unique solution for every consistent initial condition.

2. The pencil of the circuit equation has the Kronecker canonical form

$$\text{diag}(\mathcal{J}_2, \mathcal{N}_2) = \lambda \left[ \begin{array}{cc|cc} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{array} \right] - \left[ \begin{array}{cc|cc} \lambda_1 & 0 & 0 & 0 \\ 0 & \lambda_2 & 0 & 0 \\ \hline 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{array} \right],$$

with

$$\lambda_1 = -\frac{R}{2L} - \sqrt{\frac{R^2}{4L^2} - \frac{1}{LC}}, \quad \lambda_2 = -\frac{R}{2L} + \sqrt{\frac{R^2}{4L^2} - \frac{1}{LC}}.$$

This pencil is regular of index 1. Hence, there exists a unique continuous solution for every continuous voltage source  $v(t)$  and for every consistent initial condition.

## 55.4 Stability of Linear Ordinary Differential Equations

The notion of stability is used to study the behavior of dynamical systems under initial perturbations around equilibrium points. In this section, we consider the stability of linear homogeneous ordinary differential equations with constant coefficients only. For extensions of this concept to general nonlinear systems, see, e.g., [Ces63] and [Hah67].

**Definitions:**

The equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $\dot{\mathbf{x}} = A\mathbf{x}$  is called **stable in the sense of Lyapunov**, or simply **stable**, if for every  $\varepsilon > 0$  there exists a  $\delta = \delta(\varepsilon) > 0$  such that any solution  $\mathbf{x}$  of  $\dot{\mathbf{x}} = A\mathbf{x}$ ,  $\mathbf{x}(t_0) = \mathbf{x}_0$  with  $\|\mathbf{x}_0\|_2 < \delta$  satisfies  $\|\mathbf{x}(t)\|_2 < \varepsilon$  for all  $t \geq t_0$ .

The equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $\dot{\mathbf{x}} = A\mathbf{x}$  is called **asymptotically stable** if it is stable and  $\lim_{t \rightarrow \infty} \mathbf{x}(t) = 0$  for any solution  $\mathbf{x}$  of  $\dot{\mathbf{x}} = A\mathbf{x}$ .

The equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $\dot{\mathbf{x}} = A\mathbf{x}$  is called **unstable** if it is not stable.

The equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $\dot{\mathbf{x}} = A\mathbf{x}$  is called **exponentially stable** if there exist  $\alpha > 0$  and  $\beta > 0$  such that the solution  $\mathbf{x}$  of  $\dot{\mathbf{x}} = A\mathbf{x}$ ,  $\mathbf{x}(t_0) = \mathbf{x}_0$  satisfies  $\|\mathbf{x}(t)\|_2 \leq \alpha e^{-\beta(t-t_0)} \|\mathbf{x}_0\|_2$  for all  $t \geq t_0$ .

**Facts:**

1. [Gan59a, pp. 125–129] The equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $\dot{\mathbf{x}} = A\mathbf{x}$  is stable if and only if all the eigenvalues of  $A$  have nonpositive real part and those with zero real part have the same algebraic and geometric multiplicities. If at least one of these conditions is violated, then the equilibrium  $\mathbf{x}_e(t) \equiv 0$  of  $\dot{\mathbf{x}} = A\mathbf{x}$  is unstable.
2. [Gan59a, pp. 125–129] The equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $\dot{\mathbf{x}} = A\mathbf{x}$  is asymptotically stable if and only if all the eigenvalues of  $A$  have negative real part.

3. [Ces63, p. 22] Let  $p_A(\lambda) = \det(\lambda I - A) = \lambda^n + a_1\lambda^{n-1} + \dots + a_n$  be the characteristic polynomial of  $A \in \mathbb{R}^{n \times n}$ . If the equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $\dot{\mathbf{x}} = A\mathbf{x}$  is asymptotically stable, then  $a_j > 0$  for  $j = 1, \dots, n$ .
4. [Gan59b, pp. 185–189] The equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $\dot{\mathbf{x}} = A\mathbf{x}$  is asymptotically stable if and only if the Lyapunov equation  $A^*X + XA = -Q$  has a unique Hermitian, positive definite solution  $X$  for every Hermitian, positive definite matrix  $Q$ .
5. [God97] Let  $H$  be a Hermitian, positive definite solution of the Lyapunov equation

$$A^*H + HA = -I$$

and let  $\mathbf{x}$  be a solution of the initial value problem  $\dot{\mathbf{x}} = A\mathbf{x}$ ,  $\mathbf{x}(0) = \mathbf{x}_0$ . Then in terms of the original data,

$$\|\mathbf{x}(t)\|_2 \leq \sqrt{\kappa(A)} e^{-t\|A\|_2/\kappa(A)} \|\mathbf{x}_0\|_2,$$

where  $\kappa(A) = 2\|A\|_2\|H\|_2$ .

6. [Hah67, pp. 113–117] The equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $\dot{\mathbf{x}} = A\mathbf{x}$  is exponentially stable if and only if it is asymptotically stable.
7. [Hah67, p. 16] If the equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the homogeneous system  $\dot{\mathbf{x}} = A\mathbf{x}$  is asymptotically stable, then all the solutions of the inhomogeneous system  $\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$  with a bounded inhomogeneity  $\mathbf{f}$  are bounded.

**Examples:**

1. Consider the linear system  $\dot{\mathbf{x}} = A\mathbf{x}$  with

$$A = \begin{bmatrix} -1 & 0 \\ 0 & 2 \end{bmatrix}.$$

For the initial condition  $\mathbf{x}(0) = [1, 0]^T$ , this system has the solution  $\mathbf{x}(t) = [e^{-t}, 0]^T$  that is bounded for all  $t \geq 0$ . However, this does not mean that the equilibrium  $\mathbf{x}_e(t) \equiv 0$  is stable. For linear systems with constant coefficients, stability means that the solution  $\mathbf{x}(t)$  remains bounded for all time and for all initial conditions, but not just for some specific initial condition. If we can find at least one initial condition that causes one of the states to approach infinity with time, then the equilibrium is unstable. For the above system, we can choose, for example,  $\mathbf{x}(0) = [1, 1]^T$ . In this case  $\mathbf{x}(t) = [e^{-t}, e^{2t}]^T$  is unbounded, which proves that the equilibrium  $\mathbf{x}_e(t) \equiv 0$  is unstable.

2. Consider the linear system  $\dot{\mathbf{x}} = A\mathbf{x}$  with

$$A = \begin{bmatrix} -0.1 & -1 \\ 1 & -0.1 \end{bmatrix}.$$

The eigenvalues of  $A$  are  $-0.1 \pm i$ , and, hence, the equilibrium  $\mathbf{x}_e(t) \equiv 0$  is asymptotically stable. Indeed, the solution of this system is given by  $\mathbf{x}(t) = e^{At}\mathbf{x}(0)$ , which can be written in the real form as

$$\begin{aligned} x_1(t) &= e^{-0.1t}(x_1(0) \cos(t) - x_2(0) \sin(t)), \\ x_2(t) &= e^{-0.1t}(x_1(0) \sin(t) + x_2(0) \cos(t)). \end{aligned}$$

(See also Chapter 56.) Thus, for all initial conditions  $x_1(0)$  and  $x_2(0)$ , the solution tends to zero as  $t \rightarrow \infty$ . The phase portrait for  $x_1(0) = 1$  and  $x_2(0) = 0$  is presented in Figure 55.4.

3. Consider the linear system  $\dot{\mathbf{x}} = A\mathbf{x}$  with

$$A = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}.$$

FIGURE 55.4 Asymptotic stability.

The matrix  $A$  has the eigenvalues  $\pm i$ . The solution of this system  $\mathbf{x}(t) = e^{At}\mathbf{x}(0)$  can be written in the real form as

$$\begin{aligned}x_1(t) &= x_1(0) \cos(t) - x_2(0) \sin(t), \\x_2(t) &= x_1(0) \sin(t) + x_2(0) \cos(t).\end{aligned}$$

It remains bounded for all initial values  $x_1(0)$  and  $x_2(0)$ , and, hence, the equilibrium  $\mathbf{x}_e(t) \equiv 0$  is stable. The phase portrait for  $x_1(0) = 1$  and  $x_2(0) = 0$  is given in Figure 55.5.

4. Consider the linear system  $\dot{\mathbf{x}} = A\mathbf{x}$  with

$$A = \begin{bmatrix} 0.1 & -1 \\ 1 & 0.1 \end{bmatrix}.$$

The eigenvalues of  $A$  are  $0.1 \pm i$ . The solution of this system in the real form is given by

$$\begin{aligned}x_1(t) &= e^{0.1t}(x_1(0) \cos(t) - x_2(0) \sin(t)), \\x_2(t) &= e^{0.1t}(x_1(0) \sin(t) + x_2(0) \cos(t)).\end{aligned}$$

It is unbounded for all nontrivial initial conditions. Thus, the equilibrium  $\mathbf{x}_e(t) \equiv 0$  is unstable. The phase portrait of the solution with  $x_1(0) = 1$  and  $x_2(0) = 0$  is shown in Figure 55.6.

5. Consider the linear system  $\dot{\mathbf{x}} = A\mathbf{x}$  with

$$A = \begin{bmatrix} a & b \\ c & d \end{bmatrix} \in \mathbb{R}^{2 \times 2}.$$

The characteristic polynomial of the matrix  $A$  is given by  $p_A(\lambda) = \lambda^2 - (a+d)\lambda + (ad-bc)$  and the eigenvalues of  $A$  have the form

$$\lambda_1 = \frac{a+d}{2} + \frac{\sqrt{(a+d)^2 - 4(ad-bc)}}{2}, \quad \lambda_2 = \frac{a+d}{2} - \frac{\sqrt{(a+d)^2 - 4(ad-bc)}}{2}.$$

FIGURE 55.5 Stability.

FIGURE 55.6 Instability.

We have the following cases:

$a + d < 0,$	$ad - bc > 0$	$\operatorname{Re}(\lambda_1) < 0, \operatorname{Re}(\lambda_2) < 0,$	Asymptotically stable
$a + d < 0,$	$ad - bc = 0$	$\lambda_1 = 0, \lambda_2 < 0$	Stable
$a + d < 0,$	$ad - bc < 0$	$\lambda_1 > 0, \lambda_2 < 0$	Unstable
$a + d = 0,$	$ad - bc > 0$	$\lambda_1 = i\alpha, \lambda_2 = -i\alpha, \alpha$ - real	Stable
$a + d = 0,$	$ad - bc = 0$	$\lambda_1 = 0, \lambda_2 = 0$	Unstable
$a^2 + b^2 + c^2 + d^2 \neq 0$			
$a = 0, b = 0, c = 0, d = 0$		$\lambda_1 = 0, \lambda_2 = 0$	Stable
$a + d = 0,$	$ad - bc < 0$	$\lambda_1 > 0, \lambda_2 < 0$	Unstable
$a + d > 0,$	$ad - bc \leq 0$	$\lambda_1 > 0, \lambda_2 \leq 0$	Unstable
$a + d > 0,$	$ad - bc > 0$	$\operatorname{Re}(\lambda_1) > 0, \operatorname{Re}(\lambda_2) > 0$	Unstable

### Applications:

1. Consider the semidiscretized heat equation; see Application 2 in Section 55.1. Let  $\alpha_1 = \beta_1 = 1$  and  $\alpha_2 = \beta_2 = 0$ . Then  $a = b = 2$  and the matrix  $A_{2,2}$  has the eigenvalues

$$\lambda_j(A_{2,2}) = -\frac{4c}{h^2} \sin^2 \frac{j\pi}{2(n+1)}.$$

In this case, the equilibrium  $\mathbf{x}_e(t) \equiv \mathbf{0}$  of the system  $\dot{\mathbf{x}} = A_{2,2}\mathbf{x}$  is asymptotically stable. However, for  $\alpha_1 = \beta_1 = 0$  and  $\alpha_2 = \beta_2 = 1$ , we have  $a = b = 1$ . Then the matrix  $A_{1,1}$  has a simple zero eigenvalue and, hence, the equilibrium  $\mathbf{x}_e(t) \equiv \mathbf{0}$  of  $\dot{\mathbf{x}} = A_{1,1}\mathbf{x}$  is only stable.

2. Consider the mass–spring–damper model with  $m > 0$ ,  $d \geq 0$ , and  $k \geq 0$ . The coefficient matrix of this model has eigenvalues

$$\lambda_1 = \frac{-d - \sqrt{d^2 - 4km}}{2m}, \quad \lambda_2 = \frac{-d + \sqrt{d^2 - 4km}}{2m}.$$

For  $d = 0$ , the equilibrium  $\mathbf{x}_e(t) \equiv \mathbf{0}$  is unstable if  $k = 0$ , and it is stable if  $k > 0$ . For  $d > 0$ , the equilibrium  $\mathbf{x}_e(t) \equiv \mathbf{0}$  is stable if  $k = 0$ , and it is asymptotically stable if  $k > 0$ .

## 55.5 Stability of Linear Differential-Algebraic Equations

### Definitions:

The equilibrium  $\mathbf{x}_e(t) \equiv \mathbf{0}$  of the system  $E\dot{\mathbf{x}} = A\mathbf{x}$  is called **stable in the sense of Lyapunov**, or simply **stable**, if for every  $\varepsilon > 0$  there exists a  $\delta = \delta(\varepsilon) > 0$  such that any solution  $\mathbf{x}$  of  $E\dot{\mathbf{x}} = A\mathbf{x}$ ,  $\mathbf{x}(t_0) = P_r \mathbf{x}_0$  with  $\|P_r \mathbf{x}_0\|_2 < \delta$  satisfies  $\|\mathbf{x}(t)\|_2 < \varepsilon$  for all  $t \geq t_0$ .

The equilibrium  $\mathbf{x}_e(t) \equiv \mathbf{0}$  of the system  $E\dot{\mathbf{x}} = A\mathbf{x}$  is called **asymptotically stable** if it is stable and  $\lim_{t \rightarrow \infty} \mathbf{x}(t) = \mathbf{0}$  for every solution  $\mathbf{x}$  of  $E\dot{\mathbf{x}} = A\mathbf{x}$ .

The equilibrium  $\mathbf{x}_e(t) \equiv \mathbf{0}$  of the system  $E\dot{\mathbf{x}} = A\mathbf{x}$  is called **unstable** if it is not stable.

The equilibrium  $\mathbf{x}_e(t) \equiv \mathbf{0}$  of the system  $E\dot{\mathbf{x}} = A\mathbf{x}$  is called **exponentially stable** if there exist constants  $\alpha > 0$  and  $\beta > 0$  such that the solution  $\mathbf{x}$  of  $E\dot{\mathbf{x}} = A\mathbf{x}$ ,  $\mathbf{x}(t_0) = P_r \mathbf{x}_0$  satisfies  $\|\mathbf{x}(t)\|_2 \leq \alpha e^{-\beta(t-t_0)} \|P_r \mathbf{x}_0\|_2$  for all  $t \geq t_0$ .

### Facts:

1. [Dai89, pp. 68–69] If the pencil  $\lambda E - A$  is regular, then the equilibrium  $\mathbf{x}_e(t) \equiv \mathbf{0}$  of the system  $E\dot{\mathbf{x}} = A\mathbf{x}$  is stable if and only if all finite eigenvalues of the pencil  $\lambda E - A$  have nonpositive real part and those with zero real part have the same algebraic and geometric multiplicities.

2. [Dai89, pp. 68–69] If the pencil  $\lambda E - A$  is regular, then the equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $E\dot{\mathbf{x}} = A\mathbf{x}$  is asymptotically stable if and only if all finite eigenvalues of  $\lambda E - A$  have negative real part.
3. [Sty02, p. 48] Let  $Q$  be a Hermitian matrix such that  $\mathbf{v}^*Q\mathbf{v} > 0$  for all nonzero vectors  $\mathbf{v} \in \text{range}(P_r)$ . The equilibrium  $\mathbf{x}_e(t) \equiv 0$  of  $E\dot{\mathbf{x}} = A\mathbf{x}$  is asymptotically stable if the generalized Lyapunov equation  $E^*XA + A^*XE = -Q$  has a Hermitian, positive semidefinite solution  $X$ .
4. [Sty02, pp. 49–52] The equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $E\dot{\mathbf{x}} = A\mathbf{x}$  is asymptotically stable and the pencil  $\lambda E - A$  is of index at most one if and only if the generalized Lyapunov equation  $E^*XA + A^*XE = -E^*QE$ , with Hermitian, positive definite  $Q$  has a Hermitian, positive semidefinite solution  $X$ .
5. [TMK95] The equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $E\dot{\mathbf{x}} = A\mathbf{x}$  is asymptotically stable and the pencil  $\lambda E - A$  is of index at most one if and only if the generalized Lyapunov equation

$$A^*X + Y^*A = -Q, \quad Y^*E = E^*X,$$

with Hermitian, positive definite  $Q$  has a solution  $(X, Y)$  such that  $E^*X$  is Hermitian, positive semidefinite.

6. [Sty02, pp. 52–54] The equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $E\dot{\mathbf{x}} = A\mathbf{x}$  is asymptotically stable if and only if the projected generalized Lyapunov equation

$$E^*XA + A^*XE = -P_r^*QP_r, \quad X = P_l^*XP_l$$

has a unique Hermitian, positive semidefinite solution  $X$  for every Hermitian, positive definite matrix  $Q$ .

7. [Sty02] The equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $E\dot{\mathbf{x}} = A\mathbf{x}$  is asymptotically stable if and only if the projected generalized Lyapunov equation

$$EYA^* + AYE^* = -P_lQP_l^*, \quad Y = P_rYP_r^*$$

has a unique Hermitian, positive semidefinite solution  $Y$  for every Hermitian, positive definite matrix  $Q$ .

8. [Sty02, pp. 28–31] Let  $H$  be a symmetric, positive semidefinite solution of the projected generalized Lyapunov equation  $E^*HA + A^*HE = -P_r^*P_r$ ,  $H = P_l^*HP_l$  and let  $\mathbf{x}$  be a solution of the initial value problem  $E\dot{\mathbf{x}} = A\mathbf{x}$ ,  $\mathbf{x}(0) = P_r\mathbf{x}_0$ . Then in terms of the original data,

$$\|\mathbf{x}(t)\|_2 \leq \sqrt{\kappa(E, A)\|E\|_2\|(EP_r + A(I - P_r))^{-1}\|_2} e^{-t\|A\|_2/(\kappa(E, A)\|E\|_2)} \|P_r\mathbf{x}_0\|_2,$$

where  $\kappa(E, A) = 2\|E\|_2\|A\|_2\|H\|_2$ .

9. From the previous fact it follows that the equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $E\dot{\mathbf{x}} = A\mathbf{x}$  is exponentially stable if and only if it is asymptotically stable.

### Applications:

1. The finite eigenvalues of the pencil  $\lambda E - A$  in the RLC electrical circuit example are given by

$$\lambda_1 = -\frac{R}{2L} - \sqrt{\frac{R^2}{4L^2} - \frac{1}{LC}}, \quad \lambda_2 = -\frac{R}{2L} + \sqrt{\frac{R^2}{4L^2} - \frac{1}{LC}}.$$

Hence, the equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $E\dot{\mathbf{x}} = A\mathbf{x}$  is asymptotically stable.

2. The pencil  $\lambda E - A$  in the linearized pendulum example has the finite eigenvalues  $\lambda_1 = -i\sqrt{g/l}$  and  $\lambda_2 = i\sqrt{g/l}$ . In this case the equilibrium  $\mathbf{x}_e(t) \equiv 0$  of the system  $E\dot{\mathbf{x}} = A\mathbf{x}$  is stable but not asymptotically stable.

**Examples:**

1. The generalized Lyapunov equation  $E^*XA + A^*XE = -Q$  with

$$E = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}, \quad A = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}, \quad Q = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

has no solution, although the finite eigenvalue of  $\lambda E - A$  is negative and  $\lambda E - A$  has index one.

2. The generalized Lyapunov equation  $E^*XA + A^*XE = -E^*QE$  with

$$E = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}, \quad A = \begin{bmatrix} -2 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad Q = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 2 \end{bmatrix}$$

has no Hermitian, positive semidefinite solution, although the finite eigenvalue of  $\lambda E - A$  is negative.

3. The generalized Lyapunov equation  $A^*X + Y^*A = -Q$ ,  $Y^*E = E^*X$  with

$$E = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}, \quad A = \begin{bmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad Q = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

has no solution, although the finite eigenvalue of  $\lambda E - A$  is negative.

Linear algebra plays a key role in the theory of dynamical systems, and concepts from dynamical systems allow the study, characterization, and generalization of many objects in linear algebra, such as similarity of matrices, eigenvalues, and (generalized) eigenspaces. The most basic form of this interplay can be seen as a matrix  $A$  gives rise to a continuous time dynamical system via the linear ordinary differential equation  $\dot{\mathbf{x}} = A\mathbf{x}$ , or a discrete time dynamical system via iteration  $\mathbf{x}_{n+1} = A\mathbf{x}_n$ . The properties of the solutions are intimately related to the properties of the matrix  $A$ . Matrices also define nonlinear systems on smooth manifolds, such as the sphere  $\mathbb{S}^{d-1}$  in  $\mathbb{R}^d$ , the Grassmann manifolds, or on classical (matrix) Lie groups. Again, the behavior of such systems is closely related to matrices and their properties. And the behavior of nonlinear systems, e.g., of differential equations  $\dot{\mathbf{y}} = f(\mathbf{y})$  in  $\mathbb{R}^d$  with a fixed point  $\mathbf{y}_0 \in \mathbb{R}^d$ , can be described locally around  $\mathbf{y}_0$  via the linear differential equation  $\dot{\mathbf{x}} = D_{\mathbf{y}}f(\mathbf{y}_0)\mathbf{x}$ .

Since A. M. Lyapunov's thesis in 1892, it has been an intriguing problem how to construct an appropriate linear algebra for time varying systems. Note that, e.g., for stability of the solutions of  $\dot{\mathbf{x}} = A(t)\mathbf{x}$ , it is not sufficient that for all  $t \in \mathbb{R}$  the matrices  $A(t)$  have only eigenvalues with negative real part (see [Hah67], Chapter 62). Of course, Floquet theory (see [Flo83]) gives an elegant solution for the periodic case, but it is not immediately clear how to build a linear algebra around Lyapunov's "order numbers" (now called Lyapunov exponents). The multiplicative ergodic theorem of Oseledets [Ose68] resolves the issue for measurable linear systems with stationary time dependencies, and the Morse spectrum together with Selgrade's theorem [Sel75] clarifies the situation for continuous linear systems with chain transitive time dependencies.

This chapter provides a first introduction to the interplay between linear algebra and analysis/topology in continuous time. Section 56.1 recalls facts about  $d$ -dimensional linear differential equations  $\dot{\mathbf{x}} = A\mathbf{x}$ ,

emphasizing eigenvalues and (generalized) eigenspaces. Section 56.2 studies solutions in Euclidian space  $\mathbb{R}^d$  from the point of view of topological equivalence and conjugacy with related characterizations of the matrix  $A$ . Section 56.3 presents, in a fairly general set-up, the concepts of chain recurrence and Morse decompositions for dynamical systems. These ideas are then applied in section 56.4 to nonlinear systems on Grassmannian and flag manifolds induced by a single matrix  $A$ , with emphasis on characterizations of the matrix  $A$  from this point of view. Section 56.5 introduces linear skew product flows as a way to model time varying linear systems  $\dot{\mathbf{x}} = A(t)\mathbf{x}$  with, e.g., periodic, measurable ergodic, and continuous chain transitive time dependencies. The following sections 56.6, 56.7, and 56.8 develop generalizations of (real parts of) eigenvalues and eigenspaces as a starting point for a linear algebra for classes of time varying linear systems, namely periodic, random, and robust systems. (For the corresponding generalization of the imaginary parts of eigenvalues see, e.g., [Arn98] for the measurable ergodic case and [CFJ06] for the continuous, chain transitive case.) Section 56.9 introduces some basic ideas to study genuinely nonlinear systems via linearization, emphasizing invariant manifolds and Grobman–Hartman-type results that compare nonlinear behavior locally to the behavior of associated linear systems.

### Notation:

In this chapter, the set of  $d \times d$  real matrices is denoted by  $gl(d, \mathbb{R})$  rather than  $\mathbb{R}^{d \times d}$ .

## 56.1 Linear Differential Equations

Linear differential equations can be solved explicitly if one knows the eigenvalues and a basis of eigenvectors (and generalized eigenvectors, if necessary). The key idea is that of the Jordan form of a matrix. The real parts of the eigenvectors determine the exponential behavior of the solutions, described by the Lyapunov exponents and the corresponding Lyapunov subspaces.

For information on matrix functions, including the matrix exponential, see Chapter 11. For information on the Jordan canonical form see Chapter 6. Systems of first order linear differential equations are also discussed in Chapter 55.

### Definitions:

For a matrix  $A \in gl(d, \mathbb{R})$ , the **exponential**  $e^A \in GL(d, \mathbb{R})$  is defined by  $e^A = I + \sum_{n=1}^{\infty} \frac{1}{n!} A^n \in GL(d, \mathbb{R})$ , where  $I \in gl(d, \mathbb{R})$  is the identity matrix.

A **linear differential equation** (with constant coefficients) is given by a matrix  $A \in gl(d, \mathbb{R})$  via  $\dot{\mathbf{x}}(t) = A\mathbf{x}(t)$ , where  $\dot{\mathbf{x}}$  denotes differentiation with respect to  $t$ . Any function  $\mathbf{x} : \mathbb{R} \rightarrow \mathbb{R}^d$  such that  $\dot{\mathbf{x}}(t) = A\mathbf{x}(t)$  for all  $t \in \mathbb{R}$  is called a solution of  $\dot{\mathbf{x}} = A\mathbf{x}$ .

The **initial value problem** for a linear differential equation  $\dot{\mathbf{x}} = A\mathbf{x}$  consists in finding, for a given **initial value**  $\mathbf{x}_0 \in \mathbb{R}^d$ , a solution  $\mathbf{x}(\cdot, \mathbf{x}_0)$  that satisfies  $\mathbf{x}(0, \mathbf{x}_0) = \mathbf{x}_0$ .

The distinct (complex) eigenvalues of  $A \in gl(d, \mathbb{R})$  will be denoted  $\mu_1, \dots, \mu_r$ . (For definitions and more information about eigenvalues, eigenvectors, and eigenspaces, see Section 4.3. For information about generalized eigenspaces, see Chapter 6.) The real version of the generalized eigenspace is denoted by  $E(A, \mu_k) \subset \mathbb{R}^d$  or simply  $E_k$  for  $k = 1, \dots, r \leq d$ .

The **real Jordan form** of a matrix  $A \in gl(d, \mathbb{R})$  is denoted by  $J_A^{\mathbb{R}}$ . Note that for any matrix  $A$  there is a matrix  $T \in GL(d, \mathbb{R})$  such that  $A = T^{-1}J_A^{\mathbb{R}}T$ .

Let  $\mathbf{x}(\cdot, \mathbf{x}_0)$  be a solution of the linear differential equation  $\dot{\mathbf{x}} = A\mathbf{x}$ . Its **Lyapunov exponent** for  $\mathbf{x}_0 \neq 0$  is defined as  $\lambda(\mathbf{x}_0) = \limsup_{t \rightarrow \infty} \frac{1}{t} \log \|\mathbf{x}(t, \mathbf{x}_0)\|$ , where  $\log$  denotes the natural logarithm and  $\|\cdot\|$  is any norm in  $\mathbb{R}^d$ .

Let  $\mu_k = \lambda_k + i\nu_k$ ,  $k = 1, \dots, r$ , be the distinct eigenvalues of  $A \in gl(d, \mathbb{R})$ . We order the distinct real parts of the eigenvalues as  $\lambda_1 < \dots < \lambda_l$ ,  $1 \leq l \leq r \leq d$ , and define the **Lyapunov space** of  $\lambda_j$  as  $L(\lambda_j) = \bigoplus E_k$ , where the direct sum is taken over all generalized real eigenspaces associated to eigenvalues with real part equal to  $\lambda_j$ . Note that  $\bigoplus_{j=1}^l L(\lambda_j) = \mathbb{R}^d$ .

The **stable, center, and unstable subspaces** associated with the matrix  $A \in gl(d, \mathbb{R})$  are defined as  $L^- = \bigoplus\{L(\lambda_j), \lambda_j < 0\}$ ,  $L^0 = \bigoplus\{L(\lambda_j), \lambda_j = 0\}$ , and  $L^+ = \bigoplus\{L(\lambda_j), \lambda_j > 0\}$ , respectively.

The zero solution  $\mathbf{x}(t, 0) \equiv 0$  is called **exponentially stable** if there exists a neighborhood  $U(0)$  and positive constants  $a, b > 0$  such that  $\mathbf{x}(t, \mathbf{x}_0) \leq a \|\mathbf{x}_0\| e^{-bt}$  for all  $t \in \mathbb{R}$  and  $\mathbf{x}_0 \in U(0)$ .

**Facts:**

Literature: [Ama90], [HSD04].

1. For each  $A \in gl(d, \mathbb{R})$  the solutions of  $\dot{\mathbf{x}} = A\mathbf{x}$  form a  $d$ -dimensional vector space  $sol(A) \subset C^\infty(\mathbb{R}, \mathbb{R}^d)$  over  $\mathbb{R}$ , where  $C^\infty(\mathbb{R}, \mathbb{R}^d) = \{f : \mathbb{R} \rightarrow \mathbb{R}^d, f \text{ is infinitely often differentiable}\}$ . Note that the solutions of  $\dot{\mathbf{x}} = A\mathbf{x}$  are even real analytic.
2. For each initial value problem given by  $A \in gl(d, \mathbb{R})$  and  $\mathbf{x}_0 \in \mathbb{R}^d$ , the solution  $\mathbf{x}(\cdot, \mathbf{x}_0)$  is unique and given by  $\mathbf{x}(t, \mathbf{x}_0) = e^{At}\mathbf{x}_0$ .
3. Let  $\mathbf{v}_1, \dots, \mathbf{v}_d \in \mathbb{R}^d$  be a basis of  $\mathbb{R}^d$ . Then the functions  $\mathbf{x}(\cdot, \mathbf{v}_1), \dots, \mathbf{x}(\cdot, \mathbf{v}_d)$  form a basis of the solution space  $sol(A)$ . The matrix function  $X(\cdot) := [\mathbf{x}(\cdot, \mathbf{v}_1), \dots, \mathbf{x}(\cdot, \mathbf{v}_d)]$  is called a fundamental matrix of  $\dot{\mathbf{x}} = A\mathbf{x}$ , and it satisfies  $\dot{X}(t) = AX(t)$ .
4. Let  $A \in gl(d, \mathbb{R})$  with distinct eigenvalues  $\mu_1, \dots, \mu_r \in \mathbb{C}$  and corresponding multiplicities  $n_k = \alpha(\mu_k), k = 1, \dots, r$ . If  $E_k$  are the corresponding generalized real eigenspaces, then  $\dim E_k = n_k$  and  $\bigoplus_{k=1}^r E_k = \mathbb{R}^d$ , i.e., every matrix has a set of generalized real eigenvectors that form a basis of  $\mathbb{R}^d$ .
5. If  $A = T^{-1}J_A^{\mathbb{R}}T$ , then  $e^{At} = T^{-1}e^{J_A^{\mathbb{R}}t}T$ , i.e., for the computation of exponentials of matrices it is sufficient to know the exponentials of Jordan form matrices.
6. Let  $\mathbf{v}_1, \dots, \mathbf{v}_d$  be a basis of generalized real eigenvectors of  $A$ . If  $\mathbf{x}_0 = \sum_{i=1}^d \alpha_i \mathbf{v}_i$ , then  $\mathbf{x}(t, \mathbf{x}_0) = \sum_{i=1}^d \alpha_i \mathbf{x}(t, \mathbf{v}_i)$  for all  $t \in \mathbb{R}$ . This reduces the computation of solutions to  $\dot{\mathbf{x}} = A\mathbf{x}$  to the computation of solutions for Jordan blocks; see the examples below or [HSD04, Chap. 5] for a discussion of this topic.
7. Each generalized real eigenspace  $E_k$  is invariant for the linear differential equation  $\dot{\mathbf{x}} = A\mathbf{x}$ , i.e., for  $\mathbf{x}_0 \in E_k$  it holds that  $\mathbf{x}(t, \mathbf{x}_0) \in E_k$  for all  $t \in \mathbb{R}$ .
8. The Lyapunov exponent  $\lambda(\mathbf{x}_0)$  of a solution  $\mathbf{x}(\cdot, \mathbf{x}_0)$  (with  $\mathbf{x}_0 \neq 0$ ) satisfies  $\lambda(\mathbf{x}_0) = \lim_{t \rightarrow \pm\infty} \frac{1}{t} \log \|\mathbf{x}(t, \mathbf{x}_0)\| = \lambda_j$  if and only if  $\mathbf{x}_0 \in L(\lambda_j)$ . Hence, associated to a matrix  $A \in gl(d, \mathbb{R})$  are exactly  $l$  Lyapunov exponents, the distinct real parts of the eigenvalues of  $A$ .
9. The following are equivalent:
  - (a) The zero solution  $\mathbf{x}(t, 0) \equiv 0$  of the differential equation  $\dot{\mathbf{x}} = A\mathbf{x}$  is asymptotically stable.
  - (b) The zero solution is exponentially stable
  - (c) All Lyapunov exponents are negative.
  - (d)  $L^- = \mathbb{R}^d$ .

**Examples:**

1. Let  $A = \text{diag}(a_1, \dots, a_d)$  be a diagonal matrix. Then the solution of the linear differential equation  $\dot{\mathbf{x}} = A\mathbf{x}$  with initial value  $\mathbf{x}_0 \in \mathbb{R}^d$  is given by  $\mathbf{x}(t, \mathbf{x}_0) = e^{At}\mathbf{x}_0 = \begin{bmatrix} e^{a_1 t} & & & \\ & \ddots & & \\ & & \ddots & \\ & & & e^{a_d t} \end{bmatrix} \mathbf{x}_0$ .
2. Let  $\mathbf{e}_1 = (1, 0, \dots, 0)^T, \dots, \mathbf{e}_d = (0, 0, \dots, 1)^T$  be the standard basis of  $\mathbb{R}^d$ . Then  $\{\mathbf{x}(\cdot, \mathbf{e}_1), \dots, \mathbf{x}(\cdot, \mathbf{e}_d)\}$  is a basis of the solution space  $sol(A)$ .
3. Let  $A = \text{diag}(a_1, \dots, a_d)$  be a diagonal matrix. Then the standard basis  $\{\mathbf{e}_1, \dots, \mathbf{e}_d\}$  of  $\mathbb{R}^d$  consists of eigenvectors of  $A$ .

4. Let  $A \in gl(d, \mathbb{R})$  be diagonalizable, i.e., there exists a transformation matrix  $T \in GL(d, \mathbb{R})$  and a diagonal matrix  $D \in gl(d, \mathbb{R})$  with  $A = T^{-1}DT$ . Then the solution of the linear differential equation  $\dot{\mathbf{x}} = A\mathbf{x}$  with initial value  $\mathbf{x}_0 \in \mathbb{R}^d$  is given by  $\mathbf{x}(t, \mathbf{x}_0) = T^{-1}e^{Dt}T\mathbf{x}_0$ , where  $e^{Dt}$  is given in Example 1.
5. Let  $B = \begin{bmatrix} \lambda & -\nu \\ \nu & \lambda \end{bmatrix}$  be the real Jordan block associated with a complex eigenvalue  $\mu = \lambda + i\nu$  of the matrix  $A \in gl(d, \mathbb{R})$ . Let  $\mathbf{y}_0 \in E(A, \mu)$ , the real eigenspace of  $\mu$ . Then the solution  $\mathbf{y}(t, \mathbf{y}_0)$  of  $\dot{\mathbf{y}} = B\mathbf{y}$  is given by  $\mathbf{y}(t, \mathbf{y}_0) = e^{\lambda t} \begin{bmatrix} \cos \nu t & -\sin \nu t \\ \sin \nu t & \cos \nu t \end{bmatrix} \mathbf{y}_0$ . According to Fact 6 this is also the  $E(A, \mu)$ -component of the solutions of  $\dot{\mathbf{x}} = J_A^{\mathbb{R}}\mathbf{x}$ .
6. Let  $B$  be a Jordan block of dimension  $n$  associated with the real eigenvalue  $\mu$  of a matrix  $A \in gl(d, \mathbb{R})$ . Then for

$$B = \begin{bmatrix} \mu & 1 & & & \\ & \cdot & \cdot & & \\ & & \cdot & \cdot & \\ & & & \cdot & \cdot \\ & & & & \mu \end{bmatrix} \quad \text{one has } e^{Bt} = e^{\mu t} \begin{bmatrix} 1 & t & \frac{t^2}{2!} & \cdot & \cdot & \frac{t^{n-1}}{(n-1)!} \\ & \cdot & \cdot & \cdot & & \cdot \\ & & \cdot & \cdot & \cdot & \cdot \\ & & & \cdot & \cdot & \cdot \\ & & & & \cdot & \frac{t^2}{2!} \\ & & & & & \cdot & t \\ & & & & & & 1 \end{bmatrix}.$$

In other words, for  $\mathbf{y}_0 = [y_1, \dots, y_n]^T \in E(A, \mu)$ , the  $j$ th component of the solution of  $\dot{\mathbf{y}} = B\mathbf{y}$  reads  $y_j(t, \mathbf{y}_0) = e^{\mu t} \sum_{k=j}^n \frac{t^{k-j}}{(k-j)!} y_k$ . According to Fact 6 this is also the  $E(A, \mu)$ -component of  $e^{J_A^{\mathbb{R}}t}$ .

7. Let  $B$  be a real Jordan block of dimension  $n = 2m$  associated with the complex eigenvalue  $\mu = \lambda + i\nu$  of a matrix  $A \in gl(d, \mathbb{R})$ . Then with  $D = \begin{bmatrix} \lambda & -\nu \\ \nu & \lambda \end{bmatrix}$  and  $I = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$ , for

$$B = \begin{bmatrix} D & I & & & \\ & \cdot & \cdot & & \\ & & \cdot & \cdot & \\ & & & \cdot & \cdot \\ & & & & I \\ & & & & & D \end{bmatrix} \quad \text{one has } e^{Bt} = e^{\lambda t} \begin{bmatrix} \widehat{D} & t\widehat{D} & \frac{t^2}{2!}\widehat{D} & \cdot & \cdot & \frac{t^{n-1}}{(n-1)!}\widehat{D} \\ & \cdot & \cdot & \cdot & & \cdot \\ & & \cdot & \cdot & \cdot & \cdot \\ & & & \cdot & \cdot & \cdot \\ & & & & \cdot & \frac{t^2}{2!}\widehat{D} \\ & & & & & \cdot & t\widehat{D} \\ & & & & & & \widehat{D} \end{bmatrix},$$

where  $\widehat{D} = \begin{bmatrix} \cos \nu t & -\sin \nu t \\ \sin \nu t & \cos \nu t \end{bmatrix}$ . In other words, for  $\mathbf{y}_0 = [y_1, z_1, \dots, y_m, z_m]^T \in E(A, \mu)$ , the  $j$ th components,  $j = 1, \dots, m$ , of the solution of  $\dot{\mathbf{y}} = B\mathbf{y}$  read

$$y_j(t, \mathbf{y}_0) = e^{\mu t} \sum_{k=j}^m \frac{t^{k-j}}{(k-j)!} (y_k \cos \nu t - z_k \sin \nu t),$$

$$z_j(t, \mathbf{y}_0) = e^{\mu t} \sum_{k=j}^m \frac{t^{k-j}}{(k-j)!} (z_k \cos \nu t + y_k \sin \nu t).$$

According to Fact 6, this is also the  $E(A, \mu)$ -component of  $e^{J_A^{\mathbb{R}}t}$ .

8. Using these examples and Facts 5 and 6, it is possible to compute explicitly the solutions to any linear differential equation in  $\mathbb{R}^d$ .
9. Recall that for any matrix  $A$  there is a matrix  $T \in GL(d, \mathbb{R})$  such that  $A = T^{-1}J_A^{\mathbb{R}}T$ , where  $J_A^{\mathbb{R}}$  is the real Jordan canonical form of  $A$ . The exponential behavior of the solutions of  $\dot{\mathbf{x}} = A\mathbf{x}$  can be read off from the diagonal elements of  $J_A^{\mathbb{R}}$ .

## 56.2 Linear Dynamical Systems in $\mathbb{R}^d$

The solutions of a linear differential equation  $\dot{x} = Ax$ , where  $A \in gl(d, \mathbb{R})$ , define a (continuous time) dynamical system, or linear flow in  $\mathbb{R}^d$ . The standard concepts for comparison of dynamical systems are equivalences and conjugacies that map trajectories into trajectories. For linear flows in  $\mathbb{R}^d$  these concepts lead to two different classifications of matrices, depending on the smoothness of the conjugacy or equivalence.

### Definitions:

The real square matrix  $A$  is **hyperbolic** if it has no eigenvalues on the imaginary axis.

A **continuous dynamical system** over the “time set”  $\mathbb{R}$  with state space  $M$ , a complete metric space, is defined as a map  $\Phi : \mathbb{R} \times M \rightarrow M$  with the properties

- (i)  $\Phi(0, x) = x$  for all  $x \in M$ ,
- (ii)  $\Phi(s + t, x) = \Phi(s, \Phi(t, x))$  for all  $s, t \in \mathbb{R}$  and all  $x \in M$ ,
- (iii)  $\Phi$  is continuous (in both variables).

The map  $\Phi$  is also called a (continuous) flow.

For each  $x \in M$  the set  $\{\Phi(t, x), t \in \mathbb{R}\}$  is called the **orbit (or trajectory)** of the system through  $x$ .

For each  $t \in \mathbb{R}$  the **time- $t$  map** is defined as  $\varphi_t = \Phi(t, \cdot) : M \rightarrow M$ . Using time- $t$  maps, the properties (i) and (ii) above can be restated as (i)'  $\varphi_0 = id$ , the identity map on  $M$ , (ii)'  $\varphi_{s+t} = \varphi_s \circ \varphi_t$  for all  $s, t \in \mathbb{R}$ .

A **fixed point (or equilibrium)** of a dynamical system  $\Phi$  is a point  $x \in M$  with the property  $\Phi(t, x) = x$  for all  $t \in \mathbb{R}$ .

An orbit  $\{\Phi(t, x), t \in \mathbb{R}\}$  of a dynamical system  $\Phi$  is called **periodic** if there exists  $\hat{t} \in \mathbb{R}, \hat{t} > 0$  such that  $\Phi(\hat{t} + s, x) = \Phi(s, x)$  for all  $s \in \mathbb{R}$ . The infimum of the positive  $\hat{t} \in \mathbb{R}$  with this property is called the **period** of the orbit. Note that an orbit of period 0 is a fixed point.

Denote by  $C^k(X, Y)$  ( $k \geq 0$ ) the set of  $k$ -times **differentiable functions** between  $C^k$ -manifolds  $X$  and  $Y$ , with  $C^0$  denoting continuous.

Let  $\Phi, \Psi : \mathbb{R} \times M \rightarrow M$  be two continuous dynamical systems of class  $C^k$  ( $k \geq 0$ ), i.e., for  $k \geq 1$  the state space  $M$  is at least a  $C^k$ -manifold and  $\Phi, \Psi$  are  $C^k$ -maps. The flows  $\Phi$  and  $\Psi$  are:

- (i)  **$C^k$ -equivalent** ( $k \geq 1$ ) if there exists a (local)  $C^k$ -diffeomorphism  $h : M \rightarrow M$  such that  $h$  takes orbits of  $\Phi$  onto orbits of  $\Psi$ , **preserving the orientation** (but not necessarily parametrization by time), i.e.,
  - (a) For each  $x \in M$  there is a strictly increasing and continuous parametrization map  $\tau_x : \mathbb{R} \rightarrow \mathbb{R}$  such that  $h(\Phi(t, x)) = \Psi(\tau_x(t), h(x))$  or, equivalently,
  - (b) For all  $x \in M$  and  $\delta > 0$  there exists  $\varepsilon > 0$  such that for all  $t \in (0, \delta), h(\Phi(t, x)) = \Psi(t', h(x))$  for some  $t' \in (0, \varepsilon)$ .
- (ii)  **$C^k$ -conjugate** ( $k \geq 1$ ) if there exists a (local)  $C^k$ -diffeomorphism  $h : M \rightarrow M$  such that  $h(\Phi(t, x)) = \Psi(t, h(x))$  for all  $x \in M$  and  $t \in \mathbb{R}$ .

Similarly, the flows  $\Phi$  and  $\Psi$  are  **$C^0$ -equivalent** if there exists a (local) homeomorphism  $h : M \rightarrow M$  satisfying the properties of (i) above, and they are  **$C^0$ -conjugate** if there exist a (local) homeomorphism  $h : M \rightarrow M$  satisfying the properties of (ii) above. Often,  $C^0$ -equivalence is called **topological equivalence**, and  $C^0$ -conjugacy is called **topological conjugacy** or simply **conjugacy**.

**Warning:** While this terminology is standard in dynamical systems, the terms *conjugate* and *equivalent* are used differently in linear algebra. *Conjugacy* as used here is related to matrix similarity (cf. Fact 6), *not* to matrix conjugacy, and *equivalence* as used here is *not* related to matrix equivalence.

**Facts:**

Literature: [HSD04], [Rob98].

1. If the flows  $\Phi$  and  $\Psi$  are  $C^k$ -conjugate, then they are  $C^k$ -equivalent.
2. Each time- $t$  map  $\varphi_t$  has an inverse  $(\varphi_t)^{-1} = \varphi_{-t}$ , and  $\varphi_t : M \rightarrow M$  is a homeomorphism, i.e., a continuous bijective map with continuous inverse.
3. Denote the set of time- $t$  maps again by  $\Phi = \{\varphi_t, t \in \mathbb{R}\}$ . A dynamical system is a group in the sense that  $(\Phi, \circ)$ , with  $\circ$  denoting composition of maps, satisfies the group axioms, and  $\varphi : (\mathbb{R}, +) \rightarrow (\Phi, \circ)$ , defined by  $\varphi(t) = \varphi_t$ , is a group homomorphism.
4. Let  $M$  be a  $C^\infty$ -differentiable manifold and  $X$  a  $C^\infty$ -vector field on  $M$  such that the differential equation  $\dot{x} = X(x)$  has unique solutions  $x(t, x_0)$  for all  $x_0 \in M$  and all  $t \in \mathbb{R}$ , with  $x(0, x_0) = x_0$ . Then  $\Phi(t, x_0) = x(t, x_0)$  defines a dynamical system  $\Phi : \mathbb{R} \times M \rightarrow M$ .
5. A point  $x_0 \in M$  is a fixed point of the dynamical system  $\Phi$  associated with a differential equation  $\dot{x} = X(x)$  as above if and only if  $X(x_0) = 0$ .
6. For two linear flows  $\Phi$  (associated with  $\dot{\mathbf{x}} = A\mathbf{x}$ ) and  $\Psi$  (associated with  $\dot{\mathbf{x}} = B\mathbf{x}$ ) in  $\mathbb{R}^d$ , the following are equivalent:
  - $\Phi$  and  $\Psi$  are  $C^k$ -conjugate for  $k \geq 1$ .
  - $\Phi$  and  $\Psi$  are linearly conjugate, i.e., the conjugacy map  $h$  is a linear operator in  $GL(\mathbb{R}^d)$ .
  - $A$  and  $B$  are similar, i.e.,  $A = TBT^{-1}$  for some  $T \in GL(d, \mathbb{R})$ .
7. Each of the statements in Fact 6 implies that  $A$  and  $B$  have the same eigenvalue structure and (up to a linear transformation) the same generalized real eigenspace structure. In particular, the  $C^k$ -conjugacy classes are exactly the real Jordan canonical form equivalence classes in  $gl(d, \mathbb{R})$ .
8. For two linear flows  $\Phi$  (associated with  $\dot{\mathbf{x}} = A\mathbf{x}$ ) and  $\Psi$  (associated with  $\dot{\mathbf{x}} = B\mathbf{x}$ ) in  $\mathbb{R}^d$ , the following are equivalent:
  - $\Phi$  and  $\Psi$  are  $C^k$ -equivalent for  $k \geq 1$ .
  - $\Phi$  and  $\Psi$  are linearly equivalent, i.e., the equivalence map  $h$  is a linear map in  $GL(\mathbb{R}^d)$ .
  - $A = \alpha TBT^{-1}$  for some positive real number  $\alpha$  and  $T \in GL(d, \mathbb{R})$ .
9. Each of the statements in Fact 8 implies that  $A$  and  $B$  have the same real Jordan structure and their eigenvalues differ by a positive constant. Hence, the  $C^k$ -equivalence classes are real Jordan canonical form equivalence classes modulo a positive constant.
10. The set of hyperbolic matrices is open and dense in  $gl(d, \mathbb{R})$ . A matrix  $A$  is hyperbolic if and only if it is structurally stable in  $gl(d, \mathbb{R})$ , i.e., there exists a neighborhood  $U \subset gl(d, \mathbb{R})$  of  $A$  such that all  $B \in U$  are topologically equivalent to  $A$ .
11. If  $A$  and  $B$  are hyperbolic, then the associated linear flows  $\Phi$  and  $\Psi$  in  $\mathbb{R}^d$  are  $C^0$ -equivalent (and  $C^0$ -conjugate) if and only if the dimensions of the stable subspaces (and, hence, the dimensions of the unstable subspaces) of  $A$  and  $B$  agree.

**Examples:**

1. Linear differential equations: For  $A \in gl(d, \mathbb{R})$  the solutions of  $\dot{\mathbf{x}} = A\mathbf{x}$  form a continuous dynamical system with time set  $\mathbb{R}$  and state space  $M = \mathbb{R}^d$ : Here  $\Phi : \mathbb{R} \times \mathbb{R}^d \rightarrow \mathbb{R}^d$  is defined by  $\Phi(t, \mathbf{x}_0) = \mathbf{x}(t, \mathbf{x}_0) = e^{At}\mathbf{x}_0$ .
2. Fixed points of linear differential equations: A point  $\mathbf{x}_0 \in \mathbb{R}^d$  is a fixed point of the dynamical system  $\Phi$  associated with the linear differential equation  $\dot{\mathbf{x}} = A\mathbf{x}$  if and only if  $\mathbf{x}_0 \in \ker A$ , the kernel of  $A$ .
3. Periodic orbits of linear differential equations: The orbit  $\Phi(t, \mathbf{x}_0) := \mathbf{x}(t, \mathbf{x}_0)$ ,  $t \in \mathbb{R}$  is periodic with period  $\hat{t} > 0$  if and only if  $\mathbf{x}_0$  is in the eigenspace of a nonzero complex eigenvalue with zero real part.

4. For each matrix  $A \in gl(d, \mathbb{R})$  its associated linear flow in  $\mathbb{R}^d$  is  $C^k$ -conjugate (and, hence,  $C^k$ -equivalent) for all  $k \geq 0$  to the dynamical system associated with the Jordan form  $J_A^{\mathbb{R}}$ .

### 56.3 Chain Recurrence and Morse Decompositions of Dynamical Systems

A matrix  $A \in gl(d, \mathbb{R})$  and, hence, a linear differential equation  $\dot{x} = Ax$  maps subspaces of  $\mathbb{R}^d$  into subspaces of  $\mathbb{R}^d$ . Therefore, the matrix  $A$  also defines dynamical systems on spaces of subspaces, such as the Grassmann and the flag manifolds. These are nonlinear systems, but they can be studied via linear algebra, and vice versa; the behavior of these systems allows for the investigation of certain properties of the matrix  $A$ . The key topological concepts for the analysis of systems on compact spaces like the Grassmann and flag manifolds are chain recurrence, Morse decompositions, and attractor–repeller decompositions. This section concentrates on the first two approaches, the connection to attractor–repeller decompositions can be found, e.g., in [CK00, App. B2].

**Definitions:**

Given a dynamical system  $\Phi : \mathbb{R} \times M \rightarrow M$ , for a subset  $N \subset M$  the  $\alpha$ -**limit set** is defined as  $\alpha(N) = \{y \in M, \text{there exist sequences } x_n \text{ in } N \text{ and } t_n \rightarrow -\infty \text{ in } \mathbb{R} \text{ with } \lim_{n \rightarrow \infty} \Phi(t_n, x_n) = y\}$ , and similarly the  $\omega$ -**limit set** of  $N$  is defined as  $\omega(N) = \{y \in M, \text{there exist sequences } x_n \text{ in } N \text{ and } t_n \rightarrow \infty \text{ in } \mathbb{R} \text{ with } \lim_{n \rightarrow \infty} \Phi(t_n, x_n) = y\}$ .

For a flow  $\Phi$  on a complete metric space  $M$  and  $\varepsilon, T > 0$ , an  $(\varepsilon, T)$ -**chain** from  $x \in M$  to  $y \in M$  is given by

$$n \in \mathbb{N}, x_0 = x, \dots, x_n = y, T_0, \dots, T_{n-1} > T$$

with

$$d(\Phi(T_i, x_i), x_{i+1}) < \varepsilon \text{ for all } i,$$

where  $d$  is the metric on  $M$ .

A set  $K \subset M$  is **chain transitive** if for all  $x, y \in K$  and all  $\varepsilon, T > 0$  there is an  $(\varepsilon, T)$ -chain from  $x$  to  $y$ .

The **chain recurrent set**  $\mathcal{CR}$  is the set of all points that are chain reachable from themselves, i.e.,  $\mathcal{CR} = \{x \in M, \text{for all } \varepsilon, T > 0 \text{ there is an } (\varepsilon, T)\text{-chain from } x \text{ to } x\}$ .

A set  $\mathcal{M} \subset M$  is a **chain recurrent component**, if it is a maximal (with respect to set inclusion) chain transitive set. In this case  $\mathcal{M}$  is a connected component of the chain recurrent set  $\mathcal{CR}$ .

For a flow  $\Phi$  on a complete metric space  $M$ , a compact subset  $K \subset M$  is called **isolated invariant**, if it is invariant and there exists a neighborhood  $N$  of  $K$ , i.e., a set  $N$  with  $K \subset \text{int } N$ , such that  $\Phi(t, x) \in N$  for all  $t \in \mathbb{R}$  implies  $x \in K$ .

A **Morse decomposition** of a flow  $\Phi$  on a complete metric space  $M$  is a finite collection  $\{\mathcal{M}_i, i = 1, \dots, l\}$  of nonvoid, pairwise disjoint, and isolated compact invariant sets such that

(i) For all  $x \in M, \omega(x), \alpha(x) \subset \bigcup_{i=1}^l \mathcal{M}_i$ ; and

(ii) Suppose there are  $\mathcal{M}_{j_0}, \mathcal{M}_{j_1}, \dots, \mathcal{M}_{j_n}$  and  $x_1, \dots, x_n \in M \setminus \bigcup_{i=1}^l \mathcal{M}_i$  with  $\alpha(x_i) \subset \mathcal{M}_{j_{i-1}}$  and  $\omega(x_i) \subset \mathcal{M}_{j_i}$  for  $i = 1, \dots, n$ ; then  $\mathcal{M}_{j_0} \neq \mathcal{M}_{j_n}$ .

The elements of a Morse decomposition are called **Morse sets**.

A Morse decomposition  $\{\mathcal{M}_i, i = 1, \dots, l\}$  is **finer** than another decomposition  $\{\mathcal{N}_j, j = 1, \dots, n\}$ , if for all  $\mathcal{M}_i$  there exists an index  $j \in \{1, \dots, n\}$  such that  $\mathcal{M}_i \subset \mathcal{N}_j$ .

**Facts:**

Literature: [Rob98], [CK00], [ACK05].

1. For a Morse decomposition  $\{\mathcal{M}_i, i = 1, \dots, l\}$  the relation  $\mathcal{M}_i < \mathcal{M}_j$ , given by  $\alpha(x) \subset \mathcal{M}_i$  and  $\omega(x) \subset \mathcal{M}_j$  for some  $x \in M \setminus \bigcup_{i=1}^l \mathcal{M}_i$ , induces an order.
2. Let  $\Phi, \Psi : \mathbb{R} \times M \longrightarrow M$  be two dynamical systems on a state space  $M$  and let  $h : M \rightarrow M$  be a topological equivalence for  $\Phi$  and  $\Psi$ . Then
  - (i) The point  $p \in M$  is a fixed point of  $\Phi$  if and only if  $h(p)$  is a fixed point of  $\Psi$ ;
  - (ii) The orbit  $\Phi(\cdot, p)$  is closed if and only if  $\Psi(\cdot, h(p))$  is closed;
  - (iii) If  $K \subset M$  is an  $\alpha$ -(or  $\omega$ -) limit set of  $\Phi$  from  $p \in M$ , then  $h[K]$  is an  $\alpha$ -(or  $\omega$ -) limit set of  $\Psi$  from  $h(p) \in M$ .
  - (iv) Given, in addition, two dynamical systems  $\Theta_{1,2} : \mathbb{R} \times N \longrightarrow N$ , if  $h : M \rightarrow M$  is a topological conjugacy for the flows  $\Phi$  and  $\Psi$  on  $M$ , and  $g : N \rightarrow N$  is a topological conjugacy for  $\Theta_1$  and  $\Theta_2$  on  $N$ , then the product flows  $\Phi \times \Theta_1$  and  $\Psi \times \Theta_2$  on  $M \times N$  are topologically conjugate via  $h \times g : M \times N \longrightarrow M \times N$ . This result is, in general, not true for topological equivalence.
3. Topological equivalences (and conjugacies) on a compact metric space  $M$  map chain transitive sets onto chain transitive sets.
4. Topological equivalences map invariant sets onto invariant sets, and minimal closed invariant sets onto minimal closed invariant sets.
5. Topological equivalences map Morse decompositions onto Morse decompositions.

**Examples:**

1. Dynamical systems in  $\mathbb{R}^1$ : Any limit set  $\alpha(x)$  and  $\omega(x)$  from a single point  $x$  of a dynamical system in  $\mathbb{R}^1$  consists of a single fixed point. The chain recurrent components (and the finest Morse decomposition) consist of single fixed points or intervals of fixed points. Any Morse set consists of fixed points and intervals between them.
2. Dynamical systems in  $\mathbb{R}^2$ : A nonempty, compact limit set of a dynamical system in  $\mathbb{R}^2$ , which contains no fixed points, is a closed, i.e., a periodic orbit (Poincaré–Bendixson). Any nonempty, compact limit set of a dynamical system in  $\mathbb{R}^2$  consists of fixed points, connecting orbits (such as homoclinic or heteroclinic orbits), and periodic orbits.
3. Consider the following dynamical system  $\Phi$  in  $\mathbb{R}^2 \setminus \{0\}$ , given by a differential equation in polar form for  $r > 0, \theta \in [0, 2\pi)$ , and  $a \neq 0$ :

$$\dot{r} = 1 - r, \quad \dot{\theta} = a.$$

For each  $\mathbf{x} \in \mathbb{R}^2 \setminus \{0\}$  the  $\omega$ -limit set is the circle  $\omega(\mathbf{x}) = \mathbb{S}^1 = \{(r, \theta), r = 1, \theta \in [0, 2\pi)\}$ . The state space  $\mathbb{R}^2 \setminus \{0\}$  is not compact, and  $\alpha$ -limit sets exist only for  $\mathbf{y} \in \mathbb{S}^1$ , for which  $\alpha(\mathbf{y}) = \mathbb{S}^1$ .

4. Consider the flow  $\Phi$  from the previous example and a second system  $\Psi$ , given by

$$\dot{r} = 1 - r, \quad \dot{\theta} = b$$

with  $b \neq 0$ . Then the flows  $\Phi$  and  $\Psi$  are topologically equivalent, but not conjugate if  $b \neq a$ .

5. An example of a flow for which the limit sets from points are strictly contained in the chain recurrent components can be obtained as follows: Let  $M = [0, 1] \times [0, 1]$ . Let the flow  $\Phi$  on  $M$  be defined such that all points on the boundary are fixed points, and the orbits for points  $(x, y) \in (0, 1) \times (0, 1)$  are straight lines  $\Phi(\cdot, (x, y)) = \{(z_1, z_2), z_1 = x, z_2 \in (0, 1)\}$  with  $\lim_{t \rightarrow \pm\infty} \Phi(t, (x, y)) = (x, \pm 1)$ . For this system, each point on the boundary is its own  $\alpha$ - and  $\omega$ -limit set. The  $\alpha$ -limit sets for points in the interior  $(x, y) \in (0, 1) \times (0, 1)$  are of the form  $\{(x, -1)\}$ , and the  $\omega$ -limit sets are  $\{(x, +1)\}$ .

The only chain recurrent component for this system is  $M = [0, 1] \times [0, 1]$ , which is also the only Morse set.

## 56.4 Linear Systems on Grassmannian and Flag Manifolds

### Definitions:

The  $k$ th **Grassmannian**  $\mathbb{G}_k$  of  $\mathbb{R}^d$  can be defined via the following construction: Let  $F(k, d)$  be the set of  $k$ -frames in  $\mathbb{R}^d$ , where a  **$k$ -frame** is an ordered set of  $k$  linearly independent vectors in  $\mathbb{R}^d$ . Two  $k$ -frames  $X = [\mathbf{x}_1, \dots, \mathbf{x}_k]$  and  $Y = [\mathbf{y}_1, \dots, \mathbf{y}_k]$  are said to be equivalent,  $X \sim Y$ , if there exists  $T \in GL(k, \mathbb{R})$  with  $X^T = TY^T$ , where  $X$  and  $Y$  are interpreted as  $d \times k$  matrices. The quotient space  $\mathbb{G}_k = F(k, d)/\sim$  is a compact,  $k(d - k)$ -dimensional differentiable manifold. For  $k = 1$ , we obtain the projective space  $\mathbb{P}^{d-1} = \mathbb{G}_1$  in  $\mathbb{R}^d$ .

The  $k$ th **flag** of  $\mathbb{R}^d$  is given by the following  $k$ -sequences of subspace inclusions,

$$\mathbb{F}_k = \{F_k = (V_1, \dots, V_k), V_i \subset V_{i+1} \text{ and } \dim V_i = i \text{ for all } i\}.$$

For  $k = d$ , this is the **complete flag**  $\mathbb{F} = \mathbb{F}_d$ .

Each matrix  $A \in gl(d, \mathbb{R})$  defines a map on the subspaces of  $\mathbb{R}^d$  as follows: Let  $V = \text{Span}(\{\mathbf{x}_1, \dots, \mathbf{x}_k\})$ . Then  $AV = \text{Span}(\{A\mathbf{x}_1, \dots, A\mathbf{x}_k\})$ .

Denote by  $\mathbb{G}_k\Phi$  and  $\mathbb{F}_k\Phi$  the induced flows on the Grassmannians and the flags, respectively.

### Facts:

Literature: [Rob98], [CK00], [ACK05].

1. Let  $\mathbb{P}\Phi$  be the projection onto  $\mathbb{P}^{d-1}$  of a linear flow  $\Phi(t, x) = e^{At}x$ . Then  $\mathbb{P}\Phi$  has  $l$  chain recurrent components  $\{\mathcal{M}_1, \dots, \mathcal{M}_l\}$ , where  $l$  is the number of different Lyapunov exponents (i.e., of different real parts of eigenvalues) of  $A$ . For each Lyapunov exponent  $\lambda_i$ ,  $\mathcal{M}_i = \mathbb{P}L_i$ , the projection of the  $i$ th Lyapunov space onto  $\mathbb{P}^{d-1}$ . Furthermore  $\{\mathcal{M}_1, \dots, \mathcal{M}_l\}$  defines the finest Morse decomposition of  $\mathbb{P}\Phi$  and  $\mathcal{M}_i < \mathcal{M}_j$  if and only if  $\lambda_i < \lambda_j$ .
2. For  $A, B \in gl(d, \mathbb{R})$ , let  $\mathbb{P}\Phi$  and  $\mathbb{P}\Psi$  be the associated flows on  $\mathbb{P}^{d-1}$  and suppose that there is a topological equivalence  $h$  of  $\mathbb{P}\Phi$  and  $\mathbb{P}\Psi$ . Then the chain recurrent components  $\mathcal{N}_1, \dots, \mathcal{N}_n$  of  $\mathbb{P}\Psi$  are of the form  $\mathcal{N}_i = h[\mathcal{M}_i]$ , where  $\mathcal{M}_i$  is a chain recurrent component of  $\mathbb{P}\Phi$ . In particular, the number of chain recurrent components of  $\mathbb{P}\Phi$  and  $\mathbb{P}\Psi$  agree, and  $h$  maps the order on  $\{\mathcal{M}_1, \dots, \mathcal{M}_l\}$  onto the order on  $\{\mathcal{N}_1, \dots, \mathcal{N}_l\}$ .
3. For  $A, B \in gl(d, \mathbb{R})$  let  $\mathbb{P}\Phi$  and  $\mathbb{P}\Psi$  be the associated flows on  $\mathbb{P}^{d-1}$  and suppose that there is a topological equivalence  $h$  of  $\mathbb{P}\Phi$  and  $\mathbb{P}\Psi$ . Then the projected subspaces corresponding to real Jordan blocks of  $A$  are mapped onto projected subspaces corresponding to real Jordan blocks of  $B$  preserving the dimensions. Furthermore,  $h$  maps projected eigenspaces corresponding to real eigenvalues and to pairs of complex eigenvalues onto projected eigenspaces of the same type. This result shows that while  $C^0$ -equivalence of projected linear flows on  $\mathbb{P}^{d-1}$  determines the number  $l$  of distinct Lyapunov exponents, it also characterizes the Jordan structure within each Lyapunov space (but, obviously, not the size of the Lyapunov exponents nor their sign). It imposes very restrictive conditions on the eigenvalues and the Jordan structure. Therefore,  $C^0$ -equivalences are not a useful tool to characterize  $l$ . The requirement of mapping orbits into orbits is too strong. A weakening leads to the following characterization.
4. Two matrices  $A$  and  $B$  in  $gl(d, \mathbb{R})$  have the same vector of the dimensions  $d_i$  of the Lyapunov spaces (in the natural order of their Lyapunov exponents) if and only if there exist a homeomorphism  $h : \mathbb{P}^{d-1} \rightarrow \mathbb{P}^{d-1}$  that maps the finest Morse decomposition of  $\mathbb{P}\Phi$  onto the finest Morse decomposition of  $\mathbb{P}\Psi$ , i.e.,  $h$  maps Morse sets onto Morse sets and preserves their orders.

5. Let  $A \in gl(d, \mathbb{R})$  with associated flows  $\Phi$  on  $\mathbb{R}^d$  and  $\mathbb{F}_k \Phi$  on the  $k$ -flag.
- (i) For every  $k \in \{1, \dots, d\}$  there exists a unique finest Morse decomposition  $\{ {}_k \mathcal{M}_{i_j} \}$  of  $\mathbb{F}_k \Phi$ , where  $i_j \in \{1, \dots, d\}^k$  is a multi-index, and the number of chain transitive components in  $\mathbb{F}_k$  is bounded by  $\frac{d!}{(d-k)!}$ .
  - (ii) Let  $\mathcal{M}_i$  with  $i \in \{1, \dots, d\}^k$  be a chain recurrent component in  $\mathbb{F}_{k-1}$ . Consider the  $(d-k+1)$ -dimensional vector bundle  $\pi : \mathcal{W}(\mathcal{M}_i) \rightarrow \mathcal{M}_i$  with fibers

$$\mathcal{W}(\mathcal{M}_i)_{F_{k-1}} = \mathbb{R}^d / V_{k-1} \text{ for } F_k = (V_1, \dots, V_{k-1}) \in \mathcal{M}_i \subset \mathbb{F}_{k-1}.$$

Then every chain recurrent component  ${}_{\mathbb{P}}\mathcal{M}_{i_j}$ ,  $j = 1, \dots, k_i \leq d - k + 1$ , of the projective bundle  $\mathbb{P}\mathcal{W}(\mathcal{M}_i)$  determines a chain recurrent component  ${}_k \mathcal{M}_{i_j}$  on  $\mathbb{F}_k$  via

$${}_k \mathcal{M}_{i_j} = \{ F_k = (F_{k-1}, V_k) \in \mathbb{F}_k : F_{k-1} \in \mathcal{M}_i \text{ and } \mathbb{P}(V_k / V_{k-1}) \in {}_{\mathbb{P}}\mathcal{M}_{i_j} \}.$$

Every chain recurrent component in  $\mathbb{F}_k$  is of this form; this determines the multiindex  $i_j$  inductively for  $k = 2, \dots, d$ .

6. On every Grassmannian  $\mathbb{G}_i$  there exists a finest Morse decomposition of the dynamical system  $\mathbb{G}_i \Phi$ . Its Morse sets are given by the projection of the chain recurrent components from the complete flag  $\mathbb{F}$ .
7. Let  $A \in gl(d, \mathbb{R})$  be a matrix with flow  $\Phi$  on  $\mathbb{R}^d$ . Let  $L_i$ ,  $i = 1, \dots, l$ , be the Lyapunov spaces of  $A$ , i.e., their projections  $\mathbb{P}L_i = \mathcal{M}_i$  are the finest Morse decomposition of  $\mathbb{P}\Phi$  on the projective space. For  $k = 1, \dots, d$  define the index set

$$I(k) = \{ (k_1, \dots, k_m) : k_1 + \dots + k_m = k \text{ and } 0 \leq k_i \leq d_i = \dim L_i \}.$$

Then the finest Morse decomposition on the Grassmannian  $\mathbb{G}_k$  is given by the sets

$$\mathcal{N}_{k_1, \dots, k_m}^k = \mathbb{G}_{k_1} L_1 \oplus \dots \oplus \mathbb{G}_{k_m} L_m, \quad (k_1, \dots, k_m) \in I(k).$$

8. For two matrices  $A, B \in gl(d, \mathbb{R})$  the vector of the dimensions  $d_i$  of the Lyapunov spaces (in the natural order of their Lyapunov exponents) are identical if and only if certain graphs defined on the Grassmannians are isomorphic; see [ACK05].

### Examples:

1. For  $A \in gl(d, \mathbb{R})$  let  $\Phi$  be its linear flow in  $\mathbb{R}^d$ . The flow  $\Phi$  projects onto a flow  $\mathbb{P}\Phi$  on  $\mathbb{P}^{d-1}$ , given by the differential equation

$$\dot{s} = h(s, A) = (A - s^T A s) s, \text{ with } s \in \mathbb{P}^{d-1}.$$

Consider the matrices

$$A = \text{diag}(-1, -1, 1) \text{ and } B = \text{diag}(-1, 1, 1).$$

We obtain the following structure for the finest Morse decompositions on the Grassmannians for  $A$ :

$$\mathbb{G}_1: \quad \mathcal{M}_1 = \{\text{Span}(\mathbf{e}_1, \mathbf{e}_2)\} \text{ and } \mathcal{M}_3 = \{\text{Span}(\mathbf{e}_3)\}$$

$$\mathbb{G}_2: \quad \mathcal{M}_{1,2} = \{\text{Span}(\mathbf{e}_1, \mathbf{e}_2)\} \text{ and } \mathcal{M}_{1,3} = \{ \{\text{Span}(\mathbf{x}, \mathbf{e}_3)\} : \mathbf{x} \in \text{Span}(\mathbf{e}_1, \mathbf{e}_2) \}$$

$$\mathbb{G}_3: \quad \mathcal{M}_{1,2,3} = \{\text{Span}(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)\}$$

and for  $B$  we have

$$\mathbb{G}_1: \quad \mathcal{N}_1 = \{\text{Span}(\mathbf{e}_1)\} \text{ and } \mathcal{N}_2 = \{\text{Span}(\mathbf{e}_2, \mathbf{e}_3)\}$$

$$\mathbb{G}_2: \quad \mathcal{N}_{1,2} = \{ \text{Span}(\mathbf{e}_1, \mathbf{x}) : \mathbf{x} \in \text{Span}(\mathbf{e}_2, \mathbf{e}_3) \} \text{ and } \mathcal{N}_{2,3} = \{\text{Span}(\mathbf{e}_2, \mathbf{e}_3)\}$$

$$\mathbb{G}_3: \quad \mathcal{N}_{1,2,3} = \{\text{Span}(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)\}.$$

On the other hand, the Morse sets in the full flag are given for  $A$  and  $B$  by

$$\begin{bmatrix} \mathcal{M}_{1,2,3} \\ \mathcal{M}_{1,2} \\ \mathcal{M}_1 \end{bmatrix} \preceq \begin{bmatrix} \mathcal{M}_{1,2,3} \\ \mathcal{M}_{1,3} \\ \mathcal{M}_1 \end{bmatrix} \preceq \begin{bmatrix} \mathcal{M}_{1,2,3} \\ \mathcal{M}_{1,3} \\ \mathcal{M}_3 \end{bmatrix} \quad \text{and} \quad \begin{bmatrix} \mathcal{N}_{1,2,3} \\ \mathcal{N}_{1,2} \\ \mathcal{N}_1 \end{bmatrix} \preceq \begin{bmatrix} \mathcal{N}_{1,2,3} \\ \mathcal{N}_{1,2} \\ \mathcal{N}_2 \end{bmatrix} \preceq \begin{bmatrix} \mathcal{N}_{1,2,3} \\ \mathcal{N}_{2,3} \\ \mathcal{N}_2 \end{bmatrix},$$

respectively. Thus, in the full flag, the numbers and the orders of the Morse sets coincide, while on the Grassmannians (together with the projection relations between different Grassmannians) one can distinguish also the dimensions of the corresponding Lyapunov spaces. (See [ACK05] for a precise statement.)

## 56.5 Linear Skew Product Flows

Developing a linear algebra for time varying systems  $\dot{\mathbf{x}} = A(t)\mathbf{x}$  means defining appropriate concepts to generalize eigenvalues, linear eigenspaces and their dimensions, and certain normal forms that characterize the behavior of the solutions of a time varying system and that reduce to the constant matrix case if  $A(t) \equiv A \in gl(d, \mathbb{R})$ . The eigenvalues and eigenspaces of the family  $\{A(t), t \in \mathbb{R}\}$  do not provide an appropriate generalization; see, e.g., [Hah67], Chapter 62. For certain classes of time varying systems it turns out that the Lyapunov exponents and Lyapunov spaces introduced in section 56.1 capture the key properties of (real parts of) eigenvalues and of the associated subspace decomposition of  $\mathbb{R}^d$ . These systems are linear skew product flows for which the base is a (nonlinear) system  $\theta_t$  that enters into the linear dynamics of a differential equation in the form  $\dot{\mathbf{x}} = A(\theta_t)\mathbf{x}$ . Examples for this type of systems include periodic and almost periodic differential equations, random differential equations, systems over ergodic or chain recurrent bases, linear robust systems, and bilinear control systems. This section concentrates on periodic linear differential equations, random linear dynamical systems, and robust linear systems. It is written to emphasize the correspondences between the linear algebra in Section 56.1, Floquet theory, the multiplicative ergodic theorem, and the Morse spectrum and Selgrade's theorem.

Literature: [Arn98], [BK94], [CK00], [Con97], [Rob98].

### Definitions:

A (continuous time) **linear skew-product flow** is a dynamical system with state space  $M = \Omega \times \mathbb{R}^d$  and flow  $\Phi : \mathbb{R} \times \Omega \times \mathbb{R}^d \rightarrow \Omega \times \mathbb{R}^d$ , where  $\Phi = (\theta, \varphi)$  is defined as follows:  $\theta : \mathbb{R} \times \Omega \rightarrow \Omega$  is a dynamical system, and  $\varphi : \mathbb{R} \times \Omega \times \mathbb{R}^d \rightarrow \mathbb{R}^d$  is linear in its  $\mathbb{R}^d$ -component, i.e., for each  $(t, \omega) \in \mathbb{R} \times \Omega$  the map  $\varphi(t, \omega, \cdot) : \mathbb{R}^d \rightarrow \mathbb{R}^d$  is linear. Skew-product flows are called measurable (continuous, differentiable) if  $\Omega = (\theta, \varphi)$  is a measurable space (topological space, differentiable manifold) and  $\Phi$  is measurable (continuous, differentiable). For the time- $t$  maps, the notation  $\theta_t = \theta(t, \cdot) : \Omega \rightarrow \Omega$  is used again.

Note that the **base component**  $\theta : \mathbb{R} \times \Omega \rightarrow \Omega$  is a dynamical system itself, while the **skew-component**  $\varphi$  is not a dynamical system. The skew-component  $\varphi$  is often called a **co-cycle** over  $\theta$ .

Let  $\Phi : \mathbb{R} \times \Omega \times \mathbb{R}^d \rightarrow \Omega \times \mathbb{R}^d$  be a linear skew-product flow. For  $\mathbf{x}_0 \in \mathbb{R}^d$ ,  $\mathbf{x}_0 \neq 0$ , the **Lyapunov exponent** is defined as  $\lambda(\mathbf{x}_0, \omega) = \limsup_{t \rightarrow \infty} \frac{1}{t} \log \|\varphi(t, \omega, \mathbf{x}_0)\|$ , where  $\log$  denotes the natural logarithm and  $\|\cdot\|$  is any norm in  $\mathbb{R}^d$ .

### Examples:

1. Time varying linear differential equations: Let  $A : \mathbb{R} \rightarrow gl(d, \mathbb{R})$  be a uniformly continuous function and consider the linear differential equation  $\dot{\mathbf{x}}(t) = A(t)\mathbf{x}(t)$ . The solutions of this differential equation define a dynamical system via  $\Phi : \mathbb{R} \times \mathbb{R} \times \mathbb{R}^d \rightarrow \mathbb{R} \times \mathbb{R}^d$ , where  $\theta : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R}$  is given by  $\theta(t, \tau) = t + \tau$ , and  $\varphi : \mathbb{R} \times \mathbb{R} \times \mathbb{R}^d \rightarrow \mathbb{R}^d$  is defined as  $\varphi(t, \tau, \mathbf{x}_0) = X(t + \tau, \tau)\mathbf{x}_0$ . Here  $X(t, \tau)$  is a fundamental matrix of the differential equation  $\dot{X}(t) = A(t)X(t)$  in  $gl(d, \mathbb{R})$ . Note that for  $\varphi(t, \tau, \cdot) : \mathbb{R}^d \rightarrow \mathbb{R}^d$ ,  $t \in \mathbb{R}$ , we have  $\varphi(t + s, \tau) = \varphi(t, \theta(s, \tau)) \circ \varphi(s, \tau)$  and, hence, the

solutions of  $\dot{\mathbf{x}}(t) = A(t)\mathbf{x}(t)$  themselves do not define a flow. The additional component  $\theta$  “keeps track of time.”

2. **Metric dynamical systems:** Let  $(\Omega, \mathcal{F}, P)$  be a probability space, i.e., a set  $\Omega$  with  $\sigma$ -algebra  $\mathcal{F}$  and probability measure  $P$ . Let  $\theta : \mathbb{R} \times \Omega \rightarrow \Omega$  be a measurable flow such that the probability measure  $P$  is invariant under  $\theta$ , i.e.,  $\theta_t P = P$  for all  $t \in \mathbb{R}$ , where for all measurable sets  $X \in \mathcal{F}$  we define  $\theta_t P(X) = P\{\theta_t^{-1}(X)\} = P(X)$ . Flows of this form are often called metric dynamical systems.
3. **Random linear dynamical systems:** A random linear dynamical system is a skew-product flow  $\Phi : \mathbb{R} \times \Omega \times \mathbb{R}^d \rightarrow \Omega \times \mathbb{R}^d$ , where  $(\Omega, \mathcal{F}, P, \theta)$  is a metric dynamical system and each  $\varphi : \mathbb{R} \times \Omega \times \mathbb{R}^d \rightarrow \mathbb{R}^d$  is linear in its  $\mathbb{R}^d$ -component. Examples for random linear dynamical systems are given, e.g., by linear stochastic differential equations or linear differential equations with stationary background noise; see [Arn98].
4. **Robust linear systems:** Consider a linear system with time varying perturbations of the form  $\dot{\mathbf{x}} = A(u(t))\mathbf{x} := A_0\mathbf{x} + \sum_{i=1}^m u_i(t)A_i\mathbf{x}$ , where  $A_0, \dots, A_m \in gl(d, \mathbb{R})$ ,  $u \in \mathcal{U} = \{u : \mathbb{R} \rightarrow U, \text{ integrable on every bounded interval}\}$ , and  $U \subset \mathbb{R}^m$  is compact, convex with  $0 \in \text{int } U$ . A robust linear system defines a linear skew-product flow via the following construction: We endow  $\mathcal{U}$  with the weak\*-topology of  $L^\infty(\mathbb{R}, U)^*$  to make it a compact, metrizable space. The base component is defined as the shift  $\theta : \mathbb{R} \times \mathcal{U} \rightarrow \mathcal{U}$ ,  $\theta(t, u(\cdot)) = u(\cdot + t)$ , and the skew-component consists of the solutions  $\varphi(t, u(\cdot), \mathbf{x})$ ,  $t \in \mathbb{R}$  of the perturbed differential equation. Then  $\Phi : \mathbb{R} \times \mathcal{U} \times \mathbb{R}^d \rightarrow \mathcal{U} \times \mathbb{R}^d$ ,  $\Phi(t, u, \mathbf{x}) = (\theta(t, u), \varphi(t, u, \mathbf{x}))$  defines a continuous linear skew-product flow. The functions  $u$  can also be considered as (open loop) controls.

## 56.6 Periodic Linear Differential Equations: Floquet Theory

### Definitions:

A **periodic linear differential equation**  $\dot{\mathbf{x}} = A(\theta_t)\mathbf{x}$  is given by a matrix function  $A : \mathbb{R} \rightarrow gl(d, \mathbb{R})$  that is continuous and periodic (of period  $\hat{t} > 0$ ). As above, the solutions define a dynamical system via  $\Phi : \mathbb{R} \times \mathbb{S}^1 \times \mathbb{R}^d \rightarrow \mathbb{S}^1 \times \mathbb{R}^d$ , if we identify  $\mathbb{R} \bmod \hat{t}$  with the circle  $\mathbb{S}^1$ .

### Facts:

Literature: [Ama90], [GH83], [Hah67], [Sto92], [Wig96].

1. Consider the periodic linear differential equation  $\dot{\mathbf{x}} = A(\theta_t)\mathbf{x}$  with period  $\hat{t} > 0$ . A fundamental matrix  $X(t)$  of the system is of the form  $X(t) = P(t)e^{Rt}$  for  $t \in \mathbb{R}$ , where  $P(\cdot)$  is a nonsingular, differentiable, and  $\hat{t}$ -periodic matrix function and  $R \in gl(d, \mathbb{C})$ .
2. Let  $X(\cdot)$  be a fundamental solution with  $X(0) = I \in GL(d, \mathbb{R})$ . The matrix  $X(\hat{t}) = e^{R\hat{t}}$  is called the monodromy matrix of the system. Note that  $R$  is, in general, not uniquely determined by  $X$ , and does not necessarily have real entries. The eigenvalues  $\alpha_j$ ,  $j = 1, \dots, d$  of  $X(\hat{t})$  are called the characteristic multipliers of the system, and the eigenvalues  $\mu_j = \lambda_j + i\nu_j$  of  $R$  are the characteristic exponents. It holds that  $\mu_j = \frac{1}{\hat{t}} \log \alpha_j + \frac{2m\pi i}{\hat{t}}$ ,  $j = 1, \dots, d$  and  $m \in \mathbb{Z}$ . This determines uniquely the real parts of the characteristic exponents  $\lambda_j = \text{Re } \mu_j = \log |\alpha_j|$ ,  $j = 1, \dots, d$ . The  $\lambda_j$  are called the Floquet exponents of the system.
3. Let  $\Phi = (\theta, \varphi) : \mathbb{R} \times \mathbb{S}^1 \times \mathbb{R}^d \rightarrow \mathbb{S}^1 \times \mathbb{R}^d$  be the flow associated with a periodic linear differential equation  $\dot{\mathbf{x}} = A(t)\mathbf{x}$ . The system has a finite number of Lyapunov exponents  $\lambda_j$ ,  $j = 1, \dots, l \leq d$ . For each exponent  $\lambda_j$  and each  $\tau \in \mathbb{S}^1$  there exists a splitting  $\mathbb{R}^d = \bigoplus_{j=1}^l L(\lambda_j, \tau)$  of  $\mathbb{R}^d$  into linear subspaces with the following properties:

- (a) The subspaces  $L(\lambda_j, \tau)$  have the same dimension independent of  $\tau$ , i.e., for each  $j = 1, \dots, l$  it holds that  $\dim L(\lambda_j, \sigma) = \dim L(\lambda_j, \tau) =: d_j$  for all  $\sigma, \tau \in \mathbb{S}^1$ .

- (b) The subspaces  $L(\lambda_j, \tau)$  are invariant under the flow  $\Phi$ , i.e., for each  $j = 1, \dots, l$  it holds that  $\varphi(t, \tau)L(\lambda_j, \tau) = L(\lambda_j, \theta(t, \tau)) = L(\lambda_j, t + \tau)$  for all  $t \in \mathbb{R}$  and  $\tau \in \mathbb{S}^1$ .
  - (c)  $\lambda(\mathbf{x}, \tau) = \lim_{t \rightarrow \pm\infty} \frac{1}{t} \log \|\varphi(t, \tau, \mathbf{x})\| = \lambda_j$  if and only if  $\mathbf{x} \in L(\lambda_j, \tau) \setminus \{0\}$ .
4. The Lyapunov exponents of the system are exactly the Floquet exponents. The linear subspaces  $L(\lambda_j, \cdot)$  are called the Lyapunov spaces (or sometimes the Floquet spaces) of the periodic matrix function  $A(t)$ .
  5. For each  $j = 1, \dots, l \leq d$  the map  $L_j : \mathbb{S}^1 \rightarrow \mathbb{G}_{d_j}$  defined by  $\tau \mapsto L(\lambda_j, \tau)$  is continuous.
  6. These facts show that for periodic matrix functions  $A : \mathbb{R} \rightarrow gl(d, \mathbb{R})$  the Floquet exponents and Floquet spaces replace the real parts of eigenvalues and the Lyapunov spaces, concepts that are so useful in the linear algebra of (constant) matrices  $A \in gl(d, \mathbb{R})$ . The number of Lyapunov exponents and the dimensions of the Lyapunov spaces are constant for  $\tau \in \mathbb{S}^1$ , while the Lyapunov spaces themselves depend on the time parameter  $\tau$  of the periodic matrix function  $A(t)$ , and they form periodic orbits in the Grassmannians  $\mathbb{G}_{d_j}$  and in the corresponding flag.
  7. As an application of these results, consider the problem of stability of the zero solution of  $\dot{\mathbf{x}}(t) = A(t)\mathbf{x}(t)$  with period  $\hat{t} > 0$ : The stable, center, and unstable subspaces associated with the periodic matrix function  $A : \mathbb{R} \rightarrow gl(d, \mathbb{R})$  are defined as  $L^-(\tau) = \bigoplus\{L(\lambda_j, \tau), \lambda_j < 0\}$ ,  $L^0(\tau) = \bigoplus\{L(\lambda_j, \tau), \lambda_j = 0\}$ , and  $L^+(\tau) = \bigoplus\{L(\lambda_j, \tau), \lambda_j > 0\}$ , respectively, for  $\tau \in \mathbb{S}^1$ . The zero solution  $\mathbf{x}(t, 0) \equiv 0$  of the periodic linear differential equation  $\dot{\mathbf{x}} = A(t)\mathbf{x}$  is asymptotically stable if and only if it is exponentially stable if and only if all Lyapunov exponents are negative if and only if  $L^-(\tau) = \mathbb{R}^d$  for some (and hence for all)  $\tau \in \mathbb{S}^1$ .
  8. Another approach to the study of time-dependent linear differential equations is via transforming an equation with bounded coefficients into an equation of known type, such as equations with constant coefficients. Such transformations are known as Lyapunov transformations; see [Hah67, Secs. 61–63].

**Examples:**

1. Consider the  $\hat{t}$ -periodic differential equation  $\dot{\mathbf{x}} = A(t)\mathbf{x}$ . This equation has a nontrivial  $\hat{t}$ -periodic solution iff the system has a characteristic multiplier equal to 1; see Example 2.3 for the case with constant coefficients ([Ama90, Prop. 20.12]).
2. Let  $H$  be a continuous quadratic form in  $2d$  variables  $x_1, \dots, x_d, y_1, \dots, y_d$  and consider the Hamiltonian system

$$\dot{x}_i = \frac{\partial H}{\partial y_i}, \dot{y}_i = -\frac{\partial H}{\partial x_i}, i = 1, \dots, d.$$

Using  $\mathbf{z}^T = [\mathbf{x}^T, \mathbf{y}^T]$ , we can set  $H(\mathbf{x}, \mathbf{y}, t) = \mathbf{z}^T A(t)\mathbf{z}$ , where  $A = \begin{bmatrix} A_{11} & A_{12} \\ A_{12}^T & A_{22} \end{bmatrix}$  with  $A_{11}$  and  $A_{22}$  symmetric, and, hence, the equation takes the form

$$\dot{\mathbf{z}} = \begin{bmatrix} A_{12}^T(t) & A_{22}(t) \\ -A_{11}(t) & -A_{12}(t) \end{bmatrix} \mathbf{z} =: P(t)\mathbf{z}.$$

Note that  $-P^T(t) = QP(t)Q^{-1}$  with  $Q = \begin{bmatrix} 0 & -I \\ I & 0 \end{bmatrix}$ , where  $I$  is the  $d \times d$  identity matrix. Assume that  $H$  is  $\hat{t}$ -periodic, then the equation for  $z$  and its adjoint have the same Floquet exponents and for each exponent  $\lambda$  its negative  $-\lambda$  is also a Floquet exponent. Hence, the fixed point  $0 \in \mathbb{R}^{2d}$  cannot be exponentially stable ([Hah67, Sec. 60]).

3. Consider the periodic linear oscillator

$$\ddot{y} + q_1(t)\dot{y} + q_2(t)y = 0.$$

Using the substitution  $y = z \exp(-\frac{1}{2} \int q_1(u) du)$  one obtains Hill's differential equation

$$\ddot{z} + p(t)z = 0, \quad p(t) := q_2(t) - \frac{1}{4}q_1(t)^2 - \frac{1}{2}\dot{q}_1(t).$$

Its characteristic equation is  $\lambda^2 - 2a\lambda + 1 = 0$ , with  $a$  still to be determined. The multipliers satisfy the relations  $\alpha_1\alpha_2 = 1$  and  $\alpha_1 + \alpha_2 = 2a$ . The exponential stability of the system can be analyzed using the parameter  $a$ : If  $a^2 > 1$ , then one of the multipliers has absolute value  $> 1$  and, hence, the system has an unbounded solution. If  $a^2 = 1$ , then the system has a nontrivial periodic solution according to Example 1. If  $a^2 < 1$ , then the system is stable. The parameter  $a$  can often be expressed in form of a power series; see [Hah67, Sec. 62] for more details. A special case of Hill's equation is the Mathieu equation

$$\ddot{z} + (\beta_1 + \beta_2 \cos 2t)z = 0,$$

with  $\beta_1, \beta_2$  real parameters. For this equation numerically computed stability diagrams are available; see [Sto92, Secs. VI. 3 and 4].

## 56.7 Random Linear Dynamical Systems

### Definitions:

Let  $\theta : \mathbb{R} \times \Omega \rightarrow \Omega$  be a metric dynamical system on the probability space  $(\Omega, \mathcal{F}, P)$ . A set  $\Delta \in \mathcal{F}$  is called  **$P$ -invariant under  $\theta$**  if  $P[(\theta^{-1}(t, \Delta) \setminus \Delta) \cup (\Delta \setminus \theta^{-1}(t, \Delta))] = 0$  for all  $t \in \mathbb{R}$ . The flow  $\theta$  is called **ergodic**, if each invariant set  $\Delta \in \mathcal{F}$  has  $P$ -measure 0 or 1.

### Facts:

Literature: [Arn98], [Con97].

1. (Oseledets Theorem, Multiplicative Ergodic Theorem) Consider a random linear dynamical system  $\Phi = (\theta, \varphi) : \mathbb{R} \times \Omega \times \mathbb{R}^d \rightarrow \Omega \times \mathbb{R}^d$  and assume

$$\sup_{0 \leq t \leq 1} \log^+ \|\varphi(t, \omega)\| \in \mathcal{L}^1(\Omega, \mathcal{F}, \mathbb{P}) \text{ and } \sup_{0 \leq t \leq 1} \log^+ \|\varphi(t, \omega)^{-1}\| \in \mathcal{L}^1(\Omega, \mathcal{F}, \mathbb{P}),$$

where  $\|\cdot\|$  is any norm on  $GL(d, \mathbb{R})$ ,  $\mathcal{L}^1$  is the space of integrable functions, and  $\log^+$  denotes the positive part of  $\log$ , i.e.,

$$\log^+(x) = \begin{cases} \log(x) & \text{for } \log(x) > 0 \\ 0 & \text{for } \log(x) \leq 0. \end{cases}$$

Then there exists a set  $\widehat{\Omega} \subset \Omega$  of full  $P$ -measure, invariant under the flow  $\theta : \mathbb{R} \times \Omega \rightarrow \Omega$ , such that for each  $\omega \in \widehat{\Omega}$  there is a splitting  $\mathbb{R}^d = \bigoplus_{j=1}^{l(\omega)} L_j(\omega)$  of  $\mathbb{R}^d$  into linear subspaces with the following properties:

- (a) The number of subspaces is  $\theta$ -invariant, i.e.,  $l(\theta(t, \omega)) = l(\omega)$  for all  $t \in \mathbb{R}$ , and the dimensions of the subspaces are  $\theta$ -invariant, i.e.,  $\dim L_j(\theta(t, \omega)) = \dim L_j(\omega) =: d_j(\omega)$  for all  $t \in \mathbb{R}$ .
- (b) The subspaces are invariant under the flow  $\Phi$ , i.e.,  $\varphi(t, \omega)L_j(\omega) \subset L_j(\theta(t, \omega))$  for all  $j = 1, \dots, l(\omega)$ .
- (c) There exist finitely many numbers  $\lambda_1(\omega) < \dots < \lambda_{l(\omega)}(\omega)$  in  $\mathbb{R}$  (with possibly  $\lambda_1(\omega) = -\infty$ ), such that for each  $\mathbf{x} \in \mathbb{R}^d \setminus \{0\}$  the Lyapunov exponent  $\lambda(\mathbf{x}, \omega)$  exists as a limit and

$\lambda(\mathbf{x}, \omega) = \lim_{t \rightarrow \pm\infty} \frac{1}{t} \log \|\varphi(t, \tau, \mathbf{x})\| = \lambda_j(\omega)$  if and only if  $\mathbf{x} \in L_j(\omega) \setminus \{0\}$ . The subspaces  $L_j(\omega)$  are called the Lyapunov (or sometimes the Oseledets) spaces of the system  $\Phi$ .

2. The following maps are measurable:  $l : \Omega \rightarrow \{1, \dots, d\}$  with the discrete  $\sigma$ -algebra, and for each  $j = 1, \dots, l(\omega)$  the maps  $L_j : \Omega \rightarrow \mathbb{G}_d$  with the Borel  $\sigma$ -algebra,  $d_j : \Omega \rightarrow \{1, \dots, d\}$  with the discrete  $\sigma$ -algebra, and  $\lambda_j : \Omega \rightarrow \mathbb{R} \cup \{-\infty\}$  with the (extended) Borel  $\sigma$ -algebra.
3. If the base flow  $\theta : \mathbb{R} \times \Omega \rightarrow \Omega$  is ergodic, then the maps  $l, d_j$ , and  $\lambda_j$  are constant on  $\widehat{\Omega}$ , but the Lyapunov spaces  $L_j(\omega)$  still depend (in a measurable way) on  $\omega \in \widehat{\Omega}$ .
4. As an application of these results, we consider random linear differential equations: Let  $(\Gamma, \mathcal{E}, Q)$  be a probability space and  $\xi : \mathbb{R} \times \Gamma \rightarrow \mathbb{R}^m$  a stochastic process with continuous trajectories, i.e., the functions  $\xi(\cdot, \gamma) : \mathbb{R} \rightarrow \mathbb{R}^m$  are continuous for all  $\gamma \in \Gamma$ . The process  $\xi$  can be written as a measurable dynamical system in the following way: Define  $\Omega = \mathcal{C}(\mathbb{R}, \mathbb{R}^m)$ , the space of continuous functions from  $\mathbb{R}$  to  $\mathbb{R}^m$ . We denote by  $\mathcal{F}$  the  $\sigma$ -algebra on  $\Omega$  generated by the cylinder sets, i.e., by sets of the form  $Z = \{\omega \in \Omega, \omega(t_1) \in F_1, \dots, \omega(t_n) \in F_n, n \in \mathbb{N}, F_i \text{ Borel sets in } \mathbb{R}^m\}$ . The process  $\xi$  induces a probability measure  $P$  on  $(\Omega, \mathcal{F})$  via  $P(Z) = Q\{\gamma \in \Gamma, \xi(t_i, \gamma) \in F_i \text{ for } i = 1, \dots, n\}$ . Define the shift  $\theta : \mathbb{R} \times \Omega \rightarrow \mathbb{R} \times \Omega$  as  $\theta(t, \omega(\cdot)) = \omega(t + \cdot)$ . Then  $(\Omega, \mathcal{F}, P, \theta)$  is a measurable dynamical system. If  $\xi$  is stationary, i.e., if for all  $n \in \mathbb{N}$ , and  $t, t_1, \dots, t_n \in \mathbb{R}$ , and all Borel sets  $F_1, \dots, F_n$  in  $\mathbb{R}^m$ , it holds that  $Q\{\gamma \in \Gamma, \xi(t_i, \gamma) \in F_i \text{ for } i = 1, \dots, n\} = Q\{\gamma \in \Gamma, \xi(t_i + t, \gamma) \in F_i \text{ for } i = 1, \dots, n\}$ , then the shift  $\theta$  on  $\Omega$  is  $P$ -invariant, and  $(\Omega, \mathcal{F}, P, \theta)$  is a metric dynamical system.
5. Let  $A : \Omega \rightarrow gl(d, \mathbb{R})$  be measurable with  $A \in \mathcal{L}^1$ . Consider the random linear differential equation  $\dot{\mathbf{x}}(t) = A(\theta(t, \omega))\mathbf{x}(t)$ , where  $(\Omega, \mathcal{F}, P, \theta)$  is a metric dynamical system as described before. We understand the solutions of this equation to be  $\omega$ -wise. Then the solutions define a random linear dynamical system. Since we assume that  $A \in \mathcal{L}^1$ , this system satisfies the integrability conditions of the Multiplicative Ergodic Theorem.
6. Hence, for random linear differential equations  $\dot{\mathbf{x}}(t) = A(\theta(t, \omega))\mathbf{x}(t)$  the Lyapunov exponents and the associated Oseledets spaces replace the real parts of eigenvalues and the Lyapunov spaces of constant matrices  $A \in gl(d, \mathbb{R})$ . If the “background” process  $\xi$  is ergodic, then all the quantities in the Multiplicative Ergodic Theorem are constant, except for the Lyapunov spaces that do, in general, depend on chance.
7. The problem of stability of the zero solution of  $\dot{\mathbf{x}}(t) = A(\theta(t, \omega))\mathbf{x}(t)$  can now be analyzed in analogy to the case of a constant matrix or a periodic matrix function: The stable, center, and unstable subspaces associated with the random matrix process  $A(\theta(t, \omega))$  are defined as  $L^-(\omega) = \bigoplus\{L_j(\omega), \lambda_j(\omega) < 0\}$ ,  $L^0(\omega) = \bigoplus\{L_j(\omega), \lambda_j(\omega) = 0\}$ , and  $L^+(\omega) = \bigoplus\{L_j(\omega), \lambda_j(\omega) > 0\}$ , respectively for  $\omega \in \widehat{\Omega}$ . We obtain the following characterization of stability: The zero solution  $\mathbf{x}(t, \omega, 0) \equiv 0$  of the random linear differential equation  $\dot{\mathbf{x}}(t) = A(\theta(t, \omega))\mathbf{x}(t)$  is  $P$ -almost surely exponentially stable if and only if  $P$ -almost surely all Lyapunov exponents are negative if and only if  $P\{\omega \in \Omega, L^-(\omega) = \mathbb{R}^d\} = 1$ .

**Examples:**

1. The case of constant matrices: Let  $A \in gl(d, \mathbb{R})$  and consider the dynamical system  $\varphi : \mathbb{R} \times \mathbb{R}^d \rightarrow \mathbb{R}^d$  generated by the solutions of the linear differential equation  $\dot{\mathbf{x}} = A\mathbf{x}$ . The flow  $\varphi$  can be considered as the skew-component of a random linear dynamical system over the base flow given by  $\Omega = \{0\}$ ,  $\mathcal{F}$  the trivial  $\sigma$ -algebra,  $P$  the Dirac measure at  $\{0\}$ , and  $\theta : \mathbb{R} \times \Omega \rightarrow \Omega$  defined as the constant map  $\theta(t, \omega) = \omega$  for all  $t \in \mathbb{R}$ . Since the flow is ergodic and satisfies the integrability condition, we can recover all the results on Lyapunov exponents and Lyapunov spaces for  $\varphi$  from the Multiplicative Ergodic Theorem.
2. Weak Floquet theory: Let  $A : \mathbb{R} \rightarrow gl(d, \mathbb{R})$  be a continuous, periodic matrix function. Define the base flow as follows:  $\Omega = \mathbb{S}^1, \mathcal{B}$  is the Borel  $\sigma$ -algebra on  $\mathbb{S}^1, P$  is the uniform distribution on  $\mathbb{S}^1$ , and  $\theta$  is the shift  $\theta(t, \tau) = t + \tau$ . Then  $(\Omega, \mathcal{F}, P, \theta)$  is an ergodic metric dynamical system. The solutions  $\varphi(\cdot, \tau, \mathbf{x})$  of  $\dot{\mathbf{x}} = A(t)\mathbf{x}$  define a random linear dynamical system  $\Phi : \mathbb{R} \times \Omega \times \mathbb{R}^d \rightarrow \Omega \times \mathbb{R}^d$  via

$\Phi(t, \omega, \mathbf{x}) = (\theta(t, \omega), \varphi(t, \omega, \mathbf{x}))$ . With this set-up, the Multiplicative Ergodic Theorem recovers the results of Floquet Theory with  $P$ -probability 1.

3. Average Lyapunov exponent: In general, Lyapunov exponents for random linear systems are difficult to compute explicitly—numerical methods are usually the way to go. In the ergodic case, the average Lyapunov exponent  $\bar{\lambda} := \frac{1}{d} \sum d_j \lambda_j$  is given by  $\bar{\lambda} = \frac{1}{d} \text{tr} E(A | \mathcal{I})$ , where  $A : \Omega \rightarrow \text{gl}(d, \mathbb{R})$  is the random matrix of the system, and  $E(\cdot, \mathcal{I})$  is the conditional expectation of the probability measure  $P$  given the  $\sigma$ -algebra  $\mathcal{I}$  of invariant sets on  $\Omega$ . As an example, consider the linear oscillator with random restoring force

$$\ddot{y}(t) + 2\beta \dot{y}(t) + (1 + \sigma f(\theta(t, \omega)))y(t) = 0,$$

where  $\beta, \sigma \in \mathbb{R}$  are positive constants and  $f : \Omega \rightarrow \mathbb{R}$  is in  $\mathcal{L}^1$ . We assume that the background process is ergodic. Using the notation  $x_1 = y$  and  $x_2 = \dot{y}$  we can write the equation as

$$\dot{\mathbf{x}}(t) = A(\theta(t, \omega))\mathbf{x}(t) = \begin{bmatrix} 0 & 1 \\ -1 - \sigma f(\theta(t, \omega)) & -2\beta \end{bmatrix} \mathbf{x}(t).$$

For this system we obtain  $\bar{\lambda} = -\beta$  ([Arn98, Remark 3.3.12]).

## 56.8 Robust Linear Systems

### Definitions:

Let  $\Phi : \mathbb{R} \times \mathcal{U} \times \mathbb{R}^d \rightarrow \mathcal{U} \times \mathbb{R}^d$  be a linear skew-product flow with continuous base flow  $\theta : \mathbb{R} \times \mathcal{U} \rightarrow \mathcal{U}$ . Throughout this section,  $\mathcal{U}$  is compact and  $\theta$  is chain recurrent on  $\mathcal{U}$ . Denote by  $\mathcal{U} \times \mathbb{P}^{d-1}$  the projective bundle and recall that  $\Phi$  induces a dynamical system  $\mathbb{P}\Phi : \mathbb{R} \times \mathcal{U} \times \mathbb{P}^{d-1} \rightarrow \mathcal{U} \times \mathbb{P}^{d-1}$ . For  $\varepsilon, T > 0$  an  $(\varepsilon, T)$ -chain  $\zeta$  of  $\mathbb{P}\Phi$  is given by  $n \in \mathbb{N}$ ,  $T_0, \dots, T_n \geq T$ , and  $(u_0, p_0), \dots, (u_n, p_n) \in \mathcal{U} \times \mathbb{P}^{d-1}$  with  $d(\mathbb{P}\Phi(T_i, u_i, p_i), (u_{i+1}, p_{i+1})) < \varepsilon$  for  $i = 0, \dots, n-1$ .

Define the **finite time exponential growth rate** of such a chain  $\zeta$  (or **chain exponent**) by

$$\lambda(\zeta) = \left( \sum_{i=0}^{n-1} T_i \right)^{-1} \sum_{i=0}^{n-1} (\log \|\varphi(T_i, x_i, u_i)\| - \log \|x_i\|),$$

where  $x_i \in \mathbb{P}^{-1}(p_i)$ .

Let  $\mathcal{M} \subset \mathcal{U} \times \mathbb{P}^{d-1}$  be a chain recurrent component of the flow  $\mathbb{P}\Phi$ . Define the **Morse spectrum over  $\mathcal{M}$**  as

$$\Sigma_{Mo}(\mathcal{M}) = \left\{ \lambda \in \mathbb{R}, \text{ there exist sequences } \varepsilon_n \rightarrow 0, T_n \rightarrow \infty \text{ and } \right. \\ \left. (\varepsilon_n, T_n)\text{-chains } \zeta_n \text{ in } \mathcal{M} \text{ such that } \lim \lambda(\zeta_n) = \lambda \right\}$$

and the **Morse spectrum of the flow** as

$$\Sigma_{Mo}(\Phi) = \left\{ \lambda \in \mathbb{R}, \text{ there exist sequences } \varepsilon_n \rightarrow 0, T_n \rightarrow \infty \text{ and } (\varepsilon_n, T_n)\text{-} \right. \\ \left. \text{chains } \zeta_n \text{ in the chain recurrent set of } \mathbb{P}\Phi \text{ such that } \lim \lambda(\zeta_n) = \lambda \right\}.$$

Define the **Lyapunov spectrum over  $\mathcal{M}$**  as

$$\Sigma_{Ly}(\mathcal{M}) = \{\lambda(u, x), (u, x) \in \mathcal{M}, x \neq 0\}$$

and the **Lyapunov spectrum of the flow  $\Phi$**  as

$$\Sigma_{Ly}(\Phi) = \{\lambda(u, \mathbf{x}), (u, \mathbf{x}) \in \mathcal{U} \times \mathbb{R}^d, \mathbf{x} \neq 0\}.$$

**Facts:**

Literature: [CK00], [Gru96], [HP05].

1. The projected flow  $\mathbb{P}\Phi$  has a finite number of chain-recurrent components  $\mathcal{M}_1, \dots, \mathcal{M}_l, l \leq d$ . These components form the finest Morse decomposition for  $\mathbb{P}\Phi$ , and they are linearly ordered  $\mathcal{M}_1 < \dots < \mathcal{M}_l$ . Their lifts  $\mathbb{P}^{-1}\mathcal{M}_i \subset \mathcal{U} \times \mathbb{R}^d$  form a continuous subbundle decomposition of  $\mathcal{U} \times \mathbb{R}^d = \bigoplus_{i=1}^l \mathbb{P}^{-1}\mathcal{M}_i$ .
2. The Lyapunov spectrum and the Morse spectrum are defined on the Morse sets, i.e.,  $\Sigma_{Ly}(\Phi) = \bigcup_{i=1}^l \Sigma_{Ly}(\mathcal{M}_i)$  and  $\Sigma_{Mo}(\Phi) = \bigcup_{i=1}^l \Sigma_{Mo}(\mathcal{M}_i)$ .
3. For each Morse set  $\mathcal{M}_i$  the Lyapunov spectrum is contained in the Morse spectrum, i.e.,  $\Sigma_{Ly}(\mathcal{M}_i) \subset \Sigma_{Mo}(\mathcal{M}_i)$  for  $i = 1, \dots, l$ .
4. For each Morse set, its Morse spectrum is a closed, bounded interval  $\Sigma_{Mo}(\mathcal{M}_i) = [\kappa_i^*, \kappa_i]$ , and  $\kappa_i^*, \kappa_i \in \Sigma_{Ly}(\mathcal{M})$  for  $i = 1, \dots, l$ .
5. The intervals of the Morse spectrum are ordered according to the order of the Morse sets, i.e.,  $\mathcal{M}_i < \mathcal{M}_j$  is equivalent to  $\kappa_i^* < \kappa_j^*$  and  $\kappa_i < \kappa_j$ .
6. As an application of these results, consider robust linear systems of the form  $\Phi : \mathbb{R} \times \mathcal{U} \times \mathbb{R}^d \longrightarrow \mathcal{U} \times \mathbb{R}^d$ , given by a perturbed linear differential equation  $\dot{\mathbf{x}} = A(u(t))\mathbf{x} := A_0\mathbf{x} + \sum_{i=1}^m u_i(t)A_i\mathbf{x}$ , with  $A_0, \dots, A_m \in gl(d, \mathbb{R})$ ,  $u \in \mathcal{U} = \{u : \mathbb{R} \longrightarrow U, \text{ integrable on every bounded interval}\}$  and  $U \subset \mathbb{R}^m$  is compact, convex with  $0 \in \text{int}U$ . Explicit equations for the induced perturbed system on the projective space  $\mathbb{P}^{d-1}$  can be obtained as follows: Let  $\mathbb{S}^{d-1} \subset \mathbb{R}^d$  be the unit sphere embedded into  $\mathbb{R}^d$ . The projected system on  $\mathbb{S}^{d-1}$  is given by

$$\dot{s}(t) = h(u(t), s(t)), \quad u \in \mathcal{U}, \quad s \in \mathbb{S}^{d-1}$$

where

$$h(u, s) = h_0(s) + \sum_{i=1}^m u_i h_i(s) \text{ with } h_i(s) = (A_i - s^T A_i s \cdot I) s, \quad i = 0, 1, \dots, m.$$

Define an equivalence relation on  $\mathbb{S}^{d-1}$  via  $s_1 \sim s_2$  if  $s_1 = -s_2$ , identifying opposite points. Then the projective space can be identified as  $\mathbb{P}^{d-1} = \mathbb{S}^{d-1} / \sim$ . Since  $h(u, s) = -h(u, -s)$ , the differential equation also describes the projected system on  $\mathbb{P}^{d-1}$ . For the Lyapunov exponents one obtains in the same way

$$\lambda(u, \mathbf{x}) = \limsup_{t \rightarrow \infty} \frac{1}{t} \log \|\mathbf{x}(t)\| = \limsup_{t \rightarrow \infty} \frac{1}{t} \int_0^t q(u(\tau), s(\tau)) d\tau$$

with

$$q(u, s) = q_0(s) + \sum_{i=1}^m u_i q_i(s) \text{ with } q_i(s) = (A_i - s^T A_i s \cdot I) s, \quad i = 0, 1, \dots, m.$$

For a constant perturbation  $u(t) \equiv u \in \mathbb{R}$  for all  $t \in \mathbb{R}$  the corresponding Lyapunov exponents  $\lambda(u, \mathbf{x})$  of the flow  $\Phi$  are the real parts of the eigenvalues of the matrix  $A(u)$  and the corresponding Lyapunov spaces are contained in the subbundles  $\mathbb{P}^{-1}\mathcal{M}_i$ . Similarly, if a perturbation  $u \in \mathcal{U}$  is periodic, the Floquet exponents of  $\dot{\mathbf{x}} = A(u(\cdot))\mathbf{x}$  are part of the Lyapunov (and, hence, of the Morse) spectrum of the flow  $\Phi$ , and the Floquet spaces are contained in  $\mathbb{P}^{-1}\mathcal{M}_i$ . The systems treated in this example can also be considered as “bilinear control systems” and studied relative to their control behavior and (exponential) stabilizability — this is the point of view taken in [CK00].

7. For robust linear systems “generically” the Lyapunov spectrum and the Morse spectrum agree see [CK00] for a precise definition of “generic” in this context.
8. Of particular interest is the upper spectral interval  $\Sigma_{Mo}(\mathcal{M}_l) = [\kappa_l^*, \kappa_l]$ , as it determines the robust stability of  $\dot{\mathbf{x}} = A(u(t))\mathbf{x}$  (and stabilizability of the system if the set  $\mathcal{U}$  is interpreted as a

set of admissible control functions; see [Gru96]). The stable, center, and unstable subbundles of  $\mathcal{U} \times \mathbb{R}^d$  associated with the perturbed linear system  $\dot{\mathbf{x}} = A(u(t))\mathbf{x}$  are defined as  $L^- = \bigoplus\{\mathbb{P}^{-1}\mathcal{M}_j, \kappa_j < 0\}$ ,  $L^0 = \bigoplus\{\mathbb{P}^{-1}\mathcal{M}_j, 0 \in [\kappa_j^*, \kappa_j]\}$ , and  $L^+ = \bigoplus\{\mathbb{P}^{-1}\mathcal{M}_j, \kappa_j^* > 0\}$ , respectively. The zero solution of  $\dot{\mathbf{x}} = A(u(t))\mathbf{x}$  is exponentially stable for all perturbations  $u \in \mathcal{U}$  if and only if  $\kappa_l < 0$  if and only if  $L^- = \mathcal{U} \times \mathbb{R}^d$ .

**Examples:**

1. In general, it is not possible to compute the Morse spectrum and the associated subbundle decompositions explicitly, even for relatively simple systems, and one has to revert to numerical algorithms; compare [CK00, App. D]. Let us consider, e.g., the linear oscillator with uncertain restoring force

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -1 & -2b \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + u(t) \begin{bmatrix} 0 & 0 \\ -1 & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$$

with  $u(t) \in [-\rho, \rho]$  and  $b > 0$ . Figure 56.1 shows the spectral intervals for this system depending on  $\rho \geq 0$ .

2. We consider robust linear systems as described in Fact 6, with varying perturbation range by introducing the family  $U^\rho = \rho U$  for  $\rho \geq 0$ . The resulting family of systems is

$$\dot{\mathbf{x}}^\rho = A(u^\rho(t))\mathbf{x}^\rho := A_0\mathbf{x}^\rho + \sum_{i=1}^m u_i^\rho(t)A_i\mathbf{x}^\rho,$$

with  $u^\rho \in \mathcal{U}^\rho = \{u : \mathbb{R} \rightarrow U^\rho, \text{ integrable on every bounded interval}\}$ . The corresponding maximal spectral value  $\kappa_l(\rho)$  is continuous in  $\rho$  and we define the (asymptotic) stability radius of this family as  $r = \inf\{\rho \geq 0, \text{ there exists } u_0 \in \mathcal{U}^\rho \text{ such that } \dot{\mathbf{x}}^\rho = A(u_0(t))\mathbf{x}^\rho \text{ is not exponentially stable}\}$ . This stability radius is based on asymptotic stability under all time varying perturbations. Similarly one can introduce stability radii based on time invariant perturbations (with values in  $\mathbb{R}^m$  or  $\mathbb{C}^m$ ) or on quadratic Lyapunov functions ([CK00], Chapter 11 and [HP05]).

3. Linear oscillator with uncertain damping: Consider the oscillator

$$\ddot{y} + 2(b + u(t))\dot{y} + (1 + c)y = 0$$

FIGURE 56.1 Spectral intervals depending on  $\rho \geq 0$  for the system in Example 1.

FIGURE 56.2 Stability radii for the system in Example 4.

with  $u(t) \in [-\rho, \rho]$  and  $c \in \mathbb{R}$ . In equivalent first-order form the system reads

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -1 - c & -2b \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + u(t) \begin{bmatrix} 0 & 0 \\ 0 & -2 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}.$$

Clearly, the system is not exponentially stable for  $c \leq -1$  with  $\rho = 0$ , and for  $c > -1$  with  $\rho \geq b$ . It turns out that the stability radius for this system is

$$r(c) = \begin{cases} 0 & \text{for } c \leq -1 \\ b & \text{for } c > -1. \end{cases}$$

4. Linear oscillator with uncertain restoring force: Here we look again at a system of the form

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -1 & -2b \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + u(t) \begin{bmatrix} 0 & 0 \\ -1 & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$$

with  $u(t) \in [-\rho, \rho]$  and  $b > 0$ . (For  $b \leq 0$  the system is unstable even for constant perturbations.) A closed form expression of the stability radius for this system is not available and one has to use numerical methods for the computation of (maximal) Lyapunov exponents (or maxima of the Morse spectrum); compare [CK00, App. D]. Figure 56.2 shows the (asymptotic) stability radius  $r$ , the stability radius under constant real perturbations  $r_{\mathbb{R}}$ , and the stability radius based on quadratic Lyapunov functions  $r_{Lf}$ , all in dependence on  $b > 0$ ; see [CK00, Ex. 11.1.12].

## 56.9 Linearization

The local behavior of the dynamical system induced by a nonlinear differential equation can be studied via the linearization of the flow. At a fixed point of the nonlinear system the linearization is just a linear differential equation as studied in Sections 56.1 to 56.4. If the linearized system is hyperbolic, then the theorem of Hartman and Grobman states that the nonlinear flow is topologically conjugate to the linear flow. The invariant manifold theorem deals with those solutions of the nonlinear equation that are asymptotically attracted to (or repelled from) a fixed point. Basically these solutions live on manifolds that are described by nonlinear changes of coordinates of the linear stable (and unstable) subspaces.

Fact 4 below describes the simplest form of the invariant manifold theorem at a fixed point. It can be extended to include a “center manifold” (corresponding to the Lyapunov space with exponent 0). Furthermore, (local) invariant manifolds can be defined not just for the stable and unstable subspace,

but for all Lyapunov spaces; see [BK94], [CK00], and [Rob98] for the necessary techniques and precise statements.

Both the Grobman–Hartman theorem as well as the invariant manifold theorem can be extended to time varying systems, i.e., to linear skew product flows as described in Sections 56.5 to 56.8. The general situation is discussed in [BK94], the case of linearization at a periodic solution is covered in [Rob98], random dynamical systems are treated in [Arn98], and robust systems (control systems) are the topic of [CK00].

### Definitions:

A (nonlinear) **differential equation** in  $\mathbb{R}^d$  is of the form  $\dot{\mathbf{y}} = f(\mathbf{y})$ , where  $f$  is a vector field on  $\mathbb{R}^d$ . Assume that  $f$  is at least of class  $C^1$  and that for all  $\mathbf{y}_0 \in \mathbb{R}^d$  the solutions  $\mathbf{y}(t, \mathbf{y}_0)$  of the initial value problem  $\mathbf{y}(0, \mathbf{y}_0) = \mathbf{y}_0$  exist for all  $t \in \mathbb{R}$ .

A point  $\mathbf{p} \in \mathbb{R}^d$  is a **fixed point** of the differential equation  $\dot{\mathbf{y}} = f(\mathbf{y})$  if  $\mathbf{y}(t, \mathbf{p}) = \mathbf{p}$  for all  $t \in \mathbb{R}$ .

The **linearization** of the equation  $\dot{\mathbf{y}} = f(\mathbf{y})$  at a fixed point  $\mathbf{p} \in \mathbb{R}^d$  is given by  $\dot{\mathbf{x}} = D_{\mathbf{y}}f(\mathbf{p})\mathbf{x}$ , where  $D_{\mathbf{y}}f(\mathbf{p})$  is the Jacobian (matrix of partial derivatives) of  $f$  at the point  $\mathbf{p}$ .

A fixed point  $\mathbf{p} \in \mathbb{R}^d$  of the differential equation  $\dot{\mathbf{y}} = f(\mathbf{y})$  is called **hyperbolic** if  $D_{\mathbf{y}}f(\mathbf{p})$  has no eigenvalues on the imaginary axis, i.e., if the matrix  $D_{\mathbf{y}}f(\mathbf{p})$  is hyperbolic.

Consider a differential equation  $\dot{\mathbf{y}} = f(\mathbf{y})$  in  $\mathbb{R}^d$  with flow  $\Phi : \mathbb{R} \times \mathbb{R}^d \rightarrow \mathbb{R}^d$ , hyperbolic fixed point  $\mathbf{p}$  and neighborhood  $U(\mathbf{p})$ . In this situation the **local stable manifold** and the **local unstable manifold** are defined as

$$W_{loc}^s(\mathbf{p}) = \{\mathbf{q} \in U : \lim_{t \rightarrow \infty} \Phi(t, \mathbf{q}) = \mathbf{p}\} \text{ and } W_{loc}^u(\mathbf{p}) = \{\mathbf{q} \in U : \lim_{t \rightarrow -\infty} \Phi(t, \mathbf{q}) = \mathbf{p}\},$$

respectively.

The local stable (and unstable) manifolds can be extended to **global invariant manifolds** by following the trajectories, i.e.,

$$W^s(\mathbf{p}) = \bigcup_{t \geq 0} \Phi(-t, W_{loc}^s(\mathbf{p})) \text{ and } W^u(\mathbf{p}) = \bigcup_{t \geq 0} \Phi(t, W_{loc}^u(\mathbf{p})).$$

### Facts:

Literature: [Arn98], [AP90], [BK94], [CK00], [Rob98].

See Facts 3 and 4 in Section 56.2 for dynamical systems induced by differential equations and their fixed points.

1. (Hartman–Gobman) Consider a differential equation  $\dot{\mathbf{y}} = f(\mathbf{y})$  in  $\mathbb{R}^d$  with flow  $\Phi : \mathbb{R} \times \mathbb{R}^d \rightarrow \mathbb{R}^d$ . Assume that the equation has a hyperbolic fixed point  $\mathbf{p}$  and denote the flow of the linearized equation  $\dot{\mathbf{x}} = D_{\mathbf{y}}f(\mathbf{p})\mathbf{x}$  by  $\Psi : \mathbb{R} \times \mathbb{R}^d \rightarrow \mathbb{R}^d$ . Then there exist neighborhoods  $U(\mathbf{p})$  of  $\mathbf{p}$  and  $V(\mathbf{0})$  of the origin in  $\mathbb{R}^d$ , and a homeomorphism  $h : U(\mathbf{p}) \rightarrow V(\mathbf{0})$  such that the flows  $\Phi|_{U(\mathbf{p})}$  and  $\Psi|_{V(\mathbf{0})}$  are (locally)  $C^0$ -conjugate, i.e.,  $h(\Phi(t, \mathbf{y})) = \Psi(t, h(\mathbf{y}))$  for all  $\mathbf{y} \in U(\mathbf{p})$  and  $t \in \mathbb{R}$  as long as the solutions stay within the respective neighborhoods.
2. Consider two differential equations  $\dot{\mathbf{y}} = f_i(\mathbf{y})$  in  $\mathbb{R}^d$  with flows  $\Phi_i : \mathbb{R} \times \mathbb{R}^d \rightarrow \mathbb{R}^d$  for  $i = 1, 2$ . Assume that  $\Phi_i$  has a hyperbolic fixed point  $\mathbf{p}_i$  and the flows are  $C^k$ -conjugate for some  $k \geq 1$  in neighborhoods of the  $\mathbf{p}_i$ . Then  $\sigma(D_{\mathbf{y}}f_1(\mathbf{p}_1)) = \sigma(D_{\mathbf{y}}f_2(\mathbf{p}_2))$ , i.e., the eigenvalues of the linearizations agree; compare Facts 5 and 6 in Section 56.2 for the linear situation.
3. Consider two differential equations  $\dot{\mathbf{y}} = f_i(\mathbf{y})$  in  $\mathbb{R}^d$  with flows  $\Phi_i : \mathbb{R} \times \mathbb{R}^d \rightarrow \mathbb{R}^d$  for  $i = 1, 2$ . Assume that  $\Phi_i$  has a hyperbolic fixed point  $\mathbf{p}_i$  and the number of negative (or positive) Lyapunov exponents of  $D_{\mathbf{y}}f_i(\mathbf{p}_i)$  agrees. Then the flows  $\Phi_i$  are locally  $C^0$ -conjugate around the fixed points.
4. (Invariant Manifold Theorem) Consider a differential equation  $\dot{\mathbf{y}} = f(\mathbf{y})$  in  $\mathbb{R}^d$  with flow  $\Phi : \mathbb{R} \times \mathbb{R}^d \rightarrow \mathbb{R}^d$ . Assume that the equation has a hyperbolic fixed point  $p$  and denote the linearized equation by  $\dot{\mathbf{x}} = D_{\mathbf{y}}f(p)\mathbf{x}$ .

- (i) There exists a neighborhood  $U(\mathbf{p})$  in which the flow  $\Phi$  has a local stable manifold  $W_{loc}^s(\mathbf{p})$  and a local unstable manifold  $W_{loc}^u(\mathbf{p})$ .

- (ii) Denote by  $L^-$  (and  $L^+$ ) the stable (and unstable, respectively) subspace of  $D_y f(\mathbf{p})$ ; compare the definitions in Section 56.1. The dimensions of  $L^-$  (as a linear subspace of  $\mathbb{R}^d$ ) and of  $W_{loc}^s(\mathbf{p})$  (as a topological manifold) agree, similarly for  $L^+$  and  $W_{loc}^u(\mathbf{p})$ .
  - (iii) The stable manifold  $W_{loc}^s(\mathbf{p})$  is tangent to the stable subspace  $L^-$  at the fixed point  $\mathbf{p}$ , similarly for  $W_{loc}^u(\mathbf{p})$  and  $L^+$ .
5. Consider a differential equation  $\dot{\mathbf{y}} = f(\mathbf{y})$  in  $\mathbb{R}^d$  with flow  $\Phi : \mathbb{R} \times \mathbb{R}^d \rightarrow \mathbb{R}^d$ . Assume that the equation has a hyperbolic fixed point  $\mathbf{p}$ . Then there exists a neighborhood  $U(\mathbf{p})$  on which  $\Phi$  is  $C^0$ -equivalent to the flow of a linear differential equation of the type

$$\begin{aligned} \dot{\mathbf{x}}_s &= -\mathbf{x}_s, \mathbf{x}_s \in \mathbb{R}^{d_s}, \\ \dot{\mathbf{x}}_u &= \mathbf{x}_u, \mathbf{x}_u \in \mathbb{R}^{d_u}, \end{aligned}$$

where  $d_s$  and  $d_u$  are the dimensions of the stable and the unstable subspace of  $D_y f(\mathbf{p})$ , respectively, with  $d_s + d_u = d$ .

**Examples:**

1. Consider the nonlinear differential equation in  $\mathbb{R}$  given by  $\ddot{z} + z - z^3 = 0$ , or in first-order form in  $\mathbb{R}^2$

$$\begin{bmatrix} \dot{y}_1 \\ \dot{y}_2 \end{bmatrix} = \begin{bmatrix} y_2 \\ -y_1 + y_1^3 \end{bmatrix} = f(\mathbf{y}).$$

The fixed points of this system are  $\mathbf{p}_1 = [0, 0]^T$ ,  $\mathbf{p}_2 = [1, 0]^T$ ,  $\mathbf{p}_3 = [-1, 0]^T$ . Computation of the linearization yields

$$D_y f = \begin{bmatrix} 0 & 1 \\ -1 + 3y_1^2 & 0 \end{bmatrix}.$$

Hence, the fixed point  $\mathbf{p}_1$  is not hyperbolic, while  $\mathbf{p}_2$  and  $\mathbf{p}_3$  have this property.

2. Consider the nonlinear differential equation in  $\mathbb{R}$  given by  $\ddot{z} + \sin(z) + \dot{z} = 0$ , or in first-order form in  $\mathbb{R}^2$

$$\begin{bmatrix} \dot{y}_1 \\ \dot{y}_2 \end{bmatrix} = \begin{bmatrix} y_2 \\ -\sin(y_1) - y_2 \end{bmatrix} = f(\mathbf{y}).$$

The fixed points of the system are  $\mathbf{p}_n = [n\pi, 0]^T$  for  $n \in \mathbb{Z}$ . Computation of the linearization yields

$$D_y f = \begin{bmatrix} 0 & 1 \\ -\cos(y_1) & -1 \end{bmatrix}.$$

Hence, for the fixed points  $\mathbf{p}_n$  with  $n$  even the eigenvalues are  $\mu_1, \mu_2 = -\frac{1}{2} \pm i\sqrt{\frac{3}{4}}$  with negative real part (or Lyapunov exponent), while at the fixed points  $\mathbf{p}_n$  with  $n$  odd one obtains as eigenvalues  $v_1, v_2 = -\frac{1}{2} \pm \sqrt{\frac{5}{4}}$ , resulting in one positive and one negative eigenvalue. Hence, the flow of the differential equation is locally  $C^0$ -conjugate around all fixed points with even  $n$ , and around all fixed points with odd  $n$ , while the flows around, e.g.,  $\mathbf{p}_0$  and  $\mathbf{p}_1$  are not conjugate.

Given a dynamical system described by the ordinary differential equation (ODE)

$$\dot{\mathbf{x}}(t) = \mathbf{f}(t, \mathbf{x}(t), \mathbf{u}(t)), \quad \mathbf{x}(t_0) = \mathbf{x}^0,$$

where  $\mathbf{x}$  is the state of the system and  $\mathbf{u}$  serves as input, the major problem in control theory is to steer the state from  $\mathbf{x}^0$  to some desired state; i.e., for a given initial value  $\mathbf{x}(t_0) = \mathbf{x}^0$  and target  $\mathbf{x}^1$ , can we find a piecewise continuous or  $L_2$  (i.e., square-integrable, Lebesgue measurable) control function  $\hat{\mathbf{u}}$  such that there exists  $t_1 \geq t_0$  with  $\mathbf{x}(t_1; \hat{\mathbf{u}}) = \mathbf{x}^1$ , where  $\mathbf{x}(t; \hat{\mathbf{u}})$  is the solution trajectory of the ODE given above for  $\mathbf{u} \equiv \hat{\mathbf{u}}$ ? Often, the target is  $\mathbf{x}^1 = 0$ , in particular if  $\mathbf{x}$  describes the deviation from a nominal path. A weaker demand is to asymptotically stabilize the system, i.e., to find an admissible control function  $\hat{\mathbf{u}}$  (i.e., a piecewise continuous or  $L_2$  function  $\hat{\mathbf{u}} : [t_0, t_1] \mapsto \mathcal{U}$ ) such that  $\lim_{t \rightarrow \infty} \mathbf{x}(t; \hat{\mathbf{u}}) = 0$ .

Another major problem in control theory arises from the fact that often, not all states are available for measurements or observations. Thus, we are faced with the question: Given partial information about the states, is it possible to reconstruct the solution trajectory from the measurements/observations? If this is the case, the states can be estimated by state observers. The classical approach leads to the Luenberger observer, but nowadays most frequently the famous Kalman–Bucy filter [KB61] is used as it can be considered as an optimal state observer in a least-squares sense and allows for stochastic uncertainties in the system.

Analyzing the above questions concerning controllability, observability, etc. for general control systems is beyond the scope of linear algebra. Therefore, we will mostly focus on linear time-invariant (LTI) systems that can be analyzed with tools relying on linear algebra techniques. (For further reading, see, e.g., [Lev96], [Mut99], and [Son98].)

Once the above questions are settled, it is interesting to ask how the desired control objectives can be achieved in an optimal way. The linear-quadratic regulator (LQR) problem is equivalent to a dynamic optimization problem for linear differential equations. Its significance for control theory was fully discovered first by Kalman in 1960 [Kal60]. One of its main applications is to steer the solution of the underlying linear differential equation to a desired reference trajectory with minimal cost given full information on the states. If full information is not available, then the states can be estimated from the measurements or observations using a Kalman–Bucy filter. This leads to the linear-quadratic Gaussian (LQG) control problem. The latter problem and its solution were first described in the classical papers [Kal60] and [KB61] and are nowadays contained in any textbook on control theory.

In the past decades, the interest has shifted from optimal control to robust control. The question raised is whether a given control law is still able to achieve a desired performance in the presence of uncertain disturbances. In this sense, the LQR control law has some robustness, while the LQG design cannot be considered to be robust [Doy78]. The  $H_\infty$  control problem aims at minimizing the worst-case error that can occur if the system is perturbed by exogenous perturbations. It is, thus, one example of a *robust control* problem. We will only introduce the standard  $H_\infty$  control problem, though there exist many other robust control problems and several variations of the  $H_\infty$  control problem; see [GL95], [PUA00], [ZDG96].

Many of the above questions lead to methods that involve the solution of linear and nonlinear matrix equations, in particular Lyapunov, Sylvester, and Riccati equations. For instance, stability, controllability, and observability of LTI systems can be related to solutions of Lyapunov equations (see, e.g., [LT85, Sec. 13] and [HJ91]), while the LQR, LQG, and  $H_\infty$  control problems lead to the solution of algebraic Riccati equations, (see, e.g., [AKFIJ03], [Dat04], [LR95], [Meh91], and [Sim96]). Therefore, we will provide the most relevant properties of these matrix equations.

The concepts and solution techniques contained in this chapter and many other control-related algorithms are implemented in the MATLAB<sup>®</sup> Control System Toolbox, the Subroutine Library in Control SLICOT [BMS<sup>+</sup>99], and many other computer-aided control systems design tools.

Finally, we note that all concepts described in this section are related to *continuous-time* systems. Analogous concepts hold for *discrete-time systems* whose dynamics are described by difference equations; see, e.g., [Kuc91].

## 57.1 Basic Concepts

---

### Definitions:

Given vector spaces  $\mathcal{X}$  (the **state space**),  $\mathcal{U}$  (the **input space**), and  $\mathcal{Y}$  (the **output space**) and measurable functions  $\mathbf{f}, \mathbf{g} : [t_0, t_f] \times \mathcal{X} \times \mathcal{U} \mapsto \mathbb{R}^n$ , a **control system** is defined by

$$\dot{\mathbf{x}}(t) = \mathbf{f}(t, \mathbf{x}(t), \mathbf{u}(t)),$$

$$\mathbf{y}(t) = \mathbf{g}(t, \mathbf{x}(t), \mathbf{u}(t)),$$

where the differential equation is called the **state equation**, the second equation is called the **observer equation**, and  $t \in [t_0, t_f]$  ( $t_f \in [0, \infty]$ ).

Here,

$$\mathbf{x} : [t_0, t_f] \mapsto \mathcal{X} \text{ is the } \mathbf{state (vector)},$$

$$\mathbf{u} : [t_0, t_f] \mapsto \mathcal{U} \text{ is the } \mathbf{control (vector)},$$

$$\mathbf{y} : [t_0, t_f] \mapsto \mathcal{Y} \text{ is the } \mathbf{output (vector)}.$$

A control system is called **autonomous (time-invariant)** if

$$\mathbf{f}(t, \mathbf{x}, \mathbf{u}) \equiv \mathbf{f}(\mathbf{x}, \mathbf{u}) \text{ and } \mathbf{g}(t, \mathbf{x}, \mathbf{u}) \equiv \mathbf{g}(\mathbf{x}, \mathbf{u}).$$

The number of state-space variables  $n$  is called the **order** or **degree** of the system.

Let  $\mathbf{x}^1 \in \mathbb{R}^n$ . A control system with initial value  $\mathbf{x}(t_0) = \mathbf{x}^0$  is **controllable to  $\mathbf{x}^1$  in time  $t_1 > t_0$**  if there exists an **admissible** control function  $\mathbf{u}$  (i.e., a piecewise continuous or  $L_2$  function  $\mathbf{u} : [t_0, t_1] \mapsto \mathcal{U}$ ) such that  $\mathbf{x}(t_1; \mathbf{u}) = \mathbf{x}^1$ . (Equivalently,  $(t_1, \mathbf{x}^1)$  is **reachable from**  $(t_0, \mathbf{x}^0)$ .)

A control system with initial value  $\mathbf{x}(t_0) = \mathbf{x}^0$  is **controllable to  $\mathbf{x}^1$**  if there exists  $t_1 > t_0$  such that  $(t_1, \mathbf{x}^1)$  is reachable from  $(t_0, \mathbf{x}^0)$ .

If the control system is controllable to all  $\mathbf{x}^1 \in \mathcal{X}$  for all  $(t_0, \mathbf{x}^0)$  with  $\mathbf{x}^0 \in \mathcal{X}$ , it is (**completely controllable**).

A control system is **linear** if  $\mathcal{X} = \mathbb{R}^n$ ,  $\mathcal{U} = \mathbb{R}^m$ ,  $\mathcal{Y} = \mathbb{R}^p$ , and

$$\begin{aligned}\mathbf{f}(t, \mathbf{x}, \mathbf{u}) &= A(t)\mathbf{x}(t) + B(t)\mathbf{u}(t), \\ \mathbf{g}(t, \mathbf{x}, \mathbf{u}) &= C(t)\mathbf{x}(t) + D(t)\mathbf{u}(t),\end{aligned}$$

where  $A : [t_0, t_f] \mapsto \mathbb{R}^{n \times n}$ ,  $B : [t_0, t_f] \mapsto \mathbb{R}^{n \times m}$ ,  $C : [t_0, t_f] \mapsto \mathbb{R}^{p \times n}$ ,  $D : [t_0, t_f] \mapsto \mathbb{R}^{p \times m}$  are smooth functions.

A linear **time-invariant system (LTI system)** has the form

$$\begin{aligned}\dot{\mathbf{x}}(t) &= A\mathbf{x}(t) + B\mathbf{u}(t), \\ \mathbf{y}(t) &= C\mathbf{x}(t) + D\mathbf{u}(t),\end{aligned}$$

with  $A \in \mathbb{R}^{n \times n}$ ,  $B \in \mathbb{R}^{n \times m}$ ,  $C \in \mathbb{R}^{p \times n}$ , and  $D \in \mathbb{R}^{p \times m}$ .

An LTI system is **(asymptotically) stable** if the corresponding linear homogeneous ODE  $\dot{\mathbf{x}} = A\mathbf{x}$  is (asymptotically) stable. (For a definition of (asymptotic) stability confer Chapter 55 and Chapter 56.)

An LTI system is **stabilizable (by state feedback)** if there exists an admissible control in the form of a **state feedback**

$$\mathbf{u}(t) = F\mathbf{x}(t), \quad F \in \mathbb{R}^{m \times n},$$

such that the unique solution of the corresponding **closed-loop** ODE

$$\dot{\mathbf{x}}(t) = (A + BF)\mathbf{x}(t) \tag{57.1}$$

is asymptotically stable.

An LTI system is **observable (reconstructible)** if for two solution trajectories  $\mathbf{x}(t)$  and  $\tilde{\mathbf{x}}(t)$  of its state equation, it holds that

$$C\mathbf{x}(t) = C\tilde{\mathbf{x}}(t) \quad \forall t \leq t_0 \quad (\forall t \geq t_0)$$

implies  $\mathbf{x}(t) = \tilde{\mathbf{x}}(t) \quad \forall t \leq t_0 \quad (\forall t \geq t_0)$ .

An LTI system is **detectable** if for any solution  $\mathbf{x}(t)$  of  $\dot{\mathbf{x}} = A\mathbf{x}$  with  $C\mathbf{x}(t) \equiv 0$  we have  $\lim_{t \rightarrow \infty} \mathbf{x}(t) = 0$ .

### Facts:

1. For LTI systems, all controllability and reachability concepts are equivalent. Therefore, we only speak of controllability of LTI systems.
2. Observability implies that one can obtain all necessary information about the LTI system from the output equation.
3. Detectability weakens observability in the same sense as stabilizability weakens controllability: Not all of  $\mathbf{x}$  can be observed, but the unobservable part is asymptotically stable.
4. Observability (detectability) and controllability (stabilizability) are dual concepts in the following sense: an LTI system is observable (detectable) if and only if the dual system

$$\dot{\mathbf{z}}(t) = A^T \mathbf{z}(t) + C^T \mathbf{v}(t)$$

is controllable (stabilizable). This fact is sometimes called the **duality principle of control theory**.

### Examples:

1. A fundamental problem in robotics is to control the position of a single-link rotational joint using a motor placed at the “pivot.” A simple mathematical model for this is the pendulum [Son98]. Applying a torque  $\mathbf{u}$  as external force, this can serve as a means to control the motion of the pendulum (Figure 57.1).

FIGURE 57.1 Pendulum as mathematical model of a single-link rotational joint .

If we neglect friction and assume that the mass is concentrated at the tip of the pendulum, Newton's law for rotating objects

$$m\ddot{\Theta}(t) + mg \sin \Theta(t) = \mathbf{u}(t)$$

describes the counter clockwise movement of the angle between the vertical axis and the pendulum subject to the control  $\mathbf{u}(t)$ . This is a first example of a (nonlinear) control system if we set

$$\mathbf{x}(t) = \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} = \begin{bmatrix} \Theta(t) \\ \dot{\Theta}(t) \end{bmatrix},$$

$$\mathbf{f}(t, \mathbf{x}, \mathbf{u}) = \begin{bmatrix} x_2 \\ -mg \sin(x_1) \end{bmatrix}, \quad \mathbf{g}(t, \mathbf{x}, \mathbf{u}) = x_1,$$

where we assume that only  $\Theta(t)$  can be measured, but not the angular velocity  $\dot{\Theta}(t)$ .

For  $\mathbf{u}(t) \equiv 0$ , the stationary position  $\Theta = \pi, \dot{\Theta} = 0$  is an unstable equilibrium, i.e., small perturbations will lead to unstable motion. The objective now is to apply a torque (control  $\mathbf{u}$ ) to correct for deviations from this unstable equilibrium, i.e., to keep the pendulum in the upright position, (Figure 57.2).

- Scaling the variables such that  $m = 1 = g$  and assuming a small perturbation  $\Theta - \pi$  in the inverted pendulum problem described above, we have

$$\sin \Theta = -(\Theta - \pi) + o((\Theta - \pi)^2).$$

(Here,  $\mathbf{g}(x) = o(x)$  if  $\lim_{x \rightarrow \infty} \frac{\mathbf{g}(x)}{x} = 0$ .) This allows us to linearize the control system in order to obtain a linear control system for  $\varphi(t) := \Theta(t) - \pi$ :

$$\ddot{\varphi}(t) - \varphi(t) = \mathbf{u}(t).$$

This can be written as an LTI system, assuming only positions can be observed, with

$$\mathbf{x} = \begin{bmatrix} \varphi \\ \dot{\varphi} \end{bmatrix}, \quad A = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \quad C = [1 \quad 0], \quad D = 0.$$

FIGURE 57.2 Inverted pendulum; apply control to move to upright position.

Now the objective translates to: Given initial values  $x_1(0) = \varphi(0)$ ,  $x_2(0) = \dot{\varphi}(0)$ , find  $\mathbf{u}(t)$  to bring  $\mathbf{x}(t)$  to zero “as fast as possible.” It is usually an additional goal to avoid overshoot and oscillating behavior as much as possible.

## 57.2 Frequency-Domain Analysis

So far, LTI systems are treated in state-space. In systems and control theory, it is often beneficial to use the **frequency domain** formalism obtained from applying the Laplace transformation to its state and observer equations.

### Definitions:

The rational matrix function

$$G(s) = C(sI - A)^{-1}B + D \in \mathbb{R}^{p \times m}[s]$$

is called the **transfer function** of the LTI system defined in section 57.1.

In a **frequency domain analysis**,  $G(s)$  is evaluated for  $s = i\omega$ , where  $\omega \in [0, \infty]$  has the physical interpretation of a frequency and the input is considered as a signal with frequency  $\omega$ .

The  $L_\infty$ -**norm** of a transfer function is the operator norm induced by the frequency domain analogue of the  $L_2$ -norm that applies to Laplace transformed input functions  $\mathbf{u} \in L_2(-\infty, \infty; \mathbb{R}^m)$ , where  $L_2(a, b; \mathbb{R}^m)$  is the Lebesgue space of square-integrable, measurable functions on the interval  $(a, b) \subset \mathbb{R}$  with values in  $\mathbb{R}^m$ .

The  $p \times m$ -matrix-valued functions  $G$  for which  $\|G\|_{L_\infty}$  is bounded form the space  $L_\infty$ .

The subset of  $L_\infty$  containing all  $p \times m$ -matrix-valued functions that are analytical and bounded in the open right-half complex plane form the **Hardy space**  $H_\infty$ .

The  $H_\infty$ -**norm** of  $G \in H_\infty$  is defined as

$$\|G\|_{H_\infty} = \operatorname{ess\,sup}_{\omega \in \mathbb{R}} \sigma_{\max}(G(i\omega)), \quad (57.2)$$

where  $\sigma_{\max}(M)$  is the maximum singular value of the matrix  $M$  and  $\operatorname{ess\,sup}_{t \in M} h(t)$  is the essential supremum of a function  $h$  evaluated on the set  $M$ , which is the function’s supremum on  $M \setminus L$  where  $L$  is a set of Lebesgue measure zero.

For  $T \in \mathbb{R}^{n \times n}$  nonsingular, the mapping implied by

$$(A, B, C, D) \mapsto (TAT^{-1}, TB, CT^{-1}, D)$$

is called a **state-space transformation**.

$(A, B, C, D)$  is called a **realization** of an LTI system if its transfer function can be expressed as  $G(s) = C(sI_n - A)^{-1}B + D$ .

The minimum number  $\hat{n}$  so that there exists no realization of a given LTI system with  $n < \hat{n}$  is called the **McMillan degree** of the system.

A realization with  $n = \hat{n}$  is a **minimal realization**.

### Facts:

1. If  $\mathbf{X}, \mathbf{Y}, \mathbf{U}$  are the Laplace transforms of  $\mathbf{x}, \mathbf{y}, \mathbf{u}$ , respectively,  $s$  is the Laplace variable, and  $\mathbf{x}(0) = 0$ , the state and observer equation of an LTI system transform to

$$\begin{aligned} s\mathbf{X}(s) &= \mathbf{A}\mathbf{X}(s) + \mathbf{B}\mathbf{U}(s), \\ \mathbf{Y}(s) &= \mathbf{C}\mathbf{X}(s) + \mathbf{D}\mathbf{U}(s). \end{aligned}$$

Thus, the resulting input–output relation

$$\mathbf{Y}(s) = (\mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B} + \mathbf{D})\mathbf{U}(s) = G(s)\mathbf{U}(s) \quad (57.3)$$

is completely determined by the transfer function of the LTI system.

2. As a consequence of the maximum modulus theorem,  $H_\infty$  functions must be bounded on the imaginary axis so that the essential supremum in the definition of the  $H_\infty$ -norm simplifies to a supremum for rational functions  $G$ .
3. The transfer function of an LTI system is invariant w.r.t. state-space transformations:

$$D + (CT^{-1})(sI - TAT^{-1})^{-1}(TB) = C(sI_n - A)^{-1}B + D = G(s).$$

Consequently, there exist infinitely many realizations of an LTI system.

4. Adding zero inputs/outputs does not change the transfer function, thus the order  $n$  of the system can be increased arbitrarily.

### Examples:

1. The LTI system corresponding to the inverted pendulum has the transfer function

$$G(s) = \begin{bmatrix} 1 & 0 \end{bmatrix} \begin{bmatrix} s & -1 \\ -1 & s \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ 1 \end{bmatrix} + [0] = \frac{1}{s^2 - 1}.$$

2. The  $L_\infty$ -norm of the transfer function corresponding to the inverted pendulum is

$$\|G\|_{L_\infty} = 1.$$

3. The transfer function corresponding to the inverted pendulum is not in  $H_\infty$  as  $G(s)$  has a pole at  $s = 1$  and, thus, is not bounded in the right-half plane.

## 57.3 Analysis of LTI Systems

In this section, we provide characterizations of the properties of LTI systems defined in the introduction. Controllability and the related concepts can be checked using several algebraic criteria.

### Definitions:

A matrix  $A \in \mathbb{R}^{n \times n}$  is **Hurwitz** or **(asymptotically) stable** if all its eigenvalues have strictly negative real part.

The **controllability matrix** corresponding to an LTI system is

$$\mathcal{C}(A, B) = [B, AB, A^2B, \dots, A^{n-1}B] \in \mathbb{R}^{n \times n \cdot m}.$$

The **observability matrix** corresponding to an LTI system is

$$\mathcal{O}(A, C) = \begin{bmatrix} C \\ CA \\ CA^2 \\ \vdots \\ CA^{n-1} \end{bmatrix} \in \mathbb{R}^{n \cdot p \times n}.$$

The following transformations are **state-space transformations**:

- **Change of basis:**

$$\begin{aligned} \mathbf{x} &\mapsto P\mathbf{x} && \text{for } P \in \mathbb{R}^{n \times n} && \text{nonsingular,} \\ \mathbf{u} &\mapsto Q\mathbf{u} && \text{for } Q \in \mathbb{R}^{m \times m} && \text{nonsingular,} \\ \mathbf{y} &\mapsto R\mathbf{y} && \text{for } R \in \mathbb{R}^{p \times p} && \text{nonsingular.} \end{aligned}$$

- **Linear state feedback:**  $\mathbf{u} \mapsto F\mathbf{x} + \mathbf{v}$ ,  $F \in \mathbb{R}^{m \times n}$ ,  $\mathbf{v} : [t_0, t_f] \mapsto \mathbb{R}^m$ .
- **Linear output feedback:**  $\mathbf{u} \mapsto G\mathbf{y} + \mathbf{v}$ ,  $G \in \mathbb{R}^{m \times p}$ ,  $\mathbf{v} : [t_0, t_f] \mapsto \mathbb{R}^m$ .

The **Kalman decomposition** of  $(A, B)$  is

$$V^T A V = \begin{bmatrix} A_1 & A_2 \\ 0 & A_3 \end{bmatrix}, \quad V^T B = \begin{bmatrix} B_1 \\ 0 \end{bmatrix}, \quad V \in \mathbb{R}^{n \times n} \text{ orthogonal,}$$

where  $(A_1, B_1)$  is controllable.

The **observability Kalman decomposition** of  $(A, C)$  is

$$W^T A W = \begin{bmatrix} A_1 & 0 \\ A_2 & A_3 \end{bmatrix}, \quad C W = [C_1 \ 0], \quad W \in \mathbb{R}^{n \times n} \text{ orthogonal,}$$

where  $(A_1, C_1)$  is observable.

### Facts:

1. An LTI system is asymptotically stable if and only if  $A$  is Hurwitz.
2. For a given LTI system, the following are equivalent.
  - (a) The LTI system is controllable.
  - (b) The controllability matrix corresponding to the LTI system has full (row) rank, i.e.,  $\text{rank } \mathcal{C}(A, B) = n$ .

(c) (**Hautus–Popov test**) If  $\mathbf{p} \neq 0$  and  $\mathbf{p}^* A = \lambda \mathbf{p}^*$ , then  $\mathbf{p}^* B \neq 0$ .

(d)  $\text{rank}([\lambda I - A, B]) = n \quad \forall \lambda \in \mathbb{C}$ .

The essential part of the proof of the above characterizations (which is “d) $\Rightarrow$ b)”) is an application of the Cayley–Hamilton theorem (Section 4.3).

3. For a given LTI system, the following are equivalent:

(a) The LTI system is stabilizable, i.e.,  $\exists F \in \mathbb{R}^{m \times n}$  such that  $A + BF$  is Hurwitz.

(b) (**Hautus–Popov test**) If  $\mathbf{p} \neq 0$ ,  $\mathbf{p}^* A = \lambda \mathbf{p}^*$ , and  $\text{Re}(\lambda) \geq 0$ , then  $\mathbf{p}^* B \neq 0$ .

(c)  $\text{rank}([A - \lambda I, B]) = n, \quad \forall \lambda \in \mathbb{C} \text{ with } \text{Re}(\lambda) \geq 0$ .

(d) In the Kalman decomposition of  $(A, B)$ ,  $A_3$  is Hurwitz.

4. Using the change of basis  $\tilde{\mathbf{x}} = V^T \mathbf{x}$  implied by the Kalman decomposition, we obtain

$$\begin{aligned}\dot{\tilde{\mathbf{x}}}_1 &= A_1 \tilde{\mathbf{x}}_1 + A_2 \tilde{\mathbf{x}}_2 + B_1 \mathbf{u}, \\ \dot{\tilde{\mathbf{x}}}_2 &= A_3 \tilde{\mathbf{x}}_2.\end{aligned}$$

Thus,  $\tilde{\mathbf{x}}_2$  is not controllable. The eigenvalues of  $A_3$  are, therefore, called **uncontrollable modes**.

5. For a given LTI system, the following are equivalent:

(a) The LTI system is observable.

(b) The observability matrix corresponding to the LTI system has full (column) rank, i.e.,  $\text{rank } \mathcal{O}(A, C) = n$ .

(c) (**Hautus–Popov test**),  $\mathbf{p} \neq 0$ ,  $A\mathbf{p} = \lambda \mathbf{p} \implies C^T \mathbf{p} \neq 0$ .

(d)  $\text{rank} \begin{bmatrix} \lambda I - A \\ C \end{bmatrix} = n, \quad \forall \lambda \in \mathbb{C}$ .

6. For a given LTI system, the following are equivalent:

(a) The LTI system is detectable.

(b) The dual system  $\dot{\mathbf{z}} = A^T \mathbf{z} + C^T \mathbf{v}$  is stabilizable.

(c) (**Hautus–Popov test**)  $\mathbf{p} \neq 0$ ,  $A\mathbf{p} = \lambda \mathbf{p}$ ,  $\text{Re}(\lambda) \geq 0 \implies C^T \mathbf{p} \neq 0$ .

(d)  $\text{rank} \begin{bmatrix} \lambda I - A \\ C \end{bmatrix} = n, \quad \forall \lambda \in \mathbb{C} \text{ with } \text{Re}(\lambda) \geq 0$ .

(e) In the observability Kalman decomposition of  $(A, C)$ ,  $A_3$  is Hurwitz.

7. Using the change of basis  $\tilde{\mathbf{x}} = W^T \mathbf{x}$  implied by the observability Kalman decomposition we obtain

$$\begin{aligned}\dot{\tilde{\mathbf{x}}}_1 &= A_1 \tilde{\mathbf{x}}_1 + B_1 \mathbf{u}, \\ \tilde{\mathbf{x}}_2 &= A_2 \tilde{\mathbf{x}}_1 + A_3 \tilde{\mathbf{x}}_2 + B_2 \mathbf{u}, \\ \mathbf{y} &= C_1 \tilde{\mathbf{x}}_1.\end{aligned}$$

Thus,  $\tilde{\mathbf{x}}_2$  is not observable. The eigenvalues of  $A_3$  are, therefore, called **unobservable modes**.

8. The characterizations of observability and detectability are proved using the duality principle and the characterizations of controllability and stabilizability.

9. If an LTI system is controllable (observable, stabilizable, detectable), then the corresponding LTI system resulting from a state-space transformation is controllable (observable, stabilizable, detectable).

10. For  $A \in \mathbb{R}^{n \times n}, B \in \mathbb{R}^{n \times m}$  there exist  $P \in \mathbb{R}^{n \times n}, Q \in \mathbb{R}^{m \times m}$  orthogonal such that

$$P A P^T = \begin{bmatrix} A_{11} & & & & A_{1,s-1} & & & A_{1,s} \\ A_{21} & \ddots & & & \vdots & & & \vdots \\ 0 & \ddots & \ddots & & \vdots & & & \vdots \\ \vdots & \ddots & & & \vdots & & & \vdots \\ 0 & \cdots & 0 & A_{s-1,s-2} & A_{s-1,s-1} & & & A_{s-1,s} \\ 0 & \cdots & 0 & 0 & 0 & & & A_{s,s} \end{bmatrix} \begin{matrix} n_1 \\ n_2 \\ \\ \\ n_{s-1} \\ n_s \end{matrix}, \\
 P B Q = \begin{bmatrix} B_1 & 0 \\ 0 & 0 \\ \vdots & \vdots \\ 0 & 0 \end{bmatrix} \begin{matrix} n_1 \\ n_2 \\ \vdots \\ n_s \end{matrix}, \\
 \begin{matrix} n_1 & & & n_{s-2} & n_{s-1} & & n_s \end{matrix} \quad \begin{matrix} n_1 \\ m - n_1 \end{matrix}$$

where  $n_1 \geq n_2 \geq \dots \geq n_{s-1} \geq n_s \geq 0, n_{s-1} > 0, A_{i,i-1} = [\Sigma_{i,i-1} \ 0] \in \mathbb{R}^{n_i \times n_{i-1}}, \Sigma_{i,i-1} \in \mathbb{R}^{n_i \times n_i}$  nonsingular for  $i = 1, \dots, s - 1, \Sigma_{s-1,s-2}$  is diagonal, and  $B_1$  is nonsingular.

Moreover, this transformation to **staircase form** can be computed by a finite sequence of singular value decompositions.

11. An LTI system is controllable if in the staircase form of  $(A, B), n_s = 0$ .
12. An LTI system is observable if  $n_s = 0$  in the staircase form of  $(A^T, C^T)$ .
13. An LTI system is stabilizable if in the staircase form of  $(A, B), A_{s,s}$  is Hurwitz.
14. An LTI system is detectable if in the staircase form of  $(A^T, C^T), A_{s,s}$  is Hurwitz.
15. In case  $m = 1$ , the staircase form of  $(A, B)$  is given by

$$P A P^T = \begin{bmatrix} a_{11} & \cdots & \cdots & a_{1,n} \\ a_{21} & & & \vdots \\ & \ddots & & \vdots \\ & & a_{n,n-1} & a_{n,n} \end{bmatrix}, P B = \begin{bmatrix} b_1 \\ 0 \\ \vdots \\ 0 \end{bmatrix}$$

and is called the **controllability Hessenberg form**. The corresponding staircase form of  $(A^T, C^T)$  in case  $p = 1$  is called the **observability Hessenberg form**.

**Examples:**

1. The LTI system corresponding to the inverted pendulum problem is not asymptotically stable as  $A$  is not Hurwitz:  $\sigma(A) = \{\pm 1\}$ .
2. The LTI system corresponding to the inverted pendulum problem is controllable as the controllability matrix

$$\mathcal{C}(A, B) = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$$

has full rank. Thus, it is also stabilizable.

3. The LTI system corresponding to the inverted pendulum problem is observable as the observability matrix

$$\mathcal{O}(A, C) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

has full rank. Thus, it is also detectable.

## 57.4 Matrix Equations

A fundamental role in many tasks in control theory is played by matrix equations. We, therefore, review their most important properties. More details can be found in [AKFIJ03], [HJ91], [LR95], and [LT85].

### Definitions:

A linear matrix equation of the form

$$AX + XB = W, \quad A \in \mathbb{R}^{n \times n}, B \in \mathbb{R}^{m \times m}, W \in \mathbb{R}^{n \times m},$$

is called **Sylvester equation**.

A linear matrix equation of the form

$$AX + XA^T = W, \quad A \in \mathbb{R}^{n \times n}, W = W^T \in \mathbb{R}^{n \times n},$$

is called **Lyapunov equation**.

A quadratic matrix equation of the form

$$0 = Q + A^T X + XA - XGX, \quad A \in \mathbb{R}^{n \times n}, G = G^T, Q = Q^T \in \mathbb{R}^{n \times n},$$

is called **algebraic Riccati equation (ARE)**.

### Facts:

1. The Sylvester equation is equivalent to the linear system of equations

$$[(I_m \otimes A) + (B^T \otimes I_n)] \text{vec}(X) = \text{vec}(W),$$

where  $\otimes$  and  $\text{vec}$  denote the Kronecker product and the  $\text{vec}$ -operator defined in Section 10.4. Thus, the Sylvester equation has a unique solution if and only if  $\sigma(A) \cap \sigma(-B) = \emptyset$ .

2. The Lyapunov equation is equivalent to the linear system of equations

$$[(I_m \otimes A) + (A \otimes I_n)] \text{vec}(X) = \text{vec}(W).$$

Thus, it has a unique solution if and only if  $\sigma(A) \cap \sigma(-A^T) = \emptyset$ . In particular, this holds if  $A$  is Hurwitz.

3. If  $G$  and  $Q$  are positive semidefinite with  $(A, G)$  stabilizable and  $(A, Q)$  detectable, then the ARE has a unique positive semidefinite solution  $X_*$  with the property that  $\sigma(A - GX_*)$  is Hurwitz.
4. If the assumptions given above are not satisfied, there may or may not exist a stabilizing solution with the given properties. Besides, there may exist a continuum of solutions, a finite number of solutions, or no solution at all. The solution theory for AREs is a vast topic by itself; see the monographs [AKFIJ03], [LR95] and [Ben99], [Dat04], [Meh91], and [Sim96] for numerical algorithms to solve these equations.

**Examples:**

1. For

$$A = \begin{bmatrix} 1 & 2 \\ 0 & 1 \end{bmatrix}, \quad B = \begin{bmatrix} 2 & -1 \\ 1 & 0 \end{bmatrix}, \quad W = \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix},$$

a solution of the Sylvester equation is

$$X = \frac{1}{4} \begin{bmatrix} -3 & 3 \\ 1 & -3 \end{bmatrix}.$$

Note that  $\sigma(A) = \sigma(B) = \{1, 1\}$  so that  $\sigma(A) \cap \sigma(-B) = \emptyset$ . Thus, this Sylvester equation has the unique solution  $X$  given above.

2. For

$$A = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, \quad G = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}, \quad Q = \begin{bmatrix} 1 & 0 \\ 0 & 2 \end{bmatrix},$$

the stabilizing solution of the associated ARE is

$$X_* = \begin{bmatrix} 2 & 1 \\ 1 & 2 \end{bmatrix}$$

and the spectrum of the closed-loop matrix

$$A - GX_* = \begin{bmatrix} 0 & 1 \\ -1 & -2 \end{bmatrix}$$

is  $\{-1, -1\}$ .

3. Consider the ARE

$$0 = C^T C + A^T X + X A - X B B^T X$$

corresponding to an LTI system with

$$A = \begin{bmatrix} -1 & 0 \\ 0 & 0 \end{bmatrix}, \quad B = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad C = [\sqrt{2} \quad 0], \quad D = 0.$$

For this ARE,  $X = \begin{bmatrix} -1 + \sqrt{3} & 0 \\ 0 & \xi \end{bmatrix}$  is a solution for all  $\xi \in \mathbb{R}$ . It is positive semidefinite for all  $\xi \geq 0$ , but this ARE does not have a stabilizing solution as the LTI system is neither stabilizable nor detectable.

## 57.5 State Estimation

---

In this section, we present the two most famous approaches to state observation, that is, finding a function  $\hat{\mathbf{x}}(t)$  that approximates the state  $\mathbf{x}(t)$  of a given LTI system if only its inputs  $\mathbf{u}(t)$  and outputs  $\mathbf{y}(t)$  are known. While the first approach (the Luenberger observer) assumes a deterministic system behavior, the Kalman–Bucy filter allows for uncertainty in the system, modeled by white-noise, zero-mean stochastic processes.

**Definitions:**

Given an LTI system with  $D = 0$ , a **state observer** is a function

$$\hat{\mathbf{x}} : [0, \infty) \mapsto \mathbb{R}^n$$

such that for some nonsingular matrix  $Z \in \mathbb{R}^{n \times n}$  and  $\mathbf{e}(t) = \hat{\mathbf{x}}(t) - Z\mathbf{x}(t)$ , we have

$$\lim_{t \rightarrow \infty} \mathbf{e}(t) = 0.$$

Given an LTI system with stochastic disturbances

$$\begin{aligned}\dot{\mathbf{x}}(t) &= A\mathbf{x}(t) + B\mathbf{u}(t) + \tilde{B}\mathbf{w}(t), \\ \mathbf{y}(t) &= C\mathbf{x}(t) + \mathbf{v}(t),\end{aligned}$$

where  $A, B, C$  are as before,  $\tilde{B} \in \mathbb{R}^{n \times \tilde{m}}$ , and  $\mathbf{w}(t), \mathbf{v}(t)$  are white-noise, zero-mean stochastic processes with corresponding covariance matrices  $W = W^T \in \mathbb{R}^{\tilde{m} \times \tilde{m}}$  (positive semidefinite),  $V = V^T \in \mathbb{R}^{p \times p}$  (positive definite), the problem to minimize the mean square error

$$E [\|\mathbf{x}(t) - \hat{\mathbf{x}}(t)\|_2^2]$$

over all state observers is called the **optimal estimation problem**. (Here,  $E[r]$  is the **expected value** of  $r$ .)

**Facts:**

1. A state observer, called the **Luenberger observer**, is obtained as the solution of the dynamical system

$$\dot{\hat{\mathbf{x}}}(t) = H\hat{\mathbf{x}}(t) + F\mathbf{y}(t) + G\mathbf{u}(t),$$

where  $H \in \mathbb{R}^{n \times n}$  and  $F \in \mathbb{R}^{n \times p}$  are chosen so that  $H$  is Hurwitz and the **Sylvester observer equation**

$$HX - XA + FC = 0$$

has a nonsingular solution  $X$ . Then  $G = XB$  and the matrix  $Z$  in the definition of the state observer equals the solution  $X$  of the Sylvester observer equation.

2. Assuming that

- $\mathbf{w}$  and  $\mathbf{v}$  are uncorrelated stochastic processes,
- the initial state  $\mathbf{x}^0$  is a Gaussian zero-mean random variable, uncorrelated with  $\mathbf{w}$  and  $\mathbf{v}$ ,
- $(A, B)$  is controllable and  $(A, C)$  is observable,

the solution to the optimal estimation problem is given by the **Kalman–Bucy filter**, defined as the solution of the linear differential equation

$$\dot{\hat{\mathbf{x}}}(t) = (A - Y_*C^TV^{-1}C)\hat{\mathbf{x}}(t) + B\mathbf{u}(t) + Y_*C^TV^{-1}\mathbf{y}(t),$$

where  $Y_*$  is the unique stabilizing solution of the **filter ARE**:

$$0 = \tilde{B}W\tilde{B}^T + AY + YA^T - YC^TV^{-1}CY.$$

3. Under the same assumptions as above, the stabilizing solution of the filter ARE can be shown to be symmetric positive definite.

**Examples:**

1. A Luenberger observer for the LTI system corresponding to the inverted pendulum problem can be constructed as follows: Choose  $H = \text{diag}(-2, -\frac{1}{2})$  and  $F = [2 \ 1]^T$ . Then the Sylvester observer equation has the unique solution

$$X = \frac{1}{3} \begin{bmatrix} 4 & -2 \\ -2 & 4 \end{bmatrix}.$$

Note that  $X$  is nonsingular. Thus, we get  $G = XB = \frac{1}{3} [-2 \ 4]$ .

2. Consider the inverted pendulum with disturbances  $v, w$  and  $\tilde{B} = [1 \ 1]^T$ . Assume that  $V = W = 1$ . The Kalman–Bucy filter is determined via the filter ARE, yielding

$$Y_* = (1 + \sqrt{2}) \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}.$$

Thus, the state estimation obtained from the Kalman filter is given by the solution of

$$\dot{\hat{\mathbf{x}}}(t) = \begin{bmatrix} -1 - \sqrt{2} & 1 \\ -\sqrt{2} & 0 \end{bmatrix} \hat{\mathbf{x}}(t) + \begin{bmatrix} 0 \\ 1 \end{bmatrix} \mathbf{u}(t) + (1 + \sqrt{2}) \begin{bmatrix} 1 \\ 1 \end{bmatrix} \mathbf{y}(t).$$

## 57.6 Control Design for LTI Systems

---

This section provides the background for some of the most important control design methods.

**Definitions:**

A (**feedback**) **controller** for an LTI system is given by another LTI system

$$\begin{aligned} \dot{\mathbf{r}}(t) &= E\mathbf{r}(t) + F\mathbf{y}(t), \\ \mathbf{u}(t) &= H\mathbf{r}(t) + K\mathbf{y}(t), \end{aligned}$$

where  $E \in \mathbb{R}^{N \times N}$ ,  $F \in \mathbb{R}^{N \times p}$ ,  $H \in \mathbb{R}^{m \times N}$ ,  $K \in \mathbb{R}^{m \times p}$ , and the “output”  $\mathbf{u}(t)$  of the controller serves as the input for the original LTI system.

If  $E, F, H$  are zero matrices, a controller is called **static feedback**, otherwise it is called a **dynamic compensator**.

A static feedback control law is a **state feedback** if in the controller equations, the output function  $\mathbf{y}(t)$  is replaced by the state  $\mathbf{x}(t)$ , otherwise it is called **output feedback**.

The **closed-loop system** resulting from inserting the control law  $\mathbf{u}(t)$  obtained from a dynamic compensator into the LTI system is illustrated by the block diagram in Figure 57.3, where  $\mathbf{w}$  is as in the definition of LTI systems with stochastic disturbances in Section 57.5 and  $\mathbf{z}$  will only be needed later when defining the  $H_\infty$  control problem.

The linear-quadratic optimization (optimal control) problem

$$\min_{\mathbf{u} \in L_2(0, \infty; \mathcal{U})} \mathcal{J}(\mathbf{u}), \quad \text{where } \mathcal{J}(\mathbf{u}) = \frac{1}{2} \int_0^\infty (\mathbf{y}(t)^T Q \mathbf{y}(t) + \mathbf{u}(t)^T R \mathbf{u}(t)) dt$$

FIGURE 57.3 Closed-loop diagram of an LTI system and a dynamic compensator.

subject to the dynamical constraint given by an LTI system is called the **linear-quadratic regulator (LQR) problem**.

The linear-quadratic optimization (optimal control) problem

$$\min_{\mathbf{u} \in L_2(0, \infty; \mathcal{U})} \mathcal{J}(\mathbf{u}), \quad \text{where } \mathcal{J}(\mathbf{u}) = \lim_{t_f \rightarrow \infty} \frac{1}{2t_f} E \left[ \int_{-t_f}^{t_f} (\mathbf{y}(t)^T \mathbf{Q} \mathbf{y}(t) + \mathbf{u}(t)^T \mathbf{R} \mathbf{u}(t)) dt \right]$$

subject to the dynamical constraint given by an LTI system with stochastic disturbances is called the **linear-quadratic Gaussian (LQG) problem**.

Consider an LTI system where inputs and outputs are split into two parts, so that instead of  $B\mathbf{u}(t)$  we have

$$B_1 \mathbf{w}(t) + B_2 \mathbf{u}(t),$$

and instead of  $\mathbf{y}(t) = C\mathbf{x}(t) + D\mathbf{u}(t)$ , we write

$$\mathbf{z}(t) = C_1 \mathbf{x}(t) + D_{11} \mathbf{w}(t) + D_{12} \mathbf{u}(t),$$

$$\mathbf{y}(t) = C_2 \mathbf{x}(t) + D_{21} \mathbf{w}(t) + D_{22} \mathbf{u}(t),$$

where  $\mathbf{u}(t) \in \mathbb{R}^{m_2}$  denotes the control input,  $\mathbf{w}(t) \in \mathbb{R}^{m_1}$  is an **exogenous input** that may include noise, linearization errors, and unmodeled dynamics,  $\mathbf{y}(t) \in \mathbb{R}^{p_2}$  contains **measured outputs**, while  $\mathbf{z}(t) \in \mathbb{R}^{p_1}$  is the **regulated output** or an **estimation error**. Let  $G = \begin{bmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{bmatrix}$  denote the corresponding transfer function such that

$$\begin{bmatrix} \mathbf{Z} \\ \mathbf{Y} \end{bmatrix} = \begin{bmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{bmatrix} \begin{bmatrix} \mathbf{W} \\ \mathbf{U} \end{bmatrix},$$

where  $\mathbf{Y}, \mathbf{Z}, \mathbf{U}, \mathbf{W}$  denote the Laplace transforms of  $\mathbf{y}, \mathbf{z}, \mathbf{u}, \mathbf{w}$ .

The **optimal  $H_\infty$  control problem** is then to determine a dynamic compensator

$$\dot{\mathbf{r}}(t) = E\mathbf{r}(t) + F\mathbf{y}(t),$$

$$\mathbf{u}(t) = H\mathbf{r}(t) + K\mathbf{y}(t),$$

with  $E \in \mathbb{R}^{N \times N}$ ,  $F \in \mathbb{R}^{N \times p_2}$ ,  $H \in \mathbb{R}^{m_2 \times N}$ ,  $K \in \mathbb{R}^{m_2 \times p_2}$  and transfer function  $M(s) = H(sI - E)^{-1}F + K$  such that the resulting closed-loop system

$$\begin{aligned}\dot{\mathbf{x}}(t) &= (A + B_2 K Z_1 C_2)\mathbf{x}(t) + (B_2 Z_2 H)\mathbf{r}(t) + (B_1 + B_2 K Z_1 D_{21})\mathbf{w}(t), \\ \dot{\mathbf{r}}(t) &= F Z_1 C_2 \mathbf{x}(t) + (E + F Z_1 D_{22} H)\mathbf{r}(t) + F Z_1 D_{21} \mathbf{w}(t), \\ \mathbf{z}(t) &= (C_1 + D_{12} Z_2 K C_2)\mathbf{x}(t) + D_{12} Z_2 H \mathbf{r}(t) + (D_{11} + D_{12} K Z_1 D_{21})\mathbf{w}(t),\end{aligned}$$

with  $Z_1 = (I - D_{22}K)^{-1}$  and  $Z_2 = (I - K D_{22})^{-1}$ ,

- is **internally stable**, i.e., the solution of the system with  $\mathbf{w}(t) \equiv 0$  is asymptotically stable, and
- the closed-loop transfer function  $T_{zw}(s) = G_{22}(s) + G_{21}(s)M(s)(I - G_{11}(s)M(s))^{-1}G_{12}(s)$  from  $\mathbf{w}$  to  $\mathbf{z}$  is minimized in the  $H_\infty$ -norm.

The **suboptimal  $H_\infty$  control problem** is to find an internally stabilizing controller so that

$$\|T_{zw}\|_{H_\infty} < \gamma,$$

where  $\gamma > 0$  is a robustness threshold.

### Facts:

1. If  $D = 0$  and the LTI system is both stabilizable and detectable, the weighting matrix  $Q$  is positive semidefinite, and  $R$  is positive definite, then the solution of the LQR problem is given by the state feedback controller

$$\mathbf{u}_*(t) = -R^{-1}B^T X_* \mathbf{x}(t), \quad t \geq 0,$$

where  $X_*$  is the unique stabilizing solution of the LQR ARE,

$$0 = C^T Q C + A^T X + X A - X B R^{-1} B^T X.$$

2. The LQR problem does not require an observer equation — inserting  $\mathbf{y}(t) = C\mathbf{x}(t)$  into the cost functional, we obtain a problem formulation depending only on states and inputs:

$$\begin{aligned}\mathcal{J}(\mathbf{u}) &= \frac{1}{2} \int_0^\infty (\mathbf{y}(t)^T Q \mathbf{y}(t) + \mathbf{u}(t)^T R \mathbf{u}(t)) dt \\ &= \frac{1}{2} \int_0^\infty (\mathbf{x}(t)^T C^T Q C \mathbf{x}(t) + \mathbf{u}(t)^T R \mathbf{u}(t)) dt.\end{aligned}$$

3. Under the given assumptions, it can also be shown that  $X_*$  is symmetric and the unique positive semidefinite matrix among all solutions of the LQR ARE.
4. The assumptions for the feedback solution of the LQR problem can be weakened in several aspects; see, e.g., [Gee89] and [SSC95].
5. Assuming that

- $\mathbf{w}$  and  $\mathbf{v}$  are uncorrelated stochastic processes,
- the initial state  $\mathbf{x}^0$  is a Gaussian zero-mean random variable, uncorrelated with  $\mathbf{w}$  and  $\mathbf{v}$ ,
- $(A, B)$  is controllable and  $(A, C)$  is observable,

the solution to the LQG problem is given by the feedback controller

$$\mathbf{u}(t) = -R^{-1}B^T X_* \hat{\mathbf{x}}(t),$$

where  $X_*$  is the solution of the LQR ARE and  $\hat{\mathbf{x}}$  is the Kalman–Bucy filter

$$\dot{\hat{\mathbf{x}}}(t) = (A - BR^{-1}B^T X_* - Y_* C^T V^{-1}C)\hat{\mathbf{x}}(t) + Y_* C^T V^{-1}\mathbf{y}(t),$$

corresponding to the closed-loop system resulting from the LQR solution with  $Y_*$  being the stabilizing solution of the corresponding filter ARE.

6. In principle, there is no restriction on the degree  $N$  of the  $H_\infty$  controller, although smaller dimensions  $N$  are preferred for practical implementation and computation.
7. The state-space solution to the  $H_\infty$  suboptimal control problem [DGKF89] relates  $H_\infty$  control to AREs: under the assumptions that
  - $(A, B_k)$  is stabilizable and  $(A, C_k)$  is detectable for  $k = 1, 2$ ,
  - $D_{11} = 0, D_{22} = 0$ , and

$$D_{12}^T \begin{bmatrix} C_1 & D_{12} \end{bmatrix} = \begin{bmatrix} 0 & I \end{bmatrix}, \quad \begin{bmatrix} B_1 \\ D_{21} \end{bmatrix} D_{21}^T = \begin{bmatrix} 0 \\ I \end{bmatrix},$$

a suboptimal  $H_\infty$  controller exists if and only if the AREs

$$\begin{aligned} 0 &= C_1^T C_1 + AX + XA^T + X \left( \frac{1}{\gamma^2} B_1 B_1^T - B_2 B_2^T \right) X, \\ 0 &= B_1^T B_1 + A^T Y + YA + Y \left( \frac{1}{\gamma^2} C_1 C_1^T - C_2 C_2^T \right) Y \end{aligned}$$

both have positive semidefinite stabilizing solutions  $X_\infty$  and  $Y_\infty$ , respectively, satisfying the spectral radius condition

$$\rho(XY) < \gamma^2.$$

8. The solution of the optimal  $H_\infty$  control problem can be obtained by a bisection method (or any other root-finding method) minimizing  $\gamma$  based on the characterization of an  $H_\infty$  suboptimal controller given in Fact 7, starting from  $\gamma_0$  for which no suboptimal  $H_\infty$  controller exists and  $\gamma_1$  for which the above conditions are satisfied.
9. The assumptions made for the state-space solution of the  $H_\infty$  control problem can mostly be relaxed.
10. The robust numerical solution of the  $H_\infty$  control problem is a topic of ongoing research — the solution via AREs may suffer from several difficulties in the presence of roundoff errors and should be avoided if possible. One way out is a reformulation of the problem using structured generalized eigenvalue problems; see [BBMX99b], [CS92] and [GL97].
11. Once a (sub-)optimal  $\gamma$  is found, it remains to determine a realization of the  $H_\infty$  controller. One possibility is the **central (minimum entropy) controller** [ZDG96]:

$$\begin{aligned} E &= A + \frac{1}{\gamma^2} B_1 B_1^T - B_2 B_2^T X_\infty - Z_\infty Y_\infty C_2^T C_2, \\ F &= Z_\infty Y_\infty C_2^T, \quad K = -B_2^T X_\infty, \quad H = 0, \end{aligned}$$

where

$$Z_\infty = \left( I - \frac{1}{\gamma^2} Y_\infty X_\infty \right)^{-1}.$$

**Examples:**

1. The cost functional in the LQR and LQG problems values the energy needed to reach the desired state by the weighting matrix  $R$  on the inputs. Thus, usually

$$R = \text{diag}(\rho_1, \dots, \rho_m).$$

The weighting on the states or outputs in the LQR or LQG problems is usually used to penalize deviations from the desired state of the system and is often also given in diagonal form. Common examples of weighting matrices are  $R = \rho I_m$ ,  $Q = \gamma I_p$  for  $\rho, \gamma > 0$ .

2. The solution to the LQR problem for the inverted pendulum with  $Q = R = 1$  is given via the stabilizing solution of the LQR ARE, which is

$$X_* = \begin{bmatrix} 2\sqrt{1+\sqrt{2}} & 1+\sqrt{2} \\ 1+\sqrt{2} & \sqrt{2}\sqrt{1+\sqrt{2}} \end{bmatrix},$$

resulting in the state feedback law

$$\mathbf{u}(t) = - \begin{bmatrix} 1+\sqrt{2} & \sqrt{2}\sqrt{1+\sqrt{2}} \end{bmatrix} \mathbf{x}(t).$$

The eigenvalues of the closed-loop system are (up to four digits)  $\sigma(A - BR^{-1}B^T X_*) = \{-1.0987 \pm 0.4551i\}$ .

3. The solution to the LQG problem for the inverted pendulum with  $Q, R$  as above and uncertainties  $\mathbf{v}, \mathbf{w}$  with  $\tilde{B} = \begin{bmatrix} 1 & 1 \end{bmatrix}^T$  is obtained by combining the LQR solution derived above with the Kalman-Bucy filter obtained as in the examples part of the previous section. Thus, we get the LQG control law

$$\mathbf{u}(t) = - \begin{bmatrix} 1+\sqrt{2} & \sqrt{2}\sqrt{1+\sqrt{2}} \end{bmatrix} \hat{\mathbf{x}}(t),$$

where  $\hat{\mathbf{x}}$  is the solution of

$$\dot{\hat{\mathbf{x}}}(t) = - \begin{bmatrix} 1+\sqrt{2} & -1 \\ 1+2\sqrt{2} & \sqrt{2}\sqrt{1+\sqrt{2}} \end{bmatrix} \hat{\mathbf{x}}(t) + (1+\sqrt{2}) \begin{bmatrix} 1 \\ 1 \end{bmatrix} \mathbf{y}(t).$$

### 58.1 Introduction

---

Fourier analysis has been employed with great success in a wide range of applications. The underlying theory is based on a small set of linear transforms on particular linear spaces. It may, in fact, be best to refer to two parallel theories of Fourier analysis—the function/functional theory and the discrete theory—according to whether these linear spaces are infinite or finite dimensional. The function/functional theory involves infinite dimensional spaces of functions on  $\mathbb{R}^n$  and can be further divided into two “subtheories”—one concerned with functions that are periodic on  $\mathbb{R}^n$  (or can be treated as periodic extensions of functions on finite subregions) and one concerned with more general functions and functionals on  $\mathbb{R}^n$ . This theory played the major role in applications up to half a century or so ago. However, the tools from the discrete theory (involving vectors in  $\mathbb{C}^N$  instead of functions on  $\mathbb{R}^n$ ) are much more easily implemented on digital computers. This became of interest both because much of the function/functional theory analysis can be closely approximated within the discrete theory and because the discrete theory is a natural setting for functions known only by samplings. In addition, “fast” algorithms for computing the discrete transforms were developed, allowing discrete analysis to be done very quickly even with very large data sets. For these reasons the discrete theory has become extremely important in modern applications, and its utility, in turn, has greatly extended the applicability of Fourier analysis.

In the first part of this chapter, elements of the function/functional theory are presented and illustrated. For expediency, attention will be restricted to functions and functionals over subsets of  $\mathbb{R}^1$ . A corresponding review of the analogous elements of the discrete theory then follows, with a discussion of the relations between the two theories following that. Finally, one of the fast algorithms is described and the extent to which this algorithm improves speed and applicability is briefly discussed.

The development here is necessarily abbreviated and covers only a small fraction of the theory and applications of Fourier analysis. The reader interested in more complete treatments of the subject is encouraged to consult the references given throughout this chapter.

## 58.2 The Function/Functional Theory

### Definitions:

The following function spaces often arise in Fourier analysis. In each case  $\mathcal{I}$  is a subinterval of  $\mathbb{R}$ , and all functions on  $\mathcal{I}$  are assumed to be complex valued.

- $\mathcal{C}^0(\mathcal{I})$ , the normed linear space of bounded and continuous functions on  $\mathcal{I}$  with the norm  $\|f\| = \sup\{|f(x)| : x \in \mathcal{I}\}$ .
- $\mathcal{L}^1(\mathcal{I})$ , the normed linear space of absolutely integrable functions on  $\mathcal{I}$  with the norm  $\|f\| = \int_{\mathcal{I}} |f(x)| dx$ .
- $\mathcal{L}^2(\mathcal{I})$ , the inner product space of square integrable functions on  $\mathcal{I}$  with the inner product  $\langle f, g \rangle = \int_{\mathcal{I}} f(x)\overline{g(x)} dx$ .

If  $\mathcal{I}$  is not specified, then  $\mathcal{I} = \mathbb{R}$ .

Let  $\phi \in \mathcal{L}^1(\mathbb{R})$ . The **Fourier transform**  $\mathcal{F}[\phi]$  and the **inverse Fourier transform**  $\mathcal{F}^{-1}[\phi]$  of  $\phi$  are the functions

$$\mathcal{F}[\phi]|_x = \int_{-\infty}^{\infty} \phi(y)e^{-i2\pi xy} dy \quad \text{and} \quad \mathcal{F}^{-1}[\phi]|_x = \int_{-\infty}^{\infty} \phi(y)e^{i2\pi xy} dy.$$

Additionally, the terms “Fourier transform” and “inverse Fourier transform” can refer to the processes for computing these functions from  $\phi$ .

A function  $\phi$  on  $\mathbb{R}$  is said to be **periodic** if there is a positive value  $p$ , called a **period** for  $\phi$ , such that

$$\phi(x + p) = \phi(x) \quad \forall x \in \mathbb{R}.$$

The smallest period, if it exists, is called the **fundamental period**.

The **Fourier series** for a suitably integrable, periodic function  $\phi$  with period  $p > 0$  is the infinite series

$$\sum_{k=-\infty}^{\infty} c_k e^{i2\pi\omega_k x}$$

where

$$\omega_k = \frac{k}{p} \quad \text{and} \quad c_k = \frac{1}{p} \int_0^p \phi(y)e^{-i2\pi\omega_k y} dy.$$

The theory for Fourier transforms and series can be generalized so that the requirement of  $\phi$  being “suitably integrable” can be greatly relaxed (see [How01, Chap. 20, 30–34] or [Str94, Chap. 1–4]). Within this generalized theory the **delta function** at  $a \in \mathbb{R}$ ,  $\delta_a$ , is the functional limit

$$\delta_a(x) = \lim_{\epsilon \rightarrow 0^+} \frac{1}{2\epsilon} \text{pulse}_{\epsilon}(x - a) \quad \text{where} \quad \text{pulse}_{\epsilon}(s) = \begin{cases} 1 & \text{if } |s| \leq \epsilon \\ 0 & \text{if } |s| > \epsilon \end{cases}.$$

That is,  $\delta_a$  is the (generalized) function such that

$$\int_{-\infty}^{\infty} \psi(x)\delta_a(x) dx = \lim_{\epsilon \rightarrow 0^+} \int_{-\infty}^{\infty} \psi(x) \frac{1}{2\epsilon} \text{pulse}_{\epsilon}(x - a) dx$$

whenever  $\psi$  is a function continuous at  $a$ .

An **array of delta functions** is any expression of the form

$$\sum_{k=-\infty}^{\infty} c_k \delta_{k\Delta x}$$

where  $\Delta x > 0$  is fixed (the **spacing** of the array) and  $c_k \in \mathbb{C}$  for each  $k \in \mathbb{Z}$ . If the array is also periodic with period  $p$ , then the corresponding **index period** is the positive integer  $N$  such that

$$p = N\Delta x \quad \text{and} \quad \phi_{k+N} = \phi_k \quad \forall k \in \mathbb{Z}.$$

The **convolution**  $\phi * \psi$  of a suitably integrable pair of functions  $\phi$  and  $\psi$  on  $\mathbb{R}$  is the function given by

$$\phi * \psi(x) = \int_{-\infty}^{\infty} \phi(x - y)\psi(y) dy.$$

**Facts:**

All the following facts except those with specific reference can be found in [How01] or [Str94].

1. Warning: Slight variations of the above integral formulas, e.g.,

$$\frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \phi(y)e^{-ixy} dy \quad \text{and} \quad \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \phi(y)e^{ixy} dy,$$

are also often used to define, respectively,  $\mathcal{F}[\phi]$  and  $\mathcal{F}^{-1}[\phi]$  (or even  $\mathcal{F}^{-1}[\phi]$  and  $\mathcal{F}[\phi]$ ). There is little difference in the resulting “Fourier theories,” but the formulas resulting from using different versions of the Fourier transforms do differ in details. Thus, when computing Fourier transforms using different tables or software, it is important to take into account the specific integral formulas on which the table or software is based.

2. Both  $\mathcal{F}$  and  $\mathcal{F}^{-1}$  are continuous, linear mappings from  $\mathcal{L}^1(\mathbb{R})$  into  $\mathcal{C}^0(\mathbb{R})$ . Moreover, if both  $\phi$  and  $\mathcal{F}[\phi]$  are absolutely integrable, then  $\mathcal{F}^{-1}[\mathcal{F}[\phi]] = \phi$ .
3. In the generalized theory (which will be assumed hereafter),  $\mathcal{F}$  and  $\mathcal{F}^{-1}$  are defined on a linear space of (generalized) functions that contains all elements of  $\mathcal{L}^1(\mathbb{R})$  and  $\mathcal{L}^2(\mathbb{R})$ , all Fourier transforms of elements of  $\mathcal{L}^1(\mathbb{R})$  and  $\mathcal{L}^2(\mathbb{R})$ , all piecewise continuous periodic functions, the delta functions, and all periodic arrays of delta functions.  $\mathcal{F}$  and  $\mathcal{F}^{-1}$  are one-to-one linear mappings from this space onto this space, and are inverses of each other.
4. Every nonconstant, piecewise continuous periodic function has a fundamental period, and every period of such a function is an integral multiple of that fundamental period. Moreover, any two Fourier series for a single periodic function computed using two different periods will be identical after simplification (e.g., after eliminating zero-valued terms).
5. The Fourier series  $\sum_{k \in \mathbb{Z}} c_k e^{i2\pi \omega_k x}$  for a periodic function  $\phi$  with period  $p$  can be written in *trigonometric form*

$$c_0 + \sum_{k=1}^{\infty} [a_k \cos(2\pi \omega_k x) + b_k \sin(2\pi \omega_k x)]$$

where

$$a_k = c_k + c_{-k} = \frac{2}{p} \int_0^p \phi(x) \cos(2\pi \omega_k x) dx$$

and

$$b_k = ic_k - ic_{-k} = \frac{2}{p} \int_0^p \phi(x) \sin(2\pi \omega_k x) dx.$$

6. On  $\mathcal{I} = (0, p)$  (or any other interval  $\mathcal{I}$  of length  $p$ ), the exponentials

$$\{e^{i2\pi \omega_k x} : \omega_k = k/p, k \in \mathbb{Z}\}$$

form an orthogonal set in  $\mathcal{L}^2(\mathcal{I})$ , and the Fourier series  $\sum_{k \in \mathbb{Z}} c_k e^{i2\pi\omega_k x}$  for a periodic function  $\phi$  with period  $p$  is simply the expansion of  $\phi$  with respect to this orthogonal set. That is,

$$c_k = \frac{\langle \phi(x), e^{i2\pi\omega_k x} \rangle}{\|e^{i2\pi\omega_k x}\|^2} \quad \forall k \in \mathbb{Z}.$$

Similar comments apply regarding the trigonometric form for the Fourier series and the set

$$\{1, \cos(2\pi\omega_k x), \sin(2\pi\omega_k x) : \omega_k = k/p, k \in \mathbb{N}\}.$$

7. A periodic function  $\phi$  can be identified with its Fourier series  $\sum_{k \in \mathbb{Z}} c_k e^{i2\pi\omega_k x}$  under a wide range of criteria. In particular:

- If  $\phi$  is smooth, then its Fourier series converges uniformly to  $\phi$ .
- If  $\phi$  is piecewise smooth, then its Fourier series converges pointwise to  $\phi$  everywhere  $\phi$  is continuous.
- If  $\phi$  is square-integrable on  $(0, p)$ , then

$$\lim_{(M,N) \rightarrow (-\infty, \infty)} \int_0^p \left| \phi(x) - \sum_{k=M}^N c_k e^{i2\pi\omega_k x} \right|^2 dx = 0.$$

- Within the generalized theory,

$$\lim_{(M,N) \rightarrow (-\infty, \infty)} \int_{-\infty}^{\infty} \psi(x) \left[ \phi(x) - \sum_{k=M}^N c_k e^{i2\pi\omega_k x} \right] dx = 0$$

whenever  $\psi$  is a sufficiently smooth function vanishing sufficiently rapidly at infinity (e.g., any Gaussian function).

8. [BH95, p. 186] Suppose  $\phi$  is a periodic function with Fourier series  $\sum_{k \in \mathbb{Z}} c_k e^{i2\pi\omega_k x}$ . If  $\phi$  is  $m$ -times differentiable on  $\mathbb{R}$  and  $\phi^{(m)}$  is piecewise continuous for some  $m \in \mathbb{N}$ , then there is a finite constant  $\beta$  such that

$$|c_k| \leq \frac{\beta}{|k|^m} \quad \forall k \in \mathbb{Z}.$$

9. For each  $a \in \mathbb{R}$  and function  $\phi$  continuous at  $a$ :

$$\int_{-\infty}^{\infty} \phi(x) \delta_a(x) dx = \phi(a) \quad \text{and} \quad \phi \delta_a = \phi(a) \delta_a.$$

10. For each  $a \in \mathbb{R}$ :

- $\mathcal{F}[\delta_a]|_x = e^{-i2\pi ax}$  and  $\mathcal{F}^{-1}[e^{-i2\pi ax}] = \delta_a$ .
- $\mathcal{F}[e^{i2\pi ax}]|_x = \delta_a$  and  $\mathcal{F}^{-1}[\delta_a]|_x = e^{i2\pi ax}$ .

11. A function  $\phi$  is periodic with period  $p$  and Fourier series  $\sum_{k \in \mathbb{Z}} c_k e^{i2\pi\omega_k x}$  if and only if its transforms are the arrays

$$\mathcal{F}[\phi] = \sum_{k=-\infty}^{\infty} c_k \delta_{k\Delta\omega} \quad \text{and} \quad \mathcal{F}^{-1}[\phi] = \sum_{k=-\infty}^{\infty} c_{-k} \delta_{k\Delta\omega}$$

with spacing  $\Delta\omega = 1/p$ .

12. If

$$\phi = \sum_{k=-\infty}^{\infty} \phi_k \delta_{k\Delta x}$$

is a periodic array with spacing  $\Delta x$ , period  $p$ , and corresponding index period  $N$ , then:

- The Fourier series for  $\phi$  is given by

$$\sum_{n=-\infty}^{\infty} \Phi_n e^{i2\pi\omega_n x}$$

where  $\omega_n = n/p = n/(N\Delta x)$  and

$$\Phi_n = \frac{1}{N\Delta x} \sum_{k=0}^{N-1} \phi_k e^{-i2\pi kn/N}.$$

- The Fourier transforms of  $\phi$  are also periodic arrays of delta functions with index period  $N$ . Both have spacing  $\Delta\omega = 1/p$  and period  $P = 1/\Delta x$ . These transforms are given by

$$\mathcal{F}[\phi] = \sum_{n=-\infty}^{\infty} \Phi_n \delta_{n\Delta\omega} \quad \text{and} \quad \mathcal{F}^{-1}[\phi] = \sum_{n=-\infty}^{\infty} \Phi_{-n} \delta_{n\Delta\omega}.$$

13. (*Convolution identities*) Let  $f, F, g,$  and  $G$  be functions with  $F = \mathcal{F}[f]$  and  $G = \mathcal{F}[g]$ . Then, provided the convolutions exist,

$$\mathcal{F}[fg] = F * G \quad \text{and} \quad \mathcal{F}[f * g] = FG.$$

**Examples:**

1. For  $\alpha > 0,$

$$\begin{aligned} \mathcal{F}[\text{pulse}_\alpha] |_{x} &= \int_{-\infty}^{\infty} \text{pulse}_\alpha(y) e^{-i2\pi xy} dy \\ &= \int_{-\alpha}^{\alpha} e^{-i2\pi xy} dy \\ &= \frac{e^{i2\pi\alpha x} - e^{-i2\pi\alpha x}}{i2\pi x} = \frac{\sin(2\pi\alpha x)}{\pi x}. \end{aligned}$$

2. Let  $f$  be the periodic function,

$$f(x) = \begin{cases} |x| & \text{for } -1 \leq x < 1 \\ f(x - 2) & \text{for all } x \in \mathbb{R} \end{cases}.$$

The period of this function is  $p = 2,$  and its Fourier series  $\sum_{k \in \mathbb{Z}} c_k e^{i2\pi\omega_k x}$  is given by

$$\omega_k = \frac{k}{2} \quad (\text{so } e^{i2\pi\omega_k x} = e^{i\pi kx})$$

and

$$\begin{aligned} c_k &= \frac{1}{2} \int_0^2 \begin{cases} |x| & \text{if } x < 1 \\ |x - 2| & \text{if } 1 < x \end{cases} e^{-i\pi kx} dx \\ &= \begin{cases} 1/2 & \text{if } k = 0 \\ (k\pi)^{-2} [(-1)^k - 1] & \text{if } k \neq 0 \end{cases}. \end{aligned}$$

Since  $f$  is continuous and piecewise smooth,  $f$  equals its Fourier series,

$$f(x) = \frac{1}{2} + \sum_{k \in \mathbb{Z} \setminus \{0\}} \frac{(-1)^k - 1}{k^2 \pi^2} e^{i\pi k x} \quad \forall x \in \mathbb{R}.$$

Moreover,

$$\mathcal{F}[f] = \frac{1}{2} \delta_0 + \sum_{k \in \mathbb{Z} \setminus \{0\}} \frac{(-1)^k - 1}{k^2 \pi^2} \delta_{k/2}.$$

3. Let

$$\phi = \sum_{k=-\infty}^{\infty} \phi_k \delta_{\Delta x}$$

be the periodic array with spacing  $\Delta x = 1/3$ , index period  $N = 4$ , and coefficients

$$\phi_0 = 0, \quad \phi_1 = 1, \quad \phi_2 = 2, \quad \text{and} \quad \phi_3 = 1.$$

The period  $p$  of  $\phi$  is then

$$p = N \Delta x = 4 \cdot \frac{1}{3} = \frac{4}{3}.$$

Its Fourier transform  $\Phi = \mathcal{F}[\phi]$  is also a periodic array,

$$\Phi = \sum_{n=-\infty}^{\infty} \Phi_n \delta_{n \Delta \omega},$$

with index period  $N = 4$ . The spacing  $\Delta \omega$  and period  $P$  of  $\Phi$  are determined, respectively, from the period  $p$  and spacing  $\Delta x$  of  $\phi$  by

$$\Delta \omega = \frac{1}{p} = \frac{1}{4/3} = \frac{3}{4} \quad \text{and} \quad P = \frac{1}{\Delta x} = \frac{1}{1/3} = 3.$$

The coefficients are given by

$$\begin{aligned} \Phi_n &= \frac{1}{N \Delta x} \sum_{k=0}^{N-1} \phi_k e^{-i2\pi kn/N} \\ &= \frac{1}{N \Delta x} [\phi_0 e^{-i2\pi 0n/4} + \phi_1 e^{-i2\pi 1n/4} + \phi_2 e^{-i2\pi 2n/4} + \phi_3 e^{-i2\pi 3n/4}] \\ &= \frac{1}{4(1/3)} [0e^0 + 1e^{-in\pi/2} + 2e^{-in\pi} + 1e^{-i3n\pi/2}] \\ &= \frac{3}{4} [0 + (-i)^n + 2 + i^n]. \end{aligned}$$

Thus,

$$\Phi_0 = 3, \quad \Phi_1 = \frac{3}{2}, \quad \Phi_2 = 0 \quad \text{and} \quad \Phi_3 = \frac{3}{2}.$$

**Applications:**

- [BC01, p. 155] or [Col88, pp. 159–160] (*Partial differential equations*) Using polar coordinates, the steady-state temperature  $u$  at position  $(r, \theta)$  on a uniform, insulated disk of radius 1 satisfies

$$r^2 \frac{\partial^2 u}{\partial r^2} + r \frac{\partial u}{\partial r} + \frac{\partial^2 u}{\partial \theta^2} = 0 \quad \text{for } 0 < r < 1.$$

As a function of  $\theta$ ,  $u$  is periodic with period  $2\pi$  and has (equivalent) Fourier series

$$\sum_{k=-\infty}^{\infty} c_k e^{ikx} \quad \text{and} \quad c_0 + \sum_{k=1}^{\infty} [a_k \cos(kx) + b_k \sin(kx)]$$

where the coefficients are functions of  $r$ . If  $u$  satisfies the boundary condition

$$u(1, \theta) = f(\theta) \quad \text{for } 0 \leq \theta < 2\pi$$

for some function  $f$  on  $[0, 2\pi)$ , then the coefficients in the series can be determined, yielding

$$u(r, \theta) = \sum_{k=-\infty}^{\infty} r^k \gamma_k e^{ik\theta} = \gamma_0 + \sum_{k=1}^{\infty} [r^k \alpha_k \cos(k\theta) + r^k \beta_k \sin(k\theta)]$$

where

$$\gamma_k = \frac{1}{2\pi} \int_0^{2\pi} f(\theta) e^{-ik\theta} d\theta,$$

$$\alpha_k = \frac{1}{\pi} \int_0^{2\pi} f(\theta) \cos(k\theta) d\theta, \quad \text{and} \quad \beta_k = \frac{1}{\pi} \int_0^{2\pi} f(\theta) \sin(k\theta) d\theta.$$

- (*Systems analysis*) In systems analysis, a “system”  $S$  transforms any “input” function  $f_I$  to a corresponding “output” function  $f_O = S[f_I]$ . Often, the output of  $S$  can be described by the convolution formula

$$f_O = h * f_I$$

where  $h$  is some fixed function called the impulse response of the system. The corresponding Fourier transform  $H = \mathcal{F}[h]$  is the system’s transfer function. By the convolution identity, the output is also given by

$$f_O = \mathcal{F}^{-1}[HF_I] \quad \text{where } F_I = \mathcal{F}[f_I].$$

Two such systems are

- A delayed output system, for which

$$h(x) = \delta_T(x) \quad \text{and} \quad H(\omega) = e^{-i2\pi T\omega}$$

for some  $T > 0$ . Then

$$f_O(x) = f_I * \delta_T(x) = \int_{-\infty}^{\infty} f_I(x - y) \delta_T(y) dy = f_I(x - T).$$

- [ZTF98, p. 178] or [How01, p. 477] An ideal low pass filter, for which

$$h(x) = \frac{\sin(2\pi \Omega x)}{\pi x} \quad \text{and} \quad H(y) = \text{pulse}_{\Omega}(y)$$

for some  $\Omega > 0$ . If an input function  $f_I$  is periodic with Fourier series  $\sum_{k \in \mathbb{Z}} c_k e^{i2\pi\omega_k x}$ , then

$$\begin{aligned} HF_I &= \text{pulse}_\Omega \cdot \sum_{k=-\infty}^{\infty} c_k \delta_{\omega_k} \\ &= \sum_{k=-\infty}^{\infty} c_k \text{pulse}_\Omega(\omega_k) \delta_{\omega_k} \\ &= \sum_{k=-\infty}^{\infty} c_k \begin{cases} 1 & \text{if } |\omega_k| \leq \Omega \\ 0 & \text{if } |\omega_k| > \Omega \end{cases} \delta_{\omega_k} = \sum_{|\omega_k| \leq \Omega} c_k \delta_{\omega_k}. \end{aligned}$$

Thus,

$$f_O(x) = \mathcal{F}^{-1}[HF_I]|_x = \mathcal{F}^{-1} \left[ \sum_{|\omega_k| \leq \Omega} c_k \delta_{\omega_k} \right] \Big|_x = \sum_{|\omega_k| \leq \Omega} c_k e^{i2\pi\omega_k x}.$$

3. [ZTF98, pp. 520–521] (*Deconvolution*) Suppose  $S$  is a system given by

$$S[f_I] = h * f_I,$$

but with  $h$  and  $H = \mathcal{F}[h]$  being unknown. Since

$$f_O = \mathcal{F}^{-1}[HF_I] \quad \text{where } F_I = \mathcal{F}[f_I],$$

both  $h$  and  $H$  can be determined as follows:

- Find the output  $f_O = S[f_I]$  for some known input  $f_I$  for which  $F_I = \mathcal{F}[f_I]$  is never zero.
- Compute

$$H = \frac{F_O}{F_I} \quad \text{where } F_O = \mathcal{F}[f_O].$$

- Compute  $h = \mathcal{F}^{-1}[H]$ .

Similarly, an input  $f_I$  can be reconstructed from an output  $f_O$  by

$$f_I = \mathcal{F}^{-1} \left[ \frac{F_O}{H} \right]$$

provided the transfer function  $H$  is known and is never zero.

## 58.3 The Discrete Theory

---

### Definitions:

In all the following,  $N \in \mathbb{N}$ , and the indexing of any “ $N$  items” (including rows and columns of matrices) will run from 0 to  $N - 1$ .

An  $N$ th **order sequence** is an ordered list of  $N$  complex numbers,

$$(c_0, c_1, c_2, \dots, c_{N-1}).$$

Such a sequence will often be written as the column vector

$$\mathbf{c} = [c_0, c_1, c_2, \dots, c_{N-1}]^T,$$

and the  $k$ th component of the sequence will be denoted by either  $c_k$  or  $[\mathbf{c}]_k$ . In addition, any such sequence will be viewed as part of an infinite repeating sequence

$$(\dots, c_{-1}, c_0, c_1, c_2, \dots, c_{N-1}, c_N, \dots)$$

in which  $c_{N+k} = c_k$  for all  $k \in \mathbb{Z}$ .

Let  $\mathbf{c}$  be an  $N$ th order sequence. The ( $N$ th order) **discrete Fourier transform (DFT)**  $\widehat{\mathcal{F}}_N \mathbf{c}$  and the ( $N$ th order) **inverse discrete Fourier transform (inverse DFT)**  $\widehat{\mathcal{F}}_N^{-1} \mathbf{c}$  of  $\mathbf{c}$  are the two  $N$ th order sequences given by

$$[\widehat{\mathcal{F}}_N \mathbf{c}]_n = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} c_k e^{-i2\pi kn/N} \quad \text{and} \quad [\widehat{\mathcal{F}}_N^{-1} \mathbf{c}]_k = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} c_n e^{i2\pi nk/N}.$$

Additionally, the terms “discrete Fourier transform” and “inverse discrete Fourier transform” can refer to the processes for computing these sequences from  $\mathbf{c}$ .

Given two  $N$ th order sequences  $\mathbf{a}$  and  $\mathbf{b}$ , the corresponding product  $\mathbf{a}\mathbf{b}$  and convolution  $\mathbf{a} * \mathbf{b}$  are the  $N$ th order sequences given by

$$[\mathbf{a}\mathbf{b}]_k = a_k b_k \quad \text{and} \quad [\mathbf{a} * \mathbf{b}]_k = \frac{1}{\sqrt{N}} \sum_{j=0}^{N-1} a_{k-j} b_j.$$

**Facts:**

All the following facts can be found in [BH95, Chap. 2, 3] or [How01, Chap. 38, 39].

1. Warning: Slight variations of the above summation formulas, e.g.,

$$\sum_{k=0}^{N-1} c_k e^{-i2\pi kn/N} \quad \text{and} \quad \frac{1}{N} \sum_{n=0}^{N-1} c_n e^{i2\pi nk/N},$$

are also often used to define, respectively,  $\widehat{\mathcal{F}}_N \mathbf{c}$  and  $\widehat{\mathcal{F}}_N^{-1} \mathbf{c}$  (or even  $\widehat{\mathcal{F}}_N^{-1} \mathbf{c}$  and  $\widehat{\mathcal{F}}_N \mathbf{c}$ ).

2.  $\widehat{\mathcal{F}}_N$  and  $\widehat{\mathcal{F}}_N^{-1}$  are one-to-one linear transformations from  $\mathbb{C}^N$  onto  $\mathbb{C}^N$ . They preserve the standard inner product and are inverses of each other.
3. Letting  $w = e^{-i2\pi/N}$ , the matrices (with respect to the standard basis for  $\mathbb{C}^N$ ) for the  $N$ th order discrete Fourier transforms (also denoted by  $\widehat{\mathcal{F}}_N$  and  $\widehat{\mathcal{F}}_N^{-1}$ ) are

$$\widehat{\mathcal{F}}_N = \frac{1}{\sqrt{N}} \begin{bmatrix} 1 & 1 & 1 & 1 & \dots & 1 \\ 1 & w^{1 \cdot 1} & w^{1 \cdot 2} & w^{1 \cdot 3} & \dots & w^{1 \cdot (N-1)} \\ 1 & w^{2 \cdot 1} & w^{2 \cdot 2} & w^{2 \cdot 3} & \dots & w^{2 \cdot (N-1)} \\ 1 & w^{3 \cdot 1} & w^{3 \cdot 2} & w^{3 \cdot 3} & \dots & w^{3 \cdot (N-1)} \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & w^{(N-1)1} & w^{(N-1)2} & w^{(N-1)3} & \dots & w^{(N-1)(N-1)} \end{bmatrix}$$

and

$$\widehat{\mathcal{F}}_N^{-1} = \frac{1}{\sqrt{N}} \begin{bmatrix} 1 & 1 & 1 & 1 & \cdots & 1 \\ 1 & w^{-1 \cdot 1} & w^{-1 \cdot 2} & w^{-1 \cdot 3} & \cdots & w^{-1(N-1)} \\ 1 & w^{-2 \cdot 1} & w^{-2 \cdot 2} & w^{-2 \cdot 3} & \cdots & w^{-2(N-1)} \\ 1 & w^{-3 \cdot 1} & w^{-3 \cdot 2} & w^{-3 \cdot 3} & \cdots & w^{-3(N-1)} \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & w^{-(N-1)1} & w^{-(N-1)2} & w^{-(N-1)3} & \cdots & w^{-(N-1)(N-1)} \end{bmatrix}.$$

4.  $\widehat{\mathcal{F}}_N$  and  $\widehat{\mathcal{F}}_N^{-1}$  are symmetric matrices, and are complex conjugates of each other (i.e.,  $[\widehat{\mathcal{F}}_N]^* = \widehat{\mathcal{F}}_N^{-1}$ ).
5. (*Convolution identities*) Let  $\mathbf{v}$ ,  $\mathbf{V}$ ,  $\mathbf{w}$ , and  $\mathbf{W}$  be  $N$ th order sequences with  $\mathbf{V} = \widehat{\mathcal{F}}_N \mathbf{v}$  and  $\mathbf{W} = \widehat{\mathcal{F}}_N \mathbf{w}$ . Then

$$\widehat{\mathcal{F}}_N[\mathbf{vw}] = \mathbf{V} * \mathbf{W} \quad \text{and} \quad \widehat{\mathcal{F}}_N[\mathbf{v} * \mathbf{w}] = \mathbf{V}\mathbf{W}.$$

### Examples:

1. The matrices for the four lowest order DFTs are  $\widehat{\mathcal{F}}_1 = [1]$ ,

$$\widehat{\mathcal{F}}_2 = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}, \quad \widehat{\mathcal{F}}_3 = \frac{1}{2\sqrt{3}} \begin{bmatrix} 2 & 2 & 2 \\ 2 & -1 - \sqrt{3} & -1 + \sqrt{3} \\ 2 & -1 + \sqrt{3} & -1 - \sqrt{3} \end{bmatrix},$$

and

$$\widehat{\mathcal{F}}_4 = \frac{1}{2} \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & -i & 1 & i \\ 1 & -1 & 1 & -1 \\ 1 & i & -1 & -i \end{bmatrix}.$$

2. The DFT of  $\mathbf{v} = [1, 2, 3, 4]^T$  is  $\mathbf{V} = [V_0, V_1, V_2, V_3]^T$  where

$$\begin{bmatrix} V_0 \\ V_1 \\ V_2 \\ V_3 \end{bmatrix} = \frac{1}{2} \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & -i & 1 & i \\ 1 & -1 & 1 & -1 \\ 1 & i & -1 & -i \end{bmatrix} \begin{bmatrix} 1 \\ 2 \\ 3 \\ 4 \end{bmatrix} = \begin{bmatrix} 5 \\ 2 + i \\ -1 \\ -1 - i \end{bmatrix}.$$

### Applications:

1. [CG00, p. 153] Assume

$$f(z) = \sum_{n=0}^{2M} f_n z^n$$

is the product of two known  $M$ th order polynomials

$$g(z) = \sum_{k=0}^M g_k z^k \quad \text{and} \quad h(z) = \sum_{k=0}^M h_k z^k.$$

The coefficients of  $f$  form a sequence  $\mathbf{f} = [f_0, f_1, f_2, \dots, f_{2M}]^T$  of order  $N = 2M + 1$ . These coefficients can be computed from the coefficients of  $g$  and  $h$  using either of the following approaches:

- Let  $\mathbf{g} = [g_0, g_1, g_2, \dots, g_{2M}]^T$  and  $\mathbf{h} = [h_0, h_1, h_2, \dots, h_{2M}]^T$  be the  $N$ th order sequences in which  $g_k$  and  $h_k$  are the corresponding coefficients of the polynomials  $g$  and  $h$  when  $k \leq M$  and are zero when  $M < k \leq N$ . The coefficients of  $f$  can then be computed by

$$f_k = \sum_{j=0}^{2M} g_{k-j} h_j = \sqrt{N} [\mathbf{g} * \mathbf{h}]_k \quad \text{for } k = 0, 1, 2, \dots, 2M.$$

- Let  $\mathbf{F} = [F_0, F_1, F_2, \dots, F_{2M}]^T$  be the  $N$ th order DFT of  $\mathbf{f}$ , and note that, for  $n = 0, 1, 2, \dots, N - 1$ ,

$$F_n = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} f_k e^{-i2\pi kn/N} = \frac{1}{\sqrt{N}} f(w^n) = \frac{1}{\sqrt{N}} h(w^n)g(w^n)$$

where  $w = e^{-i2\pi/N}$ . Thus, the coefficients of  $f$  can be computed by first using the formulas for  $g$  and  $h$  to compute

$$F_n = \frac{1}{\sqrt{N}} h(w^n)g(w^n) \quad \text{for } n = 0, 1, 2, \dots, N - 1,$$

and then taking the inverse DFT of  $\mathbf{F} = [F_0, F_1, F_2, \dots, F_{N-1}]^T$ .

2. [BH95, p.247] Consider finding the solution  $\mathbf{v} = [v_0, v_1, v_2, \dots, v_{N-1}]^T$  to the difference equation

$$\alpha v_{k-1} + \beta v_k + \alpha v_{k+1} = f_k \quad \text{for } n = 0, 1, 2, \dots, N - 1$$

where  $\alpha$  and  $\beta$  are constants and  $\mathbf{f} = [f_0, f_1, f_2, \dots, f_{N-1}]^T$  is a known  $N$ th order sequence. If the boundary conditions are periodic (i.e.,  $v_0 = v_N$  and  $v_{-1} = v_{N-1}$ ), then setting

$$\mathbf{v} = \widehat{\mathcal{F}}_N^{-1} \mathbf{V} \quad \text{and} \quad \mathbf{f} = \widehat{\mathcal{F}}_N^{-1} \mathbf{F}$$

yields the sequence  $\mathbf{v}$  that satisfies the periodic boundary conditions, and whose DFT,  $\mathbf{V}$ , satisfies

$$\sum_{n=0}^{N-1} C_n e^{i2\pi nk/N} = 0 \quad \text{for } k = 0, 1, 2, \dots, N - 1$$

where

$$C_n = \left[ 2\alpha \cos\left(\frac{2\pi n}{N}\right) + \beta \right] V_n - F_n.$$

From this, it follows that the solution  $\mathbf{v}$  to the original difference equation is the DFT of the sequence  $[V_0, V_1, V_2, \dots, V_{N-1}]^T$  given by

$$V_n = \frac{F_n}{2\alpha \cos\left(\frac{2\pi n}{N}\right) + \beta},$$

provided the denominator never vanishes.

3. A difference equation of the form just considered with periodic boundary conditions arises when considering the steady-state temperature distribution on a uniform ring containing heat sources and sinks. In this case, the temperature  $v$ , as a function of angular position  $\theta$ , is modeled by the

one-dimensional Poisson's equation

$$\frac{d^2v}{d\theta^2} = f(\theta),$$

where  $f(\theta)$  describes the heat source/sink density at angular position  $\theta$ . The discrete analog of this equation is

$$v_{k-1} - 2v_k + v_{k+1} = f_k \quad \text{for } n = 0, 1, 2, \dots, N-1$$

where

$$\mathbf{v} = [v_0, v_1, v_2, \dots, v_{N-1}]^T \quad \text{and} \quad \mathbf{f} = [f_0, f_1, f_2, \dots, f_{N-1}]^T$$

describe, respectively, the temperatures at  $N$  evenly space positions around the ring, and the net sources and sinks of thermal energy about these positions. Setting

$$\mathbf{v} = \widehat{\mathcal{F}}_N^{-1} \mathbf{V} \quad \text{and} \quad \mathbf{f} = \widehat{\mathcal{F}}_N^{-1} \mathbf{F}$$

and applying the formulas given above yields

$$\left[ 2 \cos \left( \frac{2\pi n}{N} \right) - 2 \right] V_n = F_n \quad \text{for } n = 0, 1, 2, \dots, N-1.$$

The coefficient on the left is nonzero when  $n \neq 0$ . Thus,

$$V_n = \frac{F_n}{2 \cos \left( \frac{2\pi n}{N} \right) - 2} \quad \text{for } n = 1, 2, \dots, N-1.$$

However, for  $n = 0$ ,

$$0 \cdot V_0 = F_0 = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} f_k e^{-i2\pi k \cdot 0/N} = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} f_k,$$

pointing out that, for an equilibrium temperature distribution to exist, the net applied heat energy,  $\sum_{k=0}^{N-1} f_k$ , must be zero. Assuming this, the last equation then implies that  $V_0$  is arbitrary, which, since

$$V_0 = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} v_k e^{-i2\pi k \cdot 0/N} = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} v_k$$

means that the given conditions are not sufficient to determine the average temperature throughout the ring.

## 58.4 Relating the Functional and Discrete Theories

### Definitions:

Let  $f$  be a (continuous) function on a finite interval  $[0, L]$ . For any  $N \in \mathbb{N}$  and  $\Delta x > 0$  satisfying  $N\Delta x \leq L$ , the corresponding ( **$N$ th order**) **sampling** (with **spacing**  $\Delta x$ ) is the sequence

$$\mathbf{f} = [f_0, f_1, f_2, \dots, f_{N-1}]^T \quad \text{where } f_k = f(k\Delta x).$$

Corresponding to this is the **scaled sampling**

$$\widehat{\mathbf{f}} = [\widehat{f}_0, \widehat{f}_1, \widehat{f}_2, \dots, \widehat{f}_{N-1}]^T$$

and the **discrete approximation**

$$\widehat{f} = \sum_{k=-\infty}^{\infty} \widehat{f}_k \delta_{k\Delta x}$$

where, in both,

$$\widehat{f}_k = \begin{cases} f_k \Delta x & \text{for } k = 0, 1, 2, \dots, N-1 \\ \widehat{f}_{k+N} & \text{in general} \end{cases}.$$

**Facts:**

- [How01, pp. 713–715] Let  $\widehat{f}$  be the discrete approximation of a continuous function  $f$  based on an  $N$ th order sampling with spacing  $\Delta x$ . Then  $\widehat{f}$  is a periodic array of delta functions with spacing  $\Delta x$  and index period  $N$  that approximates  $f$  over the interval  $(0, N\Delta x)$ . In particular, for any other function  $\psi$  which is continuous on  $[0, N\Delta x]$ ,

$$\int_0^{N\Delta x} \psi(x) f(x) dx \approx \int_0^{N\Delta x} \psi(x) \widehat{f}(x) dx = \sum_{k=0}^{N-1} \psi(k\Delta x) \widehat{f}_k.$$

Attempting to approximate  $f$  with  $\widehat{f}$  outside the interval  $(0, N\Delta x)$ , however, cannot be justified unless  $f$  is also periodic with period  $N\Delta x$ .

- [How01, chap. 38] Let

$$\mathbf{f} = [f_0, f_1, f_2, \dots, f_{N-1}]^T \quad \text{and} \quad \mathbf{F} = [F_0, F_1, F_2, \dots, F_{N-1}]^T$$

be two  $N$ th order sequences, and let

$$f = \sum_{k=-\infty}^{\infty} f_k \delta_{k\Delta x} \quad \text{and} \quad F = \sum_{n=-\infty}^{\infty} F_n \delta_{n\Delta\omega}$$

be two corresponding periodic arrays of delta functions with index period  $N$ , and with spacings  $\Delta x$  and  $\Delta\omega$  satisfying  $\Delta x \Delta\omega = 1/N$ . Then

$$F = \mathcal{F}[f] \iff \mathbf{F} = \Delta\omega \sqrt{N} \widehat{\mathcal{F}}_N \mathbf{f}.$$

In particular, if  $\Delta\omega = \Delta x = N^{-1/2}$ , then

$$F = \mathcal{F}[f] \iff \mathbf{F} = \widehat{\mathcal{F}}_N \mathbf{f}.$$

- [How01, pp. 719–723] Suppose  $f$  is a continuous, piecewise smooth function that vanishes outside the finite interval  $(0, L)$ . Let  $F = \mathcal{F}[f]$ , and let  $\mathbf{f}$  be the  $N$ th order scaled sampling of  $f$  with spacing  $\Delta x$  chosen so that  $L = (N-1)\Delta x$ . Then, for each  $n \in \mathbb{Z}$ ,

$$F(n\Delta\omega) \approx \sqrt{N} [\widehat{\mathcal{F}}_N \mathbf{f}]_n$$

where  $\Delta\omega = (N\Delta x)^{-1}$ . The error in this approximation is bounded by

$$(\max |f'| + 2\pi |n| \Delta\omega \max |f|) \frac{L^2 N}{2(N-1)^2}.$$

In practice, this bound may significantly overestimate the actual error.

4. [BH95, pp. 181–188] If  $f$  is a continuous, piecewise smooth, periodic function with period  $p$  and Fourier series  $\sum_{n \in \mathbb{Z}} c_n e^{i2\pi\omega_n x}$ , then

$$c_n \approx \frac{1}{\sqrt{N}} [\widehat{\mathcal{F}}_N \mathbf{f}]_n \quad \text{for } -\frac{N}{2} < n \leq \frac{N}{2}$$

where  $\mathbf{f}$  is the  $N$ th order sampling of  $f$  over  $[0, p]$  with spacing  $\Delta x = p/N$ . Moreover, if  $f$  is  $m$ -times differentiable on  $\mathbb{R}$  and  $f^{(m)}$  is piecewise continuous and piecewise monotone for some  $m \in \mathbb{N}$ , then the error in this approximation is bounded by

$$\frac{\beta}{N^{m+1}}$$

for some positive constant  $\beta$  independent of  $n$  and  $N$ .

### Examples:

1. Let

$$f = \sum_{k=-\infty}^{\infty} f_k \delta_{k/3}$$

be the periodic array with index period  $N = 4$  and coefficients

$$f_0 = 0, \quad f_1 = 1, \quad f_2 = 2, \quad \text{and} \quad f_3 = 1.$$

The Fourier transform of  $f$  is then the periodic array

$$F = \sum_{n=-\infty}^{\infty} F_n \delta_{n\Delta\omega}$$

with index period 4, spacing  $\Delta\omega = 3/4$ , and coefficients given by

$$\begin{bmatrix} F_0 \\ F_1 \\ F_2 \\ F_3 \end{bmatrix} = \Delta\omega \sqrt{4} \widehat{\mathcal{F}}_4 \mathbf{f} = \frac{3}{4} \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & -i & 1 & i \\ 1 & -1 & 1 & -1 \\ 1 & i & -1 & -i \end{bmatrix} \begin{bmatrix} 0 \\ 1 \\ 2 \\ 1 \end{bmatrix} = \frac{1}{2} \begin{bmatrix} 6 \\ 3 \\ 0 \\ -3 \end{bmatrix}.$$

2. The 8th order sampling with spacing  $\Delta x = 1/6$  of

$$f(x) = \begin{cases} x & \text{for } 0 \leq x \leq 1/2 \\ 1 - x & \text{for } 1/2 \leq x \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

is  $\mathbf{f} = [f_0, f_1, f_2, \dots, f_7]^T$  with

$$f_k = f\left(\frac{k}{6}\right) = \begin{cases} k/6 & \text{for } k = 0, 1, 2, 3 \\ 1 - k/6 & \text{for } k = 4, 5, 6 \\ 0 & \text{for } k = 7 \end{cases}.$$

That is,

$$\mathbf{f} = \left[ 0, \frac{1}{6}, \frac{2}{6}, \frac{3}{6}, \frac{2}{6}, \frac{1}{6}, 0, 0 \right]^T.$$

Multiplying this by the spacing  $\Delta x = 1/6$  yields the scaled sampling

$$\widehat{\mathbf{f}} = \left[ 0, \frac{1}{36}, \frac{2}{36}, \frac{3}{36}, \frac{2}{36}, \frac{1}{36}, 0, 0 \right]^T.$$

Letting  $F = \mathcal{F}[f]$ ,  $\Delta\omega = (N\Delta x)^{-1} = 3/4$ , and  $w = e^{-i2\pi/8}$ ,

$$\begin{aligned} F(n\Delta\omega) &\approx \sqrt{8} [\widehat{\mathcal{F}}_8 \widehat{\mathbf{f}}]_n \\ &= \frac{1}{36} [0w^{0n} + 1w^{1n} + 2w^{2n} + 3w^{3n} + 2w^{4n} + 1w^{5n} + 0w^{6n} + 0w^{7n}] \\ &= \frac{1}{36} w^{3n} [w^{-2n} + 2w^{-n} + 3 + 2w^n + w^{2n}], \end{aligned}$$

which simplifies to

$$F(n\Delta\omega) \approx \sqrt{8} [\widehat{\mathcal{F}}_8 \widehat{\mathbf{f}}]_n = \frac{1}{36} e^{-i3n\pi/4} \left[ 3 + 2 \cos\left(\frac{n\pi}{2}\right) + 4 \cos\left(\frac{n\pi}{4}\right) \right].$$

The error bound on this approximation is

$$E_n = (\max |f'| + 2\pi |n| \Delta\omega \max |f|) \frac{L^2 N}{2(N-1)^2} = \frac{4 + 3\pi |n|}{36}.$$

In fact, the Fourier transform of  $f$  is easily found to be

$$F(\omega) = e^{-i\pi\omega} \left[ \frac{\sin(\pi\omega/2)}{\pi\omega} \right]^2.$$

So

$$F(n\Delta\omega) = F\left(\frac{3n}{4}\right) = e^{-i3n\pi/4} \left[ \frac{4 \sin(3n\pi/8)}{3n\pi} \right]^2,$$

and the actual error in the approximation is

$$\begin{aligned} \varepsilon_n &= \left| F(n\Delta\omega) - \sqrt{8} [\widehat{\mathcal{F}}_8 \widehat{\mathbf{f}}]_n \right| \\ &= \frac{1}{36} \left| 64 \left[ \frac{\sin(n\pi/8)}{n\pi} \right]^2 - 3 - 2 \cos\left(\frac{n\pi}{2}\right) - 4 \cos\left(\frac{n\pi}{4}\right) \right|. \end{aligned}$$

For  $n = 0$  through 4, the actual and approximate values of  $F(n\Delta\omega)$  (to five decimal places) are

$F(0\Delta\omega) = 0.25000$	$\sqrt{8} [\widehat{\mathcal{F}}_8 \widehat{\mathbf{f}}]_0 = 0.25000$
$F(1\Delta\omega) = -0.10872(1+i)$	$\sqrt{8} [\widehat{\mathcal{F}}_8 \widehat{\mathbf{f}}]_1 = -0.11448(1+i)$
$F(2\Delta\omega) = 0.02252i$	$\sqrt{8} [\widehat{\mathcal{F}}_8 \widehat{\mathbf{f}}]_2 = 0.02778i$
$F(3\Delta\omega) = 0.00207(1-i)$	$\sqrt{8} [\widehat{\mathcal{F}}_8 \widehat{\mathbf{f}}]_3 = 0.00337(1-i)$
$F(4\Delta\omega) = -0.01126$	$\sqrt{8} [\widehat{\mathcal{F}}_8 \widehat{\mathbf{f}}]_4 = -0.02778$

The corresponding error bounds and actual errors (to five decimal places) are

$$\begin{aligned} E_0 &= 0.11111 & \varepsilon_0 &= 0.00000 \\ E_1 &= 0.37291 & \varepsilon_1 &= 0.00815 \\ E_2 &= 0.63471 & \varepsilon_2 &= 0.00526 \\ E_3 &= 0.89651 & \varepsilon_3 &= 0.00183 \\ E_4 &= 1.15831 & \varepsilon_4 &= 0.01652. \end{aligned}$$

### Applications:

- Let  $f$  be a continuous, piecewise smooth function to be sampled that is nonzero only in the interval  $(0, 1)$  and which satisfies

$$|f(x)| \leq \frac{1}{4} \quad \text{and} \quad |f'(x)| \leq 1 \quad \forall x \in \mathbb{R}.$$

Consider the problem of approximating  $F(n\Delta\omega)$  where  $F = \mathcal{F}[f]$ ,  $\Delta\omega = 1/2$ , and  $n$  is any integer from 0 to 10. For each  $N \in \mathbb{N}$ , set

$$\Delta x = \frac{1}{N\Delta\omega} = \frac{2}{N} \quad \text{and} \quad L = (N-1)\Delta x = \frac{2(N-1)}{N},$$

and let  $\hat{\mathbf{f}} = [\hat{f}_0, \hat{f}_1, \hat{f}_2, \dots, \hat{f}_{N-1}]^T$  be the corresponding scaled sampling of  $f$ ,

$$\hat{f}_k = f(k\Delta x)\Delta x = f\left(\frac{2k}{N}\right) \cdot \frac{2}{N}.$$

Then, for  $n = 0, 1, 2, \dots, 10$ ,

$$F(n\Delta\omega) \approx \sqrt{N} [\hat{\mathcal{F}}_N \hat{\mathbf{f}}]_n = \frac{2}{N} \sum_{k=0}^{N-1} f\left(\frac{2k}{N}\right) e^{-i2\pi kn/N}$$

with an error bound of

$$(\max |f'| + 2\pi|n|\Delta\omega \max |f|) \frac{L^2 N}{2(N-1)^2} = \frac{4 + 10\pi}{2N} < \frac{18}{N}.$$

- [CG00, p. 157] (*Deconvolution*) Assume  $g = f * h$  where  $g$  and  $h$  are known by  $N$ th order samplings  $\mathbf{g}$  and  $\mathbf{h}$ , each with spacing  $\Delta x$ . The deconvolution formula for finding  $f$ ,

$$f = \mathcal{F}^{-1}[V] \quad \text{where} \quad V = \frac{G}{H} = \frac{\mathcal{F}[g]}{\mathcal{F}[h]},$$

is approximated by

$$f(k\Delta x) \approx \sqrt{N} \left[ \hat{\mathcal{F}}_N^{-1} \hat{\mathbf{V}} \right]_k$$

where, letting  $\Delta\omega = (N\Delta x)^{-1}$ ,  $\hat{\mathbf{V}}$  is the sequence given by

$$\hat{V}_n = \Delta\omega \frac{\sqrt{N} \left[ \hat{\mathcal{F}}_N[\hat{\mathbf{g}}] \right]_n}{\sqrt{N} \left[ \hat{\mathcal{F}}_N[\hat{\mathbf{h}}] \right]_n} \quad \text{for } n = 0, 1, 2, \dots, N-1.$$

This reduces to

$$f(k\Delta x) \approx \frac{1}{\Delta x \sqrt{N}} \left[ \widehat{\mathcal{F}}_N^{-1} \mathbf{V} \right]_k$$

where, letting  $\mathbf{G} = \widehat{\mathcal{F}}_N \mathbf{g}$  and  $\mathbf{H} = \widehat{\mathcal{F}}_N \mathbf{h}$ ,

$$V_n = \frac{G_n}{H_n} \quad \text{for } n = 0, 1, 2, \dots, N-1.$$

This requires, of course, that each  $H_n$  be nonzero.

## 58.5 The Fast Fourier Transform

A **fast Fourier transform (FFT)** is any of a number of algorithms for computing DFTs in which the number of arithmetic computations is greatly reduced through clever use of symmetries and cyclic structures in the DFT matrices. The FFT described here is the standard *radix 2* FFT for computing the  $N$ th order “alternative” discrete Fourier transform  $\mathcal{D}_N \mathbf{v}$  given by

$$[\mathcal{D}_N \mathbf{v}]_n = \sqrt{N} [\widehat{\mathcal{F}}_N \mathbf{v}]_n = \sum_{k=0}^{N-1} v_k e^{-i2\pi nk/N}.$$

For additional details on implementing a radix 2 FFT and descriptions of other FFTs, see [BH95, chap. 10], [CG00], or [Wal96].

### Algorithms:

Two algorithms for computing the alternative DFT

$$\mathbf{V} = [V_0, V_1, V_2, \dots, V_{N-1}]^T$$

of an  $N$ th order sequence

$$\mathbf{v} = [v_0, v_1, v_2, \dots, v_{N-1}]^T$$

are given. The first is the “first level” radix 2 FFT illustrating the basic concepts. The second is the more complete radix 2 FFT.

1. (*First level radix 2 FFT*) This requires  $N = 2M$  for some  $M \in \mathbb{N}$ :

- First, split  $\mathbf{v}$  into two  $M$ th order sequences  $\mathbf{v}^O$  and  $\mathbf{v}^E$  composed, respectively, of the even-indexed and odd-indexed elements of  $\mathbf{v}$ ,

$$\mathbf{v}^E = [v_0^E, v_1^E, v_2^E, \dots, v_{M-1}^E]^T = [v_0, v_2, v_4, \dots, v_{2M-2}]^T$$

and

$$\mathbf{v}^O = [v_0^O, v_1^O, v_2^O, \dots, v_{M-1}^O]^T = [v_1, v_3, v_5, \dots, v_{2M-1}]^T.$$

- Then compute the  $M$ th order alternative DFTs

$$[V_0^E, V_1^E, V_2^E, \dots, V_{M-1}^E]^T = \mathbf{V}^E = \mathcal{D}_N \mathbf{v}^E$$

and

$$[V_0^O, V_1^O, V_2^O, \dots, V_{M-1}^O]^T = \mathbf{V}^O = \mathcal{D}_N \mathbf{v}^O.$$

- Then construct the  $N$ th order sequence  $\mathbf{V} = [V_0, V_1, V_2, \dots, V_{N-1}]^T$  from  $\mathbf{V}^E$  and  $\mathbf{V}^O$  via the **butterfly relations**

$$V_n = \begin{cases} V_n^E + w^n V_n^O & \text{for } n = 0, 1, 2, \dots, M-1 \\ V_{n-M}^E - w^{n-M} V_{n-M}^O & \text{for } n = M, M+1, M+2, \dots, N-1 \end{cases}$$

where  $w = e^{-i2\pi/N}$ .

2. (*Full radix 2 FFT*) This requires  $N = 2^P$  for some  $P \in \mathbb{N}$ . To simplify the description, let

$$\sigma_k \in \begin{cases} \{0\} & \text{if } k = 0 \\ \{E, O\} & \text{if } k = 1, 2, 3, \dots, P \end{cases}.$$

- Recursively, split  $\mathbf{v}$  into the sequences in the set

$$\{\mathbf{v}^{\sigma_0 \sigma_1 \sigma_2 \dots \sigma_K} : K = 0, 1, 2, \dots, P\}$$

where  $\mathbf{v}^{\sigma_0} = \mathbf{v}$  and, letting  $\Sigma = \sigma_0 \sigma_1 \sigma_2 \dots \sigma_K$  and  $M = 2^{P-K-1}$ ,

$$\mathbf{v}^{\Sigma E} = [v_0^{\Sigma E}, v_1^{\Sigma E}, v_2^{\Sigma E}, \dots, v_{M-1}^{\Sigma E}]^T = [v_0^{\Sigma}, v_2^{\Sigma}, v_4^{\Sigma}, \dots, v_{2M-2}^{\Sigma}]^T$$

and

$$\mathbf{v}^{\Sigma O} = [v_0^{\Sigma O}, v_1^{\Sigma O}, v_2^{\Sigma O}, \dots, v_{M-1}^{\Sigma O}]^T = [v_1^{\Sigma}, v_3^{\Sigma}, v_5^{\Sigma}, \dots, v_{2M-1}^{\Sigma}]^T.$$

- For each of the  $2^P$  first order sequences in  $\{\mathbf{v}^{\sigma_0 \sigma_1 \sigma_2 \dots \sigma_P} = [v^{\sigma_1 \sigma_2 \dots \sigma_P}]\}$ , set

$$\mathbf{V}^{\sigma_1 \sigma_2 \dots \sigma_P} = [V^{\sigma_1 \sigma_2 \dots \sigma_P}] = [v^{\sigma_1 \sigma_2 \dots \sigma_P}] = \mathbf{v}^{\sigma_1 \sigma_2 \dots \sigma_P}$$

- Set  $\mathbf{V} = \mathbf{V}^{\sigma_0}$  where

$$\{\mathbf{V}^{\sigma_0 \sigma_1 \sigma_2 \dots \sigma_K} : K = 0, 1, 2, \dots, P\}$$

is the set of sequences recursively constructed via the **butterfly relations**

$$V_n^{\Sigma} = \begin{cases} V_n^{\Sigma E} + w^n V_n^{\Sigma O} & \text{for } n = 0, 1, 2, \dots, M-1 \\ V_{n-M}^{\Sigma E} - w^{n-M} V_{n-M}^{\Sigma O} & \text{for } n = M, M+1, M+2, \dots, 2M-1 \end{cases}$$

where  $\Sigma = \sigma_0 \sigma_1 \sigma_2 \dots \sigma_K$ ,  $M = 2^{P-K-1}$ , and  $w = e^{(-i2\pi/N)2^K}$ .

### Facts:

All the following facts except those with specific reference can be found in [BH95], [CG00], or [Wal96].

1. Let  $\mathbf{V}$  be the sequence computed from an  $N$ th order sequence  $\mathbf{v}$  by either of the two algorithms above. Then  $\mathbf{V} = \mathcal{D}_N \mathbf{v}$ . Multiplying  $\mathbf{V}$  by  $N^{-1/2}$  yields  $\widehat{\mathcal{F}}_N \mathbf{v}$ .
2. For corresponding “fast” algorithms for computing the inverse DFT of  $\mathbf{v}$ , replace  $w = e^{-i2\pi/N}$  and  $w = e^{(-i2\pi/N)2^K}$ , respectively, with  $w = e^{i2\pi/N}$  and  $w = e^{(i2\pi/N)2^K}$  in the above algorithms.
3. [BH95, p. 393] Assume  $N = 2^P \gg 1$  for some  $P \in \mathbb{N}$ . Using just the defining formulas, the computation of an  $N$ th order DFT requires approximately  $2N^2$  arithmetic operations ( $(N-1)^2$  multiplications and  $N(N-1)$  additions). Using the above described radix 2 FFT allows this same DFT to be computed with approximately  $(3N/2) \log_2 N$  arithmetic operations ( $N \log_2 N$  additions and  $(N/2) \log_2 N$  multiplications, plus another  $N$  multiplications by  $N^{-1/2}$  if it is desired to convert

the alternative DFT to the one previously described). Thus, the ratio of the number of arithmetic operations used to compute an  $N$ th order DFT by the two methods is

$$\frac{\text{operations if using the FFT}}{\text{operations if not using the FFT}} \approx \frac{3 \log_2 N}{4N}.$$

4. Assume  $N = 2^P \gg 1$  for some  $P \in \mathbb{N}$ . Simply using the basic formulas, the computation of the discrete convolution of two sequences of order  $N$ ,

$$[\mathbf{v} * \mathbf{w}]_k = \frac{1}{\sqrt{N}} \sum_{j=0}^{N-1} v_{k-j} w_j,$$

requires approximately  $2N^2$  arithmetic operations ( $(N+1)N$  multiplies and  $(N-1)N$  additions). On the other hand, this convolution can be computed using the convolution identity

$$\mathbf{v} * \mathbf{w} = \widehat{\mathcal{F}}_N^{-1}[\mathbf{V}\mathbf{W}] \quad \text{where} \quad \mathbf{V} = \widehat{\mathcal{F}}_N \mathbf{v} \quad \text{and} \quad \mathbf{W} = \widehat{\mathcal{F}}_N \mathbf{w}.$$

Employing this identity along with the radix 2 FFT to compute the three DFTs involved requires approximately

- $3 \times (3N/2) \log_2 N$  arithmetic operations for the DFTs,
- Plus  $N$  multiplications for the product  $\mathbf{V}\mathbf{W}$ ,

for a total of approximately  $(9N/2) \log_2 N$  arithmetic operations. The ratio of operations required to compute this convolution by the two methods is

$$\frac{\text{operations if using identities and the FFT}}{\text{operations if not using identities and the FFT}} \approx \frac{9 \log_2 N}{4N}.$$

**Examples:**

1. Consider finding the DFT of

$$\mathbf{v} = [v_0, v_1, v_2, v_3]^T = [1, 2, 3, 4]^T$$

using the full radix 2 FFT. The order here is  $N = 4$  (so  $P = 2$ ). Recursively splitting  $\mathbf{v}$  into the even and odd index subsequences yields

$$\mathbf{v}^E = [1, 3]^T \quad \text{and} \quad \mathbf{v}^O = [2, 4]^T$$

and then

$$\mathbf{v}^{EE} = [1], \quad \mathbf{v}^{EO} = [3], \quad \mathbf{v}^{OE} = [2], \quad \text{and} \quad \mathbf{v}^{OO} = [4].$$

(The  $\sigma_0 = 0$  superscript is being suppressed.) Setting  $\mathbf{V}^{\sigma_1 \sigma_2} = \mathbf{v}^{\sigma_1 \sigma_2}$  yields

$$\mathbf{V}^{EE} = [1], \quad \mathbf{V}^{EO} = [3], \quad \mathbf{V}^{OE} = [2], \quad \text{and} \quad \mathbf{V}^{OO} = [4].$$

Applying the first round of butterfly relations (in which  $K = 1$ ,  $M = 2^{P-K-1} = 1$  and  $w = e^{(-i2\pi/4)^{2^1}} = -1$ ),

$$\begin{aligned}V_0^E &= V_0^{EE} + w^0 V_0^{EO} = 1 + (-1)^0 3 = 4 \\V_1^E &= V_0^{EE} - w^{1-1} V_0^{EO} = 1 - (-1)^0 3 = -2 \\V_0^O &= V_0^{OE} + w^0 V_0^{OO} = 2 + (-1)^0 4 = 6 \\V_1^O &= V_0^{OE} - w^{1-1} V_0^{OO} = 2 - (-1)^0 4 = -2,\end{aligned}$$

yields the second order sequences

$$\mathbf{V}^E = [4, -2]^T \quad \text{and} \quad \mathbf{V}^O = [6, -2]^T.$$

Applying the second (and last) round of butterfly relations (in which  $K = 0$ ,  $M = 2^{P-K-1} = 2$  and  $w = e^{(-i2\pi/4)^{2^0}} = -i$ ),

$$\begin{aligned}V_0 &= V_0^E + w^0 V_0^O = 4 + (-i)^0 6 = 10 \\V_1 &= V_1^E + w^1 V_1^O = -2 + (-i)^1 (-2) = -2 + 2i \\V_2 &= V_{2-2}^E - w^{2-2} V_{2-2}^O = 4 - (-i)^0 6 = -2 \\V_3 &= V_{3-2}^E - w^{3-2} V_{3-2}^O = -2 - (-i)^1 (-2) = -2 - 2i,\end{aligned}$$

yields the alternative DFT

$$\mathbf{V} = \mathcal{D}\mathbf{v} = [10, -2 + 2i, -2, -2 - 2i]^T.$$

2. Consider the computation of an  $N$ th order DFT. When  $N = 1024 = 2^{10}$ , the ratio of operations required to compute this DFT with and without using the FFT is

$$\frac{\text{operations if using the FFT}}{\text{operations if not using the FFT}} \approx \frac{3 \cdot 10}{4 \cdot 2^{10}} \approx 7.3 \times 10^{-3}.$$

When  $N = 11,048,576 = 2^{20}$ , this ratio is

$$\frac{\text{operations if using the FFT}}{\text{operations if not using the FFT}} \approx \frac{3 \cdot 20}{4 \cdot 2^{20}} \approx 1.4 \times 10^{-5}.$$

3. Consider computing the convolution of two  $N$ th order sequences. When  $N = 1024 = 2^{10}$ , the ratio of operations required to compute this convolution with and without using the FFT and identities is

$$\frac{\text{operations if using identities and the FFT}}{\text{operations if not using identities and the FFT}} \approx \frac{9 \cdot 10}{4 \cdot 2^{10}} \approx 2.2 \times 10^{-2}.$$

When  $N = 11,048,576 = 2^{20}$ , this ratio is

$$\frac{\text{operations if using identities and the FFT}}{\text{operations if not using identities and the FFT}} \approx \frac{9 \cdot 20}{4 \cdot 2^{20}} \approx 4.3 \times 10^{-5}.$$

### 59.1 Introduction

---

Linear algebra appears throughout physics. Linear differential equations, both ordinary and partial, appear through classical and quantum physics. Even where the equations are nonlinear, linear approximations are extremely powerful.

Two big ideas underpin linear analysis in physics. The first is the *Superposition Principle*. Suppose we have a linear problem where we need to compute the output for an arbitrary input. If there is a solution to the problem with input  $I_1$  and output  $O_1$ , a solution with input  $I_2$  and output  $O_2$ , etc., then the response to the input  $c_1 I_1 + \cdots + c_k I_k$  is  $c_1 O_1 + \cdots + c_k O_k$ . It is, therefore, enough to solve our problem for a limited set of inputs  $I_k$ , as long as an arbitrary input can be written as a linear combination of these special cases.

The second big idea is the *Decoupling Principle*. If a system of coupled differential equations (or difference equations) involves a diagonalizable square matrix  $A$ , then it is helpful to pick new coordinates  $\mathbf{y} = [\mathbf{x}]_{\mathcal{B}}$ , where  $\mathcal{B}$  is a basis of eigenvectors of  $A$ . Rewriting our equations in terms of the  $y$  variables, we discover that the evolution of each variable  $y_k$  depends only on  $y_k$ , and not on the other variables, and that the form of the equation depends only on the  $k$ th eigenvalue of  $A$ . We can then solve our equations, one variable at a time, to get  $\mathbf{y}$  as a function of time and, hence, get  $\mathbf{x}$  as a function of time. (When  $A$  is not diagonalizable, one uses a basis for which  $[A]_{\mathcal{B}}$  is in Jordan canonical form. The resulting equations for  $\mathbf{y}$  are not completely decoupled, but are still relatively easy.)

Thanks to Newton's Law,  $F = ma$ , much of classical physics is expressed in terms of systems of second order ordinary differential equations. If the force is a linear function of position, the resulting equations are linear, and the special solutions that come from eigenvectors of the force matrix are called *normal modes of oscillation*. For nonlinear problems near equilibrium, the force can always be expanded in a Taylor series, and for small oscillations the leading (linear) term is dominant. Solutions to realistic nonlinear problems, such as small oscillations of a pendulum, are then closely approximated by solutions to linear problems.

Linear field equations also permeate classical physics. Maxwell's equations, which govern electromagnetism, are linear. There are an infinite number of degrees of freedom, namely the value of the field at each point, but the Superposition Principle and the Decoupling Principle still apply. We use a continuous basis of possible inputs, namely Dirac  $\delta$  functions, and the resulting outputs are called Green's functions. The response to an arbitrary input is then the convolution of the input and the relevant Green's function.

Nonrelativistic quantum mechanics is governed by Schrödinger's equation, which is also linear. Much of quantum mechanics reduces to diagonalizing the Hamiltonian operator and applying the Decoupling Principle.

Symmetry plays a big role in quantum mechanics. Both vectors and operators decompose into representations of the rotation groups  $SO(3)$  and  $SU(2)$ . The irreducible representations are finite-dimensional, so the study of rotations (and angular momentum) often reduces to a study of finite matrices.

## 59.2 Normal Modes of Oscillation

Suppose we have two blocks, each with mass  $m$ , attached to three springs, as in Figure 59.1, with the spring constants as shown, and let  $x_i(t)$  be the displacement of the  $i$ th block from equilibrium at time  $t$ . It is easy to see that if  $x_1(0) = x_2(0)$ , and if  $\dot{x}_1(0) = \dot{x}_2(0)$ , then  $x_1(t) = x_2(t)$  for all time. The middle spring never gets stretched, and the two blocks oscillate, in phase, with angular frequency  $\omega_1 = \sqrt{k_1/m}$ . If  $x_2(0) = -x_1(0)$  and  $\dot{x}_2(0) = -\dot{x}_1(0)$ , then by symmetry  $x_2(t) = -x_1(t)$  for all time, and each block oscillates with angular frequency  $\omega_2 = \sqrt{(k_1 + 2k_2)/m}$ . (This example is worked out in detail below.) These two solutions, with  $x_1(t) = \pm x_2(t)$ , are called *normal modes of oscillation*. Remarkably, every solution to the equations of motion is a linear combination of these two normal modes.

### Definitions:

Suppose we have an arrangement of blocks, all of the same mass  $m$ , and springs with varying spring constants. Let  $x_1(t), \dots, x_n(t)$  denote the locations of the blocks, relative to equilibrium, and  $\mathbf{x} = [x_1, \dots, x_n]^T$ . For any function  $f(t)$ , let  $\dot{f}(t) = df/dt$ . The **kinetic energy** is  $T = m \sum_k \dot{x}_k^2/2$ . The **potential energy** is

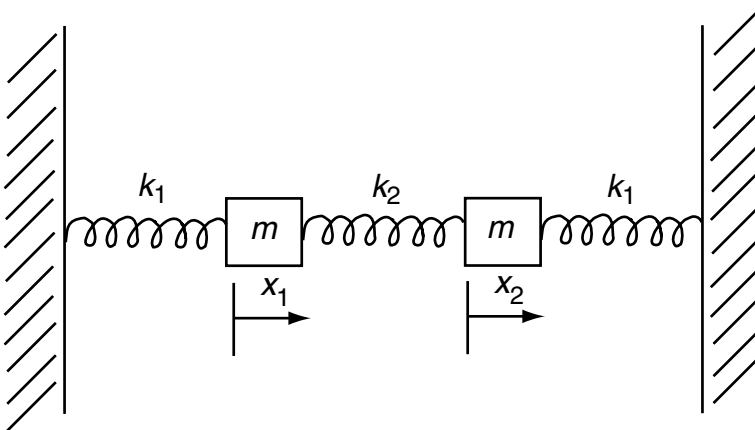

FIGURE 59.1 Coupled oscillators.

$V(\mathbf{x}) = \sum_{ij} a_{ij} x_i x_j / 2$ , where  $A = (a_{ij})$  is a symmetric matrix. The **equations of motion** are

$$m \frac{d^2 \mathbf{x}}{dt^2} = -A\mathbf{x}.$$

Let  $\mathcal{B} = \{\mathbf{z}_1, \dots, \mathbf{z}_n\}$  be a basis of eigenvectors of  $A$ , and let  $\mathbf{y}(t) = [\mathbf{x}(t)]_{\mathcal{B}}$  be the coordinates of  $\mathbf{x}(t)$  in this basis.

**Facts:**

(See Chapter 13 of [Mar70], Chapter 6 of [Gol80], and Chapter 5 of [Sad01].)

1.  $A$  is diagonalizable, and the eigenvalues of  $A$  are all real.
2. The eigenvectors can be chosen orthonormal with respect to the standard inner product:  $\langle \mathbf{z}_i, \mathbf{z}_j \rangle = \delta_{ij}$ .
3. The initial conditions for  $\mathbf{y}(t)$  can be computed using the inner product:  $y_k(0) = \langle \mathbf{z}_k, \mathbf{x}(0) \rangle$ ,  $\dot{y}_k(0) = \langle \mathbf{z}_k, \dot{\mathbf{x}}(0) \rangle$ .
4. In terms of the  $\mathbf{y}$  variables, the equations of motion reduce to  $m d^2 y_k / dt^2 = -\lambda_k y_k$ , where  $\lambda_k$  is the eigenvalue corresponding to the eigenvector  $\mathbf{z}_k$ .
5. The solution to this equation depends on the sign of  $\lambda_k$ . If  $\lambda_k > 0$ , set  $\omega_k = \sqrt{\lambda_k / m}$ . We then have

$$y_k(t) = y_k(0) \cos(\omega_k t) + \frac{\dot{y}_k(0)}{\omega_k} \sin(\omega_k t).$$

If  $\lambda_k < 0$ , set  $\kappa_k = \sqrt{-\lambda_k / m}$  and we have

$$y_k(t) = y_k(0) \cosh(\kappa_k t) + \frac{\dot{y}_k(0)}{\kappa_k} \sinh(\kappa_k t).$$

Finally, if  $\lambda_k = 0$ , then

$$y_k(t) = y_k(0) + \dot{y}_k(0)t.$$

6. If the system has translational symmetry, then there is a  $\lambda = 0$  mode describing uniform motion of the system.
7. If the system has rotational symmetry, then there is a  $\lambda = 0$  mode describing uniform rotation.
8. All solutions of the equations of motion are of the form  $\mathbf{x}(t) = \sum y_k(t) \mathbf{z}_k$ , where for each nonzero  $\lambda_k$ ,  $y_k(t)$  is of the form given in Fact 5.

**Examples:**

1. In the block-and-spring example above, the kinetic energy is  $m(\dot{x}_1^2 + \dot{x}_2^2)/2$ , while the potential energy is  $(k_1 x_1^2 + k_2(x_1 - x_2)^2 + k_1 x_2^2)/2 = \langle \mathbf{x}, A\mathbf{x} \rangle / 2$ , where  $A = \begin{pmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_1 + k_2 \end{pmatrix}$ . The eigenvalues of  $A$  are  $k_1$  and  $k_1 + 2k_2$ , with normalized eigenvectors  $(\sqrt{2}/2, \sqrt{2}/2)^T$  and  $(\sqrt{2}/2, -\sqrt{2}/2)^T$ . Both eigenvalues are positive, so we have oscillations with angular frequencies  $\omega_1 = \sqrt{k_1/m}$  and  $\omega_2 = \sqrt{(k_1 + 2k_2)/m}$ . Suppose we start by pushing the first block to the right and letting go. That is, suppose  $\mathbf{x}(0) = (1, 0)^T$  and  $\dot{\mathbf{x}}(0) = (0, 0)^T$ . From the initial data we compute

$$\begin{aligned}
y_1(0) &= \frac{\sqrt{2}}{2}(x_1(0) + x_2(0)) = \sqrt{2}/2 \\
y_2(0) &= \frac{\sqrt{2}}{2}(x_1(0) - x_2(0)) = \sqrt{2}/2 \\
\dot{y}_1(0) &= \frac{\sqrt{2}}{2}(\dot{x}_1(0) + \dot{x}_2(0)) = 0 \\
\dot{y}_2(0) &= \frac{\sqrt{2}}{2}(\dot{x}_1(0) - \dot{x}_2(0)) = 0 \\
y_1(t) &= y_1(0) \cos(\omega_1 t) + \frac{\dot{y}_1(0)}{\omega_1} \sin(\omega_1 t) = \sqrt{2} \cos(\omega_1 t)/2 \\
y_2(t) &= y_2(0) \cos(\omega_2 t) + \frac{\dot{y}_2(0)}{\omega_2} \sin(\omega_2 t) = \sqrt{2} \cos(\omega_2 t)/2 \\
\mathbf{x}(t) &= y_1(t)\mathbf{z}_1 + y_2(t)\mathbf{z}_2 = \frac{1}{2} \begin{pmatrix} \cos(\omega_1 t) + \cos(\omega_2 t) \\ \cos(\omega_1 t) - \cos(\omega_2 t) \end{pmatrix}.
\end{aligned}$$

- LC circuits obey the same equations as blocks and springs, with the capacitances playing the role of spring constants and the inductances playing the role of mass, and with the current around each loop playing the role of  $x_i$ .
- Small oscillations: A particle in an arbitrary potential  $V(\mathbf{x})$ , or a system of identical-mass particles in an arbitrary  $n$ -body potential, follows the equation  $m d^2 \mathbf{x} / dt^2 = -\nabla V(\mathbf{x})$ . If  $\mathbf{x} = \mathbf{x}_0$  is a critical point of the potential, so  $\nabla V(\mathbf{x}_0) = 0$ , then we expand  $V(\mathbf{x})$  around  $\mathbf{x} = \mathbf{x}_0$  in a Taylor series:

$$V(\mathbf{x}) = V(\mathbf{x}_0) + \frac{1}{2} \sum_{ij} a_{ij} (\mathbf{x} - \mathbf{x}_0)_i (\mathbf{x} - \mathbf{x}_0)_j + O(|\mathbf{x} - \mathbf{x}_0|^3),$$

where  $a_{ij} = \left. \frac{\partial^2 V}{\partial x_i \partial x_j} \right|_{\mathbf{x}=\mathbf{x}_0}$ , so  $\nabla V(\mathbf{x}) = A(\mathbf{x} - \mathbf{x}_0) + O(|\mathbf{x} - \mathbf{x}_0|^2)$ , and our displacement  $\mathbf{x} - \mathbf{x}_0$  from equilibrium is governed by the approximate equation  $m d^2(\mathbf{x} - \mathbf{x}_0) / dt^2 = -A(\mathbf{x} - \mathbf{x}_0)$ .

For example, a pendulum of mass  $m$  and length  $\ell$  has quadratic kinetic energy  $m\ell^2 \dot{\theta}^2 / 2$  and nonlinear potential energy  $mg\ell(1 - \cos(\theta))$ . For  $\theta$  small, this potential energy is approximated by  $mg\ell\theta^2/2$ , and the equations of motion are approximated by  $\ell d^2\theta/dt^2 = -g\theta$ , and yields oscillations of angular frequency  $\sqrt{g/\ell}$ . The same ideas apply to motion of a pendulum near the top of the circle:  $\theta = \pi$ . Then  $V(\theta) \approx mg\ell(2 - (\theta - \pi)^2/2)$ , and our equations of motion are approximately  $\ell d^2(\theta - \pi)/dt^2 = +g(\theta - \pi)$ . The deviation of  $\theta$  from the unstable equilibrium grows as  $e^{\kappa t}$ , with  $\kappa = \sqrt{g/\ell}$ , until  $\theta - \pi$  is large enough that our quadratic approximation for  $V(\theta)$  is no longer valid.

Finally, one can consider two pendula, near their stable equilibria, attached by a weak spring. The resulting equations are almost identical to those of the coupled springs of Figure 59.1.

- Central force motion (see Chapter 3 of [Gol80] or Chapter 8 of [Mar70]): In systems with symmetry, it is often possible to use conserved quantities to integrate out some of the variables, obtaining reduced equations for the remaining variables. For instance, if an object is moving in a central force (e.g., a planet around a star or a classical electron around the nucleus), conservation of angular momentum allows us to integrate out the angular variables and get an equation for the distance  $r$ . The radius then oscillates in a pseudopotential  $V(r)$ , obtained by adding a  $1/r^2$  centrifugal term to the true potential  $V_0(r)$ . Orbits that are almost circular are described by small oscillations of the variable  $r$  around the minimum of the pseudopotential  $V(r)$ , and the frequency of oscillation is  $\sqrt{V''(r_0)/m}$ , where the pseudopotential has a minimum at  $r = r_0$ . When the true potential is a  $1/r$  attraction (as with gravitation and electromagnetism), these oscillations have the same period as the orbital motion itself. Planets traverse elliptical orbits, with the sun at a focus, and the nearest approach to the sun (the perihelion) occurs at the same point each year. When the true potential is an  $r^2$  attraction (simple harmonic motion), the radial oscillations occur with frequency twice that of the orbit. The motion is elliptical with the center of force at the center of the orbit, and there are

two perihelia per cycle. For almost any other kind of force, the radial oscillations and the rotation are incommensurate, the orbit is not a closed curve, and the perihelion precesses.

### 59.3 Lagrangian Mechanics

In the previous section, we assumed that all the particles had the same mass or, equivalently, that the kinetic energy was proportional to the squared norm of the velocity. Here we relax this assumption and we also allow generalized coordinates.

**Definitions:**

The **Lagrangian function** is  $L(\mathbf{q}, \dot{\mathbf{q}}) = T - V$ , where  $T$  is the kinetic energy and  $V$  is the potential energy. One can express the Lagrangian in terms of arbitrary generalized coordinates  $\mathbf{q}$  and their derivatives  $\dot{\mathbf{q}}$ . The **kinetic energy** is typically quadratic in the velocity:  $T = \langle \dot{\mathbf{q}}, B(\mathbf{q})\dot{\mathbf{q}} \rangle / 2$ , where the symmetric “mass matrix”  $B$  may depend on the coordinates  $\mathbf{q}$ , but not on the velocities  $\dot{\mathbf{q}}$ . The **potential energy**  $V$  depends only on the coordinates  $\mathbf{q}$  (and not on  $\dot{\mathbf{q}}$ ), but may be nonlinear.

If  $\mathbf{q}_0$  is a critical point of  $V$ , we consider motion with  $\mathbf{q}$  close to  $\mathbf{q}_0$  and  $\dot{\mathbf{q}}$  small.

**Facts:**

(See Chapter 7 of [Mar70] or Chapters 2 and 6 of [Gol80].)

1. The Euler–Lagrange equations

$$\frac{d}{dt} \left( \frac{\partial L}{\partial \dot{q}_k} \right) = \frac{\partial L}{\partial q_k}$$

reduce to the approximate equations of motion

$$B \frac{d^2(\mathbf{q} - \mathbf{q}_0)}{dt^2} = -A(\mathbf{q} - \mathbf{q}_0),$$

where  $a_{ij} = \left. \frac{\partial^2 V}{\partial q_i \partial q_j} \right|_{\mathbf{q}=\mathbf{q}_0}$ , essentially as before, and the mass matrix  $B$  is evaluated at  $\mathbf{q} = \mathbf{q}_0$ . Instead of looking for eigenvalues and eigenvectors of  $A$ , we look for numbers  $\lambda_k$  and vectors  $\mathbf{z}_k$  such that  $A\mathbf{z}_k = \lambda_k B\mathbf{z}_k$ . (See Chapter 43.) We then let  $\mathbf{y} = [\mathbf{q} - \mathbf{q}_0]_B$ .

2. The matrices  $A$  and  $B$  are symmetric, and the eigenvalues of  $B$  are all positive.
3. The numbers  $\lambda_k$  are the roots of the polynomial  $\det(xB - A)$ . When  $B$  is the identity matrix, these reduce to the eigenvalues of  $A$ .
4. One can find a basis of solutions  $\mathbf{z}_k$  to  $A\mathbf{z}_k = \lambda_k B\mathbf{z}_k$ , with  $\lambda_k$  real. The numbers  $\lambda_k$  are the eigenvalues of  $B^{-1}A$ , or equivalently of the symmetric matrix  $B^{-1/2}AB^{-1/2}$ , which explains why the  $\lambda_k$ 's are real.
5. The eigenvectors can be chosen orthonormal with respect to an inner product involving  $B$ . (See Chapter 5.) That is, if  $\langle \mathbf{u}, \mathbf{v} \rangle_B = \mathbf{u}^T B\mathbf{v}$ , then  $\langle \mathbf{z}_i, \mathbf{z}_j \rangle_B = \delta_{ij}$ .
6. The initial conditions for  $\mathbf{y}(t)$  can be computed using the modified inner product of the previous fact:  $y_k(0) = \langle \mathbf{z}_k, \mathbf{q}(0) - \mathbf{q}_0(0) \rangle_B$ ,  $\dot{y}_k(0) = \langle \mathbf{z}_k, \dot{\mathbf{q}}(0) \rangle_B$ .
7. In terms of the  $\mathbf{y}$  variables, the approximate equations of motion reduce to the decoupled equations  $d^2 y_k / dt^2 = -\lambda_k y_k$ .
8. The solution to these equations depends on the sign of  $\lambda_k$ . If  $\lambda_k > 0$ , set  $\omega_k = \sqrt{\lambda_k}$ ; if  $\lambda_k < 0$ , set  $\kappa_k = \sqrt{-\lambda_k}$ . With values of  $\omega_k$  or  $\kappa_k$ , these the solutions take the same form as in Fact 5 of section 59.2.
9. If the system is symmetric under the action of a continuous group, then there is a  $\lambda = 0$  mode for each generator of this group.

FIGURE 59.2 A double pendulum.

10. All solutions of the approximate equations of motion are of the form  $\mathbf{q}(t) = \mathbf{q}_0 + \sum y_k(t)\mathbf{z}_k$ , where for each nonzero  $\lambda_k$ ,  $y_k(t)$  is of the form given by Fact 8 above (and Fact 5 of Section 59.2).

### Examples:

- Consider the double pendulum of Figure 59.2, where each ball has mass  $m$  and each rod has length  $\ell$ . For large motions, this system is famously chaotic, but for small oscillations it is simple. The two coordinates are the angles  $\theta_1$  and  $\theta_2$ , and the potential energy of the system is  $mg\ell(3 - 2\cos(\theta_1) - \cos(\theta_2)) \approx mg\ell(\theta_1^2 + \theta_2^2/2)$ , so  $A = mg\ell \begin{pmatrix} 2 & 0 \\ 0 & 1 \end{pmatrix}$ . The kinetic energy is  $\frac{m\ell^2}{2} (\dot{\theta}_1^2 + (\sin(\theta_1)\dot{\theta}_1 + \sin(\theta_2)\dot{\theta}_2)^2 + (\cos(\theta_1)\dot{\theta}_1 + \cos(\theta_2)\dot{\theta}_2)^2)$ . For small values of  $\theta_1$  and  $\theta_2$ , this is approximately  $\frac{m\ell^2}{2}(2\dot{\theta}_1^2 + \dot{\theta}_2^2 + 2\dot{\theta}_1\dot{\theta}_2)$ , so  $B = m\ell^2 \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}$ .  $\det(xB - A) = m^2\ell^4(x^2 - 4(g/\ell)x + 2g^2/\ell^2)$ , with roots  $\lambda_1 = (g/\ell)(2 + \sqrt{2})$  and  $\lambda_2 = (g/\ell)(2 - \sqrt{2})$ , and with  $\mathbf{z}_i = c_i(1, \mp\sqrt{2})^T$ ,  $i = 1, 2$ , where  $c_i$  are normalization constants. The two normal modes are as follows: There is a fast mode, with  $\omega_1 = \sqrt{(g/\ell)(2 + \sqrt{2})} \approx 1.8478\sqrt{g/\ell}$ , with the two pendula swinging in opposite directions, and with the bottom pendulum swinging  $\sqrt{2}$  more than the top; there is a slow mode, with  $\omega_2 = \sqrt{(g/\ell)(2 - \sqrt{2})} \approx 0.7654\sqrt{g/\ell}$ , with the two pendula swinging in the same direction, and with the bottom pendulum swinging  $\sqrt{2}$  more than the top.

## 59.4 Schrödinger's Equation

In quantum mechanics, the evolution of a particle of mass  $m$ , moving in a time-dependent potential  $V(x, t)$ , is described by Schrödinger's equation,

$$i\hbar \frac{\partial \psi(x, t)}{\partial t} = -\frac{\hbar^2}{2m} \nabla^2 \psi(x, t) + V(x, t) \psi(x, t),$$

where  $\hbar$  is Planck's constant divided by  $2\pi$ , and the square of the complex wavefunction  $\psi(x, t)$  describes the probability of finding a particle at position  $x$  at time  $t$ . Space and time are not treated on equal footing. We consider the wavefunction  $\psi$  to be a square-integrable function of  $x$  that evolves in time.

**Definitions:**

Let  $\mathcal{H} = L^2(\mathbb{R}^n)$  be the Hilbert space of square-integrable functions on  $\mathbb{R}^n$  with “inner product”

$$\langle \phi | \psi \rangle = \int_{\mathbb{R}^n} \overline{\phi(x)} \psi(x) d^n x.$$

Note that this inner product is linear in the *second* factor and conjugate-linear in the first factor. Although mathematicians usually choose their complex inner products  $\langle u, v \rangle$  to be linear in  $u$  and conjugate-linear in  $v$ , among physicists the convention, and notation, is invariably that of the above equation. The bracket of  $\phi$  and  $\psi$  can be viewed as a pairing of two pieces, the “bra”  $\langle \phi |$  and the “ket”  $|\psi \rangle$ . The ket  $|\psi \rangle$  is a vector in  $\mathcal{H}$ , while  $\langle \phi |$  is a map from  $\mathcal{H}$  to the complex numbers, namely, “take the inner product of  $\phi$  with an input vector.”

The Hermitian adjoint of an operator  $A$ , denoted  $A^*$ , is the unique operator such that  $\langle A^* \phi | \psi \rangle = \langle \phi | A \psi \rangle$ , for all vectors  $\phi, \psi$ . An operator  $A$  is called **Hermitian**, or **self-adjoint**, if  $A^* = A$ , and **unitary** if  $A^* = A^{-1}$ .

The **commutator** of two operators  $A$  and  $B$ , denoted  $[A, B]$ , is the difference  $AB - BA$ .  $A$  and  $B$  are said to **commute** if  $AB = BA$ .

The **expectation value** of an operator  $A$  in the state  $|\psi \rangle$  is the statistical average of repeated measurements of  $A$  in the state  $|\psi \rangle$ , and is denoted  $\langle A \rangle$ , with the dependence on  $|\psi \rangle$  implicit. The **uncertainty in  $A$** , denoted  $\Delta A$ , is the root mean squared variation in measurements of  $A$ .

The **generalized eigenvalues** of an operator  $A$  are points in the spectrum of  $A$ , and the **generalized eigenvectors** are formal solutions to  $A|\psi \rangle = \lambda|\psi \rangle$ . These may not be true eigenvalues and eigenvectors if  $\psi$  is not square integrable. (See Facts 11 to 15 below.) This use of the term “generalized eigenvector,” which is standard in physics, has *nothing* to do with the same term in matrix theory (where it signifies vectors  $\mathbf{v}$  for which  $(A - \lambda I)^k \mathbf{v} = 0$  for some positive integer  $k$ ).

**Facts:**

(See Chapter 6 of [Sch68] or Chapters 5 and 7 of [Mes00].)

1. The Schrödinger equation can be recast as an ordinary differential equation with values in  $\mathcal{H}$ :

$$i\hbar \frac{d|\psi \rangle}{dt} = H(t)|\psi \rangle,$$

where  $H = -\frac{\hbar^2}{2m} \nabla^2 + V$  is the Hamiltonian operator.

2. Physically measurable quantities, also called *observables*, are represented by Hermitian operators. It is easy to see that the position operator  $(X\psi)(x) = x\psi(x)$ , the momentum operator  $(P\psi)(x) = -i\hbar \nabla \psi(x)$ , and the Hamiltonian  $H = P^2/2m + V$  are all self-adjoint.
3. If an observable  $a$  is represented by the operator  $A$ , then the possible values of a measurement of  $a$  are the (generalized) eigenvalues of  $A$ .
4. Two Hermitian operators  $A, B$  can be simultaneously diagonalized if and only if they commute.
5. Suppose the state of the system is described by the vector  $|\psi \rangle = \sum_n c_n |\phi_n \rangle$ , where  $\sum |c_n|^2 = 1$  and each  $|\phi_n \rangle$  is a normalized eigenvector of  $A$  with eigenvalue  $\lambda_n$ . Then the probability of a measurement of  $a$  yielding the value  $\lambda_n$  is  $|c_n|^2$ .
6. If  $|\psi \rangle$  is as in the previous Fact, then the expectation value of  $A$  is  $\langle A \rangle = \sum_n \lambda_n |c_n|^2$ .
7. The uncertainty of  $A$  satisfies  $(\Delta A)^2 = \langle A^2 \rangle - \langle A \rangle^2$ .
8. If  $A, B$ , and  $C$  are Hermitian operators with  $[A, B] = iC$ , then  $\Delta A \Delta B \geq |\langle C \rangle|/2$ .
9. In particular,  $XP - PX = i\hbar$ , so  $\Delta X \Delta P \geq \hbar/2$ . This is *Heisenberg’s uncertainty principle*.
10. If the Hamiltonian operator does not depend on time, then energy is conserved. In fact, if  $|\psi(0) \rangle = \sum c_n |\phi_n \rangle$ , where  $H|\phi_n \rangle = E_n |\phi_n \rangle$ , then  $|\psi(t) \rangle = \sum c_n e^{-iE_n t/\hbar} |\phi_n \rangle$ . (Eigenvalues of the Hamiltonian are usually denoted  $E_n$ , for energy.) Solving the Schrödinger equation is tantamount to diagonalizing the Hamiltonian and using a basis of eigenvectors.

11. Operators may have continuous spectrum, in which case the generalized eigenvectors are not square-integrable. In particular,  $e^{ikx}$  is a generalized eigenvector for  $P = -i\hbar d/dx$  with generalized eigenvalue  $\hbar k$ , and the Dirac delta function  $\delta(x - a)$  is a generalized eigenvector for  $X$  with eigenvalue  $a$ .
12. Let  $|A, \alpha\rangle$  be a generalized eigenvector of the operator  $A$  with generalized eigenvalue  $\alpha$ . If  $A$  has continuous spectrum, then the decomposition of a state  $|\psi\rangle$  involves integrating over eigenvalues instead of summing:  $|\psi\rangle = \int f(\alpha)|A, \alpha\rangle d\alpha$ . The generalized eigenstates are usually normalized so that  $\langle\psi|\psi\rangle = \int |f(\alpha)|^2 d\alpha$ . Equivalently,  $\langle A, \alpha|A, \beta\rangle = \delta(\alpha - \beta)$ .
13. For continuous spectra,  $|f(\alpha)|^2$  is not the probability of a measurement of  $A$  yielding the value  $\alpha$ . Rather,  $|f(\alpha)|^2$  is a probability *density*, and the probability of a measurement yielding a value between  $a$  and  $b$  is  $\int_a^b |f(\alpha)|^2 d\alpha$ .
14. The two most common expansions in terms of generalized eigenvalues are for the position operator and the momentum operator:  $|\psi\rangle = \int \psi(x)|X, x\rangle dx = \int \hat{\psi}(k)|P, \hbar k\rangle dk$ . The coefficients  $\hat{\psi}(k)$  of  $|\psi\rangle$  in the momentum basis are the Fourier transform of the coefficients  $\psi(x)$  in the position basis. From this perspective, the Fourier transform is just a change-of-basis.
15. An operator may have both discrete and continuous spectrum, in which case eigenfunction expansions involve summing over discrete eigenvalues and integrating over continuous eigenvalues. For example, for the Hamiltonian of a hydrogen atom, there are discrete negative eigenvalues that describe bound states, and a continuum of positive eigenvalues that describe ionized hydrogen, with the electron having broken free of the nucleus.

### Examples:

1. *The one dimensional harmonic oscillator.* We have seen that a classical harmonic oscillator with potential energy  $kx^2/2$  has frequency  $\omega = \sqrt{k/m}$ , so we write the Hamiltonian of a quantum mechanical harmonic oscillator as

$$H = \frac{P^2}{2m} + \frac{kX^2}{2} = \frac{P^2 + m^2\omega^2 X^2}{2m}.$$

We will compute the eigenvalues and eigenvectors of this Hamiltonian.

We define a *lowering operator*

$$a = \frac{P - im\omega X}{\sqrt{2m\hbar\omega}}.$$

The Hermitian conjugate of  $a$  is the *raising operator*

$$a^* = \frac{P + im\omega X}{\sqrt{2m\hbar\omega}}.$$

Note that  $a$  and  $a^*$  do not commute. Rather,  $[a, a^*] = 1$ . In terms of  $a$  and  $a^*$ , the Hamiltonian takes the form

$$H = \hbar\omega(a^*a + aa^*)/2 = \frac{\hbar\omega}{2}(2a^*a + 1) = \frac{\hbar\omega}{2}(2aa^* - 1).$$

Note that  $a^*a$  is positive-definite, since  $\langle\psi|a^*a\psi\rangle = \langle a\psi|a\psi\rangle \geq 0$ , so the eigenvalues of energy must all be at least  $\hbar\omega/2$ .

Since  $Ha = a(H - \hbar\omega)$ , the operator  $a$  serves to lower the energy of a state by  $\hbar\omega$ . If  $|\phi\rangle$  is an eigenvector of  $H$  with eigenvalue  $E$ , then  $Ha|\phi\rangle = a(H - \hbar\omega)|\phi\rangle = a(E - \hbar\omega)|\phi\rangle = (E - \hbar\omega)a|\phi\rangle$ , so  $a|\phi\rangle$  is either the zero vector or a state with energy  $E - \hbar\omega$ . Since we cannot reduce the energy below  $\hbar\omega/2$ , by applying  $a$  repeatedly (say,  $n \geq 0$  times), we must eventually get a vector  $|\phi_0\rangle$  for which  $a|\phi_0\rangle = 0$ . But then  $H|\phi_0\rangle = \frac{\hbar\omega}{2}(2a^*a + 1)|\phi_0\rangle = \frac{\hbar\omega}{2}|\phi_0\rangle$ . Since it took  $n$  lowerings to get the energy to  $\hbar\omega/2$ , our original state  $|\phi\rangle$  must have had energy  $(n + \frac{1}{2})\hbar\omega$ .

The notation  $|n\rangle$  is often used for this  $n$ th excited state, so  $a|n\rangle$  is a constant times  $|n-1\rangle$ . It remains to compute that constant. Normalizing  $\langle n|n\rangle = 1$  and picking the phases such that  $\langle n-1|an\rangle > 0$ , we compute  $\langle an|an\rangle = \langle n|a^*an\rangle = \frac{\langle n|Hn\rangle}{\hbar\omega} - \frac{1}{2} = n\langle n|n\rangle = n$ , so  $a|n\rangle = \sqrt{n}|n-1\rangle$ . A similar calculation yields  $a^*|n\rangle = \sqrt{n+1}|n+1\rangle$  and, hence,  $|n\rangle = (a^*)^n|0\rangle/\sqrt{n!}$ .

The state  $|0\rangle$  is in the kernel of  $a$ . In a coordinate basis, where  $X$  is multiplication by  $x$  and  $P = -i\hbar d/dx$ , the equation  $a|0\rangle = 0$  becomes a first-order differential equation

$$\frac{d\psi(x)}{dx} + \frac{m\omega x}{\hbar}\psi(x) = 0,$$

whose solution is the Gaussian  $\psi(x) = \exp(-m\omega x^2/2\hbar)$  times a normalization constant. The  $n$ th state is obtained by applying the differential operator  $\frac{d}{dx} - \frac{m\omega x}{\hbar}$  to the Gaussian  $n$  times. The result is an  $n$ th order polynomial in  $x$  times the Gaussian.

## 59.5 Angular Momentum and Representations of the Rotation Group

The same techniques that solved the harmonic oscillator also work to diagonalize the angular momentum operator.

### Definitions:

**Angular momentum** is a vector:  $\vec{L} = \vec{X} \times \vec{P}$ , or in coordinates,  $L_1 = X_2P_3 - X_3P_2$ ,  $L_2 = X_3P_1 - X_1P_3$ ,  $L_3 = X_1P_2 - X_2P_1$ . Each  $L_i$  is a self-adjoint observable. We define  $L^2 = L_1^2 + L_2^2 + L_3^2$ , and define a **raising operator**  $L_+ = L_1 + iL_2$  and a **lowering operator**  $L_- = L_1 - iL_2$ .

### Facts:

(See Chapter 7 of [Sch68] or Chapter 13 of [Mes00].)

1. The three components of angular momentum do not commute. Rather,

$$[L_1, L_2] = i\hbar L_3, \quad [L_2, L_3] = i\hbar L_1, \quad [L_3, L_1] = i\hbar L_2.$$

By the uncertainty principle, this means that only one component of the angular momentum can be known at a time.

2.  $L^2$  is Hermitian, and each  $[L_i, L^2] = 0$ . It is possible to know both  $L^2$  and  $L_3$ , and we consider simultaneous eigenstates  $|\ell, m\rangle$  of  $L^2$  and  $L_3$ , where  $\ell$  labels the eigenvalue of  $L^2$  and  $\hbar m$  is the eigenvalue of  $L_3$ .
3.  $[L^2, L_\pm] = 0$  and  $[L_3, L_\pm] = \pm\hbar L_\pm$ . This means that  $L_+$  does not change the eigenvalue of  $L^2$ , but increases the eigenvalue of  $L_3$  by  $\hbar$ . Likewise,  $L_-$  decreases the eigenvalue of  $L_3$  by  $\hbar$ .
4. Since  $L^2 - L_3^2 = L_1^2 + L_2^2 \geq 0$ , there is a limit to how big  $m$  (or  $-m$ ) can get. For each  $\ell$ , there is a state  $|\ell, m_{max}\rangle$  for which  $L_+|\ell, m_{max}\rangle = 0$ , and a state  $|\ell, m_{min}\rangle$  for which  $L_-|\ell, m_{min}\rangle = 0$ . We set the label  $\ell$  to be equal to  $m_{max}$ .
5.  $L_-L_+ = L_1^2 + L_2^2 - \hbar L_3$  and  $L_+L_- = L_1^2 + L_2^2 + \hbar L_3$ , so we can write  $L^2$  in terms of  $L_\pm$  and  $L_3$ :  $L^2 = L_-L_+ + L_3^2 + \hbar L_3 = L_+L_- + L_3^2 - \hbar L_3$ .
6. The minimum value of  $m$  is  $-\ell$ . Since  $2\ell = m_{max} - m_{min}$  is an integer,  $\ell$  must be half of a nonnegative integer.
7. The states  $|\ell, m\rangle$ , with  $m$  ranging from  $-\ell$  to  $\ell$ , form a  $(2\ell + 1)$  dimensional irreducible representation of the Lie algebra of  $SO(3)$ . We denote this representation  $V_\ell$ , and call it the “spin- $\ell$ ” representation.
8. In  $V_\ell$ , we have  $L^2|\ell, m\rangle = \hbar^2\ell(\ell + 1)|\ell, m\rangle$ ,  $L_3|\ell, m\rangle = m\hbar|\ell, m\rangle$ , and  $L_\pm|\ell, m\rangle = \hbar\sqrt{\ell(\ell + 1) - m(m \pm 1)}|\ell, m \pm 1\rangle$ .

9. If  $u$  is a unit vector, then a rotation by the angle  $\theta$  about the  $u$  axis is implemented by the unitary operator  $\exp(-i\theta L \cdot u/\hbar)$ .
10. Since rotation by  $2\pi$  equals the identity, representations of the Lie group  $SO(3)$  satisfy the additional condition  $\exp(2\pi i L_3) = 1$ , which forces  $m$  (and, therefore,  $\ell$ ) to be an integer.
11. If one particle has angular momentum  $\ell_1$  and another has angular momentum  $\ell_2$ , then the combined angular momentum can be any integer between  $|\ell_1 - \ell_2|$  and  $\ell_1 + \ell_2$ . In terms of representations,  $V_{\ell_1} \otimes V_{\ell_2} = \bigoplus_{\ell=|\ell_1-\ell_2|^{\ell_1+\ell_2}} V_{\ell}$ .
12. The Lie group  $SU(2)$  is the double cover of  $SO(3)$ , and has the same Lie algebra. The generators are usually denoted  $J$  rather than  $L$ , and the maximum value of  $m$  is denoted  $j$  rather than  $\ell$ , but otherwise the computations are the same.  $J$  describes the total angular momentum of a particle, including spin, and  $j$  can be either an integer or a half-integer.
13. Particles with  $j$  integral are called bosons, while particles with  $j$  half-integral are called fermions.
14. If the Hamiltonian is rotationally symmetric, then angular momentum is conserved, and our energy eigenstates can be chosen to be eigenstates of  $J^2$  and  $J_3$ .

## 59.6 Green's Functions

Expansions in a continuous basis of eigenfunctions are not limited to quantum mechanics. The Dirac  $\delta$  is an eigenfunction of position, and any function can be written trivially as an integral over  $\delta$  functions:

$$f(x) = \int f(y)\delta(x-y)dy = \int f(y)|X, y\rangle dy.$$

It, therefore, suffices to solve linear input–output problems in the case where the input is a  $\delta$ -function located at an arbitrary point  $y$ . The resulting solution  $G(y, x)$  is called a **Green's function** (or in some texts, **Green function**) for the problem, and the solution for an arbitrary input  $f(x)$  is the convolution  $\int f(y)G(y, x)dy$ .

### Facts:

(See [Jac75], especially Chapters 1 to 3, for many applications to electrostatics, and see Chapter 11 of [Sad01] for a general introduction to Green's functions.)

1. Green's functions are sometimes called *integral kernels*, especially in the mathematics literature, or *propagators* in quantum field theory. The term *propagator* is also sometimes used for the Fourier transform of a Green's function.
2. Linear partial differential equations appear throughout physics. Examples include Maxwell's equations, Laplace's equation, Schrödinger's equation, the heat equation, the wave equation, and the Dirac equation. Each equation generates its own Green's function.
3. Some boundary value problems involve Neumann boundary conditions, in which the normal derivative of a function (as opposed to the value of a function) is specified on  $S$ , and some problems involve mixed Neumann and Dirichlet conditions. The formalism for these cases is a simple modification of the Dirichlet formalism.
4. Two common techniques for computing Green's functions are Fourier transforms and the method of images.
5. Fourier transforms apply when the problem has translational symmetry, as in the heat equation example, above. We decompose a  $\delta$  function as a linear combination of exponentials  $e^{ikx}$ , compute the response for each exponential, and re-sum.
6. The method of images is illustrated in Example 2, where the actual response  $G(y, x)$  is a sum of two terms. The first is the response  $G_0(y, x)$  to the actual charge at  $y$ , computed without boundary, and the second is the response to a mirror charge, located at a point outside  $D$ , and chosen so that the sum of the two terms is zero on  $S$ .

**Examples:**

1. *Electrostatics without boundaries.* The electrostatic potential  $\phi(x)$  is governed by Poisson's equation:

$$\nabla^2\phi = -4\pi\rho(x),$$

where  $\rho(x)$  is the charge density. Here,  $\rho$  is the input and  $\phi$  is the output. Since the solution to  $\nabla^2 G(y, x) = -4\pi\delta^3(x - y)$  is  $G(y, x) = |x - y|^{-1}$ , the potential due to a charge distribution  $\rho(x)$  is  $\phi(x) = \int d^3y \rho(y)/|x - y|$ . (Note that, when we write  $\nabla^2 G(y, x)$ , we are taking the second derivative of  $G(y, x)$  with respect to  $x$ . The variable  $y$  is just a parameter.)

2. *Electrostatics with boundary conditions.* Poisson's equation on a domain  $D$  with boundary  $S$  is more subtle, as we need to apply boundary conditions on  $S$ . Suppose that  $D$  is the exterior of a ball of radius  $R$ , and that we apply the homogeneous Dirichlet boundary condition  $\phi = 0$  on  $S$ . (This corresponds to  $S$  being a grounded conducting sphere.) The function  $G_0(y, x) = 1/|x - y|$  satisfies  $\nabla^2 G_0(y, x) = -4\pi\delta^3(x - y)$ , but does not satisfy the boundary condition. The function  $G(y, x) = G_0(y, x) - \frac{R}{|y|} G_0(R^2y/|y|^2, x)$  satisfies  $\nabla^2 G(y, x) = -4\pi\delta^3(x - y)$  and  $G(y, x) = 0$  for  $x \in S$ .

Nonzero boundary values can be considered part of the input. If we want to solve the equation  $\nabla^2\phi = -4\pi\rho$  on  $D$  with boundary values  $f(x)$  on  $S$ , then we have two different Green's functions to compute. For each  $y \in D$ , we compute  $G_1(y, x)$ , the solution to  $\nabla^2 G_1(y, x) = -4\pi\delta^3(x - y)$  with boundary value zero on  $S$ . For each  $z \in S$ , we compute  $G_2(z, x)$ , the solution to  $\nabla^2 G_2(z, x) = 0$  on  $D$  with boundary value  $\delta^2(x - z)$  on  $S$ . Our solution to the entire problem is then  $\phi(x) = \int_D d^3y G_1(y, x)\rho(y) + \int_S d^2z f(z)G_2(z, x)$ .

3. *The heat kernel.* In  $\mathbb{R}^2$ , with variables  $x$  and  $t$ , let  $D$  be the region  $t > 0$ , so  $S$  is the  $x$ -axis. We look for solutions to the *heat equation*

$$\frac{\partial f}{\partial t} - \frac{\partial^2 f}{\partial x^2} = 0,$$

with boundary value  $f(x, 0) = f_0(x)$ . Since  $G(y, x, t) = \exp(-(x - y)^2/4t)/\sqrt{4\pi t}$  is a solution to (3) and approaches  $\delta(x - y)$  as  $t \rightarrow 0$ , the solution to our problem is

$$f(x, t) = \int G(y, x, t) f_0(y) dy = \frac{1}{\sqrt{4\pi t}} \int \exp(-(x - y)^2/4t) f_0(y) dy.$$

### 60.1 Introduction

---

Biomolecular modeling is an active research area in computational biology. It studies the structures and functions of biomolecules by using computer modeling and simulation [Sch03]. Proteins are an important class of biomolecules. They are encoded in genes and produced in cells through genetic translation. Proteins are life supporting (or sometimes, destructing) ingredients (Figure 60.1) and are indispensable for almost all biological processes [Boy99]. In order to understand the diverse biological functions of proteins, the knowledge of the three-dimensional structures of proteins is essential. Several structure determination techniques have been used, including x-ray crystallography, nuclear magnetic resonance spectroscopy (NMR), and homology modeling. They all require intensive mathematical computing, ranging from data analysis to model building [Cre93].

As in all other types of scientific computing, linear algebra is one of the most powerful mathematical tools for biological computing. Here we review several subjects in biomolecular modeling, where linear algebra has played a major role, including mapping from distances to coordinates in NMR structure determination (Section 60.2), solving the Procrustes problem for structural comparison (Section 60.3), exploiting the structure of the Karle–Hauptman matrix in protein x-ray crystallography (Section 60.4), computing the fast and slow modes of protein motions (Section 60.5), and solving the flux balancing equations in metabolic network simulation (Section 60.6). The last subject actually involves the modeling of a large biological system, something beyond conventional biomolecular modeling, yet of increased research interests in computational systems biology [Kit99].

**FIGURE 60.1** Example proteins: Humans have hundreds of thousands of different proteins (e.g., hemoglobin protein, 1BUW, in blood in 1a) and would not be able to maintain normal life even if short of a single type of protein. On the other hand, with the help of some proteins (e.g., protein, 2PLV, supporting poliovirus in 1b), viruses are able to grow, translate, integrate, and replicate, causing diseases. Some proteins themselves are toxic and even infectious such as the proteins in poisonous plants and in beef causing the Mad Cow Disease (e.g., prion protein, 1I4M-D, in human in 1c).

## 60.2 Mapping from Distances to Coordinates: NMR Protein Structure Determination

A fundamental problem in protein modeling is to find the three-dimensional structure of a protein and its relationship with the protein's biological function. One of the experimental techniques for structure determination is to use the nuclear magnetic resonance (NMR) to obtain some information on the distances for certain pairs of atoms in the protein and then find the coordinates of the atoms based on the obtained distance information. Mathematically, the second part of the work requires the solution of a so-called distance geometry problem, i.e., determine the coordinates for a set of points in a given topological space, given the distances for a subset of all pairs of points. We consider such a problem with the distances for all pairs of points assumed to be given.

### Definitions:

The **coordinate vector** for atom  $i$  is a vector  $\mathbf{x}_i = (x_{i,1}, x_{i,2}, x_{i,3})^T$ , where  $x_{i,1}$ ,  $x_{i,2}$ , and  $x_{i,3}$  are the first, second, and third coordinates of atom  $i$ , respectively.

The **distance** between atoms  $i$  and  $j$  is defined as  $d_{i,j} = \|\mathbf{x}_i - \mathbf{x}_j\|$ , where  $\mathbf{x}_i$  and  $\mathbf{x}_j$  are coordinate vectors of atoms  $i$  and  $j$ , and  $\|\cdot\|$  is the Euclidean norm.

The **coordinate matrix** for a protein is a matrix of coordinates denoted by  $X = \{x_{i,j} : i = 1, \dots, n, j = 1, 2, 3\}$ , where  $n$  is the total number of atoms in the protein, and row  $i$  of  $X$  is the coordinate vector of atom  $i$ .

The **distance matrix** for a protein is a matrix of distances denoted by  $D = \{d_{i,j} : i, j = 1, \dots, n\}$ , where  $d_{i,j}$  is the distance between atoms  $i$  and  $j$ .

The problem of computing the coordinates of atoms ( $X$ ) given a set of distances between pairs of atoms ( $D$ ) is known as the **molecular distance geometry problem**.

### Facts:

1. [Sax79] If the protein structure and, hence,  $X$  are known,  $D$  can immediately be computed from  $X$ . Conversely, if  $D$  is known or even partially known,  $X$  can also be obtained from  $D$ , but the computation is not as straightforward. The latter is proved to be *NP*-complete for arbitrary sparse distance matrices.

2. [Blu53] Choose a reference system so that the origin is located at the last atom, or in other words,  $x_n = (0, 0, 0)^T$ . Let  $X^\circ$  be a submatrix of  $X$ ,  $X^\circ = \{x_{i,j} : i = 1, \dots, n-1, j = 1, 2, 3\}$ , and  $D^\circ$  be a matrix derived from  $D$ ,  $D^\circ = \{(d_{i,n}^2 - d_{i,j}^2 + d_{j,n}^2)/2 : i, j = 1, \dots, n-1\}$ . Then, matrix  $D^\circ$  is maximum rank 3 and  $X^\circ X^{\circ T} = D^\circ$ .
3. [CH88] Let  $D^\circ = U\Sigma U^T$  be the singular-value decomposition of  $D^\circ$ , where  $U$  is an orthogonal matrix and  $\Sigma$  a diagonal matrix with the singular values of  $D^\circ$  along the diagonal. If  $D^\circ$  is a matrix of rank less than or equal to 3, the decomposition can be obtained with  $U$  being  $(n-1) \times 3$  and  $\Sigma$  being  $3 \times 3$ , and  $X^\circ = U\Sigma^{1/2}$  solves the equation  $X^\circ X^{\circ T} = D^\circ$ .

**Algorithm 2: Computing Coordinates from Distances**

Given an  $n \times n$  distance matrix  $D$ ,

1. Compute  $D^\circ = \{(d_{i,n}^2 - d_{i,j}^2 + d_{j,n}^2)/2 : i, j = 1, \dots, n-1\}$ .
2. Decompose  $D^\circ = U\Sigma U^T$  to obtain  $X^\circ U[1:n-1, 1:3]\Sigma^{1/2}[1:3, 1:3]$ .
3.  $X[1:n-1, 1:3] = X^\circ[1:n-1, 1:3]$ ,  $X[n, 1:3] = [0, 0, 0]$ .

**Examples:**

1. Given the distances among four atoms,  $D$ , determine the coordinates of the atoms,  $X$ , where

$$D = \begin{bmatrix} 0 & \sqrt{2} & \sqrt{2} & 1 \\ \sqrt{2} & 0 & \sqrt{2} & 1 \\ \sqrt{2} & \sqrt{2} & 0 & 1 \\ 1 & 1 & 1 & 0 \end{bmatrix}.$$

Following Algorithm 1,

$$D^\circ = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

Compute the singular value decomposition of  $D^\circ$ . Obviously,  $D^\circ = U\Sigma U^T$ , with

$$U = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad \acute{O} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

Then,

$$X^\circ = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix}$$

and

$$X = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}.$$

**FIGURE 60.2** 3D structures of protein 1HMV p66 subunit: The structure on the left was determined by x-ray crystallography, while on the right by solving a distance geometry problem given the distances for all the pairs of atoms. The RMSD for the two structures when compared on all the atoms is around  $1.0\text{e-}04 \text{ \AA}$ . (Photo courtesy of Qunfeng Dong.)

- Figure 60.2 shows two 3D structures of the p66 subunit of the HIV-1 retrotranscriptase (1HMV), one determined experimentally by x-ray crystallography [RGH95] and another computationally by solving a molecular distance geometry problem using the SVD method with the distance data generated from the known crystal structure. The RMSD (see description in section 60.3) for the two structures when compared on all the atoms is around  $1.0\text{e-}04 \text{ \AA}$ , showing that the two structures are almost identical.

## 60.3 The Procrustes Problem for Protein Structure Comparison

The structural differences between two proteins can be measured by the differences in the coordinates of the atoms for all corresponding atom pairs. The comparison is often required for either structural validation or functional analysis. The calculation can be done by solving a special linear algebra problem called the Procrustes problem [GL89].

### Definitions:

Let  $X$  and  $Y$  be two  $n \times 3$  coordinate matrices for two lists of atoms in proteins  $A$  and  $B$ , respectively, where  $\mathbf{x}_i = (x_{i,1}, x_{i,2}, x_{i,3})^T$  is the coordinate vector of the  $i$ th atom selected from protein  $A$  to be compared with  $\mathbf{y}_i = (y_{i,1}, y_{i,2}, y_{i,3})^T$ , the coordinate vector of the  $i$ th atom selected from protein  $B$ . Assume that  $X$  and  $Y$  have been translated so that their centers of geometry are located at the same position, say, at the origin. Then, the structural difference between the two proteins can be measured by using **the root-mean-square deviation** (RMSD) of the structures,  $\text{RMSD}(X, Y) = \min_Q \|X - YQ\|_F / \sqrt{n}$ , where  $Q$  is a  $3 \times 3$  rotation matrix and  $QQ^T = I$ , and  $\|\cdot\|_F$  is the matrix Frobenius norm.

The RMSD is basically the smallest average coordinate errors of the structures for all possible rotations  $Q$  of structure  $Y$  to fit structure  $X$ . It is called **the Procrustes problem** for its analogy to the Greek story about cutting a person's legs to fit a fixed-sized iron bed. Note that  $X$  and  $Y$  may be the coordinate matrices for the same ( $A = B$ ) or different ( $A \neq B$ ) proteins and therefore, each pair of corresponding atoms do not have to be of the same type (when  $A \neq B$ ). However, the number of atoms selected to compare must be the same from  $A$  and  $B$  ( $\# \text{ rows of } X = \# \text{ rows of } Y$ ).

### Facts:

- Let  $A$  and  $B$  be two matrices. Suppose that  $A$  is similar to  $B$ , then  $\text{trace}(A) = \text{trace}(B)$ . In particular,  $\text{trace}(A) = \text{trace}(V^T A V)$ , for any orthogonal matrix  $V$ .

2. [GL89] Let  $C = Y^T X$  and  $C = U \Sigma V^T$  be the singular-value decomposition of  $C$ . Then,  $Q = UV^T$  minimizes  $\|X - YQ\|_F$ .

**Algorithm 2: Computing the RMSD of Two Protein Structures**

1. Compute the geometric centers of  $X$  and  $Y$ :

$$\mathbf{x}_c[j] = \left( \sum_{i=1}^n X[i, j] \right) / n, \quad j = 1, 2, 3;$$

$$\mathbf{y}_c[j] = \left( \sum_{i=1}^n Y[i, j] \right) / n, \quad j = 1, 2, 3.$$

2. Translate  $X$  and  $Y$  to the origin:

$$X = X - \mathbf{1}_n \mathbf{x}_c^T, \quad Y = Y - \mathbf{1}_n \mathbf{y}_c^T, \quad \mathbf{1}_n = (1, \dots, 1)^T \text{ in } \mathbb{R}^n.$$

3. Compute  $C = Y^T X$  and  $C = U \Sigma V^T$ . Then,

$$Q = UV^T, \quad \text{RMSD}(X, Y) = \|X - YQ\|_F / \sqrt{n}.$$

**Examples:**

1. Suppose that  $X$  and  $Y$  are given as the following.

$$X = \begin{bmatrix} -1 & -1 & -2 \\ -1 & -1 & 0 \\ -1 & 1 & -2 \\ -1 & 1 & 0 \\ 1 & -1 & -2 \\ 1 & -1 & 0 \\ 1 & 1 & -2 \\ 1 & 1 & 0 \end{bmatrix}$$

$$Y = \begin{bmatrix} 1 & 1 & 0 \\ 1 & -1 & 0 \\ -1 & 1 & 0 \\ -1 & -1 & 0 \\ 1 & 1 & 2 \\ 1 & -1 & 2 \\ -1 & 1 & 2 \\ -1 & -1 & 2 \end{bmatrix}.$$

Then  $\mathbf{x}_c = (0, 0, -1)^T$  and  $\mathbf{y}_c = (0, 0, 1)^T$ . Following the Step 2 in Algorithm 2,  $X$  and  $Y$  are changed to

$$X = \begin{bmatrix} -1 & -1 & -1 \\ -1 & -1 & 1 \\ -1 & 1 & -1 \\ -1 & 1 & 1 \\ 1 & -1 & -1 \\ 1 & -1 & 1 \\ 1 & 1 & -1 \\ 1 & 1 & 1 \end{bmatrix}$$

$$Y = \begin{bmatrix} 1 & 1 & -1 \\ 1 & -1 & -1 \\ -1 & 1 & -1 \\ -1 & -1 & -1 \\ 1 & 1 & 1 \\ 1 & -1 & 1 \\ -1 & 1 & 1 \\ -1 & -1 & 1 \end{bmatrix}.$$

Let  $C = Y^T X$ . Then,

$$C = \begin{bmatrix} 0 & -8 & 0 \\ 0 & 0 & -8 \\ 8 & 0 & 0 \end{bmatrix}.$$

Compute the singular value decomposition of  $C$  to obtain  $C = U \Sigma V^T$ , with

$$U = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & -1 \\ -1 & 0 & 0 \end{bmatrix} \quad \text{and} \quad V = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & -1 \\ -1 & 0 & 0 \end{bmatrix}.$$

Then,

$$Q = UV^T = \begin{bmatrix} 0 & -1 & 0 \\ 0 & 0 & -1 \\ 1 & 0 & 0 \end{bmatrix}.$$

By calculating  $\|X - YQ\|_F / \sqrt{n}$ , we obtain  $\text{RMSD}(X, Y) = 0$ .

2. RMSD calculation has been widely used in structural computing. A straightforward application is for comparing and validating the structures obtained from different (x-ray crystallography, NMR, or homology modeling) sources for the same protein [Rho00]. Even from the same source, such as NMR, multiple structures are often obtained, and the average RMSD for the pairs of the multiple structures has been calculated as an indicator for the consistency and sometimes the flexibility of the structures [SNB03]. It has also been an important tool for structural classification, motif recognition, and structure prediction, where a large number of different proteins need to be aligned and compared [EJT00]. Figure 60.3 gives an example of using RMSD to compare NMR and x-ray crystal structures. Three structures of the second domain of the immunoglobulin-binding protein

**FIGURE 60.3** NMR and x-ray crystal structures of 2IGG: Two NMR structures of 2IGG are superposed to its x-ray crystal structure to find out which one is closer to the x-ray crystal structure (dark line). The RMSD values for the two NMR structures against the x-ray structure are 1.97 Å and 1.75 Å, respectively. (Photo courtesy of Feng Cui.)

(2IGG) [LDS92] are displayed in the figure. Two of them are NMR structures. They are compared using RMSD against the x-ray structure (dark line).

## 60.4 The Karle–Hauptman Matrix in X-Ray Crystallographic Computing

X-ray crystallography has been a major experimental tool for protein structure determination and is responsible for about 80% of 30,000 protein structures so far determined and deposited in the Protein Data Bank [BWF00]. The structure determination process involves crystallizing the protein, applying x-ray to the protein crystal to obtain x-ray diffractions, and using the diffraction data to deduce the electron density distribution of the crystal (Figure 60.4). Once the electron density distribution of the crystal is known, a 3D structure for the protein can be assigned [Dre94].

### Definitions:

Define  $\rho: R^3 \rightarrow R$  to be **the electron density distribution function** for a protein and  $F_H$  in complex space  $C$  to be the structure factor representing the diffraction spot specified by the integral triplet  $H$  [Dre94].

**FIGURE 60.4** Example diffraction image and electron density map: The left one is the diffraction image of a 12-atom polygon generated by the program in [PNB01]. The right one is the electron density map of benzene generated by Stewart using program DENSITY in MOPAC [Ste02].

A **Karle–Hauptman matrix** for a set of structure factors  $\{F_H : H = H_0, \dots, H_{n-1}\}$  is defined as

$$K = \begin{bmatrix} F_{H_0} & F_{H_{n-1}} & \cdots & F_{H_1} \\ F_{H_1} & F_{H_0} & \cdots & F_{H_2} \\ \vdots & \vdots & \ddots & \vdots \\ F_{H_{n-1}} & F_{H_{n-2}} & \cdots & F_{H_0} \end{bmatrix} \quad [KH52].$$

**Facts:**

- [Dre94] The electron density distribution function  $\rho$  can be expanded as a Fourier series with the structure factors  $F_H$  as the coefficients. In other words,  $F_H$  is a Fourier transform of  $\rho$ .

$$\rho(r) = \sum_{H \in Z^3} F_H \exp(-2\pi i H^T r),$$

$$F_H = \int_{R^3} \rho(r) \exp(2\pi i H^T r) dr.$$

- [Bri84] If  $K$  is a Karle–Hauptman matrix, then the inverse of  $K$  is also a Karle–Hauptman matrix and can be formed directly as

$$K^{-1} = \begin{bmatrix} E_{H_0} & E_{H_{n-1}} & \cdots & E_{H_1} \\ E_{H_1} & E_{H_0} & \cdots & E_{H_2} \\ \vdots & \vdots & \ddots & \vdots \\ E_{H_{n-1}} & E_{H_{n-2}} & \cdots & E_{H_0} \end{bmatrix},$$

where

$$E_{H_j} = \int_{R^3} \rho^{-1}(r) \exp(2\pi i H_j^T r) dr, \quad j = 0, 1, \dots, n-1.$$

- [GL89] Suppose that we have a linear system  $K\mathbf{x} = \mathbf{h}$ , where  $K$  is an  $n \times n$  Karle–Hauptman matrix and  $\mathbf{h}$  an  $n$ -dimensional complex vector. If a conventional method, such as Gaussian Elimination, is used, the solution of the system usually takes  $O(n^3)$  floating-point operations, which is expensive if  $n$  is larger than 1000 and if the solution is also required multiple times.
- [Loa92], [WPT01] Since each element in the inverse matrix can be obtained by doing a Fourier transform for the inverse of  $\rho$  and only  $n$  distinct elements in the first column are required to form the whole matrix, the calculations can be done in  $O(n \log n)$  floating-point operations by using the Fast Fourier Transform.
- [TML97], [WPT01] The matrix  $K^{-1}$  as well as  $K$  has only  $n$  distinct elements listed repeatedly in the columns of the matrix with each column having the elements in the previous column circulated by one element from top to the bottom and then bottom to the top. This type of matrix is called the circulant matrix. According to the discrete convolution theory, if  $h$  is the Fourier transform of  $t$ , then  $K^{-1}h$  can be computed by doing a Fourier transform for  $\rho^{-1} \cdot t$ , where  $t$  can be obtained through an inverse Fourier transform for  $h$  and the product  $\cdot$  is applied component-wise. Therefore, the whole computation for the solution of  $K\mathbf{x} = \mathbf{h}$  can be done with at most  $O(n \log n)$  floating-point operations.

**Examples:**

1. Let  $\rho = [0.1250, 0.1250, 0.5000, 0.1250, 0.1250]$  be an electron density distribution. Then  $\rho^{-1} = [8, 8, 2, 8, 8]$ , and the Fourier transforms for  $\rho$  and  $\rho^{-1}$  are equal to

$$F = [0.2000, -0.0607 + 0.0441i, 0.0232-0.0713i, 0.0232 + 0.0713i, -0.0607-0.0441i] \text{ and}$$

$$F_{\text{inv}} = [6.8000, 0.9708 - 0.7053i, -0.3708 + 1.1413i, -0.3708 - 1.1413i, 0.9708 + 0.7053i],$$

respectively. And it is not hard to verify that the inverse of the Karle–Hauptman matrix  $K(F)$  formed by using  $F$  is equal to the Karle–Hauptman matrix  $K_{\text{inv}}(F_{\text{inv}})$  formed by using  $F_{\text{inv}}$ .

2. The Karle–Hauptman matrix is an important matrix in x-ray crystallography computing, named after two Nobel Laureates, chemist Jerold Karle and mathematician Herbert Hauptman, who received the Nobel Prize in chemistry in 1985 for their work on the phase problem in x-ray crystallography [HK53]. The Karle–Hauptman matrix is frequently used for computing the covariance of the structure factors [KH52] or the electron density distribution that maximizes the entropy of a crystal system [WPT01].

## 60.5 Calculation of Fast and Slow Modes of Protein Motions

In a reduced model for protein, a residue is represented by a point, in many cases, the position of the backbone atom  $C_\alpha$  or the sidechain atom  $C_\beta$  in the residue, and a protein is considered as a sequence of such points connected with strings [HL92]. If the reduced model of a protein is known, a so-called contact map can be constructed to show how the residues in the protein interact with each other. The map is represented by a matrix with its  $i, j$ -entry equal to  $-1$  if residues  $i$  and  $j$  are within, say  $7\text{\AA}$  distance, and  $0$  otherwise. The contact matrix can be used to compare different proteins. Similar contact patterns often imply structural or functional similarities between proteins [MJ85]. When a protein reaches its equilibrium state, the residues in contact can be considered as a set of masses connected with springs. A simple energy function can also be defined for the protein using the contact matrix.

**Definitions:**

Suppose that a protein has  $n$  residues with  $n$  coordinate vectors  $\mathbf{x}_1, \dots, \mathbf{x}_n$ . A **contact matrix**  $\Gamma$  for the protein in its equilibrium state can be defined such that

$$\tilde{A}_{i,j} = \begin{cases} -1, & \|x_i - x_j\| \leq 7 \text{ \AA} \\ 0, & \text{otherwise} \end{cases} \quad i \neq j = 1, \dots, n \quad [\text{HBE97}].$$

$$\tilde{A}_{i,i} = -\sum_{j=1}^n \tilde{A}_{i,j} \quad i = 1, \dots, n$$

A **potential energy function**  $E$  for a protein at its equilibrium state can be defined such that for any vector  $\Delta \mathbf{x} = (\Delta \mathbf{x}_1, \dots, \Delta \mathbf{x}_n)^T$  of the displacements of the residues from their equilibrium positions,

$$E(\Delta \mathbf{x}) = \frac{1}{2} k \Delta \mathbf{x}^T \tilde{A} \Delta \mathbf{x},$$

where  $k$  is a spring constant.

**FIGURE 60.5** Mean-square fluctuations: The fluctuations for protein 2KNT based on the mean-square fluctuations calculated with GNM (a) and the B-factors determined by x-ray crystallography (b). The two sets of values show a high correlation (0.82) (c). (Photos courtesy of Di Wu.)

### Facts:

- [HBE97] Given a potential energy function  $E$ , the probability for a protein to have a displacement  $\Delta \mathbf{x}$  at temperature  $T$  should be subject to the Boltzmann distribution,

$$p_T(\Delta \mathbf{x}) = \frac{1}{Z} \exp(-E(\Delta \mathbf{x})/k_B T) = \frac{1}{Z} \exp(-k \Delta \mathbf{x}^T \bar{\mathbf{A}} \Delta \mathbf{x}/2k_B T),$$

where  $Z$  is the normalization factor and  $k_B$  the Boltzmann constant.

- [HBE97] Let the singular-value decomposition of  $\Gamma$  be given as  $\Gamma = U \Lambda U^T$ . Then, the mean-square residue fluctuations of a protein at its equilibrium state can be estimated as

$$\langle \Delta \mathbf{x}_i, \Delta \mathbf{x}_i \rangle \equiv \frac{1}{Z} \int_{R^{3n}} \Delta \mathbf{x}_i^T \Delta \mathbf{x}_i \exp(-E(\Delta \mathbf{x})/k_B T) d\Delta \mathbf{x} = \sum_{j=1}^n k_B T U_{i,j} \bar{\mathbf{E}}_{j,j}^{-1} U_{i,j} / k.$$

### Examples:

- The energy model defined above for a protein at its equilibrium state is called the Gaussian Network Model. The model can be used to find how the residues in the protein move around their equilibrium positions dynamically and in particular, to estimate the so-called mean-square fluctuations for the residues  $\langle \Delta \mathbf{x}_i, \Delta \mathbf{x}_i \rangle$ ,  $i = 1, \dots, n$ . If the mean-square fluctuation is large, the residue is called hot, and otherwise, is cold, which often correlates with the experimentally detected average atomic fluctuation such as the B-factor in x-ray crystallography [Dre94] and the order parameter in NMR [Gun95]. In fact, the Gaussian Network Model is equivalent to the Normal Mode Analysis for predicting the mean-squares residue fluctuations of a protein, with the energy function defined for the residues instead of the atoms.
- Figure 60.5 shows the mean-square fluctuations calculated using the Gaussian Network Model for the protein 2KNT and the comparison with the B-factors of the structure determined by x-ray crystallography. The two sets of values appear to be highly correlated. Based on the facts stated above, the calculation of the mean-squares fluctuations requires only a singular-value decomposition of the contact matrix for the protein.

## 60.6 Flux Balancing Equation in Metabolic Network Simulation

A metabolic system is maintained through constant reactions or interactions among a large number of biological and chemical compounds called metabolites [Fel97]. The reaction network describes the structure of a metabolic system and is key to the study of the metabolic function of the system. Figure 60.6 shows the reaction network for an example metabolic system of five metabolites given in [SLP00].

**FIGURE 60.6** Example metabolic networks: A, B, C, D, E are metabolites;  $v_j$ ,  $j = 1, \dots, 6$  are internal fluxes;  $b_j$ ,  $j = 1, \dots, 4$  are external fluxes. Each flux  $v_j$  corresponds to an internal reaction.

**Definitions:**

Each metabolite has a concentration, which changes constantly. **The rate of the change** is proportional to the amount of the metabolite consumed or produced in all the reactions.

Let  $C_i$  be **the concentration of metabolite  $i$** . Let  $v_j$  be **the chemical flux** in reaction  $j$ , i.e., the amount of metabolites produced in reaction  $j$  per mole. Then,

$$\frac{dC_i}{dt} = \sum_{j=1}^n s_{i,j} v_j,$$

where  $s_{i,j}$  is **the stoichiometric coefficient of metabolite  $i$**  in reaction  $j$ , and  $s_{i,j} = \pm k$ , if  $\pm k$  moles of metabolite  $i$  are produced (or consumed) in reaction  $j$ .

Let  $C = (C_1, \dots, C_m)^T$  be a vector of concentrations of  $m$  metabolites, and  $v = (v_1, \dots, v_n)^T$  a vector of fluxes of  $n$  reactions. Then, the equations can be written in a compact form,

$$\frac{dC}{dt} = S v,$$

where  $S = \{s_{i,j} : i = 1, \dots, m, j = 1, \dots, n\}$  is called the **stoichiometry matrix**, and the equations are called **the reaction equations** [HS96].

The fluxes are functions of the concentrations and some other system parameters. Therefore, the above reaction equations are nonlinear equations of  $C$ . However, when the system reaches its equilibrium,  $dC/dt = S v = 0$ , and the vector  $v$  becomes constant and is called a solution of **the steady-state flux equation**  $S v = 0$  [HS96].

The steady-state fluxes are important quantities for characterizing metabolic networks. They can be obtained by solving the steady-state flux equation  $S v = 0$ . However, since the number of reactions is usually larger than the number of metabolites, the solution to the equation is not unique. Also, because the internal fluxes are nonnegative, the solution set forms a convex cone, called the **steady-state flux cone**.

Usually, a convex cone can be defined in terms of a set of extreme rays such that any vector in the cone can be expressed as a nonnegative linear combination of the extreme rays,

$$\text{cone}(S) = \{v = \sum_{i=1}^l w_i p_i, \quad w_i \geq 0\},$$

where  $p = \{p_1, \dots, p_l\}$  is a set of extreme rays. An **extreme ray** is a vector that cannot be expressed as a nonnegative linear combination of any other vectors in the cone.

A set of vectors is said to be systematically independent if none of them can be expressed as a nonnegative linear combination of others. Since the extreme rays can be used to express all the vectors in a convex cone, they are also called the generating vectors of the cone. For metabolic networks, they are called the **extreme pathways** [PPP02].

**Facts:**

- [PPP02] A convex flux cone has a set of systematically independent generating vectors or extreme pathways. They are unique up to positive scalar multiplications. If the extreme pathways of the convex flux cone of a metabolic network are found, all the solutions for the steady-state flux equation can be generated by using the extreme pathways. In other words, the extreme pathways provide a unique description for the solution space of the steady-state flux equation, and can be used to characterize the whole steady-state capacity of the system.
- [PPP02] Let  $P$  be a matrix with each column corresponding to an extreme pathway of a given metabolic network. Let  $Q$  be the binary form of  $P$  such that  $Q_{i,j} = 1$  if  $P_{i,j} \neq 0$  and  $Q_{i,j} = 0$  otherwise. Then, the diagonal elements of  $Q^T Q$  are equal to the lengths of the extreme pathways, while the diagonal elements of  $Q Q^T$  show the numbers of extreme pathways the reactions participate in.

**Examples:**

- Consider the example network in Figure 60.6 and let  $S$  be the stoichiometric matrix with 10 columns for the internal ( $v_1, \dots, v_6$ ) as well as external ( $b_1, \dots, b_4$ ) fluxes,

$$S = \begin{array}{cccccccccc} v_1 & v_2 & v_3 & v_4 & v_5 & v_6 & b_1 & b_2 & b_3 & b_4 \\ \left[ \begin{array}{cccccccccc} -1 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 \\ 1 & -1 & 1 & 0 & 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 1 & -1 & -1 & 1 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & -1 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & -1 \end{array} \right] \begin{array}{l} \leftarrow A \\ \leftarrow B \\ \leftarrow C \\ \leftarrow D \\ \leftarrow E \end{array} \end{array}$$

Then, by using an appropriate algorithm (such as the one given in [SLP00]), a matrix of 7 extreme pathways of the system can be found as follows:

$$P^T = \begin{array}{cccccccccc} v_1 & v_2 & v_3 & v_4 & v_5 & v_6 & b_1 & b_2 & b_3 & b_4 \\ \left[ \begin{array}{cccccccccc} 1 & 0 & 0 & 0 & 0 & 0 & -1 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 1 & 0 & 0 & 0 & -1 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 & 1 & 0 & -1 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 & 0 & 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & -1 & 1 \end{array} \right] \begin{array}{l} \leftarrow p_1 \\ \leftarrow p_2 \\ \leftarrow p_3 \\ \leftarrow p_4 \\ \leftarrow p_5 \\ \leftarrow p_6 \\ \leftarrow p_7 \end{array} \end{array}$$

where row  $i$  corresponds to extreme pathway  $p_i$ ,  $i = 1, \dots, 7$ .

- By forming the binary form  $Q$  for  $P$  and computing

$$Q^T Q = \begin{bmatrix} 3 & 0 & 1 & 1 & 1 & 0 & 0 \\ 0 & 2 & 1 & 1 & 1 & 0 & 0 \\ 1 & 1 & 4 & 2 & 2 & 1 & 1 \\ 1 & 1 & 2 & 4 & 1 & 0 & 2 \\ 1 & 1 & 2 & 1 & 4 & 1 & 2 \\ 0 & 0 & 1 & 0 & 1 & 2 & 1 \\ 0 & 0 & 1 & 2 & 2 & 1 & 4 \end{bmatrix}$$

and

$$QQ^T = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 3 & 1 & 1 & 0 & 1 & 0 & 2 & 1 & 1 \\ 0 & 1 & 2 & 0 & 1 & 0 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 2 & 1 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 & 3 & 1 & 0 & 1 & 2 & 1 \\ 0 & 1 & 0 & 0 & 1 & 2 & 0 & 1 & 1 & 2 \\ 1 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 \\ 1 & 2 & 1 & 1 & 1 & 1 & 1 & 4 & 2 & 1 \\ 0 & 1 & 1 & 1 & 2 & 1 & 0 & 2 & 3 & 1 \\ 0 & 1 & 0 & 0 & 1 & 2 & 0 & 1 & 1 & 2 \end{bmatrix},$$

we obtain, from the diagonal elements of the matrices, the lengths of the pathways,  $p_1: 3, p_2: 2, p_3: 4, p_4: 4, p_5: 4, p_6: 2, p_7: 4$ , and the participations of the reactions in the extreme pathways,  $v_1: 1, v_2: 3, v_3: 2, v_4: 2, v_5: 3, v_6: 2, b_1: 1, b_2: 4, b_3: 3, b_4: 2$ . The off-diagonal elements of  $Q^T Q$  show the numbers of common reactions in different extreme pathways. For example,  $(Q^T Q)_{3,4} = 2$  means that  $p_3$  and  $p_4$  share two common reactions, and  $(Q^T Q)_{3,5} = 1$  means that  $p_3$  and  $p_5$  have one common reaction. The off-diagonal elements of  $QQ^T$  show the numbers of extreme pathways in which different reactions participate. For example,  $(QQ^T)_{2,3} = 1$  means that  $v_2$  and  $v_3$  participate in one extreme pathway together, and  $(QQ^T)_{2,8} = 2$  means that  $v_2$  and  $b_2$  participate in two extreme pathways together.

## 60.7 Conclusion

---

In this chapter, we have reviewed several subjects in biomolecular modeling, where linear algebra has played a central role in related computations. The review has focused on simple showcases and demonstrated important applications of linear algebra in biomolecular modeling. The subjects discussed are of great research interest in computational biology and are related directly to the solutions of many critical but challenging computational problems in biology yet to be solved, including the general distance geometry problem in NMR, the phase problem in x-ray crystallography, the structural comparison problem in comparative modeling, molecular dynamics simulation, and biosystems modeling and optimization, which we have not elaborated in detail here, but the interested readers can further explore.

Linear algebra has also been used to support many basic algebraic calculations required for solving other types of mathematical problems in biomolecular modeling, such as the optimization problems in potential energy minimization [WS99], the initial value problem in molecular dynamics simulation [BKP88], and the boundary value problem in simulation of protein conformational transformation [EMO99]. They are usually straightforward or routine linear algebra calculations, so we have not covered them in this chapter, but they should be considered as equally important as the applications we have discussed.

## Acknowledgments

---

I would like to thank my students, Feng Cui, Ajith Gunaratne, Kriti Mukhopadhyay, Rahul Ravindrudu, Andrew Severin, Matthew Studham, Peter Vedell, Di Wu, Eun-Mee YoonAnn, and Rich Wen Zhou, and my colleagues, Dr. Qunfeng Dong and Dr. Wonbin Young, who have read the paper carefully, helped produce some of the figures, and provided valuable comments and suggestions. The subjects discussed in the chapter have actually been the frequent topics of our research meetings. I would also like to thank the

Mathematical Biosciences Institute, Ohio State University, for providing support during my visit to the Institute in Spring 2005 where I completed the writing of this chapter.

Sometimes errors occur when data is transmitted over a channel. A binary 0 may be corrupted to a 1, or vice versa. Error control coding adds redundancy to a transmitted message allowing for detection and correction of errors. For example, if 0 stands for “no” and 1 stands for “yes”, a single bit error will completely change a message. If we repeat the message seven times, so 0000000 stands for “no” and 1111111 stands for “yes”, then it would require at least 4 bit errors to change a message, assuming that a message is decoded to either 0000000 or 1111111 according to which bit is in the majority in the received string. Thus, this simple code can be used to correct up to 3 errors. This code also detects up to 6 errors, in the sense that if between 1 and 6 errors occur in transmission, the received string will not be a codeword, and the receiver will recognize that one or more errors have occurred. The extra bits provide *error protection*.

Let  $\mathbb{F} = \mathbb{F}_q$  be the finite field with  $q$  elements. It is customary in the coding literature to write message blocks and vectors of the vector spaces  $\mathbb{F}^k$  and  $\mathbb{F}^n$  as row vectors, and we shall follow that practice in this chapter.

### 61.1 Basic Concepts

---

#### Definitions:

A **block code of length  $n$  over  $\mathbb{F}$**  is a subset  $\mathcal{C}$  of the vector space  $\mathbb{F}^n$ . Elements of  $\mathcal{C}$  are **codewords**. Elements of the finite field  $\mathbb{F}$  form the **alphabet**.

**Message blocks of length  $k$**  are strings of  $k$  symbols from the alphabet. Message blocks may also be identified with vectors in the vector space  $\mathbb{F}^k$ .

An **encoder** is a one-to-one mapping

$$\varphi : \mathbb{F}^k \longrightarrow \mathbb{F}^n$$

whose image is contained in the code  $\mathcal{C}$ .

The process of applying  $\varphi$  to a  $k$ -digit message block to obtain a codeword is **encoding**.

A **noisy channel** is a channel in which transmission errors may occur.

A codeword  $\mathbf{v} \in \mathcal{C} \subseteq \mathbb{F}^n$  that has been transmitted may be received as  $\mathbf{y} = \mathbf{v} + \mathbf{e}$ , where  $\mathbf{e} \in \mathbb{F}^n$  is an **error vector**.

Given a received word  $\mathbf{y} = \mathbf{v} + \mathbf{e} \in \mathbb{F}^n$ , the receiver estimates the corresponding codeword, thus, obtaining  $\tilde{\mathbf{v}} \in \mathcal{C}$ . This estimation process is called **decoding**. If  $\tilde{\mathbf{v}} = \mathbf{v}$ , then correct decoding has occurred.

Decoding may be thought of as a mapping  $\psi : \mathbb{F}^n \rightarrow \mathcal{C}$ . The mapping  $\psi$  is a **decoder**. Generally a decoder  $\psi$  should have the property that if the received word is in fact a codeword, it is decoded to itself.

The **word error rate** for a particular decoder is the probability  $P_{\text{err}}$  that the decoder outputs a wrong codeword.

The process of encoding, transmission, and decoding is summarized by

$$\begin{array}{ccccccc} \mathbb{F}^k & \xrightarrow{\varphi} & \mathbb{F}^n & \xrightarrow{\text{n.t.}} & \mathbb{F}^n & \xrightarrow{\psi} & \mathcal{C} \\ \mathbf{u} & \mapsto & \mathbf{v} & \mapsto & \mathbf{y} & \mapsto & \tilde{\mathbf{v}}, \end{array}$$

where “n.t.” stands for “noisy transmission.”

For  $\mathbf{v}, \mathbf{w} \in \mathbb{F}^n$  the **Hamming distance**, or simply the **distance**, between  $\mathbf{v}$  and  $\mathbf{w}$  is  $d(\mathbf{v}, \mathbf{w}) = |\{i \mid v_i \neq w_i\}|$ .

The **distance of a code**  $\mathcal{C} \subseteq \mathbb{F}^n$  is defined by  $d(\mathcal{C}) = \min\{d(\mathbf{v}, \mathbf{w}) \mid \mathbf{v}, \mathbf{w} \in \mathcal{C} \text{ and } \mathbf{v} \neq \mathbf{w}\}$ .

The **Hamming weight** or **weight** of  $\mathbf{v}$  is defined to be  $\text{wt}(\mathbf{v}) = d(\mathbf{v}, \mathbf{0})$ .

The **closed ball of radius  $t$  about the vector  $\mathbf{v} \in \mathbb{F}^n$**  is the set

$$B(\mathbf{v}, t) = \{\mathbf{y} \in \mathbb{F}^n \mid d(\mathbf{v}, \mathbf{y}) \leq t\}.$$

**Nearest-neighbor decoding** refers to decoding a received word  $\mathbf{y}$  to a nearest codeword (with respect to Hamming distance).

A code  $\mathcal{C} \subseteq \mathbb{F}^n$  is called a **perfect code** if there exists a nonnegative integer  $t$  such that

1.  $\mathbb{F}^n = \bigcup_{\mathbf{v} \in \mathcal{C}} B(\mathbf{v}, t)$ , and
2. For distinct  $\mathbf{v}, \mathbf{w} \in \mathcal{C}$ ,  $B(\mathbf{v}, t) \cap B(\mathbf{w}, t) = \emptyset$ .

That is,  $\mathbb{F}^n$  is the disjoint union of closed  $t$ -balls about the codewords.

### Facts:

1. The minimum number of symbol errors it would take for  $\mathbf{v}$  to be changed to  $\mathbf{w}$  is  $d(\mathbf{v}, \mathbf{w})$ .
2. A nearest-neighbor decoder need not be unique as it is possible that some received words  $\mathbf{y}$  might have two or more codewords at an equal minimum distance. The decoder may decode  $\mathbf{y}$  to any of these nearest codewords.
3. [Hil86, p. 5] The Hamming distance is a metric on  $\mathbb{F}^n$ .
4. [Hil86, p. 7] If the distance of a code  $\mathcal{C}$  is  $d$ , then  $\mathcal{C}$  can detect up to  $d - 1$  errors. It can correct up to  $\lfloor \frac{d-1}{2} \rfloor$  errors.

### Examples:

1. The binary message block 1011 can be identified with the vector  $(1, 0, 1, 1) \in \mathbb{F}_2^4$ .
2. The distance between the binary strings 0011 and 1110 is 3 since these two bit strings differ in three places.
3. We may picture nearest-neighbor decoding by taking a closed ball of expanding radius about the received word  $\mathbf{y}$ . As soon as the ball includes a codeword, that codeword is a nearest-neighbor to which we may decode  $\mathbf{y}$ .

## 61.2 Linear Block Codes

### Definitions:

A **linear block code of length  $n$  and dimension  $k$**  over  $\mathbb{F} = \mathbb{F}_q$  is a  $k$ -dimensional *linear* subspace,  $\mathcal{C}$ , of the vector space  $\mathbb{F}^n$ . One says that  $\mathcal{C}$  is an  $[n, k]$ -code over  $\mathbb{F}$ . If one wants to include the distance as a parameter, one says that  $\mathcal{C}$  is an  $[n, k, d]$ -code over  $\mathbb{F}$ . A **binary linear block code (BLBC)** is a linear block code over the binary field  $\mathbb{F}_2 = \{0, 1\}$ .

Two linear codes over  $\mathbb{F}_q$  are **equivalent** if one can be obtained from the other by steps of the following types: (i) permutation of the coordinates of the codewords, and (ii) multiplication of the field elements in one coordinate of the code by a nonzero scalar in  $\mathbb{F}_q$ .

The **rate** of a linear  $[n, k]$ -code is  $\frac{k}{n}$ .

Let  $\mathcal{C}$  be a linear  $[n, k]$ -code over  $\mathbb{F}$ . A **generator matrix for  $\mathcal{C}$**  is a matrix  $G \in \mathbb{F}^{k \times n}$  whose  $k$  rows form a basis for  $\mathcal{C}$ . A generator matrix for  $\mathcal{C}$  is also called an **encoder for  $\mathcal{C}$** .

A generator matrix  $G$  for an  $[n, k]$ -code is a **systematic encoder** if  $G$  can be partitioned, perhaps after a column permutation, as  $G = [I_k \mid A]$ , where  $A \in \mathbb{F}^{k \times (n-k)}$ . Then  $\mathbf{u} \in \mathbb{F}^k$  is encoded as  $\mathbf{u}G = [\mathbf{u} \mid \mathbf{u}A]$  so that the first  $k$  symbols of the codeword  $\mathbf{u}G$  are the message word  $\mathbf{u}$ , and the last  $n - k$  symbols form the **parity check** symbols.

Let  $\mathcal{C}$  be a linear  $[n, k]$ -code over  $\mathbb{F}$ . A **parity check matrix for  $\mathcal{C}$**  is a matrix  $H \in \mathbb{F}^{(n-k) \times n}$  such that  $\mathcal{C} = \{\mathbf{v} \in \mathbb{F}^n \mid \mathbf{v}H^T = \mathbf{0} \in \mathbb{F}^{(n-k)}\}$ .

Let  $\mathcal{C}$  be a linear  $[n, k]$ -code over  $\mathbb{F}$  with generator matrix  $G \in \mathbb{F}^{k \times n}$  and parity check matrix  $H \in \mathbb{F}^{(n-k) \times n}$ . Then  $H$  itself is the generator matrix of another code, denoted  $\mathcal{C}^\perp$ .  $\mathcal{C}^\perp$  is the **dual code** of  $\mathcal{C}$ .

A linear block code,  $\mathcal{C}$ , is **self-dual** if  $\mathcal{C} = \mathcal{C}^\perp$ .

Let  $\mathcal{C}$  be an  $[n, k]$ -code with parity check matrix  $H$ . For any vector  $\mathbf{y} \in \mathbb{F}^n$ , the **syndrome of  $\mathbf{y}$**  is the vector  $\mathbf{y}H^T \in \mathbb{F}^{(n-k)}$ .

### Facts:

- [Hil86, p. 47] There are  $q^k$  codewords in an  $[n, k]$ -code over  $\mathbb{F} = \mathbb{F}_q$ .
- The rate,  $\frac{k}{n}$ , of an  $[n, k]$ -code tells what fraction of transmitted symbols carry information. The complementary fraction,  $\frac{n-k}{n}$ , tells how much of the transmission is redundant (for error protection).
- If  $G$  is a generator matrix for the linear  $[n, k]$ -code,  $\mathcal{C}$ , then  $\mathcal{C} = \{\mathbf{u}G \mid \mathbf{u} \in \mathbb{F}^k\}$ . Thus, the mapping  $\varphi: \mathbb{F}^k \rightarrow \mathbb{F}^n$  given by  $\varphi(\mathbf{u}) = \mathbf{u}G$  is an encoder for  $\mathcal{C}$ .
- [Hil86, p. 48] The distance of a linear code is equal to the minimum weight of all nonzero codewords.
- Every  $[n, k]$  linear block code has an  $(n - k) \times n$  parity check matrix.
- For a given  $[n, k]$  linear code  $\mathcal{C}$  with generator matrix  $G$ , an  $(n - k) \times n$  matrix  $H$  is a parity check matrix for  $\mathcal{C}$  if and only if the rows of  $H$  are a basis for the left kernel of  $G^T$ .
- If  $H$  is a parity check matrix for the linear code  $\mathcal{C}$ , then  $\mathcal{C}$  is the left kernel of  $H^T$ .
- A generator matrix of  $\mathcal{C}$  is a parity check matrix of  $\mathcal{C}^\perp$ .
- [MS77, p. 33] Suppose  $H \in \mathbb{F}^{(n-k) \times n}$  is a parity check matrix for an  $[n, k]$ -code  $\mathcal{C}$  over  $\mathbb{F}$ . Then the distance of  $\mathcal{C}$  is equal to the smallest number of columns of  $H$  for which a linear dependency may be found.
- [Hil86, p. 70] If  $G = [I_k \mid A]$  is a systematic encoder for the  $[n, k]$ -code  $\mathcal{C}$ , then  $H = [-A^T \mid I_{n-k}]$  is a parity check matrix for  $\mathcal{C}$ .
- [MS77, p. 22] *Shannon's Coding Theorem for the Binary Symmetric Channel.* Assume that the transmission channel has a fixed symbol error probability  $p$  that the symbol 1 is corrupted to a 0 or vice versa. Let

$$C := 1 + p \log_2 p + (1 - p) \log_2(1 - p).$$

Then for every  $\epsilon > 0$  and every  $R < C$  there exists, for any sufficiently large  $n$ , a binary linear  $[n, k]$  code having transmission rate  $k/n \geq R$  and word error probability  $P_{\text{err}} \leq \epsilon$ .

### Examples:

1. The binary repetition code of length 7 is a  $[7, 1]$  BLBC. A generator matrix is

$$G = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{bmatrix}.$$

This code consists of two codewords, namely 0000000 and 1111111. The rate of this code is  $\frac{1}{7}$ . For every 7 bits transmitted, there is only 1 bit of information, with the remaining 6 redundant bits providing error protection. The distance of this code is 7. A parity check matrix for this code is the  $6 \times 7$  matrix

$$H = [J_{6,1} \mid I_6].$$

2. *Binary even weight codes.* The binary even weight code of length  $n$  is a  $[n, n-1]$ -code that consists of all even weight words in  $\mathbb{F}_2^n$ . A generator matrix is given by

$$G = [I_{n-1} \mid J_{(n-1),1}].$$

This code detects any single error, but cannot correct any errors. A binary even weight code may also be constructed by taking all binary strings of length  $n-1$  and to each adding an  $n$ th parity check bit chosen so that the weight of the resulting string is even. The 8-bit ASCII code (American Standard Code for Information Interchange) is constructed in this manner.

Note that the binary even weight code of length  $n$  and the binary repetition code of length  $n$  are dual codes.

3. The ISBN (International Standard Book Number) code is a  $[10, 9]$ -code over  $\mathbb{F}_{11}$  (the finite field  $\{0, 1, 2, 3, 4, 5, 6, 7, 8, 9, X\}$  where field operations are performed modulo 11.  $X$  is the symbol for 10 in this field). This code may be defined by the parity check matrix

$$H = [1 \ 2 \ 3 \ 4 \ 5 \ 6 \ 7 \ 8 \ 9 \ X].$$

Thus, a string of 10 digits,  $v_1v_2v_3v_4v_5v_6v_7v_8v_9v_{10}$ , from  $\mathbb{F}_{11}$  is a valid ISBN if and only if  $\sum_{i=1}^{10} i v_i \equiv 0 \pmod{11}$ . The ISBN code will detect any single error or any error where two digits are interchanged (transposition error). The first nine digits of an ISBN carry information about the book (such as publisher). The tenth digit is a check digit. Given the first 9 digits of an ISBN, the check digit may be computed by forming the sum  $\sum_{i=1}^9 i v_i$  and reducing modulo 11. The value thus obtained is  $v_{10}$  (if the value is 10, then  $v_{10} = X$ ).

*Note:* Currently the ISBN system does not use  $X$  as any of the first 9 digits. However, mathematically there is no reason not to use  $X$  anywhere in an ISBN.

4. The binary linear  $[8, 4]$  code with generator matrix

$$G = \begin{bmatrix} 1 & 0 & 1 & 1 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 1 & 1 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 & 1 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 1 & 1 & 1 \end{bmatrix}$$

is a self-dual code (note that over the binary field,  $GG^T = 0$ ). This code is called the extended binary  $[8, 4, 4]$  code. All pairs of different codewords are at distance 4 or 8.

## 61.3 Main Linear Coding Problem and Distance Bounds

---

### Definitions:

Let  $A_q(n, d)$  be the largest possible number so that there exists a block code  $\mathcal{C} \subseteq \mathbb{F}_q^n$  of distance  $d = d(\mathcal{C})$  and cardinality  $|\mathcal{C}| = A_q(n, d)$ . The **Main Coding Theory Problem** asks for the determination of  $A_q(n, d)$  for different values of  $n, d, q$ .

Similarly, let  $B_q(n, d)$  be the largest possible number so that there exists a linear  $[n, k]$  block code  $\mathcal{C}$  of distance  $d = d(\mathcal{C})$  and cardinality  $|\mathcal{C}| = B_q(n, d)$ . The **Main Linear Coding Problem** asks for the determination of  $B_q(n, d)$  for different values of  $n, d, q$ .

An  $[n, k, d]$  linear code is **maximum distance separable (MDS)** if  $d = n - k + 1$ .

### Facts:

1. Finding a value of  $B_q(n, d)$  is equivalent to finding the largest dimension,  $k$ , for which there is an  $[n, k, d]$ -code over  $\mathbb{F}_q$ . For such maximal  $k$ , we have  $B_q(n, d) = q^k$ .
2.  $B_q(n, d) \leq A_q(n, d)$  for all  $n, q, d$ .
3. [Rom92, p. 170]  $A_q(n, 1) = B_q(n, 1) = q^n$ .
4.  $B_q(n, 2) = q^{n-1}$ . Such a code is achieved by taking  $\mathcal{C}$  to be a code with parity check matrix  $J_{1,n}$ .
5. [Rom92, p. 170]  $A_q(n, n) = B_q(n, n) = q$ .
6. [Rom92, p. 170] For  $n \geq 2$ ,  $A_q(n, d) \leq q A_q(n-1, d)$ .
7. [Hil86, Theorem 14.5]  $B_q(n, 3) = q^{n-r}$ , where  $r$  is the unique integer such that

$$(q^{r-1} - 1)/(q - 1) < n \leq (q^r - 1)/(q - 1).$$

8. [Rom92, Theorem 4.5.7] *The sphere-packing bound.* Suppose  $\mathcal{C}$  is a block code of length  $n$  over  $\mathbb{F}_q$  with distance  $d$ . Let  $t = \lfloor \frac{d-1}{2} \rfloor$ . Then

$$A_q(n, d) \left( 1 + \binom{n}{1}(q-1) + \binom{n}{2}(q-1)^2 + \cdots + \binom{n}{t}(q-1)^t \right) \leq q^n.$$

9. [Hil86, pp. 20–21] The code  $\mathcal{C}$  is perfect if and only if equality holds in the sphere-packing bound.
10. [Rom92, Theorem 4.5.7] Suppose  $\mathcal{C}$  is a block code of length  $n$  over  $\mathbb{F}_q$  with distance  $d$ . Then

$$A_q(n, d) \leq q^{n-d+1}.$$

11. *The Singleton bound for linear block codes.* For any  $[n, k, d]$  linear code over  $\mathbb{F}_q$ , we have

$$d \leq n - k + 1.$$

12. An  $(n - k) \times n$  matrix  $H$  with entries in  $\mathbb{F}$  is the parity check matrix of an MDS code if and only if any  $n - k$  columns of  $H$  are linearly independent. Equivalently,  $H$  has the property that any full size minor of  $H$  is invertible.
13. [MS77, pp. 546–547] *The Griesmer bound.* Let  $N(k, d)$  be the length of the shortest binary linear code of dimension  $k$  and distance  $d$ . Then one has

$$N(k, d) \geq \sum_{i=0}^{k-1} \left\lceil \frac{d}{2^i} \right\rceil.$$

The right-hand side in the above inequality is, of course, always at least  $d + k - 1$ .

14. [Rom92, Theorem 4.5.16] *The Plotkin bound.* If  $d \geq \frac{qn-n}{q}$ , then

$$A_q(n, d) \leq \frac{dq}{d - qn - n}.$$

15. [Hil86, pp. 91–92] *The Gilbert Varshamov bound.* Assume  $q$  is a prime power. For any  $n$  and  $d$ , if  $k$  is the largest integer satisfying

$$q^k < \frac{q^n}{\sum_{i=0}^{d-2} \binom{n-1}{i} (q-1)^i},$$

then  $A_q(n, d) \geq q^k$ .

### Examples:

1. Consider the binary  $[7,4]$  code  $\mathcal{C}$  defined by the parity check matrix

$$H = \begin{bmatrix} 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 1 & 0 & 1 & 0 & 1 & 0 & 1 \end{bmatrix}.$$

This code has  $2^4 = 16$  elements. Since any two columns of  $H$  are linearly independent, but the first three columns are dependent, it follows that  $d(\mathcal{C}) = 3$ . So this code meets the sphere packing bound with  $t = 1$ . Observe that reading downward, the 7 columns of  $H$  form the numbers 1 through 7 in binary. This leads to a very nice nearest-neighbor decoding scheme that corrects any single error. If the received word is  $\mathbf{y}$ , the syndrome  $\mathbf{s} = \mathbf{y}H^T$  consists of 3 bits. Interpret these 3 bits as a binary number,  $x$ . If  $x$  is 0, the received word is a codeword and we assume that no errors have occurred. If  $x$  is not 0, it is one of the numbers from 1 to 7. In  $\mathbf{y}$  we change the bit in position  $x$ . This will give us a codeword (the unique codeword) at a distance of 1 from  $\mathbf{y}$ . We presume that this codeword is the intended transmission. For instance, if we receive the vector  $\mathbf{y} = 1100100$ , we compute the syndrome  $\mathbf{s} = \mathbf{y}H^T = 110$ . Interpreting 110 as a binary number, we obtain  $x = 6$ . We change the sixth bit of  $\mathbf{y}$  and obtain the codeword 1100110. This codeword is at a Hamming distance 1 from  $\mathbf{y}$ , and we assume it was the intended transmission.

2. Assume  $\alpha_1, \dots, \alpha_n$  are pairwise different nonzero elements of a finite field  $\mathbb{F}$ . Let

$$H := \begin{bmatrix} \alpha_1 & \alpha_2 & \dots & \alpha_n \\ \alpha_1^2 & \alpha_2^2 & \dots & \alpha_n^2 \\ \vdots & & & \vdots \\ \alpha_1^{n-k} & \alpha_2^{n-k} & \dots & \alpha_n^{n-k} \end{bmatrix}.$$

Then any full-size minor is the determinant of a Vandermonde matrix and, hence, nonzero. So  $H$  represents the parity check matrix of an MDS code.

## 61.4 Important Classes of Linear Codes 1

### Definitions:

Let  $\mathbb{F} = \mathbb{F}_q$ .

Let  $r$  be a positive integer. Let  $\mathbb{P}(\mathbb{F}^r)$  be the set of all 1-dimensional subspaces of  $\mathbb{F}^r$ . Choose a basis vector for each element of  $\mathbb{P}(\mathbb{F}^r)$ . Let  $H$  be a matrix whose columns are these basis vectors. The matrix  $H$  is the parity check matrix of a **Hamming code**,  $\mathcal{C}$ .

A **cyclic code** is a linear code  $\mathcal{C}$  for which every cyclic shift of a codeword is again a codeword.

Let  $\mathbb{F}[x]$  be the polynomial ring in one indeterminate over  $\mathbb{F}$ . Let  $\langle x^n - 1 \rangle$  be the ideal generated by  $x^n - 1$ . The quotient ring  $\mathbb{F}[x]/\langle x^n - 1 \rangle$  is denoted  $R_n$ . The polynomials of  $R_n$  are identified with vectors

in  $\mathbb{F}^n$  via

$$a_0 + a_1x + a_2x^2 + \cdots + a_{n-1}x^{n-1} \mapsto [a_0 \ a_1 \ a_2 \ \cdots \ a_{n-1}].$$

Suppose  $k < n$  are positive integers and  $r = n - k$ . A polynomial  $g(x) = a_0 + a_1x + a_2x^2 + \cdots + a_rx^r$  dividing  $x^n - 1 \in \mathbb{F}[x]$  is a **generator polynomial** of a cyclic  $[n, k]$ -code,  $\mathcal{C}$ . The polynomial  $h(x) = b_0 + b_1x + b_2x^2 + \cdots + b_kx^k$  chosen so that  $g(x)h(x) = x^n - 1$  is the **parity check polynomial** of  $\mathcal{C}$ .

**Facts:**

1. The ring  $R_n$  forms an  $n$ -dimensional vector space over  $\mathbb{F}$ . The monomials  $\{1, x, x^2, \dots, x^{n-1}\}$  form a basis. It further has an algebra structure over  $\mathbb{F}$  (i.e., there is a well-defined multiplication). In fact, polynomials in  $R_n$  are multiplied as usual, but  $x^n = 1$  in  $R_n$ , so exponents are reduced modulo  $n$ .
2. The cardinality of  $\mathbb{P}(\mathbb{F}^r)$  is  $n = (q^r - 1)/(q - 1)$ . Thus, the parity check matrix,  $H$ , of a Hamming code is of size  $r \times n$ . The corresponding Hamming code  $\mathcal{C}$  has  $q^k$  elements where  $k = n - r$ . Furthermore, the distance  $d(\mathcal{C}) = 3$ . The Hamming code reaches the sphere packing bound and hence is a perfect code in all cases.
3. [Hil86, pp. 147–148] For cyclic codes,  $R_n$  has the structure of a principal ideal ring (any ideal is generated by a single polynomial). Thus, any cyclic code has a generator polynomial  $g(x)$  where  $g(x)$  is a divisor of  $x^n - 1$ . Moreover, every cyclic code has a parity check polynomial, namely  $h(x) = (x^n - 1)/g(x)$ .
4. [Hil86, Chap. 12] If  $\mathcal{C}$  is a cyclic code with generator polynomial  $g(x) = a_0 + a_1x + a_2x^2 + \cdots + a_rx^r$  and parity check polynomial  $h(x) = b_0 + b_1x + b_2x^2 + \cdots + b_kx^k$ , then the corresponding generator matrix,  $G$ , and parity check matrix,  $H$ , of  $\mathcal{C}$  are given by

$$G = \begin{bmatrix} a_0 & a_1 & a_2 & \cdots & a_r & 0 & 0 & \cdots & 0 \\ 0 & a_0 & a_1 & a_2 & \cdots & a_r & 0 & \cdots & 0 \\ 0 & 0 & a_0 & a_1 & a_2 & \cdots & a_r & \cdots & 0 \\ & \ddots & \ddots & \ddots & \ddots & \ddots & \ddots & \ddots & \\ 0 & 0 & 0 & \cdots & a_0 & a_1 & a_2 & \cdots & a_r \end{bmatrix}$$

and

$$H = \begin{bmatrix} b_k & \cdots & b_2 & b_1 & b_0 & 0 & 0 & \cdots & 0 \\ 0 & b_k & \cdots & b_2 & b_1 & b_0 & 0 & \cdots & 0 \\ 0 & 0 & b_k & \cdots & b_2 & b_1 & b_0 & \cdots & 0 \\ & \ddots & \ddots & \ddots & \ddots & \ddots & \ddots & \ddots & \\ 0 & 0 & 0 & \cdots & b_k & \cdots & b_2 & b_1 & b_0 \end{bmatrix}.$$

**Examples:**

1. For  $q = 5$  and  $r = 2$ , we get the  $[6, 4, 3]$ -Hamming code over  $\mathbb{F}_5$  with parity check matrix

$$H = \begin{bmatrix} 1 & 0 & 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 2 & 3 & 4 \end{bmatrix}$$

and generator matrix

$$G = \begin{bmatrix} 4 & 4 & 1 & 0 & 0 & 0 \\ 4 & 3 & 0 & 1 & 0 & 0 \\ 4 & 2 & 0 & 0 & 1 & 0 \\ 4 & 1 & 0 & 0 & 0 & 1 \end{bmatrix}.$$

- The binary repetition code of length  $n$  is a cyclic code with generator polynomial  $1 + x + \dots + x^{n-1}$ . The binary even weight code is a cyclic code with generator polynomial  $1 + x$ .
- Over  $\mathbb{F}_2$ , the polynomial  $x^7 - 1 = x^7 + 1 = (1 + x)(1 + x + x^3)(1 + x^2 + x^3)$ . Hence,  $g(x) = 1 + x + x^3$  is the generator polynomial of a binary  $[7, 4]$ -cyclic code. The corresponding parity check polynomial is  $h(x) = (1 + x)(1 + x^2 + x^3) = 1 + x + x^2 + x^4$ . So, the generator matrix  $G$  and parity check matrix  $H$  for this code are given by

$$G = \begin{bmatrix} 1 & 1 & 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 1 & 0 & 1 \end{bmatrix} \quad \text{and} \quad H = \begin{bmatrix} 1 & 0 & 1 & 1 & 1 & 0 & 0 \\ 0 & 1 & 0 & 1 & 1 & 1 & 0 \\ 0 & 0 & 1 & 0 & 1 & 1 & 1 \end{bmatrix}.$$

Noting that the columns of  $H$  represent all the nonzero elements of  $\mathbb{F}_2^3$ , we see that this code is an equivalent version of the Hamming  $[7, 4]$ -perfect code.

## 61.5 Important Classes of Linear Codes 2

### Definitions:

The **Golay codes** [Gol49] are two cyclic codes defined as follows.

The **binary Golay code**,  $G_{23}$ , is a  $[23, 12, 7]$  binary cyclic code with generator polynomial  $g(x) = (x^{11} + x^{10} + x^6 + x^5 + x^4 + x^2 + 1)$ .

The **ternary Golay code**,  $G_{11}$ , is an  $[11, 6, 5]$  cyclic code over the ternary field  $\mathbb{F}_3$  with generator polynomial  $g(x) = (x^5 + 2x^3 + x^2 + 2x + 2)$ .

Denote by  $\mathbb{F}[x; k-1]$  the set of all polynomials of degree at most  $k-1$  over  $\mathbb{F}$ . Assume  $\mathbb{F}$  has size  $|\mathbb{F}| > n$  and let  $\alpha$  be a primitive of  $\mathbb{F}$  (i.e.,  $\alpha$  is a generator of the cyclic group  $\mathbb{F}^*$ ). Define the linear map (called the evaluation map) by

$$\begin{aligned} ev : \mathbb{F}[x; k-1] &\longrightarrow \mathbb{F}^n \\ f &\longmapsto (f(\alpha), \dots, f(\alpha^n)). \end{aligned}$$

The image of this map is a **Reed–Solomon code**.

Let  $\mathbb{F} = \mathbb{F}_q$  be a fixed finite field and consider the polynomial  $p(x) = x^n - 1 \in \mathbb{F}[x]$  and let the root  $w$  of  $p(x)$  be a primitive  $n$ th root of unity. Let  $b, d$  be positive integers.

$$\mathcal{B}_q(n, d, b, w) := \{c(x) \in \mathbb{F}[x; k-1] \mid c(w^{b+i}) = 0 \text{ for } i = 0, \dots, d-2\}$$

is called a **Bose–Chadhuri–Hocquenghem (BCH) code** having designed distance  $d$ . In the special case when  $n = q^m - 1$ ,  $\mathcal{B}_q(n, d, b, w)$  is a **primitive BCH code**; and if  $b = 1$ ,  $\mathcal{B}_q(n, d, b, w)$  is a **narrow sense BCH code**.

**Facts:**

1. Over the binary field  $\mathbb{F}_2$ ,

$$x^{23} + 1 = (x^{11} + x^{10} + x^6 + x^5 + x^4 + x^2 + 1)(x^{11} + x^9 + x^7 + x^6 + x^5 + x + 1)(x + 1).$$

Therefore, the binary Golay code,  $G_{23}$ , has parity check polynomial  $h(x) = (x^{11} + x^9 + x^7 + x^6 + x^5 + x + 1)(x + 1)$ .

2. [Hil86, pp. 153–157] The binary Golay code  $G_{23}$  is a  $[23, 12, 7]$  code having 4096 elements.  $G_{23}$  is a perfect code.
3. Over the ternary field  $\mathbb{F}_3$ ,

$$x^{11} - 1 = (x^5 + 2x^3 + x^2 + 2x + 2)(x^5 + x^4 + 2x^3 + x^2 + 2)(x + 2).$$

Therefore, the ternary Golay code,  $G_{11}$ , has parity check polynomial  $h(x) = (x^5 + x^4 + 2x^3 + x^2 + 2)(x + 2)$ .

4. [Hil86, pp. 157–159] The Golay code  $G_{11}$  is a ternary  $[11, 6, 5]$  code having 729 elements.  $G_{11}$  is a perfect code.
5. [Hil86, Theorem 9.5] Here is a complete catalog of perfect linear codes up to equivalence:
  - (a) The trivial perfect codes: All of  $\mathbb{F}^n$ , and the binary repetition codes of odd length.
  - (b) The Hamming codes.
  - (c) The Golay codes  $G_{23}$  and  $G_{11}$ .

6. Regarding Reed–Solomon codes, the linear map  $e\nu$  is one-to-one. Hence, the defined Reed–Solomon code is an  $[n, k]$  code. By the fundamental theorem of algebra the minimum weight of a nonzero code word is  $n - k + 1$ . It follows that a Reed–Solomon code is MDS. With regard to the natural basis  $1, x, \dots, x^{k-1}$  of  $\mathbb{F}[x; k - 1]$ , this code has a generator matrix:

$$G := \begin{bmatrix} 1 & 1 & \dots & 1 \\ \alpha & \alpha^2 & \dots & \alpha^n \\ \vdots & & & \vdots \\ \alpha^{k-1} & \alpha^{2(k-1)} & \dots & \alpha^{n(k-1)} \end{bmatrix}.$$

7. Regarding BCH codes, it is immediate from the definition that  $\mathcal{B}_q(n, d, b, w)$  has a parity check matrix of the form

$$H := \begin{bmatrix} 1 & w^b & \dots & w^{(n-1)b} \\ 1 & w^{b+1} & \dots & w^{(n-1)(b+1)} \\ \vdots & & & \vdots \\ 1 & w^{b+d-2} & \dots & w^{(n-1)(b+d-2)} \end{bmatrix}.$$

We would like to stress that  $\mathcal{B}_q(n, d, b, w)$  is the  $\mathbb{F}_q$  kernel of  $H$  and that the entries of  $H$  are in general not in the base field  $\mathbb{F}_q$ . Assume  $w \in \mathbb{F}_{q^s}$ , where  $\mathbb{F}_{q^s}$  is an extension field of  $\mathbb{F}_q$ . The  $\mathbb{F}_{q^s}$  kernel of  $H$  is a Reed–Solomon code of distance  $d$ . As a consequence, we have that  $\mathcal{B}_q(n, d, b, w)$  has distance at least  $d$ .

8. [Rom92, Chap. 8] The BCH code  $\mathcal{B}_q(n, d, b, w)$  is a cyclic code. For  $i = 0, \dots, d - 2$ , let  $m_i(x) \in \mathbb{F}_q[x]$  be the minimal polynomial of  $w^{b+i}$  and let

$$g(x) := \text{lcm}\{m_i(x) \mid i = 0, \dots, d - 2\} \in \mathbb{F}_q[x].$$

Then  $g(x)$  is a generator of the cyclic code  $\mathcal{B}_q(n, d, b, w)$  and its dimension is

$$\dim \mathcal{B}_q(n, d, b, w) = n - \deg g(x).$$

9. [Mas69], [FWRT94], [Sud97], [KV03] Reed–Solomon codes and BCH codes can be efficiently decoded up to half the designed distance using the Berlekamp–Massey algorithm [Mas69]. Extensions for this algorithm exist for algebraic geometric codes [FWRT94]. These algorithms have the major drawback that no **soft information** can be processed. This means that the decoder needs a vector in  $\mathbb{F}^n$  as an input and it is not possible to process real numbers as they naturally occur in wireless communication. In 1997 Sudan [Sud97] achieved a major breakthrough when he came up with a polynomial time algorithm for list decoding of Reed–Solomon codes. Since that time the technique has been vastly improved and generalized and a broad overview is given in [Gur04] and [KV03].

### Examples:

1. *Algebraic Geometric Codes.* In 1977, V.D. Goppa had the idea to vastly generalize the construction techniques of Reed–Solomon codes and BCH codes. Goppa codes became famous in 1982 when Tsfasman, Vladut, and Zink [TVZ82] constructed an infinite family of codes that exceeds the Gilbert Varshamov bound. (For further details, the reader is referred to the extensive literature on this subject [Gop81], [Gop88], [LG88], [TV91], and [Wal00].

Consider the **projective plane**  $\mathbb{P}_{\mathbb{F}}^2$  and let  $V \subset \mathbb{P}_{\mathbb{F}}^2$  be a **smooth curve** of degree  $\theta$ . This means there is an irreducible homogeneous polynomial  $\varphi(x, y, z) \in \mathbb{F}[x, y, z]$  of degree  $\theta$  with

$$V = \{(\alpha, \beta, \gamma) \in \mathbb{P}_{\mathbb{F}}^2 \mid \varphi(\alpha, \beta, \gamma) = 0\}.$$

The smoothness is characterized by the fact that there is no point on the curve where the partial derivatives vanish simultaneously.  $\Gamma(V) := \mathbb{F}[x, y, z] / \langle \varphi \rangle$  is called the homogeneous coordinate ring. As  $\Gamma(V)$  is a domain, there is a well-defined quotient field  $k(V)$ , which is called the **homogeneous function field**. (See e.g. [Ful89, p.91].)

If  $f \in k(V)$ , then  $f$  has an **associated divisor**

$$(f) := \sum_{P \in V} \text{ord}_P(f) P,$$

where  $\text{ord}_P(f)$  is  $m$  if  $f$  has a pole of order  $m$  at  $P$  and  $-m$  if  $f$  has a zero of order  $m$  at  $P$ .

Let  $D = P_1 + \cdots + P_n$  be a divisor on  $V$  of degree  $n$ . Define the vector space

$$L(D) := \{f \in k(V)^* \mid (f) + D \geq 0\} \cup \{0\}.$$

Let  $G$  be a divisor on  $V$  having support disjoint from  $D$ . Consider the linear map:

$$\begin{aligned} ev : L(G) &\longrightarrow \mathbb{F}^n \\ f &\longmapsto (f(P_1), \dots, f(P_n)). \end{aligned}$$

The image  $\mathcal{C}(D, G)$  of the linear evaluation map  $ev$  is called an **algebraic geometric Goppa (AG) code**. Note that  $\mathbb{F}[x; k-1]$  is a linear space of the form  $L(G)$  and in this way Reed–Solomon codes are AG codes.

Let  $\mathcal{C}(D, G)$  be an algebraic geometric Goppa code defined from a curve of degree  $\theta$ . If  $\deg G < n$ , then

$$\dim \mathcal{C}(D, G) = \dim L(G) - \dim L(G - D) \geq \deg G + 1 - \frac{1}{2}(\theta - 1)(\theta - 2)$$

and for the distance one has the lower bound

$$d(\mathcal{C}(D, G)) \geq n - \deg G.$$

Note that  $\frac{1}{2}(\theta - 1)(\theta - 2)$  is the genus of the curve. One way to construct AG codes with good distance parameters is, therefore, to construct curves of low genus having many  $\mathbb{F}_q$  rational points.

2. *Low density parity check codes.* A class of linear codes of tremendous practical importance was introduced by R.G. Gallager in his dissertation [Gal63]. These binary linear codes were called **low density parity check (LDPC) codes** by the author and are characterized by the property that the code can be written as the kernel of a very sparse matrix. For example, Gallager studied codes whose parity check matrix had three 1s in every column and six 1s in every row randomly chosen.

LDPC codes come with the remarkable property that efficient decoding algorithms exist whose complexity increases linearly with the code length [RU01]. One of simplest algorithms is the **bit flipping algorithm**. For this, assume that  $H$  is a sparse parity check matrix, a code word  $\mathbf{v}$  was sent, and a vector  $\mathbf{y} = \mathbf{v} + \mathbf{e}$  was received. The algorithm then checks bit-by-bit if the weight of the syndrome vector  $\mathbf{y}H^T$  increases or decreases if the bit under consideration is flipped. The bit flipping algorithm is one of the most simple type of message passing algorithms.

LDPC codes were later generalized by R. M. Tanner [Tan81] who defined linear codes defined through graphs. A good overview to this active area of research can be found in [MR01]. The class of LDPC codes and codes on graphs became prominent again after the discovery of Turbo codes [BGT93].

## 61.6 Convolutional Codes

Aside from linear block codes, the codes most used in engineering practice are convolutional codes. For this, consider the situation where a large amount of data has to be encoded by a linear block code. Let  $\mathbf{m}_0, \dots, \mathbf{m}_\tau \in \mathbb{F}^k$  be  $\tau + 1$  blocks of messages to be transmitted and assume  $G$  is the generator matrix of a linear  $[n, k]$  code. The encoding scheme:

$$\mathbf{m}_i \mapsto \mathbf{m}_i G = \mathbf{x}_i, \quad i = 0, \dots, \tau$$

can be compactly written in the form

$$\mathbf{m}(z) \mapsto \mathbf{m}(z)G = \mathbf{x}(z),$$

where

$$\mathbf{m}(z) := \sum_{i=0}^{\tau} \mathbf{m}_i z^i \in \mathbb{F}^k[z] \quad \text{and} \quad \mathbf{x}(z) := \sum_{i=0}^{\tau} \mathbf{x}_i z^i \in \mathbb{F}^n[z].$$

Elias [Eli55] had the original idea to replace in this encoding scheme the generator matrix  $G$  with a  $k \times n$  matrix  $G(z)$  whose entries are elements of the polynomial ring  $\mathbb{F}[z]$ .

### Definitions:

Consider the polynomial ring  $R := \mathbb{F}[z]$ . A submodule  $\mathcal{C} \subseteq R^n$  is called a **convolutional code**. The **rank** of the code  $\mathcal{C}$  is the rank,  $k$ , of  $\mathcal{C}$  considered as an  $R$ -module.  $\mathcal{C}$  is an  $[n, k]$ -convolutional code. The **rate** of  $\mathcal{C}$  is  $k/n$ .

A **generator matrix** for the rate  $k/n$  convolutional code  $\mathcal{C}$  is a  $k \times n$  polynomial matrix  $G$  with entries in  $R$  such that

$$\mathcal{C} = \{\mathbf{m}G = \mathbf{x} \mid \mathbf{m} \in R^k, \mathbf{x} \in R^n\}.$$

The **degree** of the convolutional code  $\mathcal{C}$  with generator matrix  $G$  is defined to be the largest degree of any  $k \times k$  minor of  $G$ .

Let  $\mathbf{x}(z) = \sum_{i=0}^{\tau} \mathbf{x}_i z^i \in R^n$  be a code vector. Define the **weight of  $\mathbf{x}(z)$**  by

$$\text{wt}(\mathbf{x}(z)) := \sum_{i=0}^{\tau} \text{wt}(\mathbf{x}_i).$$

The **free distance** of the convolutional code  $\mathcal{C}$  is defined as

$$d_{\text{free}}(\mathcal{C}) := \min\{\text{wt}(\mathbf{x}(z)) \mid \mathbf{0} \neq \mathbf{x}(z) \in \mathcal{C}\}. \quad (61.1)$$

**Facts:**

1. [Hun74]  $R$  is a principal ideal domain and  $\mathcal{C}$  is, therefore, a free  $R$ -module. As such,  $\mathcal{C}$  has a well-defined rank  $k$ , and a  $k \times n$  generator matrix  $G$  with entries in  $R$ , such that

$$\mathcal{C} = \{\mathbf{m}G = \mathbf{x} \mid \mathbf{m} \in R^k, \mathbf{x} \in R^n\}.$$

2. If  $G_1$  and  $G_2$  are both  $k \times n$  generator matrices of the same convolutional code  $\mathcal{C}$ , then there exists a unimodular matrix  $U \in \text{Gl}_k(R)$  such that  $G_2 = UG_1$ .
3. The degree of a convolutional code is well-defined (i.e., it does not depend on the particular generator matrix chosen). In the literature the degree is sometimes also called the **total memory** [LC83] or the **overall constraint length** [JZ99] or the **complexity** [Pir88].
4. The free distance of a convolutional code measures the smallest distance between any two different code words.
5. A major design problem in the area of convolutional codes is the construction of  $[n, k]$  codes of degree  $\delta$  whose free distance is maximal or near maximal. This question constitutes the generalization of the **main linear coding problem**.
6. If  $\mathcal{C}$  is an  $[n, k]$  convolutional code having  $G(z)$  as a generator matrix, then there exists an  $(n-k) \times n$  parity check matrix  $H(z)$  with entries in  $R$ .  $H(z)$  is characterized by the property that  $G(z)H(z)^T = \mathbf{0}_{k \times k}$ .
7. Convolutional codes of degree zero correspond to linear block codes.
8. Convolutional codes of small degree can be efficiently decoded using the Viterbi decoding algorithm [LC83, Chap. 11]. This algorithm has the distinct advantage that soft decision can be processed and due to this fact convolutional codes became the codes of choice for many wireless applications.
9. The free distance of an  $[n, k]$  convolutional code of degree  $\delta$  must satisfy the **generalized Singleton bound** [RS99]:

$$d_{\text{free}}(\mathcal{C}) \leq (n-k) \left( \left\lceil \frac{\delta}{k} \right\rceil + 1 \right) + \delta + 1.$$

10. Convolutional codes achieving the generalized Singleton bound are called **MDS convolutional codes**. Such codes exist as soon as the field size is large enough [RS99].
11. The literature on convolutional codes is not consistent in terms of terminology and definitions. Classical articles are [MS67] and [For70]. The articles [McE98] and [Ros01] provide surveys on recent developments and further connections. Generalizations to multidimensional convolutional codes were considered and the reader will find further reading and references in [GLRW00].

In contrast to the theory of linear block codes, there are not so many algebraic construction techniques of convolutional codes with a good designed distance and even fewer constructions of codes that can be efficiently decoded. The reader will find algebraic constructions of convolutional codes in [GLS04], [Jus75], [Pir88], [RSY96], [SGLR01], and in the bibliography of these articles.

**Examples:**

1. Consider the finite field  $\mathbb{F}_5$ . The generator matrix  $G(z) = (z, z+1, z+2, z+3)$  defines an  $[n, k] = [4, 1]$  convolutional code  $\mathcal{C}$  of degree  $\delta = 1$  and distance  $d_{\text{free}}(\mathcal{C}) = 7$ . The generalized Singleton bound for these parameters  $n, k$ , and  $\delta$  is 8 and the defined code is, therefore, not an MDS convolutional code.

2. [RS99, Ex. 2.13]. Consider the finite field  $\mathbb{F}_7$  and the generator matrix

$$G(z) = \begin{bmatrix} (z^2 + 1) & (3z^2 + 1) & (5z^2 + 1) \\ (z - 1) & (z - 2) & (2z - 3) \end{bmatrix}.$$

Then  $G(z)$  defines an  $[n, k] = [3, 2]$  convolutional code  $\mathcal{C}$  of degree  $\delta = 3$  and distance  $d_{\text{free}}(\mathcal{C}) = 6$ . The generalized Singleton bound for these parameters  $n, k$ , and  $\delta$  is 6 and the defined code is therefore an MDS convolutional code.

Modern computer science emerged when the eminent British mathematician Alan Turing invented the concept of Turing machine (TM) in 1936. Though very simple and primitive, TM serves as the universal model for all known physical computation devices. The principles of quantum mechanics, another revolutionary scientific discovery of the 20<sup>th</sup> century, had never been incorporated in the theory of computation until the early 1980s. P. Benioff first coined the concept of quantum Turing machine (QTM). Motivated by the problem that classical computers cannot simulate quantum systems efficiently, R. Feynman posed the quantum computer as the solution. The field of quantum computation was born.

Quantum computation mainly studies the construction and analysis of quantum algorithms that outperform the classical counterparts. In terms of computability, quantum computers and classical computers possess exactly the same computational power. But in terms of computational complexity, which measures the efficiency of computation, there are many examples confirming that quantum computers do solve certain problems faster. The two most significant ones are Shor’s factorization algorithm and Grover’s search algorithm, among other examples such as the Deutsch–Jozsa problem, the Bernstein–Vazirani problem, and Simon’s problem.

Quantum computers share many common features of the classical computers. In a classical computer, information is encoded in binary states (for example, 0 denotes the low voltage state and 1 denotes the high voltage state), and processed by various logic gates. In a quantum computer, information is represented by the states of the microscopic quantum systems, called qubits, and manipulated by various quantum gates. A qubit could be a two-level atom in the excited/ground states, a photon with horizontal/vertical polarizations, or a spin- $\frac{1}{2}$  particle with up/down spins. The state of a qubit can be controlled via physical devices such as laser and microwave. The distinctions between quantum and classical computers originate from the special characteristic of quantum mechanics. In contrast to a classical system, a quantum system can exist in different states at the same time, an interesting phenomenon called *superposition*. Superposition enables quantum computers to process data in parallel. That is why a quantum computer can solve certain

problems faster than a classical computer. But, when we measure a quantum system, it randomly collapses to one of the basis states. This indeterministic nature makes the design of efficient quantum algorithms highly nontrivial. Another distinctive feature of the quantum computer is that the operations performed by quantum gates must be unitary. This is the natural consequence of the unobserved quantum systems evolving according to the Schrödinger equation.

Throughout this chapter, we will use Dirac's bra-ket notation (see Section 59.4 for more information). In quantum mechanics, the state of a quantum system is described by a unit vector in a complex Hilbert space (a complete inner product vector space). Under Dirac's bra-ket notation, we use  $|\psi\rangle$  ("ket") to denote a vector in the Hilbert space and  $\langle\psi|$  ("bra") for its dual. The inner product of two vectors  $|\psi\rangle$  and  $|\phi\rangle$  is denoted  $\langle\psi|\phi\rangle$ . We also use  $|\psi\rangle|\phi\rangle$  and  $|\psi\phi\rangle$  interchangeably with the notation for the tensor product  $|\psi\rangle \otimes |\phi\rangle$ .

## 62.1 Basic Concepts

---

### Definitions:

A **(classical) Turing machine** (TM) is an abstract computing device consisting of a finite control, a two-way infinite tape, and a read/write head that moves to the left or right on the tape. It can be described by a 6-tuple  $(Q, A, B, \delta, q_0, q_a)$ , where  $Q$  is a finite set of control states,  $A$  a finite alphabet,  $B \in A$  the blank symbol,  $q_0, q_a \in Q$  the initial and accepting states, and  $\delta$  the transition function

$$\delta : Q \times A \rightarrow Q \times A \times \{L, R\}.$$

$L$  and  $R$  stand for moving left and right, respectively.

A **quantum Turing machine** (QTM) is an abstract computing device consisting of a finite control, a two-way infinite tape, and a read/write head that moves to the left or right of the tape. It can be described by a 6-tuple  $(Q, A, B, \delta, q_0, q_a)$ , where  $Q$  is a finite set of control states,  $A$  a finite alphabet,  $B \in A$  the blank symbol,  $q_0, q_a \in Q$  the initial and accepting states, and  $\delta$  the transition amplitude function

$$\delta : Q \times A \times Q \times A \times \{L, R\} \rightarrow \mathbb{C}.$$

The transition amplitude function satisfies

$$\sum_{(q_2, a_2, d) \in Q \times A \times \{L, R\}} |\delta(q_1, a_1, q_2, a_2, d)|^2 = 1,$$

for any  $(q_1, a_1) \in Q \times A$ .  $L$  and  $R$  stand for moving left and right, respectively.

A **quantum bit** (qubit) is a two-level quantum system, modeled by the two-dimensional Hilbert space  $H_2$ , with basis  $\{|0\rangle, |1\rangle\}$ . For example, for a spin- $\frac{1}{2}$  particle,  $|0\rangle$  and  $|1\rangle$  denote the spin-down and spin-up states, respectively. They can be mapped to the standard basis for  $H_2$  as  $|0\rangle = [1 \ 0]^T$  and  $|1\rangle = [0 \ 1]^T$ .

A **quantum register** of length  $n$  is an ordered system of  $n$  qubits, modeled by the  $2^n$ -dimensional Hilbert space  $H_{2^n} = H_2 \otimes H_2 \otimes \dots \otimes H_2$  with basis  $\{|00\dots 00\rangle, |00\dots 01\rangle, |00\dots 10\rangle, |00\dots 11\rangle, \dots, |11\dots 11\rangle\}$ . The basis states are ordered in lexicographic order. We may also write each basis state as  $|i\rangle$  for  $0 \leq i < 2^n$ , interpreting the  $n$ -bit string of 0s and 1s as the binary representation of  $i$ .

An **one-bit quantum gate** is a unitary map  $U : H_2 \rightarrow H_2$ .

An  **$n$ -bit quantum gate** is a unitary map  $U : H_2 \otimes H_2 \otimes \dots \otimes H_2 \rightarrow H_2 \otimes H_2 \otimes \dots \otimes H_2$ .

A **quantum circuit** on  $n$  bits is a unitary map on  $H_{2^n}$ , which can be represented by a concatenation of a finite number of quantum gates.

**Facts:**

1. [BV93] Any function which is computable by a TM is computable by a QTM.
2. [Fey82] Any function that is computable by a QTM is computable by a TM.
3. [NC00, pp. 13] A general state of a qubit is a unit vector  $a|0\rangle + b|1\rangle$ , where  $a, b \in \mathbb{C}$  and  $|a|^2 + |b|^2 = 1$ .  $a$  and  $b$  are the probability amplitudes of  $|0\rangle$  and  $|1\rangle$ , respectively. A measurement of a qubit yields either  $|0\rangle$  or  $|1\rangle$ , with probability  $|a|^2$  or  $|b|^2$ , respectively.
4. [BB02] A general state of  $n$ -bit quantum register is a unit vector

$$\sum_{x=00\dots 0}^{11\dots 1} \psi_x |x\rangle,$$

where  $\psi_x \in \mathbb{C}$  and  $\sum_{x=00\dots 0}^{11\dots 1} |\psi_x|^2 = 1$ .  $\psi_x$  is the probability amplitude of  $|x\rangle$ . A measurement of a quantum register yields  $|x\rangle \in \{|00\dots 0\rangle, |00\dots 1\rangle, \dots, |11\dots 1\rangle\}$ , with probability  $|\psi_x|^2$ .

**Examples:**

This section contains a list of quantum gates that are frequently used. We provide the description of their effects on the basis states, matrix representations, and circuit diagrams. In the circuit diagrams, the horizontal lines stand for the qubits. When there is no gate on the line, no operation is done, which can be interpreted as the identity operation. When the diagram of a gate shows up on a horizontal line/lines, the corresponding gate operation is applied to the qubit/qubits, with the input coming from the left and the output (result) going out to the right. The entire circuit diagram is read from left to right.

1. NOT gate  $\Lambda_0$ :  $\Lambda_0|0\rangle = |1\rangle$ ,  $\Lambda_0|1\rangle = |0\rangle$ , or  $\Lambda_0 = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$ .

2. The Walsh–Hadamard gate  $H$ :  $H|0\rangle = \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$ ,  $H|1\rangle = \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)$ , or

$$H = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}.$$

3. The  $x$ -rotation gate  $X_\theta$ :  $X_\theta|0\rangle = \cos \frac{\theta}{2}|0\rangle - i \sin \frac{\theta}{2}|1\rangle$ ,  $X_\theta|1\rangle = -i \sin \frac{\theta}{2}|0\rangle + \cos \frac{\theta}{2}|1\rangle$ , or

$$X_\theta = \begin{bmatrix} \cos \frac{\theta}{2} & -i \sin \frac{\theta}{2} \\ -i \sin \frac{\theta}{2} & \cos \frac{\theta}{2} \end{bmatrix}.$$

4. The  $y$ -rotation gate  $Y_\theta$ :  $Y_\theta|0\rangle = \cos\frac{\theta}{2}|0\rangle + \sin\frac{\theta}{2}|1\rangle$ ,  $Y_\theta|1\rangle = -\sin\frac{\theta}{2}|0\rangle + \cos\frac{\theta}{2}|1\rangle$ , or

$$Y_\theta = \begin{bmatrix} \cos\frac{\theta}{2} & -\sin\frac{\theta}{2} \\ \sin\frac{\theta}{2} & \cos\frac{\theta}{2} \end{bmatrix}.$$

5. The  $z$ -rotation gate  $Z_\theta$ :  $Z_\theta|0\rangle = e^{-i\theta/2}|0\rangle$ ,  $Z_\theta|1\rangle = e^{i\theta/2}|1\rangle$ , or

$$Z_\theta = \begin{bmatrix} e^{-i\theta/2} & 0 \\ 0 & e^{i\theta/2} \end{bmatrix}.$$

6. Controlled-NOT gate  $\Lambda_1$ :  $\Lambda_1|00\rangle = |00\rangle$ ,  $\Lambda_1|01\rangle = |01\rangle$ ,  $\Lambda_1|10\rangle = |11\rangle$ ,  $\Lambda_1|11\rangle = |10\rangle$ , or,

$$\Lambda_1 = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{bmatrix}.$$

The first qubit acts as the control bit; the operation on the second qubit is controlled by it. If the control bit is  $|0\rangle$ , no operation is done on the second qubit. If the control bit is  $|1\rangle$ , the NOT gate is applied to the second qubit. There is no change on the control bit in either case. In the diagram for the Controlled-NOT gate, a black dot denotes the control bit and a vertical line signifies the control action.

7. Two-bit Controlled- $U$  gate  $\Lambda_1(U)$ , where  $U$  is any arbitrary one-bit unitary transform:  $\Lambda_1(U)|00\rangle = |00\rangle$ ,  $\Lambda_1(U)|01\rangle = |01\rangle$ ,  $\Lambda_1(U)|10\rangle = |1\rangle U|0\rangle$ ,  $\Lambda_1(U)|11\rangle = |1\rangle U|1\rangle$ , or,

$$\Lambda_1(U) = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & & \\ 0 & 0 & & U \end{bmatrix}.$$

The first qubit acts as the control bit; the operation on the second qubit is controlled by it. If the control bit is  $|0\rangle$ , no operation is done on the second qubit. If the control bit is  $|1\rangle$ , the one-bit gate  $U$  is applied to the second qubit. There is no change on the control bit in either case. In the diagram for the Controlled- $U$  gate, a black dot denotes the control bit and a vertical line signifies the control action.

8. Function evaluation operator  $U_f : H_{2^n} \otimes H_{2^m} \rightarrow H_{2^n} \otimes H_{2^m}$ , where  $f : \{0, 1\}^n \rightarrow \{0, 1\}^m$ ,  $|x\rangle \in H_{2^n}$ , and  $|y\rangle \in H_{2^m}$ , is given by

$$|x\rangle|y\rangle \rightarrow |x\rangle|y + f(x)\text{mod}2^m\rangle.$$

Two special cases of this operator will be used in the algorithms discussed later.

- $m = 1$ ,  $U_f$  is given by:  $|x\rangle|y\rangle \rightarrow |x\rangle|y \oplus f(x)\rangle$ , where  $\oplus$  is the addition mod 2.

- $y = 0$ ,  $U_f$  is given by:  $|x\rangle|0\rangle \rightarrow |x\rangle|f(x)\rangle$ .

9. Quantum Fourier transform (QFT) ( $n$ -bit):

$$|x\rangle \rightarrow \frac{1}{2^{n-1}} \sum_{y=0}^{2^n-1} e^{2\pi i xy/2^n} |y\rangle,$$

where  $x \in \{0, 1, \dots, 2^n - 1\}$ . This operator is a crucial building block of Shor's Factorization Algorithm. The following example manifests the power of QFT.

*Example:* Define a function  $f : \{0, 1, 2, 3\} \rightarrow \{0, \frac{1}{\sqrt{2}}\}$  by  $f(1) = f(3) = \frac{1}{\sqrt{2}}$  and  $f(0) = f(2) = 0$ . This function has period 2. Consider a 2-bit quantum system with state  $\frac{1}{\sqrt{2}}(|1\rangle + |3\rangle)$ , where the probability amplitudes of the basis states  $|0\rangle$ ,  $|1\rangle$ ,  $|2\rangle$ , and  $|3\rangle$  are specified by the function values of  $f$  at 0, 1, 2, and 3. Apply QFT to this state.

$$\begin{aligned} & \frac{1}{\sqrt{2}}(|1\rangle + |3\rangle) \\ & \rightarrow \frac{1}{2\sqrt{2}}(|0\rangle + i|1\rangle - |2\rangle - i|3\rangle) + \frac{1}{2\sqrt{2}}(|0\rangle - i|1\rangle - |2\rangle + i|3\rangle) \\ & = \frac{1}{\sqrt{2}}(|0\rangle - |2\rangle). \end{aligned}$$

Measurement of the result yields 2, the period of  $f$ , with probability  $\frac{1}{2}$ . Thus, QFT provides a tool for period finding.

In the diagram for QFT,  $x_{n-1}x_{n-2} \dots x_2x_1x_0$  and  $y_{n-1}y_{n-2} \dots y_2y_1y_0$  are the binary representations of  $x$  and  $y$ , respectively.

## 62.2 Universal Quantum Gates

### Definitions:

A 1-bit gate  $A$  is **special** if  $\det(A) = 1$ .

A 2-bit gate  $V$  is **primitive** if  $V$  is decomposable, i.e., there exist 1-bit gates  $S$  and  $T$  such that  $V|x\rangle|y\rangle = S|x\rangle \otimes T|y\rangle$ , or  $V|x\rangle|y\rangle = S|y\rangle \otimes T|x\rangle$ , for any state  $|xy\rangle$ .

A 2-bit gate  $V$  is **imprimitive** if it is not primitive.

A collection of quantum gates  $G$  is **universal** if, for each  $n \in \mathbb{N}$ , every  $n$ -bit quantum gate can be approximated with arbitrary accuracy by a circuit consisting of quantum gates in  $G$ .

A collection of quantum gates  $G$  is **exactly universal** if, for each  $n \in \mathbb{N}$ , every  $n$ -bit quantum gate can be obtained exactly by a circuit consisting of quantum gates in  $G$ .

### Facts:

The following facts can be found in [BB02].

1. The collection of all 1-bit gates and any imprimitive 2-bit gate is universal.
2. The collection of all 1-bit gates and any imprimitive 2-bit gate is exactly universal.
3. The collection of all special 1-bit gates and any imprimitive 2-bit gate  $V$  with  $\det(V)$  not being a root of unity is universal.

### Examples:

1. The  $X_\theta$ ,  $Y_\theta$ , and  $Z_\theta$  gates are special.
2. The NOT gate and Walsh–Hadamard gate are not special.
3. The 2-bit gate  $V = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 1 & 0 & -1 & 0 \\ 0 & 1 & 0 & -1 \end{bmatrix}$  is primitive,  $V|x\rangle|y\rangle = H|x\rangle \otimes |y\rangle$ .

4. The Controlled-NOT gate is imprimitive.
5. The collection of all 1-bit gates and Controlled-NOT gate is universal, and exactly universal.
6. The collection of all  $X_\theta$ ,  $Y_\theta$ , and  $Z_\theta$  gates and Controlled-phase gate  $\Lambda_1(Q_\theta)$ , where  $Q_\theta = \begin{bmatrix} 1 & 0 \\ 0 & e^{i\theta} \end{bmatrix}$  and  $e^{i\theta}$  is not a root of unity, is universal.

## 62.3 Deutsch's Problem

---

### Definitions:

A **Boolean function** is a function with codomain  $\{0, 1\}$ .

A Boolean function  $f : \{0, 1\} \rightarrow \{0, 1\}$  is **constant** if  $f(0) = f(1)$ .

A Boolean function  $f : \{0, 1\} \rightarrow \{0, 1\}$  is **balanced** if  $f(0) \neq f(1)$ .

### Problem: Deutsch

Given a Boolean function  $f : \{0, 1\} \rightarrow \{0, 1\}$ , determine whether it is constant or balanced.

### Algorithm: Deutsch

1. Prepare a two-bit quantum register and initialize it to the state  $|0\rangle|1\rangle$ .
2. Apply the Walsh–Hadamard transform to both qubits.
3. Apply the function evaluation operator  $U_f$

$$U_f : |x\rangle|y\rangle \rightarrow |x\rangle|y \oplus f(x)\rangle.$$

4. Apply the Walsh–Hadamard transform to the first qubit.
5. Measure the first qubit. If the outcome is  $|0\rangle$ ,  $f$  is constant. If the outcome is  $|1\rangle$ ,  $f$  is balanced.

### Circuit Diagram: Deutsch

### Facts:

The following facts can be found in [CEM98].

1. With the classical computer, we need two evaluations of  $f$  to determine whether  $f$  is constant or balanced.
2. With the quantum computer, we need only one evaluation of  $f$  to determine whether  $f$  is constant or balanced.

**Examples:**

1. Let  $f(0) = 0$  and  $f(1) = 1$ . The following sequence of quantum states shows the result of computation utilizing Deutsch's Algorithm. We start from the initial state  $|0\rangle|1\rangle$ . Then,

$$\begin{aligned}
 & |0\rangle|1\rangle \\
 \rightarrow & \frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} = \frac{|0\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|1\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\
 \rightarrow & \frac{|0\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|1\rangle}{\sqrt{2}} \frac{|1\rangle - |0\rangle}{\sqrt{2}} \\
 = & \frac{|0\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} - \frac{|1\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} = \frac{|0\rangle - |1\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\
 \rightarrow & |1\rangle \frac{|0\rangle - |1\rangle}{\sqrt{2}}.
 \end{aligned}$$

The outcome of measuring the first qubit is  $|1\rangle$ , hence,  $f$  is balanced.

2. Let  $f(0) = 0$  and  $f(1) = 0$ . The following sequence of quantum states shows the result of computation utilizing Deutsch's Algorithm. We start from the initial state  $|0\rangle|1\rangle$ . Then,

$$\begin{aligned}
 & |0\rangle|1\rangle \\
 \rightarrow & \frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} = \frac{|0\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|1\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\
 \rightarrow & \frac{|0\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|1\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} = \frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\
 \rightarrow & |0\rangle \frac{|0\rangle - |1\rangle}{\sqrt{2}}.
 \end{aligned}$$

The outcome of measuring the first qubit is  $|0\rangle$ , hence,  $f$  is constant.

## 62.4 Deutsch–Jozsa Problem

---

**Definitions:**

A Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  is **constant** if  $f(x) = c$ ,  $c \in \{0, 1\}$ , for all  $x \in \{0, 1\}^n$ .

A Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  is **balanced** if the function value is 1 (or 0) for exactly half of the input values, i.e.,  $\text{card}(f^{-1}(\{1\})) = \text{card}(f^{-1}(\{0\}))$ .

**Problem: Deutsch–Jozsa**

Given a Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ , which is either constant or balanced, determine whether it is constant or balanced.

**Algorithm: Deutsch–Jozsa**

1. Prepare an  $(n + 1)$ -bit quantum register and initialize it to the state  $(|0\rangle)^n|1\rangle$ .
2. Apply the Walsh–Hadamard transform to all the qubits.
3. Apply the function evaluation operator  $U_f$ :

$$U_f : |x\rangle|y\rangle \rightarrow |x\rangle|y \oplus f(x)\rangle.$$

4. Apply the Walsh–Hadamard transform to the first  $n$  qubits.
5. Measure the first  $n$  qubit. If the outcome is  $|00 \dots 0\rangle$ ,  $f$  is constant. If the outcome is not  $|00 \dots 0\rangle$ ,  $f$  is balanced.

**Circuit Diagram: Deutsch–Jozsa****Facts:**

The following facts can be found in [CEM98].

1. With the classical computer, we need at least  $2^{n-1} + 1$  evaluations of  $f$  to determine with certainty whether  $f$  is constant or balanced.
2. With the quantum computer, we need only one evaluation of  $f$  to determine with certainty whether  $f$  is constant or balanced.

**Examples:**

1. Let  $n = 2$  and  $f(00) = f(01) = f(10) = f(11) = 1$ . The following sequence of quantum states shows the result of computation utilizing Deutsch–Jozsa’s Algorithm. We start from the initial state  $|00\rangle|1\rangle$ . Then,

$$\begin{aligned}
& |00\rangle|1\rangle \\
\rightarrow & \frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} = \frac{|00\rangle + |01\rangle + |10\rangle + |11\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\
= & \frac{|00\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|01\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|10\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|11\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\
\rightarrow & \frac{|00\rangle}{2} \frac{|1\rangle - |0\rangle}{\sqrt{2}} + \frac{|01\rangle}{2} \frac{|1\rangle - |0\rangle}{\sqrt{2}} + \frac{|10\rangle}{2} \frac{|1\rangle - |0\rangle}{\sqrt{2}} + \frac{|11\rangle}{2} \frac{|1\rangle - |0\rangle}{\sqrt{2}} \\
= & -\frac{|00\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} - \frac{|01\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} - \frac{|10\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} - \frac{|11\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\
= & \frac{-|00\rangle - |01\rangle - |10\rangle - |11\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} = -\frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\
\rightarrow & -|00\rangle \frac{|0\rangle - |1\rangle}{\sqrt{2}}.
\end{aligned}$$

The outcome of measuring the first 2 qubit is  $|00\rangle$ , hence,  $f$  is constant.

2. Let  $n = 2$ ,  $f(00) = f(01) = 0$ , and  $f(10) = f(11) = 1$ . The following sequence of quantum states shows the result of computation utilizing Deutsch–Jozsa’s Algorithm. We start from the initial state  $|00\rangle|1\rangle$ . Then,

$$\begin{aligned}
& |00\rangle|1\rangle \\
\rightarrow & \frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} = \frac{|00\rangle + |01\rangle + |10\rangle + |11\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\
= & \frac{|00\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|01\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|10\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|11\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\
\rightarrow & \frac{|00\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|01\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|10\rangle}{2} \frac{|1\rangle - |0\rangle}{\sqrt{2}} + \frac{|11\rangle}{2} \frac{|1\rangle - |0\rangle}{\sqrt{2}} \\
= & \frac{|00\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|01\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} - \frac{|10\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} - \frac{|11\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\
= & \frac{|00\rangle + |01\rangle - |10\rangle - |11\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} = \frac{|0\rangle - |1\rangle}{\sqrt{2}} \frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\
\rightarrow & |10\rangle \frac{|0\rangle - |1\rangle}{\sqrt{2}}.
\end{aligned}$$

The outcome of measuring the first 2 qubit is  $|10\rangle$ , hence,  $f$  is balanced.

## 62.5 Bernstein–Vazirani Problem

### Definitions:

Let  $x = x_1x_2 \dots x_n$  and  $y = y_1y_2 \dots y_n$  be two  $n$ -bit strings from  $\{0, 1\}^n$ . The **dot product**  $x \cdot y$  is the mod 2 sum of the bitwise products:

$$x \cdot y = x_1y_1 \oplus x_2y_2 \oplus \dots \oplus x_ny_n.$$

### Problem: Bernstein–Vazirani

Given a Boolean function  $f_a : \{0, 1\}^n \rightarrow \{0, 1\}$  defined by  $f_a(x) = a \cdot x$ , where  $a$  is an unknown  $n$ -bit string in  $\{0, 1\}^n$ , determine the value of  $a$ .

**Algorithm: Bernstein–Vazirani**

1. Prepare an  $(n + 1)$ -bit quantum register and initialize it to the state  $(|0\rangle)^n|1\rangle$ .
2. Apply the Walsh–Hadamard transform to all the qubits.
3. Apply the function evaluation operator  $U_{f_a}$ :

$$U_{f_a} : |x\rangle|y\rangle \rightarrow |x\rangle|y \oplus f_a(x)\rangle.$$

4. Apply the Walsh–Hadamard transform to the first  $n$  qubits.
5. Measure the first  $n$  qubits. The outcome is  $|a\rangle$ .

**Circuit Diagram: Bernstein–Vazirani****Facts:**

The following facts can be found in [BV93].

1. With the classical computer, we need  $n$  evaluations of  $f_a$  to determine the value of  $a$ .
2. With the quantum computer, we need only one evaluation of  $f_a$  to determine the value of  $a$ .

**Examples:**

Let  $a = 11$ , a 2-bit string. The following sequence of quantum states shows the result of computation utilizing Bernstein–Vazirani’s Algorithm. We start from the initial state  $|00\rangle|1\rangle$ . Then,

$$\begin{aligned} & |00\rangle|1\rangle \\ \rightarrow & \frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} = \frac{|00\rangle + |01\rangle + |10\rangle + |11\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\ = & \frac{|00\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|01\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|10\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|11\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \end{aligned}$$

$$\begin{aligned}
&\rightarrow \frac{|00\rangle |0\rangle - |1\rangle}{2\sqrt{2}} + \frac{|01\rangle |1\rangle - |0\rangle}{2\sqrt{2}} + \frac{|10\rangle |1\rangle - |0\rangle}{2\sqrt{2}} + \frac{|11\rangle |0\rangle - |1\rangle}{2\sqrt{2}} \\
&= \frac{|00\rangle |0\rangle - |1\rangle}{2\sqrt{2}} - \frac{|01\rangle |0\rangle - |1\rangle}{2\sqrt{2}} - \frac{|10\rangle |0\rangle - |1\rangle}{2\sqrt{2}} + \frac{|11\rangle |0\rangle - |1\rangle}{2\sqrt{2}} \\
&= \frac{|00\rangle - |01\rangle - |10\rangle + |11\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} = \frac{|0\rangle - |1\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\
&\rightarrow |11\rangle \frac{|0\rangle - |1\rangle}{\sqrt{2}}.
\end{aligned}$$

The outcome of measuring the first 2 qubits is  $|11\rangle$ , hence,  $a = 11$ .

## 62.6 Simon's Problem

---

### Definitions:

A function  $f : \{0, 1\}^n \rightarrow \{0, 1\}^n$  is **2-1** if for each  $z \in \text{range}(f)$ , there are exactly two distinct  $n$ -bit strings  $x$  and  $y$  such that  $f(x) = f(y) = z$ .

A function  $f : \{0, 1\}^n \rightarrow \{0, 1\}^n$  has a **period**  $a$  if  $f(x) = f(x \oplus a), \forall x \in \{0, 1\}^n$ .

### Problem: Simon

Given a function  $f : \{0, 1\}^n \rightarrow \{0, 1\}^n$  which is 2-1 and has period  $a$ , determine the period  $a$ .

### Algorithm: Simon

1. Repeat the following procedure for  $n$  times.
  - (a) Prepare a  $2n$ -bit quantum register and initialize it to the state  $(|0\rangle)^n(|0\rangle)^n$ .
  - (b) Apply the Walsh–Hadamard transform to the first  $n$  qubits.
  - (c) Apply the function evaluation operator  $U_f$ :

$$U_f : |x\rangle|y\rangle \rightarrow |x\rangle|y \oplus f(x)\rangle.$$

- (d) Apply the Walsh–Hadamard transform to the first  $n$  qubits.
  - (e) Measure the first  $n$  qubits. Record the outcome  $|x\rangle$ .
2. With the  $n$  outcomes  $x_1, x_2, \dots, x_n$ , solve the following system of linear equations:

$$\begin{cases} x_1 \cdot a = 0 \\ x_2 \cdot a = 0 \\ \vdots \\ x_n \cdot a = 0. \end{cases}$$

The solution  $a$  is the period of  $f$ .

**Circuit Diagram: Simon****Facts:**

The following facts can be found in [Sim94].

1. With the classical computer, we need exponentially many evaluations of  $f$  to determine the period  $a$ .
2. With the quantum computer, we need  $O(n)$  evaluations (on average) of  $f$  to determine the period  $a$ .

**Examples:**

Let  $f(00) = 01$ ,  $f(01) = 11$ ,  $f(10) = 01$ , and  $f(11) = 11$ . The following sequence of quantum states shows the result of computation utilizing Simon's Algorithm. We start from the initial state  $|00\rangle|00\rangle$ . Then,

$$\begin{aligned}
 & |00\rangle|00\rangle \\
 \rightarrow & \frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|0\rangle + |1\rangle}{\sqrt{2}} |00\rangle = \frac{|00\rangle + |01\rangle + |10\rangle + |11\rangle}{2} |00\rangle \\
 = & \frac{|00\rangle|00\rangle}{2} + \frac{|01\rangle|00\rangle}{2} + \frac{|10\rangle|00\rangle}{2} + \frac{|11\rangle|00\rangle}{2} \\
 \rightarrow & \frac{|00\rangle|01\rangle}{2} + \frac{|01\rangle|11\rangle}{2} + \frac{|10\rangle|01\rangle}{2} + \frac{|11\rangle|11\rangle}{2}
 \end{aligned}$$

$$\begin{aligned}
&= \frac{|00\rangle + |10\rangle}{2}|01\rangle + \frac{|01\rangle + |11\rangle}{2}|11\rangle = \frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|0\rangle}{\sqrt{2}}|01\rangle + \frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|1\rangle}{\sqrt{2}}|11\rangle \\
&\rightarrow |0\rangle \frac{|0\rangle + |1\rangle}{2}|01\rangle + |0\rangle \frac{|0\rangle - |1\rangle}{2}|11\rangle = \frac{|00\rangle + |01\rangle}{2}|01\rangle + \frac{|00\rangle - |01\rangle}{2}|11\rangle.
\end{aligned}$$

The outcome of measuring the first 2 qubits yields either  $|00\rangle$  or  $|01\rangle$ . Suppose that we have run the computation above twice and obtained  $|00\rangle$  and  $|01\rangle$ , respectively. We now have a system of linear equations:

$$\begin{cases} 00 \cdot a = 0 \\ 01 \cdot a = 0. \end{cases}$$

The solution is  $a = 10$ , the period of this function.

## 62.7 Grover's Search Algorithm

---

### Problem: Grover

Given an unsorted database with  $N$  items, find a target item  $w$ . This problem can be formulated using an oracle function  $f : \{0, 1, \dots, N - 1\} \rightarrow \{0, 1\}$ , where

$$f(x) = \begin{cases} 0, & \text{if } x \neq w, \\ 1, & \text{if } x = w. \end{cases}$$

Given such an oracle function, find the  $w$  such that  $f(w) = 1$ .

### Algorithm: Grover

Without loss of generality, let  $N = 2^n$ .

1. Prepare an  $(n + 1)$ -bit quantum register and initialize it to the state  $(|0\rangle)^n|1\rangle$ .
2. Apply the Walsh–Hadamard transform to all the  $n + 1$  qubits.
3. Repeat the following procedure for about  $\frac{\pi}{4}\sqrt{N}$  times. Cf. Figure 62.1.

(a) Apply the function evaluation operator  $U_f$  (selective sign flipping operator):

$$U_f : |x\rangle|y\rangle \rightarrow |x\rangle|y \oplus f(x)\rangle.$$

This is equivalent to the unitary operator  $\mathcal{I}_w = I - 2|w\rangle\langle w|$  on the first  $n$  qubits.

(b) Apply unitary operator (inversion about the average operator)  $\mathcal{I}_s = 2|s\rangle\langle s| - I$  on the first  $n$  qubits. Cf. Figure 62.2.

4. Measure the first  $n$  qubits. We obtain the search target with high probability.

### Facts:

1. [Gro97] With the classical computer, on average, we need  $O(N)$  oracle calls (evaluations of  $f$ ) to find the search target.
2. [Gro97] With the quantum computer, on average, we need  $O(\sqrt{N})$  oracle calls to find the search target.

**Circuit Diagrams: Grover**

**FIGURE 62.1** Grover's Algorithm.

**FIGURE 62.2** Inversion about the average operator  $\mathcal{I}_s$ .

3. [BBH98] When  $N = 4$ , using Grover's Algorithm, exactly one oracle call suffices to find the search target with certainty.

**Examples:**

Let  $N = 2^2 = 4$  and Item 3 be the search target, which is encoded by the quantum state  $|11\rangle$  (11 is the binary representation of 3). The following sequence of quantum states shows the result of computation utilizing Grover's Algorithm. We start from the initial state  $|00\rangle|1\rangle$ . Then,

$$\begin{aligned}
 & |00\rangle|1\rangle \\
 \rightarrow & \frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|0\rangle + |1\rangle}{\sqrt{2}} \frac{|0\rangle - |1\rangle}{\sqrt{2}} = \frac{|00\rangle + |01\rangle + |10\rangle + |11\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\
 = & \frac{|00\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|01\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|10\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|11\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\
 \rightarrow & \frac{|00\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|01\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|10\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} + \frac{|11\rangle}{2} \frac{|1\rangle - |0\rangle}{\sqrt{2}}
 \end{aligned}$$

$$\begin{aligned}
&= \frac{|00\rangle |0\rangle - |1\rangle}{2\sqrt{2}} + \frac{|01\rangle |0\rangle - |1\rangle}{2\sqrt{2}} + \frac{|10\rangle |0\rangle - |1\rangle}{2\sqrt{2}} - \frac{|11\rangle |0\rangle - |1\rangle}{2\sqrt{2}} \\
&= \frac{|00\rangle + |01\rangle + |10\rangle - |11\rangle}{2} \frac{|0\rangle - |1\rangle}{\sqrt{2}} \\
&\rightarrow |11\rangle \frac{|0\rangle - |1\rangle}{\sqrt{2}}.
\end{aligned}$$

The outcome of measuring the first 2 qubits yields  $|11\rangle$ , which is the search target  $w = 3$ .

### Comments:

Grover's Algorithm was discovered by L.K. Grover of Bell Labs in 1996. This algorithm provides a quadratic speedup over classical algorithms. Although it is not exponentially fast (as Shor's Algorithm is), it has a wide range of applications. It could be used to accelerate any algorithms related to searching an unsorted database, including quantum database search, finding the solution of NP problems, finding the median and minimum of a data set, and breaking the Data Encryption Standard (DES) cryptography system.

## 62.8 Shor's Factorization Algorithm

### Integer Factorization Problem:

Given a composite positive integer  $N$ , factor it into the product of its prime factors.

### Algorithm: Shor

1. Choose a random number  $a < N$ ; make sure that  $a$  and  $N$  are coprime. This can be done by using a random number generator and Euclidean algorithm on a classical computer.
2. Find the period  $T$  of function  $f_{a,N}(x) = a^x \bmod N$ . This step can be further expanded as follows:

- (a) Prepare two  $L$ -bit quantum registers in initial state

$$\left( \frac{1}{\sqrt{2^L}} \sum_{x=0}^{2^L-1} |x\rangle \right) |0\rangle,$$

where  $L$  is chosen such that  $N^2 \leq 2^L < 2N^2$ .

- (b) Apply the function evaluation operator  $U_f : |x\rangle|0\rangle \rightarrow |x\rangle|f_{a,N}(x)\rangle$ :

$$\frac{1}{\sqrt{2^L}} \sum_{x=0}^{2^L-1} |x\rangle|0\rangle \rightarrow \frac{1}{\sqrt{2^L}} \sum_{x=0}^{2^L-1} |x\rangle|f_{a,N}(x)\rangle.$$

- (c) Apply QFT to the first register:

$$\frac{1}{\sqrt{2^L}} \sum_{x=0}^{2^L-1} |x\rangle|f_{a,N}(x)\rangle \rightarrow \frac{1}{2^L} \sum_{y=0}^{2^L-1} \left( \sum_{x=0}^{2^L-1} e^{2\pi i xy/2^L} |y\rangle \right) |f(x)\rangle.$$

- (d) Make a measurement on the first register, obtaining  $y$ .

- (e) Find  $T$  from  $y$  via the continued fraction for  $\frac{y}{2^L}$ . This step might fail; in that case, repeat from 2a.

3. If  $T$  is odd, repeat from Step 1. If  $T$  is even and  $N \mid (a^{T/2} + 1)$ , repeat from Step 1. If  $T$  is even and  $N \nmid (a^{T/2} + 1)$ , compute  $d = \gcd(a^{T/2} - 1, N)$ , which is a nontrivial factor of  $N$ .

**Circuit Diagrams: Shor**

**Facts:**

The following facts can be found in [Sho94].

1. The integer factorization problem is classically *intractable*. The most efficient classical algorithm to date, a *number field sieve*, has a time complexity of  $O(\exp(\log N)^{1/3}(\log \log N)^{2/3})$ .
2. Shor's quantum factorization algorithm has a time complexity of  $O((\log N)^2 \log \log N \log \log \log N)$ . Hence, it is a polynomial time algorithm.

**Examples:**

Let  $N = 15$ . Choose  $L = 8$  such that  $N^2 = 225 < 2^L < 450 = 2N^2$ . Choose a random integer  $a = 2$ , which is coprime with 15. Thus,  $f_{a,N}(x) = 2^x \pmod{15}$ . The following sequence of quantum states shows the result of computation utilizing Shor's Algorithm:

$$\begin{aligned}
 |0\rangle|0\rangle &\rightarrow \frac{1}{2^4} \sum_{x=0}^{2^8-1} |x\rangle|0\rangle \\
 &\rightarrow \frac{1}{2^4} \sum_{x=0}^{2^8-1} |x\rangle|f_{a,N}(x)\rangle \\
 &= \frac{1}{2^4} (|0\rangle|1\rangle + |1\rangle|2\rangle + |2\rangle|4\rangle + |3\rangle|8\rangle \\
 &\quad + |4\rangle|1\rangle + |5\rangle|2\rangle + |6\rangle|4\rangle + |7\rangle|8\rangle + \dots + |2^8 - 2\rangle|4\rangle + |2^8 - 1\rangle|8\rangle) \\
 &\rightarrow \frac{1}{2^4} \sum_{x=0}^{2^8-1} \frac{1}{2^4} \sum_{y=0}^{2^8-1} \omega^{xy} |y\rangle |2^x \pmod{15}\rangle \\
 &\rightarrow \frac{1}{2^8} \sum_{y=0}^{2^8-1} |y\rangle \sum_{x=0}^{2^8-1} \omega^{xy} |2^x \pmod{15}\rangle,
 \end{aligned}$$

where  $\omega = e^{2\pi i/2^8}$ . Suppose that the outcome of measuring the first  $n$  qubits is  $|56\rangle$ . We can compute the continued fraction of  $\frac{56}{256}$  to be  $[0, 4, \dots]$ . The second number 4 satisfies  $2^4 = 1 \pmod{15}$ . So 4 is the period of  $f_{a,N}$ .  $2^{4/2} - 1 = 3$  yields a factor of 15 and  $15 = 3 \times 5$ .

### Comments:

Shor's Algorithm was discovered by P. Shor of AT&T Labs in 1994. It is the most important breakthrough in the research of quantum computation so far. It solves the integer factorization problem, an extremely hard problem for classical computers, in polynomial time. The security of the RSA cryptographic system, which is widely used nowadays over the Internet, is based on the difficulty of factoring large integers. Equipped with a quantum computer, one could easily break the RSA codes with Shor's Algorithm.

	References .....	63-14

Information retrieval is the process of searching within a document collection for information most relevant to a user's query. However, the type of document collection significantly affects the methods and algorithms used to process queries. In this chapter, we distinguish between two types of document collections: traditional and Web collections. Traditional information retrieval is search within small, controlled, nonlinked collections (e.g., a collection of medical or legal documents), whereas Web information retrieval is search within the world's largest and linked document collection. In spite of the proliferation of the Web, more traditional nonlinked collections still exist, and there is still a place for the older methods of information retrieval.

### 63.1 The Traditional Vector Space Method

---

Today most search systems that deal with traditional document collections use some form of the vector space method [SB83] developed by Gerard Salton in the early 1960s. Salton's method transforms textual data into numeric vectors and matrices and employs matrix analysis techniques to discover key features and connections in the document collection.

#### Definitions:

For a given collection of documents and for a dictionary of  $m$  terms, document  $i$  is represented by an  $m \times 1$  **document vector**  $\mathbf{d}_i$  whose  $j$ th element is the number of times term  $j$  appears in document  $i$ .

The **term-by-document matrix** is the  $m \times n$  matrix

$$A = [ \mathbf{d}_1 \ \mathbf{d}_2 \ \cdots \ \mathbf{d}_n ]$$

whose columns are the document vectors.

**Recall** is a measure of performance that is defined to be

$$0 \leq \text{Recall} = \frac{\# \text{ relevant docs retrieved}}{\# \text{ relevant docs in collection}} \leq 1.$$

**Precision** is another measure of performance, defined to be

$$0 \leq \text{Precision} = \frac{\# \text{ relevant docs retrieved}}{\# \text{ docs retrieved}} \leq 1.$$

**Query processing** is the act of retrieving documents from the collection that are most related to a user's query, and the **query vector**  $\mathbf{q}_{m \times 1}$  is the binary vector defined by

$$q_i = \begin{cases} 1 & \text{if term } i \text{ is present in the user's query,} \\ 0 & \text{otherwise.} \end{cases}$$

The **relevance** of document  $i$  to a query  $\mathbf{q}$  is defined to be

$$\delta_i = \cos \theta_i = \mathbf{q}^T \mathbf{d}_i / \|\mathbf{q}\|_2 \|\mathbf{d}_i\|_2.$$

For a selected tolerance  $\tau$ , the **retrieved documents** that are returned to the user are the documents for which  $\delta_i > \tau$ .

### Facts:

1. The term-by-document matrix  $A$  is sparse and nonnegative, but otherwise unstructured.
2. [BB05] In practice, weighting schemes other than raw frequency counts are used to construct the term-by-document matrix because weighted frequencies can improve performance.
3. [BB05] Query weighting may also be implemented in practice.
4. The tolerance  $\tau$  is usually tuned to the specific nature of the underlying document collection.
5. Tuning can be accomplished with the technique of relevance feedback, which uses a revised query vector such as  $\tilde{\mathbf{q}} = \delta_1 \mathbf{d}_1 + \delta_3 \mathbf{d}_3 + \delta_7 \mathbf{d}_7$ , where  $\mathbf{d}_1$ ,  $\mathbf{d}_3$ , and  $\mathbf{d}_7$  are the documents the user judges most relevant to a given query  $\mathbf{q}$ .
6. When the columns of  $A$  and  $\mathbf{q}$  are normalized, as they usually are, the vector  $\boldsymbol{\delta}^T = \mathbf{q}^T A$  provides the complete picture of how well each document in the collection matches the query.
7. The vector space model is efficient because  $A$  is usually very sparse, and  $\mathbf{q}^T A$  can be executed in parallel, if necessary.
8. [BB05] Because of linguistic issues such as polysomes and synonyms, the vector space model provides only decent performance on query processing tasks.
9. The underlying basis for the vector space model is the standard basis  $\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_m$ , and the orthogonality of this basis can impose an unrealistic independence among terms.
10. The vector space model is a good starting place, but variations have been developed that provide better performance.

### Examples:

1. Consider a collection of seven documents and nine terms (taken from [BB05]). Terms not in the system's index are ignored. Suppose further that only the titles of each document are used for indexing. The indexed terms and titles of documents are shown below.

Terms	Documents
T1: Bab(y,ies,y's)	D1: <i>Infant &amp; Toddler</i> First Aid
T2: Child(ren's)	D2: <i>Babies</i> and <i>Children's</i> Room (For Your <i>Home</i> )
T3: Guide	D3: <i>Child Safety</i> at <i>Home</i>
T4: Health	D4: Your <i>Baby's</i> <i>Health</i> and <i>Safety</i> : From <i>Infant</i> to <i>Toddler</i>
T5: Home	D5: <i>Baby Proofing</i> Basics
T6: Infant	D6: Your <i>Guide</i> to Easy Rust <i>Proofing</i>
T7: Proofing	D7: Beanie <i>Babies</i> Collector's <i>Guide</i>
T8: Safety	
T9: Toddler	

The indexed terms are italicized in the titles. Also, the stems [BB05] of the terms for baby (and its variants) and child (and its variants) are used to save storage and improve performance. The term-by-document matrix for this document collection is

$$A = \begin{bmatrix} 0 & 1 & 0 & 1 & 1 & 0 & 1 \\ 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 & 0 \end{bmatrix}.$$

For a query on *baby health*, the query vector is

$$\mathbf{q} = [1 \ 0 \ 0 \ 1 \ 0 \ 0 \ 0 \ 0 \ 0]^T.$$

To process the user's query, the cosines

$$\delta_i = \cos \theta_i = \frac{\mathbf{q}^T \mathbf{d}_i}{\|\mathbf{q}\|_2 \|\mathbf{d}_i\|_2}$$

are computed. The documents corresponding to the largest elements of  $\delta$  are most relevant to the user's query. For our example,

$$\delta \approx [0 \ 0.40824 \ 0 \ 0.63245 \ 0.5 \ 0 \ 0.5],$$

so document vector 4 is scored most relevant to the query on *baby health*. To calculate the recall and precision scores, one needs to be working with a small, well-studied document collection. In this example, documents  $\mathbf{d}_4$ ,  $\mathbf{d}_1$ , and  $\mathbf{d}_3$  are the three documents in the collection relevant to baby health. Consequently, with  $\tau = .1$ , the recall score is 1/3 and the precision is 1/4.

## 63.2 Latent Semantic Indexing

In the 1990s, an improved information retrieval system replaced the vector space model. This system is called Latent Semantic Indexing (LSI) [Dum91] and was the product of Susan Dumais, then at Bell Labs. LSI simply creates a low rank approximation  $A_k$  to the term-by-document matrix  $A$  from the vector space model.

**Facts:**

1. [Mey00] If the term-by-document matrix  $A_{m \times n}$  has the singular value decomposition  $A = U\Sigma V^T = \sum_{i=1}^r \sigma_i \mathbf{u}_i \mathbf{v}_i^T$ ,  $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_r > 0$ , then  $A_k$  is created by truncating this expansion after  $k$  terms, where  $k$  is a user tunable parameter.
2. The recall and precision measures are generally used in conjunction with each other to evaluate performance.
3.  $A$  is replaced by  $A_k = \sum_{i=1}^k \sigma_i \mathbf{u}_i \mathbf{v}_i^T$  in the query process so that if  $\mathbf{q}$  and the columns of  $A_k$  have been normalized, then the angle vector is computed as  $\boldsymbol{\delta}^T = \mathbf{q}^T A_k$ .
4. The truncated SVD approximation to  $A$  is optimal in the sense that of all rank- $k$  matrices, the truncated SVD  $A_k$  is the closest to  $A$ , and

$$\|A - A_k\|_F = \min_{\text{rank}(B) \leq k} \|A - B\|_F = \sqrt{\sigma_{k+1}^2 + \dots + \sigma_r^2}.$$

5. This rank- $k$  approximation reduces the so-called linguistic noise present in the term-by-document matrix and, thus, improves information retrieval performance.
6. [Dum91], [BB05], [BR99], [Ber01], [BDJ99] LSI is known to outperform the vector space model in terms of precision and recall.
7. [BR99], [Ber01], [BB05], [BF96], [BDJ99], [BO98], [Blo99], [BR01], [Dum91], [HB00], [JL00], [JB00], [LB97], [WB98], [ZBR01], [ZMS98] LSI and the truncated singular value decomposition dominated text mining research in the 1990s.
8. A serious drawback to LSI is that while it might appear at first glance that  $A_k$  should save storage over the original matrix  $A$ , this is often not the case, even when  $k \ll r$ . This is because  $A$  is generally very sparse, but the singular vectors  $\mathbf{u}_i$  and  $\mathbf{v}_i^T$  are almost always completely dense. In many cases,  $A_k$  requires more (sometimes much more) storage than  $A$  itself requires.
9. A significant problem with LSI is the fact that while  $A$  is a nonnegative matrix, the singular vectors are mixed in sign. This loss of important structure means that the truncated singular value decomposition provides no textual or semantic interpretation. Consider a particular document vector, say, column 1 of  $A$ . The truncated singular value decomposition represents document 1 as

$$A_1 = \begin{bmatrix} \vdots \\ \mathbf{u}_1 \\ \vdots \end{bmatrix} \sigma_1 v_{11} + \begin{bmatrix} \vdots \\ \mathbf{u}_2 \\ \vdots \end{bmatrix} \sigma_2 v_{12} + \dots + \begin{bmatrix} \vdots \\ \mathbf{u}_k \\ \vdots \end{bmatrix} \sigma_k v_{1k},$$

so document 1 is a linear combination of the basis vectors  $\mathbf{u}_i$  with the scalar  $\sigma_i v_{1i}$  being a weight that represents the contribution of basis vector  $i$  in document 1. What we would really like to do is say that basis vector  $i$  is mostly concerned with some subset of the terms, but any such textual or semantic interpretation is difficult (or impossible) when SVD components are involved. Moreover, if there were textual or semantic interpretations, the orthogonality of the singular vectors would ensure that there is no overlap of terms in the topics in the basis vectors, which is highly unrealistic.

10. [Ber01], [ZMS98] It is usually a difficult problem to determine the most appropriate value of  $k$  for a given dataset because  $k$  must be large enough so that  $A_k$  can capture the essence of the document collection, but small enough to address storage and computational issues. Various heuristics have been developed to deal with this issue.

**Examples:**

1. Consider again the  $9 \times 7$  term-by-document matrix used in section 63.1. The rank-4 approximation to this matrix is

$$A_4 = \begin{bmatrix} 0.020 & 1.048 & -0.034 & 0.996 & 0.975 & 0.027 & 0.975 \\ -0.154 & 0.883 & 1.067 & 0.078 & 0.027 & -0.033 & 0.027 \\ -0.012 & -0.019 & 0.013 & 0.004 & 0.509 & 0.990 & 0.509 \\ 0.395 & 0.058 & 0.020 & 0.756 & 0.091 & -0.087 & 0.091 \\ -0.154 & 0.883 & 1.067 & 0.078 & 0.027 & -0.033 & 0.027 \\ 0.723 & -0.144 & 0.068 & 1.152 & 0.004 & -0.012 & 0.004 \\ -0.012 & -0.019 & 0.013 & 0.004 & 0.509 & 0.990 & 0.509 \\ 0.443 & 0.334 & 0.810 & 0.776 & -0.074 & 0.091 & -0.074 \\ 0.723 & -0.144 & 0.068 & 1.152 & 0.004 & -0.012 & 0.004 \end{bmatrix}.$$

Notice that while  $A$  is sparse and nonnegative,  $A_4$  is dense and mixed in sign. Of course, as  $k$  increases,  $A_k$  looks more and more like  $A$ . For a query on *baby health*, the angle vector is

$$\delta \approx [.244 \quad .466 \quad -.006 \quad .564 \quad .619 \quad -.030 \quad .619]^T.$$

Thus, the information retrieval system returns documents  $\mathbf{d}_5, \mathbf{d}_7, \mathbf{d}_4, \mathbf{d}_2, \mathbf{d}_1$ , in order from most to least relevant. As a result, the recall improves to  $2/3$ , while the precision is  $2/5$ . Adding another singular triplet and using the approximation matrix  $A_5$  does not change the recall or precision measures, but does give a slightly different angle vector

$$\delta \approx [.244 \quad .466 \quad -.006 \quad .564 \quad .535 \quad -.030 \quad .535]^T,$$

which is better than the  $A_4$  angle vector because the most relevant document,  $\mathbf{d}_4$ , *Your Baby's Health and Safety: From Infant to Toddler*, gets the highest score.

## 63.3 Nonnegative Matrix Factorizations

---

The lack of semantic interpretation due to the mixed signs in the singular vectors is a major obstacle in using LSI. To circumvent this problem, alternative low rank approximations that maintain the nonnegative structure of the original term-by-document matrix have been proposed [LS99], [LS00], [PT94], [PT97].

**Facts:**

1. If  $A_{m \times n} \geq 0$  has rank  $r$ , then for a given  $k < r$  the goal of a nonnegative matrix factorization (NMF) is to find the nearest rank- $k$  approximation  $WH$  to  $A$  such that  $W_{m \times k} \geq 0$  and  $H_{k \times n} \geq 0$ . Once determined, an NMF simply replaces the truncated singular value decomposition in any text mining task such as clustering documents, classifying documents, or processing queries on documents.
2. An NMF can be formulated as a constrained nonlinear least squares problem by first specifying  $k$  and then determining

$$\min \|A - WH\|_F^2 \quad \text{subject to} \quad W_{m \times k} \geq 0, \quad H_{k \times n} \geq 0.$$

The rank of the approximation (i.e.,  $k$ ) becomes the number of topics or clusters in a text mining application.

3. [LS99] The Lee and Seung algorithm to compute an NMF using MATLAB is as follows.

**Algorithm 1: Lee–Seung NMF**

```

W = abs(randn(m, k))           % initialize with random dense matrix
H = abs(randn(k, n))           % initialize with random dense matrix
for i = 1 : maxiter
    H = H .* (WTA) ./ (WTWH + 10-9) % 10-9 avoids division by 0
    W = W .* (AHT) ./ (WHHT + 10-9)
end

```

4. The objective function  $\|A - WH\|_F^2$  in the Lee and Seung algorithm tends to tail off within 50 to 100 iterations. Faster algorithms exist, but the Lee and Seung algorithm is guaranteed to converge to a local minimum in a finite number of steps.
5. [Hoy02], [Hoy04], [SBP04] Other NMF algorithms contain a tunable sparsity parameter that produces any desired level of sparseness in  $W$  and  $H$ . The storage savings of the NMF over the truncated SVD are substantial.
6. Because  $A_j \approx \sum_{i=1}^k W_i h_{ij}$ , and because  $W$  and  $H$  are nonnegative, each column  $W_i$  can be viewed as a topic vector—if  $w_{ij_1}, w_{ij_2}, \dots, w_{ij_p}$  are the largest entries in  $W_i$ , then terms  $j_1, j_2, \dots, j_p$  dictate the topics that  $W_i$  represents. The entries  $h_{ij}$  measure the strength to which topic  $i$  appears in basis document  $j$ , and  $k$  is the number of topic vectors that one expects to see in a given set of documents.
7. The NMF has some disadvantages. Unlike the SVD, uniqueness and robust computations are missing in the NMF. There is no unique global minimum for the NMF (the defining constrained least squares problem is not convex in  $W$  and  $H$ ), so algorithms can only guarantee convergence to a local minimum, and many do not even guarantee that.
8. Not only will different NMF algorithms produce different NMF factors, the same NMF algorithm, run with slightly different parameters, can produce very different NMF factors. For example, the results can be highly dependent on the initial values.

**Examples:**

1. When the term-by-document matrix of the MEDLINE dataset [Med03] is approximated with an NMF as described above with  $k = 10$ , the charts in Figure 63.1 show the highest weighted terms from four representative columns of  $W$ . For example, this makes it clear that  $W_1$  represents heart related topics, while  $W_2$  concerns blood issues, etc.

When document 5 (column  $A_5$ ) from MEDLINE is expressed as an approximate linear combination of  $W_1, W_2, \dots, W_{10}$  in order of the size of the entries of  $H_5$ , which are

$$h_{95} = .1646 > h_{65} = .0103 > h_{75} = .0045 > \dots,$$

we have that

$$A_5 \approx .1646 W_9 + .0103 W_6 + .0045 W_7 + \dots$$

$$= .1646 \begin{bmatrix} \text{fatty} \\ \text{glucose} \\ \text{acids} \\ \text{ffa} \\ \text{insulin} \\ \vdots \end{bmatrix} + .0103 \begin{bmatrix} \text{kidney} \\ \text{marrow} \\ \text{dna} \\ \text{cells} \\ \text{neph.} \\ \vdots \end{bmatrix} + .0045 \begin{bmatrix} \text{hormone} \\ \text{growth} \\ \text{hgh} \\ \text{pituitary} \\ \text{mg} \\ \vdots \end{bmatrix} + \dots$$

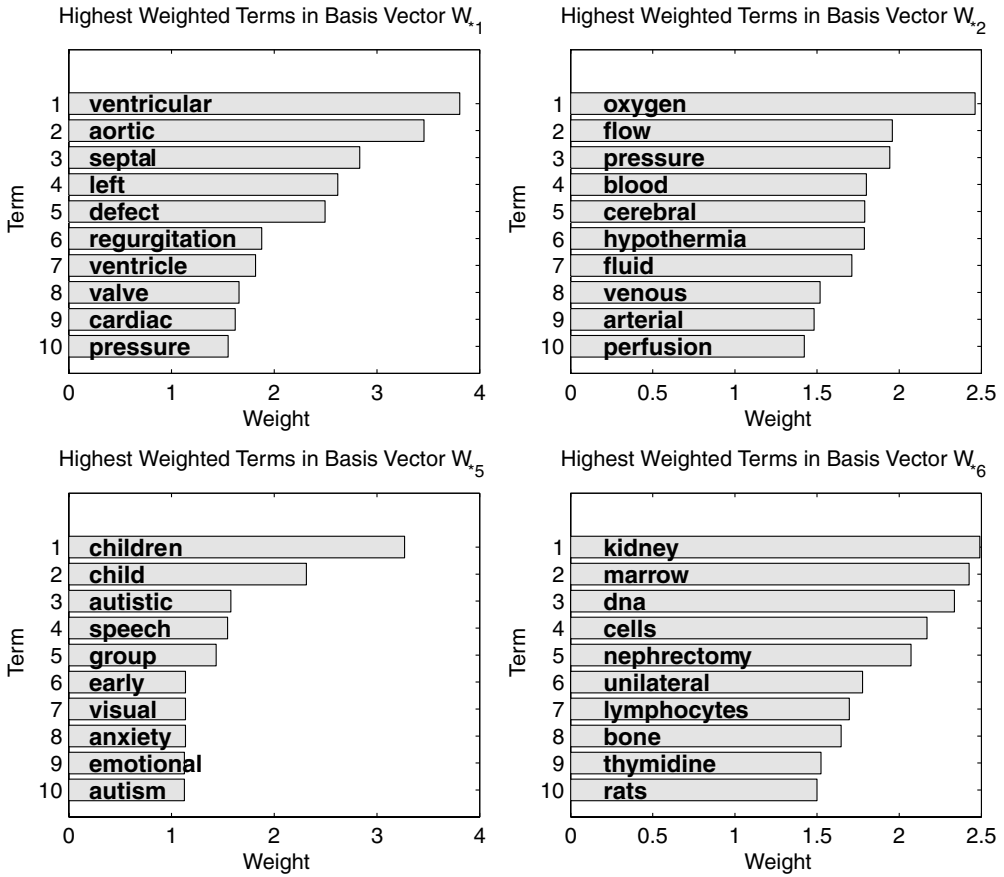

FIGURE 63.1 MEDLINE charts.

Therefore, document 5 is largely about terms contained in topic vector  $W_9$  followed by topic vectors  $W_6$  and  $W_7$ .

- Consider the same  $9 \times 7$  term-by-document matrix  $A$  from the example in Section 63.1. A rank-4 approximation  $A_4 = W_9 \times 4 H_4 \times 7$  that is produced by the Lee and Seung algorithm is

$$A_4 = \begin{bmatrix} 0.027 & 0.888 & 0.196 & 1.081 & 0.881 & 0.233 & 0.881 \\ 0 & 0.852 & 1.017 & 0.173 & 0.058 & 0.031 & 0.058 \\ 0.050 & 0.084 & 0.054 & 0.102 & 0.496 & 0.899 & 0.496 \\ 0.360 & 0.172 & 0.073 & 0.729 & 0.179 & 0.029 & 0.179 \\ 0 & 0.852 & 1.017 & 0.173 & 0.058 & 0.031 & 0.058 \\ 0.760 & 0.032 & 0.155 & 1.074 & 0.033 & 0.061 & 0.033 \\ 0.050 & 0.084 & 0.054 & 0.102 & 0.496 & 0.899 & 0.496 \\ 0.445 & 0.481 & 0.647 & 0.718 & 0.047 & 0.053 & 0.047 \\ 0.760 & 0.032 & 0.155 & 1.074 & 0.033 & 0.061 & 0.033 \end{bmatrix},$$

where

$$W_4 = \begin{bmatrix} 0.202 & 0.017 & 0.160 & 1.357 \\ 0 & 0 & 0.907 & 0.104 \\ 0.805 & 0 & 0 & 0.008 \\ 0 & 0.415 & 0 & 0.321 \\ 0 & 0 & 0.907 & 0.104 \\ 0 & 0.875 & 0 & 0.060 \\ 0.805 & 0 & 0 & 0.008 \\ 0 & 0.513 & 0.500 & 0.085 \\ 0 & 0.876 & 0 & 0.060 \end{bmatrix},$$

$$H_4 = \begin{bmatrix} 0.062 & 0.010 & 0.067 & 0.119 & 0.610 & 1.117 & 0.610 \\ 0.868 & 0 & 0.177 & 1.175 & 0 & 0.070 & 0 \\ 0 & 0.878 & 1.121 & 0.105 & 0 & 0.034 & 0 \\ 0 & 0.537 & 0 & 0.752 & 0.559 & 0 & 0.559 \end{bmatrix}.$$

Notice that both  $A$  and  $A_4$  are nonnegative, and the sparsity of  $W$  and  $H$  makes the storage savings apparent. The error in this NMF approximation as measured by  $\|A - WH\|_F^2$  is 1.56, while the error in the best rank-4 approximation from the truncated SVD is 1.42. In other words, the NMF approximation is not far from the optimal SVD approximation — this is frequently the case in practice in spite of the fact that  $W$  and  $H$  can vary with the initial conditions. For a query on *baby health*, the angle vector is

$$\delta \approx [ .224 \quad .472 \quad .118 \quad .597 \quad .655 \quad .143 \quad .655 ]^T.$$

Thus, the information retrieval system that uses the nonnegative matrix factorization gives the same ranking as a system that uses the truncated singular value decomposition. However, the factors are sparse and nonnegative and can be interpreted.

## 63.4 Web Search

Only a few years ago, users of Web search engines were accustomed to waiting, for what would now seem to be an eternity, for search engines to return results to their queries. And when a search engine finally responded, the returned list was littered with links to information that was either irrelevant, unimportant, or downright useless. Frustration was compounded by the fact that useless links invariably appeared at or near the top of the list while useful links were deeply buried. Users had to sift through links a long way down in the list to have a chance of finding something satisfying, and being less than satisfied was not uncommon.

The reason for this is that the Web's information is not structured like information in the organized databases and document collections that generations of computer scientists had honed their techniques on. The Web is unique in the sense that it is *self organized*. That is, unlike traditional document collections that are accumulated, edited, and categorized by trained specialists, the Web has no standards, no reviewers, and no gatekeepers to police content, structure, and format. Information on the Web is volatile and heterogeneous — links and data are rapidly created, changed, and removed, and Web information exists in multiple formats, languages, and alphabets. And there is a multitude of different purposes for Web data,

e.g., some Web pages are designed to inform while others try to sell, cheat, steal, or seduce. In addition, the Web's self organization opens the door for spammers, the nefarious people who want to illicitly commandeer your attention to sell or advertise something that you probably do not want. Web spammers are continually devising diabolical schemes to trick search engines into listing their (or their client's) Web pages near the top of the list of search results. They had an easy time of it when Web search relied on traditional IR methods based on semantic principles. Spammers could create Web pages that contained things such as miniscule or hidden text fonts, hidden text with white fonts on a white background, and misleading metatag descriptions designed to influence semantic based search engines. Finally, the enormous size of the Web, currently containing  $O(10^9)$  pages, completely overwhelmed traditional IR techniques.

By 1997 it was clear that in nearly all respects the database and IR technology of the past was not well suited for Web search, so researchers set out to devise new approaches. Two big ideas emerged (almost simultaneously), and each capitalizes on the link structure of the Web to differentiate between relevant information and fluff. One approach, HITS (Hypertext Induced Topic Search), was introduced by Jon Kleinberg [Kle99], [LM06], and the other, which changed everything, is Google's *PageRank*<sup>TM</sup> that was developed by Sergey Brin and Larry Page [BP98], [BPM99], [LM06]. While variations of HITS and PageRank followed (e.g., Lempel's SALSA [LM00], [LM05], [LM06]), the basic idea of PageRank became the driving force, so the focus is on this concept.

### Definitions:

Early in the game, search companies such as Yahoo!<sup>®</sup> employed students to surf the Web and record key information about the pages they visited. This quickly overwhelmed human capability, so today all Web search engines use **Web Crawlers**, which is software that continuously scours the Web for information to return to a central repository.

Web pages found by the robots are temporarily stored in entirety in a **page repository**. Pages remain in the repository until they are sent to an indexing module, where their vital information is stripped to create a compressed version of the page. Popular pages that are repeatedly requested by users are stored here longer, perhaps indefinitely.

The **indexing module** extracts only key words, key phrases, or other vital descriptors, and it creates a compressed description of the page that can be "indexed." Depending on the popularity of a page, the uncompressed version is either deleted or returned to the page repository.

There are three general kinds of **indices** that contain compressed information for each Web page. The **content index** contains information such as key words or phrases, titles, and anchor text, and this is stored in a compressed form using an **inverted file** structure, which is simply the electronic version of a book index, i.e., each morsel of information points to a list of pages containing it. Information regarding the hyperlink structure of a page is stored in compressed form in the **structure index**. The crawler module sometimes accesses the structure index to find uncrawled pages. Finally, there are **special-purpose indices** such as an image index and a pdf index. The crawler, page repository, indexing module, and indices, along with their corresponding data files, exist and operate independent of users and their queries.

The **query module** converts a user's natural language query into a language that the search engine can understand (usually numbers), and consults the various indices in order to answer the query. For example, the query module consults the content index and its inverted file to find which pages contain the query terms.

The **pertinent pages** are the pages that contain query terms. After pertinent pages have been identified, the query module passes control to the ranking module.

The **ranking module** takes the set of pertinent pages and ranks them according to some criterion, and this criterion is the heart of the search engine — it is the distinguishing characteristic that differentiates one search engine from another. The ranking criterion must somehow discern which Web pages best respond to a user's query, a daunting task because there might be millions of pertinent pages. Unless a search engine wants to play the part of a censor (which most do not), the user is given the opportunity of seeing a list of links to a large proportion of the pertinent pages, but with less useful links permuted downward.

**PageRank** is Google's patented ranking system, and some of the details surrounding PageRank are discussed below.

#### Facts:

1. Google assigns at least two scores to each Web page. The first is a popularity score and the second is a content score. Google blends these two scores to determine the final ranking of the results that are returned in response to a user's query.
2. [BP98] The rules used to give each pertinent page a content score are trade secrets, but they generally take into account things such as whether the query terms appear in the title or deep in the body of a Web page, the number of times query terms appear in a page, the proximity of multiple query words to one another, and the appearance of query terms in a page (e.g., headings in bold font score higher). The content of neighboring Web pages is also taken into account.
3. Google is known to employ over a hundred such metrics in this regard, but the details are proprietary. While these metrics are important, they are secondary to the the popularity score, which is the primary component of PageRank. The content score is used by Google only to temper the popularity score.

## 63.5 Google's PageRank

---

The popularity score is where the mathematics lies, so it is the focus of the remainder of this exposition. We will identify the term "PageRank" with just the mathematical component of Google's PageRank (the popularity score) with the understanding that PageRank may be tweaked by a content score to produce a final ranking.

Both PageRank and Google were conceived by Sergey Brin and Larry Page while they were computer science graduate students at Stanford University, and in 1998 they took a leave of absence to focus on their growing business. In a public presentation at the Seventh International World Wide Web conference (WWW98) in Brisbane, Australia, their paper "The PageRank citation ranking: Bringing order to the Web" [BPM99] made small ripples in the information science community that quickly turned into waves.

The original idea was that a *page is important if it is pointed to by other important pages*. That is, the importance of your page (its PageRank) is determined by summing the PageRanks of all pages that point to yours. Brin and Page also reasoned that when an important page points to several places, its weight (PageRank) should be distributed proportionately.

In other words, if YAHOO! points to 99 pages in addition to yours, then you should only get credit for 1/100 of YAHOO!'s PageRank. This is the intuitive motivation behind Google's PageRank concept, but significant modifications are required to turn this basic idea into something that works in practice.

For readers who want to know more, the book *Google's PageRank and Beyond: The Science of Search Engine Rankings* [LM06] (Princeton University Press, 2006) contains over 250 pages devoted to link analysis algorithms, along with other ranking schemes such as HITS and SALSA as well as additional background material, examples, code, and chapters dealing with more advanced issues in Web search ranking.

#### Definitions:

The **hyperlink matrix** is the matrix  $H_{n \times n}$  that represents the link structure of the Web, and its entries are given by

$$h_{ij} = \begin{cases} 1/|O_i| & \text{if there is a link from page } i \text{ to page } j, \\ 0 & \text{otherwise,} \end{cases}$$

where  $|O_i|$  is the number of outlinks from page  $i$ .

Suppose that there are  $n$  Web pages, and let  $r_i(0)$  denote the initial rank of the  $i$ th page. If the ranks are successively modified by setting

$$r_i(k+1) = \sum_{j \in I_i} \frac{r_j(k)}{|O_j|}, \quad k = 1, 2, 3, \dots,$$

where  $r_i(k)$  is the rank of page  $i$  at iteration  $k$  and  $I_i$  is the set of pages pointing (linking) to page  $i$ , then the rankings after the  $k$ th iteration are

$$\mathbf{r}^T(k) = (r_1(k), r_2(k), \dots, r_n(k)) = \mathbf{r}^T(0)H^k.$$

The **conceptual PageRank** of the  $i$ th Web page is defined to be

$$r_i = \lim_{k \rightarrow \infty} r_i(k),$$

provided that the limit exists. However, this definition is strictly an intuitive concept because the natural structure of the Web generally prohibits these limits from existing.

A **dangling node** is a Web page that contain no out links. Dangling nodes produce zero rows in the hyperlink matrix  $H$ , so even if  $\lim_{k \rightarrow \infty} H^k$  exists, the limiting vector  $\mathbf{r}^T = \lim_{k \rightarrow \infty} \mathbf{r}^T(k)$  would be dependent on the initial vector  $\mathbf{r}^T(0)$ , which is not good.

The **stochastic hyperlink matrix** is produced by perturbing the hyperlink matrix to be stochastic. In particular,

$$S = H + \mathbf{a}\mathbf{1}^T/n, \quad (63.1)$$

where  $\mathbf{a}$  is the column in which

$$a_i = \begin{cases} 1 & \text{if page } i \text{ is a dangling node,} \\ 0 & \text{otherwise.} \end{cases}$$

$S$  is a stochastic matrix that is identical to  $H$  except that zero rows in  $H$  are replaced by  $\mathbf{1}^T/n$  ( $\mathbf{1}$  is a vector of 1s and  $n = O(10^9)$ , so entries in  $\mathbf{1}^T/n$  are pretty small). The effect is to eliminate dangling nodes. Any probability vector  $\mathbf{p}^T > 0$  can be used in place of the uniform vector.

The **Google matrix** is defined to be the stochastic matrix

$$G = \alpha S + (1 - \alpha)E, \quad (63.2)$$

where  $E = \mathbf{1}\mathbf{v}^T$  in which  $\mathbf{v}^T > 0$  can be any probability vector. Google originally set  $\alpha = .85$  and  $\mathbf{v}^T = \mathbf{1}^T/n$ . The choice of  $\alpha$  is discussed later in Facts 12, 13, and 14.

The **personalization vector** is the vector  $\mathbf{v}^T$  in  $E = \mathbf{1}\mathbf{v}^T$  in Equation 63.2. Manipulating  $\mathbf{v}^T$  gives Google the flexibility to make adjustments to PageRanks as well as to personalize them (thus, the name “personalization vector”) [HKJ03], [LM04a].

The **PageRank vector** is the left Perron vector (i.e., stationary distribution)  $\boldsymbol{\pi}^T$  of the Google matrix  $G$ . In particular,  $\boldsymbol{\pi}^T(I - G) = 0$ , where  $\boldsymbol{\pi}^T > 0$  and  $\|\boldsymbol{\pi}^T\|_1 = 1$ . The components of this vector constitute Google’s popularity score of each Web page.

### Facts:

1. [Mey00, Chap. 8] The Google matrix  $G$  is a primitive stochastic matrix, so the spectral radius  $\rho(G) = 1$  is a simple eigenvalue, and 1 is the only eigenvalue on the unit circle.
2. The iteration defined by  $\boldsymbol{\pi}^T(k+1) = \boldsymbol{\pi}^T(k)G$  converges, independent of the starting vector, to a unique stationary probability distribution  $\boldsymbol{\pi}^T$ , which is the PageRank vector.
3. The irreducible aperiodic Markov chain defined by  $\boldsymbol{\pi}^T(k+1) = \boldsymbol{\pi}^T(k)G$  is a constrained random walk on the Web graph. The random walker can be characterized as a Web surfer who, at each step, randomly chooses a link from his current page to click on except that

- (a) When a dangling node is encountered, the excursion is continued by jumping to another page selected at random (i.e., with probability  $1/n$ ).
- (b) At each step, the random Web surfer has a chance (with probability  $1 - \alpha$ ) of becoming bored with following links from the current page, in which case the random Web surfer continues the excursion by jumping to page  $j$  with probability  $v_j$ .
- The random walk defined by  $\mathbf{r}^T(k+1) = \mathbf{r}^T(k)S$  will generally not converge because Web's graph structure is not strongly connected, which results in a reducible chain with many isolated ergodic classes.
  - The power method has been Google's computational method of choice for computing the PageRank vector. If formed explicitly,  $G$  is completely dense, and the size of  $n$  would make each power iteration extremely costly — billions of flops for each step. But writing the power method as

$$\boldsymbol{\pi}^T(k+1) = \boldsymbol{\pi}^T(k)G = \alpha \boldsymbol{\pi}^T(k)H + (\alpha \boldsymbol{\pi}^T(k)\mathbf{a})\mathbf{1}^T/n + (1 - \alpha)\mathbf{v}^T$$

shows that only extremely sparse vector-matrix multiplications are required. Only the nonzero  $h_{ij}$ 's are needed, so  $G$  and  $S$  are neither formed nor stored.

- When implemented as shown above, each power step requires only  $\text{nnz}(H)$  flops, where  $\text{nnz}(H)$  is the number of nonzeros in  $H$ , and, since the average number of nonzeros per column in  $H$  is significantly less than 10, we have  $O(\text{nnz}(H)) \approx O(n)$ . Furthermore, the inherent parallelism is easily exploited, and the current iterate is the only vector stored at each step.
- Because the Web has many disconnected components, the hyperlink matrix is highly reducible, and compensating for the dangling nodes to construct the stochastic matrix  $S$  does not significantly affect this.
- [Mey00, p. 695–696] Since  $S$  is also reducible,  $S$  can be symmetrically permuted to have the form

$$S \sim \left[ \begin{array}{cccc|cccc} S_{11} & S_{12} & \cdots & S_{1r} & S_{1,r+1} & S_{1,r+2} & \cdots & S_{1m} \\ 0 & S_{22} & \cdots & S_{2r} & S_{2,r+1} & S_{2,r+2} & \cdots & S_{2m} \\ \vdots & & \ddots & \vdots & \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & \cdots & S_{rr} & S_{r,r+1} & S_{r,r+2} & \cdots & S_{rm} \\ \hline 0 & 0 & \cdots & 0 & S_{r+1,r+1} & 0 & \cdots & 0 \\ 0 & 0 & \cdots & 0 & 0 & S_{r+2,r+2} & \cdots & 0 \\ \vdots & \vdots & \cdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 0 & 0 & 0 & \cdots & S_{mm} \end{array} \right],$$

where the following are true.

- For each  $1 \leq i \leq r$ ,  $S_{ii}$  is either irreducible or  $[0]_{1 \times 1}$ .
  - For each  $1 \leq i \leq r$ , there exists some  $j > i$  such that  $S_{ij} \neq 0$ .
  - $\rho(S_{ii}) < 1$  for each  $1 \leq i \leq r$ .
  - $S_{r+1,r+1}, S_{r+2,r+2}, \dots, S_{m,m}$  are each stochastic and irreducible.
  - 1 is an eigenvalue for  $S$  that is repeated exactly  $m - r$  times.
- The natural structure of the Web forces the algebraic multiplicity of the eigenvalue 1 to be large.
  - [LM04a][LM06][Mey00, Ex. 7.1.17, p. 502] If the eigenvalues of  $S_{n \times n}$  are

$$\lambda(S) = \{ \underbrace{1, 1, \dots, 1}_{m-r}, \mu_{m-r+1}, \dots, \mu_n \}, \quad 1 > |\mu_{m-r+1}| \geq \dots \geq |\mu_n|,$$

then the eigenvalues of the Google matrix  $G = \alpha S + (1 - \alpha)E$  are

$$\lambda(G) = \{1, \underbrace{\alpha, \dots, \alpha}_{m-r-1}, (\alpha\mu_{m-r+1}), \dots, (\alpha\mu_n)\}. \quad (63.3)$$

11. [Mey00] The asymptotic rate of convergence of any aperiodic Markov chain is governed by the magnitude of its largest subdominant eigenvalue. In particular, if the distinct eigenvalues  $\lambda_i$  of an aperiodic chain are ordered  $\lambda_1 = 1 > |\lambda_2| \geq |\lambda_3| \geq \dots \geq |\lambda_n|$ , then the number of incorrect digits in each component of  $\pi^T(k)$  is eventually going to be reduced by about  $-\log_{10}|\lambda_2|$  digits per iteration.
12. Determining (or even estimating)  $|\lambda_2|$  normally requires substantial effort, but Equation 63.3 says that  $\lambda_2 = \alpha$  for the Google matrix  $G$ . This is an extremely happy accident because it means that Google's engineers can completely control the rate of convergence, regardless of the value of the personalization vector  $\mathbf{v}^T$  in  $E = \mathbf{1}\mathbf{v}^T$ .
13. At the last public disclosure Google was setting  $\alpha = .85$ , so, at this value, the asymptotic rate of convergence of the power method is  $-\log_{10}(.85) \approx .07$ , which means that the power method will eventually take about 14 iterations for each significant place of accuracy that is required.
14. [LM04a] Even though they can control the rate of convergence with  $\alpha$ , Google's engineers are forced to perform a delicate balancing act because while decreasing  $\alpha$  increases the rate of convergence, decreasing  $\alpha$  also lessens the effect of the true hyperlink structure of the Web, which is Google's primary mechanism for measuring Webpage importance. Increasing  $\alpha$  more accurately reflects the Web's true link structure, but, along with slower convergence, sensitivity issues begin to surface in the sense that slightly different values for  $\alpha$  near 1 can produce significantly different PageRanks.
15. [KHM03a] The power method can be substantially accelerated by a quadratic extrapolation technique similar to Aitken's  $\Delta^2$  method, and there is reason to believe that Google has adopted this procedure.
16. [KHM03b], [KHG04] Other improvements to the basic power method include a block algorithm and an adaptive algorithm that monitors the convergence of individual elements of the PageRank vector. As soon as components of the vector have converged to an acceptable tolerance, they are no longer computed. Convergence is faster because the work per iteration decreases as the process evolves.
17. [LM02], [LM04a], [LM04b], [LZG03] Other methods partition  $H$  into two groups according to dangling nodes and nondangling nodes. The problem is then aggregated by lumping all of the dangling nodes into one super state to produce a problem that is significantly reduced in size — this is due to the fact that the dangling nodes account for about one fourth of the Web's nodes. The most exciting feature of all these algorithms is that they do not compete with one another. In fact, it is possible to combine some of these algorithms to achieve even greater performance.
18. The accuracy of PageRank computations is an important implementation issue, but we do not know the accuracy with which Google works. It seems that it must be at least high enough to differentiate between the often large list of ranked pages that Google usually returns, and since  $\pi^T$  is a probability vector containing  $O(10^9)$  components, it is reasonable to expect that accuracy giving at least ten significant places is needed to distinguish among the elements.
19. A weakness of PageRank is "topic drift." The PageRank vector might be mathematically accurate, but this is of little consequence if the results point the user to sites that are off-topic. PageRank is a query-independent measure that is essentially determined by a popularity contest with everyone on Web having a vote, and this tends to skew the results in the direction of importance (measured by popularity) over relevance to the query. This means that PageRank may have trouble distinguishing between pages that are authoritative in general and pages that are authoritative more specifically to the query topic. It is believed that Google engineers devote much effort to mitigate this problem, and this is where the metrics that determine the content score might have an effect.

20. In spite of topic drift, Google's decision to measure importance by means of popularity over relevance turned out to be the key to Google's success and the source of its strength. The query-dependent measures employed by Google's predecessors were major stumbling blocks in maintaining query processing speed as the Web grew. PageRank is query-independent, so at query time only a quick lookup into an inverted file storage is required to determine pertinent pages, which are then returned in order by the precomputed PageRanks. The small compromise of topic drift in favor of processing speed won the day.
21. A huge advantage of PageRank is its virtual imperviousness to spamming (artificially gaming the system). High PageRank is achieved by having many inlinks from highly ranked pages, and while it may not be so hard for a page owner to have many of his cronies link to his page, it is difficult to generate a lot of inlinks from *important* sites that have a high rank.
22. [TM03] Another strength of PageRank concerns the flexibility of the "personalization" (or "intervention") vector  $\mathbf{v}^T$  that Google is free to choose when defining the perturbation term  $E = \mathbf{1}\mathbf{v}^T$ . The choice of  $\mathbf{v}^T$  affects neither mathematical nor computational aspects, but it does alter the rankings in a predictable manner. This can be a terrific advantage if Google wants to intervene to push a site's PageRank down or up, perhaps to punish a suspected "link farmer" or to reward a favored client. Google has claimed that it does not make a practice of rewarding favored clients, but it is known that Google is extremely vigilant and sensitive concerning people who try to manipulate PageRank, and such sites are punished. However, the outside world is not privy to the extent to which either the stick or carrot is employed.
23. [FLM<sup>+</sup>04], [KH03], [KHG04], [KHM03a], [LM04a], [LM06], [LGZ03], [LM03], [NZJ01] In spite of the simplicity of the basic concepts, subtle issues such as personalization, practical implementations, sensitivity, and updating lurk just below the surface.
24. We have summarized only the mathematical component of Google's ranking system, but, as mentioned earlier, there are a hundred or more nonmathematical content metrics that are also considered when Google responds to a query. The results seen by a user are in fact PageRank tempered by these other metrics. While Google is secretive about most of its other metrics, it has made it clear that the other metrics are subservient to their mathematical PageRank scores.

A signal is a function of time, depending on either a continuous, real time variable or a discrete integer time variable. Signal processing is a collection of diverse mathematical, statistical, and computational techniques for transforming, extracting information from, and modeling of signals. Common signal processing techniques include filtering a signal to remove undesired frequency components, extracting a model that describes key features of a signal, estimation of the frequency components of a signal, prediction of the future behavior of a signal from past data, and finding the direction from which a signal arrives at an array of sensors.

Many modern methods for signal processing have deep connections to linear algebra. Rather than attempting to give a complete overview of such a diverse field, we survey a selection of contemporary methods for the processing of discrete time signals with deep connections to matrix theory and numerical linear algebra. These topics include linear prediction, Wiener filtering, spectral estimation, and direction of arrival estimation. Notable omissions include classical methods of filter design, the fast Fourier transform (FFT), and filter structures. (See Chapter 58.)

### 64.1 Basic Concepts

---

We begin with basic definitions which are standard and can be found in [PM96].

#### Definitions:

A **signal**  $\mathbf{x}$  is a real sequence with element  $k$  of the sequence for  $k = 0, \pm 1, \pm 2, \dots$  given by  $x(k)$ . The set of all signals is a vector space with the sum  $\mathbf{w} = \mathbf{x} + \mathbf{y}$  defined by  $w(k) = x(k) + y(k)$  and the scalar product  $\mathbf{v} = a\mathbf{x}$  where  $a$  is a real scalar given by  $v(k) = ax(k)$ .

A **linear time-invariant system** is a mapping  $L(\mathbf{x}) = \mathbf{y}$  of an input signal  $\mathbf{x}$  to an output signal  $\mathbf{y}$  that satisfies the following properties:

1. Linearity: If  $L(\mathbf{x}_0) = \mathbf{y}_0$  and  $L(\mathbf{x}_1) = \mathbf{y}_1$ , then  $L(a\mathbf{x}_0 + b\mathbf{y}_0) = a\mathbf{y}_0 + b\mathbf{y}_1$  for any  $a, b \in \mathbb{R}$ .
2. Time-invariance: If  $L(\mathbf{x}) = \mathbf{y}$  and  $\hat{\mathbf{x}}$  is a shifted version of  $\mathbf{x}$  given by  $\hat{x}(k) = x(k - k_0)$ , then  $L(\hat{\mathbf{x}}) = \hat{\mathbf{y}}$  where  $\hat{y}(k) = y(k - k_0)$ . That is, shifted inputs lead to correspondingly shifted outputs.

The **impulse response** of a linear time-invariant system is the output  $\mathbf{h}$  that results from applying as input the unit impulse  $\delta$  where  $\delta(0) = 1$  and  $\delta(k) = 0$  for  $k \neq 1$ .

The **convolution**  $y$  of  $\mathbf{h}$  and  $\mathbf{x}$  is written  $y = \mathbf{h} * \mathbf{x}$  and is defined by the sum

$$y(k) = \sum_{j=-\infty}^{\infty} h(j)x(k-j).$$

A signal  $\mathbf{x}$  is **causal** if  $x(k) = 0$  for  $k < 0$ .

A linear time-invariant system is **causal** if every causal input gives a causal output. An equivalent definition is that a system is **causal** if its impulse response sequence is causal.

The **z-transform** of a signal or impulse response  $\mathbf{x}$  is

$$X(z) = \sum_{k=-\infty}^{\infty} x(k)z^{-k}$$

where  $X(z)$  is defined in the region of convergence of the sum.

The **transfer function** of a linear system with impulse response  $\mathbf{h}$  is the  $z$ -transform of the impulse response

$$H(z) = \sum_{k=-\infty}^{\infty} h(k)z^{-k}.$$

The **discrete time Fourier transform** of  $\mathbf{x}$  is the function of  $\omega$  obtained by evaluating the  $z$ -transform on the unit circle

$$X(e^{i\omega}) = \sum_{k=-\infty}^{\infty} x(k)e^{-i\omega k}.$$

If  $\mathbf{x}$  is an impulse response of a system, then  $X(e^{i\omega})$  is the **frequency response** of the system. The discrete time Fourier transform is defined only if the region of convergence of the  $z$ -transform includes the unit circle.

A filter is **minimum phase** if the zeros of the transfer function are in the unit circle.

A **finite impulse response** (FIR) filter is a system that maps an input signal  $\mathbf{x}$  to an output signal  $\mathbf{y}$  through the sum

$$y(k) = \sum_{j=0}^{n-1} b(j)x(k-j).$$

A rational **infinite impulse response** (IIR) filter is a causal system that maps inputs  $\mathbf{x}$  to outputs  $\mathbf{y}$  via a relation of the form

$$y(k) = \sum_{j=0}^{n-1} b(j)x(k-j) - \sum_{j=1}^m a(j)y(k-j).$$

Causality is an essential part of the definition; without this assumption the above relation does not uniquely define a mapping from inputs to outputs.

A signal  $\mathbf{x}$  has **finite energy** if

$$\sum_{k=-\infty}^{\infty} |x(k)|^2 < \infty.$$

A system mapping input  $\mathbf{x}$  to output  $\mathbf{y}$  is **stable** if  $|x(k)| < B_x$  for  $0 < B_x < \infty$  and for all  $k$  implies that there is  $0 < B_y < \infty$  such that the output satisfies  $|y(k)| < B_y$  for all  $k$ .

**Facts:**

1. The impulse response  $\mathbf{h}$  uniquely determines a linear time-invariant system. The mapping from the input  $\mathbf{x}$  to the output  $\mathbf{y}$  is given by  $\mathbf{y} = \mathbf{h} * \mathbf{x}$ . Convolution is commutative so that if  $\mathbf{y} = \mathbf{g} * (\mathbf{h} * \mathbf{x})$ , then  $\mathbf{y} = \mathbf{h} * (\mathbf{g} * \mathbf{x})$ . Thus, the order in which two linear time-invariant filters are applied to a signal does not matter.
2. A causal system can be applied in real time in the sense that output  $y(k)$  can be computed from the convolution  $\mathbf{y} = \mathbf{h} * \mathbf{x}$  as soon as  $x(k)$  is available.
3. A system defined by its impulse response  $\mathbf{h}$  is stable if and only if

$$\sum_{k=-\infty}^{\infty} |h(k)| < \infty.$$

4. An expression for the  $z$ -transform of a signal (or an impulse response) does not uniquely determine the signal. It is also necessary to know the region of convergence. If  $X(z)$  is the  $z$ -transform of  $\mathbf{x}$ , then the inverse transform is

$$x(k) = \frac{1}{2\pi i} \oint X(z)z^{k-1} dz$$

where the integral is taken over any contour enclosing the origin and in the region where  $X(z)$  is analytic. A system is uniquely determined by its transfer function and the region of convergence of the transfer function.

5. An FIR filter has impulse response

$$h(k) = \begin{cases} b(k) & \text{for } 0 \leq k \leq n-1 \\ 0 & \text{otherwise.} \end{cases}$$

6. An FIR filter has transfer function

$$H(z) = b(0) + b(1)z^{-1} + \dots + b(n-1)z^{-(n-1)}.$$

7. The impulse response  $\mathbf{h}$  of a causal IIR filter is the unique solution to the recurrence

$$h(k) = \begin{cases} 0 & k \leq 0 \\ b(k) - \sum_{j=1}^m a(j)h(k-j) & 0 \leq k \leq n-1 \\ -\sum_{j=1}^m a(j)h(k-j) & k \geq n \end{cases}.$$

This recurrence uniquely determines a causal impulse response  $\mathbf{h}$  and, hence, uniquely determines the mapping from inputs to outputs.

8. A rational IIR filter has transfer function

$$H(z) = \frac{b(0) + b(1)z^{-1} + \dots + b(n-1)z^{-(n-1)}}{1 + a(1)z^{-1} + \dots + a(m)z^{-m}}.$$

9. A linear time-invariant system with input  $\mathbf{x}$  and impulse response  $\mathbf{h}$  with  $z$ -transform  $X(z)$  and transfer function  $H(z)$  has output  $\mathbf{y}$  with  $z$ -transform

$$Y(z) = H(z)X(z).$$

10. A discrete version of the Paley–Wiener theorem states that  $\mathbf{x}$  is causal and has finite energy if and only if the corresponding  $z$ -transform  $X(z)$  is analytic in the exterior of the unit circle and

$$\sup_{1 < r < \infty} \int_{-\pi}^{\pi} |X(re^{i\omega})|^2 d\omega < \infty.$$

If  $|X(e^{i\omega})|$  is square integrable, then  $|X(e^{i\omega})|$  is the Fourier transform of some causal system finite energy signal if and only if

$$\int_{-\pi}^{\pi} |\ln(|X(e^{i\omega})|)| d\omega < \infty.$$

11. For rational transfer functions  $H(z)$  corresponds to a causal stable system if and only if the poles of  $H(z)$  are in the unit circle. Thus, FIR filters are always stable and IIR filters are stable when the poles of the transfer function are in the unit circle.
12. A filter that is minimum phase has a causal stable inverse filter with transfer function  $G(z) = 1/H(z)$ . That is, filtering a signal  $\mathbf{x}$  by a filter with  $z$ -transform  $H(z)$  and then by a filter with  $z$ -transform  $G(z)$  gives an output with  $z$ -transform  $G(z)H(z)X(z) = X(z)$ . The minimum phase property is of particular significance since the only filters that can be applied in real time and without excessive growth of errors due to noise are those that are causal and stable. In most circumstances only minimum phase filters are invertible in practice.

### Examples:

1. The causal impulse response  $\mathbf{h}$  with  $h(k) = a^k$  for  $k \geq 0$  and  $h(k) = 0$  for  $k < 0$  has  $z$ -transform  $H(z) = 1/(1 - az^{-1})$  with region of convergence  $|z| > |a|$ . The anticausal impulse response  $\hat{\mathbf{h}}$  with  $\hat{h}(k) = -a^k$  for  $k < 0$  and  $\hat{h}(k) = 0$  for  $k \geq 0$  has  $z$ -transform  $H(z) = 1/(1 - az^{-1})$  with region of convergence  $|z| < |a|$ .
2. The causal impulse response  $\mathbf{h}$  with

$$h(k) = \begin{cases} 2^{-k} + 3^{-k} & \text{for } k \geq 0 \\ 0 & \text{for } k < 0 \end{cases}$$

has  $z$ -transform

$$H(z) = \frac{1}{1 - (2z)^{-1}} + \frac{1}{1 - (3z)^{-1}} = \frac{2 - \frac{5}{6}z^{-1}}{1 - \frac{5}{6}z^{-1} + \frac{1}{6}z^{-2}}$$

with region of convergence  $|z| > 1/2$ . The impulse response can be realized by a rational IIR filter of the form

$$y(k) = 2x(k) - \frac{5}{6}x(k-1) + \frac{5}{6}y(k-1) + \frac{1}{6}y(k-2).$$

The zeros of  $z^2 - (5/6)z + (1/6)$  are  $1/2$  and  $1/3$  so that the system is stable.

## 64.2 Random Signals

Definitions of statistical terms can be found in Chapter 52.

### Definitions:

A **random signal** or **random process**  $\mathbf{x}$  is a sequence  $x(k)$  of real random variables indexed by  $k = 0, \pm 1, \pm 2, \dots$

A random signal  $\mathbf{x}$  is **wide-sense stationary** (for brevity, we will use **stationary** to mean the same thing) if the mean  $\mu_x = E[x(k)]$  and **autocorrelation sequence**  $r_{xx}(k) = E[x(j)x(j-k)]$  do not depend on  $j$ . We assume that all random signals are wide-sense stationary. Two stationary random signals  $\mathbf{x}$  and  $\mathbf{y}$  are jointly stationary if the **cross correlation** sequence  $r_{yx}(k) = E[y(j)x(j-k)]$  does not depend on  $j$ . When referring to two stationary signals, we always assume that the signals are jointly stationary as well.

A sequence  $\mathbf{x}(k)$  of real random  $n \times 1$  vectors indexed by  $k = 0, \pm 1, \pm 2, \dots$  is **stationary** if  $E[\mathbf{x}(k)]$  and  $E[\mathbf{x}(k)\mathbf{x}^T(k)]$  do not depend on  $k$ .

The **autocorrelation matrix** of a sequence of stationary random vectors  $\mathbf{x}(k)$  is

$$R_{\mathbf{x}} = E[\mathbf{x}(k)\mathbf{x}^T(k)].$$

A zero mean stationary random signal  $n$  is a **white noise process** if it has autocorrelation sequence

$$r_{nn}(j) = E[n(k)n(k-j)] = \begin{cases} \sigma_n^2 & j = 0 \\ 0 & j \neq 0 \end{cases}$$

where  $\sigma_n^2$  is the **variance** of  $n$ .

A white noise driven **autoregressive process** (AR process)  $\mathbf{x}$  is of the form

$$x(k) = n(k) - \sum_{j=1}^n a(j)x(k-j)$$

where  $n$  is a white noise process and the filtering of  $n$  to obtain  $\mathbf{x}$  is causal.

Given a signal  $\mathbf{x}$ , we denote the  $z$ -transform of the autocorrelation sequence of  $\mathbf{x}$  by  $S_x(z)$ . The **spectral density** of a stationary random signal  $\mathbf{x}$  with autocorrelation sequence  $r_{xx}(k)$  is the function of  $\omega$  given by evaluating  $S_x(z)$  on the unit circle

$$S_x(e^{i\omega}) = \sum_{j=-\infty}^{\infty} r_{xx}(j)e^{-ij\omega}.$$

A random signal with spectral density  $S_x(e^{i\omega})$  is **bandlimited** if  $S_x(e^{i\omega}) = 0$  on a subset of  $[-\pi, \pi]$  of nonzero measure.

A random signal with spectral density  $S_x(e^{i\omega})$  has **finite power** if

$$\int_{-\pi}^{\pi} S_x(e^{i\omega}) d\omega < \infty.$$

The **spectral factorization**, when it exists, of a spectral density  $S_x(z)$  is a factorization of the form

$$S_x(z) = L(z)\overline{L(z^{-1})}$$

where  $L(z)$  and  $1/L(z)$  are both analytic for  $|z| > 1$ . Interpreted as transfer functions  $L(z)$  and  $1/L(z)$  both describe causal, stable systems. That is,  $L(z)$  is causal and stable and causally and stably invertible.

### Facts:

1. If  $\mathbf{x}(k)$  is a sequence of vectors obtained by sampling a random sequence of vectors, then under suitable ergodicity assumptions

$$R_{\mathbf{x}} = \lim_{n \rightarrow \infty} \frac{1}{n} \sum_{k=0}^n \mathbf{x}(k)\mathbf{x}^T(k).$$

In computational practice  $R_{\mathbf{x}}$  is often estimated using a truncated sum in which  $n$  is finite.

2. The expectation  $\langle x, y \rangle = E[xy]$  can be viewed as an inner product on a real Hilbert space of zero mean random variables with  $E[|x|^2] < \infty$ . This gives many results in optimal filtering a geometric interpretation in terms of orthogonalization and projection on the span of a set of random variables in a way that is perfectly analogous to least squares problems in any other Hilbert space. From this point of view, a white noise process  $n$  is a sequence of orthogonal random variables.

3. If a random signal  $\mathbf{x}$  with autocorrelation sequence  $r_x$  is passed through a system with impulse response  $\mathbf{h}$ , then the output  $\mathbf{y}$  has autocorrelation

$$\mathbf{r}_y = \mathbf{h} * \mathbf{r}_x * \tilde{\mathbf{h}}$$

where  $\tilde{\mathbf{h}}$  is defined by  $\tilde{h}(j) = h(-j)$ .

4. The spectral density is nonnegative,  $S_x(e^{i\omega}) \geq 0$ .  
 5. The spectral density of white noise is  $S_n(e^{i\omega}) = \sigma_n^2$ .  
 6. [Pap85] If a random signal  $\mathbf{x}$  with spectral density  $S_x(z)$  passes through a filter with transfer function  $H(z)$ , then the output  $\mathbf{y}$  is a stationary signal with

$$S_y(z) = S_x(z)H(z)\overline{H(z^{-1})} \quad \text{or} \quad S_y(e^{i\omega}) = S_x(e^{i\omega})|H(e^{i\omega})|^2.$$

7. If  $L(z)$  is the spectral factor of  $S_x(z)$ , then on the unit circle we have  $S_x(e^{i\omega}) = |L(e^{i\omega})|^2$ .  
 8. [SK01], [GS84] The spectral factorization exists if and only if the signal has finite power and satisfies

$$\int_{-\pi}^{\pi} \ln(S_x(e^{i\omega})) d\omega > -\infty.$$

If  $S_x(e^{i\omega})$  is zero on a set of nonzero measure, then the condition is not satisfied. Thus, bandlimited signals do not have a spectral factorization.

9. If a spectral factor  $L(z)$  exists for a signal  $\mathbf{x}$  with spectral density  $S_x(e^{i\omega})$  and

$$L(z) = \sum_{k=0}^{\infty} l(k)z^{-k} \quad \text{and} \quad M(z) = \frac{1}{L(z)} = \sum_{k=0}^{\infty} m(k)z^{-k},$$

then the filtered signal  $\mathbf{n} = \mathbf{m} * \mathbf{x}$  given by

$$n(k) = \sum_{j=0}^{\infty} m(j)x(k-j)$$

is a white noise process with  $S_n(e^{i\omega}) = 1$ . The original signal can be obtained by causally and stably filtering  $\mathbf{n}$  with  $\mathbf{l}$ :

$$x(k) = \sum_{j=0}^{\infty} l(j)n(k-j).$$

The signal  $\mathbf{n}$  is the **innovations** process for  $\mathbf{x}$  and the representation of  $\mathbf{x}$  through filtering  $\mathbf{n}$  by  $\mathbf{l}$  is the **innovations representation** for  $\mathbf{x}$ . It is a model of  $\mathbf{x}$  as a filter driven by white noise. The innovations representation is an orthogonalization of the sequence of random variables  $\mathbf{x}$ . The innovations representation for  $\mathbf{x}$  is analogous to the  $QR$  factorization of a matrix.

### Examples:

1. For a white noise process  $\mathbf{n}$  with variance  $\sigma_n^2 = 1$ , define the autoregressive process  $\mathbf{x}$  by

$$x(k) = n(k) + ax(k-1)$$

where  $|a| < 1$ . The impulse response and transfer function of the IIR filter generating  $\mathbf{x}$  are

$$h(k) = \begin{cases} 0 & k < 0 \\ a^k & k \geq 0 \end{cases}, \quad \text{and} \quad H(z) = \frac{1}{1 - az^{-1}}.$$

The autocorrelation sequence for  $\mathbf{x}$  is the sequence  $r_{xx}$  given by

$$r_{xx}(k) = \frac{1}{1 - a^2} a^{|k|}.$$

The autocorrelation sequence has  $z$ -transform

$$S_x(z) = \frac{1}{(1 - az^{-1})(1 - az)}$$

so that the spectral density is

$$S_x(e^{i\omega}) = \frac{1}{1 + a^2 - 2a \cos(\omega)}.$$

The spectral factor is

$$L(z) = \frac{1}{1 - az^{-1}}.$$

## 64.3 Linear Prediction

---

### Definitions:

The **linear prediction** problem is to find an estimate  $\hat{\mathbf{x}}$  of a stationary random signal  $\mathbf{x}$  as a linear combination

$$\hat{x}(k) = \sum_{j=1}^{\infty} a(j)x(k-j),$$

with the  $a(j)$  chosen to minimize the **mean square prediction error**  $E_{\infty} = E[|e(k)|^2]$  where  $e(k) = \hat{x}(k) - x(k)$  is the **prediction error**. Thus, the goal is to find a current estimate  $\hat{x}(k)$  of  $x(k)$  from the past values  $x(k-1), x(k-2), \dots$

A random signal is **predictable** if  $E_{\infty} = 0$ . A signal that is not predictable is **regular**.

The **order  $n$  linear prediction problem** is to find an estimate of a stationary random signal  $\mathbf{x}$  with a signal  $\hat{\mathbf{x}}$  of the form  $\hat{x}(k) = \sum_{j=1}^n a_n(j)x(k-j)$  so as to minimize the mean square error  $E_n = E[|e(k)|^2]$  where  $e(k) = \hat{x}(k) - x(k)$ .

A random signal is **order  $n$  predictable** if  $E_n = 0$ .

The **prediction error filter** and the **order  $n$  prediction error filter** are the filters with transfer functions

$$E(z) = 1 - \sum_{j=1}^{\infty} a(j)z^{-j}$$

and

$$E_n(z) = 1 - \sum_{j=1}^n a_n(j)z^{-j}.$$

The **Wiener-Hopf equations** for the optimal prediction coefficients  $a(j)$  are

$$r_{xx}(l) = \sum_{j=1}^{\infty} a(j)r_{xx}(l-j)$$

for  $l \geq 1$ .

Given a random signal  $x(k)$  with autocorrelation  $r_{xx}(k)$ , the optimal prediction coefficients  $a^{(n)}(j)$  and mean square prediction error  $E_n$  that satisfy the **Yule–Walker equations** are

$$\begin{bmatrix} r_{xx}(0) & r_{xx}(1) & \cdots & r_{xx}(n) \\ r_{xx}(1) & r_{xx}(0) & \ddots & \vdots \\ \vdots & \ddots & \ddots & r_{xx}(1) \\ r_{xx}(n) & \cdots & r_{xx}(1) & r_{xx}(0) \end{bmatrix} \begin{bmatrix} 1 \\ -a_n(1) \\ \vdots \\ -a_n(n) \end{bmatrix} = \begin{bmatrix} E_n \\ 0 \\ \vdots \\ 0 \end{bmatrix}$$

or  $T_n \mathbf{a}_n = E_n \mathbf{e}_1$ .

The **Levinson–Durbin algorithm** for the computation solution of the order  $n$  linear prediction problem is

$$\mathbf{a}_n = \begin{bmatrix} \mathbf{a}_{n-1} \\ 0 \end{bmatrix} + \gamma_n \begin{bmatrix} 0 \\ R\mathbf{a}_{n-1} \end{bmatrix}$$

where  $R$  is the permutation that reverses the order of the elements of  $\mathbf{a}_{n-1}$ . The quantity  $\gamma_n$  is computed from the relation

$$\gamma_n = -\frac{r_{xx}(n) - \sum_{j=1}^{n-1} a_{n-1}(j)r_{xx}(n-j)}{E_{n-1}}$$

and the mean square prediction error is computed from  $E_n = E_{n-1}(1 - |\gamma_n|^2)$ . The algorithm starts with  $E_0 = r_{xx}(0)$  and  $\mathbf{a}_0 = 1$ . If  $x(k)$  is order  $n$  predictable, then the process terminates with the order  $n$  predictor and  $E_n = 0$ .

The parameters  $\gamma_k$  are known as **reflection coefficients**, **partial correlation coefficients** or **Schur parameters**. The **complementary parameters** are  $\delta_k = \sqrt{1 - |\gamma_k|^2}$ .

### Facts:

- [Pap85] The Wold decomposition theorem: Every stationary random signal can be represented as the sum of a regular and a predictable signal

$$x(k) = x_r(k) + x_p(k).$$

The two components are orthogonal with  $E[x_r(k)x_p(k)] = 0$ .

- [Pap85] The Wiener–Hopf equations can be interpreted as stating that the prediction error  $\hat{x}(k) - x(k)$  is orthogonal to  $x(k-l)$  for  $l \geq 1$  in the inner product  $\langle x, y \rangle = E[xy]$ .
- The Toeplitz matrix  $T_n$  in the Yule–Walker equations is positive semidefinite.
- The Levinson–Durbin algorithm is an  $O(n^2)$  order recursive method for solving the linear prediction problem. In most cases the numerical results from applying the algorithm are comparable to the numerically stable Cholesky factorization procedure [Cyb80]. An alternative fast method, the Schur algorithm, computes a Cholesky factorization and can be proven to be numerically stable [BBH95].
- The following are equivalent:
  - $T_{n-1}$  is positive definite and  $T_n$  is positive semidefinite.
  - $|\gamma_j| < 1$  for  $1 \leq j \leq n-1$  and  $|\gamma_n| = 1$ .
  - $E_j > 0$  for  $1 \leq j \leq n-1$  and  $E_n = 0$ .
  - The polynomial  $z^n E_n(z)$  has all zeros on the unit circle and each polynomial  $z^k E_k(z)$  for  $k = 1, 2, \dots, n-1$  has all zeros strictly inside the unit circle.
- [Pap85] The prediction errors are monotonic:  $E_k \geq E_{k+1}$  and  $E_k \rightarrow E_\infty \geq 0$  as  $k \rightarrow \infty$ .

7. [SK01] Let

$$a_k(z) = 1 - a_k(1)z - a_k(2)z^2 - \dots - a_k(k)z^k$$

where  $\underline{a_k(j)}$  are the prediction coefficients for a signal  $\mathbf{x}$  with spectral density  $S_x(z)$ . If  $S_x(z) = L(z)L(\overline{z^{-1}})$  is the spectral factorization of  $S_x(z)$ , then

$$L(z) = \lim_{k \rightarrow \infty} \frac{E_k^{1/2}}{r_{xx}(0)} \frac{1}{a_k(\overline{z^{-1}})}.$$

A survey, including other representations of the spectral factor and algorithms for computing it, is given in [SK01].

8. [GS84] A finite power random signal  $\mathbf{x}$  is predictable (i.e.,  $E_\infty = 0$ ) if and only if

$$\int_{-\pi}^{\pi} \ln(S_x(e^{i\omega})) d\omega > -\infty.$$

If the signal is regular, then we have the Kolmogorov–Szegő error formula

$$E_\infty = \exp\left(\int_{-\pi}^{\pi} \ln S(e^{i\omega}) d\omega\right) > 0.$$

### Examples:

1. Consider the autoregressive process  $\mathbf{x}$  given by

$$x(k) = n(k) + ax(k-1)$$

where  $\mathbf{n}$  is a white noise process with  $\sigma_n^2 = 1$ . The solution to the order 1 linear prediction problem is given by the Yule–Walker system

$$\begin{bmatrix} \frac{1}{1-a^2} & \frac{a}{1-a^2} \\ \frac{a}{1-a^2} & \frac{1}{1-a^2} \end{bmatrix} \begin{bmatrix} 1 \\ -a_1(1) \end{bmatrix} = \begin{bmatrix} E_1 \\ 0 \end{bmatrix}.$$

The Levinson–Durbin algorithm starts with  $E_0 = r_{xx}(0) = 1/(1-a^2)$  and  $\mathbf{a}_0 = 1$ . Thus,

$$\gamma_1 = -\frac{r_{xx}(1)}{E_0} = -\frac{a/(1-a^2)}{1/(1-a^2)} = -a$$

so that

$$\begin{bmatrix} 1 \\ -a_1(1) \end{bmatrix} = \mathbf{a}_1 = \begin{bmatrix} \mathbf{a}_0 \\ 0 \end{bmatrix} + \gamma_1 \begin{bmatrix} 0 \\ \mathbf{a}_0 \end{bmatrix} = \begin{bmatrix} 1 \\ -a \end{bmatrix}.$$

Thus,  $a_1(1) = a$  and the optimal linear prediction of  $x(k)$  from  $x(k-1)$  is given by

$$\hat{x}(k) = ax(k-1).$$

The prediction error is given by

$$E_1 = E[\hat{x}(k) - x(k)] = E[n(k)] = 1.$$

## 64.4 Wiener Filtering

Linear optimal filtering of stationary signals was introduced by Wiener [Wie49] and Kolmogorov [Kol41]. The material here is covered in books on adaptive filtering [Hay91] and linear estimation [KSH00].

### Definitions:

The general **discrete Wiener filtering problem** is the following: Given stationary signals  $\mathbf{x}$  and  $\mathbf{y}$  find a filter with impulse response  $\mathbf{w}$  such that

$$E_w = E \left[ \left| y(k) - \sum_{j=-\infty}^{\infty} w(j)x(k-j) \right|^2 \right]$$

is minimal. The filter with impulse response  $\mathbf{w}$  minimizing  $E_w$  is the **Wiener filter**. The goal is to approximate a desired signal  $\mathbf{y}$  by filtering the signal  $\mathbf{x}$ . Equivalently, we seek the best approximation to  $y(k)$  in the span of the  $x(j)$  for  $-\infty < j < \infty$ . Note that we leave open the possibility that the Wiener filter is not causal.

Depending on specific relations that may be imposed on  $\mathbf{y}$  and  $\mathbf{x}$ , the Wiener filtering problem specializes in several important ways: The **Wiener prediction problem** for which  $y(k) = x(k+l)$  where  $l \geq 1$  and  $\mathbf{w}$  is assumed causal; the **Wiener smoothing problem** for which  $\mathbf{y}$  is arbitrary and  $\mathbf{x}$  is a noise corrupted version of  $\mathbf{y}$  given by  $\mathbf{x} = \mathbf{y} + \mathbf{n}$  where  $\mathbf{n}$  is the noise; and the **Wiener deconvolution problem** for which we have arbitrary desired signals  $\mathbf{y}$  and  $\mathbf{x}$  obtained from  $\mathbf{y}$  by convolution and the addition of noise,  $\mathbf{x} = \mathbf{h} * \mathbf{y} + \mathbf{n}$ . For the Wiener prediction problem, the goal is to predict future values of  $\mathbf{x}$  from past values. For the Wiener smoothing problem, the goal is to recover an approximation to a signal  $\mathbf{y}$  from a noise corrupted version of the signal  $\mathbf{x}$ . For the Wiener deconvolution, the goal is to invert a filter in the presence of noise to obtain the signal  $\mathbf{y}$  from the filtered and noise corrupted version  $\mathbf{x}$ .

The **FIR Wiener filtering problem** is to choose an FIR filter with impulse response  $w(k)$  such that

$$E \left[ \left| y(k) - \sum_{j=0}^{n-1} w(j)x(k-j) \right|^2 \right]$$

is minimal.

The **causal part** of a signal  $x(k)$  is

$$[x(k)]_+ = \begin{cases} x(k) & \text{if } k \geq 0 \\ 0 & \text{if } k < 0 \end{cases} \quad \text{or} \quad [X(z)]_+ = \sum_{k=0}^{\infty} x(k)z^{-k}.$$

### Facts:

1. The stationarity assumptions ensure that the coefficients  $w(j)$  that are used to estimate  $y(k)$  from the signal  $\mathbf{x}$  do not depend on  $k$ . That is, the coefficients  $w(j)$  that minimize  $E_w$  also minimize

$$E \left[ \left| y(k-k_0) - \sum_{j=0}^{n-1} w(j)x(k-k_0-j) \right|^2 \right]$$

so that the Wiener filter is a linear time invariant system.

2. Let  $S_x(z) = L(z)L(\overline{z^{-1}})$ ,

$$r_{yx}(k) = E [y(j)x(j-k)], \quad \text{and} \quad S_{yx}(e^{i\omega}) = \sum_{k=-\infty}^{\infty} r_{yx}(k)e^{ik\omega}.$$

If we do not require causality, then the Wiener filter has  $z$ -transform

$$W(z) = \frac{S_{yx}(z)}{S_{xx}(z)}.$$

If we do impose causality, then the Wiener filter is

$$\left[ \frac{S_{yx}(z)}{L^*(z^{-*})} \right]_+ \frac{1}{L(z)}.$$

- As seen above the Wiener filter depends on the cross correlations  $r_{yx}(k)$ , but not on knowledge of the elements of the unknown sequence  $y(k)$ . Thus, it is possible to estimate the signal  $y$  by filtering  $x$  without direct knowledge of  $y$ . If the autocorrelation sequences  $r_{xx}(k)$  and  $r_{nn}(k)$  are available (or can be estimated), then  $r_{yx}(k)$  can often be computed in a straightforward way. For the Wiener prediction problem,  $r_{yx}(k) = r_{xx}(l+k)$ . If the noise  $n$  and signal  $y$  are uncorrelated so that  $r_{ny}(k) = 0$  for all  $k$ , then for the Wiener smoothing problem  $r_{yx} = r_{xx} - r_{nn}$ . For the Wiener deconvolution problem, if  $g$  is the inverse filter of  $h$  and if  $y$  and  $n$  are uncorrelated, then  $r_{yx} = g * (r_{xx} - r_{nn})$ .
- The coefficients for an FIR Wiener filter satisfy the Wiener–Hopf equation

$$\begin{bmatrix} r_{xx}(0) & r_{xx}(-1) & \cdots & r_{xx}(-m+1) \\ r_{xx}(1) & r_{xx}(0) & \ddots & \vdots \\ \vdots & \ddots & \ddots & r_{xx}(-1) \\ r_{xx}(m-1) & \cdots & r_{xx}(1) & r_{xx}(0) \end{bmatrix} \begin{bmatrix} w(0) \\ w(1) \\ \vdots \\ w(m-1) \end{bmatrix} = \begin{bmatrix} r_{yx}(0) \\ r_{yx}(1) \\ \vdots \\ r_{yx}(m-1) \end{bmatrix}.$$

As with linear prediction, this system of equations can be solved using fast algorithms for Toeplitz systems.

### Examples:

- We consider the first order FIR Wiener prediction problem of predicting  $y(k) = x(k+2)$  from the autoregressive process  $x$  with  $x(k) = n(k) + ax(k-1)$ . Thus, we seek  $w(0)$  such that

$$E [|x(k+2) - w(0)x(k)|^2]$$

is minimal. Since

$$r_{xx}(0) = \frac{1}{1-a^2}$$

and

$$r_{yx}(0) = r_{xx}(2) = \frac{a^2}{1-a^2}$$

the Wiener–Hopf equation for  $w(0)$  is

$$\frac{1}{1-a^2} w(0) = \frac{a^2}{1-a^2}.$$

## 64.5 Adaptive Filtering

### Definitions:

An FIR **adaptive filter** is a filter with coefficients that are updated to match the possibly changing statistics of the input  $\mathbf{x}$  and the desired output  $\mathbf{y}$ . The output is

$$\hat{y}(k) = \sum_{j=0}^{m-1} w_k(j)x(k-j)$$

where the  $w_k(j)$  depend on  $k$ . The goal is similar to that of the Wiener filter, that is, to approximate the sequence  $\mathbf{y}$ . The difference is that instead of computing a fixed set of coefficients  $w(j)$  from knowledge of the statistics of stationary signals  $\mathbf{x}$  and  $\mathbf{y}$ , the coefficients are allowed to vary with  $k$  and are computed from actual samples of the sequences  $\mathbf{x}$  and  $\mathbf{y}$ .

A **recursive least squares (RLS)** adaptive FIR filter is a rule for updating the coefficients  $w_k(j)$ . The coefficients are chosen to minimize

$$\min_{\mathbf{w}_k} \left\| D_{\rho,k} \begin{bmatrix} x(l) & x(l-1) & \cdots & x(l-m+1) \\ x(l+1) & x(l) & \cdots & x(l-m+2) \\ \vdots & \ddots & \ddots & \vdots \\ x(k) & x(k-1) & \cdots & x(k-m+1) \end{bmatrix} \begin{bmatrix} w_k(0) \\ w_k(1) \\ \vdots \\ w_k(m-1) \end{bmatrix} - D_{\rho,k} \begin{bmatrix} y(l) \\ y(l+1) \\ \vdots \\ y(k) \end{bmatrix} \right\|_2$$

where  $k \geq l+m-1$  and  $D_{\rho,k} = \text{diag}(\rho^{k-l}, \rho^{k-l-1}, \dots, \rho^0)$  with  $0 < \rho \leq 1$ . Equivalently, the vector  $\mathbf{w}_k$  is chosen to solve  $\min_{\mathbf{w}_k} \|D_{\rho,k} T_{l,k} \mathbf{w}_k - D_{\rho,k} \mathbf{y}_k\|$ . The parameter  $\rho$  is chosen to decrease the influence of older data. This is of use when the signals  $\mathbf{x}$  and  $\mathbf{y}$  are only approximately stationary, i.e., their statistical properties are slowly time varying.

A signal  $\mathbf{x}$  is **persistently exciting of order  $m$**  if there exist  $c_1 > 0$ ,  $c_2 \geq c_1$ , and  $j$  such that

$$c_1 I \leq \lambda_p \left( \frac{1}{k-l+1} T_{l,k}^T T_{l,k} \right) \leq c_2 I$$

for each eigenvalue  $\lambda_p$  of  $T_{l,k}^T T_{l,k}/(k-l+1)$  and for all  $k \geq j$ .

### Facts:

1. The vector  $\mathbf{w}_k$  can be updated using using the following recursive formulas:

$$\mathbf{w}_k = \mathbf{w}_{k-1} + \mathbf{g}_k (y(k) - \mathbf{w}_{k-1}^T \mathbf{x}_k)$$

where

$$\mathbf{x}_k = \begin{bmatrix} x(k) \\ \vdots \\ x(k-m+1) \end{bmatrix},$$

$$\mathbf{g}_k = \frac{\rho^{-2} P_{k-1} \mathbf{x}_k}{1 + \rho^{-2} \mathbf{x}_k^T P_{k-1} \mathbf{x}_k},$$

with

$$P_k = \rho^{-2} P_{k-1} - \rho^{-2} \mathbf{g}_k \mathbf{x}_k^T P_{k-1}.$$

With initialization  $P_k = (T_{l,k}^T D_{\rho,k}^2 T_{l,k})^{-1}$  and  $\mathbf{w}_k = P_k T_{l,k}^T D_{\rho,k}^2 \mathbf{y}_k$ , the recurrences compute the solution  $\mathbf{w}_k$  to the recursive least squares problem.

- [GV96] The weight vector  $\mathbf{w}_k$  can also be updated as  $k$  increases with an  $O(n^2)$  cost using a standard  $QR$  updating algorithm. Such algorithms have good numerical properties.
- If  $\mathbf{x}$  and  $\mathbf{y}$  are stationary, if  $\rho = 1$ , and if  $\mathbf{x}$  is persistently exciting, then  $\mathbf{w}_k$  converges to the Wiener filter as  $k \rightarrow \infty$ . Under these assumptions the effect of initializing  $P_k$  incorrectly becomes negligible as  $k \rightarrow \infty$ . Thus, convergence does not depend on the correct initialization of  $P_k = T_{l,k}^T T_{l,k}$ . For simplicity, it is common to choose an initial  $P_k$  that is a multiple of the identity.
- If  $\mathbf{x}$  and  $\mathbf{y}$  are not stationary, then  $\rho$  is typically chosen to be less than one in order to allow the filter to adapt to changing statistics. If the signals really are stationary, then choice of  $\rho < 1$  sacrifices convergence of the filter.
- There are a variety of algorithms that exploit the Toeplitz structure of the least squares problem, reducing the cost per update of  $\mathbf{w}_k$  to  $O(n)$  operations [CK84]. An algorithm that behaves well in finite precision is analyzed in [Reg93].

### Examples:

- Consider applying a recursive least squares adaptive filter to signals  $\mathbf{x}$  and  $\mathbf{y}$  with

$$x(1) = 1, x(2) = 2, x(3) = 3, x(4) = 4$$

and

$$y(2) = 5, y(3) = 6, y(4) = 8.$$

The vector of filter coefficients  $\mathbf{w}_3$  satisfies

$$\begin{bmatrix} 2 & 1 \\ 3 & 1 \end{bmatrix} \mathbf{w}_3 = \begin{bmatrix} 5 \\ 6 \end{bmatrix},$$

so that

$$\mathbf{w}_3 = \begin{bmatrix} 4 \\ -3 \end{bmatrix}.$$

We also have

$$P_3 = \left( \begin{bmatrix} 2 & 1 \\ 3 & 1 \end{bmatrix}^T \begin{bmatrix} 2 & 1 \\ 3 & 1 \end{bmatrix} \right)^{-1} = \begin{bmatrix} 13 & 8 \\ 8 & 5 \end{bmatrix},$$

so that

$$\mathbf{g}_4 = \frac{P_3 \mathbf{x}_4}{1 + \mathbf{x}_4^T P_3 \mathbf{x}_4} = \frac{1}{6} \begin{bmatrix} -4 \\ 7 \end{bmatrix}.$$

Thus, the next coefficient vector  $\mathbf{w}_4$  is

$$\mathbf{w}_4 = \mathbf{w}_3 + \mathbf{g}_3 (y(4) - \mathbf{w}_3^T \mathbf{x}_4) = \begin{bmatrix} 10/3 \\ -11/6 \end{bmatrix}.$$

The process can be continued by updating  $P_4$ ,  $\mathbf{g}_5$ , and  $\mathbf{w}_5$ .

## 64.6 Spectral Estimation

### Definitions:

The **deterministic spectral estimation** problem is to estimate the spectral density  $S_x(e^{i\omega})$  from a finite number of correlations  $r_{xx}(k)$  for  $0 \leq k \leq n$ . Note that this definition is not taken to imply that the signal  $\mathbf{x}$  is deterministic, but that the given data are correlations rather than samples of the random signals.

The **stochastic spectral estimation** problem is to estimate  $S(e^{i\omega})$  from samples of the random signal  $x(k)$  for  $0 \leq k \leq n$ .

The problem of estimating **sinusoids in noise** is to find the frequencies  $\omega_j$  of

$$\hat{x}(k) = \alpha_1 \cos(\omega_1 k + \eta_1) + \alpha_2 \cos(\omega_2 k + \eta_2) + \cdots + \alpha_p \cos(\omega_p k + \eta_p) + w(k) = x(k) + n(k)$$

where  $\mathbf{n}$  is zero mean white noise with variance  $\sigma_n^2$  and  $\mathbf{x}$  is the exact sinusoidal signal with random frequencies  $\omega_j \in [0, 2\pi)$  and phases  $\eta_j$ . The frequencies and phases are assumed to be uncorrelated with the noise  $\mathbf{n}$ . The available data can be the samples of the signal  $\mathbf{x}$  or the autocorrelation sequence  $r_{xx}(j)$ .

### Facts:

- [PM96] A traditional method for the deterministic spectral estimation problem is to assume that any  $r_{xx}(j)$  not given are equal to zero. When additional information is available in the form of a signal model, it is possible to do better by extending the autocorrelation sequence in a way that is consistent with the model.
- [Pap85] The method of maximum entropy: The sequence  $r_{xx}(k)$  is extended so as to maximize the entropy rate

$$\int_{-\pi}^{\pi} \ln S(e^{i\omega}) d\omega,$$

where it is assumed that the random signal  $\mathbf{x}$  is a sequence of normal random variables. It can be shown that the spectrum that achieves this is the spectrum of an autoregressive signal

$$S(e^{i\omega}) = \frac{E_n}{\left| 1 - \sum_{j=1}^n a_n(j) e^{-i\omega j} \right|^2},$$

where the  $a_n(j)$  are the coefficients obtained from the Yule–Walker equations.

- [Pis73] Pisarenko's method: Given a signal comprised of sinusoids in noise, if  $\sigma_n = 0$ , then the signal sequence  $\mathbf{x}$  is order  $p$  predictable and the signal and its autocorrelation sequence  $\mathbf{r}_{xx}$  satisfy

$$\begin{aligned} x(k) &= a(1)x(k-1) + a(2)x(k-2) + \cdots + a(p)x(k-p), \\ r_{xx}(k) &= a(1)r_{xx}(k-1) + a(2)r_{xx}(k-2) + \cdots + a(p)r_{xx}(k-p), \end{aligned}$$

where  $\mathbf{a}_p = [1 \quad -a_p(1) \quad \cdots \quad -a_p(p)]^T$  is a null vector of the  $(p+1) \times (p+1)$  autocorrelation matrix  $T = [t_{ij}] = [r_{xx}(i-j)]$ . This is the Yule–Walker system with  $n = p$  and  $E_p = 0$ . When  $\sigma_n \neq 0$ , we have  $\hat{T} = T + \sigma_n^2 I$  where  $\hat{T}$  is the autocorrelation matrix for  $\hat{x}(k)$ . The value of  $\sigma_n^2$  is the smallest eigenvalue of  $\hat{T}$ . Given knowledge of  $\sigma_n$ ,  $T$  can be computed from  $T = \hat{T} - \sigma_n^2 I$ . The prediction coefficients can then be computed from the Yule–Walker equation  $T\mathbf{a}_p = 0$ . The zeros of the prediction error filter

$$z^p E_p(z) = z^p \left( 1 - \sum_{j=1}^p a(j) z^{-j} \right)$$

all lie on the unit circle at  $e^{i\omega_j}$  for  $j = 1, 2, \dots, p$ , giving the frequencies of the sinusoids.

4. [AGR87] The zeros of a polynomial are often sensitive to small errors in the coefficients. Computing such zeros accurately can be difficult. As an alternative the zeros of  $z^p E_p(z)$  can be found as the eigenvalues of a unitary Hessenberg matrix. Let  $\gamma_j$  and  $\delta_j$  be the Schur parameters and complementary parameters for the autocorrelation matrix  $R$ . Then  $|\gamma_j| < 1$  for  $1 \leq j \leq p-1$  and  $|\gamma_p| = 1$ . The matrix

$$H = G_1(\gamma_1)G_2(\gamma_2) \cdots G_p(\gamma_p)$$

with

$$G_j(\gamma_j) = I_{j-1} \oplus \begin{bmatrix} -\gamma_j & \delta_j \\ \delta_j & \bar{\gamma}_j \end{bmatrix} \oplus I_{p-j-1}$$

is unitary and upper Hessenberg. An explicit formula for the elements of  $H$  is

$$H = \begin{bmatrix} -\gamma_1 & -\delta_1\gamma_2 & -\delta_1\delta_2\gamma_3 & \cdots & -\delta_1 \cdots \delta_{p-1}\gamma_p \\ \delta_1 & -\bar{\gamma}_1\gamma_2 & -\bar{\gamma}_1\delta_2\gamma_3 & \cdots & -\bar{\gamma}_1\delta_2 \cdots \delta_{p-1}\gamma_p \\ & \delta_2 & -\bar{\gamma}_2\gamma_3 & & \vdots \\ & & \ddots & \ddots & \vdots \\ & & & \delta_{p-1} & -\bar{\gamma}_{p-1}\gamma_p \end{bmatrix}.$$

The eigenvalues of  $H$  are the zeros of  $z^p E_p(z)$ . The eigenvalues of a  $p \times p$  unitary Hessenberg matrix can be found with  $O(p^2)$  operations. An algorithm exploiting connections with Szegő polynomials was given in [Gra86] and stabilized in [Gra99]. A different, stable algorithm involving matrix pencils was given in [BE91].

### Examples:

1. Consider a stationary random signal with known autocorrelations  $r_{xx}(0) = 1$  and  $r_{xx}(1) = a < 1$ . The other autocorrelations are assumed to be unknown. The Yule-Walker system

$$\begin{bmatrix} 1 & a \\ a & 1 \end{bmatrix} \begin{bmatrix} 1 \\ -a_1(1) \end{bmatrix} = \begin{bmatrix} E_1 \\ 0 \end{bmatrix}$$

has solution  $a_1(1) = a$  and  $E_1 = 1 - a^2$ . Thus, the maximum entropy estimate of the spectral density  $S_x(e^{i\omega})$  is

$$S(e^{i\omega}) = \frac{1 - a^2}{|1 - ae^{-i\omega}|}.$$

## 64.7 Direction of Arrival Estimation

### Definitions:

The **direction of arrival estimation** problem can be described as follows. We assume that  $n$  plane waves  $s_j(k)$ ,  $1 \leq j \leq n$  arrive at an array of  $m$  sensors from angles  $\theta_j$  resulting in output  $x_l(k)$ ,  $1 \leq l \leq m$  from the sensors. We assume that the sensors lie in a plane and that it is necessary to estimate only a single angle of arrival for each signal. It is assumed that each sensor output is corrupted by noise  $n_l(k)$ ,  $1 \leq l \leq m$ .

The sensors experience different delays and attenuations of the signal  $s_j(k)$  depending on their position and the direction of arrival. If the signals are **narrow-band signals**

$$s_j(k) = \operatorname{Re} \left( u_j(k) e^{i(\omega_0 k + v_j(k))} \right)$$

for slowly varying  $u_j(k)$  and  $v_j(k)$ , then a signal delayed by  $l$  is approximately

$$s_j(k-l) = \operatorname{Re} \left( u_j(k-l) e^{i(\omega_0 k + v_j(k-l))} e^{-i\omega_0 l} \right) \approx \operatorname{Re} \left( u_j(k) e^{i(\omega_0 k + v_j(k))} e^{-i\omega_0 l} \right).$$

Thus, both delay and attenuation of the signals can be described by multiplication by a complex scalar dependent on  $\theta_j$ . The observed signals are, therefore,

$$\mathbf{x}(k) = \sum_{j=1}^n \mathbf{a}(\theta_j) s_j(k) + \mathbf{n}(k),$$

where

$$\mathbf{x}(k) = \begin{bmatrix} x_1(k) \\ \vdots \\ x_m(k) \end{bmatrix}$$

and  $\mathbf{a}(\theta)$  is the complex **array response vector**. In matrix notation the **signal model** is

$$\mathbf{x}(k) = A\mathbf{s}(k) + \mathbf{n}(k),$$

where

$$A = [\mathbf{a}(\theta_1) \quad \mathbf{a}(\theta_2) \quad \cdots \quad \mathbf{a}(\theta_n)].$$

The problem is to estimate the angles  $\theta_j$  from a sequence  $\mathbf{x}(k)$  of sensor output vectors. We assume that the components of the noise vector  $\mathbf{n}(k)$  are uncorrelated, stationary, and zero mean. A more complete description of the problem is given in [RK89].

The **array manifold** is the set of all  $\mathbf{a}(\theta)$  for  $\theta$  in  $[-\pi, \pi]$ .

The **signal subspace** is the range space of the matrix  $A$ .

The **noise subspace** is the orthogonal complement of the signal subspace.

We define the spatial correlation matrices

$$R_{\mathbf{x}} = E[\mathbf{x}\mathbf{x}^*], \quad R_{\mathbf{s}} = E[\mathbf{s}\mathbf{s}^*], \quad \text{and} \quad R_{\mathbf{n}} = E[\mathbf{n}\mathbf{n}^*]$$

where we assume  $R_{\mathbf{s}}$  is positive definite. These definitions apply directly when dealing with stationary random signals. In the deterministic case they can be replaced with time averages.

### Facts:

1. If the signal and noise are uncorrelated, then

$$R_{\mathbf{x}} = AR_{\mathbf{s}}A^* + R_{\mathbf{n}}.$$

2. The signal model implies that except for the effect of noise the observation vectors  $\mathbf{x}(k)$  lie in the signal subspace. Thus, in the absence of noise, any  $n$  linearly independent observation vectors  $\mathbf{x}(k)$  will give a basis for the signal subspace. The directions  $\theta_j$  are determined by the signal subspace so long as the mapping from the set of angles  $\theta_j$  to the signal subspace is invertible. We assume that the sensor array is designed to ensure invertibility.

3. The signal subspace can be estimated by solving a generalized eigenvalue problem. The  $n$  eigenvectors associated with the  $n$  largest generalized eigenvalues of the pencil

$$R_x - \lambda R_n$$

are the basis for the estimated signal subspace. This method can be used to obtain matrices  $X_s$  and  $X_n$  such that  $X_s X_s^*$  is a projection for the signal subspace and  $X_n X_n^*$  is a projection for the noise subspace.

4. [Sch79] In order to obtain the angles  $\theta_j$  the **MUSIC algorithm** searches the array manifold to find angles which are close to the signal subspace in the sense that

$$M(\theta) = \frac{\mathbf{a}^*(\theta)\mathbf{a}(\theta)}{\mathbf{a}^*(\theta)X_n X_n^* \mathbf{a}(\theta)}$$

is large. The values of  $\theta$  for which  $M(\theta)$  has a peak are taken as the estimates of the angles  $\theta_j$ ,  $1 \leq j \leq n$ . The basic approach of the MUSIC algorithm can be used for a variety of parameter estimation problems, including the problem of finding sinusoids in noise.

5. [RK89] The **ESPRIT** algorithm imposes a structure on the array of sensors. It is assumed that the array is divided into two identical subarrays displaced along an  $\mathbb{R}^2$  vector  $\mathbf{\Delta}$ . Let  $x_j(k)$  be the output of sensor  $j$  in the first subarray and  $y_j(k)$  be the output of the corresponding sensor in the second subarray. The displacement  $\mathbf{\Delta}$  causes a delay in the signal  $x_j(k)$  relative to  $y_j(k)$ . If the signals arriving at the array are again narrow band signals centered at frequency  $\omega_0$ , then the signal model is

$$\mathbf{x}(k) = \sum_{j=1}^n s_j(k)\mathbf{a}(\theta_j) + \mathbf{n}_x(k),$$

$$\mathbf{y}(k) = \sum_{j=1}^n s_j(k)e^{i\omega_0\|\mathbf{\Delta}\|_2 \sin(\theta_j)/c} \mathbf{a}(\theta_j) + \mathbf{n}_y(k),$$

where  $\theta_k$  is the angle of arrival relative to the subarray displacement vector. The combined ESPRIT signal model including both subarrays is

$$\begin{bmatrix} \mathbf{x}(k) \\ \mathbf{y}(k) \end{bmatrix} = \begin{bmatrix} A \\ A\Phi \end{bmatrix} \mathbf{s}(k) + \begin{bmatrix} \mathbf{n}_x(k) \\ \mathbf{n}_y(k) \end{bmatrix},$$

where the diagonal matrix  $\Phi = \text{diag}(e^{i\omega_0\|\mathbf{\Delta}\|_2 \sin(\theta_1)/c}, \dots, e^{i\omega_0\|\mathbf{\Delta}\|_2 \sin(\theta_n)/c})$  characterizes the delay between the subarrays.

6. To compute the  $\theta_j$  using the ESPRIT algorithm, we start with the signal subspace associated with the ESPRIT signal model estimated as before using a generalized eigenvalue problem. We assume that a  $2m \times n$  matrix  $S$  with columns spanning the signal subspace

$$S = \begin{bmatrix} S_x \\ S_y \end{bmatrix}$$

has been computed and compute the  $2n \times 2n$  matrix

$$V = \begin{bmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \end{bmatrix}$$

of right singular vectors of  $\begin{bmatrix} S_x & S_y \end{bmatrix}$ . Here,  $V_{11}$  and  $V_{22}$  are  $n \times n$ . The ESPRIT estimates of the values  $e^{i\omega_0 \|\Delta\|_2 \sin(\theta_j)/c}$  are the eigenvalues  $\lambda_j$  of  $-V_{12} V_{22}^{-1}$  so that the estimate  $\hat{\theta}_j$  of  $\theta_j$  is

$$\hat{\theta}_j = \sin^{-1}(c \arg(\lambda_j) / (\|\Delta\|_2 \omega_0))$$

for  $j = 1, 2, \dots, n$ .

### Examples:

1. We consider a single signal arriving at an array of two sensors with array response vector

$$\mathbf{a}(\theta) = \begin{bmatrix} e^{-i(\pi/2 - \theta)} \\ 1 \end{bmatrix}.$$

If observations of the sensor outputs and solution of the generalized eigenvalue problem  $R_x - \lambda R_n$  suggest that

$$X_s X_s^* = \begin{bmatrix} i/\sqrt{3} \\ 2/\sqrt{3} \end{bmatrix} \begin{bmatrix} -i/\sqrt{3} & 2/\sqrt{3} \end{bmatrix}$$

is the projection for the signal subspace, then the projection for the noise subspace is

$$X_n X_n^T = \begin{bmatrix} -2i/\sqrt{3} \\ 1/\sqrt{3} \end{bmatrix} \begin{bmatrix} 2i/\sqrt{3} & 1/\sqrt{3} \end{bmatrix}.$$

In applying the MUSIC algorithm, we have

$$M(\theta) = \frac{2}{3|2e^{i\theta} + 1|^2}.$$

This function has a maximum of  $2/3$  at  $\theta = \pi$ . Thus, the MUSIC estimate of the angle from which the signal arrives is  $\theta = \pi$ .

Many topics taught in an introductory linear algebra course are often motivated by reference to elementary geometry. The geometry is treated as something the student is already familiar with, and reference to it is made to give the student a better understanding of algebraic concepts that may be considered, at least on first acquaintance, to be rather abstract. What is interesting and important is that the process can be reversed: Assuming the linear algebra as known, geometric concepts can be defined and developed on a rigorous basis. The use of vector methods in geometry often provides new ways of looking at old problems and also helps demonstrate deep and beautiful connections between algebra and geometry.

This chapter begins by discussing affine geometry, which can be defined, very roughly, as Euclidean geometry without any mention of measurement. Thus, affine theorems concern such things as incidence and parallelism. An affine space is defined in terms of an action of a vector space  $V$  on a set  $X$ , pursuant to which a vector  $\mathbf{v}$  acts on a point  $A$  of  $X$  by sending it to another element  $\mathbf{v}(A)$  of  $X$ , and two points  $A$  and  $B$  of  $X$  define a unique vector  $\overrightarrow{AB}$ , which acts on  $A$  by sending it to  $B$ . It might be helpful for the reader to think of  $\overrightarrow{AB}$  as an arrow starting at point  $A$  and ending at point  $B$ . This vector then acts on an arbitrary point  $C$  of  $X$  by placing the starting point of the arrow at  $C$  and letting the end point of the arrow be  $\mathbf{v}(C)$ .

By introducing an inner product on a real affine space, Euclidean geometry can be defined. Actually, a very interesting mathematical theory can be developed by considering, more generally, an arbitrary bilinear form, but in the interest of simplicity, only (positive definite) real inner products are considered in this chapter. The general theory is discussed in Chapter III of [Art57] and Chapter 2 of [ST91].

Finally, projective geometry is considered. Here the points of the geometry are not vectors but one-dimensional subspaces and the resulting incidence properties are different than for Euclidean geometry. Projective geometry plays an important role in (among other things) the mathematical theories of elliptic curves and algebraic geometry, but these topics are far beyond the scope of this chapter.

Throughout this chapter,  $F$  is a field and  $V$  is a finite dimensional vector space over  $F$ .

### 65.1 Affine Spaces

---

#### Definitions:

An **affine  $n$ -space** is an ordered pair  $(X, V)$  where  $X$  is a nonempty set and  $V$  is an  $n$ -dimensional vector space over a field  $F$ , which acts on  $X$  in the following way: if  $\mathbf{v} \in V$  and  $A \in X$  then there is an element  $\mathbf{v}(A) \in X$ , and

1. If  $\mathbf{u}, \mathbf{v} \in V$  and  $A \in X$ , then  $(\mathbf{u} + \mathbf{v})(A) = \mathbf{u}(\mathbf{v}(A))$ , and
2. For any two points  $A, B \in X$  there exists a unique vector  $\mathbf{v} \in V$  such that  $\mathbf{v}(A) = B$ . This vector  $\mathbf{v}$  is denoted  $\overrightarrow{AB}$ .

The elements of  $X$  are called the **points** of the affine space  $(X, V)$ , and sometimes, when no confusion will result, one speaks of “the affine space  $X$ .”

A **real affine space** is an affine space  $(X, V)$  where  $V$  is a vector space over the field  $\mathbb{R}$  of real numbers.

If  $(X, V)$  is an affine  $n$ -space,  $W$  is a (vector) subspace of  $V$  of dimension  $m \leq n$ , and  $A$  is a fixed point in  $X$ , then the **affine subspace determined by  $A$  and  $W$** , denoted  $S(A, W)$ , is the set of all points  $\mathbf{w}(A)$  as  $\mathbf{w}$  ranges over  $W$ . A subset of  $X$  is called an affine subspace of dimension  $m$  if it is of the form  $S(A, W)$  for some  $A$  in  $X$  and subspace  $W$  of dimension  $m$  (cf. Fact 2, below).

A one-dimensional affine subspace of  $X$  is called a **line**; a two-dimensional affine subspace, a **plane**.

The vector subspace  $W$  is called the **direction space** of the affine subspace  $S(A, W)$ .

Two affine subspaces of the same dimension are **parallel** if they have the same direction space. More generally, two affine subspaces (of possibly different dimension) are **parallel** if the direction space of one is a subspace of the direction space of another.

If  $C$  is a point in  $X$ , the map  $P \rightarrow \overrightarrow{CP}$  is a bijection between  $X$  and  $V$ . By identifying a point of  $X$  with its image in  $V$  under this bijection, addition and scalar multiplication in  $X$  can be defined so that it becomes a vector space isomorphic to  $V$ , called the **tangent space** at  $C$  and denoted  $X(C)$ .

The elements of a set  $\{X_1, \dots, X_d\}$  of  $d$  points in an affine space are **in general position**, or **affine-independent**, if they are not contained in any affine subspace of dimension less than or equal to  $d - 2$ .

Three points that are affine-independent are called **noncollinear**.

If  $A$  and  $B$  are distinct points in a real affine space, the set of points  $P$  such that  $\overrightarrow{AP} = t\overrightarrow{AB}$  for some  $t$ ,  $0 \leq t \leq 1$ , is called the **line segment** from  $A$  to  $B$  and is denoted  $[A, B]$ . The point  $P$  which corresponds to  $t = 1/2$  is the **midpoint** of the line segment.

If  $A, B$ , and  $C$  are three points in general position in a real affine space, then the set of points  $P$  such that  $\overrightarrow{AP} = t\overrightarrow{AB} + u\overrightarrow{AC}$ , where  $u$  and  $t$  are nonnegative real numbers whose sum does not exceed 1, is called the **triangle** with vertices  $A, B$ , and  $C$ .

A subset  $Y$  of a real affine space is **convex** if whenever  $A$  and  $B$  are in  $Y$ , every point on the line segment  $[A, B]$  is also in  $Y$ .

If  $(X, V)$  is an affine  $n$ -space and  $n \geq 2$ , then a bijection  $T: X \rightarrow X$  is **semiaffine** if the image under  $T$  of any  $d$ -dimensional affine subspace is also a  $d$ -dimensional affine subspace, and is **affine** if it is semiaffine and satisfies the following additional condition: If  $A$  and  $B$  are distinct points and  $C$  and  $D$  are distinct points, and  $\overrightarrow{AB} = k\overrightarrow{CD}$  for some nonzero scalar  $k$ , then  $\overrightarrow{T(A)T(B)} = k\overrightarrow{T(C)T(D)}$ .

If  $(X, V)$  is an affine  $n$ -space and  $\mathbf{v} \in V$ , the translation  $T_{\mathbf{v}}$  is the map  $T_{\mathbf{v}}: X \rightarrow X$  defined by  $T_{\mathbf{v}}(A) = \mathbf{v}(A)$ .

**Facts:** For proofs, see [ST71].

1. If  $A$  and  $B$  are points in an affine space, then
  - (a)  $\overrightarrow{AB} = 0$  if and only if  $A = B$ .
  - (b)  $\overrightarrow{AB} = -\overrightarrow{BA}$ .
  - (c)  $\overrightarrow{AB} + \overrightarrow{BC} = \overrightarrow{AC}$ .
2. If  $S = S(A, W)$  is an affine subspace of the affine space  $(X, V)$ , then  $W = \{\overrightarrow{AB}: A, B \in S\}$ . In particular,  $W$  is uniquely determined by  $S$ .
3. The affine subspaces  $S(A, W)$  and  $S(B, W)$  are equal if and only if  $\overrightarrow{AB} \in W$ .
4. The intersection of two affine subspaces is either empty or is an affine subspace. Specifically, if the point  $P$  is in both  $S(A, U)$  and  $S(B, W)$ , then  $S(A, U) \cap S(B, W) = S(P, U \cap W)$ .

5. (Generalized Euclidean Parallel Postulate) If  $S = S(A, W)$  is a  $d$ -dimensional affine subspace of an affine space  $X$ , and  $P$  is any point of  $X$ , then there exists a unique  $d$ -dimensional affine subspace of  $X$ , namely  $S(P, W)$ , that is parallel to  $S$  and contains the point  $P$ .
6. Given any two distinct points  $A$  and  $B$  in an affine space, there is a unique line containing them both.
7. The intersection of two convex subsets of a real affine space is convex (possibly empty). In addition, every affine subspace of a real affine space is convex.
8. The set of all semiaffine transformations of an affine  $n$ -space  $(X, V)$  forms a group under the operation of function composition. The set of all affine transformations of the affine space is a subgroup of this group.
9. A semiaffine transformation of an affine space of dimension at least two maps parallel subspaces to parallel subspaces, i.e. if  $S$  and  $S'$  are parallel subspaces of the affine space  $X$  and  $T$  is a semiaffine transformation, then  $T(S)$  and  $T(S')$  are parallel.
10. If  $(X, V)$  is an affine space of dimension at least two and  $V$  is a vector space over a field that, like the field of real numbers, has no nontrivial automorphisms, then any semiaffine transformation is an affine transformation.
11. A translation of an affine  $n$ -space, where  $n$  is at least two, is an affine transformation of that space.
12. If  $\{A_0, \dots, A_n\}$  and  $\{B_0, \dots, B_n\}$  are two sets of points in general position in an affine  $n$ -space  $X$ , then there is a unique affine transformation  $T$  such that  $T(A_i) = B_i$  for each  $i = 0, 1, \dots, n$ .
13. If  $C$  is an arbitrary but fixed point of  $X$  and  $T$  is an affine transformation of  $X$ , then  $T$  can be realized as the composition of a mapping that is a nonsingular linear transformation on the tangent space  $X(C)$ , followed by a translation of  $X$ .

**Examples:**

1. If  $V$  is any vector space over a field  $F$ , then by taking  $X = V$  and  $\mathbf{v}(A) = \mathbf{v} + A$  we obtain an affine space, denoted  $\mathcal{A}(V)$ . For two points (i.e., vectors)  $A$  and  $B$ ,  $\overrightarrow{AB} = B - A$ . The affine subspaces of  $\mathcal{A}(V)$  are precisely the additive cosets of the vector subspaces. When  $V = F^n$ , the vector space of column  $n$ -tuples of elements of a field  $F$ , the resulting affine space is often denoted  $A^n(F)$ .
2. Any affine subspace  $S = \mathbf{v} + W$  of the affine space  $\mathcal{A}(V)$  is an affine space  $(S, W)$ , with  $\mathbf{u}(\mathbf{v} + W) = (\mathbf{u} + \mathbf{v}) + W$ . It can also be an affine space with a different (but isomorphic) vector space, however. For example, in the affine space  $A^2(F)$ , let  $S$  be the set of all points  $\begin{bmatrix} x \\ y \end{bmatrix}$  which satisfy  $x + y = 1$ , so  $(S, W)$  is an affine space with  $W = \left\{ \begin{bmatrix} u \\ -u \end{bmatrix} : u \in F \right\}$ . But  $S$  is also an affine space with associated vector space  $F$ , with the action of  $F$  on  $W$  given by  $u \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} x + u \\ y - u \end{bmatrix}$  for  $u \in F$ .
3. In the affine space  $\mathcal{A}(V)$ , the tangent space  $V(\mathbf{0})$  is identical, not just as a set, but also with regard to the vector space operations, to the vector space  $V$ . Fact 13 therefore implies that any affine transformation of this affine space is of the form  $T(\mathbf{v}) = L(\mathbf{v}) + \mathbf{b}$ , where  $L$  is a nonsingular linear transformation from  $V$  to itself and  $\mathbf{b}$  is a fixed vector.
4. The vectors  $\{v_0, \dots, v_n\}$  in  $\mathcal{A}(V)$  are affine-independent if and only if the vectors  $\{v_1 - v_0, \dots, v_n - v_0\}$  are linearly independent in the vector space  $V$ . Thus, for example, if  $\{\mathbf{u}, \mathbf{v}, \mathbf{w}\}$  and  $\{\mathbf{x}, \mathbf{y}, \mathbf{z}\}$  are two sets of vectors in general position in the affine space  $\mathcal{A}(V)$ , where  $V$  is two-dimensional, then to find the unique affine transformation mapping  $\mathbf{u}$  to  $\mathbf{x}$ ,  $\mathbf{v}$  to  $\mathbf{y}$ , and  $\mathbf{w}$  to  $\mathbf{z}$ , we first use translation by  $-\mathbf{u}$  to map  $\{\mathbf{u}, \mathbf{v}, \mathbf{w}\}$  to  $\{\mathbf{0}, \mathbf{v} - \mathbf{u}, \mathbf{w} - \mathbf{u}\}$ , then use the (unique) linear transformation that maps the linearly independent vectors  $\mathbf{v} - \mathbf{u}$  and  $\mathbf{w} - \mathbf{u}$  to  $\mathbf{y} - \mathbf{x}$  and  $\mathbf{z} - \mathbf{x}$ , respectively, and finally use translation by  $\mathbf{x}$ .

5. As a specific illustration of the idea discussed in the previous example, consider  $A^2(\mathbb{R})$ . Let  $\mathbf{u} = \begin{bmatrix} 1 \\ 1 \end{bmatrix}$ ,  $\mathbf{v} = \begin{bmatrix} 2 \\ 1 \end{bmatrix}$ ,  $\mathbf{w} = \begin{bmatrix} 1 \\ 2 \end{bmatrix}$ ,  $\mathbf{x} = \begin{bmatrix} 1 \\ 4 \end{bmatrix}$ ,  $\mathbf{y} = \begin{bmatrix} 4 \\ 7 \end{bmatrix}$ , and  $\mathbf{z} = \begin{bmatrix} 6 \\ 12 \end{bmatrix}$ . If  $T$  denotes translation by  $\begin{bmatrix} -1 \\ -1 \end{bmatrix}$ , then  $T$  maps  $\mathbf{u}$ ,  $\mathbf{v}$ , and  $\mathbf{w}$ , respectively, to  $\mathbf{u}' = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$ ,  $\mathbf{v}' = \begin{bmatrix} 1 \\ 0 \end{bmatrix}$ , and  $\mathbf{w}' = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$ . The linear transformation  $L$  that maps  $\mathbf{v}'$  and  $\mathbf{w}'$  to  $\mathbf{y}-\mathbf{x}$  and  $\mathbf{z}-\mathbf{x}$  is given by the matrix  $\begin{bmatrix} 3 & 5 \\ 3 & 8 \end{bmatrix}$ . Thus, the composite transformation  $LT$ , which in coordinates is given by  $\begin{bmatrix} x \\ y \end{bmatrix} \rightarrow \begin{bmatrix} 3x + 5y - 8 \\ 3x + 8y - 11 \end{bmatrix}$ , maps  $\mathbf{u}$ ,  $\mathbf{v}$ , and  $\mathbf{w}$  to  $\begin{bmatrix} 0 \\ 0 \end{bmatrix}$ ,  $\begin{bmatrix} 3 \\ 3 \end{bmatrix}$ ,  $\begin{bmatrix} 5 \\ 8 \end{bmatrix}$ . Composing this composite map with translation by  $\begin{bmatrix} 1 \\ 4 \end{bmatrix}$  gives an affine map which maps  $\mathbf{u}$ ,  $\mathbf{v}$ ,  $\mathbf{w}$  to  $\mathbf{x}$ ,  $\mathbf{y}$ ,  $\mathbf{z}$ . In coordinates, this affine map is given by  $\begin{bmatrix} x \\ y \end{bmatrix} \rightarrow \begin{bmatrix} 3x + 5y - 7 \\ 3x + 8y - 7 \end{bmatrix}$ , which can be viewed as  $T'L$ , where  $T'$  is translation by  $\begin{bmatrix} -7 \\ -7 \end{bmatrix}$ .
6. If  $\{2\mathbf{u}, 2\mathbf{v}, 2\mathbf{w}\}$  is a set of three vectors in general position in the affine plane  $A^2(\mathbb{R})$ , then we can think of these vectors as the vertices of a triangle in the Cartesian plane. (The coefficients appear simply to make subsequent calculations less messy.) The midpoint of the line containing  $2\mathbf{u}$  and  $2\mathbf{v}$  is  $\mathbf{u} + \mathbf{v}$ , and similarly for the other sides of the triangle. Thus, the median of the triangle emanating from vertex  $2\mathbf{w}$  is the line containing  $2\mathbf{w}$  and  $\mathbf{u} + \mathbf{v}$ , which is the coset  $2\mathbf{w} + \text{Span}(\mathbf{u} + \mathbf{v} - 2\mathbf{w})$ . It is easy to verify that  $(1/3)(2\mathbf{u} + 2\mathbf{v} + 2\mathbf{w})$  is on this line. Similar calculations show that this point is on the other two medians as well. This gives an algebraic proof of the familiar result from high school geometry that the medians of a triangle are concurrent.
7. Let  $F$  be a field that has a nonidentity automorphism  $f$ , such as the complex numbers with complex conjugation. In the affine plane  $A^2(F)$ , the mapping  $T: \begin{bmatrix} x \\ y \end{bmatrix} \rightarrow \begin{bmatrix} f(x) \\ f(y) \end{bmatrix}$  is a semiaffine transformation that is not affine. To verify that it is not affine, let  $a$  be an element of  $F$  that is not fixed by  $f$ , and consider the vectors  $\mathbf{u} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$ ,  $\mathbf{v} = \begin{bmatrix} 0 \\ a \end{bmatrix}$ ,  $\mathbf{w} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$ , and  $\mathbf{z} = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$ . It is then easily verified that  $\overrightarrow{\mathbf{u}\mathbf{v}} = a(\overrightarrow{\mathbf{w}\mathbf{z}})$  but  $\overrightarrow{T(\mathbf{u})T(\mathbf{v})} = f(a)\overrightarrow{T(\mathbf{w})T(\mathbf{z})}$ .

## 65.2 Euclidean Spaces

### Definitions:

**Euclidean  $n$ -space** is an affine  $n$ -space  $(X, V)$  where  $V$  is a real inner product space. When  $n = 2$ , Euclidean  $n$ -space is called a **Euclidean plane**.

The **distance** between two points  $A$  and  $B$  in the Euclidean  $n$ -space  $(X, V)$  is  $\|\overrightarrow{AB}\|$ , where the norm is taken pursuant to the inner product in  $V$ . This distance is denoted  $d(A, B)$ .

Two lines in a Euclidean plane are **orthogonal** if the vectors that span their respective direction spaces are orthogonal with respect to the inner product of  $V$ .

If  $A$  and  $B$  are distinct points in a Euclidean plane, the **perpendicular bisector** of line segment  $[A, B]$  is the line passing through the midpoint of this segment whose direction space is the orthogonal complement of the space spanned by the vector  $\overrightarrow{AB}$ .

An **isometry** or **rigid motion** of a Euclidean  $n$ -space  $(X, V)$  is a bijection  $T$  of  $X$  that preserves distances:  $d(A, B) = d(T(A), T(B))$ , for all  $A$  and  $B$  in  $X$ .

The **linear transformation associated with  $T$**  is the mapping  $T': V \rightarrow V$  defined by  $T'(\overrightarrow{AB}) = \overrightarrow{T(A)T(B)}$  (cf. Fact 4, below).

The isometry  $T$  is **direct** if  $T'$  has positive determinant, **indirect** if  $T'$  has negative determinant.

The remaining definitions in this section apply to the Euclidean plane  $A^2(\mathbb{R})$  with the ordinary dot product as the inner product. (Recall from the preceding section that this is the affine plane obtained by taking  $X = V = \mathbb{R}^2$ .)

A  $2 \times 2$  **rotation matrix** is a matrix of the form  $R_\theta = \begin{bmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{bmatrix}$ .

A  $2 \times 2$  **reflection matrix** is a matrix of the form  $S_\theta = \begin{bmatrix} \cos \theta & \sin \theta \\ \sin \theta & -\cos \theta \end{bmatrix}$ .

If  $C$  is a fixed point in  $\mathbb{R}^2$ , a **rotation about point  $C$**  is a mapping from  $\mathbb{R}^2$  to itself of the form  $T(X) = R_\theta(X - C) + C$ , for some  $2 \times 2$  rotation matrix  $R_\theta$ .

If  $l$  is a line, the **reflection through  $l$**  is the mapping from  $A^2(\mathbb{R})$  to itself which sends every point on  $l$  to itself, and which sends a point  $C$  not on  $l$  to the unique point  $C'$  with the property that  $l$  is the perpendicular bisector of the line segment  $[C, C']$ .

A **glide reflection** is a reflection through a line  $l$  followed by translation by a nonzero vector that spans the direction space of  $l$ .

**Facts:** For proofs, see [Roe93] and [Ree83].

1. The distance function  $d$  on a Euclidean  $n$ -space is a metric on the set  $X$ . Specifically, this means that if  $A, B$ , and  $C$  are arbitrary points of  $X$ , then
  - (a)  $d(A, B)$  is nonnegative, and equal to 0 if and only if  $A = B$ .
  - (b)  $d(A, B) = d(B, A)$ .
  - (c)  $d(A, B) \leq d(A, C) + d(C, B)$ .
2. The point  $C$  is in the line segment  $[A, B]$  if and only if  $d(A, C) + d(C, B) = d(A, B)$ .
3. (Pythagorean Theorem) If  $A, B$ , and  $C$  are three noncollinear points in a Euclidean  $n$ -space and  $\overrightarrow{AB}$  is orthogonal to  $\overrightarrow{BC}$  then  $d(A, B)^2 + d(B, C)^2 = d(A, C)^2$ .
4. An isometry is an affine mapping.
5. The associated linear transformation of an isometry is a well-defined orthogonal linear transformation.
6. In the Euclidean space  $A^n(\mathbb{R})$ , when an isometry is written as  $T(\mathbf{v}) = \mathbf{L}(\mathbf{v}) + \mathbf{b}$  for a nonsingular linear transformation  $L$  and vector  $\mathbf{b}$ , the associated linear transformation  $T'$  is simply  $L$ . (Such an expression for an isometry  $T$  is always possible.)
7. Any translation in a Euclidean  $n$ -space is an isometry of that space. The associated linear transformation of a translation is the identity map.
8. The set of all isometries of a Euclidean space  $(X, V)$  is a group (under the operation of function composition).
9. The map that associates to every isometry  $T$  its associated linear transformation  $T'$  is a homomorphism from the isometry group onto the group of all orthogonal linear transformations of  $V$ , the kernel of which is the set of all translations.
10. If  $l$  is a line in the affine space  $A^2(\mathbb{R})$ , then reflection through  $l$  is an isometry.
11. If  $l$  is a line that passes through the origin in  $A^2(\mathbb{R})$ , then reflection through  $l$  is a linear transformation given by a reflection matrix. Conversely, the linear transformation defined by multiplication of a vector by a (fixed) reflection matrix  $S_\theta$  is a reflection through the line passing through the origin with direction space spanned by  $\begin{bmatrix} \cos(\theta/2) \\ \sin(\theta/2) \end{bmatrix}$ .
12. A rotation is an isometry.
13. In  $A^2(\mathbb{R})$ , a rotation about the origin  $\mathbf{0}$  is a linear transformation given by a rotation matrix.
14. In  $A^2(\mathbb{R})$ , the point  $C$  is the unique fixed point of a nonidentity rotation about  $C$ . Any isometry with a unique fixed point is a rotation.
15. Any isometry of  $A^2(\mathbb{R})$  can be written as the product of three or fewer reflections.

16. Every isometry of  $A^2(\mathbb{R})$  is either a translation, rotation, reflection, or glide reflection.
17. In  $A^2(\mathbb{R})$ , the product of a reflection with itself is the identity mapping. The product of two distinct reflections is a translation if the reflections are through parallel lines; if the reflections are through two lines intersecting at a point, the product of the two reflections is a rotation about that point. The product of three reflections is either a reflection or glide reflection.
18. The translations and rotations are the direct isometries of  $A^2(\mathbb{R})$  and the reflections and glide reflections are the indirect ones.
19. Two triangles  $ABC$  and  $A'B'C'$  in  $A^2(\mathbb{R})$  are congruent in the sense of high school geometry (i.e., corresponding sides and angles are equal) if and only if there is an isometry of  $A^2(\mathbb{R})$ , which maps  $A$  to  $A'$ ,  $B$  to  $B'$ , and  $C$  to  $C'$ .

### Examples:

1. In  $A^2(\mathbb{R})$ , the line segment between  $\begin{bmatrix} 1 \\ 1 \end{bmatrix}$  and  $\begin{bmatrix} 3 \\ 3 \end{bmatrix}$  lies on a line with direction space spanned by  $\begin{bmatrix} 1 \\ 1 \end{bmatrix}$ ; the span of  $\begin{bmatrix} -1 \\ 1 \end{bmatrix}$  is the orthogonal complement of this direction space. The midpoint of this line segment is  $\begin{bmatrix} 2 \\ 2 \end{bmatrix}$ . Therefore, the perpendicular bisector of this segment is the line  $l$  given by  $\begin{bmatrix} 2 \\ 2 \end{bmatrix} + \text{Span} \left( \begin{bmatrix} -1 \\ 1 \end{bmatrix} \right)$ .
2. In  $A^2(\mathbb{R})$  the map  $\begin{bmatrix} x \\ y \end{bmatrix} \rightarrow \begin{bmatrix} -y \\ -x \end{bmatrix}$  has matrix  $\begin{bmatrix} 0 & -1 \\ -1 & 0 \end{bmatrix}$ , which is a reflection matrix. To determine the line through which this mapping is a reflection, note that its eigenvalues are 1 and  $-1$ . An eigenvector for the eigenvalue 1 is  $\begin{bmatrix} 1 \\ -1 \end{bmatrix}$ . Thus, the line spanned by  $\begin{bmatrix} 1 \\ -1 \end{bmatrix}$  is the line through which this mapping reflects. Alternatively,  $\begin{bmatrix} 0 & -1 \\ -1 & 0 \end{bmatrix} = S_{3\pi/2}$ , so by Fact 11, the line of reflection is spanned by  $\begin{bmatrix} \cos(3\pi/4) \\ \sin(3\pi/4) \end{bmatrix} = \begin{bmatrix} -1/\sqrt{2} \\ 1/\sqrt{2} \end{bmatrix}$ .
3. The mapping  $\begin{bmatrix} x \\ y \end{bmatrix} \rightarrow \begin{bmatrix} -y \\ x \end{bmatrix}$  has matrix  $\begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}$ , which is a rotation matrix (corresponding to  $\theta = \pi/2$ ). The mapping  $T: \begin{bmatrix} x \\ y \end{bmatrix} \rightarrow \begin{bmatrix} -y + 1 \\ x \end{bmatrix}$ , which is a direct isometry and not a translation, must correspond to a rotation also, through a point other than the origin. To determine the center of this rotation, we compute the unique fixed point to be  $x = 1/2 = y$ . Thus,  $T$  is a rotation around the point  $\begin{bmatrix} 1/2 \\ 1/2 \end{bmatrix}$ .

## 65.3 Projective Spaces

---

### Definitions:

If  $V$  is an  $(n+1)$ -dimensional vector space over a field  $F$ , then the  $n$ -dimensional projective space based on  $V$ , denoted  $\mathcal{P}(V)$ , is the set of all subspaces of  $V$ . The one-dimensional subspaces of  $V$  are the **points** of  $\mathcal{P}(V)$ ; the two-dimensional subspaces of  $V$  are the **lines** of  $\mathcal{P}(V)$ . More generally, the  $k$ -dimensional projective subspaces are the  $(k+1)$ -dimensional subspaces of  $V$ .

When  $V$  has dimension 3,  $\mathcal{P}(V)$  is called the **projective plane** based on  $V$ .

A point  $\text{Span}(\mathbf{v})$  **lies on** a projective subspace if it is a subset of that projective subspace.

Relative to a fixed ordered basis of  $V$ , any nonzero element of  $V$  can be identified with an  $(n + 1)$ -tuple of elements of  $F$ . Thus, by selecting a spanning vector of any point of  $\mathcal{P}(V)$ , that point can be identified with an  $(n + 1)$ -tuple of elements of  $F$ , where not all of the components are zero and where two such  $(n + 1)$ -tuples are identified if one is a nonzero scalar multiple of the other. Under this identification, the  $(n + 1)$ -tuple is denoted  $[a_1 : a_2 : \dots : a_{n+1}]$  and called the **homogeneous coordinates** of the point. (In many geometry books, homogenous coordinates are denoted  $[a_1, a_2, \dots, a_{n+1}]$ , but here that notation risks confusion with a  $1 \times n$  matrix.)

When  $\mathcal{P}(V)$  is a projective space of dimension  $n$ , with ordered basis  $\mathcal{B}$  for  $V$ , then for any  $r$ -dimensional subspace  $W$  of  $V$  there is an  $(n + 1 - r)$ -dimensional subspace of the dual space  $V^*$  consisting of those linear functionals of  $V$  that vanish on  $W$  (cf. Section 3.8). In particular, if  $\mathcal{P}(V)$  is a projective plane, then points (respectively, lines) of  $\mathcal{P}(V)$  correspond to lines (respectively, points) of  $\mathcal{P}(V^*)$ . Since, relative to the dual basis of  $V^*$ , any point can be given homogenous coordinates, any line of  $\mathcal{P}(V)$  can be given the homogenous coordinates of its annihilator; these are **homogenous line coordinates**.

The **dual** of a statement concerning points and lines in a projective plane is the statement obtained by interchanging the terms “point” and “line.”

If  $\{A, B, C\}$  and  $\{A', B', C'\}$  are two sets of noncollinear points in a projective plane  $\mathcal{P}(V)$ , then the triangles  $ABC$  and  $A'B'C'$  are **perspective from the point**  $P$  if and only if the lines containing  $A$  and  $A'$ ,  $B$  and  $B'$ , and  $C$  and  $C'$  all pass through the point  $P$ .

The triangles  $ABC$  and  $A'B'C'$  are **perspective from the line**  $l$  if the points of intersection of the corresponding sides of the triangles all lie on the line  $l$ .

If  $T$  is a nonsingular linear transformation of  $V$ , then the mapping  $\hat{T}$  from  $\mathcal{P}(V)$  to itself, defined by mapping  $\text{Span}(\{\mathbf{v}_1, \dots, \mathbf{v}_m\})$  to  $\text{Span}\{T(\mathbf{v}_1), \dots, T(\mathbf{v}_m)\}$ , is called the **projective transformation** (or **projectivity**) **determined by T**.

A **collineation** of  $\mathcal{P}(V)$  is a bijective mapping from  $\mathcal{P}(V)$  onto itself which maps subspaces to subspaces of the same dimension and which preserves set inclusion.

**Facts:** For proofs see [Kap69] or specific references.

1. In a projective plane  $\mathcal{P}(V)$ , points and lines satisfy the following incidence properties:
  - (a) Two distinct points  $A$  and  $B$  lie on a unique line, denoted  $AB$ .
  - (b) Two distinct lines meet in a unique point.
  - (c) There are four distinct points, no three of which are collinear.
2. In the projective plane  $\mathcal{P}(V)$ , the dual of any theorem involving the incidence of points and lines is also a theorem. (In the preceding Fact, for example, statement (b) is the dual of statement (a), and vice versa.)
3. [Art57] Any projective transformation of the projective space  $\mathcal{P}(V)$  is a collineation of  $\mathcal{P}(V)$ . If  $F$  is a field that does not have any nontrivial automorphisms (such as, for example, the field of real numbers), then any collineation of the projective space  $\mathcal{P}(V)$  is a projective transformation.
4. In the projective plane  $\mathcal{P}(V)$ , if a point  $P$  has homogenous coordinates  $[a:b:c]$  and a line  $l$  has homogenous coordinates  $[x:y:z]$ , then  $P$  lies on  $l$  if and only if  $ax + by + cz = 0$ . Thus, to find the homogenous line coordinates of the line containing the points  $[a:b:c]$  and  $[d:e:f]$ , we can use the

formula for vector cross product to find a vector  $\begin{bmatrix} x \\ y \\ z \end{bmatrix}$ , which is orthogonal to the two vectors  $\begin{bmatrix} a \\ b \\ c \end{bmatrix}$  and  $\begin{bmatrix} d \\ e \\ f \end{bmatrix}$  under the usual dot product. For an arbitrary field  $F$ , this formula yields the homogenous line coordinates  $[x: y: z]$  of the line containing the two points.

5. (Desargues' Theorem and its converse) Two triangles in a projective plane  $\mathcal{P}(V)$  are perspective from a point if and only if they are perspective from a line.
6. (Pappus' Theorem) Let  $A, B, C$  and  $A', B', C'$  be two triples of distinct collinear points in a projective plane. Let  $P, Q,$  and  $R$  denote, respectively, the points of intersection of the lines  $AB'$  and  $A'B, AC'$  and  $C'A,$  and  $BC'$  and  $B'C.$  Then  $P, Q,$  and  $R$  are collinear.
7. Let  $A, B, C,$  and  $D$  be four distinct points in a projective plane  $\mathcal{P}(V)$  with the property that no three are collinear. Let  $A', B', C',$  and  $D'$  be four other distinct points with this property. Then there is a unique projective transformation which maps  $A$  to  $A', B$  to  $B', C$  to  $C',$  and  $D$  to  $D'.$

### Examples:

1. If  $V$  is a two-dimensional vector space over the field of complex numbers, then the projective line  $\mathcal{P}(V)$  can be realized as the set of all homogeneous coordinates  $[x: y]$  where  $x$  and  $y$  are complex numbers, not both zero. By identifying  $[x: y]$  with the complex number  $x/y$  if  $y$  is nonzero, and with  $\infty$  if  $y = 0,$  we can identify  $\mathcal{P}(V)$  with the extended complex plane studied in courses on complex analysis. Note also that the complex-linear transformation of  $V$  given by a nonsingular matrix  $\begin{bmatrix} a & b \\ c & d \end{bmatrix}$  represents the mapping of the extended plane given by  $z \mapsto \frac{az + b}{cz + d};$  these are the linear fractional transformations studied in such a course.
2. The smallest projective space of dimension greater than 1 is obtained by letting  $V$  be a three-dimensional vector space over the two-element field  $Z_2.$  In homogenous coordinates, every element of  $\mathcal{P}(V)$  is represented by a triple  $[a: b: c]$  where each entry is either 0 or 1 and not all entries are 0. Thus, there are seven points in this projective plane, and by duality there are seven lines as well. It is easy to verify that each line of this projective plane consists of three points, and each point is contained on three lines. For example, the line containing the points  $[1:1:1]$  and  $[1:0:0],$  obtained by taking the span of these vectors, contains these points, the point with homogenous coordinates  $[0:1:1],$  and no other points (i.e., no other nonzero vector spans a one-dimensional subspace of the span of these two points).
3. If  $V$  is a three-dimensional vector space over the field of real numbers, then, thinking of the points of  $\mathcal{P}(V)$  in terms of homogenous coordinates relative to a given fixed ordered basis of  $V,$  the points  $[0:1:0]$  and  $[0:0:1]$  lie on a unique line, which is the span of these vectors (i.e., the two-dimensional subspace of  $V$  consisting of all points with homogenous coordinates with first component zero). In the dual space of  $V,$  relative to the dual basis of the given ordered basis of  $V,$  this subspace corresponds to the subspace of all linear functionals of  $V$  that annihilate all such vectors. This is clearly the span of the first vector in the ordered dual basis. Thus, the homogenous line coordinates for the line containing the two given points is  $[1:0:0].$  This can also be obtained as a cross product.
4. To illustrate Pappus' Theorem, let six points be given as follows in the real projective plane:  $A = [1:0:0], B = [0:1:0], C = [1:1:0], A' = [1:1:2], B' = [1:2:2], C' = [0:0:1].$  It was observed above that the line  $BC'$  consists of all points with homogenous coordinates with first component zero. It is easy to see that the line containing  $C$  and  $B'$  is the set of triples of real numbers of the form  $\begin{bmatrix} a + b \\ a + b \\ a \end{bmatrix}.$  The intersection of these two lines is obtained by letting  $a = -b,$  and, therefore, is the point with homogenous coordinates  $[0:0:1].$  By similar calculations, the intersection of the lines  $AB'$  and  $A'B$  is seen to be the point with homogenous coordinates  $[1:2:2]$  and the intersection of the lines  $CA'$  and  $C'A$  is the point with homogenous coordinates  $[0:0:1].$  Since the vectors  $\begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix},$ 
 $\begin{bmatrix} 1 \\ 2 \\ 2 \end{bmatrix},$  and  $\begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix}$  are linearly dependent, the one-dimensional subspaces spanned by these vectors are collinear points, as required by Pappus' Theorem.

5. The three incidence relations described in Fact 1 are usually taken as the defining relations for an axiomatic definition of projective plane, in which “point,” “line,” and “incidence” are taken as undefined notions. It is not the case that any projective plane defined axiomatically in this way is of the form  $\mathcal{P}(V)$  for some vector space  $V$  over a field  $F$ . As an example, if we interpret “point” to mean the set of all ordered pairs of real numbers and “line” to mean any horizontal Euclidean line, vertical Euclidean line, Euclidean line of negative slope, or broken Euclidean line of positive slope  $m$  above the  $x$ -axis and slope  $2m$  below the  $x$ -axis, we obtain a geometric system that satisfies the standard incidence relations for points and lines, and the Euclidean parallel postulate. We can convert this example into a projective plane by the addition of “ideal points”: To every line we add a new point, with the same point being added to two lines if and only if they are parallel. We also add a new line consisting of the ideal points, and no other points. The augmented geometric system satisfies the axioms of a projective plane, but neither Desargues’ Theorem nor Pappus’ Theorem holds in this plane. (This example is called the *Moulton Plane*.)
6. The addition of ideal points, as in the preceding example, can be carried out in any affine plane  $A^2(F)$ . An affine point  $\begin{bmatrix} a \\ b \end{bmatrix}$  can be identified with the projective point with homogenous coordinates  $[a:b:1]$  and the ideal points are those with homogenous coordinates with a zero in the third component.
7. In a projective  $n$ -space  $\mathcal{P}(V)$ , let  $H$  be a subspace of  $V$  of dimension  $n$ . Starting from an ordered basis for  $H$ , obtain an ordered basis for  $V$  by adding a single vector as the last element of the basis. Then, in homogenous coordinates, every point of  $\mathcal{P}(V)$  that is not in  $H$  has nonzero last component. By associating the point with homogenous coordinates  $[a_1 : \dots : a_{n+1}]$  with the  $n$ -tuple  $\begin{bmatrix} a_1 \\ a_{n+1} \\ \vdots \\ a_n \\ a_{n+1} \end{bmatrix}$  we can think of the set of points that are not in  $H$  as the affine  $n$ -space  $A^n(F)$ .
8. Let  $\mathcal{P}(V)$  be a projective plane, where  $V$  is a vector space over a field  $F$  that has a nonidentity automorphism  $f$ . The mapping  $[a : b : c] \mapsto [f(a) : f(b) : f(c)]$  is a collineation. Since this mapping fixes the points  $[0:0:1]$ ,  $[0:1:0]$ ,  $[1:0:0]$ , and  $[1:1:1]$  and is not the identity, it cannot, by Fact 7, be a projective transformation.
9. In the real projective plane, consider the six points  $A = [1:2:1]$ ,  $B = [2:0:1]$ ,  $C = [5:5:1]$ ,  $A' = [2:4:1]$ ,  $B' = [4:0:1]$ , and  $C' = [10:10:1]$ . Identifying the projective point with homogenous coordinates  $[a:b:1]$  with the ordinary Euclidean point  $\begin{bmatrix} a \\ b \end{bmatrix}$ , as in Example 6 above, it can be seen by a simple diagram that the triangles  $ABC$  and  $A'B'C'$  are perspective from the origin, since all lines  $AA'$ ,  $BB'$ , and  $CC'$  pass through this point. Thus, in the real projective plane these triangles are perspective from the point  $[0:0:1]$ . Desargues’ Theorem, therefore, asserts that the points of intersection of the lines  $AB$  and  $A'B'$ ,  $AC$  and  $A'C'$ ,  $BC$  and  $B'C'$  will lie on a line. A simple calculation shows that these three points, in homogenous coordinates, have third component zero, so these points are indeed collinear. This corresponds to the fact that as Euclidean lines there are no points of intersection — the corresponding sides of the triangles are parallel in pairs. The points with third component zero are the “ideal points” that have been added to Euclidean geometry to form the real projective plane.

This chapter presents some facts and examples illustrating the interplay between matrix theory, graph theory, and  $n$ -dimensional Euclidean geometry. The main objects of Euclidean geometry are, of course, the points. The simplest way of introducing them is to identify points with the endpoints of vectors; formally, one introduces an artificial point, the origin  $\mathbf{O}$ , and the points are sums of this origin with any vector. A more general treatment of Euclidean  $n$ -space can be found in Chapter 65.

### 66.1 Euclidean Point Space

---

#### Definitions:

An **arithmetic Euclidean vector space** is the real inner product space  $\mathbb{R}^n$  with the standard inner product  $\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{y}^T \mathbf{x}$ .

The **arithmetic point Euclidean  $n$ -space**  $E^n$  based on the vector space  $\mathbb{R}^n$  has as **points** the column  $n + 1$ -tuples with last coordinate 1, e.g.,  $\mathbf{C} = [c_1, c_2, \dots, c_n, 1]^T$ , and as **vectors** the column  $n + 1$ -tuples with last coordinate 0, e.g.,  $\mathbf{v} = [v_1, v_2, \dots, v_n, 0]^T$ .

The origin  $\mathbf{O}$  is the point  $[0, \dots, 0, 1]^T$ ; the numbers  $c_1, \dots, c_n$  are **coordinates** of the point  $\mathbf{C}$ .

Algebraic operations are defined with points: If  $\mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_m$  are points,  $a_1, a_2, \dots, a_m$  real numbers, then the symbol

$$a_1 \mathbf{A}_1 + a_2 \mathbf{A}_2 + \dots + a_m \mathbf{A}_m$$

means a **point** if and only if  $\sum a_k = 1$ , and a **vector** if and only if  $\sum a_k = 0$ . In no other case is this symbol defined.

The **Euclidean distance**, or **distance**, of two points  $\mathbf{A}$  and  $\mathbf{B}$  is the **length** of the vector  $\mathbf{A} - \mathbf{B}$ , i.e., for  $\mathbf{A} = [a_1, a_2, \dots, a_n, 1]^T$  and  $\mathbf{B} = [b_1, b_2, \dots, b_n, 1]^T$ ,

$$\|\mathbf{A} - \mathbf{B}\| = \sqrt{(a_1 - b_1)^2 + \dots + (a_n - b_n)^2}.$$

Let  $S = \{\mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_m\}$  be a set of points in  $E^n$ . The point

$$\mathbf{C} = a_1\mathbf{A}_1 + a_2\mathbf{A}_2 + \dots + a_m\mathbf{A}_m \quad \text{and} \quad \sum_{k=1}^m a_k = 1,$$

is a **linear combination** of  $S$ . The set of all linear combinations of  $S$  is the **linear hull** of  $S$ , denoted by  $\mathcal{L}(S)$ .

A point  $\mathbf{C}$  is **linearly dependent** on  $S$  if  $\mathbf{C} \in \mathcal{L}(S)$ . The set  $S$  is called **linearly dependent** if there is a point in  $S$  that is linearly dependent on the remaining points. Otherwise, the set  $S$  is called **linearly independent**.

Linear hulls of systems of points are called **linear subspaces** of  $E^n$ .

A linear subspace  $M$  has **dimension**  $k$  if the maximum number of linearly independent points in  $M$  is  $k + 1$ .

Linear subspaces of dimension 1 in  $E^n$  are called **lines**.

Linear subspaces of dimension  $n - 1$  in  $E^n$  (i.e., of **codimension** 1) are called **hyperplanes**.

If  $\hat{\alpha}$  is a hyperplane in  $E^n$  defined by the equation  $\alpha_1x_1 + \alpha_2x_2 + \dots + \alpha_nx_n + \alpha_0 = 0$  (cf. Fact 10), the vector  $\mathbf{u} = [\alpha_1, \dots, \alpha_n, 0]^T$  is a **normal vector** to  $\hat{\alpha}$ .

The **distance** of point  $\mathbf{C}$  to a hyperplane  $\hat{\alpha}$  is the minimum of all distances of the point  $\mathbf{C}$  from the points in the hyperplane  $\hat{\alpha}$ .

Two hyperplanes are called **parallel** if their normal vectors are proportional, i.e., one is a scalar multiple of the other. They are called **orthogonal** (or **perpendicular**) if their normal vectors are orthogonal.

Let  $S = \{\mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_m\}$  be a set of points in  $E^n$ . Then the set of all points of the form

$$a_1\mathbf{A}_1 + a_2\mathbf{A}_2 + \dots + a_m\mathbf{A}_m,$$

for which all the coefficients  $a_i$  are nonnegative and  $\sum a_k = 1$ , is called the **convex hull** of  $S$ ; we denote it by  $\mathcal{C}(S)$ .

The convex hull of two distinct points  $\mathbf{A}$ ,  $\mathbf{B}$  is called the **segment** and is denoted by  $\overline{\mathbf{AB}}$ .

The point  $\frac{1}{2}\mathbf{A} + \frac{1}{2}\mathbf{B}$  is the **midpoint** of the segment  $\overline{\mathbf{AB}}$ .

A set  $S \in E^n$  is **convex** if  $S$  has the property that with any two points  $\mathbf{A}$  and  $\mathbf{B}$  in  $S$ , all points of the segment  $\overline{\mathbf{AB}}$  are in  $S$ .

A hyperplane  $\hat{\alpha}$  with normal vector  $[\alpha_1, \alpha_2, \dots, \alpha_n]$  determines two **open halfspaces**; one is the set of all points  $\mathbf{X} = [x_1, x_2, \dots, x_n, 1]^T$  satisfying

$$\alpha_1x_1 + \alpha_2x_2 + \dots + \alpha_nx_n + \alpha_0 > 0,$$

while the other is the set of all points satisfying the reverse inequality.

In addition, one can speak about **closed halfspace** if in the inequality, equality is also admitted.

### Facts:

These facts follow from facts in Chapter 1 and Chapter 65.

1. Points and vectors in arithmetic Euclidean  $n$ -space satisfy the following:

(E1.) The sum of a point and a vector is a point.

(E2.) The difference of two points is a vector.

(E3.)  $(\mathbf{C} + \mathbf{v}) + \mathbf{w} = \mathbf{C} + (\mathbf{v} + \mathbf{w})$ , where  $\mathbf{C}$  is a point and  $\mathbf{v}$ ,  $\mathbf{w}$  are vectors.

2. Arithmetic Euclidean  $n$ -space, with vectors acting on points by addition, is a Euclidean  $n$ -space as defined in Chapter 65.
3. A linear hull is an affine subspace as defined in Chapter 65.
4. The set  $\mathcal{S} = \{\mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_m\}$  is linearly independent if and only if  $\lambda_1 = \lambda_2 = \dots = \lambda_m = 0$  are the only numbers  $\lambda_1, \dots, \lambda_m$  for which the zero vector  $\mathbf{0}$  satisfies  $\mathbf{0} = \lambda_1 \mathbf{A}_1 + \lambda_2 \mathbf{A}_2 + \dots + \lambda_m \mathbf{A}_m$  and  $\sum_{k=1}^m \lambda_k = 0$ .
5. The set  $\mathcal{S} = \{\mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_m\}$  is linearly independent if and only if every point  $\mathbf{P} \in \mathcal{L}(\mathcal{S})$  has a unique expression as

$$\mathbf{P} = \lambda_1 \mathbf{A}_1 + \lambda_2 \mathbf{A}_2 + \dots + \lambda_m \mathbf{A}_m \quad \text{and} \quad \sum_{k=1}^m \lambda_k = 1.$$

6. A linearly independent set in  $E^n$  contains at most  $n + 1$  points. A linearly independent set with  $n + 1$  linearly independent points in  $E^n$  exists.
7. Any linearly independent set has the property that each of its nonempty subsets is linearly independent as well.
8. Let the set  $\mathcal{S}$  consist of  $m$  points  $\mathbf{A}, \mathbf{B}, \dots, \mathbf{G}$  defined by

$$\mathbf{A} = [a_1, a_2, \dots, a_n, 1]^T, \mathbf{B} = [b_1, b_2, \dots, b_n, 1]^T, \dots, \mathbf{G} = [g_1, g_2, \dots, g_n, 1]^T.$$

Then  $\mathcal{S}$  is linearly independent if and only if the  $m \times (n + 1)$  matrix

$$\begin{bmatrix} a_1 & a_2 & \dots & a_n & 1 \\ b_1 & b_2 & \dots & b_n & 1 \\ \dots & \dots & \dots & \dots & \dots \\ g_1 & g_2 & \dots & g_n & 1 \end{bmatrix}$$

has rank  $m$ .

9. Let  $\mathbf{A} = [a_1, a_2, \dots, a_n, 1]^T$ ,  $\mathbf{B} = [b_1, b_2, \dots, b_n, 1]^T$ ,  $\dots$ ,  $\mathbf{F} = [f_1, f_2, \dots, f_n, 1]^T$  be  $n$  linearly independent points in  $E^n$ . Then the linear hull of these points consists of all points  $\mathbf{X} = [x_1, x_2, \dots, x_n, 1]^T$  in  $E^n$  which satisfy the equation

$$\det \begin{bmatrix} x_1 & x_2 & \dots & x_n & 1 \\ a_1 & a_2 & \dots & a_n & 1 \\ b_1 & b_2 & \dots & b_n & 1 \\ \dots & \dots & \dots & \dots & \dots \\ f_1 & f_2 & \dots & f_n & 1 \end{bmatrix} = 0.$$

10. A hyperplane can be characterized as the set of points  $\mathbf{X} = [x_1, x_2, \dots, x_n, 1]^T$  such that the coordinates satisfy one linear equation of the form

$$\alpha_1 x_1 + \alpha_2 x_2 + \dots + \alpha_n x_n + \alpha_0 = 0,$$

in which not all of the numbers  $\alpha_1, \alpha_2, \dots, \alpha_n$  are equal to zero.

11. We can generalize linear independence as well as the equation of the hyperplane in Fact 9 by including cases when some of the points (but not all of them) are replaced by vectors. We simply put into the corresponding row the  $(n + 1)$ -tuple  $a_1, a_2, \dots, a_n, 0$  instead that for the point.
12. Two parallel but distinct hyperplanes have no point in common. Conversely, if two hyperplanes in  $E^n$ ,  $n \geq 2$ , have no point in common, then they are parallel.
13. Hyperplanes are parallel if and only if they are parallel as affine subspaces as defined in Chapter 65.
14. The definitions of segment and midpoint are equivalent to the definitions of these terms in Chapter 65 for arithmetic Euclidean  $n$ -space.

15. The distance of a point  $\mathbf{C} = [c_1, c_2, \dots, c_n, 1]^T$  from a hyperplane  $\hat{\alpha}$  given by equation  $\alpha_1 x_1 + \alpha_2 x_2 + \dots + \alpha_n x_n + \alpha_0 = 0$  is

$$\frac{|\alpha_1 c_1 + \alpha_2 c_2 + \dots + \alpha_n c_n + \alpha_0|}{\sqrt{\alpha_1^2 + \alpha_2^2 + \dots + \alpha_n^2}}.$$

16. The distance of a point  $\mathbf{C} = [c_1, c_2, \dots, c_n, 1]^T$  from a hyperplane  $\hat{\alpha}$  given by equation  $\alpha_1 x_1 + \alpha_2 x_2 + \dots + \alpha_n x_n + \alpha_0 = 0$  is the distance of  $\mathbf{C}$  from the point  $\mathbf{F} = \mathbf{C} - \gamma \mathbf{u}$ , where  $\mathbf{u} = [\alpha_1, \alpha_2, \dots, \alpha_n, 0]^T$  is the normal vector to  $\hat{\alpha}$  and

$$\gamma = \frac{\alpha_1 c_1 + \alpha_2 c_2 + \dots + \alpha_n c_n + \alpha_0}{\alpha_1^2 + \alpha_2^2 + \dots + \alpha_n^2}.$$

### Examples:

1. In  $E^3$ , the points  $\mathbf{A}_1 = [2, -1, 2, 1]^T$ ,  $\mathbf{A}_2 = [1, 1, 3, 1]^T$ , and  $\mathbf{A}_3 = [0, 0, 1, 1]^T$  are linearly independent since the rank of the matrix

$$\begin{bmatrix} 2 & -1 & 2 & 1 \\ 1 & 1 & 3 & 1 \\ 0 & 0 & 1 & 1 \end{bmatrix}$$

is 3.

2. The point  $\mathbf{A}_4 = [2, 0, 3, 1]^T$  is linearly dependent on the points  $\mathbf{A}_1, \mathbf{A}_2$ , and  $\mathbf{A}_3$  from Example 1, since  $\mathbf{A}_4 = \frac{2}{3}\mathbf{A}_1 + \frac{2}{3}\mathbf{A}_2 - \frac{1}{3}\mathbf{A}_3$ .
3. The equation of the hyperplane (which is a plane) determined by the points in Example 1 is

$$0 = \det \begin{bmatrix} x_1 & x_2 & x_3 & 1 \\ 2 & -1 & 2 & 1 \\ 1 & 1 & 3 & 1 \\ 0 & 0 & 1 & 1 \end{bmatrix} = -3x_1 - 3x_2 + 3x_3 - 3.$$

4. The triangle with vertices  $\mathbf{A}_1, \mathbf{A}_2, \mathbf{A}_3$  from Example 1 is the convex hull of the three points  $\mathbf{A}_1, \mathbf{A}_2$ , and  $\mathbf{A}_3$ .
5. Let  $n \geq 3$  be an integer. In the Euclidean  $n$ -space  $E^n$ , define points

$$\mathbf{F}_k = [\underbrace{n-k, n-k, \dots, n-k}_{k\text{-times}}, \underbrace{-k, -k, \dots, -k}_{(n-k)\text{-times}}, 1], \quad k = 1, \dots, n;$$

$$\mathbf{F}_0 = [n-1, n-2, \dots, 0, 1]^T, \text{ and}$$

$$\mathbf{C} = \left[ \frac{1}{2}(n-1), \frac{1}{2}(n-3), \frac{1}{2}(n-5), \dots, -\frac{1}{2}(n-3), -\frac{1}{2}(n-1), 1 \right]^T.$$

Observe first that the points  $\mathbf{C}, \mathbf{F}_1, \mathbf{F}_2, \dots, \mathbf{F}_n$  are linearly dependent since  $\mathbf{C} = \frac{1}{n}\mathbf{F}_1 + \frac{1}{n}\mathbf{F}_2 + \dots + \frac{1}{n}\mathbf{F}_n$ . On the other hand, the points  $\mathbf{F}_0, \mathbf{F}_1, \dots, \mathbf{F}_n$  form a linearly independent set by Fact 8 since the determinant (of an  $(n+1) \times (n+1)$  matrix)

$$\det \begin{bmatrix} n-1 & n-2 & n-3 & n-4 & \dots & 0 & 1 \\ n-1 & -1 & -1 & -1 & \dots & -1 & 1 \\ n-2 & n-2 & -2 & -2 & \dots & -2 & 1 \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 2 & 2 & 2 & 2 & \dots & -(n-2) & 1 \\ 1 & 1 & 1 & 1 & \dots & -(n-1) & 1 \\ 0 & 0 & 0 & 0 & \dots & 0 & 1 \end{bmatrix}$$

is different from zero: Subtracting the  $\frac{1}{n}$ -multiple of the sum of the second till last row, from the first row, the first row is a  $\frac{1}{2}(n-1)$ -multiple of the row of all ones. Factoring out this number  $\frac{1}{2}(n-1)$  from the determinant, subtracting the resulting first row from the  $n$ th row, the 2-multiple of the first row from the  $(n-1)$ st row, etc., till the  $(n-1)$ -multiple of the first row from the second row, we obtain the determinant of an upper triangular matrix with all diagonal entries different from zero. The value of the determinant is then also easily determined.

The Euclidean distances between the points  $\mathbf{F}_i$  and  $\mathbf{F}_{i+1}$ ,  $i = 1, \dots, n-1$ , as well as between  $\mathbf{F}_n$  and  $\mathbf{F}_1$ , are all equal, equal to  $\sqrt{n(n-1)}$ . The point  $\mathbf{C}$  has same distances from all points  $\mathbf{F}_i$ ,  $i = 1, 2, \dots, n$ , equal to  $\sqrt{\frac{1}{12}(n-1)n(n+1)}$ .

All the points  $\mathbf{F}_i$ ,  $i = 1, 2, \dots, n$ , as well as the point  $\mathbf{C}$ , are points of the hyperplane  $H$  with equation  $\sum_{i=1}^n x_i = 0$ .

The vector  $\mathbf{F}_0 - \mathbf{C}$  is the  $\frac{1}{2}(n-1)$ -multiple of the vector  $\mathbf{u} = [1, 1, \dots, 1]^T$  (which is throughout denoted as  $\mathbf{1}$ ). This vector is at the same time the normal vector to the hyperplane  $H$ . It follows that the distance of the point  $\mathbf{F}_0$  from  $H$  is equal to the length of the vector  $\mathbf{F}_0 - \mathbf{C}$ , which is  $\frac{1}{2}(n-1)\sqrt{n}$ . The same result can be obtained using Fact 15.

The hyperplane with equation

$$x_1 + x_2 + \dots + x_n - 1 = 0$$

is parallel to  $H$ ; the hyperplane

$$x_1 - x_2 = 0$$

is orthogonal to  $H$  since the vector  $[1, -1, 0, \dots, 0, 0]^T$  is orthogonal to the vector  $\mathbf{u}$ .

## 66.2 Gram Matrices

### Definitions:

The **Gram matrix**  $G(S)$  of an ordered system  $S = (\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_m)$  of vectors in the Euclidean vector  $n$ -space  $\mathbb{R}^n$  is the  $m \times m$  matrix  $G(S) = G(\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_m) = [(\mathbf{a}_i, \mathbf{a}_j)]$ . (See also Section 8.1.)

Let  $\mathbf{O}, \mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_k$ ,  $k \geq 2$ , be linearly independent points in  $E^n$ , and let  $\mathbf{u}_1 = \mathbf{A}_1 - \mathbf{O}$ ,  $\mathbf{u}_2 = \mathbf{A}_2 - \mathbf{O}$ ,  $\dots$ ,  $\mathbf{u}_k = \mathbf{A}_k - \mathbf{O}$ , be the corresponding vectors. We call the set of all points of the form  $\mathbf{O} + \sum_{i=1}^k a_i \mathbf{u}_i$ , where the numbers  $a_i$  satisfy  $0 \leq a_i \leq 1$ ,  $i = 1, \dots, k$ , the **parallelepiped** spanned by the vectors  $\mathbf{u}_i$ . For  $k = 2$ , we speak about the **parallelogram** spanned by  $\mathbf{u}_1$  and  $\mathbf{u}_2$ .

If  $\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_n$  is a basis of an  $n$ -dimensional arithmetic Euclidean vector space and  $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n$  is a set of vectors such that the inner product of  $\mathbf{u}_i$  and  $\mathbf{v}_j$  is the Kronecker delta  $\delta_{ij}$ , then this pair of ordered sets is a **biorthogonal pair of bases**.

### Facts:

Facts for which no specific reference is given follow from facts in Chapter 1.

1. The Gram matrix is always a positive semidefinite matrix. Its rank is equal to the dimension of the Euclidean space of smallest dimension which contains all the vectors of the system.
2. Every positive semidefinite matrix is a Gram matrix of some system of vectors  $S$  in some Euclidean space.
3. Every linear relationship among the vectors in  $S$  is reflected in the same linear relationship among the rows of  $G(S)$ , and conversely.
4. The  $k$ -dimensional volume of the parallelepiped spanned by the vectors

$\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_k$  is

$$\sqrt{\det G(\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_k)}.$$

5. To every basis  $\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_n$  of an  $n$ -dimensional Euclidean vector space there exists a set of vectors  $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n$  such that this pair is a biorthogonal pair of bases. The set of the  $\mathbf{v}_i$ s is also a basis and is uniquely determined.
6. If both bases in the biorthogonal pair coincide, the common basis is orthonormal, and an orthonormal basis forms a biorthogonal pair with itself.
7. The Gram matrices  $G(\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_n)$  and  $G(\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n)$  of a pair of biorthogonal bases are inverse to each other:

$$G(\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_n)G(\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n) = I.$$

8. [Fie64] Let  $A = [a_{ij}]$  be a positive semidefinite matrix with row sums zero. Then

$$2 \max_i \sqrt{a_{ii}} \leq \sum_i \sqrt{a_{ii}}.$$

9. [Fie61b] If  $A$  is positive definite, then the matrix  $A \circ A^{-1} - I$  is positive semidefinite and its row sums are equal to zero.
10. If  $A = [a_{ij}]$  is positive definite and  $A^{-1} = [\alpha_{ij}]$ , then

$$a_{ii}\alpha_{ii} \geq 1 \quad \text{for all } i$$

and

$$2 \max_i \sqrt{a_{ii}\alpha_{ii} - 1} \leq \sum_i \sqrt{a_{ii}\alpha_{ii} - 1}.$$

11. [Fie64] Let  $A = [a_{ik}]$  be a positive definite matrix, and let  $A^{-1} = [\alpha_{ik}]$ . Then the diagonal entries of  $A$  and  $A^{-1}$  satisfy the first condition in Fact 10 and

$$2 \max_i (\sqrt{a_{ii}\alpha_{ii}} - 1) \leq \sum_i (\sqrt{a_{ii}\alpha_{ii}} - 1).$$

Conversely, if some  $n$ -tuples of positive numbers  $a_{ii}$  and  $\alpha_{ii}$  satisfy these conditions, then there exists a positive definite  $n \times n$  matrix  $A$  with diagonal entries  $a_{ii}$  such that the diagonal entries of  $A^{-1}$  are  $\alpha_{ii}$ .

12. [Fie64] Let the vectors  $\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_n, \mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n$  form a pair of biorthogonal bases in a Euclidean  $n$ -space  $E$ . Then

$$\|\mathbf{u}_i\| \|\mathbf{v}_i\| \geq 1, \quad i = 1, \dots, n,$$

$$2 \max_i (\|\mathbf{u}_i\| \|\mathbf{v}_i\| - 1) \leq \sum_i (\|\mathbf{u}_i\| \|\mathbf{v}_i\| - 1).$$

Conversely, if nonnegative numbers  $\alpha_1, \alpha_2, \dots, \alpha_n, \beta_1, \beta_2, \dots, \beta_n$  satisfy

$$\alpha_i \beta_i \geq 1, \quad i = 1, \dots, n,$$

$$2 \max_i (\alpha_i \beta_i - 1) \leq \sum_i (\alpha_i \beta_i - 1),$$

then there exists in  $E^n$  a pair of biorthogonal bases  $\mathbf{u}_i, \mathbf{v}_j$ , such that

$$\|\mathbf{u}_i\| = \alpha_i, \|\mathbf{v}_i\| = \beta_i, \quad i = 1, \dots, n.$$

13. [Fie64] Let  $A = [a_{ij}]$  be an  $n \times n$  positive definite matrix,  $n \geq 2$ , and let  $A^{-1} = [\alpha_{ij}]$ . Then the following are equivalent:

- (a)  $\sqrt{a_{nn}\alpha_{nn}} - 1 = \sum_{i=1}^{n-1} (\sqrt{a_{ii}\alpha_{ii}} - 1)$ .
- (b)  $\frac{a_{ij}}{\sqrt{a_{ii}}\sqrt{a_{jj}}} = \frac{\alpha_{ij}}{\sqrt{\alpha_{ii}}\sqrt{\alpha_{jj}}}$ ,  $i, j = 1, \dots, n - 1$ , and  
 $\frac{a_{in}}{\sqrt{a_{ii}}\sqrt{a_{nn}}} = -\frac{\alpha_{in}}{\sqrt{\alpha_{ii}}\sqrt{\alpha_{nn}}}$ ,  $i = 1, \dots, n - 1$ .
- (c)  $A$  is diagonally similar to

$$C = \begin{bmatrix} I_1 + \omega \mathbf{c}\mathbf{c}^T & \mathbf{c} \\ \mathbf{c}^T & 1 + \omega \mathbf{c}^T \mathbf{c} \end{bmatrix},$$

where  $\mathbf{c}$  is a real vector with  $n - 1$  coordinates and

$$\omega = \frac{\sqrt{1 + \mathbf{c}^T \mathbf{c}} - 1}{\mathbf{c}^T \mathbf{c}}$$

if  $\mathbf{c} \neq \mathbf{0}$ ; if  $\mathbf{c} = \mathbf{0}$ ,  $\omega = 0$ .

- 14. To realize a positive definite  $n \times n$  matrix  $C$  as a Gram matrix of some  $n$  vectors, say  $\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_n$ , it suffices to find a nonsingular matrix  $A$  such that  $C = AA^T$  and to use the entries in the  $k$ th row of  $A$  as coordinates of the vector  $\mathbf{a}_k$ . Such matrix  $A$  can be found, e.g., by the Gram-Schmidt process (cf. Section 5.5).

**Examples:**

- 1. The vectors  $\mathbf{u}_1 = [1, 3]^T$ ,  $\mathbf{u}_2 = [2, -1]^T$  in  $\mathbb{R}^2$  are linearly independent and form a basis in  $\mathbb{R}^2$ .  
 The Gram matrix  $G(\mathbf{u}_1, \mathbf{u}_2) = \begin{bmatrix} 10 & -1 \\ -1 & 5 \end{bmatrix}$  is nonsingular.
- 2. To find the pair of vectors  $\mathbf{v}_1, \mathbf{v}_2$  that form a biorthogonal pair with the vectors  $\mathbf{u}_1, \mathbf{u}_2$  in Example 1, observe that  $\mathbf{v}_1$  should satisfy  $\langle \mathbf{u}_1, \mathbf{v}_1 \rangle = 1$  and  $\langle \mathbf{u}_2, \mathbf{v}_1 \rangle = 0$ . Set  $\mathbf{v}_1 = [x_1, x_2]^T$ ; thus  $x_1 + 3x_2 = 1$ ,  $2x_1 - x_2 = 0$ , i.e.,  $\mathbf{v}_1 = [\frac{1}{7}, \frac{2}{7}]^T$ . Analogously,  $\mathbf{v}_2 = [\frac{3}{7}, -\frac{1}{7}]^T$ . The Gram matrix is  $G(\mathbf{v}_1, \mathbf{v}_2) = \begin{bmatrix} \frac{5}{49} & \frac{1}{49} \\ \frac{1}{49} & \frac{10}{49} \end{bmatrix}$ . It is easily verified that  $G(\mathbf{v}_1, \mathbf{v}_2)$  is the inverse of  $G(\mathbf{u}_1, \mathbf{u}_2)$ , as stated in Fact 7.
- 3. The pairs of vectors  $(\mathbf{e}_1 = [1, 0]^T, \mathbf{e}_2 = [0, 1]^T)$  and  $(\mathbf{u}_1 = [\frac{3}{5}, \frac{4}{5}]^T, \mathbf{u}_2 = [-\frac{4}{5}, \frac{3}{5}]^T)$  are orthonormal bases for  $\mathbb{R}^2$ , so  $G(\mathbf{e}_1, \mathbf{e}_2) = I$  and  $G(\mathbf{u}_1, \mathbf{u}_2) = I$  are inverses, but  $(\mathbf{e}_1, \mathbf{e}_2)$  and  $(\mathbf{u}_1, \mathbf{u}_2)$  are not a biorthogonal pair of bases.

### 66.3 General Theory of Euclidean Simplexes

An  $n$ -simplex in  $E^n$  is a generalization of the triangle in the plane and the tetrahedron in the three-dimensional space. Just as not every triplet of positive numbers can serve as lengths of three sides of a triangle (they have to satisfy the strict triangle inequality), we can ask about analogous conditions for the simplex.

**Definitions:**

An  $n$ -**simplex** is the convex hull of  $n + 1$  linearly independent points in  $E^n$ .

The points are called **vertices** of the simplex. The convex hull of a subset of the set of vertices is called a **face** of the simplex.

If the subset of vertices has  $k + 1$  elements, the face has **dimension**  $k$ . One-dimensional faces are called **edges**.

If  $\mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_{n+1}$  are the vertices of an  $n$ -simplex  $\Sigma$ , we write  $\Sigma = \{\mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_{n+1}\}$ . The  $(n - 1)$ -dimensional face opposite  $\mathbf{A}_i$  is denoted by  $\omega_i$ . A vector  $\mathbf{n}$  is an **outer normal** to  $\omega_i$  if  $\mathbf{n}$  is a normal to  $\omega_i$  and for  $\mathbf{C} \in \omega_i$ ,  $\mathbf{C} + \mathbf{n}$  is not in the same halfspace as  $\mathbf{A}_i$ .

The **dihedral interior angle** between  $\omega_i$  and  $\omega_j$ ,  $i \neq j$  (opposite the edge  $\mathbf{A}_i \mathbf{A}_j$ ) is  $\pi -$ (the angle between an outer normal to  $\omega_i$  and an outer normal to  $\omega_j$ ), and is denoted by  $\phi_{ij}$ .

The **barycentric coordinates** with respect to the simplex  $\Sigma = \{\mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_{n+1}\}$  of a point  $\mathbf{P}$  in  $\mathcal{L}(\mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_{n+1})$  are the unique numbers  $\lambda_i$  such that  $\mathbf{P} = \lambda_1 \mathbf{A}_1 + \lambda_2 \mathbf{A}_2 + \dots + \lambda_{n+1} \mathbf{A}_{n+1}$  and  $\sum_{k=1}^{n+1} \lambda_k = 1$  (cf. Fact 5 of section 66.1). Strictly speaking, these numbers are the **inhomogeneous barycentric coordinates**.

The **homogeneous barycentric coordinates** of  $\lambda_1 \mathbf{A}_1 + \lambda_2 \mathbf{A}_2 + \dots + \lambda_{n+1} \mathbf{A}_{n+1}$  are the numbers  $\lambda_i$  (not all 0). The expression  $\lambda_1 \mathbf{A}_1 + \lambda_2 \mathbf{A}_2 + \dots + \lambda_{n+1} \mathbf{A}_{n+1}$  means a **proper point** if  $\sum_{k=1}^{n+1} \lambda_k \neq 0$  (namely the point with inhomogeneous barycentric coordinates  $\rho \lambda_1, \dots, \rho \lambda_{n+1}$  with  $\rho = (\sum_{k=1}^{n+1} \lambda_k)^{-1}$ ), or an **improper point** (determined by the (nonzero) vector  $\lambda_1 \mathbf{A}_1 + \lambda_2 \mathbf{A}_2 + \dots + \lambda_{n+1} \mathbf{A}_{n+1}$ ) if  $\sum_{k=1}^{n+1} \lambda_k = 0$ . These coordinates can be viewed as in projective  $n$ -dimensional geometry (see Chapter 65). The set of improper points is, thus, characterized by the equation  $\sum_{k=1}^{n+1} \lambda_k = 0$  in homogeneous barycentric coordinates, and is called the **improper hyperplane**.

The **circumcenter** of a simplex is the point that is equidistant from the all vertices of the simplex. The set of all points at that common distance from the circumcenter is the **circumscribed hypersphere**.

The  $(n + 1) \times (n + 1)$  matrix  $M = [m_{ij}]$  with  $m_{ij}$  equal to the square of the distance between the  $i$ th and  $j$ th vertex of an  $n$ -simplex  $\Sigma$  is called the **Menger matrix** of  $\Sigma$ .

The **Gramian** of an  $n$ -simplex  $\Sigma = \{\mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_{n+1}\}$  is defined as the Gram matrix  $Q$  of  $n + 1$  vectors  $\mathbf{n}_1, \mathbf{n}_2, \dots, \mathbf{n}_{n+1}$  determined as follows: The first  $n$  of them form the biorthogonal pair with the  $n$  vectors  $\mathbf{u}_1 = \mathbf{A}_1 - \mathbf{A}_{n+1}, \mathbf{u}_2 = \mathbf{A}_2 - \mathbf{A}_{n+1}, \dots, \mathbf{u}_n = \mathbf{A}_n - \mathbf{A}_{n+1}$ , the remaining  $\mathbf{n}_{n+1}$  is defined by  $\mathbf{n}_{n+1} = -\sum_{i=1}^n \mathbf{n}_i$ .

**Facts:**

1. There are  $\binom{n+1}{2}$  edges  $\{\mathbf{A}_i, \mathbf{A}_j\}, i \neq j$ , in an  $n$ -simplex.
2. A 2-simplex is a segment and its circumcenter is its midpoint. The circumcenter of an  $n$ -simplex is the intersection of the lines  $\ell_i$ , where  $\ell_i$  is the line normal to face  $\omega_i$  and through the circumcenter of  $\omega_i$ .
3. [Blu53] (Menger, Schoenberg, etc.) The numbers  $m_{ij}, i, j = 1, \dots, n + 1$ , can serve as squares of the lengths of edges (i.e., of distances between vertices) of an  $n$ -simplex if and only if  $m_{ii} = 0$  for all  $i$ , and

$$\sum_{i,j} m_{ij} x_i x_j < 0, \quad \text{whenever} \quad \sum_i x_i = 0.$$

4. (Consequence of Fact 3) The matrix

$$M_0 = \begin{bmatrix} 0 & \mathbf{1}^T \\ \mathbf{1} & M \end{bmatrix},$$

where  $\mathbf{1}$  is the column vector of all ones and  $M = [m_{ij}]$  is a Menger matrix, is elliptic, i.e., has one eigenvalue positive and the remaining negative.

5. The Menger matrix is the matrix of the quadratic form  $\sum_{i,j} m_{ij} x_i x_j$ . If  $x_1, \dots, x_{n+1}$  are considered as homogeneous barycentric coordinates of the point  $\mathbf{X} = [x_1, \dots, x_{n+1}]$ , then the equation

$$\sum_{i,j} m_{ij} x_i x_j = 0$$

is the equation of the circumscribed hypersphere of the  $n$ -simplex  $\Sigma$ . (Thus, the condition in Fact 3 can be interpreted that for all improper points, the value of the quadratic form  $\sum_{i,j} m_{ij} x_i x_j$  is strictly negative.)

6. The  $n$ -dimensional volume  $V$  of an  $n$ -simplex  $\Sigma$  satisfies

$$V^2 = \frac{(-1)^{n-1}}{2^n (n!)^2} \det M_0,$$

where  $M_0$  is the matrix in Fact 4 using the Menger matrix  $M$  of  $\Sigma$ .

7. The volume  $V_s$  of the  $n$ -simplex with vertices in  $\mathbf{O}, \mathbf{A}_1, \dots, \mathbf{A}_n$  is equal to  $V_s = \frac{1}{n!} V_p$ , where  $V_p$  is the volume of the parallelepiped defined in Fact 4 of section 66.2 by  $n$  vectors  $\mathbf{A}_i - \mathbf{O}$ . Thus,  $V_s = \frac{1}{n!} \sqrt{\det G(\mathbf{u}_1, \dots, \mathbf{u}_n)}$ , where  $G(\dots)$  means the Gram matrix and  $\mathbf{u}_k = \mathbf{A}_k - \mathbf{O}$ .
8. Let  $Q_0 = \begin{bmatrix} q_{00} & \mathbf{q}_0^T \\ \mathbf{q}_0 & Q \end{bmatrix}$ , where the matrix  $Q$  is the Gramian of the  $n$ -simplex  $\Sigma$ , the numbers in the column vector  $\mathbf{q}_0$  are  $(-2)$ -multiples of the inhomogeneous barycentric coordinates of the circumcenter of  $\Sigma$ , and  $\frac{1}{2} \sqrt{q_{00}}$  is the radius of the circumsphere of  $\Sigma$ . Then  $M_0 Q_0 = -2I$ .
9. The vectors  $\mathbf{n}_1, \mathbf{n}_2, \dots, \mathbf{n}_{n+1}$  from the definition of the Gramian are the vectors of outer normals of the simplex, in some sense normalized.
10. The Gramian of every  $n$ -simplex is an  $(n + 1) \times (n + 1)$  positive semidefinite matrix of rank  $n$  with row sums equal to zero. Conversely, every such matrix determines uniquely (apart from the position in the space) an  $n$ -simplex in  $E^n$  whose Gramian this matrix is.
11. Let  $\Sigma_S$  be a face of an  $n$ -simplex  $\Sigma$  determined by the vertices with index set  $S \subset \{1, \dots, n + 1\}$ . Let  $Q$  be the Gramian of  $\Sigma$ . Then the Gramian of  $\Sigma_S$  is the Schur complement  $Q/Q(S)$ , where  $Q(S)$  denotes the principal submatrix of  $Q$  corresponding to indices in the complement of  $S$ .

**Examples:**

1. Let us find the Menger matrix and the Gramian in the case of the segment  $\{\mathbf{A}_1, \mathbf{A}_2\}$  of length  $d$  (i.e., a 1-simplex). The Menger matrix is  $\begin{bmatrix} 0 & d^2 \\ d^2 & 0 \end{bmatrix}$ . If  $\mathbf{u}_1 = \mathbf{A}_1 - \mathbf{A}_2$ , then  $\mathbf{n}_1 = \frac{1}{d^2} \mathbf{u}_1$  since

$\langle \mathbf{u}_1, \mathbf{n}_1 \rangle$  has to be 1. Thus, the Gramian is the Gram matrix  $G(\mathbf{n}_1, -\mathbf{n}_1)$ , i.e.,  $\begin{bmatrix} \frac{1}{d^2} & -\frac{1}{d^2} \\ -\frac{1}{d^2} & \frac{1}{d^2} \end{bmatrix}$ . Indeed,

$$\begin{bmatrix} 0 & 1 & 1 \\ 1 & 0 & d^2 \\ 1 & d^2 & 0 \end{bmatrix} \begin{bmatrix} d^2 & -1 & -1 \\ -1 & \frac{1}{d^2} & -\frac{1}{d^2} \\ -1 & -\frac{1}{d^2} & \frac{1}{d^2} \end{bmatrix} = -2I_3, \text{ as asserted in Fact 8.}$$

2. Consider the simplex  $\Sigma = \{\mathbf{A}_1 = [0, 0, 1]^T, \mathbf{A}_2 = [1, 0, 1]^T, \mathbf{A}_3 = [1, 2, 1]^T\}$  in  $E^2$ . We show how Fact 6 and Fact 7 can be used to find the volume  $V$  of this simplex.

To use Fact 6, compute the squares of the distances between the vertices to obtain the Menger

matrix:  $M = \begin{bmatrix} 0 & 1 & 5 \\ 1 & 0 & 4 \\ 5 & 4 & 0 \end{bmatrix}$ , so  $M_0 = \begin{bmatrix} 0 & 1 & 1 & 1 \\ 1 & 0 & 1 & 5 \\ 1 & 1 & 0 & 4 \\ 1 & 5 & 4 & 0 \end{bmatrix}$ . Since  $\det M_0 = -16$ ,  $V = 1$  by Fact 6.

To use Fact 7, compute the vectors  $\mathbf{u}_1 = [1, 0, 0]^T$  and  $\mathbf{u}_2 = [1, 2, 0]^T$ , so  $G(\mathbf{u}_1, \mathbf{u}_2) = \begin{bmatrix} 1 & 1 \\ 1 & 5 \end{bmatrix}$ . By

Fact 7,  $V = \frac{1}{2!} \sqrt{\det G(\mathbf{u}_1, \mathbf{u}_2)} = \frac{1}{2} \sqrt{4} = 1$ .

In this example, the volume can be found directly by finding the area of the triangle.

3. Consider the simplex in Example 2. Let us compute the Gramian to illustrate Fact 8 for this simplex. Since  $\mathbf{u}_1 = \mathbf{A}_1 - \mathbf{A}_3 = [-1, -2, 0]^T$ ,  $\mathbf{u}_2 = \mathbf{A}_2 - \mathbf{A}_3 = [0, -2, 0]^T$ , the vectors  $\mathbf{n}_1, \mathbf{n}_2$  forming a biorthogonal pair with  $\mathbf{u}_1, \mathbf{u}_2$  are (as in Example 2 of Section 66.2)  $\mathbf{n}_1 = [-1, 0, 0]^T$ ,  $\mathbf{n}_2 =$

$$[1, -\frac{1}{2}, 0]^T. \text{ Thus, } \mathbf{n}_3 = [0, \frac{1}{2}, 0]^T \text{ and } G(\mathbf{n}_1, \mathbf{n}_2, \mathbf{n}_3) = \begin{bmatrix} 1 & -1 & 0 \\ -1 & \frac{5}{4} & -\frac{1}{4} \\ 0 & -\frac{1}{4} & \frac{1}{4} \end{bmatrix}.$$

The line  $\ell_1$  is the set of points of the form  $[x, 1, 1]^T$ , and line  $\ell_3$  is the set of points of the form  $[\frac{1}{2}, y, 1]^T$ , so the circumcenter of the simplex is  $\mathbf{c} = [\frac{1}{2}, 1, 1]^T$ . The (inhomogeneous) barycentric coordinates  $b_1, b_2, b_3$  of  $\mathbf{c}$  can be found by solving  $b_1 \mathbf{A}_1 + b_2 \mathbf{A}_2 + b_3 \mathbf{A}_3 = \mathbf{c}$ ,  $b_1 + b_2 + b_3 = 1$

to obtain  $b_1 = \frac{1}{2}, b_2 = 0, b_3 = \frac{1}{2}$ . The radius of the circumsphere is  $\frac{\sqrt{5}}{2}$ , so  $q_{00} = 5$ . Thus,

$$Q_0 = \begin{bmatrix} 5 & -1 & 0 & -1 \\ -1 & 1 & -1 & 0 \\ 0 & -1 & \frac{5}{4} & -\frac{1}{4} \\ -1 & 0 & -\frac{1}{4} & \frac{1}{4} \end{bmatrix}, \text{ which is indeed equal to the matrix } -2M_0^{-1}.$$

4. We can use either Example 1 or Fact 11 and Example 3 to find the Gramian of  $\Sigma_S$  for  $\{2, 3\}$  (again with  $\Sigma$  defined in Example 2). By Example 1, the Gramian is  $\begin{bmatrix} \frac{1}{d^2} & -\frac{1}{d^2} \\ -\frac{1}{d^2} & \frac{1}{d^2} \end{bmatrix} = \begin{bmatrix} \frac{1}{4} & -\frac{1}{4} \\ -\frac{1}{4} & \frac{1}{4} \end{bmatrix}$ .

## 66.4 Special Simplexes

### Definitions:

Let us color an edge  $\{A_i, A_j\}$  of an  $n$ -simplex with vertices  $A_1, \dots, A_{n+1}$ ,  $n \geq 2$ , in: **red**, if the opposite interior angle  $\phi_{ij}$  is acute; **blue**, if the opposite interior angle  $\phi_{ij}$  is obtuse; it will stay **uncolored**, if the opposite interior angle  $\phi_{ij}$  is right.

The edge  $\{A_i, A_k\}$  is called **colored** if it is colored red or blue. The assignment of red and blue colors is a **coloring** of the simplex.

The **graph** of the  $n$ -simplex is the graph with vertices  $1, 2, \dots, n+1$  and edges  $\{i, k\}$ ,  $i \neq k$ , for which  $\{A_i, A_k\}$  is colored. The **colored graph** of the simplex is the graph of the simplex colored in red and blue in the same way as the corresponding edges of the simplex.

An  $n$ -simplex is called **hypercute** if each of its dihedral interior angles  $\phi_{ij}$  is either acute or right.

A hyperacute  $n$ -simplex is called **totally hyperacute** if its circumcenter is either an interior point of the simplex, or an interior point of one of its faces.

Let  $C$  denote the circumcenter of the  $n$ -simplex with vertices  $A_1, \dots, A_{n+1}$ . We extend the coloring of the simplex as follows: We assign the segment  $\overline{CA_k}$  the **red** color if the point  $C$  is in the same open halfspace determined by the face  $\omega_k$  as the vertex  $A_k$ , and the **blue** color, if  $C$  is in the opposite open halfspace. We do not assign to  $\overline{CA_k}$  any color if  $C$  belongs to  $\omega_k$ . This is the **extended coloring** of the simplex.

In the same way, we speak about the **extended graph** and **extended colored graph** of the simplex, adding to  $n+1$  vertices another vertex  $n+2$  which corresponds to the circumcenter.

A **right simplex** (cf. [Fie57]) is an  $n$ -simplex which has exactly  $n$  acute interior angles and all the remaining  $\binom{n}{2}$  interior angles right.

In a right simplex, the edges opposite the acute angles are called **legs**. The subgraph of legs and their endpoints is called **tree of legs** (see Fact 5).

A right simplex whose tree of legs is a path is called a **Schlaefli simplex**.

The face of a right simplex spanned by all pendent vertices (i.e., vertices of degree one) of the tree of legs is called the **hypotenuse** of the simplex.

A **net** on a simplex is a subset of the set of edges (not necessarily connected) such that every vertex of the simplex belongs to some edge in the net. A net is **metric** if for each edge in the net its length is given.

A **box** in a Euclidean  $n$ -space is a parallelepiped all of whose edges at some vertex (and then at all vertices) are mutually perpendicular.

**Facts** (cf. [Fie57]):

1. A simplex is hyperacute if and only if it has no blue edge in its coloring.
2. The set of red edges connects all the vertices of the simplex.
3. If we color the edges of an  $n$ -simplex by the two colors red and blue in such a way that the red edges connect all vertices, then there exists such deformation of the simplex that opposite red edges there are acute, opposite blue edges obtuse, and opposite uncolored edges right interior angles.

4. Every  $n$ -simplex has at least  $n$  acute interior angles.
5. There exist right  $n$ -simplexes. The red edges span a tree containing all the vertices of the simplex.
6. The legs of a right simplex are mutually perpendicular.
7. The tree of legs of a right  $n$ -simplex can be completed to a ( $n$ -dimensional) box; its center of symmetry is thus the circumcenter of the simplex. Conversely, every right  $n$ -simplex can be obtained by choosing among the edges of some box a subset of  $n$  edges with the property that any two are perpendicular and together form a connected set. These are then the legs of the simplex.
8. Let  $G_T = (N, E, W)$  be a tree with the numbered vertex set  $N = \{1, 2, \dots, n + 1\}$  and edge set  $E$ ; let every edge  $\{i, j\} \in E$  be assigned a positive number  $w_{ij}$ . Construct the matrices  $Q_0 = [q_{rs}]$ ,  $r, s = 0, 1, \dots, n + 1$ , and  $M = [m_{ij}]$ ,  $i, j = 1, \dots, n + 1$ , as follows:

$$q_{00} = \sum_{i,j \in E} \frac{1}{w_{ij}}, \quad q_{0i} = q_{i0} = d_i - 2, \quad i \in N,$$

where  $d_i$  is the degree of the vertex  $i$  in  $G_T$ ,

$$q_{ij} = -w_{ij} \text{ if } \{i, j\} \in E, \quad q_{ii} = \sum_{j, \{i,j\} \in E} w_{ij}, \quad q_{ij} = 0 \text{ otherwise;}$$

$$m_{ii} = 0, \quad i \in N, \quad m_{ij} = w_{ik_1}^{-1} + w_{k_1k_2}^{-1} + \dots + w_{k_rj}^{-1},$$

where  $i, j \in N$ ,  $i \neq j$ , and  $i, k_1, k_2, \dots, k_r, j$  is the (unique) path in  $G_T$  from  $i$  to  $j$ .

Then the matrices  $Q_0$  and  $M_0 = \begin{bmatrix} 0 & \mathbf{1}^T \\ \mathbf{1} & M \end{bmatrix}$  satisfy

$$M_0 Q_0 = -2I_{n+2}$$

and they are matrices corresponding to a right  $n$ -simplex whose tree of legs is  $G_T$ .

9. The inhomogeneous barycentric coordinates of the circumcenter of a right  $n$ -simplex are  $q_{0i} = 1 - \frac{1}{2}d_i$ , where  $d_i$  is the degree of the vertex  $i$  in the tree of legs.
10. The hypotenuse of a Schlaefli simplex is the longest edge; the midpoint of the hypotenuse is the circumcenter of the simplex.
11. Every face of a Schlaefli simplex is also a Schlaefli simplex.
12. The Schlaefli simplex is the only simplex all 2-dimensional faces of which are right triangles.
13. An  $n$ -simplex  $\Sigma$  is a Schlaefli simplex if and only if there exist real distinct numbers  $c_1, \dots, c_{n+1}$  such that the Menger matrix  $M = [m_{ij}]$  of  $\Sigma$  has the form  $m_{ij} = |c_i - c_j|$ . If this holds for  $c_1 > c_2 > \dots > c_{n+1}$ , then, in the usual notation, the edges  $\{\mathbf{A}_k, \mathbf{A}_{k+1}\}$ ,  $k = 1, \dots, n$ , are the legs of  $\Sigma$ .
14. Let  $\Sigma$  be a hyperacute  $n$ -simplex. Then the Gramian  $Q$  of  $\Sigma$  is a singular  $M$ -matrix of rank  $n$ , with annihilating vector  $\mathbf{1}$ .
15. Every face of a hyperacute simplex  $\Sigma$  is also a hyperacute simplex. The distribution of acute and right angles in the face is completely determined by the distribution of acute and right angles in the simplex as follows: If the face is determined by vertices with indices in  $S$ , the edge  $\{\mathbf{A}_i, \mathbf{A}_j\}$  in the face will be red if and only if one can proceed from the vertex  $\mathbf{A}_i$  to the vertex  $\mathbf{A}_j$  along a path in the set of red edges of  $\Sigma$  which does not contain any vertex with index in  $S$  (except  $\mathbf{A}_i$  and  $\mathbf{A}_j$ ).
16. ([Fie61]). In the extended colored graph of an  $n$ -simplex,  $n \geq 2$ , the red part has vertex connectivity at least two.
17. ([Fie61]). In the definition of the extended graph and extended coloring, the vertex  $n + 2$  has no privileged position in the following sense: Let  $G$  be the extended colored graph of some  $n$ -simplex  $\Sigma_1$ , with vertex  $n + 2$  corresponding to the circumcenter of  $\Sigma_1$ . If  $k \in \{1, 2, \dots, n + 1\}$ , then there exists another  $n$ -simplex  $\Sigma_2$  whose extended colored graph is  $G$  and such that  $k$  is the vertex corresponding to the circumcenter of  $\Sigma_2$ .

FIGURE 66.1 Coloring of triangles.

18. Every face (of dimension at least two) of a totally hyperacute simplex is also a totally hyperacute simplex. The extended coloring of the face is by the extended coloring of the simplex uniquely determined; it is obtained in the same way as in the usual coloring of a hyperacute simplex in Fact 15.
19. Let  $\Sigma$  be a totally hyperacute  $n$ -simplex. Then the extended graph of  $\Sigma$  is either a cycle, and then  $\Sigma$  is a Schlaefli simplex, or it has vertex connectivity at least three.
20. ([Fie61]) Let a metric net  $N$  on a simplex be given. There exists a simplex of maximum volume with this net if and only if the net  $N$  is connected, i.e., if it is possible to pass from any vertex of the net to any other vertex using edges in the net only. In addition, every simplex with this maximum volume has the property that every interior angle opposite an unspecified edge of the simplex (i.e., not belonging to  $N$ ) is right.

**Examples:**

1. Figure 66.1 shows examples of three colored triangles. In these diagrams, the heaviest line represents red, the ordinary line represents blue, and the light gray line represents white.
2. Figure 66.2 shows examples of the two types of right tetrahedra. The dashed lines indicate the box described in Fact 7. The tetrahedron on the right is a Schlaefli simplex.
3. Figure 66.3 shows examples of extended graphs of triangles in Figure 66.1.
4. We apply the result in Fact 20 to so-called **cyclic simplexes** (cf. [Fie61]), which are maximum volume simplexes in the case that the metric net is a cycle. We call a simplex **regularly cyclic** if all edges in this net have the same length.

The Gramian of the regularly cyclic  $n$ -simplex is a multiple of the matrix

$$\begin{bmatrix} 2 & -1 & 0 & \dots & 0 & -1 \\ -1 & 2 & -1 & \dots & 0 & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & 0 & \dots & 2 & -1 \\ -1 & 0 & 0 & \dots & -1 & 2 \end{bmatrix}$$

with  $n + 1$  rows and columns, if the net is formed by the edges  $\{\mathbf{A}_k, \mathbf{A}_{k+1}\}$ ,  $k = 1, \dots, n$ , and  $\{\mathbf{A}_{n+1}, \mathbf{A}_1\}$ .

The corresponding Menger matrix is then proportional to the matrix with entries  $m_{ik} = |i - k|(n + 1 - |i - k|)$ . It is possible to show that any two of the edges in the cycle span the same angle.

FIGURE 66.2 The two types of right tetrahedra.

FIGURE 66.3 Extended graphs of triangles.

It is immediate that the regularly cyclic 2-simplex is the equilateral triangle. The regularly cyclic 3-simplex is the tetrahedron, which is obtained from a square by parallely lifting one diagonal in the perpendicular direction to the plane so that the distance of the two new diagonals equals half of the length of each diagonal.

Thus, the volume of every  $n$ -simplex with vertices  $\mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_{n+1}$  in a Euclidean  $n$ -space for which all the edges  $\{\mathbf{A}_1, \mathbf{A}_2\}, \{\mathbf{A}_2, \mathbf{A}_3\}, \dots, \{\mathbf{A}_n, \mathbf{A}_{n+1}\}, \{\mathbf{A}_{n+1}, \mathbf{A}_1\}$  have length one, does not exceed  $\frac{1}{n!} \sqrt{\frac{(n+1)^{n-1}}{n^n}}$ .

## 66.5 An Application to Resistive Electrical Networks

We conclude with applications of matrices and graphs in another, maybe surprising, field.

### Definitions:

A **resistive electrical network** is a network consisting of a finite number of nodes, say  $1, 2, \dots, n$ , some pairs of which are directly connected by a conductor of some resistance. The assumptions are that the whole network is connected, and that there are no other electrical elements than resistors. As usual, **conductivity** of the conductor between two nodes is the reciprocal of the resistance of that conductor. If there is no direct connection between a pair of nodes, we set the conductivity of that “conductor” as zero.

A resistive electrical network of which just some of the nodes, **outlets**, are accessible, is called a **black-box**. The matrix of mutual resistances between the outlets of a black-box is called a **black-box matrix**.

The **problem** is: Characterize the set of all possible black-box  $n \times n$  matrices.

**Facts** ([Moo68], [Fie78]):

1. Resistances of conductors in series add and conductivities of conductors in parallel add. If conductors having resistances  $R_1, R_2$  are placed in series (see left illustration in Figure 66.4) the resistance  $R$  between the nodes is  $R_1 + R_2$ . If conductors having resistances  $R_1, R_2$  are placed in parallel (see right illustration in Figure 66.4) the resistance  $R$  between the nodes satisfies  $\frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2}$ .
2. The  $3 \times 3$  black-box matrices are all matrices

$$\begin{bmatrix} 0 & r_{12} & r_{13} \\ r_{12} & 0 & r_{23} \\ r_{13} & r_{23} & 0 \end{bmatrix}$$

FIGURE 66.4 Resistors in series and parallel.

in which the numbers  $r_{12}$ ,  $r_{13}$ , and  $r_{23}$  are nonnegative, at least two different from zero, and fulfill the nonstrict triangle inequality.

3. The  $n \times n$  black-box matrices are exactly Menger matrices of hyperacute  $(n - 1)$ -simplexes.
4. If a black-box matrix is given, then the corresponding network can be realized as such for which the conductivities between pairs of outlets are equal to the negatively taken corresponding entries of the Gramian of the simplex whose Menger matrix the given matrix is.
5. ([Fie78]) Let the given black-box  $B$  with  $n$  outlets correspond to an  $(n - 1)$ -simplex  $\Sigma$ . Let  $S$  be a nonvoid proper subset of the set of outlets of  $B$ . Join all outlets in  $S$  by shortcuts. The resulting device can be considered as a new black-box  $B_S$ , which has just one outlet instead those outlets in  $S$  and, of course, all the remaining outlets. We construct the simplex corresponding to  $B_S$  and its black-box matrix as follows.

If  $L$  is the linear space in the corresponding  $E^{n-1}$  determined by the vertices corresponding to  $S$ , project orthogonally all the remaining vertices as well as  $L$  itself on (some) orthogonal complement  $L^\perp$  to  $L$ , thus obtaining a new simplex. The Menger matrix  $M_S$  of this simplex will be the black-box matrix of  $B_S$ . An algebraic construction is to pass from the Menger matrix of  $\Sigma$ , to the Gramian  $Q$  of  $\Sigma$  using Fact 8 of section 66.3; in this Gramian  $Q$ , add together all the rows corresponding to  $S$  into a single row and all the columns corresponding to  $S$  into a single column. The resulting symmetric matrix  $\hat{Q}$  is again a singular  $M$ -matrix with row-sums zero. The simplex whose Gramian is  $\hat{Q}$  is then that whose Menger matrix is  $B_S$ .

6. Let  $S_1$  and  $S_2$  be two disjoint nonempty subsets of the set of outlets of a black-box, and let  $\Sigma$  be the simplex in the geometric model. Join all outlets in  $S_1$  with a source of potential zero, and all outlets in  $S_2$  with the source of potential one. What will be the distribution of potentials in the remaining outlets using the geometric interpretation?

The answer is: Let  $L_1, L_2$ , respectively, be linear spaces determined by vertices of  $\Sigma$  corresponding to  $S_1, S_2$ , respectively. There exists a unique pair of parallel hyperplanes  $H_1$  and  $H_2$ , such that  $H_1$  contains  $L_1$  and  $H_2$  contains  $L_2$ , and the distance between  $H_1$  and  $H_2$  is maximal among all such pairs of parallel hyperplanes. Then the square of the distance of the hyperplanes  $H_1$  and  $H_2$  measures the resistance between  $S_1$  and  $S_2$  (similarly like the square of the distance between two vertices of  $\Sigma$  measures the resistance between the corresponding outlets), and if  $V_0$  is a vertex corresponding to an outlet  $S_0$ , then the potential in  $S_0$  is obtained by linear interpolation corresponding to the position of the hyperplane  $H_0$  containing  $V_0$  and parallel to  $H_1$  with respect to the hyperplanes  $H_1$  and  $H_2$ . Let us remark that the whole simplex  $\Sigma$  is in the layer between  $H_1$  and  $H_2$ , thanks to the property of hyperacuteness of  $\Sigma$ .

### Examples:

1. Suppose the three nodes 1, 2, and 3 are connected as follows: The nodes 1 and 2 are connected by a conductor of resistance 18 ohms, the nodes 1 and 3 by conductor of resistance 12 ohms, and the nodes 2 and 3 by conductor of resistance 6 ohms. We compute the resistances for the black-box with the three outlets 1, 2, and 3. For  $r_{12}$ , the total resistance between outlets 1 and 2, note that there are two parallel paths between 1 and 2: the direct path with resistance 18 ohms, and the path through node 3 with resistance 6 ohms + 12 ohms = 18 ohms. Thus  $\frac{1}{r_{12}} = \frac{1}{18} + \frac{1}{18} = \frac{1}{9}$ , so  $r_{12} = 9$  ohms. Similar computations show that the resistance between outlets 1 and 3 is 8 ohms and the

resistance between outlets 2 and 3 is 5 ohms. The black-box matrix is 
$$\begin{bmatrix} 0 & 9 & 8 \\ 9 & 0 & 5 \\ 8 & 5 & 0 \end{bmatrix}.$$

2. Let us remark that the properties of the outlets of a black-box do not depend on the way the conductors and resistors in the box are set. Here is another way the black-box-matrix in Example 1 could be obtained: There are no direct connections between nodes 1, 2, and 3, but there is a fourth node 4, which is connected with node 1 by a conductor of resistance 6 ohms, with node 2 by a conductor of resistance 3 ohms, and with node 3 by a conductor of resistance 2 ohms. Since

resistors in series add, this produces the same black-box matrix. If we then connect the outlets 1 and 2 by a short-circuit (conductor of no resistance), in both cases the resulting resistance between the new outlet {1, 2} and outlet 3 will be the same, equal to 4 ohms.

The topics of this chapter and the next (on group representations) are closely related. Here we consider some particular groups that arise most naturally as matrix groups or quotients of them, and special properties of matrix groups that are not shared by arbitrary groups. In representation theory, we consider what we learn about a group by considering all its homomorphisms to matrix groups. In this chapter we discuss properties of specific matrix groups, especially the general linear group (consisting of all invertible matrices of given size over a given field) and the related “classical groups.” Most group theoretic terminology is standard and can be found in any textbook or in the Preliminaries in the Front Matter of the book.

### 67.1 Introduction

---

#### Definitions:

The **general linear group**  $GL(n, F)$  is the group consisting of all invertible  $n \times n$  matrices over the field  $F$ .

A **matrix group** is a subgroup of  $GL(n, F)$  for some natural number  $n$  and field  $F$ .

If  $V$  is a vector space of dimension  $n$  over  $F$ , the **group of invertible linear operators** on  $V$  is denoted by  $GL(V)$ .

A **linear group of degree  $n$**  is a subgroup of  $GL(V)$  (where  $\dim V = n$ ). (A subgroup of  $GL(n, F)$  is a linear group of degree  $n$ , since an  $n \times n$  matrix can be viewed as a linear operator acting on  $F^n$  by matrix multiplication.)

A linear group  $G \leq GL(V)$  is said to be **reducible** if there is a  $G$ -invariant subspace  $U$  of  $V$  other than  $\{0\}$  and  $V$ , and is **irreducible** otherwise. If  $G \leq GL(V)$  is irreducible, then  $V$  is called  **$G$ -irreducible**.

A linear group  $G \leq GL(V)$  is said to be **decomposable** if  $V$  is the direct sum of two nonzero  $G$ -invariant subspaces, and is **indecomposable** otherwise.

If  $V$  can be expressed as the direct sum of  $G$ -irreducible subspaces, then  $G$  is **completely reducible**. (An irreducible group is completely reducible.)

If the matrix group  $G \leq GL(n, K)$  is irreducible regarded as a subgroup of  $GL(n, K)$  for any algebraic extension  $K$  of  $F$ , we say that  $G$  is **absolutely irreducible**.

A linear group of degree  $n$  is **unipotent** if all its elements have  $n$  eigenvalues equal to 1.

Let  $X$  and  $Y$  be group-theoretic properties.

A group  $G$  is **locally  $X$**  if every finite subset of  $G$  is contained in a subgroup with property  $X$ .

**Facts:**

For these facts and general background reading see [Dix71], [Sup76], and [Weh73].

1. If  $V$  is a vector space of dimension  $n$  over  $F$ , then  $\text{GL}(V)$  is isomorphic to  $\text{GL}(n, F)$ .
2. Every finite group is isomorphic to a matrix group.
3. Basic facts from linear algebra about similarity of matrices can be interpreted as statements about conjugacy classes in  $\text{GL}(n, F)$ . For example:
  - Two nonsingular matrices are conjugate in  $\text{GL}(n, F)$  if and only if they have the same invariant factors.
  - If  $F$  is algebraically closed, then two nonsingular matrices are conjugate in  $\text{GL}(n, F)$  if and only if they have the same Jordan canonical form.
  - Two real symmetric matrices are conjugate in  $\text{GL}(n, \mathbb{R})$  if and only if they have the same rank and signature.

(See Chapter 6 for more information on the Jordan canonical form and invariant factors and Chapter 12 for more information on signature.)
4. A matrix group  $G$  of degree  $n$  is reducible if and only if there exists a nonsingular matrix  $M \in F^{n \times n}$  and  $k$  with  $1 \leq k \leq n - 1$  such that for all  $A \in G$ ,  $M^{-1}AM$  is of the form  $\begin{bmatrix} B_{11} & B_{12} \\ \mathbf{0} & B_{22} \end{bmatrix}$ , where  $B_{11} \in F^{k \times k}$ ,  $B_{22} \in F^{(n-k) \times (n-k)}$ .
5. (See Chapter 68) The image of a representation of a group is a linear group. The image of a matrix representation of a group is a matrix group. We apply descriptions of the linear group to the representation: If  $\rho : G \rightarrow \text{GL}(V)$  is a representation, and  $\rho(G)$  is irreducible, indecomposable, absolutely irreducible, etc., then we say that the representation  $\rho$  is irreducible, etc.
6. If every finitely generated subgroup of a group  $G$  is isomorphic to a linear group of degree  $n$  over a field  $F$  (of arbitrary characteristic), then  $G$  is isomorphic to a linear group of degree  $n$ .
7. Any free group is linear of degree 2 in every characteristic. More generally, a free product of linear groups is linear.
8. (Maschke's Theorem) Let  $G$  be a finite linear group over  $F$ , and suppose that the characteristic of  $F$  is either zero or coprime to  $|G|$ . If  $G$  is reducible, then it is decomposable.
9. A locally finite linear group in characteristic zero is completely reducible.
10. (Clifford's Theorem) Let  $G$  be an irreducible linear group on a vector space  $V$  of dimension  $n$ , and let  $N$  be a normal subgroup of  $G$ . Then  $V$  is a direct sum of minimal  $N$ -spaces  $W_1, \dots, W_d$  permuted transitively by  $G$ . In particular,  $d$  divides  $n$ , the group  $N$  is completely reducible, and the linear groups induced on  $W_i$  by  $N$  are all isomorphic.
11. A normal (or even a subnormal) subgroup of a completely reducible linear group is completely reducible.
12. A unipotent matrix group is conjugate (in the general linear group) to the group of upper unit triangular matrices.
13. A linear group  $G$  on  $V$  has a unipotent normal subgroup  $U$  such that  $G/U$  is isomorphic to a completely reducible linear group on  $V$ ; the subgroup  $U$  is a nilpotent group of class at most  $n - 1$ , where  $n = \dim(V)$ .
14. (Mal'cev) If every finitely generated subgroup of the linear group  $G$  is completely reducible, then  $G$  is completely reducible.
15. Let  $G$  be a linear group on  $F^n$ , where  $F$  is algebraically closed. Then  $G$  is irreducible if and only if the elements of  $G$  span the space  $F^{n \times n}$  of all  $n \times n$  matrices over  $F$ .

**Examples:**

1. The matrix group

$$G = \left\{ \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}, \begin{bmatrix} \frac{1}{3} & \frac{2}{3} \\ \frac{4}{3} & -\frac{1}{3} \end{bmatrix}, \begin{bmatrix} -\frac{1}{3} & -\frac{2}{3} \\ -\frac{4}{3} & \frac{1}{3} \end{bmatrix} \right\}$$

is decomposable and completely reducible: the subspaces of  $\mathbb{R}^2$  spanned by the vectors  $[1, 1]^T$  and  $[-1, 2]^T$  are  $G$ -invariant. That is, with  $M = \begin{bmatrix} 1 & -1 \\ 1 & 2 \end{bmatrix}$ , for any  $A \in G$ ,  $M^{-1}AM$  is a diagonal matrix.

2. The matrix group

$$\left\{ \begin{bmatrix} 1 & a \\ 0 & 1 \end{bmatrix} : a \in \mathbb{R} \right\}$$

is reducible, but neither decomposable nor completely reducible.

3. The matrix group

$$\left\{ \begin{bmatrix} \cos x & \sin x \\ -\sin x & \cos x \end{bmatrix} : x \in \mathbb{R} \right\}$$

of real rotations is irreducible over  $\mathbb{R}$  but not over  $\mathbb{C}$ : The subspace spanned by  $[1, i]^T$  is invariant. The matrices in this group span the 2-dimensional subspace of  $\mathbb{R}^{2 \times 2}$  consisting of matrices  $A = [a_{ij}]$  satisfying the equations  $a_{11} = a_{22}$  and  $a_{12} + a_{21} = 0$ .

4. A group is locally finite if and only if every finitely generated subgroup is finite.

## 67.2 The General and Special Linear Groups

---

### Definitions:

The **special linear group**  $SL(n, F)$  is the subgroup of  $GL(n, F)$  consisting of matrices of determinant 1. If  $V$  is a vector space of dimension  $n$  over  $F$ , the group of invertible linear operators on  $V$  having determinant 1 is denoted by  $SL(V)$ .

The **special linear group**  $SL(n, F)$  is the subgroup of  $GL(n, F)$  consisting of matrices of determinant 1.

The **projective general linear group** and **projective special linear group**  $PGL(n, F)$  and  $PSL(n, F)$  are the quotients of  $GL(n, F)$  and  $SL(n, F)$  by their normal subgroups  $Z$  and  $Z \cap SL(n, F)$ , respectively, where  $Z$  is the group of nonzero scalar matrices.

*Notation:* If  $F = GF(q)$  is the finite field of order  $q$ , then  $GL(n, F)$  is denoted  $GL(n, q)$ ,  $SL(n, F)$  is denoted  $SL(n, q)$ , etc.

A **transvection** is a linear operator  $T$  on  $V$  with all eigenvalues equal to 1 and satisfying  $\text{rank}(T - I) = 1$ .

### Facts:

For these facts and general background reading see [HO89], [Tay92], or [Kra02].

1. The special linear group  $SL(n, F)$  is a normal subgroup of the general linear group  $GL(n, F)$ .
2. The order of  $GL(n, q)$  is equal to the number of ordered bases of  $GF(q)^n$ , namely

$$|GL(n, q)| = \prod_{i=0}^{n-1} (q^n - q^i) = q^{n(n-1)/2} \prod_{i=0}^{n-1} (q^{n-i} - 1).$$

3. A transvection has determinant 1, and so lies in  $SL(V)$ .
4. A transvection on  $F^n$  has the form  $I + \mathbf{v}\mathbf{w}^T$  for some  $\mathbf{v}, \mathbf{w} \in F^n$  and  $\mathbf{w}^T \mathbf{v} = 0$ , and anything in this form is a transvection.
5. A transvection  $T$  on  $V$  has the form  $T : x \mapsto x + f(\mathbf{x})\mathbf{v}$ , where  $\mathbf{v} \in V$ ,  $f \in V^*$ , and  $f(\mathbf{v}) = 0$ , and anything in this form is a transvection.
6. The group  $SL(n, F)$  is generated by transvections, for any  $n \geq 2$  and any field  $F$ .

7. The group  $\mathrm{PSL}(n, F)$  is simple for all  $n \geq 2$  and all fields  $F$ , except for the two cases  $\mathrm{PSL}(2, 2)$  and  $\mathrm{PSL}(2, 3)$ . The groups  $\mathrm{PSL}(2, 2)$  and  $\mathrm{PSL}(2, 3)$  are isomorphic to the symmetric group on 3 letters and the alternating group on 4 letters, respectively. The groups  $\mathrm{PSL}(2, 4)$  and  $\mathrm{PSL}(2, 5)$  are both isomorphic to the alternating group on 5 letters.

**Examples:**

1.  $\mathrm{GL}(2, 2) = \mathrm{SL}(2, 2) = \mathrm{PSL}(2, 2) =$

$$\left\{ \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}, \begin{bmatrix} 1 & 0 \\ 1 & 1 \end{bmatrix}, \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \right\}.$$

2.  $\mathrm{SL}(2, 3) =$

$$\left\{ \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}, \begin{bmatrix} 1 & 2 \\ 0 & 1 \end{bmatrix}, \begin{bmatrix} 1 & 0 \\ 1 & 1 \end{bmatrix}, \begin{bmatrix} 1 & 0 \\ 2 & 1 \end{bmatrix}, \begin{bmatrix} 2 & 0 \\ 0 & 2 \end{bmatrix}, \begin{bmatrix} 2 & 1 \\ 0 & 2 \end{bmatrix}, \begin{bmatrix} 2 & 2 \\ 0 & 2 \end{bmatrix}, \begin{bmatrix} 2 & 0 \\ 1 & 2 \end{bmatrix}, \begin{bmatrix} 2 & 0 \\ 2 & 2 \end{bmatrix}, \begin{bmatrix} 1 & 1 \\ 1 & 2 \end{bmatrix}, \begin{bmatrix} 1 & 2 \\ 2 & 2 \end{bmatrix}, \begin{bmatrix} 2 & 1 \\ 1 & 1 \end{bmatrix}, \begin{bmatrix} 2 & 2 \\ 2 & 1 \end{bmatrix}, \begin{bmatrix} 0 & 1 \\ 2 & 0 \end{bmatrix}, \begin{bmatrix} 0 & 2 \\ 1 & 0 \end{bmatrix} \right\}.$$

- 3.

$$T = \begin{bmatrix} -13 & -10 & -2 \\ 14 & 11 & 2 \\ 28 & 20 & 5 \end{bmatrix}$$

is a transvection.  $T = I + \mathbf{v}\mathbf{w}^T$  with  $\mathbf{v} = [-2, 2, 4]^T$ , and  $\mathbf{w} = [7, 5, 1]^T$ .

## 67.3 The BN Structure of the General Linear Group

**Definitions:**

A **BN-pair** (or **Tits system**) is an ordered quadruple  $(G, B, N, S)$  where

- $G$  is a group generated by subgroups  $B$  and  $N$ .
- $T := B \cap N$  is normal in  $N$ .
- $S$  is a subset of  $W := N/T$  and  $S$  generates  $W$ .
- The elements of  $S$  are all of order 2.
- If  $\rho, \sigma \in N$  and  $\rho T \in S$ , then  $\rho B \sigma \subseteq B \sigma B \cup B \rho \sigma B$ .
- If  $\rho T \in S$ , then  $\rho B \rho \neq B$ .

If  $(G, B, N, S)$  is a BN-pair, the subgroups  $B$  and  $W = N/T$  are known as the **Borel subgroup** and **Weyl group** of  $G$ .

A **parabolic subgroup** of  $G$  (relative to a given BN-pair) is a subgroup of the form  $P_I = \langle B, s_i : i \in I \rangle$  for some subset  $I$  of  $\{1, \dots, |S|\}$ .

**Facts:**

For these facts and general background reading see [HO89], [Tay92], or [Kra02].

1. The general linear group  $\mathrm{GL}(n, F)$  with  $n \geq 2$  has the following Tits system:
  - $B$  is the group of upper-triangular matrices in  $G$ .
  - $U$  the group of unit upper-triangular matrices (with diagonal entries 1).

- $T$  the group of diagonal matrices.
  - $N$  is the group of matrices having a unique nonzero element in each row or column.
  - $S = \{s_i : i = 1, \dots, n-1\}$ , where  $s_i = P_i T$  and  $P_i$  is the reflection which interchanges the  $i$ th and  $(i+1)$ st standard basis vectors ( $P_i$  is obtained from the identity matrix by interchanging rows  $i$  and  $i+1$ ).
  - $N$  is the normalizer of  $T$  in  $\text{GL}(n, F)$ .
  - $B = UT$ .
  - $B \cap N = T$ .
  - $N/T$  is isomorphic to the symmetric group  $S_n$ .
2. If  $G$  has a BN-pair, any subgroup of  $G$  containing  $B$  is a parabolic subgroup.
  3. In  $\text{GL}(n, F)$ , there are  $2^{n-1}$  parabolic subgroups for the BN-pair in Fact 1, hence, there are  $2^{n-1}$  subgroups of  $\text{GL}(n, F)$  containing the subgroup  $B$  of upper-triangular matrices.
  4. More generally, with respect to any basis of  $V$  there is a BN-structure. The terms *Borel subgroup* and *parabolic subgroup* are used to refer to the subgroups defined with respect to an arbitrary basis. All the Borel subgroups of  $\text{GL}(V)$  are conjugate. The maximal parabolic subgroups are precisely the maximal reducible subgroups.

### Examples:

1. The maximal parabolic subgroups of  $\text{GL}(n, F)$  with the BN-pair in Fact 1 are those for which  $I = \{1, \dots, n-1\} \setminus \{k\}$  for some  $k$ ; it is easy to see that in this case  $P_I$  is the stabilizer of the subspace spanned by the first  $k$  basis vectors. This subgroup consists of all matrices with block form as in 67.1, Fact 4.

## 67.4 Classical Groups

---

The classical groups form several important families of linear groups. We give a brief description here, and refer to the books [HO89], [Tay92], or the article [Kra02] for more details. For information on bilinear, sesquilinear, and quadratic forms, see Chapter 12.

### Definitions:

A  $\varphi$ -sesquilinear form  $B$  is  $\varphi$ -**Hermitian** if  $B(\mathbf{v}, \mathbf{w}) = \varphi(B(\mathbf{w}, \mathbf{v}))$  for all  $\mathbf{v}, \mathbf{w} \in V$ . In the case where  $F = \mathbb{C}$  and  $\varphi$  is conjugation, a  $\varphi$ -Hermitian form is called a **Hermitian** form.

A **formed space** is a finite dimensional vector space carrying a nondegenerate  $\varphi$ -Hermitian, symmetric, or alternating form  $B$ .

A **classical group** over a formed space  $V$  is the subgroup of  $\text{GL}(V)$  consisting of the linear operators that preserve the form. We distinguish three types of classical groups:

1. **Orthogonal group:** Preserving a nondegenerate symmetric bilinear form  $B$ .
2. **Symplectic group:** Preserving a nondegenerate alternating bilinear form  $B$ .
3. **Unitary group:** Preserving a nondegenerate  $\sigma$ -Hermitian form  $B$ , with  $\sigma \neq 1$ .

We denote a classical subgroup of  $\text{GL}(V)$  by  $\text{O}(V)$ ,  $\text{Sp}(V)$ , or  $\text{U}(V)$  depending on type. If necessary, we add extra notation to specify which particular form is being used. If  $V = F^n$ , we also write  $\text{O}(n, F)$ ,  $\text{Sp}(n, F)$ , or  $\text{U}(n, F)$ .

The **Witt index** of a formed space  $V$  is the dimension of the largest subspace on which the form is identically zero. The Witt index of the corresponding classical group is the Witt index of the formed space.

An **isometry** between subspaces of a formed space is a linear transformation preserving the value of the form.

A representation of a group  $G$  over the complex numbers is said to be **unitary** if its image is contained in the unitary group.

**Facts:**

For these facts and for general background reading see [HO89], [Tay92], or [Kra02].

1. The only automorphism of  $\mathbb{R}$  is the identity, so any sesquilinear form on a real vector space is bilinear and any  $\varphi$ -Hermitian form is symmetric. A real formed space has a symmetric or alternating bilinear form as its form. The classical subgroups of a real formed space are orthogonal or symplectic.
2. The only automorphisms of  $\mathbb{C}$  that preserve the reals are the identity and complex conjugation. Any  $\varphi$ -Hermitian form such that  $\varphi$  preserves the reals is a Hermitian form.
3. Classification of classical groups up to conjugacy in  $GL(n, F)$  is equivalent to classification of forms of the appropriate type up to the natural action of the general linear group together with scalar multiplication. Often this is a very difficult problem; the next fact gives a few cases where the classification is more straightforward.
4. (a) A nondegenerate alternating form on  $V = F^n$  exists if and only if  $n$  is even, and all such forms are equivalent. So there is a unique conjugacy class of symplectic groups in  $GL(n, F)$  if  $n$  is even (with Witt index  $n/2$ ), and none if  $n$  is odd.  
 (b) Let  $F = GF(q)$ . Then, up to conjugacy,  $GL(n, q)$  contains one conjugacy class of unitary subgroups (with Witt index  $\lfloor n/2 \rfloor$ ), one class of orthogonal subgroups if  $n$  is odd (with Witt index  $(n-1)/2$ ), and two classes if  $n$  is even (with Witt indices  $n/2$  and  $n/2-1$ ).  
 (c) A nondegenerate symmetric bilinear form on  $\mathbb{R}^n$  is determined up to the action of  $GL(n, \mathbb{R})$  by its signature. Its Witt index is  $\min\{s, t\}$ , where  $s$  and  $t$  are the numbers of positive and negative eigenvalues. So there are  $\lfloor n/2 \rfloor + 1$  conjugacy classes of orthogonal subgroups of  $GL(n, \mathbb{R})$ , with Witt indices  $0, 1, \dots, \lfloor n/2 \rfloor$ .
5. (Witt's Lemma) Suppose that  $U_1$  and  $U_2$  are subspaces of the formed space  $V$ , and  $h : U_1 \rightarrow U_2$  is an isometry. Then there is an isometry  $g$  of  $V$  that extends  $h$ .
6. From Witt's Lemma it is possible to write down formulas for the orders of the classical groups over finite fields similar to the formula in Fact 2 general linear group.
7. The analogues of Facts 6 and 7 in section 67.2 hold for the classical groups with nonzero Witt index. However, the situation is more complicated. Any symplectic transformation has determinant 1, so  $Sp(2r, F) \leq SL(2r, F)$ . Moreover,  $Sp(2r, F)$  is generated by symplectic transvections (those preserving the alternating form) for  $r \geq 2$ , except for  $Sp(4, 2)$ . Similarly, the **special unitary group**  $SU(n, F)$  (the intersection of  $U(n, F)$  with  $SL(n, F)$ ) with positive Witt index is generated by unitary transvections (those preserving the Hermitian form), except for  $SU(3, 2)$ . Results for orthogonal groups are more difficult. See [HO89] for more information.
8. Like the general linear groups, the classical groups contain BN-pairs (configurations of subgroups satisfying conditions like those in the previous section). The difference is that the Weyl group  $W = N/H$  is not the symmetric group, but one of the other types of Coxeter group (finite groups generated by reflections).
9. Although this treatment of classical groups has been as far as possible independent of fields, for most of mathematics, the classical groups over the real and complex numbers are the most important, and among these, the real orthogonal and complex unitary groups preserving positive definite forms most important; see [Wey39].
10. The theory can be extended to classical groups over rings. This has important connections with algebraic K-theory. The book [HO89] gives details.
11. Every representation of a finite group is equivalent to a unitary representation.

**Examples:**

1. The function  $B$  given by  $B((x_1, y_1), (x_2, y_2)) = x_1 y_2 - x_2 y_1$  is an alternating bilinear form on  $F^2$ . Any matrix with determinant 1 will preserve this form. So  $Sp(2, F) = SL(2, F)$ .
2. The symmetric group  $S_6$  acts on  $F^6$ , where  $F$  is the field with two elements. It preserves the 1-dimensional subspace  $U$  spanned by  $(1, 1, 1, 1, 1, 1)$ , as well as the 5-dimensional subspace consisting of vectors with coordinate sum zero. The usual dot product on  $F^6$  is alternating when

restricted to  $W$ , and its radical is  $U$ , so it induces a symplectic form on  $W/U$ . Thus  $S_6$  is a subgroup of the symplectic group  $Sp(4, 2)$ . Since both groups have order 720, we see that  $Sp(4, 2) = S_6$ .

Representation theory is the study of the various ways a given group can be mapped into a general linear group. This information has proven to be effective at providing insight into the structure of the given group as well as the objects on which the group acts. Most notable is the central contribution made by representation theory to the complete classification of finite simple groups [Gor94]. (See also Fact 3 of Section 68.1 and Fact 5 of Section 68.6.)

Representations of finite groups can be defined over an arbitrary field and such have been studied extensively. Here, however, we discuss only the most widely used, classical theory of representations over the field of complex numbers (many results of which fail to hold over other fields).

### 68.1 Basic Concepts

---

Throughout,  $G$  denotes a finite group,  $e$  denotes its identity element, and  $V$  denotes a finite dimensional complex vector space.

#### Definitions:

The **general linear group** of a vector space  $V$  is the group  $GL(V)$  of linear isomorphisms of  $V$  onto itself with operation given by function composition.

A **(linear) representation** of the finite group  $G$  (over the complex field  $\mathbb{C}$ ) is a homomorphism  $\rho = \rho_V : G \rightarrow GL(V)$ , where  $V$  is a finite dimensional vector space over  $\mathbb{C}$ .

The **degree** of a representation  $\rho_V$  is the dimension of the vector space  $V$ .

Two representations  $\rho : G \rightarrow GL(V)$  and  $\rho' : G \rightarrow GL(V')$  are **equivalent** (or **isomorphic**) if there exists a linear isomorphism  $\tau : V \rightarrow V'$  such that  $\tau \circ \rho(s) = \rho'(s) \circ \tau$  for all  $s \in G$ .

Given a representation  $\rho_V$  of  $G$ , a subspace  $W$  of  $V$  is  **$G$ -stable** (or  **$G$ -invariant**) if  $\rho_V(s)(W) \subseteq W$  for all  $s \in G$ .

If  $\rho_V$  is a representation of  $G$  and  $W$  is a  $G$ -stable subspace of  $V$ , then the induced maps  $\rho_W : G \rightarrow GL(W)$  and  $\rho_{V/W} : G \rightarrow GL(V/W)$  are the corresponding **subrepresentation** and **quotient representation**, respectively.

A representation  $\rho_V$  of  $G$  with  $V \neq \{0\}$  is **irreducible** if  $V$  and  $\{0\}$  are the only  $G$ -stable subspaces of  $V$ ; otherwise,  $\rho_V$  is **reducible**.

The **kernel** of a representation  $\rho_V$  of  $G$  is the set of all  $s \in G$  for which  $\rho_V(s) = 1_V$ .

A representation of  $G$  is **faithful** if its kernel consists of the identity element alone.

An **action** of  $G$  on a set  $X$  is a function  $G \times X \rightarrow X$ ,  $(s, x) \mapsto sx$ , satisfying

- $(st)x = s(tx)$  for all  $s, t \in G$  and  $x \in X$ ,
- $ex = x$  for all  $x \in X$ .

A  **$\mathbb{C}G$ -module** is a finite-dimensional vector space  $V$  over  $\mathbb{C}$  together with an action  $(s, v) \mapsto sv$  of  $G$  on  $V$  that is linear in the variable  $v$ , meaning

- $s(v + w) = sv + sw$  for all  $s \in G$  and  $v, w \in V$ ,
- $s(\alpha v) = \alpha(sv)$  for all  $s \in G$ ,  $v \in V$  and  $\alpha \in \mathbb{C}$ .

(See Fact 6 below.)

### Facts:

The following facts can be found in [Isa94, pp. 4–10] or [Ser77, pp. 3–13, 47].

1. If  $\rho = \rho_V$  is a representation of  $G$ , then
  - $\rho(e) = 1_V$ ,
  - $\rho(st) = \rho(s)\rho(t)$  for all  $s, t \in G$ ,
  - $\rho(s^{-1}) = \rho(s)^{-1}$  for all  $s \in G$ .
2. A representation of  $G$  of degree one is a group homomorphism from  $G$  into the group  $\mathbb{C}^\times$  of nonzero complex numbers under multiplication (identifying  $\mathbb{C}^\times$  with  $GL(\mathbb{C})$ ). Every representation of degree one is irreducible.
3. The group  $G$  is abelian if and only if every irreducible representation of  $G$  is of degree one.
4. *Maschke's Theorem:* If  $\rho_V$  is a representation of  $G$  and  $W$  is a  $G$ -stable subspace of  $V$ , then there exists a  $G$ -stable vector space complement of  $W$  in  $V$ .
5. *Schur's Lemma:* Let  $\rho : G \rightarrow GL(V)$  and  $\rho' : G \rightarrow GL(V')$  be two irreducible representations of  $G$  and let  $f : V \rightarrow V'$  be a linear map satisfying  $f \circ \rho(s) = \rho'(s) \circ f$  for all  $s \in G$ .
  - If  $\rho'$  is not equivalent to  $\rho$ , then  $f$  is the zero map.
  - If  $V' = V$  and  $\rho' = \rho$ , then  $f$  is a scalar multiple of the identity map:  $f = \alpha 1_V$  for some  $\alpha \in \mathbb{C}$ .
6. If  $\rho = \rho_V$  is a representation of  $G$ , then  $V$  becomes a  $\mathbb{C}G$ -module with action given by  $sv = \rho(s)(v)$  ( $s \in G$ ,  $v \in V$ ). Conversely, if  $V$  is a  $\mathbb{C}G$ -module, then  $\rho_V(s)(v) = sv$  defines a representation  $\rho_V : G \rightarrow GL(V)$  (called the **representation of  $G$  afforded by  $V$** ). The study of representations of the finite group  $G$  is the same as the study of  $\mathbb{C}G$ -modules.
7. The vector space  $\mathbb{C}G$  over  $\mathbb{C}$  with basis  $G$  is a ring (the **group ring** of  $G$  over  $\mathbb{C}$ ) with multiplication obtained by linearly extending the operation in  $G$  to arbitrary products. If  $V$  is a  $\mathbb{C}G$ -module and the action of  $G$  on  $V$  is extended linearly to a map  $\mathbb{C}G \times V \rightarrow V$ , then  $V$  becomes a (left unitary)  $\mathbb{C}G$ -module in the ring theoretic sense, that is,  $V$  satisfies the usual vector space axioms (see Section 1.1) with the scalar field replaced by the ring  $\mathbb{C}G$ .

### Examples:

See also examples in the next section.

1. Let  $n \in \mathbb{N}$  and let  $\omega \in \mathbb{C}$  be an  $n$ th root of unity (meaning  $\omega^n = 1$ ). Then the map  $\rho : \mathbf{Z}_n \rightarrow \mathbb{C}^\times$  given by  $\rho(m) = \omega^m$  is a representation of degree one of the group  $\mathbf{Z}_n$  of integers modulo  $n$ . It is irreducible.
2. *Regular representation:* Let  $V = \mathbb{C}G$  be the complex vector space with basis  $G$ . For each  $s \in G$  there is a unique linear map  $\rho(s) : V \rightarrow V$  satisfying  $\rho(s)(t) = st$  for all  $t \in G$ . Then  $\rho : G \rightarrow GL(V)$  is a representation of  $G$  called the (**left**) **regular representation**. If  $|G| > 1$ , then the regular representation is reducible (see Example 3 of Section 68.5).

3. *Permutation representation:* Let  $X$  be a finite set, let  $(s, x) \mapsto sx$  be an action of  $G$  on  $X$ , and let  $V$  be the complex vector space with basis  $X$ . For each  $s \in G$  there is a unique linear map  $\rho(s) : V \rightarrow V$  satisfying  $\rho(s)(x) = sx$  for all  $x \in X$ . Then  $\rho : G \rightarrow GL(V)$  is a representation of  $G$  called a **permutation representation**. The regular representation of  $G$  (Example 2) is the permutation representation corresponding to the action of  $G$  on itself given by left multiplication.
4. The representation of  $G$  of degree 1 given by  $\rho(s) = 1 \in \mathbb{C}^\times$  for all  $s \in G$  is the **trivial representation**.
5. *Direct sum:* If  $V$  and  $W$  are  $\mathbb{C}G$ -modules, then the  $\mathbb{C}$ -vector space direct sum  $V \oplus W$  is a  $\mathbb{C}G$ -module with action given by  $s(v, w) = (sv, sw)$  ( $s \in G, v \in V, w \in W$ ).
6. *Tensor product:* If  $V_1$  is a  $\mathbb{C}G_1$ -module and  $V_2$  is a  $\mathbb{C}G_2$ -module, then the  $\mathbb{C}$ -vector space tensor product  $V_1 \otimes V_2$  is a  $\mathbb{C}(G_1 \times G_2)$ -module with action given by  $(s_1, s_2)(v_1 \otimes v_2) = (s_1v_1) \otimes (s_2v_2)$  ( $s_i \in G_i, v_i \in V_i$ ). If both groups  $G_1$  and  $G_2$  equal the same group  $G$ , then  $V_1 \otimes V_2$  is a  $\mathbb{C}G$ -module with action given by  $s(v_1 \otimes v_2) = (sv_1) \otimes (sv_2)$  ( $s \in G, v_i \in V_i$ ).
7. *Contragredient:* If  $V$  is a  $\mathbb{C}G$ -module, then the  $\mathbb{C}$ -vector space dual  $V^*$  is a  $\mathbb{C}G$ -module (called the **contragredient** of  $V$ ) with action given by  $(sf)(v) = f(s^{-1}v)$  ( $s \in G, f \in V^*, v \in V$ ).

## 68.2 Matrix Representations

Throughout,  $G$  denotes a finite group,  $e$  denotes its identity element, and  $V$  denotes a finite dimensional complex vector space.

### Definitions:

A **matrix representation** of  $G$  of **degree**  $n$  (over the field  $\mathbb{C}$ ) is a homomorphism  $R : G \rightarrow GL_n(\mathbb{C})$ , where  $GL_n(\mathbb{C})$  is the group of nonsingular  $n \times n$  matrices over the field  $\mathbb{C}$ . (For the relationship between representations and matrix representations, see the facts below.)

The **empty matrix** is a  $0 \times 0$  matrix having no entries. The trace of the empty matrix is 0.  $GL_0(\mathbb{C})$  is the trivial group whose only element is the empty matrix.

Two matrix representations  $R$  and  $R'$  are **equivalent** (or **isomorphic**) if they have the same degree, say  $n$ , and there exists a nonsingular  $n \times n$  matrix  $P$  such that  $R'(s) = PR(s)P^{-1}$  for all  $s \in G$ .

A matrix representation of  $G$  is **reducible** if it is equivalent to a matrix representation  $R$  having the property that for each  $s \in G$ , the matrix  $R(s)$  has the block form

$$R(s) = \begin{bmatrix} X(s) & Z(s) \\ 0 & Y(s) \end{bmatrix}$$

(block sizes independent of  $s$ ).

A matrix representation is **irreducible** if it has nonzero degree and it is not reducible.

The **kernel** of a matrix representation  $R$  of  $G$  of degree  $n$  is the set of all  $s \in G$  for which  $R(s) = I_n$ .

A matrix representation of  $G$  is **faithful** if its kernel consists of the identity element alone.

### Facts:

The following facts can be found in [Isa94, pp. 10–11, 32] or [Ser77, pp. 11–14].

1. If  $R$  is a matrix representation of  $G$ , then
  - $R(e) = I$ ,
  - $R(st) = R(s)R(t)$  for all  $s, t \in G$ ,
  - $R(s^{-1}) = R(s)^{-1}$  for all  $s \in G$ .

- If  $\rho = \rho_V$  is a representation of  $G$  of degree  $n$  and  $\mathcal{B}$  is an ordered basis for  $V$ , then  $R_{\rho, \mathcal{B}}(s) = [\rho(s)]_{\mathcal{B}}$  defines a matrix representation  $R_{\rho, \mathcal{B}}: G \rightarrow GL_n(\mathbb{C})$  called the **matrix representation of  $G$  afforded by the representation  $\rho$**  (or **by the  $\mathbb{C}G$ -module  $V$** ) **with respect to the basis  $\mathcal{B}$** . Conversely, if  $R$  is a matrix representation of  $G$  of degree  $n$  and  $V = \mathbb{C}^n$ , then  $\rho(s)(v) = R(s)v$  ( $s \in G, v \in V$ ) defines a representation  $\rho$  of  $G$  and  $R = R_{\rho, \mathcal{B}}$ , where  $\mathcal{B}$  is the standard ordered basis of  $V$ .
- If  $R$  and  $R'$  are matrix representations afforded by representations  $\rho$  and  $\rho'$ , respectively, then  $R$  and  $R'$  are equivalent if and only if  $\rho$  and  $\rho'$  are equivalent. In particular, two matrix representations that are afforded by the same representation are equivalent regardless of the chosen bases.
- If  $\rho = \rho_V$  is a representation of  $G$  and  $W$  is a  $G$ -stable subspace of  $V$  and a basis for  $W$  is extended to a basis  $\mathcal{B}$  of  $V$ , then for each  $s \in G$  the matrix  $R_{\rho, \mathcal{B}}(s)$  is of block form

$$R_{\rho, \mathcal{B}}(s) = \begin{bmatrix} X(s) & Z(s) \\ 0 & Y(s) \end{bmatrix},$$

where  $X$  and  $Y$  are the matrix representations afforded by  $\rho_W$  (with respect to the given basis) and  $\rho_{V/W}$  (with respect to the induced basis), respectively.

- If the matrix representation  $R$  of  $G$  is afforded by a representation  $\rho$ , then  $R$  is irreducible if and only if  $\rho$  is irreducible.
- The group  $G$  is Abelian if and only if every irreducible matrix representation of  $G$  is of degree one.
- Maschke's Theorem (for matrix representations)*: If  $R$  is a matrix representation of  $G$  and for each  $s \in G$  the matrix  $R(s)$  is of block form

$$R(s) = \begin{bmatrix} X(s) & Z(s) \\ 0 & Y(s) \end{bmatrix}$$

(block sizes independent of  $s$ ), then  $R$  is equivalent to the matrix representation  $R'$  given by

$$R'(s) = \begin{bmatrix} X(s) & 0 \\ 0 & Y(s) \end{bmatrix}$$

( $s \in G$ ).

- Schur relations*: Let  $R$  and  $R'$  be irreducible matrix representations of  $G$  of degrees  $n$  and  $n'$ , respectively. For  $1 \leq i, j \leq n$  and  $1 \leq i', j' \leq n'$  define functions  $r_{ij}, r'_{i'j'}: G \rightarrow \mathbb{C}$  by  $R(s) = [r_{ij}(s)]$ ,  $R'(s) = [r'_{i'j'}(s)]$  ( $s \in G$ ).

- If  $R'$  is not equivalent to  $R$ , then for all  $1 \leq i, j \leq n$  and  $1 \leq i', j' \leq n'$

$$\sum_{s \in G} r_{ij}(s^{-1})r'_{i'j'}(s) = 0.$$

- For all  $1 \leq i, j, k, l \leq n$

$$\sum_{s \in G} r_{ij}(s^{-1})r_{kl}(s) = \begin{cases} |G|/n & \text{if } i = l \text{ and } j = k \\ 0 & \text{otherwise.} \end{cases}$$

### Examples:

- An example of a degree two matrix representation of the symmetric group  $S_3$  is given by

$$R(e) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad R(12) = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad R(23) = \begin{bmatrix} -1 & -1 \\ 0 & 1 \end{bmatrix},$$

$$R(13) = \begin{bmatrix} 1 & 0 \\ -1 & -1 \end{bmatrix}, \quad R(123) = \begin{bmatrix} 0 & 1 \\ -1 & -1 \end{bmatrix}, \quad R(132) = \begin{bmatrix} -1 & -1 \\ 1 & 0 \end{bmatrix}.$$

(Cf. Example 2 of section 68.4.)

2. The matrix representation  $R$  of the additive group  $\mathbf{Z}_3$  of integers modulo 3 afforded by the regular representation with respect to the basis  $\mathbf{Z}_3 = \{0, 1, 2\}$  (ordered as indicated) is given by

$$R(0) = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad R(1) = \begin{bmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix}, \quad R(2) = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{bmatrix}.$$

3. Let  $\rho : G \rightarrow GL(V)$  and  $\rho' : G \rightarrow GL(V')$  be two representations of  $G$ , let  $\mathcal{B}$  and  $\mathcal{B}'$  be bases of  $V$  and  $V'$ , respectively, and let  $R = R_{\rho, \mathcal{B}}$  and  $R' = R_{\rho', \mathcal{B}'}$  be the afforded matrix representations.
- The matrix representation afforded by the direct sum  $V \oplus V'$  with respect to the basis  $\{(b, 0), (0, b') \mid b \in \mathcal{B}, b' \in \mathcal{B}'\}$  is given by  $s \mapsto R(s) \oplus R'(s)$  (direct sum of matrices).
  - The matrix representation afforded by the tensor product  $V \otimes V'$  with respect to the basis  $\{b \otimes b' \mid b \in \mathcal{B}, b' \in \mathcal{B}'\}$  is given by  $s \mapsto R(s) \otimes R'(s)$  (Kronecker product of matrices).
  - The matrix representation afforded by the contragredient  $V^*$  with respect to the dual basis of  $\mathcal{B}$  is given by  $s \mapsto (R(s)^{-1})^T$  (inverse transpose of matrix).

## 68.3 Characters

Throughout,  $G$  denotes a finite group,  $e$  denotes its identity element, and  $V$  denotes a finite dimensional complex vector space.

### Definitions:

The **character of  $G$  afforded by a matrix representation**  $R$  of  $G$  is the function  $\chi : G \rightarrow \mathbb{C}$  defined by  $\chi(s) = \text{tr } R(s)$ .

The **character of  $G$  afforded by a representation**  $\rho = \rho_V$  of  $G$  is the character afforded by the corresponding matrix representation  $R_{\rho, \mathcal{B}}$ , where  $\mathcal{B}$  is a basis for  $V$ .

The **character of  $G$  afforded by a  $\mathbb{C}G$ -module**  $V$  is the character afforded by the corresponding representation  $\rho_V$ .

An **irreducible character** is a character afforded by an irreducible representation.

The **degree** of a character  $\chi$  of  $G$  is the number  $\chi(e)$ .

A **linear character** is a character of degree one.

If  $\chi_1$  and  $\chi_2$  are two characters of  $G$ , their **sum** is defined by  $(\chi_1 + \chi_2)(s) = \chi_1(s) + \chi_2(s)$  and their **product** is defined by  $(\chi_1 \chi_2)(s) = \chi_1(s) \chi_2(s)$  ( $s \in G$ ).

If  $\chi$  is a character of  $G$ , its **complex conjugate** is defined by  $\overline{\chi}(s) = \overline{\chi(s)}$  ( $s \in G$ ), where  $\overline{\chi(s)}$  denotes the conjugate of the complex number  $\chi(s)$ .

The **kernel** of a character  $\chi$  of  $G$  is the set  $\{s \in G \mid \chi(s) = \chi(e)\}$ .

A character  $\chi$  of  $G$  is **faithful** if its kernel consists of the identity element alone.

The **principal character** of  $G$  is the character  $1_G$  satisfying  $1_G(s) = 1$  for all  $s \in G$ .

The **zero character** of  $G$  is the character  $0_G$  satisfying  $0_G(s) = 0$  for all  $s \in G$ .

If  $\chi$  and  $\psi$  are two characters of  $G$ , then  $\psi$  is called a **constituent** of  $\chi$  if  $\chi = \psi + \psi'$  with  $\psi'$  a character (possibly zero) of  $G$ .

### Facts:

The following facts can be found in [Isa94, pp. 14–23, 38–40, 59] or [Ser77, pp. 10–19, 27, 52].

1. The principal character of  $G$  is the character afforded by the representation of  $G$  that maps every  $s \in G$  to  $[1] \in GL_1(\mathbb{C})$ . The zero character of  $G$  is the character afforded by the representation of  $G$  that maps every  $s \in G$  to the empty matrix in  $GL_0(\mathbb{C})$ .

2. The degree of a character of  $G$  equals the dimension of  $V$ , where  $\rho_V$  is a representation affording the character.
3. If  $\chi$  is a character of  $G$ , then  $\chi(s^{-1}) = \overline{\chi(s)}$  and  $\chi(t^{-1}st) = \chi(s)$  for all  $s, t \in G$ .
4. Two characters of  $G$  are equal if and only if representations affording them are equivalent.
5. The number of distinct irreducible characters of  $G$  is the same as the number of conjugacy classes of  $G$ .
6. Every character  $\chi$  of  $G$  can be expressed in the form  $\chi = \sum_{\varphi \in Irr(G)} m_{\varphi} \varphi$ , where  $Irr(G)$  denotes the set of irreducible characters of  $G$  and where each  $m_{\varphi}$  is a nonnegative integer (called the **multiplicity** of  $\varphi$  as a constituent of  $\chi$ ).
7. A nonzero character of  $G$  is irreducible if and only if it is not the sum of two nonzero characters of  $G$ .
8. The kernel of a character equals the kernel of a representation affording the character.
9. The degree of an irreducible character of  $G$  divides the order of  $G$ .
10. A character of  $G$  is linear if and only if it is a homomorphism from  $G$  into the multiplicative group of nonzero complex numbers under multiplication.
11. The group  $G$  is abelian if and only if every irreducible character of  $G$  is linear.
12. The sum of the squares of the irreducible character degrees equals the order of  $G$ .
13. *Irreducible characters of direct products:* Let  $G_1$  and  $G_2$  be finite groups. Denoting by  $Irr(G)$  the set of irreducible characters of the group  $G$ , we have  $Irr(G_1 \times G_2) = Irr(G_1) \times Irr(G_2)$ , where an element  $(\chi_1, \chi_2)$  of the Cartesian product on the right is viewed as a function on the direct product  $G_1 \times G_2$  via  $(\chi_1, \chi_2)(s_1, s_2) = \chi_1(s_1)\chi_2(s_2)$ .
14. *Burnside's Vanishing Theorem:* If  $\chi$  is a nonlinear irreducible character of  $G$ , then  $\chi(s) = 0$  for some  $s \in G$ .

### Examples:

See also examples in the next section.

1. If  $V_1$  and  $V_2$  are  $\mathbb{C}G$ -modules and  $\chi_1$  and  $\chi_2$ , respectively, are the characters of  $G$  they afford, then the direct sum  $V_1 \oplus V_2$  affords the sum  $\chi_1 + \chi_2$  and the tensor product  $V_1 \otimes V_2$  affords the product  $\chi_1 \chi_2$ .
2. If  $V$  is a  $\mathbb{C}G$ -module and  $\chi$  is the character it affords, then the contragredient  $V^*$  affords the complex conjugate character  $\overline{\chi}$ .
3. Let  $X$  be a finite set on which an action of  $G$  is given and let  $\rho$  be the corresponding permutation representation of  $G$  (see Example 3 of Section 68.1). If  $\chi$  is the character afforded by  $\rho$ , then for each  $s \in G$ ,  $\chi(s)$  is the number of ones on the main diagonal of the permutation matrix  $[\rho(s)]_X$ , which is the same as the number of fixed points of  $X$  under the action of  $s$ :  $\chi(s) = |\{x \in X \mid sx = x\}|$ . The matrix representation of  $\mathbf{Z}_3$  given in Example 2 of Section 68.2 is afforded by a permutation representation, namely, the regular representation; it affords the character  $\chi$  given by  $\chi(0) = 3$ ,  $\chi(1) = 0$ ,  $\chi(2) = 0$  in accordance with the statement above.

## 68.4 Orthogonality Relations and Character Table

Throughout,  $G$  denotes a finite group,  $e$  denotes its identity element, and  $V$  denotes a finite dimensional complex vector space.

### Definitions:

A function  $f: G \rightarrow \mathbb{C}$  is called a **class function** if it is constant on the conjugacy classes of  $G$ , that is, if  $f(t^{-1}st) = f(s)$  for all  $s, t \in G$ .

The **inner product** of two functions  $f$  and  $g$  from  $G$  to  $\mathbb{C}$  is the complex number

$$(f, g)_G = \frac{1}{|G|} \sum_{s \in G} f(s) \overline{g(s)}.$$

The **character table** of the group  $G$  is the square array with entry in the  $i$ th row and  $j$ th column equal to the complex number  $\chi_i(c_j)$ , where  $\text{Irr}(G) = \{\chi_1, \dots, \chi_k\}$  is the set of distinct irreducible characters of  $G$  and  $\{c_1, \dots, c_k\}$  is a set consisting of exactly one element from each conjugacy class of  $G$ .

**Facts:**

The following facts can be found in [Isa94, pp. 14–21, 30] or [Ser77, pp.10–19].

1. Each character of  $G$  is a class function.
2. *First Orthogonality Relation:* If  $\varphi$  and  $\psi$  are two irreducible characters of  $G$ , then

$$(\varphi, \psi)_G = \frac{1}{|G|} \sum_{s \in G} \varphi(s) \overline{\psi(s)} = \begin{cases} 1 & \text{if } \varphi = \psi \\ 0 & \text{if } \varphi \neq \psi. \end{cases}$$

3. *Second Orthogonality Relation:* If  $s$  and  $t$  are two elements of  $G$ , then

$$\sum_{\chi \in \text{Irr}(G)} \chi(s) \overline{\chi(t)} = \begin{cases} |G|/c(s) & \text{if } t \text{ is conjugate to } s \\ 0 & \text{if } t \text{ is not conjugate to } s, \end{cases}$$

where  $c(s)$  denotes the number of elements in the conjugacy class of  $s$ .

4. *Generalized Orthogonality Relation:* If  $\varphi$  and  $\psi$  are two irreducible characters of  $G$  and  $t$  is an element of  $G$ , then

$$\frac{1}{|G|} \sum_{s \in G} \varphi(st) \overline{\psi(s)} = \begin{cases} \varphi(t)/\varphi(e) & \text{if } \varphi = \psi \\ 0 & \text{if } \varphi \neq \psi. \end{cases}$$

This generalizes the First Orthogonality Relation (Fact 2).

5. The set of complex-valued functions on  $G$  is a complex inner product space with inner product as defined above. The set of class functions on  $G$  is a subspace.
6. A character  $\chi$  of  $G$  is irreducible if and only if  $(\chi, \chi)_G = 1$ .
7. The set  $\text{Irr}(G)$  of irreducible characters of  $G$  is an orthonormal basis for the inner product space of class functions on  $G$ .
8. If the character  $\chi$  of  $G$  is expressed as a sum of irreducible characters (see Fact 6 of Section 68.3), then the number of times the irreducible character  $\varphi$  appears as a summand is  $(\chi, \varphi)_G$ . In particular,  $\varphi \in \text{Irr}(G)$  is a constituent of  $\chi$  if and only if  $(\chi, \varphi)_G \neq 0$ .
9. Isomorphic groups have identical character tables (up to a reordering of rows and columns). The converse of this statement does not hold since, for example, the dihedral group and the quaternion group (both of order eight) have the same character table, yet they are not isomorphic.

**Examples:**

1. The character table of the group  $\mathbf{Z}_4$  of integers modulo four is

	0	1	2	3
$\chi_0$	1	1	1	1
$\chi_1$	1	$i$	$-1$	$-i$
$\chi_2$	1	$-1$	1	$-1$
$\chi_3$	1	$-i$	$-1$	$i$

2. The character table of the symmetric group  $S_3$  is

	(1)	(12)	(123)
$\chi_0$	1	1	1
$\chi_1$	1	-1	1
$\chi_2$	2	0	-1

Note that  $\chi_2$  is the character afforded by the matrix representation of  $S_3$  given in Example 1 of Section 68.2.

3. The character table of the symmetric group  $S_4$  is

	(1)	(12)	(12)(34)	(123)	(1234)
$\chi_0$	1	1	1	1	1
$\chi_1$	1	-1	1	1	-1
$\chi_2$	2	0	2	-1	0
$\chi_3$	3	1	-1	0	-1
$\chi_4$	3	-1	-1	0	1

4. The character table of the alternating group  $A_4$  is

	(1)	(12)(34)	(123)	(132)
$\chi_0$	1	1	1	1
$\chi_1$	1	1	$\omega$	$\omega^2$
$\chi_2$	1	1	$\omega^2$	$\omega$
$\chi_3$	3	-1	0	0

where  $\omega = e^{2\pi i/3} = -\frac{1}{2} + i\frac{\sqrt{3}}{2}$ .

5. Let  $\rho_V$  be a representation of  $G$  and for each irreducible character  $\varphi$  of  $G$  put

$$T_\varphi = \frac{\varphi(e)}{|G|} \sum_{s \in G} \varphi(s^{-1}) \rho_V(s) : V \rightarrow V.$$

Then the Generalized Orthogonality Relation (Fact 4) shows that

$$T_\varphi T_\psi = \begin{cases} T_\varphi & \text{if } \varphi = \psi \\ 0 & \text{if } \varphi \neq \psi \end{cases}$$

and

$$\sum_{\varphi \in \text{Irr}(G)} T_\varphi = 1_V,$$

where  $1_V$  denotes the identity operator on  $V$ . Moreover,  $V = \bigoplus_{\varphi \in \text{Irr}(G)} T_\varphi(V)$  (internal direct sum).

## 68.5 Restriction and Induction of Characters

Throughout,  $G$  denotes a finite group,  $e$  denotes its identity element, and  $V$  denotes a finite dimensional complex vector space.

### Definitions:

If  $\chi$  is a character of  $G$  and  $H$  is a subgroup of  $G$ , then the **restriction** of  $\chi$  to  $H$  is the character  $\chi_H$  of  $H$  obtained by restricting the domain of  $\chi$ .

A character  $\varphi$  of a subgroup  $H$  of  $G$  is **extendible** to  $G$  if  $\varphi = \chi_H$  for some character  $\chi$  of  $G$ .

If  $\varphi$  is a character of a subgroup  $H$  of  $G$ , then the **induced character** from  $H$  to  $G$  is the character  $\varphi^G$  of  $G$  given by the formula

$$\varphi^G(s) = \frac{1}{|H|} \sum_{t \in G} \varphi^\circ(t^{-1}st),$$

where  $\varphi^\circ$  is defined by  $\varphi^\circ(x) = \varphi(x)$  if  $x \in H$  and  $\varphi^\circ(x) = 0$  if  $x \notin H$ .

If  $\varphi$  is a character of a subgroup  $H$  of  $G$  and  $s$  is an element of  $G$ , then the **conjugate character** of  $\varphi$  by  $s$  is the character  $\varphi^s$  of  $H^s = s^{-1}Hs$  given by  $\varphi^s(h^s) = \varphi(h)$  ( $h \in H$ ), where  $h^s = s^{-1}hs$ .

### Facts:

The following facts can be found in [Isa94, pp. 62–63, 73–79] or [Ser77, pp. 55–58].

1. The restricted character defined above is indeed a character:  $\chi_H$  is afforded by the restriction to  $H$  of a representation affording  $\chi$ .
2. The induced character defined above is indeed a character: Let  $V$  be a  $\mathbb{C}H$ -module affording  $\varphi$  and put  $V^G = \bigoplus_{t \in T} V_t$ , where  $G = \bigcup_{t \in T} tH$  (disjoint union) and  $V_t = V$  for each  $t$ . Then  $V^G$  is a  $\mathbb{C}G$ -module that affords  $\varphi^G$ , where the action is given as follows: For  $s \in G$  and  $v \in V_t$ ,  $sv$  is the element  $hv$  of  $V_{t'}$ , where  $st = t'h$  ( $t' \in T, h \in H$ ).
3. The conjugate character defined above is indeed a character:  $\varphi^s$  is afforded by the representation of  $H^s$  obtained by composing the homomorphism  $H^s \rightarrow H, h^s \mapsto h$  with a representation affording  $\varphi$ .
4. *Additivity of restriction:* Let  $H$  be a subgroup of  $G$ . If  $\chi$  and  $\chi'$  are characters of  $G$ , then  $(\chi + \chi')_H = \chi_H + \chi'_H$ .
5. *Additivity of induction:* Let  $H$  be a subgroup of  $G$ . If  $\varphi$  and  $\varphi'$  are characters of  $H$ , then  $(\varphi + \varphi')^G = \varphi^G + \varphi'^G$ .
6. *Transitivity of induction:* Let  $H$  and  $K$  be subgroups of  $G$  with  $H \subseteq K$ . If  $\varphi$  is a character of  $H$ , then  $(\varphi^K)^G = \varphi^G$ .
7. *Degree of induced character:* If  $H$  is a subgroup of  $G$  and  $\varphi$  is a character of  $H$ , then the degree of the induced character  $\varphi^G$  equals the product of the index of  $H$  in  $G$  and the degree of  $\varphi$ :  $\varphi^G(e) = [G : H]\varphi(e)$ .
8. Let  $\chi$  be a character of  $G$  and let  $H$  be a subgroup of  $G$ . If the restriction  $\chi_H$  is irreducible, then so is  $\chi$ . The converse of this statement does not hold. In fact, if  $H$  is the trivial subgroup then  $\chi_H = \chi(e)1_H$ , so any nonlinear irreducible character (e.g.,  $\chi_2$  in Example 2 of section 68.4) provides a counterexample.
9. Let  $H$  be a subgroup of  $G$  and let  $\varphi$  be a character of  $H$ . If the induced character  $\varphi^G$  is irreducible, then so is  $\varphi$ . The converse of this statement does not hold (see Example 3).
10. Let  $H$  be a subgroup of  $G$ . If  $\varphi$  is an irreducible character of  $H$ , then there exists an irreducible character  $\chi$  of  $G$  such that  $\varphi$  is a constituent of  $\chi_H$ .
11. *Frobenius Reciprocity:* If  $\chi$  is a character of  $G$  and  $\varphi$  is a character of a subgroup  $H$  of  $G$ , then  $(\varphi^G, \chi)_G = (\varphi, \chi_H)_H$ .
12. If  $\chi$  is a character of  $G$  and  $\varphi$  is a character of a subgroup  $H$  of  $G$ , then  $(\varphi_{\chi_H})^G = \varphi^G \chi$ .
13. *Mackey's Subgroup Theorem:* If  $H$  and  $K$  are subgroups of  $G$  and  $\varphi$  is a character of  $H$ , then  $(\varphi^G)_K = \sum_{t \in T} (\varphi^t_{H' \cap K})^K$ , where  $T$  is a set of representatives for the  $(H, K)$ -double cosets in  $G$  (so that  $G = \bigcup_{t \in T} HtK$ , a disjoint union).
14. If  $\varphi$  is a character of a normal subgroup  $N$  of  $G$ , then for each  $s \in G$ , the conjugate  $\varphi^s$  is a character of  $N$ . Moreover,  $\varphi^s(n) = \varphi(sns^{-1})$  ( $n \in N$ ).
15. *Clifford's Theorem:* Let  $N$  be a normal subgroup of  $G$ , let  $\chi$  be an irreducible character of  $G$ , and let  $\varphi$  be an irreducible constituent of  $\chi_N$ . Then  $\chi_N = m \sum_{i=1}^h \varphi_i$ , where  $\varphi_1, \dots, \varphi_h$  are the distinct conjugates of  $\varphi$  under the action of  $G$  and  $m = (\chi_N, \varphi)_N$ .

**Examples:**

1. Given a subgroup  $H$  of  $G$ , the induced character  $(1_H)^G$  equals the permutation character corresponding to the action of  $G$  on the set of left cosets of  $H$  in  $G$  given by  $s(tH) = (st)H$  ( $s, t \in G$ ).
2. The induced character  $(1_{\{e\}})^G$  equals the permutation character corresponding to the action of  $G$  on itself given by left multiplication. It is the character of the (left) regular representation of  $G$ . This character satisfies

$$(1_{\{e\}})^G(s) = \begin{cases} |G| & \text{if } s = e \\ 0 & \text{if } s \neq e. \end{cases}$$

3. As an illustration of Frobenius Reciprocity (Fact 11), we have  $((1_{\{e\}})^G, \chi)_G = (1_{\{e\}}, \chi_{\{e\}})_{\{e\}} = \chi(e)$  for any irreducible character  $\chi$  of  $G$ . Hence,  $(1_{\{e\}})^G = \sum_{\chi \in \text{Irr}(G)} \chi(e)\chi$  (cf. Fact 8 of section 68.4), that is, in the character of the regular representation (see Example 2), each irreducible character appears as a constituent with multiplicity equal to its degree.

## 68.6 Representations of the Symmetric Group

---

**Definitions:**

Given a natural number  $n$ , a tuple  $\alpha = [\alpha_1, \dots, \alpha_h]$  of nonnegative integers is a (**proper**) **partition** of  $n$  (written  $\alpha \vdash n$ ) provided

- $\alpha_i \geq \alpha_{i+1}$  for all  $1 \leq i < h$ ,
- $\sum_{i=1}^h \alpha_i = n$ .

The **conjugate partition** of a partition  $\alpha \vdash n$  is the partition  $\alpha' \vdash n$  with  $i$ th component  $\alpha'_i$  equal to the number of indices  $j$  for which  $\alpha_j \geq i$ . This partition is also called the **partition associated with  $\alpha$** .

Given two partitions  $\alpha = [\alpha_1, \dots, \alpha_h]$  and  $\beta = [\beta_1, \dots, \beta_k]$  of  $n$ ,  $\alpha$  **majorizes** (or **dominates**)  $\beta$  if

$$\sum_{i=1}^j \alpha_i \geq \sum_{i=1}^j \beta_i$$

for each  $1 \leq j \leq h$ . This is expressed by writing  $\alpha \geq \beta$  (or  $\beta \leq \alpha$ ).

The **Young subgroup** of the symmetric group  $S_n$  corresponding to a partition  $\alpha = [\alpha_1, \dots, \alpha_h]$  of  $n$  is the internal direct product  $S_\alpha = S_{A_1} \times \dots \times S_{A_h}$ , where  $S_{A_i}$  is the subgroup of  $S_n$  consisting of those permutations that fix every integer *not* in the set

$$A_i = \left\{ 1 \leq k \leq n \mid \sum_{j=1}^{i-1} \alpha_j < k \leq \sum_{j=1}^i \alpha_j \right\}$$

(an empty sum being interpreted as zero).

The **alternating character** of the symmetric group  $S_n$  is the character  $\epsilon_n$  given by

$$\epsilon_n(\sigma) = \begin{cases} 1 & \text{if } \sigma \text{ is even,} \\ -1 & \text{if } \sigma \text{ is odd.} \end{cases}$$

Let  $G$  be a subgroup of  $S_n$  and let  $\chi$  be a character of  $G$ . The **generalized matrix function**  $d_\chi : \mathbb{C}^{n \times n} \rightarrow \mathbb{C}$  is defined by

$$d_\chi(A) = \sum_{s \in G} \chi(s) \prod_{j=1}^n a_{js(j)}.$$

When  $G = S_n$  and  $\chi$  is irreducible,  $d_\chi$  is called an **immanant**.

**Facts:**

The following facts can be found in [JK81, pp. 15, 35–37] or [Mer97, pp. 99–103, 214].

1. If  $\chi$  is a character of the symmetric group  $S_n$ , then  $\chi(\sigma)$  is an integer for each  $\sigma \in S_n$ .
2. *Irreducible character associated with a partition:* Given a partition  $\alpha$  of  $n$ , there is a unique irreducible character  $\chi_\alpha$  that is a constituent of both the induced character  $(1_{S_\alpha})^{S_n}$  and the induced character  $((\epsilon_n)_{S_{\alpha'}})^{S_n}$ . The map  $\alpha \mapsto \chi_\alpha$  defines a bijection from the set of partitions of  $n$  to the set  $\text{Irr}(S_n)$  of irreducible characters of  $S_n$ .
3. If  $\alpha$  and  $\beta$  are partitions of  $n$ , then the irreducible character  $\chi_\alpha$  is a constituent of the induced character  $(1_{S_\beta})^{S_n}$  if and only if  $\alpha$  majorizes  $\beta$ .
4. If  $\alpha$  is a partition of  $n$ , then  $\chi_{\alpha'} = \epsilon_n \chi_\alpha$ .
5. *Schur's inequality:* Let  $\chi$  be an irreducible character of a subgroup  $G$  of  $S_n$ . For any positive semidefinite matrix  $A \in \mathbb{C}^{n \times n}$ ,  $d_\chi(A)/\chi(e) \geq \det A$ .

**Examples:**

1.  $\alpha = [5, 3^2, 2, 1^3]$  (meaning  $[5, 3, 3, 2, 1, 1, 1]$ ) is a partition of 16. Its conjugate is  $\alpha' = [7, 4, 3, 1, 1]$ .
2.  $\chi_{[n]} = 1_{S_n}$  and  $\chi_{[1^n]} = \epsilon_n$ .
3. In the notation of Example 3 of section 68.4, we have  $\chi_0 = \chi_{[4]}$ ,  $\chi_1 = \chi_{[1^4]}$ ,  $\chi_2 = \chi_{[2^2]}$ ,  $\chi_3 = \chi_{[3,1]}$ , and  $\chi_4 = \chi_{[2,1^2]}$ .
4. According to Fact 4, a partition  $\alpha$  of  $n$  is self-conjugate (meaning  $\alpha' = \alpha$ ) if and only if  $\chi_\alpha(\sigma) = 0$  for every odd permutation  $\sigma \in S_n$ .
5. As an illustration of Fact 3, we have

$$(1_{S_{[2,1^2]}})^{S_4} = \chi_{[4]} + \chi_{[3,1]} + \chi_{[3,1]} + \chi_{[2^2]} + \chi_{[2,1^2]}.$$

The irreducible constituents of the induced character  $(1_{S_{[2,1^2]}})^{S_4}$  are the terms on the right-hand side of the equation. Note that  $[4]$ ,  $[3, 1]$ ,  $[2^2]$ , and  $[2, 1^2]$  are precisely the partitions of 4 that majorize  $[2, 1^2]$  in accordance with the fact.

6. When  $G = S_n$  and  $\chi = \epsilon_n$  (the alternating character),  $d_\chi(A)$  is the determinant of  $A \in \mathbb{C}^{n \times n}$ .
7. When  $G = S_n$  and  $\chi = 1_G$  (the principal character),  $d_\chi(A) = \sum_{s \in G} \prod_{j=1}^n a_{js(j)}$  is called the **permanent** of  $A \in \mathbb{C}^{n \times n}$ , denoted *per*  $A$ .
8. The following open problem is known as the **Permanental Dominance** (or **Permanent-on-Top Conjecture**): Let  $\chi$  be an irreducible character of a subgroup  $G$  of  $S_n$ . For any positive semidefinite matrix  $A \in \mathbb{C}^{n \times n}$ , *per*  $A \geq d_\chi(A)/\chi(e)$  (cf. Fact 5 and Examples 6 and 7).

One of the earliest surveys on nonassociative algebras is the article by Shirshov [Shi58] that introduced the phrase “rings that are nearly associative.” The first book in the English language devoted to a systematic study of nonassociative algebras is Schafer [Sch66]. A comprehensive exposition of the work of the Russian school is Zhevlakov, Slinko, Shestakov, and Shirshov [ZSS82]. A collection of open research problems in algebra, including many problems on nonassociative algebra, is the *Dniester Notebook* [FKS93]; the survey article by Kuzmin and Shestakov [KS95] is from the same period. Three books on Jordan algebras that contain substantial material on general nonassociative algebras are Braun and Koecher [BK66], Jacobson [Jac68], and McCrimmon [McC04]. Recent research appears in the *Proceedings of the International Conferences on Nonassociative Algebra and Its Applications* [Gon94], [CGG00], [SSS06]. The present chapter provides very limited information on Lie algebras, since they are the subject of Chapter 70. The last section (Section 69.9) presents three applications of computational linear algebra to the study of polynomial identities for nonassociative algebras: Pseudorandom vectors in a nonassociative algebra, the expansion matrix for a nonassociative operation, and the representation theory of the symmetric group.

### 69.1 Introduction

---

#### Definitions:

An **algebra** is a vector space  $A$  over a field  $F$  together with a bilinear **multiplication**  $(x, y) \mapsto xy$  from  $A \times A$  to  $A$ ; that is, **distributivity** holds for all  $a, b \in F$  and all  $x, y, z \in A$ :

$$(ax + by)z = a(xz) + b(yz), \quad x(ay + bz) = a(xy) + b(xz).$$

The **dimension** of an algebra  $A$  is its dimension as a vector space.

An algebra  $A$  is **finite dimensional** if  $A$  is a finite dimensional vector space.

The **structure constants** of a finite dimensional algebra  $A$  over  $F$  with basis  $\{x_1, \dots, x_n\}$  are the scalars  $c_{ij}^k \in F$  ( $i, j, k = 1, \dots, n$ ) defined by:

$$x_i x_j = \sum_{k=1}^n c_{ij}^k x_k.$$

An algebra  $A$  is **unital** if there exists an element  $1 \in A$  for which

$$1x = x1 = x \quad \text{for all } x \in A.$$

An **involution** of the algebra  $A$  is a linear mapping  $j: A \rightarrow A$  satisfying

$$j(j(x)) = x \quad \text{and} \quad j(xy) = j(y)j(x) \quad \text{for all } x, y \in A.$$

An algebra  $A$  is a **division algebra** if for every  $x, y \in A$  with  $x \neq 0$  the equations  $xv = y$  and  $wx = y$  are solvable in  $A$ .

The **associator** in an algebra is the trilinear function

$$(x, y, z) = (xy)z - x(yz).$$

An algebra  $A$  is **associative** if the associator vanishes identically:

$$(x, y, z) = 0 \quad \text{for all } x, y, z \in A.$$

An algebra is **nonassociative** if the above identity is not necessarily satisfied.

An algebra  $A$  is **alternative** if it satisfies the **right and left alternative identities**

$$(y, x, x) = 0 \quad \text{and} \quad (x, x, y) = 0 \quad \text{for all } x, y \in A.$$

An algebra  $A$  is **anticommutative** if it satisfies the identity

$$x^2 = 0 \quad \text{for all } x \in A.$$

(This implies that  $xy = -yx$ , and the converse holds in characteristic  $\neq 2$ .)

The **Jacobian** in an anticommutative algebra is defined by

$$J(x, y, z) = (xy)z + (yz)x + (zx)y.$$

A **Lie algebra** is an anticommutative algebra satisfying the **Jacobi identity**

$$J(x, y, z) = 0 \quad \text{for all } x, y, z \in A.$$

A **Malcev algebra** is an anticommutative algebra satisfying the identity

$$J(x, y, xz) = J(x, y, z)x \quad \text{for all } x, y, z \in A.$$

The **commutator** in an algebra  $A$  is the bilinear function

$$[x, y] = xy - yx.$$

The **minus algebra**  $A^-$  of an algebra  $A$  is the algebra with the same underlying vector space as  $A$  but with  $[x, y]$  as the multiplication.

An algebra  $A$  is **commutative** if it satisfies the identity

$$xy = yx \quad \text{for all } x, y \in A.$$

A **Jordan algebra** is a commutative algebra satisfying the **Jordan identity**

$$(x^2, y, x) = 0 \quad \text{for all } x, y \in A.$$

The **Jordan product** (or **anticommutator**) in an algebra  $A$  is the bilinear function

$$x * y = xy + yx.$$

(The notation  $x \circ y$  is also common.)

The **plus algebra**  $A^+$  of an algebra  $A$  over a field  $F$  of characteristic  $\neq 2$  is the algebra with the same underlying vector space as  $A$  but with  $x \cdot y = \frac{1}{2}(x * y)$  as the multiplication.

A Jordan algebra is called **special** if it is isomorphic to a subalgebra of  $A^+$  for some associative algebra  $A$ ; otherwise it is called **exceptional**.

Given two algebras  $A$  and  $B$  over a field  $F$ , a **homomorphism** from  $A$  to  $B$  is a linear mapping  $f: A \rightarrow B$  that satisfies  $f(xy) = f(x)f(y)$  for all  $x, y \in A$ .

An **isomorphism** is a homomorphism that is a linear isomorphism of vector spaces.

Let  $A$  be an algebra. Given two subsets  $B, C \subseteq A$  we write  $BC$  for the **subspace spanned by the products**  $yz$  where  $y \in B, z \in C$ .

A **subalgebra** of  $A$  is a subspace  $B$  satisfying  $BB \subseteq B$ .

The **subalgebra generated by a set**  $S \subseteq A$  is the smallest subalgebra of  $A$  containing  $S$ .

A (two-sided) **ideal** of an algebra  $A$  is a subalgebra  $B$  satisfying  $AB + BA \subseteq B$ .

Given two algebras  $A$  and  $B$  over the field  $F$ , the **(external) direct sum** of  $A$  and  $B$  is the vector space direct sum  $A \oplus B$  with the multiplication

$$(w, x)(y, z) = (wy, xz) \quad \text{for all } w, y \in A \quad \text{and all } x, z \in B.$$

Given an algebra  $A$  with two ideals  $B$  and  $C$ , we say that  $A$  is the **(internal) direct sum** of  $B$  and  $C$  if  $A = B \oplus C$  (direct sum of subspaces).

**Facts:** ([Shi58], [Sch66], [ZSS82], [KS95])

1. Every finite dimensional associative algebra over a field  $F$  is isomorphic to a subalgebra of a matrix algebra  $F^{n \times n}$  for some  $n$ .
2. The algebra  $A^-$  is always anticommutative. If  $A$  is associative, then  $A^-$  is a Lie algebra.
3. (Poincaré–Birkhoff–Witt Theorem or PBW Theorem) Every Lie algebra is isomorphic to a subalgebra of  $A^-$  for some associative algebra  $A$ .
4. The algebra  $A^+$  is always commutative. If  $A$  is associative, then  $A^+$  is a Jordan algebra. (See Example 2 in Section 69.9.) If  $A$  is alternative, then  $A^+$  is a Jordan algebra.
5. The analogue of the PBW theorem for Jordan algebras is false: Not every Jordan algebra is special. (See Example 4 below.)
6. Every associative algebra is alternative.
7. (Artin's Theorem) An algebra is alternative if and only if every subalgebra generated by two elements is associative.
8. Every Lie algebra is a Malcev algebra.
9. Every Malcev algebra generated by two elements is a Lie algebra.
10. If  $A$  is an alternative algebra, then  $A^-$  is a Malcev algebra. (See Example 3 in Section 69.9.)
11. In an external direct sum of algebras, the summands are ideals.

**Examples:**

1. Associativity is satisfied when the elements of the algebra are mappings of a set into itself with the composition of mappings taken as multiplication. Such is the multiplication in the algebra  $\text{End } V$ , the algebra of linear operators on the vector space  $V$ . Every associative algebra is isomorphic to a subalgebra of the algebra  $\text{End } V$ , for some  $V$ . Thus, the condition of associativity of multiplication

characterizes the **algebras of linear operators**. (Note that  $\text{End } V$  is also denoted  $L(V, V)$  elsewhere in this book, but  $\text{End } V$  is the standard notation in the study of algebras.)

2. **Cayley–Dickson doubling process.** Let  $A$  be a unital algebra over  $F$  with an involution  $x \mapsto \bar{x}$  satisfying

$$x + \bar{x}, x\bar{x} \in F \quad \text{for all } x \in A. \quad (69.1)$$

Let  $a \in F, a \neq 0$ . The algebra  $(A, a)$  is defined as follows: The underlying vector space is  $A \oplus A$ , addition and scalar multiplication are defined by the vector space formulas

$$(x_1, x_2) + (y_1, y_2) = (x_1 + y_1, x_2 + y_2), \quad c(x_1, x_2) = (cx_1, cx_2) \quad \text{for all } c \in F, \quad (69.2)$$

and multiplication is defined by the formula

$$(x_1, x_2)(y_1, y_2) = (x_1y_1 + ay_2\bar{x}_2, \bar{x}_1y_2 + y_1x_2). \quad (69.3)$$

This algebra has an involution defined by

$$\overline{(x_1, x_2)} = (\bar{x}_1, -x_2). \quad (69.4)$$

In particular, starting with a field  $F$  of characteristic  $\neq 2$ , we obtain the following examples:

- (a) The algebra  $\mathbb{C}(a) = (F, a)$  is commutative and associative. If the polynomial  $x^2 + a$  is irreducible over  $F$ , then  $\mathbb{C}(a)$  is a field, otherwise  $\mathbb{C}(a) \cong F \oplus F$  (algebra direct sum).
- (b) The algebra  $\mathbb{H}(a, b) = (\mathbb{C}(a), b)$  is an algebra of **generalized quaternions**, which is associative but not commutative.
- (c) The algebra  $\mathbb{O}(a, b, c) = (\mathbb{H}(a, b), c)$  is an algebra of **generalized octonions** or a **Cayley–Dickson algebra**, which is alternative but not associative. (See Example 1 in Section 69.9.)

The algebras of generalized quaternions and octonions may also be defined over a field of characteristic 2 (see [Sch66], [ZSS82]).

3. **Real division algebras** [EHH91, Part B]. In the previous example, taking  $F$  to be the field  $\mathbb{R}$  of real numbers and  $a = b = c = -1$ , we obtain the field  $\mathbb{C}$  of **complex numbers**, the associative division algebra  $\mathbb{H}$  of **quaternions**, and the alternative division algebra  $\mathbb{O}$  of **octonions** (also known as the **Cayley numbers**). Real division algebras exist only in dimensions 1, 2, 4, and 8, but there are many other examples: The algebras  $\mathbb{C}$ ,  $\mathbb{H}$ , and  $\mathbb{O}$  with the multiplication  $x \cdot y = \bar{x}\bar{y}$  are still division algebras, but they are not alternative and they are not unital.
4. **The Albert algebra.** Let  $\mathbb{O}$  be the octonions and let  $M_3(\mathbb{O})$  be the algebra of  $3 \times 3$  matrices over  $\mathbb{O}$  with involution induced by the involution of  $\mathbb{O}$ , that is  $(a_{ij}) \mapsto (\bar{a}_{ji})$ . The subalgebra  $H_3(\mathbb{O})$  of Hermitian matrices in  $M_3(\mathbb{O})^+$  is an exceptional Jordan algebra, the Albert algebra: There is no associative algebra  $A$  such that  $H_3(\mathbb{O})$  is isomorphic to a subalgebra of  $A^+$ .

## 69.2 General Properties

### Definitions:

Given an algebra  $A$  and an ideal  $I$ , the **quotient algebra**  $A/I$  is the quotient space  $A/I$  with multiplication defined by  $(x + I)(y + I) = xy + I$  for all  $x, y \in A$ .

The algebra  $A$  is **simple** if  $AA \neq \{0\}$  and  $A$  has no ideals apart from  $\{0\}$  and  $A$ .

The algebra  $A$  is **semisimple** if it is the direct sum of simple algebras. (The definition of semisimple that is used in the theory of Lie algebras is different; see Chapter 70.)

Set  $A^1 = A^{(1)} = A$ , and then by induction define

$$A^{n+1} = \sum_{i+j=n+1} A^i A^j \quad \text{and} \quad A^{(n+1)} = A^{(n)} A^{(n)} \quad \text{for } n \geq 1.$$

The algebra  $A$  is **nilpotent** if  $A^n = \{0\}$  for some  $n$  and **solvable** if  $A^{(s)} = \{0\}$  for some  $s$ . The smallest natural number  $n$  (respectively  $s$ ) with this property is the **nilpotency index** (respectively, **solvability index**) of  $A$ .

An element  $x \in A$  is **nilpotent** if the subalgebra it generates is nilpotent.

A **nil algebra** (respectively **nil ideal**) is an algebra (respectively ideal) in which every element is nilpotent.

An algebra is **power associative** if every element generates an associative subalgebra.

An **idempotent** is an element  $e \neq 0$  of an algebra  $A$  satisfying  $e^2 = e$ . Two idempotents  $e, f$  are **orthogonal** if  $ef = fe = 0$ .

For an algebra  $A$  over a field  $F$ , the **degree** of  $A$  is defined to be the maximal number of mutually orthogonal idempotents in the scalar extension  $\overline{F} \otimes_F A$ , where  $\overline{F}$  is the algebraic closure of  $F$ .

The **associator ideal**  $D(A)$  of the algebra  $A$  is the ideal generated by all the associators. The **associative center** or **nucleus**  $N(A)$  of  $A$  is defined by

$$N(A) = \{ x \in A \mid (x, A, A) = (A, x, A) = (A, A, x) = \{0\} \}.$$

The **center**  $Z(A)$  of the algebra  $A$  is defined by

$$Z(A) = \{ x \in N(A) \mid [x, A] = \{0\} \}.$$

The **right and left multiplication operators** by an element  $x \in A$  are defined by

$$R_x: y \mapsto yx, \quad L_x: y \mapsto xy.$$

The **multiplication algebra** of the algebra  $A$  is the subalgebra  $M(A)$  of the associative algebra  $\text{End } A$  (of endomorphisms of the vector space  $A$ ) generated by all  $R_x$  and  $L_x$  for  $x \in A$ .

The **right multiplication algebra** of the algebra  $A$  is the subalgebra  $R(A)$  of  $\text{End } A$  generated by all  $R_x$  for  $x \in A$ .

The **centroid**  $C(A)$  of the algebra  $A$  is the centralizer of the multiplication algebra  $M(A)$  in the algebra  $\text{End } A$ ; that is,

$$C(A) = \{ T \in \text{End } A \mid TR_x = R_x T = R_{Tx}, \quad TL_x = L_x T = L_{Tx}, \quad \text{for any } x \in A \}.$$

An algebra  $A$  over a field  $F$  is **central** if  $C(A) = F$ .

The **unital hull**  $A^\sharp$  of an algebra  $A$  over a field  $F$  is defined as follows: If  $A$  is unital, then  $A^\sharp = A$ ; and when  $A$  has no unit, we set  $A^\sharp = A \oplus F$  (vector space direct sum) and define multiplication by assuming that  $A$  is a subalgebra and the unit of  $F$  is the unit of  $A^\sharp$ .

Let  $\mathcal{M}$  be a class of algebras closed under homomorphic images. A subclass  $\mathcal{R}$  of  $\mathcal{M}$  is said to be **radical** if

1.  $\mathcal{R}$  is closed under homomorphic images.
2. For each  $A \in \mathcal{M}$  there is an ideal  $\mathcal{R}(A)$  of  $A$  such that  $\mathcal{R}(A) \in \mathcal{R}$  and  $\mathcal{R}(A)$  contains every ideal of  $A$  contained in  $\mathcal{R}$ .
3.  $\mathcal{R}(A/\mathcal{R}(A)) = \{0\}$ .

In this case, we call the ideal  $\mathcal{R}(A)$  the  **$\mathcal{R}$ -radical** of  $A$ . The algebra  $A$  is said to be  **$\mathcal{R}$ -semisimple** if  $\mathcal{R}(A) = \{0\}$ .

If the subclass  $\text{Nil}$  of nil-algebras is radical in the class  $\mathcal{M}$ , then the corresponding ideal  $\text{Nil } A$ , for  $A \in \mathcal{M}$ , is called the **nil radical** of  $A$ . In this case, the algebra  $A$  is called **nil-semisimple** if  $\text{Nil } A = \{0\}$ . By definition,  $\text{Nil } A$  contains all two-sided nil-ideals of  $A$ , and the quotient algebra  $A/\text{Nil } A$  is nil-semisimple, that is,  $\text{Nil } (A/\text{Nil } A) = \{0\}$ .

If the subclass *Nilp* of nilpotent algebras (or the subclass *Solv* of solvable algebras) is radical in the class  $\mathcal{M}$ , then the corresponding ideal  $\text{Nilp } A$  (respectively  $\text{Solv } A$ ), for  $A \in \mathcal{M}$ , is called the **nilpotent radical** (respectively the **solvable radical**) of  $A$ .

For an algebra  $A$  over  $F$ , an  $A$ -**bimodule** is a vector space  $M$  over  $F$  with bilinear mappings

$$A \times M \rightarrow M, (x, m) \mapsto xm \quad \text{and} \quad M \times A \rightarrow M, (m, x) \mapsto mx.$$

The **split null extension**  $E(A, M)$  of  $A$  by  $M$  is the algebra over  $F$  with underlying vector space  $A \oplus M$  and multiplication

$$(x + m)(y + n) = xy + (xn + my) \quad \text{for all } x, y \in A, m, n \in M.$$

For an algebra  $A$ , the **regular bimodule**  $\text{Reg}(A)$  is the underlying vector space of  $A$  considered as an  $A$ -bimodule, interpreting  $mx$  and  $xm$  as multiplication in  $A$ .

If  $M$  is an  $A$ -bimodule, then the mappings

$$\rho(x): m \mapsto mx, \quad \lambda(x): m \mapsto xm,$$

are linear operators on  $M$ , and the mappings

$$x \mapsto \rho(x), \quad x \mapsto \lambda(x),$$

are linear mappings from  $A$  to the algebra  $\text{End}_F M$ . The pair  $(\lambda, \rho)$  is called the **birepresentation** of  $A$  associated with the bimodule  $M$ .

The notions of **sub-bimodule**, **homomorphism of bimodules**, **irreducible bimodule**, and **faithful birepresentation** are defined in the natural way. The sub-bimodules of a regular  $A$ -bimodule are exactly the two-sided ideals of  $A$ .

**Facts:** ([Sch66], [Jac68], [ZSS82])

1. If  $A$  is a simple algebra, then  $AA = A$ .
2. (Isomorphism theorems)
  - (a) If  $f: A \rightarrow B$  is a homomorphism of algebras over the field  $F$ , then  $A/\ker(f) \cong \text{im}(f) \subseteq B$ .
  - (b) If  $B_1$  and  $B_2$  are ideals of the algebra  $A$  with  $B_2 \subseteq B_1$ , then  $(A/B_2)/(B_1/B_2) \cong A/B_1$ .
  - (c) If  $S$  is a subalgebra of  $A$  and  $B$  is an ideal of  $A$ , then  $B \cap S$  is an ideal of  $S$  and  $(B + S)/B \cong S/(B \cap S)$ .
3. The algebra  $A$  is nilpotent of index  $n$  if and only if any product of  $n$  elements (with any arrangement of parentheses) equals zero, and if there exists a nonzero product of  $n - 1$  elements.
4. Every nilpotent algebra is solvable; the converse is not generally true. (See Example 1 below.)
5. In any algebra  $A$ , the sum of two solvable ideals is again a solvable ideal. If  $A$  is finite-dimensional, then  $A$  contains a unique maximal solvable ideal  $\text{Solv } A$ , and the quotient algebra  $A/\text{Solv } A$  does not contain nonzero solvable ideals. In other words, the subclass *Solv* of solvable algebras is radical in the class of all finite dimensional algebras.
6. An algebra  $A$  is associative if and only if  $D(A) = \{0\}$ , if and only if  $N(A) = A$ .
7. Every solvable associative algebra is nilpotent.
8. The subclass *Nilp* of nilpotent algebras is radical in the class of all finite dimensional associative algebras.
9. A finite dimensional associative algebra  $A$  is semisimple if and only if  $\text{Nilp } A = \{0\}$ .
10. The previous two facts imply that every finite dimensional associative algebra  $A$  contains a unique maximal nilpotent ideal  $N$  such that the quotient algebra  $A/N$  is isomorphic to a direct sum of simple algebras.

11. Over an algebraically closed field  $F$ , every finite dimensional simple associative algebra is isomorphic to the algebra  $F^{n \times n}$  of  $n \times n$  matrices over  $F$ , for some  $n \geq 1$ .
12. The subclass  $Nilp$  is not radical in the class of finite dimensional Lie algebras. (See Example 1 below.)
13. Over a field of characteristic zero, an algebra is power associative if and only if

$$x^2x = xx^2 \quad \text{and} \quad (x^2x)x = x^2x^2 \quad \text{for all } x.$$

14. Every power associative algebra  $A$  contains a unique maximal nil ideal  $Nil A$ , and the quotient algebra  $A/Nil A$  is nil-semisimple, that is, it does not contain nonzero nil ideals. In other words, the subclass  $Nil$  of nil-algebras is radical in the class of all power associative algebras.
15. For a finite dimensional alternative or Jordan algebra  $A$  we have  $Nil A = Solv A$ .
16. For finite dimensional commutative power associative algebras, the question of the equality of the nil and solvable radicals is still open, and is known as *Albert's problem*. An equivalent question is: Are there any simple finite dimensional commutative power associative nil algebras?
17. Every nil-semisimple finite dimensional commutative power associative algebra over a field of characteristic  $\neq 2, 3, 5$  has a unit element and decomposes into a direct sum of simple algebras. Every such simple algebra is either a Jordan algebra or a certain algebra of degree 2 over a field of positive characteristic.
18. Direct expansion shows that these two identities are valid in every algebra:

$$\begin{aligned} x(y, z, w) + (x, y, z)w &= (xy, z, w) - (x, yz, w) + (x, y, zw), \\ [xy, z] - x[y, z] - [x, z]y &= (x, y, z) - (x, z, y) + (z, x, y). \end{aligned}$$

From these it follows that the associative center and the center are subalgebras, and

$$D(A) = (A, A, A) + (A, A, A)A = (A, A, A) + A(A, A, A).$$

19. If  $z \in Z(A)$ , then for any  $x \in A$  we have

$$R_z R_x = R_x R_z = R_{zx} = R_{xz}.$$

20. If  $A$  is unital, then its centroid  $C(A)$  is isomorphic to its center  $Z(A)$ . If  $A$  is simple, then  $C(A)$  is a field which contains the base field  $F$ .
21. Let  $A$  be a finite dimensional algebra with multiplication algebra  $M(A)$ . Then
  - (a)  $A$  is nilpotent if and only if  $M(A)$  is nilpotent.
  - (b) If  $A$  is semisimple, then so is  $M(A)$ .
  - (c) If  $A$  is simple, then so is  $M(A)$ , and  $M(A) \cong \text{End}_{C(A)} A$ .
22. An algebra  $A$  is simple if and only if the bimodule  $\text{Reg}(A)$  is irreducible.
23. If  $A$  is an alternative algebra (respectively a Jordan algebra), then its unital hull  $A^\sharp$  is also alternative (respectively Jordan).

**Examples:**

1. Let  $A$  be algebra with basis  $x, y$ , and multiplication given by  $x^2 = y^2 = 0$  and  $xy = -yx = y$ . Then  $A$  is a Lie algebra and  $A^{(2)} = \{0\}$  but  $A^n \neq \{0\}$  for any  $n \geq 1$ . Thus,  $A$  is solvable but not nilpotent.
2. Let  $A$  be an algebra over a field  $F$  with basis  $x_1, x_2, y, z$  and the following nonzero products of basis elements:

$$yx_1 = ax_1y = x_2, \quad zx_2 = ax_2z = x_1,$$

where  $0 \neq a \in F$ . Then  $I_1 = Fx_1 + Fx_2 + Fy$  and  $I_2 = Fx_1 + Fx_2 + Fz$  are different maximal nilpotent ideals in  $A$ . By choosing  $a = 1$  or  $a = -1$  we obtain a commutative or anticommutative algebra  $A$ .

3. In general, in a nonassociative algebra, a power of an element is not uniquely determined. In the previous example, for the element  $w = x_1 + x_2 + y + z$  we have

$$w^2w^2 = 0 \quad \text{but} \quad w(ww^2) = (1+a)(x_1 + x_2).$$

4. Let  $A_1, \dots, A_n$  be simple algebras over a field  $F$  with bases

$$\{v_i^1 \mid i \in I_1\}, \dots, \{v_i^n \mid i \in I_n\}.$$

Consider the algebra  $A = Fe \oplus A_1 \oplus \dots \oplus A_n$  (vector space direct sum) with multiplication defined by the following conditions:

- (a) The  $A_i$  are subalgebras of  $A$ .
- (b)  $A_i A_j = \{0\}$  for  $i \neq j$ .
- (c)  $ev_i^j = v_i^j e = e$  for all  $i, j$ .
- (d)  $e^2 = e$ .

Then  $I = Fe$  is the unique minimal ideal in  $A$ , and  $I^2 = I$ . In particular,  $\text{Solv } A = \{0\}$ , but  $A$  is not semisimple (compare with the Lie algebra case).

5. **Suttles' example.** (Notices AMS 19 (1972) A-566) Let  $A$  be a commutative algebra over a field  $F$  of characteristic  $\neq 2$ , with basis  $x_i$  ( $1 \leq i \leq 5$ ) and the following multiplication table (all other products are zero):

$$x_1x_2 = x_2x_4 = -x_1x_5 = x_3, \quad x_1x_3 = x_4, \quad x_2x_3 = x_5.$$

Then  $A$  is a solvable power associative nil algebra that is not nilpotent. Moreover,  $\text{Nil } A = \text{Solv } A = A$ , and  $\text{Nilp } A$  does not exist (if  $F$  is infinite then  $A$  has infinitely many maximal nilpotent ideals).

## 69.3 Composition Algebras

### Definitions:

A **composition algebra** is an algebra  $A$  with unit 1 over a field  $F$  of characteristic  $\neq 2$  together with a **norm**  $n(x)$  (a nondegenerate quadratic form on the vector space  $A$ ) that **admits composition** in the sense that

$$n(xy) = n(x)n(y) \quad \text{for all } x \in A.$$

A **quadratic algebra**  $A$  over a field  $F$  is a unital algebra in which every  $x \in A$  satisfies the condition  $x^2 \in \text{Span}(x, 1)$ . In other words, every subalgebra of  $A$  generated by a single element has dimension  $\leq 2$ .

A composition algebra  $A$  is **split** if it contains zero-divisors, that is, if  $xy = 0$  for some nonzero  $x, y \in A$ .

**Facts:** ([Sch66], [Jac68], [ZSS82], [Bae02])

1. Every composition algebra  $A$  is alternative and quadratic. Moreover, every element  $x \in A$  satisfies the equation

$$x^2 - t(x)x + n(x) = 0,$$

where  $t(x)$  is a linear form on  $A$  (the **trace**) and  $n(x)$  is the original quadratic form on  $A$  (the **norm**).

2. For a composition algebra  $A$  the following conditions are equivalent:
  - (a)  $A$  is split;
  - (b)  $n(x) = 0$  for some nonzero  $x \in A$ ;
  - (c)  $A$  contains an idempotent  $e \neq 1$ .
3. Let  $A$  be a unital algebra over a field  $F$  with an involution  $x \mapsto \bar{x}$  satisfying Equation 69.1 from Example 2 of Section 69.1. The Cayley–Dickson doubling process gives the algebra  $(A, a)$  defined by Equations 69.2 to 69.4. It is clear that  $A$  is isomorphically embedded into  $(A, a)$  and that  $\dim(A, a) = 2 \dim A$ . For  $v = (0, 1)$ , we have  $v^2 = a$  and  $(A, a) = A \oplus Av$ . For any  $y = y_1 + y_2v \in (A, a)$ , we have  $\bar{y} = \overline{y_1} - y_2v$ .
4. In a composition algebra  $A$ , the mapping  $x \mapsto \bar{x} = t(x) - x$  is an involution of  $A$  fixing the elements of the field  $F = F \cdot 1$ . Conversely, if  $A$  is an alternative algebra with unit 1 and involution  $x \mapsto \bar{x}$  satisfying Equation 69.1 from Example 2 of Section 69.1, then  $x\bar{x} \in F$  and the quadratic form  $n(x) = x\bar{x}$  satisfies  $n(xy) = n(x)n(y)$ .
5. The mapping  $y \mapsto \bar{y}$  is an involution of  $(A, a)$  extending the involution  $x \mapsto \bar{x}$  of  $A$ . Moreover,  $y + \bar{y}$  and  $y\bar{y}$  are in  $F$  for every  $y \in (A, a)$ . If the quadratic form  $n(x) = x\bar{x}$  is nondegenerate on  $A$ , then the quadratic form  $n(y) = y\bar{y}$  is nondegenerate on  $(A, a)$ , and the form  $n(y)$  admits composition on  $(A, a)$  if and only if  $A$  is associative.
6. Every composition algebra over a field  $F$  of characteristic  $\neq 2$  is isomorphic to  $F$  or to one of the algebras of types  $2a-2c$  obtained from  $F$  by the Cayley–Dickson process as in Example 2 of Section 69.1.
7. Every split composition algebra over a field  $F$  is isomorphic to one of the algebras  $F \oplus F, M_2(F), \text{Zorn}(F)$  described in Examples 2 to 4 below.
8. Every finite dimensional composition algebra without zero divisors is a division algebra, and so every composition algebra is either split or a division algebra.
9. Every composition algebra of dimension  $> 1$  over an algebraically closed field is split, and so every composition algebra over an algebraically closed field  $F$  is isomorphic to one of the algebras  $F, F \oplus F, M_2(F), \text{Zorn}(F)$ .

**Examples:**

1. The fields of real numbers  $\mathbb{R}$  and complex numbers  $\mathbb{C}$ , the quaternions  $\mathbb{H}$ , and the octonions  $\mathbb{O}$ , are real composition algebras with the Euclidean norm  $n(x) = x\bar{x}$ . The first three are associative; the algebra  $\mathbb{O}$  provides us with the first and most important example of a nonassociative alternative algebra.
2. Let  $F$  be a field and let  $A = F \oplus F$  be the direct sum of two copies of the field with the exchange involution  $\overline{(a, b)} = (b, a)$ , the trace  $t((a, b)) = a + b$ , and the norm  $n((a, b)) = ab$ . Then  $A$  is a two-dimensional split composition algebra.
3. Let  $A = M_2(F)$  be the algebra of  $2 \times 2$  matrices over  $F$  with the symplectic involution

$$x = \begin{bmatrix} a & b \\ c & d \end{bmatrix} \mapsto \bar{x} = \begin{bmatrix} d & -b \\ -c & a \end{bmatrix},$$

the matrix trace  $t(x) = a + d$ , and the determinant norm  $n(x) = ad - bc$ . Then  $A$  is a 4-dimensional split composition algebra.

4. An eight-dimensional split composition algebra is the **Zorn vector-matrix algebra** (or the **Cayley–Dickson matrix algebra**), obtained by taking  $A = \text{Zorn}(F)$ , which consists of all  $2 \times 2$  block matrices with scalars on the diagonal and  $3 \times 1$  column vectors off the diagonal

$$\text{Zorn}(F) = \left\{ x = \begin{bmatrix} a & \mathbf{u} \\ \mathbf{v} & b \end{bmatrix} \mid a, b \in F, \mathbf{u}, \mathbf{v} \in F^3 \right\},$$

with norm, involution, and product

$$n(x) = ab - (\mathbf{u}, \mathbf{v}), \quad \bar{x} = \begin{bmatrix} b & -\mathbf{u} \\ -\mathbf{v} & a \end{bmatrix},$$

$$x_1 x_2 = \begin{bmatrix} a_1 a_2 + (\mathbf{u}_1, \mathbf{v}_2) & a_1 \mathbf{u}_2 + \mathbf{u}_1 b_2 - \mathbf{v}_1 \times \mathbf{v}_2 \\ \mathbf{v}_1 a_2 + b_1 \mathbf{v}_2 + \mathbf{u}_1 \times \mathbf{u}_2 & b_1 b_2 + (\mathbf{v}_1, \mathbf{u}_2) \end{bmatrix};$$

the scalar and vector products are defined for  $\mathbf{u} = [u_1, u_2, u_3]^T$  and  $\mathbf{v} = [v_1, v_2, v_3]^T$  by

$$(\mathbf{u}, \mathbf{v}) = u_1 v_1 + u_2 v_2 + u_3 v_3, \quad \mathbf{u} \times \mathbf{v} = [u_2 v_3 - u_3 v_2, u_3 v_1 - u_1 v_3, u_1 v_2 - u_2 v_1].$$

### Applications:

1. If we write the equation  $n(x)n(y) = n(xy)$  in terms of the coefficients of the algebra elements  $x, y$  with respect to an orthogonal basis for each of the composition algebras  $\mathbb{R}, \mathbb{C}, \mathbb{H}, \mathbb{O}$  given in Example 3 of Section 69.1, then we obtain an identity expressing the multiplicativity of a quadratic form:

$$(x_1^2 + \cdots + x_k^2)(y_1^2 + \cdots + y_k^2) = z_1^2 + \cdots + z_k^2.$$

Here the  $z_i$  are bilinear functions in the  $x_i$  and  $y_i$ : To be precise,  $z_i$  is the coefficient of the  $i$ th basis vector in the product of the elements  $x = (x_1, \dots, x_k)$  and  $y = (y_1, \dots, y_k)$ . By Hurwitz' theorem, such a  $k$ -square identity exists only for  $k = 1, 2, 4, 8$ .

## 69.4 Alternative Algebras

---

### Definitions:

A **left alternative algebra** is one satisfying the identity  $(x, x, y) = 0$ .

A **right alternative algebra** is one satisfying the identity  $(y, x, x) = 0$ .

A **flexible algebra** is one satisfying the identity  $(x, y, x) = 0$ .

An **alternative algebra** is one satisfying all three identities (any two imply the third).

The **Moufang identities** play an important role in the theory of alternative algebras:

$$\begin{array}{ll} (xy \cdot z)y = x(yzy) & \text{right Moufang identity} \\ (yzy)x = y(z \cdot yx) & \text{left Moufang identity} \\ (xy)(zx) = x(yz)x & \text{central Moufang identity.} \end{array}$$

(The terms  $yzy$  and  $x(yz)x$  are well-defined by the flexible identity.)

An **alternative bimodule** over an alternative algebra  $A$  is an  $A$ -bimodule  $M$  for which the split null extension  $E(A, M)$  is alternative.

Let  $A$  be an alternative algebra, let  $M$  be an alternative  $A$ -bimodule, and let  $(\lambda, \rho)$  be the associated birepresentation of  $A$ . The algebra  $A$  **acts nilpotently** on  $M$  if the subalgebra of  $\text{End } M$ , which is generated by the elements  $\lambda(x), \rho(x)$  for all  $x \in A$ , is nilpotent. If  $y \in A$ , then  $y$  **acts nilpotently** on  $M$  if the elements  $\lambda(y), \rho(y)$  generate a nilpotent subalgebra of  $\text{End } M$ .

A finite dimensional alternative algebra  $A$  over a field  $F$  is **separable** if the algebra  $A_K = K \otimes_F A$  is nil-semisimple for any extension  $K$  of the field  $F$ .

**Facts:** ([Sch66], [ZSS82]) Additional facts about alternative algebras are given in Section 69.1 and facts about right alternative algebras are given in Section 69.6:

1. Every commutative or anticommutative algebra is flexible.
2. Substituting  $x + z$  for  $x$  in the left alternative identity, and using distributivity, we obtain

$$(x, z, y) + (z, x, y) = 0.$$

This is the **linearization on  $x$**  of the left alternative identity. Linearizing the right alternative identity in the same way, we get

$$(y, x, z) + (y, z, x) = 0.$$

From the last two identities, it follows that in any alternative algebra  $A$  the associator  $(x, y, z)$  is a skew-symmetric (alternating) function of the arguments  $x, y, z$ .

3. Every alternative algebra is power associative (Corollary of Artin's Theorem, Fact 7, Section 69.1). In particular, the nil radical  $\text{Nil } A$  exists in the class of alternative algebras.
4. Every alternative algebra satisfies the three Moufang identities and the identities

$$(x, y, yz) = (x, y, z)y, \quad (x, y, zy) = y(x, y, z).$$

5. A bimodule  $M$  over an alternative algebra  $A$  is alternative if and only if the following relations hold in the split null extension  $E(A, M)$ :

$$(x, m, x) = 0 \quad \text{and} \quad (x, m, y) = (m, y, x) = (y, x, m) \quad \text{for all } x, y \in A \quad \text{and} \quad m \in M.$$

6. It follows from the definition of alternative bimodule and the Moufang identities that

$$[\rho(x), \lambda(x)] = 0, \quad \rho(x^k) = (\rho(x))^k \quad \text{for } k \geq 1, \quad \lambda(x^k) = (\lambda(x))^k \quad \text{for } k \geq 1.$$

This implies that any nilpotent element of an alternative algebra acts nilpotently on any bimodule.

7. If every element of an alternative algebra  $A$  acts nilpotently on a finite dimensional alternative  $A$ -bimodule  $M$ , then  $A$  acts nilpotently on  $M$ .
8. A nilpotent algebra  $A$  acts nilpotently on the  $A$ -bimodule  $M$  if and only if the algebra  $E(A, M)$  is nilpotent.
9. In a finite dimensional alternative algebra  $A$ , every nil subalgebra is nilpotent. In particular, the nil radical  $\text{Nil } A$  is nilpotent.
10. The subclass  $\text{Nilp}$  of nilpotent algebras is radical in the class of all finite dimensional alternative algebras. For any finite dimensional alternative algebra  $A$ , we have

$$\text{Nil } A = \text{Solv } A = \text{Nilp } A.$$

11. Let  $A$  be a finite dimensional alternative algebra. The quotient algebra  $A/\text{Nil } A$  is semisimple, that is, it decomposes into a direct sum of simple algebras. Every finite dimensional nil-semisimple alternative algebra is isomorphic to a direct sum of simple algebras, where every simple algebra is either a matrix algebra over a skew-field or a Cayley–Dickson algebra over its center.
12. Let  $A$  be a finite dimensional alternative algebra over a field  $F$ . If the quotient algebra  $A/\text{Nil } A$  is separable over  $F$ , then there exists a subalgebra  $B$  of  $A$  such that  $B$  is isomorphic to  $A/\text{Nil } A$  and  $A = B \oplus \text{Nil } A$  (vector space direct sum).
13. Every alternative bimodule over a separable alternative algebra is completely reducible (as in the case of associative algebras).
14. Let  $A$  be a finite dimensional alternative algebra, let  $M$  be a faithful irreducible  $A$ -bimodule, and let  $(\lambda, \rho)$  be the associated birepresentation of  $A$ . Either  $M$  is an associative bimodule over  $A$  (which must then be associative), or one of the following holds:

- (a) The algebra  $A$  is an algebra of generalized quaternions,  $\lambda$  is a (right) associative irreducible representation of  $A$ , and  $\rho(x) = \lambda(\bar{x})$  for every  $x \in A$ .
- (b) The algebra  $A = \mathbb{O}$  is a Cayley–Dickson algebra and  $M$  is isomorphic to  $\text{Reg}(\mathbb{O})$ .
15. Every simple alternative algebra (of any dimension) is either associative or is isomorphic to a Cayley–Dickson algebra over its center.

## 69.5 Jordan Algebras

In this section, we assume that the base field  $F$  has characteristic  $\neq 2$ .

### Definitions:

A **Jordan algebra** is a commutative nonassociative algebra satisfying the **Jordan identity**

$$(x^2 y)x = x^2(yx).$$

The **linearization on  $x$**  of the Jordan identity is

$$2((xz)y)x + (x^2 y)z = 2(xz)(xy) + x^2(yz).$$

A Jordan algebra  $J$  is **special** if it is isomorphic to a subalgebra of the algebra  $A^+$  for some associative algebra  $A$ ; otherwise, it is **exceptional**.

**Facts:** ([BK66], [Jac68], [ZSS82], [McC04]) Additional facts about Jordan algebras are given in Section 69.1, and facts about noncommutative Jordan algebras are given in Section 69.6:

1. (Zelmanov's Simple Theorem) Every simple Jordan algebra (of any dimension) is isomorphic to one of the following: (a) an algebra of a bilinear form, (b) an algebra of Hermitian type, (c) an Albert algebra. For definitions see Examples 3, 4, and 5 below.
2. Let  $J$  be a Jordan algebra. Consider the regular birepresentation  $x \mapsto L_x, x \mapsto R_x$  of the algebra  $J$ . Commutativity and the Jordan identity imply that for all  $x, y \in J$  we have

$$L_x = R_x, \quad [R_x, R_{x^2}] = 0, \quad R_{x^2 y} - R_y R_{x^2} + 2R_x R_y R_x - 2R_x R_{yx} = 0.$$

Linearizing the last equation on  $x$  we see that for all  $x, y, z \in J$  we have

$$R_{(xz)y} - R_y R_{xz} + R_x R_y R_z + R_z R_y R_x - R_x R_{yz} - R_z R_{yx} = 0.$$

3. For every  $k \geq 1$ , the operator  $R_{x^k}$  belongs to the subalgebra  $A \subseteq \text{End } J$  generated by  $R_x$  and  $R_{x^2}$ . Since  $A$  is commutative, we have  $[R_{x^k}, R_{x^\ell}] = 0$  for all  $k, \ell \geq 1$ , which can be written as  $(x^k, J, x^\ell) = \{0\}$ .
4. It follows from the previous fact that every Jordan algebra is power associative and the radical  $\text{Nil } J$  is defined.
5. Let  $J$  be a finite dimensional Jordan algebra. As for alternative algebras, we have

$$\text{Nil } J = \text{Solv } J = \text{Nilp } J,$$

that is, the radical  $\text{Nil } J$  is nilpotent. The quotient algebra  $J/\text{Nil } J$  is semisimple, that is, isomorphic to a direct sum of simple algebras. If the quotient algebra  $J/\text{Nil } J$  is separable over  $F$ , then there exists a subalgebra  $B$  of  $J$  such that  $B$  is isomorphic to  $J/\text{Nil } J$  and  $J = B \oplus \text{Nil } J$  (vector space direct sum).

6. If a Jordan algebra  $J$  contains an idempotent  $e$ , the operator  $R_e$  satisfies the equation  $R_e(2R_e - 1)(R_e - 1) = 0$ , and the algebra  $J$  has the following analogue of the Pierce decomposition from the theory of associative algebras:

$$J = J_1 \oplus J_{1/2} \oplus J_0, \quad \text{where } J_i = J_i(e) = \{x \in J \mid xe = ix\}.$$

For  $i, j = 0, 1$  ( $i \neq j$ ), we have the inclusions

$$J_i^2 \subseteq J_i, \quad J_i J_{1/2} \subseteq J_{1/2}, \quad J_i J_j = \{0\}, \quad J_{1/2}^2 \subseteq J_1 + J_2.$$

More generally, if  $J$  has unit  $1 = \sum_{i=1}^n e_i$  where  $e_i$  are orthogonal idempotents, then

$$J = \bigoplus_{i \leq j} J_{ij}, \quad \text{where } J_{ii} = J_1(e_i), \quad J_{ij} = J_{1/2}(e_i) \cap J_{1/2}(e_j) \quad \text{for } i \neq j,$$

and the components  $J_{ij}$  are multiplied according to the rules

$$J_{ii}^2 \subseteq J_{ii}, \quad J_{ij} J_{ii} \subseteq J_{ij}, \quad J_{ij}^2 \subseteq J_{ii} + J_{jj}, \quad J_{ii} J_{jj} = \{0\} \quad \text{for distinct } i, j;$$

$$J_{ij} J_{jk} \subseteq J_{ik}, \quad J_{ij} J_{kk} = \{0\}, \quad J_{ij} J_{k\ell} = \{0\} \quad \text{for distinct } i, j, k, \ell.$$

7. Every Jordan algebra that contains  $>3$  strongly connected orthogonal idempotents is special. (Orthogonal idempotents  $e_1, e_2$  are **strongly connected** if there exists an element  $u_{12} \in J_{12}$  for which  $u_{12}^2 = e_1 + e_2$ .)
8. (Coordinatization Theorem) Let  $J$  be a Jordan algebra with unit  $1 = \sum_{i=1}^n e_i$  ( $n \geq 3$ ), where the  $e_i$  are mutually strongly connected orthogonal idempotents. Then  $J$  is isomorphic to the Jordan algebra  $H_n(D)$  of Hermitian  $n \times n$  matrices over an alternative algebra  $D$  (which is associative for  $n > 3$ ) with involution  $*$  such that  $H(D, *) \subseteq N(D)$ , where  $N(D)$  is the associative center of  $D$ .
9. Every Jordan bimodule over a separable Jordan algebra is completely reducible, and the structure of irreducible bimodules is known.

**Examples:**

- The algebra  $A^+$ .** If  $A$  is an associative algebra, then the algebra  $A^+$  is a Jordan algebra. Every subspace  $J$  of  $A$  closed with respect to the operation  $x \cdot y = \frac{1}{2}(xy + yx)$  is a subalgebra of the algebra  $A^+$  and every special Jordan algebra  $J$  is (up to isomorphism) of this type. The subalgebra of  $A$  generated by  $J$  is called the **associative enveloping algebra** of  $J$ . Properties of the algebras  $A$  and  $A^+$  are closely related:  $A$  is simple (respectively nilpotent) if and only if  $A^+$  is simple (respectively nilpotent).
- The algebra  $A^+$  may be a Jordan algebra for nonassociative  $A$ ; for instance, if  $A$  is a right alternative (in particular, alternative) algebra, then  $A^+$  is a special Jordan algebra.
- The algebra of a bilinear form.** Let  $X$  be a vector space of dimension  $> 1$  over  $F$ , with a symmetric nondegenerate bilinear form  $f(x, y)$ . Consider the vector space direct sum  $J(X, f) = F \oplus X$ , and define on it a multiplication by assuming that the unit element  $1 \in F$  is the unit element of  $J(X, f)$  and by setting  $xy = f(x, y)1$  for any  $x, y \in X$ . Then  $J(X, f)$  is a simple special Jordan algebra; its associative enveloping algebra is the Clifford algebra  $C(X, f)$  of the bilinear form  $f$ . When  $F = \mathbb{R}$  and  $f(x, y)$  is the ordinary dot product on  $X$ , the algebra  $J(X, f)$  is called a **spin-factor**.
- Algebras of Hermitian type.** Let  $A$  be an associative algebra with involution  $*$ . The subspace  $H(A, *) = \{x \in A \mid x^* = x\}$  of  $*$ -symmetric elements is closed with respect to the Jordan multiplication  $x \cdot y$  and, therefore, is a special Jordan algebra. For example, let  $D$  be an associative composition algebra with involution  $x \mapsto \bar{x}$  and let  $D^{n \times n}$  be the algebra of  $n \times n$  matrices over  $D$ . Then the mapping  $S: (x_{ij}) \mapsto (\overline{x_{ji}})$  is an involution of  $D^{n \times n}$  and the set of  $D$ -Hermitian matrices  $H_n(D) = H(D^{n \times n}, S)$  is a special Jordan algebra. If  $A$  is  $*$ -simple (if it contains no proper ideal  $I$  with  $I^* \subseteq I$ ), then  $H(A, *)$  is simple. In particular, all the algebras  $H_n(D)$  are simple. Every

algebra  $A^+$  is isomorphic to the algebra  $H(B, *)$  where  $B = A \oplus A^{\text{opp}}$  (algebra direct sum) and  $(x_1, x_2)^* = (x_2, x_1)$ .

5. **Albert algebras.** If  $D = \mathbb{O}$  is a Cayley–Dickson algebra, then the algebra  $H_n(\mathbb{O})$  of Hermitian matrices over  $D$  is a Jordan algebra only for  $n \leq 3$ . For  $n = 1, 2$  the algebras are isomorphic to algebras of bilinear forms and are, therefore, special. The algebra  $H_3(\mathbb{O})$  is exceptional (not special). An algebra  $J$  is called an Albert algebra if  $K \otimes_F J \cong H_3(\mathbb{O})$  for some extension  $K$  of the field  $F$ . Every Albert algebra is simple, exceptional, and has dimension 27 over its center.

## 69.6 Power Associative Algebras, Noncommutative Jordan Algebras, and Right Alternative Algebras

A natural generalization of Jordan algebras is the class of algebras that satisfy the Jordan identity but which are not necessarily commutative. If the algebra has a unit element, then the Jordan identity easily implies the flexible identity. The right alternative algebras have been the most studied among the power associative algebras that do not satisfy the flexible identity.

As in the previous section, we assume that  $F$  is a field of characteristic  $\neq 2$ .

### Definitions:

A **noncommutative Jordan algebra** is an algebra satisfying the flexible and Jordan identities. In this definition the Jordan identity may be replaced by any of the identities

$$x^2(xy) = x(x^2y), \quad (yx)x^2 = (yx^2)x, \quad (xy)x^2 = (x^2y)x.$$

A subspace  $V$  of an algebra  $A$  is **right nilpotent** if  $V^{(n)} = \{0\}$  for some  $n \geq 1$ , where  $V^{(1)} = V$  and  $V^{(n+1)} = V^{(n)}V$ .

**Facts:** ([Sch66], [ZSS82], [KS95])

- Let  $A$  be a finite dimensional power associative algebra with a bilinear symmetric form  $(x, y)$  satisfying the following conditions:
  - $(xy, z) = (x, yz)$  for all  $x, y, z \in A$ .
  - $(e, e) \neq 0$  for every idempotent  $e \in A$ .
  - $(x, y) = 0$  if the product  $xy$  is nilpotent.

Then  $\text{Nil } A = \text{Nil } A^+ = \{x \in A \mid (x, A) = \{0\}\}$ , and if  $F$  has characteristic  $\neq 2, 3, 5$ , then the quotient algebra  $A/\text{Nil } A$  is a noncommutative Jordan algebra.

- Let  $A$  be a finite dimensional nil-semisimple flexible power associative algebra over an infinite field of characteristic  $\neq 2, 3$ . Then  $A$  has a unit element and is a direct sum of simple algebras, each of which is either a noncommutative Jordan algebra or (in the case of positive characteristic) an algebra of degree 2.
- The structure of arbitrary finite dimensional nil-semisimple power associative algebras is still unclear. In particular, it is not known whether they are semisimple. It is known that in this case new simple algebras arise even in characteristic zero.
- An algebra  $A$  is a noncommutative Jordan algebra if and only if it is flexible and the corresponding plus-algebra  $A^+$  is a Jordan algebra.
- Let  $A$  be a noncommutative Jordan algebra. For  $x \in A$ , the operators  $R_x, L_x, L_{x^2}$  generate a commutative subalgebra in the multiplication algebra  $M(A)$ , containing all the operators  $R_{x^k}$  and  $L_{x^k}$  for  $k \geq 1$ .

6. Every noncommutative Jordan algebra is power associative.
7. Let  $A$  be a finite dimensional nil-semisimple noncommutative Jordan algebra over  $F$ . Then  $A$  has a unit element and is a direct sum of simple algebras. If  $F$  has characteristic 0, then every simple summand is either a (commutative) Jordan algebra, a quasi-associative algebra (see Example 3 below), or a quadratic flexible algebra. In the case of positive characteristic, there are more examples of simple noncommutative Jordan algebras.
8. Unlike alternative and Jordan algebras, an analogue of the Wedderburn Principal Theorem on splitting of the nil radical does not hold in general for noncommutative Jordan algebras.
9. Every quasi-associative algebra (see Example 3 below) is a noncommutative Jordan algebra.
10. Every flexible quadratic algebra is a noncommutative Jordan algebra.
11. The right multiplication operators in every right alternative algebra  $A$  satisfy

$$R_{x^2} = R_x^2, \quad R_{x \cdot y} = R_x \cdot R_y,$$

where  $x \cdot y = \frac{1}{2}(xy + yx)$  is the multiplication in the algebra  $A^+$ . (Recall that, in this section, we assume that the characteristic of the base field is  $\neq 2$ .)

12. If  $A$  is a right alternative algebra (respectively, noncommutative Jordan algebra), then its unital hull  $A^\#$  is also right alternative (respectively, noncommutative Jordan).
13. If  $A$  is a right alternative algebra, then the mapping  $x \mapsto R_x$  is a homomorphism of the algebra  $A^+$  into the special Jordan algebra  $R(A)^+$ . If  $A$  has a unit element, then this mapping is injective. For every right alternative algebra  $A$ , the algebra  $A^+$  is embedded into the algebra  $R(A^\#)^+$  and, hence, is a special Jordan algebra.
14. Every right alternative algebra  $A$  satisfies the identity

$$R_{x^k} R_{x^\ell} = R_{x^{k+\ell}} \quad \text{for any } x \in A \quad \text{and } k, \ell \geq 1.$$

Therefore,  $A$  is power associative and the nil radical  $\text{Nil } A$  is defined.

15. Let  $A$  be an arbitrary right alternative algebra. Then the quotient algebra  $A/\text{Nil } A$  is alternative. In particular, every right alternative algebra without nilpotent elements is alternative.
16. Every simple right alternative algebra that is not a nil algebra is alternative (and, hence, either associative or a Cayley–Dickson algebra). The nonnil restriction is essential: There exists a nonalternative simple right alternative nil algebra.
17. A finite dimensional right alternative nil algebra is right nilpotent and, therefore, solvable, but such an algebra can be nonnilpotent. In particular, the subclass *Nilp* is not radical in the class of finite dimensional right alternative algebras.

**Examples:**

1. The Suttles algebra (Example 5 in Section 69.2) is a power associative algebra that is not a noncommutative Jordan algebra. For another example see Example 5 below.
2. The class of noncommutative Jordan algebras contains, apart from Jordan algebras, all alternative algebras (and, thus, all associative algebras) and all anticommutative algebras.
3. **Quasi-associative algebras.** Let  $A$  be an algebra over a field  $F$  and let  $a \in F, a \neq \frac{1}{2}$ . Define a new multiplication on  $A$  as follows:

$$x \cdot_a y = axy + (1 - a)yx,$$

and denote the resulting algebra by  $A^a$ . The passage from  $A$  to  $A^a$  is reversible:  $A = (A^a)^b$  for  $b = a/(2a - 1)$ . Properties of  $A$  and  $A^a$  are closely related: The ideals (respectively subalgebras) of  $A$  are those of  $A^a$ ; the algebra  $A^a$  is nilpotent (respectively solvable, simple) if and only if the same holds for  $A$ . If  $A$  is associative, then  $A^a$  is a noncommutative Jordan algebra; furthermore, if the identity  $[[x, y], z] = 0$  does not hold in  $A$ , then  $A^a$  is not associative. In particular, if  $A$  is

a simple noncommutative associative algebra, then  $A^a$  is an example of a simple nonassociative noncommutative Jordan algebra. The algebras of the form  $A^a$  for an associative algebra  $A$  are **split** quasi-associative algebras. More generally, an algebra  $A$  is quasi-associative if it has a scalar extension, which is a split quasi-associative algebra.

4. **Generalized Cayley–Dickson algebras.** For  $a_1, \dots, a_n \in F - \{0\}$  let

$$A(a_1) = (F, a_1), \quad \dots, \quad A(a_1, \dots, a_n) = (A(a_1, \dots, a_{n-1}), a_n),$$

be the algebras obtained from  $F$  by successive application of the Cayley–Dickson process (Example 2 of section 69.1). Then  $A(a_1, \dots, a_n)$  is a central simple quadratic noncommutative Jordan algebra of dimension  $2^n$ .

5. Let  $V$  be a vector space of dimension  $2n$  over a field  $F$  with a nondegenerate skew-symmetric bilinear form  $(x, y)$ . On the vector space direct sum  $A = F \oplus V$  define a multiplication (as for the Jordan algebra of bilinear form) by letting the unit element  $1$  of  $F$  be the unit of  $A$  and by setting  $xy = (x, y)1$  for any  $x, y \in V$ . Then  $A$  is a simple quadratic algebra (and, hence, it is power associative), but  $A$  is not flexible and, thus, is not a noncommutative Jordan algebra.

## 69.7 Malcev Algebras

Some of the theory of Malcev algebras generalizes the theory of Lie algebras. For information about Lie algebras, the reader is advised to consult Chapter 70.

### Definitions:

A **Malcev algebra** is an anticommutative algebra satisfying the identity

$$J(x, y, xz) = J(x, y, z)x, \quad \text{where} \quad J(x, y, z) = (xy)z + (yz)x + (zx)y.$$

In a **left-normalized product** we omit the parenthesis, for example,

$$xyzx = ((xy)z)x, \quad yzxx = ((yz)x)x.$$

A **representation** of a Malcev algebra  $A$  is a linear mapping  $\rho: A \rightarrow \text{End } V$  satisfying the following identity for all  $x, y, z \in A$ :

$$\rho(x \cdot y \cdot z) = \rho(x)\rho(y)\rho(z) - \rho(z)\rho(x)\rho(y) + \rho(y)\rho(zx) - \rho(yz)\rho(x).$$

We call  $V$  a **Malcev module** for  $A$ . The anticommutativity of  $A$  implies that the notion of a Malcev module is equivalent to that of Malcev bimodule; we set  $xv = -vx$  for all  $x \in A, v \in V$ .

The **Killing form**  $K(x, y)$  on a Malcev algebra  $A$  is defined (as for a Lie algebra) by

$$K(x, y) = \text{trace}(R_x R_y).$$

**Facts:** ([KS95], [She00], [PS04], [SZ06])

1. After expanding the Jacobians, the Malcev identity takes the form

$$xyzx + yzxx + zxx y = xy \cdot xz,$$

(using our convention on left-normalized products). If  $F$  has characteristic  $\neq 2$ , the Malcev identity is equivalent to the more symmetric identity

$$xyzt + yztx + ztxy + txyz = xz \cdot yt.$$

2. Any two elements in a Malcev algebra generate a Lie subalgebra.

3. The structure theory of finite dimensional Malcev algebras repeats the main features of the corresponding theory for Lie algebras. For any alternative algebra  $A$ , the minus algebra  $A^-$  is a Malcev algebra. Let  $\mathbb{O} = \mathbb{O}(a, b, c)$  be a Cayley–Dickson algebra over a field  $F$  of characteristic  $\neq 2$ . Then  $\mathbb{O} = F \oplus M$  (vector space direct sum), where  $M = \{x \in \mathbb{O} \mid t(x) = 0\}$ . The subspace  $M$  is a subalgebra (in fact, an ideal) of the Malcev algebra  $\mathbb{O}^-$ , and  $M \cong \mathbb{O}^-/F$  (in fact,  $\mathbb{O}^-$  is the Malcev algebra direct sum of the ideals  $F$  and  $M$ ). The Malcev algebra  $M = M(a, b, c)$  is central simple and has dimension 7 over  $F$ ; if  $F$  has characteristic  $\neq 3$ , then  $M$  is not a Lie algebra.
4. Every central simple Malcev algebra of characteristic  $\neq 2$  is either a Lie algebra or an algebra  $M(a, b, c)$ . There are no non-Lie simple Malcev algebras in characteristic 3.
5. Two Malcev algebras  $M(a, b, c)$ ,  $M(a', b', c')$  are isomorphic if and only if the corresponding Cayley–Dickson algebras  $\mathbb{O}(a, b, c)$ ,  $\mathbb{O}(a', b', c')$  are isomorphic.
6. Let  $A$  be a finite dimensional Malcev algebra over a field  $F$  of characteristic 0 and let  $\text{Solv } A$  be the solvable radical of  $A$ . The algebra  $A$  is semisimple (it decomposes into a direct sum of simple algebras) if and only if  $\text{Solv } A = \{0\}$  (in fact, this is often used as the definition of “semisimple” for Malcev algebras, following the terminology for Lie algebras). If the quotient algebra  $A/\text{Solv } A$  is separable, then  $A$  contains a subalgebra  $B \cong A/\text{Solv } A$  and  $A = B \oplus \text{Solv } A$  (vector space direct sum).
7. The Killing form  $K(x, y)$  is symmetric and associative:

$$K(x, y) = K(y, x), \quad K(xy, z) = K(x, yz).$$

The algebra  $A$  is semisimple if and only if the form  $K(x, y)$  is nondegenerate. For the solvable radical we have  $\text{Solv } A = \{x \in A \mid K(x, A^2) = \{0\}\}$ . In particular,  $A$  is solvable if and only if  $K(A, A^2) = \{0\}$ .

8. If all the operators  $\rho(x)$  for  $x \in A$  are nilpotent, then they generate a nilpotent subalgebra in  $\text{End } V$  ( $A$  acts nilpotently on  $V$ ). If the representation  $\rho$  is almost faithful (that is,  $\ker \rho$  does not contain nonzero ideals of  $A$ ), then  $A$  is nilpotent.
9. Every representation of a semisimple Malcev algebra  $A$  is completely reducible.
10. If  $A$  is a Malcev algebra and  $V$  is an  $A$ -bimodule, then  $V$  is a Malcev module for  $A$  if and only if the split null extension  $E(A, V)$  is a Malcev algebra.
11. Let  $A$  be a Malcev algebra, and let  $V$  be a faithful irreducible  $A$ -module. Then the algebra  $A$  is simple, and either  $V$  is a Lie module over  $A$  (which must then be a Lie algebra) or one of the following holds:
  - (a)  $A \cong M(a, b, c)$  and  $V$  is a regular  $A$ -module.
  - (b)  $A$  is isomorphic to the Lie algebra  $sl(2, F)$  with  $\dim V = 2$  and  $\rho(x) = x^*$ , where  $x^*$  is the matrix adjoint to  $x \in A \subseteq M_2(F)$ . (Here the matrix adjoint is defined by the equation  $x x^* = x^* x = \det(x)I$ , where  $I$  is the identity matrix.)
12. The **speciality problem** for Malcev algebras is still open: Is every Malcev algebra embeddable into the algebra  $A^-$  for some alternative algebra  $A$ ? This is the generalization of the Poincaré–Birkhoff–Witt theorem for Malcev algebras.

## 69.8 Akivis and Sabinin Algebras

The theory of Akivis and Sabinin algebras generalizes the theory of Lie algebras and their universal enveloping algebras. For information about Lie algebras, the reader is advised to consult Chapter 70.

### Definitions:

An **Akivis algebra** is a vector space  $A$  over a field  $F$ , together with an anticommutative bilinear operation  $A \times A \rightarrow A$  denoted  $[x, y]$ , and a trilinear operation  $A \times A \times A \rightarrow A$  denoted  $(x, y, z)$ , satisfying the

**Akivis identity** for all  $x, y, z \in A$ :

$$[[x, y], z] + [[y, z], x] + [[z, x], y] = (x, y, z) + (y, z, x) + (z, x, y) - (x, z, y) - (y, x, z) - (z, y, x).$$

A **Sabinin algebra** is a vector space  $A$  over a field  $F$ , together with multilinear operations

$$\langle x_1, \dots, x_m; y, z \rangle \quad (m \geq 0),$$

satisfying these identities:

$$\langle x_1, \dots, x_m; y, y \rangle = 0, \quad (69.5)$$

$$\begin{aligned} & \langle x_1, \dots, x_r, u, v, x_{r+1}, \dots, x_m; y, z \rangle - \langle x_1, \dots, x_r, v, u, x_{r+1}, \dots, x_m; y, z \rangle \\ & + \sum_{k=0}^r \sum_s \langle x_{s(1)}, \dots, x_{s(k)}, \langle x_{s(k+1)}, \dots, x_{s(r)}; u, v \rangle, x_{r+1}, \dots, x_m; y, z \rangle = 0, \end{aligned} \quad (69.6)$$

$$K_{u,v,w} \left[ \langle x_1, \dots, x_r, u; v, w \rangle + \sum_{k=0}^r \sum_s \langle x_{s(1)}, \dots, x_{s(k)}; \langle x_{s(k+1)}, \dots, x_{s(r)}; v, w \rangle, u \right] = 0, \quad (69.7)$$

where  $s$  is a  $(k, r - k)$ -shuffle (a permutation of  $1, \dots, r$  satisfying  $s(1) < \dots < s(k)$  and  $s(k + 1) < \dots < s(r)$ ) and the operator  $K_{u,v,w}$  denotes the sum over all cyclic permutations. (See Fact 9 below for an alternative formulation of this definition.)

An algebra  $\mathcal{F}_{\mathcal{M}}[X]$  from a class  $\mathcal{M}$ , with a set of generators  $X$ , is called the **free algebra** in  $\mathcal{M}$  with the set  $X$  of free generators, if any mapping of  $X$  into an arbitrary algebra  $A \in \mathcal{M}$  extends uniquely to a homomorphism of  $\mathcal{F}_{\mathcal{M}}[X]$  to  $A$ .

Let  $I$  be any subset of  $\mathcal{F}_{\mathcal{M}}[X]$ . The  **$T$ -ideal** in  $\mathcal{F}_{\mathcal{M}}[X]$  determined by  $I$ , denoted by  $T = T(I, X)$ , is the smallest ideal of  $\mathcal{F}_{\mathcal{M}}[X]$  containing all elements of the form  $f(x_1, \dots, x_n)$  for all  $f \in I$  and all  $x_1, \dots, x_n \in \mathcal{F}_{\mathcal{M}}[X]$ .

**Facts:** ([HS90], [She99], [SU02], [GH03], [Per05], [BHP05], [BDE05])

- Free algebras may be constructed as follows. Let  $S$  be a set of generating elements and let  $\Omega$  be a set of operation symbols. Let  $r: \Omega \rightarrow \mathbb{N}$  (the nonnegative integers) be the arity function, that is,  $\omega \in \Omega$  will represent an  $n$ -ary operation for  $n = r(\omega)$ . The set  $W(S, \Omega)$  of nonassociative  $\Omega$ -words on the set  $S$  is defined inductively as follows:

- $S \subseteq W(S, \Omega)$ .
- If  $\omega \in \Omega$  and  $x_1, \dots, x_n \in W(S, \Omega)$  where  $n = r(\omega)$ , then  $\omega(x_1, \dots, x_n) \in W(S, \Omega)$ .

Let  $F$  be a field and let  $F(S, \Omega)$  be the vector space over  $F$  with basis  $W(S, \Omega)$ . For each  $\omega \in \Omega$  we define an  $n$ -ary operation with  $n = r(\omega)$  on  $F(S, \Omega)$ , denoted by the same symbol  $\omega$ , as follows: Given any basis elements  $x_1, \dots, x_n \in W(S, \Omega)$ , we set the value of  $\omega$  on the arguments  $x_1, \dots, x_n$  equal to the nonassociative word  $\omega(x_1, \dots, x_n)$ , and extend linearly to all of  $F(S, \Omega)$ . The algebra  $F(S, \Omega)$  is the free  $\Omega$ -algebra on the generating set  $S$  over the field  $F$  with the operations  $\omega \in \Omega$ .

- The quotient algebra  $F(S, \Omega)/T(I, S, \Omega)$  is the free  $\mathcal{M}$ -algebra for the class  $\mathcal{M} = \mathcal{M}(I)$  of  $\Omega$ -algebras defined by the set of identities  $I$ .
- Every subalgebra of a free Akivis algebra is again free.
- Every Akivis algebra is isomorphic to a subalgebra of  $Akivis(A)$  for some nonassociative algebra  $A$ . This generalizes the Poincaré–Birkhoff–Witt theorem for Lie algebras. The free nonassociative algebra is the universal enveloping algebra of the free Akivis algebra. (See Example 1 below.)
- The free nonassociative algebra with generating set  $X$  has a natural structure of a (nonassociative) Hopf algebra, generalizing the Hopf algebra structure on the free associative algebra. The **Akivis elements** (the elements of the subalgebra generated by  $X$  using the commutator and associator) are properly contained in the **primitive elements** (the elements satisfying  $\Delta(x) = x \otimes 1 + 1 \otimes x$  where  $\Delta$  is the co-multiplication). The Akivis elements and the primitive elements have a natural

structure of an Akivis algebra. The primitive elements have the additional structure of a Sabinin algebra.

6. The Witt dimension formula for free Lie algebras (the primitive elements in the free associative algebra) has a generalization to the primitive elements in the free nonassociative algebra.
7. Sabinin algebras are a nonassociative generalization of Lie algebras in the following sense: The tangent space at the identity of any local analytic loop (without associativity assumptions) has a natural structure of a Sabinin algebra, and the classical correspondence between Lie groups and Lie algebras generalizes to this case.
8. Every Sabinin algebra arises as the subalgebra of primitive elements in some nonassociative Hopf algebra.
9. Another (equivalent) way to define Sabinin algebras, which exploits the Hopf algebra structure, is as follows. Let  $A$  be a vector space and let  $T(A)$  be the tensor algebra of  $A$ . We write  $\Delta: T(A) \rightarrow T(A) \otimes T(A)$  for the co-multiplication on  $T(A)$ : the algebra homomorphism that extends the diagonal mapping  $\Delta: u \mapsto 1 \otimes u + u \otimes 1$  for  $u \in A$ . We will use the Sweedler notation and write  $\Delta(x) = \sum x_{(1)} \otimes x_{(2)}$  for any  $x \in T(A)$ . Then  $A$  is a Sabinin algebra if it is equipped with a trilinear mapping

$$T(A) \otimes A \otimes A \rightarrow A, \quad x \otimes y \otimes z \mapsto \langle x; y, z \rangle, \quad \text{for } x \in T(A) \text{ and } y, z \in A,$$

satisfying the identities

$$\langle x; y, y \rangle = 0, \tag{69.8}$$

$$\begin{aligned} &\langle x \otimes u \otimes v \otimes x'; y, z \rangle - \langle x \otimes v \otimes u \otimes x'; y, z \rangle + \sum \langle x_{(1)} \otimes \langle x_{(2)}; u, v \rangle \otimes x'; y, z \rangle \\ &= 0, \end{aligned} \tag{69.9}$$

$$K_{u,v,w} \left[ \langle x \otimes u; v, w \rangle + \sum \langle x_{(1)}; \langle x_{(2)}; v, w \rangle, u \right] = 0, \tag{69.10}$$

where  $x, x' \in T(A)$  and  $u, v, w, y, z \in A$ . Identities (8 to 10) exploit the Sweedler notation to express identities (5 to 7) in a more compact form.

**Examples:**

1. Any nonassociative algebra  $A$  becomes an Akivis algebra  $Akivis(A)$  if we define  $[x, y]$  and  $(x, y, z)$  to be the commutator  $xy - yx$  and the associator  $(xy)z - x(yz)$ . If  $A$  is an associative algebra, then the trilinear operation of  $Akivis(A)$  is identically zero; in this case the Akivis identity reduces to the Jacobi identity, and so  $Akivis(A)$  is a Lie algebra. If  $A$  is an alternative algebra, then the alternating property of the associator shows that the right side of the Akivis identity reduces to  $6(x, y, z)$ .
2. Every Lie algebra is an Akivis algebra with the identically zero trilinear operation. Every Malcev algebra (over a field of characteristic  $\neq 2, 3$ ) is an Akivis algebra with the trilinear operation equal to  $\frac{1}{6}J(x, y, z)$ .
3. Every Akivis algebra  $A$  is a Sabinin algebra if we define

$$\langle a, b \rangle = -[a, b], \quad \langle x; a, b \rangle = (x, b, a) - (x, a, b), \quad \langle x_1, \dots, x_m; a, b \rangle = 0 \ (m > 1),$$

for all  $a, b, x, x_i \in A$ .

4. Let  $L$  be a Lie algebra with a subalgebra  $H \subseteq L$  and a subspace  $V \subseteq L$  for which  $L = H \oplus V$ . We write  $P_V: L \rightarrow V$  for the projection onto  $V$  with respect to this decomposition of  $L$ . We define an operation

$$\langle -, -; - \rangle: T(V) \otimes V \otimes V \rightarrow V$$

by (using the Sweedler notation again)

$$\{x \otimes a \otimes b\} + \sum \{x_{(1)} \otimes \langle x_{(2)}; a, b \rangle\} = 0,$$

where for  $x = x_1 \otimes \cdots \otimes x_n \in T(V)$  we write

$$\{x\} = P_V([x_1, [\dots, [x_{n-1}, x_n]] \cdots]).$$

Then the vector space  $V$  together with the operation  $\langle -, -; - \rangle$  is a Sabinin algebra, and every Sabinin algebra can be obtained in this way.

## 69.9 Computational Methods

For homogeneous multilinear polynomial identities of degree  $n$ , the number of associative monomials is  $n!$  and the number of association types is  $C_n$  (the Catalan number); hence, the number of nonassociative monomials grows superexponentially:

$$n! \cdot \frac{1}{n} \binom{2n-2}{n-1} = \frac{(2n-2)!}{(n-1)!} > n^{n-1}.$$

One way to reduce the size of the computations is to apply the theory of superalgebras [Vau98]. Another technique is to decompose the space of multilinear identities into irreducible representations of the symmetric group  $S_n$ . The application of the representation theory of the symmetric group to the theory of polynomial identities for algebras was initiated in 1950 by Malcev and Specht. The computational implementation of these techniques was pioneered by Hentzel in the 1970s [Hen77]; for detailed discussions of recent applications see [HP97] and [BH04]. Another approach has been implemented in the Albert system [Jac03]. In this section, we present three small examples ( $n \leq 4$ ) of computational techniques in nonassociative algebra.

### Examples:

1. *The identities of degree 3 satisfied by the division algebra of real octonions.*

There are 12 distinct multilinear monomials of degree 3 for a nonassociative algebra:

$$(xy)z, (xz)y, (yx)z, (yz)x, (zx)y, (zy)x, x(yz), x(zy), y(xz), y(zx), z(xy), z(yx).$$

We create a matrix of size  $8 \times 12$  and initialize it to zero; the columns correspond to the nonassociative monomials. We use a pseudorandom number generator to produce three octonions  $x, y, z$  represented as vectors with respect to the standard basis  $1, i, j, k, \ell, m, n, p$ . We store the evaluation of monomial  $j$  in column  $j$  of the matrix. For example, generating random integers from the set  $\{-1, 0, 1\}$  using the base 3 expansion of  $1/\sqrt{2}$  gives

$$x = [1, -1, 0, -1, -1, 1, 0, 0], \quad y = [-1, 1, 1, 1, 0, 0, 1, 0], \quad z = [-1, 1, 1, 1, 0, 0, 0, -1].$$

Evaluation of the monomials gives the matrix in Table 69.1; its reduced row echelon form appears in Table 69.2. The nullspace contains the identities satisfied by the octonion algebra: the span of the rows of the matrix in Table 69.3. These rows represent the linearizations of the right alternative identity (row 1), the left alternative identity (row 2), and the flexible identity (row 5), together with the assocyclic identities  $(x, y, z) = (y, z, x)$  and  $(x, y, z) = (z, x, y)$  (rows 3 and 4).

2. *The identities of degree 4 satisfied by the Jordan product  $x * y = xy + yx$  in every associative algebra over a field of characteristic 0.*

**TABLE 69.1** The octonion evaluation matrix

-3	-9	-9	-3	-3	-9	-3	-9	-9	-3	-3	-9

0	0	0	0	0	1	0	0	0	0	0	1
0	0	0	0	0	0	1	-1	-1	1	1	-1

**TABLE 69.3** A basis for the nullspace of the octonion evaluation matrix

-1	-1	0	0	0	0	1	1	0	0	0	0
-1	0	-1	0	0	0	1	0	1	0	0	0
1	0	0	-1	0	0	-1	0	0	1	0	0
1	0	0	0	-1	0	-1	0	0	0	1	0
-1	0	0	0	0	-1	1	0	0	0	0	1

The operation  $x * y$  satisfies commutativity in degree 2, and there are no new identities of degree 3, so we consider degree 4. There are 15 distinct multilinear monomials for a commutative nonassociative operation, 12 for association type  $((--)--)-$  and 3 for association type  $(--)(--)$ :

$$\begin{aligned}
 &((w * x) * y) * z, ((w * x) * z) * y, ((w * y) * x) * z, ((w * y) * z) * x, ((w * z) * x) * y, \\
 &((w * z) * y) * x, ((x * y) * w) * z, ((x * y) * z) * w, ((x * z) * w) * y, ((x * z) * y) * w, \\
 &((y * z) * x) * w, ((y * z) * w) * x, (w * x) * (y * z), (w * y) * (x * z), (w * z) * (x * y).
 \end{aligned}$$

When each of these monomials is expanded in terms of the associative product, there are 24 possible terms, namely the permutations of  $w, x, y, z$  in lexicographical order:  $wxyz, \dots, zyxw$ . We construct a  $24 \times 15$  matrix in which the  $i, j$  entry is the coefficient of the  $i$ th associative monomial in the expansion of the  $j$ th commutative monomial (see Table 69.4). The nontrivial identities of degree 4 satisfied by  $x * y$  correspond to the nonzero vectors in the nullspace. The reduced row echelon form appears in Table 69.5. The rank is 11 and, so, the nullspace has dimension 4. A basis for the nullspace consists of the rows of Table 69.6. The first row represents the linearization of the Jordan identity; this is the only identity that involves monomials of both association types. (This proves that the plus algebra  $A^+$  of any associative algebra  $A$  is a Jordan algebra.) The Jordan identity implies the identities in the other three rows, which are permuted forms of the identity

$$w * (x * (y * z)) - x * (w * (y * z)) = (w * (x * y)) * z - (x * (w * y)) * z + y * (w * (x * z)) - y * (x * (w * z));$$

that is, the commutator of multiplication operators is a derivation.

3. The identities of degree 4 satisfied by the commutator  $[x, y] = xy - yx$  in every alternative algebra over a field of characteristic zero.

The group algebra  $\mathbb{Q}S_n$  decomposes as a direct sum of full matrix algebras of size  $d_\lambda \times d_\lambda$  where the index  $\lambda$  runs over all partitions  $\lambda$  of the integer  $n$ ; here  $d_\lambda$  is the dimension of the irreducible representation of  $S_n$  corresponding to the partition  $\lambda$ . We choose the “natural representation” to fix a particular decomposition. For each  $\lambda$  there is a projection  $p_\lambda$  from  $\mathbb{Q}S_n$  onto the matrix algebra of size  $d_\lambda \times d_\lambda$ . In the case  $n = 4$  the partitions and the dimensions of the corresponding irreducible

**TABLE 69.7** Partitions of 4 and irreducible representations of  $S_4$

$\lambda$	4	31	22	211	1111
$d_\lambda$	1	3	2	3	1

representation  $S_4$  are given in Table 69.7. For a nonassociative operation in degree 4 there are 5 association types:

$$((--)-)-, \quad (-(--))-, \quad (---)(--), \quad -((--)-), \quad -(-(--)),$$

and so any nonassociative identity can be represented as an element of the direct sum of 5 copies of  $\mathbb{Q}S_n$ : Given a partition  $\lambda$ , the nonassociative identity projects via  $p_\lambda$  to a matrix of size  $d_\lambda \times 5d_\lambda$ . For an anticommutative operation in degree 4 there are 2 association types:

$$[[[-, -], -], -], \quad [[-, -], [-, -]],$$

and so any anticommutative identity projects via  $p_\lambda$  to a matrix of size  $d_\lambda \times 2d_\lambda$ . The linearizations of the left and right alternative identities are

$$L(x, y, z) = (xy)z - x(yz) + (yx)z - y(xz), \quad R(x, y, z) = (xy)z - x(yz) + (xz)y - x(zy).$$

Each of these can be “lifted” to degree 4 in five ways; for  $L(a, b, c)$  we have

$$wL(x, y, z), \quad L(xw, y, z), \quad L(x, yw, z), \quad L(x, y, zw), \quad L(x, y, z)w;$$

and similarly for  $R(x, y, z)$ . Altogether we have 10 lifted alternative identities that project via  $p_\lambda$  to a matrix of size  $10d_\lambda \times 5d_\lambda$ . Using the commutator to expand the two anticommutative association types gives

$$\begin{aligned} [[x, y], z], w &= ((xy)z)w - ((yx)z)w - (z(xy))w + (z(yx))w \\ &\quad - w((xy)z) + w((yx)z) + w(z(xy)) - w(z(yx)), \\ [x, y], [z, w] &= (xy)(zw) - (yx)(zw) - (xy)(wz) + (yx)(wz) \\ &\quad - (zw)(xy) + (zw)(yx) + (wz)(xy) - (wz)(yx). \end{aligned}$$

Given a partition  $\lambda$  we can store these two relations in a matrix of size  $2d_\lambda \times 7d_\lambda$ : We use all 7 association types, store the right sides of the relations in the first 5 types, and  $-I$  ( $I$  is the identity matrix) in type 6 (respectively 7) for the first (respectively second) expansion. For each partition  $\lambda$ , all of this data can be stored in a matrix  $A_\lambda$  of size  $12d_\lambda \times 7d_\lambda$ , which is schematically displayed in Table 69.8. We compute the reduced row echelon form of  $A_\lambda$ : Let  $i$  be the largest number for which rows  $1 - i$  of  $\text{RREF}(A_\lambda)$  have a nonzero entry in the first 5 association types. Then the remaining rows of  $\text{RREF}(A_\lambda)$  have only zero entries in the first 5 types; if one of these

**TABLE 69.8** The matrix of Malcev identities for partition  $\lambda$

$A_\lambda =$		0	0
	Lifted alternative identities	$\vdots$	$\vdots$
		0	0
	Expansion of $[[x, y], z], w$	$-I$	0
	Expansion of $[x, y], [z, w]$	0	$-I$

rows contains nonzero entries in the last 2 types, this row represents an identity that is satisfied by the commutator in every alternative algebra. However, such an identity may be a consequence of the obvious anticommutative identities:

$$\begin{aligned} & [[[x, y], z], w] + [[[y, x], z], w] = 0, \\ & [[x, y], [z, w]] + [[y, x], [z, w]] = 0, \quad [[x, y], [z, w]] + [[z, w], [x, y]] = 0. \end{aligned}$$

These identities are represented by a matrix of size  $3d_\lambda \times 7d_\lambda$  in which the first  $5d_\lambda$  columns are zero. We need to determine if any of the rows  $i + 1$  to  $12d_\lambda$  of  $\text{RREF}(A_\lambda)$  do not lie in the row space of the matrix of anticommutative identities. If such a row exists, it represents a nontrivial identity satisfied by the commutator in every alternative algebra. For example, consider the partition  $\lambda = 22$  ( $d_\lambda = 2$ ). The  $24 \times 14$  matrix  $A_\lambda$  for this partition appears in Table 69.9, and its reduced row echelon form appears in Table 69.10. The  $6 \times 14$  matrix representing the anticommutative identities for this partition appears in Table 69.11, and its reduced row echelon form appears in Table 69.12. Comparing the last four rows of Table 69.10 with Table 69.12, we see that there is one new identity for  $\lambda = 22$  represented by the third-last row of Table 69.10. Similar computations for the other partitions show that there is one nontrivial identity for partition  $\lambda = 211$  and no nontrivial identities for the other partitions. The two identities from partitions 22 and 211 are the irreducible components of the Malcev identity: The submodule generated by the linearization of the Malcev identity (in the  $S_4$ -module of all multilinear anticommutative polynomials of degree 4) is the direct sum of two irreducible submodules corresponding to these two partitions.

A Lie algebra is a (nonassociative) algebra satisfying  $x^2 = 0$  for all elements  $x$  of the algebra (which implies anticommutativity) and the Jacobi identity. Lie algebras arise naturally as (vector) subspaces of associative algebras closed under the commutator operation  $[a, b] = ab - ba$ . The finite-dimensional simple Lie algebras over algebraically closed fields of characteristic zero occur in many applications. This chapter outlines the structure, classification, and representation theory of these algebras. We also give examples of other types of algebras, e.g., one class of infinite-dimensional simple algebras and one class of finite-dimensional simple Lie algebras over fields of prime characteristic. Section 70.1 is devoted to general definitions about Lie algebras. Section 70.2 discusses semisimple and simple algebras. This section includes the classification of finite-dimensional simple Lie algebras over algebraically closed fields of characteristic zero. Section 70.3 discusses module theory and includes the classification of finite-dimensional irreducible modules for the aforementioned algebras as well as the explicit construction of some of these modules. Section 70.4 discusses graded algebras and modules and uses this formalism to present results on dimensions of irreducible modules.

### 70.1 Basic Concepts

---

Unless specified otherwise,  $F$  denotes an arbitrary field. All vector spaces and algebras are over  $F$ . The reader is referred to Chapter 69 for definitions of many basic algebra terms.

#### Definitions:

Let  $A$  be an algebra over a field  $F$ . An **automorphism** is an algebra isomorphism of  $A$  to itself. The set of all automorphisms of  $A$  is denoted  $Aut(A)$ .

A linear transformation  $D : A \rightarrow A$  is a **derivation** of  $A$  if  $D(ab) = D(a)b + aD(b)$  for all  $a, b \in A$ . The set of all derivations of  $A$  is denoted  $Der(A)$ .

Let  $A$  be an associative algebra and  $X$  be a subset of  $A$ . Then the smallest ideal of  $A$  containing  $X$  is denoted by  $\langle X \rangle$  and called the **ideal generated by  $X$** .

Let  $V$  be a vector space over a field  $F$ . Let  $V^{\otimes n}$  denote the tensor product of  $n$  copies of  $V$  and set  $T(V) = F1 + \sum_{n=1}^{\infty} V^{\otimes n}$ . Define a linear map  $T(V) \otimes T(V) \rightarrow T(V)$ ,  $u \otimes v \mapsto uv$ , by  $1u = u1 = u$  for all  $u \in T(V)$  and

$$(v_1 \otimes \dots \otimes v_m)(u_1 \otimes \dots \otimes u_n) = v_1 \otimes \dots \otimes v_m \otimes u_1 \otimes \dots \otimes u_n$$

whenever  $m, n \geq 1, v_1, \dots, v_m, u_1, \dots, u_n \in V$ .  $T(V)$  is the **tensor algebra** on the vector space  $V$ . This algebra is defined, and denoted  $\otimes V$ , in Section 13.9.

An algebra  $L$  over a field  $F$  with product  $[\ , \ ] : L \times L \rightarrow L, (a, b) \mapsto [a, b]$  is a **Lie algebra** if it satisfies both

$$[a, a] = 0$$

and

$$[a, [b, c]] + [b, [c, a]] + [c, [a, b]] = 0 \quad (\text{Jacobi identity})$$

for all  $a, b, c \in L$ . The first condition implies

$$[a, b] = -[b, a] \quad (\text{anticommutativity})$$

and is equivalent to anticommutativity if the characteristic of  $F \neq 2$ .

A Lie algebra  $L$  is **abelian** if  $[a, b] = 0$  for all  $a, b \in L$ .

If  $A$  is an algebra, the vector space  $A$  together with the product  $[\ , \ ] : A \times A \rightarrow A$  defined by  $[a, b] = ab - ba$  is an algebra denoted by  $A^-$ .

Let  $L$  be a Lie algebra. Let  $I$  denote the ideal in  $T(L)$  (the tensor algebra on the vector space  $L$ ) generated by  $\{a \otimes b - b \otimes a - [a, b] \mid a, b \in L\}$ . The quotient algebra  $T(L)/I$  is called the **universal enveloping algebra** of  $L$  and is denoted by  $U(L)$ .

Let  $V$  be a vector space with basis  $X$ . Define a map  $\iota : X \rightarrow T(V)^-$  by  $\iota : x \mapsto x \in V^{\otimes 1} \subseteq F1 + \sum_{n=1}^{\infty} V^{\otimes n} = T(V)^-$ . Let  $Fr(X)$  be the Lie subalgebra of  $T(V)^-$  generated by  $\iota(X)$ .  $Fr(X)$  is called the **free Lie algebra generated by  $X$** .

Let  $V$  be a vector space and let  $I$  be the ideal in  $T(V)$  generated by  $\{a \otimes b - b \otimes a \mid a, b \in V\}$ . The quotient  $T(V)/I$  is called the **symmetric algebra** on  $V$  and denoted by  $S(V)$ . The image of  $V^{\otimes n}$  in  $S(V)$  is denoted by  $S^n(V)$ . An equivalent construction of this algebra (as a subalgebra, denoted  $\bigvee V$ , of  $T(V)$ ) is given in Section 13.9.

Let  $V$  be a vector space and let  $I$  be the ideal in  $T(V)$  generated by  $\{a \otimes a \mid a \in V\}$ . The quotient  $T(V)/I$  is called the **exterior algebra** on  $V$  and denoted by  $\Lambda(V)$ . The image of  $a_1 \otimes \dots \otimes a_l$  is denoted by  $a_1 \wedge \dots \wedge a_l$  and the image of  $V^{\otimes n}$  in  $\Lambda(V)$  is denoted by  $\Lambda^n(V)$ . An equivalent construction of this algebra (as a subalgebra, denoted  $\bigwedge V$ , of  $T(V)$ ) is given in Section 13.9.

Let  $End V$  denote the vector space of all linear transformations from  $V$  to  $V$  (also denoted  $L(V, V)$  elsewhere in this book). Let  $L$  be a Lie algebra. If  $a \in A$ , the map  $ad : L \rightarrow End L$  defined by  $ad(a) : b \mapsto [a, b]$  for all  $b \in L$  is called the **adjoint map**.

Let  $F$  be a field of prime characteristic  $p$  and let  $L$  be a Lie algebra over  $F$ . If for every  $a \in L$  there is some element  $a^{[p]} \in L$  such that  $(ad(a))^p = ad(a^{[p]})$ , then  $L$  is called a **p-Lie algebra**.

### Facts:

The following facts (except those with a specific reference) can be found in [Jac62, Chap. 5].

1. [Jac62, p. 6] If  $A$  is an associative algebra, then  $A^-$  is a Lie algebra. If  $F$  is a field of prime characteristic  $p$ , then  $A^-$  is a  $p$ -Lie algebra.
2. Let  $A$  be an algebra over  $F$ . Then  $Der(A)$  is a Lie algebra. If  $F$  is a field of prime characteristic  $p$ , then  $Der(A)$  is a  $p$ -Lie algebra.
3. Let  $V$  be a vector space. The tensor algebra  $T(V)$  has the structure of an associative algebra and  $T(V)^-$  is a Lie algebra.
4. Let  $L$  be a Lie algebra. A subspace  $I \subseteq L$  is an *ideal* of  $L$  if  $[a, b] \in I$  whenever  $a \in A, b \in I$ . The quotient space  $L/I$  with the product  $[a + I, b + I] = [a, b] + I$  is a Lie algebra.
5. *Universal property of  $U(L)$* : Let  $L$  be a Lie algebra. Define a map  $\iota : L \rightarrow U(L)$  by  $\iota : a \mapsto a \in L^{\otimes 1} \subseteq F1 + \sum_{n=1}^{\infty} L^{\otimes n} = T(L) \rightarrow U(L)$ . Then  $\iota$  is a (Lie algebra) homomorphism of  $L$  into

- $U(L)^-$ . If  $A$  is any associative algebra with unit 1 and  $\phi$  is a homomorphism of  $L$  into  $A^-$ , then there is a unique homomorphism  $\psi : U(L) \rightarrow A$  such that  $\psi(1) = 1$  and  $\phi = \psi\iota$ .
6. *Poincaré–Birkhoff–Witt Theorem*: Let  $L$  be a Lie algebra with ordered basis  $\{l_i | i \in I\}$ . Then  $\{l_{i_1} \dots l_{i_k} | k \geq 0, i_1 \leq \dots \leq i_k\}$  is a basis for  $U(L)$ . Consequently,  $\iota : L \rightarrow U(L)$  is injective.
  7. *Universal property of the free Lie algebra*: If  $L$  is any Lie algebra and if  $\phi : X \rightarrow L$  is any map, there is a unique homomorphism of Lie algebras  $\psi : Fr(X) \rightarrow L$  such that  $\phi = \psi\iota$ .
  8. *Universal property of  $S(V)$* : Let  $V$  be a vector space. Define a map  $\iota : V \rightarrow S(V)$  by  $\iota : a \mapsto a \in V^{\otimes 1} \subseteq F1 + \sum_{n=1}^{\infty} V^{\otimes n} \rightarrow S(V)$ . Let  $A$  be a commutative associative algebra and  $\phi : V \rightarrow A$  be a linear map. Then there is a unique algebra homomorphism  $\psi : S(V) \rightarrow A$  such that  $\phi = \psi\iota$ .
  9. *Structure of  $S(V)$* : Let  $V$  be a vector space with ordered basis  $B = \{b_i | i \in I\}$ . Then  $S(V)$  has basis  $\{b_{i_1} \dots b_{i_l} | l \geq 0, i_1 \leq \dots \leq i_l\}$ . Consequently,  $S(V)$  is isomorphic to the algebra of polynomials on  $B$ .
  10. [Lam01, p. 12] *Structure of  $\Lambda(V)$* : Let  $V$  be a vector space with ordered basis  $B = \{b_i | i \in I\}$ . Then  $\Lambda(V)$  has basis  $\{b_{i_1} \wedge \dots \wedge b_{i_l} | l \geq 0, i_1 < \dots < i_l\}$ . Consequently, if  $V$  has finite dimension  $l$ , then  $\dim \Lambda(V) = 2^l$ .

**Examples:**

1.  $(End V)^-$  is a Lie algebra, denoted  $gl(V)$ . Similarly,  $(F^{n \times n})^-$  is a Lie algebra, denoted  $gl(n, F)$ . These algebras are isomorphic.
2.  $sl(n, F) = \{x \in gl(n, F) | tr(x) = 0\}$  is a Lie subalgebra, and in fact, a Lie ideal of  $gl(n, F)$ .
3. Let  $L$  be a vector space with basis  $\{e, f, h\}$ . Defining  $[e, f] = h, [h, e] = 2e$ , and  $[h, f] = -2f$  gives  $L$  the structure of a Lie algebra. The linear map  $L \rightarrow sl(2, F)$  defined by  $e \mapsto \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, f \mapsto \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix}, h \mapsto \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$  is an isomorphism of Lie algebras.

## 70.2 Semisimple and Simple Algebras

---

**Definitions:**

Let  $L$  be a Lie algebra. The subspace spanned by all products  $[a, b], a, b \in L$ , is a subalgebra of  $L$ . It is called the **derived algebra** of  $L$  and is denoted by  $L^{(1)}$ .

Let  $L$  be a Lie algebra. For  $n \geq 2, L^{(n)}$  is defined to be  $(L^{(n-1)})^{(1)}$  and is called the **nth-derived algebra** of  $L$ .

A Lie algebra  $L$  is **solvable** if  $L^{(n)} = \{0\}$  for some  $n \geq 1$ .

Let  $L$  be a Lie algebra. The sum of all the solvable ideals of  $L$  is the **radical** of  $L$  and denoted  $Rad(L)$ . (In Section 69.2,  $Rad(L)$  is called the *solvable radical* and denoted  $Solv(L)$ .)

A Lie algebra  $L$  is **semisimple** if  $Rad(L) = \{0\}$ . N.B. This is standard terminology in the study of Lie algebras, but does *not* always coincide with the definition of semisimple given for nonassociative algebras in Section 69.2; cf. Fact 5 and Example 3.

A Lie algebra  $L$  is **simple** if  $L$  contains no nonzero proper ideals and  $L^{(1)} \neq \{0\}$ . (The second condition excludes the one-dimensional algebra.)

Let  $A, B$  be Lie algebras. Then the vector space  $A \oplus B$  can be given the structure of a Lie algebra, called the **direct sum** of  $A$  and  $B$  and also denoted  $A \oplus B$ , by setting  $[a_1 + b_1, a_2 + b_2] = [a_1, a_2] + [b_1, b_2]$  for  $a_1, a_2 \in A, b_1, b_2 \in B$ .

Let  $L$  be a finite-dimensional Lie algebra. The **Killing form**,  $\kappa_L$ , is the symmetric bilinear form on  $L$  defined by  $\kappa_L(a, b) = tr((ad(a))(ad(b)))$ .

For  $V$  a finite dimensional vector space over an algebraically closed field  $F$  and  $x \in End V, x$  is **semisimple** if the minimum polynomial of  $x$  has no repeated roots.

Let  $L$  be a Lie algebra over an algebraically closed field  $F$  and  $x \in L$ .  $x$  is **ad-nilpotent** if  $ad(x)$  is a nilpotent linear transformation of  $L$  and  $x$  is **ad-semisimple** if  $ad(x)$  is a semisimple linear transformation of  $L$ .

Let  $L$  be a Lie algebra. A subalgebra  $T \subseteq L$  is a **torus** if every element of  $T$  is ad-semisimple.

Let  $T$  be a torus in  $L$  and let  $\alpha \in T^*$ , the dual of  $T$ . Define  $L_\alpha$ , the  **$\alpha$ -root space** of  $L$  by

$$L_\alpha = \{x \in L \mid [t, x] = \alpha(t)x \ \forall t \in T\}.$$

A vector space  $E$  over  $\mathbb{R}$  with an inner product (i.e., a positive definite symmetric bilinear form)  $\langle \cdot, \cdot \rangle$  is a **Euclidean space**.

Let  $E$  be a Euclidean space.

For  $0 \neq x \in E$  and  $y \in E$  set  $\langle y, x \rangle = \frac{2\langle y, x \rangle}{\langle x, x \rangle}$ .

For  $0 \neq x \in E$  define  $\sigma_x$ , the **reflection** in the hyperplane orthogonal to  $x$ , by

$$\sigma_x(y) = y - \langle y, x \rangle x$$

for all  $y \in E$ .

A finite subset  $R \subseteq E$  that spans  $E$  and does not contain 0 is a **root system** in  $E$  if the following three conditions are satisfied:

- If  $x \in R$ ,  $a \in \mathbb{R}$ , and  $ax \in R$ , then  $a = \pm 1$ .
- If  $x \in R$ , then  $\sigma_x R = R$
- If  $x, y \in R$ , then  $\langle x, y \rangle \in \mathbb{Z}$ .

Let  $R$  be a root system in  $E$ . The **rank** of  $R$  is  $\dim E$ .

A root system  $R$  is **decomposable** if  $R = R_1 \cup R_2$  with  $\emptyset \neq R_1, R_2 \subset R$  and  $(R_1, R_2) = \{0\}$ . If  $R$  is not decomposable, it is **indecomposable**.

Let  $R$  be a root system in  $E$ . The subgroup of  $End E$  generated by  $\{\sigma_\alpha \mid \alpha \in R\}$  is called the **Weyl group** of  $R$ .

Let  $R$  be a root system in  $E$ . A subset  $B \subseteq R$  is a **base** for  $R$  if  $B$  is a basis for  $E$  and every  $x \in R$  may be written

$$x = \sum_{b \in B} k_b b$$

where all  $k_b \geq 0$  or all  $k_b \leq 0$ .

Let  $R$  be a root system in  $E$  with base  $B$  and let  $\alpha \in R$ .  $\alpha$  is a **positive root** if  $\alpha = \sum_{b \in B} k_b b$  where all  $k_b \geq 0$ . Denote the set of positive roots by  $R^+$ .

Let  $B = \{b_1, \dots, b_l\}$  be a base for a root system  $R$ . The matrix  $[\langle b_i, b_j \rangle]$ , is called the **Cartan matrix** of  $R$  with respect to  $B$ .

### Facts:

Most of the following facts (except those with a specific reference) can be found in [Hum72, pp. 35–65].

1. The **radical**,  $Rad(L)$ , is a solvable ideal of  $L$ .
2. For  $V$  a finite dimensional vector space over an algebraically closed field  $F$ ,  $x \in End V$  is semisimple if and only if  $x$  is similar to a diagonal matrix.
3. [Jac62, p. 69] *Cartan's Criterion for Semisimplicity*: Let  $L$  be a finite-dimensional Lie algebra over a field of characteristic 0. Then  $L$  is semisimple if and only if  $\kappa_L$  is nondegenerate.
4. [Jac62, p. 74] Let  $L$  be a finite-dimensional semisimple Lie algebra over a field of characteristic zero and let  $D \in Der(L)$ . Then  $D = ad(a)$  for some  $a \in L$ .
5. [Jac62, p. 71] Let  $L$  be a finite-dimensional semisimple Lie algebra over a field of characteristic 0. Then  $L$  is a direct sum of simple ideals.

6. Let  $L$  be a finite-dimensional Lie algebra over an algebraically closed field of characteristic 0. Any torus of  $L$  is abelian.
7. Let  $L$  be a finite-dimensional semisimple Lie algebra over an algebraically closed field of characteristic 0. Let  $T$  be a maximal torus of dimension  $l$  in  $L$  and  $\Delta = \{\alpha \in T^* | \alpha \neq 0, L_\alpha \neq \{0\}\}$ . Then:
- $\dim L_\alpha = 1$  for all  $\alpha \in \Delta$ .
  - $L = T \oplus \sum_{\alpha \in \Delta} L_\alpha$ .
  - For  $\alpha \in \Delta$  there exists  $t_\alpha \in T$  such that  $\alpha(t) = \kappa_L(t_\alpha, t)$  for all  $t \in T$ . Then, defining  $(\alpha, \beta) = \kappa_L(t_\alpha, t_\beta)$  gives the  $\mathbb{R}$  span of  $\Delta$  the structure of a Euclidean space of dimension  $l$  and  $\Delta$  is a root system of rank  $l$  in this space.
  - $\Delta$  is indecomposable if and only if  $L$  is simple.
  - $\Delta$  spans  $T^*$  and so each  $w \in W$  acts on  $T^*$ .
8. Let  $R$  be a root system in  $E$  with Weyl group  $W$ . Then  $W$  is finite and  $R$  has a base. Furthermore, if  $B_1, B_2$  are two bases for  $R$ , then  $B_1 = w(B_2)$  for some  $w \in W$ . Consequently, when  $B_1$  and  $B_2$  are appropriately ordered, the Cartan matrix of  $R$  with respect to  $B_1$  is the same as the Cartan matrix of  $R$  with respect to  $B_2$ . Thus, we may refer to the Cartan matrix of  $R$ .
9. Let  $L$  be a semisimple Lie algebra over a field of characteristic 0, let  $T_1, T_2$  be maximal tori in  $L$ , and let  $\Delta_1, \Delta_2$  be the corresponding root systems. Then there is an automorphism  $\phi \in \text{Aut}(L)$  such that  $\phi(T_1) = T_2$ . Consequently, when bases for  $\Delta_1$  and  $\Delta_2$  are appropriately ordered, the Cartan matrix for  $\Delta_1$  is the same as the Cartan matrix for  $\Delta_2$ . Thus, we may refer to the Cartan matrix of  $L$ .
10. Let  $L_1, L_2$  be semisimple Lie algebras over an algebraically closed field of characteristic 0. If the Cartan matrices of  $L_1$  and  $L_2$  coincide, then  $L_1$  and  $L_2$  are isomorphic.
11. Let  $M = [m_{i,j}]$  be the  $l \times l$  Cartan matrix of an indecomposable root system, with base appropriately ordered. Then the diagonal entries of  $M$  are all 2 and one of the following occurs.
- $M$  is of type  $A_l$  for some  $l \geq 1$ :  $m_{i,j} = -1$  if  $|i - j| = 1$ ;  $m_{i,j} = 0$  if  $|i - j| > 1$ .
  - $M$  is of type  $B_l$  for some  $l \geq 3$ :  $m_{l-1,l} = -2$ ;  $m_{i,j} = -1$  if  $|i - j| = 1$  and  $(i, j) \neq (l-1, l)$ ;  $m_{i,j} = 0$  if  $|i - j| > 1$ .
  - $M$  is of type  $C_l$  for some  $l \geq 2$ :  $m_{l,l-1} = -2$ ;  $m_{i,j} = -1$  if  $|i - j| = 1$  and  $(i, j) \neq (l, l-1)$ ;  $m_{i,j} = 0$  if  $|i - j| > 1$ .
  - $M$  is of type  $D_l$  for some  $l \geq 4$ :  $m_{i,j} = -1$  if  $|i - j| = 1$  and  $(i, j) \neq (l-1, l), (l, l-1)$  or if  $(i, j) = (l-2, l), (l, l-2)$ ;  $m_{i,j} = 0$  if  $|i - j| > 1$  and  $(i, j) \neq (l-2, l), (l, l-2)$  or if  $(i, j) = (l-1, l), (l, l-1)$ .
  - $M$  is of type  $E_l, l = 6, 7, 8$ :  $m_{i,j} = -1$  if  $|i - j| = 1$  and  $i, j \neq 2$  or if  $(i, j) = (1, 3)(3, 1)(2, 4), (4, 2)$ ;  $m_{i,j} = 0$  if  $|i - j| > 1, (i, j) \neq (1, 3)(3, 1)(2, 4), (4, 2)$  or if  $|i - j| = 1$  and  $i = 2$  or  $j = 2$ .
- $M$  is of type  $F_4$ :  $M = \begin{bmatrix} 2 & -1 & 0 & 0 \\ -1 & 2 & -2 & 0 \\ 0 & -1 & 2 & -1 \\ 0 & 0 & -1 & 2 \end{bmatrix}$ .
  - $M$  is of type  $G_2$ :  $M = \begin{bmatrix} 2 & -1 \\ -3 & 2 \end{bmatrix}$ .
12. Let  $L$  be a finite-dimensional simple Lie algebra over an algebraically closed field of characteristic zero. Then  $L$  is determined up to isomorphism by its root system with respect to any maximal torus. The Cartan matrix of the root system is of type  $A_l, l \geq 1; B_l, l \geq 3; C_l, l \geq 2; D_l, l \geq 4; E_6, E_7, E_8, F_4$ , or  $G_2$ .

**Examples:**

1. The set  $\mathbb{R}^3$  with  $[\mathbf{u}, \mathbf{v}] = \mathbf{u} \times \mathbf{v}$  (vector cross product) is a three dimensional simple Lie algebra.
2. The set of all upper triangular complex  $n \times n$  matrices is a solvable subalgebra of  $gl(n, \mathbb{C})$ .
3. [Pol69, p. 72] Let  $p > 3$  be a prime. The only ideals of  $gl(p, \mathbb{Z}_p)$  are  $0 \subset scal(p, \mathbb{Z}_p) \subset sl(p, \mathbb{Z}_p) \subset gl(p, \mathbb{Z}_p)$ , where  $scal(p, \mathbb{Z}_p)$  is the set of scalar matrices. Thus, the only ideals of  $L = gl(p, \mathbb{Z}_p)/scal(p, \mathbb{Z}_p)$  are  $L, S = sl(p, \mathbb{Z}_p)/scal(p, \mathbb{Z}_p)$  and  $\{0\}$ . By considering  $D = diag(0, 1, 2, \dots, p-1)$ , we see that  $[sl(n, \mathbb{Z}_p), sl(n, \mathbb{Z}_p)] = sl(n, \mathbb{Z}_p)$ , so  $[S, S] = S$ . Thus,  $S$  is not solvable and  $Rad(L) = 0$ . But  $L$  cannot be the sum of simple ideals.
4. The following are Cartan matrices of type  $A_3, B_3, C_3$  respectively:

$$\begin{bmatrix} 2 & -1 & 0 \\ -1 & 2 & -1 \\ 0 & -1 & 2 \end{bmatrix}, \quad \begin{bmatrix} 2 & -1 & 0 \\ -1 & 2 & -2 \\ 0 & -1 & 2 \end{bmatrix}, \quad \begin{bmatrix} 2 & -1 & 0 \\ -1 & 2 & -1 \\ 0 & -2 & 2 \end{bmatrix}.$$

5. If  $n > 1$  and if  $n$  is not a multiple of the characteristic of  $F$ , let  $L = sl(n, F)$ . Then  $L$  is a simple Lie algebra of dimension  $n^2 - 1$ . If  $T$  denotes the set of diagonal matrices in  $sl(n, F)$  and if  $\epsilon_i \in T^*$  is defined by  $\epsilon_i(diag(d_1, \dots, d_n)) = d_i$ , then  $T$  is a maximal torus in  $sl(n, F)$ ,  $\Delta$ , the set of roots of  $sl(n, F)$  with respect to  $T$ , is  $\{\epsilon_i - \epsilon_j | i \neq j\}$ , and the root space  $L_{\epsilon_i - \epsilon_j} = FE_{i,j}$ . In addition,  $\{\epsilon_i - \epsilon_{i+1} | 1 \leq i \leq n-1\}$  is a base for  $\Delta$  and so the Cartan matrix of  $sl(n, F)$  is of type  $A_{n-1}$ .

6. Let  $(\cdot, \cdot)$  be the symmetric bilinear form on  $F^{2l+1}$  with matrix  $\begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & I_l \\ 0 & I_l & 0 \end{bmatrix}$ . Then  $L = \{x \in gl(2l+1, F) | (xu, v) = -(u, xv) \forall u, v \in F^{2l+1}\}$  is a Lie subalgebra of  $gl(2l+1, F)$ , denoted by  $o(2l+1, F)$ . If the characteristic of  $F$  is not 2, it is a simple algebra of dimension  $2l^2 + l$ . Let  $T$  denote the set of diagonal matrices in  $o(2l+1, F)$ . If  $\epsilon_i \in T^*$  is defined by  $\epsilon_i(diag(d_1, \dots, d_{2l+1})) = d_i$ , and if  $v_i = \epsilon_{i+1}$  for  $1 \leq i \leq l$ , then  $T$  is a maximal torus in  $o(2l+1, F)$ ;  $\Delta$ , the set of roots of  $o(2l+1, F)$  with respect to  $T$ , is  $\{\pm v_i | 1 \leq i \leq l\} \cup \{\pm v_i \pm v_j | 1 \leq i \neq j \leq l\}$ , and, for  $1 \leq i \neq j \leq l$ ,  $L_{v_i} = F(E_{1, l+i+1} - E_{i+1, 1})$ ,  $L_{-v_i} = F(E_{1, i+1} - E_{l+i+1, 1})$ ,  $L_{v_i - v_j} = F(E_{i+1, j+1} - E_{l+j+1, l+i+1})$ ,  $L_{v_i + v_j} = F(E_{i+1, l+j+1} - E_{j+1, l+i+1})$ ,  $L_{-v_i - v_j} = F(E_{l+i+1, j+1} - E_{l+j+1, i+1})$ . In addition,  $\{v_i - v_{i+1} | 1 \leq i \leq l-1\} \cup \{v_l\}$  is a base for  $\Delta$ , and so the Cartan matrix of  $o(2l+1, F)$  is of type  $B_l$ .

7. Let  $(\cdot, \cdot)$  be the skew-symmetric bilinear form on  $F^{2l}$  with matrix  $\begin{bmatrix} 0 & I_l \\ -I_l & 0 \end{bmatrix}$ . Then  $L = \{x \in gl(2l, F) | (xu, v) = -(u, xv) \forall u, v \in F^{2l}\}$  is a Lie subalgebra of  $gl(2l, F)$ , denoted by  $sp(2l, F)$ . If the characteristic of  $F$  is not 2, it is a simple algebra of dimension  $2l^2 + l$ . Let  $T$  denote the set of diagonal matrices in  $sp(2l, F)$ . If  $\epsilon_i \in T^*$  is defined by  $\epsilon_i(diag(d_1, \dots, d_{2l})) = d_i$ , and if  $\mu_i = \epsilon_i$  for  $1 \leq i \leq l$ , then  $T$  is a maximal torus in  $sp(2l, F)$ ,  $\Delta$ , the set of roots of  $sp(2l, F)$  with respect to  $T$ , is  $\{\pm 2\mu_i | 1 \leq i \leq l\} \cup \{\pm \mu_i \pm \mu_j | i \neq j\}$ , and, for  $1 \leq i \leq l$ ,  $L_{2\mu_i} = FE_{i, l+i}$ ,  $L_{-2\mu_i} = FE_{l+i, i}$ ,  $L_{\mu_i - \mu_j} = F(E_{i, j} - E_{l+j, l+i})$ ,  $L_{\mu_i + \mu_j} = F(E_{i, l+j} + E_{j, l+i})$ ,  $L_{-\mu_i - \mu_j} = F(E_{l+i, j} + E_{l+j, i})$ . In addition,  $\{\mu_i - \mu_{i+1} | 1 \leq i \leq l-1\} \cup \{2\mu_l\}$  is a base for  $\Delta$ , and so the Cartan matrix of  $sp(2l, F)$  is of type  $C_l$ .

8. Let  $(\cdot, \cdot)$  be the symmetric bilinear form on  $F^{2l}$  with matrix  $\begin{bmatrix} 0 & I_l \\ I_l & 0 \end{bmatrix}$ . Then  $L = \{x \in gl(2l, F) | (xu, v) = -(u, xv) \forall u, v \in F^{2l}\}$  is a Lie subalgebra of  $gl(2l, F)$ , denoted by  $o(2l, F)$ . If the characteristic of  $F$  is not 2, it is a simple algebra of dimension  $2l^2 - l$ . Let  $T$  denote the set of diagonal matrices in  $o(2l, F)$ . If  $\epsilon_i \in T^*$  is defined by  $\epsilon_i(diag(d_1, \dots, d_{2l})) = d_i$ , and if  $v_i = \epsilon_i$  for  $1 \leq i \leq l$ , then  $T$  is a maximal torus in  $o(2l, F)$ ,  $\Delta$ , the set of roots of  $o(2l, F)$  with respect to  $T$ , is  $\{\pm v_i \pm v_j | 1 \leq i \neq j \leq l\}$ , and, for  $1 \leq i \neq j \leq l$ ,  $L_{v_i - v_j} = F(E_{i, j} - E_{l+j, l+i})$ ,  $L_{v_i + v_j} = F(E_{i, l+j} - E_{j, l+i})$ ,  $L_{-v_i - v_j} = F(E_{l+i, j} - E_{l+j, i})$ . In addition,  $\{v_i - v_{i+1} | 1 \leq i \leq l-1\} \cup \{v_{l-1} + v_l\}$  is a base for  $\Delta$ , and so the Cartan matrix of  $o(2l, F)$  is of type  $D_l$ .

9. Let  $V$  be a vector space of dimension  $n \geq 1$  over a field of characteristic 0. Let  $W(n) = \text{Der}(S(V))$ . Then  $W(n)$  is an infinite-dimensional simple Lie algebra.
10. Let  $F$  be a field of characteristic  $p > 0$ . Let  $V$  be a vector space of dimension  $n \geq 1$  with basis  $\{x_1, \dots, x_n\}$ . Let  $I$  denote the ideal  $\langle x_1^p, \dots, x_n^p \rangle \subseteq S(V)$ ,  $B(n : \mathbf{1})$  denote  $S(V)/I$ , and  $W(n : \mathbf{1}) = \text{Der}(B(n : \mathbf{1}))$ . Then  $W(n : \mathbf{1})$  is a  $p$ -Lie algebra of dimension  $np^n$ . It is a simple Lie algebra unless  $p = 2$  and  $n = 1$ .

## 70.3 Modules

---

### Definitions:

Let  $A$  be an associative algebra and  $V$  be a vector space over  $F$ . A **representation** of  $A$  on  $V$  is a homomorphism  $\phi : A \rightarrow \text{End } V$ .

Let  $L$  be a Lie algebra and  $V$  be a vector space over  $F$ . A **representation** of  $L$  on  $V$  is a homomorphism  $\phi : L \rightarrow \mathfrak{gl}(V)$ .

Let  $B$  be an associative algebra or a Lie algebra. A representation  $\phi : B \rightarrow \mathfrak{gl}(V)$  is **reducible** if there is some nonzero proper subspace  $W \subset V$  such that  $\phi(x)(W) \subseteq W$  for all  $x \in B$ . If  $\phi$  is not reducible, it is **irreducible**.

Let  $L$  be a Lie algebra and  $M$  be a vector space.  $M$  is an **L-module** if there is a linear map  $L \otimes M \rightarrow M, a \otimes m \mapsto am$  such that  $[a, b]m = a(bm) - b(am)$  for all  $a, b \in L, m \in M$ .

Let  $M$  be an  $L$ -module. A subspace  $N \subseteq M$  is a **submodule** of  $M$  if  $LN \subseteq N$ .

Let  $M$  be an  $L$ -module.  $M$  is **reducible** if  $M$  contains a nonzero proper submodule. If  $M$  is not reducible it is **irreducible**. If  $M$  is a direct sum of irreducible submodules, it is **completely reducible**.

Let  $M$  be an  $L$ -module and  $X$  be a subset of  $M$ . The submodule of  $M$  **generated by**  $X$  is the smallest submodule of  $M$  containing  $X$ .

Let  $L$  be a Lie algebra and  $M, N$  be  $L$ -modules. A linear transformation  $\phi : M \rightarrow N$  is a **homomorphism** of  $L$ -modules if  $\phi(xm) = x\phi(m)$  for all  $x \in L, m \in M$ . The set of all  $L$ -module homomorphisms from  $M$  to  $N$  is denoted  $\text{Hom}(M, N)$ .

Let  $L$  be a finite-dimensional semisimple Lie algebra over an algebraically closed field of characteristic 0. Let  $T$  be a maximal torus in  $L$  and  $M$  be an  $L$ -module. For  $\lambda \in T^*$  define  $M_\lambda$ , the  $\lambda$ -**weight space** of  $M$ , to be  $\{m \in M \mid tm = \lambda(t)m \forall t \in T\}$ .

Let  $L$  be a finite-dimensional simple Lie algebra over an algebraically closed field of characteristic 0. Let  $T$  be a maximal torus,  $\Delta$  the corresponding root system,  $B$  a base for  $\Delta$ , and  $\Delta^+$  the corresponding set of positive roots. Let  $M$  be an  $L$ -module and  $\lambda \in T^*$ . An element  $0 \neq m \in M_\lambda$  is a **highest weight vector of weight**  $\lambda$  if  $L_\alpha m = 0$  for all  $\alpha \in \Delta^+$ .

### Facts:

Unless specified otherwise,  $V$  denotes a vector space over a field  $F$ .

The following facts may be found in [Hum, Sect. 6].

1. Let  $L$  be a Lie algebra and  $\phi : L \rightarrow \mathfrak{gl}(V)$  be a representation of  $L$  on  $V$ . Then  $V$  may be given the structure of an  $L$ -module by setting  $xv = \phi(x)(v)$  for all  $x \in L, v \in V$ . Conversely, if  $M$  is an  $L$ -module, then the map  $\phi : L \rightarrow \mathfrak{gl}(M)$  defined by  $\phi(x)(m) = xm$  is a representation of  $L$  on  $M$ . A representation  $\phi$  is irreducible if and only if the corresponding module is.
2. Let  $\phi$  be a representation of a Lie algebra  $L$  on  $V$ . Then, by the universal property of the universal enveloping algebra,  $\phi$  extends to a representation of  $U(L)$  on  $V$ . Conversely, every representation of  $U(L)$  on  $V$  restricts to a representation of  $L$  on  $V$ . A representation  $\phi$  of  $U(L)$  on  $V$  is irreducible if and only if its restriction to  $L$  is.
3. Let  $L$  be a Lie algebra,  $M$  be an  $L$ -module, and  $N \subseteq M$  be a submodule. Then the quotient space  $M/N$  may be given the structure of an  $L$ -module by setting  $x(m + N) = xm + N$  for all  $x \in L, m \in M$ .

4. Let  $L$  be a Lie algebra and  $M, N$  be  $L$ -modules. Then the vector space  $M \oplus N$  may be given the structure of an  $L$ -module by setting  $x(m + n) = xm + xn$  for all  $x \in L, m \in M, n \in N$ .
5. Let  $L$  be a Lie algebra and  $M, N$  be  $L$ -modules. Then the vector space  $M \otimes N$  may be given the structure of an  $L$ -module by setting  $x(m \otimes n) = xm \otimes n + m \otimes xn$  for all  $x \in L, m \in M, n \in N$ .
6. Let  $L$  be a Lie algebra and  $M, N$  be  $L$ -modules. Then  $\text{Hom}(M, N)$  may be given the structure of an  $L$ -module by setting  $(x\phi)(m) = x\phi(m) - \phi(xm)$  for all  $x \in L, m \in M$ .
7. Let  $L$  be a Lie algebra and  $V$  be an  $L$ -module. Then  $T(V)$  is an  $L$ -module and the ideals occurring in the definitions of  $S(V)$  and  $\Lambda(V)$  are submodules. Hence,  $S(V)$  and  $\Lambda(V)$  are  $L$ -modules. Furthermore, each  $S^n(V)$  is a submodule of  $S(V)$  and each  $\Lambda^n(V)$  is a submodule of  $\Lambda(V)$ .
8. [Jac62, p. 79] *Weyl's Theorem*: Let  $L$  be a finite-dimensional semisimple Lie algebra over a field of characteristic zero and let  $M$  be a finite-dimensional  $L$ -module. Then  $M$  is completely reducible.
9. [Hum72, pp. 107–114] Let  $L$  be a finite-dimensional semisimple Lie algebra over an algebraically closed field of characteristic 0 and  $M$  be a finite-dimensional  $L$ -module. Let  $T$  be a maximal torus in  $L$ ,  $\Delta$  be the corresponding root system,  $B = \{\alpha_1, \dots, \alpha_l\}$  a base for  $\Delta$ , and  $\Delta^+$  be the corresponding set of positive roots. Then:

- $M = \sum_{\lambda \in T^*} M_\lambda$ .
- $M$  contains a highest weight vector of weight  $\lambda$  for some  $\lambda \in T^*$  and setting  $h_i = \frac{2\alpha_i}{(\alpha_i, \alpha_i)}$  for  $1 \leq i \leq l$ , we have  $\lambda(h_i) \geq 0, \lambda(h_i) \in \mathbb{Z}$  for  $1 \leq i \leq l$ .
- If  $M$  is irreducible and  $m_1, m_2$  are highest weight vectors corresponding to  $\lambda_1, \lambda_2 \in T^*$ , then  $\lambda_1 = \lambda_2$  and  $Fm_1 = Fm_2$ .
- If  $M, N$  are irreducible finite-dimensional  $L$ -modules containing highest weight vectors corresponding to the same  $\lambda \in T^*$ , then  $M$  and  $N$  are isomorphic.
- Let  $\lambda \in T^*$  satisfy  $\lambda(h_i) \in \mathbb{Z}, \lambda(h_i) \geq 0$  for  $1 \leq i \leq l$ . Then there exists a finite-dimensional  $L$ -module with highest weight  $\lambda$ .

### Examples:

1. Let  $V$  be a vector space of dimension  $n > 1$ . Then  $V$  is a  $gl(V)$ -module and, hence, a  $gl(n, F)$ -module. Therefore, for each  $k > 0$ ,  $S^k(V)$  and  $\Lambda^k(V)$  are modules for  $gl(V)$  and, thus, modules for any subalgebra of  $gl(n, F)$ .
2. Let  $V$  be a vector space with basis  $\{x, y\}$ . Let  $\{e, f, h\}$  be a basis for  $sl(2, F)$  with  $[e, f] = h, [h, e] = 2e, [h, f] = -2f$ . The linear map  $sl(2, F) \rightarrow \text{Der}(F[x, y])$  defined by  $e \mapsto \frac{x\partial}{\partial y}, f \mapsto \frac{y\partial}{\partial x}, h \mapsto \frac{x\partial}{\partial x} - \frac{y\partial}{\partial y}$  is an isomorphism of  $sl(2, F)$  into  $\text{Der}(F[x, y])$ . Consequently,  $F[x, y] = S(V)$  is an  $sl(2, F)$ -module and each  $S^n(V)$  is an  $sl(2, F)$  submodule.  $S^n(V)$  has basis  $\{x^n, x^{n-1}y, \dots, y^n\}$  and so is an  $(n + 1)$ -dimensional  $sl(2, F)$ -module. It is irreducible.

## 70.4 Graded Algebras and Modules

---

### Definitions:

Let  $V$  be a vector space and  $A$  be an additive abelian group. For each  $\alpha \in A$ , let  $V_\alpha$  be a subspace of  $V$ . If  $V = \bigoplus_{\alpha \in A} V_\alpha$ , then  $V$  is an  **$A$ -graded vector space**.

Let  $B$  be an algebra and an  $A$ -graded vector space.  $B$  is an  **$A$ -graded algebra** if  $B_\alpha B_\beta \subseteq B_{\alpha+\beta}$  for all  $\alpha, \beta \in A$ .

Let  $B$  be an  $A$ -graded associative algebra or an  $A$ -graded Lie algebra. Let  $M$  be a  $B$ -module and an  $A$ -graded vector space.  $M$  is an  **$A$ -graded module** for  $B$  if  $B_\alpha M_\beta \subseteq M_{\alpha+\beta}$  for all  $\alpha, \beta \in A$ .

Let  $V$  be an  $A$ -graded vector space.  $V$  has **graded dimension** if  $\dim(V_\alpha) < \infty$  for all  $\alpha \in A$ . In this case, we define the **graded dimension** of  $V$  to be the formal sum

$$gr \dim(V) = \sum_{\alpha \in A} \dim(V_\alpha)t^\alpha.$$

The graded dimension of  $V$  is sometimes called the **character** of  $V$ .

**Facts:**

1. [FLM88, Sect. 1.10] Let  $V, W$  be  $A$ -graded vector spaces with graded dimensions. Then  $V \oplus W$  is a graded vector space with graded dimension and  $gr \dim(V \oplus W) = gr \dim(V) + gr \dim(W)$ . If  $W$  is a subspace of  $V$  and  $W_\alpha \subseteq V_\alpha$  for all  $\alpha \in A$ , then the quotient space  $V/W$  has graded dimension and  $gr \dim(V/W) = gr \dim(V) - gr \dim(W)$ . If  $\{(\alpha, \beta) \in A \times A \mid V_\alpha, W_\beta \neq \{0\}, \alpha + \beta = \gamma\}$  is finite for all  $\gamma \in A$ , then  $V \otimes W$  is a graded vector space with graded dimension, where  $(V \otimes W)_\gamma = \sum_{\alpha+\beta=\gamma} V_\alpha \otimes W_\beta$  and  $gr \dim(V \otimes W) = (gr \dim(V))(gr \dim(W))$  (where we set  $t^\alpha t^\beta = t^{\alpha+\beta}$ ).
2. [Bou72, p. 36] Let  $V$  be a vector space with basis  $X$ . Setting  $Fr(X)_i = Fr(X) \cap V^{\otimes i}$  gives  $Fr(X)$  the structure of a graded Lie algebra. If  $|X| = l$  is finite,  $Fr(X)$  has graded dimension and  $gr \dim(Fr(X)) = \sum_{n>0} \frac{1}{n} (\sum_{d|n} \mu(d) l^{\frac{n}{d}}) t^n$ , where  $\mu$  is the Möbius function (i.e.,  $\mu(p_1 \dots p_r) = (-1)^r$  if  $p_1, \dots, p_r$  are distinct primes and  $\mu(n) = 0$  if  $p^2|n$  for some prime  $p$ ).
3. [Jac62, Sect. VIII.3] Let  $L$  be a finite-dimensional semisimple Lie algebra over an algebraically closed field of characteristic 0,  $T$  be a maximal torus in  $L$ ,  $\Delta$  be the corresponding root system,  $W$  be the Weyl group,  $\Delta^+$  be the set of positive roots with respect to some base, and  $M$  be a finite-dimensional  $L$ -module. Then:
  - Let  $\mathbb{Z}\Delta$  denote the additive subgroup of  $T^*$  generated by  $\Delta$ . Then the root space decomposition  $L = T + \sum_{\alpha \in \Delta} L_\alpha$  gives  $L$  the structure of a  $\mathbb{Z}\Delta$ -graded Lie algebra. Here  $L_0 = T$ .
  - The weight space decomposition  $M = \sum_{\alpha \in T^*} M_\alpha$  gives  $M$  the structure of a graded module with graded dimension.
  - *Weyl character formula:* Assume  $M$  is irreducible with highest weight  $\lambda$ . Let  $\delta = \frac{1}{2} \sum_{\alpha \in \Delta^+} \alpha$ . Then

$$gr \dim(M) = \left( \sum_{w \in W} (\det(w)t^{w(\lambda+\delta)}) \right) / \left( \sum_{w \in W} (\det(w)t^{w\delta}) \right).$$

**Examples:**

1. Setting  $T(V)_i = V^{\otimes i}$  gives  $T(V)$  the structure of a  $\mathbb{Z}$ -graded algebra. If  $V$  has finite dimension  $l$ , then  $T(V)$  has graded dimension and  $gr \dim(T(V)) = (1 - lt)^{-1}$ .
2. Setting  $S(V)_i = S^i(V)$  gives  $S(V)$  the structure of a  $\mathbb{Z}$ -graded algebra. If  $V$  has finite dimension  $l$ , then  $S(V)$  has graded dimension and  $gr \dim(S(V)) = (1 - t)^{-l}$ .
3. Setting  $\Lambda(V)_i = \Lambda^i(V)$  gives  $\Lambda(V)$  the structure of a  $\mathbb{Z}$ -graded algebra. If  $V$  has finite dimension  $l$ , then  $\Lambda(V)$  has graded dimension and  $gr \dim(\Lambda(V)) = (1 + t)^l$ .
4. Let  $L$  be a finite-dimensional semisimple Lie algebra over an algebraically closed field of characteristic 0,  $T$  be a maximal torus in  $L$ ,  $\Delta$  be the corresponding root system, and  $B = \{\alpha_1, \dots, \alpha_l\}$  be a base. For  $1 \leq i \leq l$  define  $\lambda_i$  by  $\lambda_i(\frac{2t_{\alpha_j}}{(\alpha_j, \alpha_j)}) = \delta_{i,j}$ . Then:
  - If  $L = sl(V)$ , where  $V$  is an  $l + 1$ -dimensional vector space and the base for  $\Delta$  is as described in Example 5 of section 70.2, then  $\Lambda^i(V)$  is the irreducible  $sl(V)$ -module of highest weight  $\lambda_i$  for  $1 \leq i \leq l$ .

- If  $L = \mathfrak{o}(V)$ , where  $V$  is a  $2l + 1$ -dimensional vector space and the base for  $\Delta$  is as described in Example 6 of section 70.2, then  $\Lambda^i(V)$  is the irreducible  $\mathfrak{o}(V)$ -module of highest weight  $\lambda_i$  for  $1 \leq i \leq l - 1$ .
- If  $L = \mathfrak{o}(V)$ , where  $V$  is a  $2l$ -dimensional vector space and the base for  $\Delta$  is as described in Example 8 of section 70.2, then  $\Lambda^i(V)$  is the irreducible  $\mathfrak{o}(V)$ -module of highest weight  $\lambda_i$  for  $1 \leq i \leq l - 2$ .

MATLAB<sup>®</sup> is generally recognized as the leading software for scientific computation. It was originally developed in the 1970s by Cleve Moler as an interactive Matrix Laboratory with matrix routines based on the algorithms in the LINPACK and EISPACK software libraries. In the original 1978 version everything in MATLAB was done with matrices, even the graphics. MATLAB has continued to grow and expand from the classic 1978 Fortran version to the current version, MATLAB 7, which was released in May 2004. Each new release has included significant improvements. The graphics capabilities were greatly enhanced with the introduction of Handle Graphics and Graphical User Interfaces in version 4 (1992). A sparse matrix package was also included in version 4. Over the years, dozens of toolboxes (application libraries of specialized MATLAB files) have been added in areas such as signal processing, statistics, optimization, symbolic math, splines, and image processing. MATLAB's matrix computations are now based on the LAPACK and BLAS software libraries. MATLAB is widely used in linear algebra courses. Books such as [Leo06], [LHF03], and [HZ04] have extensive sets of MATLAB exercises and projects for the standard first course in linear algebra. The book by D.J. Higham and N.J. Higham [HH03] provides a comprehensive guide to all the basic features of MATLAB.

## 71.1 Matrices, Submatrices, and Multidimensional Arrays

### Facts:

1. The basic data elements that MATLAB uses are matrices. Matrices can be entered into a MATLAB session using square brackets.
2. If  $A$  and  $B$  are matrices with the same number of rows, then one can append the columns of  $B$  to the matrix  $A$  and form an augmented matrix  $C$  by setting  $C = [A, B]$ . If  $E$  is a matrix with the same number of columns as  $A$ , then one can append the rows of  $E$  to  $A$  and form an augmented matrix  $F$  by setting  $F = [A; E]$ .

- Row vectors of evenly spaced entries can be generated using MATLAB's `:` operator.
- A submatrix of a matrix  $A$  is specified by  $A(u, v)$  where  $u$  and  $v$  are vectors that specify the row and column indices of the submatrix.
- MATLAB arrays can have more than two dimensions.

### Commands:

- The number of rows and columns of a matrix can be determined using MATLAB's `size` command.
- The command `length(x)` can be used to determine the number of entries in a vector  $x$ . The `length` command is equivalent to the command `max(size(x))`.
- MATLAB's `cat` command can be used to concatenate two or more matrices along a single dimension and it can also be used to create multidimensional arrays. If two matrices  $A$  and  $B$  have the same number of columns, then the command `cat(1, A, B)` produces the same matrix as the command `[A; B]`. If the matrices  $B$  and  $C$  have the same number of rows, the command `cat(2, B, C)` produces the same matrix as the command `[B, C]`. The `cat` command can be used with more than two matrices as arguments. For example, the command `cat(2, A, B, C, D)` generates the same matrix as the command `[A, B, C, D]`. If  $A_1, A_2, \dots, A_k$  are  $m \times n$  matrices, the command  $S = \text{cat}(3, A_1, A_2, \dots, A_k)$  will generate an  $m \times n \times k$  array  $S$ .

### Examples:

- The matrix

$$A = \begin{bmatrix} 1 & 2 & 4 & 3 \\ 3 & 5 & 7 & 2 \\ 2 & 4 & 1 & 1 \end{bmatrix}$$

is generated using the command

$$A = \begin{bmatrix} 1 & 2 & 4 & 3 \\ 3 & 5 & 7 & 2 \\ 2 & 4 & 1 & 1 \end{bmatrix}.$$

Alternatively, one could generate the matrix on a single line using semicolons to designate the ends of the rows

$$A = [ 1 \ 2 \ 4 \ 3; 3 \ 5 \ 7 \ 2; 2 \ 4 \ 1 \ 1 ].$$

The command `size(A)` will return the vector  $(3, 4)$  as the answer. The command `size(A,1)` will return the value 3, the number of rows of  $A$ , and the command `size(A,2)` will return the value 4, the number of columns of  $A$ .

- The command

$$x = 3 : 7$$

will generate the vector  $x = (3, 4, 5, 6, 7)$ . To change the step size to  $\frac{1}{2}$ , set

$$z = 3 : 0.5 : 7.$$

This will generate the vector  $z = (3, 3.5, 4, 4.5, 5, 5.5, 6, 6.5, 7)$ . The MATLAB commands `length(x)` and `length(z)` will generate the answers 5 and 9, respectively.

- If  $A$  is the matrix in Example 1, then the command `A(2,:)` will generate the second row vector of  $A$  and the command `A(:,3)` will generate the third column vector of  $A$ . The submatrix of elements that are in the first two rows and last two columns is given by `A(1:2, 3:4)`. Actually there is no need to use adjacent rows or columns. The command  $C = A([1 \ 3], [1 \ 3 \ 4])$  will generate the submatrix

$$C = \begin{bmatrix} 1 & 4 & 3 \\ 2 & 1 & 1 \end{bmatrix}.$$

## 4. The command

$$S = \text{cat}(3, [5 \ 1 \ 2; 3 \ 2 \ 1], [1 \ 2 \ 3; 4 \ 5 \ 6])$$

will produce a  $2 \times 3 \times 2$  array  $S$  with

$$S(:, :, 1) = \begin{array}{ccc} 5 & 1 & 2 \\ 3 & 2 & 1 \end{array}$$

and

$$S(:, :, 2) = \begin{array}{ccc} 1 & 2 & 3 \\ 4 & 5 & 6. \end{array}$$

## 71.2 Matrix Arithmetic

---

The six basic MATLAB operators for doing matrix arithmetic are:  $+$ ,  $-$ ,  $*$ ,  $^{\wedge}$ ,  $\backslash$ , and  $/$ . The matrix left and right divide operators,  $\backslash$  and  $/$ , are described in Section 71.5. These same operators are also used for doing scalar arithmetic.

### Facts:

1. If  $A$  and  $B$  are matrices with the same dimensions, then their sum and difference are computed using the commands:  $A + B$  and  $A - B$ .
2. If  $B$  and  $C$  are matrices and the multiplication  $BC$  is possible, then the product  $E = BC$  is computed using the command

$$E = B * C.$$

3. The  $k$ th power of a square matrix  $A$  is computed with the command  $A^k$ .
4. Scalars can be either real or complex numbers. A complex number such as  $3 + 4i$  is entered in MATLAB as  $3 + 4i$ . It can also be entered as  $3 + 4 * \text{sqrt}(-1)$  or by using the command  $\text{complex}(3, 4)$ . If  $i$  is used as a variable and assigned a value, say  $i = 5$ , then MATLAB will assign the expression  $3 + 4 * i$  the value 23; however, the expression  $3 + 4i$  will still represent the complex number  $3 + 4i$ . In the case that  $i$  is used as a variable and assigned a numerical value, one should be careful to enter a complex number of the form  $a + i$  (where  $a$  real) as  $a + 1i$ .
5. MATLAB will perform arithmetic operations element-wise when the operator is preceded by a period in the MATLAB command.
6. The conjugate transpose of a matrix  $B$  is computed using the command  $B'$ . If the matrix  $B$  is real, then  $B'$  will be equal to the transpose of  $B$ . If  $B$  has complex entries, then one can take its transpose without conjugating using the command  $B'$ .

### Commands:

1. The inverse of a nonsingular matrix  $C$  is computed using the command  $\text{inv}(C)$ .
2. The determinant of a square matrix  $A$  is computed using the command  $\text{det}(A)$ .

**Examples:**

1. If

$$A = \begin{bmatrix} 1 & 2 \\ 3 & 4 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 5 & 1 \\ 2 & 3 \end{bmatrix}$$

the commands  $A * B$  and  $A \cdot B$  will generate the matrices

$$\begin{bmatrix} 9 & 7 \\ 23 & 15 \end{bmatrix}, \quad \begin{bmatrix} 5 & 2 \\ 6 & 12 \end{bmatrix}.$$

### 71.3 Built-In MATLAB Functions

---

The `inv` and `det` commands are examples of built-in MATLAB functions. Both functions have a single input and a single output. Thus, the command  $d = \text{det}(A)$  has the matrix  $A$  as its input argument and the scalar  $d$  as its output argument. A MATLAB function may have many input and output arguments. When a command of the form

$$[A_1, \dots, A_k] = \text{fname}(B_1, \dots, B_n) \quad (71.1)$$

is used to call a function `fname` with input arguments  $B_1, \dots, B_n$ , MATLAB will execute the function routine and return the values of the output arguments  $A_1, \dots, A_k$ .

**Facts:**

1. The number of allowable input and output arguments for a MATLAB function is defined by a function statement in the MATLAB file that defines the function. (See section 71.8.) The function may require some or all of its input arguments. A MATLAB command of the form (71.1) may be used with  $j$  output arguments where  $0 \leq j \leq k$ . The MATLAB help facility describes the various input and output options for each of the MATLAB commands.

**Examples:**

1. The MATLAB function `pi` is used to generate the number  $\pi$ . This function is used with no input arguments.
2. The MATLAB function `kron` has two input arguments. If  $A$  and  $B$  are matrices, then the command `kron(A,B)` computes the Kronecker product of  $A$  and  $B$ . Thus, if  $A = [1, 2; 3, 4]$  and  $B = [1, 1; 1, 1]$ , then the command  $K = \text{kron}(A, B)$  produces the matrix

$$K = \begin{bmatrix} 1 & 1 & 2 & 2 \\ 1 & 1 & 2 & 2 \\ 3 & 3 & 4 & 4 \\ 3 & 3 & 4 & 4 \end{bmatrix}$$

and the command  $L = \text{kron}(B, A)$  produces the matrix

$$L = \begin{bmatrix} 1 & 2 & 1 & 2 \\ 3 & 4 & 3 & 4 \\ 1 & 2 & 1 & 2 \\ 3 & 4 & 3 & 4 \end{bmatrix}.$$

3. One can compute the  $QZ$  factorization (see section 71.6) for the generalized eigenvalue problem using a command

$$[E, F, Q, Z] = \text{qz}(A, B)$$

with two input arguments and four outputs. The input arguments are square matrices  $A$  and  $B$  and the outputs are quasitriangular matrices  $E$  and  $F$  and unitary matrices  $Q$  and  $Z$  such that

$$QAZ = E \quad \text{and} \quad QBZ = F.$$

The command

$$[E, F, Q, Z, V, W] = \text{qz}(A, B)$$

will also compute matrices  $V$  and  $W$  of generalized eigenvectors.

## 71.4 Special Matrices

---

The ELMAT directory of MATLAB contains a collection of MATLAB functions for generating special types of matrices.

### Commands:

- The following table lists commands for generating various types of special matrices.

Matrix	Command Syntax	Description
eye	eye( $n$ )	Identity matrix
ones	ones( $n$ ) or ones( $m, n$ )	Matrix whose entries are all equal to 1
zeros	zeros( $n$ ) or zeros( $m, n$ )	Matrix whose entries are all equal to 0
rand	rand( $n$ ) or rand( $m, n$ )	Random matrix
compan	compan( $p$ )	Companion matrix
hadamard	hadamard( $n$ )	Hadamard matrix
gallery	gallery(matname, $p1, p2, \dots$ )	Large collection of special test matrices
hankel	hankel( $c$ ) or hankel( $c, r$ )	Hankel matrix
hilb	hilb( $n$ )	Hilbert matrix
invhilb	invhilb( $n$ )	Inverse Hilbert matrix
magic	magic( $n$ )	Magic square
pascal	pascal( $n$ )	Pascal matrix
rosser	rosser	Test matrix for eigenvalue solvers
toeplitz	toeplitz( $c$ ) or toeplitz( $c, r$ )	Toeplitz matrix
vander	vander( $x$ )	Vandermonde matrix
wilkinson	wilkinson( $n$ )	Wilkinson's eigenvalue test matrix

- The command `gallery` can be used to access a large collection of test matrices developed by N. J. Higham. Enter `help gallery` to obtain a list of all classes of gallery test matrices.

### Examples:

- The command `rand( $n$ )` will generate an  $n \times n$  matrix whose entries are random numbers that are uniformly distributed in the interval  $(0, 1)$ . The command may be used with two input arguments

to generate nonsquare matrices. For example, the command `rand(3,2)` will generate a random  $3 \times 2$  matrix. The command `rand` when used by itself with no input arguments will generate a single random number between 0 and 1.

- The command

$$A = [ \text{eye}(2), \text{ones}(2,3); \text{zeros}(2), 2 * \text{ones}(2,3) ]$$

will generate the matrix

$$A = \begin{bmatrix} 1 & 0 & 1 & 1 & 1 \\ 0 & 1 & 1 & 1 & 1 \\ 0 & 0 & 2 & 2 & 2 \\ 0 & 0 & 2 & 2 & 2. \end{bmatrix}$$

- The command `toeplitz(c)` will generate a symmetric toeplitz matrix whose first column is the vector `c`. Thus, the command

$$\text{toeplitz}([1; 2; 3])$$

will generate

$$T = \begin{bmatrix} 1 & 2 & 3 \\ 2 & 1 & 2 \\ 3 & 2 & 1. \end{bmatrix}$$

Note that in this case, since the `toeplitz` command was used with no output argument, the computed value of the command `toeplitz(c)` was assigned to the temporary variable `ans`. Further computations may end up overwriting the value of `ans`. To keep the matrix for further use in the MATLAB session, it is advisable to include an output argument in the calling statement.

For a nonsymmetric Toeplitz matrix it is necessary to include a second input argument `r` to define the first row of the matrix. If  $r(1) \neq c(1)$ , the value of  $c(1)$  is used for the main diagonal. Thus, commands

$$c = [1; 2; 3], \quad r = [9, 5, 7], \quad T = \text{toeplitz}(c, r)$$

will generate

$$T = \begin{bmatrix} 1 & 5 & 7 \\ 2 & 1 & 5 \\ 3 & 2 & 1. \end{bmatrix}$$

The Toeplitz matrix generated is stored using the variable `T`.

- One of the classes of gallery test matrices is circulant matrices. These are generated using the MATLAB function `circul`. To see how to use this function, enter the command

$$\text{help private} \backslash \text{circul}.$$

The help information will tell you that the `circul` function requires an input vector `v` and that the command

$$C = \text{gallery}(' \text{circul}', v)$$

will generate a circulant matrix whose first row is  $\mathbf{v}$ . Thus, the command

$$C = \text{gallery}('circul', [4, 5, 6])$$

will generate the matrix

$$C = \begin{bmatrix} 4 & 5 & 6 \\ 6 & 4 & 5 \\ 5 & 6 & 4 \end{bmatrix}$$

## 71.5 Linear Systems and Least Squares

---

The simplest way to solve a linear system in MATLAB is to use the matrix left divide operator.

### Facts:

1. The symbol  $\backslash$  represents MATLAB's matrix left divide operator. One can compute the solution to a linear system  $A\mathbf{x} = \mathbf{b}$  by setting

$$\mathbf{x} = A \backslash \mathbf{b}.$$

If  $A$  is an  $n \times n$  matrix, then MATLAB will compute the solution using Gaussian elimination with partial pivoting. A warning message is given when the matrix is badly scaled or nearly singular. If the coefficient matrix is nonsquare, then MATLAB will return a least squares solution to the system that is essentially equivalent to computing  $A^\dagger \mathbf{b}$  (where  $A^\dagger$  denotes the pseudoinverse of  $A$ ). In this case, MATLAB determines the numerical rank of the coefficient matrix using a  $QR$  decomposition and gives a warning when the matrix is rank deficient.

If  $A$  is an  $m \times n$  matrix and  $B$  is  $m \times k$ , then the command

$$C = A \backslash B$$

will produce an  $n \times k$  matrix whose column vectors satisfy

$$\mathbf{c}_j = A \backslash \mathbf{b}_j \quad j = 1, \dots, k.$$

2. The symbol  $/$  represents MATLAB's matrix right divide operator. It is defined by

$$B/A = (A' \backslash B')'.$$

In the case that  $A$  is nonsingular, the computation  $B/A$  is essentially the same as computing  $BA^{-1}$ , however, the computation is carried out without actually computing  $A^{-1}$ .

### Commands:

The following table lists some of the main MATLAB commands that are useful for linear systems.

Function	Command Syntax	Description
rref	$U = \text{rref}(A)$	Reduced row echelon form of a matrix
lu	$[L, U] = \text{lu}(A)$	LU factorization
linsolve	$x = \text{linsolve}(A, b, \text{opts})$	Efficient solver for structured linear systems
chol	$R = \text{chol}(A)$	Cholesky factorization of a matrix
norm	$p = \text{norm}(X)$	Norm of a matrix or a vector
null	$U = \text{null}(A)$	Basis for the null space of a matrix
null	$R = \text{null}(A, 'r')$	Basis for null space rational form
orth	$Q = \text{orth}(A)$	Orthonormal basis for the column space of a matrix
rank	$r = \text{rank}(A)$	Numerical rank of a matrix
cond	$c = \text{cond}(A)$	2-norm condition number for solving linear systems
rcond	$c = \text{rcond}(A)$	Reciprocal of approximate 1-norm condition number
qr	$[Q, R] = \text{qr}(A)$	QR factorization
svd	$s = \text{svd}(A)$	Singular values of a matrix
svd	$[U, S, V] = \text{svd}(A)$	Singular value decomposition
pinv	$B = \text{pinv}(A)$	Pseudoinverse of a matrix

**Examples:**

- The null command can be used to produce an orthonormal basis for the nullspace of a matrix. It can also be used to produce a “rational” nullspace basis obtained from the reduced row echelon form of the matrix. If

$$A = \begin{bmatrix} 1 & 1 & 1 & -1 \\ 1 & 1 & 1 & -1 \\ 1 & 1 & 1 & 1 \end{bmatrix},$$

then the command  $U = \text{null}(A)$  will produce the matrix

$$U = \begin{bmatrix} -0.8165 & -0.0000 \\ 0.4082 & 0.7071 \\ 0.4082 & -0.7071 \\ -0.0000 & 0.0000 \end{bmatrix}$$

where the entries of  $U$  are shown in MATLAB's format short (with four-digit mantissas). The column vectors of  $U$  form an orthonormal basis for the nullspace of  $A$ . The command  $R = \text{null}(A, 'r')$  will produce a matrix  $R$  whose columns form a simple basis for the nullspace.

$$R = \begin{bmatrix} -1 & -1 \\ 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{bmatrix}$$

- MATLAB defines the numerical rank of a matrix to the number of singular values of the matrix that are greater than

$$\max(\text{size}(A)) * \text{norm}(A) * \text{eps}$$

where `eps` has the value  $2^{-52}$ , which is a measure of the precision used in MATLAB computations. Let  $H$  be the  $12 \times 12$  Hilbert matrix. The singular values of  $H$  can be computed using the command `s = svd(H)`. The smallest singular values are  $s(11) \approx 2.65 \times 10^{-14}$  and  $s(12) \approx 10^{-16}$ . Since the value of `eps` is approximately  $2.22 \times 10^{-16}$ , the computed value of `rank(H)` will be the numerical rank 11, even though the exact rank of  $H$  is 12. The computed value of `cond(H)` is approximately  $1.8 \times 10^{16}$  and the computed value of `rcond(H)` is approximately  $2.6 \times 10^{-17}$ .

## 71.6 Eigenvalues and Eigenvectors

MATLAB's `eig` function can be used to compute both the eigenvalues and eigenvectors of a matrix.

### Commands:

1. The `eig` command. Given a square matrix  $A$ , the command `e = eig(A)` will generate a column vector  $e$  whose entries are the eigenvalues of  $A$ . The command `[X, D] = eig(A)` will generate a matrix  $X$  whose column vectors are the eigenvectors of  $A$  and a diagonal matrix  $D$  whose diagonal entries are the eigenvalues of  $A$ .
2. The `eigshow` command. MATLAB's `eigshow` utility provides a visual demonstration of eigenvalues and eigenvectors of  $2 \times 2$  matrices. The utility is invoked by the command `eigshow(A)`. The input argument  $A$  must be a  $2 \times 2$  matrix. The command can also be used with no input argument, in which case MATLAB will take  $[1\ 3; 4\ 2]/4$  as the default  $2 \times 2$  matrix. The `eigshow` utility shows how the image  $Ax$  changes as we rotate a unit vector  $x$  around a circle. This rotation is carried out manually using a mouse. If  $A$  has real eigenvalues, then we can observe the eigenvectors of the matrix when the vectors  $x$  and  $Ax$  are in the same or opposite directions.
3. The command `J = jordan(A)` can be used to compute the Jordan canonical form of a matrix  $A$ . This command will only give accurate results if the entries of  $A$  are exactly represented, i.e., the entries must be integers or ratios of small integers. The command `[X, J] = jordan(A)` will also compute the similarity matrix  $X$  so that  $A = XJX^{-1}$ .
4. The following table lists some additional MATLAB functions that are useful for eigenvalue related problems.

Function	Command Syntax	Description
<code>poly</code>	<code>p = poly(A)</code>	Characteristic polynomial of a matrix
<code>hess</code>	<code>H = hess(A)</code> or <code>[U, H] = hess(A)</code>	Hessenberg form
<code>schur</code>	<code>T = schur(A)</code> or <code>[U, T] = schur(A)</code>	Schur decomposition
<code>qz</code>	<code>[E, F, Q, Z] = qz(A, B)</code>	QZ factorization for generalized eigenvalues
<code>condeig</code>	<code>s = condeig(A)</code>	Condition numbers for the eigenvalues of $A$
<code>expm</code>	<code>E = expm(A)</code>	Matrix exponential

## 71.7 Sparse Matrices

A matrix is *sparse* if most of its entries are zero. MATLAB has a special data structure for handling sparse matrices. This structure stores the nonzero entries of a sparse matrix together with their row and column indices.

### Commands:

1. The command `sparse` is used to generate sparse matrices. When used with a single input argument the command

$$S = \text{sparse}(A)$$

will convert an ordinary MATLAB matrix  $A$  into a matrix  $S$  having the sparse data structure. More generally, a command of the form

$$S = \text{sparse}(i, j, s, m, n, \text{nzmax})$$

will generate an  $m \times n$  sparse matrix  $S$  whose nonzero entries are the entries of the vector  $s$ . The row and column indices of the nonzero entries are given by the vectors  $i$  and  $j$ . The last input argument  $\text{nzmax}$  specifies the total amount of space allocated for nonzero entries. If the allocation argument is omitted, by default MATLAB will set it to equal the value of  $\text{length}(s)$ .

- MATLAB's `spy` command can be used to plot the sparsity pattern of a matrix. In these plots the matrix is represented by a rectangular box with dots corresponding to the positions of its nonzero entries.
- The MATLAB directory SPARFUN contains a large collection of MATLAB functions for working with sparse matrices. The general sparse linear algebra functions are given in the following table.

MATLAB Function	Description
<code>eigs</code>	A few eigenvalues, using ARPACK
<code>svds</code>	A few singular values, using eigs
<code>luinc</code>	Incomplete LU factorization
<code>cholinc</code>	Incomplete Cholesky factorization
<code>normest</code>	Estimate the matrix 2-norm
<code>condest</code>	1-norm condition number estimate
<code>sprank</code>	Structural rank

All of these functions require a sparse matrix as an input argument. All have one basic output argument except in the case of `luinc`, where the basic output consists of the  $L$  and  $U$  factors.

- The SPARFUN directory also includes a collection of routines for the iterative solution of sparse linear systems.

MATLAB Function	Description
<code>pcg</code>	Preconditioned Conjugate Gradients Method
<code>bicg</code>	BiConjugate Gradients Method
<code>bicgstab</code>	BiConjugate Gradients Stabilized Method
<code>cgs</code>	Conjugate Gradients Squared Method
<code>gmres</code>	Generalized Minimum Residual Method
<code>lsqr</code>	Conjugate Gradients on the Normal Equations
<code>minres</code>	Minimum Residual Method
<code>qmr</code>	Quasi-Minimal Residual Method
<code>symmlq</code>	Symmetric LQ Method

If  $A$  is a sparse coefficient matrix and  $B$  is a matrix of right-hand sides, then one can solve the equation  $AX = B$  using a command of the form  $X = \text{fname}(A, B)$ , where `fname` is one of the iterative solver functions in the table.

### Examples:

- The command

$$S = \text{sparse}([25, 37, 8], [211, 15, 92], [4.5, 3.2, 5.7], 200, 300)$$

will generate a  $200 \times 300$  sparse matrix  $S$  whose only nonzero entries are

$$s_{25,211} = 4.5, \quad s_{37,15} = 3.2, \quad s_{8,92} = 5.7.$$

FIGURE 71.1 Spy(B).

2. The command `B = bucky` will generate the  $60 \times 60$  sparse adjacency matrix  $B$  of the connectivity graph of the Buckminster Fuller geodesic dome and the command `spy(B)` will generate the spy plot shown in Figure 71.1.

## 71.8 Programming

MATLAB has built in all of the main structures one would expect from a high-level computer language. The user can extend MATLAB by adding on programs and new functions.

### Facts:

1. MATLAB programs are called *M-files* and should be saved with a `.m` extension.
2. MATLAB programs may be in the form of *script* files that list a series of commands to be executed when the file is called in a MATLAB session, or they can be in the form of MATLAB functions.
3. MATLAB programs frequently include for loops, while loops, and if statements.
4. A function file must start with a function statement of the form

$$\text{function } [\text{oarg1}, \dots, \text{oargk}] = \text{fname}(\text{iarg1}, \dots, \text{iargj})$$

where `fname` is the name of the function, `iarg1, ..., iargj` are its input arguments, and `oarg1, ..., oargk` are the output arguments. In calling a MATLAB function, it is not necessary to use all of the input and output allowed for in the general syntax of the command. In fact, MATLAB functions are commonly used with no output arguments whatsoever.

5. One can construct simple functions interactively in a MATLAB session using MATLAB's `inline` command. A simple function such as  $f(t) = t^2 + 4$  can be described by the character array (or string)

" $t^2 + 4$ ." The inline command will transform the string into a function for use in the current MATLAB session. Inline functions are particularly useful for creating functions that are used as input arguments for other MATLAB functions. An inline function is not saved as an m-file and consequently is lost when the MATLAB session is ended.

- One can use the same MATLAB command with varying amounts of input and output arguments. MATLAB keeps track of the number of input and output arguments included in the call statement using the functions `nargin` (the number of input arguments) and `nargout` (the number of output arguments). These commands are used inside the body of a MATLAB function to tailor the computations and output to the specifications of the calling statement.
- MATLAB has six relational operators that are used for comparisons of scalars or elementwise comparisons of arrays. These operators are:

Relational Operators	
<	less than
<=	less than or equal
>	greater than
>=	greater than or equal
==	equal
~=	not equal

- There are three logical operators as shown in the following table:

Logical Operators	
&	AND
	OR
~	NOT

These logical operators regard any nonzero scalar as corresponding to TRUE and 0 as corresponding to FALSE. The operator `&` corresponds to the logical AND. If  $a$  and  $b$  are scalars, the expression  $a \& b$  will equal 1 if  $a$  and  $b$  are both nonzero (TRUE) and 0 otherwise. The operator `|` corresponds to the logical OR. The expression  $a | b$  will have the value 0 if  $a$  and  $b$  are both 0 and otherwise it will be equal to 1. The operator `~` corresponds to the logical NOT. For a scalar  $a$ , the expression  $\sim a$  takes on the value 1 (TRUE) if  $a = 0$  (FALSE) and the value 0 (FALSE) if  $a \neq 0$  (TRUE).

For matrices these operators are applied element-wise. Thus, if  $A$  and  $B$  are both  $m \times n$  matrices, then  $A \& B$  is a matrix of zeros and ones whose  $(i, j)$  entry is  $a(i, j) \& b(i, j)$ .

### Examples:

- Given two  $m \times n$  matrices  $A$  and  $B$ , the command  $C = A < B$  will generate an  $m \times n$  matrix consisting of zeros and ones. The  $(i, j)$  entry will be equal to 1 if and only if  $a_{ij} < b_{ij}$ . If

$$A = \begin{bmatrix} -1 & 1 & 0 \\ 4 & -2 & 5 \\ 1 & -3 & -2 \end{bmatrix},$$

then command  $A >= 0$  will generate

```
ans =
     0     1     1
     1     0     1
     1     0     0.
```

2. If

$$A = \begin{bmatrix} 3 & 0 \\ 0 & 2 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 0 & 2 \\ 0 & 3 \end{bmatrix},$$

then

$$A \& B = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}, \quad A|B = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}, \quad \sim A = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}.$$

3. To construct the function  $g(t) = 3 \cos t - 2 \sin t$  interactively set

$$g = \text{inline}('3 * \cos(t) - 2 * \sin(t)').$$

If one then enters  $g(0)$  on the command line, MATLAB will return the answer 3. The command `ezplot(g)` will produce a plot of the graph of  $g(t)$ . (See Section 71.9 for more information on producing graphics.)

4. If the numerical nullity of a matrix is defined to be the number of columns of the matrix minus the numerical rank of the matrix, then one can create a file `numnull.m` to compute the numerical nullity of a matrix. This can be done using the following lines of code.

```
function k = numnull(A)
% The command numnull(A) computes the numerical nullity of A
[m,n] = size(A);
k = n - rank(A);
```

The line beginning with the `%` is a comment that is not executed. It will be displayed when the command `help numnull` is executed. The semicolons suppress the printouts of the individual computations that are performed in the function program.

5. The following is an example of a MATLAB function to compute the circle that gives the best least squares fit to a collection of points in the plane.

```
function [center,radius,e] = circfit(x,y,w)
% The command [center,radius] = circfit(x,y) generates
% the center and radius of the circle that gives the
% best least squares fit to the data points specified
% by the input vectors x and y. If a third input
% argument is specified then the circle and data
% points will be plotted. Specify a third output
% argument to get an error vector showing how much
% each point deviates from the circle.
if size(x,1) == 1 & size(y,1) == 1
    x = x'; y = y';
end
A = [2 * x, 2 * y, ones(size(x))];
b = x.^2 + y.^2;
c = A \ b;
center = c(1:2)';
radius = sqrt(c(3) + c(1)^2 + c(2)^2);
```

```

if nargin > 2
    t = 0:0.1:6.3;
    u = c(1) + radius * cos(t);
    v = c(2) + radius * sin(t);
    plot(x,y,'x',u,v)
    axis('equal')
end
if nargin == 3
    e = sqrt((x - c(1)).^2 + (y - c(2)).^2) - radius;
end

```

The command `plot(x,y,'x',u,v)` is used to plot the original  $(x, y)$  data as discrete points in the plane, with each point designated by an “x,” and to also, on the same axis system, plot the  $(u, v)$  data points as a continuous curve. The following section explains MATLAB plot commands in greater detail.

## 71.9 Graphics

---

MATLAB graphics utilities allow the user to do simple two- and three-dimensional plots as well as more sophisticated graphical displays.

### Facts:

1. MATLAB incorporates an objected-oriented graphics system called *Handle Graphics*. This system allows the user to modify and add on to existing figures and is useful in producing computer animations.
2. MATLAB's graphics capabilities include digital imaging tools. MATLAB images may be indexed or true color.
3. An indexed image requires two matrices, a  $k \times 3$  colormap matrix whose rows are triples of numbers that specify red, green, blue intensities, and an  $m \times n$  image matrix whose entries assign a colormap triple to each pixel of the image.
4. A true color image is one derived from an  $m \times n \times 3$  array, which specifies the red, green, blue triplets for each pixel of the image.

### Commands:

1. The `plot` command is used for simple plots of  $x$ - $y$  data sets. Given a set of  $(x_i, y_i)$  data points, the command `plot(x,y)` plots the data points and by default sequentially draws line segments to connect the points. A third input argument may be used to specify a color (the default color for plots is black) or to specify a different form of plot such as discrete points or dashed line segments.
2. The `ezplot` command is used for plots of functions. The command `ezplot(f)` plots the function  $f(x)$  on the default interval  $(-2\pi, 2\pi)$  and the command `ezplot(f,[a,b])` plots the function over the interval  $[a,b]$ .
3. The commands `plot3` and `ezplot3` are used for three-dimensional plots.
4. The command `meshgrid` is used to generate an  $xy$ -grid for surface and contour plots. Specifically the command `[X,Y] = meshgrid(u,v)` transforms the domain specified by vectors  $u$  and  $v$  into arrays  $X$  and  $Y$  that can be used for the evaluation of functions of two variables and 3-D surface plots. The rows of the output array  $X$  are copies of the vector  $u$  and the columns of the output array  $Y$  are copies of the vector  $v$ . The command can be used with only one input argument in which case `meshgrid(u)` will produce the same arrays as the command `meshgrid(u,u)`.

5. The `mesh` command is used to produce wire frame surface plots and the command `surf` produces a solid surface plot. If  $[X, Y] = \text{meshgrid}(u, v)$  and  $Z(i, j) = f(u_i, v_j)$ , then the command `mesh(X, Y, Z)` will produce a wire frame plot of the function  $z = f(x, y)$  over the domain specified by the vectors  $u$  and  $v$ . Similarly the command `surf(X, Y, Z)` will generate a surface plot over the domain.
6. The MATLAB functions `contour` and `ezcontour` produce contour plots for functions of two variables.
7. The command `meshc` is used to graph both the mesh surface and the contour plot in the same graphics window. Similarly the command `surfc` will produce a surf plot with a contour graph appended.
8. Given an array  $C$  whose entries are all real, the command `image(C)` will produce a two-dimensional image representation of the array. Each entry of  $C$  will correspond to a small patch of the image. The image array  $C$  may be either  $m \times n$  or  $m \times n \times 3$ . If  $C$  is an  $m \times n$  matrix, then the colors assigned to each patch are determined by MATLAB's current colormap. If  $C$  is  $m \times n \times 3$ , a true color array, then no color map is used. In this case the entries of  $C(:, :, 1)$  determine the red intensities of the image, the entries of  $C(:, :, 2)$  determine green intensities, and the elements of  $C(:, :, 3)$  define the blue intensities.
9. The `colormap` command is used to specify the current colormap for image plots of  $m \times n$  arrays.
10. The `imread` command is used to translate a standard graphics file, such as a gif, jpeg, or tiff file, into a true color array. The command can also be used with two output arguments to determine an indexed image representation of the graphics file.

### Examples:

1. The graph of the function  $f(x) = \cos(x) + \sin^2(x)$  on the interval  $(-2\pi, 2\pi)$  can be generated in MATLAB using the following commands:

```
x = -6.3: 0.1: 6.3;
y = cos(x) + sin(x).^2;
plot(x,y)
```

The graph can also be generated using the `ezplot` command. (See Figure 71.2.)

```
f = inline('cos(x) + sin(x).^2')
ezplot(f)
```

FIGURE 71.2

FIGURE 71.3

2. We can generate a three-dimensional plot using the following commands:

```
t = 0:pi/50:10*pi;
plot3(t.^2.*sin(5*t), t.^2.*cos(5*t), t)
grid on
axis square
```

These commands generate the plot shown in Figure 71.3.

FIGURE 71.4

3. MATLAB's peaks function is a function of two variables obtained by translating and scaling Gaussian distributions. The commands

```
[X,Y] = meshgrid(-3:0.1:3);
Z = peaks(X,Y);
meshc(X,Y,Z);
```

generate the mesh and contour plots of the peaks function. (See Figure 71.4.)

## 71.10 Symbolic Mathematics in MATLAB

---

MATLAB's Symbolic Toolbox is based upon the Maple kernel from the software package produced by Waterloo Maple, Inc. The toolbox allows users to do various types of symbolic computations using the MATLAB interface and standard MATLAB commands. All symbolic computations in MATLAB are performed by the Maple kernel. For details of how symbolic linear algebra computations such as matrix inverses and eigenvalues are carried out see Chapter 72.

### Facts:

1. MATLAB's symbolic toolbox allows the user to define a new data type, a symbolic object. The user can create symbolic variables and symbolic matrices (arrays containing symbolic variables).
2. The standard matrix operations  $+$ ,  $-$ ,  $*$ ,  $^{\wedge}$ ,  $'$  all work for symbolic matrices and also for combinations of symbolic and numeric matrices. To add a symbolic matrix and a numeric matrix, MATLAB first transforms the numeric matrix into a symbolic object and then performs the addition using the Maple kernel. The result will be a symbolic matrix. In general if the matrix operation involves at least one symbolic matrix, then the result will be a symbolic matrix.
3. Standard MATLAB commands such as `det`, `inv`, `eig`, `null`, `trace`, `rref`, `rank`, and `sum` work for symbolic matrices.
4. Not all of the MATLAB matrix commands work for symbolic matrices. Commands such as `norm` and `orth` do not work and none of the standard matrix factorizations such as  $LU$  or  $QR$  work.
5. MATLAB's symbolic toolbox supports variable precision floating arithmetic, which is carried out within the Maple kernel.

### Commands:

1. The `sym` command can be used to transform any MATLAB data structure into a symbolic object. If the input argument is a string, the result is a symbolic number or variable. If the input argument is a numeric scalar or matrix, the result is a symbolic representation of the given numeric values.
2. The `syms` command allows the user to create multiple symbolic variables with a single command.
3. The command `subs` is used to substitute for variables in a symbolic expression.
4. The command `colspace` is used to find a basis for the column space of a symbolic matrix.
5. The commands `ezplot`, `ezplot3`, and `ezsurf` are used to plot symbolic functions of one or two variables.
6. The command `vpa(A,d)` evaluates the matrix  $A$  using variable precision floating point arithmetic with  $d$  decimal digits of accuracy. The default value of  $d$  is 32, so if the second input argument is omitted, the matrix will be evaluated with 32 digits of accuracy.

### Examples:

1. The command

$$t = \text{sym}('t')$$

transforms the string 't' into a symbolic variable t. Once the symbolic variable has been defined, one can then perform symbolic operations. For example, the command

$$\text{factor}(t^2 - 4)$$

will result in the answer

$$(t - 2) * (t + 2).$$

2. The command

$$\text{syms } a \ b \ c$$

creates the symbolic variables a, b, and c. If we then set

$$A = [a, b, c; b, c, a; c, a, b]$$

the result will be the symbolic matrix

$$A = \begin{bmatrix} a & b & c \\ c & a & b \\ b & c & a \end{bmatrix}.$$

Note that for a symbolic matrix the MATLAB output is in the form of a matrix of row vectors with each row vector enclosed by square brackets.

3. Let  $A$  be the matrix defined in the previous example. We can add the  $3 \times 3$  Hilbert matrix to  $A$  using the command  $B = A + \text{hilb}(3)$ . The result is the symbolic matrix

$$B = \begin{bmatrix} a + 1 & b + 1/2 & c + 1/3 \\ c + 1/4 & a + 1/5 & b + 1/6 \\ b + 1/7 & c + 1/8 & a + 1/9 \end{bmatrix}.$$

To substitute 2 for a in the matrix  $A$  we set

$$A = \text{subs}(A, a, 2).$$

The matrix  $A$  then becomes

$$A = \begin{bmatrix} 2 & b & c \\ c & 2 & b \\ b & c & 2 \end{bmatrix}.$$

Multiple substitutions are also possible. To replace b by b + 1 and c by 5, one need only set

$$A = \text{subs}(A, [b, c], [b + 1, 5]).$$

4. If  $a$  is declared to be a symbolic variable, the command

$$A = [1 \ 2 \ 1; 2 \ 4 \ 2; 0 \ 0 \ a]$$

will produce the symbolic matrix

$$A = \begin{bmatrix} 1 & 2 & 1 \\ 2 & 4 & 6 \\ 0 & 0 & a \end{bmatrix}.$$

The eigenvalues 0, 5, and  $a$  are computed using the command `eig(A)`. The command

$$[X, D] = \text{eig}(A)$$

generates a symbolic matrix of eigenvectors

$$X = \begin{bmatrix} -2, & 1/2 * (a + 8)/(-2 + 3 * a), & 1 \\ 1, & & 1, & 2 \\ 0, & 1/2 * a * (a - 5)/(-2 + 3 * a), & 0 \end{bmatrix}$$

and the diagonal matrix

$$D = \begin{bmatrix} 0 & 0 & 0 \\ 0 & a & 0 \\ 0 & 0 & 5 \end{bmatrix}.$$

When  $a = 0$  the matrix  $A$  will be defective. One can substitute 0 for  $a$  in the matrix of eigenvectors using the command

$$X = \text{subs}(X, a, 0).$$

This produces the numeric matrix

$$X = \begin{bmatrix} -2 & -2 & 1 \\ 1 & 1 & 2 \\ 0 & 0 & 0 \end{bmatrix}.$$

5. If we set  $z = \exp(1)$ , then MATLAB will compute an approximation to  $e$  that is accurate to 16 decimal digits. The command `vpa(z)` will produce a 32 digit representation of  $z$ , but only the first 16 digits will be accurate approximations to the digits of  $e$ . To compute  $e$  more accurately one should apply the `vpa` function to the symbolic expression `'exp(1)'`. The command `z = vpa('exp(1)')` produces an answer  $z = 2.7182818284590452353602874713527$ , which is accurate to 32 digits.

## 71.11 Graphical User Interfaces

---

A graphical user interface (GUI) is a user interface whose components are graphical objects such as pushbuttons, radio buttons, text fields, sliders, checkboxes, and menus. These interfaces allow users to perform sophisticated computations and plots by simply typing numbers into boxes, clicking on buttons, or by moving slidebars.

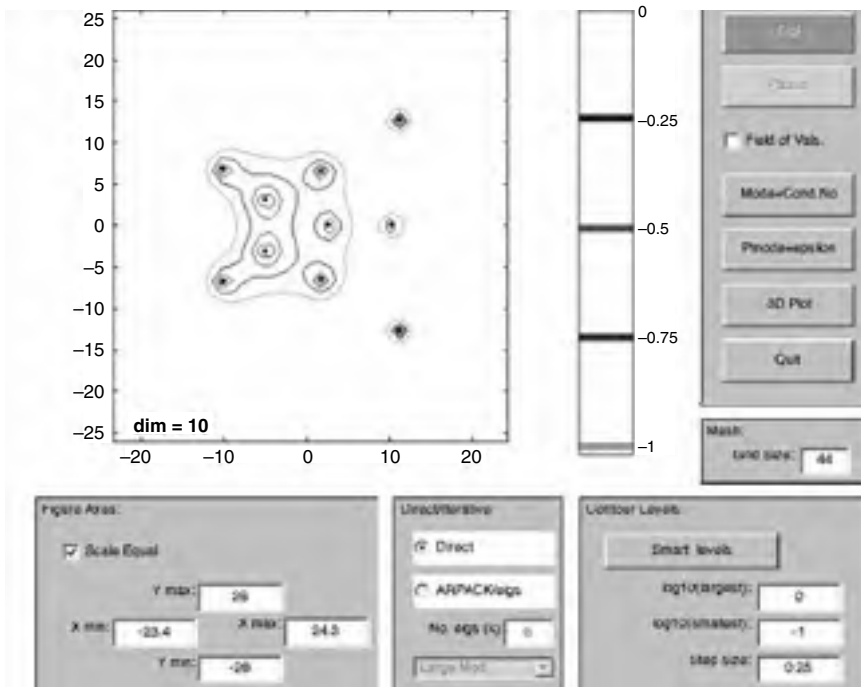

FIGURE 71.5 Eigtool GUI.

### Commands:

1. The command guide opens up the MATLAB GUI Design Environment. This environment is essentially a GUI containing tools to facilitate the creation of new GUIs.

### Examples:

1. Thomas G. Wright of Oxford University has developed a MATLAB GUI, eigtool, for computing eigenvalues, pseudospectra, and related quantities for nonsymmetric matrices, both dense and sparse. It allows the user to graphically visualize the pseudospectra and field of values of a matrix with just the click of a button.

The *epsilon-pseudospectrum* of a square matrix  $A$  is defined by

$$\Lambda_\epsilon(A) = \{z \in \mathbb{C} \mid z \in \sigma(A + E) \text{ for some } E \text{ with } \|E\| \leq \epsilon\}. \quad (71.2)$$

In Figure 71.5 the eigtool GUI is used to plot the  $\epsilon$ -pseudospectra of a  $10 \times 10$  matrix for  $\epsilon = 10^{-k/4}$ ,  $k = 0, 1, 2, 3, 4$ .

For further information, see Chapter 16 and also references [Tre99] and [WT01].

2. The NSF-sponsored ATLAST Project has developed a large collection of MATLAB exercises, projects, and M-files for use in elementary linear algebra classes. (See [LHF03].) The ATLAST M-file collection contains a number of programs that make use of MATLAB's graphical user interface features to present user friendly tools for visualizing linear algebra. One example is the ATLAST cogame utility where students play a game to find linear combinations of two given vectors with the objective of obtaining a third vector that terminates at a given target point in the plane. Students can play the game at any one of four levels or play it competitively by selecting the two person game option. (See Figure 71.6.) At each step of the game a player must enter a pair of coordinates. MATLAB then plots the corresponding linear combination as a directed line segment. The game terminates when

FIGURE 71.6 ATLAST Coordinate Game.

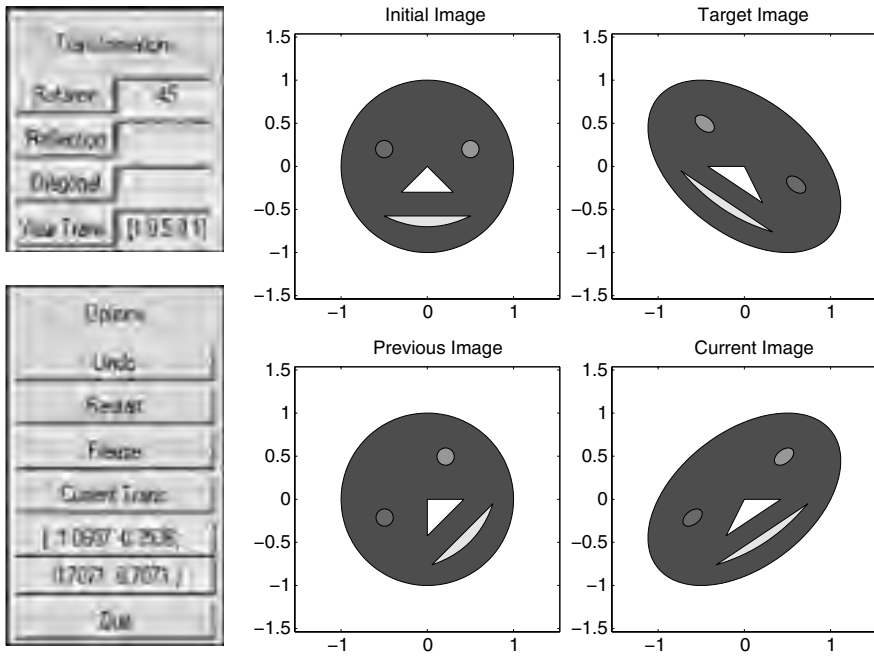

FIGURE 71.7 ATLAST Transformation Utility.

the tip of the plotted line segment lies in the small target circle. A running list of the coordinates entered in the game is displayed in the lower box to the left of the figure. The cogame GUI is useful for teaching lessons on the span of vectors in  $R^2$  and for teaching about different bases for  $R^2$ .

3. The ATLAST transform GUI helps students to visualize the effect of linear transformations on figures in the plane. With this utility students choose an image from a list of figures and then apply various transformations to the image. Each time a transformation is applied, the resulting image is shown in the current image window. The user can then click on the *current transformation* button to see the matrix representation of the transformation that maps the original image into the current image. In Figure 71.7 two transformations were applied to an initial image. First a  $45^\circ$  rotation was applied. Next a transformation matrix  $[1, 0; 0.5, 1]$  was entered into the “Your Transformation” text field and the corresponding transformation was applied to the lower left image with the result being displayed in the Current Image window on the lower right. To transform the Current Image into the Target Image directly above it, one would need to apply a reflection transformation.

### 72.1 Introduction

---

Maple<sup>®</sup> is a general purpose computational system, which combines symbolic computation with exact and approximate (floating-point) numerical computation and offers a comprehensive suite of scientific graphics as well. The main library of functions is written in the Maple programming language, a rich language designed to allow easy access to advanced mathematical algorithms. A special feature of Maple is user access to the source code for the library, including the ability to trace Maple's execution and see its internal workings; only the parts of Maple that are compiled, for example, the kernel, cannot be traced. Another feature is that users can link to LAPACK library routines transparently, and thereby benefit from fast and reliable floating-point computation. The development of Maple started in the early 80s, and the company **Maplesoft** was founded in 1988. A strategic partnership with NAG Inc. in 2000 brought highly efficient numerical routines to Maple, including LAPACK.

There are two linear algebra packages in Maple: `LinearAlgebra` and `linalg`. The `linalg` package is older and considered obsolete; it was replaced by `LinearAlgebra` in MAPLE 6. Here we describe only the `LinearAlgebra` package. The reader should be careful when reading other reference books, or the Maple help pages, to check whether reference is made to `vector`, `matrix`, `array` (notice the lower-case initial letter), which means that the older package is being discussed, or to `Vector`, `Matrix`, `Array` (with an upper-case initial letter), which means that the newer package is being discussed.

**Facts:**

1. Maple commands are typed after a prompt symbol, which by default is “greater than” (`>`). In examples below, keyboard input is simulated by prefixing the actual command typed with the prompt symbol.
2. In the examples below, some of the commands are too long to fit on one line. In such cases, the Maple continuation character backslash (`\`) is used to break the command across a line.
3. Maple commands are terminated by either semicolon (`;`) or colon (`:`). Before Maple 10, a terminator was required, but in the Maple 10 GUI it can be replaced by a carriage return. The semicolon terminator allows the output of a command to be displayed, while the colon suppresses the display (but the command still executes).
4. To access the commands described below, load the `LinearAlgebra` package by typing the command (after the prompt, as shown)
 

```
> with( LinearAlgebra );
```

 If the package is not loaded, then either a typed command will not be recognized, or a different command with the same name will be used.
5. The results of a command can be assigned to one or more variables. Thus,
 

```
> a := 1 ;
```

 assigns the value 1 to the variable  $a$ , while
 

```
> (a,b,c) := 1,2,3 ;
```

 assigns  $a$  the value 1,  $b$  the value 2 and  $c$  the value 3. *Caution:* The operator colon-equals (`:=`) is assignment, while the operator equals (`=`) defines an equation with a left-hand side and a right-hand side.
6. A sequence of expressions separated by commas is an expression sequence in Maple, and some commands return expression sequences, which can be assigned as above.
7. Ranges in Maple are generally defined using a pair of periods (`..`). The rules for the ranges of subscripts are given below.

## 72.2 Vectors

---

**Facts:**

1. In Maple, vectors are not just lists of elements. Maple separates the idea of the mathematical object `Vector` from the data object `Array` (see Section 72.4).
2. A Maple `Vector` can be converted to an `Array`, and an `Array` of appropriate shape can be converted to a `Vector`, but they cannot be used interchangeably in commands. See the help file for `convert` to find out about other conversions.
3. Maple distinguishes between column vectors, the default, and row vectors. The two types of vectors behave differently, and are not merely presentational alternatives.

**Commands:**

1. Generation of vectors:
  - `Vector( [x1, x2, ...] )` Construct a column vector by listing its elements. The length of the list specifies the dimension.
  - `Vector[column]( [x1, x2, ... ] )` Explicitly declare the column attribute.
  - `Vector[row]( [x1, x2, ... ] )` Construct a row vector by initializing its elements from a list.
  - `<v1, v2, ...>` Construct a column vector with elements  $v_1, v_2$ , etc. An element can be another column vector.

- $\langle v_1|v_2|\dots \rangle$  Construct a row vector with elements  $v_1, v_2$ , etc. An element can be another row vector. A useful mnemonic is that the vertical bars remind us of the column dividers in a table.
- `Vector( n, k->f(k) )`. Construct an  $n$ -dimensional vector using a function  $f(k)$  to define the elements.  $f(k)$  is evaluated sequentially for  $k$  from 1 to  $n$ . The notation  $k \rightarrow f(k)$  is Maple syntax for a univariate function.
- `Vector( n, fill=v )` An  $n$ -dimensional vector with every element  $v$ .
- `Vector( n, symbol=v )` An  $n$ -dimensional vector containing symbolic components  $v_k$ .
- `map( x->f(x), V )` Construct a new vector by applying function  $f(x)$  to each element of the vector named  $V$ . *Caution:* the command is `map` not `Map`.

2. Operations and functions:

- `v[i]` Element  $i$  of vector  $\mathbf{v}$ . The result is a scalar. *Caution:* A symbolic reference `v[i]` is typeset as  $v_i$  on output in a Maple worksheet.
- `v[p..q]` Vector consisting of elements  $v_i, p \leq i \leq q$ . The result is a `Vector`, even for the case `v[p..p]`. Either of  $p$  or  $q$  can be negative, meaning that the location is found by counting backwards from the end of the vector, with  $-1$  being the last element.
- `u+v, u-v` Add or subtract `Vectors`  $\mathbf{u}, \mathbf{v}$ .
- `a*v` Multiply vector  $\mathbf{v}$  by scalar  $a$ . Notice the operator is “asterisk” (\*).
- `u . v, DotProduct( u, v )` The inner product of `Vectors`  $\mathbf{u}$  and  $\mathbf{v}$ . See examples for complex conjugation rules. Notice the operator is “period” (.) not “asterisk” (\*) because inner product is not commutative over the field of complex numbers.
- `Transpose( v ), v^%T` Change a column vector into a row vector, or *vice versa*. Complex elements are not conjugated.
- `HermitianTranspose( v ), v^%H` Transpose with complex conjugation.
- `OuterProductMatrix( u, v )` The outer product of `Vectors`  $\mathbf{u}$  and  $\mathbf{v}$  (ignoring the row/column attribute).
- `CrossProduct( u, v ), u &x v` The vector product, or cross product, of three-dimensional vectors  $\mathbf{u}, \mathbf{v}$ .
- `Norm( v, 2 )` The 2-norm or Euclidean norm of vector  $\mathbf{v}$ . Notice that the second argument, namely the 2, is necessary, because `Norm( v )` defaults to the infinity norm, which is different from the default in many textbooks and software packages.
- `Norm( v, p )` The  $p$ -norm of  $\mathbf{v}$ , namely  $(\sum_{i=1}^n |v_i|^p)^{1/p}$ .

**Examples:**

In this section, the imaginary unit is the Maple default  $I$ . That is,  $\sqrt{-1} = I$ . In the matrix section, we show how this can be changed. To save space, we shall mostly use row vectors in the examples.

1. Generate vectors. The same vector created different ways.

```
> Vector[row]( [0, 3, 8] ): <0|3|8>: Transpose( <0, 3, 8> ): Vector[row]
( 3, i->i^2-1 );
```

$$[0, 3, 8]$$

2. Selecting elements.

```
> V:=<a|b|c|d|e|f>: V1 := V[2 .. 4]; V2:=V[-4 .. -1];
V3:=V[-4 .. 4];
```

$$V1 := [b, c, d], \quad V2 := [c, d, e, f], \quad V3 := [c, d]$$

3. A Gram–Schmidt exercise.

```
> u1 := <3|0|4>: u2 := <2|1|1>: w1n := u1/Norm( u1, 2 );
```

$$w1n := [3/5, 0, 4/5]$$

```
> w2 := u2 - (u2 . w1n)*w1n; w2n := w2/Norm( w2, 2 );
```

$$w2n := \left[ \frac{2\sqrt{2}}{5}, \frac{\sqrt{2}}{2}, -\frac{3\sqrt{2}}{10} \right]$$

4. Vectors with complex elements. Define column vectors  $\mathbf{u}_c, \mathbf{v}_c$  and row vectors  $\mathbf{u}_r, \mathbf{v}_r$ .

```
> uc := <1 + I, 2>: ur := Transpose( uc ): vc := <5, 2 - 3*I>:
vr := Transpose( vc ):
```

The inner product of column vectors conjugates the first vector in the product, and the inner product of row vectors conjugates the second.

```
> inner1 := uc . vc; inner2 := ur . vr;
      inner1 := 9-11 I , inner2 := 9+11 I
```

Maple computes the product of two similar vectors, i.e., both rows or both columns, as a true mathematical inner product, since that is the only definition possible; in contrast, if the user mixes row and column vectors, then Maple does not conjugate:

```
> but := ur . vc;
```

$$but := 9 - I$$

*Caution:* The use of a period (.) with complex row and column vectors together differs from the use of a period (.) with complex  $1 \times m$  and  $m \times 1$  matrices. In case of doubt, use matrices and conjugate explicitly where desired.

## 72.3 Matrices

---

### Facts:

1. One-column matrices and vectors are not interchangeable in Maple.
2. Matrices and two-dimensional arrays are not interchangeable in Maple.

### Commands:

1. Generation of Matrices.

- `Matrix( [[a,b,...], [c,d,...], ... ] )` Construct a matrix row-by-row, using a list of lists.
- `<< a|b|...>, <c|d|...>, ...>` Construct a matrix row-by-row using vectors. Notice that the rows are specified by row vectors, requiring the | notation.
- `<< a,b,...>|<c,d,...>|...>` Construct a matrix column-by-column using vectors. Notice that each vector is a column, and the columns are joined using |, the column operator.

*Caution:* Both variants of the `<< ... >>` constructor are meant for interactive use, not programmatic use. They are slow, especially for large matrices.

- `Matrix( n, m, (i, j) -> f(i, j) )` Construct a matrix  $n \times m$  using a function  $f(i, j)$  to define the elements.  $f(i, j)$  is evaluated sequentially for  $i$  from 1 to  $n$  and  $j$  from 1 to  $m$ . The notation  $(i, j) -> f(i, j)$  is Maple syntax for a bivariate function  $f(i, j)$ .
- `Matrix( n, m, fill=a )` An  $n \times m$  matrix with each element equal to  $a$ .
- `Matrix( n, m, symbol=a )` An  $n \times m$  matrix containing subscripted entries  $a_{ij}$ .
- `map( x -> f(x), M )` A matrix obtained by applying  $f(x)$  to each element of  $M$ .  
[Caution: the command is `map` not `Map`.]
- `<< A|B>, < C|D>>` Construct a partitioned or block matrix from matrices  $A, B, C, D$ . Note that `< A|B >` will be formed by adjoining columns; the block `< C|D >` will be placed below `< A|B >`. The Maple syntax is similar to a common textbook notation for partitioned matrices.

## 2. Operations and functions

- `M[i, j]` Element  $i, j$  of matrix  $M$ . The result is a scalar.
- `M[1..-1, k]` Column  $k$  of Matrix  $M$ . The result is a Vector.
- `M[k, 1..-1]` Row  $k$  of Matrix  $M$ . The result is a row Vector.
- `M[p..q, r..s]` Matrix consisting of submatrix  $m_{ij}$ ,  $p \leq i \leq q, r \leq j \leq s$ . In HANDBOOK notation,  $M[\{p, \dots, q\}, \{r, \dots, s\}]$ .
- `Transpose( M )`, `M^%T` Transpose matrix  $M$ , without taking the complex conjugate of the elements.
- `HermitianTranspose( M )`, `M^%H` Transpose matrix  $M$ , taking the complex conjugate of elements.
- `A ± B` Add/subtract compatible matrices or vectors  $A, B$ .
- `A . B` Product of compatible matrices or vectors  $A, B$ . The examples below detail the ways in which Maple interprets products, since there are differences between Maple and other software packages.
- `MatrixInverse( A )`, `A^(-1)` Inverse of matrix  $A$ .
- `Determinant( A )` Determinant of matrix  $A$ .
- `Norm( A, 2 )` The (subordinate) 2-norm of matrix  $A$ , namely  $\max_{\|u\|_2=1} \|Au\|_2$  where the norm in the definition is the vector 2-norm.

### Cautions:

- Notice that the second argument, i.e., 2, is necessary because `Norm( A )` defaults to the infinity norm, which is different from the default in many textbooks and software packages.
  - Notice also that this is the largest *singular value* of  $A$ , and is usually different from the Frobenius norm  $\|A\|_F$ , accessed by `Norm( A, Frobenius )`, which is the Euclidean norm of the vector of elements of the matrix  $A$ .
  - Unless  $A$  has floating-point entries, this norm will not usually be computable explicitly, and it may be expensive even to try.
- `Norm( A, p )` The (subordinate) matrix  $p$ -norm of  $A$ , for integers  $p \geq 1$  or for  $p$  being the symbol `infinity`, which is the default value.

**Examples:**

1. A matrix product.

> A := <<1|-2|3>>, <0|1|1>>; B := Matrix(3, 2, symbol=b); C := A . B;

$$A := \begin{bmatrix} 1 & -2 & 3 \\ 0 & 1 & 1 \end{bmatrix}, \quad B := \begin{bmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \\ b_{31} & b_{32} \end{bmatrix},$$

$$C := \begin{bmatrix} b_{11} - 2b_{21} + 3b_{31} & b_{12} - 2b_{22} + 3b_{32} \\ b_{21} + b_{31} & b_{22} + b_{32} \end{bmatrix}.$$

2. A Gram–Schmidt calculation revisited.

If  $u_1, u_2$  are  $m \times 1$  column matrices, then the Gram–Schmidt process is often written in textbooks as

$$w_2 = u_2 - \frac{u_2^T u_1}{u_1^T u_1} u_1.$$

Notice, however, that  $u_2^T u_1$  and  $u_1^T u_1$  are strictly  $1 \times 1$  matrices. Textbooks often skip over the conversion of  $u_2^T u_1$  from a  $1 \times 1$  matrix to a scalar. Maple, in contrast, does not convert automatically.

Transcribing the printed formula into Maple will cause an error. Here is the way to do it, reusing the earlier numerical data.

> u1 := <<3,0,4>>; u2 := <<2,1,1>>; r := u2^%T . u1;  
s := u1^%T . u1;

$$u1 := \begin{bmatrix} 3 \\ 0 \\ 4 \end{bmatrix}, \quad u2 := \begin{bmatrix} 2 \\ 1 \\ 1 \end{bmatrix}, \quad r := [10], \quad s := [25].$$

Notice the brackets in the values of  $r$  and  $s$  because they are matrices. Since  $r[1,1]$  and  $s[1,1]$  are scalars, we write

> w2 := u2 - r[1,1]/s[1,1]\*u1;

and reobtain the result from Example 3 in Section 72.2. Alternatively,  $u1$  and  $u2$  can be converted to `Vectors` first and then used to form a proper scalar inner product.

> r := u2[1..-1,1] . u1[1..-1,1]; s := u1[1..-1,1] . u1[1..-1,1];  
w2 := u2-r/s\*u1;

$$r := 10, \quad s := 25, \quad w2 := \begin{bmatrix} 4/5 \\ 1 \\ -3/5 \end{bmatrix}.$$

3. Vector–Matrix and Matrix–Vector products.

Many textbooks equate a column vector and a one-column matrix, but this is not generally so in Maple. Thus

> b := <1,2>; B := <<1,2>>; C := <<4|5|6>>;

$$b := \begin{bmatrix} 1 \\ 2 \end{bmatrix} \quad B := \begin{bmatrix} 1 \\ 2 \end{bmatrix} \quad C := [4 \ 5 \ 6].$$

Only the product  $B . C$  is defined, and the product  $b . C$  causes an error.

> B . C

$$\begin{bmatrix} 4 & 5 & 6 \\ 8 & 10 & 12 \end{bmatrix}.$$

The rules for mixed products are

$$\begin{aligned} \text{Vector}[\text{row}](n) \cdot \text{Matrix}(n, m) &= \text{Vector}[\text{row}](m) \\ \text{Matrix}(n, m) \cdot \text{Vector}[\text{column}](m) &= \text{Vector}[\text{column}](n) \end{aligned}$$

The combinations  $\text{Vector}(n) \cdot \text{Matrix}(1, m)$  and  $\text{Matrix}(m, 1) \cdot \text{Vector}[\text{row}](n)$  cause errors. If users do not want this level of rigor, then the easiest thing to do is to use only the `Matrix` declaration.

4. Working with matrices containing complex elements.

First, notation: In linear algebra,  $I$  is commonly used for the identity matrix. This corresponds to the `eye` function in `MATLAB`. However, by default, Maple uses  $I$  for the imaginary unit, as seen in section 72.2. We can, however, use  $I$  for an identity matrix by changing the imaginary unit to something else, say `_i`.

```
> interface( imaginaryunit=_i );
```

As the saying goes: An `_i` for an  $I$  and an  $I$  for an eye.

Now we can calculate eigenvalues using notation similar to introductory textbooks.

```
> A := <<1,2>>|<-2,1>>; I := IdentityMatrix( 2 );
p := Determinant ( x*I-A );
```

$$A := \begin{bmatrix} 1 & -2 \\ 2 & 1 \end{bmatrix}, \quad I := \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad p := x^2 - 2x + 5.$$

Solving  $p = 0$ , we obtain eigenvalues  $1 + 2i, 1 - 2i$ . With the above setting of `imaginaryunit`, Maple will print these values as  $1+2\_i, 1-2\_i$ , but we have translated back to standard mathematical  $i$ , where  $i^2 = -1$ .

5. Moore–Penrose inverse. Consider `M := Matrix(3,2,[[1,1],[a,a^2],[a^2,a]])`; a  $3 \times 2$  matrix containing a symbolic parameter  $a$ . We compute its Moore–Penrose pseudoinverse and a proviso guaranteeing correctness by the command `> (Mi, p):= MatrixInverse(M, method=pseudo, output=[inverse, proviso]);` which assigns the  $2 \times 3$  pseudoinverse to `Mi` and an expression, which if nonzero guarantees that `Mi` is the correct (unique) Moore–Penrose pseudoinverse of  $M$ . Here we have

$$Mi := \begin{bmatrix} (2 + 2a^3 + a^2 + a^4)^{-1} & -\frac{a^3 + a^2 + 1}{a(a^5 + a^4 - a^3 - a^2 + 2a - 2)} & \frac{a^4 + a^3 + 1}{a(a^5 + a^4 - a^3 - a^2 + 2a - 2)} \\ (2 + 2a^3 + a^2 + a^4)^{-1} & \frac{a^4 + a^3 + 1}{a(a^5 + a^4 - a^3 - a^2 + 2a - 2)} & -\frac{a^3 + a^2 + 1}{a(a^5 + a^4 - a^3 - a^2 + 2a - 2)} \end{bmatrix}$$

and  $p = a^2 - a$ . Thus, if  $a \neq 0$  and  $a \neq 1$ , the computed pseudoinverse is correct. By separate computations we find that the pseudoinverse of  $M|_{a=0}$  is

$$\begin{bmatrix} 1/2 & 0 & 0 \\ 1/2 & 0 & 0 \end{bmatrix}$$

and that the pseudoinverse of  $M|_{a=1}$  is

$$\begin{bmatrix} 1/6 & 1/6 & 1/6 \\ 1/6 & 1/6 & 1/6 \end{bmatrix}$$

and moreover that these are not special cases of the generic answer returned previously. In a certain sense this is obvious: the Moore–Penrose inverse is *discontinuous*, even for square matrices (consider  $(A - \lambda I)^{-1}$ , for example, as  $\lambda \rightarrow$  an eigenvalue of  $A$ ).

## 72.4 Arrays

---

Before describing Maple's `Array` structure, it is useful to say why Maple distinguishes between an `Array` and a `Vector` or `Matrix`, when other books and software systems do not. In linear algebra, two different types of operations are performed with vectors or matrices. The first type is described in Sections 72.2 and 72.3, and comprises operations derived from the mathematical structure of vector spaces. The other type comprises operations that treat vectors or matrices as data arrays; they manipulate the individual elements directly. As an example, consider dividing the elements of `Array [1, 3, 5]` by the elements of `[7, 11, 13]` to obtain `[1/7, 3/11, 5/13]`.

The distinction between the operations can be made in two places: in the name of the operation or the name of the object. In other words we can overload the data objects or overload the operators. Systems such as `MATLAB` choose to leave the data object unchanged, and define separate operators. Thus, in `MATLAB` the statements `[1, 3, 5]/[7, 11, 13]` and `[1, 3, 5]./[7, 11, 13]` are different because of the operators. In contrast, Maple chooses to make the distinction in the data object, as will now be described.

### Facts:

1. The Maple `Array` is a general data structure akin to arrays in other programming languages.
2. An array can have up to 63 indices and each index can lie in any integer range.
3. The description here only addresses the overlap between Maple `Array` and `Vector`.

*Caution:* A Maple `Array` might look the same as a vector or matrix when printed.

### Commands:

1. Generation of arrays.
  - `Array([x1, x2, ...])` Construct an array by listing its elements.
  - `Array( m . . n )` Declare an empty 1-dimensional array indexed from  $m$  to  $n$ .
  - `Array( v )` Use an existing `Vector` to generate an array.
  - `convert( v, Array )` Convert a `Vector`  $v$  into an `Array`. Similarly, a `Matrix` can be converted to an `Array`. See the help file for `rtable_options` for advanced methods to convert efficiently, in-place.
2. Operations (memory/stack limitations may restrict operations).
  - `a ^ n` Raise each element of  $a$  to power  $n$ .
  - `a * b`, `a + b`, `a - b` Multiply (add, subtract) elements of  $b$  by (to, from) elements of  $a$ .
  - `a / b` Divide elements of  $a$  by elements of  $b$ . Division by zero will produce undefined or infinity (or exceptions can be caught by user-set traps; see the help file for `Numeric_Events`).

### Examples:

1. Array arithmetic.
 

```
> simplify( (Array([25, 9, 4]) * Array(1..3, x->x^2-1) / Array(<5, 3, 2>\
))^(1/2));
```

[0, 3, 4]

- Getting Vectors and Arrays to do the same thing.

```
> Transpose( map(x->x*x,<1,2,3> ) ) - convert(Array( [1,2,3] )^2,\
Vector);
```

[0,0,0]

## 72.5 Equation Solving and Matrix Factoring

---

### Cautions:

- If a matrix contains exact numerical entries, typically integers or rationals, then the material studied in introductory textbooks transfers to a computer algebra system without special considerations. However, if a matrix contains symbolic entries, then the fact that computations are completed without the user seeing the intermediate steps can lead to unexpected results.
- Some of the most popular matrix functions are discontinuous when applied to matrices containing symbolic entries. Examples are given below.
- Some algorithms taught to educate students about the concepts of linear algebra often turn out to be ill-advised in practice: computing the characteristic polynomial and then solving it to find eigenvalues, for example; using Gaussian elimination without pivoting on a matrix containing floating-point entries, for another.

### Commands:

- `LinearSolve( A, B )` The vector or matrix  $X$  satisfying  $AX = B$ .
- `BackwardSubstitute( A, B )`, `ForwardSubstitute( A, B )` The vector or matrix  $X$  satisfying  $AX = B$  when  $A$  is upper or lower triangular (echelon) form, respectively.
- `ReducedRowEchelonForm( A )`. The reduced row-echelon form (RREF) of the matrix  $A$ . For matrices with symbolic entries, see the examples below for recommended usage.
- `Rank( A )` The rank of the matrix  $A$ . *Caution:* If  $A$  has floating-point entries, see the section below on Numerical Linear Algebra. On the other hand, if  $A$  contains symbolic entries, then the rank may change discontinuously and the generic answer returned by `Rank` may be incorrect for some specializations of the parameters.
- `NullSpace( A )` The nullspace (kernel) of the matrix  $A$ . *Caution:* If  $A$  has floating-point entries, see the section below on Numerical Linear Algebra. Again on the other hand, if  $A$  contains symbolic entries, the nullspace may change discontinuously and the generic answer returned by `NullSpace` may be incorrect for some specializations of the parameters.
- `( P, L, U, R ) := LUDecomposition( A, method='RREF' )` The  $PLUR$ , or Turing, factors of the matrix  $A$ . See examples for usage.
- `( P, L, U ) := LUDecomposition( A )` The  $PLU$  factors of a matrix  $A$ , when the RREF  $R$  is not needed. This is usually the case for a Turing factoring where  $R$  is guaranteed (or known *a priori*) to be  $I$ , the identity matrix, for all values of the parameters.
- `( Q, R ) := QRDecomposition( A, fullspan )` The  $QR$  factors of the matrix  $A$ . The option `fullspan` ensures that  $Q$  is square.
- `SingularValues( A )` See Section 72.8, Numerical Linear Algebra.
- `ConditionNumber( A )` See Section 72.8, Numerical Linear Algebra.

### Examples:

- Need for Turing factoring.

One of the strengths of Maple is computation with symbolic quantities. When standard linear algebra methods are applied to matrices containing symbolic entries, the user must be aware of new mathematical features that can arise. The main feature is the discontinuity of standard matrix

functions, such as the reduced row-echelon form and the rank, both of which can be discontinuous. For example, the matrix

$$B = A - \lambda I = \begin{bmatrix} 7 - \lambda & 4 \\ 6 & 2 - \lambda \end{bmatrix}$$

has the reduced row-echelon form

$$\text{ReducedRowEchelonForm}(B) = \begin{cases} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} & \lambda \neq -1, 10 \\ \begin{bmatrix} 1 & -4/3 \\ 0 & 0 \end{bmatrix} & \lambda = 10, \\ \begin{bmatrix} 1 & 1/2 \\ 0 & 0 \end{bmatrix} & \lambda = -1. \end{cases}$$

Notice that the function is discontinuous precisely at the interesting values of  $\lambda$ . Computer algebra systems in general, and Maple in particular, return “generic” results. Thus, in Maple, we have

```
> B := << 7-x | 4 >, < 6 | 2-x >>;
```

$$B := \begin{bmatrix} 7-x & 4 \\ 6 & 2-x \end{bmatrix},$$

```
> ReducedRowEchelonForm( B )
```

$$\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}.$$

This difficulty is discussed at length in [CJ92] and [CJ97]. The recommended solution is to use Turing factoring (generalized  $PLU$  decomposition) to obtain the reduced row-echelon form with provisos. Thus, for example,

```
> A := <<1 | -2 | 3 | sin(x)>, <1 | 4*cos(x) | 3 | 3*sin(x)>, <-1 | 3 | cos(x) - 3 | \cos(x)>>;
```

$$A := \begin{bmatrix} 1 & -2 & 3 & \sin x \\ 1 & 4 \cos x & 3 & 3 \sin x \\ -1 & 3 & \cos x - 3 & \cos x \end{bmatrix}.$$

```
> ( P, L, U, R ) := LUDecomposition( A, method='RREF' );
```

The generic reduced row-echelon form is then given by

$$R = \begin{bmatrix} 1 & 0 & 0 & (2 \sin x \cos x - 3 \sin x - 6 \cos x - 3)/(2 \cos x + 1) \\ 0 & 1 & 0 & \sin x/(2 \cos x + 1) \\ 0 & 0 & 1 & (2 \cos x + 1 + 2 \sin x)/(2 \cos x + 1) \end{bmatrix}$$

This shows a visible failure when  $2 \cos x + 1 = 0$ , but the other discontinuity is invisible, and requires the  $U$  factor from the Turing ( $PLUR$ ) factors,

$$U = \begin{bmatrix} 1 & -2 & 3 \\ 0 & 4 \cos x + 2 & 0 \\ 0 & 0 & \cos x \end{bmatrix}$$

to see that the case  $\cos x = 0$  also causes failure. In both cases (meaning the cases  $2 \cos x + 1 = 0$  and  $\cos x = 0$ ), the RREF must be recomputed to obtain the singular cases correctly.

## 2. QR factoring.

Maple does not offer column pivoting, so in pathological cases the factoring may not be unique, and will vary between software systems. For example,

```
> A := <<0,0>|<5,12>>: QRDecomposition( A, fullspan )
```

$$\begin{bmatrix} 5/13 & 12/13 \\ 12/13 & -5/13 \end{bmatrix}, \begin{bmatrix} 0 & 13 \\ 0 & 0 \end{bmatrix}.$$

## 72.6 Eigenvalues and Eigenvectors

---

### Facts:

1. In exact arithmetic, explicit expressions are not possible in general for the eigenvalues of a matrix of dimension 5 or higher.
2. When it has to, Maple represents polynomial roots (and, hence, eigenvalues) *implicitly* by the `RootOf` construct. Expressions containing `RootOfs` can be simplified and evaluated numerically.

### Commands:

1. `Eigenvalues( A )` The eigenvalues of matrix  $A$ .
2. `Eigenvectors( A )` The eigenvalues and corresponding eigenvectors of  $A$ .
3. `CharacteristicPolynomial( A, 'x' )` The characteristic polynomial of  $A$  expressed using the variable  $x$ .
4. `JordanForm( A )` The Jordan form of the matrix  $A$ .

### Examples:

1. Simple eigensystem computation.

```
> Eigenvectors( <<7,6>|<4,2>> );
```

$$\begin{bmatrix} -1 \\ 10 \end{bmatrix}, \begin{bmatrix} -1/2 & 4/3 \\ 1 & 1 \end{bmatrix}.$$

So the eigenvalues are  $-1$  and  $10$  with the corresponding eigenvectors  $[-1/2, 1]^T$  and  $[4/3, 1]^T$ .

2. A defective matrix.

If the matrix is defective, then by convention the matrix of “eigenvectors” returned by Maple contains one or more columns of zeros.

```
> Eigenvectors( <<1,0>|<1,1>> );
```

$$\begin{bmatrix} 1 \\ 1 \end{bmatrix}, \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}.$$

3. Larger systems.

For larger matrices, the eigenvectors will use the Maple `RootOf` construction,

$$A := \begin{bmatrix} 3 & 1 & 7 & 1 \\ 5 & 6 & -3 & 5 \\ 3 & -1 & -1 & 0 \\ -1 & 5 & 1 & 5 \end{bmatrix}.$$

```
> ( L, V ) := Eigenvectors( A ): The colon suppresses printing. The vector of eigenvalues is returned as
```

> L;

$$\begin{bmatrix} \text{RootOf}(\mathcal{Z}^4 - 13\mathcal{Z}^3 - 4\mathcal{Z}^2 + 319\mathcal{Z} - 386, \text{index} = 1) \\ \text{RootOf}(\mathcal{Z}^4 - 13\mathcal{Z}^3 - 4\mathcal{Z}^2 + 319\mathcal{Z} - 386, \text{index} = 2) \\ \text{RootOf}(\mathcal{Z}^4 - 13\mathcal{Z}^3 - 4\mathcal{Z}^2 + 319\mathcal{Z} - 386, \text{index} = 3) \\ \text{RootOf}(\mathcal{Z}^4 - 13\mathcal{Z}^3 - 4\mathcal{Z}^2 + 319\mathcal{Z} - 386, \text{index} = 4) \end{bmatrix}.$$

This, of course, simply reflects the characteristic polynomial:

> CharacteristicPolynomial(A, 'x');

$$x^4 - 13x^3 - 4x^2 + 319x - 386$$

The `Eigenvalues` command solves a 4th degree characteristic polynomial explicitly in terms of radicals unless the option `implicit` is used.

4. Jordan form. *Caution:* As with the reduced row-echelon form, the Jordan form of a matrix containing symbolic elements can be discontinuous. For example, given

$$A = \begin{bmatrix} 1 & t \\ 0 & 1 \end{bmatrix},$$

> ( J, Q ) := JordanForm(A, output=['J','Q']);

$$J, Q := \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}, \begin{bmatrix} t & 0 \\ 0 & 1 \end{bmatrix}$$

with  $A = QJQ^{-1}$ . Note that  $Q$  is invertible precisely when  $t \neq 0$ . This gives a proviso on the correctness of the result:  $J$  will be the Jordan form of  $A$  only for  $t \neq 0$ , which we see is the generic case returned by Maple.

*Caution:* Exact computation has its limitations, even without symbolic entries. If we ask for the Jordan form of the matrix

$$B = \begin{bmatrix} -1 & 4 & -1 & -14 & 20 & -8 \\ 4 & -5 & -63 & 203 & -217 & 78 \\ -1 & -63 & 403 & -893 & 834 & -280 \\ -14 & 203 & -893 & 1703 & -1469 & 470 \\ 20 & -217 & 834 & -1469 & 1204 & -372 \\ -8 & 78 & -280 & 470 & -372 & 112 \end{bmatrix},$$

a relatively modest  $6 \times 6$  matrix with a triple eigenvalue 0, then the transformation matrix  $Q$  as produced by Maple has entries over 35,000 characters long. Some scheme of compression or large expression management is thereby mandated.

## 72.7 Linear Algebra with Modular Arithmetic in Maple

There is a subpackage, `LinearAlgebra[Modular]`, designed for programmatic use, that offers access to modular arithmetic with matrices and vectors.

### Facts:

1. The subpackage can be loaded by issuing the command  
 > with( LinearAlgebra[Modular] ); which gives access to the commands  
`[AddMultiple, Adjoint, BackwardSubstitute, Basis, CharacteristicPolynomial, ChineseRemainder, Copy, Create, Determinant, Fill,`

ForwardSubstitute, Identity, Inverse, LUApply, LUdecomposition, LinIntSolve, MatBasis, MatGcd, Mod, Multiply, Permute, Random, Rank, RankProfile, RowEchelonTransform, RowReduce, Swap, Transpose, ZigZag]

2. Arithmetic can be done modulo a prime  $p$  or, in some cases, a composite modulus  $m$ .
3. The relevant matrix and vector datatypes are `integer[4]`, `integer[8]`, `integer[]`, and `float[8]`. Use of the correct datatype can improve efficiency.

### Examples:

```
> p := 13;
> A := Mod( p, Matrix([[1,2,3],[4,5,6],[7,8,-9]]), integer[4] );
```

$$\begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \\ 7 & 8 & 4 \end{bmatrix},$$

```
> Mod( p, MatrixInverse( A ), integer[4] );
```

$$\begin{bmatrix} 12 & 8 & 5 \\ 0 & 11 & 3 \\ 5 & 3 & 5 \end{bmatrix}$$

### Cautions:

1. This is not to be confused with the `mod` utilities, which together with the inert `Inverse` command, can also be used to calculate inverses in a modular way.
2. One must always specify the datatype in `Modular` commands, or a cryptic error message will be generated.

## 72.8 Numerical Linear Algebra in Maple

---

The above sections have covered the use of Maple for exact computations of the types met during a standard first course on linear algebra. However, in addition to exact computation, Maple offers a variety of floating-point numerical linear algebra support.

### Facts:

1. Maple can compute with either “hardware floats” or “software floats.”
2. A hardware float is IEEE double precision, with a mantissa of (approximately) 15 decimal digits.
3. A software float has a mantissa whose length is set by the Maple variable `Digits`.

### Cautions:

1. If an integer is typed with a decimal point, then Maple treats it as a software float.
2. Software floats are significantly slower than hardware floats, even for the same precision.

### Commands:

1. `Matrix( n, m, datatype=float[8] )` An  $n \times m$  matrix of hardware floats (initialization data not shown). The elements must be real numbers. The 8 refers to the number of bytes used to store the floating point real number.
2. `Matrix( n, m, datatype=complex(float[8] ) )` An  $n \times m$  matrix of hardware floats, including complex hardware floats. A complex hardware float takes two 8-byte storage locations.

3. `Matrix( n, m, datatype=sfloat )` An  $n \times m$  matrix of software floats. The entries must be real and the precision is determined by the value of `Digits`.
4. `Matrix( n, m, datatype=complex(sfloat) )` As before with complex software floats.
5. `Matrix( n, m, shape=symmetric )` A matrix declared to be symmetric. Maple can take advantage of shape declarations such as this.

### Examples:

1. A characteristic surprise.

When asked to compute the characteristic polynomial of a floating-point matrix, Maple first computes eigenvalues (by a good numerical method) and then presents the characteristic polynomial in factored form, with good approximate roots. Thus,

```
> CharacteristicPolynomial( Matrix( 2, 2, [[666,667],[665,666]], \
    datatype=float[8]), 'x' );
```

$$(x - 1331.99924924882612 - 0.0i)(x - 0.000750751173882235889 - 0.0i).$$

Notice the signed zero in the imaginary part; though the roots in this case are real, approximate computation of the eigenvalues of a nonsymmetric matrix takes place over the complex numbers. (n.b.: The output above has been edited for clarity.)

2. Symmetric matrices.

If Maple knows that a matrix is symmetric, then it uses appropriate routines. Without the symmetric declaration, the calculation is

```
> Eigenvalues( Matrix( 2, 2, [[1,3],[3,4]], datatype=float[8]) );
```

$$\begin{bmatrix} -0.854101966249684707 + 0.0i \\ 5.85410196624968470 + 0.0i \end{bmatrix}.$$

With the declaration, the computation is

```
> Eigenvalues( Matrix( 2, 2, [[1,3],[3,4]], shape=symmetric,
    datatype=float[8]) );
```

$$\begin{bmatrix} -0.854101966249684818 \\ 5.85410196624968470 \end{bmatrix}.$$

*Cautions:* Use of the `shape=symmetric` declaration will force Maple to treat the matrix as being symmetric, even if it is not.

3. Printing of hardware floats.

Maple prints hardware floating-point data as 18-digit numbers. This does not imply that all 18 digits are correct; Maple prints the hardware floats this way so that a cycle of converting from binary to decimal and back to binary will return to exactly the starting binary floating-point number. Notice in the previous example that the last 3 digits differ between the two function calls. In fact, neither set of digits is correct, as a calculation in software floats with higher precision shows:

```
> Digits := 30: Eigenvalues( Matrix( 2, 2, [[1,3],[3,4]], \
    datatype=sfloat, shape=symmetric ) );
```

$$\begin{bmatrix} -0.854101966249684544613760503093 \\ 5.85410196624968454461376050310 \end{bmatrix}.$$

4. NullSpace. Consider

```
> B := Matrix( 2, 2, [[666,667],[665,666]] ): A := Transpose(B).B;
```

We make a floating-point version of  $A$  by

```
> Af := Matrix( A, datatype=float[8] );
```

and then take the `NullSpace` of both  $A$  and  $Af$ . The nullspace of  $A$  is correctly returned as the empty set —  $A$  is not singular (in fact, its determinant is 1). The nullspace of  $Af$  is correctly returned as

$$\left\{ \begin{bmatrix} -0.707637442412755612 \\ 0.706575721416702662 \end{bmatrix} \right\}.$$

The answers are different — quite different — even though the matrices differ only in `datatype`. The surprising thing is that both answers are correct: Maple is doing the right thing in each case. See [Cor93] for a detailed explanation, but note that  $Af$  times the vector in the reported nullspace is about  $3.17 \cdot 10^{-13}$  times the 2-norm of  $Af$ .

5. Approximate Jordan form (not!).<sup>1</sup>

As noted previously, the Jordan form is discontinuous as a function of the entries of the matrix. This means that rounding errors may cause the computed Jordan form of a matrix with floating-point entries to be incorrect, and for this reason Maple refuses to compute the Jordan form of such a matrix.

6. Conditioning of eigenvalues.

To explore Maple's facilities for the conditioning of the unsymmetric matrix eigenproblem, consider the matrix "gallery(3)" from MATLAB.

```
> A := Matrix( [[-149, -50, -154], [537, 180, 546], [-27, -9, -25]] );
```

The Maple command `EigenConditionNumbers` computes estimates for the reciprocal condition numbers of each eigenvalue, and estimates for the reciprocal condition numbers of the computed eigenvectors as well. At this time, there are no built-in facilities for the computation of the sensitivity of arbitrary invariant subspaces.

```
> E, V, rconds, rveconds := EigenConditionNumbers( A, output= \
['values', 'vectors', 'conditionvalues', 'conditionvectors'] );
> seq( 1/rconds[i], i=1..3 );
417.6482708, 349.7497543, 117.2018824
```

A separate computation using the definition of the condition number of an eigentriplet  $(\mathbf{y}^*, \lambda, \mathbf{x})$  (see Chapter 15) as

$$C_\lambda = \frac{\|\mathbf{y}^*\|_\infty \|\mathbf{x}\|_\infty}{|\mathbf{y}^* \cdot \mathbf{x}|}$$

gives exact condition numbers (in the infinity norm) for the eigenvalues 1, 2, 3 as 399, 252, and 147. We see that the estimates produced by `EigenConditionNumbers` are of the right order of magnitude.

## 72.9 Canonical Forms

There are several canonical forms in Maple: Jordan form, Smith form, Hermite form, and Frobenius form, to name a few. In this section, we talk only about the Smith form (defined in Chapter 6.5 and Chapter 23.2).

<sup>1</sup>An out-of-date, humorous reference.

**Commands:**

1. `SmithForm( B, output=['S', 'U', 'V'] )` Smith form of  $B$ .

**Examples:**

The Smith form of

$$B = \begin{bmatrix} 0 & -4y^2 & 4y & -1 \\ -4y^2 & 4y & -1 & 0 \\ 4y & -1 & 4(2y^2 - 2)y & 4(y^2 - 1)^2 y^2 - 2y^2 + 2 \\ -1 & 0 & 4(y^2 - 1)^2 y^2 - 2y^2 + 2 & -4(y^2 - 1)^2 y \end{bmatrix}$$

is

$$S = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1/4(2y^2 - 1)^2 & 0 \\ 0 & 0 & 0 & (1/64)(2y^2 - 1)^6 \end{bmatrix}.$$

Maple also returns two unimodular (over the domain  $\mathbb{Q}[y]$ ) matrices  $\mathbf{u}$  and  $\mathbf{v}$  for which  $A = U.S.V$ .

## 72.10 Structured Matrices

---

**Facts:**

1. Computer algebra systems are particularly useful for computations with structured matrices.
2. User-defined structures may be programmed using *index functions*. See the help pages for details.
3. Examples of built-in structures include *symmetric*, *skew-symmetric*, *Hermitian*, *Vandermonde*, and *Circulant* matrices.

**Examples:**

**Generalized Companion Matrices.** Maple can deal with several kinds of generalized companion matrices. A generalized companion matrix<sup>2</sup> *pencil* of a polynomial  $p(x)$  is a pair of matrices  $C_0, C_1$  such that  $\det(xC_1 - C_0) = 0$  precisely when  $p(x) = 0$ . Usually, in fact,  $\det(xC_1 - C_0) = p(x)$ , though in some definitions proportionality is all that is needed. In the case  $C_1 = I$ , the identity matrix, we have  $C_0 = C(p(x))$  is the *companion matrix* of  $p(x)$ . MATLAB's `roots` function computes roots of polynomials by first computing the eigenvalues of the companion matrix, a venerable procedure only recently proved stable.

The generalizations allow direct use of alternative polynomial bases, such as the Chebyshev polynomials, Lagrange polynomials, Bernstein (Bézier) polynomials, and many more. Further, the generalizations allow the construction of generalized companion matrix pencils for *matrix polynomials*, allowing one to easily solve *nonlinear eigenvalue problems*.

We give three examples below.

If  $p := 3 + 2x + x^2$ , then `CompanionMatrix( p, x )` produces “the” (standard) companion matrix (also called Frobenius form companion matrix):

$$\begin{bmatrix} 0 & -3 \\ 1 & -2 \end{bmatrix}$$

---

<sup>2</sup>Sometimes known as “colleague” or “comrade” matrices, an unfortunate terminology that inhibits keyword search.

and it is easy to see that  $\det(tI - C) = p(t)$ . If instead

$$p := B_0^3(x) + 2B_1^3(x) + 3B_2^3(x) + 4B_3^3(x)$$

where  $B_k^n(x) = \binom{n}{k}(1-x)^{n-k}(x+1)^k$  is the  $k$ th Bernstein (Bézier) polynomial of degree  $n$  on the interval  $-1 \leq x \leq 1$ , then `CompanionMatrix( p, x )` produces the pencil (note that this is not in Frobenius form)

$$C_0 = \begin{bmatrix} -3/2 & 0 & -4 \\ 1/2 & -1/2 & -8 \\ 0 & 1/2 & -\frac{52}{3} \end{bmatrix}$$

$$C_1 = \begin{bmatrix} 3/2 & 0 & -4 \\ 1/2 & 1/2 & -8 \\ 0 & 1/2 & -\frac{20}{3} \end{bmatrix}$$

(from a formula by Jonsson & Vavasis [JV05] and independently by J. Winkler [Win04]), and we have  $p(x) = \det(xC_1 - C_0)$ . Note that the program does not change the basis of the polynomial  $p(x)$  of Equation (72.9) to the monomial basis (it turns out that  $p(x) = 20 + 12x$  in the monomial basis, in this case: note that  $C_1$  is singular). It is well-known that changing polynomial bases can be ill-conditioned, and this is why the routine avoids making the change.

Next, if we choose nodes  $[-1, -1/3, 1/3, 1]$  and look at the degree 3 polynomial taking the values  $[1, -1, 1, -1]$  on these four nodes, then `CompanionMatrix( values, nodes )` gives  $C_0$  and  $C_1$  where  $C_1$  is the  $5 \times 5$  identity matrix with the  $(5, 5)$  entry replaced by 0, and

$$C_0 = \begin{bmatrix} 1 & 0 & 0 & 0 & -1 \\ 0 & 1/3 & 0 & 0 & 1 \\ 0 & 0 & -1/3 & 0 & -1 \\ 0 & 0 & 0 & -1 & 1 \\ -\frac{9}{16} & \frac{27}{16} & -\frac{27}{16} & \frac{9}{16} & 0 \end{bmatrix}.$$

We have that  $\det(tC_1 - C_0)$  is of degree 3 (in spite of these being  $5 \times 5$  matrices), and that this polynomial takes on the desired values  $\pm 1$  at the nodes. Therefore, the finite eigenvalues of this pencil are the roots of the given polynomial. See [CWO4] and [Cor04] for example, for more information.

Finally, consider the nonlinear eigenvalue problem below: find the values of  $x$  such that the matrix  $C$  with  $C_{ij} = T_0(x)/(i+j+1) + T_1(x)/(i+j+2) + T_2(x)/(i+j+3)$  is singular. Here  $T_k(x)$  means the  $k$ th Chebyshev polynomial,  $T_k(x) = \cos(k \cos^{-1}(x))$ . We issue the command

```
> ( C0, C1 ) := CompanionMatrix( C, x );
```

from which we find

$$C0 = \begin{bmatrix} 0 & 0 & 0 & -2/15 & -1/12 & -\frac{2}{35} \\ 0 & 0 & 0 & -1/12 & -\frac{2}{35} & -1/24 \\ 0 & 0 & 0 & -\frac{2}{35} & -1/24 & -\frac{2}{63} \\ 1 & 0 & 0 & -1/4 & -1/5 & -1/6 \\ 0 & 1 & 0 & -1/5 & -1/6 & -1/7 \\ 0 & 0 & 1 & -1/6 & -1/7 & -1/8 \end{bmatrix}$$

and

$$C1 = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2/5 & 1/3 & 2/7 \\ 0 & 0 & 0 & 1/3 & 2/7 & 1/4 \\ 0 & 0 & 0 & 2/7 & 1/4 & 2/9 \end{bmatrix}.$$

This uses a formula from [Goo61], extended to matrix polynomials. The six generalized eigenvalues of this pencil include, for example, one near to  $-0.6854 + 1.909i$ . Substituting this eigenvalue in for  $x$  in  $C$  yields a three-by-three matrix with ratio of smallest to largest singular values  $\sigma_3/\sigma_1 \approx 1.7 \cdot 10^{-15}$ . This is effectively singular and, thus, we have found the solutions to the nonlinear eigenvalue problem. Again note that the generalized companion matrix is not in Frobenius standard form, and that this process works for a variety of bases, including the Lagrange basis.

**Circulant matrices and Vandermonde matrices.**

> A := Matrix( 3, 3, shape=Circulant[a,b,c] );

$$\begin{bmatrix} a & b & c \\ c & a & b \\ b & c & a \end{bmatrix},$$

> F3 := Matrix( 3,3,shape=Vandermonde[[1,exp(2\*Pi\*I/3),exp(4\*Pi\*I/3)]] );

$$\begin{bmatrix} 1 & 1 & 1 \\ 1 & -1/2 + 1/2i\sqrt{3} & (-1/2 + 1/2i\sqrt{3})^2 \\ 1 & -1/2 - 1/2i\sqrt{3} & (-1/2 - 1/2i\sqrt{3})^2 \end{bmatrix}.$$

It is easy to see that the F3 matrix diagonalizes the circulant matrix A.

**Toeplitz and Hankel matrices.** These can be constructed by calling `ToeplitzMatrix` and `HankelMatrix`, or by direct use of the `shape` option of the `Matrix` constructor.

> T := ToeplitzMatrix( [a,b,c,d,e,f,g] );

> T := Matrix( 4,4,shape=Toeplitz[false,Vector(7,[a,b,c,d,e,f,g])] );

both yield a matrix that looks like

$$\begin{bmatrix} d & c & b & a \\ e & d & c & b \\ f & e & d & c \\ g & f & e & d \end{bmatrix},$$

though in the second case only 7 storage locations are used, whereas 16 are used in the first. This economy may be useful for larger matrices. The `shape` constructor for `Toeplitz` also takes a Boolean argument `true`, meaning symmetric.

Both `Hankel` and `Toeplitz` matrices may be specified with an indexed symbol for the entries:

> H := Matrix( 4, 4, shape=Hankel[a] ); yields

$$\begin{bmatrix} a_1 & a_2 & a_3 & a_4 \\ a_2 & a_3 & a_4 & a_5 \\ a_3 & a_4 & a_5 & a_6 \\ a_4 & a_5 & a_6 & a_7 \end{bmatrix}.$$

## 72.11 Functions of Matrices

The exponential of the matrix  $A$  is computed in the `MatrixExponential` command of Maple by *polynomial interpolation* (see Chapter 11.1) of the exponential at each of the eigenvalues of  $A$ , including multiplicities. In an exact computation context, this method is not so “dubious” [Lab97]. This approach is also used by the general `MatrixFunction` command.

### Examples:

```
> A := Matrix( 3, 3, [[-7,-4,-3],[10,6,4],[6,3,3]] );
> MatrixExponential( A );
```

$$\begin{bmatrix} 6 - 7e^1 & 3 - 4e^1 & 2 - 3e^1 \\ 10e^1 - 6 & -3 + 6e^1 & -2 + 4e^1 \\ 6e^1 - 6 & -3 + 3e^1 & -2 + 3e^1 \end{bmatrix} \quad (72.1)$$

Now a square root: `> MatrixFunction( A, sqrt(x), x ):`

$$\begin{bmatrix} -6 & -7/2 & -5/2 \\ 8 & 5 & 3 \\ 6 & 3 & 3 \end{bmatrix} \quad (72.2)$$

Another matrix square root example, for a matrix close to one that has no square root:

```
> A := Matrix( 2, 2, [[epsilon^2, 1], [0, delta^2]] );
> S := MatrixFunction( A, sqrt(x), x );
> simplify( S ) assuming positive;
```

$$\begin{bmatrix} \epsilon & \frac{1}{\epsilon + \delta} \\ 0 & \delta \end{bmatrix} \quad (72.3)$$

If  $\epsilon$  and  $\delta$  both approach zero, we see that the square root has an entry that approaches infinity. Calling `MatrixFunction` on the above matrix with  $\epsilon = \delta = 0$  yields an error message, `Matrix function x^(1/2) is not defined for this Matrix, which is correct.`

Now for the matrix logarithm.

```
> Pascal := Matrix( 4, 4, (i,j)->binomial(j-1,i-1) );
```

$$\begin{bmatrix} 1 & 1 & 1 & 1 \\ 0 & 1 & 2 & 3 \\ 0 & 0 & 1 & 3 \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (72.4)$$

```
> MatrixFunction( Pascal, log(x), x );
```

$$\begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 3 \\ 0 & 0 & 0 & 0 \end{bmatrix} \quad (72.5)$$

Now a function not covered in Chapter 11, instead of redoing the sine and cosine examples:

```
> A := Matrix( 2, 2, [[-1/5, 1], [0, -1/5]] );
```

```
> W := MatrixFunction( A, LambertW(-1,x), x );
```

$$W := \begin{bmatrix} \text{LambertW}(-1, -1/5) & -5 \frac{\text{LambertW}(-1, -1/5)}{1 + \text{LambertW}(-1, -1/5)} \\ 0 & \text{LambertW}(-1, -1/5) \end{bmatrix} \quad (72.6)$$

```
> evalf( W );
```

$$\begin{bmatrix} -2.542641358 & -8.241194055 \\ 0.0 & -2.542641358 \end{bmatrix} \quad (72.7)$$

That matrix satisfies  $W \exp(W) = A$ , and is a *primary matrix function*. (See [CGH<sup>+</sup>96] for more details about the Lambert  $W$  function.)

Now the matrix sign function (cf. Chapter 11.6). Consider

```
> Pascal2 := Matrix( 4, 4, (i,j)->(-1)^(i-1)*binomial(j-1,i-1) );
```

$$\begin{bmatrix} 1 & 1 & 1 & 1 \\ 0 & -1 & -2 & -3 \\ 0 & 0 & 1 & 3 \\ 0 & 0 & 0 & -1 \end{bmatrix}. \quad (72.8)$$

Then we compute the matrix sign function of this matrix by

```
> S := MatrixFunction( Pascal2, csgn(z), z );
```

which turns out to be the same matrix (Pascal2).

*Note:* The complex “sign” function we use here is not the usual complex sign function for scalars

$$\text{signum}(re^{i\theta}) := e^{i\theta},$$

but rather (as desired for the definition of the matrix sign function)

$$\text{csgn}(z) = \begin{cases} 1 & \text{if } \text{Re}(z) > 0 \\ -1 & \text{if } \text{Re}(z) < 0. \\ \text{signum}(\text{Im}(z)) & \text{if } \text{Re}(z) = 0 \end{cases}$$

This has the side effect of making the function defined even when the input matrix has purely imaginary eigenvalues. The `signum` and `csgn` of 0 are both 0, by default, but can be specified differently if desired.

*Cautions:*

1. Further, it is not the `sign` function in MAPLE, which is a different function entirely: That function (`sign`) returns the sign of the leading coefficient of the polynomial input to `sign`.
2. (In General) This general approach to computing matrix functions can be slow for large exact or symbolic matrices (because manipulation of symbolic representations of the eigenvalues using `RootOf`, typically encountered for  $n \geq 5$ , can be expensive), and on the other hand can be unstable for floating-point matrices, as is well known, especially those with nearly multiple eigenvalues. However, for small or for structured matrices this approach can be very useful and can give insight.

## 72.12 Matrix Stability

As defined in Chapter 19, a matrix is (negative) *stable* if all its eigenvalues are in the left half plane (in this section, “stable” means “negative stable”). In Maple, one may test this by direct computation of the eigenvalues (if the entries of the matrix are numeric) and this is likely faster and more accurate than any purely rational operation based test such as the Hurwitz criterion. If, however, the matrix contains symbolic entries, then one usually wishes to know for what values of the parameters the matrix is stable. We may obtain conditions on these parameters by using the `Hurwitz` command of the `PolynomialTools` package on the characteristic polynomial.

**Examples:**

Negative of `gallery(3)` from MATLAB.

```
> A := -Matrix( [[-149, -50, -154], [537, 180, 546], [-27, -9, -25]] ):
> E := Matrix( [[130, -390, 0], [43, -129, 0], [133, -399, 0]] ):
> AtE := A - t*E;
```

$$\begin{bmatrix} 149 - 130t & 50 + 390t & 154 \\ -537 - 43t & -180 + 129t & -546 \\ 27 - 133t & 9 + 399t & 25 \end{bmatrix} \quad (72.9)$$

For which  $t$  is that matrix stable?

```
> p := CharacteristicPolynomial( AtE, lambda );
> PolynomialTools[Hurwitz]( p, lambda, 's', 'g' );
```

This command returns “FAIL,” meaning that it cannot tell whether  $p$  is stable or not; this is only to be expected as  $t$  has not yet been specified. However, according to the documentation, all coefficients of  $\lambda$  returned in `s` must be positive, in order for  $p$  to be stable. The coefficients returned are

$$\left[ \frac{\lambda}{6+t}, 1/4 \frac{(6+t)^2 \lambda}{15 + 433453t + 123128t^2}, \frac{(60 + 1733812t + 492512t^2) \lambda}{(6+t)(6 + 1221271t)} \right] \quad (72.10)$$

and analysis (not given here) shows that these are all positive if and only if  $t > -6/1221271$ .

## Acknowledgements

---

Many people have contributed to linear algebra in Maple, for many years. Dave Hare and David Linder deserve particular credit, especially for the LinearAlgebra package and its connections to CLAPACK, and have also greatly helped our understanding of the best way to use this package. We are grateful to Dave Linder and to Jürgen Gerhard for comments on early drafts of this chapter.

### 73.1 Introduction

---

#### About *Mathematica*<sup>®</sup>

*Mathematica* is a comprehensive software system for doing symbolic and numerical calculations, creating graphics and animations, writing programs, and preparing documents.

The heart of *Mathematica* is its broad collection of tools for symbolic and exact mathematics, but numerical methods also form an essential part of the system. *Mathematica* is known for its high-quality graphics, and the system is also a powerful programming language, supporting both traditional procedural techniques and functional and rule-based programming. In addition, *Mathematica* is an environment for preparing high-quality documents.

The first version of *Mathematica* was released in 1988. The current version, version 5, was released in 2003. *Mathematica* now contains over 4000 commands and is one of the largest single application programs ever developed. *Mathematica* is a product of Wolfram Research, Inc. The founder, president, and CEO of Wolfram Research is Stephen Wolfram.

*Mathematica* contains two main parts — the **kernel** and the **front end**. The kernel does the computations. For example, the implementation of the **Integrate** command comprises about 500 pages of *Mathematica* code and 600 pages of C code. The front end is a user interface that takes care of the communication between the user and the kernel. In addition, there are **packages** that supplement the kernel; packages have to be loaded as needed.

The most common type of user interface is based on interactive documents known as **notebooks**. *Mathematica* is often used like an advanced calculator for a moment's need, in which case a notebook is simply an interface to write the commands and read the results. However, often a notebook grows to be a useful document that you will save or print or use in a presentation.

Notebooks consist of **cells**. Each cell is indicated with a **cell bracket** at the right side of the notebook. Cells are grouped in various ways so as to form a hierarchical structure. For example, each input is in a cell, each output is in a cell, and each input–output pair forms a higher-level cell.

### About this Chapter

Within the limited space of this chapter, we cover the essentials of doing linear algebra calculations with *Mathematica*. The chapter covers many of the topics of the handbook done via *Mathematica*, and the reader should consult the relevant section for further information.

Most commands are demonstrated in the Examples sections, but note that the examples are very simple. Indeed, the aim of these examples is only to show how the commands are used and what kind of result we get in simple cases. We do not demonstrate the full power and every feature of the commands.

Commands relating to packages are frequently mentioned in this chapter, but they are often not fully explained or demonstrated. *Mathematica* has advanced technology for sparse matrices, but we only briefly mention them in Section 73.3; for a detailed coverage, we refer to [WR03]. The basic principle is that all calculations with sparse matrices work as for usual matrices. [WR03] also considers performance and efficiency questions.

The Appendix contains a short introduction to the use of *Mathematica*. There we also refer to some books, documents, and Help Browser material where you can find further information about linear algebra with *Mathematica*.

This chapter was written with *Mathematica* 5.2. However, many users of *Mathematica* have earlier versions. To help these users, we have denoted by (Mma 5.0) and (Mma 5.1) the features of *Mathematica* that are new in versions 5.0 and 5.1, respectively. In the Appendix we list ways to do some calculations with earlier versions.

As in *Mathematica* notebooks, in this chapter *Mathematica* commands and their arguments are in boldface while outputs are in a plain font. *Mathematica* normally shows the output below the input, but here, in order to save space, we mostly show the output next to the input.

Matrices are traditionally denoted by capital letters like *A* or *M*. However, in *Mathematica* we have the general advice that all user-defined names should begin with lower-case letters so that they do not conflict with the built-in names, which always begin with an upper-case letter. We follow this advice and mainly use the lower-case letter **m** for matrices. In principle, we could use most upper-case letters, but note that the letters **C**, **D**, **E**, **I**, **N**, and **O** are reserved names in *Mathematica* and they cannot be used as user-defined names.

Because the **LinearAlgebra`MatrixManipulation`** package appears quite frequently in this chapter, we abbreviate it to **LAMM**.

## 73.2 Vectors

---

### Commands:

Vectors in *Mathematica* are lists. In Section 73.3, we will see that matrices are lists of lists, each sublist being a row of the matrix. Note that *Mathematica* does not distinguish between row and column vectors. Indeed, when we compute with vectors and matrices, in most cases it is evident for *Mathematica* how an expression has to be calculated. Only in some rare cases do we need to be careful and write an expression in such a way that *Mathematica* understands the expression in the correct way. One of these cases is the multiplication of a column by a row vector; this has to be done with an outer product (see **Outer** in item 4 below).

1. Vectors in *Mathematica*:

- **{a, b, c, ...}** A vector with elements **a, b, c, ...**
- **MatrixForm[v]** Display vector **v** in a column form.

- **Length**[**v**] The number of elements of vector **v**.
  - **VectorQ**[**v**] Test whether **v** is a vector.
2. Generation of vectors:
- **Range**[**n<sub>1</sub>**] Create the vector  $(1, 2, \dots, \mathbf{n}_1)$ . With **Range**[**n<sub>0</sub>**, **n<sub>1</sub>**] we get the vector  $(\mathbf{n}_0, \mathbf{n}_0 + 1, \dots, \mathbf{n}_1)$  and with **Range**[**n<sub>0</sub>**, **n<sub>1</sub>**, **d**] the vector  $(\mathbf{n}_0, \mathbf{n}_0 + \mathbf{d}, \mathbf{n}_0 + 2\mathbf{d}, \dots, \mathbf{n}_1)$ .
  - **Table**[**expr**, {**i**, **n<sub>1</sub>**}] Create a vector by giving **i** the values  $1, 2, \dots, \mathbf{n}_1$  in **expr**. If the iteration specification is {**i**, **n<sub>0</sub>**, **n<sub>1</sub>**}, then **i** gets the values  $\mathbf{n}_0, \mathbf{n}_0 + 1, \dots, \mathbf{n}_1$ , and for {**i**, **n<sub>0</sub>**, **n<sub>1</sub>**, **d**}, the values of **i** are between **n<sub>0</sub>** and **n<sub>1</sub>** in steps of **d**. For {**n<sub>1</sub>**}, simply **n<sub>1</sub>** copies of **expr** are taken.
  - **Array**[**f**, **n<sub>1</sub>**] Create the **n<sub>1</sub>** vector  $(\mathbf{f}[1], \dots, \mathbf{f}[\mathbf{n}_1])$ . With **Array**[**f**, **n<sub>1</sub>**, **n<sub>0</sub>**] we get the **n<sub>1</sub>** vector  $(\mathbf{f}[\mathbf{n}_0], \dots, \mathbf{f}[\mathbf{n}_0 + \mathbf{n}_1 - 1])$ .
3. Calculating with vectors:
- **a v** Multiply vector **v** with scalar **a**.
  - **u + v** Add two vectors.
  - **u v** Multiply the corresponding elements of two vectors and form a vector from the products (there is a space between **u** and **v**); for an inner product, write **u.v**.
  - **u/v** Divide the corresponding elements of two vectors.
  - **v<sup>p</sup>** Calculate the **p**th power of each element of a vector.
  - **a<sup>v</sup>** Generate a vector by calculating the powers of scalar **a** that are given in vector **v**.
4. Products of vectors:
- **u.v** The inner product of two vectors of the same size.
  - **Outer**[**Times**, **u**, **v**] The outer product (a matrix) of vectors **u** and **v**.
  - **Cross**[**u**, **v**] The cross product of two vectors.
5. Norms and sums of vectors:
- **Norm**[**v**] (Mma 5.0) The 2-norm (or Euclidean norm) of a vector.
  - **Norm**[**v**, **p**] (Mma 5.0) The **p**-norm of a vector (**p** is a number in  $[1, \infty)$  or  $\infty$ ).
  - **Total**[**v**] (Mma 5.0) The sum of the elements of a vector.
  - **Apply**[**Times**, **v**] The product of the elements of a vector.
6. Manipulation of vectors:
- **v[[i]]** Take element **i** (output is the corresponding scalar).
  - **v[[i]] = a** Change the value of element **i** into scalar **a** (output is **a**).
  - **v[{{i, j, ...}}]** Take elements **i, j, ...** (output is the corresponding vector).
  - **First**[**v**], **Last**[**v**] Take the first/last element (output is the corresponding scalar).
  - **Rest**[**v**], **Most**[**v**] Drop the first/last element (output is the corresponding vector).
  - **Take**[**v**, **n**], **Take**[**v**, **-n**], **Take**[**v**, {**n<sub>1</sub>**, **n<sub>2</sub>**}] Take the first **n** elements / the last **n** elements / elements **n<sub>1</sub>, ..., n<sub>2</sub>** (output is the corresponding vector).
  - **Drop**[**v**, **n**], **Drop**[**v**, **-n**], **Drop**[**v**, {**n<sub>1</sub>**, **n<sub>2</sub>**}] Drop the first **n** elements / the last **n** elements / elements **n<sub>1</sub>, ..., n<sub>2</sub>** (output is the corresponding vector).
  - **Prepend**[**v**, **a**], **Append**[**v**, **a**] Insert element **a** at the beginning/end of a vector (output is the corresponding vector).
  - **Join**[**u**, **v**, ...] Join the given vectors into one vector (output is the corresponding vector).

7. In the `LinearAlgebra`Orthogonalization`` package:
- `GramSchmidt[{u, v, ...}]` Generate an orthonormal set from the given vectors.
  - `Projection[u, v]` Calculate the orthogonal projection of  $\mathbf{u}$  onto  $\mathbf{v}$ .
8. In the `Geometry`Rotations`` package: rotations of vectors.

### Examples:

1. Vectors in *Mathematica*.

```
v = {4, 2, 3}  {4, 2, 3}
MatrixForm[v]   $\begin{pmatrix} 4 \\ 2 \\ 3 \end{pmatrix}$ 
Length[v]  3
VectorQ[v]  True
```

2. Generation of vectors. `Range` is nice for forming lists of integers or reals:

```
Range[10]  {1, 2, 3, 4, 5, 6, 7, 8, 9, 10}
Range[0, 10, 2]  {0, 2, 4, 6, 8, 10}
Range[1.5, 2, 0.1]  {1.5, 1.6, 1.7, 1.8, 1.9, 2.}
```

`Table` is one of the most useful commands in *Mathematica*:

```
Table[Random[], {3}]  {0.454447, 0.705133, 0.226419}
Table[Random[Integer, {1, 6}], {5}]  {2, 3, 6, 3, 4}
Table[xi, {i, 5}]  {x, x2, x3, x4, x5}
Table[x[i], {i, 5}]  {x[1], x[2], x[3], x[4], x[5]}
Table[xi, {i, 5}]  {x1, x2, x3, x4, x5}
```

`Array` is nice for forming lists of indexed variables:

```
Array[x, 5]  {x[1], x[2], x[3], x[4], x[5]}
Array[x, 5, 0]  {x[0], x[1], x[2], x[3], x[4]}
```

3. Calculating with vectors. The arithmetic operations of multiplying a vector with a scalar and adding two vectors work in *Mathematica* as expected. However, note that *Mathematica* also does other types of arithmetic operations with vectors — multiplication, division, and powers. All arithmetic operations are done in an element-by-element way. For example,  $\mathbf{u} \cdot \mathbf{v}$  and  $\mathbf{u}/\mathbf{v}$  form a vector from the products or quotients of the corresponding elements of  $\mathbf{u}$  and  $\mathbf{v}$ . This is a useful property in many calculations, but remember to use `Dot[u, v]` (which is the same as `Dot[u, v]`) for an inner product.

```
u = {a, b, c}; v = {4, 2, 3};
{10 v, u + v, u v}
{{40, 20, 30}, {4 + a, 2 + b, 3 + c}, {4 a, 2 b, 3 c}}
{1/v, u/v, u2}  {{1/4, 1/2, 1/3}, {a/4, b/2, c/3}, {a2, b2, c2}}
```

Functions of vectors are also calculated elementwise:

```
Log[v]  {Log[4], Log[2], Log[3]}
```

4. Products of vectors. With  $\mathbf{u}$  and  $\mathbf{v}$  as in Example 3, we calculate an inner product, an outer product, and a cross product:

```
v.u  4 a + 2 b + 3 c
Outer[Times, v, u]
{{4 a, 4 b, 4 c}, {2 a, 2 b, 2 c}, {3 a, 3 b, 3 c}}
```

```

MatrixForm[%] 
$$\begin{pmatrix} 4a & 4b & 4c \\ 2a & 2b & 2c \\ 3a & 3b & 3c \end{pmatrix}$$

Cross[v, u] {-3b + 2c, 3a - 4c, -2a + 4b}

```

5. Norms and sums of vectors. The default vector norm is the 2-norm:

```

Norm[u]  $\sqrt{\text{Abs}[a]^2 + \text{Abs}[b]^2 + \text{Abs}[c]^2}$ 
Norm[u, 2]  $\sqrt{\text{Abs}[a]^2 + \text{Abs}[b]^2 + \text{Abs}[c]^2}$ 
Norm[u, 1] Abs[a] + Abs[b] + Abs[c]
Norm[u,  $\infty$ ] Max[Abs[a], Abs[b], Abs[c]]
Total[u] a + b + c
Apply[Times, u] a b c

```

### Applications:

1. (Plotting of vectors) A package [WR99, p. 133] defines the graphic primitive **Arrow** which can be used to plot vectors. As an example, we compute the orthogonal projection of a vector onto another vector and show the three vectors (for graphics primitives like **Arrow**, **Line**, and **Text**, see [Rus04, pp. 132–146]):

```

<< LinearAlgebra`Orthogonalization`
<< Graphics`Arrow`
u = {5, 1}; v = {2, 4};
pr = Projection[v, u]  $\left\{\frac{35}{13}, \frac{7}{13}\right\}$ 
Show[Graphics[{Arrow[{0, 0}, u], Arrow[{0, 0}, v],
  Arrow[{0, 0}, pr], Line[{v, pr}], Text["u", u, {-1, 0}],
  Text["v", v, {-1, -0.4}]}], Axes -> True,
  AspectRatio -> Automatic, PlotRange -> All];

```

## 73.3 Basics of Matrices

---

### Commands:

Matrices in *Mathematica* are lists of lists, each sublist being a row of the matrix. Although the traditional symbols for matrices are capital letters like *A* or *M*, we use the lower-case letter **m** for most matrices because, in *Mathematica*, all user-defined names should begin with a lower-case letter.

Here we only briefly mention sparse matrices; a detailed exposition can be found in [WR03]; this document is the item Built-in Functions > Advanced Documentation > Linear Algebra in the Help Browser of *Mathematica*.

1. Matrices in *Mathematica*:

- $\{\{\mathbf{a}, \mathbf{b}, \dots\}, \{\mathbf{c}, \mathbf{d}, \dots\}, \dots\}$  A matrix with rows  $(\mathbf{a}, \mathbf{b}, \dots)$ ,  $(\mathbf{c}, \mathbf{d}, \dots)$ ,  $\dots$
- **MatrixForm**[**m**] Display matrix **m** in a two-dimensional form.
- **Length**[**m**] The number of rows of matrix **m**.
- **Dimensions**[**m**] The number of rows and columns of matrix **m**.
- **MatrixQ**[**m**] Test whether **m** is a matrix.
- The menu command Input  $\triangleright$  Create Table/Matrix/Palette generates an empty matrix into which the elements can be written.

## 2. Generation of matrices:

- **IdentityMatrix**[**n**] An  $n \times n$  identity matrix.
- **DiagonalMatrix**[ $\{\mathbf{a}, \mathbf{b}, \dots\}$ ] A diagonal matrix with diagonal elements  $\mathbf{a}, \mathbf{b}, \dots$
- **HilbertMatrix**, **HankelMatrix**, **ZeroMatrix**, **UpperDiagonalMatrix**, **LowerDiagonalMatrix**, **TridiagonalMatrix** (in the **LAMM** package).
- **Table**[**expr**,  $\{\mathbf{i}, \mathbf{m}_1\}$ ,  $\{\mathbf{j}, \mathbf{n}_1\}$ ] Create a matrix by giving, in **expr**, **i** the values 1, 2,  $\dots$ ,  $\mathbf{m}_1$  and, for each **i**, **j** the values 1,  $\dots$ ,  $\mathbf{n}_1$ . Other forms of an iteration specification are  $\{\mathbf{m}_1\}$ ,  $\{\mathbf{i}, \mathbf{m}_0, \mathbf{m}_1\}$ , and  $\{\mathbf{i}, \mathbf{m}_0, \mathbf{m}_1, \mathbf{d}\}$  (see item 2 in Section 73.2).
- **Array**[**f**,  $\{\mathbf{m}_1, \mathbf{n}_1\}$ ] Create an  $\mathbf{m}_1 \times \mathbf{n}_1$  matrix with elements **f**[**i**, **j**].
- **Array**[**f**,  $\{\mathbf{m}_1, \mathbf{n}_1\}$ ,  $\{\mathbf{m}_0, \mathbf{n}_0\}$ ] Create an  $\mathbf{m}_1 \times \mathbf{n}_1$  matrix using starting values  $\mathbf{m}_0$  and  $\mathbf{n}_0$  for the indices (the default values of  $\mathbf{m}_0$  and  $\mathbf{n}_0$  are 1).

## 3. Sparse matrices:

- **SparseArray**[**rules**] (Mma 5.0) Create a vector or matrix by taking nonzero elements from **rules** and setting other elements to zero.
- **Normal**[**s**] (Mma 5.0) Show a sparse vector or matrix **s** in the usual list form.
- **ArrayRules**[**m**] (Mma 5.0) Show all nonzero elements of a vector or matrix as rules.

## 4. Arithmetic of matrices (see also Section 73.4):

- **a m** Multiply matrix **m** by scalar **a**.
- **m + n** Add two matrices.
- **m n** Multiply *the corresponding elements* of two matrices (giving the Hadamard product of the matrices; there is a space between **m** and **n**); for a proper matrix product, write **m.n** (see item 2 in Section 73.4).
- **m<sup>p</sup>** Calculate the **p**th power of *each element* of a matrix; for a proper matrix power, write **MatrixPower**[**m**, **p**] (see item 3 in Section 73.4).
- **m<sup>-1</sup>** Calculate the reciprocal of *each element* of a matrix; for a proper matrix inverse, write **Inverse**[**m**] (see item 5 in Section 73.4).

## 5. Sums and trace of matrices:

- **Total[m]** (Mma 5.0) The vector of column sums (i.e., the sums of the elements of each column).
- **Total[Transpose[m]]** or **Map[Total, m]** (Mma 5.0) The vector of row sums.
- **Total[Flatten[m]]** or **Total[m, 2]** (Mma 5.0) The sum of all elements.
- **Tr[m]** Trace.
- **Tr[m, List]** List of diagonal elements.

## 6. Plots of matrices:

- **ArrayPlot[m]** (Mma 5.1) Plot a matrix by showing zero values as white squares, the maximum absolute value as black squares, and values between as gray squares.
- **ArrayPlot[m, ColorRules → {0 → White, \_ → Black}]** (Mma 5.1) Show all nonzero values as black squares (also **MatrixPlot[m]** (Mma 5.0) from the **LAMM** package).

**Examples:**1. Matrices in *Mathematica*. Matrices are lists of rows:

```
m = {{5, 2, 3}, {4, 0, 2}}  {{5, 2, 3}, {4, 0, 2}}
MatrixForm[m]   $\begin{pmatrix} 5 & 2 & 3 \\ 4 & 0 & 2 \end{pmatrix}$ 
```

The number of rows and the size of the matrix are

```
Length[m]  2
Dimensions[m]  {2, 3}
```

With the menu command Input > Create Table/Matrix/Palette, we get a matrix with empty slots that can then be filled with the help of the Tab key:

```
 $\begin{pmatrix} \square & \square & \square \\ \square & \square & \square \end{pmatrix}$ 
```

With the **TableSpacing** option of **MatrixForm** we can control the space between rows and columns (the default value of the option is 1):

```
MatrixForm[m, TableSpacing → {.5, .5}]   $\begin{pmatrix} 5 & 2 & 3 \\ 4 & 0 & 2 \end{pmatrix}$ 
```

Note that *Mathematica* will not do any calculations with a matrix that is in a matrix form! For example, writing

```
m = {{5, 2, 3}, {4, 0, 2}} // MatrixForm   $\begin{pmatrix} 5 & 2 & 3 \\ 4 & 0 & 2 \end{pmatrix}$ 
```

defines **m** to be the matrix form of the given matrix and *Mathematica* does not do any calculations with this **m**. Write instead

```
MatrixForm[m = {{5, 2, 3}, {4, 0, 2}}]   $\begin{pmatrix} 5 & 2 & 3 \\ 4 & 0 & 2 \end{pmatrix}$ 
```

or (**m = {{5, 2, 3}, {4, 0, 2}}**) // **MatrixForm** or do as we did above, define the matrix with **m = {{5, 2, 3}, {4, 0, 2}}** and then display the matrix with **MatrixForm[m]**.

## 2. Generation of matrices.

```

IdentityMatrix[3]  {{1, 0, 0}, {0, 1, 0}, {0, 0, 1}}
DiagonalMatrix[{3, 1, 2}]  {{3, 0, 0}, {0, 1, 0}, {0, 0, 2}}
Table[Random[], {2}, {2}]
{{0.544884, 0.397472}, {0.308083, 0.191191}}
Table[1/(i + j - 1), {i, 3}, {j, 3}]
{{1, 1/2, 1/3}, {1/2, 1/3, 1/4}, {1/3, 1/4, 1/5}}

```

**If**, **Which**, and **Switch** are often useful in connection with **Table**. In the following examples, we form the same tridiagonal matrix in three ways (we show the result only for the first example):

```

Table[If[i == j, 13, If[i == j - 1, 11,
If[i == j + 1, 12, 0]]], {i, 4}, {j, 4}] // MatrixForm

```

$$\begin{pmatrix} 13 & 11 & 0 & 0 \\ 12 & 13 & 11 & 0 \\ 0 & 12 & 13 & 11 \\ 0 & 0 & 12 & 13 \end{pmatrix}$$

```

Table[Which[i == j, 13, i == j - 1, 11, i == j + 1, 12, True,
0], {i, 4}, {j, 4}];

```

```

Table[Switch[i - j, -1, 11, 0, 13, 1, 12, _, 0],
{i, 4}, {j, 4}];

```

Here are matrices with general elements:

```

Table[f[i, j], {i, 2}, {j, 2}]
{{f[1, 1], f[1, 2]}, {f[2, 1], f[2, 2]}}
Table[fi,j, {i, 2}, {j, 2}]  {{f1,1, f1,2}, {f2,1, f2,2}}
Array[f, {2, 2}]  {{f[1, 1], f[1, 2]}, {f[2, 1], f[2, 2]}}

```

3. Sparse matrices. With **SparseArray** we can input a matrix by specifying only the nonzero elements. With **Normal** we can show a sparse matrix as a usual matrix. One way to specify the rules is to write them separately:

```

SparseArray[{{1, 1} → 3, {2, 3} → 2, {3, 2} → 4}]
SparseArray[<3>, {3, 3}]
% // Normal  {{3, 0, 0}, {0, 0, 2}, {0, 4, 0}}

```

Another way is to gather the left- and right-hand sides of the rules together into lists:

```

SparseArray[{{1, 1}, {2, 3}, {3, 2}} → {3, 2, 4}];

```

Still another way is to give the rules in the form of index patterns. As an example, we generate the same tridiagonal matrix as we generated in Example 2 with **Table**:

```

SparseArray[{{i-, i-} → 13, {i-, j-} /; i - j == -1 → 11,
{i-, j-} /; i - j == 1 → 12}, {4, 4}];

```

4. Arithmetic of matrices. The arithmetic operations of multiplying a matrix with a scalar and adding two matrices work in *Mathematica* as expected. However, note that *Mathematica* also does other types of arithmetic operations with matrices, especially multiplication and powers. All arithmetic operations are done in an element-by-element way. For example, **m n** forms a matrix from the products of the corresponding elements of **m** and **n**. This is a useful property in some calculations, but remember to use **m.n** (which is the same as **Dot** [**m**, **n**]) for an inner product, **MatrixPower** [**m**, **p**] for a matrix power, and **Inverse** [**m**] for a matrix inverse (see Section 73.4).

```

m = {{2, 5}, {3, 1}};
n = {{a, b}, {c, d}};

```

```

3 n {{3 a, 3 b}, {3 c, 3 d}}
m + n {{2 + a, 5 + b}, {3 + c, 1 + d}}
m n {{2 a, 5 b}, {3 c, d}}
n^2 {{a^2, b^2}, {c^2, d^2}}
n^-1 {{1/a, 1/b}, {1/c, 1/d}}

```

5. Sums and trace of matrices. With **m** as in Example 4, here are the column sums, row sums, the sum of all elements, and trace:

```

{Total[m], Total[Transpose[m]], Total[Flatten[m]], Tr[m]}
{{5, 6}, {7, 4}, 11, 3}

```

6. Plots of matrices.

```

ArrayPlot[[{5, 2, 3}, {4, 0, 2}]];
m = SparseArray[[{i_, j_} /; Mod[i - j, 10] == 0 -> 1], {30, 30}];
ArrayPlot [m];

```

## 73.4 Matrix Algebra

---

### Commands:

- Transpose:
  - **Transpose[m]** Transpose.
  - **ConjugateTranspose[m]** (Mma 5.1) Conjugate transpose.
- Product:
  - **m.n** Product of two matrices.
  - **m.v** Product of a matrix and a (column) vector.
  - **v.m** Product of a (row) vector and a matrix.
- Power and matrix exponential:
  - **MatrixPower[m, p]** **p**th power of a square matrix.
  - **MatrixExp[m]** Matrix exponential  $e^{\mathbf{m}} = \sum_{i=0}^{\infty} \frac{1}{i!} \mathbf{m}^i$  of a square matrix.

4. Determinant and minors:
  - **Det [m]** Determinant of a square matrix.
  - **Minors [m]** Minors of a square matrix.
  - **Minors [m, k]**  $k$ th minors.
5. Inverse and pseudo-inverse:
  - **Inverse [m]** Inverse of a square matrix.
  - **PseudoInverse [m]** Pseudo-inverse (of a possibly rectangular matrix).
6. Norms and condition numbers:
  - **Norm [m]** (Mma 5.0) The 2-norm of a numerical matrix.
  - **Norm [m, p]** (Mma 5.0) The  $p$ -norm of a matrix ( $p$  is a number in  $[1, \infty)$  or  $\infty$  or **Frobenius**).
  - **InverseMatrixNorm [m, p]** The  $p$ -norm of the inverse (in the **LAMM** package).
  - **MatrixConditionNumber [m, p]** The  $p$ -norm matrix condition number (in the **LAMM** package).
7. Nullspace, rank, and row reduction:
  - **NullSpace [m]** Basis vectors of the null space (kernel).
  - **MatrixRank [m]** (Mma 5.0) Rank.
  - **RowReduce [m]** Do Gauss–Jordan elimination to produce the reduced row echelon form.

### Examples:

1. Transpose.

$$\begin{aligned}
 \mathbf{m} &= \{\{2 + 3 \mathbf{I}, 1 - 2 \mathbf{I}\}, \{3 - 4 \mathbf{I}, 4 + \mathbf{I}\}\}; \\
 \mathbf{MatrixForm}[\mathbf{m}] & \begin{pmatrix} 2 + 3i & 1 - 2i \\ 3 - 4i & 4 + i \end{pmatrix} \\
 \mathbf{MatrixForm}[\mathbf{Transpose}[\mathbf{m}]] & \begin{pmatrix} 2 + 3i & 3 - 4i \\ 1 - 2i & 4 + i \end{pmatrix} \\
 \mathbf{MatrixForm}[\mathbf{ConjugateTranspose}[\mathbf{m}]] & \begin{pmatrix} 2 - 3i & 3 + 4i \\ 1 + 2i & 4 - i \end{pmatrix}
 \end{aligned}$$

2. Product. Consider the following matrices and vectors:

$$\begin{aligned}
 \mathbf{m} &= \{\{1, 2, 3\}, \{4, 5, 6\}\}; \quad \mathbf{n} = \{\{p, q\}, \{r, s\}, \{t, u\}\}; \\
 \mathbf{v} &= \{1, 2\}; \quad \mathbf{w} = \{1, 2, 3\}; \\
 \mathbf{Map}[\mathbf{MatrixForm}, \{\mathbf{m}, \mathbf{n}, \mathbf{v}, \mathbf{w}\}] & \\
 & \left\{ \begin{pmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{pmatrix}, \begin{pmatrix} p & q \\ r & s \\ t & u \end{pmatrix}, \begin{pmatrix} 1 \\ 2 \end{pmatrix}, \begin{pmatrix} 1 \\ 2 \\ 3 \end{pmatrix} \right\}
 \end{aligned}$$

Here are some products:

$$\begin{aligned}
 \mathbf{m.n} & \{\{p + 2r + 3t, q + 2s + 3u\}, \{4p + 5r + 6t, 4q + 5s + 6u\}\} \\
 \mathbf{n.v} & \{p + 2q, r + 2s, t + 2u\} \\
 \mathbf{w.n} & \{p + 2r + 3t, q + 2s + 3u\}
 \end{aligned}$$

3. Power and matrix exponential. Powers can be calculated with **MatrixPower** or by using the dot repeatedly:

```

k = {{2, 3}, {-2, 1}};
MatrixPower[k, 4]  {{-50, -63}, {42, -29}}
k.k.k.k  {{-50, -63}, {42, -29}}
MatrixExp[k // N]  {{-2.6658, 3.79592}, {-2.53061, -3.93111}}

```

4. Determinant and minors. First, we consider a nonsingular matrix:

```

m = {{6, 2, 3}, {2, 7, 5}, {4, 2, 5}};
Det[m]  98
Minors[m]  {{38, 24, -11}, {4, 18, 4}, {-24, -10, 25}}

```

Here is a singular matrix:

```

n = {{7, 7, 2, 7}, {2, 5, 0, 7}, {8, 7, 8, 3}, {5, 6, 4, 5}};
Det[n]  0

```

5. Inverse and pseudo-inverse. First, we consider the nonsingular matrix **m** from Example 4:

```

i = Inverse[m]  {{25/98, -2/49, -11/98}, {5/49, 9/49, -12/49}, {-12/49, -2/49, 19/49}}
m.i-IdentityMatrix[3]  {{0, 0, 0}, {0, 0, 0}, {0, 0, 0}}

```

Then, we consider the singular matrix **n**. The inverse does not exist, but the Moore–Penrose pseudo-inverse does exist:

```

Inverse[n]
Inverse::sing :
Matrix {{7, 7, 2, 7}, {2, 5, 0, 7}, {8, 7, 8, 3}, {5, 6, 4, 5}} is
singular. More...
Inverse[{{7, 7, 2, 7}, {2, 5, 0, 7}, {8, 7, 8, 3},
{5, 6, 4, 5}}]
ps = PseudoInverse[n // N]
{{0.324527, -0.235646, -0.0236215, -0.129634},
{-0.054885, 0.0700676, 0.020876, 0.0454718},
{-0.256434, 0.102381, 0.121511, 0.111946},
{-0.0535186, 0.136327, -0.031972, 0.0521774}}

```

Next, we check the four characterizing properties of a pseudo-inverse:

```

{n.ps.n - n, ps.n.ps - ps, ConjugateTranspose[n.ps] - n.ps,
ConjugateTranspose[ps.n] - ps.n} // Chop
{{{0, 0, 0, 0}, {0, 0, 0, 0}, {0, 0, 0, 0}, {0, 0, 0, 0}},
{{0, 0, 0, 0}, {0, 0, 0, 0}, {0, 0, 0, 0}, {0, 0, 0, 0}},
{{0, 0, 0, 0}, {0, 0, 0, 0}, {0, 0, 0, 0}, {0, 0, 0, 0}},
{{0, 0, 0, 0}, {0, 0, 0, 0}, {0, 0, 0, 0}, {0, 0, 0, 0}}}

```

For the option **Tolerance** of **PseudoInverse**, see **SingularValueList** in section 73.7.

6. Norms and condition numbers. The default matrix norm is the 2-norm (the largest singular value):

```

Norm[{{3, 1}, {4, 2}}]   $\sqrt{15 + \sqrt{221}}$ 
MatrixForm[m = {{p, q}, {r, s}}]   $\begin{pmatrix} p & q \\ r & s \end{pmatrix}$ 
Norm[m, Frobenius]   $\sqrt{\text{Abs}[p]^2 + \text{Abs}[q]^2 + \text{Abs}[r]^2 + \text{Abs}[s]^2}$ 
Norm[m, 1]  Max[Abs[p] + Abs[r], Abs[q] + Abs[s]]
Norm[m,  $\infty$ ]  Max[Abs[p] + Abs[q], Abs[r] + Abs[s]]

```

7. Nullspace, rank, and row reduction. The null space (or kernel) of a matrix  $M$  consists of vectors  $v$  for which  $Mv = 0$ . **NullSpace** gives a list of basis vectors for the null space. The matrix multiplied with any linear combination of these basis vectors gives a zero vector. For a nonsingular matrix  $M$ , the null space is empty (*Mathematica* gives the empty list  $\{\}$ ), that is, there is no nonzero vector  $v$  such that  $Mv = 0$ . The null space of the following matrix contains two basis vectors:

```
p = {{7, 4, 8, 0}, {7, 4, 8, 0}, {1, 8, 3, 3}};
ns = NullSpace[p] {{12, -21, 0, 52}, {-4, -1, 4, 0}}
```

The matrix **p** multiplied with any linear combination of the basis vectors gives a null vector:

```
p.(a ns[[1]] + b ns[[2]]) // Simplify {0, 0, 0}
```

Matrix **p** is rank deficient:

```
MatrixRank[p] 2
```

The number of basis vectors of the null space plus the rank is the number of columns:

```
Length[NullSpace[p]] + MatrixRank[p] 4
```

The reduced row echelon form of a nonsingular square matrix is the identity matrix. Here is the reduced row echelon form of **p**:

```
RowReduce[p] // MatrixForm  $\begin{pmatrix} 1 & 0 & 1 & -\frac{3}{13} \\ 0 & 1 & \frac{1}{4} & \frac{21}{52} \\ 0 & 0 & 0 & 0 \end{pmatrix}$ 
```

The number of nonzero rows in the reduced row echelon form is the rank. **RowReduce** is also considered in item 6 of Section 73.9.

### Applications:

- (Prediction of a Markov chain) We classify days to be either wet or dry and assume that weather follows a Markov chain having the states wet and dry [Rus04, pp. 730–735]. From the weather statistics of Snoqualmie Falls in Western Washington, we have estimated the transition probability matrix to be  $P = \begin{pmatrix} 0.834 & 0.166 \\ 0.398 & 0.602 \end{pmatrix}$ . This means that if today is a wet day, then tomorrow will be a wet day with probability 0.834 and a dry day with probability 0.166, and if today is a dry day, tomorrow will be a wet day with probability 0.398 and a dry day with probability 0.602. (See Application 1 of Section 4.3, or Chapter 54 for more information on Markov chains.)

If  $\mu(n)$  is a row vector containing the probabilities of the states for day  $n$ , then  $\mu(n) = \mu(0)P^n$ . Assume that today is Monday and we have a dry day, then  $\mu(0) = (0, 1)$ . We predict the weather for Friday:

```
p = {{0.834, 0.166}, {0.398, 0.602}};
{0, 1}.MatrixPower[p, 4] {0.680173, 0.319827}
```

Thus, Friday is wet with probability 0.68 and dry with probability 0.32.

- (Permanent) (See Chapter 31 for the definition and more information about permanents.) A permanent of a square matrix  $M$  with  $n$  rows can be computed as the coefficient of the product  $x_1x_2\cdots x_n$  in the product of the components of the vector  $Mv$ , where  $v = (x_1, \dots, x_n)$ . So, a permanent can be calculated with the following program:

```
permanent[m] := With[{v = Array[x, Length[m]]},
Coefficient[Apply[Times, m.v], Apply[Times, v]]]
m = {{6, 2, 3}, {2, 7, 5}, {4, 2, 5}};
permanent[m] 426
```

## 73.5 Manipulation of Matrices

---

### Commands:

1. Taking and resetting elements:
  - **m[[i, j]]** Take element (i, j) (output is the corresponding scalar).
  - **m[[i, j]] = a** Change the value of element (i, j) into scalar a (output is a).
2. Taking, dropping, and inserting rows:
  - **m[[i]]** Take row i (output is the corresponding vector).
  - **m[{{i<sub>1</sub>, i<sub>2</sub>, ...}}]** Take the given rows (output is the corresponding matrix).
  - **First[m], Last[m]** Take the first/last row (output is the corresponding vector).
  - **Rest[m], Most[m]** Drop the first/last row (output is the corresponding matrix).
  - **Take[m, n], Take[m, -n], Take[m, {n<sub>1</sub>, n<sub>2</sub>}]** Take the first n rows / the last n rows / rows n<sub>1</sub>, ..., n<sub>2</sub> (output is the corresponding matrix).
  - **Drop[m, n], Drop[m, -n], Drop[m, {n<sub>1</sub>, n<sub>2</sub>}]** Drop the first n rows / the last n rows / rows n<sub>1</sub>, ..., n<sub>2</sub> (output is the corresponding matrix).
  - **Prepend[m, r], Append[m, r]** Insert row r at the beginning/end of a matrix (output is the corresponding matrix).
  - **Insert[m, r, i]** Insert row r between rows i - 1 and i (so, r becomes row i) (output is the corresponding matrix).
3. Taking and dropping columns:
  - **m[[All, j]]** Take column j (output is the corresponding vector).
  - **m[[All, {j<sub>1</sub>, j<sub>2</sub>, ...}]]** Take the given columns (output is the corresponding matrix).
  - **Take[m, All, n], Drop[m, {}, n]** Take/drop the first n columns (output is the corresponding matrix).
4. Taking submatrices:
  - **m[{{i<sub>1</sub>, i<sub>2</sub>, ...}, {j<sub>1</sub>, j<sub>2</sub>, ...}}]** Take the elements having the given indices.
  - **Take[m, {i<sub>1</sub>, i<sub>2</sub>}, {j<sub>1</sub>, j<sub>2</sub>}]** Take the elements having row indices between i<sub>1</sub> and i<sub>2</sub> and column indices between j<sub>1</sub> and j<sub>2</sub>.
5. Combining and extending matrices:
  - **Join[m<sub>1</sub>, m<sub>2</sub>, ...]** Put matrices m<sub>i</sub> one below the other.
  - **MapThread[Join, {m<sub>1</sub>, m<sub>2</sub>, ...}]** Put matrices m<sub>i</sub> side by side; another way: **Transpose[Join[Transpose[m<sub>1</sub>], Transpose[m<sub>2</sub>], ...]]**.
  - **PadRight[m, {n<sub>1</sub>, n<sub>2</sub>}]** Extend m with zeros to an n<sub>1</sub> × n<sub>2</sub> matrix.
  - **PadRight[m, {n<sub>1</sub>, n<sub>2</sub>}, a]** Extend m with replicates of matrix a to an n<sub>1</sub> × n<sub>2</sub> matrix.
6. In the **LAMM** package:
  - Taking parts of matrices: **TakeRows, TakeColumns, TakeMatrix, SubMatrix**.
  - Combining matrices: **AppendColumns, AppendRows, BlockMatrix**.
7. Permuting rows and columns:
  - **m[{{i<sub>1</sub>, ..., i<sub>n</sub>}}]** Permute the rows into the given order.
  - **RotateLeft[m], RotateRight[m]** Move the first/last row to be the last/first row.
  - **RotateLeft[m, {0, 1}], RotateRight[m, {0, 1}]** Move the first/last column to be the last/first column.

## 8. Flattening and partitioning:

- **Flatten[m]** Flatten out a matrix into a vector by concatenating the rows.
- **Partition[v, k]** Partition a vector into a matrix having **k** columns and as many rows as become complete.

## 73.6 Eigenvalues

---

### Commands:

## 1. Eigenvalues and eigenvectors:

- **CharacteristicPolynomial[m, x]** Characteristic polynomial of a square matrix [note that *Mathematica* defines the characteristic polynomial of a matrix  $M$  to be  $\det(M - xI)$  while the handbook uses the definition  $\det(xI - M)$ ].
- **Eigenvalues[m]** Eigenvalues of a square matrix, in order of decreasing absolute value (repeated eigenvalues appear with their appropriate multiplicity).
- **Eigenvectors[m]** Eigenvectors of a square matrix, in order of decreasing absolute value of their eigenvalues (eigenvectors are not normalized).
- **Eigensystem[m]** Eigenvalues and eigenvectors of a square matrix.

## 2. Options:

- **Eigenvalues**, **Eigenvectors**, and **Eigensystem** have the options **Cubics** (Mma 5.0) and **Quartics** (Mma 5.0) with default value **False**; if you want explicit radicals for all cubics and quartics, set **Cubics**  $\rightarrow$  **True** and **Quartics**  $\rightarrow$  **True**.

## 3. Largest eigenvalues and generalized eigenvalues:

- **Eigenvalues[m, k]** (Mma 5.0) Calculate the **k** largest eigenvalues; similarly for **Eigenvectors** and **Eigensystem**.
- **Eigenvalues[{m, a}]** (Mma 5.0) Calculate the generalized eigenvalues of matrix **m** with respect to matrix **a**; similarly for **Eigenvectors** and **Eigensystem**.

### Examples:

1. Eigenvalues. First, we calculate the characteristic polynomial of **m** in two ways:

```

m = {{6, 2, 3}, {2, 7, 5}, {4, 2, 5}};
chp = CharacteristicPolynomial[m, x] 98 - 81 x + 18 x2 - x3
Det[m - x IdentityMatrix[3]] 98 - 81 x + 18 x2 - x3

```

Then, we calculate the eigenvalues in two ways:

```

lam = Eigenvalues[m] {8 +  $\sqrt{15}$ , 8 -  $\sqrt{15}$ , 2}
Solve[chp == 0] {{x  $\rightarrow$  2}, {x  $\rightarrow$  8 -  $\sqrt{15}$ }, {x  $\rightarrow$  8 +  $\sqrt{15}$ }}

```

Here are the eigenvectors:

```

vec = Eigenvectors[m]
{{ $\left\{1, -\frac{9}{2} + \frac{1}{2}(8 + \sqrt{15}), 1\right\}$ ,  $\left\{1, -\frac{9}{2} + \frac{1}{2}(8 - \sqrt{15}), 1\right\}$ ,
 $\left\{-5, -14, 16\right\}$ }}

```

An eigenvalue  $\lambda$  of a matrix  $M$  and the corresponding eigenvector  $x$  should satisfy  $Mx = \lambda x$ . We check this for the first eigenvalue and then for all the eigenvalues:

```

m.vec[[1]] - lam[[1]] vec[[1]] // Simplify {0, 0, 0}
m.Transpose[vec] - Transpose[vec].DiagonalMatrix[lam] //
Simplify
{{0, 0, 0}, {0, 0, 0}, {0, 0, 0}}

```

With **Eigensystem** we can compute both the eigenvalues and the eigenvectors. The result is a list where the first element is a list of eigenvalues and the second element a list of the corresponding eigenvectors:

```

{lam, vec} = Eigensystem[m]
{{8 +  $\sqrt{15}$ , 8 -  $\sqrt{15}$ , 2},
 {1,  $-\frac{9}{2} + \frac{1}{2}(8 + \sqrt{15})$ , 1}, {1,  $-\frac{9}{2} + \frac{1}{2}(8 - \sqrt{15})$ , 1},
 {-5, -14, 16}}

```

- Options. For more complex eigenvalues, we may get only representations of the values as some root objects, but with **N** we get numerical values and with the **Cubics** and **Quartics** options we may get explicit eigenvalues. Note that often we only need the decimal values of the eigenvalues (not their exact expressions), and then we can input the matrix **m // N**.

```

n = {{7, 7, 2, 7}, {2, 5, 0, 7}, {8, 7, 8, 3}, {5, 6, 4, 5}};
Eigenvalues[m]
{Root[-171 + 112 #1 - 25 #12 + #13 &, 1],
 Root[-171 + 112 #1 - 25 #12 + #13 &, 3],
 Root[-171 + 112 #1 - 25 #12 + #13 &, 2], 0}
% // N {19.7731, 2.61345 + 1.34834 i, 2.61345 - 1.34834 i, 0.}
Eigenvalues[n // N]
{19.7731, 2.61345 + 1.34834 i, 2.61345 - 1.34834 i,
 -2.85924 × 10-16}
Eigenvalues[n, Cubics → True][[1]]
 $\frac{25}{3} + \frac{1}{3} \left( \frac{10667}{2} - \frac{261\sqrt{253}}{2} \right)^{1/3} + \frac{1}{3} \left( \frac{1}{2}(10667 + 261\sqrt{253}) \right)^{1/3}$ 

```

### Applications:

- (Positive and negative definite matrices) A symmetric (or Hermitian) matrix is positive [negative] definite if and only if all of the eigenvalues are positive [negative]. (See Section 8.4 for more information about positive definite matrices.) With this result we can easily test the definiteness of a matrix (note that *Mathematica* does not have a special command for this test). For example, the following symmetric matrix is positive definite:

```

m = {{2, 0, 1}, {0, 4, 2}, {1, 2, 3}};
Eigenvalues[m] // N {5.66908, 2.47602, 0.854897}

```

- (A sufficient condition for a minimum or maximum) A sufficient condition for a local minimum [maximum] point of a function is that the Hessian is positive [negative] definite [BSS93, p. 134]. Calculate the stationary points of a function (for a program for classical optimization with constraints, see [Rus04, pp. 543–547]):

```

f = x3 + x2 y2 + 2 x y - 3 x - y
- 3 x + x3 - y + 2 x y + x2 y2
grad = {D[f, x], D[f, y]}
{-3 + 3 x2 + 2 y + 2 x y2, -1 + 2 x + 2 x2 y}
stat = Solve[grad == 0, {x, y}] // N
{{y → 1.22959, x → -1.16294},
 {y → 0.956992, x → 0.369407}, {y → -0.497601, x → 1.07442},
 {y → -0.844491 - 2.24741 i, x → -0.140442 - 0.584262 i},
 {y → -0.844491 + 2.24741 i, x → -0.140442 + 0.584262 i}}

```

Pick the real points (see Section 73.5, the second command in item 2 of Commands):

```
stat2 = stat[{{1, 2, 3}}]
{{y → 1.22959, x → -1.16294},
 {y → 0.956992, x → 0.369407}, {y → -0.497601, x → 1.07442}}
```

Calculate the Hessian and its eigenvalues at the real stationary points:

```
hes = {{D[f, x, x], D[f, x, y]}, {D[f, y, x], D[f, y, y]}}
{{6 x + 2 y2, 2 + 4 x y}, {2 + 4 x y, 2 x2}}
Map[Eigenvalues[hes /. #] &, stat2]
{{-5.61664, 4.36764}, {6.06166, -1.74063}, {6.94587, 2.30462}}
```

Thus, the first two points are saddle points while the third point is a point of minimum. Note that the gradient and the Hessian can in *Mathematica* 5.1 also be calculated as follows:

```
grad = D[f, {{x, y}, 1}]
{-3 + 3 x2 + 2 y + 2 x y2, -1 + 2 x + 2 x2 y}
hes = D[f, {{x, y}, 2}]
{{6 x + 2 y2, 2 + 4 x y}, {2 + 4 x y, 2 x2}}
```

3. (Eigenvector–eigenvalue decomposition) Let  $\text{diag}(\lambda)$  be a diagonal matrix whose diagonal elements are the eigenvalues of a matrix  $M$ , and let  $P$  be a matrix whose columns are the eigenvectors of  $M$ . If  $P$  is nonsingular, we have the decomposition  $M = P\text{diag}(\lambda)P^{-1}$  or diagonalization  $P^{-1}MP = \text{diag}(\lambda)$ . The former equality shows that  $M$  and  $\text{diag}(\lambda)$  are similar matrices, so that, for example, they have the same determinant, trace, and rank. (See Section 4.3 for more information about diagonalization.) As an example of the eigenvector–eigenvalue decomposition, first compute the eigenvalues and eigenvectors:

```
m = {{6, 2, 3}, {2, 7, 5}, {4, 2, 5}};
{lam, vec} = Eigensystem[m]
{{8 + √15, 8 - √15, 2},
 {{1, -9/2 + 1/2 (8 + √15), 1}, {1, -9/2 + 1/2 (8 - √15), 1},
 {-5, -14, 16}}}
```

Then, define the diagonal matrix of eigenvalues and the matrix whose columns are the eigenvectors:

```
diag = DiagonalMatrix[lam]
{{8 + √15, 0, 0}, {0, 8 - √15, 0}, {0, 0, 2}}
p = Transpose[vec]
{{1, 1, -5}, {-9/2 + 1/2 (8 + √15), -9/2 + 1/2 (8 - √15), -14},
 {1, 1, 16}}
```

The following computation verifies the decomposition:

```
p.diag.Inverse[p] - m // Simplify
{{0, 0, 0}, {0, 0, 0}, {0, 0, 0}}
```

## 73.7 Singular Values

### Commands:

1. Singular values:

- **SingularValueList[m]** (Mma 5.0) Nonzero singular values of a (possibly rectangular) numerical matrix with at least one entry that has a decimal point; the singular values are given in order of decreasing value (repeated singular values appear with their appropriate multiplicity).

## 2. Singular value decomposition:

- **SingularValueDecomposition[m]** (Mma 5.0) Singular value decomposition of a (possibly rectangular) numerical matrix with at least one entry that has a decimal point. For matrix  $M$ , the decomposition is  $M = UWV^*$  where  $U$  and  $V$  are orthonormal and  $W$  is diagonal with singular values as the diagonal elements (\* means conjugate transpose). Output is  $\{U, W, V\}$ .

## 3. An option:

- The default value **Automatic** of the option **Tolerance** (Mma 5.0) keeps only singular values larger than  $100 \times 10^{-p}$ , where  $p$  is **Precision[m]**. **Tolerance**  $\rightarrow$  **t** keeps only singular values that are at least **t** times the largest singular value. **Tolerance**  $\rightarrow$  **0** returns all singular values.

## 4. Largest singular values and generalized singular values:

- **SingularValueList[m, k]** (Mma 5.0) Calculate the **k** largest singular values.
- **SingularValueList[{m, a}]** (Mma 5.0) Calculate the generalized singular values of **m** with respect to **a**.

**Examples:**

1. Singular values. The singular values of a matrix  $M$  are the square roots of the eigenvalues of the matrix  $M^*M$ :

```
m = {{6, 2, 3}, {2, 7, 5}, {4, 2, 5}};
SingularValueList[m // N] {12.1048, 4.75064, 1.70418}
Sqrt[Eigenvalues[ConjugateTranspose[m].m]] // N
{12.1048, 4.75064, 1.70418}
```

Only nonzero singular values are returned by **SingularValueList**:

```
n = {{7, 7, 2, 7}, {2, 5, 0, 7}, {8, 7, 8, 3}, {5, 6, 4, 5}};
SingularValueList[n // N] {21.5225, 7.09914, 1.84001}
```

By giving **Tolerance** the value 0, we get all singular values:

```
SingularValueList[n // N, Tolerance  $\rightarrow$  0]
{21.5225, 7.09914, 1.84001, 5.46569  $\times$  10-17}
```

2. Singular value decomposition. Here is an example of this decomposition:

```
Map[MatrixForm, {u, w, v} = SingularValueDecomposition[m // N]]
{
  (
    (-0.516443  0.629389  -0.580652)
    (-0.672542  -0.717852  -0.179933)
    (-0.53007   0.297588   0.79402)
  ),
  (
    (12.1048  0.      0.)
    (0.      4.75064  0.)
    (0.      0.      1.70418)
  ),
  (
    (-0.542264  0.743264  -0.391801)
    (-0.561826  -0.667491  -0.488678)
    (-0.624741  -0.0448685  0.779542)
  )
}
```

The following verifies the decomposition:

```

m - u.w.ConjugateTranspose[v] // Chop
  {{0, 0, 0}, {0, 0, 0}, {0, 0, 0}}
u.ConjugateTranspose[u] // Chop
  {{1., 0, 0}, {0, 1., 0}, {0, 0, 1.}}
v.ConjugateTranspose[v] // Chop
  {{1., 0, 0}, {0, 1., 0}, {0, 0, 1.}}

```

### Applications:

1. (Condition numbers) Relative to a matrix norm  $\|M\|$ , the condition number of an invertible matrix  $M$  is  $\|M\|\|M^{-1}\|$ . (See Chapter 37 for more information about condition numbers.) A condition number is  $\geq 1$ ; a large condition number indicates sensitivity to round-off errors. The 2-norm condition number can be shown to be the maximum singular value divided by the minimum singular value:

```

cond[m] := With[{s = SingularValueList[m // N,
Tolerance -> 0]}, First[s]/Last[s]]

```

For example, consider the condition numbers of Hilbert matrices:

```

h[n] := Table[1/(i + j - 1), {i, n}, {j, n}]
Table[cond[h[i]], {i, 1, 6}]
{1., 19.2815, 524.057, 15513.7, 476607., 1.49511 × 107}

```

The condition numbers grow rapidly and they are large even for small Hilbert matrices. This indicates numerical difficulties associated with Hilbert matrices. Note that the **LAMM** package defines both **HilbertMatrix** and **MatrixConditionNumber**.

## 73.8 Decompositions

---

### Commands:

1. Decompositions into triangular matrices:
  - **LUdecomposition[m]** PLU decomposition of a square matrix. For matrix  $M$ , the decomposition is  $PM = LU$ , where  $L$  is unit lower triangular (with ones on the diagonal),  $U$  is upper triangular, and  $P$  is a permutation matrix. Output is  $\{K, p, c\}$ , where matrix  $K$  contains both  $L$  and  $U$ ,  $p$  is a permutation vector, that is, a list specifying rows used for pivoting, and  $c$  is the  $L^\infty$  condition number of  $M$  (however, for exact matrices with no decimal points,  $c$  is 1).
  - **CholeskyDecomposition[m]** (Mma 5.0) Cholesky decomposition of a Hermitian, positive definite matrix. For matrix  $M$ , the decomposition is  $M = U^*U$ , where  $U$  is upper triangular. Output is  $U$ .
2. Orthogonal decompositions:
  - **SingularValueDecomposition[m]** (Mma 5.0) Singular value decomposition of a (possibly rectangular) numerical matrix with at least one entry that has a decimal point. For matrix  $M$ , the decomposition is  $M = UVV^*$  where  $U$  and  $V$  are orthonormal and  $W$  is diagonal with singular values as the diagonal elements (\* means conjugate transpose). Output is  $\{U, W, V\}$ . See item 2 in Section 73.7.
  - **QRdecomposition[m]** QR decomposition of a numerical matrix. For matrix  $M$ , the decomposition is  $M = Q^*R$ , where  $Q$  is orthonormal and  $R$  is upper triangular. Output is  $\{Q, R\}$ .
3. Decompositions related to eigenvalue problems:
  - **JordanDecomposition[m]** Jordan decomposition of a square matrix. For matrix  $M$ , the decomposition is  $M = SJS^{-1}$ , where  $S$  is a similarity matrix and  $J$  is the Jordan canonical form of  $M$ . Output is  $\{S, J\}$ .

- **SchurDecomposition[m]** Schur decomposition of a square, numerical matrix with at least one entry that has a decimal point. For matrix  $M$ , the decomposition is  $M = QTQ^*$ , where  $Q$  is orthonormal and  $T$  is block upper triangular. Output is  $\{Q, T\}$ .
- **HessenbergDecomposition[m]** (Mma 5.1) Hessenberg decomposition of a square, numerical matrix with at least one entry that has a decimal point. For matrix  $M$ , the decomposition is  $M = PHP^*$ , where  $P$  is an orthonormal and  $H$  a Hessenberg matrix. Output is  $\{P, H\}$ .
- **PolarDecomposition[m]** Polar decomposition of a numerical matrix. For matrix  $M$ , the decomposition is  $M = US$ , where  $U$  is orthonormal and  $S$  is positive definite. Output is  $\{U, S\}$ . (In the **LAMM** package.)

### Examples:

1. Decompositions into triangular matrices. As an example, we consider the PLU decomposition:

```
m = {{2., 7, 5}, {6, 2, 3}, {4, 2, 5}};
Map[MatrixForm, {lu, perm, cond}] = LUdecomposition[m]
```

$$\left\{ \left( \begin{pmatrix} 6. & 0.333333 & 0.666667 \\ 2. & 6.333333 & 0.105263 \\ 3. & 4. & 2.57895 \end{pmatrix}, \begin{pmatrix} 2 \\ 1 \\ 3 \end{pmatrix}, 9.42857 \right) \right\}$$

The matrix **lu** contains both the  $L$  and the  $U$  matrix, **perm** is a permutation vector specifying rows used for pivoting, and **cond** is the  $L^\infty$  condition number of **m**. With a package we can extract the  $L$  and  $U$  matrices from the **lu** matrix:

```
<< LinearAlgebra`MatrixManipulation`
Map[MatrixForm, {l, u}] = LUMatrices[lu]
```

$$\left\{ \left( \begin{pmatrix} 1. & 0. & 0. \\ 0.333333 & 1. & 0. \\ 0.666667 & 0.105263 & 1. \end{pmatrix}, \begin{pmatrix} 6. & 2. & 3. \\ 0 & 6.333333 & 4. \\ 0 & 0 & 2.57895 \end{pmatrix} \right) \right\}$$

The following calculation verifies the PLU decomposition (see Section 73.5, the first command in item 7 of Commands):

```
m1 = m[[perm]] {{6, 2, 3}, {2., 7, 5}, {4, 2, 5}}
m1 - l.u {{0., 0., 0.}, {0., 0., 0.}, {0., 0., 0.}}
```

We can also verify the decomposition with the corresponding permutation matrix:

```
permMatr = IdentityMatrix[3][[perm]]
{{0, 1, 0}, {1, 0, 0}, {0, 0, 1}}
m2 = permMatr.m {{6., 2., 3.}, {2., 7., 5.}, {4., 2., 5.}}
m2 - l.u {{0., 0., 0.}, {0., 0., 0.}, {0., 0., 0.}}
```

Once the PLU decomposition of **m** is ready, we can solve a system of linear equations with coefficient matrix **m**. Define **b**, the constant vector, and use then **LUBackSubstitution**:

```
b = {2, 4, 1};
LUBackSubstitution[{lu, perm, cond}, b]
{0.826531, 0.530612, -0.673469}
```

However, the PLU decomposition and the back substitution are automatically done with **LinearSolve**:

```
LinearSolve[m, b] {0.826531, 0.530612, -0.673469}
```

## 73.9 Linear Systems

---

### Commands:

1. Solving equations written explicitly:
  - **lhs == rhs** An equation with left-hand side **lhs** and right-hand side **rhs** (after you have written the two equal signs `==`, *Mathematica* replaces them with a corresponding single symbol).
  - **eqns = {eqn<sub>1</sub>, eqn<sub>2</sub>, ...}** A system of equations with the name **eqns**.
  - **Solve[eqns]** Solve the list of equations **eqns** for the symbols therein.
  - **Solve[eqns, vars]** Solve the list of equations **eqns** for the variables in list **vars**.
  - **Reduce[eqns, vars]** Give a full analysis of the solution.
2. Solving equations defined by the coefficient matrix and the constant vector:
  - **LinearSolve[m, v]** Solve the linear system **m.vars == v**.
  - **Solve[m.vars == v]** Solve the linear system **m.vars == v**.
  - If it is possible that the system has more than one solution, it is better to use **Solve**, as **LinearSolve** only gives one solution (with no warning).
3. Conversion between the two forms of linear equations:
  - **eqns = Thread[m.vars == v]** Generate explicit equations from a coefficient matrix **m** and a constant vector **v** by using the list of variables **vars**.
  - **{m, v} = LinearEquationsToMatrices[eqns, vars]** Give the coefficient matrix **m** and the constant vector **v** of given linear equations **eqns** containing variables **vars** (in the **LAMM** package).
4. Solving several systems with the same coefficient matrix:
  - **f = LinearSolve[m]** (Mma 5.0) Give a function **f** for which **f[v]** solves the system **m.x == v**.
  - **LUBackSubstitution[lu, v]** Solve the system **m.x == v**; here **lu = LUDecomposition[m]**.
5. Using the inverse and pseudo-inverse:
  - **Inverse[m].v** Give the solution of the equations **m.x == v** (this method is not recommended).
  - **PseudoInverse[m].v** Give the least-squares solution of the equations **m.x == v**.
6. Special methods:
  - **RowReduce[a]** Do Gauss–Jordan elimination to the augmented matrix **a** to produce the reduced row echelon form, where the last column is the solution of the system.
  - **TridiagonalSolve[sub, main, super, rhs]** Solve a tridiagonal system (in the **LinearAlgebra`Tridiagonal`** package).
7. Eliminating variables:
  - **Solve[eqns, vars, elims]** Solve **eqns** for **vars**, eliminating **elims**.
  - **Eliminate[eqns, elims]** Eliminate **elims** from **eqns**.

### Examples:

1. Solving equations written explicitly. If the system does not have any symbols other than the variables for which the system has to be solved, we need not declare the variables in **Solve**:

```
sol = Solve[{2 x + 5 y + z == 2, 3 x + 4 y + 3 z == 2,
6 x + y + 2 z == 5}]
{{x -> 47/49, y -> 5/49, z -> -3/7}}
sol // N {{x -> 0.959184, y -> 0.102041, z -> -0.428571}}
```

Here is an example where we declare the variables:

```
eqns = {2 x + 5 y + z == 2, 3 x + 4 y + 3 z == 2,
6 x + y + 2 z == 5};
vars = {x, y, z};
sol = Solve[eqns, vars] {{x -> 47/49, y -> 5/49, z -> -3/7}}
```

**Solve** gives the solution in the form of transformation rules. If we want a list of the values of the variables, we can write

```
vars /. sol[[1]] {47/49, 5/49, -3/7}
```

To check the solution, write

```
eqns /. sol {True, True, True}
```

(Note that for an inexact solution the test may yield **False** for some equations due to round-off errors.) If a solution does not exist, we get an empty list:

```
Solve[{x + 2 y == 2, 2 x + 4 y == 1}] {}
```

If an infinite number of solutions exist, we get all of them (with a message):

```
Solve[{x + 2 y == 2, 2 x + 4 y == 4}] {{x -> 2 - 2 y}}
Solve::svars : Equations may not give solutions for all solve
variables. More...
```

This means that **x** has the value  $2 - 2y$ , while **y** can be arbitrary. The message tells that the equations may not determine the values of all of the variables (this is, indeed, the case in our example because the solution does not give the value of **y**).

The system may contain symbols:

```
eqns2 = {2 x + 5 y == 3, 3 x + d y == 2};
Solve[eqns2, {x, y}] {{x -> -10 - 3 d / -15 + 2 d, y -> -5 / -15 + 2 d}}
```

Note that this is a generic solution that is valid for most values of the parameter **d**. To get a full analysis of the equations, use **Reduce**. The result is a logical statement where, for example, **&&** means logical AND and **||** means logical OR:

```
Reduce[eqns2, {x, y}]
-15 + 2 d != 0 && x == -10 + 3 d / -15 + 2 d && y == 1/5 (3 - 2 x)
```

- Solving equations defined by the coefficient matrix and the constant vector. We continue with the same system that we considered in Example 1:

```
m = {{2, 5, 1}, {3, 4, 3}, {6, 1, 2}}; v = {2, 2, 5};
sol = LinearSolve[m, v] {47/49, 5/49, -3/7}
sol // N {0.959184, 0.102041, -0.428571}
```

We can check the solution:

```
m.sol - v {0, 0, 0}
```

We can also use **Solve** if we form an equation with variables:

```
Solve[m.{x, y, z} == v] {{x -> 47/49, y -> 5/49, z -> -3/7}}
```

If a solution does not exist, **LinearSolve** gives a message:

```
LinearSolve[{{1, 2}, {2, 4}}, {2, 1}]
```

LinearSolve::nosol : Linear equation encountered which has no solution. More...

LinearSolve[{{1, 2}, {2, 4}}, {2, 1}]

If an infinite number of solutions exist, we are given one of them (with no warning):

**LinearSolve[{{1, 2}, {2, 4}}, {2, 4}] {2, 0}**

The system may contain symbols:

**LinearSolve[{{2, 5}, {3, d}}, {3, 2}]**  
 $\left\{ \frac{-10 + 3d}{-15 + 2d}, -\frac{5}{-15 + 2d} \right\}$

3. Conversion between the two forms of linear equations. Consider again the familiar system:

**eqns = {2 x + 5 y + z == 2, 3 x + 4 y + 3 z == 2,**  
**6 x + y + 2 z == 5};**

The corresponding coefficient matrix and constant vector are

**<< LinearAlgebra`MatrixManipulation`**  
**{m, v} = LinearEquationsToMatrices[eqns, {x, y, z}]**  
**{{{2, 5, 1}, {3, 4, 3}, {6, 1, 2}}, {2, 2, 5}}**

If we know **m** and **v**, we can obtain explicit equations as follows (here we use indexed variables):

**eqns = Thread[m.Table[x<sub>i</sub>, {i, 3}] == v]**  
**{2 x<sub>1</sub> + 5 x<sub>2</sub> + x<sub>3</sub> == 2, 3 x<sub>1</sub> + 4 x<sub>2</sub> + 3 x<sub>3</sub> == 2,**  
**6 x<sub>1</sub> + x<sub>2</sub> + 2 x<sub>3</sub> == 5}**

4. Solving several systems with the same coefficient matrix. Suppose that we have one coefficient matrix **m**, but we would like to solve three systems by using the constant vectors **v1**, **v2**, and **v3**:

**m = {{2, 5, 1}, {3, 4, 3}, {6, 1, 2}};**  
**v1 = {2, 2, 5}; v2 = {1, 4, 3}; v3 = {4, 2, 6};**

First, we create a function with **LinearSolve**:

**f = LinearSolve[m] LinearSolveFunction[{3, 3}, "<>"]**

Then, we give the three constant vectors as arguments:

**{f[v1], f[v2], f[v3]}**  
 $\left\{ \left\{ \frac{47}{49}, \frac{5}{49}, -\frac{3}{7} \right\}, \left\{ \frac{2}{49}, -\frac{5}{49}, \frac{10}{7} \right\}, \left\{ \frac{68}{49}, \frac{26}{49}, -\frac{10}{7} \right\} \right\}$

In this way we solve three systems, but the LU decomposition is done only once, thus saving computing time. We could also use **LUdecomposition**:

**lu = LUdecomposition[m];**  
**Map[LUBackSubstitution[lu, #] &, {v1, v2, v3}]**  
 $\left\{ \left\{ \frac{47}{49}, \frac{5}{49}, -\frac{3}{7} \right\}, \left\{ \frac{2}{49}, -\frac{5}{49}, \frac{10}{7} \right\}, \left\{ \frac{68}{49}, \frac{26}{49}, -\frac{10}{7} \right\} \right\}$

5. Using the inverse and pseudo-inverse. The inverse of the coefficient matrix can, in principle, be used to solve a linear system:

**m = {{2, 5, 1}, {3, 4, 3}, {6, 1, 2}}; v = {2, 2, 5};**  
**Inverse[m].v**  $\left\{ \frac{47}{49}, \frac{5}{49}, -\frac{3}{7} \right\}$

However, this method should not be used, since inverting a matrix is a more demanding task than solving a linear system with Gaussian elimination. If the coefficient matrix is singular or nonsquare, we can, however, use a pseudo-inverse to calculate a least-squares solution. (See Sections 5.7, 5.8, and 5.9 for definitions and more information on the pseudo-inverse and least squares solution.) If the system is  $Mx = v$ , the least-squares solution minimizes the norm  $\|Mx - v\|_2$ . As an example, consider a system with coefficient matrix **p** and constant vector **c**:

```
p = {{7, 4, 8, 0}, {7, 4, 8, 0}, {1, 8, 3, 3}}; c = {4, 1, 2};
```

The equations do not have any solutions in the usual sense, but a least-squares solution can be calculated:

```
PseudoInverse[p].c { 671/6738, 565/3369, 1907/13476, 201/4492 }
```

6. Special methods. **RowReduce** can be used to solve a system of equations. First we form the augmented matrix by appending the constant vector into the rows of the coefficient matrix:

```
m = {{2, 5, 1}, {3, 4, 3}, {6, 1, 2}}; v = {2, 2, 5};
a = Transpose[Append[Transpose[m], v]]
{{2, 5, 1, 2}, {3, 4, 3, 2}, {6, 1, 2, 5}}
```

Then, we do Gauss–Jordan elimination to produce the reduced row echelon form; the solution is the last column:

```
g = RowReduce[a]
{{ {1, 0, 0, 47/49}, {0, 1, 0, 5/49}, {0, 0, 1, -3/7} }}
sol = g[All, 4] { 47/49, 5/49, -3/7 }
```

7. Eliminating variables. The following equations contain the parameter **d**, which we would like to eliminate:

```
eqns = {x + y - z == d, x - 2 y + z == -d,
  -x + y + z == 2 d}; vars = {x, y, z};
Solve[eqns, vars, {d}] {{ {x → 3/5 z, y → 6/5 z } }}
Solve::svars : Equations may not give solutions for all solve
variables. More...
```

Alternatively, we can use **Eliminate**. The result is then expressed as a logical expression:

```
Eliminate[eqns, {d}] 5 x == 3 z && 5 y == 6 z
```

### Applications:

1. (Stationary Distribution of a Markov chain) The stationary distribution  $\pi$  (a row vector) of a Markov chain with transition probability matrix  $P$  is obtained by using the equations  $\pi P = \pi$  and  $\sum \pi_i = 1$ . One of the equations of the linear system  $\pi P = \pi$  can be dropped. We continue Application 1 of Section 73.4:

```
p = {{0.834, 0.166}, {0.398, 0.602}}; st = { $\pi_1$ ,  $\pi_2$ };
eqns = Append[Most[Thread[st.p == st]], Total[st] == 1]
{0.834  $\pi_1$  + 0.398  $\pi_2$  ==  $\pi_1$ ,  $\pi_1$  +  $\pi_2$  == 1}
Solve[eqns] {{ $\pi_1$  → 0.705674,  $\pi_2$  → 0.294326}}
```

So, in the long run, about 71% of days are wet and 29% dry.

## 73.10 Linear Programming

---

### Commands:

- Solving linear optimization problems written explicitly:
  - Minimize**[{**obj**, **cons**}, **vars**] (Mma 5.0) Give the global minimum of **obj** subject to constraints **cons** with respect to variables **vars**.
  - Maximize**[{**obj**, **cons**}, **vars**] (Mma 5.0) Give the global maximum of **obj** subject to constraints **cons** with respect to variables **vars**.

2. Solving linear optimization problems defined by vectors and matrices:

- **LinearProgramming**[**c**, **a**, **b**] Minimize **c**.**x** subject to **a**.**x** ≥ **b** and **x** ≥ 0.
- **LinearProgramming**[**c**, **a**, {{**b**<sub>1</sub>, **s**<sub>1</sub>}, {**b**<sub>2</sub>, **s**<sub>2</sub>}, ...}] The *i*th constraint is **a**<sub>*i*</sub>.**x** ≤ **b**<sub>*i*</sub>, **a**<sub>*i*</sub>.**x** == **b**<sub>*i*</sub>, or **a**<sub>*i*</sub>.**x** ≥ **b**<sub>*i*</sub> according to whether **s**<sub>*i*</sub> is < 0, = 0, or > 0.

### Examples:

1. Solving linear optimization problems written explicitly.

```
obj = 2 x + 3 y;
cons = {x + y ≥ 4, x + 3 y ≥ 5, x ≥ 0, y ≥ 0};
vars = {x, y};
Minimize[{obj, cons}, vars] {17/2, {x → 7/2, y → 1/2}}
```

Here the minimum value of the objective function is 17/2. Next, we solve an integer problem. The constraint **vars** ∈ **Integers** or **Element**[**vars**, **Integers**] restricts the variables in **vars** to be integer-valued.

```
Minimize[{obj, cons, vars ∈ Integers}, vars]
{9, {x → 3, y → 1}}
```

2. Solving linear optimization problems defined by vectors and matrices. We solve the first problem in Example 1:

```
c = {2, 3}; a = {{1, 1}, {1, 3}}; b = {4, 5};
sol = LinearProgramming[c, a, b] {7/2, 1/2}
c.sol 17/2
```

### Applications:

1. (A transportation problem) (See Chapter 50 for definitions and more information about linear programming.) Consider the following transportation problem (cf. [Rus04, pp. 524–526]). Supplies of plants 1 and 2, demands of cities 1, 2, and 3, and costs between the plants and the cities are as follows:

```
supply = {40, 60}; demand = {35, 40, 25};
costs = {{4, 9, 6}, {5, 3, 7}};
```

For example, to transport one unit from plant 1 to city 3 costs \$6. The problem is to minimize the total cost of transportation. Let  $x_{i,j}$  be the amount transported from plant *i* to city *j*:

```
vars = Table[xi,j, {i, 2}, {j, 3}]
{{x1,1, x1,2, x1,3}, {x2,1, x2,2, x2,3}}
```

The objective function is

```
obj = Flatten[costs].Flatten[vars]
4 x1,1 + 9 x1,2 + 6 x1,3 + 5 x2,1 + 3 x2,2 + 7 x2,3
```

The supply, demand, and nonnegativity constraints are as follows:

```
sup = Thread[Map[Total, vars] ≤ supply]
{x1,1 + x1,2 + x1,3 ≤ 40, x2,1 + x2,2 + x2,3 ≤ 60}
dem = Thread[Total[vars] ≥ demand]
{x1,1 + x2,1 ≥ 35, x1,2 + x2,2 ≥ 40, x1,3 + x2,3 ≥ 25}
non = Thread[Flatten[vars] ≥ 0]
{x1,1 ≥ 0, x1,2 ≥ 0, x1,3 ≥ 0, x2,1 ≥ 0, x2,2 ≥ 0, x2,3 ≥ 0}
```

Then, we solve the problem:

```
sol = Minimize[{obj, sup, dem, non}, Flatten[vars]]
{430, {x1,1 → 15, x1,2 → 0, x1,3 → 25, x2,1 → 20,
x2,2 → 40, x2,3 → 0}}
```

## Appendix

---

### Introduction to Mathematica

1. Executing commands:
  - To do a calculation with *Mathematica*, write the command into the notebook document (possibly with the help of a palette) and then execute it by pressing the Enter key in the numeric keypad or by holding down the Shift key and then pressing the Return key.
2. Arithmetic:
  - For addition, subtraction, division, and power, use **+**, **-**, **/**, and **^**.
  - For multiplication, usually the space key is used, but the **\*** key can also be used. For example, **a b** or **a\*b** is a product but **ab** is a single variable.
3. Useful techniques:
  - To give a name for a result, use **=**; for example, **a = 17 ^ 2**.
  - To clear the value of a name, use **=.**; for example, **a =.**
  - To refer to the last result, use **%**; for example, **% + 18 ^ 2**.
  - If an input is ended with a semicolon (**a = 17 ^ 2;**), the input is processed (after pressing, say, Enter), but the result is not shown in the notebook.
  - Input and output labels of the form **In[n]** and **Out[n]** can be turned off with the menu command **Kernel ▸ Show In/Out Names**.
4. Important conventions:
  - All built-in names start with a capital letter.
  - The argument of functions and commands are given within square brackets **[ ]**.
  - Parentheses **( )** are only used for grouping terms in expressions.
5. Constants and mathematical functions:
  - **Pi** (3.141...), **E** (2.718...), **I** ( $\sqrt{-1}$ ), **Infinity**.
  - **Sqrt[z]** or **z^(1/2)**, **Exp[z]** or **E^z**, **Log[z]** (the natural logarithm), **Log[b, z]** (a logarithm to base **b**), **Abs[z]**, **Sin[z]**, **ArcSin[z]**, **n!**, **Binomial[n, m]**.
6. Lists:
  - A list is formed with curly braces **{ }**; an example: **v = {4, 7, 5}**. A list is simply an ordered collection of elements. Lists can be nested, for example **m = {{4, 7, 5}, {2, 6, 3}}**.
  - Parts of lists (and of more general expressions) can be picked up with double square brackets **[ [ ] ]**. For example, **m[[2]]** gives **{2, 6, 3}** and **m[[2, 1]]** gives **2**.
7. Useful commands:
  - A decimal value can be obtained using **N[expr]**.
  - A decimal value to **n** digit precision can be obtained using **N[expr, n]**.
  - Numbers near to zero can be set to 0 with **Chop[expr]**.
  - An expression can be simplified with **Simplify[expr]**.
  - An expression can be expanded out with **Expand[expr]**.
  - All commands with a single argument can also be applied with **//**; e.g., **expr // N** means **N[expr]**.

## 8. Replacements:

- The syntax `expr /. x -> a` is used to replace `x` in `expr` with `a`. Here, `x -> a` is a transformation rule and `/.` is the replacement operator. The arrow `->` can be written by typing the two characters `->` with no space in between; *Mathematica* transforms `->` to a genuine arrow.

## 9. Mapping and threading:

- With `Map` we can map the elements of a list with a function, that is, with `Map` we can calculate the value of a function at points given in a list. For example, `Map[f[#] &, {a, b, c}]` gives `{f[a], f[b], f[c]}` (a function like `f[#] &` is called a pure function). If `f` is a built-in function with one argument, the name of the function suffices. For example, if we want to calculate the 2-norms of the rows of a matrix `m`, we can write `Map[Norm[#] &, m]`, but also simply `Map[Norm, m]`.
- With `Thread` we can apply an operation to corresponding parts of two lists. For example, `Thread[{x + y, x - y} == {2, 5}]` gives `{x + y == 2, x - y == 5}`.

## 10. Functions and programs:

- The syntax `f[x_] := expr` is used to define functions. For example, `f[x_, y_] := x + Sin[y]`.
- In programs, we often use `Module` to define local variables or `With` to define local constants. The syntax is `f[x_] := Module[{local variables}, body]` (similarly for `With`).

## 11. Loading packages:

- A package is loaded with `<<`. For example, `<<LinearAlgebra`MatrixManipulation``.

## 12. Using saved notebooks:

- When you open a saved notebook, *Mathematica* will not automatically process the inputs anew. So, if the notebook contains the definition `a = 17^2` and you also want to use this definition in the new *Mathematica* session, you have to process the input anew; simply put the cursor anywhere in the input and press Enter or Shift-Return.

## Getting Help

## 1. Books, documents, and internet addresses:

- [Wol03]: A complete description of *Mathematica* 5; for linear algebra, see Sections 1.5.7 (Solving Equations), 1.8.3 (Vectors and Matrices), and 3.7 (Linear Algebra).
- [WR99]: A description of the packages of *Mathematica* 4.
- [WR03]: Linear algebra with *Mathematica* 5; a long Help Browser document.
- [Sza00]: Linear algebra with *Mathematica* 3.
- [Rus04]: A general introduction to *Mathematica* 5.
- <http://library.wolfram.com/infocenter/BySubject/Mathematics/Algebra/LinearAlgebra/>: about 100 documents relating to linear algebra with *Mathematica*.

## 2. Using the Help Browser:

- To open the Help Browser, select the menu command Help ▸ Help Browser.
- In the Help Browser, write a command into the input field and press the Go-button, or choose from the lists of topics.

- In a notebook, write a command like **Eigenvalues** and then press the F1 key (Windows) or Help key (Macintosh) to read the corresponding Help Browser material.
  - In a notebook, execute a command like **?Eigenvalues** to get a short description of a command and a link to the more complete information in the Help Browser.
3. Useful material in the Help Browser:
- The *Mathematica* Book ▷ A Practical Introduction to *Mathematica* ▷ Symbolic Mathematics ▷ Solving Equations: Section 1.5.7 of [Wol03].
  - The *Mathematica* Book ▷ A Practical Introduction to *Mathematica* ▷ Lists ▷ Vectors and Matrices: Section 1.8.3 of [Wol03].
  - The *Mathematica* Book ▷ Advanced Mathematics in *Mathematica* ▷ Linear Algebra: Section 3.7 of [Wol03].
  - Built-in Functions ▷ Advanced Documentation ▷ Linear Algebra: [WR03].
  - Built-in Functions ▷ Lists and Matrices ▷ Vector Operations: A list of commands related to vectors.
  - Built-in Functions ▷ Lists and Matrices ▷ Matrix Operations: A list of commands related to matrices.
  - Add-ons and Links ▷ Standard Packages ▷ Linear Algebra: Descriptions of linear algebra packages.

### For Users of Earlier Versions

Some commands presented in this chapter are new in *Mathematica* 5.0 or 5.1. Below we have collected information about how to do similar calculations with earlier versions (mainly with 4.2).

- **ArrayPlot[m]**: replace with **ListDensityPlot[Reverse[Abs[m]], ColorFunction → (GrayLevel[1 - #] &), AspectRatio → Automatic, Mesh → False, FrameTicks → False]**.
- **CholeskyDecomposition**: replace with a command of the same name from the **LinearAlgebra`Cholesky`** package.
- **ConjugateTranspose[m]**: replace with **Conjugate[Transpose[m]]**.
- **HessenbergDecomposition**: replace with **Developer`HessenbergDecomposition**.
- **MatrixRank[m]**: replace with **Dimensions[m][[2]] - Length[NullSpace[m]]**.
- **Maximize[{f, cons}, vars]**: replace with **ConstrainedMax[f, cons, vars]**.
- **Minimize[{f, cons}, vars]**: replace with **ConstrainedMin[f, cons, vars]**.
- **Most[v]**: replace with **Drop[v, -1]**.
- **Norm**: Replace with **VectorNorm** or **MatrixNorm** from the **LAMM** package (note: the default is the  $\infty$ -norm).
- **SingularValueDecomposition**: replace with **SingularValues**.
- **SingularValueList[m]**: replace with **SingularValues[m][[2]]**.
- **Total**: Replace with **Apply**. For vectors use **Apply[Plus, v]**. For column sums of matrices, use **Apply[Plus, m]**; for row sums, use **Apply[Plus, Transpose[m]]**; and for the sum of all elements, use **Apply[Plus, Flatten[m]]**.

### 74.1 Introduction

---

A significant amount of execution time in complicated linear algebraic programs is known to be spent in a few low-level operations. Consequently, reducing the overall execution time of an application program leads to the problem of optimizing these low-level operations. Such low-level optimization are highly machine-dependent and are a matter for specialists. A separation has, therefore, been made by the computational linear algebra community: On the one hand highly efficient, machine-dependent building blocks of linear algebra, the BLAS, (basic linear algebra subprograms) are provided on a given computational platform. On the other hand, linear algebra programs attempt to make the most use of those computational blocks in order to have as good performance as possible across a wide range of platforms.

The first major concerted effort to achieve agreement on the specification of a set of linear algebra kernels resulted in the Level-1 BLAS [LHK79]. The Level-1 BLAS specification and implementation are the result of a collaborative project in 1973 through 1977. The Level-1 BLAS were extensively and successfully exploited by LINPACK [DBM79], a software package for the solution of dense and banded linear equations and linear least squares problems.

With the advent of vector machines, hierarchical memory machines, and shared memory parallel machines, specifications for the Level-2 and -3 BLAS [DDD90a], [DDD90b], [DDH88a], [DDH88b], concerned with matrix–vector and matrix–matrix operations, respectively, were drawn up in 1984 through 1986 and 1987 to 1988. These specifications made it possible to construct new software to utilize the memory hierarchy of modern computers more effectively. In particular, the Level-3 BLAS allowed the construction of software based upon block-partitioned algorithms, typified by the linear algebra software package LAPACK (see Chapter 75).

In this chapter, we present information about the BLAS. We begin with basic definition, then describe the calling sequences, report a number of facts, and finally conclude with a few examples.

#### Definitions:

**Two-dimensional column-major format.** A two-dimensional array is said to be in column-major format when its entries are stored by column. This is the way the Fortran language stores two-dimensional

arrays. For example, the declaration `double precision A(2,2)` stores the entries of the 2-by-2 two-dimensional array in the one-dimensional order: `A(1,1), A(2,1), A(1,2), A(2,2)`.

**Row-major format.** Storage of the entries by row. This is the way C stores two-dimensional arrays.

**Packed format.** The packed format is relevant for symmetric, Hermitian, or triangular matrices. Half of the matrix (either the upper part or the lower part depending on an `UPLO` parameter) is stored in a one-dimensional array. For example, if `UPLO='L'`, the 3-by-3 symmetric matrix `A` is stored as `A(1,1), A(2,1), A(3,1), A(2,2), A(3,2), A(3,3)`.

**Leading dimension.** In column-major format, the leading dimension is the first dimension of a two-dimensional array (as opposed to the dimension of the matrix stored in that array). The leading dimension of an array is necessary to access its elements. For example, if `LDA` is the leading dimension of `A`, and `A` is stored in the two-dimensional column-major format, `Ai,j` is stored in position  $i + (j - 1) * LDA$ . The leading dimension of an  $m$ -by- $n$  matrix is often  $m$ . It enables convenient abstraction to access submatrices (see examples). An  $m$ -by- $n$  matrix should have `LDA`  $\geq m$ .

**Increment.** The increment of a vector is the number of storage elements from one element to the next. If the increment of a vector is 1, this means that the vector is stored contiguously in memory; an increment of 2 corresponds to using every other array element. The increment is useful to manipulate rows of a matrix stored in column-major format (see Example 3).

**BLAS vector description.** A vector description in BLAS is defined by three quantities — a vector length, an array or a starting element within an array, and the increment. This gives  $(n, X, 1)$  for a vector of size  $n$  starting at index  $X$  with increment of 1.

**BLAS description of a general matrix.** A general matrix is described in BLAS by four quantities: a `TRANS` label ('N', 'T', or 'H'), its dimensions  $m$  and  $n$ , an array or a starting element within an array, and a leading dimension. This gives  $(TRANS, M, N, A, LDA)$  if one wants to operate on the `TRANS` of an  $M$ -by- $N$  matrix starting in `A(1,1)` and stored in an array of leading dimension `LDA`.

**Prefixes** The first letter of the name of a BLAS routine indicates the Fortran type on which it operates.

S - REAL	C - COMPLEX
D - DOUBLE PRECISION	Z - COMPLEX*16

### Prefixes for Level-2 and Level-3 BLAS

Matrix types:

GE - General	GB - General Band	
SY - SYmmetric	SB - Sym. Band	SP - Sym. Packed
HE - HErmitian	HB - Herm. Band	HP - Herm. Packed
TR - TRIangular	TB - Triang. Band	TP - Triang. Packed

### Level-2 and Level-3 BLAS Options

<code>TRANS</code>	= 'No transpose', 'Transpose', 'Conjugate transpose'
<code>UPLO</code>	= 'Upper triangular', 'Lower triangular'
<code>DIAG</code>	= 'Non-unit triangular', 'Unit triangular'
<code>SIDE</code>	= 'Left', 'Right' (on the right)

Calls:

1. Below is the calling sequence for the `GEMV` matrix-vector multiply subroutine. The `GEMV` routine performs the mathematical operation

$$y \leftarrow \alpha Ax + \beta y, \quad \text{or} \quad y \leftarrow \alpha A^T x + \beta y.$$

For double precision, the calling sequence looks like

```
SUBROUTINE DGEMV ( TRANS, M, N, ALPHA, A, LDA, X, INCX,
$                BETA, Y, INCY )
```

The types of the variables are as follows:

```
DOUBLE PRECISION  ALPHA, BETA
INTEGER           INCX, INCY, LDA, M, N
CHARACTER*1      TRANS
DOUBLE PRECISION  A( LDA, * ), X( * ), Y( * )
```

The meaning of the variables is as follows:

TRANS : Specifies the operation to be performed as

TRANS= 'N'  $y \leftarrow \alpha Ax + \beta y$ ,

TRANS= 'T'  $y \leftarrow \alpha A^T x + \beta y$ .

M : Specifies the number of rows of the matrix A.

N : Specifies the number of columns of the matrix A.

ALPHA: Specifies the scalar  $\alpha$ .

A : Points to the first entry of the two-dimensional array that stores the elements of A in column major format.

LDA : Specifies the leading dimension of A.

X : Points to the incremented array that contains the vector x.

INCX : Specifies the increment for the elements of X.

BETA : Specifies the scalar  $\beta$ .

Y : Points to the incremented array that contains the vector y.

INCY : Specifies the increment for the elements of Y.

All variables are left unchanged after completion of the routines, except Y.

- The following table is the quick reference to the BLAS.

### Facts:

- The BLAS represent fairly simple linear algebra kernels that are easily coded in a few lines. One could also download reference source codes and compile them (<http://www.netlib.org/blas>). However, this strategy is unlikely to give good performance, no matter the level of sophistication of the compiler. The recommended way to obtain an efficient BLAS is to use vendor BLAS libraries, or to install the ATLAS [WPD01] package. Figure 74.1 illustrates the fact that ATLAS BLAS clearly outperform the reference implementation for the matrix–matrix multiply by a factor of five on a modern architecture.
- To a great extent, the user community has embraced the BLAS, not only for performance reasons, but also because developing software around a core of common routines like the BLAS is good software engineering practice. Highly efficient, machine-specific implementations of the BLAS are available for most modern high-performance computers. To obtain an up-to-date list of available optimized BLAS, see the BLAS FAQ at <http://www.netlib.org/blas>.
- Level-1 BLAS operates on  $\mathcal{O}(n)$  data and performs  $\mathcal{O}(n)$  operations. Level-2 BLAS operates on  $\mathcal{O}(n^2)$  data and performs  $\mathcal{O}(n^2)$  operations. Level-3 BLAS operates on  $\mathcal{O}(n^2)$  data and performs  $\mathcal{O}(n^3)$  operations. Therefore, the ratio operation/data is  $\mathcal{O}(1)$  for Level-1 BLAS and Level-2 BLAS, but  $\mathcal{O}(n)$  for Level-3 BLAS. On modern architecture, where memory access is particularly slow compared to computation time, Level-3 BLAS exploit this  $\mathcal{O}(n)$  ratio to mask the memory access bottleneck (latency and bandwidth). Figure 74.1 illustrates the fact that Level-3 BLAS on a modern

**FIGURE 74.1** Performance in GFlops of four BLAS routines for two different BLAS libraries on an Intel Xeon CPU running at 3.20 GHz. The first BLAS library represents an optimized BLAS library (here, ATLAS v3.7.8), its four performance curves are given with a solid line on the graph. The second library represents straightforward implementation (here reference BLAS from netlib); its four performance curves are given with a dotted line on the graph. This graph illustrates two facts: An optimized Level-3 BLAS is roughly five times faster than Level-1 or Level-2 BLAS and it is also roughly five times faster than a reference Level-3 BLAS implementation. To give an idea of the actual time, multiplying two 6000-by-6000 matrices on this machine will take about 2 minutes using the ATLAS BLAS while it will take about 10 minutes using the reference BLAS implementation.

architecture performs 5 times more floating-point operations per second than a Level-2 or Level-1 BLAS routine. Most of the linear algebra libraries try to make as much as possible use of Level-3 BLAS.

4. Most of shared memory computers have a multithreaded BLAS library. By programming a sequential code and linking with the multithreaded BLAS library, the application will use all the computing units of the shared memory system without any explicit parallelism in the user application code.
5. Although here we present only calling sequences from Fortran, it is possible to call the BLAS from C. The major problem for C users is the Fortran interface used by the BLAS. The data layout (the BLAS interface assumes column-major format) and the passage of parameters by reference (as opposed to values) has to be done carefully. See Example 2 for an illustration. Nowadays most BLAS distributions provide a C-interface to the BLAS. This solves these two issues and, thus, we highly recommend its use.
6. The Level-1, Level-2, and Level-3 BLAS are now extended by a new standard with more functionality and better software standard; see [BDD02], [Don02]. For example, the C-interface to the BLAS (see Fact 5) is included in this new BLAS.

### Examples:

In all of these examples,  $A$  is an  $m$ -by- $n$  matrix and it is stored in an  $M$ -by- $N$  array starting at position  $A$ ,  $B$  is an  $n$ -by- $n$  matrix and it is stored in an  $N$ -by- $N$  array starting at position  $B$ ,  $C$  is an  $m$ -by- $m$  matrix and it is stored in an  $M$ -by- $M$  array starting at position  $C$ ,  $X$  is a vector of size  $n$  and it is stored in an  $N$  array starting at position  $X$ , and  $Y$  is a vector of size  $m$  and it is stored in an  $M$  array starting at position  $Y$ . All the two-dimensional arrays are in column-major format, all the one-dimensional arrays have increment one. We assume that  $m$  and  $n$  are both greater than 11 in Example 3.

1. To perform the operation  $y \leftarrow Ax$  the BLAS calling sequence is

```
CALL DGEMV ( 'N', M, N, 1.0D0, A, M, X, 1, 0.0D0, Y, 1 )
```

2. To perform the operation  $x \leftarrow \alpha A^T y + \beta x$  the BLAS calling sequence is

```
CALL DGEMV ( 'T', M, N, ALPHA, A, M, Y, 1, BETA, X, 1 )
```

From C, this would give

```
IONE = 1;
dgemv ( "T", &M, &N, &ALPHA, A, &M, Y, &IONE, &BETA, X, &IONE );
```

3. To perform the operation

$$y(2:10) \leftarrow 2A(3:11,4:11) * B(4,3:10)^T - 3y(2:10);$$

the BLAS calling sequence is

```
CALL DGEMV ( 'N', 9, 8, 2.0D0, A(3,4), M, B(4,3), N, -3.0D0,
Y(2), 1 )
```

(Note the use of LDA to operate on the submatrix of A and the use of INCX to operate on a row of B.)

4. LAPACK (see Chapter 75) is a library based on the BLAS. Opening its Fortran files enables one to gain a good understanding of how to use BLAS routines. For example, a good way to start is to have a look at `dgetrf.f`, which performs a right-looking LU factorization by making calls to DTRSM and DGEMM.

### 75.1 Introduction

---

LAPACK (linear algebra package) is an open source library of programs for solving the most commonly occurring numerical linear algebra problems [LUG99]. Original codes of LAPACK are written in Fortran 77. Complete documentation as well as source codes are available online at the Netlib repository [LAP]. LAPACK provides driver routines for solving complete problems such as linear equations, linear least squares problems, eigenvalue problems, and singular value problems. Each driver routine calls a sequence of computational routines, each of which performs a distinct computational task. In addition, LAPACK provides comprehensive error bounds for most computed quantities. LAPACK is designed to be portable for sequential and shared memory machines with deep memory hierarchies, in which most performance issues could be reduced to providing optimized versions of the Basic Linear Algebra Subroutines (BLAS). (See Chapter 74).

There have been a number of extensions of LAPACK. LAPACK95 is a Fortran 95 interface to the Fortran 77 LAPACK [LAP95]. CLAPACK and JLAPACK libraries are built using the Fortran to C (f2c) and Fortran to Java (f2j) conversion utilities, respectively [CLA], [JLA]. LAPACK++ is implemented in C++ and includes a subset of the features in LAPACK with emphasis on solving linear systems with nonsymmetric matrices, symmetric positive definite systems, and linear least squares systems [LA+]. ScaLAPACK is a portable implementation of some of the core routines in LAPACK for parallel distributed computing [Sca]. ScaLAPACK is designed for distributed memory machines with very powerful homogeneous sequential processors and with homogeneous network interconnections.

The purpose of this chapter is to acquaint the reader with 10 essential numerical linear algebra problems and LAPACK's way of solving those problems. The reader may find it helpful to consult Chapter 74, where some of the terms used here are defined. The following table summarizes these problems and sections that are treated in version 3.0 of LAPACK.

Type of Problem	Acronyms	Section
Linear system of equations	SV	75.2
Linear least squares problems	LLS	75.3
Linear equality-constrained least squares problem	LSE	75.4
General linear model problem	GLM	75.5
Symmetric eigenproblems	SEP	75.6
Nonsymmetric eigenproblems	NEP	75.7
Singular value decomposition	SVD	75.8
Generalized symmetric definite eigenproblems	GSEP	75.9
Generalized nonsymmetric eigenproblems	GNEP	75.10
Generalized (or quotient) singular value decomposition	GSVD (QSVD)	75.11

Sections have been subdivided into the following headings: (1) Definition: defines the problem, (2) Background: discusses the background of the problem and references to the related sections in this handbook, (3) Driver Routines: describes different types of driver routines available that solve the same problem, (4) Example: specifies the calling sequence for a driver routine that solves the problem followed by numerical examples.

All LAPACK routines are available in four data types, as indicated by the initial letter “x” of each subroutine name: x = “S” means real single precision, x = “D”, real double precision, x = “C”, complex single precision, and x = “Z”, complex\*16 or double complex precision. In single precision (and complex single precision), the computations are performed with a unit roundoff of  $5.96 \times 10^{-8}$ . In double precision (and complex double precision) the computations are performed with a unit roundoff of  $1.11 \times 10^{-16}$ .

All matrices are assumed to be stored in column-major format. The software can also handle submatrices of matrices, even though these submatrices may not be stored in consecutive memory locations. For example, to specify the 10-by-10 submatrix lying in rows and columns 11 through 20 of a 30-by-30 matrix A, one must specify

- A(11, 11), the upper left corner of the submatrix
- 30 = Leading dimension of A in its declaration (often denoted LDA in calling sequences)
- 10 = Number of rows of the submatrix (often denoted M, can be at most LDA)
- 10 = Number of columns of submatrix (often denoted N)

All matrix arguments require these 4 parameters (some subroutines may have fewer inputs if, for example, the submatrix is assumed square so that  $M = N$ ). (See Chapter 74, for more details.)

Most of the LAPACK routines require the users to provide them a workspace (WORK) and its dimension (LWORK). The *optimal* workspace dimension refers to the workspace dimension, which enables the code to have the best performance on the targeted machine. The computation of the optimal workspace dimension is often complex so that most of LAPACK routines have the ability to compute it. If a LAPACK routine is called with LWORK=-1, then a workspace query is assumed. The routine only calculates the optimal size of the WORK array and returns this value as the first entry of the WORK array. If a larger workspace is provided, the extra part is not used, so that the code runs at the optimal performance. A *minimal* workspace dimension is provided in the document of routines. If a routine is called with a workspace dimension smaller than the minimal workspace dimension, the computation cannot be performed.

## 75.2 Linear System of Equations

### Definitions:

The problem of linear equations is to compute a solution  $X$  of the system of linear equations

$$AX = B, \quad (75.1)$$

where  $A$  is an  $n$ -by- $n$  matrix and  $X$  and  $B$  are  $n$ -by- $m$  matrices.

**Backgrounds:**

The theoretical and algorithmic background of the solution of linear equations is discussed extensively in Chapter 37 through Chapter 41, especially Chapter 38.

**Driver Routines:**

There are two types of driver routines for solving the systems of linear equations — simple driver and expert driver. The expert driver solves the system (Equation 75.1), allows  $A$  be replaced by  $A^T$  or  $A^*$ ; and provides error bounds, condition number estimate, scaling, and can refine the solution. Each of these types of drivers has different implementations that take advantage of the special properties or storage schemes of the matrix  $A$ , as listed in the following table.

Data Structure (Matrix Storage Scheme)	Routine Names	
	Simple Driver	Expert Driver
General dense	xGESV	xGESVX
General band	xGBSV	xGBSVX
General tridiagonal	xGTSV	xGTSVX
Symmetric/Hermitian positive definite	xPOSV	xPOSVX
Symmetric/Hermitian positive definite (packed storage)	xPPSV	xPPSVX
Banded symmetric positive definite	xPBSV	xPBSVX
Tridiagonal symmetric positive definite	xPTSV	xPTSVX
Symmetric/Hermitian indefinite	xSYSV/xHESV	xSYSVX/xHESVX
Symmetric/Hermitian indefinite (packed storage)	xSPSV/xHPSV	xSPSVX/xHPSVX
Complex symmetric	CSYSV/ZSYSV	CSYSVX/ZSYSVX

The prefixes GE (for general dense), GB (for general band), etc., have standard meanings for all the BLAS and LAPACK routines.

**Examples:**

Let us show how to use the simple driver routine SGESV to solve a general linear system of equations. SGESV computes the solution of a real linear Equation 75.1 in single precision by first computing the LU decomposition with row partial pivoting of the coefficient matrix  $A$ , followed by the back and forward substitutions. SGESV has the following calling sequence:

```
CALL SGESV( N, NRHS, A, LDA, IPIV, B, LDB, INFO )
```

Input to SGESV:

**N:** The number of linear equations, i.e., the order of  $A$ .  $N \geq 0$ .

**NRHS:** The number of right-hand sides, i.e., the number of columns of  $B$ .  $NRHS \geq 0$ .

**A, LDA:** The  $N$ -by- $N$  coefficient matrix  $A$  and the leading dimension of the array  $A$ .  
 $LDA \geq \max(1, N)$ .

**B, LDB:** The  $N$ -by- $NRHS$  matrix  $B$  and the leading dimension of the array  $B$ .  $LDB \geq \max(1, N)$ .

Output from SGESV:

**A:** The factors  $L$  and  $U$  from factorization  $A = PLU$ ; the unit diagonal elements of  $L$  are not stored.

**IPIV:** The pivot indices that define the permutation matrix  $P$ ; row  $i$  of the matrix was interchanged with row  $IPIV(i)$ .

**B:** If  $INFO = 0$ , the  $N$ -by- $NRHS$  solution  $X$ .

**INFO:** = 0, successful exit. If  $INFO = -j$ , the  $j$ th argument had an illegal value. If  $INFO = j$ ,  $U(j, j)$  is exactly zero. The factorization has been completed, but the factor  $U$  is singular, so the solution could not be computed.

Consider a 4-by-4 linear system of Equation (75.1), where

$$A = \begin{bmatrix} 5 & 7 & 6 & 5 \\ 7 & 10 & 8 & 7 \\ 6 & 8 & 10 & 9 \\ 5 & 7 & 9 & 10 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 23 \\ 32 \\ 33 \\ 31 \end{bmatrix}.$$

The exact solution is  $\mathbf{x} = [1 \ 1 \ 1 \ 1]^T$ . Upon calling SGESV, the program successfully exits with  $\text{INFO} = 0$  and the solution  $X$  of (75.1) resides in the array  $\mathbb{B}$

$$X = \begin{bmatrix} 0.9999998 \\ 1.0000004 \\ 0.9999998 \\ 1.0000001 \end{bmatrix}.$$

Since SGESV performs the computation in single precision arithmetic, it is normal to have an error of the order of  $10^{-6}$  in the solution  $X$ . By reading the lower diagonal entries in the array  $\mathbb{A}$  and filling the diagonal entries with ones, we recover the lower unit triangular matrix  $L$  of the LU factorization with row partial pivoting of  $A$  as follows:

$$L = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0.8571429 & 1 & 0 & 0 \\ 0.7142857 & 0.2500000 & 1 & 0 \\ 0.7142857 & 0.2500000 & -0.2000000 & 1 \end{bmatrix}.$$

The upper triangular matrix  $U$  is recovered by reading the diagonal and upper diagonal entries in  $\mathbb{A}$ . That is:

$$U = \begin{bmatrix} 7.0000000 & 10.0000000 & 8.0000000 & 7.0000000 \\ 0 & -0.5714293 & 3.1428566 & 2.9999995 \\ 0 & 0 & 2.5000000 & 4.2500000 \\ 0 & 0 & 0 & 0.1000000 \end{bmatrix}.$$

Finally, the permutation matrix  $P$  is the identity matrix that exchanges its  $i$ th row with row  $\text{IPIV}(i)$ , for  $i = n, \dots, 1$ . Since

$$\text{IPIV} = [2 \ 3 \ 4 \ 4],$$

we have

$$P = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}.$$

## 75.3 Linear Least Squares Problems

---

### Definitions:

The linear least squares (LLS) problem is to find

$$\min_{\mathbf{x}} \|\mathbf{b} - A\mathbf{x}\|_2, \tag{75.2}$$

where  $A$  is an  $m$ -by- $n$  matrix and  $\mathbf{b}$  is an  $m$  element vector.

**Backgrounds:**

The most usual case is  $m \geq n$  and  $\text{rank}(A) = n$ . In this case, the solution to the LLS problem (75.2) is unique, and the problem is also referred to as finding a least squares solution to an overdetermined system of linear equations. When  $m < n$  and  $\text{rank}(A) = m$ , there are an infinite number of solutions  $\mathbf{x}$  that exactly satisfy  $\mathbf{b} - A\mathbf{x} = 0$ . In this case, it is often useful to find the unique solution  $\mathbf{x}$  that minimizes  $\|\mathbf{x}\|_2$ , and the problem is referred to as finding a *minimum norm solution* to an underdetermined system of linear equations. (See Chapter 5.8 and Chapter 39 for more information on linear least squares problems.)

**Driver Routines:**

There are four types of driver routines that solve the LLS problem (75.2) and also allow  $A$  be replaced by  $A^*$ . In the general case when  $\text{rank}(A) < \min(m, n)$ , we seek the *minimum norm least squares* solution  $\mathbf{x}$  that minimizes both  $\|\mathbf{x}\|_2$  and  $\|\mathbf{b} - A\mathbf{x}\|_2$ . The types of driver routines are categorized by the methods used to solve the LLS problem, as shown in the following table.

Type of Matrix	Algorithm	Routine Names
General dense	QR or LQ factorization	xGELS
General dense	Complete orthogonal factorization	xGELSY
General dense	SVD	xGELSS
General dense	Divide-and-conquer SVD	xGELSD

xGELSD is significantly faster than xGELSS, but it demands somewhat more workspace depending on the matrix dimensions. Among these routines, only xGELS requires  $A$  to be full rank while xGELSY, xGELSS, and xGELSD allow less than full rank.

Note that all driver routines allow several right-hand side vectors  $\mathbf{b}$  and corresponding solutions  $\mathbf{x}$  to be handled in a single call, storing these vectors as columns of matrices  $B$  and  $X$ , respectively. However, the LLS problem (75.2) is solved for each right-hand side independently; that is not the same as finding a matrix  $X$  which minimizes  $\|B - AX\|_2$ .

**Examples:**

Let us show how to use the simple driver routine SGELS to solve the LLS problem (75.2). SGELS computes the QR decomposition of the matrix  $A$ , updates the vector  $\mathbf{b}$ , and then computes the solution  $\mathbf{x}$  by back substitution. SGELS has the following calling sequence:

```
CALL SGELS( TRANS, M, N, NRHS, A, LDA, B, LDB, WORK, LWORK, INFO )
```

Input to SGELS:

TRANS: = 'N' or 'T': solves the LLS with  $A$  or  $A^T$ .

M, N: The numbers of rows and columns of the matrix  $A$ .  $M \geq 0$  and  $N \geq 0$ .

M, NRHS: The number of rows and columns of the matrices  $B$  and  $X$ .  $\text{NRHS} \geq 0$ .

A, LDA: The  $M$ -by- $N$  matrix  $A$  and the leading dimension of the array  $A$ ,  $\text{LDA} \geq \max(1, M)$ .

B, LDB: The matrix  $B$  and the leading dimension of the array  $B$ ,  $\text{LDB} \geq \max(1, M, N)$ .

If TRANS = 'N', then  $B$  is  $M$ -by- $\text{NRHS}$ . If TRANS = 'T', then  $B$  is  $N$ -by- $\text{NRHS}$ .

WORK, LWORK: The workspace array and its dimension.  $\text{LWORK} \geq \min(M, N) + \max(1, M, N, \text{NRHS})$ .

If LWORK = -1, then a workspace query is assumed; the routine only calculates the optimal size of the WORK array, and returns this value as the first entry of the WORK array.

Output from SGELS:

B: It is overwritten by the solution vectors, stored columnwise.

- If TRANS = 'N' and  $M \geq N$ , rows 1 to  $N$  of  $B$  contain the solution vectors of the LLS problem  $\min_{\mathbf{x}} \|\mathbf{b} - A\mathbf{x}\|_2$ ; the residual sum of squares in each column is given by the sum of squares of elements  $N + 1$  to  $M$  in that column;

- If TRANS = 'N' and  $M < N$ , rows 1 to  $N$  of  $B$  contain the minimum norm solution vectors of the underdetermined system  $AX = B$ ;
- If TRANS = 'T' and  $M \geq N$ , rows 1 to  $M$  of  $B$  contain the minimum norm solution vectors of the underdetermined system  $A^T X = B$ ;
- If TRANS = 'T' and  $M < N$ , rows 1 to  $M$  of  $B$  contain the solution vectors of the LLS problem  $\min_x \|\mathbf{b} - A^T \mathbf{x}\|_2$ ; the residual sum of squares for the solution in each column is given by the sum of the squares of elements  $M+1$  to  $N$  in that column.

WORK: If INFO = 0, WORK(1) returns the optimal LWORK.

INFO: INFO = 0 if successful exit. If INFO =  $-j$ , the  $j$ th input argument had an illegal value.

Consider an LLS problem (75.2) with a 6-by-5 matrix  $A$  and a 6-by-1 matrix  $\mathbf{b}$ :

$$A = \begin{bmatrix} -74 & 80 & 18 & -11 & -4 \\ 14 & -69 & 21 & 28 & 0 \\ 66 & -72 & -5 & 7 & 1 \\ -12 & 66 & -30 & -23 & 3 \\ 3 & 8 & -7 & -4 & 1 \\ 4 & -12 & 4 & 4 & 0 \end{bmatrix} \quad \text{and} \quad \mathbf{b} = \begin{bmatrix} 51 \\ -61 \\ -56 \\ 69 \\ 10 \\ -12 \end{bmatrix}.$$

The exact solution of the LLS problem is  $\mathbf{x} = [1 \quad 2 \quad -1 \quad 3 \quad -4]^T$  with residual  $\|\mathbf{b} - A\mathbf{x}\|_2 = 0$ . Upon calling SGELS, the first 5 elements of  $B$  are overwritten by the solution vector  $\mathbf{x}$ :

$$\mathbf{x} = \begin{bmatrix} 1.0000176 \\ 2.0000196 \\ -0.9999972 \\ 3.0000386 \\ -4.0000405 \end{bmatrix},$$

while the sixth element of  $B$  contains the residual sum of squares 0.0000021. With  $M = 6$ ,  $N = 5$ , NRHS = 1, LWORK has been set to 11. For such a small matrix, the minimal workspace is also the optimal workspace.

## 75.4 The Linear Equality-Constrained Least Squares Problem

### Definitions:

The linear equality-constrained least squares (LSE) problem is

$$\min_{\mathbf{x}} \|\mathbf{c} - A\mathbf{x}\|_2 \quad \text{subject to} \quad B\mathbf{x} = \mathbf{d}, \quad (75.3)$$

where  $A$  is an  $m$ -by- $n$  matrix and  $B$  is a  $p$ -by- $n$  matrix,  $\mathbf{c}$  is an  $m$ -vector, and  $\mathbf{d}$  is a  $p$ -vector, with  $p \leq n \leq m + p$ .

### Backgrounds:

Under the assumptions that  $B$  has full row rank  $p$  and the matrix  $\begin{bmatrix} A \\ B \end{bmatrix}$  has full column rank  $n$ , the LSE problem (75.3) has a unique solution  $\mathbf{x}$ .

**Driver Routines:**

The driver routine for solving the LSE is xGGLSE, which uses a generalized QR factorization of the matrices  $A$  and  $B$ .

**Examples:**

Let us show how to use the driver routine SGGLSE to solve the LSE problem (75.3). SGGLSE first computes a generalized QR decomposition of  $A$  and  $B$ , and then computes the solution by back substitution. SGGLSE has the following calling sequence:

```
CALL SGGLSE( M, N, P, A, LDA, B, LDB, C, D, X, WORK, LWORK, INFO )
```

Input to SGGLSE:

$M, P$ : The numbers of rows of the matrices  $A$  and  $B$ , respectively.  $M \geq 0$  and  $P \geq 0$ .

$N$ : The number of columns of the matrices  $A$  and  $B$ .  $N \geq 0$ . Note that  $0 \leq P \leq N \leq M+P$ .

$A, LDA$ : The  $M$ -by- $N$  matrix  $A$  and the leading dimension of the array  $A$ .  $LDA \geq \max(1, M)$ .

$B, LDB$ : The  $P$ -by- $N$  matrix  $B$  and the leading dimension of the array  $B$ .  $LDB \geq \max(1, P)$ .

$C, D$ : The right-hand side vectors for the least squares part, and the constrained equation part of the LSE, respectively.

$WORK, LWORK$ : The workspace array and its dimension.  $LWORK \geq \max(1, M + N + P)$ .

If  $LWORK = -1$ , then a workspace query is assumed; the routine only calculates the optimal size of the  $WORK$  array, and returns this value as the first entry of the  $WORK$  array.

Output from SGGLSE:

$C$ : The residual sum of squares for the solution is given by the sum of squares of elements  $N-P+1$  to  $M$  of vector  $C$ .

$X$ : The solution of the LSE problem.

$WORK$ : If  $INFO = 0$ ,  $WORK(1)$  returns the optimal  $LWORK$ .

$INFO$ :  $= 0$  if successful exit. If  $INFO = -j$ , the  $j$ th argument had an illegal value.

Let us demonstrate the use of SGGLSE to solve the LSE problem (75.3), where

$$A = \begin{bmatrix} 1 & 1 & 1 \\ 1 & 3 & 1 \\ 1 & -1 & 1 \\ 1 & 1 & 1 \end{bmatrix}, \quad B = \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & -1 \end{bmatrix}, \quad \mathbf{c} = \begin{bmatrix} 1 \\ 2 \\ 3 \\ 4 \end{bmatrix}, \quad \mathbf{d} = \begin{bmatrix} 7 \\ 4 \end{bmatrix}.$$

The unique exact solution is  $\mathbf{x} = \frac{1}{8}[46 \quad -2 \quad 12]^T$ . Upon calling SGGLSE with this input data and  $M = 4, N = 3, P = 2, LWORK = 9$ , an approximate solution of the LSE problem is returned in  $X$ :

$$X = [5.7500000 \quad -0.2500001 \quad 1.4999994]^T.$$

The array  $C$  is overwritten by the residual sum of squares for the solution:

$$C = [4.2426405 \quad 8.9999981 \quad 2.1064947 \quad 0.2503501]^T.$$

## 75.5 A General Linear Model Problem

---

### Definitions:

The general linear model (GLM) problem is

$$\min_{\mathbf{x}, \mathbf{y}} \|\mathbf{y}\|_2 \quad \text{subject to} \quad \mathbf{d} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{y}, \quad (75.4)$$

where  $A$  is an  $n$ -by- $m$  matrix,  $B$  is an  $n$ -by- $p$  matrix, and  $\mathbf{d}$  is a  $n$ -vector, with  $m \leq n \leq m + p$ .

### Backgrounds:

When  $B = I$ , the problem reduces to an ordinary linear least squares problem (75.2). When  $B$  is square and nonsingular, the GLM problem is equivalent to the *weighted linear least squares problem*:

$$\min_{\mathbf{x}} \|B^{-1}(\mathbf{d} - \mathbf{A}\mathbf{x})\|_2.$$

Note that the GLM is equivalent to the LSE problem

$$\min_{\mathbf{x}, \mathbf{y}} \left\| \begin{bmatrix} 0 & I \end{bmatrix} \begin{bmatrix} \mathbf{x} \\ \mathbf{y} \end{bmatrix} \right\|_2 \quad \text{subject to} \quad \begin{bmatrix} A & B \end{bmatrix} \begin{bmatrix} \mathbf{x} \\ \mathbf{y} \end{bmatrix} = \mathbf{d}.$$

Therefore, the GLM problem has a unique solution of the matrix  $\begin{bmatrix} 0 & I \\ A & B \end{bmatrix}$  and has full column rank  $m + p$ .

### Driver Routines:

The driver routine for solving the GLM problem (75.4) is xGGGLM, which uses a generalized QR factorization of the matrices  $A$  and  $B$ .

### Examples:

Let us show how to use the driver routine SGGGLM to solve the GLM problem (75.4). SGGGLM computes a generalized QR decomposition of the matrices  $A$  and  $B$ , and then computes the solution by back substitution. SGGGLM has the following calling sequence:

```
CALL SGGGLM( N, M, P, A, LDA, B, LDB, D, X, Y, WORK, LWORK, INFO )
```

Input to SGGGLM:

**N:** The number of rows of the matrices  $A$  and  $B$ .  $N \geq 0$ .

**M, P:** The number of columns of the matrices  $A$  and  $B$ , respectively.  $0 \leq M \leq N$  and  $P \geq N - M$ .

**A, LDA:** The  $N$ -by- $M$  matrix  $A$  and the leading dimension of the array  $A$ .  $LDA \geq \max(1, N)$ .

**B, LDB:** The  $N$ -by- $P$  matrix  $B$  and the leading dimension of the array  $B$ .  $LDB \geq \max(1, N)$ .

**D:** The left-hand side of the GLM equation.

**WORK, LWORK:** The workspace array and its dimension.  $LWORK \geq \max(1, N + M + P)$ .

If  $LWORK = -1$ , then a workspace query is assumed; the routine only calculates the optimal size of the **WORK** array, and returns this value as the first entry of the **WORK** array.

Output from SGGGLM:

$X, Y$ : Solution vectors.

WORK: If INFO = 0, WORK(1) returns the optimal LWORK.

INFO: INFO = 0 if successful exit. If INFO =  $-j$ , the  $j$ th argument had an illegal value.

Let us demonstrate the use of SGGGLM for solving the GLM problem (75.4), where

$$A = \begin{bmatrix} 1 & 2 & 1 & 4 \\ -1 & 1 & 1 & 1 \\ -1 & -2 & -1 & 1 \\ -1 & 2 & -1 & -1 \\ 1 & 1 & 1 & 2 \end{bmatrix}, \quad B = \begin{bmatrix} 1 & 2 & 2 \\ -1 & 1 & -2 \\ 3 & 1 & 6 \\ 2 & -2 & 4 \\ 1 & -1 & 2 \end{bmatrix}, \quad \mathbf{d} = \begin{bmatrix} 7.99 \\ 0.98 \\ -2.98 \\ 3.04 \\ 4.02 \end{bmatrix}.$$

Upon calling SGGGLM with this input data,  $N = 5, M = 4, P = 3, LWORK = 12$ , the program successfully exits and returns the following solution vectors:

$$X = [1.002950 \quad 2.001435 \quad -0.987797 \quad 0.009080]^T$$

and

$$Y = [0.003435 \quad -0.004417 \quad 0.006871]^T.$$

## 75.6 Symmetric Eigenproblems

---

### Definitions:

The symmetric eigenvalue problem (SEP) is to find the eigenvalues,  $\lambda$ , and corresponding eigenvectors,  $\mathbf{x} \neq 0$ , such that

$$A\mathbf{x} = \lambda\mathbf{x}, \tag{75.5}$$

where  $A$  is real and symmetric. If  $A$  is complex and Hermitian, i.e.,  $A^* = A$ , then it is referred to as the *Hermitian eigenvalue problem*.

### Backgrounds:

When all eigenvalues and eigenvectors have been computed, we write

$$A = X\Lambda X^*, \tag{75.6}$$

where  $\Lambda$  is a diagonal matrix whose diagonal elements are real and are the eigenvalues, and  $X$  is an orthogonal (or unitary) matrix whose columns are the eigenvectors. This is the classical *spectral decomposition* of  $A$ . The theoretical and algorithmic backgrounds of the solution of the symmetric eigenvalue problem are discussed in Chapter 42.

### Driver Routines:

There are four types of driver routines for solving the SEP (75.5) and each has its own variations that take advantage of the special structure or storage of the matrix  $A$ , as summarized in the following table.

Types of Matrix (Storage Scheme)	Routine Names			
	Simple Driver	Divide-and-Conquer	Expert Driver	RRR Driver
General symmetric	xSYEV	xSYEVD	xSYEVX	xSYEVR
General symmetric (packed storage)	xSPEV	xSPEVD	xSPEVX	–
Band matrix	xSBEV	xSBEVD	xSBEVX	–
Tridiagonal matrix	xSTEV	xSTEVD	xSTEVX	xSTEVR

The simple driver computes all eigenvalues and (optionally) eigenvectors. The expert driver computes all or a selected subset of the eigenvalues and (optionally) eigenvectors. The divide-and-conquer driver has the same functionality as, yet outperforms, the simple driver, but it requires more workspace. The relative robust representation (RRR) driver computes all or a subset of the eigenvalues and (optionally) the eigenvectors. The last one is generally faster than any other types of driver routines and uses the least amount of workspace.

### Examples:

Let us show how to use the simple driver SSYEV to solve the SEP (75.5) by computing the spectral decomposition (75.6). SSYEV first reduces  $A$  to a tridiagonal form, and then uses the implicit QL or QR algorithm to compute eigenvalues and optionally eigenvectors. SSYEV has the following calling sequence:

```
CALL SSYEV( JOBZ, UPLO, N, A, LDA, W, WORK, LWORK, INFO )
```

Input to SSYEV:

JOBZ: = 'N', compute eigenvalues only;

= 'V', compute eigenvalues and eigenvectors.

UPLO: = 'U', the upper triangle of  $A$  is stored in the array  $A$ ; if UPLO = 'L', the lower triangle of  $A$  is stored.

N: The order of the matrix  $A$ .  $N \geq 0$ .

A, LDA: The symmetric matrix  $A$  and the leading dimension of the array  $A$ .  $LDA \geq \max(1, N)$ .

WORK, LWORK: The workspace array and its dimension.  $LWORK \geq \max(1, 3 * N - 1)$ .

If LWORK = -1, then a workspace query is assumed; the routine only calculates the optimal size of the WORK array, and returns this value as the first entry of the WORK array.

Output from SSYEV:

A: The orthonormal eigenvectors  $X$ , if JOBZ = 'V'.

W: The eigenvalues  $\lambda$  in ascending order.

WORK: If INFO = 0, WORK(1) returns the optimal LWORK.

INFO: = 0 if successful exit. If INFO = - $j$ , the  $j$ th input argument had an illegal value. If INFO =  $j$ , the  $j$  off-diagonal elements of an intermediate tridiagonal form did not converge to zero.

Let us demonstrate the use of SSYEV to solve the SEP (75.5), where

$$A = \begin{bmatrix} 5 & 4 & 1 & 1 \\ 4 & 5 & 1 & 1 \\ 1 & 1 & 4 & 2 \\ 1 & 1 & 2 & 4 \end{bmatrix}.$$

The exact eigenvalues are 1, 2, 5, and 10. Upon calling SSYEV with the matrix  $A$  and  $N = 4$ ,  $LWORK = 3 * N - 1 = 11$ ,  $A$  is overwritten by its orthonormal eigenvectors  $X$ .

$$X = \begin{bmatrix} 0.7071068 & -0.0000003 & 0.3162279 & 0.6324555 \\ -0.7071068 & 0.0000001 & 0.3162278 & 0.6324555 \\ 0.0000002 & 0.7071069 & -0.6324553 & 0.3162278 \\ -0.0000001 & -0.7071066 & -0.6324556 & 0.3162278 \end{bmatrix}.$$

The eigenvalues that correspond to the eigenvectors in each column of  $X$  are returned in  $W$ :

$$W = [0.9999996 \quad 1.9999999 \quad 4.9999995 \quad 10.0000000].$$

## 75.7 Nonsymmetric Eigenproblems

As is customary in numerical linear algebra, in this section the term *left eigenvector* of  $A$  means a (column) vector  $y$  such that  $y^* A = \lambda y^*$ . This is contrary to the definition in Section 4.3, under which  $y^*$  would be called a left eigenvector.

### Definitions:

The nonsymmetric eigenvalue problem (NEP) is to find the eigenvalues,  $\lambda$ , and corresponding (right) eigenvectors,  $x \neq 0$ , such that

$$Ax = \lambda x \tag{75.7}$$

and, perhaps, the left eigenvectors,  $y \neq 0$ , satisfying

$$y^* A = \lambda y^*. \tag{75.8}$$

### Backgrounds:

The problem is solved by computing the *Schur decomposition* of  $A$ , defined in the real case as

$$A = ZTZ^T,$$

where  $Z$  is an orthogonal matrix and  $T$  is an upper quasi-triangular matrix with 1-by-1 and 2-by-2 diagonal blocks, the 2-by-2 blocks corresponding to complex conjugate pairs of eigenvalues of  $A$ . In the complex case, the Schur decomposition is

$$A = ZTZ^*,$$

where  $Z$  is unitary and  $T$  is a complex upper triangular matrix.

The columns of  $Z$  are called the *Schur vectors*. For each  $k$  ( $1 \leq k \leq n$ ), the first  $k$  columns of  $Z$  form an orthonormal basis for the invariant subspace corresponding to the first  $k$  eigenvalues on the diagonal of  $T$ . It is possible to order the Schur factorization so that any desired set of  $k$  eigenvalues occupies the  $k$  leading positions on the diagonal of  $T$ . The theoretical and algorithmic background of the solution of the nonsymmetric eigenvalue problem is discussed in Chapter 43.

### Driver Routines:

Both the simple driver xGEEV and expert driver xGEEVX are provided. The simple driver computes all the eigenvalues of  $A$  and (optionally) the right or left eigenvectors (or both). The expert driver performs the same task as the simple driver plus the additional feature that it balances the matrix to try to improve the conditioning of the eigenvalues and eigenvectors, and it computes the condition numbers for the eigenvalues or eigenvectors (or both).

### Examples:

Let us show how to use the simple driver SGEEV to solve the NEP (75.7). SGEEV first reduces  $A$  to an upper Hessenberg form (a Hessenberg matrix is a matrix where all entries below the first lower subdiagonal are

zeros), and then uses the implicit QR algorithm to compute the Schur decomposition, and finally computes eigenvectors of the upper quasi-triangular matrix. SGEEV has the following calling sequence:

```
CALL SGEEV( JOBVL, JOBVR, N, A, LDA, WR, WI, VL, LDVL, VR, LDVR, WORK,
LWORK, INFO )
```

Input to SGEEV:

JOBVL, JOBVR: = 'V', the left and/or right eigenvectors are computed;  
= 'N', the left and/or right eigenvectors are not computed.

N: The order of the matrix  $A$ .  $N \geq 0$ .

A, LDA: The matrix  $A$  and the leading dimension of the array  $A$ .  $LDA \geq \max(1, N)$ .

LDVL, LDVR: The leading dimensions of the arrays VL and VR if the left and right eigenvectors are computed.  $LDVL, LDVR \geq N$ .

WORK, LWORK: The workspace array and its dimension.  $LWORK \geq \max(1, 3 * N)$ . If eigenvectors are computed,  $LWORK \geq 4 * N$ . For good performance, LWORK must generally be larger.

If LWORK = -1, then a workspace query is assumed; the routine only calculates the optimal size of the WORK array, and returns this value as the first entry of the WORK array.

Output from SGEEV:

WR, WI: The real and imaginary parts of the computed eigenvalues. Complex conjugate pairs of eigenvalues appear consecutively with the eigenvalue having the positive imaginary part first.

VL: If the  $j$ th eigenvalue  $\lambda_j$  is real, then the  $j$ th left eigenvector  $\mathbf{y}_j$  is stored in  $VL(:, j)$ . If the  $j$ th and  $(j + 1)$ -st eigenvalues  $\lambda_j$  and  $\lambda_{j+1}$  form a complex conjugate pair, then  $VL(:, j) + i \cdot VL(:, j + 1)$  and  $VL(:, j) - i \cdot VL(:, j + 1)$  are the corresponding left eigenvectors  $\mathbf{y}_j$  and  $\mathbf{y}_{j+1}$ .

VR: If the  $j$ th eigenvalue  $\lambda_j$  is real, then the  $j$ th right eigenvector  $\mathbf{x}_j$  is stored in  $VR(:, j)$ . If the  $j$ th and  $(j + 1)$ -st eigenvalues  $\lambda_j$  and  $\lambda_{j+1}$  form a complex conjugate pair, then  $VR(:, j) + i \cdot VR(:, j + 1)$  and  $VR(:, j) - i \cdot VR(:, j + 1)$  are the corresponding right eigenvectors  $\mathbf{x}_j$  and  $\mathbf{x}_{j+1}$ .

WORK: If INFO = 0, WORK(1) returns the optimal LWORK.

INFO: = 0 if successful exit. If INFO = - $j$ , the  $j$ th argument had an illegal value. If INFO =  $j$ , the QR algorithm failed to compute all the eigenvalues, and no eigenvectors have been computed; elements  $j + 1 : N$  of WR and WI contain eigenvalues, which have converged.

Let us demonstrate the use of SGEEV for solving the NEP (75.7), where

$$A = \begin{bmatrix} 4 & -5 & 0 & 3 \\ 0 & 4 & -3 & -5 \\ 5 & -3 & 4 & 0 \\ 3 & 0 & 5 & 4 \end{bmatrix}.$$

The exact eigenvalues are  $2, 1 + i \cdot 5, 1 - i \cdot 5$ , and  $2$ . Upon calling SGEEV with this matrix and  $N = 4, LWORK = 4 * N = 16$ , each eigenvalue,  $\lambda_j$ , is retrieved by combining the  $j$ th entry in WR and WI.

such that  $\lambda_j = \text{WR}(j) + i \cdot \text{WI}(j)$ . If  $\text{WI}(j)$  is 0, then the  $j$ th eigenvalue is real. For this example, we have

$$\begin{aligned}\lambda_1 &= 12.0000000 \\ \lambda_2 &= 1.000000 + i \cdot 5.0000005 \\ \lambda_3 &= 1.000000 - i \cdot 5.0000005 \\ \lambda_4 &= 1.9999999.\end{aligned}$$

The left eigenvectors are stored in  $\text{VL}$ . Since the first and fourth eigenvalues are real, their eigenvectors are the corresponding columns in  $\text{VL}$ , that is,  $\mathbf{y}_1 = \text{VL}(:, 1)$  and  $\mathbf{y}_4 = \text{VL}(:, 4)$ . Since the second and third eigenvalues form a complex conjugate pair, the second eigenvector,  $\mathbf{y}_2 = \text{VL}(:, 2) + i \cdot \text{VL}(:, 3)$  and the third eigenvector,  $\mathbf{y}_3 = \text{VL}(:, 2) - i \cdot \text{VL}(:, 3)$ . If we place all the eigenvectors in a matrix  $Y$  where  $Y = [\mathbf{y}_1, \mathbf{y}_2, \mathbf{y}_3, \mathbf{y}_4]$ , we have

$$Y = \begin{bmatrix} -0.5000001 & 0.0000003 - i \cdot 0.4999999 & 0.0000003 + i \cdot 0.4999999 & 0.5000000 \\ 0.4999999 & -0.5000002 & -0.5000002 & 0.5000001 \\ -0.5000000 & -0.5000000 - i \cdot 0.0000002 & -0.5000000 + i \cdot 0.0000002 & -0.4999999 \\ -0.5000001 & -0.0000003 + i \cdot 0.5000000 & -0.0000003 - i \cdot 0.5000000 & 0.5000001 \end{bmatrix}.$$

The right eigenvectors  $\mathbf{x}_j$  can be recovered from  $\text{VR}$  in the way similar to the left eigenvectors. The right eigenvector matrix  $X$  is

$$X = \begin{bmatrix} -0.5000000 & 0.5000002 & 0.5000002 & 0.5000001 \\ 0.4999999 & -0.0000001 - i \cdot 0.5000000 & -0.0000001 + i \cdot 0.5000000 & 0.5000000 \\ -0.5000000 & -0.0000001 - i \cdot 0.4999999 & -0.0000001 + i \cdot 0.4999999 & -0.5000000 \\ -0.5000001 & -0.5000001 & -0.5000001 & 0.5000000 \end{bmatrix}.$$

## 75.8 Singular Value Decomposition

---

### Definitions:

The singular value decomposition (SVD) of an  $m$ -by- $n$  matrix  $A$  is

$$A = U \Sigma V^T \quad (A = U \Sigma V^* \quad \text{in the complex case}), \quad (75.9)$$

where  $U$  and  $V$  are orthogonal (unitary) and  $\Sigma$  is an  $m$ -by- $n$  diagonal matrix with real diagonal elements,  $\sigma_j$ , such that

$$\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_{\min(m, n)} \geq 0.$$

The  $\sigma_j$  are the singular values of  $A$  and the first  $\min(m, n)$  columns of  $U$  and  $V$  are the left and right singular vectors of  $A$ .

### Backgrounds:

The singular values  $\sigma_j$  and the corresponding left singular vectors  $\mathbf{u}_j$  and right singular vectors  $\mathbf{v}_j$  satisfy

$$A \mathbf{v}_j = \sigma_j \mathbf{u}_j \quad \text{and} \quad A^T \mathbf{u}_j = \sigma_j \mathbf{v}_j \quad (\text{or} \quad A^* \mathbf{u}_j = \sigma_j \mathbf{v}_j \quad \text{in complex case}),$$

where  $\mathbf{u}_j$  and  $\mathbf{v}_j$  are the  $j$ th columns of  $U$  and  $V$ , respectively. (See Chapter 17 and Chapter 45 for more information on singular value decompositions.)

**Driver Routines:**

Two types of driver routines are provided in LAPACK. The simple driver xGESVD computes, all the singular values and (optionally) left and/or right singular vectors. The divide and conquer driver xGESDD has the same functionality as the simple driver except that it is much faster for larger matrices, but uses more workspace.

**Examples:**

Let us show how to use the simple driver SGESVD to compute the SVD (75.9). SGESVD first reduces  $A$  to a bidiagonal form, and then uses an implicit QR-type algorithm to compute singular values and optionally singular vectors. SGESVD has the following calling sequence:

```
CALL SGESVD( JOBU, JOBVT, M, N, A, LDA, S, U, LDU, VT, LDVT, WORK,
            LWORK, INFO )
```

Input to SGESVD:

**JOBU:** Specifies options for computing all or part of the left singular vectors  $U$ :

- = 'A', all  $M$  columns of  $U$  are returned in the array  $U$ ;
- = 'S', the first  $\min(M, N)$  columns of  $U$  are returned;
- = 'O', the first  $\min(M, N)$  columns of  $U$  are overwritten on the array  $A$ ;
- = 'N', no left singular vectors are computed. *Note that JOBVT and JOBU cannot both be 'O'.*

**JOBVT:** Specifies options for computing all or part of the right singular vectors  $V^T$ :

- = 'A', all  $N$  rows of  $V^T$  are returned in the array  $VT$ ;
- = 'S', the first  $\min(M, N)$  rows of  $V^T$  are returned;
- = 'O', the first  $\min(M, N)$  rows of  $V^T$  are overwritten on the array  $A$ ;
- = 'N', no right singular vectors are computed.

**M, N:** The number of rows and columns of the matrix  $A$ .  $M, N \geq 0$ .

**A, LDA:** The  $M$ -by- $N$  matrix  $A$  and the leading dimension of the array  $A$ .  $LDA \geq \max(1, M)$ .

**LDU, LDVT:** The leading dimension of the arrays  $U$  and  $VT$ .  $LDU, LDVT \geq 1$ ;

If **JOBU** = 'S' or 'A',  $LDU \geq M$ .

If **JOBVT** = 'A',  $LDVT \geq N$ ; If **JOBVT** = 'S',  $LDVT \geq \min(M, N)$ .

**WORK, LWORK:** The workspace array and its dimension.  $LWORK \geq \max(3 \min(M, N) + \max(M, N), 5 \min(M, N))$ .

If **LWORK** = -1, then a workspace query is assumed; the routine only calculates the optimal size of the **WORK** array and returns this value as the first entry of the **WORK** array.

Output from SGESVD:

**A:** If **JOBU** = 'O',  $A$  is overwritten with the first  $\min(M, N)$  columns of  $U$  (the left singular vectors, stored columnwise);

If **JOBVT** = 'O',  $A$  is overwritten with the first  $\min(M, N)$  rows of  $V^T$  (the right singular vectors, stored rowwise);

**S:** Singular values of  $A$ , sorted so that  $S(i) \geq S(i + 1)$ .

**U:** If **JOBU** = 'A',  $U$  contains  $M$ -by- $M$  orthogonal matrix  $U$ . If **JOBU** = 'S',  $U$  contains the first  $\min(M, N)$  columns of  $U$ . If **JOBU** = 'N' or 'O',  $U$  is not referenced.

VT: If JOBVT = 'A', VT contains right N-by-N orthogonal matrix  $V^T$ . If JOBVT = 'S', VT contains the first  $\min(M, N)$  rows of  $V^T$  (the right singular vectors stored rowwise). If JOBVT = 'N' or 'O', VT is not referenced.

WORK: If INFO = 0, WORK(1) returns the optimal LWORK.

INFO: = 0 if successful exit. If INFO = -j, the jth argument had an illegal value. If INFO > 0, the QR-type algorithm (subroutine SBDSQR) did not converge. INFO specifies how many superdiagonals of an intermediate bidiagonal form  $B$  did not converge to zero. WORK(2:min(M, N)) contains the unconverged superdiagonal elements of an upper bidiagonal matrix  $B$  whose diagonal is in S (not necessarily sorted).  $B$  satisfies  $A = UBVT$ , so it has the same singular values as  $A$ , and singular vectors related by  $U$  and  $V^T$ .

Let us show the numerical results of SGESVD in computing the SVD by an 8-by-5 matrix  $A$  as follows:

$$A = \begin{bmatrix} 22 & 10 & 2 & 3 & 7 \\ 14 & 7 & 10 & 0 & 8 \\ -1 & 13 & -1 & -11 & 3 \\ -3 & -2 & 13 & -2 & 4 \\ 9 & 8 & 1 & -2 & 4 \\ 9 & 1 & -7 & 5 & -1 \\ 2 & -6 & 6 & 5 & 1 \\ 4 & 5 & 0 & -2 & 2 \end{bmatrix}.$$

The exact singular values are  $\sqrt{1248}$ , 20,  $\sqrt{384}$ , 0, 0. The rank of the matrix  $A$  is 3. Upon calling SGESVD with  $M = 8$ ,  $N = 5$ , LWORK = 25, the computed singular values of  $A$  are returned in S:

$$S = [35.3270454 \quad 20.0000038 \quad 19.5959187 \quad 0.0000007 \quad 0.0000004].$$

The columns in  $U$  contain the left singular vectors  $U$  of  $A$ :

$$U = \begin{bmatrix} -7.0711e-001 & 1.5812e-001 & -1.7678e-001 & 2.4818e-001 & -4.0289e-001 & -3.2305e-001 & -3.3272e-001 & -6.9129e-002 \\ -5.3033e-001 & 1.5811e-001 & 3.5355e-001 & -6.2416e-001 & 2.5591e-001 & -3.9178e-002 & 3.0548e-001 & -1.3725e-001 \\ -1.7678e-001 & -7.9057e-001 & 1.7677e-001 & 3.0146e-001 & 1.9636e-001 & -3.1852e-001 & 2.3590e-001 & -1.6112e-001 \\ 0 & 1.5811e-001 & 7.0711e-001 & 2.9410e-001 & 3.1907e-001 & 4.7643e-002 & -5.2856e-001 & 7.1055e-002 \\ -3.5355e-001 & -1.5811e-001 & -1.0000e-006 & 2.3966e-001 & -7.8607e-002 & 8.7800e-001 & 1.0987e-001 & -5.8528e-002 \\ -1.7678e-001 & 1.5812e-001 & -5.3033e-001 & 1.7018e-001 & 7.9071e-001 & -7.0484e-003 & -9.0913e-002 & -8.3220e-004 \\ 0 & 4.7434e-001 & 1.7678e-001 & 5.2915e-001 & -1.5210e-002 & -1.3789e-001 & 6.6193e-001 & 7.9763e-002 \\ -1.7678e-001 & -1.5811e-001 & -1.0000e-006 & -7.1202e-002 & 1.3965e-002 & -2.0712e-002 & 4.9676e-002 & 9.6726e-001 \end{bmatrix}.$$

The rows in VT contain the right singular vectors  $V^T$  of  $A$ :

$$V^T = \begin{bmatrix} -8.0064e-001 & -4.8038e-001 & -1.6013e-001 & 0 & -3.2026e-001 \\ 3.1623e-001 & -6.3246e-001 & 3.1622e-001 & 6.3246e-001 & -1.8000e-006 \\ -2.8867e-001 & -3.9000e-006 & 8.6603e-001 & -2.8867e-001 & 2.8868e-001 \\ -4.0970e-001 & 3.4253e-001 & -1.2426e-001 & 6.0951e-001 & 5.7260e-001 \\ 8.8224e-002 & -5.0190e-001 & -3.3003e-001 & -3.8100e-001 & 6.9730e-001 \end{bmatrix}.$$

## 75.9 Generalized Symmetric Definite Eigenproblems

### Definitions:

The generalized symmetric definite eigenvalue problem (GSEP) is to find the eigenvalues,  $\lambda$ , and corresponding eigenvectors,  $\mathbf{x} \neq 0$ , such that

$$A\mathbf{x} = \lambda B\mathbf{x} \quad (\text{type 1}) \tag{75.10}$$

or

$$AB\mathbf{x} = \lambda\mathbf{x} \quad (\text{type 2}) \quad (75.11)$$

or

$$B A \mathbf{x} = \lambda \mathbf{x} \quad (\text{type 3}) \quad (75.12)$$

where  $A$  and  $B$  are symmetric or Hermitian and  $B$  is positive definite.

### Backgrounds:

For all these problems the eigenvalues  $\lambda$  are real. The matrix  $Z$  of the computed eigenvectors satisfies  $Z^*AZ = \Lambda$  (problem types 1 and 3) or  $Z^{-1}AZ^{-*} = I$  (problem type 2), where  $\Lambda$  is a diagonal matrix with the eigenvalues on the diagonal.  $Z$  also satisfies  $Z^*BZ = I$  (problem types 1 and 2) or  $Z^*B^{-1}Z = I$  (problem type 3). These results are consequences of spectral theory for symmetric matrices. For example, the GSEP type 1 can be rearranged as

$$B^{-\frac{1}{2}}AB^{-\frac{1}{2}}\mathbf{y} = \lambda\mathbf{y},$$

where  $\mathbf{y} = B^{\frac{1}{2}}\mathbf{x}$ .

### Driver Routines:

There are three types of driver routines for solving the GSEP, and each has variations that take advantage of the special structure or storage of the matrices  $A$  and  $B$ , as shown in the following table:

Types of Matrix (Storage Scheme)	Routine Names		
	Simple Driver	Divide-and-Conquer	Expert Driver
General dense	xSYGV/xHEGV	xSYGVD/xHEGVD	xSYGVX/xHEGVX
General dense (packed storage)	xSPGV/xHPGV	xSPGVD/xHPGVD	xSPGVX/xHPGVX
Band matrix	xSBGV/xHBGV	xSBBVD/xHBGVD	xSBGVX/xHBGVX

The simple driver computes all the eigenvalues and (optionally) the eigenvectors. The expert driver computes all or a selected subset of the eigenvalues and (optionally) eigenvectors. The divide-and-conquer driver solves the same problem as the simple driver. It is much faster than the simple driver, but uses more workspace.

### Examples:

Let us show how to use the simple driver SSYGV to compute the GSEPs (75.10), (75.11), and (75.12). SSGYV first reduces each of these problems to a standard symmetric eigenvalue problem, using a Cholesky decomposition of  $B$ , and then computes eigenvalues and eigenvectors of the standard symmetric eigenvalue problem by an implicit QR-type algorithm. SSYGV has the following calling sequence:

```
CALL SSYGV( ITYPE, JOBZ, UPLO, N, A, LDA, B, LDB, W, WORK, LWORK, INFO )
```

Input to SSYGV:

ITYPE: Specifies the problem type to be solved:

JOBZ: = 'N', compute eigenvalues only;

= 'V', compute eigenvalues and eigenvectors.

UPLO: = 'U', the upper triangles of  $A$  and  $B$  are stored;

= 'L', the lower triangles of  $A$  and  $B$  are stored.

N: The order of the matrices  $A$  and  $B$ .  $N \geq 0$ .

A, LDA: The symmetric matrix  $A$  and the leading dimension of the array A.  $LDA \geq \max(1, N)$ .

B: The symmetric positive definite matrix  $B$  and the leading dimension of the array B.  $LDB \geq \max(1, N)$ .

WORK, LWORK: The workspace array and its length.  $LWORK \geq \max(1, 3 * N - 1)$ .

If  $LWORK = -1$ , then a workspace query is assumed; the routine only calculates the optimal size of the WORK array, and returns this value as the first entry of the WORK array.

Output from SSYGV:

A: Contains the normalized eigenvector matrix  $Z$  if requested.

B: If  $INFO \leq N$ , the part of  $B$  containing the matrix is overwritten by the triangular factor  $U$  or  $L$  from the Cholesky factorization  $B = U^T U$  or  $B = L L^T$ .

W: The eigenvalues in ascending order.

WORK: If  $INFO = 0$ ,  $WORK(1)$  returns the optimal LWORK.

INFO:  $= 0$ , then successful exit. If  $INFO = -j$ , then the  $j$ th argument had an illegal value.

If  $INFO > 0$ , then SSYGV returned an error code:

- $INFO \leq N$ : if  $INFO = j$ , the algorithm failed to converge;
- $INFO > N$ : if  $INFO = N + j$ , for  $1 \leq j \leq N$ , then the leading minor of order  $j$  of  $B$  is not positive definite. The factorization of  $B$  could not be completed and no eigenvalues or eigenvectors were computed.

Let us show the use of SSYGV to solve the type 1 GSEP (75.10) for the following 5-by-5 matrices  $A$  and  $B$ :

$$A = \begin{bmatrix} 10 & 2 & 3 & 1 & 1 \\ 2 & 12 & 1 & 2 & 1 \\ 3 & 1 & 11 & 1 & -1 \\ 1 & 2 & 1 & 9 & 1 \\ 1 & 1 & -1 & 1 & 15 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 12 & 1 & -1 & 2 & 1 \\ 1 & 14 & 1 & -1 & 1 \\ -1 & 1 & 16 & -1 & 1 \\ 2 & -1 & -1 & 12 & -1 \\ 1 & 1 & 1 & -1 & 11 \end{bmatrix}.$$

Upon calling SSYGV with  $N = 5$ ,  $LWORK = 3 * N - 1 = 14$ , A is overwritten by the eigenvector matrix  $Z$ :

$$Z = \begin{bmatrix} -0.1345906 & 0.0829197 & -0.1917100 & 0.1420120 & -0.0763867 \\ 0.0612948 & 0.1531484 & 0.1589912 & 0.1424200 & 0.0170980 \\ 0.1579026 & -0.1186037 & -0.0748390 & 0.1209976 & -0.0666645 \\ -0.1094658 & -0.1828130 & 0.1374690 & 0.1255310 & 0.0860480 \\ 0.0414730 & 0.0035617 & -0.0889779 & 0.0076922 & 0.2894334 \end{bmatrix}.$$

The corresponding eigenvalues are returned in W:

$$W = [0.4327872 \quad 0.6636626 \quad 0.9438588 \quad 1.1092844 \quad 1.4923532].$$

## 75.10 Generalized Nonsymmetric Eigenproblems

---

### Definitions:

The generalized nonsymmetric eigenvalue problem (GNEP) is to find the eigenvalues,  $\lambda$ , and corresponding (right) eigenvectors,  $\mathbf{x} \neq 0$ , such that

$$A\mathbf{x} = \lambda B\mathbf{x} \tag{75.13}$$

and optionally, the corresponding left eigenvectors  $\mathbf{y} \neq 0$ , such that

$$\mathbf{y}^* A = \lambda \mathbf{y}^* B, \quad (75.14)$$

where  $A$  and  $B$  are  $n$ -by- $n$  matrices. In this section the terms *right eigenvector* and *left eigenvector* are used as just defined.

### Backgrounds:

Sometimes an equivalent notation is used to refer to the GNEP of the pair  $(A, B)$ . The GNEP can be solved via the generalized Schur decomposition of the pair  $(A, B)$ , defined in the real case as

$$A = QSZ^T, \quad B = QTZ^T,$$

where  $Q$  and  $Z$  are orthogonal matrices,  $T$  is upper triangular, and  $S$  is an upper quasi-triangular matrix with 1-by-1 and 2-by-2 diagonal blocks, the 2-by-2 blocks corresponding to complex conjugate pairs of eigenvalues. In the complex case, the generalized Schur decomposition is

$$A = QSZ^*, \quad B = QTZ^*,$$

where  $Q$  and  $Z$  are unitary and  $S$  and  $T$  are both upper triangular. The columns of  $Q$  and  $Z$  are called left and right generalized Schur vectors and span pairs of deflating subspaces of  $A$  and  $B$ . Deflating subspaces are a generalization of invariant subspaces: For each  $k$ ,  $1 \leq k \leq n$ , the first  $k$  columns of  $Z$  span a right deflating subspace mapped by both  $A$  and  $B$  into a left deflating subspace spanned by the first  $k$  columns of  $Q$ . It is possible to order the generalized Schur form so that any desired subset of  $k$  eigenvalues occupies the  $k$  leading position on the diagonal of  $(S, T)$ . (See Chapter 43 and Chapter 15 for more information on generalized eigenvalue problems.)

### Driver Routines:

Both the simple and expert drivers are provided in LAPACK. The simple driver xGGEV computes all eigenvalues of the pair  $(A, B)$ , and optionally the left and/or right eigenvectors. The expert driver xGGEVX performs the same task as the simple driver routines; in addition, it also balances the matrix pair to try to improve the conditioning of the eigenvalues and eigenvectors, and computes the condition numbers for the eigenvalues and/or left and right eigenvectors.

### Examples:

Let us show how to use the simple driver SGGEV to solve the GNEPs (75.13) and (75.14). SGGEV first reduces the pair  $(A, B)$  to generalized upper Hessenberg form  $(H, R)$ , where  $H$  is upper Hessenberg (zero below the first lower subdiagonal) and  $R$  is upper triangular. Then SGGEV computes the generalized Schur form  $(S, T)$  of the generalized upper Hessenberg form  $(H, R)$ , using an QZ algorithm. The eigenvalues are computed from the diagonals of  $(S, T)$ . Finally, SGGEV computes left and/or right eigenvectors if requested. SGGEV has the following calling sequence:

```
CALL SGGEV( JOBVL, JOBVR, N, A, LDA, B, LDB, ALPHAR, ALPHAI, BETA, VL,
LDVL, VR, LDVR, WORK, LWORK, INFO )
```

Input to SGGEV:

JOBVL, JOBVR: = 'N', do not compute the left and/or right eigenvectors;  
= 'V', compute the left and/or right eigenvectors.

N: The order of the matrices  $A$  and  $B$ .  $N \geq 0$ .

A, LDA: The matrix  $A$  and the leading dimension of the array A.  $LDA \geq \max(1, N)$ .

B, LDB: The matrix  $B$  and the leading dimension of the array B.  $LDB \geq \max(1, N)$ .

LDVL, LDVR: The leading dimensions of the eigenvector matrices VL and VR. LDVL, LDVR  $\geq 1$ . If eigenvectors are required, then LDVL, LDVR  $\geq N$ .

WORK, LWORK: The workspace array and its length. LWORK  $\geq \max(1, 8 * N)$ . For good performance, LWORK must generally be larger.

If LWORK = -1, then a workspace query is assumed; the routine only calculates the optimal size of WORK, and returns this value in WORK(1) on return.

Output from SGGEV:

ALPHAR, ALPHAI, BETA: (ALPHAR( $j$ ) +  $i$  · ALPHAI( $j$ ))/BETA( $j$ ) for  $j = 1, 2, \dots, N$ , are the generalized eigenvalues. If ALPHAI( $j$ ) is zero, then the  $j$ th eigenvalue is real; if positive, then the  $j$ th and ( $j + 1$ )-st eigenvalues are a complex conjugate pair, with ALPHAI( $j + 1$ ) negative.

VL: If JOBVL = 'V', the left eigenvectors  $y_j$  are stored in the columns of VL, in the same order as their corresponding eigenvalues. If the  $j$ th eigenvalue is real, then  $y_j = \text{VL}(:, j)$ , the  $j$ th column of VL. If the  $j$ th and ( $j + 1$ )th eigenvalues form a complex conjugate pair, then  $y_j = \text{VL}(:, j) + i \cdot \text{VL}(:, j + 1)$  and  $y_{j+1} = \text{VL}(:, j) - i \cdot \text{VL}(:, j + 1)$ .

VR: If JOBVR = 'V', the right eigenvectors  $x_j$  are stored one after another in the columns of VR, in the same order as their eigenvalues. If the  $j$ th eigenvalue is real, then  $x_j = \text{VR}(:, j)$ , the  $j$ th column of VR. If the  $j$ th and ( $j + 1$ )th eigenvalues form a complex conjugate pair, then  $x_j = \text{VR}(:, j) + i \cdot \text{VR}(:, j + 1)$  and  $x_{j+1} = \text{VR}(:, j) - i \cdot \text{VR}(:, j + 1)$ .

WORK: If INFO = 0, WORK(1) returns the optimal LWORK.

INFO: INFO = 0 if successful exit. If INFO = - $j$ , the  $j$ th argument had an illegal value. If INFO = 1, . . . , N, then the QZ iteration failed. No eigenvectors have been calculated, but ALPHAR( $j$ ), ALPHAI( $j$ ), and BETA( $j$ ) should be correct for  $j = \text{INFO} + 1, \dots, N$ . If INFO = N+1, then other than QZ iteration failed in SHGEQZ. If INFO = N+2, then error return from STGEVC.

Note that the quotients ALPHAR( $j$ )/BETA( $j$ ) and ALPHAI( $j$ )/BETA( $j$ ) may easily over- or underflow, and BETA( $j$ ) may even be zero. Thus, the user should avoid naively computing the ratio. However, ALPHAR and ALPHAI will be always less than and usually comparable to  $\|A\|$  in magnitude, and BETA always less than and usually comparable to  $\|B\|$ .

Let us demonstrate the use of SGGEV in solving the GNEP of the following 6-by-6 matrices  $A$  and  $B$ :

$$A = \begin{bmatrix} 50 & -60 & 50 & -27 & 6 & 6 \\ 38 & -28 & 27 & -17 & 5 & 5 \\ 27 & -17 & 27 & -17 & 5 & 5 \\ 27 & -28 & 38 & -17 & 5 & 5 \\ 27 & -28 & 27 & -17 & 16 & 5 \\ 27 & -28 & 27 & -17 & 5 & 16 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 16 & 5 & 5 & 5 & -6 & 5 \\ 5 & 16 & 5 & 5 & -6 & 5 \\ 5 & 5 & 16 & 5 & -6 & 5 \\ 5 & 5 & 5 & 16 & -6 & 5 \\ 5 & 5 & 5 & 5 & -6 & 16 \\ 6 & 6 & 6 & 6 & -5 & 6 \end{bmatrix}.$$

The exact eigenvalues are  $\frac{1}{2} + i \cdot \frac{\sqrt{3}}{2}$ ,  $\frac{1}{2} + i \cdot \frac{\sqrt{3}}{2}$ ,  $\frac{1}{2} - i \cdot \frac{\sqrt{3}}{2}$ ,  $\frac{1}{2} - i \cdot \frac{\sqrt{3}}{2}$ ,  $\infty$ ,  $\infty$ . Upon calling SGGEV with  $N = 6$ , LWORK = 48, on exit, arrays ALPHAR, ALPHAI, and BETA are

$$\begin{aligned} \text{ALPHAR} &= \begin{bmatrix} -25.7687130 & 6.5193458 & 5.8156629 & 5.8464251 & 5.5058141 & 11.2021322 \end{bmatrix}, \\ \text{ALPHAI} &= \begin{bmatrix} 0.0000000 & 11.2832556 & -10.0653677 & 10.1340599 & -9.5436525 & 0.0000000 \end{bmatrix}, \\ \text{BETA} &= \begin{bmatrix} 0.0000000 & 13.0169611 & 11.6119413 & 11.7124090 & 11.0300474 & 0.0000000 \end{bmatrix}. \end{aligned}$$

Therefore, there are two infinite eigenvalues corresponding to  $\text{BETA}(1) = \text{BETA}(6) = 0$  and four finite eigenvalues  $\lambda_j = (\text{ALPHAR}(j) + i \cdot \text{ALPHAI}(j))/\text{BETA}(j)$  for  $j = 2, 3, 4, 5$ .

$$(\text{ALPHAR}(2:5) + i \cdot \text{ALPHAI}(2:5))/\text{BETA}(2:5) = \begin{bmatrix} 0.50083 + i \cdot 0.86681 \\ 0.50083 - i \cdot 0.86681 \\ 0.49917 + i \cdot 0.86524 \\ 0.49917 - i \cdot 0.86524 \end{bmatrix}.$$

The left eigenvectors  $\mathbf{y}_j$  are stored in VL. Since  $\text{ALPHAI}(1) = \text{ALPHAI}(6) = 0$ ,  $\mathbf{y}_1 = \text{VL}(:, 1)$  and  $\mathbf{y}_6 = \text{VL}(:, 6)$ . The second and third eigenvalues form a complex conjugate pair, the  $\mathbf{y}_2 = \text{VL}(:, 2) + i \cdot \text{VL}(:, 3)$  and  $\mathbf{y}_3 = \text{VL}(:, 2) - i \cdot \text{VL}(:, 3)$ . Similarly,  $\mathbf{y}_4 = \text{VL}(:, 4) + i \cdot \text{VL}(:, 5)$  and  $\mathbf{y}_5 = \text{VL}(:, 4) - i \cdot \text{VL}(:, 5)$ . If we place all the left eigenvectors in a matrix  $Y$ , where  $Y = [\mathbf{y}_1, \mathbf{y}_2, \mathbf{y}_3, \mathbf{y}_4, \mathbf{y}_5, \mathbf{y}_6]$ , we have

$$Y = \begin{bmatrix} -0.1666666 & 0.2632965 + i \cdot 0.3214956 & 0.2632965 - i \cdot 0.3214956 & -0.4613968 + i \cdot 0.1902102 & -0.4613968 - i \cdot 0.1902102 & 0.1666667 \\ -0.1666666 & -0.2834885 - i \cdot 0.7165115 & -0.2834885 + i \cdot 0.7165115 & 0.9231794 - i \cdot 0.0765849 & 0.9231794 + i \cdot 0.0765849 & 0.1666667 \\ -0.1666666 & 0.1623165 + i \cdot 0.7526108 & 0.1623165 - i \cdot 0.7526108 & -0.9240005 - i \cdot 0.0759995 & -0.9240005 + i \cdot 0.0759995 & 0.1666667 \\ -0.1666666 & 0.0396326 - i \cdot 0.4130635 & 0.0396326 + i \cdot 0.4130635 & 0.4619284 + i \cdot 0.1907958 & 0.4619284 - i \cdot 0.1907958 & 0.1666666 \\ -0.1666671 & -0.0605860 + i \cdot 0.0184893 & -0.0605860 - i \cdot 0.0184893 & 0.0000969 - i \cdot 0.0761408 & 0.0000969 + i \cdot 0.0761408 & 0.1666666 \\ 1.0000000 & -0.0605855 + i \cdot 0.0184900 & -0.0605855 - i \cdot 0.0184900 & 0.0000959 - i \cdot 0.0761405 & 0.0000959 + i \cdot 0.0761405 & -1.0000000 \end{bmatrix}.$$

The right eigenvectors can be recovered from VR in a way similar to the left eigenvectors. If we place all the right eigenvectors in a matrix  $X$ , where  $X = [\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3, \mathbf{x}_4, \mathbf{x}_5, \mathbf{x}_6]$ , we have

$$U = \begin{bmatrix} 0.1666672 & -0.2039835 - i \cdot 0.5848466 & -0.2039835 + i \cdot 0.5848466 & 0.5722237 - i \cdot 0.0237538 & 0.5722237 + i \cdot 0.0237538 & 0.1666672 \\ 0.1666664 & -0.7090308 - i \cdot 0.2908980 & -0.7090308 + i \cdot 0.2908980 & 0.4485306 - i \cdot 0.5514694 & 0.4485306 + i \cdot 0.5514694 & 0.1666664 \\ 0.1666666 & -0.7071815 + i \cdot 0.2928185 & -0.7071815 - i \cdot 0.2928185 & -0.0709520 - i \cdot 0.7082051 & -0.0709520 + i \cdot 0.7082051 & 0.1666666 \\ 0.1666666 & -0.2013957 + i \cdot 0.5829236 & -0.2013957 - i \cdot 0.5829236 & -0.4667411 - i \cdot 0.3361499 & -0.4667411 + i \cdot 0.3361499 & 0.1666666 \\ 1.0000000 & -0.2023994 + i \cdot 0.0000001 & -0.2023994 - i \cdot 0.0000001 & 0.0536732 - i \cdot 0.1799536 & 0.0536732 + i \cdot 0.1799536 & 1.0000000 \\ 0.1666666 & -0.2023991 - i \cdot 0.0000002 & -0.2023991 + i \cdot 0.0000002 & 0.0536734 - i \cdot 0.1799532 & 0.0536734 + i \cdot 0.1799532 & 0.1666664 \end{bmatrix}.$$

## 75.11 Generalized Singular Value Decomposition

### Definitions:

The generalized (or quotient) singular value decomposition (GSVD or QSVD) of an  $m$ -by- $n$  matrix  $A$  and a  $p$ -by- $n$  matrix  $B$  is given by the pair of factorizations

$$A = U \Sigma_1 \begin{bmatrix} 0 & R \end{bmatrix} Q^T \quad \text{and} \quad B = V \Sigma_2 \begin{bmatrix} 0 & R \end{bmatrix} Q^T. \quad (75.15)$$

The matrices in these factorizations have the following properties:

- $U$  is  $m$ -by- $m$ ,  $V$  is  $p$ -by- $p$ ,  $Q$  is  $n$ -by- $n$ , and all three matrices are orthogonal. If  $A$  and  $B$  are complex, these matrices are unitary instead of orthogonal, and  $Q^T$  should be replaced by  $Q^*$  in the pair of factorizations.
- $R$  is  $r$ -by- $r$ , upper triangular and nonsingular.  $\begin{bmatrix} 0 & R \end{bmatrix}$  is  $r$ -by- $n$  (in other words, the 0 is an  $r$ -by- $(n-r)$  zero matrix). The integer  $r$  is the rank of  $\begin{bmatrix} A \\ B \end{bmatrix}$ .
- $\Sigma_1$  is  $m$ -by- $r$  and  $\Sigma_2$  is  $p$ -by- $r$ . Both are real, nonnegative, and diagonal, satisfying  $\Sigma_1^T \Sigma_1 + \Sigma_2^T \Sigma_2 = I$ . Write  $\Sigma_1^T \Sigma_1 = \text{diag}(\alpha_1^2, \dots, \alpha_r^2)$  and  $\Sigma_2^T \Sigma_2 = \text{diag}(\beta_1^2, \dots, \beta_r^2)$ . The ratios  $\alpha_j/\beta_j$  for  $j = 1, 2, \dots, r$  are called the *generalized singular values*.

$\Sigma_1$  and  $\Sigma_2$  have the following detailed structures, depending on whether  $m-r \geq 0$  or  $m-r < 0$ .

- In the first case, when  $m - r \geq 0$ ,

$$\Sigma_1 = \begin{matrix} & & k & \ell \\ & & \left( \begin{array}{cc} I & 0 \\ 0 & C \\ 0 & 0 \end{array} \right) \\ & & m-k-\ell & \end{matrix} \quad \text{and} \quad \Sigma_2 = \begin{matrix} & & k & \ell \\ & & \left( \begin{array}{cc} 0 & S \\ 0 & 0 \end{array} \right) \\ & & p-\ell & \end{matrix}. \quad (75.16)$$

Here  $k + \ell = r$ , and  $\ell$  is the rank of  $B$ .  $C$  and  $S$  are diagonal matrices satisfying  $C^2 + S^2 = I$ , and  $S$  is nonsingular. Let  $c_j$  and  $s_j$  be the diagonal entries of  $C$  and  $S$ , respectively. Then we have  $\alpha_1 = \cdots = \alpha_k = 1$ ,  $\alpha_{k+j} = c_j$  for  $j = 1, \dots, \ell$ ,  $\beta_1 = \cdots = \beta_k = 0$ , and  $\beta_{k+j} = s_j$  for  $j = 1, \dots, \ell$ . Thus, the first  $k$  generalized singular values  $\alpha_1/\beta_1, \dots, \alpha_k/\beta_k$  are infinite and the remaining  $\ell$  generalized singular values are finite.

- In the second case, when  $m - r < 0$ ,

$$\Sigma_1 = \begin{matrix} & & k & m-k & k+\ell-m \\ & & \left( \begin{array}{ccc} I & 0 & 0 \\ 0 & C & 0 \end{array} \right) \\ & & m-k & & \end{matrix} \quad \text{and} \quad \Sigma_2 = \begin{matrix} & & k & m-k & k+\ell-m \\ & & \left( \begin{array}{ccc} 0 & S & 0 \\ 0 & 0 & I \\ 0 & 0 & 0 \end{array} \right) \\ & & m-k & & \\ & & k+\ell-m & & \\ & & p-\ell & & \end{matrix}. \quad (75.17)$$

Again,  $k + \ell = r$ , and  $\ell$  is the rank of  $B$ .  $C$  and  $S$  are diagonal matrices satisfying  $C^2 + S^2 = I$ , and  $S$  is nonsingular. Let  $c_j$  and  $s_j$  be the diagonal entries of  $C$  and  $S$ , respectively. Then we have  $\alpha_1 = \cdots = \alpha_k = 1$ ,  $\alpha_{k+j} = c_j$  for  $j = 1, \dots, m - k$ ,  $\alpha_{m+1} = \cdots = \alpha_r = 0$ , and  $\beta_1 = \cdots = \beta_k = 0$ ,  $\beta_{k+j} = s_j$  for  $j = 1, \dots, m - k$ ,  $\beta_{m+1} = \cdots = \beta_r = 1$ . Thus, the first  $k$  generalized singular values  $\alpha_1/\beta_1, \dots, \alpha_k/\beta_k$  are infinite, and the remaining  $\ell$  generalized singular values are finite.

### Backgrounds:

Here are some important special cases of the QSVD. First, when  $B$  is square and nonsingular, then  $r = n$  and the QSVD of  $A$  and  $B$  is equivalent to the SVD of  $AB^{-1}$ , where the singular values of  $AB^{-1}$  are equal to the generalized singular values of  $A$  and  $B$ :

$$AB^{-1} = (U\Sigma_1RQ^T)(V\Sigma_2RQ^T)^{-1} = U(\Sigma_1\Sigma_2^{-1})V^T.$$

Second, if the columns of  $\begin{bmatrix} A^T & B^T \end{bmatrix}^T$  are orthonormal, then  $r = n$ ,  $R = I$ , and the QSVD of  $A$  and  $B$  is equivalent to the CS (Cosine-Sine) decomposition of  $\begin{bmatrix} A^T & B^T \end{bmatrix}^T$ :

$$\begin{bmatrix} A \\ B \end{bmatrix} = \begin{bmatrix} U & 0 \\ 0 & V \end{bmatrix} \begin{bmatrix} \Sigma_1 \\ \Sigma_2 \end{bmatrix} Q^T.$$

Third, the generalized eigenvalues and eigenvectors of the pencil  $A^T A - \lambda B^T B$  can be expressed in terms of the QSVD of  $A$  and  $B$ , namely,

$$X^T A^T A X = \begin{bmatrix} 0 & 0 \\ 0 & \Sigma_1^T \Sigma_1 \end{bmatrix} \quad \text{and} \quad X^T B^T B X = \begin{bmatrix} 0 & 0 \\ 0 & \Sigma_2^T \Sigma_2 \end{bmatrix},$$

where  $X = Q \begin{bmatrix} I & 0 \\ 0 & R^{-1} \end{bmatrix}$ . Therefore, the columns of  $X$  are the eigenvectors of  $A^T A - \lambda B^T B$ , and the “nontrivial” eigenvalues are the squares of the generalized singular values. “Trivial” eigenvalues are those corresponding to the leading  $n - r$  columns of  $X$ , which span the common null space of  $A^T A$  and  $B^T B$ .

The “trivial eigenvalues” are not well defined.<sup>1</sup> (See Chapter 15 for more information on generalized singular value problems.)

### Driver Routines:

The driver routine xGGSVD computes the GSVD (75.15) of  $A$  and  $B$ .

### Examples:

Let us show how to use the driver routine SGGSD to compute the QSVD (75.15). SGGSD first reduces the matrices  $A$  and  $B$  to a pair of triangular matrices, and then use a Jacobi-like method to compute the QSVD of the triangular pair. SGGSD has the following calling sequence:

```
CALL SGGSD( JOBU, JOBV, JOBQ, M, N, P, K, L, A, LDA, B, LDB, ALPHA,
BETA, U, LDU, V, LDV, Q, LDQ, WORK, IWORK, INFO )
```

Input to SGGSD:

JOBU, JOBV, JOBQ: = 'U', orthogonal matrices  $U$ ,  $V$  and  $Q$  are computed;  
= 'N', these orthogonal matrices are not computed.

M, N, P: The number of rows or columns of the matrices  $A$  and  $B$  as defined in (15)

A, LDA: The  $M$ -by- $N$  matrix  $A$  and the leading dimension of the array A.  $LDA \geq \max(1, M)$ .

B, LDB: The  $P$ -by- $N$  matrix  $B$  and the leading dimension of the array B.  $LDB \geq \max(1, P)$ .

LDU, LDV, LDQ: The leading dimension of the arrays U, V, and Q if the orthogonal matrices  $U$ ,  $V$ , and  $Q$  are computed,  $LDU \geq \max(1, M)$ ,  $LDV \geq \max(1, P)$ ,  $LDQ \geq \max(1, N)$ .

WORK: The real workspace array, dimension  $\max(3N, M, P) + N$ .

IWORK: The integer workspace array, dimension N.

Output from SGGSD:

K, L: The dimension of the subblocks described in the definition of GSVD.  $K + L$  is the effective numerical rank of the matrix  $\begin{bmatrix} A^T & B^T \end{bmatrix}^T$ .

A: The entire triangular matrix  $R$  is stored in  $A(1:K+L, N-K-L+1:N)$  if  $m - r \geq 0$ . Otherwise, the subblock  $R(1:m, 1:k+l)$  of  $R$  are stored in  $A(1:M, N-K-L+1:N)$ .

B: The subblock  $R(m+1:k+l, m+1:k+l)$  of  $R$  are stored in  $B(M-K+1:L, N+M-K-L+1:N)$  if  $m - r < 0$ .

ALPHA, BETA: The generalized singular value pairs;

$ALPHA(1:K) = 1$  and  $BETA(1:K) = 0$ .

- If  $M-K-L \geq 0$ , then  $ALPHA(K+1:K+L) = C$  and  $BETA(K+1:K+L) = S$ .
- If  $M-K-L < 0$ , then

$ALPHA(K+1:M) = C$  and  $ALPHA(M+1:K+L) = 0$ ,

$BETA(K+1:M) = S$  and  $BETA(M+1:K+L) = 1$ ;

And  $ALPHA(K+L+1:N) = 0$ ,  $BETA(K+L+1:N) = 0$ .

U, V, Q: Contains computed orthogonal matrices  $U$ ,  $V$ , and  $Q$  if requested.

<sup>1</sup>If we tried to compute the trivial eigenvalues in the same way as the nontrivial ones, that is by taking ratios of the leading  $n - r$  diagonal entries of  $X^T A^T A X$  and  $X^T B^T B X$ , we would get  $0/0$ .

INFO: INFO = 0 if successful exit. If INFO =  $-j$ , then the  $j$ th argument had an illegal value. If INFO = 1, the Jacobi-type procedure failed to converge.

Let us demonstrate the use of SGGSD in computing the QSVD of the following 6-by-5 matrices  $A$  and  $B$ :

$$A = \begin{bmatrix} 1 & 2 & 3 & 1 & 5 \\ 0 & 3 & 2 & 0 & 2 \\ 1 & 0 & 2 & 1 & 0 \\ 0 & 2 & 3 & 0 & -1 \\ 1 & 0 & 2 & 1 & 1 \\ 0 & 2 & 1 & 0 & 1 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 1 & -2 & 2 & 1 & 1 \\ 0 & 3 & 0 & 0 & 0 \\ 1 & -2 & 2 & 1 & 1 \\ 0 & 2 & 0 & 0 & 0 \\ 2 & -4 & 4 & 2 & 2 \\ 1 & 3 & 2 & 1 & 1 \end{bmatrix}.$$

Upon calling SGGSD with  $M = 6, P = 6, N = 5, LWORK = 20$ , we have  $K = 2$  and  $L = 2$ . The QSVD (75.15) of  $A$  and  $B$  falls in the first case (75.16) since  $M - K - L = 6 - 2 - 2 = 2 > 0$ . The arrays ALPHA and BETA are

$$\begin{aligned} \text{ALPHA} &= \begin{bmatrix} 1.0000000 & 1.0000000 & 0.1537885 & 0.5788464 & 0.0000000 \end{bmatrix}, \\ \text{BETA} &= \begin{bmatrix} 0.0000000 & 0.0000000 & 0.9881038 & 0.8154366 & 0.0000000 \end{bmatrix}. \end{aligned}$$

Hence,  $\Sigma_1$  and  $\Sigma_2$  have the structure as described in (75.16), namely,

$$\Sigma_1 = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0.1537885 & 0 \\ 0 & 0 & 0 & 0.5788464 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \quad \text{and} \quad \Sigma_2 = \begin{bmatrix} 0 & 0 & 0.9881038 & 0 \\ 0 & 0 & 0 & 0.8154366 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}.$$

The first two generalized singular values are infinite,  $\alpha_1/\beta_1 = \alpha_2/\beta_2 = \infty$ , and the remaining two generalized singular values are finite,  $\alpha_3/\beta_3 = 0.15564$  and  $\alpha_4/\beta_4 = 0.70986$ .

Furthermore, the array  $A(1:4, 2:5)$  contains the 4-by-4 upper triangular matrix  $R$  as defined in (75.15):

$$R = \begin{bmatrix} 3.6016991 & -1.7135643 & -0.2843603 & 1.8104467 \\ 0 & -2.6087811 & -4.2943931 & 5.1107349 \\ 0 & 0 & 6.9692163 & 3.5063875 \\ 0 & 0 & 0 & 7.3144341 \end{bmatrix}.$$

The orthogonal matrices  $U$ ,  $V$ , and  $Q$  are returned in the arrays  $U$ ,  $V$ , and  $Q$ , respectively:

$$\begin{aligned} U &= \begin{bmatrix} -0.6770154 & -0.4872811 & -0.4034495 & -0.2450049 & -0.2151961 & 0.1873468 \\ -0.0947438 & -0.5723576 & 0.4163284 & 0.1218751 & 0.0785425 & -0.6848933 \\ 0.2098812 & 0.0670342 & 0.2612190 & -0.7393155 & -0.5670457 & -0.1228532 \\ 0.6974092 & -0.5903998 & -0.3678919 & 0.0010751 & -0.0196356 & 0.1712235 \\ 0.0000000 & 0.0000001 & -0.0735656 & -0.6152450 & 0.7822418 & -0.0644937 \\ -0.0473719 & -0.2861788 & 0.6744684 & -0.0019711 & 0.1170180 & 0.6687696 \end{bmatrix}, \\ V &= \begin{bmatrix} -0.3017521 & -0.2581125 & 0.9018297 & -0.0002676 & -0.1695592 & -0.0166328 \\ 0.4354534 & -0.2679386 & 0.1028928 & 0.0704557 & 0.2595005 & -0.8097517 \\ -0.3017520 & -0.2581124 & -0.1784097 & -0.8828155 & -0.0002829 & -0.1764375 \\ 0.2903022 & -0.1786257 & -0.1298870 & -0.0008522 & -0.9259184 & -0.0980879 \\ -0.6035041 & -0.5162248 & -0.3568195 & 0.4625078 & -0.0224125 & -0.1660080 \\ 0.4240036 & -0.7046767 & -0.0097810 & -0.0419325 & 0.2146671 & 0.5250862 \end{bmatrix}, \\ Q &= \begin{bmatrix} -0.7071068 & -0.2073452 & -0.5604916 & -0.0112638 & -0.3777966 \\ 0.0000000 & 0.0000000 & 0.0000000 & 0.9995558 & -0.0298012 \\ 0.0000001 & 0.5853096 & 0.2932303 & -0.0225276 & -0.7555932 \\ 0.7071067 & -0.2073452 & -0.5604916 & -0.0112638 & -0.3777965 \\ -0.0000001 & -0.7559289 & 0.5345224 & -0.0112638 & -0.3777965 \end{bmatrix}. \end{aligned}$$

D. C. Sorensen  
*Rice University*

ARPACK is a library of Fortran77 subroutines designed to compute a selected subset of the eigenvalues of a large matrix. It is based upon a limited storage scheme called the implicitly restarted Arnoldi method (IRAM) [Sor92]. This software can solve largescale non-Hermitian or Hermitian (standard and generalized) eigenvalue problems. The IRA method is described in Chapter 44, Implicitly Restarted Arnoldi Method.

This chapter describes the design and performance features of the eigenvalue software ARPACK and gives a brief discussion of usage. More detailed descriptions are available in the papers [Sor92] and [Sor02] and in the ARPACK Users' Guide [LSY98].

The design goals were robustness, efficiency, and portability. Two very important principles that have helped to achieve these goals are modularity and independence from specific vendor supplied communication and performance libraries.

In this chapter, multiplication of a vector  $\mathbf{x}$  by a scalar  $\lambda$  is denoted by  $\mathbf{x}\lambda$  so that the eigenvector-eigenvalue relation is  $A\mathbf{x} = \mathbf{x}\lambda$ . This convention provides for direct generalizations to the more general invariant subspace relations  $AX = XH$ , where  $X$  is an  $n \times k$  matrix and  $H$  is a  $k \times k$  matrix with  $k < n$ .

### 76.1 The ARPACK Software

---

The ARPACK software has been used on a wide range of applications. P\_ARPACK is a parallel extension to the ARPACK library and is targeted for distributed memory message passing systems. Both packages are freely available and can be downloaded at <http://www.caam.rice.edu/software/ARPACK/>.

**Features** (of ARPACK and P\_ARPACK):

1. A reverse communication interface.
2. Computes  $k$  eigenvalues that satisfy a user-specified criterion, such as largest real part, largest absolute value, etc.
3. A fixed predetermined storage requirement of  $n \cdot \mathcal{O}(k) + \mathcal{O}(k^2)$  words.
4. Driver routines are included as templates for implementing various spectral transformations to enhance convergence and to solve the generalized eigenvalue problem, or the SVD problem.
5. Special consideration is given to the generalized problem  $A\mathbf{x} = M\mathbf{x}\lambda$  for singular or ill-conditioned symmetric positive semidefinite  $M$ .
6. A Schur basis of dimension  $k$  that is numerically orthogonal to working precision is always computed. These are also eigenvectors in the Hermitian case. In the non-Hermitian case eigenvectors are available on request. Eigenvalues are computed to a user specified accuracy.

## 76.2 Reverse Communication

---

Reverse communication is a means to overcome certain restrictions in the Fortran language; with reverse communication, control is returned to the calling program when interaction with the matrix is required. This is a convenient interface for experienced users. However, it may be more challenging for inexperienced users. It has proven to be extremely useful for interfacing with large application codes.

This interface avoids having to express a matrix-vector product through a subroutine with a fixed calling sequence or to provide a sparse matrix with a specific data structure. The user is free to choose any convenient data structure for the matrix representation.

**Examples:**

1. A typical use of this interface is illustrated as follows:

```

10  continue
    call snaupd (ido, bmat, n, which,..., workd,..., info)
    if (ido .eq. newprod) then
        call matvec ('A', n, workd(ipntr(1)), workd(ipntr(2)))
    else
        return
    endif
    go to 10
%
```

This shows a code segment of the routine the user must write to set up the reverse communication call to the top level ARPACK routine `snaupd` to solve a nonsymmetric eigenvalue problem in single precision. With reverse communication, control is returned to the calling program when interaction with the matrix  $A$  is required. The action requested of the calling program is specified by the reverse communication parameter `ido`, which is set in the call to `snaupd`. In this case, there are two possible requests indicated by `ido`. One action is to multiply the vector held in the array `workd` beginning at location `ipntr(1)` by  $A$  and then place the result in the array `workd` beginning at location `ipntr(2)`. The other action is to halt the iteration due to successful convergence or due to an error.

When the parameter `ido` indicates a new matrix vector product is required, a call is made to a subroutine `matvec` in this example. However, it is only necessary to supply the action of the matrix on the specified vector and put the result in the designated location. No specified data structure is imposed on  $A$  and if a subroutine is used, no particular calling sequence is specified. Because of this, reverse communication is very flexible and even provides a convenient way to use ARPACK interfaced with code written in another language, such as C or C++.

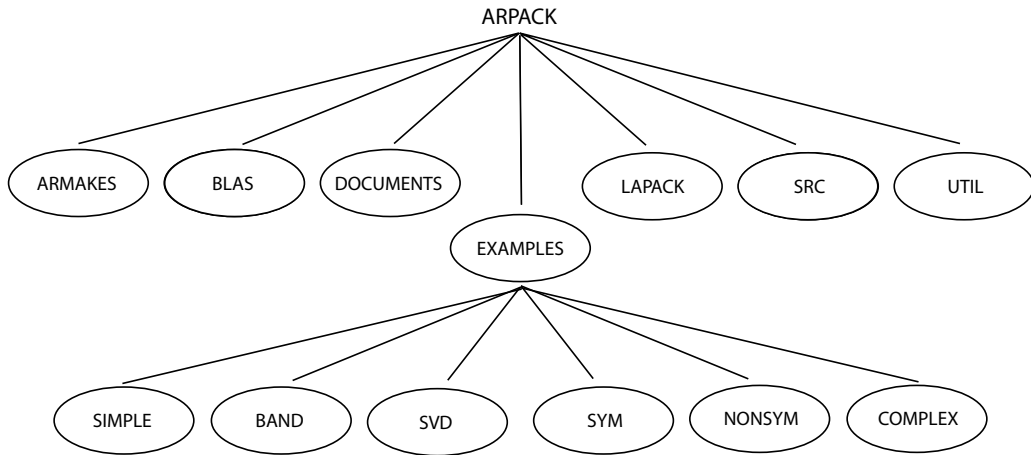

FIGURE 76.1 The ARPACK directory structure.

## 76.3 Directory Structure and Contents

---

Once the ARPACK software has been downloaded and unbundled, a directory structure will have been created as pictured in Figure 76.1.

### Subdirectories:

1. The `ARMAKES` subdirectory contains sample files with machine specific information needed during the building of the ARPACK library.
2. The `BLAS` and `LAPACK` subdirectories contain the necessary codes from those libraries.
3. The `DOCUMENTS` subdirectory contains files that have example templates showing how to invoke the different computational modes offered by ARPACK.
4. Example driver programs illustrating all of the computational modes, data types, and precisions may be found in the `EXAMPLES` directory.
5. Programs for banded, complex, nonsymmetric, symmetric eigenvalue problems, and singular value decomposition may be found in the directories `BAND`, `COMPLEX`, `NONSYM`, `SYM`, `SVD`.
6. The `README` files in each subdirectory provide further information.
7. The `SRC` subdirectory contains all the ARPACK source codes.
8. The `UTIL` subdirectory contains the various utility routines needed for printing results and timing the execution of the ARPACK subroutines.

## 76.4 Naming Conventions, Precisions, and Types

---

1. ARPACK has two interface routines that must be invoked by the user. They are `__aupd` that implements the IRAM and `__eupd` to post process the results of `__aupd`.
2. The user may request an orthogonal basis for a selected invariant subspace or eigenvectors corresponding to selected eigenvalues with `__eupd`. If a spectral transformation is used, `__eupd` automatically transforms the computed eigenvalues of the shift-invert operator to those of the original problem.
3. Both `__aupd` and `__eupd` are available for several combinations of problem type (symmetric and nonsymmetric), data type (real, complex), and precision (single, double). The first letter (`s`, `d`, `c`, `z`) denotes precision and data type. The second letter denotes whether the problem is symmetric (`s`) or nonsymmetric (`n`).

4. Thus, `dnaupd` is the routine to use if the problem is a double precision nonsymmetric (standard or generalized) problem and `dneupd` is the post-processing routine to use in conjunction with `dnaupd` to recover eigenvalues and eigenvectors of the original problem upon convergence. For complex matrices, one should use `_naupd` and `_neupd` with the first letter either `c` or `z` regardless of whether the problem is Hermitian or non-Hermitian.

## 76.5 Getting Started

---

Perhaps the easiest way to rapidly become acquainted with the possible uses of ARPACK is to run the example driver routines that have been supplied for each of the computational modes. These may be used as templates and adapted to solve specific problems. To get started, it is recommended that the user execute driver routines from the `SIMPLE` subdirectory.

The `dssimp` driver implements the reverse communication interface to the routine `dsaupd` that will compute a few eigenvalues and eigenvectors of a symmetric matrix. It illustrates the simplest case and has exactly the same structure as shown previously except that the top level routine is `dsaupd` instead of `snaupd`. The full call issued by `dssimp` is as follows.

```
call dsaupd ( ido, bmat, n, which, nev, tol, resid,
&           ncv, v, ldv, iparam, ipntr, workd,
&           workl, lworkl, info )
```

This `dssimp` driver is intended to serve as template to enable a user to create a program to use `dsaupd` on a specific problem in the simplest computational mode. All of the driver programs in the various `EXAMPLES` subdirectories are intended to be used as templates. They all follow the same principle, but the usage is slightly more complicated.

The only thing that must be supplied in order to use this routine on your problem is to change the array dimensions and to supply a means to compute the matrix-vector product

$$\mathbf{w} \leftarrow A\mathbf{v}$$

on request from `dsaupd`. The selection of which eigenvalues to compute may be altered by changing the parameter `which`.

Once usage of `dsaupd` in the simplest mode is understood, it will be easier to explore the other available options such as solving generalized eigenvalue problems using a shift-invert computational mode.

If the computation is successful, `dsaupd` indicates that convergence has taken place through the parameter `ido`. Then various steps may be taken to recover the results in a useful form. This is done through the subroutine `dseupd` as illustrated below.

```
call dseupd(rvec, howmny, select, d, v, ldv, sigma, bmat,
&          n, which, nev, tol, resid, ncv, v, ldv,
&          iparam, ipntr, workd, workl, lworkl, ierr)
```

Eigenvalues are returned in the first column of the two-dimensional array `d` and the corresponding eigenvectors are returned in the first `NCONV` (`=IPARAM(5)`) columns of the two-dimensional array `v` if requested. Otherwise, an orthogonal basis for the invariant subspace corresponding to the eigenvalues in `d` is returned in `v`.

The input parameters that must be specified are

- The logical variable `rvec = .true.` if eigenvectors are requested, `.false.` if only eigenvalues are desired.
- The character\*1 parameter `howmny` that specifies how many eigenvectors are desired.  
`howmny = 'A':` compute `nev` eigenvectors;  
`howmny = 'S':` compute some of the eigenvectors,  
 specified by the logical array `select`.

- `sigma` should contain the value of the shift used if `iparam(7) = 3, 4, 5`. It is not referenced if `iparam(7) = 1` or `2`.

When requested, the eigenvectors returned by `dseupd` are normalized to have unit length with respect to the  $M$  semi-inner product that was used. Thus, if  $M = I$ , they will have unit length in the standard 2-norm. In general, a computed eigenvector  $\mathbf{x}$  will satisfy  $1 = \mathbf{x}^T M \mathbf{x}$ .

## 76.6 Setting Up the Problem

---

To set up the problem, the user needs to specify the number of eigenvalues to compute which eigenvalues are of interest, the number of basis vectors to use, and whether or not the problem is standard or generalized. These items are controlled by the following parameters.

Parameters for the top-level ARPACK routines:

`ido` — Reverse communication flag.

`nev` — The number of requested eigenvalues to compute.

`ncv` — The number of Arnoldi basis vectors to use through the course of the computation.

`bmat` — Indicates whether the problem is standard `bmat = 'I'` or generalized (`bmat = 'G'`).

`which` — Specifies which eigenvalues of  $A$  are to be computed.

`tol` — Specifies the relative accuracy to which eigenvalues are to be computed.

`iparam` — Specifies the computational mode, number of IRAM iterations, the implicit shift strategy, and outputs various informational parameters upon completion of IRAM.

The value of `ncv` must be at least `nev + 1`. The options available for `which` include 'LA' and 'SA' for the algebraically largest and smallest eigenvalues, 'LM' and 'SM' for the eigenvalues of largest or smallest magnitude, and 'BE' for the simultaneous computation of the eigenvalues at both ends of the spectrum. For a given problem, some of these options may converge more rapidly than others due to the approximation properties of the IRAM as well as the distribution of the eigenvalues of  $A$ . Convergence behavior can be quite different for various settings of the `which` parameter. For example, if the matrix is indefinite then setting `which = 'SM'` will require interior eigenvalues to be computed and the Arnoldi/Lanczos process may require many steps before these are resolved.

For a given `ncv`, the computational work required is proportional to  $n \cdot ncv^2$  FLOPS. Setting `nev` and `ncv` for optimal performance is very much problem dependent. If possible, it is best to avoid setting `nev` in a way that will split clusters of eigenvalues. For example, if the five smallest eigenvalues are positive and on the order of  $10^{-4}$  and the sixth smallest eigenvalue is on the order of  $10^{-1}$ , then it is probably better to ask for `nev = 5` than for `nev = 3`, even if the three smallest are the only ones of interest.

Setting the optimal value of `ncv` relative to `nev` is not completely understood. As with the choice of `which`, it depends upon the underlying approximation properties of the IRAM as well as the distribution of the eigenvalues of  $A$ . As a rule of thumb,  $ncv \geq 2 \cdot nev$  is reasonable. There are tradeoffs due to the cost of the user supplied matrix-vector products and the cost of the implicit restart mechanism and the cost of maintaining the orthogonality of the Arnoldi vectors. If the user supplied matrix-vector product is relatively cheap, then a smaller value of `ncv` may lead to more user matrix-vector products, but an overall decrease in computation time.

### Storage Declarations:

The program is set up so that the setting of the three parameters `maxn`, `maxnev`, `maxncv` will automatically declare all of the work space needed to run `dsaupd` on a given problem.

The declarations allow a problem size of  $N \leq \text{maxn}$ , computation of  $nev \leq \text{maxnev}$  eigenvalues, and using at most  $ncv \leq \text{maxncv}$  Arnoldi basis vectors during the IRAM. The user may override the

```

Double precision
&          v(ldv,maxncv), workl(maxncv*(maxncv+8)),
&          workd(3*maxn), d(maxncv,2), resid(maxn),

```

FIGURE 76.2 Storage declarations needed for ARPACK subroutine `dsaupd`.

default settings used for the example problem by modifying `maxn`, `maxnev`, and `maxncv` in the following parameter statement in the `dssimp` code.

```

integer      maxn, maxnev, maxncv, ldv
parameter    (maxn=256, maxnev=10, maxncv=25, ldv=maxn)

```

These parameters are used in the code segment listed in Figure 76.2 for declaring all of the output and work arrays needed by the ARPACK subroutines `dsaupd` and `dseupd`. These will set the storage values in ARPACK arrays.

### Stopping Criterion:

The stopping criterion is determined by the user through specification of the parameter `tol`. The default value for `tol` is machine precision  $\epsilon_M$ . There are several things to consider when setting this parameter. In absence of all other considerations, one should expect a computed eigenvalue  $\lambda_c$  to roughly satisfy

$$|\lambda_c - \lambda_t| \leq \text{tol} \|A\|_2,$$

where  $\lambda_t$  is the eigenvalue of  $A$  nearest to  $\lambda_c$ . Typically, decreasing the value of `tol` will increase the work required to satisfy the stopping criterion. However, setting `tol` too large may cause eigenvalues to be missed when they are multiple or very tightly clustered. Typically, a fairly small setting of `tol` and a reasonably large setting of `ncv` is required to avoid missing multiple eigenvalues. However, some care must be taken. It is possible to set `tol` so small that convergence never occurs. There may be additional complications when the matrix  $A$  is nonnormal or when the eigenvalues of interest are clustered near the origin.

### Initial Parameter Settings:

The reverse communication flag is denoted by `ido`. This parameter must be initially set to 0 to signify the first call to `dsaupd`. Various algorithmic modes may be selected through the settings of the entries in the integer array `iparam`. The most important of these is the value of `iparam(7)`, which specifies the computational mode to use.

### Setting the Starting Vector:

The parameter `info` should be set to 0 on the initial call to `dsaupd` unless the user wants to supply the starting vector that initializes the IRAM. Normally, this default is a reasonable choice. However, if this eigenvalue calculation is one of a sequence of closely related problems, then convergence may be accelerated if a suitable starting vector is specified. Typical choices in this situation might be to use the final value of the starting vector from the previous eigenvalue calculation (that vector will already be in the first column of  $\mathcal{V}$ ) or to construct a starting vector by taking a linear combination of the computed eigenvectors from the previously converged eigenvalue calculation. If the starting vector is to be supplied, then it should be placed in the array `resid` and `info` should be set to 1 on entry to `dsaupd`. On completion, the parameter `info` may contain the value 0 indicating the iteration was successful or it may contain a nonzero value indicating an error or a warning condition. The meaning of a nonzero value returned in `info` may be found in the header comments of the subroutine `dsaupd`.

**Trace Debugging Capability:**

ARPACK provides a means to trace the progress of the computation as it proceeds. Various levels of output may be specified from no output (`level = 0`) to voluminous (`level = 3`). A detailed description of trace debugging may be found in [LSY98].

## 76.7 General Use of ARPACK

---

**The Shift and Invert Spectral Transformation Mode:**

The most general problem that may be solved with ARPACK is to compute a few selected eigenvalues and corresponding eigenvectors for

$$A\mathbf{x} = M\mathbf{x}\lambda,$$

where  $A$  and  $M$  are real or complex  $n \times n$  matrices.

The shift and invert spectral transformation is used to enhance convergence to a desired portion of the spectrum. If  $(\mathbf{x}, \lambda)$  is an eigen-pair for  $(A, M)$  and  $\sigma \neq \lambda$ , then

$$(A - \sigma M)^{-1}M\mathbf{x} = \mathbf{x}\nu \quad \text{where} \quad \nu = \frac{1}{\lambda - \sigma},$$

where we are requiring that  $A - \sigma M$  is nonsingular. Here it is possible for  $A$  or  $M$  to be singular, but they cannot have a nonzero null vector in common. This transformation is effective for finding eigenvalues near  $\sigma$  since the new eigenvalues  $\nu_j$  of  $C \equiv (A - \sigma M)^{-1}M$  that are largest in magnitude correspond to the new eigenvalues  $\lambda_j$  of the original problem that are nearest to the shift  $\sigma$  in absolute value. As discussed in Chapter 44, these transformed eigenvalues of largest magnitude are precisely the eigenvalues that are easy to compute with a Krylov method. Once they are found, they may be transformed back to eigenvalues of the original problem.

 **$M$  Is Hermitian Positive Definite:**

If  $M$  is Hermitian positive definite and well conditioned ( $\|M\| \cdot \|M^{-1}\|$  is of modest size), then computing the Cholesky factorization  $M = LL^*$  and converting  $A\mathbf{x} = M\mathbf{x}\lambda$  into

$$(L^{-1}AL^{-*})\mathbf{y} = \mathbf{y}\lambda, \quad \text{where} \quad L^*\mathbf{x} = \mathbf{y}$$

provides a transformation to a standard eigenvalue problem. In this case, a request for a matrix vector product would be satisfied with the following three steps:

1. Solve  $L^*\mathbf{z} = \mathbf{v}$  for  $\mathbf{z}$ .
2. Matrix-vector multiply  $\mathbf{z} \leftarrow A\mathbf{z}$ .
3. Solve  $L\mathbf{w} = \mathbf{z}$  for  $\mathbf{w}$ .

Upon convergence, a computed eigenvector  $\mathbf{y}$  for  $(L^{-1}AL^{-*})$  is converted to an eigenvector  $\mathbf{x}$  of the original problem by solving the triangular system  $L^*\mathbf{x} = \mathbf{y}$ . This transformation is most appropriate when  $A$  is Hermitian,  $M$  is Hermitian positive definite, and extremal eigenvalues are sought. This is because  $L^{-1}AL^{-*}$  will be Hermitian when  $A$  is the same.

If  $A$  is Hermitian positive definite and the smallest eigenvalues are sought, then it would be best to reverse the roles of  $A$  and  $M$  in the above description and ask for the largest algebraic eigenvalues or those of largest magnitude. Upon convergence, a computed eigenvalue  $\hat{\lambda}$  would then be converted to an eigenvalue of the original problem by the relation  $\lambda \leftarrow 1/\hat{\lambda}$ .

 **$M$  Is NOT Hermitian Positive Semidefinite:**

If neither  $A$  nor  $M$  is Hermitian positive semidefinite, then a direct transformation to standard form is required. One simple way to obtain a direct transformation to a standard eigenvalue problem  $C\mathbf{x} = \mathbf{x}\lambda$

is to multiply on the left by  $M^{-1}$ , which results in  $C = M^{-1}A$ . Of course, one should not perform this transformation explicitly since it will most likely convert a sparse problem into a dense one. If possible, one should obtain a direct factorization of  $M$  and when a matrix-vector product involving  $C$  is called for, it may be accomplished with the following two steps:

1. Matrix-vector multiply  $\mathbf{z} \leftarrow A\mathbf{v}$ .
2. Solve:  $M\mathbf{w} = \mathbf{z}$ .

Several problem dependent issues may modify this strategy. If  $M$  is singular or if one is interested in eigenvalues near a point  $\sigma$ , then a user may choose to work with  $C \equiv (A - \sigma M)^{-1}M$  but without using the  $M$ -inner products discussed previously. In this case the user will have to transform the converged eigenvalues  $v_j$  of  $C$  to eigenvalues  $\lambda_j$  of the original problem.

## 76.8 Using the Computational Modes

---

An extensive set of computational modes has been constructed to implement all of the shift-invert options mentioned previously. The problem set up is similar for all of the available computational modes. A detailed description of the reverse communication loop for the various modes (Shift-Invert for a Real Nonsymmetric Generalized Problem) is available in the users' guide [LSY98]. To use any of the modes listed below, the user is strongly urged to modify one of the driver routine **templates** that reside in the `EXAMPLES` directory.

### When to Use a Spectral Transformation:

The first thing to decide is whether the problem will require a spectral transformation. If the problem is generalized ( $M \neq I$ ), then a spectral transformation will be required. Such a transformation will most likely be needed for a standard problem if the desired eigenvalues are in the interior of the spectrum or if they are clustered at the desired part of the spectrum. Once this decision has been made and `OP` has been specified, an efficient means to implement the action of the operator `OP` on a vector must be devised. The expense of applying `OP` to a vector will of course have direct impact on performance.

Shift-invert spectral transformations may be implemented with or without the use of a weighted  $M$ -inner product. The relation between the eigenvalues of `OP` and the eigenvalues of the original problem must also be understood in order to make the appropriate specification of `which` in order to recover eigenvalues of interest for the original problem. The user must specify the number of eigenvalues to compute, which eigenvalues are of interest, the number of basis vectors to use, and whether or not the problem is standard or generalized.

### Computational Modes for Real Nonsymmetric Problems:

The following subroutines are used to solve nonsymmetric generalized eigenvalue problems in real arithmetic. These routines are appropriate when  $A$  is a general nonsymmetric matrix and  $M$  is symmetric and positive semidefinite. The reverse communication interface routine for the nonsymmetric double precision eigenvalue problem is `dnaupd`. The routine is called as shown below. The specification of which `nev` eigenvalues is controlled by the `character*2` argument `which`. The most commonly used options are listed below. There are templates available as indicated for each of these.

```
call dnaupd (ido, bmat, n, which, nev, tol, resid, ncv, v,
&           ldv, iparam, ipntr, workd, workl, lworkl, info)
```

There are three different shift-invert modes for nonsymmetric eigenvalue problems. These modes are specified by setting the parameter entry `iparam(7) = mode` where `mode = 1, 2, 3, or 4`.

In the following list, the specification of `OP` and  $B$  are given for the various modes. Also, the `iparam(7)` and `bmat` settings are listed along with the name of the sample driver for the given mode. Sample drivers

for the following modes may be found in the EXAMPLES/NONSYM subdirectory.

1. Regular mode (`iparam(7) = 1, bmat = 'I'` ).  
Use driver `dndrv1`.
  - (a) Solve  $Ax = x\lambda$  in regular mode.
  - (b)  $OP = A$  and  $B = I$ .
2. Shift-invert mode (`iparam(7) = 3, bmat = 'I'`).  
Use driver `dndrv2` with `sigma` a real shift.
  - (a) Solve  $Ax = x\lambda$  in shift-invert mode.
  - (b)  $OP = (A - \sigma I)^{-1}$  and  $B = I$ .
3. Regular inverse mode (`iparam(7) = 2, bmat = 'G'`).  
Use driver `dndrv3`.
  - (a) Solve  $Ax = Mx\lambda$  in regular inverse mode.
  - (b)  $OP = M^{-1}A$  and  $B = M$ .
4. Shift-invert mode (`iparam(7) = 3, bmat = 'G'`).  
Use driver `dndrv4` with `sigma` a real shift.
  - (a) Solve  $Ax = Mx\lambda$  in shift-invert mode.
  - (b)  $OP = (A - \sigma M)^{-1}M$  and  $B = M$ .

## 76.9 MATLAB'S® EIGS

MATLAB has adopted ARPACK for the computation of a selected subset of the eigenvalues of a large (sparse) matrix. The MATLAB function for this is called `eigs` and it is a MATLAB driver to a mex-file compilation of ARPACK. In fact, a user can directly reference this mex-file as `arpackc`. Exactly the same sort of interfaces discussed above can be written in MATLAB to drive `arpackc`.

However, it is far more convenient just to use the provided `eigs` function. The command `D = eigs(A)` returns a vector of the 6 eigenvalues of  $A$  of largest magnitude, while `[V,D] = eigs(A)` returns eigenvectors in  $V$  and the corresponding (6 largest magnitude) eigenvalues on the diagonal of the matrix  $D$ .

The command `eigs(A,M)` solves the generalized eigenvalue problem  $A*v = M*v*D$ . Here  $M$  must be symmetric (or Hermitian) positive definite and the same size as  $A$ . If  $M$  is nonsymmetric, this can also be handled directly, but the user will have to write and pass a function that will compute the action `w <- inv(A - sigma*M)* M*v` as needed. Of course, a sparse direct factorization of  $(A - \sigma*M)$  should be computed at the outset and reused to accomplish this action.

Other capabilities are easily utilized through `eigs`. The commands `eigs(A,k)` and `eigs(A,M,k)` return the  $k$  largest magnitude eigenvalues.

The commands `eigs(A,k,sigma)` and `eigs(A,M,k,sigma)` return  $k$  eigenvalues based on `sigma`, where `sigma` is either a scalar or one of the following strings: 'LM' or 'SM' - Largest or Smallest Magnitude

```
For real symmetric problems, SIGMA may also be:
'LA' or 'SA' - Largest or Smallest Algebraic
'BE' - Both Ends, one more from high end if K
        is odd
For nonsymmetric and complex problems, SIGMA
may also be:
'LR' or 'SR' - Largest or Smallest Real part
'LI' or 'SI' - Largest or Smallest Imaginary
part
```

If  $\sigma$  is a scalar including 0, `eigs` finds the eigenvalues in the complex plane closest to  $\sigma$ . The required sparse matrix factorizations are done automatically when a scalar is passed.

More control and flexibility can be obtained by using the commands `eigs(A,M,sigma,opts)` and `eigs(A,M,k,sigma,opts)` where `opts` is a struct. The fields of the struct `opts` will specify the following options:

```
opts.issym: symmetry of A or A-SIGMA*B
            represented by AFUN [{0} | 1]

opts.isreal: complexity of A or A-SIGMA*B
            represented by AFUN [0 | {1}]

opts.tol: convergence: Ritz estimate
          residual <= tol*NORM(A) [scalar | {eps}]

opts.maxit: maximum number of
           iterations [integer | {300}]

opts.p: number of Lanczos vectors:
       K+1<p<=N [integer | {2K}]

opts.v0: starting vector
       [N-by-1 vector | {randomly generated by ARPACK}]

opts.disp: diagnostic information display
          level [0 | {1} | 2]

opts.cholB: B is actually its Cholesky
           factor CHOL(B) [{0} | 1]

opts.permB: sparse B is actually
           CHOL(B(permB,permB)) [permB | {1:N}]

opts(AFUN,n) accepts the function AFUN
           instead of a matrix
```

In the above list, the items in square brackets denote the possible settings and the item given in curly brackets `{}` is the default setting. For example, to set the convergence tolerance to  $10^{-3}$ , one should give the command `opts.tol = .001`.

The function passing mechanism can be used to define a customized spectral transformation as in the example with a nonsymmetric  $M$ . Arguments may be passed to `AFUN(X,P1,P2,...)` by invoking the command `eigs(AFUN,n,k,sigma,opts,P1,P2,...)`.

Thus, all of the functionality of ARPACK is available through `eigs` and, in many cases, it is much easier to use. Moreover, the sparse matrix direct factorizations and reorderings available in the `sparfun` suite are easily used to implement various desirable spectral transformations. It is highly advisable to run sample problems with the characteristics of a desired very large problem in order to get an idea of the best spectral transformation to use and to get an indication of the expected convergence behavior.

## Summary of Software for Linear Algebra Freely Available on the Web

---

**Jack Dongarra**

*University of Tennessee and Oakridge National Laboratory*

**Victor Eijkhout**

*University of Tennessee*

**Julien Langou**

*University of Tennessee*

Table 77.1 to Table 77.5 present a list of freely available software for the solution of linear algebra problems. The interest is in software for high-performance computers that is available in “open source” form on the Web for solving problems in numerical linear algebra, specifically dense, sparse direct and iterative systems, and sparse iterative eigenvalue problems.

Additional pointers to software can be found at:

[www.nhse.org/rib/repositories/nhse/catalog/#Numerical\\_Programs\\_and\\_Routines](http://www.nhse.org/rib/repositories/nhse/catalog/#Numerical_Programs_and_Routines).

A survey of Iterative Linear System Solver Packages can be found at:

[www.netlib.org/utk/papers/iterative-survey](http://www.netlib.org/utk/papers/iterative-survey).

# Glossary

---

This glossary covers most of the terms defined in Chapters 1 to 49. It does not cover some terminology used in a single chapter (including most of the terminology that is specific to a particular application (Chapters 50 to 70)), nor does it cover most of the terminology used in computer software (Chapters 71 to 77). When two sections are listed, both define the term; the first listed chapter is the first instance, the second is the primary chapter dealing with the topic. Definitions in this glossary may not give all details; the reader is advised to consult the chapter/section following the term and definition).

## A

**abelian** (group  $G$ ): A commutative group, i.e.,  $ab = ba$  for all  $a, b \in G$ . **Preliminaries**

**absolute** (matrix norm): As a vector norm, each member of the family is absolute. **37.3**

**absolute** (vector norm  $\|\cdot\|$ ): For all vectors  $\mathbf{x}$ ,  $\|\mathbf{x}\| = \|\mathbf{x}\|$ . **37.1**

**absolute algebraic connectivity** (of simple graph  $G = (V, E)$ ):  $\max \alpha(G_w)$  where the maximum is taken over all nonnegative weights  $w$  of the edges of  $G$  such that  $\sum_{e \in E} w(e) = |E|$ . **36.5**

**absolute error** (in approximation  $\hat{\mathbf{z}}$  to  $\mathbf{z}$ ):  $\|\mathbf{z} - \hat{\mathbf{z}}\|$  **37.4**

**absolute value** (of complex number  $a + bi$ ):  $\sqrt{a^2 + b^2}$ . **Preliminaries**

**absolute value** (of real matrix  $A$ ): The nonnegative matrix obtained by taking element-wise absolute values of  $A$ 's entries. **9.1**

**access**: Vertex  $u$  has access to vertex  $v$  in a digraph  $\Gamma$  if there is a walk in  $\Gamma$  from  $u$  to  $v$ ; also applied to sets of vertices. **9.1, 29.5**

**access equivalence class** (of a digraph): An equivalence class under the equivalence relation of access. **9.1, 29.5**

**access equivalence class** (of a matrix): An access equivalence class of its digraph. **9.1**

**access equivalent**: Two vertices in a digraph that have access to each other. **9.1, 29.5**

**active branch** (at a Type I characteristic vertex of a tree): For some Fiedler vector  $\mathbf{y}$  the entries in  $\mathbf{y}$  corresponding to the vertices in the branch are nonzero. **36.3**

**acyclic** (square matrix  $A$ ): The graph of  $A$  has no cycles. **19.3**

**additive** (map  $\phi : F^{m \times n} \rightarrow F^{m \times n}$ ):  $\phi(A + B) = \phi(A) + \phi(B)$ , for all  $A, B \in F^{m \times n}$ . **22.4**

**additive coset** (of subspace  $W$ ): A subset of vectors the form  $\mathbf{v} + W = \{\mathbf{v} + \mathbf{w} : \mathbf{w} \in W\}$ . **2.3**

**additive  $D$ -stable** (real square matrix  $A$ ):  $A + D$  is stable for every nonnegative diagonal matrix  $D$ . **19.4**

**additive inverse eigenvalue problem (AIEP)**: Given  $A \in \mathbb{C}^{n \times n}$  and  $\lambda_1, \dots, \lambda_n \in \mathbb{C}$  find a diagonal matrix  $D \in \mathbb{C}^{n \times n}$  such that  $\sigma(A + D) = \{\lambda_1, \dots, \lambda_n\}$ . **20.9**

**additive preserver**: An additive map preserving a certain property. **22.4**

**adjacency matrix** (of a digraph  $\Gamma$  of order  $n$ ): The  $n \times n$  0, 1-matrix whose  $i, j$ th entry is 1 if there is an arc from the  $i$ th vertex to the  $j$ th vertex and 0 otherwise. **29.2**

**adjacency matrix** (of a graph  $G$  of order  $n$ ): The symmetric  $n \times n$  matrix whose  $i, j$ th entry is equal to the number of edges between the  $i$ th vertex and the  $j$ th vertex. **28.3**

**adjacent** (matrices  $A, B$ ):  $\text{rank}(A - B) = 1$ . **22.4**

**adjacent** (vertices  $u$  and  $v$  in a graph): There exists an edge with endpoints  $u$  and  $v$ . **28.1**

**adjoint** (of a matrix): See *Hermitian adjoint*.

**adjoint** (of a linear operator  $T$  on an inner product space  $V$ ):  $\langle T(\mathbf{u}), \mathbf{v} \rangle = \langle \mathbf{u}, T^*(\mathbf{v}) \rangle$  for all  $\mathbf{u}, \mathbf{v} \in V$ . **5.3**

**adjugate**: The transpose of the matrix of cofactors. **4.2**

**affine parameterized inverse eigenvalue problem**: See *Section 20.9*.

**AIEP**: See *additive inverse eigenvalue problem*.

**algebra (associative):** A vector space  $A$  over a field  $F$  with a bilinear **multiplication**  $(\mathbf{x}, \mathbf{y}) \mapsto \mathbf{xy}$  from  $A \times A$  to  $A$  satisfying  $(\mathbf{xy})\mathbf{z} = \mathbf{x}(\mathbf{yz})$ . **Preliminaries, 69.1**

**algebra (nonassociative):** See *Section 69.1*.

**algebraic connectivity** (of simple a graph): The second least Laplacian eigenvalue. **28.4, 36.1**

**algebraic multigrid preconditioner:** A preconditioner that uses principles similar to those used for PDE problems on grids, when the “grid” for the problem is unknown or nonexistent and only the matrix is available. **41.4**

**algebraic multiplicity** (of an eigenvalue): The number of times the eigenvalue occurs as a root in the characteristic polynomial of the matrix. **4.3**

**algorithm:** A precise set of instructions to perform a task. **37.7**

**allows:** If  $P$  is a property referring to a real matrix, then a sign pattern  $A$  allows  $P$  if some real matrix in  $Q(A)$  has property  $P$ . **33.1**

**allows a properly signed nest** ( $n \times n$  sign pattern  $A$ ): There exists  $B \in Q(A)$  and a permutation matrix  $P$  such that  $\text{sgn}(\det(P^T B P [\{1, \dots, k\}])) = (-1)^k$  for  $k = 1, \dots, n$ . **33.4**

**Alt:** the map  $\text{Alt}(\mathbf{v}_1 \otimes \dots \otimes \mathbf{v}_k) = \frac{1}{k!} \sum_{\pi \in \mathcal{S}_k} \text{sgn}(\pi) \mathbf{v}_{\pi(1)} \otimes \dots \otimes \mathbf{v}_{\pi(k)}$ . **13.6**

**alt multiplication:**  $(\mathbf{v}_1 \wedge \dots \wedge \mathbf{v}_p) \wedge (\mathbf{v}_{p+1} \wedge \dots \wedge \mathbf{v}_{p+q}) = \mathbf{v}_1 \wedge \dots \wedge \mathbf{v}_{p+q}$ . **13.7**

**alternate path to a single arc** (in a digraph): A path of length greater than 1 between vertices  $i$  and  $j$  such that the arc  $(i, j)$  is in the digraph. **35.7**

**alternating** (bilinear form  $f$ ):  $f(\mathbf{v}, \mathbf{v}) = 0$  for all  $\mathbf{v} \in V$ . **12.3**

**alternating** ( $n \times n$  matrix  $A$ ):  $a_{ii} = 0$ ,  $i = 1, 2, \dots, n$  and  $a_{ji} = -a_{ij}$ ,  $1 \leq i, j \leq n$ . **12.3**

**alternating** (multilinear form): See *antisymmetric*.

**alternating algebra:** See *Grassman algebra*.

**alternating product:** See *exterior product*.

**alternating space:** See *Grassman space*.

**alternator:** See *Alt*.

**angle** (between two nonzero vectors  $\mathbf{u}$  and  $\mathbf{v}$  in a real inner product space): The real number  $\theta$ ,  $0 \leq \theta \leq \pi$ , such that  $\langle \mathbf{u}, \mathbf{v} \rangle = \|\mathbf{u}\| \|\mathbf{v}\| \cos \theta$ . **5.1**

**annihilator:** The set of linear functionals that annihilate every vector in the given set. **3.8**

**antidiagonal** (of  $n \times n$  matrix  $A$ ): The elements  $a_{i,k-i}$ ,  $i = 1, \dots, k-1$  with  $2 \leq k \leq n+1$ . **48.1**

**anti-identity matrix:** The  $n \times n$  matrix with ones along the main antidiagonal, i.e.,  $a_{i,n+1-i} = 1$ ,  $i = 1, \dots, n$  and zeros elsewhere. **48.1**

**antisymmetric** (bilinear form  $f$ ):  $f(\mathbf{u}, \mathbf{v}) = -f(\mathbf{v}, \mathbf{u})$  for all  $\mathbf{u}, \mathbf{v} \in V$ . **12.3**

**antisymmetric** (multilinear form): A multilinear form that is an antisymmetric map. **13.4**

**antisymmetric** (map  $\psi \in L^m(V; U)$ ):  $\psi(\mathbf{v}_{\pi(1)}, \dots, \mathbf{v}_{\pi(m)}) = \text{sgn}(\pi) \psi(\mathbf{v}_1, \dots, \mathbf{v}_m)$  for all permutations  $\pi$ . **13.4**

**aperiodic** (matrix): An irreducible nonnegative matrix of period 1. **9.2**

**appending  $G_2$  at vertex  $v$  of  $G_1$ :** Constructing a simple graph from  $G_1 \cup G_2$  by adding an edge between  $v$  and a vertex of  $G_2$ . **36.2**

**Arbitrary Precision Approximating (APA) algorithms:** See *Section 47.4*.

**arc:** An ordered pair of vertices (part of a directed graph). **29.1**

**argument** (of a complex number):  $\theta$  in the form  $re^{i\theta}$  with  $0 \leq \theta < 2\pi$ . **Preliminaries**

**Arnoldi factorization** ( $k$ -step):  $AV_k = V_k H_k + \mathbf{f}_k \mathbf{e}_k^*$  where  $V_k \in \mathbb{C}^{n \times k}$  has orthonormal columns,  $V_k^* \mathbf{f}_k = 0$  and  $H_k = V_k^* A V_k$  is a  $k \times k$  upper Hessenberg matrix with nonnegative subdiagonal elements. **41.3, 44.2**

**associated undirected graph** (of a digraph  $\Gamma = (V, E)$ ): The undirected graph with vertex set  $V$ , having an edge between vertices  $u$  and  $v$  if and only if at least one of the arcs  $(u, v)$  and  $(v, u)$  is in  $\Gamma$ . **29.1**

**associates** (in a domain):  $a, b$  are associates if  $a|b$  and  $b|a$ . **23.1**

**association scheme:** A set of graphs  $G_0, \dots, G_d$  on a common vertex set satisfying certain axioms. **28.6**

**associative algebra:** See *algebra (associative)*.

**asymmetric** (digraph  $\Gamma = (V, E)$ ):  $(i, j) \in E$  implies  $(j, i) \notin E$  for all distinct  $i, j \in V$ . **35.1**

**augmented matrix** (of a system of linear equations): Matrix obtained by adjoining the constant column to the coefficient matrix. **1.4**

## B

**backward error** (for  $\hat{f}(\mathbf{x})$ ): A vector  $\mathbf{e} \in \mathbb{R}^n$  of smallest norm for which  $f(\mathbf{x} + \mathbf{e}) = \hat{f}(\mathbf{x})$ . **37.8**

**backward stable** (algorithm): The backward relative error  $\mathbf{e}$  exists and is small for all valid input data  $\mathbf{x}$  despite rounding and truncation errors in the algorithm. **37.8**

**badly conditioned**: See *ill-conditioned*.

**balanced** ( $(0, 1)$ -design matrix  $W$ ): Every row of  $m \times n$  matrix  $W$  has exactly  $(n + 1)/2$  ones if  $n$  odd; exactly  $n/2$  ones or exactly  $(n + 2)/2$  ones if  $n$  even. **32.4**

**balanced** (real or sign pattern vector): It is a zero vector or it has both a positive entry and a negative entry. **33.3**

**balanced column signing** (of matrix  $A$ ): A column signing of  $A$  in which all the rows are balanced. **33.3**

**balanced row signing** (of matrix  $A$ ): A row signing of  $A$  in which all the columns are balanced. **33.3**

**banded** (family of Toeplitz matrices with symbol  $a$ ): There exists some  $m \geq 0$  such that  $a_{\pm k} = 0$  for all  $k \geq m$ . **16.2**

**barely  $L$ -matrix**: An  $L$ -matrix that is not an  $L$ -matrix if any column is deleted. **33.3**

**bases**: Plural of *basis*.

**basic class** (of square nonnegative matrix  $P$ ): An access equivalence class  $B$  of  $P$  with  $\rho(P[B]) = \rho$ . **9.3**

**basic reduced digraph** (of square nonnegative matrix  $P$ ): The digraph whose vertex-set is the set of basic classes of  $P$  and whose arcs are the pairs  $(B, B')$  of distinct basic classes of  $P$  for which there exists a simple walk from  $B$  to  $B'$  in the reduced digraph of  $P$ . **9.3**

**basic solution** (to a least squares problem): A least squares solution with at least  $n - \text{rank } A$  zero components. **39.1**

**basic variable**: A variable in a system of linear equations whose value is determined by the values of the free variables. **1.4**

**basis**: A set of vectors that is linearly independent and spans the vector space. **2.2**

**BD**: See *Bezout domain*.

**Bezout domain** (**BD**): A GCCD  $\mathbb{D}$  such that for any two elements  $a, b \in \mathbb{D}$ ,  $(a, b) = pa + qb$ , for some  $p, q \in \mathbb{D}$ . **23.1**

**biacyclic** (matrix): A matrix whose sparsity pattern has an acyclic bipartite graph. **46.3**

**biadjacency matrix** (of bipartite graph  $G$ ): A matrix with rows indexed by one of the bipartition sets and columns indexed by the other, with the value of the entry being the number of edges between the vertices (or weight of the edge between the vertices). **30.1**

**BiCG algorithm**: Iterative method for solving a linear system using non-Hermitian Lanczos algorithm; the approximate solution  $\mathbf{x}_k$  is chosen so that the residual  $\mathbf{r}_k$  is orthogonal to

$\text{Span}\{\hat{\mathbf{r}}_0, A^* \hat{\mathbf{r}}_0, \dots, A^{*k-1} \hat{\mathbf{r}}_0\}$ . **41.3**

**BiCGSTAB algorithm**: Iterative method for solving a linear system using non-Hermitian Lanczos algorithm with improved stability. See *Section 41.3*.

**biclique** (of a graph): A subgraph that is a complete bipartite graph. **30.3**

**biclique cover** (of graph  $G = (V, E)$ ): A collection of bicliques of  $G$  such that each edge of  $E$  is in at least one biclique. **30.3**

**biclique cover number** (of graph  $G$ ): The smallest  $k$  such that there is a cover of  $G$  by  $k$  bicliques. **30.3**

**biclique partition** (of  $G = (V, E)$ ): A collection of bicliques of  $G$  whose edges partition  $E$ . **30.3**

**biclique partition number** (of graph  $G$ ): The smallest  $k$  such that there is a partition of  $G$  into  $k$  bicliques. **30.3**

**bidual space**: The dual of the dual space. **3.8**

**big-oh**: function  $f$  is  $O(g)$  if beyond a certain point  $|f|$  is bounded by a multiple of  $|g|$ . **Preliminaries**

**bigraph** (of the  $m \times n$  matrix  $A$ ): The simple graph with vertex set  $U \cup V$  where  $U = \{1, 2, \dots, m\}$  and  $V = \{1', 2', \dots, n'\}$ , and edge set  $\{\{i, j'\} : a_{ij} \neq 0\}$ . **30.2**

**bilinear form** (on vector space  $V$  over field  $F$ ): A map  $f$  from  $V \times V$  into  $F$  that satisfies  $f(a\mathbf{u}_1 + b\mathbf{u}_2, \mathbf{v}) = af(\mathbf{u}_1, \mathbf{v}) + bf(\mathbf{u}_2, \mathbf{v})$  and  $f(\mathbf{u}, a\mathbf{v}_1 + b\mathbf{v}_2) = af(\mathbf{u}, \mathbf{v}_1) + bf(\mathbf{u}, \mathbf{v}_2)$ . **12.1**

**bilinear noncommutative algorithms**: See *Section 47.2*.

**binary matrix**: A  $(0, 1)$ -matrix, i.e., a matrix in which each entry is either 0 or 1. **31.3**

**biorthogonal** (sets of vectors  $\{\mathbf{v}_1, \dots, \mathbf{v}_k\}$  and  $\{\mathbf{w}_1, \dots, \mathbf{w}_k\}$  in an inner product space):  $\langle \mathbf{v}_i, \mathbf{w}_j \rangle = 0$  if  $i \neq j$ . **41.3**

**bipartite** (graph  $G$ ): The vertices of  $G$  can be partitioned into disjoint subsets  $U$  and  $V$  such that each edge of  $G$  has the form  $\{u, v\}$  where  $u \in U$  and  $v \in V$ . **28.1, 30.1**

**bipartite fill-graph** of  $n \times n$  matrix  $A$  with each diagonal entry nonzero: The simple bipartite graph with vertex set  $\{1, 2, \dots, n\} \cup \{1', 2', \dots, n'\}$  with an edge joining  $i$  and  $j'$  if and only if there exists a path from  $i$  to  $j$  in the directed graph,  $\Gamma(A)$ , of  $A$  each of whose intermediate vertices has label less than  $\min\{i, j\}$ . **30.2**

**bipartite graph** (of sparsity pattern  $S$ ): The graph with vertices partitioned into row vertices  $r_1, \dots, r_m$  and column vertices  $c_1, \dots, c_n$ , where  $r_k$  and  $r_l$  are connected if and only if  $(k, l) \in S$ . **46.3**

**bipartite sign pattern**: A sign pattern whose digraph is bipartite. **33.5**

**bipartition**: The sets into which the vertices of a bipartite graph are partitioned. **30.1**

**block** (in a 2-design): A subset  $B_i$  of  $X$  (see *2-design*). **32.2**

**block** (of a graph or digraph): A maximal nonseparable sub(di)graph. **35.1**

**block** (of a matrix): An entry of a block matrix, which is a submatrix of the original matrix. **10.1**

**block-clique** (graph or digraph): Every block is a clique. **35.1**

**block diagonal** (for a particular block matrix structure): A square block matrix  $A$  with all off-diagonal blocks 0. **10.2**

**block matrix**: A matrix that is partitioned into submatrices with the row indices and column indices partitioned into consecutive subsets sequentially. **10.1**

**block lower triangular** (matrix  $A$ ):  $A^T$  is block upper triangular. **10.2**

**block-Toeplitz matrix**: A block matrix  $A = [A_{ij}]$  such that  $A_{i+k,i} = A^{(k)}$ , **48.1**

**block-Toeplitz-Toeplitz-block (BTTB) matrices**: a block-Toeplitz matrix in which the blocks  $A^{(k)}$  are themselves Toeplitz matrices. **48.1**

**block upper triangular** (for a particular block matrix structure): A block matrix having every subdiagonal block 0. **10.2**

**(0,1)-Boolean algebra**:  $\{0, 1\}$ , with  $0 + 0 = 0, 0 + 1 = 1 = 1 + 0, 1 + 1 = 1, 0 * 1 = 0 = 1 * 0, 0 * 0 = 0$ , and  $1 * 1 = 1$ . **30.3**

**Boolean matrix**: A matrix whose entries belong to the Boolean algebra. **30.3**

**Boolean rank** (of  $m \times n$  Boolean matrix  $A$ ): The minimum  $k$  such that there exists an  $m \times k$  Boolean matrix  $B$  and a  $k \times n$  Boolean matrix  $C$  such that  $A = BC$ . **30.3**

**Bose-Mesner algebra**: The algebra generated by the adjacency matrices of the graphs of an association scheme. **28.6**

**bottleneck matrix** (of a branch of tree  $T$  at vertex  $v$ ): The inverse of the principal submatrix of the Laplacian matrix corresponding to the vertices of that branch. **36.3**

**boundary** (of a subset  $S$  of  $\mathbb{R}$  or  $\mathbb{C}$ ): The intersection of the closure of  $S$  and the closure of the complement of  $S$ . **Preliminaries**

**branch** (of tree  $T$  at vertex  $v$ ): A component of  $T - v$ . **34.1**

**Bunch-Parlett factorization** (of symmetric real matrix  $H$ ): The factorization  $P^T H P = L B L^T$ , where  $P$  is a permutation matrix,  $B$  is a block-diagonal matrix with diagonal blocks of sizes  $1 \times 1$  or  $2 \times 2$ , and  $L$  is a full column rank unit lower triangular matrix, where the diagonal blocks in  $L$  which correspond to  $2 \times 2$  blocks in  $B$  are  $2 \times 2$  identity matrices. **15.5**

**Businger-Golub pivoting**: a particular pivoting strategy for QR-factorization. **46.2**

## C

**canonical angles** between the column spaces of  $X, Y \in \mathbb{C}^{n \times k}$ :  $\theta_i = \arccos \sigma_i$ , where  $\{\sigma_i\}_{i=1}^k$  are the singular values of  $(Y^* Y)^{-1/2} Y^* X (X^* X)^{-1/2}$ . **15.1** (equivalent to principal angles **17.1**)

**canonical angle matrix**:  $\text{diag}(\theta_1, \theta_2, \dots, \theta_k)$ , where  $\theta_1, \theta_2, \dots, \theta_k$  are the canonical angles. **15.1**

**canonical correlations** (between subspaces  $X$  and  $Y$  of  $\mathbb{C}^r$ ): Cosines of principal (canonical) angles **17.7**

**Cauchy matrix**: Given vectors  $\mathbf{x} = [x_1, \dots, x_n]^T$  and  $\mathbf{y} = [y_1, \dots, y_n]^T$ , the Cauchy matrix  $C(\mathbf{x}, \mathbf{y})$  has  $i, j$ -entry equal to  $\frac{1}{x_i + y_j}$ . **48.1**

**center** See *central vertex*.

**central** (real matrix  $B$ ): The zero vector is in the convex hull of the columns of  $B$ . **33.11**

**central vertex** (of a generalized star): a vertex such that each of its neighbours are pendant vertices of their branches, and each branch is a path. **34.1**

**CG**: See *conjugate gradient algorithm*.

**CGS algorithm**: Iterative method for solving a linear system using non-Hermitian Lanczos algorithm. See *Section 41.3*.

**change-of-basis matrix** (from  $\mathcal{B}$  to  $\mathcal{C}$ ): The matrix consisting of the coordinate vectors with respect to basis  $\mathcal{C}$  of the basis vectors in  $\mathcal{B}$ . **2.6**

**characteristic equation** (of the pencil  $A - xB$ ):  $\det(xB - A) = 0$ . **43.1**

**characteristic polynomial** (of matrix  $A$ ):  $\det(xI - A)$ . **4.3**

**characteristic polynomial** (of the pencil  $A - xB$ ):  $\det(xB - A)$ . **43.1**

**characteristic polynomial** (of a graph): The characteristic polynomial of its adjacency matrix. **28.3**

**characteristic vector** (of a subset of  $m$  vertices of a graph): The  $m$ -vector whose  $i$ th entry is 1 if  $i \in X$ , and 0 otherwise. **30.3**

**characteristic vertex** (of tree  $T$ ): See *Section 36.3*.

**Cholesky decomposition** (of positive-definite matrix  $A$ ):  $A = G G^*$  with  $G \in \mathbb{C}^{n \times n}$  lower triangular and having positive diagonal entries. **38.5**

**Cholesky factorization**: See *Cholesky decomposition*.

**chord** (of a cycle in a graph): An edge joining two nonconsecutive vertices on the cycle. **30.1**

**chordal bipartite graph**: Every cycle of length 6 or more has a chord. **30.1**

**chordal graph**: Every cycle of length 4 or more has a chord. **30.1**

**1-chordal**: See *block-clique*.

**chromatic index** (of graph  $G$ ): The smallest number of classes in a partition of edges of  $G$  so that no two edges in the same class meet. **27.6**

**chromatic number** (of graph  $G$ ): The smallest number of color classes of any vertex coloring of  $G$  (not defined if  $G$  has loops). **28.5**

**circulant matrix**: A Toeplitz matrix in which every row is obtained by a single cyclic shift of the previous row. **20.3, 48.1**

**clique** (of a digraph): Every vertex has a loop and for any two distinct vertices  $u, v$ , both arcs  $(u, v), (v, u)$  are present. **35.1**

**clique** (of a graph that allows loops but not multiple edges): Every vertex has a loop and for any two distinct vertices  $u, v$ , the edge  $\{u, v\}$  is present. **35.1**

**clique** (of a simple graph): A subgraph isomorphic to a complete graph. **28.5**

**clique number** (of graph  $G$ ): The largest order of a clique in  $G$ . **28.5**

**closed cone**: A cone that is a closed subset of the vector space. **8.5, 26.1**

**closed under matrix direct sums** (class of matrices  $X$ ): Whenever  $A_1, A_2, \dots, A_k$  are  $X$ -matrices, then  $A_1 \oplus A_2 \oplus \dots \oplus A_k$  is an  $X$ -matrix. **35.1**

**closed under permutation similarity** (class of matrices  $X$ ): Whenever  $A$  is an  $X$ -matrix and  $P$  is a permutation matrix, then  $P^T A P$  is an  $X$ -matrix. **35.1**

**closed under taking principal submatrices**: See *hereditary*.

**closed walk** (in a digraph): A walk in which the first vertex equals the last vertex. **54.2**

**4-cockade**: A bipartite graph created by adding 4 cycles through edge identification to a 4-cycle. **30.2**

**cocktail party graph**: The graph obtained by deleting  $a$  disjoint edges from the complete graph  $K_{2a}$ . **28.2**

**coclique** (of a graph): An induced subgraph with no edges. **28.5**

**co-cover** (of a  $(0, 1)$ -matrix): A collection of 1s such that each line of  $A$  contains at least one of the 1s. **27.1**

**co-index** (of square nonnegative matrix  $P$ ):  $\max\{v_P(\lambda) : \lambda \in \sigma(P), |\lambda| = \rho \text{ and } \lambda \neq \rho\}$ . **9.3**

**codomain** (of  $T: V \rightarrow W$ ): The vector space  $W$ . **3.1**

**coefficient matrix**: The matrix of coefficients of a system of linear equations. **1.4**

**coefficients** (of a linear equation): The scalars that occur multiplied by variables. **1.4**

**$i, j$ -cofactor**:  $(-1)^{i+j}$  times the  $i, j$ -minor. **4.1**

**Colin de Verdière parameter:** A parameter of a simple graph. **28.5**

**color class:** A coclique in a vertex coloring partition of the vertices of a graph. **28.5**

**column:** The entries of a matrix lying in a vertical line in the matrix. **1.2**

**column equivalent** (matrices  $A, B \in \mathbb{D}^{n \times n}$ ):  $B = AP$  for some  $\mathbb{D}$ -invertible  $P$ . **23.2**

**column signing** (of (real or sign pattern) matrix  $A$ ):  $AD$  where  $D$  is a signing. **33.3**

**column space:** See *range*.

**column-stochastic** (matrix): A square nonnegative matrix having all column sums equal to 1. **9.4**

**column sum vector** (of a matrix): The vector of column sums. **27.4**

**combinatorially orthogonal** (sign pattern vectors  $\mathbf{x}, \mathbf{y}$ ):  $|\{i : x_i y_i \neq 0\}| \neq 1$ . **33.10**

**combinatorially symmetric** (partial matrix  $B$ ):  $b_{ij}$  specified implies  $b_{ji}$  specified. **35.1**

**combinatorially symmetric sign pattern**  $A$ :  $a_{ij} \neq 0$  if and only if  $a_{ji} \neq 0$ . **33.5**

**communicate:** See *access equivalent*.

**commute:** Matrices or linear operators  $A, B$  such that  $AB = BA$ . **1.2, 3.2**

**companion matrix** (of a monic polynomial): Square matrix with ones on the subdiagonal and last column consisting of negatives of the polynomial coefficients **4.3, 6.4**

**comparison matrix** (of real square matrix  $A$ ): Matrix having  $i, j$ -entry  $-|a_{ij}|$  for  $i \neq j$  and  $i, i$ -entry  $|a_{ii}|$ . **19.5**

**compatible** (generalized sign patterns): The intersection of their qualitative classes is nonempty. **33.1**

**complement** (of set  $X$  in universe  $S$ ): The elements of  $S$  not in  $X$ . **Preliminaries**

**complement** (of binary matrix  $M$ ):  $J - M$  (where  $J$  is the all 1s matrix). **31.3**

**complement** (of simple graph  $G = (V, E)$ ): The simple graph having vertex set  $V$  and as edges all unordered pairs from  $V$  that are not in  $E$ . **28.1**

**complement** (orthogonal): See *orthogonal complement*.

**complete** (bipartite graph): A simple bipartite graph with bipartition  $\{U, V\}$  such that each  $\{u, v\}$  is an edge (for all  $u \in U, v \in V$ ). **28.1, 30.1**

**complete** (simple graph): The edge set consists of all unordered pairs of distinct vertices. **28.1**

**complete orthonormal set:** An orthonormal set of vectors whose orthogonal complement is 0. **5.2**

**completed max-plus semiring:** The set  $\mathbb{R} \cup \{\pm\infty\}$  equipped with the addition  $(a, b) \mapsto \max(a, b)$  and the multiplication  $(a, b) \mapsto a + b$ , with the convention that  $-\infty + (+\infty) = +\infty + (-\infty) = -\infty$ . **25.1**

**completely positive** (matrix  $A$ ):  $A = CC^T$  for some nonnegative  $n \times m$  matrix  $C$ . **35.4**

**completely reducible** (matrix  $A$ ): There is a permutation matrix  $P$  such that  $PAP^T = A_1 \oplus A_2 \oplus \cdots \oplus A_k$  where  $A_1, A_2, \dots, A_k$  are irreducible and  $k \geq 2$ . **27.3**

**completion** (of a partial matrix): A choice of values for the unspecified entries. **35.1**

**$X$ -completion property** (where  $X$  is a type of matrix): Digraph (respectively, graph)  $G$  has this property if every partial  $X$ -matrix  $B$  such that  $\mathcal{D}(B) = G$  (respectively,  $\mathcal{G}(B) = G$ ) can be completed to an  $X$ -matrix. **35.1**

**complex conjugate** (of  $a + bi \in \mathbb{C}$ ):  $a - bi$ . **Preliminaries**

**complex sign pattern matrix:** A matrix of the form  $A = A_1 + iA_2$  for sign patterns  $A_1$  and  $A_2$ . **33.8**

**complex vector space:** A vector space over the field of complex numbers. **1.1**

**component-wise relative backward error of the linear system:** See *Section 38.1*.

**component-wise relative distance** (between matrices  $H$  and  $\tilde{H}$ ):  $\text{reldist}(H, \tilde{H}) = \max_{i,j} \frac{|h_{ij} - \tilde{h}_{ij}|}{|h_{ij}|}$ , where  $0/0 = 0$ . **15.4**

**composite cycle** (in sign pattern  $A$ ): A product of disjoint simple cycles. **33.1**

**$k \times k$ -compound matrix:** A matrix formed from the  $k \times k$  minors of a given matrix. **4.2**

**condensation digraph:** See *reduced digraph*.

**condition number** (of  $\mathbf{z}$  with respect to problem  $P$ ):

$$\text{cond}_P(\mathbf{z}) = \lim_{\varepsilon \rightarrow 0} \sup \left\{ \left( \frac{\|P(\mathbf{z} + \delta\mathbf{z}) - P(\mathbf{z})\|}{\|P(\mathbf{z})\|} \right) \left( \frac{\|\mathbf{z}\|}{\|\delta\mathbf{z}\|} \right) \mid \|\delta\mathbf{z}\| \leq \varepsilon \right\}. \quad \mathbf{37.4}$$

**condition number** (of an eigenvalue): See *individual condition number*.

**condition number** (of matrix  $A$  for linear systems):  $\kappa_v(A) = \|A^{-1}\|_v \|A\|_v$ . **37.5, 38.1**

**condition number of the linear system:**  $A\hat{\mathbf{x}} = \mathbf{b}$ :  $\kappa(A, \hat{\mathbf{x}}) = \|A^{-1}\| \frac{\|\mathbf{b}\|}{\|\hat{\mathbf{x}}\|}$ . **38.1**

**condition number** (of least squares problem  $A\mathbf{x} = \mathbf{b}$ ):  $\kappa(A) = \sigma_1/\sigma_p$ , where  $\text{rank } A = p$ . **39.6**

**condition numbers for polar factors** ( $A = UP$ ) in the Frobenius norm:

$\text{cond}_F(X) = \lim_{\delta \rightarrow 0} \sup_{\|\Delta A\|_F \leq \delta} \frac{\|\Delta X\|_F}{\delta}$ , for  $X = P$  or  $U$ . **15.3**

**conductance:** A parameter of a simple graph. **28.5**

**cone:** A subset  $K$  of a real or complex vector space such that for each  $\mathbf{x}, \mathbf{y} \in K, c \geq 0, \mathbf{x} + \mathbf{y} \in K$  and  $c\mathbf{x} \in K$ ; in Section 26.1 cone is used to mean proper cone. **8.5, 26.1**

**conformable:** See *conformal*.

**conformal** (partitions of matrices  $A, B$ ): Partitions of block matrices that allow multiplication via the block structure. **10.1**

**congruent** (square matrices  $A, B$  over field  $F$ ): There is an invertible matrix  $C$  such that  $B = C^T AC$ . **12.1**

\***congruent** (square matrices  $A, B$  over  $\mathbb{C}$ ): There is an invertible matrix  $C$  such that  $B = C^* AC$ . **8.3**

**$\varphi$ -congruent** (square matrices  $A, B$  over field  $F$  with automorphism  $\varphi$ ): There is an invertible matrix  $C$  such that  $B = C^T A\varphi(C)$ . **12.4**

**conjugate:** See *complex conjugate*.

**conjugate gradient (CG) algorithm** (to solve  $H\mathbf{x} = \mathbf{b}$  for preconditioned Hermitian positive definite matrix  $H$ ): At each step  $k$ , the approximation  $\mathbf{x}_k$  of the form  $\mathbf{x}_k \in \mathbf{x}_0 + \text{Span}\{\mathbf{r}_0, H\mathbf{r}_0, \dots, H^{k-1}\mathbf{r}_0\}$  for which the  $\sqrt{H}$ -norm of the error,  $\|\mathbf{e}_k\|_{\sqrt{H}} \equiv \langle \mathbf{e}_k, H\mathbf{e}_k \rangle^{1/2}$ , is minimal. **41.2**

**conjugate partition** (of a sequence of positive integers  $(u_1, u_2, \dots, u_n)$ ): The  $i$ th element of the conjugate partition is the number of  $j$ s such that  $u_j \geq i$ . **Preliminaries**

**connected** (graph): A graph with nonempty vertex set such that there exists a walk between any two distinct vertices. **28.1**

**connected** (digraph): A digraph whose associated undirected graph is connected. **29.1**

**connected component** (of a graph): A connected (induced) subgraph not properly contained in a connected subgraph. **28.1**

**consecutive ones property** (of a  $(0, 1)$ -matrix  $A$ ): There exists a permutation matrix  $P$  such that  $PA$  is a Petrie matrix. **30.2**

**consistent:** A system of linear equations that has one or more solutions. **1.4**

**$k$ -consistent sign pattern**  $A$ : Every matrix  $B \in Q(A)$  has exactly  $k$  real eigenvalues. **33.5**

**constant** (of a linear equation): The scalar not multiplied by a variable. **1.4**

**constant vector:** The vector of constants of a system of linear equations. **1.4**

**contraction** (matrix): A matrix  $A \in \mathbb{C}^{n \times n}$  such that  $\|A\|_2 \leq 1$ . **18.6**

**contraction** (of edge  $e$  in graph  $G = (V, E)$ ): The operation that merges the endpoints of  $e$  in  $V$ , and deletes  $e$  from  $E$ . **28.2**

**convergent** (square nonnegative matrix  $P$ ):  $\lim_{m \rightarrow \infty} P^m = 0$ . **9.3**

**convergent regular splitting:** Square real matrix  $A$  has a convergent regular splitting if  $A$  has a representation  $A = M - N$  such that  $N \geq 0, M$  invertible with  $M^{-1} \geq 0$  and  $M^{-1}N$  is convergent. **9.5**

**converges geometrically to  $a$  with (geometric) rate  $\beta$**  (complex sequence  $\{a_m\}_{m=0,1,\dots}$ ):  $\{\frac{a_m - a}{\gamma^m} : m = 0, 1, \dots\}$  is bounded for each  $\beta < \gamma < 1$ . **9.1**

**convex** (set of vectors): Closed under convex combinations. **Preliminaries**

**convex combination** (of vectors  $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k$ ): A vector of the form  $a_1\mathbf{v}_1 + a_2\mathbf{v}_2 + \dots + a_k\mathbf{v}_k$  with  $a_i$  nonnegative and  $\sum a_i = 1$  (vector space is real or complex). **Preliminaries**

**convex cone:** See *cone*.

**convex function:** A function  $f : S \rightarrow \mathbb{R}$  where  $S$  is a convex set and for all  $a \in \mathbb{R}$  such that  $0 < a < 1$  and  $\mathbf{x}, \mathbf{y} \in S, f(a\mathbf{x} + (1-a)\mathbf{y}) \leq af(\mathbf{x}) + (1-a)f(\mathbf{y})$ . **Preliminaries**

**convex hull** (of a set of vectors): The set of all convex combinations of the vectors. **Preliminaries**

**convex polytope:** The convex hull of a finite set of vectors in  $\mathbb{R}^n$ . **Preliminaries**

**coordinate** (part of a vector): In the vector space  $F^n$ , one of the entries of a vector. **1.1**

**coordinate mapping:** The function that maps a vector to its coordinate vector. **2.6**

**coordinate vector:** The vector of coordinates of a vector relative to an ordered basis. **2.6**

**coordinates** (of a vector relative to a basis): The scalars that occur when the vector is expressed as a linear combination of the basis vectors. **2.6**

**copositive** (matrix  $A$ ):  $\mathbf{x}^T A \mathbf{x} \geq 0$  for all  $\mathbf{x} \geq 0$ . **35.5**

**coprime** (elements in a domain): 1 is a greatest common divisor of the elements. **23.1**

**corner minor**: The determinant of a submatrix in the upper right or lower left corner of a matrix. **21.3**

**correlation matrix**: A positive semidefinite matrix in which every main diagonal entry is 1. **8.4**

**cosine** (of a complex square matrix  $A$ ): The matrix defined by the cosine power series,

$$\cos(A) = I - \frac{A^2}{2!} + \cdots + \frac{(-1)^k}{(2k)!} A^{2k} + \cdots \quad \mathbf{11.5}$$

**cospectral** (graphs): Having the same spectrum. **28.3**

**cover** (of a  $(0, 1)$ -matrix): A collection of lines that contain all the 1s of the matrix. **27.1**

**curve segment** (from  $\mathbf{x}$  to  $\mathbf{y}$ ): The range of a continuous map  $\phi$  from  $[0, 1]$  to  $\mathbb{R}^n$  with  $\phi(0) = \mathbf{x}$  and  $\phi(1) = \mathbf{y}$ . **28.2**

**cut-vertex** (of connected simple graph  $G$ ): A vertex  $v$  of  $G$  such that  $G - v$  is disconnected. **36.2**

**( $k$ -)cycle** (in a graph or digraph): A walk (of length  $k$ ) with all vertices distinct except the first vertex equals the last vertex. **28.1, 29.1**

**cycle** (permutation): A permutation  $\tau$  that maps a subset to itself cyclically. **Preliminaries**

**$k$ -cycle** (in sign pattern  $A$ ): A formal product of the form  $a_{i_1 i_2} a_{i_2 i_3} \cdots a_{i_k i_1}$ , where each of the elements is nonzero and the index set  $\{i_1, i_2, \dots, i_k\}$  consists of distinct indices. **33.1**

**$n$ -cycle matrix**: The  $n \times n$  matrix with ones along the first subdiagonal and in the  $1, n$ -entry, and zeros elsewhere. **48.1**

**$n$ -cycle pattern**: A sign pattern  $A$  where the digraph of  $A$  is an  $n$ -cycle. **33.5**

**cycle-clique** (digraph): The induced subdigraph of every cycle is a clique. **35.7**

**cycle product**: A walk product where the walk is a cycle. **29.3**

**cyclic normal form** (of matrix  $A$ ): A matrix in specific form that is permutation similar to  $A$ . **29.7**

**cyclically real** (square ray pattern  $A$ ): The product of every cycle in  $A$  is real. **33.8**

## D

**$\Delta(G)$** :  $\max(p - q)$  over all ways in which  $q$  vertices may be deleted from graph  $G$  leaving  $p$  paths. **34.2**

**$\mathbb{D}$ -invertible,  $\mathbb{D}$ -module,  $\mathbb{D}$ -submodule**: Alphabetized under *invertible, module, submodule*.

**D-optimal** (design matrix  $W$ ):  $\det W^T W$  is maximal over all  $(\pm 1)$ - (or  $(0, 1)$ -) matrices of the given size. **32.1**

**damped least squares solution**: The solution to the problem  $(A^T A + \alpha I)\mathbf{x} = A^T \mathbf{b}$ , where  $\alpha > 0$ . **39.8**

**data fitting**: See Section **39.2**.

**data perturbations** (for linear system  $A\mathbf{x} = \mathbf{b}$ ): Perturbations of  $A$  and/or  $\mathbf{b}$ . **38.1**

**decomposable tensor**: A tensor of the form  $\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_m$ . **13.2**

**defective** (matrix  $A \in F^{n \times n}$ ): There is an eigenvalue of  $A$  (over algebraic closure of  $F$ ) having geometric multiplicity less than its algebraic multiplicity. **4.3**

**deflation**: A process of reducing the size of the matrix whose eigenvalue decomposition is to be determined, given that one eigenvector is known. **42.1**

**degenerate** (bilinear form  $f$  on vector space  $V$ ): Not nondegenerate, i.e., the rank of  $f$  less than  $\dim V$ , **12.1**; also applied to  $\varphi$ -sesquilinear form **12.4**.

**degree** (of polynomial  $p(x_1, \dots, x_n) \neq 0$ ): The largest integer  $m$  such that there is a term  $c x_1^{m_1} \cdots x_n^{m_n}$  with  $c \neq 0$  in  $p$  having degree  $m$ . **23.1**

**degree** (of term  $c x_1^{m_1} \cdots x_n^{m_n}$  in polynomial  $p(x_1, \dots, x_n)$ ): The sum of the degrees of the  $x_i$ , i.e.,  $\sum_i m_i$ .

**degree** (of a vertex  $v$ ): The number of times that  $v$  occurs as an endpoint of an edge. **28.1**

**deletion** (of edge  $e$  from graph  $G = (V, E)$ ): The operation that deletes  $e$  from  $E$ . **28.2**

**deletion** (of vertex  $v$  from graph  $G = (V, E)$ ): The operation that deletes  $v$  from  $V$  and all edges with endpoint  $v$  from  $E$ . **28.2**

**depth** (of eigenvector  $\mathbf{x}$  for eigenvalue  $\lambda$  of  $A$ ): The natural number  $h$  such that  $\mathbf{x} \in \text{range}(A - \lambda I)^h - \text{range}(A - \lambda I)^{h+1}$ . **6.2**

**derogatory** (matrix  $A \in F^{n \times n}$ ): Some eigenvalue of  $A$  (over algebraic closure of  $F$ ) has geometric multiplicity greater than 1. **4.3**

**2-design with parameters**  $(v, k, \lambda)$ : A collection of  $k$ -element subsets (blocks)  $B_i$  of a finite set  $X$  with  $|X| = v$ , such that each 2-element subset of  $X$  is contained in exactly  $\lambda$  blocks. **32.1**

**$(\pm 1)$ -design matrix**: A matrix whose entries are 1 or  $-1$ . **32.1**

**$(0, 1)$ -design matrix**: A matrix whose entries are 1 or 0. **32.1**

**det**: See *determinant*.

**determinant (det)**: A scalar-valued function of a square matrix or linear operator, defined inductively, and also given by  $\det(A) = \sum_{\sigma \in S_n} \text{sgn } \sigma \prod_{i=1}^n a_{i\sigma(i)}$ . **4.1**

**determinantal region** (of complex sign pattern or ray pattern  $A$ ):  $S_A = \{\det(B) : B \in Q(A)\}$ . **33.8**

**determined by its spectrum** (graph  $G$ ): Every graph cospectral with  $G$  is isomorphic to  $G$ . **28.3**

**diagonal** (of a matrix): *The diagonal* means the *main diagonal*, i.e., the set of diagonal entries of a matrix, **1.2**. A diagonal is a collection of  $n$  nonzero entries in  $A$  no two on the same line. **27.2**

**diagonal entry**: An entry that lies in row  $k$  and column  $k$  for some  $k$ . **1.2**

**diagonal matrix**: A matrix all of whose off-diagonal entries are zero. **1.2, 10.2**

**diagonal pattern**: A square sign pattern all of whose off-diagonal entries are zero. **33.1**

**diagonal product** (of a matrix): The product of the entries on a diagonal of the matrix. **27.6**

**diagonalizable** (matrix  $A \in F^{n \times n}$ ): There exist nonsingular matrix  $B \in F^{n \times n}$  and diagonal matrix  $D \in F^{n \times n}$  such that  $A = BDB^{-1}$ . **4.3**

**diagonally dominant** ( $n \times n$  complex matrix  $A$ ):  $|a_{ii}| \geq \sum_{j=1, j \neq i}^n |a_{ij}|$  for  $i = 1, \dots, n$ . **9.5**

**diagonally scaled representation** (of symmetric matrix  $H$  with positive diagonal entries): A factored representation  $H = DAD$  with  $D = \text{diag}(\sqrt{h_{11}}, \dots, \sqrt{h_{nn}})$ ,  $a_{ij} = \frac{h_{ij}}{\sqrt{h_{ii}h_{jj}}}$ . **15.4**

**diagonally scaled totally unimodular (DSTU)** (real matrix  $A$ ): There exist diagonal matrices  $D_1, D_2$  and totally unimodular  $Z$  such that  $A = D_1 Z D_2$ . **46.3**

**diagonally stable**: See *Lyapunov diagonally stable*.

**diameter** (of a connected graph): The largest distance that occurs between two vertices. **28.1**

**digraph**: A directed graph having at most one arc between each ordered pair of vertices (loops permitted). **29.1**

**digraph** (of  $n \times n$  matrix  $A$ ): The digraph having vertices  $\{1, \dots, n\}$  and having arc  $(i, j)$  exactly when  $a_{ij} \neq 0$ . **9.1, 29.2**

**digraph** (of  $n \times n$  partial matrix  $B$ ): The digraph having vertices  $V = \{1, \dots, n\}$  and for each  $i, j \in V$ ,  $(i, j)$  is an arc exactly when  $b_{ij}$  is specified. **35.1**

**dilation**: Matrix  $A \in \mathbb{C}^{n \times n}$  has a dilation  $B \in \mathbb{C}^{m \times m}$  if there is  $X \in \mathbb{C}^{m \times n}$  such that  $X^* X = I_n$  and  $X^* B X = A$ . **18.6**

**dim**: See *dimension*.

**dimension (dim)** (of a vector space): The number of vectors in a basis for the vector space. **2.2**

**dimension (dim)** (of a convex polytope): The smallest dimension of an affine space containing it. **27.6**

**direct sum** (of matrices): A block diagonal matrix with these matrices as the diagonal blocks. **2.4, 10.2**

**direct sum** (of subspaces):  $W_1 + \dots + W_k$  is direct if for all  $i = 1, \dots, k$ ,  $W_i \cap \sum_{j \neq i} W_j = \{0\}$ . **2.3**

**direct sum** (of vector spaces): See *external direct sum*.

**directed bigraph** (of the real  $m \times n$  matrix  $A$ ): The directed graph with vertices  $1, 2, \dots, m, 1', 2', \dots, n'$ , with arc  $(i, j')$  if and only if  $a_{ij} > 0$ , and with arc  $(j', i)$  if and only if  $a_{ij} < 0$ . **30.2**

**directed edge**: See *arc*.

**directed graph**: A finite nonempty set of vertices and a finite multiset of arcs, where each arc is an ordered pair of vertices. **29.1**

**directed multigraph**: A directed graph having more than one arc between at least one pair of vertices. **29.1**

**disjoint** (graphs): The vertex sets are disjoint sets. **28.1**

**dispersion**: See *Section 21.3*.

**distance** (between two vectors): The norm of their difference. **5.1**

**distance** (between two vertices in a graph): The length of a shortest path between the vertices (infinite if no path). **28.1**

**distance** of  $W(A)$  to the origin:  $\tilde{w}(A) = \min\{|\mu| : \mu \in W(A)\}$ . **18.1**

**distance-regular graph**: A connected graph with the property that for every pair of vertices  $u, v$ , the number of vertices that have distance  $i$  from  $u$  and distance  $j$  from  $v$  depends only on  $i, j$ , and the distance between  $u$  and  $v$ . **28.6**

**distinguished eigenvalue** (of nonnegative square matrix  $P$ ): An eigenvalue of  $P$  that has a semipositive eigenvector. **9.1**

$d$  **divides**  $a$  (in a domain  $\mathbb{D}$ ):  $a = db$  for some  $b \in \mathbb{D}$ . **23.1**

**divisor** (i.e.,  $d$  is a divisor of  $a$ ): See *divides*.

**domain** (ring): An integral domain, i.e., a commutative ring without zero divisors and containing identity 1. **23.1**

**domain** (of  $T: V \rightarrow W$ ): The vector space  $V$ . **3.1**

**dominant eigenvalue**:  $\lambda_1$  where  $|\lambda_1| > |\lambda_2| \geq \dots \geq |\lambda_n|$  are the eigenvalues. **42.1**

**dot product**: See *standard inner product*.

**double echelon form**: A special type of real matrix, see **21.1**

**double generalized star**: A tree constructed by joining the centers of two generalized stars by an edge. **34.7**

**double path**: A tree constructed by joining two degree two vertices of two paths by an edge. **34.7**

**double precision**: Typically, floating-point numbers have machine epsilon roughly  $10^{-16}$  and precision roughly 16 decimal digits. **37.6**

**doubly directed tree**: A digraph  $\Gamma$  whose associated undirected graph is a tree and whenever  $(i, j)$  is an arc in  $\Gamma$ ,  $(j, i)$  is also an arc in  $\Gamma$ . **29.1**

**doubly nonnegative** (matrix): A positive semidefinite matrix having every entry nonnegative. **35.4**

**doubly stochastic** (matrix): A square nonnegative matrix having all row and column sums equal to 1. **9.4**

**downdating** (QR factorization): See *Section 39.7*.

**DSTU**: See *diagonally scaled totally unimodular*.

$\Delta$ **TP**: See *triangular totally positive*.

**dual basis**: A specific basis for the dual space defined from a given basis for the vector space. **3.8**

**dual cone** (of cone  $K$ ): See *dual space of cone*.

**dual norm** (of vector norm  $\|\cdot\|$ ):  $\|\mathbf{y}\|^D = \max_{\mathbf{x} \neq 0} \frac{|\mathbf{y}^* \mathbf{x}|}{\|\mathbf{x}\|}$ . **37.1**

**dual space**: The vector space of linear functionals on a given vector space. **3.8**

**dual space** (of cone  $K$ ):  $K^* = \{\mathbf{y} \in V \mid \langle \mathbf{x}, \mathbf{y} \rangle \geq 0 \quad \forall \mathbf{x} \in K\}$  **8.5, 26.1**

## E

**ED**: See *Euclidean domain*.

**ED-RCF basis** (for a linear operator): See *Section 6.4*.

**ED-RCF matrix** (over  $F$ ): A block diagonal matrix of the form  $C(h_1^{m_1}) \oplus \dots \oplus C(h_t^{m_t})$  where each  $h_i(x)$  is a monic polynomial that is irreducible over  $F$ . **6.4**

**EDD**: See *elementary divisor domain*.

**edge**: A pair of vertices, part of a graph. **28.1**

**edge cut**: Let  $G = (V, E)$  be a graph, and let  $X, V \setminus X$  be a nontrivial partitioning of  $V$ . The set  $E_X$  of edges of  $G$  that have one end point in  $X$  and the other end point in  $V \setminus X$  is an edge cut. **36.2**

**efficacy** (of a processor): See *speed*.

**efficient**: One algorithm is more efficient than another, if it accomplishes the same task with a lower cost of computation. **37.7**

**eigenpair** (of  $A \in \mathbb{C}^{n \times n}$ ): A (eigenvalue, eigenvector) pair. **15.1**

**eigenspace** (of eigenvalue  $\lambda$  of  $A$ ):  $\ker(A - \lambda I)$ . **4.3**

$k$ -**eigenspace** (of matrix or linear operator  $A$  at  $\lambda$ ):  $\ker(A - \lambda I)^k$  **6.1**

**eigen triplet** (of  $A \in \mathbb{C}^{n \times n}$ ): A vector-scalar-vector triplet  $(\mathbf{y}, \lambda, \mathbf{x})$  such that  $\mathbf{x} \neq 0$ ,  $\mathbf{y} \neq 0$ , and  $A\mathbf{x} = \lambda\mathbf{x}$ ,  $\mathbf{y}^*A = \lambda\mathbf{y}^*$ . **15.1**

**eigenvalue** (of matrix or linear operator  $A$ ): A scalar  $\lambda$  such that there exists a nonzero vector  $\mathbf{x}$  such that  $A\mathbf{x} = \lambda\mathbf{x}$ . **4.3**

**eigenvalue** (of the pencil  $A - xB$ ):  $\lambda = \mu/\nu$  where  $\nu A\mathbf{v} = \mu B\mathbf{v}$  and  $\mathbf{v} \neq 0$  (if  $\nu = 0, \lambda = \infty$ ). **43.1**

**eigenvalue** (of a graph): An eigenvalue of its adjacency matrix. **28.3**

**eigenvalue decomposition (EVD)** (of real symmetric matrix  $A$ ):  $A = U\Lambda U^T$ , where  $U^T U = U U^T = I_n$ ,  $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_n)$  is a real diagonal matrix of eigenvalues, and the columns of  $U$  are eigenvectors. **42.1**

**eigenvector** (of matrix or linear operator  $A$ ): A nonzero vector  $\mathbf{x}$  such that there exists a scalar  $\lambda$  such that  $A\mathbf{x} = \lambda\mathbf{x}$ . **4.3**

**eigenvector** (of the pencil  $A - xB$ ): Nonzero vector  $\mathbf{v} \in \mathbb{C}^n$  such that there are scalars  $\mu, \nu \in \mathbb{C}$ , not both zero, such that  $\nu A\mathbf{v} = \mu B\mathbf{v}$ . **43.1**

**elementary bidiagonal matrix**: An  $n \times n$  real matrix whose main diagonal entries are all equal to one, and there is at most one nonzero off-diagonal entry and this entry must occur on the super- or sub-diagonal. **21.2**

**elementary divisor domain (EDD)**: A GCDD such that for any three elements  $a, b, c \in \mathbb{D}$  there exists  $p, q, x, y \in \mathbb{D}$  such that  $(a, b, c) = (px)a + (py)b + (qy)c$ . **23.1**

**elementary divisors** (of an ED-RCF matrix): The polynomials whose companion matrices are the diagonal blocks. **6.4**

**elementary divisors** (of matrix or linear operator  $A$ ): The elementary divisors of  $\text{RCF}_{ED}(A)$ . **6.4**

**elementary divisors rational canonical form** (of matrix  $A \in F^{n \times n}$ ): An ED-RCF matrix that is similar to  $A$ . **6.4**

**elementary divisors rational canonical form** (of a linear operator): See *Section 6.4*.

**elementary divisors rational canonical form matrix**: See *ED-RCF matrix*.

**elementary matrix**: The result of doing one elementary row operation on the identity matrix. **1.5**

**elementary column operation**: Column analog of an elementary row operation. **6.5, 23.2**

**elementary row operation** (on a matrix over a domain): Add a multiple of one row to another, interchange two rows, or multiply a row by an invertible domain element. **6.5, 23.2**

**elementary row operation** (on a matrix over a field): Add a multiple of one row to another, interchange two rows, or multiply a row by a nonzero field element. **1.3**

**elementary symmetric function**: The sum of all products of  $n$  variables taken  $k$  at a time. **Preliminaries**

**elimination graph**: A graph, digraph or bigraph associated with the principal submatrix that remains to be factored during Gaussian elimination. **40.4**

**elimination ordering** (for the rows of a matrix): A bijection that specifies the order in which the rows of the matrix are eliminated during Gaussian elimination. **40.5**

**elimination sequence**: See *elimination ordering*.

**embedding**: A representation of a graph in  $\mathbb{R}^n$  where edges intersect only at vertices. **28.2**

**empty graph**: A graph with no edges. **28.1**

**endpoint** (of an edge in a graph): One of the two vertices on the edge. **28.1**

**energy norm**: See *M-norm* (alphabetized under norm).

**$i, j$ -entry**: The scalar in row  $i$  and column  $j$  in a matrix. **1.2**

**entry sign symmetric  $P$ -matrix**  $A$ : A  $P$ -matrix such that for all  $i, j$ , either  $a_{ij}a_{ji} > 0$  or  $a_{ij} = a_{ji} = 0$ . **35.10**

**entry sign symmetric  $P_0$ -matrix**  $A$ : A  $P_0$ -matrix such that for all  $i, j$ , either  $a_{ij}a_{ji} > 0$  or  $a_{ij} = a_{ji} = 0$ . **35.10**

**entry sign symmetric  $P_{0,1}$ -matrix**  $A$ : A  $P_{0,1}$ -matrix such that for all  $i, j$ , either  $a_{ij}a_{ji} > 0$  or  $a_{ij} = a_{ji} = 0$ . **35.10**

**entry weakly sign symmetric  $P$ -matrix**  $A$ : A  $P$ -matrix such that for all  $i, j$ ,  $a_{ij}a_{ji} \geq 0$ . **35.10**

**entry weakly sign symmetric  $P_0$ -matrix**  $A$ : A  $P_0$ -matrix such that for all  $i, j$ ,  $a_{ij}a_{ji} \geq 0$ . **35.10**

**entry weakly sign symmetric  $P_{0,1}$ -matrix**  $A$ : A  $P_{0,1}$ -matrix such that for all  $i, j$ ,  $a_{ij}a_{ji} \geq 0$ . **35.10**

**envelope** (of sparse matrix  $A$ ): The set of indices of the elements between the first and last nonzero elements of every row. **40.5**

**equivalence relation**: A relation that is reflexive, symmetric, and transitive. **Preliminaries**

**equivalent** (bilinear forms  $f, g$ ): There exists an ordered basis  $\mathcal{B}$  such that the matrix of  $g$  relative to  $\mathcal{B}$  is congruent to the matrix of  $f$  relative to  $\mathcal{B}$ . **12.1**

**$\varphi$ -equivalent** (bilinear forms  $f, g$ ): There exists an ordered basis  $\mathcal{B}$  such that the matrix of  $g$  relative to  $\mathcal{B}$  is  $\varphi$ -congruent to the matrix of  $f$  relative to  $\mathcal{B}$ . **12.4**

**\*equivalent** (bilinear forms  $f, g$  on a complex vector space):  $\varphi$ -equivalent with  $\varphi =$  complex conjugation. **12.5**

**equivalent** (matrices  $A, B \in F^{m \times n}$ ):  $B = QAP$  for some invertible matrices  $Q, P$ . **2.4**

**equivalent** (matrices  $A, B \in \mathbb{D}^{m \times n}$ ):  $B = QAP$  for some  $\mathbb{D}$ -invertible matrices  $Q, P$ . **23.2**

**equivalent**: Systems of linear equations that have the same solution set. **1.4**

**ergodic class** (of stochastic matrix  $P$ ): A basic class of  $P$ . **9.4**

**ergodic state**: A state in an ergodic class. **9.4**

**ergodicity coefficient** (of complex matrix  $A$ ):  $\max\{|\lambda| : \lambda \in \sigma(P) \text{ and } |\lambda| \neq \rho(A)\}$ . **9.1**

**error** at step  $k$  of an iterative method for solving  $A\mathbf{x} = \mathbf{b}$ : The difference between the true solution  $A^{-1}\mathbf{b}$  and the approximate solution  $\mathbf{x}_k$ :  $\mathbf{e}_k \equiv A^{-1}\mathbf{b} - \mathbf{x}_k$ . **41.1**

**Euclid's Algorithm**: See *Section 23.1*.

**Euclidean distance** (matrix  $A$ ): There exist vectors  $\mathbf{x}_1, \dots, \mathbf{x}_n \in \mathbb{R}^d$  (for some  $d \geq 1$ ) such that  $a_{ij} = \|\mathbf{x}_i - \mathbf{x}_j\|_2$  for all  $i, j = 1, \dots, n$ . **35.3**

**Euclidean domain (ED)**: A domain  $\mathbb{D}$  with a function  $d : \mathbb{D} \setminus \{0\} \rightarrow \mathbb{Z}^+$  such that for all nonzero  $a, b \in \mathbb{D}$ ,  $d(a) \leq d(ab)$  and there exist  $t, r \in \mathbb{D}$  such that  $a = tb + r$ , where either  $r = 0$  or  $d(r) < d(b)$ . **23.1**

**Euclidean norm** (of a matrix): See *Frobenius norm*.

**Euclidean norm** (of a vector): See *2-norm*.

**Euclidean space**: Finite dimensional real vector space with standard inner product. **5.1**

**EVD**: See *eigenvalue decomposition*.

**even** (permutation): Can be written as the product of an even number of transpositions. **Preliminaries**

**even** (cycle in a sign pattern): The length of the simple or composite cycle is even. **33.1**

**expanders** (or family of expanders): An infinite family of graphs with constant degree and isoperimetric number bounded from below. **28.5**

**explicit restarting** (of the Arnoldi algorithm): A straightforward but inferior way to implement polynomial restarting by explicitly constructing the starting vector  $\psi(A)\mathbf{v}$  by applying  $\psi(A)$  through a sequence of matrix-vector products. **44.5**

**exponent** (of floating point number  $x$ ):  $e$  in floating point number  $x = \pm \left(\frac{m}{b^{p-1}}\right) b^e$ . **37.6**

**exponent** (of a primitive digraph): Period; equivalently, the smallest value of  $k$  that works in the definition of primitivity. **29.6**

**exponent** (of a primitive matrix  $A$ ): The exponent of the digraph of  $A$ . **29.6**

**exponent of matrix multiplication complexity**: The infimum of the real numbers  $w$  such that there exists an algorithm for multiplying  $n \times n$  matrices with  $O(n^w)$  arithmetic operations. **47.2**

**exponential** (of a square complex matrix  $A$ ): The matrix defined by the exponential power series,  $e^A = I + A + \frac{A^2}{2!} + \dots + \frac{A^k}{k!} + \dots$ . **11.3**

**extended precision**: Floating point numbers that have greater than double precision. **37.6**

**extension**: Signing  $D' = \text{diag}(d'_1, d'_2, \dots, d'_k)$  is an extension of signing  $D$  if  $D' \neq D$  and  $d'_i = d_i$  whenever  $d_i \neq 0$ . **33.3**

**external direct sum** (of vector spaces): The cartesian product of the vector spaces with component-wise operations. **2.3**

**exterior power** (of a vector space): See *Grassman space*.

**exterior product** (of vectors  $\mathbf{v}_1, \dots, \mathbf{v}_m$ ):  $\mathbf{v}_1 \wedge \dots \wedge \mathbf{v}_m = m! \text{Alt}(\mathbf{v}_1 \otimes \dots \otimes \mathbf{v}_m)$ . **13.6**

**extreme point** (of a closed convex set  $S$ ): A point in  $S$  that is not a nontrivial convex combination of other points in  $S$ . **Preliminaries**

**extreme vector**  $\mathbf{v} \in K$ : Either  $\mathbf{v}$  is the zero vector or  $\mathbf{v}$  is nonzero and  $\Phi(\mathbf{v}) = \{\lambda \mathbf{v} : \lambda \geq 0\}$ . **26.1**

## F

**face**  $F$  (of cone  $K$ ): A subcone of  $K$  such that  $\mathbf{v} \in F$ ,  $\mathbf{v} \geq^K \mathbf{w} \geq^K \mathbf{0} \implies \mathbf{w} \in F$ . **26.1**

**face of  $K$  generated by  $S \subseteq K$** : The intersection of all faces of  $K$  containing  $S$ . **26.1**

**family of Toeplitz matrices** (defined by symbol  $a = \sum_{k=-\infty}^{\infty} a_k z^k$ ): The set  $\{T_n\}_{n \geq 1}$  where  $T_n$  has constants  $a_{1-n}, \dots, a_{n-1}$ . **16.2**

**Fiedler vector** (of simple graph  $G$ ): An eigenvector of the Laplacian of  $G$  corresponding to the algebraic connectivity. **36.1**

**field**: A nonempty set with two binary operations, addition and multiplication, satisfying commutativity, associativity, distributivity and existence of identities and inverses. **Preliminaries**

**field of rational functions**: The quotient field of the field of polynomials over  $F$ . **23.1**

**field of values**: See *numerical range*.

**fill element** (in a sparse matrix  $A$ ): An element that is zero in  $A$  but becomes nonzero during Gaussian elimination. **40.3**

**fill graph** (of sparse matrix  $A$ ): The (graph, digraph, or bigraph) of  $A$ , together with all the additional edges corresponding to the fill elements that occur during Gaussian elimination. **30.2, 40.5**

**fill matrix** (of Gaussian elimination on a matrix): The matrix  $M_1 + M_2 + \dots + M_{n-1} - (n-1)I + U$ , where the  $M_i$  are Gauss transformations used in the elimination and  $U$  is the resulting upper triangular matrix. **40.3**

**final** (subset  $\alpha$  of vertices): no vertex in  $\alpha$  has access to a vertex not in  $\alpha$ . **9.1**

**finite dimensional** (vector space  $V$ ):  $V$  has a basis containing a finite number of vectors. **2.2**

**finitely generated** (ideal  $I$  of a domain  $\mathbb{D}$ ): An ideal of  $\mathbb{D}$  that is finitely generated as a  $\mathbb{D}$ -module. **23.1**

**finitely generated** (module  $\mathbf{M}$  over a domain  $\mathbb{D}$ ): There exist  $k$  elements (*generators*)  $\mathbf{v}_1, \dots, \mathbf{v}_k \in \mathbf{M}$  so that every  $\mathbf{v} \in \mathbf{M}$  is a linear combination of  $\mathbf{v}_1, \dots, \mathbf{v}_k$ , over  $\mathbb{D}$ . **23.3**

**fixed space**: the set of vectors fixed by a linear transformation. **3.6**

**flip map**: See *Section 22.2*.

**floating point addition, subtraction multiplication, division**: Operations on floating point numbers, See *Section 37.6*.

**floating point number**: A real number of the form  $x = \pm \left(\frac{m}{b^{p-1}}\right) b^e$ . **37.6**

**floating point operation**: One of floating point addition, subtraction, multiplication, division. **37.6**

**flop**: A floating point operation. **37.7**

**FOM**: See *full orthogonalization method*.

**forest**: A graph with no cycles. **28.1**

**forward error** (in  $\hat{f}(\mathbf{x})$ ):  $f(\mathbf{x}) - \hat{f}(\mathbf{x})$ , the difference between the mathematically exact function evaluation and the perturbed function evaluation. **37.8**

**forward stable** (algorithm): The forward relative error is small for all valid input data  $\mathbf{x}$  despite rounding and truncation errors in the algorithm. **37.8**

**free variable**: A variable  $x_i$  in the solution to a system of linear equations that is a free parameter. **1.4**

**Frobenius norm** (of  $m \times n$  complex matrix  $A$ ):  $\|A\|_F = \sqrt{\sum_{i=1}^m \sum_{j=1}^n |a_{ij}|^2}$ . **7.1, 37.3**

**Frobenius normal form** (of matrix  $A$ ): A block upper triangular matrix with irreducible diagonal blocks that is permutation similar to  $A$ . **27.3**

**full** (cone): Has a nonempty interior. **8.5, 26.1**

**fully indecomposable** ( $(0, 1)$ -matrix): Not partly decomposable. **27.2**

**full orthogonalization method (FOM)**: Generates, at each step  $k$ , the approximation  $\mathbf{x}_k$  of the form  $\mathbf{x}_k \in \mathbf{x}_0 + \text{Span}\{\mathbf{r}_0, A\mathbf{r}_0, \dots, A^{k-1}\mathbf{r}_0\}$  for which the residual is orthogonal to the Krylov space. **41.3**

**fundamental subspaces** (of the least squares problem  $A\mathbf{x} = \mathbf{b}$ ):  $\text{range } A, \ker A^T, \ker A$  and  $\text{range } A^T$ . **39.3**

## G

**Galerkin condition**: The defining condition for a Ritz vector and Ritz value. **44.1**

**Gauss multipliers**: The nonzero entries in a Gauss vector. **38.3**

**Gauss transformation**: The matrix  $M_k = I - \ell_k \mathbf{e}_k^T$ , where  $\ell_k$  is a Gauss vector. **38.3**

**Gauss vector:** A vector  $\ell_k \in \mathbb{C}^n$  with the leading  $k$  entries equal to zero. **38.3**

**Gauss–Jordan elimination:** A process used to find the reduced row echelon form of a matrix. **1.3**

**Gaussian elimination:** A process used to find a row echelon form of a matrix. **1.3, 38.3**

**g.c.d.:** See *greatest common divisor*.

**GCDD:** See *greatest common divisor domain*.

**general linear group** (of order  $n$  over  $F$ ): The multiplicative group consisting of all invertible  $n \times n$  matrices over the field  $F$ . **67.1**

**general solution:** A formula that describes every vector in the solution set to a system of linear equations. **1.4**

**generalized cycle** (in a digraph): A disjoint union of one or more cycles such that every vertex lies on exactly one cycle. **29.1**

**generalized cycle product:** A walk product where the walk is a generalized cycle. **29.4**

**generalized diagonal** (of square matrix  $A$ ): Entries of  $A$  corresponding to a generalized cycle in the digraph of  $A$ . **29.4**

**generalized eigenspace** (of matrix or linear operator  $A$  at  $\lambda$ ):  $\ker(A - \lambda I)^v$ , where  $v$  is the index of  $A$  at  $\lambda$ . **6.1**

**generalized eigenvector** (of a matrix or linear operator): A nonzero vector in the generalized eigenspace. **6.1**

**generalized Laplacian** (of simple graph  $G$ ): A matrix  $M$  such that for  $i \neq j$ ,  $m_{ij} < 0$  if the  $i$ th and  $j$ th vertices are adjacent and  $m_{ij} = 0$  otherwise (no restriction for  $i = j$ ). **28.4**

**generalized line graph:** See *Section 28.2*.

**generalized minimal residual (GMRES):** Algorithm generates, at each step  $k$ , the approximation  $\mathbf{x}_k$  of the form  $\mathbf{x}_k \in \mathbf{x}_0 + \text{Span}\{\mathbf{r}_0, A\mathbf{r}_0, \dots, A^{k-1}\mathbf{r}_0\}$  for which the 2-norm of the residual is minimal. **41.3**

**generalized sign pattern:** A matrix whose entries are from the set  $\{+, -, 0, \#\}$ , where  $\#$  indicates an ambiguous sum (the result of adding  $+$  with  $-$ ). **33.1**

**generalized star:** A tree in which at most one vertex has degree greater than two. **34.6**

**generators** (of an ideal): See *finitely generated*.

**generic matrix:** A matrix whose nonzero elements are independent indeterminates over the field  $F$ . **30.2**

**geometric multiplicity:** The dimension of the eigenspace. **4.3**

**Geršgorin discs** (of  $A \in \mathbb{C}^{n \times n}$ ):  $\{z \in \mathbb{C} : |z - a_{ii}| \leq \sum_{j \neq i} |a_{ij}|\}$  for  $i = 1, \dots, n$ . **14.2**

**Givens matrix:** See *Givens transformation*.

**Givens rotation:** See *Givens transformation*.

**Givens transformation:** An identity matrix modified so that the  $(i, i)$  and  $(j, j)$  entries are replaced by  $c = \cos(\theta)$ , the  $(i, j)$  entry is replaced by  $s = e^{i\theta} \sin(\theta)$ , and the  $(j, i)$  entry is replaced by  $-\bar{s} = -e^{-i\theta} \sin(\theta)$ . **38.4**

**GMRES:** See *generalized minimal residual, restarted GMRES algorithm*.

**graded** (associative algebra  $A$ ): There exist  $(A_k)_{k \in \mathbb{N}}$  vector subspaces of  $A$  such that  $A = \bigoplus_{k \in \mathbb{N}} A_k$  and  $A_i A_j \subseteq A_{i+j}$  for every  $i, j \in \mathbb{N}$ . **13.9**

**graded matrix**  $A \in \mathbb{C}^{m \times n}$ :  $A$  can be scaled as  $A = GS$  (or  $A = S^*GS$ , depending on situation) such that  $G$  is “well-behaved” (i.e.,  $\kappa_2(G)$  is of modest magnitude), where  $S$  is a scaling matrix (often diagonal). **15.3**

**Gram matrix** (of vectors  $\mathbf{v}_1, \dots, \mathbf{v}_n$  in a complex inner product space): the matrix whose  $i, j$ -entry is  $\langle \mathbf{v}_i, \mathbf{v}_j \rangle$ . **8.1**

**graph:** A finite set of vertices and a finite multiset of edges, where each edge is an unordered pair of vertices (not necessarily distinct). **28.1**

**graph** (of  $n \times n$  matrix  $A$ ): The simple graph whose vertex set is  $\{1, \dots, n\}$  and having an edge between vertices  $i$  and  $j$  ( $i \neq j$ ) if and only if  $a_{ij} \neq 0$  or  $a_{ji} \neq 0$ . **19.3, 34.1**

**graph** (of a convex polytope  $\mathcal{P}$ ): Vertices are the extreme points of  $\mathcal{P}$  and edges are the pairs of extreme points of 1-dimensional faces of  $\mathcal{P}$ . **27.6**

**graph** (of  $n \times n$  combinatorially symmetric partial matrix  $B$ ): The graph having vertices  $V = \{1, \dots, n\}$  and for each  $i, j \in V$ ,  $\{i, j\}$  is an edge exactly when  $b_{ij}$  is specified (loops permitted, no multiple edges). **35.1**

**graph of a combinatorially symmetric  $n \times n$  sign pattern**  $A = [a_{ij}]$ : The graph with vertex set  $\{1, 2, \dots, n\}$  where  $\{i, j\}$  is an edge iff  $a_{ij} \neq 0$  (note: the graph may have loops). **33.5**

**Grassman algebra** (on vector space  $V$ ):  $\bigwedge V = \bigoplus_{k \in \mathbb{N}} \binom{\wedge^k V}$  with alt multiplication. **13.9**

**Grassmann space** (of vector space  $V$ ):  $\bigwedge^m V = \text{Alt}(\bigotimes^m V)$ . **13.6**

**greatest common divisor (g.c.d.)** (of  $a_1, \dots, a_n \in \mathbb{D}$ ):  $d \in \mathbb{D}$  such that  $d|a_i$  for  $i = 1, \dots, n$ , and if  $d'|a_i, i = 1, \dots, n$ , then  $d'|d$ . **23.1**

**greatest common divisor domain (GCDD)**: A domain in which any two elements have a g.c.d. **23.1**

**greatest integer** (of a real number  $x$ ): the greatest integer less than or equal to  $x$ . **Preliminaries**

**group**: A set with one binary operation, satisfying associativity, existence of identity and inverses. **Preliminaries**

**group inverse** (of square complex matrix  $A$ ): A matrix  $X$  satisfying  $AXA = A, XAX = X$  and  $AX = XA$ . **9.1**

## H

**H-matrix** (real square matrix  $A$ ): The comparison matrix of  $A$  is an  $M$ -matrix. **19.5**

**Hadamard matrix**: A  $\pm 1$ -matrix  $H_n$  with  $H_n H_n^T = nI_n$ . **32.2**

**Hadamard product** (of  $A, B \in F^{n \times n}$ ): The  $n \times n$  matrix whose  $i, j$ -entry is  $a_{ij}b_{ij}$ . **8.5**

**Hall matrix**: An  $n \times n$   $(0, 1)$ -matrix that does not have a  $p \times q$  zero submatrix for positive integers  $p, q$  with  $p + q > n$ . **27.2**

**Hamilton cycle**: A cycle in a graph that includes all vertices. **28.1**

**Hamiltonian cycle**: See *Hamilton cycle*.

**Hankel matrix**: A matrix with constant elements along its antidiagonals. **48.1**

**height** (of basic class  $B$ ): The largest number of vertices on a simple walk that ends at  $B$  in the basic reduced digraph. **9.3**

**hereditary** (class of matrices  $X$ ): Whenever  $A$  is an  $X$ -matrix and  $\alpha \subseteq \{1, \dots, n\}$ , then  $A[\alpha]$  is an  $X$ -matrix. **35.1**

**Hermite normal form**: A generalization of reduced row echelon form used in domains. **23.2**

**Hermitian** (linear operator on an inner product space): An operator that is equal to its adjoint. **5.3**

**Hermitian** (matrix): A real or complex matrix equal to its conjugate transpose. **1.2, 7.2, 8.1**

**Hermitian adjoint** (of a matrix): The conjugate transpose of a real or complex matrix. **1.2**

**Hermitian form**  $f$  (on complex vector space  $V$ ): A sesquilinear form such that  $f(\mathbf{v}, \mathbf{u}) = \overline{f(\mathbf{u}, \mathbf{v})}$  for all  $\mathbf{u}, \mathbf{v} \in V$ . **12.5**

**Hoffman polynomial** (of graph  $G$ ): A polynomial  $h(x)$  of minimum degree such that  $h(A_G) = J$ . **28.3**

**Hölder norm**: See *p-norm*.

**homogeneous** (digraph): Either symmetric or asymmetric. **35.7**

**homogeneous** (element of graded algebra  $A = \bigoplus_{k \in \mathbb{N}} A_k$ ): An element of some  $A_k$ . **13.9**

**homogeneous** (pencil associated with  $A(x) = A_0 + xA_1 \in \mathbb{D}[x]^{m \times n}$ ):  $A(x_0, x_1) = x_0A_0 + x_1A_1 \in \mathbb{D}[x_0, x_1]^{m \times n}$ . **23.4**

**homogeneous** (polynomial): All terms have the same degree. **23.1**

**homogeneous** (system of linear equations): A system in which all the constants are zero. **1.4**

**Householder matrix**: See *Householder transformation*.

**Householder reflector**: See *Householder transformation*.

**Householder transformation** (defined by  $\mathbf{v} \in \mathbb{C}^n$ ): The matrix  $I - \frac{2}{\|\mathbf{v}\|_2^2} \mathbf{v}\mathbf{v}^*$ . **38.4**

**Householder vector**: The vector  $\mathbf{v}$  used to define a Householder transformation. **38.4**

**hyperbolic SVD decomposition** (of matrix pair  $(G, \mathcal{J})$ ): A decomposition of  $G, G = W\Sigma B^{-1}$ , where  $W$  is orthogonal,  $\Sigma$  is diagonal, and  $B$  is  $\mathcal{J}$ -orthogonal. **46.5**

## I

**IAP**: See *inertially arbitrary pattern*.

**ideal** (of a domain  $\mathbb{D}$ ): A nonempty subset  $I$  of  $\mathbb{D}$  such that if  $a, b \in I$  and  $p, q \in \mathbb{D}$ , then  $pa + qb \in I$ . **23.1**

**idempotent**: A matrix or linear transformation that squares to itself. **2.7, 3.6**

**identity matrix**: A diagonal matrix having all diagonal elements equal to one. **1.2**

**identity pattern** (of order  $n$ ): The  $n \times n$  diagonal pattern with + diagonal entries. **33.1**

**identity transformation**: A linear operator that maps each vector to itself. **3.1**

**IEP:** See *inverse eigenvalue problem*.

**IF-RCF matrix:** A block diagonal matrix of the form  $C(a_1) \oplus \cdots \oplus C(a_s)$ , where  $a_i(x)$  divides  $a_{i+1}(x)$  for  $i = 1, \dots, s - 1$ . **6.6**

**ill-conditioned** (input  $\mathbf{z}$  for  $P$ ): Some small relative perturbation of  $\mathbf{z}$  causes a large relative perturbation of  $P(\mathbf{z})$ . **37.4**

**image:** See *range*.

**imaginary part** (of complex number  $a + bi$ ):  $b$ . **Preliminaries**

**immanent:** A function  $f_\lambda$  from complex square matrices to complex numbers defined by the irreducible character of a partition  $\lambda$  of  $n$ , specifically,  $f_\lambda(M) = \sum_{\sigma \in S_n} \chi_\lambda(\sigma) \prod_{i=1}^n m_{i\sigma(i)}$ . **31.10**

**implicit restarting** (of the Arnoldi algorithm): Apply a sequence of implicitly shifted QR steps to an  $m$ -step Arnoldi or Lanczos factorization to obtain a truncated form of the implicitly shifted QR-iteration. **44.5**

**imprimitive** (digraph): Not primitive. **29.6**

**imprimitive** (matrix  $A$ ): The digraph  $\Gamma(A)$  is imprimitive. **29.6**

**improper** (divisor of  $a$  in a domain): An associate of  $a$  or a unit. **23.1**

**incidence matrix** (of a graph): A matrix with rows indexed by the vertices and columns indexed by the edges, having  $i, j$  entry 1 if vertex  $v_i$  is an endpoint of edge  $e_j$  and 0 otherwise. **28.4**

**incidence matrix** (of subsets  $S_1, S_2, \dots, S_m$  of a finite set  $\{x_1, x_2, \dots, x_n\}$ ): The  $m \times n$  (0,1)-matrix  $M = [m_{ij}]$  in which  $m_{ij} = 1$  iff  $x_j \in S_i$ . **31.3**

**( $\pm 1$ )-incidence matrix** (of a 2-design): A matrix  $W$  whose rows are indexed by the elements  $x_i$  of  $X$  and whose columns are indexed by the blocks  $B_j$  having  $w_{ij} = -1$  if  $x_i \in B_j$  and  $w_{ij} = +1$  otherwise. **32.2**

**incomplete Cholesky decomposition:** A preconditioner for a Hermitian positive definite matrix  $A$  of the form  $M = LL^*$ , where  $L$  is a sparse lower triangular matrix. **41.4**

**incomplete LU decomposition:** A preconditioner for a general matrix  $A$  of the form  $M = LU$ , where  $L$  and  $U$  are sparse lower and upper triangular matrices. **41.4**

**inconsistent:** A system of linear equations that has no solution. **1.4**

**indefinite** (Hermitian matrix  $A$ ): Neither  $A$  nor  $-A$  is positive semidefinite. **8.4**

**independent** (subspaces  $W_i$ ):  $\mathbf{w}_1 + \cdots + \mathbf{w}_k = \mathbf{0}$  and  $\mathbf{w}_i \in W_i, i = 1, \dots, k$  implies  $\mathbf{w}_i = \mathbf{0}$  for all  $i = 1, \dots, k$ . **2.3**

**independent set of vertices:** See *clique*.

**index** (of an eigenvalue): The smallest integer  $k$  such that the  $k$ -eigenspace equals the  $k + 1$ -eigenspace. **6.1**

**index** (of square nonnegative matrix  $P$ ): The index of the spectral radius of  $P$ . **9.3**

**index** (of  $A \in H_0$ ): See *Section 23.3*.

**index of imprimitivity** (of an irreducible matrix  $A$ ): The greatest common divisor of the lengths of all cycles in the digraph  $\Gamma(A)$ ; same as period. **29.7**

**index of primitivity:** See *exponent*.

**individual condition number** for eigenvalue  $\lambda$ :  $\frac{\|\mathbf{x}\|_2 \|\mathbf{y}\|_2}{|\mathbf{y}^* \mathbf{x}|}$  where  $(\mathbf{y}, \lambda, \mathbf{x})$  is an eigentriplet. **15.1**

**induced basis:** The nonzero images in the quotient  $V/W$  of vectors in a basis that contains a basis for  $W$ . **2.3**

**induced norm:** The matrix norm induced by the family of vector norms  $\|\cdot\|$  is  $\|A\| = \max_{\mathbf{x} \neq \mathbf{0}} \frac{\|A\mathbf{x}\|}{\|\mathbf{x}\|}$ . **37.3**

**induced subdigraph** (of  $\Gamma = (V, E)$ ): A subdigraph  $\Gamma = (V', E')$  containing all arcs from  $E$  with endpoints in  $V'$ . **29.1**

**induced subgraph** (of  $G = (V, E)$ ): A subgraph  $G = (V', E')$  containing all edges from  $E$  with endpoints in  $V'$ . **28.1**

**inertia** (of complex square matrix  $A$ ): The ordered triple  $\text{in}(A) = (\pi(A), \nu(A), \delta(A))$  where  $\pi(A)$  is the number of eigenvalues of  $A$  with positive real part,  $\nu(A)$  is the number of eigenvalues of  $A$  with negative real part, and  $\delta(A)$  is the number of eigenvalues of  $A$  on the imaginary axis. **8.3, 19.1**

**inertia preserving** (real square matrix  $A$ ): The inertia of  $AD$  is equal to the inertia of  $D$  for every nonsingular real diagonal matrix  $D$ . **19.3**

**inertially arbitrary pattern (IAP):** A sign pattern  $A$  of size  $n$  such that every possible ordered triple  $(p, q, z)$  of nonnegative integers  $p, q$ , and  $z$  with  $p + q + z = n$  can be achieved as the inertia of some  $B \in Q(A)$ . **33.6**

**infinite dimensional** (vector space): A vector space that is not finite dimensional. **2.2**

**initial** (minor): See *Section 21.3*

**injective**: See *one-to-one*.

**inner distribution**: Vector parameter of an association scheme. **28.6**

**inner product** (on a vector space  $V$  over  $F = \mathbb{R}$  or  $\mathbb{C}$ ): A function  $\langle \cdot, \cdot \rangle: V \times V \rightarrow F$  satisfying certain conditions. For  $F = \mathbb{R}$ ,  $\langle \cdot, \cdot \rangle$  is symmetric, bilinear and positive definite. **5.1**

**inner product space**: A real or complex vector space with an inner product. **5.1**

**integral domain**: A commutative ring without zero divisors and containing identity 1. **23.1**

**iterative method** (for solving a linear system  $Ax = \mathbf{b}$ ): Any algorithm that starts with an initial guess  $\mathbf{x}_0$  for the solution and successively modifies that guess in an attempt to obtain improved approximate solutions  $\mathbf{x}_1, \mathbf{x}_2, \dots$ . **41.1**

**internal direct sum**: See *direct sum*.

**intersection** (of two graphs  $G = (V, E)$  and  $G' = (V', E')$ ): The graph with vertex set  $V \cap V'$ , and edge (multi)set  $E \cap E'$ . **28.1**

**intersection numbers**: Parameters of an association scheme. **28.6**

**$P$ -invariant face** (of  $K$ -nonnegative matrix  $P$ ):  $PF \subseteq F$ . **26.1**

**invariant factors** (of IF-RCF matrix  $C(a_1) \oplus \dots \oplus C(a_s)$ ): The polynomials  $a_i(x), i = 1, \dots, s$ . **6.6**

**invariant factors** (of matrix or linear operator  $A \in F^{n \times n}$ ): The invariant factors of the invariant factors rational canonical form of  $A$ . **6.6**

**invariant factors** (of a matrix over a domain): See *Section 23.1*.

**invariant factors rational canonical form** (of matrix  $A \in F^{n \times n}$ ): The IF-RCF matrix similar to  $A$ . **6.6**

**invariant factors rational canonical form** (of a linear operator): See *Section 6.6*.

**invariant factors rational canonical form matrix**: See *IF-RCF matrix*.

**invariant polynomials**: See *invariant factors*.

**invariant subspace** (of linear transformation  $T: V \rightarrow W$ ): A subspace  $U$  of  $V$  such that for all  $\mathbf{u} \in U$ ,  $T(\mathbf{u}) \in U$ . **3.6**

**inverse** (of square matrix  $A$ ): A matrix  $B$  such that  $AB = BA = I$ . **1.5**

**inverse** (of linear transformation  $T: V \rightarrow W$ ): A linear transformation  $S: W \rightarrow V$  such that  $TS = I_W$  and  $ST = I_V$ . **3.7**

**inverse eigenvalue problem**: The problem of constructing a matrix with prescribed structural and spectral constraints. **20.1**

**inverse eigenvalue problem with prescribed entries**: Construct a matrix with given eigenvalues subject to given entries in given positions. **20.1**

**Inverse Eigenvalue Problem of tree  $T$** : Determine all possible spectra that occur among matrices in  $S(T)$ . **34.5**

**inverse iteration**: The power method applied to the inverse of a shifted matrix. **42.1**

**inverse  $M$ -matrix**: An invertible matrix whose inverse is an  $M$ -matrix. **9.5**

**inverse nonnegative**: A square sign pattern that allows an entrywise nonnegative inverse. **33.7**

**inverse-positive** (real square matrix  $A$ ):  $A$  is nonsingular and  $A^{-1} \geq 0$ . **9.5**

**inverse positive** (square sign pattern): Allows an entrywise positive inverse. **33.7**

**invertible** (matrix or linear transformation): Has an inverse. **1.5, 3.7**

**$\mathbb{D}$ -invertible** (matrix in  $\mathbb{D}^{n \times n}$ ): Has an inverse within  $\mathbb{D}^{n \times n}$ . **23.2**

**irreducible** (element  $a$  of a domain):  $a$  is not a unit and every divisor of  $a$  is an associate of  $a$  or a unit. **23.2**

**irreducible** (matrix): Not reducible. **9.2, 27.3**

**$K$ -irreducible** ( $K$ -nonnegative matrix  $P$ ): The only  $P$ -invariant faces are the trivial faces. **26.1**

**irreducible components** (of matrix  $A$ ): The diagonal blocks in the Frobenius normal form of  $A$ . **27.3**

**isolated vertex**: A vertex of a graph having no incident edges. **28.1**

**isomorphic** (graphs  $G = (V, E)$  and  $G' = (V', E')$ ): There exist bijections  $\phi: V \rightarrow V'$  and  $\psi: E \rightarrow E'$ , such that  $v \in V$  is an endpoint of  $e \in E$  if and only if  $\phi(v)$  is an endpoint of  $\psi(e)$ . **28.1**

**isomorphic** (vector spaces): There is an isomorphism from one vector space onto the other. **3.7**

**isomorphism** (of vector spaces): An invertible linear transformation. **3.7**

**isoperimetric number**: A parameter of a simple graph. **28.5**

## J

$\mathcal{J}$ -orthogonal: Alphabetized under *orthogonal*.

**Jacobi method** (for computing the EVD of  $A$ ): A sequence of matrices,  $A_0 = A$ ,  $A_{k+1} = G(i_k, j_k, c, s) A_k G(i_k, j_k, c, s)^T$ ,  $k = 1, 2, \dots$ , where  $G(i_k, j_k, c, s)$  is a Givens rotation matrix. **42.7**

**Jacobi rotation**: A Givens rotation used in the Jacobi method. **42.7**

**join** (of disjoint graphs  $G = (V, E)$  and  $G' = (V', E')$ ): The union of  $G \cup G'$  and the complete bipartite graph with vertex set  $V \cup V'$  and partition  $\{V, V'\}$ . **28.1**

**join** (of faces  $F, G$  of cone  $K$ ): Face generated by  $F \cup G$ . **26.1**

**Jordan basis** (for matrix  $A$ ): The ordered set of columns of  $C$  where  $\text{JCF}(A) = C^{-1}AC$ . **6.2**

**Jordan basis** (of a linear operator): See *Section 6.2*.

**Jordan block** (of size  $k$  with eigenvalue  $\lambda$ ): The  $k \times k$  matrix having every diagonal entry equal to  $\lambda$ , every first superdiagonal entry equal to 1, and every other entry equal to 0. **6.2**

**Jordan canonical form** (of matrix  $A$ ): A Jordan matrix that is similar to  $A$ . **6.2**

**Jordan canonical form** (of a linear operator  $T$ ):  ${}_B[T]_B$  that is a Jordan matrix. **6.2**

**Jordan chain** (above eigenvector  $\mathbf{x}$  for eigenvalue  $\lambda$  of  $A$ ): A sequence of vectors  $\mathbf{x}_0 = \mathbf{x}, \mathbf{x}_1, \dots, \mathbf{x}_h$  satisfying  $\mathbf{x}_i = (A - \lambda I)\mathbf{x}_{i+1}$  for  $i = 0, \dots, h - 1$  (where  $h$  is the depth of  $\mathbf{x}$ ). **6.2**

**Jordan invariants** (of matrix or linear operator  $A$ ): The set of distinct eigenvalues of  $A$  and for each eigenvalue  $\lambda$ , the number  $b_\lambda$  and sizes  $p_1, \dots, p_{b_\lambda}$  of the Jordan blocks with eigenvalue  $\lambda$  in a Jordan canonical form of  $A$ . **6.2**

**Jordan matrix**: A block diagonal matrix having Jordan blocks as the diagonal blocks. **6.2**

## K

**$K$ -irreducible,  $K$ -nonnegative,  $K$ -positive,  $K$ -semipositive**: Alphabetized under *irreducible, nonnegative, positive, semipositive*.

**ker**: See *kernel*.

**kernel (ker)** (of a linear transformation): The set of vectors mapped to zero by the transformation. **3.5**

**kernel (ker)** (of a matrix  $A$ ): The set of solutions to  $A\mathbf{x} = \mathbf{0}$ . **2.4**

**Kronecker product** (of matrices  $A$  and  $B$ ): The block matrix whose  $i, j$  block is  $a_{ij}B$ . **10.4**

**Krylov matrix** (of matrix  $A$ , vector  $\mathbf{x}$ , and positive integer  $k$ ):  $[\mathbf{x}, A\mathbf{x}, A^2\mathbf{x}, \dots, A^{k-1}\mathbf{x}]$ . **42.8**

**Krylov space**: A subspace of the form  $\text{Span}\{\mathbf{q}, A\mathbf{q}, A^2\mathbf{q}, \dots, A^{k-1}\mathbf{q}\}$ , where  $A$  is an  $n$  by  $n$  matrix and  $\mathbf{q}$  is an  $n$ -vector. **41.1, 44.1**

**Ky Fan  $k$  norms** (of  $A \in \mathbb{C}^{m \times n}$ ):  $\|A\|_{K,k} = \sum_{i=1}^k \sigma_i(A)$ . **17.3**

## L

**$L$ -matrix** (sign pattern or real matrix  $A$ ): For every  $B \in Q(A)$ , the rows of  $B$  are linearly independent. **33.3**

**Lanczos algorithm** (for Hermitian matrices): A short recurrence for constructing an orthonormal basis for a Krylov space. **41.2**

**Laplacian**: See *Laplacian matrix*.

**Laplacian eigenvalues** (of simple graph  $G$ ): The eigenvalues of the Laplacian matrix of  $G$ . **28.4**

**Laplacian matrix** (of simple graph  $G$ ): The matrix  $D - \mathcal{A}_G$ , where  $D$  is the diagonal matrix of vertex degrees and  $\mathcal{A}_G$  is the adjacency matrix of  $G$ . **28.4**

**Laplacian matrix** (of a weighted graph): The matrix  $L = [\ell_{ij}]$  such that  $\ell_{ij} = 0$  if vertices  $i$  and  $j$  are distinct and not adjacent,  $\ell_{ij} = -w(e)$  if  $e = \{i, j\}$  is an edge, and  $\ell_{i,i} = \sum w(e)$ , where the sum is taken over all edges  $e$  incident with vertex  $i$ . **36.4**

**largest size of a zero submatrix**: The maximum of  $r + s$  such that the matrix has an  $r \times s$  (possibly vacuous) zero submatrix. **27.1**

**$L$ DU factorization**: A factorization of a matrix as the product of a unit lower triangular matrix, a diagonal matrix, and a unit upper triangular matrix. **1.6**

**leading principal minor**: The determinant of a leading principal submatrix. **4.2**

**leading principal submatrix:** A principal submatrix lying in rows and columns 1 to  $k$ . **1.2**

**leading entry:** The first nonzero entry in a row of a matrix in REF. **1.3**

**least squares data fitting:** See *Section 39.2*.

**least squares problem** ( $A\mathbf{x} = \mathbf{b}$ ): Find a vector  $\mathbf{x} \in \mathbb{R}^n$  such that  $\|\mathbf{b} - A\mathbf{x}\|_2$  is minimized. **5.8, 39.1**

**least squares solution:** A solution to a least squares problem. **5.8, 39.1**

**left singular space:** See *singular spaces*.

**left singular vector:** See *singular vectors*.

**left eigenvector** (of matrix  $A$ ): A nonzero row vector  $\mathbf{y}$  such that there exists a scalar  $\lambda$  such that  $\mathbf{y}A = \lambda\mathbf{y}$ . **4.3**

**length** (of a walk, path, cycle in a graph or digraph): The number of edges (arcs) in the walk. **28.1, 29.1**

**length** (of a permutation cycle): The number of elements in the cycle. **Preliminaries**

**length** (of a vector): See *norm*.

**( $C, 0$ )-limit** (of complex sequence  $\{a_m\}_{m=0,1,\dots}$ ): Ordinary limit  $\lim_{m \rightarrow \infty} a_m$ . **9.1**

**( $C, 1$ )-limit** (of complex sequence  $\{a_m\}_{m=0,1,\dots}$ ):  $\lim_{m \rightarrow \infty} m^{-1} \sum_{s=0}^{m-1} a_s$ . **9.1**

**( $C, k$ )-limit** (of complex sequence  $\{a_m\}_{m=0,1,\dots}$ ): Defined inductively from  $(C, k-1)$ -limit. See *Section 9.1*.

**line** (of a matrix): A row or column. **27.1**

**line graph** (of simple graph  $G$ ): The simple graph that has as vertices the edges of  $G$ , and vertices are adjacent if the corresponding edges of  $G$  have an endpoint in common. **28.2**

**linear combination:** A (finite) sum of scalar multiples of vectors. **2.1**

**linear equation:** An equation of the form  $a_1x_1 + \dots + a_nx_n = b$ . **1.4**

**linear form:** See *linear functional*.

**linear functional:** A linear transformation from a vector space to the field. **3.8**

**$m$ -linear map:** See *multilinear map*.

**linear mapping:** See *linear transformation*.

**linear operator:** A linear transformation from a vector space to itself. **3.1**

**linear preserver (of function  $f$ ):** A linear operator  $\phi : \mathcal{V} \rightarrow \mathcal{V}$  such that  $f(\phi(A)) = f(A)$  for every  $A \in \mathcal{V}$ , where  $\mathcal{V}$  is a subspace of  $F^{m \times n}$ . **22.1**

**linear preserver problem** (corresponding to the property  $P$ ): The problem of characterizing all linear (bijective) maps on a subspace of matrices satisfying  $P$ . **22.2**

**linear transformation:** A function from a vector space to a vector space that preserves addition and scalar multiplication. **3.1**

**linear transformation associated to matrix  $A$ :** The transformation that multiplies each vector in  $F^n$  by  $A$ . **3.3**

**linearly dependent** (set of vectors): There is a linear combination of the vectors with at least one nonzero coefficient, that is equal to the zero vector. **2.1**

**linearly independent** (set of vectors): Not linearly dependent. **2.1**

**linked:** Two disjoint Jordan curves in  $\mathbb{R}^3$  such that there is no topological 2-sphere in  $\mathbb{R}^3$  separating them. **28.2**

**linklessly embeddable:** There is an embedding of graph  $G$  in  $\mathbb{R}^3$  such that no two disjoint cycles of  $G$  are linked. **28.2**

**little-oh:** Function  $f$  is  $o(g)$  if the limit of  $\frac{|f|}{|g|}$  is 0. **Preliminaries**

**local similarity:** A map  $\phi : F^{n \times n} \rightarrow F^{n \times n}$  such that for every  $A \in F^{n \times n}$  there exists an invertible  $R_A \in F^{n \times n}$  such that  $\phi(A) = R_A A R_A^{-1}$ . **22.4**

**Loewner (partial) ordering** (on Hermitian matrices  $A, B$ ):  $A \succ B$  if  $A - B$  is positive definite and  $A \succeq B$  if  $A - B$  is positive semidefinite. **8.5**

**logarithm** (of a square complex matrix  $A$ ): Any matrix  $B$  such that  $e^B = A$ . **11.4**

**look-ahead strategy:** A technique to overcome breakdown in some algorithms. **41.3**

**loop:** An edge (arc) of a graph (directed graph) having both endpoints equal. **29.1**

**Lovász parameter:** A parameter of a simple graph. **28.5**

**lower Hessenberg** (matrix  $A$ ):  $A^T$  is upper Hessenberg. **10.2**

**lower shift matrix:** A square matrix with ones on the first subdiagonal and zero elsewhere. **48.1**

**lower triangular matrix:** A matrix such that every entry having row number less than column number is zero. **1.2, 10.2**

**Löwner (partial) ordering:** See *Loewner (partial) ordering*

**$LU$  factorization:** A factorization of a matrix as the product of a unit lower triangular matrix and an upper triangular matrix. **1.6, 38.3**

**Lyapunov diagonally semistable** (real square matrix  $A$ ): There exists a positive diagonal matrix  $D$  such that  $AD + DA^T$  is positive semidefinite. **19.5**

**Lyapunov diagonally stable** (real square matrix  $A$ ): There exists a positive diagonal matrix  $D$  such that  $AD + DA^T$  is positive definite. **19.5**

**Lyapunov scaling factor** (of real square matrix  $A$ ): A positive diagonal matrix  $D$  such that  $AD + DA^T$  is positive (semi)definite. **19.5**

## M

**$M$ -matrix** (real square matrix  $A$ ):  $A$  can be written as  $A = sI - P$  with  $P$  a nonnegative matrix and  $s$  a scalar satisfying  $s > \rho(P)$ . **9.5**

**$M_0$ -matrix:** (real square matrix  $A$ ):  $A$  can be written as  $A = sI - P$  with  $P$  a nonnegative matrix and  $s$  a scalar satisfying  $s \geq \rho(P)$ . **9.5**

**machine epsilon:** The distance between the number one and the next larger floating point number. **37.6**

**main angles** (of a graph): The cosines of the angles between the eigenspaces of the adjacency matrix and the all-ones vector. **28.3**

**main diagonal** (of a matrix): The set of diagonal entries of a matrix. **1.2**

**majorizes:** Weakly majorizes and the sums of all entries are equal. **Preliminaries**

**( $k$ -)matching** (of a graph): A set of  $k$  mutually disjoint edges. **30.1**

**matrices:** Plural of *matrix*.

**matrix:** a rectangular array of elements of a field. **1.2**

Or if specifically stated, a rectangular array of elements of a domain, ring, or algebra. The following standard matrix terms are applied to the matrices over a domain  $\mathbb{D}$  viewed as in the quotient field of  $\mathbb{D}$ : determinant, minor, rank, *Section 23.2*. The following standard matrix terms are applied to matrices over a Bezout domain within the domain: kernel, range, system of linear equations, coefficient matrix, augmented matrix, *Section 23.3*

**matrix condition number:** See *condition number (of matrix  $A$  for linear systems)*.

**matrix cosine:** See *cosine*.

**matrix direct sum:** A block diagonal matrix. **2.4, 10.2**

**matrix exponential:** See *exponential*.

**matrix function:** A function of a square complex matrix; can be defined using power series, Jordan Canonical Form, polynomial interpretation, Cauchy integral, etc. **11.1**

**matrix logarithm:** See *logarithm*.

**matrix of a transformation  $T$**  (with respect to bases  $\mathcal{B}$  and  $\mathcal{C}$ ): The matrix consisting of the coordinate vectors with respect to  $\mathcal{C}$  of the images under  $T$  of the vectors in  $\mathcal{B}$ . **3.3**

**matrix norm  $\|\cdot\|$ :** A family of real-valued functions defined on  $m \times n$  real or complex matrices for all positive integers  $m$  and  $n$ , such that for all matrices  $A$  and  $B$  (where  $A$  and  $B$  are compatible for the given operation) and all scalars, (1)  $\|A\| \geq 0$ , and  $\|A\| = 0$  implies  $A = 0$ ; (2)  $\|\alpha A\| = |\alpha| \|A\|$ ; (3)  $\|A + B\| \leq \|A\| + \|B\|$ ; (4)  $\|AB\| \leq \|A\| \|B\|$ . **37.3**

**matrix pencil:** See *pencil*.

**matrix product:** The result of multiplying two matrices. **1.2**

**matrix representing  $f$  relative to basis  $\mathcal{B} = (\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_n)$ :** The matrix whose  $i, j$ -entry is  $f(\mathbf{w}_i, \mathbf{w}_j)$ , *Section 12.1*; also applied to  $\varphi$ -sesquilinear form. **12.4**

**matrix sine:** See *sine*.

**matrix sign function:** See *sign (of a matrix)*.

**matrix square root:** See *square root, principal square root*.

**matrix–vector product:** The result of multiplying a matrix and a vector. **1.2**

**maximal** (ideal  $I$  of a domain  $\mathbb{D}$ ): The only ideals that contain  $I$  are  $I$  and  $\mathbb{D}$ , and  $I \neq \mathbb{D}$ . **23.1**

**maximal** (sign-nonsingular-sign pattern matrix): If a zero entry is set nonzero, then the resulting pattern is not SNS. **33.2**

**maximal rank** (of sign-pattern  $A$ ):  $\max\{\text{rank} B : B \in Q(A)\}$ . **33.6**

**maximum column sum norm** (of matrix  $A \in \mathbb{C}^{m \times n}$ ):  $\|A\|_1 = \max_{1 \leq j \leq n} \sum_{i=1}^m |a_{ij}|$ . **37.3**

**maximum multiplicity** (of simple graph  $G$ ): The maximum multiplicity of any eigenvalue among matrices in  $\mathcal{S}(G)$ . **34.2**

**maximum row sum norm** (of matrix  $A \in \mathbb{C}^{m \times n}$ ):  $\|A\|_\infty = \max_{1 \leq i \leq m} \sum_{j=1}^n |a_{ij}|$ . **37.3**

**max-plus semiring:** The set  $\mathbb{R} \cup \{-\infty\}$ , equipped with the addition  $(a, b) \mapsto \max(a, b)$  and the multiplication  $(a, b) \mapsto a + b$ . The identity element for the addition, zero, is  $-\infty$ , and the identity element for the multiplication, unit, is 0. **25.1**

**measure of relative separation** (of positive real numbers  $a, b$ ):  $|\sqrt{a/b} - \sqrt{b/a}|$ . **17.4**

**meet** (of faces  $F, G$  of cone  $K$ ):  $F \cap G$  **26.1**

**metric:** A distance function. **Preliminaries**

**MIEP:** See *multiplicative inverse eigenvalue problem*.

**minimal** (matrix norm  $\|\cdot\|$ ): For any matrix norm  $\|\cdot\|_v$ ,  $\|A\|_v \leq \|A\|$  for all  $A$  implies  $\|\cdot\|_v = \|\cdot\|$ . **37.3**

**minimal polynomial** (of matrix  $A$ ): The unique monic polynomial of least degree for which  $q_A(A) = 0$ . **4.3**

**minimal rank** (of sign pattern  $A$ ):  $\min\{\text{rank} B : B \in Q(A)\}$ . **33.6**

**minimal residual (MINRES) algorithm** (to solve  $Hx = b$  with  $H$  preconditioned Hermitian): At each step  $k$ , the approximation  $x_k$  is of the form  $x_k \in x_0 + \text{Span}\{r_0, Hr_0, \dots, H^{k-1}r_0\}$  for which the 2-norm of the residual,  $\|r_k\|_2$ , is minimal. **41.2**

**minimal sign-central:** A sign-central pattern that is not sign-central if any column of  $A$  is deleted. **33.11**

**minimally connected** (digraph): Strongly connected and the deletion of any arc produces a subdigraph that is not strongly connected. **29.8**

**minimally potentially stable** (sign pattern  $A$ ):  $A$  is a potentially stable, irreducible sign pattern such that replacing any nonzero entry by zero results in a pattern that is not potentially stable. **33.4**

**minimum co-cover** (of a  $(0, 1)$ -matrix): A co-cover with the smallest number of 1s. **27.1**

**minimum cover** (of a  $(0, 1)$ -matrix): A cover with the smallest number of lines. **27.1**

**minimum-norm least squares solution:** The least squares solution of minimum Euclidean norm. **39.1**

**minimum rank** (of simple graph  $G$ ): The minimum of  $\text{rank} A$  among matrices  $A \in \mathcal{S}(G)$ . **34.2**

**minor** (of a graph  $G$ ): Any graph that can be obtained from  $G$  by a sequence of edge deletions, vertex deletions, and contractions. **28.2**

**minor** (of a matrix): The determinant of a submatrix; for the  $i, j$ -minor, the submatrix is obtained by deleting row  $i$  and column  $j$ . **4.1**

**MINRES:** See *minimal residual*.

**Möbius function:**  $\mu : \mathbb{N} \mapsto \{-1, 0, 1\}$  is defined by  $\mu(1) = 1$ ,  $\mu(m) = (-1)^e$  if  $m$  is a product of  $e$  distinct primes, and  $\mu(m) = 0$  otherwise. **20.5**

**$\mathbb{D}$ -module:** A generalization of vector space over a field; an additive group with a (scalar) multiplication by elements  $a \in \mathbb{D}$  that satisfies the standard distribution properties and  $1v = v$  for all  $v \in \mathbb{D}$ . The following standard terms are also applied to modules over a Bezout domain—linear combination, basis (may not exist), standard basis for  $\mathbb{D}^n$ , dimension (if there is a basis). **23.3**

**monic** (polynomial  $p(x)$ ): The coefficient of the highest power of  $x$  in  $p(x)$  is 1. **23.1**

**monotone** (real vector  $v = [v_i]$ ):  $v_1 \geq v_2 \geq \dots \geq v_n$ . **27.4**

**monotone** (vector norm  $\|\cdot\|$ ): For all  $x, y$ ,  $|x| \leq |y|$  implies  $\|x\| \leq \|y\|$ . **37.1**

**Moore–Penrose pseudo-inverse** (of matrix  $A \in \mathbb{C}^{m \times n}$ ): A matrix  $A^\dagger \in \mathbb{C}^{n \times m}$  satisfying:  $AA^\dagger A = A$ ;  $A^\dagger AA^\dagger = A^\dagger$ ;  $(AA^\dagger)^* = AA^\dagger$ ;  $(A^\dagger A)^* = A^\dagger A$ . **5.7**

**Moore–Penrose inverse** (of a sign pattern): Analog of the Moore–Penrose inverse of a real matrix. **33.7**

**multibigraph** (of a nonnegative integer matrix  $A$ ): Like the bigraph of  $A$ , except that edge  $\{i, j\}$  has multiplicity  $a_{ij}$ . **30.2**

**multigrid preconditioner:** A preconditioner designed for problems arising from partial differential equations discretized on grids. **41.4**

**multilinear form:** A multilinear map into the field  $F$ . **13.1**

**multilinear map ( $m$ -linear map):** A map  $\varphi$  from  $V_1 \times \cdots \times V_m$  into  $U$  that is linear on each coordinate. **13.1**

**multiple** (eigenvalue  $\lambda$  of real symmetric matrix  $B$ ):  $\alpha_B(\lambda) > 1$ . **34.1**

**multiplicative** (map  $\phi : F^{n \times n} \rightarrow F^{n \times n}$ ):  $\phi(AB) = \phi(A)\phi(B)$ , for all  $A, B \in F^{n \times n}$ . **22.4**

**multiplicative  $D$ -stable** (real square matrix  $A$ ):  $DA$  is stable for every positive diagonal matrix  $D$ . **19.3**

**multiplicative inverse eigenvalue problem (MIEP):** Given  $B \in \mathbb{C}^{n \times n}$  and  $\lambda_1, \dots, \lambda_n \in \mathbb{C}$  find a diagonal matrix  $D \in \mathbb{C}^{n \times n}$  such that  $\sigma(BD) = \{\lambda_1, \dots, \lambda_n\}$ . **20.9**

**multiplicative perturbation** (of  $A \in \mathbb{C}^{m \times n}$ ):  $D_L^* A D_R$  for some  $D_L \in \mathbb{C}^{m \times m}$ ,  $D_R \in \mathbb{C}^{n \times n}$ . **15.3**

**multiplicative preserver:** A multiplicative map preserving a certain property. **22.4**

**multiplicity** (of an eigenvalue): See *algebraic multiplicity*, *geometric multiplicity*.

**multiplicity** (of a singular value): The dimension of the right or left singular space. **45.1**

**multiset:** An unordered list of elements that allows repetition. **Preliminaries**

## N

**NaN:** Result of an operation that is not a number in a standard-conforming floating point system. **37.6**

**nearly decomposable** ( $(0, 1)$ -matrix): Fully indecomposable and each matrix obtained by replacing a 1 with a 0 is partly decomposable. **27.2**

**nearly reducible** (matrix  $A$ ): Irreducible and each matrix obtained from  $A$  by replacing a nonzero entry with a zero is reducible. **27.3**

**nearly sign-central:** A sign pattern that is not sign-central, but can be augmented to a sign-central pattern by adjoining a column. **33.11**

**nearly sign nonsingular (NSNS)** (sign pattern): A square pattern having at least two nonzero terms in the expansion of its determinant, with precisely one nonzero term having opposite sign to the others. **33.2**

**negative definite** (real symmetric or Hermitian bilinear form  $f$ ):  $-f$  is positive definite. **12.2, 12.5**

**negative semidefinite** (real symmetric or Hermitian bilinear form  $f$ ):  $-f$  is positive semidefinite. **12.2, 12.5**

**negative set of edges  $\alpha$**  (in a signed bipartite graph):  $\text{sgn}(\alpha)$  is  $-1$ . **30.1**

**negative stable** (complex polynomial): Its roots lie in the open left half plane. **19.2**

**negative stable** (complex square matrix): Its eigenvalues lie in the open left half plane. **19.2**

**neighbor** (of vertex  $v$ ): Any vertex adjacent to  $v$ . **28.1**

**NIEP:** See *nonnegative inverse eigenvalue problem*.

**nilpotent:** A matrix or linear transformation that can be multiplied by itself a finite number of times to obtain the zero matrix or transformation. **2.7, 3.6**

**node:** See *vertex*.

**noncommutative algorithms:** Algorithms that do not use commutativity of multiplication. **47.2**

**nondefective** (matrix  $A \in F^{n \times n}$ ): For each eigenvalue of  $A$  (over algebraic closure of  $F$ ), the geometric multiplicity equals the algebraic multiplicity. **4.3**

**nondegenerate** (bilinear form  $f$  on vector space  $V$ ): The rank of  $f$  is equal to  $\dim V$ , *Section 12.1*; also applied to  $\varphi$ -sesquilinear form. **12.4**

**nonderogatory** (matrix  $A \in F^{n \times n}$ ): The geometric multiplicity of each eigenvalue of  $A$  (over algebraic closure of  $F$ ) is 1. **4.3**

**nondifferentiable** (boundary point  $\mu$  of convex set  $S$ ): There is more than one support line of  $S$  passing through  $\mu$ . **18.2**

**non-Hermitian Lanczos algorithm** See *Section 41.3*

**nonnegative** (real matrix  $A$ ): All of  $A$ 's elements are nonnegative. **9.1**

**nonnegative** (sign pattern): All of its entries are nonnegative. **33.7**

**$K$ -nonnegative** (matrix  $A \in \mathbb{R}^{n \times n}$ ):  $AK \subseteq K$ . **26.1**

**$K$ -nonnegative** (vector  $\mathbf{v} \in \mathbb{R}^n$ ):  $\mathbf{v} \in K$ . **26.1**

**nonnegative inverse eigenvalue problem:** Construct a nonnegative matrix with given eigenvalues. **20.3**

**nonnegative integer rank** (of nonnegative integer matrix  $A$ ): The minimum  $k$  such that there exists an  $m \times k$  nonnegative integer matrix  $B$  and a  $k \times n$  nonnegative integer matrix  $C$  with  $A = BC$ . **30.3**

**nonnegative  $P$ -matrix**: A  $P$ -matrix in which every entry is nonnegative. **35.9**

**nonnegative  $P_0$ -matrix**: A  $P_0$ -matrix in which every entry is nonnegative. **35.9**

**nonnegative  $P_{0,1}$ -matrix**: A  $P_{0,1}$ -matrix in which every entry is nonnegative. **35.9**

**nonnegative stable** (complex square matrix  $A$ ): The real part of each eigenvalue of  $A$  is nonnegative. **9.5**

**nonprimary matrix function**: Function of a matrix defined using the Jordan Canonical Form using different branches for  $f$  and its derivatives for two Jordan blocks for the same eigenvalue. **11.1**

**nonseparable** (graph or digraph): Connected and does not have a cut-vertex. **35.1**

**nonsingular** (linear transformation): A linear transformation whose kernel is zero. **3.7**

**nonsingular** (matrix): An invertible matrix. **1.5**

**norm** (of a vector  $\mathbf{v}$ , in an inner product space):  $\sqrt{\langle \mathbf{v}, \mathbf{v} \rangle}$ . **5.1**

**norm**: See *vector norm*, *matrix norm* or *specific norm*.

**1-norm** (of vector  $\mathbf{x} \in \mathbb{C}^n$ ):  $\|\mathbf{x}\|_1 = |x_1| + |x_2| + \cdots + |x_n|$ . **37.1**

**1-norm** (of matrix  $A \in \mathbb{C}^{m \times n}$ ): See *maximum column sum norm*.

**2-norm** (of vector  $\mathbf{x} \in \mathbb{C}^n$ ):  $\|\mathbf{x}\|_2 = \sqrt{|x_1|^2 + |x_2|^2 + \cdots + |x_n|^2}$ . **37.1**

**2-norm** (of matrix  $A \in \mathbb{C}^{m \times n}$ ): see *maximum column sum norm*.

**$\infty$ -norm** (of vector  $\mathbf{x} \in \mathbb{C}^n$ ):  $\|\mathbf{x}\|_\infty = \max_{1 \leq i \leq n} |x_i|$ . **37.1**

**$\infty$ -norm** (of matrix  $A$ ): See *maximum row sum norm*.

**$M$ -norm** (where  $\|\cdot\|$  is a vector norm and  $M$  is a nonsingular matrix):  $\|\mathbf{x}\|_M \equiv \|M\mathbf{x}\|$ . **37.1**

**$\mathcal{M}$ -norm** (matrix norm): Norm induced by a family of  $M_n$ -norms for  $\mathcal{M} = \{M_n : n \geq 1\}$  a family of nonsingular  $n \times n$  matrices. **37.3**

**$p$ -norm** (of matrix  $A \in \mathbb{C}^{m \times n}$ , with  $p \geq 1$ ): The matrix norm induced by the (vector)  $p$ -norm. **37.1**

**$p$ -norm** (of vector  $\mathbf{x} \in \mathbb{C}^n$ , with  $p \geq 1$ ):  $\|\mathbf{x}\|_p = (|x_1|^p + \cdots + |x_n|^p)^{\frac{1}{p}}$ . **37.1**

**normal** (complex square matrix or linear operator): Commutes with its Hermitian adjoint. **7.2**

**normal equations** (for the least squares problem  $A\mathbf{x} = \mathbf{b}$ ): The system  $A^*A\mathbf{x} = A^*\mathbf{b}$ . **5.8**

**normalized** (representation  $\pm(m/b^{p-1})b^e$  of a floating point number):  $b^{p-1} \leq m < b^p$ . **37.6**

**normalized immanant**: Function defined by the irreducible character of a partition  $\lambda$  of  $n$ , specifically,  $f_\lambda(M) = \frac{1}{\chi_\lambda(\mathbf{e})} \sum_{\sigma \in S_n} \chi_\lambda(\sigma) \prod_{i=1}^n m_{i\sigma(i)}$ . **31.10**

**normalized scaling** (of rectangular matrix  $A$ ): A scaling  $DAE$  of  $A$  with  $\det(D) = \det(E) = 1$ . **9.6**

**NSNS**: See *nearly sign nonsingular*.

**null graph**: A graph with no vertices. **28.1**

**null space**: See *kernel*.

**nullity**: The dimension of the kernel. **2.4, 3.5**

**numerical radius** (of  $A \in \mathbb{C}^{n \times n}$ ):  $w(A) = \max\{|\mu| : \mu \in W(A)\}$ . **18.1**

**numerical range** (of  $n \times n$  complex matrix  $A$ ):  $W(A) = \{\mathbf{v}^*A\mathbf{v} | \mathbf{v}^*\mathbf{v} = 1, \mathbf{v} \in \mathbb{C}^n\}$ . **7.1, 18.1**

**numerical rank** (of matrix  $A$ , with respect to the threshold  $\tau$ ):  $\min\{\text{rank}(A + E) : \|E\|_2 \leq \tau\}$ . **39.9**

**numerically orthogonal** (vectors  $\mathbf{x}, \mathbf{y}$ ):  $|\mathbf{x}^T\mathbf{y}| \leq \varepsilon\|\mathbf{x}\|_2\|\mathbf{y}\|_2$ . **46.1**

**numerically orthogonal matrix**: Each pair of its columns are numerically orthogonal. **46.1**

**numerically stable** (algorithm): Produces results that are roughly as accurate as the errors in the input data allow. **37.8**

**numerically unstable** (algorithm): Allows rounding and truncation errors to produce results that are substantially less accurate than the errors in the input data allow. **37.8**

## O

**odd** (permutation): Can be written as the product of an odd number of transpositions. **Preliminaries**

**odd** (cycle in a sign pattern): The length of the simple or composite cycle is odd. **33.1**

**off-diagonal entry**: An entry in a matrix that is not a diagonal entry. **1.2**

**off-norm** (of  $A$ ): The Frobenius norm of the matrix consisting of all off-diagonal elements of  $A$  and a zero diagonal. **42.7**

**oh:** See *big-oh*, *little-oh*.

**one-to-one** (linear transformation  $T$ ):  $\mathbf{v}_1 \neq \mathbf{v}_2$  implies  $T(\mathbf{v}_1) \neq T(\mathbf{v}_2)$ . 3.5

**onto** (linear transformation): The codomain equals the range. 3.5

**open left half plane:**  $\{z \in \mathbb{C} : \operatorname{re}(z) < 0\}$ . Preliminaries

**open right half plane:**  $\{z \in \mathbb{C} : \operatorname{re}(z) > 0\}$ . Preliminaries

**open sector** (from ray  $e^{i\alpha}$  to ray  $e^{i\beta}$ ): The set of rays  $\{re^{i\theta} : r > 0, \alpha < \theta < \beta\}$ . 33.8

**operator norm:** See *induced norm*.

**order** (of a graph): The number of vertices in the graph. 28.1

**order** (of a square matrix): See *size*.

**ordered multiplicity list** (of real symmetric matrix  $B$ ):  $(m_1, \dots, m_r)$  where the distinct eigenvalues of  $B$  are  $\beta_1 < \dots < \beta_r$  with multiplicities  $m_1, \dots, m_r$ . 34.5

**oriented (vertex-edge) incidence matrix** (of graph  $G$ ): A matrix obtained from the incidence matrix of  $G$  by replacing a 1 in each column by a  $-1$ . 28.4

**orthogonal** (vectors): Two vectors whose inner product is 0. 5.2

**orthogonal** (set of vectors): Any two distinct vectors in the set are orthogonal. 5.2

**$\mathcal{J}$ -orthogonal** (real matrix  $B$ )  $B^T \mathcal{J} B = \mathcal{J}$  (where  $\mathcal{J}$  is a nonsingular real symmetric matrix). 46.5

**orthogonal basis:** A basis that is orthogonal as a set. 5.2

**orthogonal complement** (of subset  $S$ ): Subspace of vectors orthogonal to every vector in  $S$ . 5.2

**orthogonal iteration:** Method for computing the EVD of real symmetric  $A$ : given starting  $n \times p$  matrix  $X_0$  with orthonormal columns, the sequence of matrices  $Y_{k+1} = AX_k$ ,  $Y_{k+1} = X_{k+1}R_{k+1}$   $k = 0, 1, 2, \dots$ , where  $X_{k+1}R_{k+1}$  is the reduced QR factorization of  $Y_{k+1}$ . 42.1

**orthogonal matrix:** A real or complex matrix  $Q$  such that  $Q^T Q = I$ . 5.2, 7.1

**orthogonal projection:** Projection onto a subspace along its orthogonal complement. 5.4

**orthogonal with respect to symmetric bilinear form**  $f$  (vectors  $\mathbf{v}, \mathbf{u}$ ):  $f(\mathbf{u}, \mathbf{v}) = 0$ . 12.2

**orthonormal** (set of vectors): An orthogonal set of unit vectors. 5.2

**orthonormal basis:** A basis that is orthonormal as a set. 5.2

**oscillatory** (real square matrix  $A$ ):  $A$  is totally nonnegative and  $A^k$  is totally positive for some integer  $k \geq 1$ . 21.1

**outerplanar** (graph  $G$ ): There is an embedding of  $G$  into  $\mathbb{R}^2$  with the vertices on the unit circle and the edges contained in the unit disc. 28.2

**overflow:**  $|x|$  equals or exceeds a threshold at or near the largest floating point number. 37.6

## P

**$P$ -invariant face:** Alphabetized under *invariant*.

**$P$ -matrix:** every principal minor is positive. 19.2

**$P_0$ -matrix:** Every principal minor is nonnegative. 35.8

**$P_0^+$ -matrix:** Every principal minor is nonnegative and at least one principal minor of each order is positive. 19.2

**$P_{0,1}$ -matrix:** Every principal minor is nonnegative and every diagonal element is positive. 35.8

**pairwise orthogonal** (orthogonal projections  $P$  and  $Q$ ):  $PQ = QP = 0$ . 7.2

**Parter vertex:** See *Parter-Wiener vertex*.

**Parter-Wiener vertex** (for eigenvalue  $\lambda$  of  $n \times n$  Hermitian matrix  $A$ ):  $j$  such that  $\alpha_{A(j)}(\lambda) = \alpha_A(\lambda) + 1$ . 34.1

**partial completely positive matrix**  $B$ : Every fully specified principal submatrix of  $B$  is a completely positive matrix, whenever  $b_{ij}$  is specified, then so is  $b_{ji}$  and  $b_{ji} = b_{ij}$ , and all specified off-diagonal entries are nonnegative. 35.4

**partial copositive matrix**  $B$ : Every fully specified principal submatrix of  $B$  is a copositive matrix and whenever  $b_{ij}$  is specified, then so is  $b_{ji}$  and  $b_{ji} = b_{ij}$ . 35.5

**partial doubly nonnegative matrix**  $B$ : Every fully specified principal submatrix of  $B$  is a doubly nonnegative matrix, whenever  $b_{ij}$  is specified, then so is  $b_{ji}$  and  $b_{ji} = b_{ij}$ , and all specified off-diagonal entries are nonnegative. 35.4

**partial entry sign symmetric  $P$ -matrix  $B$ :** Every fully specified principal submatrix of  $B$  is an entry sign symmetric  $P$ -matrix and if both  $b_{ij}$  and  $b_{ji}$  are specified, then  $b_{ij}b_{ji} > 0$  or  $b_{ij} = b_{ji} = 0$ . **35.10**

**partial entry sign symmetric  $P_0$ -matrix  $B$ :** Every fully specified principal submatrix of  $B$  is an entry sign symmetric  $P_0$ -matrix and if both  $b_{ij}$  and  $b_{ji}$  are specified, then  $b_{ij}b_{ji} > 0$  or  $b_{ij} = b_{ji} = 0$ . **35.10**

**partial entry sign symmetric  $P_{0,1}$ -matrix  $B$ :** Every fully specified principal submatrix of  $B$  is an entry sign symmetric  $P_{0,1}$ -matrix and if both  $b_{ij}$  and  $b_{ji}$  are specified, then  $b_{ij}b_{ji} > 0$  or  $b_{ij} = b_{ji} = 0$ . **35.10**

**partial entry weakly sign symmetric  $P$ -matrix  $B$ :** Every fully specified principal submatrix of  $B$  is an entry weakly sign symmetric  $P$ -matrix and if both  $b_{ij}$  and  $b_{ji}$  are specified, then  $b_{ij}b_{ji} \geq 0$ . **35.10**

**partial entry weakly sign symmetric  $P_0$ -matrix  $B$ :** Every fully specified principal submatrix of  $B$  is an entry weakly sign symmetric  $P_0$ -matrix and if both  $b_{ij}$  and  $b_{ji}$  are specified, then  $b_{ij}b_{ji} \geq 0$ . **35.10**

**partial entry weakly sign symmetric  $P_{0,1}$ -matrix  $B$ :** Every fully specified principal submatrix of  $B$  is an entry weakly sign symmetric  $P_{0,1}$ -matrix and if both  $b_{ij}$  and  $b_{ji}$  are specified, then  $b_{ij}b_{ji} \geq 0$ . **35.10**

**partial Euclidean distance matrix  $B$ :** Every diagonal entry is specified and equal to 0, every fully specified principal submatrix of  $B$  is a Euclidean distance matrix, and whenever  $b_{ij}$  is specified, then so is  $b_{ji}$  and  $b_{ji} = b_{ij}$ . **35.3**

**partial inverse  $M$ -matrix  $B$ :** Every fully specified principal submatrix of  $B$  is an inverse  $M$ -matrix and every specified entry of  $B$  is nonnegative. **35.7**

**partial  $M$ -matrix  $B$ :** Every fully specified principal submatrix of  $B$  is an  $M$ -matrix and every specified off-diagonal entry of  $B$  is nonpositive. **35.6**

**partial  $M_0$ -matrix  $B$ :** Every fully specified principal submatrix of  $B$  is an  $M_0$ -matrix and every specified off-diagonal entry of  $B$  is nonpositive. **35.6**

**partial matrix:** A square array in which some entries are specified and others are not. **35.1**

**partial nonnegative  $P$ -matrix:** Every fully specified principal submatrix is a nonnegative  $P$ -matrix and all specified entries are nonnegative. **35.9**

**partial nonnegative  $P_0$ -matrix:** Every fully specified principal submatrix is a nonnegative  $P_0$ -matrix and all specified entries are nonnegative. **35.9**

**partial nonnegative  $P_{0,1}$ -matrix:** Every fully specified principal submatrix is a nonnegative  $P_{0,1}$ -matrix and all specified entries are nonnegative. **35.9**

**partial  $P$ -matrix:** Every fully specified principal submatrix is a  $P$ -matrix. **35.8**

**partial  $P_0$ -matrix:** Every fully specified principal submatrix is a  $P_0$ -matrix. **35.8**

**partial  $P_{0,1}$ -matrix:** Every fully specified principal submatrix is a  $P_{0,1}$ -matrix. **35.8**

**partial positive  $P$ -matrix:** Every fully specified principal submatrix is a positive  $P$ -matrix and all specified entries are positive. **35.9**

**partial semidefinite ordering:** See *Loewner ordering*.

**partial strictly copositive matrix  $B$ :** Every fully specified principal submatrix of  $B$  is a strictly copositive matrix and whenever  $b_{ij}$  is specified, then so is  $b_{ji}$  and  $b_{ji} = b_{ij}$ . **35.5**

**partitioned (matrix):** A matrix partitioned into submatrices by partitions of the row and column indices. **10.1**

**partly decomposable ( $n \times n$  (0,1)-matrix):** Has a  $p \times q$  zero submatrix for positive integers  $p, q$  with  $p + q = n$ . **27.2**

**path (in a graph):** A walk with all vertices distinct. **28.1**

**path (in sign pattern  $A$ ):** A formal product of the form  $\gamma = a_{i_1 i_2} a_{i_2 i_3} \dots a_{i_k i_{k+1}}$ , where each of the elements is nonzero and the index set  $\{i_1, i_2, \dots, i_{k+1}\}$  consists of distinct indices. **33.1**

**path-clique (digraph):** The induced subdigraph of every alternate path to a single arc is a clique. **35.7**

**path-connected (subset  $S$  of complex numbers):** There exists a path in  $S$  (i.e., a continuous function from  $[0,1]$  to  $S$ ) from any point in  $S$  to any other point in  $S$ . **Preliminaries**

**path cover number (of simple graph  $G$ ):** The minimum number of vertex disjoint induced paths of  $G$  that cover all vertices of  $G$ . **34.2**

**pattern (of matrix  $A$ ):** The (0,1)-matrix obtained from  $A$  by replacing each nonzero entry with a 1. **27.1**

**pattern block triangular form (partial matrix  $B$ ):** The adjacency matrix of  $\mathcal{D}(B)$  is in block triangular form. **35.1**

**PEIEP:** See *inverse eigenvalue problem with prescribed entries*.

**pencil** (defined by  $A, B \in \mathbb{C}^{n \times n}$ ):  $A - xB$ , or pair  $(A, B)$ . **43.1**

**pencil** (in  $\mathbb{D}[x]^{m \times n}$ ): A matrix  $A(x) = A_0 + xA_1$ ,  $A_0, A_1 \in \mathbb{D}^{m \times n}$ . **23.4**

**perfect elimination ordering:** An elimination ordering that does not produce any fill elements during Gaussian elimination. **30.2, 40.5**

**perfect matching:** A matching  $M$  in which each vertex of  $G$  is in one edge of  $M$ . **30.1**

**perfectly-well determined to high relative accuracy** (singular values of  $A$ ): Changing an arbitrary nonzero entry  $a_{k\ell}$  to  $\theta a_{k\ell}$ , with arbitrary  $\theta \neq 0$  causes a relative perturbation in  $\sigma_i$  bounded by  $|\theta|$  and  $1/|\theta|$ . **46.3**

**period** (of access equivalence class  $J$  of reducible nonnegative  $P$ ): The period of the irreducible matrix  $P[J]$ . **9.3**

**period** (of irreducible nonnegative matrix  $P$ ): Greatest common divisor of the lengths of the cycles of the digraph of  $P$ . **9.2**

**period** (of reducible nonnegative matrix  $P$ ): The least common multiple of the periods of its basic classes. **9.3**

**permanent** (of  $n \times n$  matrix  $A$ ):  $\text{per}(A) = \sum_{\sigma \in \mathcal{S}_n} \prod_{i=1}^n a_{i\sigma(i)}$  (also defined for rectangular matrices). **31.1**

**permutation:** A 1-1 onto function from a set to itself. **Preliminaries**

**permutation equivalent** (matrices  $A, B$ ): There exist permutation matrices  $P$  and  $Q$  such that  $B = PAQ$ . **31.1**

**permutation invariant** (vector norm  $\|\cdot\|$ ):  $\|P\mathbf{x}\| = \|\mathbf{x}\|$  for all  $\mathbf{x}$  and all permutation matrices  $P$ . **37.1**

**permutation invariant absolute norm:** s function  $g: \mathbb{R}^n \rightarrow \mathbb{R}_0^+$  that is a norm, and  $g(x_1, \dots, x_n) = g(|x_1|, \dots, |x_n|)$  and  $g(x) = g(P\mathbf{x})$  for all  $\mathbf{x} \in \mathbb{R}^n$  and all permutation matrices  $P \in \mathbb{R}^{n \times n}$ . **17.3**

**permutation matrix:** A matrix whose rows are a rearrangement of the rows of the identity matrix. **1.2**

**permutation pattern:** A square sign pattern matrix with entries 0 and +, where the entry + occurs precisely once in each row and in each column. **33.1**

**permutation similar** (square matrices  $A, B$ ): There exists a permutation matrix  $P$  such that  $B = P^{-1}AP (= P^TAP)$ . **27.2**

**permutational equivalence** (of sign pattern  $A$ ): A product of the form  $P_1AP_2$ , where  $P_1$  and  $P_2$  are permutation patterns. **33.1**

**permutational similarity** (of sign pattern  $A$ ) is a product of the form  $P^TAP$ , where  $P$  is a permutation pattern. **33.1**

**Perron branch** (at vertex  $v$  of a tree): The Perron value of the corresponding bottleneck matrix is maximal among all branches at  $v$ . **36.3**

**Perron value** (of square nonnegative matrix  $P$ ): the spectral radius of  $P$ . **9.1**

**perturbation** (of matrix  $A$ ):  $A + \Delta A$  **15.1**

**perturbation** (of scalar  $\beta$ ):  $\beta + \Delta\beta$  **15.1**

**perturbation** (of vector  $\mathbf{v}$ ):  $\mathbf{v} + \Delta\mathbf{v}$  **15.1**

**Petrie matrix:** A  $(0, 1)$ -matrix with the 1s in each of its columns occurring in consecutive rows. **30.2**

**PIEP:** Affine parameterized inverse eigenvalue problem. **20.8**

**pinching** (of a matrix): Defined recursively. See *Section 17.4*.

**pivot:** An entry of a matrix in a pivot position. **1.3**

**pivot column:** A column of a matrix that contains a pivot position. **1.3**

**pivot position:** A position in a matrix in row echelon form that contains a leading entry. **1.3**

**pivot row:** A row of a matrix that contains a pivot position. **1.3**

**planar** (graph  $G$ ): There an embedding of  $G$  into  $\mathbb{R}^2$ . **28.2**

**PLDU factorization:** A factorization of a row permutation of a given matrix as the product of a unit lower triangular matrix, diagonal matrix, and a unit upper triangular matrix. **1.6**

**PLU factorization:** A factorization of a row permutation of a given matrix as the product of a unit lower triangular matrix and an upper triangular matrix. **1.6, 38.3**

**PO:** See *potentially orthogonal*.

**pointed** (cone  $K$ ):  $K \cap -K = \{0\}$ . **8.5, 26.1**

**polar decomposition** (of matrix  $A \in \mathbb{C}^{m \times n}$  with  $m \geq n$ ): A factorization  $A = UP$  where  $P \in \mathbb{C}^{n \times n}$  is positive semidefinite and  $U \in \mathbb{C}^{m \times n}$  satisfies  $U^*U = I_n$ . **17.1**

**polar form**: See *polar decomposition*.

**polynomial restarting** (of the Arnoldi algorithm): Use  $\psi(A)\mathbf{v}$  instead of vector  $\mathbf{v}$  when restarting. **44.4**

**polytope**: See *convex polytope*.

**positionally symmetric**: See *combinatorially symmetric*.

**positive** (linear map  $\phi : \mathbb{C}^{n \times n} \rightarrow \mathbb{C}^{m \times m}$ ):  $\phi(A)$  is positive semidefinite whenever  $A$  is positive semidefinite. **18.7**

**positive** (real matrix  $A$ ): All of  $A$ 's elements are positive. **9.1**

**$K$ -positive** (matrix  $A \in \mathbb{R}^{n \times n}$ ):  $AK \subseteq \text{int } K$ . **26.1**

**$K$ -positive** (vector  $\mathbf{v} \in \mathbb{R}^n$ ):  $\mathbf{v} \in \text{int } K$ . **26.1**

**positive definite** (matrix): An  $n \times n$  Hermitian matrix satisfying  $\mathbf{x}^*A\mathbf{x} > 0$  for all nonzero  $\mathbf{x} \in \mathbb{C}^n$ . **5.1, 8.4**

**positive definite** (real symmetric or Hermitian bilinear form  $f$ ):  $f(\mathbf{v}, \mathbf{v}) > 0$  for all nonzero  $\mathbf{v} \in V$ . **12.2, 12.5**

**positive  $P$ -matrix**: A  $P$ -matrix in which every entry is positive. **35.9**

**positive semidefinite** (function  $f : \mathbb{R} \rightarrow \mathbb{C}$ ): For each  $n \in \mathbb{N}$  and all  $x_1, x_2, \dots, x_n \in \mathbb{R}$ , the  $n \times n$  matrix  $[f(x_i - x_j)]$  is positive semidefinite. **8.5**

**positive semidefinite** (matrix): An  $n \times n$  Hermitian matrix  $A$  satisfying  $\mathbf{x}^*A\mathbf{x} \geq 0$  for all  $\mathbf{x} \in \mathbb{C}^n$ . **8.4**

**positive semidefinite** (real symmetric or Hermitian bilinear form  $f$ ):  $f(\mathbf{v}, \mathbf{v}) \geq 0$  for all  $\mathbf{v} \in V$ . **12.2, 12.5**

**positive semistable** (complex square matrix): See *nonnegative stable*

**positive set  $\alpha$  of edges** (in a signed bipartite graph):  $\text{sgn}(\alpha)$  is  $+1$ . **30.1**

**positive stable** (complex polynomial): Its roots lie in the open right half plane. **19.2**

**positive stable** (complex square matrix): Its eigenvalues lie in the open right half plane. **9.5, 19.2**

**$k$ -potent** (square sign pattern or ray pattern  $A$ ):  $k$  is the smallest positive integer such that  $A = A^{k+1}$ . **33.9**

**potentially orthogonal (PO)** (sign pattern): Allows an orthogonal matrix. **33.10**

**potentially stable** (square sign pattern  $A$ ): Allows stability, i.e., some matrix  $B \in Q(A)$  is stable. **33.4**

**Powell–Reid's complete (row and column) pivoting**: A particular pivoting strategy for QR-factorization. **46.2**

**power method**: Method for computing the EVD of  $A$ : given starting vector  $\mathbf{x}_0$ , compute the sequences  $\mathbf{v}_k = \mathbf{x}_k^T A \mathbf{x}_k$ ,  $\mathbf{x}_{k+1} = A \mathbf{x}_k / \|A \mathbf{x}_k\|$ ,  $k = 0, 1, 2, \dots$ , until convergence. **42.1**

**powerful** (square sign or ray pattern  $A$ ): All the powers  $A^1, A^2, A^3, \dots$ , are unambiguously defined. **33.9**

**precision**: The number of digits, i.e.,  $p$  in  $x = \pm \left(\frac{m}{b^{p-1}}\right) b^e$ . **37.6**

**preconditioner**: A matrix  $M$  designed to improve the performance of an iterative method for solving the linear system  $A\mathbf{x} = \mathbf{b}$ . **41.1**

**preserves**: Linear operator  $T$  preserves bilinear form  $f$  if  $f(T\mathbf{u}, T\mathbf{v}) = f(\mathbf{u}, \mathbf{v})$  for all  $\mathbf{u}, \mathbf{v}$ . **12.1**; Also applied to  $\varphi$ -sesquilinear form. **12.4**

**preserves**: Linear operator  $\phi$  preserves subset of matrices  $\mathcal{M}$  if  $\phi(\mathcal{M}) \subseteq \mathcal{M}$ . **22.1**

**preserves**: Linear operator  $\phi$  preserves relation  $\sim$  on matrix subspace  $\mathcal{V}$  if  $\phi(A) \sim \phi(B)$  whenever  $A \sim B$ ,  $A, B \in \mathcal{V}$ . **22.1**

**primary decomposition** (of a nonconstant monic polynomial  $q(x)$  over  $F$ ): A factorization  $q(x) = (h_1(x))^{m_1} \dots (h_r(x))^{m_r}$ , where the  $h_i(x)$ ,  $i = 1, \dots, r$  are distinct monic irreducible polynomials over  $F$ . **6.4**

**primary factors**: The factors in a primary decomposition. **6.4**

**primary matrix function**: Function of a matrix defined using the Jordan Canonical Form and using the same branch for  $f$  and its derivatives for each Jordan block for the same eigenvalue. **11.1**

**prime** (in domain  $\mathbb{D}$ ): A nonzero, nonunit element  $p$  such that for any  $a, b \in \mathbb{D}$ ,  $p|ab$  implies  $p|a$  or  $p|b$ . **23.1**

**prime** (ideal  $I$  of a domain):  $ab \in I$  implies that either  $a$  or  $b$  is in  $I$ . **23.1**

**primitive** (digraph): There is a positive integer  $k$  such that for every pair of vertices  $u$  and  $v$ , there is a walk of length  $k$  from  $u$  to  $v$ . **29.6**

**primitive** (polynomial  $p(x) = \sum_{i=0}^m a_i x^{m-i} \in \mathbb{Z}[x]$ ,  $a_0 \neq 0$ ,  $m \geq 1$ ): 1 is a g.c.d. of  $a_0, \dots, a_m$ . **23.1**

**primitive matrix**: A square nonnegative matrix whose digraph is primitive. **29.6**

**principal angles** (between subspaces  $X$  and  $Y$  of  $\mathbb{C}^r$ ): See *Section 17.7* (equivalent to *canonical angles*, *Section 15.1*.)

**principal ideal**: An ideal generated by one element (in a domain). **23.1**

**principal ideal domain (PID)**  $\mathbb{D}$ : Any ideal of  $\mathbb{D}$  is principal. **23.1**

**principal minor**: The determinant of a principal submatrix. **4.2**

**principal logarithm** (of complex square matrix that has no real eigenvalues  $\leq 0$ ): The logarithm with all eigenvalues in the strip  $\{z : -\pi < \text{im}(z) < \pi\}$ . **11.4**

**principal square root** (of a complex square matrix that has no real eigenvalues  $\leq 0$ ): The square root with each eigenvalue having real part  $> 0$ . **11.2**

**principal submatrix**: A submatrix lying in the same rows as columns. **1.2, 10.1**

**principal submatrix at a distinguished eigenvalue  $\lambda$**  (of square nonnegative matrix  $P$ ): The principal submatrix of  $P$  corresponding to a set of vertices of  $\Gamma(P)$  having no access to a vertex of an access equivalence class  $C$  that satisfies  $\rho(P[C]) > \lambda$ . **9.3**

**principal vectors** (between subspaces  $X$  and  $Y$  of  $\mathbb{C}^r$ ): See *Section 17.7*.

**product** (of simple graphs): See (*strong*) *product*.

**profile** (of sparse matrix  $A$ ): The number of elements in the envelope of  $A$ . **40.5**

**projection** (of a vector onto  $V_1$  along  $V_2$ , assuming  $V = V_1 \oplus V_2$ ): The (unique) part of the vector in  $V_1$ ; also, the linear transformation that maps a vector to its projection. **3.6**

**proper cone**  $K$  (in a finite-dimensional real vector space  $V$ ): A convex cone that is closed, pointed, and full. **26.2**

**proper subdigraph** (of a digraph  $\Gamma = (V, E)$ ): A subdigraph  $\Gamma' = (V', E')$  such that  $V'$  is a proper subset of  $V$  or  $E'$  is a proper subset of  $E$ . **29.1**

**properly signed nest**: See *allows a properly signed nest*.

**Property C**: An  $n \times n$   $M$ -matrix  $A$  satisfies property C if there exists a representation of  $A$  of the form  $A = sI - P$  with  $s > 0$ ,  $P \geq 0$  and  $\frac{P}{s}$  semiconvergent. **9.4**

**Property L**: A property that complex square matrices  $A, B$  have if their eigenvalues  $\alpha_k, \beta_k$ , ( $k = 1, \dots, n$ ) may be ordered in such a way that the eigenvalues of  $xA + yB$  are given by  $x\alpha_k + y\beta_k$  for all complex numbers  $x$  and  $y$ . **7.2, 24.3**

**PSD square root** (of a positive semidefinite matrix): The square root with each eigenvalue  $\geq 0$  (same as principal square root for a positive definite matrix). **8.3**

**pseudo-code**: An informal computer program used for writing algorithms. **37.7**

**$\varepsilon$ -pseudoeigenvalue** (of matrix  $A \in \mathbb{C}^{n \times n}$ ): A number  $z \in \mathbb{C}$  such that there exists a nonzero vector  $\mathbf{v} \in \mathbb{C}^n$  such that  $\|A\mathbf{v} - z\mathbf{v}\| < \varepsilon\|\mathbf{v}\|$ . **16.1**

**$\varepsilon$ -pseudoeigenvector** (of matrix  $A \in \mathbb{C}^{n \times n}$ ): A nonzero vector  $\mathbf{v} \in \mathbb{C}^n$  such that there exists  $z \in \mathbb{C}$  such that  $\|A\mathbf{v} - z\mathbf{v}\| < \varepsilon\|\mathbf{v}\|$ . **16.1**

**$\varepsilon$ -pseudospectral abscissa** (of a complex square matrix): The rightmost extent of the  $\varepsilon$ -pseudospectrum. **16.3**

**$\varepsilon$ -pseudospectral radius** (of a complex square matrix): The maximum magnitude of the  $\varepsilon$ -pseudospectrum. **16.3**

**$\varepsilon$ -pseudospectrum** (of complex square matrix  $A$ ): The set  $\{z \in \mathbb{C} : z \in \sigma(A + E) \text{ for some } E \in \mathbb{C}^{n \times n} \text{ with } \|E\| < \varepsilon\}$ . **16.1**

**$\varepsilon$ -pseudospectrum of a matrix pencil**: See *Section 16.5*.

**$\varepsilon$ -pseudospectrum of a matrix polynomial**: See *Section 16.5*.

**$\varepsilon$ -pseudospectrum of a rectangular matrix**: See *Section 16.5*.

## Q

**QMR algorithm**: Iterative method for solving a linear system using non-Hermitian Lanczos algorithm. **41.3**

**QR factorization** (of matrix  $A$ ):  $A = QR$  where  $Q$  is unitary and  $R$  is upper triangular. **5.5**

**QR factorization with column pivoting** (of  $A \in \mathbb{R}^{m \times n}$ ): The factorization  $A\Pi = Q \begin{bmatrix} R \\ 0 \end{bmatrix}$ , where  $\Pi$  is a permutation matrix,  $Q$  is orthogonal, and  $R$  is  $n \times n$  upper triangular. **46.2**

**QR iteration:** Method for computing the EVD of  $A$ : starting from the matrix  $A_0 = A$ , the sequence of matrices  $A_k = Q_k R_k$ ,  $A_{k+1} = R_k Q_k$ ,  $k = 0, 1, 2, \dots$  where  $Q_k R_k$  is the QR factorization of  $A_k$ . **42.1**

**quadrangular** (bipartite graph): Simple and each pair of vertices with a common neighbor lie on a cycle of length 4. **30.1**

**quadratic form** (corresponding to symmetric bilinear form  $f$ ): The map  $g : V \rightarrow F$  defined by  $g(\mathbf{v}) = f(\mathbf{v}, \mathbf{v})$ ,  $\mathbf{v} \in V$ . **12.2**

**qualitative class** (of complex sign pattern  $A = A_1 + iA_2$ ):  $Q(A) = \{B_1 + iB_2 : B_1 \in Q(A_1) \text{ and } B_2 \in Q(A_2)\}$ . **33.8**

**qualitative class** (of real matrix  $B$ ): The qualitative class of  $\text{sgn}(B)$ . **33.1**

**qualitative class** (of sign pattern  $A$ ): The set of all real matrices  $B$  with  $\text{sgn}(B) = A$ . **33.1**

**quotient** (of vector space  $V$  by subspace  $W$ ): The set of additive cosets of  $W$  with operations  $(\mathbf{v}_1 + W) + (\mathbf{v}_2 + W) = (\mathbf{v}_1 + \mathbf{v}_2) + W$  and  $c(\mathbf{v} + W) = (c\mathbf{v}) + W$  for  $c \in F$ . **2.3**

**quotient field** (of an integral domain): The set of equivalence classes of all quotients  $\frac{a}{b}$ ,  $b \neq 0$ , constructed the same way  $\mathbb{Q}$  is constructed from  $\mathbb{Z}$ . **23.1**

## R

**$(R, S)$ -standard map,  $(R, c, f)$ -standard map:** Alphabetized under *standard*.

**radix:** The exponentiation base  $b$  in floating point number  $x = \pm \left(\frac{m}{b^{p-1}}\right) b^e$ . **37.6**

**range** (of a linear transformation  $T : V \rightarrow W$ ):  $\{T(\mathbf{v}) : \mathbf{v} \in V\}$ . **3.4**

**range** (of a matrix): The span of the columns. **2.4**

**rank** (of bilinear form  $f$ ): The rank of a matrix representing  $f$  relative to an ordered basis. **12.1**. Also applied to  $\varphi$ -sesquilinear form. **12.4**

**rank** (of a matrix or linear transformation): The dimension of the range; for a matrix, equals the number of leading entries in the reduced row echelon form of the matrix. **1.3, 2.4, 3.5**

**rank** (of a tensor  $\mathbf{z}$ ): The rank of  $\mathbf{z}$  is  $k$  if  $\mathbf{z}$  is the sum of  $k$  decomposable tensors, but it cannot be written as sum of  $l$  decomposable tensors for any  $l$  less than  $k$ . **13.3**

**rank revealing** (QR factorization (with pivoting) of  $A$ ): Small singular values of  $A$  are revealed by correspondingly small diagonal entries of  $R$ . **46.2**

**rank revealing decomposition** (of real matrix  $A$ ): a two-sided orthogonal decomposition of the form

$A = U \hat{R} V^T = U \begin{bmatrix} R \\ 0 \end{bmatrix} V^T$ , where  $U$  and  $V$  are orthogonal, and  $R$  is upper triangular and reveals the

(numerical) rank of  $A$  in the size of its diagonal elements. **39.9**

**rational canonical form:** See *invariant factors rational canonical form* or *elementary divisors rational canonical form*.

**rational function:** A quotient of polynomials. **23.1**

**ray nonsingular** (ray pattern  $A$ ): The Hadamard product  $X \circ A$  is nonsingular for every entry-wise positive  $n \times n$  matrix  $X$ . **33.8**

**ray pattern:** A matrix each of whose entries is either 0 or a ray in the complex plane represented by  $e^{i\theta}$ . **33.8**

**ray pattern class** (of ray pattern  $A$ ):  $Q(A) = \{B : b_{pq} = 0 \text{ iff } a_{pq} = 0, \text{ and otherwise } \arg b_{pq} = \arg a_{pq}\}$ . **33.8**

**Rayleigh quotient:**  $\frac{\mathbf{x}^* A \mathbf{x}}{\mathbf{x}^* \mathbf{x}}$ , where  $A$  is Hermitian and  $\mathbf{x}$  is a nonzero vector. **8.2**

**real generalized eigenspace:** See *Section 6.3*.

**real generalized eigenvector:** See *Section 6.3*.

**real-Jordan block** (of size  $2k$  with eigenvalue  $\alpha + \beta i$ ): The  $2k \times 2k$  matrix having  $k$  copies of  $M_2(\alpha, \beta) =$

$\begin{bmatrix} \alpha & \beta \\ -\beta & \alpha \end{bmatrix}$  on the (block matrix) diagonal,  $k - 1$  copies of  $I_2 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$  on the first (block matrix)

superdiagonal, and copies of  $0_2 = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}$  everywhere else. **6.3**

**real-Jordan canonical form** (of real square matrix  $A$ ): A real-Jordan matrix that is similar to  $A$ . **6.3**

**real-Jordan matrix**: A block diagonal real matrix having diagonal blocks that are Jordan blocks or real-Jordan blocks. **6.3**

**real part** (of complex number  $a + bi$ ):  $a$ . **Preliminaries**

**real structured  $\varepsilon$ -pseudospectrum** (of real square matrix  $A$ ): See *Section 16.5*.

**real vector space**: A vector space over the field of real numbers. **1.1**

**reduced digraph** (of digraph  $\Gamma$ ): A digraph whose vertices are the access equivalence classes of  $\Gamma$  (or  $\{1, \dots, k\}$  where  $k$  is the number of access equivalence classes) and having an arc from the  $i$ th vertex to the  $j$ th precisely when the  $i$ th access class has access to the  $j$ th access class. **9.1, 29.5**

**reduced QR factorization** (of matrix  $A \in \mathbb{C}^{m \times n}$ ,  $m \geq n$ ):  $A = \hat{Q}\hat{R}$  where columns of  $\hat{Q}$  are orthonormal and  $R$  is upper triangular. **5.5**

**reduced row echelon form (RREF)**: A matrix is in RREF if it is in REF, the leading entry in any nonzero row is 1, and all other entries in a column containing a leading entry are 0; matrix  $B$  is the RREF of matrix  $A$  if  $B$  is in RREF and  $A$  and  $B$  are row equivalent. **1.3**

**reduced singular value decomposition (reduced SVD)** (of complex matrix  $A$ ):  $A = \hat{U}\hat{\Sigma}\hat{V}^*$ ,  $\hat{\Sigma} = \text{diag}(\sigma_1, \sigma_2, \dots, \sigma_r) \in \mathbb{R}^{r \times r}$ , where  $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_r > 0$  and the columns of  $\hat{U} \in \mathbb{C}^{m \times r}$  and the columns of  $\hat{V} \in \mathbb{C}^{n \times r}$  are both orthonormal. **5.6, 45.1**

**reducible** (square matrix  $A$ ): There is a permutation matrix  $P$  such that  $PAP^T = \begin{bmatrix} BC \\ \mathbf{0} D \end{bmatrix}$ , where  $B, D$  are square. **9.1, 27.3**

**reducing eigenvalue** ( $\lambda$  of  $A \in \mathbb{C}^{n \times n}$ ):  $A$  is unitarily similar to  $[\lambda] \oplus A_2$ . **18.2**

**REF**: See *row echelon form*.

**( $k$ -)regular** (graph): Every vertex has the same degree  $k$ . **28.2**

**regular** ( $m \times n$  (0,1)-design matrix  $W$ ):  $W$  is balanced and  $W^T W = t(I + J)$  for some integer  $t$ . **32.4**

**regular** (pencil  $A - xB$ ): There exists a  $\lambda \in \mathbb{C}$  such that  $A - \lambda B$  is nonsingular. **43.1**

**regular** (pencil  $A_0 + xA_1 \in \mathbb{D}[x]^{n \times n}$ ):  $\det(A_0 + xA_1)$  is not the zero polynomial, or equivalently, there exists a  $\lambda \in \mathbb{D}$  such that  $A_0 + \lambda A_1$  is nonsingular. **23.4**

**relative backward error of the linear system**: See *Section 38.1*.

**relative condition number**: See *condition number*.

**relative error** (in approximation  $\hat{\mathbf{z}}$  to  $\mathbf{z}$ ):  $\|\mathbf{z} - \hat{\mathbf{z}}\|/\|\mathbf{z}\|$ . **37.4**

**requires**: If  $P$  is a property referring to a real matrix, then a sign pattern  $A$  requires  $P$  if every real matrix in  $Q(A)$  has property  $P$ . **33.1**

**requires unique inertia** (sign pattern  $A$ ):  $\text{in}(B_1) = \text{in}(B_2)$  for all symmetric matrices  $B_1, B_2 \in Q(A)$ . **33.6**

**residual vector** (of  $\tilde{\mathbf{x}}$  when solving the linear system  $A\mathbf{x} = \mathbf{b}$ ): The vector  $\mathbf{r} = \mathbf{b} - A\tilde{\mathbf{x}}$ . **38.3**

**residual vector** (at step  $k$  of an iterative method for solving  $A\mathbf{x} = \mathbf{b}$ ): The vector  $\mathbf{r}_k = \mathbf{b} - A\mathbf{x}_k$ , where  $\mathbf{x}_k$  is the approximate solution generated at step  $k$ . **41.1**

**resolvent** (of matrix  $A \in \mathbb{C}^{n \times n}$  at a point  $z \notin \sigma(A)$ ): The matrix  $(zI - A)^{-1}$ . **16.1**

**restarted GMRES algorithm, GMRES( $j$ )**: Restart GMRES every  $j$  steps, using the latest iterate as the initial guess for the next GMRES cycle. **41.3**

**right singular vector**: See *singular vectors*.

**right singular space**: See *singular spaces*.

**ring automorphism of  $F^{n \times n}$  induced by  $f$** : The map  $\phi : F^{n \times n} \rightarrow F^{n \times n}$  defined by  $\phi([a_{ij}]) = [f(a_{ij})]$ . **22.4**

**Ritz pair**:  $(\theta, \mathbf{v})$  where  $\theta$  is the Ritz value for Ritz vector  $\mathbf{v}$ . **43.3**

**Ritz value**: The scalar  $\theta$  for a Ritz vector. **43.3**

**Ritz vector** (of matrix of  $A$  from subspace  $S$  of  $\mathbb{C}^n$ ): There is a  $\theta \in \mathbb{C}$  such that  $A\mathbf{v} - \theta\mathbf{v} \perp S$ . **43.3**

**rook polynomials**: Generating functions for the rook numbers defined using permanents. **31.8**

**rounding error**: In one floating point arithmetic operation, the difference between the exact arithmetic operation and the floating point arithmetic operation; in more extensive calculations, refers to the cumulative effect of the rounding errors in the individual floating point operations. **37.6**

**rounding mode:** Maps  $x \in \mathbb{R}$  to a floating point number  $\text{fl}(x)$ ; default rounding mode in standard-conforming arithmetic is round-to-nearest, ties-to-even. **37.6**

**Routh-Hurwitz matrix:** See *Section 19.2*.

**row** (of a matrix): The entries of a matrix lying in a horizontal line in the matrix. **1.2**

**row echelon form (REF):** A matrix is in REF if every zero row is below all nonzero rows and for two nonzero rows, the leading entry in the upper row is to the left of the leading entry of the lower row; matrix  $B$  is a REF of matrix  $A$  if  $B$  is in REF and  $A$  and  $B$  are row equivalent. **1.3**

**row equivalent:** Matrix  $A$  is row equivalent to matrix  $B$  if  $B$  can be obtained from  $A$  by a sequence of elementary row operations (equivalently,  $B = QA$  for some invertible matrix  $Q$ ). **1.3**

**row equivalent** (matrices  $A, B \in \mathbb{D}^{m \times n}$ ):  $B = QA$  for some  $\mathbb{D}$ -invertible matrix  $Q$ . **23.2**

**row operation:** See *elementary row operation*.

**row signing** (of (real or sign pattern) matrix  $A$ ):  $DA$  where  $D$  is a signing. **33.3**

**row space:** The span of the rows of a matrix. **2.4**

**row-stochastic** (matrix): A square nonnegative matrix having all row sums equal to 1. **9.4**

**row sum vector** (of a matrix): The vector of row sums. **27.4**

**RRD** (of real matrix  $A$ ): A decomposition  $A = XDY^T$  with  $D$  a diagonal matrix and  $X$  and  $Y$  full column rank, well-conditioned matrices. **46.3**

**RREF:** See *reduced row echelon form*.

## S

**S-matrix:** An  $n \times (n + 1)$  matrix  $B$  such that it is an  $S^*$ -matrix and the kernel of every matrix in  $Q(B)$  contains a vector all of whose coordinates are positive. **33.3**

**$S^*$ -matrix:** An  $n \times (n + 1)$  matrix  $B$  such that each of the  $n + 1$  matrices obtained by deleting a column of  $B$  is an SNS matrix. **33.3**

**SAP:** See *spectrally arbitrary pattern*.

**scalar:** An element of a field. **1.1**

**scalar matrix (transformation):** A scalar multiple of the identity matrix (transformation). **1.2, 3.2**

**scaling** (of a real matrix  $A$ ): A matrix of the form  $D_1AD_2$  where  $D_1$  and  $D_2$  are diagonal matrices with positive diagonal entries. **9.6, 27.6**

**Schatten- $p$  norm** (of  $A \in \mathbb{C}^{m \times n}$ ):  $\|A\|_{S,p} = (\sum_{i=1}^q \sigma_i^p(A))^{1/p}$ . **17.3**

**Schur complement:** A matrix defined from a partitioned matrix. **4.2, 10.3**

**Schur product:** See *Hadamard product*.

**score vector:** The row sum vector of a tournament matrix. **27.5**

**SDR:** See *system of distinct representatives*.

**Seidel matrix** (of simple graph  $G$ ): The matrix  $J - I - 2\mathcal{A}_G$ . **28.4**

**Seidel switching:** An operation on simple graphs. **28.4**

**self-adjoint:** See *Hermitian*.

**self-inverse sign pattern:** An  $S^2NS$ -pattern  $A$  such that  $B^{-1} \in Q(A)$  for every matrix  $B \in Q(A)$ . **33.2**

**semiconvergent** (square nonnegative matrix  $P$ ):  $\lim_{m \rightarrow \infty} P^m$  exists. **9.3**

**semipositive** (real matrix  $A$ ):  $A$  is nonnegative and some element is positive. **9.1**

**$K$ -semipositive** (matrix  $A \in \mathbb{R}^{n \times n}$ ):  $A$  is  $K$ -nonnegative and  $A \neq 0$ . **26.1**

**$K$ -semipositive** (vector  $\mathbf{v} \in \mathbb{R}^n$ ):  $\mathbf{v} \in K$  and  $\mathbf{v} \neq 0$ . **26.1**

**semisimple:** An eigenvalue having algebraic multiplicity equal to its geometric multiplicity. **4.3**

**semistable matrix:** Either positive semistable (i.e., nonnegative stable) or negative semistable, depending on section.

**separation** (between two square matrices  $A_1$  and  $A_2$ ):  $\inf_{\|X\|_2=1} \|XA_1 - A_2X\|_2$ . **15.1**

**$\varphi$ -sesquilinear form** (on vector space  $V$  over field  $F$  with automorphism  $\varphi$ ): A map  $f$  from  $V \times V$  into  $F$  that satisfies  $f(a\mathbf{u}_1 + b\mathbf{u}_2, \mathbf{v}) = af(\mathbf{u}_1, \mathbf{v}) + bf(\mathbf{u}_2, \mathbf{v})$  and  $f(\mathbf{u}, a\mathbf{v}_1 + b\mathbf{v}_2) = \varphi(a)f(\mathbf{u}, \mathbf{v}_1) + \varphi(b)f(\mathbf{u}, \mathbf{v}_2)$ . **12.4**

**sesquilinear form** (on a complex vector space): A  $\varphi$ -sesquilinear form where  $\varphi$  is complex conjugation. **12**

**set of Hermitian matrices associated with graph  $G$ :**  $\mathcal{H}(G) = \{B \in \mathcal{H}_n \mid \mathcal{G}(B) = G\}$ . **34.1**

**set of symmetric matrices associated with graph  $G$ :**  $\mathcal{S}(G) = \{B \in \mathcal{S}_n \mid \mathcal{G}(B) = G\}$ . **34.1**

**sgn:** See *sign*.

**Shannon capacity:** A parameter of a simple graph. **28.5**

**shift:** The scalar  $\mu$  in a shifted matrix  $A - \mu I$ . **42.1**

**shifted matrix** (of matrix  $A$ ): The matrix  $A - \mu I$ , where  $\mu$  is the shift. **42.1**

**shifted QR iteration:** QR iteration of the shifted matrix. **42.1**

**sign** (denoted  $\text{sign}$ , of a complex number): A nonzero complex number;  $\text{sign}(0) = 1$ , otherwise the complex number with the same argument having absolute value 1. **Preliminaries**

**sign** (denoted  $\text{sgn}$ , of a complex square matrix): A function defined from the Jordan Canonical Form of the matrix. See *Section 11.6*.

**sign** (denoted  $\text{sgn}$ , of a permutation): 1, if the permutation is even and  $-1$ , if the permutation is odd.

**Preliminaries**

**sign** (denoted  $\text{sgn}$ , of a real number):  $+$ ,  $0$ ,  $-$  according as the number is  $> 0$ ,  $= 0$ ,  $< 0$ . **Preliminaries**

**sign** (denoted  $\text{sgn}$ , of a set  $\alpha$  of edges in a signed bipartite graph): The product of the weights of the edges in  $\alpha$ . **30.1**

**sign** (of a simple cycle in a sign pattern  $A$ ): The product of the entries in the cycle. **33.1**

**sign-central:** A sign pattern matrix that requires centrality. **33.11**

**sign nonsingular** (SNS) (square sign pattern  $A$ ): Every matrix  $B \in Q(A)$  is nonsingular. **33.2**

**sign pattern:** A matrix whose entries are in  $\{+, 0, -\}$ . **33.1**

**sign pattern class:** See *qualitative class*.

**sign pattern matrix:** See *sign pattern*.

**sign pattern of real matrix  $B$ :** The sign pattern whose entries are the signs of the corresponding entries in  $B$ . **33.1**

**sign potentially orthogonal SPO** (square sign pattern): Does not have a zero row or zero column and every pair of rows and every pair of columns allows orthogonality. **33.10**

**sign semistable** (square sign pattern  $A$ ): Every matrix  $B \in Q(A)$  is semistable **33.4**

**sign singular** (square sign pattern  $A$ ): Every matrix  $B \in Q(A)$  is singular. **33.2**

**sign-solvable** (system of linear equations  $Ax = b$ ): For each  $\tilde{A} \in Q(A)$  and for each  $\tilde{b} \in Q(b)$ , the system  $\tilde{A}x = \tilde{b}$  is consistent and  $\{\tilde{x} : \text{there exist } \tilde{A} \in Q(A) \text{ and } \tilde{b} \in Q(b) \text{ with } \tilde{A}\tilde{x} = \tilde{b}\}$  is entirely contained in one qualitative class. **33.3**

**sign stable** (square sign pattern  $A$ ): Requires stability, i.e., every matrix  $B \in Q(A)$  is stable. **33.4**

**sign symmetric** (square matrix  $A$ ):  $\det A[\alpha, \beta] \det A[\beta, \alpha] \geq 0$ ,  $\forall \alpha, \beta \subseteq \{1, \dots, n\}$ ,  $|\alpha| = |\beta|$ . **19.2**

**signature** (of a real symmetric or Hermitian bilinear form): The signature of a matrix representing the form relative to some basis. **12.2, 12.5**

**signature** (of real symmetric or Hermitian matrix  $A$ ): The number of positive eigenvalues minus the number of negative eigenvalues. **12.2, 12.5**

**signature** (of a composite cycle  $\gamma$  in sign pattern  $A$ ):  $(-1)^{\sum_{i=1}^m (l_i - 1)}$  where  $l_i$  are the lengths of the simple cycles in  $\gamma$ . **33.1**

**signature matrix:** A  $\pm 1$  diagonal matrix. **32.2**

**signature pattern:** A diagonal sign pattern matrix, each of whose diagonal entries is  $+$  or  $-$ . **33.1**

**signature similarity** (of the square sign pattern  $A$ ): A product of the form  $SAS$ , where  $S$  is a signature pattern. **33.1**

**signed bigraph** (of real matrix  $A$ ): The weighted graph obtained from the bigraph of  $A$  weighting the edge  $\{i, j\}$  by  $+1$  if  $a_{ij} > 0$ , and by  $-1$  if  $a_{ij} < 0$ . **30.2**

**signed bipartite graph:** A weighted bipartite graph with weights  $X = \{-1, 1\}$ . **30.1**

**signed 4-cockade:** A 4-cockade whose edges are weighted by  $\pm 1$  in such a way that every 4-cycle is negative. **30.2**

**signed digraph** (of an  $n \times n$  sign pattern  $A$ ): The digraph with vertex set  $\{1, 2, \dots, n\}$  where  $(i, j)$  is an arc (bearing  $a_{ij}$  as its sign) iff  $a_{ij} \neq 0$ . **33.1**

**significant:** The (base  $b$ ) integer  $m$  in floating point number  $x = \pm \left(\frac{m}{b^{p-1}}\right) b^e$ . **37.6**

- signing** (of order  $k$ ): A nonzero  $(0, 1, -1)$ - or  $(0, +, -)$ -diagonal matrix of order  $k$ . **33.3**
- signless Laplacian matrix** (of graph  $G$ ): The matrix  $D + \mathcal{A}_G$ , where  $D$  is the diagonal matrix of vertex degrees and  $\mathcal{A}_G$  is the adjacency matrix of  $G$ . **28.4**
- similar** (to matrix  $A$ ): Any matrix of the form  $C^{-1}AC$ . **2.4**
- similarity scaling** (of square matrix  $A$ ): A scaling  $DAD^{-1}$  of  $A$ . **9.6**
- simple (cycle)** (in a digraph): The induced subdigraph of the vertices in the cycle is the cycle. **35.1**
- simple cycle** (in sign pattern  $A$ ): See *k-cycle (in sign pattern  $A$ )*.
- simple (digraph)**: A digraph with no loops (a digraph does not have multiple arcs). **29.1**
- simple (eigenvalue)**: An eigenvalue having algebraic multiplicity 1. **4.3**
- simple (graph)**: A graph with no loops where each edge has multiplicity at most one. **28.1**
- simple (walk)** (in a digraph): A walk in which all vertices, except possibly the first and last, are distinct. **29.1**
- simple row operation**: A generalization of an elementary row operation used in domains. **23.2**
- sine** (of a complex square matrix  $A$ ): The matrix defined by the sine power series,  
 $\sin(A) = A - \frac{A^3}{3!} + \dots + \frac{(-1)^k}{(2k+1)!} A^{2k+1} + \dots$ . **13.5**
- single precision**: Typically, floating point numbers have machine epsilon roughly  $10^{-7}$  and precision roughly 7 decimal digits. **37.6**
- singular** (matrix or linear operator): Not nonsingular. **1.5, 3.7**
- singular** (pencil): A pencil that is not regular. **23.4, 43.1**
- singular space (right or left)** (of complex matrix  $A$ ): The subspace spanned by the right (or by the left) singular vectors of  $A$ . **45.1**
- singular-triplet** (of  $A \in \mathbb{C}^{m \times n}$ ): A (left singular vector, singular value, right singular vector) triplet. **15.2**
- singular value decomposition (SVD)** (of matrix  $A \in \mathbb{C}^{m \times n}$ ):  $A = U\Sigma V^*$ ,  
 $\Sigma = \text{diag}(\sigma_1, \sigma_2, \dots, \sigma_p) \in \mathbb{R}^{m \times n}$ ,  $p = \min\{m, n\}$ , where  $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_p \geq 0$  and both  $U = [\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_m] \in \mathbb{C}^{m \times m}$  and  $V = [\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n] \in \mathbb{C}^{n \times n}$  are unitary. Also forms with other dimensions. **5.6, 45.1, 17.1**
- singular value vector** (of complex matrix  $A$ ): The vector of singular values of  $A$  in nonincreasing order. **17.1**
- singular values** (of a complex matrix): The diagonal entries  $\sigma_i$  of  $\Sigma$  in a singular value decomposition. **5.6, 45.1, 17.1**
- singular vectors** (of a complex matrix): Left: the columns of  $U$ , and right: the columns of  $V$ , both in a singular value decomposition. **5.6, 45.1**
- size** (of matrix  $A$ ):  $m \times n$ , where  $A$  is an  $m \times n$  matrix; also  $m$  if  $n = m$ . **1.2**
- Skeel condition number of the linear system  $A\hat{\mathbf{x}} = \mathbf{b}$** :  $\text{cond}(A, \hat{\mathbf{x}}) = \frac{\| |A^{-1}| |A| \|\hat{\mathbf{x}}\|_\infty}{\|\hat{\mathbf{x}}\|_\infty}$ . **38.1**
- Skeel matrix condition number** (of matrix  $A$ ):  $\text{cond}(A) = \| |A^{-1}| |A| \|_\infty$ . **38.1**
- skew-Hermitian** (matrix): A real or complex matrix equal to the negative of its conjugate transpose. **1.2, 7.2**
- skew-symmetric** (matrix): A matrix equal to the negative of its transpose. **1.2**
- Smith invariant factors** (of  $A \in F^{n \times n}$ ): The nonconstant polynomials on the diagonal of the Smith normal form of  $xI - A$ . **6.5**
- Smith normal form** (of  $M \in F[x]^{n \times n}$ ): The Smith normal matrix obtained from  $M$  by elementary row and column operations. **6.5**
- Smith normal form** (over GCD domain  $\mathbb{D}_g$ ): Matrix  $B \in \mathbb{D}_g^{m \times n}$  is in Smith normal form if  $B = \text{diag}(b_1, \dots, b_r, 0, \dots, 0)$ ,  $b_i \neq 0$  for  $i = 1, \dots, r$  and  $b_{i-1} | b_i$  for  $i = 2, \dots, r$ . **23.2**
- Smith normal matrix** (in  $F[x]^{n \times n}$ ): A diagonal matrix  $\text{diag}(1, \dots, 1, a_1(x), \dots, a_s(x), 0, \dots, 0)$ , where the  $a_i(x)$  are monic nonconstant polynomials such that  $a_i(x)$  divides  $a_{i+1}(x)$  for  $i = 1, \dots, s - 1$ . **6.5**
- SNS**: See *sign nonsingular*.
- S<sup>2</sup>NS**: See *strong sign nonsingular*.
- solution**: An ordered tuple of scalars that when assigned to the variables satisfies a system of linear equations. **1.4**
- solution set**: The set of all solutions to a system of linear equations. **1.4**
- span, Span** (noun): The set of all linear combinations of the vectors in a set. **2.1**
- span, spans** (verb): A set  $S \subseteq V$  spans  $V$  if  $V = \text{Span}(S)$ . **2.1**
- spanning subgraph** (of a connected graph  $(V, E)$ ): A connected subgraph  $(V', E')$  with  $V' = V$ . **28.1**

- spanning tree** (of a connected graph): A spanning subgraph that is a tree. **28.1**
- sparse** (matrix  $A$ ): A matrix for which substantial savings in either operations or storage can be achieved when the zero elements of  $A$  are exploited during the application of Gaussian elimination to  $A$ . **40.2**
- sparse approximate inverse** (of matrix  $A$ ): A sparse matrix  $M^{-1}$  constructed to approximate  $A^{-1}$ . **41.1**
- sparsity pattern**: See *sparsity structure*.
- sparsity structure** (of matrix  $A$ ): The set of indices of nonzero elements of  $A$ . **40.3**
- special linear group** (of order  $n$  over  $F$ ): The subgroup of the general linear group consisting of all matrices that have determinant 1. **67.1**
- spectral absolute value** (of complex matrix  $A$ ):  $(A^*A)^{1/2}$ . **17.1**
- spectral norm** (of complex matrix  $A$ ):  $\|A\|_2 = \sqrt{\rho(A^*A)} = \max\{\|Av\|_2 : \|v\|_2 = 1\} =$  the largest singular value of  $A$ . **7.1, 37.3**
- spectral radius** (of  $A \in \mathbb{C}^{n \times n}$ ):  $\max\{|\lambda| : \lambda \text{ an eigenvalue of } A\}$ . **4.3**
- spectrally arbitrary pattern (SAP)**: A sign pattern  $A$  of size  $n$  such that every monic real polynomial of degree  $n$  can be achieved as the characteristic polynomial of some matrix  $B \in Q(A)$ . **33.6**
- spectrum** (of a matrix): The multiset of all eigenvalues of a matrix, each eigenvalue appearing with its algebraic multiplicity. **4.3**
- spectrum** (of a graph): The spectrum of its adjacency matrix. **28.3**
- speed** (of a processor): The number of floating-point operations per second (flops). **42.9**
- splitting**: See *preconditioner*.
- SPO**: See *sign potentially orthogonal*.
- square matrix**: The number of columns is the same as the number of rows. **1.2**
- square root** (of a square complex matrix  $A$ ): A matrix  $B$  such that  $B^2 = A$ . **11.2** (See also *principal square root*, *PSD square root*)
- stable** (algorithm): See *numerically stable*.
- stable matrix**: Either positive stable or negative stable, depending on section; positive in *Section 9.5* and *Section 19.2*.
- standard basis** (for  $F^n$  or  $F^{m \times n}$ ): The set of vectors or matrices having one entry equal to 1 and all other entries equal to 0. **2.1**
- standard-conforming** (floating point system): conforming to IEEE standard. **37.6**
- standard inner product** (in  $\mathbb{R}^n$  (or  $\mathbb{C}^n$ )):  $\langle \mathbf{u}, \mathbf{v} \rangle = \mathbf{u}^T \mathbf{v}$  ( $\langle \mathbf{u}, \mathbf{v} \rangle = \mathbf{v}^* \mathbf{u}$ ). **5.1**
- standard linear preserver problem**: A linear preserver problem where the preservers take one of the standard forms. **22.2**
- ( $R, c, f$ )-standard map**: For  $A \in F^{n \times n}$ ,  $\phi(A) = cRAR^{-1} + f(A)I$ , or  $\phi(A) = cRA^T R^{-1} + f(A)I$ .  $R$  invertible,  $c$  nonzero,  $f$  a linear functional. **22.2**
- ( $R, S$ )-standard map**: For  $A \in F^{m \times n}$ ,  $\phi(A) = RAS$ , or  $m = n$  and  $\phi(A) = RA^T S$ .  $R$  and  $S$  must be invertible and may be required satisfy some additional assumptions. **22.2**
- standard matrix of transformation**  $T : F^n \rightarrow F^m$ : The matrix of  $T$  with respect to the standard bases for  $F^n, F^m$ . **3.3**
- star** on  $n$  vertices: a tree in which there is a vertex of degree  $n - 1$ . **34.6**
- state** (of  $n \times n$  stochastic matrix  $P$ ): An index  $i \in \{1, \dots, n\}$ . **9.4**
- stationary distribution** (of stochastic matrix  $P$ ): Nonnegative vector  $\pi$  that satisfies  $\pi^T \mathbf{1} = \mathbf{1}$  and  $\pi^T P = \pi^T$ . **9.4**
- $k$ -step Arnoldi factorization**: See *Arnoldi factorization*.
- stochastic** (square nonnegative matrix  $P$ ): Same as row-stochastic; the sum of the entries in each row is 1. **9.4**
- stopping** (matrix): A transient substochastic matrix. **9.4**
- strict column signing** (of (real or sign pattern) matrix  $A$ ):  $AD$  where  $D$  is a strict signing. **33.3**
- strict row signing** (of (real or sign pattern) matrix  $A$ ):  $DA$  where  $D$  is a signing. **33.3**
- strict signing**: A signing where all the diagonal entries are nonzero. **33.3**
- strictly block lower triangular** (matrix  $A$ ):  $A^T$  is strictly block upper triangular. **10.3**

**strictly block upper triangular** (matrix): A block upper triangular matrix in which all the diagonal blocks are 0. **10.3**

**strictly copositive** (matrix  $A$ ):  $\mathbf{x}^T A \mathbf{x} > 0$  for all  $\mathbf{x} \geq 0$  and  $\mathbf{x} \neq 0$ . **35.5**

**strictly diagonally dominant** ( $n \times n$  complex matrix  $A$ ):  $|a_{ii}| > \sum_{j=1, j \neq i}^n |a_{ij}|$  for  $i = 1, \dots, n$ . **9.5**

**strictly equivalent** (pencils  $A - xB$  and  $C - xD$ ): If there exist nonsingular matrices  $S_1$  and  $S_2$  such that  $C - \lambda D = S_1(A - \lambda B)S_2$  for all  $\lambda \in \mathbb{C}$ . **43.1**

**strictly equivalent** (pencils  $A(x), C(x) \in \mathbb{D}[x]^{m \times n}$ ):  $C(x) = QA(x)P$  for some  $\mathbb{D}$ -invertible matrices  $P, Q$ . **23.4**

**strictly lower triangular** (matrix  $A$ ):  $A^T$  is strictly upper triangular **10.2**

**strictly upper triangular** (matrix): A matrix such that every entry having row number greater than or equal to column number is zero. **10.2**

**strictly unitarily equivalent** (pencils  $A - xB$  and  $C - xD$ ): strictly equivalent pencils in which  $S_1, S_2$  can be taken unitary. **43.1**

**Strong Arnold Hypothesis**: Satisfied by a real symmetric matrix  $M$  provided there does not exist a real symmetric nonzero matrix  $X$  such that  $MX = \mathbf{0}$ ,  $M \circ X = \mathbf{0}$ ,  $I \circ X = \mathbf{0}$ . **28.5**

**strong combinatorial invariant** (of a matrix): A quantity or property that does not change when the rows and/or columns are permuted. **27.1**

**strong Parter vertex**: a Parter–Wiener vertex  $j$  for an eigenvalue  $\lambda$  of an  $A \in \mathcal{H}(G)$  such that  $\lambda$  occurs as an eigenvalue of at least three direct summands of  $A(j)$ . **34.1**

**(strong) product** (of simple graphs  $G = (V, E), G' = (V', E')$ ): The simple graph with vertex set  $V \times V'$ , where two distinct vertices are adjacent whenever in both coordinate places the vertices are adjacent or equal in the corresponding graph. **28.1**

**strong sign nonsingular** ( $S^2NS$ ) (square sign pattern  $A$ ):  $A$  is an SNS-pattern such that the matrix  $B^{-1}$  is in the same sign pattern class for all  $B \in Q(A)$ . **33.2**

**strongly connected**: A digraph whose vertices all lie in a single access equivalence class. **9.1, 29.5**

**strongly connected components** (of a digraph): The subdigraphs induced by the access equivalence classes. **29.5**

**strongly inertia preserving** (real square matrix  $A$ ): The inertia of  $AD$  is equal to the inertia of  $D$  for every real diagonal matrix  $D$ . **19.5**

**strongly nonsingular** (square matrix): All its principal submatrices are nonsingular. **47.6**

$\phi$  **strongly preserves** (subset of matrices  $\mathcal{M}$ ):  $\phi(\mathcal{M}) = \mathcal{M}$ . **22.1**

$\phi$  **strongly preserves** (relation  $\sim$  on matrix subspace  $\mathcal{V}$ ): For every pair  $A, B \in \mathcal{V}$ , we have  $\phi(A) \sim \phi(B)$  if and only if  $A \sim B$ . **22.1**

**strongly regular**: A simple graph with parameters  $(n, k, \lambda, \mu)$  that has  $n$  vertices, is  $k$ -regular with  $1 \leq k \leq n - 2$ , every two adjacent vertices have exactly  $\lambda$  common neighbors, and every two distinct nonadjacent vertices have exactly  $\mu$  common neighbors. **28.2**

**strongly stable**: See *additive D-stable*.

**subdigraph** (of a digraph  $\Gamma = (V, E)$ ): A digraph  $\Gamma' = (V', E')$  with  $V' \subseteq V$  and  $E' \subseteq E$ . **29.1**

**subgraph** (of a graph  $(V, E)$ ): A graph  $G' = (V', E')$  with  $V' \subseteq V$  and  $E' \subseteq E$ . **28.1**

**submatrix**: A matrix lying in certain rows and columns of a given matrix. **1.2, 10.1**

$\mathbb{D}$ -**submodule**: A nonempty set  $\mathbf{N} \subseteq \mathbf{M}$  that is closed under addition and multiplication by ( $\mathbb{D}$ ) scalars. **23.3**

**submultiplicative** (norm  $\|\cdot\|$  on  $\mathbb{C}^{n \times n}$ ): A vector norm satisfying  $\|AB\| \leq \|A\|\|B\|$  for all  $A, B \in \mathbb{C}^{n \times n}$  (satisfies the conditions of a matrix norm except not required to be part of a family). **18.4**

**subordinate** (matrix norm): See *induced norm*.

**( $k$ -th)-subpermanent sum** (of matrix  $A$ ): The sum of the permanents of all order  $k$  submatrices of  $A$ . **31.7**

**subpattern** (of a sign pattern): A sign pattern obtained by replacing some (possibly none) of the nonzero entries with 0. **33.1**

**subspace**: Subset of a vector space  $V$  that is itself a vector space under the operations of  $V$ . **1.1**

**subspace iteration:** See *orthogonal iteration*.

**substochastic** (square nonnegative matrix  $P$ ): The sum of the entries in each row is  $\leq 1$ . **9.4**

**subtractive cancellation of significant digits:** Occurs in floating point sums when the relative error in the rounding-error-corrupted approximate sum is substantially greater than the relative error in the summands. **37.6**

**sum** (of subspaces):  $W_1 + \cdots + W_k = \{\mathbf{w}_1 + \cdots + \mathbf{w}_k : \mathbf{w}_i \in W_i\}$ . **2.3**

**sum norm:** See *1-norm*.

**sup-norm:** See  *$\infty$ -norm*.

**support** (of rectangular matrix  $A$  or vector): The set of indices  $ij$  with  $a_{ij} \neq 0$ . **9.6**

**support line** (of convex set  $S$ ): A line  $\ell$  that intersects  $\partial S$  such that  $S$  lies entirely within one of the closed half-planes determined by  $\ell$ . **18.2**

**$G$  supports rank decompositions:** Each matrix  $A \in \mathcal{M}(G)$  is the sum of  $\text{rank}(A)$  matrices in  $\mathcal{M}(G)$  each having rank 1 (also a variant for signed bipartite graphs). **30.3**

**surjective:** See *onto*.

**SVD:** See *singular value decomposition*.

**switching equivalent:** A simple graph that can be obtained from another simple graph by a Seidel switching. **28.4**

**Sym:** The map  $\text{Sym}(\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_k) = \frac{1}{m!} \sum_{\pi \in S_m} \mathbf{v}_{\pi(1)} \otimes \cdots \otimes \mathbf{v}_{\pi(k)}$ . **13.6**

**sym multiplication:**  $(\mathbf{v}_1 \vee \cdots \vee \mathbf{v}_p) \vee (\mathbf{v}_{p+1} \vee \cdots \vee \mathbf{v}_{p+q}) = \mathbf{v}_1 \vee \cdots \vee \mathbf{v}_{p+q}$ . **13.7**

**symbol** (of a family of Toeplitz matrices): The function  $a(z) = \sum a_k z^k$  where the  $a_k$  are the constants of the Toeplitz matrices. **16.2**

**symbol curve** (of a Toeplitz family): The image of the complex unit circle under the symbol. **16.2**

**symmetric** (bilinear form  $f$ ):  $f(\mathbf{u}, \mathbf{v}) = f(\mathbf{v}, \mathbf{u})$  for all  $\mathbf{u}, \mathbf{v} \in V$ . **12.2**

**symmetric** (digraph  $\Gamma = (V, E)$ ):  $(i, j) \in E$  implies  $(j, i) \in E$  for all  $i, j \in V$ . **35.1**

**symmetric** (form): A multilinear form that is a symmetric map. **13.4**

**symmetric** (map  $\psi \in L^m(V; U)$ ):  $\psi(\mathbf{v}_{\pi(1)}, \dots, \mathbf{v}_{\pi(m)}) = \psi(\mathbf{v}_1, \dots, \mathbf{v}_m)$ , for all permutations  $\pi$ . **13.4**

**symmetric** (matrix): A matrix equal to its transpose. **1.2**

**symmetric algebra** (on vector space  $V$ ):  $\bigvee V = \bigoplus_{k \in \mathbb{N}} (\bigvee^k V)$  with sym multiplication. **13.9**

**symmetric inertia set** (of a symmetric sign pattern  $A$ ):  $\text{in}(A) = \{\text{in}(B) : B = B^T \in Q(A)\}$ ; **33.6**

**symmetric matrices associated with graph  $G$ :** See *set of symmetric matrices associated with graph  $G$* .

**symmetric maximal rank** (of symmetric sign pattern  $A$ ):  $\max\{\text{rank} B : B^T = B \text{ and } B \in Q(A)\}$ . **33.6**

**symmetric minimal rank** (of symmetric sign pattern  $A$ ):  $\min\{\text{rank} B : B^T = B \text{ and } B \in Q(A)\}$ . **33.6**

**symmetric power** (of a vector space): See *symmetric space*.

**symmetric product** (of vectors  $\mathbf{v}_1, \dots, \mathbf{v}_m$ ):  $\mathbf{v}_1 \vee \cdots \vee \mathbf{v}_m = m! \text{Sym}(\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_m)$ . **13.6**

**symmetric rank revealing decomposition (SRRD)** (of symmetric real matrix  $H$ ): A decomposition  $H = XDX^T$ , where  $D$  is diagonal and  $X$  is a full column rank well-conditioned matrix. **46.5**

**symmetric space** (of vector space  $V$ ):  $\bigvee^m V = \text{Sym}(\bigotimes^m V)$ . **13.6**

**symmetric scaling** (of a matrix): A scaling where  $D_1 = D_2$ . **9.6, 27.6**

**system of distinct representatives (SDR):** For the finite sets  $S_1, S_2, \dots, S_n$ , a choice of  $x_1, x_2, \dots, x_n$  with the properties that  $x_i \in S_i$  for each  $i$  and  $x_i \neq x_j$  whenever  $i \neq j$ . **31.3**

**system of linear equations:** A set of one or more linear equations in the same variables. **1.4**

## T

**tensor:** An element of a tensor product. **13.2**

**tensor algebra** (on vector space  $V$ ):  $\bigotimes V = \bigoplus_{k \in \mathbb{N}} (\bigotimes^k V)$ . **13.9**

**tensor multiplication:**  $(\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_p) \otimes (\mathbf{v}_{p+1} \otimes \cdots \otimes \mathbf{v}_{p+q}) = \mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_{p+q}$ . **13.7**

**tensor power:** A tensor product of copies of one vector space. **13.2**

**tensor product** (of matrices): See *Kronecker product*.

**tensor product** (of vector spaces  $V_1, \dots, V_m$ ): a multilinear map satisfying a universal factorization property, See *Section 13.2*.

**term rank** (of a  $(0, 1)$ -matrix  $A$ ): The largest size of a collection of 1s of  $A$  with no two 1s in the same line. **27.1**

**term rank** (of sign pattern  $A$ ): The maximum number of nonzero entries of  $A$  no two of which are in the same row or same column. **33.6**

**tight sign-central**: A sign-central pattern  $A$  for which the Hadamard product of any two columns contains a negative element. **33.11**

**TN**: See *totally nonnegative*.

**Toeplitz** (matrix): A matrix whose entries are constant along each sub- and super- diagonal, i.e., the value of the  $i, j$ -entry is the constant  $a_k$  whenever  $i - j = k$ . **16.2, 48.1**

**Toeplitz-block matrix**: A block matrix  $A = [A_{ij}]$  where each block  $A_{ij}$  is an  $n \times n$  Toeplitz matrix. **48.1**

**Toeplitz inverse eigenvalue problem (ToIEP)**: Given  $\lambda_1, \dots, \lambda_n \in \mathbb{R}$ , find  $\mathbf{c} = [c_1, \dots, c_n]^T \in \mathbb{R}^n$  such that  $[t_{ij}]_{i,j=1}^n$  with  $t_{ij} = c_{|i-j|+1}$  has spectrum  $\{\lambda_1, \dots, \lambda_n\}$ . **20.9**

**ToIEP**: See *Toeplitz inverse eigenvalue problem*.

**total least squares problem**: See *Section 39.1*.

**total signed compound (TSC)** (sign patterns): Every square submatrix of every matrix  $A \in Q(S)$  is either sign nonsingular or sign singular. **46.3**

**total support**: An  $n \times n$   $(0, 1)$ -matrix  $A$  has total support if  $A \neq \mathbf{0}$  and each 1 of  $A$  is on a diagonal of  $A$ . **27.2**

**totally nonnegative** (real matrix  $A$ ): Every minor is nonnegative. **21.1**

**totally positive** (real matrix  $A$ ): Every minor is positive. **21.1**

**totally unimodular** (real matrix  $A$ ): All minors of  $A$  are from  $\{-1, 0, 1\}$ . **46.3**

**tournament**: Digraph of a tournament matrix. **27.5**

**tournament matrix**: A  $(0, 1)$ -matrix with 0 diagonal and exactly one of  $a_{ij}, a_{ji}$  equal to 1 for all  $i \neq j$ . **27.5**

**TP**: See *totally positive*.

**trace**: The sum of all the diagonal entries of the matrix. **1.2**

**trace-minimal** (graph  $G$  in a family  $\mathcal{F}$  of graphs): The trace-sequence of the adjacency matrix of  $G$  is least in lexicographic order among all graphs in  $\mathcal{F}$ . **32.7**

**trace norm** (of  $A \in \mathbb{C}^{m \times n}$ ): The sum of the singular values of  $A$ . **17.3**

**trace-sequence** (of  $n \times n$  matrix  $A$ ):  $(\text{tr}(A), \text{tr}(A^2), \dots, \text{tr}(A^n))$ . **32.7**

**transient class** (of a stochastic matrix  $P$ ): an access equivalence class of  $P$  that is not ergodic. **9.4**

**transient matrix**: See *convergent*.

**transient state**: A state in a transient class. **9.4**

**transition matrix**: See *change-of-basis matrix*.

**transitive tournament matrix**  $A$ :  $a_{ij} = a_{jk} = 1$  implies  $a_{ik} = 1$ . **27.5**

**transpose** (of a linear transformation): A specific linear transformation from the dual of the codomain to the dual of the domain. **3.8**

**transpose** (of  $m \times n$  matrix  $A$ ): The  $n \times m$  matrix  $B = [b_{ij}]$  where  $b_{ij} = a_{ji}$ . **1.2**

**transposition**: A 2-cycle. **Preliminaries**

**tree** (digraph): A digraph whose associated graph is a tree. **29.1**

**tree** (graph): A connected graph with no cycles. **28.1**

**tree sign pattern (t.s.p.)**: A combinatorially symmetric sign pattern matrix whose graph (suppressing loops) is a tree. **33.5**

**triangular** (matrix): Upper or lower triangular. **10.2**

**triangular property** (of class of matrices  $X$ ): Whenever  $A$  is a block triangular matrix and every diagonal block is an  $X$ -matrix, then  $A$  is an  $X$  matrix. **35.1**

**triangular system**: A linear system  $T\mathbf{x} = \mathbf{b}$  where  $T$  is a triangular matrix. **38.2**

**triangular totally positive ( $\Delta$ TP)**: A triangular matrix all of whose nontrivial minors are positive. **21.2**

**tridiagonal matrix**: A square matrix  $A$  such that  $a_{ij} = 0$  if  $|i - j| > 1$ .

**trivial face** ( $F$  of cone  $K$ ):  $F = \{0\}$  or  $F = K$ . **26.1**

**trivial linear combination**: A linear combination in which all the scalar coefficients are 0 (or over the empty set). **2.1**

**truncation error:** The error made by replacing an infinite process by a finite process. **37.6**

**TSC:** See *total signed compound*.

**t.s.p.** See *tree sign pattern*.

**two-sided Lanczos algorithm:** See *Section 41.3*.

**type I (tree):** Has exactly one characteristic vertex. **36.3**

**type II (tree):** Has two characteristic vertices. **36.3**

## U

**UFD:** See *unique factorization domain*.

**u.i.:** See *unitarily invariant*.

**underflow:**  $\text{fl}(x) = 0$  for  $x \neq 0$ . **37.6**

**unicyclic:** A graph containing precisely one cycle. **36.2**

**unimodular (matrix over a domain):** See  *$\mathbb{D}$ -invertible*.

**union (of two graphs  $G = (V, E)$  and  $G' = (V', E')$ ):** The graph with vertex set  $V \cup V'$ , and edge (multi)set  $E \cup E'$ . **28.1**

**unique factorization domain (UFD):** Any nonzero, nonunit element  $a$  can be factored as a product of irreducible elements  $a = p_1 \cdots p_r$ , and this factorization is unique within order and unit factors. **23.1**

**unisigned (real or sign pattern vector):** Not balanced. **33.3**

**unit (in a domain):** An element  $a$  such that  $a$  divides 1. **23.1**

**unit lower triangular matrix:** A lower triangular matrix such that all diagonal entries are equal to one.

**unit round:**  $u = \inf\{\delta > 0 \mid \text{fl}(1 + \delta) > 1\}$ . **37.6**

**unit upper triangular matrix:** An upper triangular matrix such that all diagonal entries are equal to one. **1.2**

**unit vector:** A vector of length 1. **5.1**

**unital (linear map  $\phi : \mathbb{C}^{n \times n} \rightarrow \mathbb{C}^{m \times m}$ ):**  $\phi(I_n) = I_m$ . **18.7**

**unitarily equivalent:** See *unitarily similar*.

**unitarily invariant (vector norm  $\|\cdot\|$  on  $\mathbb{C}^{m \times n}$ ):**  $\|A\| = \|UAV\|$  for any unitary  $U \in \mathbb{C}^{m \times m}$  and  $V \in \mathbb{C}^{n \times n}$  and any  $A \in \mathbb{C}^{m \times n}$ . **17.3**

**unitarily similar (matrices  $A$  and  $B$ ):** There exists a unitary matrix  $U$  such that  $B = U^*AU$ . **7.1**

**unitarily similarity invariant (vector norm  $\|\cdot\|$  on  $\mathbb{C}^{n \times n}$ ):**  $\|U^*AU\| = \|A\|$  for all  $A \in \mathbb{C}^{n \times n}$  and unitary  $U, V \in \mathbb{C}^{n \times n}$ . **18.4**

**unitary matrix:** A matrix  $U$  such that  $U^*U = I$ . **5.2, 7.1**

**unknown vector:** The vector of variables of a system of linear equations. **1.4**

**unreduced upper Hessenberg matrix:** An upper Hessenberg matrix  $A$  such that  $a_{j+1,j} \neq 0$  for  $j = 1, \dots, n-1$ . **43.2**

**unstable (algorithm):** See *numerically unstable*.

**updating (QR factorization):** See *Section 39.7*.

**upper Hessenberg (matrix  $A$ ):**  $a_{ij} = 0$ , for all  $i \geq j+2$ ,  $1 \leq i, j \leq n$ . **10.2, 43.2**

**upper triangular (pencil  $A - xB$ ):** Both  $A$  and  $B$  are upper triangular. **43.1**

**upper triangular matrix:** A matrix such that every entry having row number greater than column number is zero. **1.2, 10.2**

## V

**$(v, k, \lambda)$ -design:** See *2-design*.

**valency:** See *degree*.

**Vandermonde matrix:** A matrix having each row equal to successive powers of a number. **48.1**

**variables (of a linear equation):** The unknowns. **1.4**

**vec-function (of matrix  $A$ ):** The vector formed by stacking the columns of  $A$  on top of each other in their natural order. **10.4**

**vector:** An element of a vector space. **1.1**

**vector norm:** A real-valued function  $\|\cdot\|$  on  $\mathbb{R}^n$  or  $\mathbb{C}^n$  such that for all vectors  $\mathbf{x}, \mathbf{y}$  and all scalars  $\alpha$ : (1)  $\|\mathbf{x}\| \geq 0$ , and  $\|\mathbf{x}\| = 0$  implies  $\mathbf{0}$ ; (2)  $\|\alpha\mathbf{x}\| = |\alpha|\|\mathbf{x}\|$ ; (3)  $\|\mathbf{x} + \mathbf{y}\| \leq \|\mathbf{x}\| + \|\mathbf{y}\|$ . **37.1**

**vector seminorm:** A real-valued function  $\|\cdot\|$  on  $\mathbb{R}^n$  or  $\mathbb{C}^n$  such that for all vectors  $\mathbf{x}, \mathbf{y}$  and all scalars  $\alpha$ : (1)  $\|\mathbf{x}\| \geq 0$ ; (2)  $\|\alpha\mathbf{x}\| = |\alpha|\|\mathbf{x}\|$ ; (3)  $\|\mathbf{x} + \mathbf{y}\| \leq \|\mathbf{x}\| + \|\mathbf{y}\|$ . **37.2**

**vector space (over field  $F$ ):** A nonempty set  $V$  with two operations, addition and scalar multiplication, such that  $V$  is an abelian group under addition, scalar multiplication distributes over addition, scalar multiplication is associative, and the multiplicative identity of  $F$  acts as the identity on  $V$ . **1.1**

**vertex:** An element of the vertex set of a graph or digraph **28.1, 29.1**

**vertex coloring:** A partition of the vertex set of a graph into cliques. **28.5**

**vertex-edge incidence matrix:** See *incidence matrix*. **30.1**

**vertex independence number:** The largest order of a coclique in  $G$ . **28.5**

**vertices:** Plural of *vertex*.

**Volterra–Lyapunov stable:** See *Lyapunov diagonally stable*.

## W

**walk (in a digraph):** A sequence of arcs  $(v_0, v_1), (v_1, v_2), \dots, (v_{k-1}, v_k)$  (the vertices need not be distinct). **29.1**

**walk (in a graph):** An alternating sequence  $(v_{i_0}, e_{i_1}, v_{i_1}, e_{i_2}, \dots, e_{i_\ell}, v_{i_\ell})$  of vertices and edges, not necessarily distinct, such that  $v_{i_{j-1}}$  and  $v_{i_j}$  are endpoints of  $e_{i_j}$  for  $j = 1, \dots, \ell$ . **28.1**

**walk product:**  $\prod_{j=1}^k a_{v_{j-1}, v_j}$  where  $A$  is a square matrix and  $(v_0, v_1), (v_1, v_2), \dots, (v_{k-1}, v_k)$  is a walk in the digraph of  $A$ . **29.3**

**walk-regular (graph):** For every vertex  $v$  the number of walks from  $v$  to  $v$  of length  $\ell$ , depends only on  $\ell$  (not on  $v$ ). **28.2**

**weak combinatorial invariant (of a matrix):** A quantity or property that does not change when the rows and columns are simultaneously permuted (by the same permutation). **27.1**

**weakly majorizes:** Real sequence  $\alpha$  weakly majorizes  $\beta$  if for all  $k$ , the sum of the first  $k$  entries of  $\alpha$  in decreasing order is  $\geq$  the sum of the first  $k$  entries of  $\beta$  in decreasing order. **Preliminaries**

**weakly numerically stable (algorithm):** The magnitude of the forward error is roughly the same as the magnitude of the error induced by perturbing the data by small multiple of the unit round. **37.8**

**weakly sign symmetric (square matrix  $A$ ):**  $\det A[\alpha, \beta] \det A[\beta, \alpha] \geq 0, \forall \alpha, \beta \subseteq \{1, \dots, n\}, |\alpha| = |\beta| = |\alpha \cap \beta| + 1$ . **19.2**

**weakly unitarily invariant:** See *unitarily similarity invariant*.

**weighted bigraph (of matrix  $A$ ):** The bigraph of  $A$  with the weight of  $\{i, j'\} = a_{ij}$ . **30.2**

**weighted bipartite graph:** A simple bipartite graph with a weight function on the edges. **30.1**

**weighted digraph:** A digraph with a weight function on the arcs. **29.1**

**weight function:** A function from the edges or arcs of a graph, bipartite graph, or digraph to  $\mathbb{R}^+$  **36.4, 30.1, 29.1**

**weighted graph:** A simple graph with a weight function. **36.4**

**weighted least squares problem:** See *Section 39.1*.

**Wiener vertex:** See *Parter–Wiener vertex*.

**well-conditioned (input  $\mathbf{z}$  for  $P$ ):** Small relative perturbations of  $\mathbf{z}$  cause small relative perturbations of  $P(\mathbf{z})$ . **37.4**

**Wilkinson's shift:** The shift  $\mu$  is the eigenvalue of the bottom right  $2 \times 2$  submatrix of  $T$  which is closer to  $t_{n,n}$ . **42.3**

## Z

**Z-matrix (square real matrix):** All off-diagonal elements are nonpositive. **9.5, 19.2**

**zero completion (of a partial matrix):** Obtained by setting all unspecified (off-diagonal) entries to 0 (partial matrix must have all diagonal entries specified). **35.6**

**zero divisor** (in a ring  $R$ ): A nonzero element  $a \in R$  such that there exists a nonzero  $b \in R$  with  $ab = 0$  or  $ba = 0$ . **Preliminaries**

**zero-free diagonal** (property of matrix  $A$ ): All the diagonal elements of  $A$  are nonzero. **40.3**

**zero line** (in a matrix): A line of all zeros. **27.1**

**zero matrix**: A matrix with all entries equal to zero. **1.2**

**(zero) pattern** (of a matrix): See *pattern*.

**zero pattern** (of sign pattern  $A$ ): The  $(0, +)$ -pattern obtained by replacing each  $-$  entry in  $A$  by a  $+$ . **33.2**

**zero transformation**: A linear transformation that maps every vector to zero. **3.1**

# Notation Index

---

This notation index covers most of the terms defined in Chapters 1 to 49. It does not cover some terminology used in a single section (including most of the terminology that is specific to a particular application (Chapters 50 to 70)), nor does it cover most of the terminology used in computer software (Chapters 71 to 77).

Notation is in “alphabetical” order. If you are looking for something done to a matrix, like the transpose, look under  $A$ . If you are looking for something done to a field, look under  $F$ . If you are looking for something done to a linear transformation, look under  $T$ . If you are looking for something done to a vector or vector space, look under  $V$ .

The meaning of a symbol depends on what it is applied to; e.g.,  $\rho(A)$ , where  $A$  is a matrix, is the spectral radius of  $A$ , whereas  $\rho(G)$ , where  $G$  is a group, is a representation of the group.

Warning: Tilde and hat, as in  $\tilde{A}$ ,  $\hat{Q}$ , frequently have the meanings *perturbation* and *reduced*, respectively, but are also redefined in some chapters to mean other things.

For most symbols, the section where the symbol is introduced is listed at the end of the definition.

$\mathbf{0}_{mn}$	the zero matrix (in $F^{m \times n}$ ), can be shortened to $\mathbf{0}$ . <b>1.2</b>
$\mathbf{1}_n$	all 1s vector in $F^n$ can be shortened to $\mathbf{1}$ .
$A = [a_{ij}]$	matrix $A$ and its elements. <b>1.2</b>
$A^T$	transpose of matrix $A$ . <b>1.2</b>
$\overline{A}$	complex conjugate of matrix $A$ . <b>1.2</b>
$A^*$	Hermitian adjoint (conjugate-transpose) of matrix $A$ . <b>1.2</b>
$A^{-1}$	inverse of square matrix $A$ . <b>1.5</b>
$A^\dagger$	Moore–Penrose pseudo-inverse of matrix $A$ . <b>5.7</b>
$A^\#$	group inverse of square matrix $A$ . <b>9.1</b>
$A[\alpha, \beta]$	submatrix of $A$ with row indices in $\alpha$ and column indices in $\beta$ . <b>1.2, 10.1</b>
$A[\alpha]$	$= A[\alpha, \alpha]$ , principal submatrix, also denoted $A[1, 2, 3]$ for $A[\{1, 2, 3\}]$ . <b>1.2, 10.1</b>
$A(\alpha, \beta)$	submatrix of $A$ with row indices not in $\alpha$ and column indices not in $\beta$ . <b>1.2, 10.1</b>
$A(\alpha)$	$= A(\alpha, \alpha)$ , principal submatrix with row and column indices not in $\alpha$ . <b>1.2, 10.1</b>
$A_{i:k,j:l}$	submatrix $A[\{i, i + 1, \dots, k\}, \{j, j + 1, \dots, l\}]$ , analogously $A_{i,j:l}$ , $A_{i:k,j}$ .
$(A)_{ij}$	$i, j$ -entry of $A$ . <b>1.2</b>
$A_{ij}$	$i, j$ -block in a block matrix of $A$ . <b>10.1</b>
$A/A[\alpha]$	Schur complement of $A[\alpha]$ . <b>4.2, 10.3</b>
$ A $	matrix having as entries the absolute values of the entries of matrix $A$ . <b>9.1</b>
$ A _{pd}$	spectral absolute value $(A^*A)^{1/2}$ . <b>17.1</b>
$ A $	zero pattern of sign pattern $A$ . <b>33.2</b>
$\sqrt{A}$	a square root of a square complex matrix $A$ . <b>11.2</b>
$A^{1/2}$	the principal square root of a square complex matrix $A$ . <b>11.2</b>
$\tilde{A}^{1/2}$	the positive semidefinite square root of a positive semidefinite matrix $A$ . <b>8.3</b>
$\tilde{A}$	a perturbation $A + \Delta A$ of matrix $A$ . <b>15.1</b> (also other meanings)
$\ A\ _k$	operator norm of matrix $A$ (induced by $\ \mathbf{v}\ _k$ ). <b>37.3</b>
$\ A\ _F$	Frobenius (Euclidean) norm of matrix $A$ . <b>7.1, 37.3</b>
$\ A\ _{K,k}$	Ky Fan $k$ norm. <b>17.3</b>
$\ A\ _{S,p}$	Schatten- $p$ norm. <b>17.3</b>
$\ A\ _{tr}$	trace norm ( <i>not</i> same as Frobenius norm). <b>17.3</b>

$\ A\ _{UI}$	unitarily invariant matrix norm. <b>17.3</b>
$A > 0$	matrix $A$ is positive. <b>9.1</b>
$A \geq 0$	matrix $A$ is nonnegative. <b>9.1</b>
$A \succeq 0$	matrix $A$ is semipositive. <b>9.1</b>
$A > B$	$A - B$ is positive.
$A \geq B$	$A - B$ is nonnegative.
$A \succeq B$	$A - B$ is semipositive.
$A \succeq^K 0$	$A$ is $K$ -nonnegative. <b>26.1</b>
$A >^K 0$	$A$ is $K$ -positive. <b>26.1</b>
$A \succeq^K 0$	$A$ is $K$ -semipositive. <b>26.1</b>
$A \succeq^K B$	$A - B$ is $K$ -nonnegative. <b>26.1</b>
$A >^K B$	$A - B$ is $K$ -positive. <b>26.1</b>
$A \succeq^K B$	$A - B$ is $K$ -semipositive. <b>26.1</b>
$A \succ 0$	matrix $A$ is positive definite. <b>8.4</b>
$A \succeq 0$	matrix $A$ is positive semidefinite. <b>8.4</b>
$A \succ B$	$A - B$ is positive definite. <b>8.4</b>
$A \succeq B$	$A - B$ is positive semidefinite. <b>8.4</b>
$\hat{A} \preceq A$	sign pattern $\hat{A}$ is a subpattern of sign pattern $A$ . <b>33.1</b>
$A \overset{c}{\sim} B$	$A$ and $B$ are $*$ -congruent. <b>8.3</b>
$A \sim_c B$	$A$ and $B$ are column equivalent (in a domain). <b>23.2</b>
$A \sim_r B$	$A$ and $B$ are row equivalent (in a domain). <b>33.2</b>
$A \sim B$	$A$ and $B$ are equivalent (in a domain). <b>23.2</b>
$[A b]$	augmented matrix. <b>1.4</b>
$A + B$	sum of matrices $A$ and $B$ . <b>1.2</b>
$AB$	matrix product of matrices $A$ and $B$ . <b>1.2</b>
$A \oplus B$	direct sum (block diagonal matrix) of matrices $A$ and $B$ . <b>2.4, 10.2</b>
$A \circ B$	Hadamard product of $A$ and $B$ . <b>8.5</b>
$A \otimes B$	Kronecker product of $A$ and $B$ . <b>10.4</b>
$\mathcal{A}_G$	adjacency matrix of graph $G$ , can be shortened to $\mathcal{A}$ . <b>28.3</b>
$\mathcal{A}_\Gamma$	adjacency matrix of digraph $\Gamma$ , can be shortened to $\mathcal{A}$ . <b>29.2</b>
$\mathcal{A}(R, S)$	the class of all $(0, 1)$ -matrices with row sum vector $R$ and column sum vector $S$ . <b>27.4</b>
$A^m(V; U)$	subset of $L^m(V; U)$ consisting of the antisymmetric maps. <b>13.5</b>
$a b$	$a$ divides $b$ (in a domain). <b>23.1</b>
$a \equiv b$	$a, b$ are associates (in a domain). <b>23.1</b>
$\{a\}$	the set of associates (equivalence class) of $a$ (in a domain). <b>23.1</b>
$(a_1, \dots, a_n)$	any g.c.d. of $a_1, \dots, a_n$ (in a domain). <b>23.1</b>
$\{(a_1, \dots, a_n)\}$	the equivalence class of all g.c.d.s of $a_1, \dots, a_n$ (in a domain). <b>23.1</b>
$\alpha^c$	set complement of $\alpha$ in $1, \dots, n$ . <b>Preliminaries</b>
$\alpha \downarrow$	permutation of real number sequence $\alpha$ , with entries in nonincreasing order. <b>Preliminaries</b>
$\alpha \uparrow$	permutation of real number sequence $\alpha$ , with entries in nondecreasing order. <b>Preliminaries</b>
$\alpha \succeq \beta$	real number sequence $\alpha$ majorizes $\beta$ . <b>Preliminaries</b>
$\alpha \succeq_w \beta$	natural number sequence $\alpha$ weakly majorizes $\beta$ . <b>Preliminaries</b>
$\alpha_\varepsilon(A)$	$\varepsilon$ -pseudospectral abscissa of complex matrix $A$ . <b>16.3</b>
$\alpha(G)$	algebraic connectivity of graph $G$ . <b>36.1</b>
$\hat{\alpha}(G)$	absolute algebraic connectivity of $G$ . <b>36.1</b>
$\alpha(\lambda)$ or $\alpha_A(\lambda)$	algebraic multiplicity of eigenvalue $\lambda$ (of $A$ ). <b>4.3</b>
$\alpha(m, n)$	$\max\{\det W^T W   W \in \{\pm 1\}^{m \times n}\}$ . <b>32.1</b>
$\alpha(n)$	$= \alpha(n, n)$ . <b>32.1</b>

 $D(B)$   
 $\Delta(G)$
- partial order on partitions of  $n$ . **31.10**  
 adjugate (classical adjoint) of matrix  $A$ , also denoted  $\text{adj}(A)$ . **4.2**  
 $= \frac{1}{m!} \sum_{\pi \in S_m} \text{sgn}(\pi) \mathbf{v}_{\pi(1)} \otimes \cdots \otimes \mathbf{v}_{\pi(k)}$ . **13.6**  
 zero completion of partial matrix  $B$ . **35.6**  
 basis  $\{\mathbf{v}_1, \dots, \mathbf{v}_n\}$  or ordered basis  $(\mathbf{v}_1, \dots, \mathbf{v}_n)$  for a vector space. **2.2**  
 dual basis (for dual space  $V^*$ ) determined by basis  $\mathcal{B}$  of  $V$ . **3.8**  
 biadjacency matrix of a bipartite graph  $G$ , cannot be shortened. **30.1**  
 number of Jordan blocks with eigenvalue  $\lambda$ . **6.2**  
 vector space of bilinear forms on vector space  $V$  over field  $F$ . **12.1**  
 vector space of  $\varphi$ -sesquilinear forms ( $\varphi$  is an automorphism of  $F$ ). **12.4**  
 biclique of between  $X, Y \subset V$  in graph  $G = (V, E)$ . **30.3**  
 $\max\{\det W^T W \mid W \in \{0, 1\}^{m \times n}\}$ . **32.1**  
 $= \beta(n, n)$ . **32.1**  
 biclique cover number of graph  $G$ . **30.3**  
 biclique partition number of graph  $G$ . **30.3**  
 complex numbers. **Preliminaries**  
 the open right half plane. **Preliminaries**  
 the closed right half plane. **Preliminaries**  
 the open left half plane. **Preliminaries**  
 the closed left half plane. **Preliminaries**  
 complex conjugate of the complex number  $c$ . **Preliminaries**  
 the absolute value of real or complex number  $c$ . **Preliminaries**  
 $i, j$ th cofactor of a matrix. **4.1**  
 cycle on  $n$  vertices. **28.1**  
 $n$ -cycle matrix. **48.1**  
 graph formed by appending  $C_g$  to a pendent vertex of  $P_{n-g}$ . **36.2**  
 the number of lines in a minimum line cover of  $A$ . **27.1**  
 the number of 1s in a minimum co-cover of  $A$ . **27.1**  
 Euclidean length of a column of  $A$  (the  $i$ th length in nonincreasing order). **17.1**  
 $k$ th compound matrix of  $A$ . **4.2**  
 Cauchy matrix. **48.1**  
 companion matrix of polynomial  $p(x)$ . **4.3**  
 convex hull of set  $S$  of vectors. **Preliminaries**  
 individual condition number of eigenvalue  $\lambda$ . **15.1**  
 cosine of matrix  $A$ . **11.5**  
 chromatic number of graph  $G$ . **28.5**  
 measure of relative separation of real numbers  $a, b$ . **17.4**  
 an integral domain. **23.1**  
 a Bezout domain. **23.1**  
 a greatest common divisor domain. **23.1**  
 a Euclidean domain. **23.1**  
 an elementary divisor domain. **23.1**  
 a principal ideal domain. **23.1**  
 a unique factorization domain. **23.1**  
 $m \times n$  matrices over domain  $\mathbb{D}$ . **23.2**  
 graph formed by  $n - g$  isolated vertices to a single vertex of  $C_g$ . **36.2**  
 ring of polynomials  $p(\mathbf{x}) = p(x_1, \dots, x_n)$  with coefficients in  $\mathbb{D}$ . **23.1**  
 signed digraph of sign pattern  $A$ . **33.1**  
 digraph of partial matrix  $B$ . **35.1**  
 $\max\{p - q : q \text{ vertices may be deleted from graph } G \text{ leaving } p \text{ paths}\}$ . **34.2**

$\frac{\partial f}{\partial x}$	the partial derivative of $F$ with respect to $x$ .
$\partial(S)$	the boundary of a set $S$ of real or complex numbers. <b>Preliminaries</b>
$\partial(V')$	number of edges of a graph having one endpoint inside vertex subset $V'$ and other outside. <b>28.5</b>
$\delta_{ij}$	Kronecker delta, i.e., 1 if $i = j$ and 0 otherwise.
$\delta(A)$	the zero part of the inertia of complex square matrix $A$ . <b>8.3, 19.1</b>
$\delta_G(v)$	degree of vertex $v$ in graph $G$ , also denoted $\delta(v)$ . <b>28.1</b>
$\Delta_n^k$	the set of $n \times n$ matrices of nonnegative integers with each row and column sum = $k$ . <b>31.4</b>
$d(\mathbf{v}, \mathbf{u})$	distance from vector $\mathbf{v}$ to vector $\mathbf{u}$ in a normed vector space. <b>5.1</b>
$d_G(v, u)$	distance from vertex $v$ to vertex $u$ in graph $G$ , also denoted $d(v, u)$ . <b>28.1</b>
$d(T)$	diameter of tree $T$ , same as $\text{diam}(T)$ . <b>34.3</b>
$\deg(p)$	degree of polynomial $p(x)$ . <b>23.1</b>
$\det A$	determinant of matrix $A$ , also denoted $\det(A)$ . <b>4.1</b>
$\text{diag}(d_1, \dots, d_n)$	$n \times n$ diagonal matrix with listed diagonal entries. <b>1.2</b>
$\text{diam}(G)$	diameter of graph. <b>28.1</b>
$\dim \mathcal{P}$	dimension of convex polytope $\mathcal{P}$ , also denoted $\dim(\mathcal{P})$ . <b>27.6</b>
$\dim V$	dimension of vector space $V$ , also denoted $\dim(V)$ . <b>2.2</b>
$\epsilon$	machine precision (i.e., machine epsilon). <b>37.6</b>
$\mathbf{e}_i$	$i$ th standard basis vector (1 in $i$ th coordinate, 0s elsewhere). <b>2.1</b>
$E_{ij}$	standard basis matrix (1 in $i, j$ th coordinate, 0s elsewhere). <b>2.1</b>
$\mathcal{E}_n$ or $\mathcal{E}$	standard basis $\mathbf{e}_1, \dots, \mathbf{e}_n$ for $F^n$ . <b>2.1</b>
$\epsilon_n$	the identity in the symmetric group $S_n$ . <b>Preliminaries</b>
$E_\lambda$ or $E_\lambda(A)$	the eigenspace for eigenvalue $\lambda$ (of $A$ ). <b>4.3</b>
$E(A, \alpha + \beta i)$	the real generalized eigenspace of real matrix $A$ for eigenvalue $\alpha + \beta i$ . <b>6.3</b>
$E_k(\mu)$	a particular lower elementary bidiagonal matrix. <b>21.2</b>
$e^A$	exponential function of matrix $A$ . <b>11.3</b>
$\eta(G)$	a graph parameter involving minimum rank. <b>28.5</b>
$\eta_p(A, \mathbf{b}; \bar{\mathbf{x}})$	relative backward error. <b>38.1</b>
End $V$	algebra of linear operators on vector space $V$ . <b>69.1</b>
$\exp(A)$	exponential function of matrix $A$ , same as $e^A$ . <b>11.3</b>
$f g$	polynomial $f(x)$ divides $g(x)$ in $F[x]$ . <b>20.2</b>
$\mathbb{F}_q$	finite field with $q$ elements. <b>61</b>
$F^{m \times n}$	$m \times n$ matrices over the field $F$ . <b>1.2</b>
$F^n$	$F$ -vector space of column $n$ -tuples of elements of $F$ . <b>1.1</b>
$F[x]$	polynomials over $F$ . <b>1.1</b>
$F[\mathbf{x}] = F[x_1, \dots, x_n]$	ring of polynomials $p(\mathbf{x}) = p(x_1, \dots, x_n)$ with coefficients in $F$ . <b>23.1</b>
$F(\mathbf{x})$	field of rational functions in $x_1, \dots, x_n$ over $F$ . <b>23.1</b>
$F[x; n]$	polynomials of degree $\leq n$ over $F$ .
$\mathcal{F}(A)$	all doubly stochastic matrices that have 0's at least wherever the $(0,1)$ -matrix $A$ has 0s. <b>27.6</b>
$F \vee G$	the join $\Phi(F \cup G)$ (where $(F, G)$ are cone faces). <b>26.1</b>
$F \wedge G$	the meet $F \cap G$ (where $(F, G)$ are cone faces). <b>26.1</b>
$\Phi(G)$	conductance (isoperimetric number) of a graph. <b>28.5</b>
$\Phi(S)$	face generated by $S$ . <b>26.1</b>
$\Phi(\mathbf{x})$	face generated by $\{\mathbf{x}\}$ . <b>26.1</b>
fix $T$	fixed space of linear transformation $T$ . <b>3.6</b>
$G$	group. <b>Preliminaries</b>
$G$ or $G = (V_G, E_G)$	graph = (vertices, edges), also denoted $G = (V, E)$ . <b>28.1</b>
$\Gamma$ or $\Gamma = (V_\Gamma, E_\Gamma)$	digraph = (vertices, arcs), also denoted $\Gamma = (V, E)$ . <b>29.1</b>
$\overline{G}$	graph complement. <b>28.1</b>

- $G - X$  subgraph induced by  $V \setminus X$ . **28.1**  
 $G \cup H$  union of graphs  $G, H$ . **28.1**  
 $G \cap H$  intersection of graphs  $G, H$ . **28.1**  
 $G + H$  join of graphs  $G, H$ . **28.1**  
 $G \cdot H$  (strong) product of graphs  $G, H$ . **28.1**  
 $G^\ell$  the strong product of  $\ell$  copies of graph  $G$ . **28.1**  
 $G - v$  the result of deleting vertex  $v$  from graph  $G$ . **28.1**  
 $G_w$  a weighted graph. **36.4**  
 $G(A)$  (simple) graph of square matrix  $A$ . **19.3, 34.1**  
 $\mathcal{G}(B)$  graph of partial matrix  $B$ . **35.1**  
 $\mathcal{G}(S)$  bipartite graph of sparsity pattern of  $S$ . **46.3**  
 $G^F$  the fill graph, digraph, or bigraph of real square matrix  $A$ . **40.5**  
 $G^+(A)$  bipartite fill-graph of square matrix  $A$ . **30.2**  
 $G(\mathcal{P})$  simple graph of convex polytope  $\mathcal{P}$ . **27.6**  
 $\Gamma(A)$  digraph of square matrix  $A$  (may have loops). **9.1, 29.2**  
 $\mathcal{G}(v, \delta)$  the set of all  $\delta$ -regular graphs on  $v$  vertices. **32.7**  
 $G(i, j, \theta, \vartheta)$  Givens transformation. **38.4**  
 $\gcd(a_1, \dots, a_k)$  greatest common divisor of  $(a_1, \dots, a_k)$ .  
 $\text{GL}(n, F)$  general linear group of order  $n$  over  $F$ . **67.1**  
 $\text{GL}(n, \mathbb{D})$  the group of  $\mathbb{D}$ -invertible matrices in  $\mathbb{D}^{n \times n}$ . **23.2**  
 $\gamma(\lambda)$  or  $\gamma_A(\lambda)$  geometric multiplicity of eigenvalue  $\lambda$  (of  $A$ ). **4.3**  
 $H_n$  Hadamard matrix of size  $n$ . **32.2**  
 $\mathcal{H}_n$  the set of Hermitian matrices of size  $n$ . **8.1**  
 $\mathcal{H}(G)$  the set of Hermitian matrices  $A$  such that  $G(A) = G$ . **34.1**  
 $H(\Omega)$  the ring of analytic functions over a nonempty path-connected set  $\Omega \subset \mathbb{C}^n$ . **23.1**  
 $H_\zeta$  =  $H(\{\zeta\})$ . **23.1**  
 $I_n$  or  $I$  identity matrix or transformation (in  $F^{n \times n}$  or  $L(V, V)$ ). **1.2, 3.1**  
 $B'[I]_B$  change-of-basis (transition) matrix from basis  $B$  to basis  $B'$ . **2.6**  
 $i \mapsto j$  vertex  $i$  has access to vertex  $j$  (in a digraph). **9.1**  
 $\iota(G)$  the vertex independence number of graph  $G$ . **28.5**  
 $\text{im}(c)$  the imaginary part of complex number  $c$ . **Preliminaries**  
 $\text{im}(f)$  image of the function  $f$  (=  $\text{range}(f)$  if  $f$  is a linear transformation)  
 $\text{in}(A) = (\pi, \nu, \delta)$  inertia of complex square matrix  $A$ . **8.3, 19.1**  
 $\text{int}K$  interior of  $K$ . **26.1**  
 $iP(A)$  the invariant polynomials (i.e., invariant factors) of matrix  $A$ . **20.2**  
 $J_A$  Jordan canonical form of matrix  $A$ . **6.2**  
 $J_A^{\mathbb{R}}$  real-Jordan canonical form of real matrix  $A$ . **6.3**  
 $J_{mn}$  all 1s matrix in  $F^{m \times n}$ , can be shortened to  $J_n$  or  $J$  when  $m = n$ .  
 $J_k(\lambda)$  Jordan block of size  $k$  for  $\lambda$ . **6.2**  
 $J_{2k}^{\mathbb{R}}(\lambda)$  real-Jordan block of size  $2k$  for  $\lambda$ . **6.3**  
 $\text{JCF}(A)$  Jordan canonical form of matrix  $A$ . **6.2**  
 $\text{JCF}^{\mathbb{R}}(A)$  real-Jordan canonical form of matrix  $A$ . **6.3**  
 $K^*$  dual space (dual cone) of cone  $K$ . **8.5, 26.1**  
 $K_n$  complete graph on  $n$  vertices. **28.1**  
 $K_{n,m}$  complete bipartite graph on  $n$  and  $m$  vertices. **28.1**  
 $\mathcal{K}_k(A, \mathbf{v})$  Krylov subspace of dimension  $k$  for matrix  $A$  and vector  $\mathbf{v}$ . **44.1**  
 $\kappa(A), \kappa_p(A)$  condition number of matrix  $A$  for linear system  $A\mathbf{x} = \mathbf{b}$  (in  $p$  norm). **37.5**  
 $\kappa_v(G)$  vertex connectivity of graph  $G$ . **36.1**  
 $\kappa_e(G)$  edge connectivity of graph  $G$ . **36.1**  
 $\ker A$  kernel of matrix  $A$ , also denoted  $\ker(A)$ . **2.4**

$\ker T$	kernel of linear transformation $T$ , also denoted $\ker(T)$ . <b>3.5</b>
$\lambda$	eigenvalue of a matrix or transformation (can also use other Greek). <b>4.3</b>
$\Lambda$	diagonal matrix of eigenvalues. <b>15.1</b>
$\Lambda_n^k$	the set of $n \times n$ binary matrices in which each row and column sum is $k$ . <b>31.3</b>
$L_G$	the Laplacian matrix of graph $G$ . <b>28.4</b>
$L(G_w)$	Laplacian matrix of weighted graph $G_w$ . <b>36.4</b>
$ L_G $	the signless Laplacian matrix of graph $G$ . <b>28.4</b>
$L(G)$	the line graph of graph $G$ . <b>28.2</b>
$L(G; a_1, \dots, a_n)$	a generalized line graph. <b>28.2</b>
$\ell_k(x)$	Laguerre polynomial. <b>31.8</b>
$L(V, W)$	the set of all linear transformations of $V$ into $W$ . <b>3.1</b>
$L(V_1, \dots, V_m; U)$	the set of all multilinear maps from $V_1 \times \dots \times V_m$ into $U$ with operations. <b>13.1</b>
$L^m(V; U)$	$L(V_1, \dots, V_m; U)$ with $V_i = V$ for $i = 1, \dots, m$ . <b>13.5</b>
$\text{lcm}(a_1, \dots, a_n)$	least common multiple of $a_1, \dots, a_n$ .
$\lim_{m \rightarrow \infty} a_m = a$ ( $C, 0$ )	$\lim_{m \rightarrow \infty} a_m = a$ . <b>9.1</b>
$\lim_{m \rightarrow \infty} a_m = a$ ( $C, k$ )	( $C, k$ ) limit. <b>9.1</b>
$\log(A)$	principal logarithm of matrix $A$ . <b>11.4</b>
$M(A)$	the comparison matrix of $A$ . <b>19.5</b>
$m(G)$	the maximum rank deficiency of graph $G$ . <b>34.2</b>
$\mu_i$	$i$ th eigenvalue of the Laplacian matrix of a graph (nondecreasing order). <b>28.4</b>
$\mu(G)$	Colin de Verdière parameter of graph $G$ . <b>28.5</b>
$M(G)$	maximum (eigenvalue) multiplicity of graph $G$ . <b>34.2</b>
$\mathcal{M}(G)$	set of matrices $A$ such that bigraph of $A$ is a subgraph of $G$ . <b>30.3</b>
$\mathcal{M}(\Omega)$	the quotient field of $H(\Omega)$ . <b>23.1</b>
$\mathcal{M}_\zeta$	$= \mathcal{M}(\{\zeta\})$ . <b>23.1</b>
$\text{MR}(A)$	maximal rank of sign pattern $A$ . <b>33.6</b>
$\text{mr}(A)$	minimal rank of sign pattern $A$ . <b>33.6</b>
$\text{mr}(G)$	minimum rank of graph $G$ . <b>34.2</b>
$\mathbb{N}$	natural numbers, i.e., $\{0, 1, 2, \dots\}$ .
$\langle n \rangle$	the set of integers $\{1, 2, \dots, n\}$ . <b>9.1</b>
$N_\lambda^k(A)$	the $k$ th generalized eigenspace of square matrix $A$ . <b>6.1</b>
$N_\lambda^v(A)$	the generalized eigenspace of matrix $A$ , can be abbreviated $N_\lambda(A)$ . <b>6.1</b>
$\mathcal{N}(T)$	the minimum number of distinct eigenvalues of a matrix in $\mathcal{S}(T)$ where $T$ is a tree. <b>34.3</b>
$\nu(A)$	the negative part of the inertia of complex square matrix $A$ . <b>8.3, 19.1</b>
$\nu_A(\lambda)$	the index of matrix $A$ at eigenvalue $\lambda$ . <b>6.1</b>
$\nu_P$	the index of $P$ , i.e. $\nu_P(\rho)$ . <b>9.3</b>
$\bar{\nu}_P$	the co-index of $P$ . <b>9.3</b>
$N_G$	the (vertex-edge) incidence matrix of graph $G$ . <b>28.4</b>
$\text{nnz}(A)$	the number of nonzero entries in sparse matrix $A$ . <b>40.2</b>
null $A$	nullity of a matrix, also $\text{null}(A)$ . <b>2.4</b>
null $T$	nullity of a linear transformation or of a matrix, also $\text{null}(T)$ . <b>3.5</b>
$O(f)$	big-oh of function $f$ . <b>Preliminaries</b>
$o(f)$	little-oh of function $f$ . <b>Preliminaries</b>
$\Omega_n$	set of $n \times n$ doubly stochastic matrices. <b>9.4</b>
$\omega(G)$	clique number of graph $G$ . <b>28.4</b>
$P_n$	path on $n$ vertices. <b>28.1</b>
$P[\lambda]$	principal submatrix at a distinguished eigenvalue. <b>9.3</b>
$P(G)$	path cover number of graph $G$ . <b>34.2</b>
$P(n, d)$	tree constructed in a specific way. <b>36.3</b>
$\pi(A)$	the positive part of the inertia of complex square matrix $A$ . <b>8.3, 19.1</b>

$\Pi_n$	regular $n$ -sided unit polygon. <b>20.3</b>
$p_A(x)$	characteristic polynomial of matrix $A$ , or linear transformation. <b>4.3</b>
$p_G(x)$	characteristic polynomial of graph $G$ . <b>28.3</b>
$\text{PD}_n$	the set of $n \times n$ positive definite matrices, can be shortened to PD. <b>8.4</b>
per $A$	permanent of matrix $A$ , also denoted $\text{per}(A)$ . <b>31.1</b>
$\text{per}_k A$	the sum of the subpermanents of order $k$ , also denoted $\text{per}_k(A)$ . <b>31.1</b>
$\text{proj}_W(\mathbf{v})$	the orthogonal projection of $\mathbf{v}$ onto $W$ (along $W^\perp$ ). <b>5.4</b>
$\text{proj}_{W,Z}(\mathbf{v})$	the projection of $\mathbf{v}$ onto $W$ along $Z$ . <b>3.6</b>
$\text{PSD}_n$	the set of $n \times n$ positive semidefinite matrices, can be shortened to PSD. <b>8.4</b>
$\mathbb{Q}$	rational numbers.
$Q(A)$	qualitative class of sign pattern $A$ (or of $\text{sgn}(A)$ if $A$ is a real matrix). <b>33.1</b>
$q_A(x)$	minimum polynomial of matrix $A$ , or linear transformation. <b>4.3</b>
$Q_{r,n}$	the set of all strictly increasing sequences of $r$ integers chosen from the set $\{1, 2, \dots, n\}$ . <b>23.2</b>
QR	QR-factorization of a real or complex matrix. <b>5.5</b>
$\hat{Q}\hat{R}$	reduced QR-factorization of a real or complex matrix. <b>5.5</b>
$\rho(A)$	spectral radius of real or complex square matrix $A$ . <b>4.3</b>
$\rho_\varepsilon(A)$	$\varepsilon$ -pseudospectral radius of complex matrix $A$ . <b>16.3</b>
$q(A)$	term rank of matrix $A$ . <b>27.1</b>
$q^*(A)$	largest size of a zero submatrix of $A$ . <b>27.1</b>
$\rho(G)$	representation of group $G$ . <b>68.1</b>
$\rho_1(A, x), \rho_2(A, x)$	rook polynomials. <b>31.8</b>
$\mathbb{R}$	real numbers.
$\mathbb{R}^+$	positive reals (subset of $\mathbb{R}$ or $\mathbb{C}$ ).
$\mathbb{R}_0^+$	nonnegative reals (subset of $\mathbb{R}$ or $\mathbb{C}$ ).
$\mathbb{R}^-$	negative reals (subset of $\mathbb{R}$ or $\mathbb{C}$ ).
$\mathbb{R}_0^-$	nonpositive reals (subset of $\mathbb{R}$ or $\mathbb{C}$ ).
$\mathbb{R}_{\max}$	max-plus semiring. <b>25.1</b>
$\overline{\mathbb{R}}_{\max}$	completed max-plus semiring. <b>25.1</b>
$R(\Gamma)$	reduced digraph of $\Gamma$ . <b>9.1, 29.5</b>
$R^*(P)$	basic reduced digraph of matrix $P$ . <b>9.3</b>
$\mathbb{R}[x; n]$	polynomials of degree $\leq n$ over $\mathbb{R}$ .
$r_i(A)$	Euclidean length of a row of $A$ (the $i$ th length in nonincreasing order). <b>17.1</b>
$\text{RCF}_{ED}(A)$	elementary divisors rational canonical form of $A$ . <b>6.4</b>
$\text{RCF}_{IF}(A)$	invariant factors rational canonical form of $A$ . <b>6.6</b>
$\text{re}(c)$	the real part of complex number. $c$
range $A$	range of matrix $A$ , = column space of $A$ , also denoted $\text{range}(A)$ . <b>2.4</b>
range $T$	range of linear transformation $T$ , also denoted $\text{range}(T)$ . <b>3.5</b>
rank $A$	rank of matrix $A$ , also denoted $\text{rank}(A)$ . <b>1.3, 2.4</b>
$\text{rank}(f)$	rank of bilinear form $f$ . <b>12.1</b>
rank $T$	rank of linear transformation $T$ , also denoted $\text{rank}(T)$ . <b>3.5</b>
$\text{REF}(A)$	a row echelon form of matrix $A$ . <b>1.3</b>
$\text{RREF}(A)$	the reduced row echelon form of matrix $A$ . <b>1.3</b>
$\text{reldist}(H, \tilde{H})$	component-wise relative distance between $H, \tilde{H}$ . <b>46.4</b>
$RS(A)$	row space of matrix $A$ . <b>2.4</b>
$S^a$	annihilator (in the dual space $V^*$ ) of subspace $S$ of vector space $V$ . <b>3.8</b>
$S \setminus X$	set complement of $X$ in $S$ . <b>Preliminaries</b>
$S_n$	the symmetric group on $\{1, \dots, n\}$ . <b>Preliminaries</b>
$\mathcal{S}_n$	the set of real symmetric matrices of size $n$ . <b>8.1</b>
$\sigma_i$	$i$ th singular value (in nonincreasing order). <b>5.6</b>
$\sigma(A)$	spectrum of square matrix $A$ . <b>4.3</b>

$\sigma(G)$	spectrum of graph $G$ . <b>28.3</b>
$\sigma_\varepsilon(A)$	$\varepsilon$ -pseudospectrum of complex square matrix $A$ . <b>16.1</b>
$\sigma_\varepsilon^{\mathbb{R}}(A)$	real structured $\varepsilon$ -pseudospectrum of real square matrix $A$ . <b>16.5</b>
$\sigma_\varepsilon(A, B)$	$\varepsilon$ -pseudospectrum of the matrix pencil $A - xB$ . <b>16.5</b>
$\sigma_\varepsilon(A, B, C)$	spectral value set of the matrix triplet $A, B, C$ . <b>16.5</b>
$\sigma_\varepsilon(P)$	$\varepsilon$ -pseudospectrum of matrix polynomial $P$ . <b>16.5</b>
$ S $	cardinality of set $S$ .
$S_k(A)$	sum of all principal minors of size $k$ of matrix $A$ . <b>4.2</b>
$\mathcal{S}(G)$	the set of real symmetric matrices $A$ such that $G(A) = G$ . <b>34.1</b>
$S^m(V; U)$	subset of $L^m(V; U)$ consisting of the symmetric maps. <b>13.5</b>
$S_k(\alpha_1, \dots, \alpha_n)$	$k$ th elementary symmetric function of $\alpha_i, i = 1, \dots, n$ . <b>Preliminaries</b>
$S(u)$	$\sum_{k \in V} (d(u, k))^2$ where $G = (V, E)$ is a simple graph. <b>36.5</b>
$\text{sep}(A_1, A_2)$	separation between matrices $A_1, A_2$ . <b>15.1</b>
$\text{sgn}(\pi)$	sign of the permutation $\pi$ . <b>Preliminaries</b>
$\text{sgn}(a)$	sign of the real number $a$ as used in sign patterns, one of $+, 0, -$ . <b>Preliminaries</b>
$\text{sgn}(A)$	sign pattern matrix of the real matrix $A$ , with entries in $+, 0, -$ . <b>33.1</b>
$\text{sgn}(\alpha)$	sign of a set $\alpha$ of edges in a signed bipartite graph. <b>30.1</b>
$\text{sign}(A)$	matrix sign function of the complex square matrix $A$ . <b>11.6</b>
$\text{sign}(z)$	sign of the complex number $z$ as used in numerical linear algebra, always nonzero. <b>Preliminaries</b>
$\text{SL}(n, F)$	special linear group of order $n$ over $F$ . <b>67.1</b>
$\text{SMR}(A)$	symmetric maximal rank of sign pattern $A$ . <b>33.6</b>
$\text{smr}(A)$	symmetric minimal rank of sign pattern $A$ . <b>33.6</b>
$\text{Span}(S)$	span of the set $S$ of vectors. <b>2.1</b>
$\text{Struct}(A)$	the sparsity structure (support) of $A$ . <b>9.6, 40.3</b>
$\text{sv}(A)$	vector of singular values of complex matrix $A$ . <b>15.2, 17.1</b>
$\text{sv}_{\text{ext}}(A)$	extended vector of singular values of complex matrix $A$ . <b>15.2</b>
$\text{Sym}(\mathbf{v}_1 \otimes \dots \otimes \mathbf{v}_k)$	$= \frac{1}{m!} \sum_{\pi \in S_m} \mathbf{v}_{\pi(1)} \otimes \dots \otimes \mathbf{v}_{\pi(k)}$ . <b>16.6</b>
$T$	linear transformation $T$ . <b>3.1</b>
$T^{-1}$	inverse of linear transformation $T$ . <b>3.7</b>
$T^T$	transpose of linear transformation $T$ . <b>3.8</b>
$B'[T]_{\mathcal{B}}$	matrix of $T$ with respect to bases $\mathcal{B}$ (input) and $\mathcal{B}'$ (output). <b>3.3</b>
$[T]_{\mathcal{B}}$	matrix of $T$ with respect to bases $\mathcal{B}$ and $\mathcal{B}$ (same as ${}_{\mathcal{B}}[T]_{\mathcal{B}}$ ). <b>3.3</b>
$[T]$	for $T: F^n \rightarrow F^m$ , matrix of $T$ with respect to the standard bases, $[T] = \varepsilon_m [T]_{\mathcal{E}_n}$ . <b>3.3</b>
$T_A$	linear transformation associated to matrix $A$ , $T_A(\mathbf{v}) = A\mathbf{v}$ . <b>3.3</b>
$T_r^n$	triples of subsets of $\{1, \dots, n\}$ of cardinality $r$ . <b>17.6</b>
$T(k, l, d)$	tree constructed from $P_d$ by appending $k$ and $l$ isolated vertices to the ends. <b>36.3</b>
$\tau(A)$	the ergodicity coefficient of matrix $A$ . <b>9.1</b>
$\mathcal{T}(R)$	the class of all tournament matrices with score vector $R$ . <b>27.5</b>
$\vartheta(G)$	Lovász parameter of graph $G$ . <b>28.5</b>
$\Theta(G)$	Shannon capacity of graph $G$ . <b>28.5</b>
$\Theta(X, Y)$	canonical angle matrix between $X$ and $Y$ . <b>15.1</b>
$\text{tr } A$	trace of matrix $A$ , also denoted $\text{tr}(A)$ . <b>1.2</b>
$\mathcal{U}(T)$	the minimum number of simple eigenvalues of a matrix in $\mathcal{S}(T)$ where $T$ is a tree. <b>34.4</b>
$U\Sigma V^*$	singular value decomposition of a real or complex matrix. <b>5.6</b>
$\hat{U}\hat{\Sigma}\hat{V}^*$	reduced singular value decomposition of a real or complex matrix. <b>5.6</b>
$V$	vector space $V$ . <b>1.1</b>
$V^*$	dual space of $V$ . <b>3.8</b>

$V^{**}$	bidual space of $V$ (dual of the dual). <b>3.8</b>
$V_1 \times \cdots \times V_k$	external direct sum of vector spaces $V_i$ . <b>2.3</b>
$V_1 \otimes \cdots \otimes V_k$	tensor product of vector spaces $V_i$ . <b>13.2</b>
$\otimes^m V$	$V \otimes \cdots \otimes V$ ( $m$ copies of $V$ ). <b>13.2</b>
$\otimes V$	the tensor algebra on $V$ . <b>13.9</b>
$\bigvee^m V$	the symmetric space of degree $m$ . <b>13.6</b>
$\bigvee V$	the symmetric algebra on $V$ . <b>13.9</b>
$\bigwedge^m V$	the Grassman (exterior) space of degree $m$ . <b>13.6</b>
$\bigwedge V$	the Grassman algebra on $V$ . <b>13.9</b>
$V_W$	an $(n-1) \times (n-1)$ $(0, 1)$ -matrix constructed from an $n \times n$ $\pm 1$ -matrix. <b>32.2</b>
$V/W$	quotient space of $V$ by subspace $W$ . <b>2.3</b>
$\mathbf{v}$	vector $\mathbf{v}$ . <b>1.1</b>
$\tilde{\mathbf{v}}$	a perturbation $\mathbf{v} + \Delta\mathbf{v}$ of vector $\mathbf{v}$ . <b>15.1</b> (Also other meanings.)
$\langle \mathbf{v}, \mathbf{u} \rangle$	inner product of vectors $\mathbf{v}$ and $\mathbf{u}$ . <b>5.1</b>
$\ \mathbf{v}\ $	norm of vector $\mathbf{v}$ (which norm depends on context). <b>5.1, 37.1</b>
$\ \mathbf{v}\ _2$	Euclidean norm of vector $\mathbf{v}$ in $\mathbb{R}^n$ or $\mathbb{C}^n$ , = standard inner product norm. <b>5.1, 37.1</b>
$\ \mathbf{v}\ _\infty$	$\infty$ -norm (maximum of absolute values) of vector $\mathbf{v}$ in $\mathbb{R}^n$ or $\mathbb{C}^n$ . <b>37.1</b>
$\ \mathbf{v}\ _1$	1-norm (absolute column sum) of vector $\mathbf{v}$ in $\mathbb{R}^n$ or $\mathbb{C}^n$ . <b>37.1</b>
$\ \mathbf{v}\ _{UI}$	unitarily invariant norm. <b>15</b>
$[\mathbf{v}]_{\mathcal{B}}$	coordinate vector of $\mathbf{v}$ with respect to basis $\mathcal{B}$ . <b>2.6</b>
$\mathbf{v} \perp \mathbf{w}$	$\mathbf{v}$ is orthogonal to $\mathbf{w}$ . <b>5.2</b>
$\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_k$	tensor product of vectors $\mathbf{v}_i$ . <b>13.2</b>
$\mathbf{v}_1 \vee \cdots \vee \mathbf{v}_k$	symmetric product of vectors $\mathbf{v}_i$ . <b>13.6</b>
$\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_k$	exterior product of vectors $\mathbf{v}_i$ . <b>13.6</b>
$\mathbf{v} \geq \mathbf{0}$	$\mathbf{v}$ is nonnegative. <b>9.1</b>
$\mathbf{v} > \mathbf{0}$	$\mathbf{v}$ is positive. <b>9.1</b>
$\mathbf{v} \geq \mathbf{0}$	$\mathbf{v}$ is semi-positive. <b>9.1</b>
$\mathbf{v} \geq \mathbf{w}$	$\mathbf{v} - \mathbf{w}$ is nonnegative.
$\mathbf{v} > \mathbf{w}$	$\mathbf{v} - \mathbf{w}$ is positive.
$\mathbf{v} \geq \mathbf{w}$	$\mathbf{v} - \mathbf{w}$ is semi-positive.
$\mathbf{v} \geq^K \mathbf{0}$	$\mathbf{v}$ is $K$ -nonnegative. <b>26.1</b>
$\mathbf{v} >^K \mathbf{0}$	$\mathbf{v}$ is $K$ -positive. <b>26.1</b>
$\mathbf{v} \geq^K \mathbf{0}$	$\mathbf{v}$ is $K$ -semipositive. <b>26.1</b>
$\mathbf{v} \geq^K \mathbf{w}$	$\mathbf{v} - \mathbf{w}$ is $K$ -nonnegative. <b>26.1</b>
$\mathbf{v} >^K \mathbf{w}$	$\mathbf{v} - \mathbf{w}$ is $K$ -positive. <b>26.1</b>
$\mathbf{v} \geq^K \mathbf{w}$	$\mathbf{v} - \mathbf{w}$ is $K$ -semipositive. <b>26.1</b>
$\text{vec } A$	the vector of columns of $A$ . <b>10.4</b>
$W^\perp$	orthogonal complement of subspace $W$ . <b>5.2</b>
$W_1 \oplus \cdots \oplus W_k$	direct sum of subspaces $W_i$ . <b>2.3</b>
$W_1 + \cdots + W_k$	sum of subspaces $W_i$ . <b>2.3</b>
$W_V$	an $(n+1) \times (n+1)$ $\pm 1$ -matrix constructed from an $n \times n$ $(0, 1)$ -matrix. <b>32.2</b>
$W(A)$	numerical range of $A$ . <b>7.1, 18.1</b>
$w(A)$	numerical radius of complex square matrix $A$ . <b>18.1</b>
$\tilde{w}(A)$	distance of $W(A)$ to the origin. <b>18.1</b>
$\vec{X}$	characteristic vector of $X \subseteq V$ where $G = (V, E)$ . <b>30.3</b>
$\mathbf{x}_{LS}$	least squares solution. <b>39.1</b>
$\angle(\mathbf{x}, \mathbf{y})$	the canonical angle between the two vectors $\mathbf{x}, \mathbf{y} = \Theta(\{\mathbf{x}\}, \{\mathbf{y}\})$ . <b>15.1</b>
$\mathbb{Z}$	integers.
$\mathbb{Z}^+$	positive integers.
$\mathbb{Z}_n$	integers mod $n$ . <b>23.1</b>
$Z_n$	$n \times n$ lower shift matrix. <b>48.1</b>

# HANDBOOK OF LINEAR ALGEBRA

The **Handbook of Linear Algebra** provides comprehensive coverage of linear algebra concepts, applications, and computational software packages in an easy-to-use handbook format. The esteemed international contributors guide you from the very elementary aspects of the subject to the frontiers of current research.

The book features an accessible layout of parts, chapters, and sections, with each section containing definition, fact, and example segments. The five main parts of the book encompass the fundamentals of linear algebra, combinatorial and numerical linear algebra, applications of linear algebra to various mathematical and nonmathematical disciplines, and software packages for linear algebra computations. Within each section, the facts (or theorems) are presented in a list format and include references for each fact to encourage further reading, while the examples illustrate both the definitions and the facts.

Linearization often enables difficult problems to be estimated by more manageable linear ones, making the **Handbook of Linear Algebra** essential reading for professionals in diverse disciplines who deal with an assortment of mathematical problems.

## Features

- Covers combinatorial and numerical linear algebra—two important branches of linear algebra
- Features matrix notation throughout the text
- Explores both mathematical and nonmathematical applications, such as quantum computing, control theory, signal processing, and computational biology
- Discusses software packages useful for linear algebra computations, including MATLAB<sup>®</sup>, Maple<sup>™</sup>, and Mathematica<sup>®</sup>
- Provides numerous references for additional information as well as a glossary that covers all major linear algebra terminology

## About the Editor

**Leslie Hogben, Ph.D.**, is a professor of mathematics at Iowa State University, Ames, USA, where she is the founder of the ISU Combinatorial Matrix Theory Research Group. Dr. Hogben is also the assistant secretary/treasurer of the International Linear Algebra Society.

**Chapman & Hall/CRC**
